Erythroid macrocytosis (Fig. 36.6) is an early change. Individual macrocytes appear first, as detectable by hemoglobin and cell size measurements confined to reticulocytes,[108] followed by a gradual rise in overall mean corpuscular hemoglobin (MCH) and then mean corpuscular volume (MCV) that eventually crosses the line into abnormality (>97 fl) before the hemoglobin levels fall.[9] In cobalamin deficiency, with its slow progression, macrocytosis precedes anemia by months.[14,15] Macro-ovalocytes are especially characteristic of megaloblastic anemia but are not specific.[109] Early megaloblastic changes in the bone marrow precede the macrocytosis but are easily missed. Eventually, poikilocytosis becomes more pronounced with teardrop cells. Nucleated red cells, Howell-Jolly bodies, and even Cabot rings appear in the blood in severe megaloblastosis.

As anemia progresses, iron and transferrin receptor levels, sideroblast counts, and the ferritin content of erythroid precursors and macrophages increase.[45,110,111] Erythropoietin levels correlate with the severity of anemia but can vary widely.[112]

Megaloblastic anemia is the chief exemplar of ineffective hematopoiesis in all three hematopoietic cell lines; bone marrow hyperplasia is intense but reticulocytosis does not occur.[45,98,100] Precursor cells are arrested at various stages in interphase but continue to mature. As megaloblastosis advances, most precursors die within the hypercellular bone marrow and are phagocytosed. Whether early cell death is primarily apoptotic or not is controversial and may depend on the model studied.[100,113,114] Advanced megaloblastic anemia has a poorly understood component of intravascular hemolysis also; survival of normal red cells transfused into cobalamin-deficient patients is short.[115] Serum glutathione, an antioxidant, appears to be the most significant metabolic predictor of anemia in cobalamin deficiency.[116] Abnormalities of red cell membrane proteins, including spectrin, have also been described.[117]

The evolution of hematologic changes has been detailed elsewhere[45] and its laboratory characteristics are detailed further in the section "Hematologic Assessment." With progressive anemia also come fatigue, hypervolemia, and cardiovascular symptoms, as well as the pallor combined with hyperbilirubinemia that gives a classic lemon yellow skin color, and even retinal hemorrhages and, on occasion, pseudotumor cerebri.

Neurologic Dysfunction

Cobalamin Deficiency

Pathophysiology

Demyelination with subsequent axonal disruption and gliosis can affect all parts of the central nervous system. Peripheral nerves, however, tend to show axonal degeneration without

demyelination.[118,119] The classic myelopathic syndrome is subacute combined degeneration, in which posterior and lateral column damage predominates; dorsal, pyramidal, and spinocerebellar tracts are affected. The earliest changes appear in the cervical or thoracic spine and can be detected by magnetic resonance imaging (MRI) as hyperintensity on T2-weighted images (Fig. 36.7). Larger, more heavily myelinated fibers tend to be affected most often.[120]

The biochemical mechanisms are unknown. Because myeloneuropathy is much more prominent in cobalamin deficiency than in folate deficiency, suspicion fell on the folate-unrelated role of adenosylcobalamin in propionate metabolism and its possible consequences to fatty acids in myelin. Most evidence now points to methionine synthase impairment and its effects on methionine metabolism and methylations instead.[121] Animal data suggested that methionine ameliorates cobalamin deficiency-induced neurologic dysfunction, preliminary cerebrospinal fluid studies in humans described low AdoMet levels, and high AdoHcy-to-AdoMet ratios suggested inhibition of AdoMet's methylation activity by AdoHcy. Plasma homocysteine-related metabolite comparisons in neurologically impaired versus hematologically impaired patients with pernicious anemia suggest even greater complexity:[116] cysteine levels were significantly higher in the neurologically affected patients and, surprisingly, AdoMet levels were actually higher in neurologically impaired patients. Neurologically impaired patients also had significantly higher serum folate levels than those without neurologic problems.[116,122,123] It is unclear if these differences represent cause, concurrence, or consequence.

MRI appearances in subacute combined degeneration of the spinal cord due to vitamin B_{12} deficiency. J Neurol Neurosurg Psychiatry 1997;62:99–101, with permission.)

Clinical Features

The frequency of neurologic involvement in cobalamin deficiency is presumed lower than the frequency of anemia but is undefined (perhaps because it is not as explicit and quantifiable as anemia and because of patient selection biases). Often regarded as a late development, neurologic changes can precede anemia instead.[124,125,126] Interestingly, the extents of neurologic and hematologic expressions of cobalamin deficiency tend to vary inversely in patients,[116,126] and the predilection tends to recur when deficiency relapses.[126,127,128] Although genetic influences on clinical expression seem plausible, methyleneTHF reductase polymorphisms that increase folate availability for thymidylate synthase over methionine synthase did not predispose to neurologic manifestations in pernicious anemia.[129]

Neuromyelopathy is the most common neurologic feature of cobalamin deficiency,[120,126,130,131] but it is not specific to it; copper deficiency, for example, produces similar findings,[132] as well as macrocytosis.[133] Sensory changes in cobalamin deficiency include position sense disturbance and dysesthesia; pyramidal tract signs include spasticity and a Babinski reflex; neuropathy is exemplified by loss of tendon reflexes; and gait disturbances are common signs of advanced involvement. Manifestations tend to be symmetrical. Neuropathy, which is usually sensory but can be sensorimotor,[134] can be hard to differentiate clinically from posterior column involvement.[126,130,135,136]

The earliest manifestations are loss of vibratory sense in the feet and numbness, tingling, and loss of fine sensation. Others include loss of proprioception and, depending on the balance between myelopathy and neuropathy, hyperactive or diminished deep tendon reflexes. Involvement ascends up the legs, and, eventually, hands are affected as well. Muscle weakness and tenderness have been described sometimes. Ataxia, spasticity, gait disturbances, positive Babinski reflex, impotence, and bladder[137] and bowel dysfunction appear in advanced cases.

Cerebral symptoms, notably cognitive and emotional changes, can be severe in some cases[124,126] or so mild as to be recognized

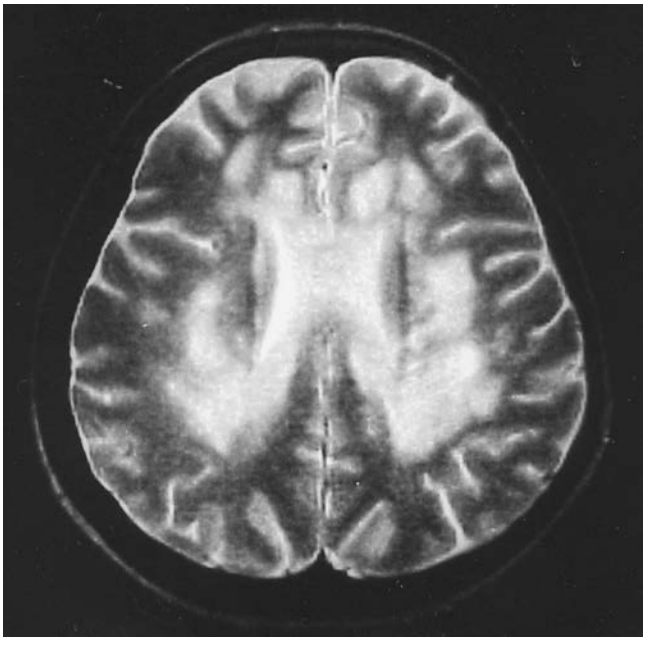

FIGURE 36.8. Magnetic resonance imaging (T2 weighted) of the brain in a woman with pernicious anemia and cognitive dysfunction. Large confluent and focal areas of increased signal intensities are seen, predominating around the ventricles. The changes improved after therapy. (From Stojsavljevic N, Levic Z, Drulovic J, et al. A 44-month clinical-brain MRI follow-up in a patient with B_{12} deficiency. Neurology 1997;49:878–881, with permission.)

only in retrospect after treatment. MRI reveals focal and diffuse changes in the brain[138] (Fig. 36.8). Tensor diffusion imaging also shows white matter changes in adjacent areas that seem normal on MRI.[139] Nevertheless, despite low cobalamin levels in 10% to 20% of patients with chronic dementias,[95,140] the low levels usually reflect only subclinical cobalamin deficiency (SCCD) and appear unrelated to chronic dementias, which rarely improve with cobalamin therapy.[141] In very young children, however, some cobalamin deficiencies can cause developmental delay, lethargy, cerebral atrophy, and seizures.[142]

Autonomic dysfunction is sometimes demonstrable with deficiency.[118,143,144,145] Other neurologic manifestations include visual changes, optic neuritis, which predominates in men, and disturbances of smell or taste.[126,146] Classic motor dysfunction is rare, other than that caused by spasticity and proprioceptive loss, but abnormal central motor conduction times have been described.[134] At early or late stages, MRI (Figs. 36.7 and 36.8) and functional electrophysiologic tests, such as electroencephalography, evoked potentials, and nerve conduction, show abnormalities.[134,138,147–150,151]

Unlike anemia, neurologic dysfunction does not always reverse after cobalamin therapy. Residual deficits persist in 6% of patients;[126] they are not always predictable but tend to accompany more extensive involvement and longer duration before treatment begins.[45,130] Mistaken folate therapy has also been tied to the risk of neurologic irreversibility in patients with clinical cobalamin deficiency. The delayed cobalamin treatment when the anemia responds to folate presumably allows neurologic abnormalities to appear, progress, and, in occasional reports,[152] perhaps even accelerate. The events are more ambiguous than assumed. Hematologic improvement after folate is usually neither complete nor long lived in pernicious anemia,[152,153] and transient neurologic responses to folate may occur too.[153] Nevertheless, the anecdotal reports of clinical acceleration cannot be completely dismissed and cannot be studied prospectively in pernicious anemia. Folate should never be given alone to cobalamin-deficient patients, even those whose deficiency is subclinical and lacks convincing evidence for adverse effects.[154]

Folate Deficiency

Neurologic defects occur in only occasional adults with folate deficiency[155–157] and are rarely as severe as in cobalamin deficiency. Although myelopathy has been reported,[158] it is exceptional. Mild mental changes, such as forgetfulness and irritability,[9] and mild neuropathy have been better accepted. A causative association with depression is controversial.[159,160] Attributions of any neurologic changes to folate deficiency, which often occurs in a setting of malnutrition, require high standards of proof, including consideration of alternative explanations such as alcohol abuse.

In sharp contrast, however, children with inborn errors of folate metabolism often have severe myelopathy and brain dysfunction, including seizures and mental retardation.[142,161,162] The explanations for the neurologic differences between folate and cobalamin deficiency or between acquired and hereditary folate disorders are unknown.

Other Manifestations

Miscellaneous Clinical Findings

Atrophy of tongue papillae is common with cobalamin deficiency and sometimes gives rise to a beefy red tongue that may or may not cause symptoms.[45,163] Aphthous stomatitis and oral soreness can be prominent in some patients, including some without anemia. However, glossitis occurs with folate deficiency and other deficiencies also. The glossitis of cobalamin deficiency does not respond to folate.[164] Mucosal changes occur elsewhere too, including megaloblastic changes in buccal epithelium, cervical cells, and intestinal villi;[45,165,166] the latter apparently caused temporary malabsorption of cobalamin and other nutrients.[167,168] Other reversible but unexplained clinical changes in pernicious anemia include: impaired osteoblastic activity,[169] although reports of bone density changes and risk of fractures have been inconsistent; darkening of nails and skin and change of hair color in severely deficient non-Caucasians;[170–172] and sometimes marked weight loss.[173]

Miscellaneous Laboratory Abnormalities

Platelet function is sometimes impaired,[106] but neutrophil dysfunction has been variable. Hemoglobin A_2 levels rise slightly.[174] Occasional patients with sickle cell trait have shown striking changes in hemoglobin S and F levels when folate-deficient.[175] Cobalamin deficiency also affects some nonhematologic serum analytes: bone alkaline phosphatase is often decreased[169] and immunoglobulin levels sometimes decline.[176] An adolescent with severe megaloblastic anemia had reduced ADAMTS13 activity.[177]

Subclinical Deficiency and Indirect Consequences of Altered Vitamin Status

Automated metabolic tests have simplified identification of asymptomatic, nonanemic vitamin deficiency. The high frequency of these early subclinical states has opened them to scrutiny as possible public health issues, with varying outcomes. The uncertainties apply especially to cobalamin, because SCCD is widespread, dominates epidemiologic surveys, and is often confused with clinical deficiency, yet has unclear health implications and, therefore, unknown need for intervention.[17,178,179]

Subclinical Cobalamin Deficiency

Many patients and healthy people—especially, but not exclusively, the elderly—have low cobalamin levels but are asymptomatic and have normal blood counts. These low serum levels were thought artifactual until sensitive deoxyuridine suppression tests

showed in 1985 that most of them reflected mild biochemical insufficiency that responded to cobalamin and, equally important, rarely involved IF-related malabsorption.[94,95,96,180] None of the subjects had cobalamin-related anemia although bone marrow cells displayed reversible metabolic defects. Similarly, none had clinical neurologic findings although some,[96,141,181] but not all,[182] displayed mild, reversible electrophysiologic changes.

Widespread methylmalonic acid (MMA) and homocysteine testing[183–185] next showed that asymptomatic nonanemic SCCD was much more common than clinical deficiency.[17,186,187,188] Thus, a survey of community-dwelling elderly subjects found that 12% had biochemical insufficiency[188] but only 2% of them had IF antibody-positive pernicious anemia[189] and, by extrapolation, 1% to 2% more may have had undetected antibody-negative disease. Readers must be aware that epidemiologic data apply to SCCD alone because too few subjects have clinical deficiency.[190] Moreover, falsely low cobalamin levels (i.e., with normal MMA and homocysteine) also outnumber clinical deficiency in surveys.[191] Nevertheless, the mild metabolic abnormalities in some asymptomatic subjects with low-normal cobalamin levels led many laboratories to raise the cutpoint for "suspicious" cobalamin levels from 200 to 300 or 350 ng/L to capture more cases.[186] The change is open to criticism because nearly 70% of cases added thereby have normal MMA and homocysteine levels and are not cobalamin-deficient. The influx of suspected SCCD expanded the concept of cobalamin deficiency at the cost of overdiagnosis based on often nonspecific biochemical findings whose need for therapy was unclear.[17,179,190,192,193]

Assumptions that SCCD, especially when unaccompanied by malabsorption, progresses inevitably to clinical deficiency are untested.[179,190] Asymptomatic persons without malabsorption have been free of symptoms and anemia for 10 years despite persistently low cobalamin levels,[194] and metabolic monitoring over 1 to 4 years showed infrequent progression of mildly elevated MMA levels.[192] Only a small minority of people with SCCD have early pernicious anemia,[189] whose progression to clinical deficiency is very predictable. Most persons with SCCD have no identifiable cause for it,[17,178] and the likelihood of progression in the 30% to 40% who have food-cobalamin malabsorption appears limited.[195]

SCCD is compared and contrasted with clinical cobalamin deficiency in Table 36.2.

Subclinical Folate Deficiency

Subclinical folate deficiency is less explicitly defined than SCCD for several reasons: folate status fluctuates more readily than cobalamin status because folate turnover is rapid;[35] folate deficiency tends to be accompanied by other deficiencies; and attention is often diverted from the deficiency to its hyperhomocysteinemia. The latter, and growing pharmacogenetic and gene-nutrient data, suggest that subclinical variations of folate status below the level of deficiency may subtly influence many health issues, which are discussed next.

Vitamins and Public Health Risks

Subclinical Cobalamin Deficiency and Cognition

Many epidemiologic associations with SCCD have been pursued but clinical trials have been infrequent. Cognitive decline in the elderly has undergone the most active study because neurologic manifestations are frequent in clinical deficiency. The most consistent associations for cognitive dysfunction have been with homocysteine status, with variable links to folate and, to often lesser extent, cobalamin status. As reviewed elsewhere,[179,196,197] early clinical trials were inadequate or inconclusive.[198–200,201,202] However, two long-term randomized clinical trials in Europe, where dietary fortification is not mandatory, reported reduced progression of brain atrophy and cognitive decline. One found that 0.8 mg of folic acid daily was effective.[203] The second demonstrated that three vitamins (0.8 mg folic acid, 500 μg cobalamin,

TABLE 36.2

COMPARISON BETWEEN CLINICAL AND SUBCLINICAL COBALAMIN DEFICIENCY STATES

Characteristics	Clinical Deficiency	Subclinical Deficiency
Biochemical abnormalities	Often severe	Usually mild
Clinical abnormalities	Megaloblastic anemia is present in >75% of cases Neurologic or cognitive changes are present in >50% of cases Electrophysiologic (neurologic) abnormalities are usually present	Anemia is absent[a] Neurologic changes are absent[a] Mild electrophysiologic changes are sometimes present
Cobalamin absorption status	IF-related malabsorption causes >90% of cases[b] FBCM is uncommon Normal absorption is uncommon (e.g., veganism)	IF-related malabsorption is usually absent[b] FBCM is present in <50% of cases Most persons have normal absorption
Diagnostic criteria	Almost always one or more clinical abnormalities At least one abnormal biochemical finding	No clinical signs of cobalamin deficiency Ideally, at least two abnormal biochemical findings should be demonstrated
Likelihood of progression of deficiency	Very high because of the usual presence of IF-related malabsorption	Unknown, but probably small Any progression to symptoms (i.e., clinical deficiency) is likely to be very slow
Need for cobalamin therapy	Urgent in all cases	Unknown
Medical implications	Clinical deficiency indicates that medical management is needed	None known, but if SCCD is found during medical evaluation it must be evaluated medically
Public health implications	None known	Unclear at present[c]

FBCM, food-bound cobalamin malabsorption; IF, intrinsic factor; SCCD, subclinical cobalamin deficiency.
[a]Any anemia or neurologic findings found in a patient with suspected SCCD must have a cobalamin-unrelated cause (otherwise it is clinical deficiency and cannot be considered SCCD).
[b]IF-related malabsorption refers to absence of IF (which defines pernicious anemia) or inability of IF to promote intestinal absorption (e.g., intestinal disease). If such malabsorption is present, SCCD is likely to progress to clinical expression.
[c]Active research into potential public health issues requiring preventive interventions is ongoing but still inconclusive. High-dose cobalamin, folic acid, and pyridoxine may slow progression of cognitive decline in some elderly persons, but it is unknown whether SCCD is a factor.

and 25 mg pyridoxine) slowed brain atrophy by 30%[204] and reduced cognitive decline.[205] Its important features were that the subjects were mildly cognitively impaired at baseline (which predicts likely progression, but avoids the irreversibility of dementia), the responders were hyperhomocysteinemic, and it is not clear which of the three vitamins was the beneficial one.

Folate and Neural Tube Defect Prevention

Supplementation with folic acid has also been scrutinized for prevention of conditions not directly attributable to folate deficiency. Of the many studied targets and associations, such as cancer, vascular and thrombotic disease, osteoporosis, cognitive dysfunction, and birth defects, the only unambiguous effect has been on neural tube defect (NTD). Folate supplementation reduces a woman's risk of having a child with NTD,[206,207] but the benefit seems pharmacologic rather than amelioration of folate inadequacy. Genetic and other susceptibilities related to folate, cobalamin, or homocysteine probably underlie the NTD risk, more so than does maternal folate deficiency. For example, the *MTHFR* C677T polymorphism increases the risk of NTD.[208] High rates of antibody to FR have also been reported in women with NTD pregnancies[209] and deficiency of FR-α in mice is associated with neural tube and other birth defects.[210]

Folate prophylaxis must begin at conception because the neural tube closes at approximately 3 weeks. Daily doses of 400 μg are effective, with 4 mg recommended for women who use anticonvulsants or have a history of previous NTD. All grain and cereal foods have been fortified with folic acid since 1998 in the United States, Canada, and a few other countries. NTD rates have fallen but not disappeared, leading some experts to urge additional fortification.[211] The benefits must be weighed against the consequences of chronic use of high folic acid doses, as discussed in the section "Preventive and Other Uses of Supplements."

Considerable human and animal data associated lower folate status with increased risk of cancer, best demonstrated with colon cancer. However, the associations are complex, may include double-edged folate impact that depends on neoplastic status and details as much as on folate status, and are beyond the scope of this chapter. These issues are discussed in the section "Preventive and Other Uses of Supplements" at the end of the chapter.

Hyperhomocysteinemia

Extrapolation from inborn errors of homocysteine metabolism suggested that severe hyperhomocysteinemia may predispose to thrombotic manifestations.[212] Extensive epidemiologic data associated even mild hyperhomocysteinemia with increased risks for coronary, cerebral, and peripheral vascular complications, although the associations were less firm in prospective, rigorously designed studies than in retrospective ones.[213,214] Genetic polymorphisms, primarily of methyleneTHF reductase, contribute to 9% of homocysteine level variation,[215] but even in the absence of vitamin deficiency folate, cobalamin, and vitamin B_6 often reverse the hyperhomocysteinemia. Indeed, folic acid fortification reduced the frequency of hyperhomocysteinemia from 20% to 32% to 5% to 14% in the elderly.[216] Nevertheless, the outcomes of large interventional vitamin trials on coronary and cerebrovascular disease prevention have been disappointing.[217] Indeed, some trials even suggested adverse effects.[218–221,222]

Laboratory Evaluation

Laboratory evaluation must have two separate targets: documenting hematologic, metabolic, and clinical chemistry changes that identify cobalamin or folate deficiency, and documenting the underlying condition or disease that caused the deficiency.

Hematologic Assessment

The mechanisms of megaloblastosis were discussed in the section "Hematopathology." The classic blood count findings in cobalamin or folate deficiency are anemia, a high MCV and MCH, and, in more advanced cases, thrombocytopenia and neutropenia. Patients are often identifiable at an early stage in which they have MCV and MCH elevation alone, which precedes anemia by months in cobalamin deficiency[15] but only by a few weeks in the more rapidly developing folate deficiency.[9] At first, the MCV and MCH may simply be higher than the patient's baseline, without being explicitly abnormal (e.g., an MCV of 90 fl replacing one of 85 fl). An early anisocytosis as new macrocytes begin to emerge can be detected by measuring the MCV or hemoglobin content of reticulocytes[108] or by an elevated red cell distribution width, which, however, is not invariable in early deficiency.[223] Red cell counts decline before hemoglobin and packed cell volume levels.

Megaloblastic anemia is not the only cause of macrocytic anemia, however, or even the most common (Table 36.3). A hospital survey found 64% of MCV values >100 fl to be due to chemotherapy, antiretroviral therapy, or alcohol abuse.[109] Cobalamin and folate deficiencies caused only 6% of the high MCV values but accounted for most MCV values above 110 fl.

Absolute reticulocyte counts typically fall slightly. The laboratory signs of ineffective erythropoiesis, serum lactate dehydrogenase and indirect bilirubin levels, are initially inapparent but rise as the hemoglobin approaches 10 g/dl.[45] As anemia worsens, lactate dehydrogenase levels may reach thousands of units per liter as intravascular hemolysis is added to ineffective erythropoiesis. Other markers include rising serum transferrin receptor, iron, ferritin, nontransferrin-bound iron, and methemalbumin levels, as well as low serum haptoglobin levels. Platelet and neutrophil counts usually decline only as the anemia progresses. The pancytopenia can ultimately mimic aplastic anemia, which too is usually macrocytic (but does not display the bilirubin and lactate dehydrogenase elevations).

Most of the hematologic variability is dictated by the stage at which the patient is discovered.[45] However, not every patient expresses the same degree of anemia for the degree of cobalamin deficiency. Many severely deficient patients have surprisingly mild anemia or even lack it.[125] The reasons are usually unknown but some may be linked to the unexplained tendency for inverse association between anemia and neurologic dysfunction.[124,125] Another influence on hematologic expression is coexisting iron deficiency or thalassemia that produces normal or low MCV in approximately 7% of patients with pernicious anemia;[224] these MCVs are above baseline for the patients and fall after vitamin therapy.[225] Iron deficiency sometimes also blunts the erythroid megaloblastic changes themselves, both morphologically and by deoxyuridine suppression testing.[226,227] Iron studies in untreated megaloblastic anemia often do not reveal the coexisting iron deficiency.[45] Because all marrow and blood indicators of iron status fall within 24 to 48 hours of vitamin therapy, sometimes transiently to low levels before rebounding, it is advisable to wait several days for the tests to stabilize and reveal the patient's true iron status.

Hypersegmentation of neutrophil nuclei is a constant feature but is variably defined[45] and may be unreliable in inexpert hands. The most serviceable criteria are finding one or more neutrophils with six or more nuclear lobes or showing that at least 4% to 5% of neutrophils have five lobes. Calculating lobe averages is considered the gold standard but comparison against published reference ranges is unreliable because interobserver variation is great. Hypersegmentation often precedes anemia,[9,104] but it is not found in subclinical deficiency.[228] Hypersegmented neutrophils are not specific for cobalamin or folate deficiency; they are found in patients receiving chemotherapeutic drugs such as 5-fluorouracil or hydroxyurea, in some patients receiving steroid therapy for immune thrombocytopenic purpura,[229] and in rare

TABLE 36.3

CAUSES OF MACROCYTOSIS, DEFINED AS MEAN CORPUSCULAR VOLUME (MCV) GREATER THAN 97 FL[a]

Causes of Macrocytosis (MCV >97 fl)	Likelihood of Severe Macrocytosis (MCV >110 fl)
Megaloblastic anemia	
Cobalamin or folate deficiency	High
Some metabolic disorders (e.g., thiamine-responsive anemia)	High
Cytotoxic drugs (e.g., hydroxyurea, 5-fluorouracil)	High
Some immunosuppressive drugs (e.g., azathioprine)	High
Alcohol[b]	
Without liver disease	Low
With liver disease	Moderate
Drugs[b]	
Antiviral drugs	Moderate
Anticonvulsant drugs	Low
Disorders of red cell production[b]	
Aplastic anemia; pure red cell aplasia	High
Myelodysplastic syndromes	Moderate
Myeloproliferative disease; leukemia	Low
Sideroblastic anemia (hereditary or acquired)	Low
Congenital dyserythropoietic anemia; Fanconi anemia; Blackfan-Diamond anemia	?
Copper deficiency anemia	Moderate
Reticulocytosis[b]	
Hemolytic anemia	Moderate
Nonhematologic disease[b]	
Liver disease (alcohol unrelated)	Low
Hypothyroidism	Low
Physiologic[b]	
Red cells are enlarged in the first 4 wk of life	Low
Idiopathic[b]	
Pregnancy	Low
Chronic lung disease; smoking	Low
Cancer	Low
Multiple myeloma	Low
Artifact of electronic cell sizing[b]	
Cold agglutinins	High
Severe hyperglycemia	High
Hyponatremia	?
Stored blood	?
Warm antibody to red blood cells	?

[a]Macrocytosis can be diagnosed when an MCV is not yet >97 fl, if the MCV is higher than in the past. The second column estimates the likelihood of finding severe macrocytosis (>110 fl in adults).
[b]Macrocytosis is not accompanied by megaloblastic changes.

patients with myelofibrosis or chronic myelogenous leukemia. It is unclear whether iron deficiency can cause hypersegmentation.[230] Neutrophil segmentation is normally greater in blacks than in whites.[228]

Laboratory Tests of Deficiency

Cobalamin and folate levels are measurable in serum and cells. The original microbiologic methods exploited the cobalamin or folate requirements of various micro-organisms, including differential sensitivities to specific forms of folate.[45,231,232] Although rarely used today, microbiologic assays remain the gold standard. Radioisotope dilution competitive-binding assays for cobalamin and folate gave way to automated chemiluminescence-based competitive-binding assays a decade ago. Technical ease and demand have grown, but transparency, documentation, and validation of assay performance have diminished.[233,234] Long suspected of critical failures to identify low cobalamin levels, and sometimes producing results above 1,000 ng/L,[234,235] many automated assays have misidentified 22% to 35% of sera from untreated patients with pernicious anemia.[236] The errors appear to involve failure to inactivate serum autoantibodies to IF, but at present the manufacturers' corrections are awaited.

No single biochemical test is diagnostically definitive for either cobalamin or folate deficiency.[190] In most clinical settings, the cobalamin test, when free of error, nevertheless suffices if the clinical picture is clear.[193] Several metabolic tests are available to clarify the vitamin levels (Table 36.4), and can be clinically decisive in difficult cases. However, a clinical "picture" is unavailable in SCCD, and all tests lack sufficient specificity.[190] Therefore, a panel evaluating cobalamin testing in epidemiologic research[237] recommended that the diagnosis of SCCD should be based on finding at least two abnormalities, one metabolic (e.g., MMA or homocysteine) and one quantitating cobalamin content (e.g., serum cobalamin

TABLE 36.4

BIOCHEMICAL TESTS FOR THE DIAGNOSIS AND DIFFERENTIATION OF CLINICALLY RELEVANT COBALAMIN AND FOLATE DEFICIENCIES

Test	Test Finding in		Sensitivity of Abnormal Test Result[a]	Specificity of Abnormal Test Result[a]
	Cobalamin Deficiency	Folate Deficiency		
Serum cobalamin	Low	N or Low	Very good[b]	Poor
Serum folate	N or High	Low	Very good	Poor
Red cell folate	N or Low	Low	Good	Moderate
Serum methylmalonic acid	High	N	Very good	Poor
Serum 2-methylcitric acid[c]	High	N	Good	Nd
Plasma homocysteine	High	High	Very good	Poor
Plasma cystathionine[c]	High	High	Nd	Nd
Serum holo-transcobalamin II	Low	N	Presumably very good	Poor
Deoxyuridine suppression test[c,d]	Abnormal[d]	Abnormal[d]	Very good	Nd

N, normal result; Nd, not determined.

[a]The sensitivity and specificity estimates (very good, >90%; good, 80% to 90%; poor <70%) apply only to clinically expressed cobalamin deficiency. They do not apply to subclinical cobalamin deficiency, in which sensitivity and specificity tend to be lower than in clinical deficiency, are usually determined only against other biochemical tests, or are unknown.

[b]Automated chemiluminescence cobalamin assays, however, appear prone to falsely normal results when serum contains antibody to intrinsic factor.

[c]The test is available only in research laboratories.

[d]The discriminatory diagnostic power arises from including testing with vitamin additives in vitro.

or holo-TC II).[190] Metabolic tests are essential in the diagnosis of inborn errors of metabolism, in which vitamin levels are often normal. Metabolites are also ideal for monitoring response of deficiency to therapy because their levels do not change unless the therapy was effective, whereas vitamin levels (serum cobalamin, holo-TC II, or folate) rise upon vitamin entry into the bloodstream regardless of efficacy. Metabolite improvement is also delayed for several days, allowing a post-therapy window of time for diagnostic reassessment if needed.

Awareness of major pre-analytic influences on some tests, such as whether supplements must be interrupted during testing, whether plasma or serum must be used, and processing requirements, can be helpful. Interpretation is affected by common confounders, such as renal failure, which affects all cobalamin-related test values, and uncertainties, such as variations in reference intervals that can create or blur mildly abnormal results and compromise comparability between laboratories and methods.[190,238,239,240] Cutpoint variations are common among clinical laboratories,[193] and may also explain discrepancies and controversies in epidemiologic research.[190]

Cobalamin Levels

In cobalamin deficiency, serum cobalamin levels fall below the generally accepted cutpoint of 200 to 250 ng/L (often expressed as 148 to 185 pmol/L; 1 ng = 0.738 pmol.) Despite a frequently cited study's unreproduced claim that serum cobalamin is insensitive to clinical deficiency,[241] diagnostic sensitivity has been 90% to 97% in clinical practice.[183,190,242,243] The lower the cobalamin level, the more likely is clinically noteworthy deficiency to exist,[231,232] but exceptions exist even at levels below 100 ng/L. Approximately 20% to 40% of low cobalamin levels are falsely low[17,190] (Table 36.4), which makes routine equation of low serum cobalamin with deficiency risky, especially when clinical findings are absent or equivocal. Although sensitivity and positive predictive value are poor in epidemiologic surveys involving SCCD,[244] subnormal cobalamin levels in patients coming to medical attention require pursuit, as does any patient with a surprisingly normal level.[193]

Many persons with SCCD have unexplained normal cobalamin levels,[186,242,243] and homocysteine and MMA abnormalities compatible with deficiency outnumber low cobalamin levels in surveys of healthy elderly people.[186,188,191] These observations led some authors to raise the cobalamin cutpoint for deficiency to 350 ng/L.[186] However, abnormal homocysteine and MMA have too many confounders to provide conclusive proof of deficiency, especially in asymptomatic patients with normal cobalamin levels (Table 36.4).

The causes of low cobalamin levels are listed in Table 36.5. Serum cobalamin frequently falls in folate deficiency, becoming subnormal in approximately 10% of cases, and recovers after folate therapy[45]; such cases must be differentiated from combined deficiency of both vitamins. Cobalamin levels also decline during pregnancy, affecting 35% of women by the last trimester.[45,245] Levels can fall below 100 ng/L, but recover within days after delivery. The explanation is unknown, and metabolic studies do not find cobalamin deficiency.[245,246] Unexplained low cobalamin levels, most often without evidence of deficiency, also occur in patients with human immunodeficiency virus (HIV) infection,[247–249] but the incidence has fallen from 27% to 8.7% because of high supplementation rates and more active retroviral therapy. Other conditions associated with unexplained low cobalamin levels include multiple myeloma[250,251] and multiple sclerosis.[252] An unexplained association with obesity[253] may result from expanded plasma volume. Hereditary TC I deficiency is a frequent cause of low cobalamin levels[80,254] but acquired TC I deficiency, such as in severe neutropenic states[255] and aplastic anemia, can also do so. Drugs, such as oral contraceptives and metformin, also cause mildly low cobalamin levels without inducing deficiency.[256,257,258]

Elevated cobalamin levels are more frequent than low ones in clinical practice and are often unexplained.[78] The most common association of high levels was with renal failure,[78] although patients undergoing chronic high-flux hemodialysis have low levels.[259] Other causes include liver disease[260] and recent cobalamin therapy. A host of uncommon diseases with high plasma TC I levels, either because TC I is overproduced or because abnormally glycosylated TC I is cleared slowly, accumulate high cobalamin levels secondarily.[72,78,79,260] The diseases include chronic myelogenous and acute promyelocytic leukemias,[56] metastatic cancer,[261] fibrolamellar hepatoma,[262] and adult-onset Still's disease.[263]

TABLE 36.5

CAUSES OF LOW SERUM COBALAMIN LEVELS

Clinical cobalamin deficiency
- Pernicious anemia (atrophic gastritis with loss of IF)
- Hereditary IF deficiency
- Post-gastrectomy state
- Acquired intestinal disease with cobalamin malabsorption
- Imerslund-Gräsbeck syndrome
- Small bowel bacterial overgrowth
- Veganism
- Infant exclusively breast-fed by mother with veganism or PA

Subclinical (biochemical) cobalamin deficiency
- Food-cobalamin malabsorption (e.g., non-PA gastritis, gastric surgery)
- Drugs
- Vegetarianism
- Idiopathic

***Conditions associated with unexplained low cobalamin level*[a]**
- *Pregnancy*
- *Folate deficiency*

Cobalamin transport changes
- Hereditary TC I deficiency
- Acquired TC I deficiency (e.g., severe granulocyte disorders, ?metformin therapy)
- Congenital specific-granule deficiency

Unexplained associations[a]
- Disorders with pancytopenia (e.g., aplastic anemia, myelodysplasia, PNH, hairy cell leukemia)
- Other diseases (e.g., HIV infection, multiple myeloma, multiple sclerosis)
- Drugs (e.g., oral contraceptives,[b] anticonvulsants)

Pre-analytic influences[a]
- Inappropriately high cutpoint and reference range selection[c]
- Hemodilution

IF, intrinsic factor; PA, pernicious anemia; PNH, paroxysmal nocturnal hemoglobinuria; TC I, transcobalamin I (haptocorrin).
[a]Evidence of metabolically or clinically defined cobalamin deficiency or malabsorption has been found in only some cases in these categories.
[b]Does not apply to post-menopausal hormone replacement.
[c]Frequencies of "low levels" depend greatly on cutpoint selection, which is often arbitrary. The impact can be great; for example, the frequency of "low levels" increases twofold or more following the shift of the cobalamin cutpoint from 200 ng/L to 300 ng/L.

In autoimmune lymphoproliferative syndrome, lymphocytes surprisingly contained TC I.[264] When chronic myelogenous leukemia coexists with pernicious anemia, cobalamin levels are normal, not low.[265] Spontaneous[82] or therapy-acquired[266] autoantibodies to TC II retain holo-TC II, leading to elevated cobalamin levels. Some blood-collection tubes containing separator gel produce higher cobalamin levels.[267] Like TC I and TC II levels, cobalamin levels tend to be higher in blacks than in whites and Asians,[268] which may have a genetic basis. Serum cobalamin is also mildly elevated in homozygotes for the common G461A nonsense mutation of the $\alpha^{1,2}$-fucosyltransferase gene *FUT2*, which regulates Lewis ABO(H) antigen expression,[269,270] but the mechanism whereby it affects the cobalamin level is unknown. *H. pylori* status was unrelated,[270] making initial assumptions that *FUT2* polymorphism affected cobalamin levels via *H. pylori*-related malabsorption unlikely.

Red cell cobalamin has little diagnostic value because levels are low in many other anemias; reticulocyte counts influence red cell cobalamin strongly.[45]

Serum Folate

Folate deficiency, using megaloblastic anemia as a criterion, is traditionally defined by a serum folate level below 2.5 μg/L (also expressed as 5.7 nmol/L; 1 μg = 2.266 nmol.) However, using homocysteine elevation as the criterion implicates serum folate below 4.5 to 5.0 μg/L[271,272] or even 6.5 μg/L.[273] These findings justify viewing serum folate levels between 2.5 and 5.0 μg/L with suspicion, especially in countries using folic acid fortification.

Pre-analytic influences abound. Ascorbate must be added to protect samples stored for a few days against oxidative damage. Spuriously high levels occur in hemolyzed blood samples, which release red cell folate into serum. Serum folate, which is mostly methylTHF, also tends to rise as cobalamin deficiency advances, and it becomes high in approximately 30% of cases[45,46] (Table 36.4). The new generation of automated nonisotopic assays is inadequately documented compared with older methods. Assay imprecision is frequently unexplained.[274] Following dietary fortification and growing supplement use, subnormal results have become rare.

Red Blood Cell (Whole Blood) Folate

MethylTHF (60%) and formylTHF (26%) are the major folates in red cells.[275] A red cell's folate content is constant and is viewed as a truer indicator of tissue folate than are serum levels, which fluctuate with changes in folate intake. Red cell levels below 160 μg/L are usually considered low,[45,276] but the reference intervals vary among laboratories and methods.

Red cell folate results cannot differentiate between folate and cobalamin deficiency (Table 36.4). Levels were low in 63% of cobalamin-deficient patients[276] because the accumulating methylTHF fraction is less easily polyglutamated and therefore poorly retained by cells. Because reticulocytes are rich in folate, red cell folate is high in states of intense reticulocytosis such as hemolytic anemia.[276] Red cell folate, much of it bound to hemoglobin,[277] is also slightly higher in deoxygenated than oxygenated cells. Transfusion, of course, invalidates red cell folate results. The greater variability and methodologic difficulties than with serum folate[45,238,274] have led to divergent views about the usefulness of red cell folate assay.[233,278]

Plasma Total Homocysteine

Homocysteine rises with either folate or cobalamin deficiency (Table 36.4) and in many other conditions (Table 36.6). This nonspecificity limits its diagnostic value, but a normal result helps to exclude clinically relevant deficiency. The sensitivity exceeds 95% in clinically expressed cobalamin deficiency, with levels often above 50 μmol/L in pernicious anemia, but sensitivity is only 86% in clinical folate deficiency.[279] Milder elevations and poorer sensitivity characterize its performance in subclinical deficiency of either vitamin.[240,280] Homocysteine falls several days after appropriate treatment of deficiency and becomes normal within a week.[242]

Plasma total homocysteine, which consists of reduced homocysteine and its oxidized forms, homocystine and mixed disulfides, can be measured by various chromatographic and automated immune or enzyme-based methods. Unfortunately, results vary among laboratories,[281] as do reference intervals. Major preanalytic influences include the requirement for plasma, as well as its immediate separation from blood cells, to minimize artificial cellular release of homocysteine, but many laboratories use serum for convenience and cost saving. Fasted samples are not necessary as long as a large meal is avoided. Age and sex affect normal levels.[282] Homocysteine values double between childhood and old age.[281] Levels above 12 to 14 μmol/L in women and 14 to 15 μmol/L in men are generally regarded as elevated. However, even normal levels can often be reduced by giving folate,[283] which may reflect either unrecognized depletion or interaction with genetic and other influences.

As reviewed elsewhere,[281] homocysteine rises in many acquired and genetic conditions (Table 36.6). Folate intake and serum creatinine levels (even if still within the normal range) are major determinants of homocysteine status; creatinine measurement is advisable whenever the homocysteine level is high. Cobalamin levels assume greater influence in the elderly,[282,284] and the influence has increased in countries with folate fortification.

Levels of both cystathionine, a product of homocysteine transsulfuration, and AdoHcy, a product of remethylation, also rise in

TABLE 36.6

CAUSES OF ELEVATED HOMOCYSTEINE LEVELS

Causes	Degree of Homocysteine Elevation[a]
Vitamin deficiency states	
Clinical cobalamin deficiency (acquired or hereditary[b])	Mild to severe
Subclinical cobalamin deficiency	Mild or none
Folate deficiency (acquired or hereditary[c])	Mild to severe
Vitamin B_6 deficiency	Mild or none[d]
Riboflavin deficiency	Mild or none
Medical conditions	
Renal failure[e]	Mild to moderate
Post-transplantation	Mild to moderate
Hypothyroidism	Mild
Acute lymphocytic leukemia	Mild
Psoriasis	Mild
Drugs and toxins	
Alcohol abuse	Mild to severe
Methotrexate and other antifols	Mild to severe
Trimethoprim; anticonvulsants; fenofibrate; cyclosporine A	Mild
Drugs affecting vitamin B_6 (e.g., niacin, azauridine)	Mild[d]
Levodopa	Mild
Nitrous oxide toxicity (causes cobalamin inactivation)	Mild to severe
Genetic disorders	
Cystathionine β-synthase deficiency	Severe
Methylene tetrahydrofolate reductase polymorphisms (homozygous C677T or A1298C mutations)	Mild or none[f]
Physiologic and lifestyle factors[g]	
Male sex; older age	Mild
Coffee, smoking	Mild
Artifact	
Use of serum sample instead of plasma; delay in centrifugation	Mild, but can be variable
Selection of inappropriately low cutpoint	Variable

[a]Homocysteine elevations are categorized arbitrarily here as mild (15 to 25 μmol/L), moderate (25 to 50 μmol/L), and severe (>50 μmol/L).
[b]Homocysteine elevation does not occur in genetic cobalamin disorders in which methylcobalamin function is spared.
[c]Plasma homocysteine elevation does not occur in cerebral folate deficiency.
[d]Often inapparent unless post-methionine–loading measurement is done.
[e]Homocysteine elevation may occur even with serum creatinine changes within the reference interval.
[f]Often inapparent unless folate status is also compromised.
[g]It is not always known if other influences contribute to the differences attributed to these factors.

folate and cobalamin deficiencies.[284] Methionine levels, surprisingly, are usually unremarkable.[116,284]

Methylmalonic Acid

MMA, a product of accumulated D-methylmalonyl CoA, increases in serum and urine in cobalamin deficiency but not in folate deficiency, making MMA a more specific test for cobalamin deficiency than homocysteine. MMA is also subject to fewer pre-analytic influences. Serum levels are elevated in 98.4% of patients with clinical deficiency, such as pernicious anemia.[279] Most laboratories consider MMA elevated above 280 nmol/L (0.28 μmol/L), but published cutpoints have varied between 210 and 480 nmol/L,[285] which predictably affects the diagnostic frequency of abnormality.[190,191] Levels often exceed 1,000 nmol/L in clinical deficiency but are usually only mildly elevated in SCCD. MMA becomes normal within a week after cobalamin therapy;[242] folate therapy has no effect.

Elevated MMA is often used as sole evidence of cobalamin deficiency in epidemiologic studies[286] and in validating the performance of other biomarkers, such as holo-TC II.[190] However, despite a high sensitivity that allows a normal MMA level to exclude the possibility of cobalamin deficiency, MMA susceptibility to many cobalamin-unrelated influences (Table 36.7) disqualifies it as a diagnostic gold standard.[190,192] Independent influences on the MMA level include not only cobalamin status but also serum creatinine, age, and sex, but these account for only 16% of MMA variation.[287] Some MMA elevations are unexplained, and mild, isolated, and often spontaneously fluctuating elevations are common in SCCD.[192,240] The observation that nonelevated MMA levels can fall after antibiotic therapy[242,288] suggests intestinal bacteria contribute to serum MMA, perhaps through bacterial propionate metabolism. High MMA levels are common during the first year of life but they are transient.[289] Their explanation is unknown, but the MMA levels respond to cobalamin therapy also.[290]

Serum MMA assay is now automated and increasingly available in reference laboratories. Less information is available about urine MMA assay. An alternative product of propionyl CoA metabolism, 2-methylcitric acid, rises in cobalamin deficiency.[291]

TABLE 36.7

CAUSES OF ELEVATED METHYLMALONIC ACID LEVELS

Cobalamin deficiency
High-normal serum creatinine
Renal failure
Old age
Unexplained transient elevation in normal babies in first year of life[a]
Hereditary disorders of cobalamin metabolism in which methylmalonate metabolism is affected
Hereditary disorders of methylmalonate metabolism (e.g., methylmalonyl CoA mutase deficiency)
Methylmalonate metabolism polymorphisms
? Bacterial contamination of the small bowel[b]
Idiopathic
[c]Application of a liberal cutpoint for methylmalonic acid assay

[a]It is unclear if subclinical cobalamin deficiency exists in some cases.
[b]Reduction of methylmalonic acid levels has been described after antibiotic therapy in patients with bacterial contamination of the small bowel. The phenomenon has been attributed to propionate metabolism by bacteria.
[c]The optimal cutpoint for methylmalonic acid has not been defined. Laboratories and studies that use lower cutpoints than usual (e.g., 210 nmol/L) identify greater numbers of subjects with "high" or "abnormal" levels.

Holo-transcobalamin II

Holo-TC II, which carries all cobalamin available to cells, is conceptually attractive as a substitute for measuring total cobalamin, most of which is carried by TC I and unavailable to cells.[292] It is presumed to be very sensitive to cobalamin depletion because it is more often abnormal than other markers of cobalamin status. Serum levels are thought to represent a balance between holo-TC II entering the bloodstream, from the gut and perhaps elsewhere, and its very rapid uptake by tissues. However, it is unclear whether serum holo-TC II, whose half-life is measured in minutes, is more sensitive to intermittent transport fluxes than to the long-term changes in cobalamin stores that lead to cobalamin deficiency;[190] for example, it is unknown if temporarily reduced (i.e., 1 or 2 weeks) inflow from the gut, due to transiently reduced dietary intake or transient malabsorption caused by drugs, may reduce serum holo-TC II without there being any cobalamin depletion, which takes years. The contribution of holo-TC II reabsorbed in the renal tubule is also unknown.

Moreover, holo-TC II validation rests largely on comparisons against cobalamin assay, with MMA as the (unsatisfactory) arbiter of cobalamin status in surveys of subjects with SCCD.[244,293] As reviewed elsewhere,[190] these analyses showed marginal superiority of holo-TC II to total cobalamin in SCCD, but clinical assessment has been insufficient and some clinical studies identified shortcomings. Chief among the shortcomings has been poor holo-TC II specificity.[190,244,294] Reported confounding causes of low holo-TC II include oral contraceptive use,[256] a common TCN2 A67G polymorphism,[71] alcoholism and various hematologic disorders such as myelodysplasia,[295] and an effect of malabsorption independent of cobalamin adequacy.[296] Much work remains to be done[297] before recommendations that holo-TC II become the primary tool to determine cobalamin status[298] can be accepted.

Other Tests

Loss of the normal ability of added deoxyuridine to suppress thymidine incorporation into DNA by bone marrow cells deficient in cobalamin or folate[299] is as sensitive a test for cobalamin deficiency as homocysteine or MMA assay.[300] The test served to first document and define SCCD.[94,95,96,180] Adding cobalamin or folates to the cells can usually differentiate between the two deficiencies.[299,301] This labor-intensive test has been replaced by metabolite testing.

Formal diagnostic trials of reticulocyte response to a dose of folic acid or cobalamin small enough to ensure the specificity of response to it[302] are no longer needed. Nevertheless, objective documentation of the clinical response to therapy often has diagnostic value and is an important part of management.

SPECIFIC DISORDERS CAUSING COBALAMIN OR FOLATE DEFICIENCY

Diagnostic evaluation must include identification of the specific condition responsible for the deficiency. Identification of the cause helps confirm the diagnosis of deficiency, ascertains the prognosis, and is invaluable for management. The underlying cause predicts the rate at which deficiency, especially of cobalamin, progresses or relapses. Often, the cause itself can also be treated directly.

Causes of Cobalamin Deficiency

The discussion of causes follows the order of the cobalamin assimilation and utilization steps illustrated in Figure 36.4. The overwhelming majority of clinically apparent cobalamin deficiencies are malabsorptive in origin, of which pernicious anemia is the most common.

Dietary Insufficiency

Adults

The circumscribed dietary source for cobalamin and the huge ratio of body stores to daily loss protect most adults from becoming severely deficient on a purely dietary basis. Malnutrition limited to a few weeks or months does not produce cobalamin deficiency. The adults at risk tend to be committed, long-term vegetarians, especially vegans, but even they seldom become sufficiently depleted to develop megaloblastic anemia or myelopathy. A study of vegetarian women showed that their cobalamin intake was 1.68 ± 1.60 μg/day, one half that of nonvegetarian controls.[303] Surveys of vegetarians identify little or no change in MCV,[304,305] and macrocytic anemia is uncommon. Most often, vegetarians display SCCD, with mild biochemical abnormalities.[306–308] The risks are greater in those with lifelong dietary inadequacy in developing countries, such as India, where public health measures may be warranted.[309] Sometimes, metabolic abnormalities persist even after the diet has been liberalized.[307] Coexisting disorders, such as malabsorption, should be explored in vegetarian adults who actually develop symptoms of deficiency.[310,311]

Children

Young children, who must negotiate normal neurologic development and normal expansion of cobalamin stores simultaneously often have more serious consequences of dietary restriction. Children in macrobiotic communities show persistent metabolic abnormalities[312] and an often suspect cognitive performance,[313] even years after starting cobalamin supplementation. Phenylketonuric diets restricted in animal protein may predispose to mild biochemical cobalamin deficiency.[314,315]

The consequences can be much more catastrophic for babies born to and exclusively breast-fed by mothers who are strict vegetarians or have undiagnosed pernicious anemia.[170,315–317,318] It is instructive of the cobalamin differences between adults and children that the mothers are asymptomatic and only mildly deficient, whereas the children have severe neurologic and developmental abnormalities, often including movement disorders, which may increase just after therapy is begun.[319] Long-term deficits may persist.[320] Although the frequency of the syndrome in at-risk babies is unknown, maternal deficiency is thought to be the most common cause of cobalamin deficiency in childhood.[142] The impact on growth and developmental retardation is unclear but preventive efforts are warranted.

Malabsorption

Pernicious Anemia

The defect that defines pernicious anemia is not the anemia but the loss of IF that produces severe malabsorption of all forms of cobalamin. The atrophic gastritis that is universal in acquired pernicious anemia differs from the more common atrophic gastritis, which maintains IF secretion long after acid secretion ceases.[321,322]

With its loss of the parietal cells that synthesize IF, pernicious anemia is irreversible and many features suggest its autoimmune nature.[45,322,323] At least one of two autoantibodies to gastric antigens is found in 85% of cases, one directed against IF and one against the parietal cell; the gastric histology suggests an inflammatory disorder, cell-mediated immune abnormalities have been reported, steroid therapy sometimes restores IF secretion, and other autoimmune disorders often coexist.

The gastritis has been subdivided into types A and B.[324] Type A gastritis is found in 80% to 90% of patients with pernicious anemia, although it is the less common gastritis form in the general population; it is characterized by the presence of parietal cell antibody and is limited to the fundus while sparing the antrum, which is often hypertrophic. Type B pangastritis usually results from *Helicobacter pylori* infection and lacks such autoantibodies. Although it is the most common gastritis generally, only 10% to 20% of patients with pernicious anemia have it, suggesting that its role in pernicious anemia is infrequent.[325]

Pernicious anemia appears to have a familial predisposition, and relatives have increased frequencies of atrophic gastritis, antibodies to parietal cells, and thyroid disease.[45,326] Pernicious anemia is diagnosed most often after the age of 60 years,[45] although the gastritis begins many years earlier.[327] A survey of the elderly in Los Angeles found that 1.9% had unrecognized, often pre-clinical pernicious anemia.[189] Earlier surveys in Scandinavia reported prevalences of 0.13% to 0.2% among all ages.[45] Women are affected almost 50% more often than men in most surveys.[45,328] Although northern Europeans have the highest rates, pernicious anemia is universal.[45,189,268,328–332] The frequency in blacks may approach that in whites.[189] The reason why black women develop the disease more often before 50 years of age than do whites and have antibody to IF more often is unknown;[328] American Hispanics display a less significantly younger age trend for pernicious anemia.[268,331] Even in whites, approximately 10% of cases occur at a young age, sometimes in childhood or adolescence.[45] Called *juvenile pernicious anemia* in children, it is accompanied by especially high rates of gastric antibodies, immune endocrinopathy, and a positive family history.

In addition to causing relentless cobalamin deficiency, pernicious anemia carries many disease-specific associations and prognostic implications. The most serious is an increased risk for two gastric tumors, both predominating in the fundus.[322] A Swedish registry showed a 26.4-fold increased risk of gastric carcinoid and a 2.2-fold increased risk for gastric adenocarcinoma.[333] The carcinoid tumors metastasize in only 20% of cases, however.[322,334] The increased risk for gastric carcinoma has been widely but not unanimously accepted.[45,322,335–338] Many authors recommend endoscopy at the time of diagnosis in every patient with pernicious anemia,[339] but routine re-examinations are not advised. An increased risk of esophageal squamous cell carcinoma[333] is controversial.

Iron deficiency affects 21% of patients at diagnosis of pernicious anemia and another 23% develop it later.[340] An independent cause is not always found, suggesting that iron malabsorption due to gastritis and achlorhydria plays a role.[341] Bacterial contamination of the stomach and upper small bowel, presumably abetted by achlorhydria, has been described in pernicious anemia.[342] An increased frequency of gallstones has also been suggested.[343]

At some point, approximately 10% of patients develop clinical or latent thyroid disease, most often hypothyroidism.[344] Related autoimmune disorders associated with pernicious anemia include vitiligo, hypoparathyroidism, hypoadrenalism, and myasthenia gravis.[45] An unusual coexistence is with agammaglobulinemia or common variable immunodeficiency;[345] the patients are young, have type B gastritis, often have bacterial overgrowth, and are at very high risk for gastric cancer. Other immune associations of pernicious anemia may include immune thrombocytopenia, immune hemolytic anemia, transient red cell aplasia, diabetes mellitus, biliary cirrhosis, chronic lymphocytic leukemia, and renal tubular acidosis.[45,346–351] Links have also been suggested with myelodysplasia, leukemia, and myeloproliferative diseases,[265,338,352–354] and perhaps with sickle cell anemia.[355,356] An increased rate of tuberculosis was reported in Asian Indians and Chinese with pernicious anemia.[330,332]

Hereditary Intrinsic Factor Deficiency

Also called *congenital pernicious anemia*, this autosomal recessive disorder is characterized by an absent, unstable, or nonfunctional gastric IF[142,357–359] (Table 36.8). Gastric status is otherwise normal, although unexplained basal hypochlorhydria sometimes occurs.[357] Several mutations of the *GIF* gene have been found,[360,361] some in patients originally misdiagnosed to have Imerslund-Gräsbeck syndrome because of spurious Schilling test results. Hereditary deficiencies of IF and TC I, whose genes lies near each other, coexisted in one family.[362] Patients with hereditary IF deficiency usually develop anemia, myelopathy, and, occasionally, developmental delay in the first few years of life as cobalamin stores from birth become depleted. Infrequently, diagnosis is delayed until adolescence or later.[357]

Food-cobalamin Malabsorption

Studies in 1973 demonstrated that absorption testing with free crystalline cyanocobalamin, such as in the Schilling test, failed to identify defective release of food-bound cobalamin.[363] As reviewed elsewhere,[195] tests using food vehicles revealed that many patients could not absorb food-bound cobalamin while absorbing free cobalamin normally, the disparity that is diagnostic for food-cobalamin malabsorption (when free cobalamin absorption fails, as in pernicious anemia, of course, food-bound cobalamin cannot be absorbed either).

The crux in food-cobalamin malabsorption appears to be the loss of pepsin and the acid secretion needed for optimal pepsin activity, without losing IF secretion[364] (Fig. 36.4, panel 1). Most prominent among patients with food-cobalamin malabsorption were those with partial gastrectomy, other gastric surgery, or gastritis, all of whom had intact IF secretion. However, the gastric disorders are heterogeneous. Some patients have severe autoimmune gastritis and achlorhydria but others have *H. pylori*-induced gastritis.[365] Although it may have therapeutic implications as a reversible cause of malabsorption,[365] the association with *H. pylori* infection lacks sufficient diagnostic sensitivity and specificity to be equated with food-cobalamin malabsorption.[240,366,367] Food-cobalamin malabsorption improves after antibiotic therapy sometimes, but whether this reflects the disappearance of *H. pylori*[365] or anaerobic bacteria,[368] or both, was not proven directly. Reported cures of cobalamin deficiency anemia solely by eradicating *H. pylori* require more documentation.[240] Patients taking acid-suppressive drugs, such as omeprazole, also malabsorb food cobalamin;[195,369] cobalamin deficiency is infrequent in them, although low cobalamin levels were reported in a retrospective study of patients who may have had other predispositions to low levels.[370]

Food-cobalamin malabsorption need not cause cobalamin deficiency, perhaps because it is sometimes reversible and because it may not abrogate reabsorption of biliary cobalamin, but it affects 30% to 40% of people with SCCD.[195] Severe deficiency occurs much less often.[96,195,311,371,372] Progression to pernicious anemia with loss of IF has been reported in a few cases.[311,371]

TABLE 36.8

HEREDITARY DISORDERS OF COBALAMIN AND COBALAMIN-RELATED METABOLISM

Disorder	Defect (and Affected Gene)	Cbl	Hcys	MMA	Megaloblastic Anemia	Myeloneuropathy	Other
Hereditary IF deficiency	IF synthesis (*GIF*)	↓	↑	↑	Yes	Often	
Imerslund-Gräsbeck syndrome	IF receptor (*CUB* or *AMN*)	↓	↑	↑	Yes	Often	
TC II deficiency	TC II synthesis (*TCN2*)	N	↑	N-↑	Yes	Occasional	
TC II receptor deficiency	TC II receptor synthesis (*TCblR/CD320*)	N	N	↑	No	No	
TC I (HC) deficiency	TC I (HC) synthesis (*TCN1*)	↓	N	N	No	No	
CblA defect	Mitochondrial reduction of cobalamin (*MMAA*)	N	N	↑	No	No	Failure to thrive, lethargy, hypotonia, acidosis
CblB defect	Cob(I)alamin adenosyl transferase (*MMAB*)	N	N	↑	No	No	Failure to thrive, lethargy, hypotonia, acidosis
CblC defect	?Cytoplasmic reduction of cobalamin (*MMACHC*)	N	↑	↑	Yes	Yes	Developmental delay, microcephaly, seizures, retinopathy
CblD defect–combined	?Cytoplasmic reduction of cobalamin (*MMADHC*)	N	↑	↑	Varies	Varies	Thrombosis
CblD–variant 1	CblD defect affects only methylcobalamin (*MMADHC*)	N	↑	N	Mild to mod	Yes	Cerebral defects, seizures
CblD–variant 2	CblD defect affects only adenosylcobalamin (*MMADHC*)	N	N	↑	No	No	Mental changes, seizures
CblE defect	Methionine synthase reductase (*MTRR*)	N	↑	N	Yes	Yes	Developmental delay, cerebral atrophy, seizures, hypotonia
CblF defect	Cobalamin release from lysosome (*LMBRD1*)	N	↑	↑	Mild	No	Poor feeding, growth retardation
CblG defect	Methionine synthase (*MTR*)	N	↑	N	Yes	Yes	Behavior changes, seizures
CblJ defect	Cobalamin release from lysosome (ATP-binding cassette transporter; *ABCD4*)	N	↑	↑	Yes	No	Developmental delay, microcephaly, hypotonia, lethargy
Mut^0 defect	Absent MM-CoA mutase (*MUT*)	N	N	↑	No	No	Failure to thrive, lethargy, hypotonia, acidosis
Mut^- defect	Decreased MM-CoA mutase (*MUT*)	N	N	↑	No	No	Failure to thrive, lethargy, hypotonia, acidosis
MM-CoA epimerase deficiency	MM-CoA epimerase deficiency (*MCEE*)	N	N	↑	No	No	

↑, increased levels; ↓, decreased levels; ado-cbl, adenosylcobalamin; Cbl, cobalamin; HC, haptocorrin; Hcys, homocysteine; IF, intrinsic factor; MMA, methylmalonic acid; MM-CoA, methylmalonyl coenzyme A; mod, moderate; N, normal levels; TC, transcobalamin.

Gastric Surgery

Subtotal gastrectomy eventuates in cobalamin deficiency in 15% to 30% of patients.[45,373,374] Some of these patients develop clinical deficiency with megaloblastic anemia and neuropsychiatric problems. However, absorption of free cobalamin (Schilling test) most often remains normal,[375] and most patients have only food-cobalamin malabsorption and SCCD.[195,363] Iron deficiency and folate malabsorption may also develop.[376,377] Food-cobalamin malabsorption and SCCD complicate other gastric procedures too, such as bariatric surgery.[378,379]

Pancreatic Insufficiency

Pancreatic proteases degrade TC I and release its cobalamin for transfer to IF.[84] One half of patients with chronic pancreatic insufficiency have abnormal Schilling test results, requiring exogenous pancreatic extract for correction. It is unclear why such apparently severe malabsorption rarely, if ever, eventuates in clinically apparent cobalamin deficiency.

Bacterial Overgrowth of the Small Bowel

Large enough numbers of bacteria may accumulate in the upper small bowel if anatomical abnormalities (e.g., fistulas, strictures, large diverticula) or motility disorders exist (e.g., autonomic dysfunction in diabetes). Bacteria take up cobalamin and, in that location, may compete with IF for it.[380] Bacteria also generate nonfunctional corrinoid analogs,[381] whose contribution to the cobalamin deficiency is unclear. The deficiency can be clinically overt and is sometimes the only obvious manifestation of bacterial

overgrowth. Antibiotics reverse the malabsorption, but relapse occurs if the cause of bacterial overgrowth persists.

Parasitic Infestation

The classic parasitic cause of cobalamin deficiency is *Diphyllobothrium latum*, which infests freshwater fish.[45,382] The tapeworms in the upper small intestine compete avidly for cobalamin. Most patients are asymptomatic, but cobalamin levels are often low.[383] It is uncertain whether the worm load or coexisting conditions, such as a frequent atrophic gastritis, determine the extent of deficiency. The infection is rare in the United States. *Giardia lamblia* has been associated with cobalamin malabsorption, particularly in children and immunocompromised patients, but it is unclear if the association is a causal one. Low cobalamin levels have been reported in heavy *Strongyloides stercoralis* infection.[382]

Gastrinoma

The Zollinger-Ellison syndrome can cause cobalamin malabsorption. The basis appears to be the low pH in the intestine.[384] Ileal uptake of the IF–cobalamin complex requires a neutral pH.

Ileal Diseases

If they involve enough of the ileum, acquired diseases impair receptor-mediated absorption of IF-bound cobalamin (Fig. 36.4, panel 3). Schilling tests had successfully demonstrated malabsorption refractory to oral IF or antibiotics and led to a diagnostic pursuit of the specific ileal disease. The tests' disappearance has made these malabsorptive diagnoses inaccessible.

Tropical sprue is endemic in the Caribbean, South Asia, and elsewhere. Manifestations can appear long after a person has emigrated. Cobalamin deficiency occurs in chronic cases and is sometimes the sole clinical finding.[385,386] Some patients have folate deficiency instead, especially early in the course, or have both deficiencies. The vitamin differences may vary regionally, as does the often impermanent response of tropical sprue to folate and antibiotics. As in all acquired ileal diseases, other nutrients are often at risk also. The disease's prevalence appears to be declining but a subclinical tropical enteropathy may exist.[387]

The frequency of cobalamin malabsorption and deficiency varies in celiac disease, inflammatory bowel disease, and dermatitis herpetiformis.[388,389] Deficiency often depends on the extent of ileal involvement, and resections that exceed 20 cm make deficiency more likely.[390] Atrophic gastritis may sometimes contribute to the deficiency. Ileal malabsorption has been associated with acquired immunodeficiency syndrome but does not explain most of the low cobalamin levels (see the "Cobalamin Levels" section of "Laboratory Tests of Deficiency").

As noted, the risk of cobalamin malabsorption and deficiency after ileal surgery appears to be proportional to its extent. Long-term malabsorption occurs with jejunoileal bypass for obesity.[391,392] Deficiency has also been attributed to malabsorption with ileal reservoirs for the ureters in patients with bladder cancer[393,394] and for restorative proctocolectomy in ulcerative colitis.[395] Puzzlingly, however, Schilling tests have been normal with ileal reservoirs.[395]

Imerslund-Gräsbeck Syndrome (Megaloblastic Anemia Type 1)

Selective malabsorption of cobalamin arises from genetic defects affecting the ileal IF receptor (Table 36.8). Two mutations of the cubilin gene have been identified in Finnish families;[396,397] some Norwegian families have mutations of the amnionless gene,[398] and other mutations of these genes have been reported in the Mediterranean area and elsewhere.[399] The malabsorption is limited to cobalamin and usually produces classical clinical signs of deficiency in the first few years of life.[142,400,401] Diagnosis is occasionally delayed and, with disappearance of the Schilling test, differentiation from hereditary IF deficiency can be difficult. The disorder is often accompanied by mild and apparently benign proteinuria because cubilin, a multiligand receptor, also reabsorbs albumin in renal tubular cells.[402,403]

Drugs, Toxins, and Related Toxicities

Many drugs and toxins interfere with cobalamin absorption, usually by unknown mechanisms. Examples include alcohol, colchicine, neomycin, cholestyramine, paraaminosalicylic acid, and slow-release potassium, but the true list of offending drugs is probably longer. Cobalamin deficiency rarely occurs with any of them because exposure and malabsorption must be uninterrupted and last for several years in order to deplete cobalamin stores. Few drugs fulfill those criteria. The low cobalamin levels in metformin users have been widely equated with cobalamin deficiency, yet MMA levels are normal;[257] the low cobalamin may represent acquired TC I deficiency instead.[258]

Transport and Cellular Defects

Most disorders of cobalamin transport to cells and cellular utilization are genetic in origin and usually affect children. In contrast with malabsorptive and dietary disorders, their effects usually develop rapidly and serum cobalamin levels are usually normal.

Transcobalamin II Deficiency and Transcobalamin II Receptor Defect

Deficiency of TC II impairs cobalamin delivery to cells, although some cobalamin enters cells by unknown, presumably nonspecific means (Table 36.8). TC I-bound cobalamin continues to circulate, so normal cobalamin levels are maintained, with rare exceptions.[404] The children typically have megaloblastic anemia and failure to thrive in the first year of life.[142] Neurologic dysfunction is less frequent[405] and may appear chiefly when treatment is inadequate.[406] Some children also have infections suggesting immune hypofunction.[407] Schilling test results have often been abnormal, perhaps because TC II must take up the absorbed cobalamin. The diagnosis requires immunoassay of total TC II, but a nonfunctional TC II has also been described.[408] Several *TCN2* mutations have been identified.[409,410] Patients respond to frequent cobalamin injections. Oral therapy has been used after stabilization, but complications have also been attributed to undertreatment.[411]

The phenotype is very different in deficiency of TC II receptor caused by homozygous *TCblR/CD320* nonsense mutation:[412] moderate methylmalonic aciduria is the lone finding and there are no symptoms. The explanation for this paradoxical presentation is unknown.

Transcobalamin I (Haptocorrin) Deficiency

This disorder, often mistaken for and treated as cobalamin deficiency, is typically uncovered in adults with unexplained low cobalamin levels (Table 36.8). Serum cobalamin is low because 70% or more of it is carried by TC I. Cellular and metabolic cobalamin status is normal.[83,254,413–415] Corrinoid analogs, typically carried by TC I, appear to be absent in severely TC I-deficient plasma;[80] tissue analog content is unknown. A few patients have had atypical, probably unrelated neurologic dysfunction that was unaffected by cobalamin therapy,[254,415] and probably reflects coincidence or selection bias for cobalamin testing (which led to TC I testing). The diagnosis requires demonstration of TC I absence in plasma and secretions, such as saliva, which is typical of severe deficiency. Nine severely deficient patients, all non-Caucasians, have been identified, and the frequency in a prospective survey of samples with low cobalamin levels appears to be 0.6%.[254] A combined deficiency of TC I and lactoferrin, which are synthesized together in specific granules of myeloid cells and in exocrine gland epithelium, was found in a family;[415] interestingly, the affected patients were not predisposed to infection. Another family had coexisting deficiencies of TC I and IF, whose genes are not far apart.[362]

TC I deficiency was thought rare until a mild deficiency identical to that seen in obligate heterozygous relatives of severely deficient patients,[415] was found in 15% of patients with low cobalamin levels.[254] Such patients have low or low-normal levels of plasma TC I and saliva TC I. The diagnosis requires ruling out cobalamin deficiency and measuring plasma TC I (serum often provides spuriously normal TC I results). Four heterozygous *TCN1* mutations,[356,416,417] also seen in severely deficient patients with homozygous or compound heterozygous mutations, were found in 34 affected members in 24 families.[80]

Nitrous Oxide Toxicity

Nitrous oxide oxidizes cob(I)alamin, irreversibly inactivating the methionine synthase to which the cobalamin is bound.[418] Because exposure during dental and surgical procedures is brief and enzyme is regenerated quickly, clinical expression does not occur despite mild metabolic abnormalities lasting a few days.[419,420] There are two exceptions to the benign consequences. One is repetitive exposure,[421,422] such as "recreational" abuse of the gas. The other is when a patient with unrecognized, clinical cobalamin deficiency is exposed to nitrous oxide during lengthy or repeated surgery.[423–426] Within days, megaloblastic anemia results but neuropsychiatric dysfunction is often especially severe.

Nitric oxide also reacts with cobalamin and inhibits methionine synthase,[427] but no clinical impact is known.

Cbl Mutations

Inborn errors affecting intracellular cobalamin metabolism, designated cbl mutations (Table 36.8), are sorted by their metabolic changes, whether homocystinuria, methylmalonic aciduria, or both. The disorders are then differentiated by complementation studies in which the metabolic behaviors of patients' fibroblasts fused with known-disease fibroblasts are compared. Most genes are known but the proteins coded by some of them are unknown.[142]

Homocystinuria without MMA elevation marks the cblE defect, caused by methionine synthase reductase deficiency; the cblG defect, caused by methionine synthase deficiency; and the cblD-variant 1. Megaloblastic anemia and prominent neurologic problems occur, usually in the first few years of life,[428] but diagnosis can sometimes be delayed.[429] Therapy is generally effective, although the neurologic problems are difficult to reverse unless treated early.

Isolated methylmalonic acidurias (cblA, cblB, cblD-variant 2, mutase, and epimerase defects) affect adenosylcobalamin, which is required in the methylmalonyl CoA mutase reaction, or other methylmalonyl enzymes. The cblB defect affects adenosyltransferase, whereas mitochondrial reduction of cobalamin appears to be defective in cblA and cblD-variant 2.[142] These disorders cause lethargy, vomiting, dehydration, failure to thrive, hypotonia, and acidosis but do not produce megaloblastic anemia.[430] Presentation is in the first months of life, but the course and response to cobalamin may vary. The clinical picture in cblD-variant 2 was complicated by an intracranial hemorrhage at birth. The two mutase defects affect the methylmalonyl CoA mutase enzyme itself: mut^0, characterized by enzyme deficiency, and mut^-, with abnormal enzyme. Methylmalonyl CoA epimerase (racemase) deficiency was described in a patient with mild MMA elevation.[431] The mutase and epimerase defects do not involve cobalamin or respond to it, have either no clinical manifestations or just the mild ones seen in other methylmalonic acidurias, and are mentioned only for the differential diagnosis of methylmalonic aciduria.

The combined homocystinuria–methylmalonic acidurias include the cblC, cblD, cblF, and cblJ defects, which affect both methylcobalamin and adenosylcobalamin. Megaloblastic anemia is prominent in cblC, often with a microangiopathic and thrombocytopenic process resembling the hemolytic uremic syndrome,[432] but megaloblastic anemia is muted in cblD and cblF defects.[93] Many children with cblC, the most common of the cbl disorders, have severe courses marked by neurologic dysfunction, acidosis, perimacular degeneration, and thromboses.[433] Prognosis is often poor. The cblD defect can vary in hematologic and neurologic severity and includes venous thromboses.[93,434] The defect involves the *MMADHC* gene, which has a cobalamin binding motif and a putative mitochondrial targeting sequence.[434] CblD is puzzling because, despite complementation identity, different mutations of the gene can produce homocystinuria, methylmalonic aciduria, or both;[434,435] each is discussed within its metabolic group. Variable presentations are seen in the cblF and cblJ defects, in which lysosomal export appears defective.[436,437,438]

Increased Requirements

High demand for cobalamin in hypermetabolic and increased cell turnover states has been proposed, but its documentation is incomplete. Patients with clinical consequences have yet to be identified satisfactorily.

Old Age

Normal aging does not cause cobalamin deficiency but common disorders of aging, such as gastritis and gastric atrophy, predispose to it.[178,322,439] The elderly are at increased risk for both clinically expressed and subclinical deficiencies, including the most common causes of each form, pernicious anemia and food-cobalamin malabsorption, respectively. Although frequencies vary with the studied population and the test cutpoint selection, most studies estimate that 10% or more of the elderly are affected, with SCCD outnumbering clinical deficiency severalfold. The frequency of low cobalamin levels outnumbers low folate levels [191,440].

Elevated cobalamin levels appear to be independent predictors of mortality in elderly patients with or without cancer.[441,442] The explanation is unknown.

Causes of Folate Deficiency

The origin of folate deficiency is often multifactorial. Limited intake may not be able to compensate for increased folate demand, or a drug or genetic polymorphism that mildly inhibits folate metabolism can convert borderline folate intake into frank deficiency. That being said, the landscape of folate deficiency has changed dramatically as a result of food fortification and folate supplement use. The incidence of deficiency has decreased sharply. Between 1988–1994 and 2001–2002, the frequency of serum folate levels below 3 μg/L declined from 18.4% to 0.2% of the American population and that of red cell folate below 160 μg/L declined from 45.8% to 7.1%, across all economic and demographic strata.[443] Other studies reported even greater impact in those who also took folate supplements.[444] The folate status of American elderly leapfrogged that of younger adults, largely because of higher rates of supplement use,[443] whereas Europeans, with less exposure to fortification and supplements, showed metabolic signs of folate deficiency as they aged further.[445]

Dietary Insufficiency

The relatively small ratio of folate stores to daily requirement makes it possible to become folate-deficient after only a few months of poor intake, and the likelihood and speed of deficiency are enhanced when other causes coexist. The most common of these is abuse of alcohol,[446] especially hard liquor, which also contains little folate.

Children

Delivery of maternal folate to the fetus is efficient,[45] so folate deficiency is rare at birth. Folate levels decline thereafter, and problems arise in some children in whom growth demands and limited diet combine. Premature infants have especially high requirements.[447] The availability of folate from milk is limited.[45] Deficiency can appear in babies whose diet depends heavily on milk and who do not receive folate-fortified foods or supplements.

Folate deficiency can also occur with restricted diets, such as those given for phenylketonuria.

Malabsorption

Intestinal Malabsorption

Documented in only 2% of folate-deficient patients in one study,[279] malabsorption is a distant second to malnutrition and alcoholism as a cause of folate deficiency. Deficiency appears early in tropical sprue, which can feature marked gastrointestinal symptoms and other absorptive defects.[385,386] The intestinal lesion itself can remit with folate therapy, although the remission can be limited. Celiac disease also causes folate malabsorption and deficiency in some patients, with or without cobalamin deficiency.[389,448] Inflammatory bowel disease, such as Crohn disease, which involves ileum most prominently, produces folate deficiency less often.[449] Folate malabsorption has been described in patients with dermatitis herpetiformis. The impact, if any, of food fortification on folate deficiency in patients with malabsorption requires study.

Other Malabsorptive Mechanisms

Folate absorption is reduced in atrophic gastritis and other gastric disorders or with drugs that cause achlorhydria.[377,450–452] It is not clear how often deficiency results.[451] Similarly, folate absorption diminishes when oral pancreatic replacement therapy, which buffers pH, is given for pancreatic insufficiency,[453] whereas cobalamin absorption may improve.

Drugs and Toxins

Alcohol abuse is a major contributor to folate deficiency[446] and should be suspected even when other causes of deficiency are found. The risk is highest in alcoholics who eat poorly, but alcohol also has direct effects on folate metabolism and transport. The latter include interruption of the enterohepatic recycling of hepatic methylTHF, direct toxicity to enterocytes, formation of aldehyde adducts, and increased degradation of folates.[454–457]

Sulfasalazine interferes with folate absorption and perhaps with folate-related enzymes.[458] Hydantoins, and to a lesser extent other anticonvulsants, have been associated with macrocytosis and low folate levels, but megaloblastic anemia is uncommon.[45] The mechanisms are unclear. Valproic acid inhibits mitochondrial folate metabolism and affects fetal folate metabolism.[459] Antifols, such as methotrexate, inhibit folate binding to dihydrofolate reductase and thus limit the availability of THF (Fig. 36.2, reaction 1). Their effect can be bypassed by administering reduced folates such as 5-formylTHF (leucovorin; folinic acid). Trimethoprim-sulfamethoxazole and pyrimethamine are potent inhibitors of bacterial dihydrofolate reductase but weak inhibitors of the human enzyme. They cause megaloblastic anemia infrequently but appear to do so especially in patients with other limitations of folate status.[460] Oral contraceptive use has been associated with diminished serum folate levels, but deficiency has not been well documented.

Inborn Errors of Folate Transport and Metabolism

Methylene Tetrahydrofolate Reductase Deficiency

Homozygous deficiency of this enzyme (Fig. 36.2, reaction 3), to be distinguished from the common polymorphism that causes no disease, produces severe neurologic dysfunction, including myelopathy, developmental delay, seizures, and microcephaly.[142] Thrombosis may also occur. Symptoms usually arise in the first year, but mild cases may not be diagnosed until adulthood. Anemia does not develop because methyleneTHF remains available for thymidylate synthesis (reaction 2). Serum folate is low because methyleneTHF cannot be converted to methylTHF, the main circulating form of folate. The diagnosis is made by measuring enzyme activity in fibroblasts or leukocytes, which correlates with disease severity. Many mutations of the reductase gene have been identified.[142] Early treatment, which includes betaine, is essential.[461]

Hereditary Folate Malabsorption

This rare disorder is characterized by impaired transport of folate across both the intestinal mucosa and the choroid plexus because of mutations affecting the proton-coupled folate transporter, which is located at both those sites.[36,37] As a result, serum, red cell, and cerebrospinal fluid folate levels are very low. Megaloblastic anemia and severe neurologic dysfunction, including seizures, appear in the first few months of life.[161] Diarrhea, mucositis, immunodeficiency, and failure to thrive also occur. Intensive parenteral and even intrathecal therapy have often been used, but some patients respond well to oral folinic acid.[37,161]

Cerebral Folate Deficiency

Cerebral folate deficiency is characterized by decreased cerebrospinal fluid methylTHF, whereas, unlike in hereditary folate malabsorption, folate absorption and systemic metabolism are normal.[162] Thus, it features mental and neurologic manifestations similar to hereditary malabsorption but lacks low serum and red cell folate levels and megaloblastic anemia. Many affected children display mutations of the *FOLR1* gene that codes for FR-α, which regulates methylTHF transport across the choroid plexus.[462,463] Others have autoantibody to FR-α instead,[162,464] including one middle-aged adult.[465] Unrelated conditions can produce varying degrees of the same cerebral methylTHF deficiency without apparent mutations or FR-α abnormality.[162,466] These miscellaneous conditions await clarification. As illustrated in the next section, various hereditary disorders can produce similar pictures. The cerebral folate deficiency often responds to folinic acid; [162,467] folic acid is contraindicated.

Miscellaneous Folate Disorders

Five members from two families with megaloblastic anemia, seizures, microcephaly, and developmental delay had dihydrofolate reductase deficiency. They had normal serum folate and cobalamin levels but displayed a cerebral folate deficiency syndrome, with methylTHF deficiency and tetrahydrobiopterin deficiency limited to cerebrospinal fluid.[467,468] Hematologic improvement rapidly followed folinic acid therapy, but neurologic improvement was incomplete.

A mutation of the *MTHFD1* gene, which encodes a single protein with three enzyme activities in folate metabolism (Fig. 36.2, reaction 6), was identified in a child with megaloblastic anemia, atypical hemolytic uremic syndrome, immunodeficiency, and homocystinuria.[469]

A single report of familial aplastic anemia with defective cellular uptake of folate[470] remains a mystery.

Genetic Polymorphisms

No clinical consequences have been confirmed for many missense mutation polymorphisms affecting genes for folate-related enzymes and transport proteins.[70] The best-studied exception is the gene for methyleneTHF reductase, whose C677T and, to a lesser extent, A1298C mutations are common in most populations except blacks. These polymorphisms produce mildly diminished enzyme activity and no direct symptoms. However, mild hyperhomocysteinemia is seen if folate intake or levels are diminished in persons homozygous for the C677T mutation. Consequences such as increased risks for neural tube defect births and cardiovascular risks have been described and often appear tied to lower levels of folate intake.[471] It is interesting that reduced leukemia and colorectal cancer risks have been associated with this mutation.[472]

Increased Demand or Increased Losses

Fetal needs divert maternal folate via placental receptors. Other settings for increased demand for folate are lactation, chronic hemolytic anemia, and perhaps psoriasis and myeloproliferative

diseases. Evidence for stress on folate metabolism by increased requirements exists but lacks clear metabolic proof of depletion.[35,473–476] Deficiency usually results when dietary intake cannot compensate adequately or disorders such as alcohol abuse or malabsorption supervene. Folic acid is often given routinely to pregnant women and patients with chronic hemolysis. However, a frequent mild elevation of homocysteine in sickle cell anemia appears unrelated to folate status or supplementation,[477] and a randomized supplementation trial in sickle cell anemia failed to show clinical benefits.[478] The increased detection of pernicious anemia in patients with sickle hemoglobinopathy suggests that monitoring is advisable by physicians who routinely prescribe folic acid.[355,356]

Folate is lost during dialysis, and supplements are often given. Alcohol abuse, anticonvulsants, and oral contraceptives have been proposed to cause increased folate catabolism and loss.[479]

Syndromes of Unknown Cause

A syndrome of acute deficiency, megaloblastic changes in bone marrow (but not peripheral blood), and pancytopenia was described in severely ill patients in intensive care units;[480] serum folate levels have been normal. The entity is unclear because such patients have many illnesses and receive many drugs.

Causes of Megaloblastic Anemia Other than Cobalamin or Folate Deficiency

Thiamine-responsive Megaloblastic Anemia

A familial syndrome of megaloblastic anemia, diabetes mellitus, and sensorineural deafness can occur during childhood or adolescence.[481,482] Some patients may have additional features.[483] The megaloblastic anemia and diabetes improve at least partially with thiamine therapy. Neither folate nor cobalamin has a known causative or therapeutic role. Several mutations of the thiamine transporter-1 gene have been found.[483,484–486] The patients have no evidence of thiamine deficiency.

Hereditary Orotic Aciduria

Megaloblastic anemia unrelated to folate or cobalamin accompanies developmental delay, orotic acid crystalluria, and ureteral problems in affected children.[487] There is clinical heterogeneity. Some patients also have congenital malformations and immune deficiency. The defect usually involves the gene for both orotate phosphoribosyltransferase and orotidine 5′-monophosphate decarboxylase, which catalyze uridine-5-monophosphate synthesis. Oral uridine is effective.

Miscellaneous Causes

Chemotherapeutic agents that affect nucleoprotein synthesis, such as hydroxyurea and 5-fluorouracil, cause megaloblastic anemia. More easily distinguishable from megaloblastic anemia are the bizarre nuclear changes in arsenic toxicity.

Myelodysplastic syndromes occasionally feature nuclear characteristics that resemble megaloblastic change, but hyposegmentation of neutrophil nuclei ("pseudo–Pelger-Hüet") is more common than hypersegmentation. Erythroleukemia and some cases of acute myelogenous leukemia also show megaloblastlike nuclear dysplasia in erythroid precursors.

Laboratory Diagnosis of the Causes of Deficiency

Cobalamin Deficiency

Malabsorption is the main suspect when evaluating causes because approximately 94% of cases of clinical cobalamin deficiency in adults have gastrointestinal origins.[279] The situation has been modified by the increasing, often accidental identifications of patients with the usually clinically irrelevant SCCD, which is much less often associated with malabsorption.[178,179]

Although malabsorptive disorders in children, whether classically acquired as in adults or hereditary, are not unusual, the diagnostic approach in children differs and depends on age and other issues. Genetic metabolic disorders tend to present in early childhood but can be delayed; MMA and homocysteine must usually be measured because cobalamin levels may be normal. Maternal cobalamin status must also be part of the evaluation of very young children.

Direct Tests of Cobalamin Absorption

The classic absorption test, the Schilling test, assessed absorption of free crystalline cobalamin by measuring urinary excretion of an oral dose of ^{57}Co-labeled cyanocobalamin that approximated the amount in a meal.[45,488] If excreted radioactivity was subnormal, the test was repeated with an oral dose of IF. Correction of an abnormal result by IF diagnosed pernicious anemia; lack of correction suggested an intestinal problem. If results became normal upon re-testing after antibiotic treatment or with an oral pancreatic extract, intestinal bacterial overgrowth or pancreatic insufficiency, respectively, were likely. The Schilling test and all its variants have disappeared because of concerns about isotope use, limited and suspect sources of IF, and the tests' inconvenience and occasional unreliabilities.[488]

Probably contributing to the test's disappearance were misperceptions that diagnosing malabsorption was clinically irrelevant, which may have been reinforced by the large influx of new patients with SCCD, whose results were consistently normal.[488] A new absorption test measuring serum holo-TC II response to oral cobalamin[489] has not been convincingly validated.

Several food-cobalamin absorption tests have identified impaired release of ingested cobalamin from its binding to food proteins, using ^{57}Co-labeled cobalamin attached to egg, egg yolk, or chicken serum as vehicles in a procedure otherwise identical to the Schilling test which tested only absorption of free cobalamin.[195,363,375] These tests have disappeared as well. Substitution of often mistaken, indirect criteria for direct food-cobalamin absorption testing has generated a series of unreliable reports by some authors, as noted elsewhere.[488] Blood tests for gastritis/gastric atrophy or *H. pylori* status are also unreliable surrogate markers.[240,366]

Autoantibody to Intrinsic Factor

Testing serum for antibody to IF sometimes permits the diagnosis of pernicious anemia without having to resort to the Schilling test. Type I antibody, which blocks the cobalamin-binding site of IF, is slightly more frequent and more easily tested than type II antibody, which complexes with a nonbinding IF epitope. Antibody is found in 50% to 70% of patients with pernicious anemia, with the higher frequencies when more sensitive assays are used.[490–492] Some groups of patients have higher rates; 96% of black women with pernicious anemia are positive.[328] With the disappearance of Schilling tests, IF antibody, whose specificity exceeds 95%,[45,493] is the only practical option for diagnosing pernicious anemia, despite its poor sensitivity. However, serum containing excess free cobalamin often produces false-positive IF antibody results; blood samples obtained within days after a cobalamin injection must be avoided.[494]

Autoantibody to Gastric Parietal Cell

Parietal cell antibody is directed to the membrane H^+,K^+-adenosine triphosphatase pump subunits pre-existing in cytoplasmic tubulovesicles.[323,495] The antibody occurs in 80% to 90% of patients with pernicious anemia. However, it is specific for immune gastritis, not for pernicious anemia.[496] Moreover, the

antibody tends to disappear with time,[497] and it is not as sensitive as IF antibody in many types of patients, such as the young and some ethnic groups.[332,491]

Functional Blood Tests of Gastritis and Gastric Atrophy

Serum gastrin is elevated in 80% to 90% of patients with pernicious anemia,[498] reflecting their gastric achlorhydria and frequent antral hypertrophy.[322,324] Levels tend to be very high, often in the thousands, particularly in women.[491,498] However, hypergastrinemia has many, more frequent causes, such as nonpernicious anemia atrophic gastritis or omeprazole use. Serum pepsinogens also reflect gastric status. Pepsinogen I, derived from fundic chief cells, is usually decreased in pernicious anemia, whereas pepsinogen II, which derives from fundus and antrum, is normal or elevated because of antral sparing in most patients with pernicious anemia.[499] A low pepsinogen I-to-II ratio or low pepsinogen I level, or both, may be the most sensitive blood tests for pernicious anemia[498] but have limited specificity. None of the tests mentioned in this section are diagnostically reliable in food-bound cobalamin malabsorption either.[366]

Direct Gastric Tests

Measuring IF content in stimulated gastric juice is the most reliable test for pernicious anemia but requires gastric intubation and is not generally available. Measuring gastric acid secretion has some diagnostic value because the presence of acid rules out Addisonian pernicious anemia.

Tests of Intestinal Function

Without the Schilling test, intestinal malabsorption of cobalamin is not identifiable. Today, intestinal malabsorption can only be suggested if other gastroenterologic tests, such as blood tests for celiac disease or ileal biopsy, identify a specific disease. Duodenal biopsy is more accessible than ileal biopsy but has much less diagnostic relevance to cobalamin.

Cobalamin-binding Proteins

Serum TC II assay identifies TC II deficiency in children with unexplained cobalamin deficiency (usually, but not always, accompanied by normal cobalamin levels) but is rarely needed when evaluating adults. TC I assay (testing plasma, and never serum) is useful in patients of all ages with unexplained low cobalamin levels who are asymptomatic or have equivocal symptoms.[254] Measuring apoproteins with cobalamin-binding capacity assays is not as useful as immunoassays for total TC II or TC I, and becomes unreliable after cobalamin injection which saturates apoproteins, rendering them unmeasurable. TC I assays, and to a lesser extent TC II assays, can sometimes also help explain high cobalamin levels.[56,78,260]

Folate Deficiency

Because dietary insufficiency, alcohol abuse, and drug effects often contribute to folate deficiency,[279] a careful history is usually the most effective diagnostic test. Malabsorption must be considered when a dietary cause is not apparent. Tests of folate absorption are unavailable, and response to oral folic acid does not rule out malabsorption.

Acquired causes of deficiency predominate in children too. Dietary deficiency may occur in specific settings and can be aggravated by the demands of growth and development. Hereditary disorders are rare but can be severe.[142] They may feature low folate levels, as in methyleneTHF reductase deficiency or hereditary malabsorption, or normal levels. Relevant enzymes can be measured and genetic mutations are increasingly identifiable. If neurologic symptoms exist, measuring cerebrospinal fluid folate, including methylTHF, can be diagnostically helpful whether serum levels are normal or not.

MANAGEMENT

Management of cobalamin and folate deficiencies extends beyond giving the right vitamin and can be complex.[193] It can be undermined by patient noncompliance[127] and by physician error, which most often involves underestimation of the disorder and its requirements, especially the value of precise diagnosis of underlying causes. Management goals are to reverse symptoms; select the appropriate dose, route, and duration of vitamin replacement; ensure that the vitamin deficiency was identified correctly and that the patient responded appropriately; identify the underlying disorder that caused the deficiency and treat it directly, if possible, define its prognosis, and manage its complications; and provide patient education. These goals do not apply easily to SCCD, whose need for therapy is undefined.[193]

Reversal of Presenting Symptoms

Course

Megaloblastic anemia reverses quickly with the correct vitamin. The patient often begins to feel better within a day, before anemia improves. New reticulocytes appear in 2 to 3 days. Effective hematopoiesis replaces ineffective hematopoiesis, as lactate dehydrogenase and bilirubin decline and maturation of erythroid precursors becomes more normoblastic. Although neutrophil hypersegmentation persists for 2 weeks or more,[105] white blood cell and platelet counts rise in the first week if they had been decreased. Peak reticulocytosis occurs at 7 to 10 days. As new normocytic cells accumulate, which can be detected with reticulocyte-specific profiling,[108] the MCV declines. The blood count becomes fully normal before 8 weeks have elapsed. In most cases, neurologic improvement becomes noticeable in the first few weeks.

There are no signs or symptoms to reverse in patients with SCCD, but occasionally mild signs can be identified retroactively upon their improvement after cobalamin therapy.

Monitoring the Response

Homocysteine and MMA levels begin to fall within a few days of therapy and can be used to monitor response;[183,184] monitoring vitamin levels, whether cobalamin, holo-TC II, or serum folate, has little value because plasma levels rise passively regardless of therapeutic effectiveness. Reticulocyte response can be assessed best at the end of the first week, and it is always useful to determine completeness of hematologic response after 8 weeks. An incomplete response at either time usually indicates a coexisting anemia, perhaps one that was initially inapparent; most often, the cause is iron deficiency, which can be masked in megaloblastic anemia. A poor response can also indicate that the original diagnosis was incorrect.

The extent of neurologic improvement cannot always be predicted. In general, the likelihood of full reversal with cobalamin is inversely related to the duration of symptoms before therapy was started and the extent of the original dysfunction. Whatever reversal can be expected is usually completed by 6 months, but improvement occasionally continues until a year or more. Progression despite therapy throws doubt on cobalamin deficiency as its cause.

Blood Transfusion

Patients with megaloblastic anemia tend to compensate for even severe anemia surprisingly well[500] and usually can be managed supportively until cobalamin therapy takes effect. The temptation

to transfuse should be resisted unless coexisting conditions or worrisome symptoms and signs (e.g., cardiopulmonary or cerebrovascular) require immediate intervention. If transfusion is given, care must be taken to avoid aggravating the pre-existing volume overload.

Vitamin Replacement

Unless folate and cobalamin deficiency coexist, using both vitamins together has uncertain benefits and, done reflexively, can muddy the specificity of the response and the patient's understanding of the medical condition.

Cobalamin Deficiency

Rapid reversal of anemia or neurologic dysfunction is achieved most reliably with intramuscular cobalamin. Cyanocobalamin use predominates in the United States and is the model here, although hydroxocobalamin is more physiologic and its better retention allows less frequent injection.[501] Methylcobalamin can also be used but its advantages are unclear. As little as 1 to 2 μg of cobalamin produces quick hematologic response, but a series of 1,000-μg injections is usually given during the first few weeks. Because nonspecific intestinal absorption of cobalamin is very limited, many details of subsequent therapy depend on whether the IF mechanism is intact. When absorption is normal, oral cyanocobalamin can usually be used, and doses of 2 to 5 μg do not substantially exceed IF capacity. Intranasal and sublingual preparations, which bypass IF, have no proven advantages, and may be ineffective if rhinitis or other mucosal conditions exist.

If free cobalamin cannot be absorbed, as in pernicious anemia, most maintenance regimens call for 100 to 1,000 μg cyanocobalamin given intramuscularly once a month. Most of the 1,000-μg dose is excreted rapidly in the urine, but the amount retained (100 to 150 μg) is greater than with 100-μg doses (55 μg retained). Very high oral doses, long known to be effective even in patients with pernicious anemia,[59] have been resurrected with daily oral doses of 1,000 μg (or even 2,000 μg) as a suitable alternative,[502] although clinical response has not been consistently optimal.[503] The advantage of oral therapy is avoidance of injection, with its discomfort, costs, and inconvenience. This must be weighed against the need to take a large dose every day, often for life; the need to monitor periodically because daily compliance is surely poorer in daily practice than it has been among research volunteers; and the incomplete documentation of equivalence of neurologic improvement after oral and parenteral cobalamin.[193] Because relapse occurs sooner when oral rather than parenteral therapy is discontinued,[128] repletion of stores by injection before embarking on oral maintenance is advisable.

Cobalamin replacement must continue for as long as the underlying cause persists. Occasional patients seem to require more frequent injections for unknown reasons[59,193] and should be allowed to do so or be given hydroxocobalamin. The only known side effects of cobalamin are rare allergic or even anaphylactic reactions, sometimes to the preservative. Some patients treated with depot preparations of hydroxocobalamin form anti-TC II antibodies, which seem to produce no effects other than very high serum cobalamin levels.[266] Isolated British reports of high rates of sudden death during treatment of severe megaloblastic anemia, attributed to the transient hypokalemia in early hematologic response to therapy (in fact, similar hypokalemia accompanies treatment of iron deficiency anemia), have not been confirmed.[504] Giving potassium preventively is unnecessary unless special circumstances dictate it.

The optimal treatment of elderly patients (or anyone) with SCCD is unclear. Oral 6-μg doses, typical of most multivitamins, are not always effective.[378,379] Controlled trials of graded oral doses in elderly persons with SCCD reported persistent MMA abnormalities until daily doses exceeded 50 to 500 μg[505–507] but did not document absorption status or why the poor responses occurred.[240] The assumption that food-cobalamin malabsorption allows normal absorption of free cobalamin when taken with meals is untested and may be mistaken.[193]

Hereditary disorders require individually tailored therapy and close monitoring because expression, severity, and response vary even in the same disorder. Other sources can be consulted for relevant details.[142]

Folate Deficiency

Oral synthetic folic acid is stable and efficiently absorbed.[35] Daily doses of 1 mg usually suffice, and it is better absorbed than food folate, even by patients with malabsorptive disorders. Monitoring the response can determine if higher doses or intramuscular injections are needed. Body stores can be repleted within a month or two. The need to continue longer is guided by the underlying disorder, its persistence or likelihood of recurrence, and the patient's dietary, medical, and social details.

Treatment of children with inborn errors of folate metabolism calls for larger doses, often given parenterally, and may require specialized regimens.[142] Folinic acid is needed for disorders that require reduced folic acid, such as cerebral folate deficiency, and in patients using drugs that inhibit dihydrofolate reductase.

Direct toxicity of folic acid is minimal.[508] Seizure disorders have worsened in some patients receiving large doses intravenously.[509] Concern about folate administration to someone with unrecognized and untreated clinical cobalamin deficiency has engaged attention because of adverse experiences in patients with pernicious anemia. The anemia of cobalamin deficiency usually responds at least partially to folic acid, although relapse occurs eventually.[152,153] In the meantime, unchecked neurologic progression can occur. This issue with diverse ramifications is discussed further in the section, "Preventive and Other Uses of Supplements."

Assurance of Response

The diagnosis of deficiency is often made with varying degrees of certainty, especially in minimally symptomatic patients. The less clear the original evidence, the greater is the value of monitoring therapeutic response.

Managing Underlying Disorders Causing the Deficiency

Pernicious anemia is the most likely cause for clinically obvious cobalamin deficiency, but other malabsorptive causes account for at least 25% of cases.[279] This sizeable minority includes independently treatable causes whose identification may be simple (e.g., the history of gastric surgery) or require greater effort (e.g., pursuing bacterial overgrowth). An important goal is to determine how long therapy must continue. As to pernicious anemia, conclusive diagnosis has tangible clinical value despite the disease's irreversibility. For example, it confers the confidence to recommend endoscopy to screen for cancer and to insist upon lifelong cobalamin therapy. Ironically, many patients (and some physicians) attribute cobalamin deficiency to dietary inadequacy, which accounts for only 1% of clinically expressed cases. The dietary inadequacy needed to create clinically overt deficiency is usually dramatic and obvious.

The diagnostic pursuit of causes of folate deficiency is diametrically different. Poor diet is by far the most common cause and malabsorption is among the least common.[279] The post-fortification era has removed much of the folate deficiency attributable to inadequate intake alone.[443,510] The causes today need to be reexamined to determine if fortification has left behind mostly the

deficiencies requiring medical interventions, such as alcoholism, small bowel disease, and drugs affecting folate status.

Patient Education

Pernicious anemia is a prototype of the ideal medical encounter: a disease with potentially disastrous consequences that is easily and safely treated. Yet, therapy is frequently discontinued.[127] Patient education about cause, course, and prognosis is critical. Noncompliance occurs in many serious diseases throughout medical practice, especially those with toxic or inconvenient therapies. Just the opposite may be operative in pernicious anemia; its simple vitamin therapy may lull patients (and sometimes physicians) into complacency about its medical importance.[511,512]

Preventive and Other Uses of Supplements

Nonmedical vitamin use is widespread, especially among the elderly, women, whites, and the affluent. Thirty-five percent of American adults report recent supplement use,[513] and 38% of the elderly have folate levels above 20 μg/L.[510] Both folate and cobalamin are generally viewed as beneficial and innocuous. However, experience with chronic supplementation using high daily doses in minimally deficient and nondeficient persons is limited.

Folic Acid

Folic acid fortification has successfully reduced NTD rates, leading to advocacy for raising fortification levels further to maximize the prevention[211] and for raising cobalamin intake.[514] Self-supplementation is popular for purposes of varying validity, and the 1 mg folic acid intake limit advised by the Food and Drug Administration to reduce the likelihood of masking undiagnosed cobalamin deficiency[35] is often exceeded with supplements.

Three categories of adverse consequences are being investigated, with still tentative conclusions. First, epidemiologic studies have not provided consistent answers about folate-related neurologic and cognitive risks in persons with SCCD,[154,179,515–519,520,521] Second, levels of unmetabolized folic acid appear to be high as serum folate levels several times normal have become common in the general population.[520,522,523,524] Whether folic acid poses adverse oxidative risks has been inconclusive.[522,525,526] Third, folate deficiency is linked with higher cancer risk, especially well documented in colorectal cancer,[527] and high folate intake has decreased that risk.[528,529] Yet, folate may also accelerate precancerous conditions, such as colonic adenomatous polyps.[527] All this suggests a binary folate effect, reducing risk of new neoplasia and accelerating transformation of precancerous lesions. To this have been added unexpected data, including clinical trials, linking high folic acid intake, with or without cobalamin and pyridoxine, with risks of other cancers, such as breast cancer,[530–532] but other studies disagree.[533,534]

A homocysteine-lowering trial in patients with diabetic nephropathy found that folic acid, cobalamin, and pyridoxine unexpectedly worsened renal function and vascular complications.[535] It seems clear that safety issues of high folate intakes need careful study.[527,536]

Cobalamin

The public health debate about cobalamin supplementation programs for SCCD is in its early stages.[179] Most supplements contain 6 μg of cyanocobalamin, but many contain 25 μg or more. However, these usual doses may not suffice in the elderly or in persons with food-cobalamin malabsorption. Studies, including clinical trials, have reported many persons whose SCCD does not fully correct despite supplements of 100 μg or more.[51,240,378,379,505–507] The absorptive or other limitations impairing responsiveness in the elderly need to be defined.

Evidence that high-dose cobalamin, folic acid, and pyridoxine supplementation may slow the progression of brain atrophy and cognitive decline[204,205] is of great interest. The mechanisms of these promising findings need elucidation, but so do concerns whether chronic intake of high daily doses of vitamins has any negative consequences.

The value of dietary fortification with cobalamin to circumvent the cobalamin deficiency-related risks of folate fortification is also unclear. Fortification with cobalamin must grapple with the paradox that bioavailability may be limited precisely in those who might benefit most, whereas those needing it the least absorb cobalamin efficiently (and may have been responsible for most of the seeming responsiveness to oral doses that studies of supplementation have reported). Studies must examine critical subsets, not just overall population-wide data. The efficacy and practicality of fortifying are not obvious currently, especially if high doses prove necessary.[537,538] The risks of chronic, daily intake of high doses are unknown, but accumulation of inactive cyanocobalamin in cells has been reported.[539]

CHAPTER 37

INHERITED APLASTIC ANEMIA SYNDROMES

Akiko Shimamura, Blanche P. Alter

The inherited bone marrow failure syndromes may primarily affect a single or multiple hematopoietic lineages. Four inherited bone marrow failure syndromes associated with aplastic anemia will be discussed in this chapter: Fanconi anemia (FA), dyskeratosis congenita (DC), Shwachman-Diamond syndrome (SDS), and congenital amegakaryocytic thrombocytopenia (CAMT). The congenital bone marrow failure disorders affecting primarily one cell line are discussed elsewhere in this text (Diamond Blackfan anemia, Chapter 39; Congenital Neutropenias, Chapter 57). While the inherited marrow failure disorders are rare, early diagnosis is important for optimal medical management, cancer surveillance, and family planning. Some of the disorders are associated with sensitivity to chemotherapy and radiation, and thus diagnosis of those underlying disorders prior to initiation of treatment of aplastic anemia or associated malignancies is crucial.

A careful medical and family history together with a thorough physical examination may provide important clues to distinguish acquired from inherited bone marrow failure.[1] A family history suggestive of cancer predisposition, such as malignancies at an unusually young age, may be obtained. A history of excessive toxicity following treatment with genotoxic agents may be present. A family history of congenital anomalies or stigmata characteristic of the inherited bone marrow failure syndromes may provide additional clues. Other potential etiologies for cytopenias should be ruled out. Once the diagnosis of an inherited bone marrow failure syndrome is made, it is important to test all family members at risk for the disease regardless of clinical symptoms since manifestations may vary widely among family members.

These disorders are increasingly being recognized in adults, who often manifest milder clinical phenotypes and whose first manifestation of an underlying inherited bone marrow failure syndrome may be aplastic anemia or malignancy.[2] With the advent of genetic and laboratory diagnostic testing, the diseases are also increasingly recognized in patients who lack the characteristic physical stigmata conventionally associated with the disease. Genetic test results must be interpreted critically and within the clinical context of the patient. Methodologic limitations of genetic testing and the distinction between functional mutations versus rare polymorphisms are important considerations.

FANCONI ANEMIA

FA is an inherited chromosomal instability syndrome with a variable clinical presentation that includes congenital anomalies, progressive pancytopenia, and cancer susceptibility. Guido Fanconi first reported a familial syndrome of pancytopenia and congenital physical abnormalities in 1927.[3,4] The diagnostic hallmark of FA is increased chromosomal breakage in response to DNA damaging agents such as mitomycin C (MMC) or diepoxybutane (DEB). Remarkable advances in the last few years have elucidated the molecular pathways disrupted in FA cells. Potential clinical implications of recent molecular studies will be discussed.

Clinical Features

FA should be considered in patients with congenital anomalies, aplastic anemia, or a family history of bone marrow failure or cancer susceptibility. The International Fanconi Anemia Registry (IFAR) analysis of 370 patients found that nearly 40% of patients had no reported physical findings.[5] Aplastic anemia or malignancy may be the presenting sign of the underlying diagnosis of FA in the absence of physical anomalies or prior family history. The manifestations of FA can vary between affected members of the same family, suggesting that additional genetic, epigenetic, or environmental factors likely influence the disease course.

A wide range of congenital anomalies has been reported in FA patients (reviewed in Refs. 1, 6) (Table 37.1). Skin pigmentary changes, short stature, and radial bone and thumb abnormalities are the most common manifestations associated with FA, although these may be seen in some of the other inherited bone marrow failure syndromes as well. Abnormalities of the skeletal, ocular, renal, genital, aural, gastrointestinal (GI), cardiac, and central nervous systems have also been reported with high frequency.

The hematologic complications of FA typically present within the first decade of life. Early manifestations include moderate single or bilineage cytopenia with red cell macrocytosis. Elevated levels of fetal hemoglobin (Hb F) help to distinguish inherited from acquired aplastic anemia. Marrow failure may range in severity from mild asymptomatic cytopenias to severe aplastic anemia. This is in contrast to other chromosomal instability syndromes, such as ataxia telangiectasia, or Bloom syndrome, which are not typically associated with bone marrow failure.

Patients with FA are at increased risk of developing myelodysplasia (MDS) or acute myeloid leukemia (AML).[7,8] In a cohort study of 145 patients with FA, the cumulative incidence of AML reached 10% by age 24 years and plateaued thereafter.[8] Patients with FA are also at increased risk of developing solid tumors, particularly squamous cell carcinomas of the head and neck, skin, GI tract, and genital tract.[9] The cumulative incidence of solid tumors was low in younger patients but progressively increased with age starting at around 20 years of age, and reached 29% by age 48 years.[8] FA patients, particularly those who have received

Imperforate anus
Cardiac malformations

androgen treatment, are also at increased risk of liver tumors. Treatment of malignancies is limited by the low tolerance of FA patients to chemotherapy and radiation. Myeloid malignancies in FA patients have been successfully treated with hematopoietic stem cell transplantation (HSCT), though patient numbers are small and follow-up is limited. The role of pretransplant chemotherapy is unclear.[10] For solid tumors, surgical resection is the mainstay of therapy. Regular and frequent surveillance for cancers is particularly important in this population and is discussed further in the section "Supportive Care." Patients with the *FANCD1/BRCA2* subtype manifest an especially high rate of early onset AML and specific solid tumors (brain and Wilms) compared with other FA subtypes.[11,12,13]

Growth hormone deficiency has been observed in rare FA patients,[14] and treatment with growth hormone improved growth in a subset of these patients[15]; its use is controversial because of a hypothetical risk of cancer or leukemia.[16] Additional endocrine disorders associated with FA include hypothyroidism with or without thyroid hormone binding globulin deficiency, abnormal glucose tolerance, and diabetes mellitus.[14,17] Although FA is associated with short stature, endocrine evaluation is important to rule out treatable endocrine causes that might further contribute to poor growth.

There are currently 15 known FA subtypes (A, B, C, D1 [*BRCA2*] , D2, E, F, G, I, J [*BRIP1, BACH1*], L, M, N [*PALB2*], O [*RAD51C*], and P [*SLX4*]). With the exception of subtype B, which is X-linked recessive, all the other FA subtypes follow an autosomal recessive pattern of inheritance.[18,19] FA is found with similar frequencies in both genders and has no known ethnic restriction. The heterozygote carrier frequency has been recently reestimated at 1 in 181 in the United States and is higher in regions with founder effects such as Israel.[20] The mean age at diagnosis is generally reported to be between 7 and 9 years of age, with 75% of cases diagnosed between the ages of 4 and 14; however, FA has been diagnosed in neonates as well as in adults in their fifties.

Differential Diagnosis

Other inherited and acquired causes of bone marrow failure should be considered (see Chapter 41). FA may be considered in patients with characteristic congenital anomalies and may be the underlying diagnosis in patients with VACTERL-H (vertebral anomalies, anal atresia, cardiovascular malformations, tracheoesophageal fistula, renal and limb anomalies, plus hydrocephalus, MIM 276950).[21] Cells derived from patients with other chromosomal breakage syndromes or syndromes with similar constitutional findings, such as Bloom syndrome or ataxia telangiectasia, may also exhibit high rates of spontaneous chromosomal breakage; however, they do not generally show increased chromosomal breakage in response to DNA crosslinkers such as MMC or DEB. Other chromosomal breakage syndromes are not typically associated with marrow failure. The exception is Nijmegen breakage syndrome, which may be associated with some increased chromosomal breakage with MMC and may be confused with FA.[22] FA may also be considered in patients with a family history suggestive of cancer predisposition, patients presenting with cancers at an unusually young age, or patients who experience severe toxicity with chemotherapy or radiation.

Laboratory

Cell morphology on peripheral blood smear is typically unremarkable except for red cell macrocytosis and mild anisocytosis, though these are variably present. Thrombocytopenia or leukopenia typically precede anemia. Pancytopenia may be progressive over time. Erythrocyte macrocytosis and increased Hb F levels may be present even in the absence of cytopenias.

Bone marrow biopsy findings vary from normal cellularity to frank aplasia. Morphologic examination of the bone marrow aspirate may show dysplastic features, with nuclear-cytoplasmic maturation disynchrony. Dyserythropoiesis with multinucleate forms or nuclear fragmentation may be seen. Bone marrow aspirates should be sent for cytogenetic analysis, as FA patients are at high risk for malignant transformation. The appearance of cytogenetic clones of unclear clinical significance in the absence of morphologic evidence of MDS must be considered carefully, since cases of persistent or transient clonal abnormalities without apparent progression to leukemia have been reported.[23] At a minimum, patients with persistent unexplained changes in blood counts or new cytogenetic marrow abnormalities should be monitored closely with serial blood counts and a follow-up bone marrow examination to assess for possible malignant evolution. Amplification or gains of chromosome 3q26q29 were shown to correlate with increased risk of MDS and AML in one study.[24]

The diagnosis of FA is based on the demonstration of increased chromosomal breakage in the presence of DNA crosslinking agents, such as MMC or DEB.[25,26] (Fig. 37.1) DEB is preferred in some centers since it is associated with less variability in chromosomal breakage among normal controls. The chromosomal breakage test is usually performed on metaphase spreads of peripheral blood lymphocytes cultured with MMC or DEB. A total of 50 metaphase cells are analyzed for chromosomal

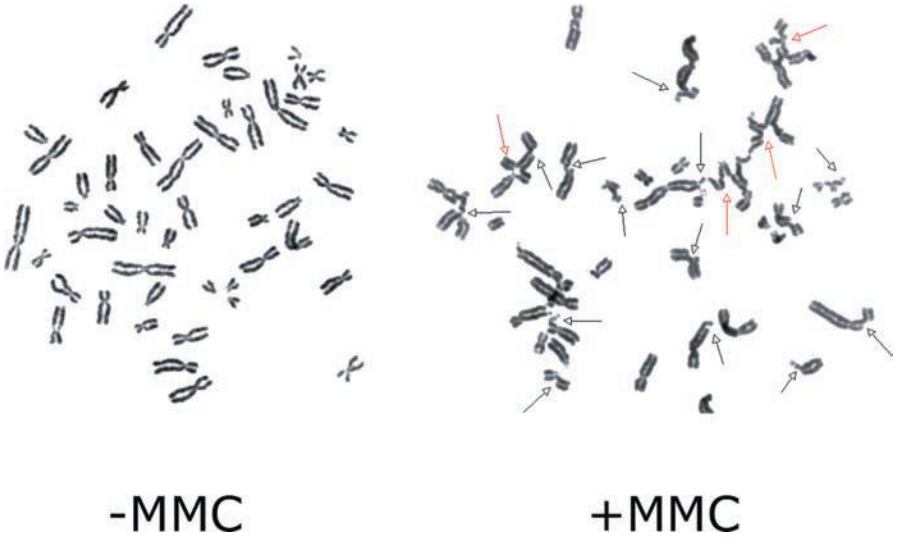

FIGURE 37.1. Chromosomal breakage in FA. Peripheral blood lymphocytes from a FA patient were cultured without (*left panel*) or with (*right panel*) mitomycin C (MMC). The *black arrows* indicate chromosomal breaks. The *red arrows* indicate radial chromosomal fusions characteristic of FA. (Courtesy of Lisa Moreau, Dana Farber Cancer Institute, Boston, MA.)

breakage, including the formation of radial figures—a hallmark of this disease. Results are compared to a normal control and a positive control that have been run in parallel. Results are generally reported as aberrations per cell and the number of cells with breaks or radial forms. Increased spontaneous chromosomal breakage may be observed in some FA patients[12]; nonetheless, the rate of breakage is markedly enhanced by exposure to MMC or DEB regardless of patient phenotype or severity of disease. Chromosomal breakage in response to MMC/DEB can also be assessed in fetal cells obtained for prenatal diagnosis by amniocentesis or chorionic villus sampling.[27,28] If the disease-causing mutation is known for a given family, these assays can be used for prenatal diagnosis or preimplantation genetic diagnosis.[29] FA patient cells also exhibit cell cycle abnormalities with G2 phase prolongation and arrest by flow cytometry.[30,31] Studies comparing results of DEB chromosomal breakage with cell cycle analyses of patients referred for FA testing showed close correlation between the results of these two tests.[32] Constitutive elevation of serum alpha-fetoprotein (AFP) has been reported in FA patients,[33] although variations in AFP levels determined by different methodologies and the lack of specificity has limited the diagnostic utility of this test so far.[34] FA heterozygous carriers cannot be reliably detected by testing for chromosomal breakage. Genetic mutation testing is available for the FA genes.[35]

Clonal somatic reversion to wild-type has been observed in a subset of cells from some FA patients. Increased chromosomal breakage may be limited to a subpopulation of lymphocytes in such patients. The reversion to normal cellular phenotype has been attributed to recombination or gene conversion events leading to selective growth advantage of the reverted cells[36,37]; somatic reversion has been reported in early hematopoietic lineages.[38] Patients with a high degree of wild-type mosaicism may be difficult to diagnose. In cases with a high degree of suspicion for FA and normal blood breakage analysis, the MMC/DEB test should be performed on skin fibroblasts, since somatic mosaicism has not been observed in fibroblasts.

Pathophysiology

Models of the FA biochemical pathway have emerged from molecular studies of the cloned FA gene products. The reader is referred to recent excellent reviews of this rapidly evolving field.[39,40,41] At least 15 different FA complementation groups (A, B, C, D1 [*BRCA2*], D2, E, F, G, I, J [*BRIP1, BACH1*], L, M, N [*PALB2*], O [*RAD51C*], and P [*SLX4*]) have been identified, and the corresponding genes have also been identified[42] (Table 37.2). The gene for Fanconi subtype D1 is the previously identified tumor suppressor gene, *BRCA2*.[43] Biallelic mutations in *BRCA2* are associated with an increased risk of early onset leukemia[11] and solid tumors, particularly Wilms and midline brain tumors.[12,13] The *FANCJ/BACH1/BRIP1* gene encodes a DNA helicase, which is an enzyme that unwinds DNA. The *FANCM* (*Hef*) gene shares regions of homology with both helicases and endonucleases, though these functions have yet to be directly demonstrated. FANCM may function in DNA translocation. The *FANCL/PHF9/POG* gene shares homology with other E3 ubiquitin ligases. The most common FA subtype is FA-A (60%), followed by FA-C (14%) and FA-G (10%)[44]; the other FA subtypes are rare. The types of mutations associated with FA are highly variable.

The FA genes function coordinately in a common molecular pathway to regulate DNA repair. Loss of function of any FA gene results in sensitivity to DNA interstrand crosslinks, which block the progression of DNA replication. The FA proteins FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, FANCL, and FANCM associate into a nuclear complex ("FA complex") together with proteins FAAP24 and FAAP100 and the E2 ubiquitin conjugating enzyme UBE2T. A model (Fig. 37.2) has emerged whereby stimuli such as S phase entry, or DNA damage by agents such as MMC, or ionizing radiation leads to activation of the FA complex, which functions as an E3 ubiquitin ligase to covalently attach a ubiquitin protein (monoubiquitinate) to the FANCI and FANCD2 proteins. The monoubiquitinated FANCD2/FANCI dimer translocates to nuclear foci with BRCA1, a known cancer susceptibility gene product implicated in DNA repair, as well as FANCD1/BRCA2, FANCN/PALB2, RAD51, ATR, NBS1, and FANCJ/BACH1/BRIP1. Monoubiquitination of FANCD2 and FANCI is required for MMC resistance and is dependent on the functional integrity of the upstream Fanconi proteins. FANCD2 monoubiquitination remains intact in bone marrow failure syndromes other than FA.[45] FANCD2 monoubiquitination can be assessed on a Western blot and serves as a useful biochemical diagnostic screen for FA.[13] FANCM, in complex with FAAP24 and MHF, binds to stalled replication forks at sites of unresolved interstrand crosslinks. FANCM recruits the FA complex, which in turn monoubiquitinates the FANCD2/FANCI dimer. Ubiquitinated FANCD2/FANCI associates

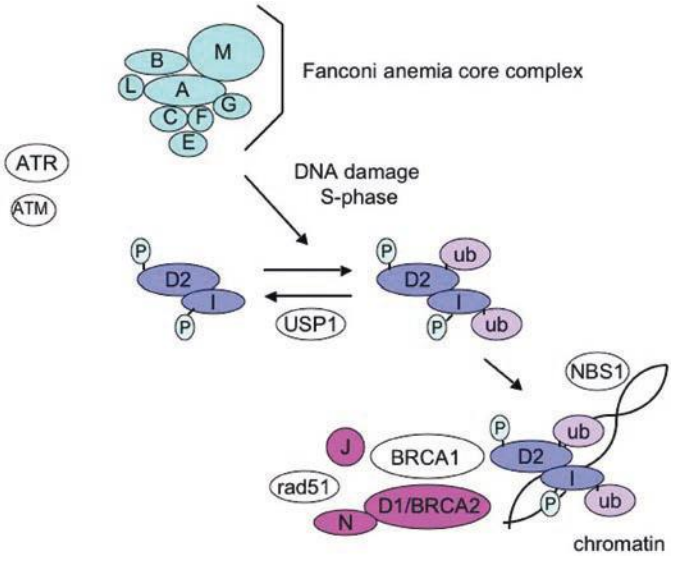

FIGURE 37.2. Schematic diagram of the Fanconi anemia (FA) pathway. FA proteins (A, B, C, D1, D2, E, F, G, I, J, L, M, N) are depicted with *shaded circles*. Additional DNA repair proteins interacting with the FA pathway are denoted in *non-shaded circles*. Following activation of the FA core complex by DNA damage or the cell cycle, the D2 and I proteins are monoubiquitinated. Monoubiquitinated D2/I are translocated to chromatin where they colocalize with additional DNA repair proteins to participate in interstrand DNA crosslink repair. Ub, ubiquitin; P, phosphorylation.

with the nuclease FAN1 which can cleave and release the crosslink to allow DNA replication to proceed by translesion synthesis. RAD51 functions in homologous recombination. FANCJ/BRIP1 is a DNA helicase that is important for homologous recombination repair. FANCP/SLX4 interacts with and stimulates the DNA repair endonucleases XPF-ERCC1, MUS81-EME1, and SLX1, and may be important for resolution of homologous recombination intermediates. Elucidation of the Fanconi biochemical pathway in turn led to the identification of interactions between the Fanconi proteins and other known tumor suppressor pathways. These findings provide biochemical support for a role of the Fanconi pathway in tumorigenesis. For example, FANCD2 was subsequently shown to be phosphorylated by ATM kinase at a serine residue at amino acid position 222.[46] This phosphorylation is required for the cell cycle S phase checkpoint in response to radiation.[46] ATM function is disrupted in the chromosomal instability syndrome ataxia telangiectasia. Thus, FANCD2 links two DNA repair pathways, the Fanconi pathway and the ataxia telangiectasia pathway. Dysfunction of the Fanconi pathway or the ATM pathway is associated with increased cancer susceptibility. The Fanconi biochemical pathway was further implicated in DNA repair by the identification of the gene for *FANCD1* as the tumor suppressor gene, *BRCA2*.[43] The FA pathway also interacts with other DNA damage checkpoint proteins including ATR, CHK1, and γ-H2AX.

Given the compelling biochemical data linking the Fanconi pathway to other known DNA repair pathways functioning in tumor suppression, the question of whether asymptomatic FA heterozygotes carry an increased risk of developing malignancies is a subject of active investigation. Heterozygous *BRCA2* mutations are associated with increased risks of breast and ovarian cancer.[47] The reason why breast and ovarian cancer is uncommon in the FA patient population is not known, but may be related to decreased estrogen levels in these patients. Currently, not all *FANCD1/BRCA2* mutations reported in FA patients have been associated with increased cancer risk in heterozygous carriers in the general population, and it is currently unclear whether all the *FANCD1/BRCA2* mutations leading to FA (when both alleles are mutated) will also confer cancer predisposition in family members in whom only one *BRCA2* allele may be mutant.[13] Counseling of family members of patients with the FA-D1 subtype must currently be tempered with caution. Cancers have been reported in some heterozygous carriers of different FA genes (*FANCD1/BRCA2 FANDJ/BRIP* and *FANCN/PALB2*) with loss of heterozygosity of the FA gene in the tumor consistent with a tumor suppressor gene model (reviewed in Ref. 48).

In addition to a nuclear role in DNA repair, numerous studies suggest additional potential functions for the FA proteins. FA cells are sensitive to many different extracellular apoptotic signals, such as interferon-γ, TNF-α, and double-stranded RNA.[49,50,51,52] Furthermore, Fanconi proteins such as FANCC may have additional roles in other signaling pathways.[53]

Studies also suggest a role for the FA proteins in mediating oxidative stress.[54,55] DEB, a clastogen to which Fanconi cells are especially susceptible, can cause oxidative DNA damage. FA cells may exhibit increased susceptibility to oxidative damage, and reactive oxygen species can damage DNA and lead to DNA crosslinks and double-stranded breaks.

The molecular etiology of marrow failure in FA remains an area of active investigation. A recent study reports *p53* hyperactivation in hematopoietic stem/progenitor cells deficient in FA gene expression resulting in cell cycle arrest.[56] This finding is further supported by the demonstration that knockdown of *p53* expression in a zebrafish model of FA rescues the developmental abnormalities.[57] Since *p53* knockdown rescues the hematopoietic abnormalities in other marrow failure syndromes, *p53* may represent a final common pathway for cellular stress or DNA damage in marrow failure syndromes. Abrogation of DNA damage checkpoints has been associated with a milder marrow failure phenotype; however, these FA patients remained at risk for malignant transformation to leukemia.[58] A potential role for environmental toxins in the severity of the FA phenotype has been demonstrated in murine models where disruption of the FA pathway results in increased sensitivity to reactive aldehydes associated with an increased risk of developmental anomalies and a propensity to develop leukemias.[59]

Supportive Care

Cancer surveillance and education play an important role in the management of FA patients. Physicians should counsel patients regarding established behavioral and environmental risk factors associated with increased cancer risk. Since FA patients have a defect in DNA repair, imaging studies should minimize exposure to ionizing radiation. For example, when clinically feasible, it is reasonable to use MRI scans or ultrasound rather than CT scans for FA patients.

Because of the increased risk of MDS and leukemia in patients with bone marrow failure syndromes, frequent complete blood counts and annual bone marrow aspirates and biopsies with cytogenetic analysis are recommended, particularly since hematopoietic stem cell transplant outcomes are superior for patients transplanted prior to emergence of leukemia. FA patients are at risk for clonal cytogenetic abnormalities (reviewed in Ref. 60). Assessment of the clinical significance of a cytogenetic clonal abnormality requires consideration of the specific clone, the number of chromosomal abnormalities, the presence of significant marrow dysplasia (some baseline mild dysplasia is common in FA), and whether there are concomitant progressive peripheral cytopenias.[23,61] Chromosomal abnormalities common in AML, such as t(8:21), inv(16), or trisomy 8, have not been reported in FA.[23,62] Amplifications of 3q are common in FA but rarely seen in AML. FA AML also had a higher frequency of 1q amplification, loss of part or all of chromosome 7, and gain of 13q and del 20q.[62,63]

For patients on androgen therapy, regular physical examinations for liver size, liver ultrasound for masses or abnormalities every 6 to 12 months, and frequent liver enzyme tests are recommended. Annual examination by an otolaryngologist for leukoplakia or other signs of squamous cell carcinoma of the

oral cavity and oropharynx is important for patients with FA, DC, and those FA patients previously treated with bone marrow transplantation. Annual endoscopy can be considered in older FA and DC patients. Regular dental exams are important both for maintenance of oral hygiene and for detecting leukoplakia. Patients should be evaluated immediately for symptoms of pain in the mouth or throat, difficulty swallowing, changes in voice, anorexia, or weight loss. Suspicious lesions should be biopsied immediately, since early surgical excision is the mainstay of cancer therapy in FA patients. Annual gynecologic examinations, including Pap smears and HPV (human papilloma virus) exams, are recommended at puberty or after the age of 16. Counseling regarding sexual activity should be provided. Barrier methods of contraception may be particularly pertinent for the FA patients who are already at risk of cervical and vulvar malignancies. Regular breast exams are also recommended, although it is not clear what role mammography should play in cancer screening of these patients. HPV, which may be associated with an increased risk of squamous cell carcinoma of the head and neck, exhibits increased proliferation and epithelial cell expansion secondary to elevated levels of the viral E7 protein when the FA pathway has been disrupted.[64] Vaccination against HPV should be offered to all FA patients, males and females, in accordance with current guidelines.

Regular endocrinology evaluations are important, particularly in the pediatric population if the patient exhibits poor growth or delayed puberty. Hypothyroidism and diabetes are not infrequent in FA patients. A recent study reported one or more endocrine abnormalities in more than 70% of patients with FA.[17,65] GI symptoms may present in FA patients, necessitating prompt referral to a gastroenterologist.

Treatment

HSCT is the only curative therapy for the hematologic manifestations of FA. Patients with FA are exquisitely sensitive to the toxicity of the usual chemotherapy and radiation regimens used in preparation for BMT,[66] particularly organ toxicity and graft-versus-host disease (GVHD). In addition, these regimens confer an increased risk of subsequent malignancies, primarily squamous cell carcinomas of the head and neck.[67,68] Reduced dose conditioning regimens are used for FA patients (reviewed in Ref. 69). An appropriate conditioning regimen combined with use of a matched sibling donor has resulted in survivorship of up to 80%.[70–72] Post-HSCT malignancies, especially squamous cell carcinomas of the head and neck, remain a long-term risk. Acute and chronic GVHD and radiation are risk factors for post-transplant squamous cell carcinomas.[67,68,73,74] Regimens with the goal of reducing transplant-related toxicity and long-term cancer risk are under investigation.[75–77] Clinical trials replacing radiation with fludarabine, a potent immunosuppressive agent with less cytotoxicity, have reported successful engraftment using either HLA-matched family member donors or alternative donors.[78–84] Some families opt to pursue preimplantation genetic diagnosis to provide a donor for patients who lack an unaffected HLA-identical sibling donor.[85] Treatment of AML in FA patients is challenging,[10] and HSCT is generally the treatment of choice for eligible candidates.

Medical therapies are available for patients who either lack a suitable HSCT donor or for whom the risk of HSCT is high. Androgens may improve the blood counts in approximately 50% of patients with FA. Experience is greatest with oxymetholone, but widespread use is limited by its associated virilizing side effects, which are particularly problematic for female patients or very young patients. In a recent study, improvement in anemia and thrombocytopenia were noted in 7 of 8 patients with FA treated with danazol with minimal side effects.[86] Suggested treatment guidelines have been proposed by a consensus committee of the FA Research Foundation, although these guidelines must be individualized for each patient and undergo continuous modification as new data emerge. The suggestion of the committee is to consider an allogeneic stem cell transplant or androgen therapy if the hemoglobin falls below 8g/dl, if anemia is symptomatic, if the platelet count falls below 30,000/mm^3, or if the neutrophil count falls below 500/mm^3 [87] The earliest and most frequent response to androgens is seen in red cells, with reticulocytosis and increase in hemoglobin generally occurring within the first 1 to 2 months of treatment. Responses in the white cell count and platelet count are variable and may not be seen until after 6 to 12 months of therapy. Resistance to therapy may develop over time (generally years). A common starting androgen regimen consists of oxymetholone 2 to 5 mg/kg/day given orally. Androgen doses may be slowly tapered to the minimal effective dose with careful monitoring of the blood counts. Side effects of androgen administration include liver toxicity, such as elevated liver enzymes, cholestasis, peliosis hepatis, and increased propensity to develop hepatic tumors (benign adenomas and malignant hepatomas). Other side effects of androgens include acne, oily skin, enlarged penis/clitoris, hoarseness/voice deepening, hair growth or hair loss, behavioral changes, hot flashes, breast enlargement or tenderness, amenorrhea, fluid retention, and secondary hypertension.

Hematopoietic growth factors such as G-CSF or GM-CSF have been shown to improve the neutrophil count in the majority of treated patients.[88,89] In a few patients, platelet or red cell counts also improved following treatment with G-CSF.[89] Growth factor treatment is generally not recommended for patients with MDS and is generally avoided for those with a clonal cytogenetic abnormality of the bone marrow, although there are no available data that directly address whether G-CSF increases leukemia risk. It is reasonable to perform a bone marrow aspirate and biopsy as well as cytogenetic studies prior to the initiation of growth factor therapy and monitor regularly throughout therapy.

Results of a gene therapy trial for FA-C patients were reported.[90] Three FA-C patients underwent 3 to 4 cycles of retroviral transduction of G-CSF–mobilized peripheral blood CD34$^+$ mononuclear cells (MNC), while a fourth patient received a single infusion of transduced cells. The transduced wild-type FANC-C gene was detected in peripheral blood and bone marrow MNC in association with increased hematopoietic colony growth in vitro. Transient improvement in bone marrow cellularity accompanied these findings and two patients experienced a transient improvement in blood counts. While the selective advantage of corrected cells makes FA an appealing candidate for gene therapy,[91] potential limitations include low CD34$^+$ cell numbers,[92] poor ex vivo expansion of hematopoietic stem/progenitor cells,[93] and the residual risk of leukemia associated with the remaining noncorrected hematopoietic cells.[38] The development of leukemia in a few patients receiving gene therapy for X-linked SCIDS[94] raises concerns about the potential growth advantage theoretically conferred by gene correction of a preleukemic hematopoietic stem/progenitor cell in FA patients. In a *Fancc*$^{-/-}$ mouse model, ex vivo cultured stem/progenitor cells exhibited a propensity to develop cytogenetic abnormalities and myeloid malignancies.[95] Additional studies to optimize ex vivo expansion of hematopoietic stem cells are ongoing.

Published data to guide management of leukemia in FA are scarce. Patients are susceptible to severe mucositis, end-organ toxicities, and prolonged or intractable cytopenias with chemotherapy. Outcomes with chemotherapy alone are poor, so the current treatment of choice for leukemia is a hematopoietic stem cell transplant. Successful treatment of solid tumors is typically best attained with surgical excision of localized tumors. Treatment of solid tumors with chemotherapy or radiation is limited by the high rates of toxic side effects such as mucositis or prolonged or intractable marrow suppression.

DYSKERATOSIS CONGENITA

DC is an inherited disorder classically characterized by lacey reticular skin pigmentation, nail dystrophy, and leukoplakia (the diagnostic triad). The advent of genetic testing and telomere length analysis revealed a broad spectrum of clinical phenotypes; indeed, the classical clinical triad is absent in a subset of patients.[96] X-linked recessive, autosomal dominant, and autosomal recessive inheritance patterns have been reported. Patients exhibit a predisposition to bone marrow failure, malignancy, and pulmonary dysfunction. See excellent recent reviews for additional details.[97,98]

Clinical Features

The DC registry established in 1995 undertook a comprehensive study of the clinical features associated with DC.[99] By 1999, the registry included 92 families from 20 countries. There were 148 DC patients, of whom 127 were male and 21 were female. Twenty-five families showed an X-linked recessive pattern of inheritance, while 51 families had sporadic affected males. Sixteen families included one or more affected females, representing both autosomal dominant and autosomal recessive forms of the disease.

The severity of the clinical phenotype can vary widely in affected members of the same family. The classic triad of skin, nail, and oral findings may be lacking. A variety of other clinical features have also been described in patients with DC (Table 37.3). The range of physical findings in female patients is similar to that reported in male patients.[99] Most of the somatic abnormalities are not present early in life but develop progressively with age. The skin pigmentation is typically reticular and mottled in appearance, and may be localized or widespread. The classical triad of abnormal skin pigmentation, nail dystrophy, and leukoplakia generally appears between the ages of 5 and 10 years, with a median age of onset between 6 and 8 years (range 0.5 to 26 years).[99] Both the tempo of symptom progression as well as symptom severity are highly variable between patients. For example, nail dystrophy can range from minimal nail irregularities to progressive atrophy and even complete nail loss.

Peripheral cytopenias of two or more peripheral lineages were affected in the majority of registry patients, though single lineage cytopenias were also reported.[99] The median age of onset of pancytopenia was 8 years, with 50% developing pancytopenia below the age of 10.[99] The bone marrow is typically hypocellular, though cellularity may be normal or even increased early in the disease. Bone marrow failure or its associated complications accounted for the majority of deaths (67%).

Approximately 20% of patients develop pulmonary disease with reduced diffusion capacity and/or restrictive pulmonary disease.[99–101] Pulmonary complications account for nearly 10% of deaths.[99] Postmortem studies reveal pulmonary fibrosis and abnormalities in the pulmonary microvasculature. Similarly, a high incidence of early and late fatal bone marrow transplant-associated pulmonary complications has also been reported in DC patients.[102]

Immunologic abnormalities, including low or high immunoglobulins, reduced numbers of B or T cells, and reduced stimulation by phytohemagglutinin, have been described in some DC patients.[99,103] Opportunistic infections such as *Pneumocystis carinii* pneumonia have been reported.[104,105]

Malignancies were noted in 13 out of 148 patients (8.8%) in the DC registry.[99] These developed in older patients, generally after the second decade of life. It is possible that a higher incidence of cancers might have been observed had not many patients succumbed to aplastic anemia at an earlier age. An increased incidence of MDS and AML has also been observed.[99] Eight cases of carcinomas were reported in patients aged 20 to 56 years.[99] A recent report from the National Cancer Institute cohort identified similar cancer risks in FA and DC, with cumulative incidences of solid tumors of 20% to 30% by age 50 years, and 10% AML for age 40 years. The majority of the tumors in DC are HNSCC.[106,107]

TABLE 37.3

CLINICAL FEATURES ASSOCIATED WITH DC

Skin pigmentary abnormalities
Nail dystrophy
Leukoplakia
Epiphora
Cognitive/developmental delay
Pulmonary disease
Short stature
Dental caries/tooth loss
Esophageal stricture
Hair loss/grey hair/sparse eyelashes
Hyperhidrosis
Intrauterine growth retardation
Gastrointestinal (GI) disorders
Ataxia
Hypogonadism/undescended testes
Microcephaly
Urethral stricture/Phimosis
Osteoporosis/aseptic necrosis/scoliosis
Deafness
Bone marrow failure
Malignancy

Pathophysiology

Reduced hematopoietic progenitor cell colonies have been described for all three hematopoietic lineages compared with controls.[108–110,111] DC patients show a reduction in the proliferative capacity of myeloid progenitors as measured by secondary colony formation following replating.[112] Bone marrow cells from DC patients show poor growth in long-term bone marrow culture assays. The defect is intrinsic to the hematopoietic stem cells since DC stromal cells are able to support hematopoietic cells from normal controls, while DC hematopoietic cells grow poorly on normal control stroma.[111]

The X-linked recessive form of DC was linked to Xq28 and the gene was identified by positional cloning and named *DKC1*[113] (Table 37.4). *DKC1* encodes a ubiquitously expressed protein, dyskerin. Dyskerin also interacts with TERC, which is the H/ACA RNA component of the human telomerase complex.[114] Cells from DC patients manifest abnormally shortened telomeres and reduced telomerase activity.[115] In further support of a telomerase defect in DC, the mutations responsible for some cases of the autosomal dominant form of DC were found to reside in the RNA template, *TERC,* itself,[116] and in *TERT*, the telomerase reverse transcriptase[117,118] (Table 37.4). Telomerase is an enzyme that adds DNA sequences to the ends of chromosomes (the telomeres) to prevent loss of terminal repeats (TTAGG) during DNA replication (reviewed in Ref. 119). Telomeres are important for the prevention of chromosomal fusions and rearrangements. Spontaneous unbalanced chromosomal rearrangements have been described in fibroblasts and bone marrow cells from DC patients.[120] While telomerase activity is abundant early in development, it is later detectable only in a subset of tissues with dividing cells, including the progenitor cells of the hematopoietic system, the basal layer of the epidermis, intestinal cells, and hair follicles. These tissues

TABLE 37.4

SUMMARY OF BONE MARROW FAILURE SYNDROMES

	Clinical Features	Inheritance Pattern	Gene	Additional Laboratory Testing	Associated Malignancies
Fanconi anemia	Radial ray, skin, craniofacial, genitourinary, gastrointestinal, cardiac	Autosomal recessive	*FANCA, FANCC, FANCD1, FANCD2, FANCE, FANCF, FANCG, FANCI, FANCJ FANCL FANCM FANCN FANCO FANCP*	Chromosome breakage	AML, carcinomas (head and neck, gynecologic); brain and Wilms in *D1/BRCA2*
		X-linked recessive	*FANCB*		
Dyskeratosis congenita	Abnormal nails, reticular rash, leukoplakia	X-linked recessive	*DKC1*	Telomere length	AML, carcinomas (head and neck, anogenital)
		Autosomal dominant	*TERC*

			TERT		
			WRAP53 CTC1		
Shwachman-Diamond syndrome	Short stature, fat malabsorption, skeletal anomalies	Autosomal recessive	*SBDS*	Serum trypsinogen, pancreatic isoamylase	AML
Congenital amegakaryocytic thrombocytopenia		Autosomal recessive	*C-MPL*		AML

AML, acute myeloid leukemia

mirror those most severely affected in DC patients. Telomere loss has also been implicated in contributing to the process of aging, and DC may represent a form of premature aging of tissues with a high replicative requirement.[121,122] The gene(s) responsible for some of the sporadic or autosomal dominant as well as the autosomal recessive forms of DC have not yet been identified. Sequence alternations in *TERT* have also been described in some patients with aplastic anemia in the absence of the characteristic physical findings of DC.[118,123] Mutations in additional components of telomerase *NOP10* (*NOLA3*)[124] and *NHP2* (*NOLA2*[125] as well as *TERT* and *CTC1*[126] are found in patients with autosomal recessive DC. In further support of DC as a telomere disorder, mutations in *TINF2*, a component of the shelterin complex that binds and protects telomeres, cause an autosomal dominant form of DC.[127] *WRAP53*, which encodes the TCAB1 protein, functions in the intracellular translocation of telomerase to the Cajal bodies for assembly.[128]

Dyskerin also exhibits strong homology to two previously characterized proteins: *Saccharomyces cerevisiae* Cbf5p[129,130] and rat NAP57.[131] Like Cbf5p and NAP57, dyskerin is localized primarily in the nucleolus and shares some homology with RNA pseudouridine synthases. Pseudouridine synthases together with small nucleolar RNAs (snoRNAs) isomerize uridine bases in ribosomal RNAs (rRNAs) to pseudouridine. In the absence of Cbf5p, yeast rRNA processing is defective.[130] Impaired translation initiation from internal ribosome entry site sequences has been observed in *Dkc1*^{m} mice and in cells from DC patients.[132]

It is increasingly apparent that the classical clinical syndrome of DC represents only the most severe form of the disease. Previously unrecognized milder forms exhibiting only isolated findings or marrow failure alone may now be identified through telomere length measurement and genetic testing.

Differential Diagnosis

DC must be distinguished from other inherited bone marrow failure syndromes that also present with aplastic anemia, congenital anomalies, and cancer predisposition, such as FA. In contrast to FA, cells from DC patients do not manifest increased chromosomal breakage in response to MMC or DEB.[133] Literature reports differ over whether cells from DC patient cells exhibit increased chromosomal breakage in response to DNA damaging agents.[134–138] Since DC patients may develop aplastic anemia in the first decade of life prior to the manifestation of skin or nail abnormalities, their underlying diagnosis may be missed. DC may mimic graft-versus-host disease in patients previously transplanted for aplastic anemia. Patients with DC typically present with very short telomeres for age; this assay is a clinically approved test.[96]

Laboratory Findings

In addition to peripheral cytopenias, red cell macrocytosis and elevated Hb F may be seen in patients with DC.[139] However, these signs of stress erythropoiesis are nonspecific, as they are seen in many patients with any of the inherited bone marrow failure syndromes. As noted above, immunologic abnormalities have also been described in some patients.[99,103]

Primary DC skin fibroblasts grow slowly in culture and exhibit abnormal morphology. X-chromosome inactivation patterns in female obligate carriers showed complete skewing, consistent with a growth or survival disadvantage for cells expressing only the defective X-chromosome allele.[140–142] Spontaneous unbalanced chromosomal translocations have been observed.[120,143]

Telomere length analysis is a useful diagnostic screen for DC since patients with DC exhibit very short (<first percentile of age-matched controls) telomeres in multiple lymphocyte subsets by multicolor flow cytometric fluorescent in situ hybridization (Flow-FISH).[96,144] Since over half of patients diagnosed clinically with DC lack mutations in the DC genes known to date, telomere length provides a useful diagnostic screen. Experience with telomere length testing is still limited, and must be interpreted within the clinical context of the patient. Genetic testing is clinically available, but negative genetic testing does not rule out the diagnosis of DC.

Supportive Care

Supportive care for DC patients is similar to that outlined for aplastic anemia and FA patients. Annual pulmonary function testing is recommended, given the risk of developing pulmonary fibrosis. Exposure to pulmonary toxins, such as cigarettes, should be avoided. Regular endocrinology visits are particularly important, since DKC patients are at increased risk of osteoporosis, and their diet, vitamin D, and parathyroid hormone levels and calcium status should be monitored. Patients with significant immunologic dysfunction resulting in reduced immunoglobulin levels may benefit from IVIG therapy.

Treatment

The only curative treatment for bone marrow failure MDS or AML in DC remains allogeneic stem cell transplantation (SCT).[102,145,146–148,149,150,151,152] Although long-term survivors have been reported, early and late fatal pulmonary and vascular complications after SCT remain a significant problem.[102,145,148,149,153] In one case, a successful lung transplant followed several years after bone marrow transplantation for aplastic anemia due to DC that had not been diagnosed.[154] The avoidance of drugs associated with pulmonary toxicity and the use of radiation-sparing conditioning regimens may provide useful avenues for future study. DC may be mistaken for chronic GVHD in patients transplanted for aplastic anemia.[155,156] Treatment with ATG and cyclosporin is generally not effective in these patients.[157] Improvement in peripheral blood counts has been described in some patients following treatment with the androgen oxymetholone.[158] Improved neutrophil counts in response to GM-CSF[159,160] or G-CSF[161,162] have been reported. Combined treatment with G-CSF and erythropoietin led to improved neutrophil and red cell counts in one case report.[163]

SHWACHMAN-DIAMOND SYNDROME

Clinical Features

SDS is characterized clinically by the combination of exocrine pancreatic insufficiency and bone marrow failure (see Refs. 164–166 for recent reviews). The differential diagnosis includes other inherited and acquired causes of marrow failure as well as other causes of exocrine pancreatic insufficiency, such as cystic fibrosis, Pearson syndrome, and cartilage hair hypoplasia.

Exocrine pancreatic insufficiency typically presents in infancy with failure to thrive and loose, foul-smelling stools consistent with steatorrhea. Fecal fat measurements may be helpful, but a normal test does not rule out the diagnosis of SDS, since exocrine pancreatic function may improve in a subset of patients. Exocrine pancreatic insufficiency may improve with age to become clinically asymptomatic in a subset of patients. The pancreas in patients with SDS shows fatty replacement of the pancreatic acini, with sparing of the ducts and islets. Fat-soluble vitamin deficiencies (vitamins A, D, E, and K) may be seen. Neutropenia is the most common feature of marrow failure in SDS. Neutropenia may be either intermittent or persistent.[167] Patients are predisposed to infections, particularly bacterial and fungal. Abnormalities of T or B cells have also been reported and may contribute to infectious complications.[168] Anemia and/or thrombocytopenia may also be seen and a subset of SDS patients develop aplastic anemia. The red blood cells may be macrocytic.

There is no pathognomonic feature of the bone marrow in SDS patients; nonetheless, a bone marrow examination with aspirate, biopsy, and cytogenetics is important to rule out other causes of cytopenias. Marrow cellularity may be normal, low, or high. As with other inherited bone marrow failure syndromes, mild dysplastic features may be seen in the erythroid, myeloid, and megakaryocytic lineages. There is a risk for progression to pancytopenia and aplastic anemia (20% to 25%) or myelodysplastic syndrome/AML (5% to 33%).[6,167,169] Hb F is elevated at some stage in approximately 80% of patients.[167]

Marrow cytogenetic abnormalities may be seen, such as abnormalities of chromosome 7 (monosomy 7, deletions/translations of 7q, isochromosome 7) as well as 20q–, which are particularly common. In the absence of morphologic evidence for MDS, the clinical significance of most cytogenetic abnormalities is unclear. These cytogenetic clonal populations may wax and wane over time or even disappear.[170]

Additional features that may be variably associated with SDS include: skeletal abnormalities, including metaphyseal dysostosis and osteopenia, failure to thrive despite early institution of pancreatic enzyme supplementation (see below), hepatic abnormalities, and abnormal dentition.[165]

Laboratory Findings

SDS is the second most common cause of inherited pancreatic insufficiency, after cystic fibrosis.[171] Sweat chloride is normal and serves to distinguish these patients from those with cystic fibrosis. Serum trypsinogen is generally depressed in SDS patients at any age, although it may improve with time.[172] Isoamylase levels remain low after the age of 3 and are useful in this older age group.[172] Other tests for exocrine pancreatic function include pancreatic stimulation or elevated fecal fat measurement, though the latter test is not specific for pancreatic dysfunction. Imaging studies may reveal a fatty, atretic pancreas. Fecal elastase may be decreased, but the sensitivity of this test as a screen for SDS remains to be ascertained. Fat-soluble vitamin levels (vitamins A, D, E, and K) may be low secondary to malabsorption. Skeletal imaging studies may reveal a wide variety of abnormalities, which are often asymptomatic, although metaphyseal dysostosis may require treatment.[173]

Over 90% of patients who meet clinical criteria for SDS harbor autosomal recessive mutations in the *SBDS* gene. While the presence of biallelic pathogenic *SBDS* mutations is helpful in confirming the diagnosis, the absence of mutations does not rule out the diagnosis of SDS if the patient meets diagnostic criteria on clinical grounds.[166]

Pathophysiology

SDS is an autosomal recessive disorder with an estimated incidence of 1 in 75,000.[174] In the majority (90%) of affected patients reported, mutations have been detected in the Shwachman-Bodian-Diamond syndrome (*SBDS*) gene located on chromosome 7q11.[175,176] SBDS is highly conserved throughout evolution and is expressed in all human tissues tested to date.[176] The human SBDS protein is found in both the nucleus and cytoplasm, and shuttles in and out of the nucleolus in a cell cycle–dependent fashion.[177]

SBDS has been implicated in multiple cellular functions. Attention has focused on its role in ribosome biogenesis. Human SBDS associates with the 60S ribosomal precursor but not with the mature 80S ribosome.[178] Yeast failing to express the *SBDS* ortholog *Sdo1* grows poorly. This slow growth is rescued by

mutations in *Tif6*, the yeast ortholog of *eIF6* which functions in ribosome biogenesis and ribosomal subunit joining.[179] Deletion of murine *Sbds* results in early embryonic lethality.[180] Using conditional *Sbds* knockout murine models, Sbds was shown to function in coupling the GTPase Efl1 to the release of eIF6 from the nascent 60S ribosomal subunit.[181] eIF6 sterically hinders the association of the 60S ribosomal subunit to the 40S subunit[182,183]; thus, eIF6 release is required for final assembly of a translationally active 80S ribosomal subunit. SBDS has also been implicated in additional molecular pathways including mitotic spindle stabilization,[184] cellular stress response,[185] actin dynamics,[186] and signaling downstream of RANK for osteoclast differentiation.[187]

Supportive Care

Regular monitorings of the peripheral blood counts and periodic bone marrow examinations are recommended. Fevers in the setting of neutropenia warrant prompt medical evaluation for appropriate cultures and treatment with broad spectrum antibiotics. Hematopoietic growth factors (such as recombinant human granulocyte colony-stimulating factor [rhG-CSF]) may stabilize or improve the neutropenia. The main indication for G-CSF therapy is serious bacterial or fungal infection related to neutropenia, though some centers opt to initiate treatment based on the neutrophil counts. Patients with a history of recurrent or severe bacterial infections may benefit from prophylactic G-CSF. Although there is a theoretical risk that G-CSF might stimulate the growth or progression of leukemic clones, there is no direct evidence to address this.[169,188] Transfusion support with red cells or platelets should be provided as clinically indicated for severe or symptomatic anemia and thrombocytopenia. There are no published reports to support the use of erythropoietin therapy unless erythropoietin levels are low.

Endocrinology evaluation is useful in these patients to rule out treatable comorbid conditions that could further exacerbate short stature or osteopenia. Dietary counseling may be helpful to ensure adequate intake of calcium and vitamin D.

Treatment

Therapy in SDS is initiated based on clinical manifestations. Fat malabsorption is treated with the administration of oral pancreatic enzymes. Exocrine pancreatic functions may vary over time, and thus regular assessment by a gastroenterologist is recommended.[189,190,191] Patients benefit from supplementation with water-soluble versions of vitamins A, D, E, and K. Fecal fat measurements, vitamin levels, and prothrombin time provide useful measures of exocrine pancreatic function.

Bone marrow transplantation can cure the hematologic aspects of SDS and has been evaluated as a potential therapy in SDS patients with marrow failure, MDS, or AML.[192–196,197] The results in the published literature, consisting largely of case reports, point to an increased risk of complications from end-organ dysfunction, particularly hepatic, cardiac, and pulmonary, as well as transplant-associated problems. Indications for transplant include severe or symptomatic cytopenias, high risk MDS, and leukemia. Outcomes for leukemia remain poor with standard chemotherapy regimens, and thus transplant is the treatment of choice. SDS patients receiving cytotoxic therapies are at risk for prolonged or intractable cytopenias, so appropriate preparations for stem cell support are warranted. As with the other inherited marrow failure syndromes, potential sibling donors regardless of clinical phenotype should be tested for pathogenic mutations identified in the proband. Reported survival rates are lower for patients transplanted for overt leukemia.[194,195] For this reason, regular surveillance of blood counts and bone marrow exams have been recommended to increase the likelihood of detecting early signs of malignant transformation.

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA

Clinical Features

Patients with CAMT typically present in the neonatal period with petechiae, purpura, or bleeding typically involving the skin, mucous membranes, or GI tract.[198] Intracranial bleeding has also been reported. Bleeding may be life threatening. Thrombocytopenia at birth is usually severe with platelet counts typically less than 50,000 and often less than 20,000. A family history of miscarriages has been reported.[198] Patients are at risk for developing cytopenias in all three hematopoietic lineages and may progress to severe aplastic anemia, which develops later in childhood, with a median age of 3.7 years.[198] A recent retrospective study reported pancytopenia in 14 out of 20 patients at a median age of 38 months with a range between 6 and 53 months.[198] Two clinical forms of CAMT have been described.[199] Patients in CAMT group I are characterized by severe, persistent thrombocytopenia and early onset of pancytopenia. Patients in CAMT group II are characterized by transient increases in platelet counts to over 50,000/μl early in life and either a delayed onset of pancytopenia or lack of pancytopenia to date.[199] The development of AML or MDS has been reported in patients with CAMT.[198]

Skeletal abnormalities are not typically seen in patients with CAMT. In a recent report, two patients with cardiac abnormalities and six with failure to thrive were reported.[198] Cerebral malformations have been detected, but the possibility that some of these may represent sequelae of prior intracranial hemorrhage could not be excluded. The presence of congenital anomalies together with thrombocytopenia should prompt diagnostic workup for other disorders such as FA, thrombocytopenia-absent-radii (TAR) syndrome, amegakaryocytic thrombocytopenia with radioulnar synostosis (ATRUS), Paris-Trousseau syndrome, or the Hoyeraal-Hreidarsson variant of DC. Mutations in *MPL* have been identified as one of many causes of familial aplastic anemia.

Differential Diagnosis

Complete blood counts and evaluation of the blood smear should be performed. In cases where primary marrow dysfunction appears likely, a bone marrow examination with cytogenetics is indicated. Thrombocytopenia in the neonate may be secondary to other causes such as infections (e.g., TORCH: toxoplasmosis, rubella, cytomegalovirus, herpes simplex, other viruses), sepsis, Kasabach-Merritt syndrome, thrombosis, or medications. Infants may exhibit transient thrombocytopenia in the setting of maternal HELLP syndrome. Immune-mediated thrombocytopenia from transplacentally acquired maternal alloantibodies or autoantibodies is also common in the neonatal period. Other rare causes of thrombocytopenia include the giant platelet syndromes: Bernard-Soulier syndrome, Glanzmann's thrombocythemia, and May-Hegglin disease. Additional inherited syndromes associated with thrombocytopenia, such as *GATA-1* mutations[200] or other inherited bone marrow failure syndromes, must also be considered. The absence of radial ray anomalies distinguishes CAMT from TAR. While patients with TAR exhibit thrombocytopenia at an early age, platelet counts generally improve with age, though counts may fluctuate. Aplastic anemia has not been reported in TAR patients, although AML or MDS has been reported.[201–203]

Laboratory Findings[198]

The platelets in CAMT are of normal size and morphology but low in number, typically in the 20,000/μl range, but higher platelet counts do not rule out the diagnosis. Laboratory tests for platelet

function are also normal. The red cells may be normocytic or macrocytic. Mean platelet volume is typically normal. The bone marrow initially shows normal cellularity but exhibits reduced or absent megakaryocytes. Thrombopoietin (TPO) levels are typically elevated (see below). Genetic testing for mutations in the *c-Mpl* gene is available.

Pathophysiology

CAMT is an autosomal recessively inherited disorder associated with mutations in the *c-Mpl* gene, which encode the receptor for TPO.[204,205] Mutations may be located throughout the gene and include nonsense, missense, and splicing mutations. A correlation between clinical severity and mutation classification has been observed.[199] Patients in the more severe CAMT group I carry mutations predicted to abrogate the production of a full length c-mpl protein. Patients in CAMT group II carry missense mutations that appear to represent hypomorphic alleles retaining some residual activity resulting in the milder clinical phenotype.[199]

CAMT patients exhibit high TPO serum levels,[206] and their endogenous serum TPO appears functional.[207] TPO is important for megakaryocyte development but also for hematopoietic stem cell survival. Mice deficient in either TPO or c-Mpl exhibit both thrombocytopenia as well as reduced numbers of hematopoietic stem cells and progenitors.[208] Stem cell dependency on TPO likely contributes to the development of aplastic anemia in CAMT patients.

Supportive Care

Indications for platelet transfusions vary, but generally they are reserved for patients who are experiencing bleeding symptoms. Prophylactic platelet transfusions may be considered for patients posing a high bleeding risk (e.g., prior to surgery). Antifibrinolytic medications such as aminocaproic acid or tranexamic acid may be helpful in stabilizing clots, particularly for mucous membrane bleeding such as oral or nasal bleeding. These agents inhibit plasminogen activation within the clot. Agents that inhibit platelet function, such as aspirin or nonsteroidal antiinflammatory agents should be avoided. Desmopressin acetate (DDAVP) has been used in some patients with thrombocytopenia, though side effects such as SIADH (syndrome of inappropriate antidiuretic hormone secretion) must be monitored.

Treatment

Currently, the only curative therapy for CAMT is a hematopoietic stem cell transplant.[198,209–213] Testing for biallelic *c-mpl* mutations is a consideration prior to choosing a sibling transplant donor. Whether c-mpl carrier status affects transplant outcomes is unclear. Abnormal platelet production has been noted in a sibling who was heterozygous for *c-mpl* mutation and exhibited decreased megakaryocyte colony formation in vitro despite normal platelet counts,[214] but a good short-term outcome using one sibling carrier donor has been reported.[210] Considerations for timing of transplant include minimizing the risk of allosensitization from donor blood products or infectious complications secondary to neutropenia. The reader is referred to several recent comprehensive reviews for additional information.[215,216]

CHAPTER 38

ACQUIRED APLASTIC ANEMIA

Robert A. Brodsky

HISTORICAL BACKGROUND

The earliest case description of aplastic anemia was by Dr. Paul Ehrlich in 1888.[1] He described a young woman who died following an abrupt illness that manifested as severe anemia, bleeding, hyperpyrexia, and a markedly hypocellular bone marrow. The term aplastic anemia was first introduced in 1904 by Chauffard. In 1972, a patient with aplastic anemia became the first recipient of successful allogeneic bone marrow transplantation.[2] The development of bone marrow transplantation and potent immunosuppressive therapy in the 1970s greatly improved the prognosis of an illness that was almost uniformly fatal within a few years of diagnosis. Although aplastic anemia remains a potentially devastating illness, with prompt intervention most patients now survive the disease.

ACQUIRED VERSUS CONSTITUTIONAL APLASTIC ANEMIA

Acquired aplastic anemia can occur in any age group and is usually the consequence of an autoimmune attack against hematopoietic stem cells. Awareness of the less common inherited forms of bone marrow failure is critical in the assessment of any new patient with aplastic anemia (Chapter 37). These inherited disorders can masquerade as acquired aplastic anemia, but rarely respond to immunosuppressive therapies; management usually consists of supportive care or in severe cases bone marrow transplantation (BMT).[3,4] Inherited forms of bone marrow failure generally present in the first decade of life and are often associated with physical anomalies, (e.g., short stature, upper-limb anomalies, hypogonadism, café-au-lait spots); however, inherited forms of bone marrow failure may present well into adulthood. Some patients have a positive family history of cytopenias, highlighting the importance of taking a careful family history when evaluating aplastic anemia patients.

Fanconi anemia, the most common form of inherited bone marrow failure, is usually an autosomal recessive disorder that is characterized by defects in DNA repair and a predisposition to leukemia and solid tumors.[5] Recently, a rare, X-linked form of Fanconi anemia has been described.[6] Dyskeratosis congenita (DKC) is an inherited bone marrow failure syndrome that results from loss of function mutations of telomerase components and displays considerable clinical and genetic heterogeneity. Although DKC classically presents with the triad of abnormal skin pigmentation, nail dystrophy, and mucosal leukoplakia, these findings can be subtle.[7,8] X-linked recessive, autosomal dominant and autosomal recessive forms of DKC are recognized.[9,10] Telomerase reverse transcriptase (TERT) and the RNA component of telomerase (TERC) form the core of the active telomerase complex. Autosomal dominant DKC can result from mutations of *TERC*[11] or *TERT*.[12] The X-linked recessive DKC results from mutations in the gene *DKC1,* whose gene product, dyskerin, is important for stabilizing the telomerase RNA–protein complex.[13,14] Mutations of the *TINF2* gene can also lead to DKC. *TINF2* mutations result in dysfunction of the shelterin complex, interfering with its protection of telomeres and leading to reduced telomere length. Accelerated telomere shortening leads to bone marrow failure, genetic instability, and premature aging.

Inherited amegakaryocytic thrombocytopenia is characterized by severe thrombocytopenia and megakaryocyte absence at birth. Missense or nonsense mutations in the *c-mpl* gene are present in most patients. A high percentage of these patients subsequently develop multilineage bone marrow failure in the second decade of life.[15] Shwachman-Diamond syndrome is an autosomal recessive disorder characterized by pancreatic exocrine dysfunction, metaphyseal dysostosis, and bone marrow failure.[16] Similar to Fanconi anemia, there is an increased risk of developing myelodysplasia or leukemia at an early age. Hypomorphic mutations in the *Shwachman-Bodian-Diamond Syndrome* (*SBDS*) gene on chromosome 7 have been found in roughly 85% of cases.[17] The *SBDS* gene is important for ribosome biogenesis, but how this leads to bone marrow failure is unclear. These inherited forms of aplastic anemia are described in more detail in Chapter 37. The remainder of this chapter focuses on acquired aplastic anemia, hereafter referred to as aplastic anemia.

EPIDEMIOLOGY

Incidence, Age, and Geographic Distribution

Precise estimates of the incidence of aplastic anemia are confounded by the imprecision in establishing the diagnosis. The International Aplastic Anemia and Agranulocytosis Study (IAAAS), conducted in Europe and Israel, is the largest and most comprehensive epidemiologic study of bone marrow failure.[18] This prospective study (performed between 1980 and 1984) reported that the overall incidence of aplastic anemia was 2 cases per 1 million people; however, the incidence may be two to threefold higher in Southeast Asia.[19]

Aplastic anemia most commonly presents in children and young adults, but there is a second smaller peak in incidence after age 60.[20,21] Similar to other autoimmune diseases, certain histocompatibility locus specificities, especially HLA-DR2, are associated with an underlying predisposition to aplastic anemia.[22] Although aplastic anemia has been causally associated with many agents, including drugs, benzene exposure, insecticides, and viruses, no etiologic agent can be identified in most cases.[23,24] A population-based case-control study of aplastic anemia in Thailand found that drugs were the most commonly implicated cause, but they explained only 5% of newly diagnosed cases.[23]

Benzene and Environmental Toxins

The medical literature is replete with case reports of aplastic anemia associated with environmental exposures, most notably benzene or radiation exposure. However, rigorous epidemiologic studies supporting an association between environmental toxins and aplastic anemia are lacking. A major confounder is that benzene and other toxins predispose people to myelodysplastic syndromes (MDS) and leukemia. Older literature was unlikely to have been able to distinguish different types of marrow failure, such as aplastic anemia, MDS, and hypoplastic leukemia, leading to an overestimation of the association between benzene and aplastic anemia. Although the magnitude of the risk remains uncertain, benzene is probably not a major risk factor for aplastic anemia in countries with modern standards of industrial hygiene. A large case-controlled study in Thailand employing modern diagnostic and epidemiologic methods found that individuals of lower economic status and younger age are at greater risk for developing aplastic anemia than their counterparts in other countries following exposure to solvents, glues, and hepatitis A. Grain farmers were also found to have a higher risk of developing aplastic

anemia (relative risk = 2.7) regardless of whether they used insecticides.[19] These same investigators noted marked differences in incidence between northern and southern rural regions of Thailand and among Bangkok suburbs, implicating potential environmental factors in causing the disease.[25]

Radiation

Ionizing radiation is directly toxic to bone marrow stem/progenitor cells, and high doses (>1.5 Gy to the whole body) can lead to severe pancytopenia within 2 to 4 weeks after exposure; the LD_{50} has been estimated at about 4.5 Gy, and a dose of 10 Gy or greater is thought to have 100% mortality.[26,27] Although pancytopenia is common after a single high dose of radiation, an increased risk of aplastic anemia is not well documented as a delayed event from atomic bomb survivors.[28] Although the principles of managing pancytopenia following radiation exposure are similar to those of aplastic anemia, it is important to recognize that the mechanism of bone marrow failure is different. Bone marrow failure in most cases of community acquired aplastic anemia is due to autoimmune destruction of bone marrow stem/progenitor cells; however, radiation-induced bone marrow failure is dose dependent and is a consequence of direct toxicity to stem and progenitor cells. Supportive care with blood transfusions, granulocyte colony-stimulating factor, and antibiotics is the mainstay of therapy for radiation-induced bone marrow failure, inasmuch as autologous reconstitution will occur in most patients who survive the immediate consequences of radiation exposure.

Drugs and Chemicals

A plethora of case reports and small series have implicated drugs as the cause of bone marrow failure; however, proving a causal association in these rare idiosyncratic reactions is difficult. The more common classes of drugs implicated in causing aplastic anemia are listed in Table 38.1. Nevertheless, drugs were not found to be a common cause of aplastic anemia in two large, controlled, population-based studies.[18,29] An epidemiologic study in Thailand examined 541 patients and 2,261 controls. Exposures were determined by in-person interview. The investigators observed significantly elevated relative risk estimates for sulfonamides (5.6), thiazides (3.8), and mebendazole (3.0). Interestingly, no increased risk was associated with chloramphenicol, perhaps the most widely implicated drug in case reports; however, chloramphenicol use is this study was infrequent.[29]

When drugs are implicated in causing aplastic anemia, it is important to recognize that unlike agranulocytosis and drug-induced thrombocytopenia, stopping the putative drug does not usually lead to hematopoietic recovery. Most cases of drug-induced aplastic anemia lead to an idiosyncratic immune response directed against hematopoietic stem cells and are managed similarly to those with idiopathic aplastic anemia. Notable exceptions include patients who receive high doses of cytotoxic chemotherapy drugs (e.g., alkylating agents, antimetabolites, antimitotics) or rare individuals who have thiopurine methyltransferase deficiency (TPMT). TPMT catalyzes the *S*-methylation of 6-mercaptopurine, 6-thioguanine, and azathioprine.[30] Most individuals have high or intermediate activity of TPMT; however, there are rare individuals (<0.1% of the population) with undetectable levels of TPMT. Exposure to even low dosages of 6-thioguanine, azathioprine, or 6-mercaptopurine, as used in inflammatory bowel disease and lupus, can result in severe bone marrow failure within weeks of starting the drug. Withdrawal of the drug usually leads to hematopoietic recovery in 2 to 4 weeks. Reliable polymerase chain reaction–based methods are now available for detecting the major inactivating mutations at the human TPMT locus.[31,32]

TABLE 38.1

CLASSIFICATION OF DRUGS MOST COMMONLY IMPLICATED IN CAUSING APLASTIC ANEMIA

Nonsteroidal Analgesics
Phenylbutazone, indomethacin, ibuprofen, sulindac, diclofenac, piroxicam
Anticonvulsants
Hydantoins, carbamazepine, phenacemide
Antibiotics
Sulfonamides, chloramphenicol
Antiprotozoals
Quinacrine, chloroquine
Antithyroid Drugs
Methimazole, propylthiouracil
Gold

Viruses

Viruses, similarly to drugs, are often implicated, but seldom proven to cause aplastic anemia. Viral infections, especially in chronically ill patients, often lead to transient cytopenias, but frank aplastic anemia is uncommon. These transient cytopenias can be due directly to infection and cytolysis of hematopoietic cells or indirectly through the elaboration of inhibitory cytokines. True aplastic anemia following viruses also appears to result usually from an idiosyncratic immune response directed against hematopoietic stem cells. Acute infection with Epstein-Barr virus (EBV) is often associated with peripheral blood cytopenias. Rarely, acute EBV infection can be complicated by the development of aplastic anemia.[33,34,35] There is no convincing data that B19 parvovirus causes aplastic anemia, but this virus is often linked with aplastic anemia due to the unfortunate term "aplastic crisis," used to describe the transient red cell aplasia and severe anemia that occurs in sickle cell anemia patients who are acutely infected with B19 parvovirus. The only known natural host cell of parvovirus B19 is the human erythroid progenitor.[36] The receptor for the virus is a neutral glycolipid, globoside, also known as the erythrocyte P antigen.[37] Globoside is expressed on erythroid progenitors, erythrocytes, fetal myocardium, placenta, some megakaryocytes, and endothelial cells; it is not present on hematopoietic stem cells. Other viruses, including a variety of herpes viruses and the human immunodeficiency virus have been implicated in triggering aplastic anemia, but convincing causal data are lacking. Spontaneous recovery, response to immunosuppression, and response to antiviral therapy have all been described; however, for those with severe disease, conventional therapy (immunosuppression or bone marrow transplantation) should be initiated early.

Seronegative (non-A through non-G) hepatitis precedes the diagnosis of aplastic anemia in 3% to 5% of cases and is recognized as hepatitis-associated aplastic anemia.[38] After orthotopic liver transplantation for fulminant seronegative hepatitis, up to 30% of patients will develop aplastic anemia (HAA).[39,40] In most cases, the hepatitis resolves spontaneously; however, when severe aplastic anemia (SAA) follows, it is often fatal and presents within a few months after the onset of hepatitis.[41] The pathophysiology of HAA is unknown, but is thought to be immune mediated because it responds to immunosuppressive therapy.[41] Furthermore, patients with HAA have a skewed T-cell repertoire, and liver biopsies from these patients show lymphocytic infiltration.[42]

Pregnancy

Pregnancy-associated aplastic anemia is a rare entity, and despite numerous case reports, the association is not well understood.[1,43,44]

The onset of aplastic anemia can occur during pregnancy or shortly after delivery. Moreover, in women with a history of aplastic anemia who had been treated into remission with immunosuppressive therapy, there is an increased risk for relapse of aplastic anemia during pregnancy. The European Group for Blood and Marrow Transplantation performed a retrospective study on the outcome of pregnancy in 36 women who had received immunosuppressive therapy to treat aplastic anemia.[45] Seven of the pregnancies (19%) were complicated by relapse of aplastic anemia. In contrast to idiopathic aplastic anemia, pregnancy-associated aplastic anemia is often associated with spontaneous remissions. However, in patients with severe disease, therapy should be initiated promptly, because maternal and fetal mortality are not uncommon.[43,44,45]

PATHOPHYSIOLOGY

Autoimmunity

Aplastic anemia was originally thought to result from a direct toxic effect on hematopoietic stem cells. In the late 1960s, Mathé and colleagues were among the first to postulate an autoimmune basis for aplastic anemia.[46] After administering antilymphocyte globulin for conditioning, they performed bone marrow transplantation in aplastic anemia patients using partially mismatched donors. Although the transplanted marrow failed to engraft, some patients experienced autologous recovery of hematopoiesis, suggesting that growth and differentiation of the patient's hematopoietic stem cells were being suppressed by the immune system. An analysis by the International Bone Marrow Transplant Registry of identical twin bone marrow transplants in aplastic anemia patients also suggests an autoimmune etiology for the majority of patients. Attempts to treat aplastic anemia by simple transfusion of bone marrow from an identical twin fails to reconstitute hematopoiesis in about 70% of patients.[47] However, repeating the procedure following a high-dose cyclophosphamide conditioning regimen is successful in most patients.[48]

The first laboratory evidence of autoimmunity in aplastic anemia was provided by experiments showing that lymphocytes from aplastic anemia patients inhibit allogeneic and autologous hematopoietic colony formation in vitro.[49] Subsequently, cytotoxic T lymphocytes were found to mediate the destruction of hematopoietic stem cells in aplastic anemia.[50,51] These cytotoxic T cells are more conspicuous in the bone marrow of aplastic anemia patients than in the peripheral blood,[52,53,54] and they overproduce interferon-γ and tumor necrosis factor (TNF).[55] TNF and interferon-γ are direct inhibitors of hematopoiesis and appear to up-regulate Fas expression on $CD34^+$ cells.[56] Immortalized $CD4^+$ and $CD8^+$ T-cell clones from aplastic anemia patients also secrete Th1 cytokines and are directly toxic to autologous CD34 cells.[50,51] There is also evidence for a humoral autoimmune response in aplastic anemia; autoantibodies against kinectin, a 1,300 amino acid molecule expressed on human hematopoietic cells, liver, ovary, testis, and brain cells have been found in approximately 40% of aplastic anemia patients.[57] Antidiazepam-binding related protein-1 is another putative autoantibody found in some patients with aplastic anemia;[58] however, the relevance of these autoantibodies to the pathophysiology of aplastic anemia is unclear. Studies in aplastic anemia patients examining T-cell diversity using complementarity-determining region (CDR3) spectratyping further implicate an autoimmune pathophysiology in aplastic anemia. T cells from aplastic anemia patients have limited T-cell receptor β-chain heterogeneity, suggesting oligoclonal T-cell expansion in response to a specific, but as yet unrecognized, antigen.[51,59]

Stem Cells

A reduction in the number of hematopoietic stem/progenitor cells is a universal laboratory finding in aplastic anemia. $CD34^+$ cells, assayable hematopoietic progenitors, and long-term culture-initiating cells are strikingly reduced in aplastic anemia.[60,61] However, some healthy hematopoietic stem cells persist in most patients with aplastic anemia inasmuch as complete recovery of normal hematopoiesis can occur with effective immunosuppressive therapy.[62,63] T cells from aplastic anemia patients kill hematopoietic stem cells in an HLA-DR restricted manner[50,51] via Fas ligand.[56] Hematopoietic stem cells represent several classes of cells with varying capacity for long-term production of the different hematopoietic lineages and variable expression of Fas ligand and HLA-DR.[64] The most primitive hematopoietic stem cells express little or no HLA-DR[64,65] or Fas,[66,67] and the expression of both HLA-DR and Fas increases as the stem cells mature. Thus, the primitive hematopoietic stem cells, which normally represent less than 10% of the total $CD34^+$ cells, may be relatively invisible to the autoreactive T cells; conversely, the more mature hematopoietic stem cells may be the principal targets of the immune attack in aplastic anemia.[68] The primitive hematopoietic stem cells eluding the autoimmune attack may be responsible for the slow hematopoietic recovery that occurs in aplastic anemia patients following immunosuppressive therapy.

Clonality and Aplastic Anemia

Clonal hematopoietic stem cell disorders such as paroxysmal nocturnal hemoglobinuria (PNH) and MDS frequently arise from aplastic anemia. Even before the widespread use of immunosuppressive therapy, 5% of patients with aplastic anemia progressed to clonal hematopoiesis. This suggests that the increase in MDS and PNH following immunosuppressive therapy is not a direct consequence of treatment. Rather, the increased survival following immunosuppressive therapy allows time for these underlying clones to develop and expand.[69,70]

MDS is a clonal hematopoietic stem cell disorder that produces multilineage hematologic cytopenias (Chapter 79). It is associated with heterogeneous karyotypic abnormalities, often involving chromosomes 5, 7, or 8. Up to 15% of children and adults with aplastic anemia will develop MDS following immunosuppressive therapy, with monosomy 7 being the most common chromosomal abnormality to emerge.[71,72] PNH results from the expansion of an abnormal hematopoietic stem cell that harbors a somatic mutation of the X-linked gene, *PIGA*.[73,74] The *PIGA* gene product is required for glycosylphosphatidylinositol (GPI) anchor biosynthesis; consequently, PNH cells are deficient in all GPI-anchored proteins (GPI-AP). The GPI-APs (CD59 and CD55) protect cells from complement-mediated destruction; their absence explains the complement-mediated intravascular hemolysis associated with PNH.

Small to moderate PNH clones are found in up to 70% of patients with aplastic anemia.[69,75] Typically, less than 20% GPI-AP–deficient granulocytes are detected in aplastic anemia patients at diagnosis, but occasional patients may have larger clones. DNA sequencing of the GPI-AP–deficient cells from aplastic anemia patients reveals clonal *PIGA* gene mutations.[76] Moreover, many of these patients exhibit expansion of the *PIGA* mutant clone and progress to clinical PNH. Although it was once thought that PNH evolving from aplastic anemia is more benign than classical PNH, this observation may be a consequence of lead time bias, inasmuch as many of these patients eventually develop classical PNH symptoms after the *PIGA* mutant clone expands. Interestingly, the PNH clone can regress, remain stable, or expand in aplastic anemia patients treated with immunosuppressive therapy; however, expansion of the PNH clone is commonly associated with relapse.[77,78]

The mechanism whereby PNH clones expand is not entirely clear; however, a preponderance of data suggests that the PNH stem cell has a conditional growth advantage in the setting of aplastic anemia. Specifically, it has be suggested that PNH cells

may be relatively resistant to an autoimmune attack on the bone marrow, possibly because they are deficient in GPI-anchored UL binding proteins (ULBP) that serve as receptors for NKG2D, a ligand that is important for natural killer cells and T cells.[79,80] Alternatively, it has been proposed that "second hit" mutations may also give the PNH clone a growth advantage.[81] These hypotheses are not mutually exclusive.

CLINICAL FEATURES AND DIAGNOSIS

Aplastic anemia can present abruptly over days, or insidiously over weeks to months. Clinical manifestations are proportional to the peripheral blood cytopenias and may include dyspnea on exertion, fatigue, easy bruising, petechia, epistaxis, gingival bleeding, heavy menses, headache, and fever. A complete blood count, leukocyte differential, reticulocyte count, and a bone marrow aspirate and biopsy can establish the diagnosis. Peripheral blood flow cytometry to rule out PNH[82,83] and bone marrow karyotyping to help exclude hypoplastic myelodysplastic syndromes (hMDS) should be performed on all patients. Flow cytometric assays to detect PNH cells can be performed with either monoclonal antibodies[83] or a fluorescein-conjugated proaerolysin variant known as FLAER.[84] Unlike monoclonal antibodies that bind the protein portion of a GPI-anchored protein, FLAER binds to the glycan portion of the GPI anchor and is highly sensitive and specific for detecting PNH cells.[69,82] Patients less than 40 years of age should be screened for Fanconi anemia using the clastogenic agents diepoxybutane or mitomycin C that test for increased chromosomal breakage.[5] Up to 10% of patients with Fanconi anemia will have a false negative chromosomal breakage analysis due to mosaicism. In these patients, fibroblasts from a skin biopsy or buccal smear can be used to establish the diagnosis. A family history of cytopenias or pulmonary fibrosis should raise suspicion for an inherited disorder, even when physical abnormalities are not present.

A hypocellular bone marrow is required for the diagnosis of aplastic anemia (Table 38.2). Spicules from an aspirate may be surprisingly cellular in some patients despite overall marrow hypocellularity as most patients will have residual pockets of ongoing hematopoiesis. Thus, a 1- to 2-cm core biopsy is essential for assessing cellularity. Mild dyserythropoiesis is not uncommon in aplastic anemia, especially in cases with simultaneous small- to moderate-sized PNH populations; however, the presence of a small percentage of myeloid blasts or dysplastic features in the myeloid or megakaryocyte lineages favors a diagnosis of hMDS (Table 38.3). Distinguishing between aplastic anemia and hMDS is often challenging, especially in older patients where hMDS is more common. The percentage of $CD34^+$ cells in the bone marrow is often helpful.[85,86] CD34 is expressed on hematopoietic progenitors and is fundamental to the pathophysiology of both diseases; in MDS clonal expansion emanates from a $CD34^+$ stem cell, and in aplastic anemia the $CD34^+$ stem cells are the target of an autoimmune attack (Fig. 38.1). Accordingly, the percentage of $CD34^+$ cells is usually ≤0.3% in aplastic anemia, whereas the CD34 percentage is either normal (0.5% to 1.0 %) or elevated in hMDS.[85]

TABLE 38.2

DIFFERENTIAL DIAGNOSIS OF PANCYTOPENIA WITH A HYPOCELLULAR BONE MARROW

Acquired aplastic anemia
Inherited aplastic anemia
Fanconi anemia
Dyskeratosis congenita
Shwachman-Diamond syndrome
Amegakaryocytic thrombocytopenia
Reticular dysgenesis
Hypoplastic myelodysplastic syndromes
Large granular lymphocytic leukemia (rare)
Hypoplastic PNH (PNH/aplastic anemia)

PNH, paroxysmal nocturnal hemoglobinuria.

TABLE 38.3

BONE MARROW FINDINGS THAT HELP TO DISCRIMINATE APLASTIC ANEMIA FROM MYELODYSPLASIA

Characteristic	Myelodysplastic Syndromes	Aplastic Anemia
Cellularity	Usually increased or normal[a]	Decreased
CD34 count	Normal to increased	Decreased
Erythropoiesis		
Megaloblastosis	Common	Common
Dyserythropoiesis	Common	Sometimes
Ringed sideroblasts	Common	Never
Myelopoiesis		
Increased blasts	Common	Never
Megakaryocytes		
Dysplastic	Common	Never

[a]A hypocellular bone marrow is found in up to 15% of cases of myelodysplastic syndromes.

Classification

As do most autoimmune diseases, aplastic anemia encompasses a wide spectrum of disease activity ranging from mild to severe. The risk of morbidity and mortality from aplastic anemia correlates best with the severity of the cytopenias rather than bone marrow cellularity. Thus, acquired aplastic anemia is classified as nonsevere (NSAA), severe (SAA), or very severe (VSAA) based on the degree of peripheral blood pancytopenia (Table 38.4). A bone marrow cellularity of less than 25% and markedly decreased values of at least two of three hematopoietic lineages (neutrophil count $<500/\mu l$, platelet count $<20{,}000/\mu l$, and absolute reticulocyte count of $<60{,}000/\mu l$) define SAA. VSAA satisfies the above criteria except the neutrophil count is $<200/\mu l$, whereas NSAA is characterized by a hypocellular bone marrow, but with cytopenias that do not meet the criteria for severe disease. The 2-year mortality rate with supportive care alone for patients with SAA or VSAA approaches 80%,[87] with invasive fungal infections and overwhelming bacterial sepsis being the most frequent causes of death. NSAA is seldom life-threatening and in many instances requires no therapy.

SUPPORTIVE CARE

Transfusions

Patients with symptomatic anemia and/or thrombocytopenia associated with wet purpura or bleeding require immediate blood transfusions. All transfusions in patients with suspected aplastic anemia should be irradiated to prevent transfusion-associated GVHD. If the patient is a potential BMT candidate and is cytomegalovirus (CMV)-negative or the CMV status is unknown, CMV transmission should be avoided by either leukoreduction or the use of CMV-negative products. Blood donation from family

TABLE 38.4

CLASSIFICATION OF APLASTIC ANEMIA BASED ON SEVERITY OF PANCYTOPENIA

Severe aplastic anemia (SAA)
Bone marrow cellularity <25%
Two of three peripheral blood criteria:
Absolute neutrophil count <500/mm^3
Platelet count <20,000/mm^3
Reticulocyte count <60,000/mm^3 or <1% corrected reticulocyte count
Very severe aplastic anemia (vSAA)
Same as SAA with absolute neutrophil count <200/mm^3
Nonsevere (moderate aplastic anemia)
Bone marrow cellularity <25%
Peripheral blood cytopenias do not fulfill criteria for SAA

members should be avoided to prevent alloimmunization that could also complicate future BMT. After stabilization of the patient, blood products should be used judiciously to prevent cardiopulmonary compromise and to reduce the risk of hemorrhage; a platelet goal of 10,000/μL will suffice for most patients, although some patients will tolerate even lower platelet goals without bleeding or petechiae.

Antibiotics

Overwhelming sepsis caused by bacteria or fungus (especially aspergillus) is the most frequent cause of death from aplastic anemia. In most circumstances, prophylactic antibiotics are unnecessary. However, for patients with absolute neutrophil counts that are consistently <200μL, prophylaxis with oral antibiotics, such as a quinolone and a triazole antifungal, is reasonable. Patients with febrile neutropenia should be treated promptly with broad-spectrum antibiotics; in patients with persistent fever after the initiation of antibacterial antibiotics, aspergillus coverage should be added. Prophylaxis for *Pneumocystis carinii pneumonia* should be given to

all patients for at least 6 months after immunosuppressive therapy, BMT, or high-dose cyclophosphamide therapy.

Growth Factors

Hematopoietic growth factor deficiency (such as erythropoietin, granulocyte colony-stimulating factor, thrombopoietin, or granulocyte–monocyte colony-stimulating factor) is not responsible for the bone marrow failure in aplastic anemia; levels of measurable hematopoietic growth factors are markedly elevated in aplastic anemia patients in a compensatory attempt to increase blood production. Hence, these factors should not be used in lieu of definitive therapy. Hematopoietic growth factors are often used after immunosuppressive therapy or high-dose cyclophosphamide therapy to accelerate hematopoietic recovery, but their use has not been shown to improve survival.

DEFINITIVE TREATMENT

Nonsevere (Moderate) Aplastic Anemia

There are limited data on the long-term prognosis of patients with moderate aplastic anemia. Although moderate aplastic anemia can progress, many patients will remain stable for years, and some may spontaneously improve, even in the absence of specific treatment.[88] Treatment should be based on the degree of cytopenia, not bone marrow cellularity. Patients with asymptomatic cytopenias probably require no therapy. Patients with more significant cytopenias, such as symptomatic anemia, may benefit from a trial of immunosuppressive therapy with antithymocyte globulin and cyclosporine (ATG/CSA)[89] or CSA alone.[90] Daclizumab, a humanized monoclonal antibody to the interleukin-2 receptor, improved blood counts in 6 of 16 patients with moderate aplastic anemia.[91] However, it is not clear that treatment of moderate aplastic anemia will effect survival.

Definitive Therapy for Severe Aplastic Anemia

Bone Marrow Transplantation

Allogeneic BMT from an HLA-matched sibling donor is the treatment of choice at most centers for young patients with SAA (Table 38.5). A major advantage of BMT over standard immunosuppressive therapy is a marked reduction in the risk of relapse and the outgrowth of late clonal disorders such as MDS and PNH.[92] Cyclophosphamide (50 mg/kg/day × 4 days) with or without ATG, is commonly used for conditioning before stem cell transplantation. Although this regimen is nonmyeloablative, the immunosuppression is sufficient to allow engraftment in most cases.[93,94,95] Avoidance of total body irradiation and busulfan reduces transplant-related complications such as mucositis, graft-versus-host disease (GVHD), second malignancies, and infertility. Alternative regimens using fludarabine, cyclophosphamide and antithymocyte globulin are increasingly being used.[96] Survival rates following matched sibling allogeneic BMT have steadily improved since the 1970s largely because of improved supportive care, improved typing, and better GVHD prophylaxis.[97] Late BMT-related complications such as chronic GVHD occur in up to one third of patients, with many of these patients requiring long-term therapy for their GVHD.[98] Patient age and the type of allograft (HLA-matched sibling, unrelated, or mismatched donors) are the most important factors influencing outcome. In patients under 30 years of age, the cure rate after HLA-matched sibling BMT ranges from 70% to 90%.[98–100] However, the risk of GVHD steadily increases with age, leading to reduced survival.

Alternative Donor Bone Marrow Transplantation

Unrelated donors and mismatched transplants have almost twice the transplant-related mortality and risk of GVHD as matched sibling donor transplants (Table 38.6).[24] Less than 30% of patients will have an HLA-matched sibling donor. Thus, bone marrow transplantation from unrelated or mismatched donors is usually reserved for patients who fail to respond to one or more courses of immunosuppressive therapy. The best results with unrelated and mismatched transplants are seen in patients under 21 with disease duration of less than 1 year.[101–103] The International Bone Marrow Transplant Registry reported on the results of 318 alternative donor transplants between 1988 and 1998.[104] Most patients in this series were young, heavily transfused, and of poor performance status. The probability of graft failure was 20% and the survival probability at 5 years was less than 40%. The Fred Hutchinson Cancer Research Center reported on the results of unrelated allogeneic bone marrow transplantation in aplastic anemia after conditioning with low-dose total body irradiation, high-dose cyclophosphamide, and ATG.[103] The median age was 19 years, and with a median follow-up of 7 years, 61% of HLA-identical and 40% of HLA nonidentical transplant recipients survived the procedure; however, more than 70% of patients acquired acute GVHD, and over 50% developed chronic GVHD. However, improved typing, newer conditioning regimens, and better GVHD prophylaxis are leading to better survival, higher engraftment rates, and less GVHD. EBMT data using fludarabine, cyclophosphamide, and ATG conditioning ± total body irradiation (TBI) demonstrated survival rates as high as 75%.[105] Survival is best

in children and in patients who undergo BMT within 2 years of diagnosis. Another promising approach to facilitate engraftment and to mitigate the risk of GVHD is the use of post-transplant cyclophosphamide for GVHD prophylaxis.[106,107]

Immunosuppressive Therapy

Immunosuppressive therapy with ATG/CSA is used in patients who are not candidates for bone marrow transplantation because of older age or lack of a matched sibling donor. ATG is produced by immunizing animals (horse or rabbit) against human thymocytes and kills human T cells through its cytolytic activity. The largest experience is with horse ATG, although rabbit ATG has recently been approved for use in the United States. CSA suppresses T-cell function by inhibiting the expression of nuclear regulatory proteins. Both single-agent ATG and single-agent CSA[90] can induce remissions in acquired aplastic anemia; however, the combination ATG/CSA leads to a higher response rate and a greater likelihood of achieving transfusion independence.[89,108] A randomized controlled trial demonstrated that horse ATG/CSA is superior to rabbit ATG/CSA. However, difficulties in maintaining quality control have led to the withdrawal of horse ATG in Europe since June of 2007.

The response rates to ATG/CSA range between 60% and 80% (Table 38.7), with 5-year survival rates comparable to BMT.[109] However, in contrast to BMT, most patients are not cured of their disease. Most patients respond within 6 to 12 weeks after receiving ATG/CSA. ATG is usually given over 4 days but CSA must be continued for at least 6 to 12 months before tapering the drug. Persistent cytopenia is common and many patients relapse, become dependent on cyclosporine, or develop secondary clonal disease such as PNH or MDS.[71,89,110,111] The European Group for Blood and Marrow Transplantation (EBMT) SAA working party performed a retrospective analysis of 468 patients treated with immunosuppressive therapy between 1975 and 1986.[112] Patients who survived more than 2 years (n = 223) were classified as long-term survivors. The actuarial mortality rate for long-term survivors was 22% at 8 years, and the actuarial risks of developing PNH and MDS were 13% and 15%, respectively, at 7 years. Bacigalupo and colleagues reported a response rate and overall survival of 77% and 87%, respectively, in 100 patients (median age, 16 years) treated with ATG/CSA, prednisolone, and granulocyte colony-stimulating factor.[62] The risk of relapse was 9% and cytogenetic abnormalities developed in 11%, but the actuarial probability of discontinuing cyclosporine therapy was only 38% at 5 years. The National Institutes of Health (NIH) treated 122 patients (median age, 35 years) with the combination of ATG/CSA and methylprednisolone and followed them over a period of 8 years.[71] The response rate was 58% and actuarial survival at 7 years was 55%; 13% of patients died within 3 months of treatment,

mostly from fungal infections. The relapse rate for responders was 40% and 13 patients developed MDS. In an attempt to improve response rate and survival, and to decrease the relapse rate and secondary MDS that occurs after ATG/CSA, the NIH added mycophenolate (1 gram twice daily for 18 months) to the standard ATG/CSA regimen. This three-drug regimen resulted in a 62% response rate, but 37% of the responders relapsed (most while taking mycophenolate) and 9% progressed to either MDS or leukemia; thus, the addition of mycophenolate did not improve response or survival.[113] Sirolimus and Tacrolimus have also been used as alternatives to cyclosporine but no clear advantage in terms of response, relaspse, or secondary clonal disease has been demonstrated. Alemtuzumab is another active immunosuppressive therapy for SAA but response rates in untreated patients are less than 30%.

High-dose Cyclophosphamide

High-dose cyclophosphamide remains (often in conjunction with ATG) the most commonly used BMT conditioning regimen for aplastic anemia.[93,114] Interestingly, complete reconstitution of autologous hematopoiesis occurs in 10% to 15% of patients undergoing allogeneic BMT for aplastic anemia.[115–117] Most of these patients have maintained long-term remissions despite autologous reconstitution. The EMBT reported that 10% of SAA patients experience autologous reconstitution following BMT using a cyclophosphamide + ATG conditioning regimen. Interestingly, 10-year survival (84%) in patients with autologous recovery was equivalent or better than in patients who engrafted (74%).[118]

Cyclophosphamide is a prodrug and is converted to 4-hydroxycyclophosphamide and its tautomer, aldophosphamide, by the hepatic cytochrome P-450 system.[119] These compounds diffuse into cells and are converted into the active alkylating compound, phosphoramide mustard, through simple intracellular decomposition. The major mechanism of cyclophosphamide detoxification appears to be inactivation of aldophosphamide by cellular aldehyde dehydrogenase to form the inert compound, carboxyphosphamide. ALDH1A1, previously called class I ALDH or cytosolic ALDH, ALDH1, or retinaldehyde dehydrogenase 1, appears to be the aldehyde dehydrogenase most responsible for cyclophosphamide detoxification.[120] ALDH1A1 also plays an important role in ethanol metabolism, but its major function appears to be the biosynthesis of retinoic acid from vitamin A (retinol).[120] After alcohol dehydrogenase oxidizes retinol to retinaldehyde, ALDH1A1 oxidizes retinaldehyde to retinoic acid. Retinoic acid is essential for cellular growth and differentiation. Cells with high proliferative potential, such as hematopoietic stem cells, express high levels of ALDH1A1 because of their requirement for retinoic acid and are thus resistant to cyclophosphamide.[121,122] Conversely, lymphocytes have low levels of aldehyde dehydrogenase and are rapidly killed by high doses of cyclophosphamide. High-dose cyclophosphamide is therefore highly immunosuppressive, but not myeloablative, allowing endogenous hematopoietic stem cells to reconstitute hematopoiesis.

High-dose cyclophosphamide without BMT has been used to treat aplastic anemia patients who lack a suitable donor.[63,123,124,125,126,127,128] In a pilot study, 7 of 10 patients achieved durable complete remissions. No relapse or clonal evolution was observed with a median follow-up of 10.8 (range, 7.3 to 17.8) years. Investigators at the National Institutes of Health initiated a randomized trial of high-dose cyclophosphamide plus CSA versus ATG/CSA.[126] This trial closed after enrolling 31 patients (17% of the planned accrual) because early toxicity appeared to be higher in the cyclophosphamide plus CSA arm. However, no stopping rules were met, and there were no statistical differences in response rate, survival, or secondary clonal disorders.

Subsequently, a large mature study has confirmed the efficacy of high-dose cyclophosphamide for treating SAA.[128] Investigators from Johns Hopkins treated 67 SAA patients with high-dose cyclophosphamide; 44 patients were treatment naïve and 23 were refractory to one or more previous immunosuppressive regimens. At 10 years, the overall actuarial survival, response rate, and event-free survival was 88%, 71%, and 58%, respectively, for the 44 treatment-naïve patients. Patients with refractory SAA fared less well: at 10 years, overall actuarial survival, response, and event-free survival rates were 62%, 48%, and 27%, respectively. For treatment-naïve patients, the median time to a neutrophil count of 0.5×10^9/L was 60 (range, 28 to 104) days, the median time to last platelet and red cell transfusion was 117 and 186 days, respectively. Relapse occurred in just 2 of the treatment-naïve patients, one of whom was retreated with high-dose cyclophosphamide into a second complete remission. Despite the high response rate and low risk of relapse and secondary clonal disease, many investigators are unwilling to accept the relatively long period of aplasia associated with this therapy. Additional large series and/or future randomized trials will be necessary to fully define the role of this promising therapy.

Relapsed and Refractory Severe Aplastic Anemia

There is no standard algorithm for managing patients with SAA who fail to respond, or relapse, after treatment with ATG/CSA; however, inasmuch as 30% to 40% of patients do not respond to initial therapy and another 20% to 40% of responding patients relapse, these patients pose a common treatment dilemma. Therapeutic options include allogeneic bone marrow transplant (usually from an unrelated or mismatched donor), re-treatment with ATG/CSA, alemtuzumab, or high-dose cyclophosphamide. Alternative donor allogeneic BMT probably offers the best chance for cure in children and young adults, but is associated with substantial morbidity and mortality in older patients. Patients with relapsed aplastic anemia are more likely to respond to a second course of ATG/CSA or to high-dose cyclophosphamide than patients with primary refractory disease. Response rates to a second course of horse or rabbit ATG/CSA ranges from 20% to 70% with the weighted average closer to 30%.[129,130,131,132,133] High-dose cyclophosphamide or alemtuzumab may also salvage up to 30% of patients with refractory SAA.[134–136] All of these potential options should be discussed with patients; however, patient age, performance status, timing and availability of a bone marrow donor, insurance coverage, and institutional expertise are factors in the decision process.

Treatment of Hepatitis-associated Severe Aplastic Anemia

There are no large prospective series to determine the best treatment for HAA, in part due to the rarity of the disease. Most reports consist of registry data, case series, or single case reports. Because HAA predominantly occurs in children, allogeneic BMT from an HLA-identical sibling is usually considered as first-line therapy. In patients without an HLA-identical sibling, ATG/CSA and high-dose cyclophosphamide have produced durable remissions.[41,137] The EBMT performed a retrospective cohort study from 257 centers to assess the epidemiology and treatment out of HAA.[138] They identified 214 patients managed between 1990 and 2007. The incidence of HAA was 5% and the response rate and outcome did not appear to differ from idiopathic SAA. Similar results were reported by the Japan Childhood Aplastic Anemia Study Group who analyzed the outcome of 44 children with HAA. They reported a 70% response rate with immunosuppressive therapy and an 88% overall survival at 10 years.[139]

Other Therapies

Numerous reports suggest that anabolic steroids are effective in treating aplastic anemia;[140,141,142] however, for SAA, controlled

clinical trials have shown no benefit in terms of hematopoietic improvement[143] or survival.[87] Although it is clear that androgens should not be used as first-line therapy in SAA, a 3- to 6-month trial is not unreasonable in patients with refractory disease. Danazol, oxymetholone, and decanoate are often tried in such cases. Careful monitoring of liver function tests and vigilance for other hepatic complications (adenomas, tumors, etc.) are required. Eculizumab is a humanized monoclonal antibody that blocks terminal complement activity and prevents intravascular hemolysis in PNH.[74] The drug is FDA approved for the treatment of PNH but it does not improve bone marrow function; thus it should not be used to treat aplastic anemia.

CHAPTER 39

RED CELL APLASIA: ACQUIRED AND CONGENITAL DISORDERS

Jeffrey M. Lipton, Bertil Glader, Robert T. Means Jr.

ACQUIRED RED CELL APLASIA

Pure red cell aplasia (PRCA) is an acquired syndrome characterized by normochromic normocytic anemia, severe reticulocytopenia (reticulocyte count <1%), and an almost complete absence of erythroblasts from the bone marrow (erythroblasts <0.5%).[1,2] In contrast to aplastic anemia, in which the aplasia involves all three cell lines, in PRCA the aplasia is selective for the erythroid cell line so that patients have normal leukocyte and platelet counts.[3] PRCA is a rare disorder that affects any age group and both males and females equally.

This disorder was first described by Kaznelson in 1922[4] and has appeared in the literature under a variety of different names, including pure aplastic anemia, erythrophthisis, chronic hypoplastic anemia, aplastic crisis, erythroblastopenia, erythrogenesis imperfecta, Blackfan-Diamond syndrome, pure red cell agenesis, and primary red cell anemia.[1] Today the term PRCA is used primarily to describe this disorder in adults, although some of the causes of RBC aplasia in adults also are seen in children. Diamond-Blackfan anemia (DBA) refers to a pathophysiologically different congenital syndrome of children. Transient erythroblastopenia of childhood (TEC) describes a typically self-limited PRCA variant that occurs most commonly in infants and children and is discussed below. It must be noted, however, that DBA can present in adulthood and should be considered in the differential diagnosis of PRCA at any age.

PRCA may be primary or may be secondary to a variety of neoplastic, autoimmune, or infectious diseases (Table 39.1). Primary acquired PRCA affects individuals of any age in the absence of any underlying disorder. It may run an acute and usually self-limited course or may persist chronically as a form of refractory anemia. In adults the acute form of primary PRCA is very rare and the chronic form of this disorder predominates. Acute PRCA in adults escapes diagnosis because acute arrest of erythropoiesis of short duration does not lead to symptoms of anemia, as a result of the long lifespan of the red cells.

Etiology and Pathogenesis

PRCA may occur as a primary disorder or may develop as a hematologic complication in the course of a variety of diseases (Table 39.1). In the section that follows, differing etiologies of PRCA and their associated pathogenetic mechanisms are described. Secondary etiologies are arranged in approximate order of clinical significance or frequency.

Primary Acquired (Autoimmune) Pure Red Cell Aplasia

In primary acquired PRCA and TEC, multiple studies have indicated that the arrest of erythropoiesis is caused by the presence in the patient's plasma of an erythropoietic inhibitor. Early studies in mice have shown that injection of patients' plasma leads to a significant suppression of in vivo erythropoiesis as measured by ^{59}Fe incorporation into newly formed red cells.[101,102] Evaluation of the response of patients' marrow cells to erythropoietin by measuring heme synthesis in vitro showed that, in the presence of normal plasma, PRCA marrow responds normally to erythropoietin, but in the presence of a patient's autologous plasma, a significant decline in heme synthesis is observed, suggesting the presence in the patient's plasma of an inhibitor acting on erythroid cells.[103,104] In about 60% of cases, patients' marrow cells respond to erythropoietin in a normal way by increasing the rate of heme synthesis by 2- to 9-fold and in about 40% an inhibitor of erythropoiesis can be detected in their plasma. This inhibitor has been localized to the IgG fraction, and it disappears from the plasma after remission of PRCA.[103–105]

The stage of erythropoiesis at which the arrest occurs has been studied by assaying PRCA marrow cells in semisolid media for erythroid progenitors. Despite a conspicuous absence of erythroblasts from the PRCA marrow, in at least 60% of patients, normal numbers of early burst-forming unit erythroid (BFU-E) and late colony-forming unit erythroid (CFU-E) erythroid progenitors can be detected, indicating that the arrest occurs at any level between CFU-E and basophilic erythroblasts. In the remainder of patients the erythroid cell compartment is affected at a stage earlier than the CFU-E, so that the CFU-E and/or BFU-E marrow pools are significantly reduced.[1,106–108] The presence of normal numbers of erythroid progenitors has been associated with a favorable outcome of immunosuppressive therapy.[106,108] The patient's serum IgG inhibits maturation and differentiation of erythroid progenitors into erythroblasts in vitro. The inhibition is dose-dependent and is no longer present in the IgG fraction of the patient's plasma collected after remission.[105] The inhibitory effect of the IgG is specific for erythroid cells, because no effect on myeloid progenitor cell growth is detected.[107–109]

The target antigen and mode of action of the IgG inhibitor of erythropoiesis has been investigated in a number of cases of primary autoimmune PRCA, but appears to be variable. As discussed above, it may target erythroid CFU-E and/or BFU-E progenitors or it may be directed against morphologically recognizable erythroblasts.[110,111] The molecule(s) on the erythroid cell membrane with which the PRCA IgG inhibitor interacts has not yet been defined. In rare cases, endogenous erythropoietin itself appears to be the target antigen.[112,113] In some cases of autoimmune hemolytic anemia, concurrent with PRCA, the antibody causing hemolysis can also suppress erythroid progenitor colony formation,[75] while in other cases the two processes result from two different antibodies.[76,77]

In addition to antibody-mediated PRCA, cases of PRCA have been reported in which the immunologic mechanism is T cell mediated. These cases appear to be particularly associated with thymomas.[114–121] There are also cases of PRCA in which no immune pathogenic mechanism or other known mechanism can be established by in vitro assays. These cases are classified as idiopathic PRCA. However, failure to demonstrate an immune mechanism does not necessarily exclude an immune pathogenesis, since the outcome of treatment seems to be the same among autoimmune and idiopathic cases.[1]

Transient Erythroblastopenia of Childhood

This is a common cause of acquired red cell aplasia in young children[122,123] due to a transient antibody-mediated suppression of normal erythropoiesis.[124,125] The disorder is characterized by the gradual (over weeks) development of anemia (hemoglobin level of 2 to 8 g/dl), reticulocytopenia, and a pronounced reduction of bone marrow erythroblasts. The platelet count is normal to increased. The leukocyte count is usually normal, although 20% of children

TABLE 39.1

CLASSIFICATION OF PURE RED CELL APLASIA

Congenital

Inherited
- Diamond-Blackfan anemia

Not inherited
- Pearson syndrome

Acquired PRCA

Primary
- Autoimmune (includes TEC)
- Preleukemic
- Idiopathic

Secondary, associated with
- Thymoma[1,5,6,7]
- Hematologic malignancies
  - Chronic lymphocytic leukemia
    - B cell type[1,8,9,10]
    - T cell type[1,11]
  - Hodgkin disease[12]
  - Non-Hodgkin lymphomas[13,14,15]
  - Angioimmunoblastic lymphadenopathy[16,17–20]
  - Multiple myeloma[21,22]
  - Waldenström macroglobulinemia[23]
  - Chronic myelogenous leukemia[24,25]
  - Chronic myelomonocytic leukemia[9]
  - Myelofibrosis with myeloid metaplasia[1,26,27]
  - Essential thrombocythemia[28,29]
  - Acute lymphoblastic leukemia[30–32]
  - Chronic eosinophilic leukemia[33]
- Solid tumors[1]
  - Gastric cancer[34]
  - Breast cancer[35]
  - Biliary cancer[36]
  - Primary lung cancer[37]
  - Primary skin cancer[38,39]
  - Thyroid cancer[40]
  - Thymus cancer[41]
  - Renal cell carcinoma[42]
  - Carcinoma of unknown primary site[1]
  - Kaposi sarcoma[43,44]
- Infections
  - Human B19 parvovirus[45–46,47,48,49,50]
  - Human immunodeficiency virus[51]
  - T cell leukemia-lymphoma virus[52]
  - Infectious mononucleosis[53,54]
  - Viral hepatitis[55–59]
  - Mumps[1]
  - Cytomegalovirus[60]
  - Bacterial infections[1,61–63]
  - Leishmaniasis[64]
- Chronic hemolytic anemias[65,66]
- Collagen vascular/Autoimmune diseases
  - Systemic lupus erythematosus[67,68,69–71]
  - Rheumatoid arthritis[72]
  - Mixed connective tissue disease[73]
  - Autoimmune multiple endocrine gland insufficiency[74]
  - Autoimmune hemolytic anemia[75,76,77]
  - Autoimmune hepatitis[78,79]
  - Primary sclerosing cholangitis[80]
  - Inflammatory bowel disease[78]
- Pregnancy[81–83,84,85,86]
- Severe renal failure[87]
- Severe nutritional deficiencies[61,88]
  - Vitamin B12 deficiency[89]
  - Riboflavin deficiency[88,90]
  - Folate deficiency[91]
- Miscellaneous
  - Post-ABO-incompatible stem cell transplantation[92,93,94,95,96]
  - Castleman's disease[97,98]
  - Anti-Epo antibodies after treatment with Epo[99,100]

Epo, erythropoietin; PRCA, pure red cell aplasia; TEC, transient erythroblastopenia of childhood.

may have significant neutropenia (less than 1,000 neutrophils per dl). The disorder uniquely occurs in previously healthy young children from 6 months to 4 years of age and is seen with equal frequency in boys and girls. Occasionally cases of the disorder occur in clusters, suggesting it may be a consequence of some seasonal environmental toxin or virus. To date, however, serologic studies have failed to reveal exposure to a common virus. The natural history of TEC is that all patients recover spontaneously in a few weeks and there are no long-term hematologic sequelae. In many children with the disorder, particularly if there is evidence of recovery at the time of diagnosis, no specific therapy other than careful observation is necessary. Erythrocyte transfusions are indicated only if a child is symptomatic from the anemia, and rarely is more than one transfusion needed. Neither iron nor steroid therapy have any role in the management of this disorder. The diagnosis often is confused with that of iron deficiency anemia, although the erythrocytes in patients with TEC are normocytic (mean corpuscular volume [MCV] 70 to 85 fl, which is normal for children), whereas iron deficiency anemia is characterized by microcytosis (MCV, 50 to 70 fl). TEC also may be confused with DBA, although the latter generally presents before 6 months of age, often is associated with congenital abnormalities, and usually is characterized by macrocytic erythrocytes with many fetal-like features. (See section "Diamond-Blackfan Anemia.")

Myelodysplastic Primary Pure Red Cell Aplasia

A small percentage of cases of idiopathic PRCA, usually refractory to treatment, may evolve into acute leukemia, and these cases are classified as preleukemic or myelodysplastic.[1,126] In a sense, such cases should be regarded not as part of a PRCA syndrome but rather as myelodysplastic morphologically resembling PRCA.

Parvovirus-induced Pure Red Cell Aplasia

It has been known for many years that human B19 parvovirus is responsible for the aplastic crisis seen in patients with chronic hemolytic anemia.[127,128,129–131] It was subsequently demonstrated that B19 parvovirus can produce chronic PRCA in immunocompromised patients, such as those with HIV, posttransplantation, or on immunosuppressive drugs.[45,46,47,132–141]

B19 parvovirus directly infects human erythroid progenitors by a process requiring the red cell surface P antigen (globoside).[142,143] Individuals who do not express P antigen are not susceptible to parvovirus infection.[144] B19 parvovirus induces apoptosis in erythroid progenitors.[145] The precise mechanism by which this occurs in unclear, but appears to involve viral nonstructural protein 1.[146,147] Hypoxia-inducible factor-1 appears to upregulate expression of viral messages in infected cells.[148]

Recombinant Erythropoietin-induced Immune Pure Red Cell Aplasia

As noted earlier, autoimmune PRCA caused by antibodies against endogenous Epo has been described infrequently.[112,113,149] Beginning in the mid- to late 1990s, cases of PRCA associated with antibodies against recombinant human (rh) Epo began to appear. These cases occurred in patients with end-stage renal disease receiving rhEpo for anemia management.[99,150–156]

These cases were unusual in that more than 90% of cases involved a particular rhEpo product, it was primarily associated with subcutaneous treatment, the vast majority of cases occurred outside the United States, and there was wide nation-to-nation variation, even allowing for use of specific rhEpo products.[99,157,158–161,162,163,164,165] Eventually the process was attributed to packaging features of the rhEpo product (such as adjuvant effects of the material used in syringes).[157,166–170] In response to changed packaging, the problem has largely resolved.

It has been suggested that the low level immunogenicity of rhEpo might be enhanced in specific patients by the presence of Epo-specific $CD4^+$ T cells, or by HLA-DRB1*09.[92,171,172,173,174]

Thymoma

The association between thymic neoplasms and PRCA has been known for many years.[5,6,7,40,175–177,178] PRCA may precede the development of thymoma, coexist with thymoma, or develop even years after the surgical removal of a thymoma. The incidence of PRCA among patients with thymoma was earlier estimated to be as high as 15%; however, in more recent reports the incidence was found to be close to 4%.[1,179] Approaching it from the other perspective, the presence of a thymoma among patients presenting with PRCA was initially reported to be as high as 50%, but in more recent series it was estimated to be close to 9%.[1,61,118,175,180] The pathogenetic mechanism involved is uncertain but presumably related to T cell–mediated processes.[118,120,181,182]

Lymphoproliferative Disorders

Various lymphoproliferative syndromes have been associated with severe erythroid aplasia (see Table 39.2), with chronic lymphocytic leukemia (CLL) of B cell, T cell type, or with the large granular lymphocyte (LGL) type, the last being the most frequent.[8,183] The incidence of severe erythroid aplasia among patients with CLL may be as high as 6%, with many cases missed because severe normochromic anemia and reticulocytopenia is a frequent manifestation of advanced-stage CLL and is usually attributed to the primary disease process. The development of erythroid aplasia does not affect the prognosis of CLL and in the majority of cases does not seem to be related to previous cytotoxic chemotherapy.[1,8] PRCA has been also described in association with Hodgkin[12] and non-Hodgkin lymphomas,[13] multiple myeloma,[21] Waldenström's macroglobulinemia,[23] angioimmunoblastic lymphadenopathy,[16] and Castleman's disease.[97]

Most pathophysiologic studies have been performed in CLL-associated PRCA. PRCA appears to derive from immune suppression, but not typically through inhibitory antibodies.[14] Various studies have demonstrated that in T cell CLL (including LGL type), the T lymphocytes are responsible for the suppression of erythropoiesis.[11,184,185] The suppression is mediated by direct cell-to-cell interaction, mainly between a subset of T cells expressing receptors for the γ chain of IgG (Tγ cells) and erythroid progenitors, and it is HLA-DR restricted.[184] The suppression is selective for the erythroid cells and is not detectable after remission of the PRCA.[184,185] Similar findings have been reported in B cell CLL, in which there seems to be a progressive increase in the marrow of Tγ cells, which, when they reach a critical concentration, suppress erythropoiesis and cause red cell aplasia.[116,117,121] In LGL lymphocytosis, clonal expansion of LGLs of the γ/δ type expressing killer-cell inhibitory receptors for Class I HLA antigens has been shown to be responsible for lysis of erythroblasts, most likely related to the declining density, with eventual disappearance of HLA-I antigens in late marrow erythroid cells. However, the role of killer-cell inhibitory receptors in the pathogenesis of PRCA in large granular lymphocytosis remains unclear, since such receptors are also detectable in large granular lymphocytosis patients without PRCA.[186,187] Expansion of the marrow population of $CD8^+$/perforin$^+$ memory T cells has also been noted in thymoma-associated PRCA patients.[188]

TABLE 39.2

DRUGS AND CHEMICALS ASSOCIATED WITH PURE RED CELL APLASIA

Allopurinol	Isoniazid
α-Methyldopa	Lamivudine
Aminopyrine	Leuprolide
Anagyrine	Linezolid
Arsphenamine	Maloprim (dapsone and pyrimethamine)
Azathioprine	Mepacrine
Benzene hexachloride	Methazolamide Micafungin
Bromsulphalein	Mycophenolate mofetil
Calomel Campath-1H	Penicillin
Carbamazepine	D-Penicillamine
Cephalothin	Pentachlorophenol
Chenopodium	Phenobarbital
Cladribine	Phenylbutazone
Chloramphenicol	Procainamide
Chlormadinone	Salicylazosulfapyridine
Chlorpropamide	Santonin
Co-trimoxazole	Sodium dipropylacetate
Diphenylhydantoin Erythropoietin (recombinant)	Sodium valproate
Estrogens	Sulfasalazine
Fenbufen	Sulfathiazole
Fenoprofen	Sulindac
FK506	Tacrolimus
Fludarabine	Thiamphenicol
Gold	Tolbutamide
Halothane	Rifampicin
Interferon-α	Zidovudine

Other Hematologic Malignancies

PRCA has been reported in association with chronic myelogenous leukemia,[24,25] chronic myelomonocytic leukemia,[9] chronic eosinophilic leukemia,[33] primary myelofibrosis,[26,27] essential thrombocythemia,[28] and acute lymphoblastic leukemia.[30,31] Few cases have been studied in detail, but in general the course of PRCA appears to run independently of the associated disease and may reflect a coincident autoimmune disorder.[24]

Nonthymic Solid Tumors

There have been a number of reports of PRCA observed in patients with nonthymic, nonhematologic malignancies (see Table 39.1). Given that these reports are rare and that the primary malignancy and PRCA typically run independent courses,[1] it is likely that the association is coincidental.

Autoimmune Disorders/Collagen Vascular Disease

It should not be surprising that PRCA is a hematologic complication of various autoimmune diseases, including collagen vascular diseases, such as systemic lupus erythematosus,[67,68] rheumatoid arthritis,[72] mixed connective tissue disease,[73] Sjögren syndrome,[6,189] autoimmune hemolytic anemia,[75,76,77] multiple endocrine gland insufficiency,[74] autoimmune hypothyroidism,[190,191] inflammatory bowel disease,[78] autoimmune liver disease,[79,80] pyoderma gangrenosum,[192] and pernicious anemia.[89] PRCA may occur prior to, during, or after the onset of these disorders. When investigated in detail, cases of PRCA associated with autoimmune or collagen vascular diseases are typically found to be mediated by antibodies which inhibit erythropoiesis.[193,194]

ABO-incompatible Stem Cell Transplantation

PRCA may occur as a consequence of ABO-incompatible bone marrow or stem cell transplantation.[93,94,195–197] In one series, this complication occurred in 26% of ABO-incompatible transplants and was most common in circumstances where a blood group O recipient was transplanted from a blood group A donor.[197] Erythroid precursors express surface blood group antibodies, and anti-A or anti-B isoagglutinins from recipient plasma cells are the etiologic agents.[94] There is a 60% to 70% frequency of spontaneous recovery, but the remainder may developed sustained PRCA requiring treatment.[197]

Pure Red Cell Aplasia with Infections Other than Parvovirus

Acute, self-limited PRCA may develop in the course of various infections.[1,51,53,55,60,62,64,199,200] Viral hepatitis and infectious mononucleosis in particular have been reported many times in association with PRCA. In general, PRCA remits with treatment or the resolution of the underlying infection. Studies on the pathogenesis of PRCA in the course of viral hepatitis, infectious mononucleosis, and HTLV-1 infection have suggested that the suppression of erythropoiesis is mediated by cytotoxic T lymphocytes.

Drugs and Chemicals

Many drugs and chemicals have been reported as causes of PRCA[38,92,139,201–222,223,224–226] (Table 39.2). Drug-induced PRCA is usually an acute disorder that remits soon after discontinuation of the drug or cessation of exposure to the chemical. It may appear after the first exposure to the drug or a significant time after its initiation. In most instances, the association of a drug with PRCA is circumstantial and is based on the evidence that PRCA remits after discontinuation of the drug.[1,227] Diphenylhydantoin, azathioprine, chlorpropamide, and isoniazid have been repeatedly implicated as causes of PRCA, and in certain instances their association with PRCA has been proven by recurrence of anemia upon reinstitution of therapy.[1]

Different drugs cause erythroid aplasia through different mechanisms. Studies on direct drug effects on erythroid cell growth in vitro may be confusing because many drugs may have nonspecific effects on hematopoietic colony formation in vitro. IgG inhibitors of erythropoiesis have been shown for diphenylhydantoin and rifampicin.[206,228] Isoniazid and procainamide appear to use a different mechanism.[229,230]

Pregnancy

Pregnancy also has been associated with PRCA that usually but not always, remits after delivery.[81–85,86] Development of PRCA during one pregnancy does not necessarily predict recurrence of the disease in subsequent pregnancies. This syndrome is also discussed in Chapter 42.

Miscellaneous Disorders

In rare cases, PRCA has been associated with renal failure,[87] severe malnutrition producing marasmus and/or kwashiorkor,[61,88] and riboflavin,[88,90] vitamin B_{12},[89,91] and folic acid deficiencies.[91]

Clinical Presentation

There are no clinical features or physical findings characteristic of PRCA other than the signs and symptoms of anemia. Since a complete arrest of erythropoiesis would cause a decline of red cell mass of roughly 1% a day, so the development of anemia in PRCA is gradual, allowing for physiologic compensation which would mitigate symptomatology for any given degree of anemia. In secondary cases, physical findings related to the underlying disease may be present. Patients with chronic PRCA requiring transfusion support may have findings suggesting iron overload.

Laboratory Evaluation

Peripheral Blood Counts

In acquired PRCA the erythrocytes are normochromic and normocytic. There is a complete absence of polychromatophilic red cells on the smear, and the reticulocyte count is between 0% and 1%. A reticulocyte count >1% should raise serious doubt about the correctness of the diagnosis. The white cell count and the differential count are usually normal. Occasionally, mild leukopenia, lymphocytosis, and/or eosinophilia may be present. The platelet count is usually normal. Mild thrombocytopenia of 100,000 to 150,000 platelets/μl is occasionally seen, and some patients may have a mild reactive thrombocytosis. When present, these abnormalities typically reflect a state of immune activation.

Bone Marrow

The hallmark of PRCA is the absence of erythroblasts from an otherwise normal marrow. The cellularity of the marrow is normal or slightly increased. Markedly increased cellularity with elimination of fat spaces should lead away from the diagnosis of PRCA. In typical cases the erythroblasts are either totally absent, or they constitute <1% on the marrow differential count (Fig. 39.1A). In a small number of cases, a few proerythroblasts and/or basophilic erythroblasts may be seen, not exceeding 5% of the differential count.[1,231] The presence of large proerythroblasts ("giant pronormoblasts") with vacuolated cytoplasm and pseudopodia formation may raise the suspicion of an active B19 parvovirus infection but are not diagnostic.[232–234]

In some cases a phase of ineffective erythropoiesis characterized by erythroid hyperplasia with maturation arrest at the stage of proerythroblasts or basophilic erythroblasts in the marrow and reticulocytopenia in the blood may precede the development of PRCA, develop during the course of PRCA, or appear after partial response to treatment and before the return of erythropoiesis to normal.[235,236] While this morphologic picture in the absence of dysplastic changes in other lineages or cytogenetic abnormalities should raise suspicion of PRCA, bone marrow examination would need to be repeated at a later time to confirm the diagnosis.

The myeloid cells and the megakaryocytes in the marrow are normal and exhibit full maturation. An increased number of lymphocytes on marrow smear, or an increased number of lymphoid aggregates in marrow biopsy, or a mild increase in plasma cells, eosinophils, or mast cells may be seen. These findings are presumed to reflect inflammatory/immune activation. Iron stores are increased and normally distributed, but during recovery or the phase of ineffective erythropoiesis, a few ring sideroblasts may be seen.[1]

Cytogenetics

Cytogenetic studies on marrow cells in PRCA are normal. An abnormal karyotype indicates a preleukemic/myelodysplastic disorder with the morphologic appearance of erythroid hypoplasia.[126,237,238] Such patients do not respond well to immunosuppression.[126,239]

Ferrokinetics

Ferrokinetic studies show a prolonged clearance of ^{59}Fe, no accumulation of iron in the sacral bone, and almost undetectable incorporation into red cells, findings consistent with an almost

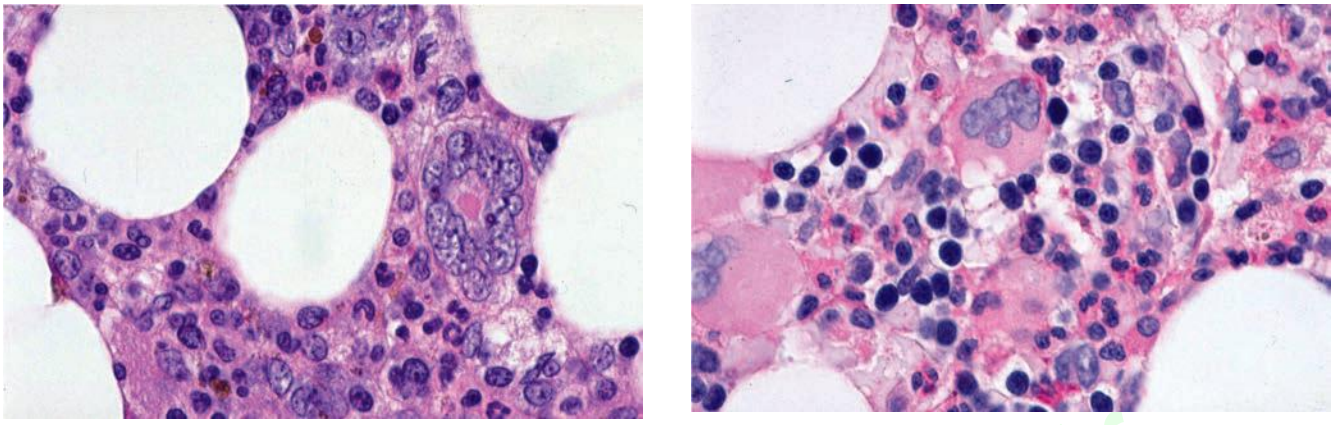

FIGURE 39.1. A: Characteristic bone marrow biopsy from a Pure red cell aplasia (PRCA) patient. B: Bone marrow biopsy from same patient after successful response to immunosuppression. Note easily identifiable erythroblasts.

complete arrest of erythropoiesis. Ferrokinetic parameters return to normal after full hematologic recovery except in adult patients in partial remission, in whom ineffective erythropoiesis may be present.[235] Bone marrow imaging by the use of ^{59}Fe or ^{98}In shows little or no uptake, but returns to normal upon remission. In both children and adults with PRCA, ^{51}Cr red cell survival is mildly shortened to a degree inadequate to explain the severity of the anemia.[235,236,240] Patients who are refractory to treatment and who are supported by regular red cell transfusions may develop a significant hemolytic component after alloimmunization or development of hypersplenism.[1]

Other Laboratory Abnormalities

Vitamin B_{12}, folic acid, ferritin, serum iron, and saturation of transferrin are normal or elevated. Serum erythropoietin levels are increased in proportion to the severity of the anemia.[3] A number of different immunologic abnormalities have been reported in patients with chronic PRCA, including hypogammaglobulinemia, monoclonal gammopathies, pyroproteins, decreased complement, antinuclear antibodies, decreased or increased B cells, and impaired PHA-induced lymphocyte cytotoxicity.[1,3,120,241] More recently, in a number of patients the presence of lymphocytes with γ or δ T cell receptor gene rearrangement has been described.[114,116,119,121,182,242,243] Some of these cases certainly represent PRCA secondary to a T cell lymphoproliferative disorder and not primary PRCA.

Evaluation and Treatment

PRCA, myelodysplastic syndromes (MDSs), and other primary marrow failure disorders are suspected in similar clinical circumstances, and the initial diagnostic approach is bone marrow examination. Specimens should be sent for cytogenetics and flow cytometry as well as routine pathology. In PRCA, a normocellular marrow in which there is almost a complete absence of erythroblasts but with normal myeloid cells and megakaryocytes is expected. A hypocellular marrow with trilineage hypoplasia suggests aplastic anemia; dyspoietic marrow morphology, or ringed sideroblasts, suggests an MDS.

In all patients with PRCA, polymerase chain reaction (PCR) testing for parvovirus DNA should be performed.[244,245] Parvovirus serology may be of value in immunocompetent patients, but is misleading in the immunocompromised.[245] For that reason, PCR on peripheral blood is the test of choice. If parvovirus testing is negative, computerized tomography should be performed on all adult patients to rule out thymoma. Flow cytometry studies performed on the diagnostic bone marrow will identify a lymphoproliferative disorder as the possible etiology of PRCA. Abnormal cytogenetics would indicate an MDS. Patients with renal failure who develop PRCA while being treated with rhEpo should be evaluated for anti-Epo antibodies. Testing for underlying autoimmune disorders can be performed if otherwise clinically indicated, but typically would not alter therapy.

Immunosuppressive/Immunomodulatory Therapy

Drugs should be reviewed as possible contributors to PRCA, and any active infection should be treated. Underlying malignancies should be treated. MDSs appearing as PRCA should be managed as MDSs (Chapter 79). Otherwise, in the absence of documented parvovirus infection or thymoma, the initial approach to PRCA is immunosuppression or immunomodulation (Table 39.3). Figures 39.1A and 39.1B display bone marrow biopsy results from a patient before and after immunosuppression. Approximately two-thirds of PRCA patients will respond to an immunosuppression approach.[1,108,239,246–248]

Corticosteroids

Corticosteroids are the traditional first line drugs. Prednisone is given orally at a dose of 1 mg/kg/day until a remission is induced. As indicated in Table 39.3, approximately 40% of patients will have a remission on steroids. Corticosteroid-induced remission usually occurs within 4 weeks and continuation of a trial with prednisone longer than 12 weeks is not recommended.[246] The effect of treatment can be assessed by weekly reticulocyte counts and measurements of hemoglobin concentration. A rising reticulocyte count and/or stabilization of the hematocrit are the first laboratory findings indicating response to treatment. Once the hematocrit reaches a level of 35%, the dose of prednisone can be tapered very slowly and the drug can be eventually discontinued, preferably after 3 to 4 months. Rapid tapering of prednisone may lead to recurrence of anemia. A number of responders may be prednisone-dependent, requiring small doses of the drug to maintain a normal hematocrit.[246,249,250] The dependence of the response on low-dose prednisone can be assessed during the period of slow tapering, and the minimum dose required can be easily determined.

For patients who do not respond to prednisone within 2 to 3 months, the dose should be rapidly tapered to approximately 20 to 30 mg daily, and the use of a second agent considered.

Cyclosporine

Cyclosporine appears to be the single most effective immunosuppressive used for PRCA (Table 39.3), and it has been

TABLE 39.3

RESPONSE OF PURE RED CELL APLASIA (PRCA) TO VARIOUS IMMUNOSUPPRESSIVE THERAPIES

Study	Dessypris[1]	Lacy et al.[239]	Charles et al.[108]	Sawada et al.[247]	Total
Number of patients	49	47	37	62	195
Primary PRCA	32	25	18	62	137
Secondary PRCA	17	22	19	0	58
Corticosteroids	18/41[a]	9/29	9/36	14/22	50/128 (39%)
Cytotoxic agents[b]	24/54	14/29	8/27	0/3	46/113 (41%)
Antithymocyte γ-globulin	2/6	0/1	8/12	—	10/19 (53%)
Cyclosporine	3/4	4/5	2/3	28/36	37/48 (77%)

Multiple treatments	35/49	28/47	28/37	—	91/133 (68%)

Note: Many patients did not respond to treatment or suffered relapses, so one patient may be included in more than one treatment modality.
[a]Number of responders/number of patients treated.
[b]Including cyclophosphamide, azathioprine, or methotrexate, each given either alone or in combination with prednisone.

suggested that it should be considered the immunosuppressive drug of choice for this disorder.[247] Figure 39.2 shows the response of a patient refractory to several other agents prior to cyclosporine therapy.[105] Cyclosporine is substantially more expensive than prednisone, and requires monitoring of drug levels and of renal function.

Cyclosporine may be used as a single agent or concurrently with low-dose prednisone (usually 30 mg prednisone/day or less). The usual starting dose of cyclosporine is 6 mg/kg/day, although initial doses as much as 12 mg/kg/day have been used.[105,248,251,252] Target trough levels are 150 to 2,500 ng/ml.[248] When the hematocrit approaches target levels (usually 35% to 36%), a slow taper is begun. Some patients may require maintenance therapy. If a patient has not responded in 3 to 4 months, cyclosporine should be tapered off and another agent started.

Although cyclosporine is not leukemogenic as are some of the cytotoxic drugs used for PRCA, there are reports of lymphoma development in PRCA patients treated with cyclosporine.[105] Whether these cases represented treatment-induced lymphomas or were cases of lymphoma-associated PRCA is not clear.

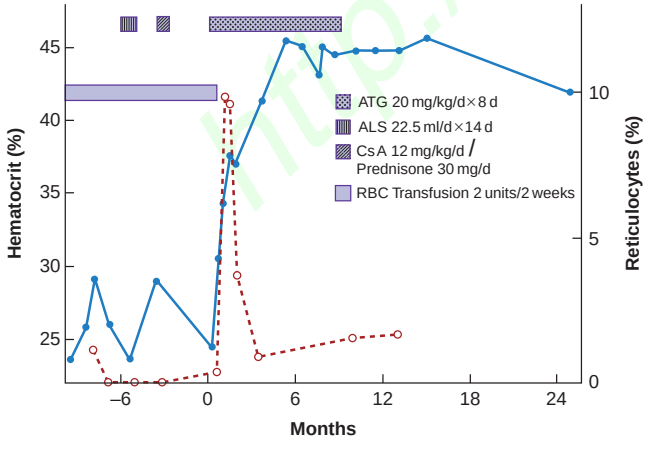

FIGURE 39.2. Time course of response of patient 9 to Cyclosporine A (CsA). Hematocrit (*closed circles*) and uncorrected reticulocyte count (*open circles*) are shown. Treatments administered in the 8 months prior to CsA (equine antithymocyte globulin [ATG] and rabbit antilymphocyte serum [ALS]), and the duration of CsA therapy, are indicated on the figure. Prior to beginning CsA (time 0), the patient had required biweekly transfusion to maintain his hematocrit at the levels indicated. No transfusions have been required subsequently. Reproduced with permission from Means et al. Br J Haematol 1991;78:114–119. RBC, Red blood cells.

Cytotoxic Agents

In patients not responding to prednisone, cyclosporine, or both, cyclophosphamide or azathioprine can be given alone, or with small doses of prednisone, which seems to increase the effectiveness of treatment. The overall response rate to cytotoxic agent–based therapy is approximately 40% (Table 39.3). The initial dose of either agent is 50 mg po daily. If the white blood and platelet counts allow it, it is increased by 50 mg weekly or biweekly to a maximum of 150 mg daily until remission occurs or bone marrow suppression develops. The mean time to response is about 11 to 12 weeks, with a broad range of 2 to 26 weeks.[1,108,239,246] If response occurs, prednisone is tapered and then the dose of cytotoxic agent is progressively decreased and eventually discontinued. If bone marrow toxicity develops, the drug is discontinued and the marrow is allowed to recover. If, after 3 months of treatment, no response and no marrow toxicity is seen, the dose can be increased progressively (by 50 mg biweekly) to a maximum tolerable or 250 mg daily under close monitoring of the blood counts. If reticulocytosis or stabilization of the hematocrit is noticed, the dose is gradually reduced. If the absolute neutrophil count decreases to $<1{,}000/\mu l$ or the platelet count drops to $<100{,}000/\mu l$, the cytotoxic drug is discontinued. In a number of patients, with the return of granulocytes and platelets to normal, a reticulocytosis is seen, followed by a return of erythropoiesis to normal. If no response occurs, another type of immunosuppressive treatment should be initiated.

Other Immunosuppressive/Immunomodulatory Modalities

Rituximab, a humanized monoclonal antibody against CD20, has been reported to be effective in PRCA whether primary/autoimmune or associated with lymphoproliferative disorders.[10,15,68,137,163,253,254,255,256] It has also been used effectively in PRCA following ABO-incompatible stem cell transplantation.[15,95,96,257,258,259–260] In isolated case reports, successful treatment of PRCA by Campath-1H[261] or alemtuzamab[262–264] have been reported.

High-dose intravenous γ-globulin is primarily used for the treatment of parvovirus-induced PRCA (below). It has also been shown to be effective in patients with immune-mediated PRCA, whether primary or secondary.[265,266,267,268] Donor lymphocyte infusion has been reported to be effective in PRCA following ABO-incompatible stem cell transplantation.[95,269,270]

There are a number of immunomodulatory modalities used primarily in PRCA patients who are refractory to other approaches. Plasmapheresis may be considered in patients who have failed other immunosuppressive approaches. Since the IgG inhibitor of erythropoiesis removed by plasmapheresis is distributed in both intravascular and extravascular spaces, an aggressive approach to plasmapheresis is required, often in concert with immunosuppression.[271,272,273,274] Antithymocyte globulin (ATG), formerly the routine therapy after corticosteroids and cytotoxic agents, is used uncommonly in refractory patients. The overall response rate to ATG is approximately 50% (Table 39.3). ATG is given on the same treatment schedule as is used for aplastic anemia (Chapter 38).[108,239,246,275]

Splenectomy has also been used as a final therapeutic maneuver in patients who are refractory to all other forms of treatment. Responses to splenectomy have been reported in ~17% of such recalcitrant-to-treatment cases within the first 2 to 3 postoperative months.[1,240,276–279] After splenectomy, patients may become responsive to agents against which they were previously resistant.

There are a small number of case reports of PRCA treated by bone marrow or stem cell transplantation.[280,281]

Parvovirus-associated Pure Red Cell Aplasia

As was discussed earlier, in immunocompetent individuals B19 parvovirus infection produces transient and self-limited erythroid suppression that is generally unnoticed except in patients with chronic hemolytic disorders. In immunocompromised patients, parvovirus infection can lead to chronic PRCA. Patient with PRCA and documented parvovirus infection (best demonstrated by PCR on peripheral blood) should be treated with high-dose intravenous γglobulin, which confers passive immunity.[45,245,268,282,283] If the immunocompromised state persists, periodic retreatment may be necessary. In HIV patients, relapses of parvovirus-induced PRCA are rare in patients with CD4 lymphocyte count greater than 300/μl.[283]

Thymoma-associated Pure Red Cell Aplasia

In the presence of a thymoma, thymectomy should be performed before the initiation of any immunosuppressive treatment. In 30% to 40% of patients with thymoma, erythropoiesis returns to normal within 4 to 8 weeks after thymectomy.[5,175,284–286,287,288] In patients who either do not respond to thymectomy or recur after thymectomy, immunosuppressive therapy is frequently effective. Thymectomy in the absence of thymoma is not recommended.[1] Responses to octreotide and tacrolimus have been reported in thymoma-associated PRCA.[289,290]

Anti-Epo Antibody-associated Pure Red Cell Aplasia

As noted earlier, many cases of anti-Epo antibody-mediated PRCA induced by rhEpo therapy in renal failure patients have been reported. Such patients should be managed with immunosuppression, like other immune-mediated PRCA patients.[92,156,158,161,267,274,291–296] The overall response rate to immunosuppression has been reported to be 78%, with cyclosporine being the most effective agents, and steroids the least effective.[156,294] Patients who undergo renal transplantation appear to have remission of PRCA.[155,156] In one series, no patient who did not receive immunosuppression (with or without renal transplantation) developed a remission,[156] while there are case reports of eventual recovery with no therapy apart from cessation of rhEpo therapy and transfusion support.[150,297]

The issue of whether or not a patient who has experienced anti-Epo antibody–induced PRCA can ever be retreated with rhEpo or a different rhEpo product remains an open one. The reported antibodies appear to cross react with all available rhEpo agents.[99] While there are several case reports of successful rechallenge with epoetin or darbepoetin, and even of recovery while continuing rhEpo therapy,[92,298–302] the practice is not recommended.[303,304]

Continuous Epo receptor agonist (CERA) is a peptide which is not immunologically similar to rhEpo but activates the Epo receptor. CERA has been proposed as a treatment for rhEpo-induced PRCA.[305] In a study of 14 patients, 13 became transfusion-independent, and anti-Epo antibodies became undetectable in 6. However, half the patients studied developed grade 3 or 4 toxicity.[305]

Refractory Pure Red Cell Aplasia

For patients who respond and relapse, retreatment is often effective. Despite the variety of therapeutic modalities available, there will be some PRCA patients who do not respond to therapy. These individuals will require transfusion support, with chelation management to minimize complications of iron overload.

The survival of patients with primary PRCA is estimated to be 14 years.[246] A poorer prognosis is associated with myelodysplastic PRCA variants. The 3% to 5% of PRCA patients who develop acute myeloid leukemia (AML) typically fall into this latter category.[126,246,306] Development of subsequent aplastic anemia in PRCA patients has been reported but is rare.[307]

DIAMOND-BLACKFAN ANEMIA

DBA (Online Mendelian Inheritance in Man, OMIM, #105,650), first recognized as a discrete clinical entity in 1938,[308] is one of a rare group of genetic disorders known as the inherited bone marrow failure syndromes (IBMFS).[309] These disorders share a predilection to bone marrow failure, birth defects, and cancer and are characterized by proapoptotic and/or prosenescent hematopoiesis. Furthermore, almost in defiance of their rarity, the IBMFS have provided extraordinary insights into DNA repair, telomerase function, the misfolded protein response, signal transduction and, in the case of Shwachman-Diamond syndrome and DBA, ribosome biogenesis and function (see Chapter 37).

With the discovery of a number of "DBA genes" and the availability of highly annotated patient databases, the diagnostic criteria for DBA have evolved considerably. The classical diagnostic criteria, established 75 years ago[308] and refined decades later,[310] are (a) normochromic, usually macrocytic, and occasionally normocytic anemia developing in early childhood; (b) reticulocytopenia; (c) normocellular bone marrow with selective deficiency of erythroid precursors; (d) normal or only slightly decreased granulocyte count; and (e) normal or slightly increased platelet count. However, with the identification of the first gene known to be mutated in DBA it has become evident that there exist many not as strictly defined cases. Ongoing gene discovery will no doubt classify patients that today are only considered to have probable or even possible DBA.[311] DBA is frequently associated with a variety of somatic malformations and rarely with developmental delay, usually in the setting of a large genetic deletion. Approximately 80% of patients respond to corticosteroids with an improvement in, or complete remission of, their anemia.[311,312] However, prolonged corticosteroid treatment has been problematic for many patients.[312]

Since the first description of this syndrome 75 years ago, a number of theories have been put forth regarding its etiology. The myriad discarded explanations have included humoral[313] or cellular[314,315] suppression of erythropoiesis, a microenvironmental defect,[316] and accessory cell failure.[317] In the late 1970s the concept of erythroid failure as a consequence of a block in the erythroid maturation pathway was introduced,[2,318] and it rapidly became evident that the erythroid failure in DBA results from an intrinsic erythroid progenitor/precursor–cell defect[2,318–320] rather than an extrinsic immune or microenvironmental abnormality. Convincing data show that there is a defective pathway from the multipotent bone marrow progenitor to the mature CFU-E, and most prominently through terminal differentiation to the proerythroblast and beyond,[319,320] in which an intrinsic defect in erythroid progenitors and precursors render them highly sensitive to death by apoptosis.[321,322] It is now clear that in at least 60% to 70% of cases, proapoptotic or prosenescent erythropoiesis and many of the other manifestations of DBA are consequences of faulty ribosome assembly or function.[323] Exactly how ribosome dysfunction leads to tissue specific red cell failure, poor growth, birth defects and cancer remains a topic of intense inquiry. However, only approximately 70% of patients with DBA can be explained by either sequence changes or deletions in either small or large subunit-associated ribosomal protein (RP) genes.[324] David Nathan suggested decades ago that DBA should result from faulty transcription regulation of erythropoiesis. Virtually unpredictably, however, DBA is in the majority of instances a ribosomopathy. However, the recent discovery of a mutation in the erythroid transcription regulator GATA1 in a family with clinical DBA[325] suggests that DBA is not only a ribosomopathy but also, as predicted by Nathan, a "transcriptionopathy."

Etiology and Pathogenesis

Normal erythropoiesis is dependent upon interactions between erythroid progenitors and accessory cells, the bone marrow stroma, and their locally acting cytokines.[326] Thus, the erythroid failure in DBA could have arisen from an absence of, or failure in,[327] any one of these elements to act or to respond appropriately. Some early investigators described a marrow microenvironmental defect[316] or implicated accessory cell dysfunction.[317] Others seemingly found evidence that the red cell failure in DBA was due to the presence of cytotoxic or autoreactive T cells,[314,315] or humoral inhibitors of erythropoiesis.[313] These findings were never substantiated,[2,318,319,327,328,329] and it is now accepted that DBA results from an intrinsic progenitor defect.[2,318–322,329,330,331] Freedman et al.[2] first suggested that some patients had decreased numbers of CFU-E; whereas studies by Nathan et al.,[318] using chronically affected either multiply-transfused or steroid-dependent patients, suggested a block in maturation between the earliest committed multipotent myeloid progenitor and the immature BFU-E. In addition, these investigators found that the progenitors expressed in culture were relatively insensitive to erythropoietin,[330,331] reiterated the concept of progenitor hyporesponsiveness to erythropoietin, and suggested that this abnormality could be corrected in part by the addition of glucocorticoids in vitro, implying a relationship between clinical response to corticosteroids and in vitro progenitor response. A series of studies by Lipton and colleagues confirmed these observations. In these studies, some patients expressed normal, or nearly normal, numbers of BFU-E–derived colonies but had decreased numbers of CFU-E–derived colonies in the presence of exogenous cytokines and erythropoietin; while other patients demonstrated normal numbers of (albeit small and poorly differentiated) colonies derived from both BFU-E and CFU-E.[319] These data suggested that DBA is a heterogeneous disorder in which erythropoiesis may be blocked at different stages of erythroid differentiation. This observation was later confirmed in studies by McGuckin and colleagues.[332]

Further investigations confirm that DBA is due to an intrinsic disorder of the erythroid progenitor that involves its inability to respond normally to inducer(s) of erythroid proliferation and differentiation,[320] resulting in accelerated apoptosis,[321] and that the effect could be ameliorated by corticosteroids.[322] The mechanism of steroid action in DBA is not clear but it is likely that the steroid response is not related to the DBA-specific defect. Recent studies by Varricchio and colleagues[333] suggest that variations in alternatively spliced species of the glucocorticoid receptor (GR) may explain how GR polymorphisms are an important modifier of disease severity and response to corticosteroids. It needs to be explored whether specific GR polymorphisms are predictive of steroid response in DBA. Clearly, the variable expression of both the hematologic and nonhematologic manifestations of DBA, particularly within multiplex families, strongly suggests robust interactions with modifying genes.

The intrinsic defect in the erythron has not been found to be associated with any abnormalities in erythropoietin or its receptor.[334,335] A mildly decreased leukocyte count and the development of pancytopenia, bone marrow hypoplasia, and reduced clonogenic cell output in lymphocyte assays,[336] as well as hypogammaglobulinemia and T cell abnormalities,[317,337] support this contention in many but not all cases. Furthermore, other studies show that, in addition to erythroid progenitors, a defect in CFU-GM can be found in a subset of patients.[332] These in vitro studies are consistent with the observation that neutropenia and even aplastic anemia occur in some DBA patients. The response of erythroid cell growth and differentiation to a variety of cytokines in addition to erythropoietin, such as SCF and IL-3, has been evaluated, with no abnormalities of the cytokines or their receptors being identified.[338–342] Moreover, somatic malformations, growth failure, and cancer predisposition cannot be easily explained by an abnormality in erythropoietin or cytokine receptors. However, for approximately 30% of patients there is not yet an identified gene. Furthermore, there are sufficient numbers of patients, in addition to those described by Gazda and colleagues as harboring a *GATA*1 mutation,[325] lacking described nonhematologic manifestations of DBA to imply that rare cases may indeed involve erythroid-restricted pathways. Additionally, the discovery by Ebert and colleagues that an acquired *RPS14* mutation can explain the erythroid failure in 5q- MDS[343] suggests that some cases of DBA may be the consequence of acquired somatic, rather than germ line, mutations.[344]

With the identification of the first DBA gene, *RPS19*, a gene that encodes an RP located at chromosome 19q13.2,[345,346] and a second gene coding for RPS24,[347] it became obvious that other RP genes would be implicated in the molecular pathogenesis of DBA. Based upon the original technique used to describe *RPS19* (cloning of a cytogenetic abnormality from an informative patient), linkage analysis, resequencing of the known ribosome-associated protein genes, or most recently, a variety of techniques for the detection of copy number variants in the genome,[324,348] a number of additional RP gene mutations/deletions have been identified, accounting for approximately 70% of all cases of DBA. Currently, the *RP* genes confirmed to be mutated in DBA are *RPL5*, *RPL11, RPL35A*, *RPS7*, *RPS10*, *RPS17*, *RPS19*, *RPS24*, and *RPS26*.[324,345–351] Rarer abnormalities of less certain significance have been identified in isolated patients or families. These likely DBA genes include *RPL3*, *RPL7*, *RPL9*, *RPL14*, *RPL19*, *RPL23A*, *RPL26*, *RPL25*, *RPL36*, *RPS8*, *RPS15*, and *RPS27A*.[351–354] The nature of the mutations studied thus far suggests that there is either complete loss of function or nonexpression of the mutated allele. Thus, current evidence strongly supports that in patients with *RPS19* (the most studied) and other small or large ribosomal subunit-associated protein gene mutations, DBA results from RP protein haploinsufficiency.[355] When the gene is knocked down in cellular models,[356,357] there is resulting failure of erythropoiesis. In the *in vitro* models this defect can also be corrected

when the normal gene is overexpressed, resulting in increased RPS19 protein expression and restoration of erythropoiesis.[358] Furthermore, a number of mouse and fish models have been developed confirming the role of RP haploinsufficiency in erythroid failure.[359–361,362] But despite the discovery of at least 9, and likely more, small and large subunit-associated RP gene mutations, the mechanism of erythroid failure and the other clinical manifestations of DBA are only partially explained. Much work needs to be done in order to connect faulty ribosome function with red cell failure, the congenital anomalies associated with DBA, as well as the clear recognition of DBA as a cancer-predisposition syndrome.[363,364] A number of theories have been proposed to account for the pathophysiology of DBA. Time will allow for the elucidation of the perhaps myriad explanations necessary to explain the pathophysiology of the DBA non-ribosomopathies. With regard to the DBA ribosomopathies, it is likely that at least one explanation provides the fundamental explanation for DBA-associated proapoptotic erythropoiesis, congenital anomalies, and cancer predisposition. While it appears that RP haploinsufficiency leads to aberrant ribosomal RNA (rRNA) processing of uncertain significance, the fundamental lesion appears to be a faulty translational apparatus created by RP haploinsufficiency leading to nucleolar stress signaling. This results from RPL5, RPL11, and 5S rRNA binding to MDM2 (murine double minute) and its human ortholog HDM2, leading to a decrease in its ubiquitin ligase activity essential for p53 degradation, thereby stabilizing p53 and resulting in accelerated apoptosis.[360,361,365] The regulatory pathway utilizing RPL5 and RPL11 to bind to HDM2, reducing its ubiquitin ligase activity, seems central to this stress signaling; so much so that even when small ribosome-associated proteins are deficient, offering no excess of RPL5 and RPL11, as is the case for large subunit-associated haploinsufficiency resulting in degraded large subunits, the *RPL5* and *RPL11* TOP (terminal oligopyrimidine tract) mRNAs are translationally upregulated. The fact that both RPL5 and RPL11 are known as "DBA" genes and that they represent a severe congenital anomaly phenotype[351] tells us that there is much more to be learned about how HDM2 is regulated when their encoding genes are haploinsufficient. Furthermore, the tissue specificity of defects manifested by a germ line mutation in a ribosome-associated protein, as opposed to a relatively more erythroid-restricted transcription regulator such as GATA1, particularly in the erythron, begs for explanation. One explanation suggests that certain proteins that are canonically translated are favored over others and that those proteins may be overrepresented in the erythron.[366] The other supports the notion that the makeup of ribosomes is tissue specific (i.e., not all 80 RPs are required in every tissue), favoring translation in some tissues and not others as a consequence of any particular RP haploinsufficiency.[367] Likely there are multiple explanations related to the complexity of tissue specific translation. Regardless, the knockdown of p53 in DBA animal models ameliorates the erythroid failure,[361,368,369] making the therapeutic targeting of p53 in DBA an intriguing although potentially risky approach. Elucidating all the downstream events leading to accelerated cell death and understanding the interdicting mutations that lead to cancer in DBA are important subjects of inquiry.

Clinical Presentation

DBA usually presents in infancy. Severe anemia is recognized at birth in 25% of patients, with 65% diagnosed by 6 months of age and 90% within the first year of life.[311,312] DBA presenting as hydrops fetalis has been reported.[370] The disease may also present in older children and adults.[311,371] Although rare instances of X-linked inheritance have been reported, the incidence in males equals that in females. The majority of cases are reported in whites, but the disorder has been reported in virtually all ethnic groups.[311]

Josephs in 1936,[372] and Diamond and Blackfan in 1938,[308] were the first to describe red cell failure in infants. The variety of descriptive names for what is now preferably called DBA include "congenital pure red cell hypoplastic anemia," "congenital red cell aregenerative anemia," "erythrogenesis imperfecta," "chronic erythroblastopenia," "primary red cell aplasia," and "Josephs-Diamond-Blackfan anemia."[310,311] The classical diagnostic criteria for DBA reflect the careful clinical analysis performed by Diamond and colleagues[310] and, more recently, by Alter.[309,373] Recently, however, a consensus conference took place during which, as a consequence of robust gene discovery, the diagnostic criteria for DBA were expanded to account for nonclassical presentations.[311] For a still valuable compilation of the clinical syndrome of DBA that is beyond the scope of this chapter, interested readers are referred to Young and Alter's classic monograph.[309]

The Diamond Blackfan Anemia Registry of North America (DBAR), a database of >600 patients, was established in 1991 and has been described in detail.[311,312,374] The DBAR has provided important information regarding the epidemiology and biology of DBA.[312,364,375] The male-to-female ratio of cases is approximately 1:1. The median age at presentation is 8 weeks, with a median age at diagnosis of 12 weeks. More than 90% of the reported cases present clinically by 1 year of age. The mainstays of therapy, as described below, remain red cell transfusions and corticosteroids. Physical anomalies, not including short stature, are found in nearly 50% of patients. Short stature is clearly a constitutional feature of DBA, but may also be due to chronic anemia, iron overload, corticosteroid administration, or a combination of all these. Thus it is difficult to always ascribe growth failure directly to the disorder. The constellation of physical anomalies found in the 47% of affected patients with typical hematologic manifestations includes a high percentage of craniofacial anomalies (50% of patients with anomalies) as well as upper limb and hand, in particular thumb (38%), as well as genitourinary (39%) and cardiac (30%) abnormalities. Table 39.4 enumerates the congenital anomalies collected in a series by Alter.[375] Of interest, there appears to be no genotype-phenotype correlation with regard to steroid responsiveness, remission, or cancer predisposition. However, mutations in RPL5 and RPL11 are disproportionally associated with orofacial and thumb anomalies.[351,376] Figure 39.3 illustrates typical thumb abnormalities in a patient with DBA as the consequence of an *RPL11* gene mutation.

Laboratory Evaluation

With the discovery of genetic mutations there are numerous "patients" recognized with minimal or no hematologic manifestations. With that in mind, classical DBA is characterized by severe anemia, with hemoglobin levels at presentation as low as 2 to 3g/dl. There is a marked reticulocytopenia, frequently as low as zero. There are usually no significant abnormalities in other cell lines. Occasionally, there is mild to moderate neutropenia and infrequently severe neutropenia requiring G-CSF support[311,375,377,378] or thrombocytopenia.[379] However, thrombocytosis in the range of 400,000 to 700,000 is more common.[379] Although originally described as a normochromic, normocytic anemia, macrocytosis was noted at presentation in ~30% of cases reviewed by Alter[378] in patients for whom data were available. The percentage of patients with macrocytosis increases with the age of the patient, as the disease becomes chronic when the normal red cell MCV would decrease during the first year of life. Indeed, the persistence of "fetal-like" red cells, with macrocytosis, "i" antigen, increased fetal hemoglobin (HbF), and red cell glycolytic and hexose-monophosphate (HMP) shunt enzyme activities characteristic of fetal cells are a consistent finding. The HbF is typical of fetal cells,[377,378] with an elevated glycine-to-alanine ratio at position 136 of the γ chain. Of note is that the fetal-like characteristics

are not concordant; cells with high HbF are not necessarily those with the "i" antigen. Although red cells contain significant HbF, as determined by hemoglobin electrophoresis, the distribution is uneven as evaluated by the Kleihauer-Betke method. Alter points out that red cells contain both fetal and adult hemoglobin and that the "re-expression of fetal erythropoiesis is thus incomplete, and not clonal."[378] Although glycolytic and HMP shunt enzymes have a fetal pattern, erythrocyte adenosine deaminase (eADA), a purine salvage pathway enzyme, is increased in activity in DBA patients but not in normal fetal or cord blood erythrocytes.[380] When compared to controls with normal eADA activity obtained from patients with hemolytic anemia, Fanconi anemia, and those with steroid-dependent nephrosis, as well as virtually all patients with TEC, approximately 85% of the patients with typical DBA have elevated eADA activity.[380,381,382] In some DBA patients with normal eADA activity there is markedly elevated orotidine decarboxylase activity.[380,383] Although abnormalities in purine or pyrimidine biosynthesis are consistent findings in most DBA patients and in some animal models and serve as a valuable screening tool, this observation has not yet been helpful in understanding the pathophysiology of DBA. Red cells of some patients with acute leukemia, adult-type chronic myelogenous leukemia, myeloproliferative disorder with Down syndrome, dyskeratosis congenita with pancytopenia, and megaloblastic anemia were also found occasionally to have increased eADA activity.[381] This may suggest an association of elevated eADA activity with abnormal progenitor function. Also of interest is the observation that W/W^v and $S1/S1^d$ mice, with genetically determined red cell failure, have elevated erythrocyte nucleoside deaminase activity.[384] Further advances in this area must await a detailed understanding of the biochemistry of hematopoiesis. However, from a practical prospective, eADA activity determinations provide a reasonably useful means for distinguishing ~85% of DBA from TEC (see section "Differential Diagnosis"). To date none of the described hematologic abnormalities have been linked to a specific pathophysiology, and they have no predictive value in distinguishing steroid responding from nonresponding patients.

Vitamin B_{12}, folate, serum iron, and transferrin saturation are elevated or normal in patients with DBA.[310,380] Erythropoietin levels seem to reflect the degree of anemia, or may be elevated for the degree of anemia and remain elevated even in steroid-responsive patients.[310,378] Approximately one-third of patients evaluated by Alter had hypogammaglobulinemia, consistent with the finding of in vitro immunologic abnormalities in some DBA patients.[317,378,385] Recently an association of hypogammaglobulinemia with RP haploinsufficiency[386] has been described, perhaps explaining this observation.

Examination of the bone marrow biopsy and aspirate at diagnosis in childhood usually reveals normal cellularity with a paucity of erythroid precursors. Myeloid and megakaryocyte lineages appear normal. Myeloid-to-erythroid (M:E) ratios at diagnosis are usually around 10:1 and with time may become as high as 100:1.[310] This progression of erythroid failure (with time) seems to parallel the more severe abnormalities in in vitro progenitor differentiation observed in older chronically affected patients as compared to those newly diagnosed.[319] The heterogeneity of the disorder is reflected in the marrow. In one series of 9 patients, all had marked erythroid hypoplasia; 4 had virtually no erythroid precursors, 2 had erythroid maturation up to the polychromatophilic or orthochromatic normoblast stage, and 3 had a maturation arrest at the proerythroblast stage, with 2% to 7% of the total nucleated cells being proerythroblasts.[319] In Alter's review, 28 of 29 DBA patients had erythroid hypoplasia. One had erythroid hyperplasia with a maturation arrest. Several of Alter's patients had normal numbers of proerythroblasts but no differentiation beyond that stage. In a series of patients studied by Bernard et al., 90% had erythroid hypoplasia, 5% had normal erythroid precursors, and 5% had erythroid hyperplasia.[387] Although all patients have a profound reticulocytopenia, the erythroid arrest in DBA has been demonstrated by progenitor assays, or morphologically, to occur at all stages of maturation from the multipotent myeloid progenitor to the late normoblast. These and other observations[336] suggest that the defect may become more profound with age and that the arrest in erythropoiesis moves to an earlier stage of differentiation

FIGURE 39.3. Typical displaced and "trigger" thumbs in a patient with Diamond-Blackfan anemia.

as patients get older. This is, however, somewhat confounding in light of the presence of remissions.[312]

Imaging studies are useful to help delineate congenital abnormalities that may be present in patients with DBA. Skeletal surveys and, in particular, CT scans are not usually warranted in light of the increased risk of cancer in DBA, but selected radiographs may define suspected bony anomalies. Renal and cardiac ultrasonography is warranted and may detect suspected and perhaps significant anomalies.

Genetics

Prior to the identification of causative mutations Alter estimated that there is more than one affected family member in ~10% of cases.[375] Early data from the DBAR provided a comparable or even slightly higher rate when robust clinical and hematologic data were available. Early case reports are representative of the now known genetics of DBA. In these families there were reports of affected same- and opposite-sex siblings,[376,388–390] including identical twins,[391] and maternal or paternal half-siblings.[392–395] There were also instances of parental transmission.[395–398] Striking evidence of autosomal dominant inheritance is illustrated in one case report of DBA in a male infant who had an affected mother and maternal grandfather.[399] Thus, the clinical evidence is consistent with the known majority of cases of autosomal dominant inheritance resulting from RP haploinsufficiency and the rare X-linked inheritance caused by a mutation in GATA1.

The genetics of the majority of cases of DBA have become firmly established since 1997, when after studying a patient with a 19:X translocation, Gustavsson and colleagues[345,346,400] used linkage analysis to show that DBA mapped to chromosome 19q13.2. That observation led to the cloning of a gene that encodes a ribosomal protein, RPS 19. Studies have shown that the RPS19 mutation accounts for only ~20% to 25% of familial as well as sporadic cases. With the description of a second "DBA gene," *RPS 24*, also a component of the 40S ribosomal subunit,[347] and the subsequent identification of mutations or deletions in both small and large subunit-associated RP genes in approximately 70% of patients,[349–354] as well as a rare causative mutation in the transcription regulator GATA1,[325] about 30% of patients remain genetically unclassified at this time. Thus the majority of familial cases are of dominant inheritance, with sporadic cases representing new dominant mutations. Within the identified pedigrees there is marked heterogeneity in the expression of the DBA phenotype. This heterogeneity exists for both the hematologic and nonhematologic manifestations of DBA. Thus the DBA phenotype appears to be the result of complex interactions between DBA and non-DBA genes. A family with discordant hematologic manifestations including a nonhematologically affected phenotype as well as discordance of craniofacial anomalies in affected family members has been reported.[401] The incidence of genetically determined cases is no doubt underestimated because of the apparent variable penetrance of the autosomal dominant cases in which an elevated HbF, MCV, or erythrocyte ADA activity may be the only abnormality in a parent or sibling of a child with typical DBA.[311,312] Indeed, in the case described, the mothers of affected cousins had none of these hematologic or nonhematologic abnormalities.[401] By tracing *RPS19* mutations in families, the UK group has shown that nearly half of all patients have autosomal dominantly inherited DBA.[402] Therefore, in the absence of a molecular diagnosis for all DBA genotypes, families of affected individuals should be evaluated to determine HbF levels, MCV, and eADA activity. A number of cases currently felt to be sporadic or autosomal recessive in nature will no doubt be recategorized, but recessive inheritance as a mode of transmission is far from ruled out. The appearance of DBA in the male and female children of unaffected parents has also been observed. Reported gonadal mosaicism in DBA is rare.[403] Furthermore, parental consanguinity has been observed,[404,405] supporting an, as of yet unconfirmed, autosomal recessive mode of inheritance. That approximately 30% of DBA cases have not been assigned a genetic cause supports the possibility that additional cases consistent with novel recessive modes of inheritance will be described in the future.

The absence of a phenotype is a particularly distressing finding, as the use of such potential hematopoietic stem cell transplantation (HSCT) donors with such a "silent phenotype" may result in transplant failure.[406] Furthermore, genetic counseling in these instances is inherently imprecise.[407]

The vast majority of DBA patients have a normal karyotype, but the few reported abnormal cases, in particular leading to the discovery of the first[400] and other genes,[350] have been of great importance; thus, karyotypic analysis is suggested as part of the initial evaluation.

Differential Diagnosis

The differential diagnosis of classical DBA includes the normochromic, normocytic (or macrocytic) anemias that present from birth through the first year of life. These anemias are pathophysiologically distinct from the majority of causes of PRCA seen in adults that are frequently associated with an underlying disorder (Table 39.1). However, it is clear that DBA does present in adulthood and these cases are often undiagnosed as such. Conversely, a patient presenting with red cell failure at age 5 and diagnosed with atypical DBA was confirmed to have 5q- MDS some 20 years later.[344] And the association of PRCA with thymoma, as described in adults, has not been described in infancy, although it has been observed in a 5-year-old girl.[408] Thus an index of suspicion for DBA should be maintained with regard to all cases of PRCA presenting at any age. In classical cases the differential almost always consists of DBA versus TEC (Table 39.5). Of note, patients with Pearson syndrome, resulting from large deletions of the mitochondrial genome, may present with pure red cell failure. Clinical suspicion or the presence of vacuolated erythroid precursors in the marrow should prompt a stain for ringed sideroblasts and the evaluation for a mitochondrial DNA deletion. A careful history, physical examination, and examination of the peripheral blood smear can usually rule out hemorrhage, myelosuppression resulting from infection, renal failure, infiltrative disease, severe

TABLE 39.5

DIFFERENTIAL DIAGNOSIS OF DIAMOND-BLACKFAN ANEMIA (DBA) VERSUS TRANSIENT ERYTHROBLASTOPENIA OF CHILDHOOD (TEC)

	DBA	TEC
Pure red cell aplasia	Present	Present
Age	<1 y	>1 y
Inheritance	Sporadic and dominant or possibly but unlikely recessive inheritance Mutation analysis available for known DBA genes	Not inherited
Congenital anomalies	Present	Absent
Mean corpuscular volume	Elevated	Normal
Fetal hemoglobin	Elevated	Normal
i RBC antigen	Present	Absent
Erythrocyte ADA activity	Elevated	Normal

ADA, adenosine deaminase; RBC, red blood cell.
All RBC characteristics except ADA activity are helpful only when tested in a reticulocytopenic child. During recovery from TEC, a transient wave of fetal-like erythropoiesis may be detected.

protein malnutrition, or drug-related red cell failure, as well as the aplastic crisis of a chronic hemolytic anemia (such as sickle cell anemia or hereditary spherocytosis). Because folate deficiency as a cause of the hypoplastic crises associated with chronic hemolytic anemia is prevented by prophylactic administration of the vitamin, acquired hypoplastic anemia in these patients is now most frequently a consequence of human parvovirus B19 infection. Evidence of human parvovirus B19 infection (see Parvovirus-induced pure red cell aplasia) has been found in patients with all congenital hemolytic disorders.[127,128,129,130,142,409–411] Red cell aplasia in otherwise normal neonates resulting in fetal hydrops, and in a patient on treatment for acute lymphoblastic leukemia, has also been described, apparently due to parvovirus infection.[412] Chronic red cell aplasia due to parvovirus B19 after 10 years of transfusion-dependent anemia has been eradicated by the use of intravenous immunoglobulin.[45] Thus, parvovirus infection should be ruled out in all atypical instances of red cell failure in children. This can be best accomplished by PCR analysis, as IgM and IgG antibody evidence will be lacking in the presence of significant immunodeficiency.

A bone marrow examination revealing red cell aplasia or severe hypoplasia with no abnormalities in myeloid or megakaryocyte lineages, as well as no evidence of infiltrative disease, congenital dyserythropoietic anemia, vacuolated precursors, or ringed sideroblasts in an infant or young child, suggests either DBA or TEC. Table 39.4 outlines the important features that distinguish TEC, a temporary immune-mediated suppression of erythropoiesis that frequently follows a viral infection, from DBA. There is a moderate to severe anemia with reticulocytopenia. The disease is not familial, and there are no associated anomalies. The age of onset is usually a bit older than for congenital PRCA. One key point in differentiating between DBA and TEC is the presence of fetal characteristics in the erythrocytes of many patients with DBA (see section "Laboratory Evaluation"). As previously described, these characteristics include an elevated MCV for age, elevated levels of HbF and "i" antigen, and a fetal erythrocyte glycolytic and HMP shunt enzyme pattern.[413] The presence of "fetal-like" cells is much less reliable in differentiating DBA from TEC in very young infants, in whom red cells normally possess fetal characteristics. However, this is a situation where measuring eADA may be useful, because the activity of this enzyme is the same in neonates and older children. Even in typical DBA, only 30% of patients have "fetal-like" erythrocytes at diagnosis. Recovery from TEC is characterized by "stress erythropoiesis," giving rise to erythrocytes with fetal characteristics."[414] Making a diagnosis of TEC retrospectively after a long course of corticosteroids subjects the child to needless toxicity. As previously described, studies by Glader and coworkers[380,381,382] have demonstrated that elevated eADA activity can be used to distinguish DBA from TEC. Unfortunately, many patients are transfused prior to consideration of the diagnosis, making an accurate eADA activity determination impossible. A molecular diagnosis can be made about 70% of patients and these assays are now commercially available. Based on the differences listed in Table 39.4, a high index of suspicion of TEC should prompt avoidance of steroids, minimal red cell transfusions, and alleviation of parental concern. Cases that are atypical or those who do not recover spontaneously deserve a genetic evaluation.

Treatment

If the diagnosis of DBA versus TEC is in doubt and the child has symptomatic anemia, the patient should be modestly transfused to a hemoglobin level of 7 to 8 g/dl so that erythropoiesis will not be suppressed, delaying recovery in those patients who have TEC. The use of corticosteroids in TEC is ineffective and should be assiduously avoided. In 1951, corticosteroid treatment in the form of ACTH was first shown to be effective in DBA[415,416]; however, the transfusion of packed red blood cells is the initial treatment. Transfusions should continue until 1 year of age if possible. The ability to defer corticosteroid treatment is dependent upon the availability of a safe blood supply and the ability to maintain appropriate venous access. The current approach is to start all patients on prednisone, 2 mg/kg/day orally in 3 to 4 divided doses, sometime as close to 1 year of age as can be accomplished. By delaying the start of corticosteroids, it is anticipated that many of the significant side effects associated with early steroid administration (growth retardation, developmental delay, osteopenia, hyperglycemia, hypertension, etc.) can be avoided.[311] A reticulocyte response usually occurs within 1 to 2 weeks. The clinical response to prednisone therapy is variable. Data from the DBAR reveal that 79% of patients were initially responsive to corticosteroids, 17% were nonresponsive, and 4% were never treated with steroids.[374] At the time of the analysis only 37% of patients were using corticosteroids. Steroid-related side effects were observed in most patients, at least transiently, with 48%, 22%, and 12% manifesting cushingoid features, pathologic fractures, and cataracts, respectively. Thirty-one percent of the patients were receiving red cell transfusions. Some patients respond rapidly and can be tapered off prednisone, remaining in remission for extended periods of time; others respond but require continued therapy, with erythropoiesis ceasing rapidly if steroids are discontinued. Thus the ability of responders to achieve an effective every-other-day dose schedule is variable. Of the transfused patients enrolled in the DBAR, 35% were never steroid-responsive, 22% became steroid-refractory, 33% could not be weaned to an acceptable dose, and 5% were never on steroids. A small number were transfused for unspecified reasons. Some patients may be tapered off steroids even after many years. Indeed, the actuarial likelihood of remission is 20% by age 25 years, with 72% entering remission during the first decade of life. Patients appear to remit equally from steroid and transfusion therapy. Almost 75% of these patients have what appears to be a sustained remission. Although high-dose corticosteroid pulses may evoke an erythroid response in some patients,[417,418] the potential side effects and the need for repeat pulses and the failure of this modality in subsequent studies[419] have limited its utility. Likewise, trials of cyclosporine (CsA), erythropoietin, interleukin-3, metoclopramide, etc., despite anecdotal reports in DBA, have not been particularly encouraging (reviewed in Ref. 311). Furthermore, the potential toxicity of this agent makes it less preferable to red cell transfusions for those patients who cannot be weaned to an acceptable corticosteroid dose. In some patients who fail to respond to prednisone there may be a response when oxymetholone (2.0 to 5.0 mg/kg/day) is added. However, experienced clinicians do not advocate the use of androgens in infants and young children because of their limited effectiveness and considerable side effects. If there is no response within a month, prednisone is discontinued in favor of transfusion and iron chelation. These patients may receive periodic prednisone trials, because they may respond at a later date.

For patients in whom there is a response, the hemoglobin is followed until a level of 10 g/dl is achieved. The steroid dose is then tapered until the patient is on the smallest possible alternate-day dose. A Monday-Wednesday-Friday dose schedule is usually effective and easier to comply with than a strict every-other-day regimen. The dosage in a Monday-Wednesday-Friday schedule may range from a few milligrams even in adolescents to as much as 40 to 50 mg. The target dose is 0.5 mg/kg/day or 1 mg/kg every other day. Arbitrary discontinuation of therapy should be discouraged, because reestablishment of erythropoiesis after discontinuation of an effective every-other-day course of prednisone requires reinstitution of the original daily dose. For patients who are steroid-refractory or in whom the dose cannot be tapered to an alternate-day regimen and thus require high daily doses that cause toxicity, chronic transfusion is instituted. Data from the DBAR and accumulated international experience demonstrate

that more patients than originally anticipated have significant steroid-related side effects even on a low-dose, every-other-day schedule. These are in addition to pathologic fractures and cataracts, and include poor growth, osteoporosis, and osteonecrosis, and may require the discontinuation of corticosteroids in favor of chronic transfusion therapy. Patients must be carefully monitored and steroid therapy discontinued when morbid side effects ensue, even if the dose is within the "accepted" range.

In recent years, HSCT has been used in DBA patients with good results. The first successful transplant for DBA was performed by August and colleagues in 1976.[420] In a 1998 review of stem cell transplantation in DBA by Alter that analyzed 35 of the 37 cases reported to that date in the literature, the actuarial survival for predominantly allogeneic HLA-matched donor transplants was 66%.[421] Two more recent studies suggest that the actuarial survival is in the range of 90% for matched related HSCT in young, otherwise healthy patients.[422,423] The historical substantial risks associated with alternative-donor bone marrow transplantation favor transfusion and chelation in those patients unable to achieve an every-other-day steroid schedule; however, the hesitancy to use unrelated donors is changing as recent results from patients transplanted since 2000 are dramatically better, likely as the result of more precise high-resolution HLA-typing, an expanded donor pool, and better pretransplant management of iron overload.[422] Modern chelation regimens seem to be very effective in reducing the consequences of iron overload in chronically transfused patients, but the long-term results of these programs are currently not known. The recent availability of an oral chelating agent promises to improve compliance with better-tolerated chelation regimens than the traditional nightly continuous subcutaneous infusions. This uncertainty and the other risks of transfusion (i.e., sensitization and infection) make the decision regarding bone marrow transplantation (when a suitable alternative donor exists) versus chelation therapy for DBA patients who are steroid-refractory or steroid-intolerant, one that must be individualized and constantly reevaluated. In particular, poor compliance with chelation regimens has resulted in significant morbidity and mortality in young adult patients with transfusion-dependent DBA.[311] A recent "How I Treat" article by Vlachos and Muir[424] provides a highly annotated approach to the treatment of DBA.

Prognosis

The DBAR describes an overall actuarial survival rate at ~40 years of age as 75.1% ± 4.8%, with 86.7% ± 7.0% for corticosteroid-maintainable patients, and 57.2% ± 8.9% for transfusion-dependent patients. There is a statistically significant survival advantage for steroid-maintainable versus transfusion-dependent patients.[311,312] Deaths due to infection in splenectomized patients with DBA are now dramatically reduced through the use of pneumococcal and *Hemophilus influenzae* vaccines, prophylactic penicillin, and careful follow-up and management. In addition, splenectomy is performed only for hypersplenism and an increased transfusion requirement, not as specific therapy for DBA. However, despite modern chelation schemes, transfusion-related hemosiderosis is a significant cause of death in DBA. Deaths from infection (*Pneumocystis jiroveci* pneumonia, varicella pneumonia, *Pseudomonas* pneumonia, sepsis, and one unknown infection), vascular access device complications, hematopoietic stem cell transplant complications, aplastic anemia, and malignancy[311,312] are described. Seventy percent of deaths were treatment-related, with alternative-donor HSCT the leading cause of death in DBA. Only one HLA-matched related and one alternative-donor HSCT recorded by the DBAR were done for the indication of severe aplastic anemia. The major indication was either steroid nonresponsiveness or intolerance. Since that publication, the results for unrelated HSCT have improved significantly, and this modality is under constant evaluation on a case-by-case basis. The most recent analysis from the DBAR reports an overall HLA-matched related-donor transplant survival of 76.9% ± 8.4 %, with a 93.8% ± 6.1% survival for patients equal to or less than 9 years of age. For unrelated donor transplants the overall survival has improved from 32.1% ± 11.7% (1994 to 1999) to 85.7% ± 13.2% (2000 to present).

For several years, it has been recognized that DBA is a syndrome predisposing to cancer, both hematopoietic and nonhematopoietic malignancies. A recent analysis of the prospective cohort of 608 patients enrolled in the DBAR since 1991 was performed to provide the first quantitative assessment of cancer incidence in DBA patients.[364] Among the 608 patients, there were 9,458 person-years of follow-up. There were 15 solid tumors, 2 cases of AML, and 2 cases of MDS diagnosed at a median age of 41 years. The cancer incidence in DBA is significantly elevated, with an observed-to-expected (O/E) ratio of 5.4 for all cancers and 287 for MDS, 28 for AML, 36 for colon cancer, 33 for osteogenic sarcoma, and 12 for female genital cancers, respectively. Clearly, in addition to understanding the mechanism of cancer predisposition in DBA, surveillance strategies must be considered for this at-risk population.

Future Directions

Advances in cellular and molecular biology have dramatically increased our understanding of the pathophysiology of DBA. DBA has been shown to be the consequence of an intrinsic progenitor cell defect and in the majority of cases the consequence of abnormal ribosome assembly/function. At least nine and likely more RP genes as well as the transcription regulator GATA1 have been implicated. Careful clinical investigation has defined the syndrome, and the study of the cellular biology of the disorder has borrowed from and contributed to the understanding of the mechanism of hematopoietic progenitor cell differentiation. Using the DBAR and other international databases, important epidemiologic, clinical, and laboratory observations have been made with regard to the clinical presentation and inheritance of DBA. These databases have yielded other important observations on the genetics of congenital malformations in DBA, the therapeutic outcomes including the efficacy of HSCT, and the recognition of DBA as a cancer-predisposing syndrome. In particular, they have provided the essential substrate of well-characterized patients and multiplex families necessary for gene discovery. Robust gene discovery will no doubt permit the molecular classification of all cases of DBA.

Dr. Louis Diamond, whose career spanned over 60 years and who had been a teacher to many and an inspiration to the rest,[425] would be pleased to know that from his description of an esoteric little disease has arisen fundamental new knowledge that has allowed extraordinary insights into the regulation of hematopoiesis and morphogenesis and the mechanisms of oncogenesis.

Acknowledgments

The authors acknowledge the contributions of Dr. Emmanuel Dessypris, whose excellent work on previous editions of this chapter served as the template for the current version.

CHAPTER 40

CONGENITAL DYSERYTHROPOIETIC ANEMIAS

Gary Kupfer, Linette Bosques, Bertil Glader

The congenital dyserythropoietic anemias (CDAs) are a heterogeneous group of inherited blood disorders characterized by anemia and morphologic abnormalities of erythroid precursors in the bone marrow, a consequence of dyserythropoiesis and ineffective erythropoiesis.[1,2] These disorders principally affect the erythroid lineage, whereas other nonerythroid hematopoietic lineages seem to be unaffected. On the basis of morphologic abnormalities of the bone marrow, CDAs were classified into three different types: type I, type II, and type III. However, additional variants requiring further characterization have also been identified.[3] Approximately 600 cases of CDA have been reported worldwide, CDA II being the most common.[3] CDA I and II are inherited in an autosomal recessive pattern, and CDA III exhibits autosomal dominant inheritance and a sporadic form.[4] The disease-related genes for CDA I, II, and III have been localized by linkage analysis, and the disease-causing genes have been identified for CDA I and II.

CDA patients display marked ineffective erythropoiesis and dyserythropoiesis.[5,6] Ineffective erythropoiesis may lead to intermittent jaundice, splenomegaly, hepatomegaly, and iron overload.[2,7] Iron overload is also a result of blood transfusion therapy, although even transfusion-independent patients may develop iron overload due to increased iron absorption.[8] Dyserythropoiesis results in a variety of dysplastic features of erythroblasts in the bone marrow: internuclear chromatin bridges, karyorrhectic nuclei, binuclearity, multinuclearity, vacuolation of the cytoplasm, and duplication of the plasma membrane.[9] Diagnosis of CDA relies on light and electron microscopy analyses to identify the characteristic morphologic abnormalities of the erythroblasts in the bone marrow.[10] Mutation analysis is becoming available for some CDAs.

CDA should be suspected in any individual with a chronic anemia that is largely due to ineffective erythropoiesis, as well as in individuals with unexplained iron overload. The presence of ineffective erythropoiesis is characterized by a low absolute reticulocyte count for the degree of anemia despite erythroid hyperplasia in the marrow. Further suggestive laboratory data include a low serum haptoglobin level and increased serum lactic dehydrogenase (LDH) activity. Generally, the anemia is mildly or moderately macrocytic in CDA I, normocytic in CDA II, and mildly macrocytic in CDA III.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE I (CDA I)

CDA I is inherited in an autosomal recessive pattern and it represents the second most common form of CDA.[6] It is most prevalent among Western Europeans, Middle Easterners (Israeli Bedouins, Lebanese, Kuwaitis, Saudi Arabians), Indians, and Japanese, with more than 150 reported cases.[2]

Clinical Features

Observations on CDA I have been enhanced by studies on a large cluster of cases in Israeli Bedouin families[11–13] and on cases in the German CDA registry.[14] The anemia varies from mild to severe, with the most severe cases presenting in infancy and the milder cases presenting in adolescence or later in life. Some degree of anemia is present in about two thirds of neonates, often requiring transfusion, but less than 10% of cases remain transfusion dependent later in life.[14,15] Occasionally, severe anemia in the fetus causes hydrops fetalis with pericardial and pleural effusions and edema.[16,17] Jaundice and splenomegaly are common findings at all ages. Gallstones may develop and require cholecystectomy. In addition, distal limb malformations, such as syndactyly, absence of phalanges and nails, an additional phalanx, and duplication or hypoplasia of the metatarsals, have been reported in several cases of CDA I.[18] Other congenital abnormalities found include café au lait spots, short stature, flattened vertebral bodies, hypoplastic rib, Madelung deformity, and deafness.[2] Deterioration of vision with retinal angioid streaks and macular degeneration has been described in two cases.[19,20]

Laboratory Features

CDA I patients usually have a macrocytic anemia with MCV values up to 115; normocytic CDA I patients still display macrocytes and thus an increased RDW. Anisocytosis, poikilocytosis (including teardrop-shaped poikilocytes), and basophilic stippling are other features of the peripheral blood smear (Fig. 40.1). Increased hemoglobin A_2 levels and unbalanced globin chain synthesis are found in some cases in the absence of β-thalassemia mutations.[13] Bone marrow examination reveals marked erythroid hyperplasia with megaloblastic erythroblasts. One of the defining features of CDA I is the presence of thin internuclear chromatin bridges between nearly completely separated erythroblasts in 0.6% to 2.8% of cells[6,10] (Fig. 40.2). In only one well-documented case were such bridges not seen.[19] A small proportion of erythroblasts are binucleate and occasional cells have three or four nuclei. Other abnormalities include RBC basophilic stippling, irregular nuclear outlines, and karyorrhexis.

A second defining structural feature of CDA I is multiple rounded electron-lucent areas within the electron-dense heterochromatin seen in up to 60% of erythroblasts, giving the nucleus a spongy or "Swiss cheese" appearance[10,21] (Fig. 40.3B,C). In some erythroblasts, there are also marked invaginations or evaginations of the nuclear envelope, and the invaginations carry cytoplasm and cytoplasmic organelles such as mitochondria into the nucleus (Fig. 40.3C).[22] Bone marrow macrophages contain phagocytosed morphologically abnormal erythroblasts (Fig. 40.4).

Management

CDA I often follows an indolent course, although patients may require red cell transfusions in infancy, with infections, and during pregnancy. Only some patients benefit from splenectomy and this is in contrast to CDA II.[2,11,14] Erythropoietin administration has no effect on the anemia of CDA I.[22] Following the fortuitous observation that treatment of hepatitis C in a CDA I patient with interferon-α2a led to a substantial hematologic improvement, several additional patients, including a severely affected infant, have been treated with interferon-α2a, interferon-α2b, or peg-interferon-α2b, and these patients also have also experienced hematologic improvement.[16,24–29] Interferon-α should be considered in the management of CDA I with severe anemia. In one case, long-term therapy was reported to reduce iron overload.[29] Careful monitoring for secondary hemochromatosis is important, at times requiring iron chelation therapy.

Molecular Biology of CDA I

In 1998 the gene for CDA I was localized to chromosome 15q15.1-15.3.[30] and it is now recognized that CDA I is caused by mutations in the *CDAN1* gene.[31] *CDANI* has 28 exons spanning 15 kb of genomic DNA and encodes a highly conserved protein of unknown function called codanin-1. Mutations in the *CDAN1*

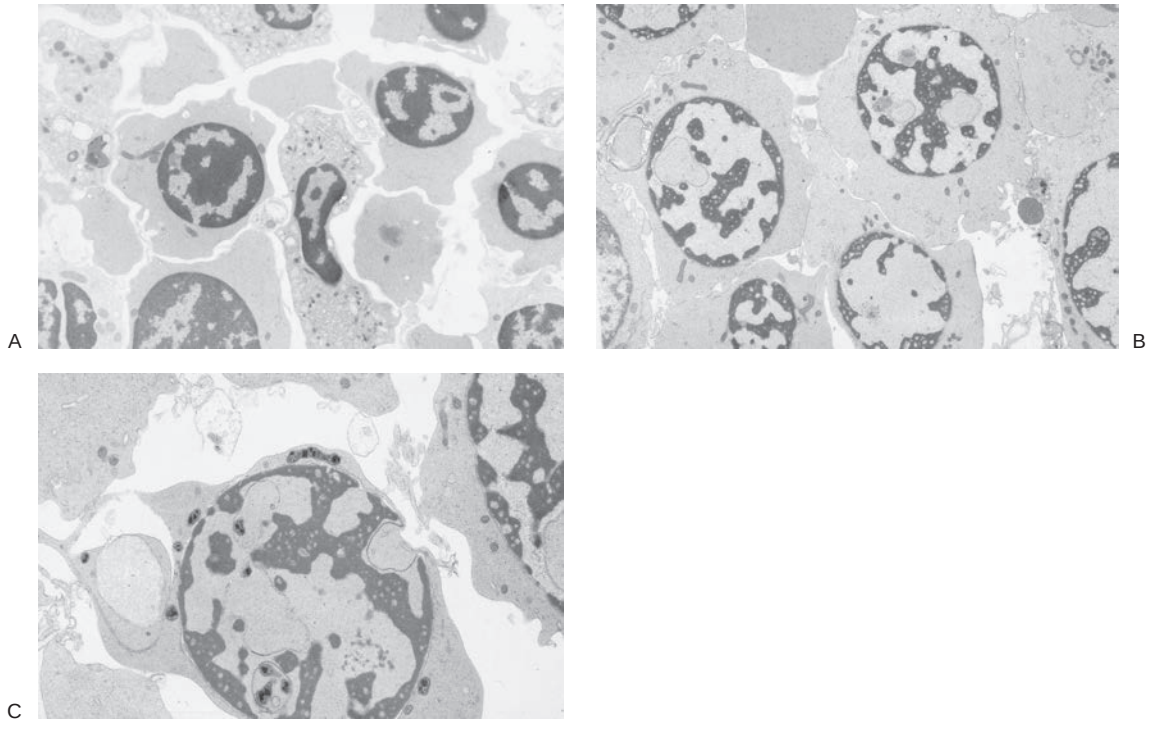

FIGURE 40.3. Ultrastructure of erythroblasts from a normal individual (A) and a patient with congenital dyserythropoietic anemia type I. **B** and **C** demonstrate the abnormal "Swiss cheese" appearance of the heterochromatin (compare with **A**), and **C** shows invagination of the nuclear membrane and nuclear membrane-bound areas of cytoplasm (containing iron-laden mitochondria) within the nucleus. (From Wickramasinghe SN. Congenital dyserythropoietic anaemias: clinical features, haematologic morphology and new biochemical data. Blood Rev 1998;12:178–200, with permission.)

gene are mainly located in the 3′ half of the gene and no homozygote for null type mutations has been identified, suggesting that the complete absence of codanin-1 may be lethal.[32] One founder missense mutation is observed mainly in Israeli Bedouins with CDA I which converts arginine to tryptophan at codon 1,040 and generates an *Nco*I restriction site.[31] This same missense mutation was found in 11 individuals with CDA I of two unrelated Lebanese families. A single mutation in *CDAN1* has been found in several sporadic cases and in one case, no mutations in *CDAN1* were found.[31]

Analysis of codanin-1 orthologs revealed the *Drosophila* homolog, *dlt*, is required for cell survival and cell cycle progression through the S phase.[33] Interestingly, codanin-1 increases during the S phase and is phosphorylated and excluded from condensed chromosomes during mitosis.[34] This study demonstrated that codanin-1 localizes to the nucleus, specifically to heterochromatin, during interphase and it is regulated by E2F1 transcription factors.[34] Another study confirmed codanin-1 localization to the nucleus, but it revealed that it is more abundant in the cytoplasm.[35] Codanin-1 mutations lead to the abnormal accumulation of heterochromatin protein HP1α in the Golgi apparatus of CDA I erythroblasts but not normal erythroblasts.[35] However, overall chromatin structure as indicated by genomewide epigenetic marks of several histone modifications is normal in CDA I erythroblasts.

Recently, codanin-1 was shown to interact with histone chaperone Asf1, which regulates the import of histones during DNA replication.[36] Codanin-1 knockdown increases the amount of chromatin-bound Asf1, enhancing DNA synthesis. Conversely, forced expression of codanin-1 interferes with Asf1 function due to Asf1 sequestration in the cytoplasm. Thus codanin-1 acts as a negative regulator of replication.

This close association with heterochromatin suggests that codanin-1 may be involved in mechanisms controlling gene transcription and chromatin structure remodeling. Thus, a clear understanding of the biochemical behavior of codanin-1 may provide us insight into how this interaction is established.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE II (CDA II)

Type II CDA was first categorized as such by Heimpel and Wendt in 1968. It is the most common type of CDA, and several hundred patients have been described.[3] The mode of inheritance is autosomal recessive.

Clinical Features

CDA II is usually a normocytic anemia with evidence of ineffective erythropoiesis and premature peripheral red cell destruction, causing jaundice and hepatosplenomegaly. In very mild cases, the anemia may be so slight as to remain undiscovered until late in adult life, although a majority of patients have a hemoglobin less than 11 g/dl. Overall, a third of affected children require transfusion in the first year of life, but transfusion requirements decrease in subsequent years, and only 5% of patients need regular transfusions in adulthood.[37] As in other congenital disorders in which ineffective erythropoiesis is a prominent feature, such as β thalassemia major, complications of extramedullary hematopoiesis may occur, such as dysmorphic facies, particularly in severely affected individuals. Cholelithiasis and secondary hemochromatosis are frequent complications, with iron overload the presenting manifestation in some cases.[38] Occasionally, transient red cell aplasia secondary to parvovirus B19 infection may develop.[39] Mental retardation,[3,40] hemihypertrophy,[3] and piebaldism and vaginal atresia have all been reported.[41]

Laboratory Features

Peripheral blood smear features include anisocytosis, poikilocytosis, basophilic stippling, and some irregularly contracted cells (Fig. 40.5). Bone marrow examination reveals marked erythroid hyperplasia without megaloblastosis. The defining erythroblast abnormality is prominent binuclearity. Proerythroblasts are morphologically normal, but basophilic and early and late polychromatic erythroblasts are binucleated, with up to 10% to 35% of late erythroblasts being so (Fig. 40.6). Some of these nuclei have irregular outlines or show karyorrhexis. In many binucleate late polychromatic erythroblasts, the nuclei are equal in size, and each of the two nuclei has a diploid DNA content suggesting the possibility that the cells resulted from a failure of cytokinesis following normal mitosis. The phagocytosis of red cells and erythroblasts by bone marrow macrophages leads to the formation of Gaucher-like macrophages (pseudo-Gaucher cells) in some individuals.

Electron microscopy reveals the characteristic presence of peripheral cisternae in erythroid cells.[40] These are discontinuous double membranes running parallel to and 40 to 60 nm away from the cell membrane (Fig. 40.7).[42] Peripheral cisternae are found in some red cells, a substantial proportion of mononucleate

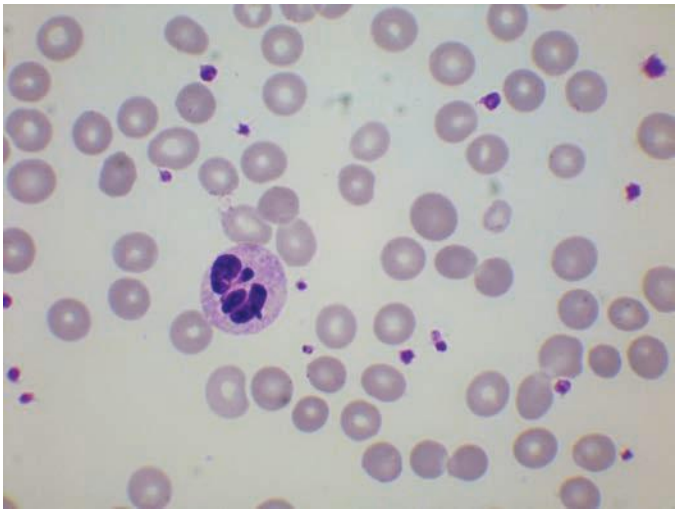

FIGURE 40.5. Blood smear from a patient with congenital dyserythropoietic anemia type II. (Courtesy of Professor B. Bain, London.)

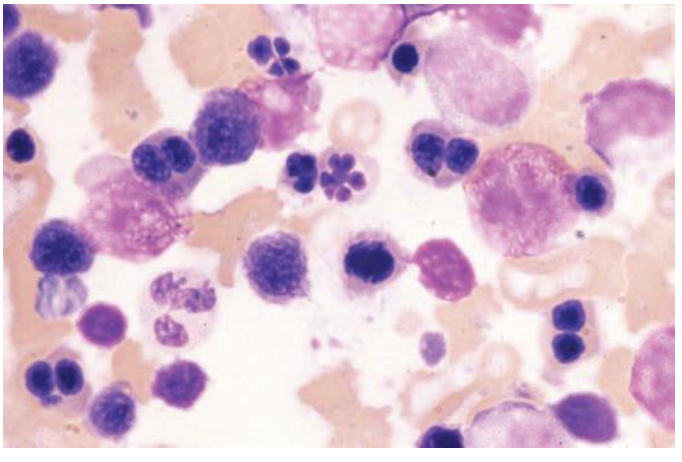

FIGURE 40.6. Bone marrow smear from a patient with congenital dyserythropoietic anemia type II, showing binucleate late polychromatic erythroblasts and karyorrhexis.

FIGURE 40.7. (Part B from Wickramasinghe SN. Congenital dyserythropoietic anemias. In: Wickramasinghe SN, McCullough J, eds. Blood and bone marrow pathology. Edinburgh: Churchill Livingstone, 2003:273–282, with permission.)

and binucleate late polychromatic erythroblasts, and a smaller proportion of early polychromatic erythroblasts. They appear to represent endoplasmic reticulum (ER) as they contain disulfide isomerase that is known to be present in ER.[43]

When tested against a panel of ABO-compatible acidified sera (pH 6.8) from normal individuals, about 30% of the sera lyses CDA II red cells (acidified serum lysis test or Ham test). Unlike paroxysmal nocturnal hemoglobinuria (PNH), there is rarely lysis of the patient's red cells by his or her own serum. In addition, CDA II cells do not lyse in isotonic sucrose as PNH cells do. The lysis in acidified heterologous sera is due to a naturally occurring complement-binding immunoglobulin (Ig) M antibody against an unidentified antigen on CDA II cells. The combination of the characteristic morphologic abnormalities and the serologic finding led Crookston et al.[44] to propose the acronym HEMPAS (hereditary erythroblastic multinuclearity with positive acidified serum test) for CDA II. The acidified serum lysis test previously was most informative and useful to diagnose PNH; however, this test now has been replaced by quantitation of CD55 and CD59 by flow cytometry (see Chapter 35). As a consequence there is decreased availability of the Ham test in clinical laboratories and this test is rarely used to help identify CDA II.

The principal biochemical feature of CDA II is defective *N*-glycosylation of the erythrocyte membrane proteins, band 3 (anion exchange protein 1) and band 4.5 (glucose transporter 1).[45–47] This causes band 3 and band 4.5 to migrate at lower molecular weights on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). During normal maturation of erythroid cells, the erythrocyte membrane proteins are glycosylated with polylactosaminoglycans. Band 3 and band 4.5 proteins normally contain long polylactosamine chains attached to complex N-linked oligosaccharides. However, in CDA II, erythrocyte membrane proteins carry altered *N*-glycans with truncated polylactosamine structures.[48] Instead, glycosylation is shifted to lipid acceptors resulting in the accumulation of polylactosamines as glycolipids. Immunogold electron microscopy analysis using antiband 3 antibodies reveals irregular clustering of underglycosylated band 3 protein in CDA II erythrocyte membranes when compared to normal erythrocytes.[49] SDS-PAGE of red cell membrane proteins can be used as a diagnostic criterion in lieu of a positive acidified serum lysis test.

Management

Some cases of CDA II follow an indolent course, whereas transfusion-dependent individuals often benefit from splenectomy, usually with a moderate increase in hemoglobin concentration.[3,37] Most important, patients should be monitored closely for secondary hemochromatosis, which can occur even in the absence of regular transfusion as a result of ineffective erythropoiesis with increased iron absorption.[50] The extent of iron overload increases progressively with age,[3,37] and about 20% of cases develop cirrhosis.[3] Iron chelation therapy may be indicated, or alternatively, phlebotomy may be considered in patients with mild anemia. In one case of CDA II with co-inherited β-thalassemia trait[51] and one of a variant CDA II with a negative Ham test,[52] allogeneic bone marrow transplantation has been curative.

Molecular Biology of CDA II

Abnormalities in two Golgi enzymes previously were implicated in the pathogenesis of CDA II: *N*-acetylglucosaminyltransferase II and α-mannosidase II.[53] In fact, an α-mannosidase II knockout mouse reproduces a phenotype similar to CDA II.[54] However, further familial studies have excluded linkage of CDA II to the N-acetyl-glucosaminotransferase and α-mannosidase II genes.[55] In addition, it has been found that abnormalities of glycosylation of red cell membrane proteins are not confined to CDA II, being present, albeit to a lesser degree, in both CDA I and III.[56,57]

From studying several families, the CDA I1 gene (*CDAN2*) has been localized to chromosome 20q11.2.[58,59] The disease-causing gene in CDA II is *SEC23B*, which spans approximately 54 kb on chromosome 20p11.23.[60,61] It encodes an essential component of the coat protein complex II (COPII)-coated vesicles that transport secretory proteins from the endoplasmic reticulum to the Golgi apparatus. The majority of CDA II patients harbor mutations in the *SEC23B* gene, although 10% of CDA II patients have no detectable mutations in this gene.[37,60,61] The most frequent *SEC23B* mutations are the coding region missense mutations, R14W and E109K, and nonsense mutations, R497C and I318T.[61–64] Splice-site mutations and frameshift mutations have also been reported.[63,64] Compound heterozygosity for a frameshift or nonsense mutation and a missense mutation result in a more severe CDA II phenotype than homozygosity for two missense mutations,

establishing a genotype–phenotype relationship. However, CDA II patients homozygous for nonsense mutations have never been reported, suggesting that some *SEC23B* expression is necessary for embryonic viability.[60,61] In light of the identification of *SEC23B*, earlier described abnormalities in two Golgi enzymes implicated in the pathogenesis of CDA II: *N*-acetylglucosaminyltransferase II and α-mannosidase II are even more compelling.[53]

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE III (CDA III)

This disorder was first described in 1951 in an American family by Wolfe and von Hofe under the name familial erythroid multinuclearity, and in 1962 in a Swedish family by Bergström and Jacobsson as hereditary benign erythroreticulosis.[65,66] CDA III represents the rarest CDA variant with a familial and a sporadic form.[67] The familial form is inherited in an autosomal dominant pattern, and the sporadic form is inherited in an autosomal recessive pattern or may arise de novo as a dominant mutation.[6,67] The disease gene has been localized in the Swedish family with CDA III to a 4.5 cM interval on chromosome 15q21-q25.[68] The possibility of an individual having CDA III is considered in the face of a mild macrocytic anemia not due to other common conditions.

Clinical Features

Individuals may experience fatigue, weakness, and episodes of abdominal pain and jaundice resulting from gallstones. Splenomegaly is absent in the dominantly inherited cases but is present in most sporadic cases. Intravascular hemolysis and consequent hemosiderinuria may be present and occasionally lead to iron deficiency. Iron overload does not develop in the Swedish cases probably because of iron loss from hemosiderinuria.[69] In the Swedish family, the prevalence of monoclonal gammopathy of unknown significance and myeloma is increased,[69] and visual disturbances due to macular degeneration and angioid streaks may be seen in older patients.[70] Single sporadic cases have been reported to develop Hodgkin disease and malignant T-cell lymphoma.[71,72]

Laboratory Features

The macrocytic anemia is generally of mild to moderate severity. The peripheral blood smear displays basophilic stippling, irregularly contracted erythrocytes, anisocytosis, and poikilocytosis (Fig. 40.8).[2] A distinguishing feature of CDA III is markedly abnormal erythroblast proliferation resulting in giant binucleated and multinucleated erythroblasts with up to 12 nuclei (Fig. 40.9A–D) and total DNA content up to 48 N.[65,73] Electron microscopy shows multinucleated erythroblasts with multiple nuclear clefts in the heterochromatin, which may lead to nuclear lobulation and karyorhexis (Fig. 40.10).[74] Individual nuclei within the same multinucleated cells (with up to 12 nuclei) can display different shapes and sizes and abnormal heterochromatin appearance.[74] The cytoplasm of many erythroblasts contains large autophagic vacuoles, inclusions containing β globin chains, iron-loaded mitochondria, and myelin figures.

CONGENITAL DYSERYTHROPOIETIC ANEMIA VARIANTS

A category, designated CDA type IV, was proposed to describe cases with bone marrow appearances typical of CDA II, but a negative Ham test with heterologous sera. Some of these cases may simply represent CDA II in which an insufficient number of heterologous sera were used in the test. Examples exist of cases that have been reclassified as CDA II when retested with more sera. The availability of *SEC23B* gene testing should help define if these are truly CDA II variants.

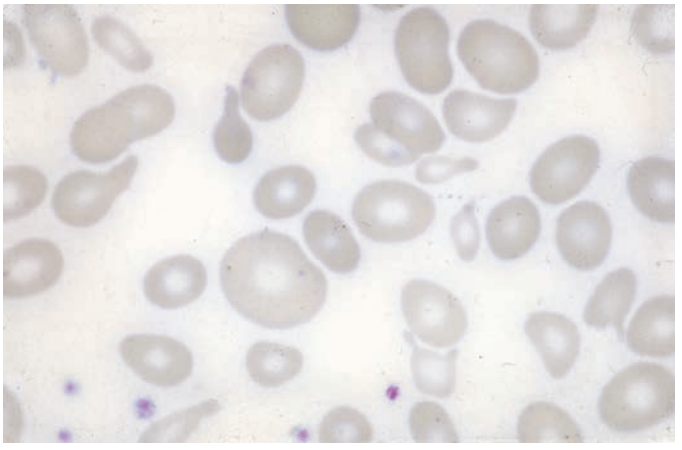

FIGURE 40.8. Blood smear from a patient with congenital dyserythropoietic anemia type III.

Several cases have been reported with features other than those of CDA I, II, or III that seem to represent distinct forms of CDA rather than variants of the three classic types. Most of these have been tentatively assigned to four phenotype-based groups designated CDA group IV, V, VI, and VII and their essential features are shown in Table 40.1;[2,6] the majority belong to group IV.[75,76] They have been designated as groups rather than types as there is evidence of phenotypic and/or genetic heterogeneity within each group. In addition to these groups, each of which includes three or more families, there are cases with unique features reported in only one or two families.

A father and daughter had a disorder with probable autosomal dominant inheritance characterized by normal hemoglobin values, macrocytes in the blood film, and dyserythropoiesis including internuclear chromatin bridges, but unlike in CDA I, the erythroblast heterochromatin was ultrastructurally normal.[77] Other single cases have shown large cytoplasmic vacuoles, macrocytosis without anemia, and marked irregularities of nuclear outline in a high proportion of erythroblasts[78] or transfusion-dependent anemia with gross nonspecific dyserythropoietic changes in many erythroblasts including marked irregularities of nuclear outline.[79] In two consanguineous Arab families, CDA was associated with microcytosis, many binucleate late erythroblasts, a negative Ham test, and chronic recurrent multifocal osteomyelitis; the inheritance was autosomal recessive and homozygous mutations in the *LPIN2* gene on chromosome 18p were present.[80,81] A third Arabic patient with this syndrome also had a homozygous mutation in *LPIN2*.[82]

A missense mutation of erythroid transcription factor KLF1 has been reported to cause CDA with erythroid hyperplasia and unique ultrastructural abnormalities in the bone marrow.[83] A characteristic feature of this CDA variant is the high number of orthochromatic erythroblasts in the peripheral blood that fail to undergo terminal erythroid differentiation and thus retain their nuclei. Furthermore, patient-derived $CD34^+$ cells induced down the erythroid lineage in vitro show impaired enucleation. Electron microscopy reveals erythroblasts with endoreplication of nuclear membrane with abnormally large nuclear pores, severe anisopoikilocytosis, and cytoplasmic inclusions. Clinically, the patient described with this mutation required frequent blood transfusions due to hemolytic anemia. Treatment with erythropoietin or interferon-α was ineffective. Following splenectomy, the patient became transfusion-independent and hemoglobin

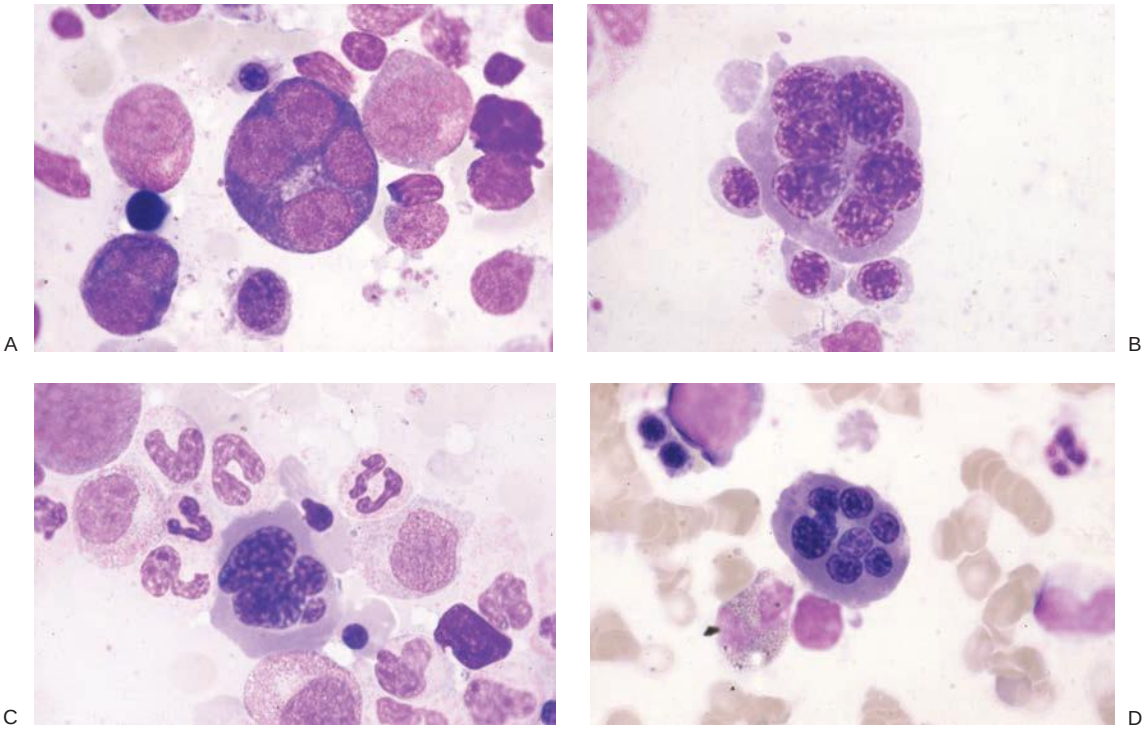

FIGURE 40.9. Multinucleate erythroblasts from the bone marrow of a case of congenital dyserythropoietic anemia type III. A: Tetranucleate basophilic erythropoietic cell. **B, C, and D:** Polychromatic erythroblasts with six, four, and eight nuclei, respectively.

levels stabilized. The patient had no mutations in the *CDAN1* and *SEC23B* genes. The disease-causing mutation was discovered to affect exon 3 of the *KLF1* gene, converting glutamate 325 to lysine (E325K). The patient displayed dysregulation of globin gene expression, resulting in the persistence of embryonic and fetal hemoglobins. Additionally, the patient's circulating erythroblasts and mature erythrocytes were deficient in the adhesion molecule CD44 and water channel AQP1. Of interest, a well-studied patient with very similar clinical features had been reported in the 1990s. This previous patient had a moderate normochromic normocytic anemia, dyserythropoiesis, circulating erythroblasts, ineffective erythropoiesis, and the following features: deficiency of erythroid but not leukocyte CD44, a unique Colton blood group, 50% hemoglobin F, small amounts of ζ- and ε-globin chains in some red cells, reduced expression of aquaporin 1 (CHIP), and rounded intraerythroblastic inclusions composed of tightly packed double

Observations on two members of the Swedish family with congenital dyserythropoietic anaemia, type III. Eur J Haematol 1993;50:213–221, with permission.)

TABLE 40.1

FEATURES OF CONGENITAL DYSERYTHROPOIETIC ANEMIA (CDA) GROUPS IV–VII[a]

Group	Defining Features
IV	Severe transfusion-dependent anemia
	Marked erythroid hyperplasia, usually normoblastic
	Markedly ineffective erythropoiesis
	Slight/moderate increase in nonspecific dyserythropoietic changes including markedly irregular or karyorrhectic nuclei
	Absence of the marrow abnormalities characteristic of CDA I-III
	Absence of precipitated protein within erythroblasts by electron microscopy (which excludes α-thalassemia syndromes and CDA group VII)
V	Normal or near-normal Hb with normal or slightly increased MCV
	Predominantly unconjugated hyperbilirubinemia
	Marked normoblastic/mildly or moderately megaloblastic erythroid hyperplasia
	Grossly ineffective erythropoiesis
	Little or no erythroid dysplasia
VI	Normal or near-normal Hb with marked macrocytosis (MCV 119-125 fl)
	Erythroid hyperplasia with cobalamin and folate-independent florid megaloblastic erythropoiesis and nonspecific dyserythropoiesis
	Ineffective erythropoiesis
VII	Severe transfusion-dependent anemia
	Marked normoblastic erythroid hyperplasia with nonspecific dyserythropoietic changes, especially irregular nuclear shapes, in many polychromatic erythroblasts
	Markedly ineffective erythropoiesis
	Intraerythroblastic inclusions resembling precipitated globin that do not react with antibodies to α- or β-globin chains (electron microscope studies)

Hb, hemoglobin; MCV, mean corpuscular volume.
[a]CDA group IV is distinct from CDA type IV, which is a term that has been used to describe a variant of CDA type II.

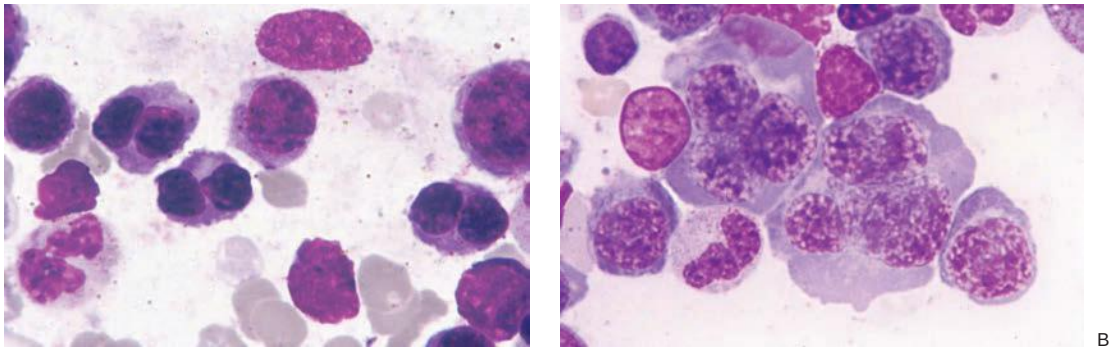

FIGURE 40.11. Bone marrow appearances resembling those of congenital dyserythropoietic anemia. A: Myelodysplastic syndrome with frequent binucleate late polychromatic erythroblasts. **B:** Thiamine-responsive anemia with multinucleate megaloblasts. (Part B from Wickramasinghe SN. Macrocytic anemia. In: Wickramasinghe SN, McCullough J, eds. Blood and bone marrow pathology. Edinburgh: Churchill Livingstone, 2003:229–247, with permission.)

membranes.[84–86] More recently, when this earlier patient was re-evaluated, she also was found to have the same *KLF1* mutation.[83]

Congenital dyserythropoiesis is associated with thrombocytopenia in patients with mutations in the gene for the transcription factor GATA1.[2,87] However, the presence of thrombocytopenia would generally be considered to exclude such cases from the category of CDAs.

In addition to the congenital dyserythropoietic disorders discussed in this chapter, acquired conditions occasionally can be associated with ineffective erythropoiesis and dyserythropoiesis.[2,6,9] These include vitamin B_{12} or folate deficiency, severe iron deficiency, thalassemia syndromes, some unstable hemoglobins, sideroblastic anemias, myelodysplastic syndromes, acute myeloid leukemia, aplastic anemia, malaria, Kala azar, alcohol abuse, and liver disease. It is noteworthy that morphologic features characteristic of CDA I, II, and III may be seen in some acquired dyserythropoietic states. For example, internuclear chromatin bridges such as those seen in CDA I may be found occasionally in myelodysplastic syndromes (MDSs), in *Plasmodium falciparum* malaria, and during marrow regeneration following transplantation. A high proportion of binucleate late erythroblasts such as is seen in CDA II may be encountered in MDS (Fig. 40.11A) and marked multinuclearity of erythroblasts as found in CDA III is seen in some cases of erythroleukemia and thiamine-responsive anemia (Fig. 40.11B).

CHAPTER 41

ANEMIAS SECONDARY TO CHRONIC DISEASE AND SYSTEMIC DISORDERS

Robert T. Means, Jr.

ANEMIA OF CHRONIC DISEASE

The anemia that is often observed in patients with infectious, inflammatory, or neoplastic diseases that persist for more than 1 or 2 months is called *anemia of chronic disease (ACD)*. The characteristic feature of this syndrome is the occurrence of hypoferremia in the presence of ample reticuloendothelial iron stores. ACD is defined by the presence of this unique combination of findings.[1–2,3] As so defined, the syndrome does not include anemias caused by marrow replacement, blood loss, hemolysis, renal insufficiency, hepatic disease, or endocrinopathy, even when those disorders are chronic. These other syndromes are discussed in the sections "Anemia of Chronic Renal Insufficiency," "Anemia in Cirrhosis and Other Liver Diseases," and "Anemias Associated with Endocrine Disorders" in this chapter. To further complicate nomenclature, the acute anemia observed in critically ill patients and that component of postsurgical anemia not attributable to blood loss appear to be pathophysiologically identical to ACD.

As the discussion above suggests, the designation *ACD* is far from perfect.[4] The alternate term, *anemia of inflammation* has become more widely used in recent years,[4,5] but also has significant etymologic deficiencies, and the more pathophysiologically correct term *cytokine-mediated anemia*[6] is not commonly used. Highly specific descriptive designations, such as *anemia of defective iron reutilization,*[7] *hypoferremic anemia with reticuloendothelial siderosis*, and *thesauric hypoferremic anemia*,[8] are also rarely used and have the limitation of focusing solely on the iron-related aspects of the syndrome.

Associated Syndromes

ACD is extremely common and, overall, is probably more common than any anemia syndrome other than blood loss with consequent iron deficiency. Cash and Sears evaluated all the anemic individuals admitted to the medical service of a busy municipal hospital during two 2-month periods in 1985 and 1986.[9] After patients with active bleeding, hemolysis, or known hematologic malignancy were excluded, 52% of anemic patients met laboratory criteria for ACD.[9] The syndrome is also observed in 27% of outpatients with rheumatoid arthritis[10] and in 58% of new admissions to inpatient rheumatology units.[11] However, it should be remembered that 40% of patients in the series reported by Cash and Sears lacked one of the traditional "ACD-associated disorders."[9] Approximately one-third of this latter group had renal insufficiency, in which pathophysiologic mechanisms implicated in ACD are active.[12] Clinical disorders commonly associated with ACD are listed in Table 41.1.

Clinical and Laboratory Description

Because this type of anemia occurs in association with so many diseases, the clinical manifestations necessarily vary widely. Usually, the signs and symptoms of the underlying disorder overshadow those of the anemia, but on rare occasions, developing anemia provides the first evidence of the primary condition. This situation may be observed particularly in difficult-to-diagnose clinical syndromes, such as temporal arteritis.[13]

Anemia

Development and Severity

Typically, anemia develops during the first 1 to 2 months of illness and thereafter does not progress.[2] The hematocrit usually is maintained between 0.25 and 0.40,[2,14,15] but significantly lower values are observed in 20% to 30% of patients.[9,10] The hemoglobin concentration and hematocrit generally provide an accurate reflection of the extent to which the circulating red cell mass is reduced, although in certain cases, expansion of the total blood volume would mean that the reduction in red cell mass is less than the hemoglobin or hematocrit indicates.[16,17]

A general correlation exists between the degree of anemia and the severity of the underlying disease.[2] For example, infections accompanied by pronounced fever, chills, and suppuration are associated with more severe anemia than those with fewer systemic manifestations.[18] In infected wounds, the degree of anemia

TABLE 41.1

CONDITIONS ASSOCIATED WITH ANEMIA OF CHRONIC DISEASE

Chronic Infections[9,16]
Pulmonary infections: abscesses, emphysema, tuberculosis, pneumonia
Subacute bacterial endocarditis
Pelvic inflammatory disease
Osteomyelitis
Chronic urinary tract infections
Chronic fungal disease
Meningitis
Human immunodeficiency virus

Chronic, Noninfectious Inflammations

Idiopathic

is related to the number of organisms present.[18] Correlation has also been observed between the severity of the anemia and the activity of rheumatoid arthritis as judged by fever, severity of joint swelling and inflammation, and the erythrocyte sedimentation rate.[19,20] In patients with malignant disease, anemia is more severe when metastases are widespread than when the disease is localized; however, the development of anemia does not require or imply neoplastic involvement of the bone marrow.[21,22]

Typically, the percentage of reticulocytes is normal or reduced,[2] although on rare occasions it may be slightly increased.[18] The reticulocyte production index is decreased, although not to the same degree seen in primary marrow failure states like aplastic anemia or pure red cell aplasia.

Morphologic Features

The erythrocytes usually are normocytic and normochromic; however, hypochromia and microcytosis may be observed. In older series, microcytosis (mean corpuscular volume [MCV] <80 fl) was observed in 2% to 8% of patients with ACD[19,23,24]; however, other, more recent studies report a frequency of 20% to 40%.[9,15] Hypochromia (mean corpuscular hemoglobin concentration, 26 to 32 g/dl) is more common than microcytosis. In various series, hypochromia was observed in 23% to 50% of patients with chronic infection, 50% to 100% of patients with rheumatoid arthritis, and 44% to 64% of patients with cancer.[2,15] Overall, it is observed in 40% to 70% of patients with ACD.[9,10,19,23,24] Hypochromia may be observed even though the hematocrit remains within normal limits.[25] Microcytosis in ACD is usually not as striking as that commonly associated with iron deficiency anemia; values for MCV <72 fl are rare.[2,15] Another distinction from iron deficiency is that hypochromia typically precedes microcytosis in ACD but typically follows the development of microcytosis in iron deficiency.[2] Slight anisocytosis and poikilocytosis may be detected, but such changes tend to be less prominent than in iron-deficient subjects. Routine examination of the blood smear rarely reveals specific morphologic abnormalities. The width of the erythrocyte size distribution curve (red cell distribution width) is typically elevated to a moderate degree, and generally does not help in distinguishing iron deficiency and ACD. Newer parameters calculated by automated hematologic analyzers, such as reticulocyte hemoglobin content (CHr), may assist in distinguishing ACD from iron deficiency.[26,27]

Laboratory Markers of Iron Status

Characteristically, serum iron concentration is decreased, total iron-binding capacity (or serum transferrin concentration) is reduced, and transferrin saturation may be below normal, though not to the same degree as in iron deficiency.[2,24] In patients with infection, hypoferremia develops early in the course of the illness, often within 24 hours, and is observed even in acute, self-limited febrile diseases or after experimentally induced fever in humans or animals.[8,14,28,29] When the infection is of short duration, the serum iron returns to normal and anemia does not develop; in prolonged illnesses, the serum iron level remains low as long as the disease is active. When the disorder subsides, anemia often is relieved before the serum iron level returns to normal. The degree of hypoferremia is related to the severity of the underlying illness.[19,24,30]

In bone marrow aspirates stained for iron, the number of sideroblasts is reduced to 5% to 20% of the total quantity of normoblasts (normal, 30% to 50%). In contrast, the amount of hemosiderin within macrophages usually is increased; exceptions to this probably represent cases complicated by iron deficiency.[2]

Serum ferritin level is a useful indicator of iron status in patients without underlying inflammatory disorders. In patients with ACD, however, the serum ferritin level indicative of adequate reticuloendothelial iron stores requires upward adjustment. Serum ferritin values usually increase in patients with inflammatory diseases,[31] and extreme elevations of serum ferritin may be a nonspecific indicator of significant underlying disease.[32] When iron deficiency coexists, the serum ferritin level falls but may not reach values as low as those found in uncomplicated iron deficiency. Values of 60 to 100 μg/L, previously suggested as the appropriate lower limit of normal for serum ferritin in chronic inflammation, may be too low, depending upon the parameters of the ferritin assay used.[33,34,35,36] At one institution, all patients with serum ferritin levels <30 μg/L were iron-deficient by marrow examination, as were the majority of hospitalized patients with serum ferritin levels of 30 to 100 μg/L and approximately one-third of hospitalized patients with serum ferritin levels between 100 and 200 μg/L (Fig. 41.1).[37] Combining the serum ferritin level with other parameters, such as erythrocyte sedimentation rate and C-reactive protein, did not improve its predictive value,[38] although it has been suggested that the combination of serum ferritin with red cell ferritin may be more predictive.[39] The recognition of iron deficiency in patients with chronic inflammatory states is not a trivial issue: Iron deficiency contributes to anemia in up to 27% of anemic rheumatoid arthritis patients[10] and probably accounts for periodic reports of successful treatment of "the anemia of chronic disease" with iron preparations.[40] A patient with chronic inflammatory disease and a serum ferritin <30 μg/L is certainly iron-deficient, and a patient with a serum ferritin >200 μg/L is certainly not iron-deficient; in other circumstances, certainty can be provided only by examination of a Prussian blue-stained marrow specimen. Elevated concentration of soluble transferrin receptors (sTfRs) in serum is another way to identify iron-deficient individuals with normal serum ferritin concentrations.[41]

Serum or plasma sTfR concentration is elevated in iron deficiency but is not elevated in uncomplicated ACD. It will be elevated in ACD cases complicated by iron deficiency.[42–45] sTfR concentration is most accurately interpreted in the context of the serum ferritin concentration,[41,46] and is often expressed as a ratio to the log of the serum or plasma ferritin concentration (called the transferrin receptor index or transferrin/ferritin index).[46]

As will be discussed later in this chapter, the iron regulatory peptide hepcidin appears to be a significant driver of the pathogenesis of ACD. Circulating hepcidin concentration is expected to be elevated in ACD.[5,47] Well-studied and reproducible assays for hepcidin have been developed,[48,49,50,51,52,53] and while none are available for routine clinical use at present it is reasonable to assume that they will be available in the near future. It has been suggested that serum hepcidin concentration can be plotted against CHr and that the combination of elevated hepcidin and normal CHr will distinguish ACD from both iron deficiency (normal hepcidin, high CHr) and the combined state of ACD and iron deficiency (low CHr, high hepcidin).[54]

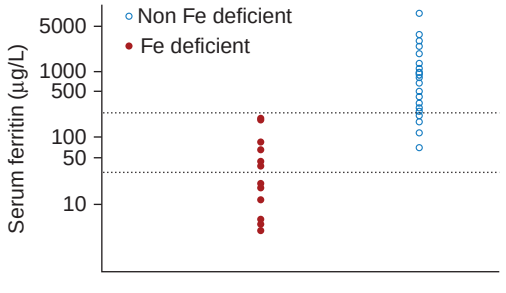

FIGURE 41.1. Comparison of serum ferritin levels from iron-deficient and non–iron-deficient patients as identified by bone marrow examination during 1994 to 1995 at the University of Cincinnati Medical Center. *Dashed lines* indicate the range of normal for the laboratory.

Other Biochemical Findings

The concentration of free protoporphyrin in the erythrocytes (FEP) tends to be elevated in patients with ACD.[14,55,56] However, FEP increases more slowly in ACD than it does in iron deficiency, and it does not become clearly abnormal until significant anemia has developed.

A variety of other biochemical changes often are detected in patients with chronic diseases. Many of these changes reflect alteration of levels of particular plasma proteins, often called *acute-phase reactants*.[57–61] The concentrations of certain plasma proteins, such as fibrinogen, ceruloplasmin, haptoglobin, C-reactive protein, orosomucoid, C3, and amyloid A protein, increase[62–64,] whereas the concentrations of albumin and transferrin characteristically decrease.[65] The increase in ceruloplasmin accounts for the increase in serum copper levels often noted in association with chronic diseases.[2,14] An elevated fibrinogen level is probably the most important factor in the increased sedimentation rate.

Patients with chronic illness develop accelerated protein catabolism and negative nitrogen balance associated with muscle proteolysis.[64,65] Over time, this phenomenon can result in muscle wasting, increased urea excretion, weight loss, and growth impairment in children. However, protein catabolism generates amino acids that can be used by the patient as alternative energy sources or to supply substrates for biosynthetic processes related to host response. In this context, it is perhaps relevant that elevated serum levels of tumor necrosis factor (TNF), a cytokine implicated in the pathogenesis of ACD, are noted in patients with significant malnutrition.[66,67]

Kinetic Characteristics

Erythrocyte survival is modestly but significantly reduced in patients with ACD. In two studies comparing red cell survival in anemic patients with rheumatoid arthritis to red cell survival in normal individuals, the mean red cell survivals noted were 81 days versus 98 days, and 90 days versus 114 days, respectively.[68,69] In a similar study comparing red cell survivals in 10 anemic patients with a variety of chronic inflammatory states to 10 normal individuals, the mean values observed were 80 days versus 88 days, respectively.[68] The usual manifestations of increased blood destruction, such as increases in serum bilirubin values and urobilinogen excretion, are not typically observed.[2,70]

There is little evidence of a compensatory erythropoietic response to this reduction in red cell survival. The reticulocyte count usually is normal or decreased, and little or no erythroid hyperplasia of the marrow is observed. The pathogenetic significance of these findings is discussed in the following section. Kinetic data indicate that anemia develops because the bone marrow fails to increase red cell production sufficiently to compensate for a mild decrease in the lifespan of the red cells.[2,8,68] Ferrokinetic studies involving patients with chronic infections,[71,72] rheumatoid arthritis,[73] and various malignant diseases[21,22,74] reveal that the rate of disappearance of iron from the plasma is rapid, the plasma iron transport rate is normal or slightly increased, the uptake of iron into erythrocytes and the amount of iron turning over through red cells daily are normal or increased, and the fraction of red cells renewed daily is increased.[2] When techniques that allow the division of marrow iron turnover (a measure of total erythropoiesis) into red cell iron turnover and ineffective iron turnover were used, marrow iron turnover was normal in patients with ACD.[68,69,75,76] Ineffective iron turnover was also normal, or even less than normal, indicating a lack of ineffective erythropoiesis as traditionally defined.[68] In iron-deficient subjects, ineffective iron turnover is increased, perhaps because of greater stimulation of the marrow.

Pathogenesis

Efforts to clarify the pathogenesis of ACD have focused on three principal abnormalities: shortened erythrocyte survival, impaired marrow response, and disturbance in iron metabolism. The modest shortening of the erythrocyte survival creates an increased demand for red cell production on the marrow. Normally, the marrow could easily accommodate this demand, but in the setting of ACD, the marrow is unable to respond fully because of a combination of a blunted erythropoietin (Epo) response, an inadequate progenitor response to Epo, and limited iron availability (Fig. 41.2).

Cytokines

ACD is one manifestation of the systemic response to immunologic or inflammatory stress, which results in the production of various cytokines.[3,77] The ability to trigger this cytokine response appears to be the common pathogenetic factor shared by the various conditions associated with this anemia syndrome.[78] The central role of these molecules suggests that ACD may be best understood as a cytokine-mediated process.[6] The cytokines most often implicated in the pathogenesis of ACD are TNF,[79,80,81] IL-1,[82,83] IL-6,[84] and the interferons,[85–87] concentrations of which have been reported to be increased in the serum or plasma of patients with disorders associated with ACD.[85,87–89,90,91] Therapeutic administration of TNF or interferon may induce anemia.[92,93] The role of IL-6 is complex. IL-6 administration itself does not suppress erythropoiesis but rather is associated with increased plasma volume; therefore there is a dilutional component to any observed anemia.[17] The association of IL-6 with hepatocyte activation may thus explain the dilutional component of the anemia observed in liver disease.[94,95,96] However, IL-6 is also a potent inducer of hepcidin, proposed as a major mediator of the iron abnormalities of ACD.[5]

The Role of Hepcidin

While inflammation-induced cytokine activation is clearly the initial event in the pathogenesis of ACD, the liver-produced antimicrobial peptide hepcidin appears to be the most important mediator through which cytokines exert their effects on the pathogenetic mechanisms of ACD.[5,97,98] Hepcidin is an acute-phase-reacting peptide, largely regulated by IL-6 but also by cytokine pathways not linked to IL-6.[5,99,100] Patients with hepatic adenomas secreting hepcidin exhibit a hypoferremic anemia that resolves with resection of the adenoma.[97] Urinary hepcidin excretion is strongly correlated with serum ferritin concentration and is markedly elevated in patients with anemia of inflammation (defined as anemia

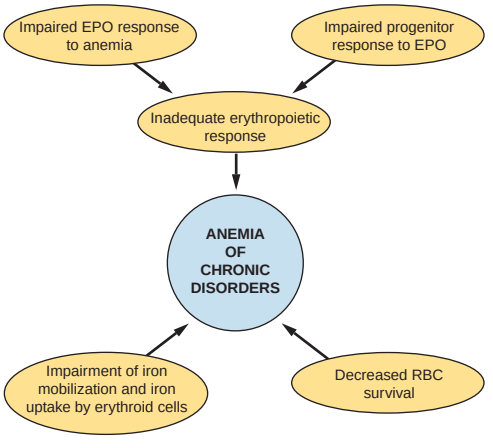

FIGURE 41.2. Schematic diagram representing contributing mechanisms in the pathogenesis of anemia of chronic disease. EPO, erythropoietin; RBC, red blood cell.

with a characteristic clinical setting and an elevated serum ferritin) compared to iron-deficient patients.[5] Hepcidin promotes macrophage iron retention by causing internalization of the iron export protein ferroportin.[101]

Of the pathogenetic mechanisms shown in Figure 41.2, hepcidin clearly drives the abnormalities in iron metabolism. However, it may be linked to other elements as well. Under conditions of limited Epo availability, hepcidin is associated with impaired erythroid colony formation in vitro.[102] Increased circulating hepcidin appears to be linked to the degree of resistance to recombinant (rh) Epo therapy in dialysis patients.[103] Hepcidin and Epo production appear to be regulated in an inverse relationship by hypoxia-inducible factor,[104] which may potentially provide some linkage between hepcidin and the relative Epo deficiency of ACD. This latter connection remains to be demonstrated.

Shortened Erythrocyte Survival

The rate of survival of cells from patients with arthritis, when transfused into normal subjects, is normal, and the survival of red cells from normal individuals in the circulation of patients with arthritis is less than the normal rate.[2,23] Therefore, shortened red cell survival in patients with chronic inflammatory disorders is attributed to an extracorpuscular mechanism.[30] IL-1 levels and shortened red cell survival are correlated in anemic patients with rheumatoid arthritis,[105] and mice that become anemic after exposure to TNF in vivo also exhibit a shortened red cell survival.[106] Neocytolysis, a selective hemolysis of newly formed erythrocytes associated with Epo deficiency,[107,108] has been proposed as a mechanism for shortened red blood cell survival in ACD. Peroxynitrite, derived from the reaction of the cytokine second messenger nitric oxide and superoxide, may contribute to red cell rigidity and thus to decreased survival.[109]

Impaired Marrow Response

Normal bone marrow, capable of a six- to eightfold increase in the red cell production rate, should easily compensate for such a modest reduction in erythrocyte survival. Its failure to do so in ACD suggests that impaired production capacity is of fundamental importance in the pathogenesis of this condition. The possible defects in erythropoiesis fall into three categories: inappropriately low Epo secretion, diminished marrow response to Epo, and iron-limited erythropoiesis.

An inverse relationship between serum or plasma Epo levels and hemoglobin normally exists: As the hemoglobin decreases, the Epo level rises.[110] A similar inverse relationship between hemoglobin and Epo level exists in anemic individuals with rheumatoid arthritis, cancer, and human immunodeficiency virus infection[111,112–114]; however, for any given anemic patient in these disease categories, the Epo level was lower than that found in equally anemic individuals with iron deficiency, indicating that the Epo response to anemia was blunted. This impaired Epo response is cytokine-mediated. IL-1, TNF-α, and transforming growth factor-β inhibit production of Epo by various hepatoma cell lines and by isolated perfused rat kidneys in vitro.[115,116] This effect occurs at the messenger RNA level.[115] It has been proposed that this inadequate Epo secretion is adaptive; that is, it reflects reduced tissue oxygen use so that normal oxygenation is maintained despite reduced hemoglobin levels. One colorful description of this process is that the "hematologic thermostat has been turned down a bit",[8] perhaps to allow diversion of substrates normally used in erythropoiesis to more immediately critical activities. Changes that ordinarily signify erythrocyte adaptation to tissue hypoxia, such as increased erythrocyte 2,3-diphosphoglycerate (2,3-DPG) levels, are observed in ACD.[117] Hemoglobin oxygen affinity is also slightly decreased in these patients but overlaps the range observed in normal subjects.[117]

Although the Epo levels of patients with ACD are lower than those observed in equally anemic iron-deficient individuals, they are still higher than are observed in normal individuals who are not anemic. This implies that inhibition of Epo production cannot entirely account for the impaired erythropoiesis associated with ACD, and that the erythroid progenitors themselves exhibit an abnormal response to Epo. Studies of anemic cancer patients support this concept.[118,119]

TNF, IL-1, and interferon have all been reported to inhibit erythropoiesis in vivo and in vitro.[90,92,120–128] TNF inhibits in vitro colony formation by human erythroid colony-forming units (CFU-E) indirectly, through interferon-β and possibly other soluble factors released from marrow accessory cells in response to TNF.[129,130] The inhibitory effect of rhIL-1 on human CFU-E colony formation was also indirect and dependent on marrow accessory cells; however, the responsible accessory cells in this case were T lymphocytes, and the mediator was interferon-γ, which also exhibits a direct inhibitory effect on human CFU-E.[131] Although interferon-α and interferon-β share a common receptor, interferon-α does not exert a direct inhibitory effect on human CFU-E colony formation. Instead, its effect is mediated through an unidentified soluble factor released by T lymphocytes.[132] The inhibitory effects of interferon-α and interferon-β exhibit synergy with interferon-γ.[132] An important point to consider in reviewing the various models for cytokine effects on erythropoiesis is that none of the systems described operates in isolation in vivo. Thus, TNF induces IL-1 production by macrophages, IL-1 induces interferon-γ production by T lymphocytes, and interferon-γ can exhibit positive or negative feedback on production of IL-1 and TNF.

Treatment with recombinant human Epo (rhEpo) can correct ACD in many cases. Inhibition of in vitro erythroid colony formation by interferon-γ, but not interferon-α and interferon-β, can be corrected by exposure to high concentrations of Epo.[132,133] Epo also suppresses hepcidin production.[134,135]

Abnormal Iron Metabolism

It has been proposed that lack of iron for erythropoiesis contributes to the inadequate marrow response in ACD. Evidence of a functional iron deficiency in this syndrome includes erythrocyte microcytosis, increased FEP,[14,56] reduced transferrin saturation,[24] and decreased marrow sideroblasts.[24]

Ferrokinetic studies have proved confusing. It has been reported that erythroid iron turnover correlated with serum iron levels, permitting a conclusion that marrow proliferation was limited by availability of iron in ACD.[118] Other studies found no correlation between marrow iron turnover and serum iron concentration.[68,69,76,136]

The major contributor to hypoferremia in patients with ACD is probably a shift of iron from a transferrin-bound, available circulating state to an intracellular storage state. Iron absorption appears to be normal, but iron tends to remain in the mucosal cell and in hepatocytes.[137,138] Macrophages, the major site from which iron is obtained for erythropoiesis, also exhibit increased iron storage. This process is mediated by hepcidin, which downregulates the iron egress regulatory ferroportin, thus trapping iron intracellularly.[101]

The dominant factor in the iron abnormalities of ACD is clearly hepcidin, discussed above and at greater length in Chapter 23. A number of other processes of less overarching significance may contribute under particular circumstances to the iron anomalies observed. Apoferritin is normally synthesized in response to increased intracellular iron concentration.[139] It has been suggested that excess apoferritin is made in inflammatory and malignant conditions, and the surplus binds a larger-than-usual amount of iron entering the cell.[140–142] In effect, such a mechanism would divert iron from the rapid to the slow pathway of iron release. Rodents injected with recombinant TNF developed

a hypoferremic anemia associated with impaired storage iron release and incorporation into erythrocytes.[106,143] It has also been reported that IL-1 increases translation of ferritin messenger RNA and that this additional ferritin could act as a trap for iron that might otherwise be available for erythropoiesis.[105] Nitric oxide, which is a common mediator of cytokine effects, has similar effects on ferritin expression.[144,145] Lactoferrin is a transferrin-like protein found in neutrophil-specific granules.[146,147] It is released from the neutrophil during phagocytosis or stimulation by IL-1.[148] At low pH, lactoferrin binds iron more avidly than does transferrin.[149] Lactoferrin-bound iron is not immediately available for erythropoiesis[150]; rather, it binds to specific receptors on macrophages (particularly in the liver and spleen) and is endocytosed and subsequently incorporated into ferritin.[151,152] Thus, lactoferrin transfers iron from its transferrin-bound, circulating state to a storage state, from which it cannot be rapidly mobilized.[153] One group of investigators found that reducing the available lactoferrin by inducing neutropenia in rats blunted the hypoferremic response to IL-1,[154] but another group found that administration of recombinant IL-1-induced hypoferremia in mice, even in the face of severe neutropenia.[155]

In addition to decreased availability of iron, erythroid progenitors may also be unable to fully use the iron available to them. Erythroblasts from anemic patients with rheumatoid arthritis express fewer surface TfR than do erythroblasts from normal individuals. These TfR also exhibit lower binding affinity for transferrin.[156] Furthermore, acute-phase reactants, such as α_1-antitrypsin, impair transferrin binding to erythroblasts and also inhibit transferrin internalization.[157] rhEpo appears to induce a greater level of TfR expression on erythroid cells.[158]

Anemia in Patients with Cancer

Much of the anemia commonly observed in patients with cancer can be attributed to the mechanisms involved in ACD; however, certain processes unique to malignancy may also contribute. Erythroid precursors may be displaced from marrow by metastatic tumor,[159] tumor-induced fibrosis,[160] or tumor-associated marrow necrosis.[161] The treatment of cancer can also produce or exacerbate anemia by a variety of mechanisms, including impaired Epo production[162] and cytotoxic effects of therapy on erythroid progenitors.[163]

Diagnosis

Studies suggest that diagnosis of anemia of moderate degree, as is commonly observed in ACD, is often missed.[164] ACD should be considered in anemic patients with associated inflammatory, infectious, or neoplastic states. As described in Table 41.1,[9] not all cases are associated with a classic chronic disease, but virtually all cases are associated with states of cytokine or immune activation. This is likely the mechanism associated with the increasing number of reports of ACD in congestive heart failure.[103,165–167] The diagnosis is confirmed by demonstrating hypoferremia with adequate reticuloendothelial iron stores in a patient with an appropriate clinical syndrome. Typically, the serum transferrin is either low or low normal, and sTfR concentration is normal in ACD. The major differential diagnosis is iron deficiency anemia. This is not a trivial distinction. The diagnosis of iron deficiency mandates identification of a source of blood loss. Incorrectly labeling a patient with ACD as iron-deficient exposes that patient to intrusive and expensive (although fairly safe) diagnostic procedures and to ineffective therapy. Mislabeling an iron-deficient patient as having ACD may result in failure to diagnose an underlying gastrointestinal malignancy at a curable stage and in failure to offer inexpensive and effective therapy. The diagnosis of iron deficiency is discussed in detail in Chapter 23 and in the section "Abnormal Iron Metabolism." It has been suggested that a marker of inflammation or cytokine activation, such as C-reactive protein or IL-6 should be an element of the diagnosis of ACD.[168,169] This may not be necessary in cases of ACD associated with "classic" ACD-related disease, like rheumatoid arthritis, but may be helpful in ACD which are less typical, or perhaps complicated by iron deficiency.

In principle, absence of an elevated serum or plasma hepcidin concentration could rule out ACD. When hepcidin assays become available for routine use in a clinical context, it will be important to carry out well-designed studies to determine whether they will contribute more to diagnosis than currently available clinical markers of iron status.[170]

Treatment

The focus of therapy should be on the underlying disorder. The anemia itself is rarely an important clinical problem. Thus, direct approaches to correction of the anemia are rarely necessary. Fewer than 30% of patients have anemia sufficiently severe to necessitate transfusion, and assessment of the symptomatic state should always be considered before administration of blood products.

rhEpo and the rhEpo analog darbepoetin, are effective in ACD but expensive,[171,172,173] and many if not most third-party payers will not reimburse for its use in ACD. It is not currently approved for this purpose in the United States. Limitations on the use of rhEpo in anemic cancer patients for safety reasons (discussed below) limit the use of rhEpo in ACD at present. Because most patients were not symptomatic from their anemia, symptomatic benefit was rarely reported in the initial studies.[171,172] Subsequent studies using more sophisticated evaluation instruments have reported increased quality of life in anemic patients with rheumatoid arthritis[174] or cancer[175] treated with Epo. It can also be used for ACD patients who wish to donate blood for autologous transfusion at elective surgery but are too anemic to do so[176] or to permit autologous blood donation by a patient with ACD and multiple alloantibodies.[177] It has been proposed that rhEpo administration may be of benefit in anemic patients with congestive heart failure.[178–181,182]

It is debated whether or not to administer iron routinely to patients receiving therapy with Epo products. It is this author's practice to do so in the absence of elevated serum ferritin levels. In one study of anemic patients with rheumatoid arthritis, the concurrent use of iron supplementation was a powerful predictor of response to Epo[183]; however, many of the patients in this study may have been iron-deficient. Although there are reports of correction of ACD by intravenous iron without Epo,[40,184] normalization of hemoglobin was largely seen in patients who were also iron-deficient.[40] Iron therapy by itself is likely to be useful only in patients who have concurrent iron deficiency,[10] and then only for the component of anemia caused by iron deficiency. There is no convincing evidence that iron alone corrects ACD per se. Anemic cancer patients treated with concurrent intravenous iron and rhEpo appear to have a better response than those treated with no iron supplementation or with iron supplementation alone.[185]

Studies of the use of rhEpo in cancer patients have been associated with increased adverse outcomes in certain cases,[186,187,188,189,190] leading to restrictions on circumstances in which rhEpo can be used in cancer therapy. While there is debate in the literature as to whether the observed outcomes reflected unique features of particular rhEpo regimens or of specific patient populations,[191–193] the clinician is encouraged to review current guidelines prior to initiating therapy.

As noted earlier, Epo downregulates hepcidin production. Given the significant role of hepcidin in the pathogenesis of ACD, therapy directed against hepcidin would be attractive in principle. Antisense hepcidin has been reported to decrease anemia in an animal inflammation model.[194] At present, however, there are no specific antihepcidin agents available for clinical use.

ANEMIA OF CHRONIC RENAL INSUFFICIENCY

Anemia is an almost invariable manifestation of chronic renal failure, often contributing substantially to the morbidity of the condition. It may be considered as typical of the disease as azotemia.[195] In the era before the availability of rhEpo, 98% of patients on hemodialysis were anemic[196]; even now, 48% of renal failure patients before dialysis and 28% of hemodialysis patients have hematocrit values <0.30.[197,198] The term *anemia of chronic renal insufficiency* refers to that anemia resulting directly from failure of the endocrine and filtering functions of the kidney. The kidney is the major source of Epo, and the ability to secrete this hormone is lost as the kidney fails. In addition, renal failure is associated with other pathologic processes, including some that may inhibit erythropoiesis and others that may shorten erythrocyte survival. Lack of sufficient Epo is by far the most important of these anemia-causing factors; consequently, the hypoproliferative features of the anemia tend to predominate.[199]

In clinical settings associated with chronic renal failure, additional factors may also contribute to the development of anemia, but these should be considered complications rather than fundamental components of the anemia of renal insufficiency itself. In the presence of infection or inflammation, ACD is likely to be observed. Iron deficiency anemia (see Chapter 23) may develop because of blood loss from the gastrointestinal tract or (less frequently) hematuria or from retention of blood in the hemodialysis apparatus tubing.[199,200] The megaloblastic anemia of folate deficiency also may occur in patients on dialysis[201,202] but is otherwise uncommon.[203] Certain types of renal disease, including the hemolytic–uremic syndrome or thrombotic thrombocytopenic purpura, are associated with microangiopathic hemolytic anemia (see Chapter 48). Finally, aluminum intoxication can cause microcytic anemia in dialysis patients, although this has become rare in modern dialysis practice.[204]

Clinical Description

Chronic renal failure occurs during the final stages of several renal diseases. As a rule, the nature of the underlying disease bears little relation to the degree of anemia, although anemia may be less severe in patients with hypertensive renal disease[205] and is considerably less severe in patients with polycystic disease.[206,207] In one series, the mean hematocrit in 12 subjects with polycystic disease was 0.297, compared with 0.212 in 24 subjects with other types of chronic renal failure.[207] Apparently, the Epo-secreting function of the kidney is preserved in polycystic disease—even when the filtering function is lost.[207,208] Erythropoietic activity can be found in the cystic fluid and may arise from single interstitial cells juxtaposed to proximal tubular cysts.[207]

In most instances, the patient seeks medical attention because of symptoms related to the underlying renal disease, and anemia is an incidental finding. Occasionally, however, the renal symptoms are so subtle and so slowly progressive that the patient cites only symptoms of pallor, exertional dyspnea, or other signs of the cardiovascular adjustment to anemia. The severity of the anemia bears a rough relationship to the degree of renal insufficiency. Anemia is not routinely observed until the creatinine clearance falls to <45 ml/minute/1.73 m^2 body surface area, which corresponds roughly to a serum creatinine of 2.0 to 2.5 mg/ml in an average-sized adult.[209] At creatinine clearance rates below that, a statistically significant correlation between creatinine clearance and hematocrit has been reported.[210,211] However, the variation in the results of these studies is so great that one cannot reliably predict the hemoglobin level in an individual patient on the basis of renal function.

Laboratory Findings

Anemia tends to become more severe as renal failure worsens, but in most patients the hematocrit ultimately stabilizes between 0.15 and 0.30.[2] Because regulation of body water and electrolyte balance is impaired in renal disease, the apparent degree of anemia may be exaggerated or minimized by alterations in plasma volume.

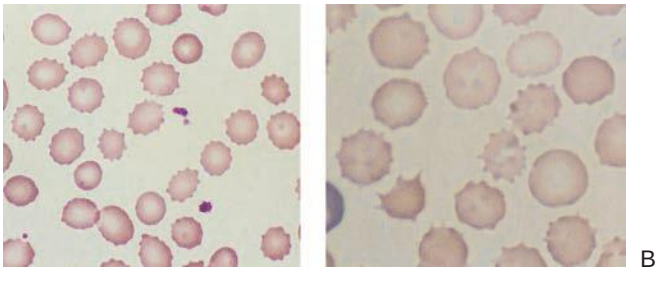
The erythrocytes usually are normocytic and normochromic, but slight macrocytosis is occasionally observed.[212] The majority of red cells appear normal on blood smears. Occasionally, however, "burr" cells (Fig. 41.3) are observed along with some triangular, helmet-shaped, or fragmented cells. The reticulocyte count often is within normal limits,[213] but it may be moderately increased.[212,214] In one study, the numbers of reticulocytes were normal when the blood urea nitrogen (BUN) value was <130 mg/dl; at higher BUN levels, however, their number often was increased.[215] The highest values (average, 6%) were observed with extreme azotemia (BUN, 300 to 350 mg/dl).

The leukocyte count typically is normal, but slight neutrophilic leukocytosis may be observed. In one series, the leukocyte count averaged 10.7 × 10^9/L.[213] The platelet count is either normal or slightly increased,[213] but platelet function may be severely impaired, resulting in defective hemostasis (see Chapter 52).

The bone marrow tends to be moderately hypercellular, and slight erythroid hyperplasia may be observed. The myeloid-to-erythroid ratio averaged 2.5:1.0 in one study.[213] Erythroid maturation appears morphologically normal. In some instances, especially when renal failure is relatively acute, hypoplasia of erythroid elements is noted.[216,217] In a study of 100 predialysis renal failure patients with hemoglobin concentrations less than 11 g/dl and not treated with rhEpo, 48% of patients had no detectable bone marrow iron.[218]

The serum bilirubin level was within normal limits in all of the 26 patients in one series.[208] The hemolytic index, a measure of urobilinogen excretion in relation to total circulating hemoglobin, was increased in ~40% of patients evaluated.[212,219]

Values for serum iron vary considerably in renal disease.[212,219] As a rule, the value is normal when renal impairment is mild. With more severe disease, some investigators observe a decrease in serum iron levels,[220] whereas others note hyperferremia.[220,221] Whether a characteristic disturbance of serum iron concentration is associated with "uncomplicated" renal failure remains to be determined. One group of investigators has reported that the gastrointestinal absorption of iron is reduced in patients with chronic renal failure.[222] Other researchers, using a different method, found that iron absorption was related to disturbances in iron balance and was unrelated to the degree of anemia, the rate of erythropoiesis, or the degree of azotemia.[223] FEP may be normal or moderately increased,[212] but the increased values seem to occur only in patients with hypoferremia.[224] The erythrocyte lactate dehydrogenase level is within normal limits.[225] Serum hepcidin levels in dialysis patients appear to track with iron status, and to be low in the iron-deficient.[226] At any given level of iron stores, higher hepcidin levels appear to predict anemia progression.[227]



A B

FIGURE 41.3. A: Crenated cells in renal disease (×1,500). B: Burr cells in renal disease (×3,000).

The glycated fraction (A_1) of hemoglobin (the best-known component of which is hemoglobin A_{1c}) tends to increase in chronic renal failure. In uremic patients who have not undergone dialysis, the hemoglobin A_1 value averaged 10.8% of the total hemoglobin, compared with 7.1% in nonuremic individuals.[228] In uremic patients treated with dialysis, the value averaged 8.8%. The increase is thought to result from carbamylation of the hemoglobin molecule by urea-derived cyanate; it can be detected by using column chromatography but not by using certain chemical methods designed for hemoglobin A_{1c}. The magnitude of the increase usually correlates with the average value for BUN over the preceding 2 to 3 months. The increase in the A_1 fraction may continue after successful renal transplantation has brought the azotemia under control; in this case, the increase might reflect disturbed carbohydrate metabolism[229] and probably reflects hemoglobin A_{1c}.

Pathogenesis

It has been known for many years that three factors are involved in the pathogenesis of anemia of chronic renal failure. These factors are Epo deficiency, suppression of marrow erythropoiesis, and shortened red cell survival.[230–232] When anemia is severe, ferrokinetic studies typically demonstrate that the plasma iron transport rate is normal, but red cell iron utilization and erythrocyte iron turnover are decreased.[199,212] With milder degrees of anemia, ferrokinetic measurements tend to be near normal. In anemic patients, however, such "normal" values indicate an insufficient marrow response to the stimulus of anemia. The success of recombinant Epo in the treatment of anemia of renal failure has caused the other two factors to receive short shrift in recent years.

As renal function deteriorates, renal Epo secretion decreases.[232,233] Measured Epo values may be lower than normal, higher than normal, or normal.[210,232–234] However, it is important to remember that even the "increased" Epo concentrations observed in this syndrome are still strikingly low for the degree of anemia.[235] Overall, the usual relationship between Epo and hemoglobin concentrations is lost, indicating a loss of customary feedback mechanisms.[211] Some capacity to induce Epo secretion is preserved, however, because even the very low levels of Epo secretion in renal disease change in response to hemorrhage or transfusion.[231] Certain extrarenal sources of erythropoietic hormone account for some of the activity found in serum, especially that found in anephric subjects.[235,236] This extrarenal Epo secretion does not, however, appear to increase sufficiently in response to anemia to compensate for deficiencies at the renal source.[237] Elegant studies in sheep[238] and subsequent confirmatory studies in human patients[239,240] have established the primacy of Epo deficiency in the pathogenesis of anemia of chronic renal failure.

There is also a significant body of data suggesting that the inadequate marrow response to anemia is not due solely to Epo deficiency. The observation that the rate of erythropoiesis improved in patients treated with dialysis even though Epo levels were unchanged[214,241] suggested that retained uremic toxins depress erythropoiesis directly. This field of research has been quite confusing, because not all investigators have been able to confirm the presence of inhibitors or to demonstrate their specificity. Several groups of investigators have shown that plasma from uremic patients can depress heme synthesis,[242] or inhibit growth of erythroid colonies in vitro, or both.[243–246] The polyamine spermine and other molecules that accumulate in renal failure have been proposed as candidates.[244,245,247–249] Inhibitors of multipotential stem cell (colony-forming unit granulocyte-erythroid-macrophage-megakaryocyte) growth have also been detected in uremic plasma,[250] but they are of uncertain pathophysiologic importance.[244] Parathyroid hormone, associated with secondary hyperparathyroidism in renal failure patients, may also contribute to marrow suppression.[251] The hematocrit increases in approximately one half of the patients with renal failure who undergo parathyroidectomy, although only to a modest degree.[252,253,254] Some, but not all, investigators suggest that levels of parathyroid hormone similar to those found in the serum of uremic patients depress the growth of erythroid colonies in vitro.[251,255–257] Hyperparathyroidism may also exert its effects by causing marrow fibrosis.[252,254]

Allen and colleagues have demonstrated that inhibition of erythroid colony formation by uremic serum can be abrogated by neutralizing antibodies to TNF and interferon-γ.[12] These data suggest that cytokine-mediated anemia mechanisms typically associated with ACD may be active in renal failure.[258] It is also possible that the excellent response of anemia of renal failure to Epo does not indicate a lack of contributing inhibitors but rather reflects the ability of Epo to overcome an inhibitor, as has been reported for interferon-γ.[133]

A third pathogenetic factor is hemolysis. Erythrocyte survival, although often within normal limits, may be slightly to moderately reduced.[259] Depending on the evaluation technique used, 20% to 70% of uremic patients show shortened red cell survival.[195,212,214,220] The extent to which red cell survival is decreased is somewhat related to the degree of azotemia.[199] Cross-transfusion studies suggest that the hemolytic factor, when present, is extracorpuscular. Survival of normal cells transfused into patients is shortened, whereas patients' cells survive normally in normal recipients.[195,212,220] Less commonly, shortened survival of uremic patients' cells is observed even in normal subjects.[220] In some patients, splenic sequestration of red cells may be a contributory factor.[260]

The hemolytic factor(s) is presumed to be a toxic substance (or substances) normally excreted or metabolized by the kidney. Guanidine and its derivatives appear to be a subset of the many retained metabolites that adversely affect erythrocyte survival.[12,261] The hypothetical factor(s) is apparently not dialyzable.[230] Peroxidation of membrane lipids by free radicals may also contribute to the shortened survival observed.[262]

In ~20% of uremic patients not treated with dialysis, the red cell pentose phosphate pathway is impaired as a result of a poorly defined substance in the plasma.[263,264] This defect is best detected by using the ascorbate-cyanide test; other tests of pentose phosphate pathway function may yield normal results.[265] Administration of glutathione returns the ascorbate-cyanide test to normal.[262] Oxidant drugs, such as primaquine or sulfonamides, produce a Heinz body hemolytic anemia in patients with the pentose phosphate pathway defect. Even in the absence of drug exposure, Heinz bodies may be observed in the red cells of uremic patients if they have undergone splenectomy.[266] Contamination of dialysate water by chloramines, which inhibit phosphoglyceromutase and thus cause accumulation of glycolytic intermediates, may worsen this defect.[267,268] Decreased oxidative stress may also contribute to the observed lower frequency of anemia in patients undergoing peritoneal dialysis compared to those on hemodialysis.[269] In one study, use of the antioxidant N-acetylcysteine was associated with improved hematocrit.[270]

Cation transport may be impaired in uremic red cells: The defect reverts toward normal after dialysis.[271,272] When sensitive measures are used, nearly all patients can be shown to have such an abnormality[272]; in those most severely affected, the erythrocyte sodium concentration is increased.[271] Considerable disagreement surrounds the nature of the defect, with various investigators reporting abnormalities in cation pump site number or function[271,272] and others reporting the presence (or absence) of soluble, dialyzable inhibitors of pump function.[273–275]

Evidence of impaired erythrocyte glycolysis has been found in uremic patients[276]; however, in most studies, the overall glycolytic rate is increased,[277,278] probably because of the elevation in plasma levels of inorganic phosphorus.[277] The increase in the glycolytic rate probably accounts for the observed increase in red cell

adenosine triphosphate levels.[277,279] Hemoglobin oxygen affinity is reduced,[280] presumably because of increased erythrocyte adenosine triphosphate and 2,3-DPG levels. Such abnormalities would not be expected to cause reduced red cell survival.

Neocytolysis, the selective hemolysis of newly formed red cells, has been reported after Epo withdrawal in dialysis patients and may contribute to shortened red cell survival in dialysis patients.[281]

Management and Course

Recombinant Human Erythropoietin

rhEpo has been available for treatment of anemia of renal disease since the mid 1980s[240,282] and has revolutionized the approach to this disorder. Therapy with this agent or rhEpo analogs such as darbepoetin,[283] is safe and effective, and has been reported to improve quality of life and cognitive function.[284,285] It is the treatment of choice for anemia in renal insufficiency, being effective in patients receiving peritoneal or hemodialysis.[286] It is equally efficacious in anemia due to renal insufficiency that is not sufficiently advanced to require dialysis, but in which the creatinine clearance is <45 ml/minute/1.73 m^2 body surface area or the serum creatinine is >2.5 mg/ml.[210,232,287,288]

Epo can be administered intravenously or subcutaneously. Although Epo was originally given three times weekly (to coincide with dialysis schedules), single weekly or less frequent dosing schedules are similarly efficacious if the dose is increased appropriately.[289] A standard starting dose would be 100 to 150 U/kg/week or its equivalent. Higher doses generally result in faster correction of anemia; target hemoglobin is typically attained within 6 to 8 weeks.[287,290] Iron supplementation is generally necessary, particularly in patients on hemodialysis. The target hemoglobin range is to be no higher than 11 to 12 g/dl; some reports suggest that higher levels may have an adverse clinical impact.[291] The long-acting Epo analog darbepoetin (novel erythropoiesis-stimulating protein) appears to be safe and effective in the anemia of renal failure.[290,291,292,293] The recommended starting dose is 0.45 μg/kg/week for patients on dialysis, and 0.45 μg/kg/ 4 weeks for patients before dialysis.

Continuous Epo receptor activator is a new peptide agent which is not an Epo analog but which activates the Epo receptor. Its role in the management of the anemia of renal failure is under study.[294]

Side Effects/Adverse Reactions

As noted earlier, rhEpo products are generally safe but complications may occur. When used for anemia in renal disease, increased blood pressure is an important complication, experienced by up to 35% of patients.[295,296] Rarely, the hypertension is abrupt and severe with encephalopathy and seizures.[297]

The occurrence of hypertension appears to be more closely related to the rate of increase in the blood hemoglobin level than the dose of rhEpo.[298] It tends to be a transient phenomenon confined to the first 3 to 6 months of treatment. The pathogenesis is incompletely understood and probably multifactorial.[298] Because heart rate, stroke volume, and cardiac output decrease as anemia is corrected, an increase in peripheral vascular resistance may be responsible. Daytime vasoconstriction may be a consequence of reduced plasma volume.[295] Left ventricular hypertrophy, an important predictor of cardiac morbidity and mortality in renal patients, tends to decrease by ~18% within a year of correction of anemia; this beneficial effect may be diminished by hypertension.[296] However, Epo can also contribute to hypertension through vasopressor effects, often mediated by nitric oxide, which appear most active in renal insufficiency.[299,300,301]

In early studies, prolonged or less effective dialysis[302,303] and increased thrombotic events were thought to be problems associated with Epo treatment, but these concerns were not borne out in a large study.[286] Anaphylaxis in response to Epo has been described but is extremely rare[304].

Erythropoietin Resistance

As mentioned earlier, more than one-fourth of hemodialysis patients have a hematocrit <0.30. The failure of patients to respond optimally to Epo therapy or a requirement for unusually high doses is referred to as *Epo resistance*. The possible causes of Epo resistance are listed in Table 41.2.

Iron deficiency is the most common cause.[305,306] Loss of blood in the dialysis apparatus is an important source of iron depletion.[307] Most patients require iron supplementation at some time during their course.[308] In general, those with serum ferritin levels <100 to 200 μg/L or with transferrin saturation values <20% to 25%[309–311] require iron supplementation, but such values may not appear until resistance to rhEpo becomes apparent. In another study, patients with serum ferritin values between 100 and 400 ng/ml were as likely to respond to iron replacement as those with serum ferritin <100 ng/ml.[312] Other investigators found that a low MCV, but not a low serum ferritin, predicted response to iron replacement.[313] The best early predictors of Epo response are serum sTfR concentration and serum fibrinogen.[314] Response rate approaches 100% when both are low and 29% when both are high, reflecting both the patient's iron status and the presence or absence of inflammation. Some authors recommend routine oral iron supplementation for all patients. However, oral iron administration can be limited by intolerance, so that compliance is relatively poor.[308] Efficacy may also be limited. Consequently, intravenous iron replacement is recommended for dialysis patients.[315,316,317] Studies comparing oral versus intravenous iron supplementation generally find that the intravenous replacement group achieves higher hemoglobin levels with lower Epo use.[313,318] In order to avoid iron overload, intravenous iron replacement is discontinued or decreased when the ferritin exceeds 500 ng/ml.[319]

Inadequate hemodialysis is associated with Epo resistance.[320] As a general rule, the intensity of dialysis must be sufficient to reduce the BUN by 65% or more to ensure optimal Epo response. Such factors as the frequency and duration of dialysis and characteristics of the dialyzer may need to be adjusted to achieve this goal.[321,322] Mortality is also reduced by attention to dialysis

TABLE 41.2

CAUSES OF ERYTHROPOIETIN RESISTANCE

Splenomegaly

intensity. Rates of reimbursement for dialysis in the United States have discouraged optimal intensity, with the result that mortality is higher there than in Western Europe and Japan.

As discussed earlier, secondary hyperparathyroidism often accompanies renal failure, and the associated marrow fibrosis may contribute to the anemia[251,252,254] and to Epo resistance. Treatment with vitamin D_3 can decrease rhEpo requirements and improve hemoglobin values.[323] Aluminum toxicity is an uncommon cause of anemia and responds to chelation therapy.[324]

If Epo resistance is associated with an increased MCV, folate supplementation is warranted.[201] Serum folate levels may not be helpful in this situation. In some cases, iron replacement may unmask folate deficiency in dialysis patients.[313]

Associated infections or inflammatory states, as in ACD, may provoke cytokine-mediated anemia mechanisms. In addition, there are a number of minor etiologies of Epo resistance. The use of angiotensin-converting enzyme inhibitors in renal failure patients (particularly those undergoing transplantation) may exacerbate Epo resistance.[325,326] Splenomegaly may create a requirement for higher Epo dosing: This is resolved by splenectomy.[260] Infrequent cases of Epo resistance due to anti-Epo antibodies, including production of pure red cell aplasia, have been reported.[327,328,329] It appears to be a result of packaging and delivery characteristics of particular Epo products (especially in Western Europe and Canada), rather than a reaction to Epo itself. This topic is discussed at length in Chapter 39.

Renal Replacement Therapy

Renal replacement approaches (transplantation and dialysis) aim to restore or substitute for lost renal function. As such, they may have some effects on anemia associated with renal failure.

Renal Transplantation

In many ways, renal transplantation is the most complete and satisfactory treatment for renal insufficiency. With a successful graft, the hematologic response is often striking. Anemia is usually corrected over an 8- to 10-week period.[330–332] For the most part, the improvement results from Epo secretion by the grafted kidney. Two peaks of Epo secretion have been documented: an early peak, in which serum Epo levels increase approximately ninefold and then return to normal after ~7 days; and a second, smaller, more sustained increase in Epo levels, which begins on approximately day 8 and is accompanied by reticulocytosis and a gradual increase in hemoglobin levels. Epo values return to normal when the hematocrit reaches 0.32. The early peak is seen only in patients with delayed graft function and is not associated with hematologic improvement.[330,332] The second peak is associated with recovery of the graft excretory function and is presumed to be the important factor in the hematologic response.

Approximately 80% of patients experience an increase in blood hemoglobin concentration after renal allograft.[331] Failure to respond usually can be explained on the basis of hemorrhage, vigorous immunosuppression, or graft rejection. The rejection phenomenon often is accompanied transiently by increased Epo levels,[333,334] but this is followed by a profound reduction in Epo levels and reticulocyte counts.[335] Improvement in erythropoiesis occurs earlier when cyclosporine is used for immunosuppression rather than with antilymphocyte globulin. With the latter, the reticulocyte peak is delayed ~2 days. Cyclosporine immunosuppression, however, may be associated with slower correction of the anemia.[335] In ~20% of transplant patients, erythrocytosis follows correction of the anemia.[330] This complication is discussed in Chapter 48 and can sometimes be avoided by pretransplant use of Epo.[335]

Dialysis

Most patients with end-stage renal disease are maintained on dialysis. As a modality for managing anemia, dialysis has been essentially eclipsed by the availability of Epo and is primarily of interest because the mild increment observed in hemoglobin concentration provides circumstantial evidence for the role of circulating inhibitors. Red cell production increases slightly in patients on hemodialysis, with attendant small increases in hematocrit and decreases in transfusion requirement.[336]

As a general rule, anemia is less severe in patients receiving peritoneal dialysis, with consequently lower Epo and transfusion requirements.[337–342] Increments in hemoglobin in the absence of Epo are gradual and of modest extent: They are accompanied by an increase in red cell mass and a reduction in plasma volume.[340] The reasons for the beneficial effects of peritoneal dialysis on erythropoiesis are not firmly established. An increase in Epo production has been reported,[339] whereas other data suggest that removal of inhibitors in the "middle molecule" range (500 to 1,500 daltons) is the important mechanism.[343] Induction of a lower degree of red cell oxidative stress by peritoneal dialysis compared to hemodialysis has been suggested as an alternative explanation.[269]

In the Epo era, the importance of other treatments for anemia of renal disease, such as androgens, has become of primarily historical interest. Blood transfusion support may still be required for patients who fail to respond to rhEpo products. The risks of bloodborne infections and of iron overload are significantly increased by the use of transfusion.[336]

ANEMIA IN CIRRHOSIS AND OTHER LIVER DISEASES

Some degree of anemia is commonly observed in patients with liver disease. Although it has been studied most extensively in patients with alcohol-induced cirrhosis (Laennec cirrhosis), changes in red cell morphology and other contributors to anemia have been observed in various other liver diseases, including biliary cirrhosis,[344] hemochromatosis,[96] postnecrotic cirrhosis, and acute hepatitis.[345] When the term *anemia of liver disease* is used, it refers to the mild to moderate anemia associated with liver disease in the absence of any complicating factors such as blood loss, marrow suppression by exogenous agents, or nutritional deficiency. This syndrome apparently results from a combination of intravascular dilution due to volume overload, shortened red cell survival, and impaired ability of the marrow to respond optimally to the anemia. In addition, some patients develop a severe hemolytic anemia associated with morphologically abnormal erythrocytes (spur cells). Hemolytic anemia associated with Wilson disease is discussed in Chapter 32.

The anemia actually observed in patients with liver disease reflects both the "uncomplicated" anemia discussed above and the consequences of factors extrinsic to the liver itself. Alcohol abusers can develop a characteristic sideroblastic anemia, often accompanied by impaired folate metabolism or overt folate deficiency (see Chapter 36), or may have direct suppression of hematopoiesis by alcohol.[346] Individuals with cirrhosis of any etiology are at increased risk for hemorrhage. Blood loss occurs in 24% to 70% of patients with alcoholic cirrhosis.[96] The upper gastrointestinal tract is the major site of bleeding, but loss of blood from the nose, hemorrhoids, and uterus often occurs in association with coagulopathy of hepatic origins.

Prevalence and Clinical Manifestations

Approximately 75% of patients with chronic liver disease develop anemia as defined by a reduction in the hematocrit or hemoglobin level.[95,96,347] The whole blood volume in liver disease (especially cirrhosis) averages 10% to 15% greater than normal but may be as much as 30% to 35% increased; thus, hemodilution tends to exaggerate the prevalence and degree of anemia.[95,96,347,348]

For the same reason, the hematocrit may be decreased despite a normal red cell mass. The majority of cirrhotic patients are described as anemic, but in only 30% to 40% is the red cell mass reduced.[95,348] Patients with more severe liver disease and bleeding tend to have reduced red cell mass.[96] The magnitude of the hypervolemia in cirrhosis appears to be related to the degree of portal hypertension, but not to the presence or absence of ascites (Table 41.3).

The anemia is usually mild to moderate. In cirrhotic patients, the hemoglobin level averages ~12 g/dl or the hematocrit ~0.36.[96,348] The hemoglobin level rarely falls below 10 g/dl in the absence of bleeding or severe hemolysis. Approximately 5% of liver disease patients, all of whom have relatively severe hepatocellular disease, develop spur cell hemolytic anemia and hemoglobin concentrations <10 g/dl.[349] Spur cell anemia may be seen chronically with cirrhosis, or it may develop rapidly in association with fulminant hepatic failure. Morphologic and hemolytic abnormalities may resolve or diminish if liver function improves. Spur cell anemia can also occur in infants with cholestatic liver disease.[350]

Episodic hemolysis can occur in association with alcoholic liver disease even before cirrhosis.[351,352] These episodes are typically related to binge drinking, are usually mild to moderate in severity, and tend to resolve in 2 to 4 weeks if the patient abstains. Splenomegaly is not a major finding in these patients. When accompanied by jaundice and hyperlipidemia, the condition is known as *Zieve syndrome*.[353,354,355] It is unclear whether this transient form of hemolysis in liver disease is a syndrome of discrete and characteristic pathogenesis or simply a coincident constellation of abnormalities to which patients with liver disease are prone independently. The clinical diagnosis of hemolysis in alcoholic liver disease is problematic in any event, because interruption of alcohol intake is frequently accompanied by reticulocytosis, and liver disease of any etiology may be associated with jaundice.

Hematologic Findings

More often than not, anemia of liver disease is mildly macrocytic: The MCV rarely exceeds 115 fl in the absence of megaloblastic changes in the bone marrow.[95,96] When macrocytosis (particularly with very elevated MCVs) is found in patients with liver disease, complicating folate deficiency or stimulated erythropoiesis must be suspected, but such findings may not explain the macrocytosis observed in patients with milder forms of the disease.[356] The reported proportion of patients with liver disease who have increased MCV varies from 33% to 65%.[96,347,357–359] Even more common is "thin" macrocytosis—an increase in mean cell diameter with a normal mean cell volume. In one study of 222 patients with various kinds of liver disease, the mean cell diameter was increased in 137 (62%).[358] The patients were classified into three groups: thin macrocytosis (81 patients), target macrocytosis (39 patients), and thick macrocytosis (17 patients). The MCV was increased only in the last group. In a sense, thin macrocytes and target macrocytes are the mirror image of the microspherocytes observed in autoimmune hemolysis. The latter result from a decreased membrane pulled more tightly over a constant volume; the former result from a membrane that is more abundant.

The reticulocyte count often is increased, but this depends on the point in the natural history of disease at which it is measured. In one series, the mean reticulocyte percent of all anemic cirrhotic patients was only 2.8%.[95] However, erythropoiesis can be transiently suppressed by alcohol, and after acute alcohol withdrawal, reticulocyte percentages in the 8% to 10% range are not uncommon.[346,357,360] Sustained reticulocytosis of 15% or more is unusual in the absence of hemorrhage, spur cell anemia, or other complicating conditions.

Target cells and cells with increased diameters are evident on blood smear (Fig. 41.4). The cells appear hypochromic, but the appearance is related to the thinness of the cell rather than to reduced hemoglobin concentration. These morphologic changes are accompanied by increased resistance to hemolysis in osmotic fragility tests.[358] When spur cell hemolytic anemia supervenes, characteristic acanthocytes—erythrocytes covered with five to ten spike-like projections—are evident. The acanthocytes are morphologically indistinguishable from the distorted erythrocytes found in patients with abetalipoproteinemia. Stomatocytes are sometimes observed in association with the transient hemolytic episodes associated with acute fatty liver disease,[361] but they are also noted in alcoholics who display no evidence of hemolysis.[362]

Approximately 50% of patients with cirrhosis have mild thrombocytopenia, but values $<50 \times 10^9$/L are uncommon.[95,347] A variety of leukocyte abnormalities may be observed; in a study of 25 patients, 16 had lymphopenia, 4 had neutropenia, and 12 had neutrophilia.[347]

Bone marrow cellularity is normal or increased.[96,347,359] Often, erythroid hyperplasia is observed. Red cell precursors at times have been described as *macronormoblasts*, a term that implies their size is increased, but their nuclear chromatin appears normal.[347,359,363] Frank megaloblastosis is seen in <20% of patients.

Pathogenesis

Shortened Erythrocyte Survival

Red cell survival is decreased in approximately two-thirds of patients with alcoholic liver disease. The precise extent to which this occurs varies depending on the technique used to measure survival, but it is usually of only moderate degree.[95,96,345] Shorter survival tends to be observed in more anemic patients.

TABLE 41.3

CHANGES IN BLOOD VOLUME IN PATIENTS WITH CIRRHOSIS

Measurement	Normal Subjects	Patients with Cirrhosis	
		Without Ascites	With Ascites
Hematocrit	0.42	0.35 (−17%)	0.34 (−19%)
Red cell mass (ml/kg)	23	20 (−13%)	19 (−17%)
Plasma volume (ml/kg)	42	57 (+35%)	55 (+31%)
Whole blood volume (ml/kg)	65	74 (+14%)	74 (+14%)

Values are means of 24 normal subjects, 63 patients with cirrhosis and no ascites, and 34 patients with cirrhosis and ascites. All groups included approximately twice as many men as women.
Data modified from Lieberman FL, Reynolds TB. Plasma volume in cirrhosis of the liver. J Clin Invest 1967;46:1297–1308.

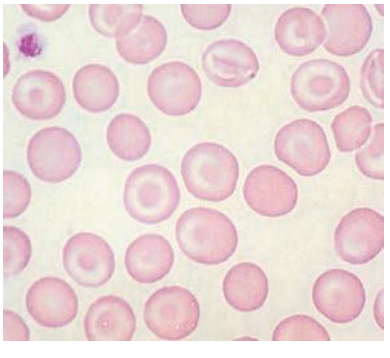

FIGURE 41.4. Macrocytes and target cells in liver disease (×1,500).

When indirect bilirubinemia is observed in a liver disease patient (elevated total bilirubin with >70% indirect), erythrocyte survival is particularly likely to be reduced.[364] Erythrocyte survival also was significantly shortened in patients with biliary cirrhosis,[344] obstructive jaundice, and infectious hepatitis,[345,364] even in the absence of anemia.

The mechanism for the observed decrease in red cell lifespan is not fully understood; it is most probably multifactorial. Results of cross-transfusion studies demonstrate improved survival when patients' cells are transfused to normal recipients, suggesting that the hemolytic mechanism is extracorpuscular (i.e., not intrinsic to the erythrocyte).[365] Congestive splenomegaly and splenic sequestration are major suspects in this category,[96,351,357,366,367] although they cannot always be demonstrated.[96] In some cases, correction of the hemolytic process may occur after splenectomy.

Abnormal erythrocyte metabolism is a possible intracorpuscular factor leading to reduced erythrocyte survival in liver disease. Activity of the methylene blue-stimulated pentose phosphate shunt is decreased, with consequent glutathione instability and a tendency to form Heinz bodies.[368,369] This metabolic abnormality renders the cell sensitive to oxidant hemolysis, but whether this form of hemolysis is an important mechanism of shortened erythrocyte survival in liver disease is uncertain, because a comparable shunt defect in most patients with glucose 6-phosphate dehydrogenase deficiency does not lead to hemolysis unless oxidant drugs are encountered. However, oxidant drugs can produce hemolysis in liver disease, as when patients with hepatitis C are treated with ribavirin.[370] Another metabolic abnormality encountered occasionally in liver disease is hypophosphatemia, with reduced erythrocyte adenosine triphosphate levels and consequent hemolysis.[371]

Characteristic alterations in red cell membrane lipids are found in patients with hepatitis, cirrhosis, and obstructive jaundice and may also be another contributor to shortened red cell survival.[351,372–375,376,377] In the usual uncomplicated case, a 25% to 50% increase in both cholesterol and lecithin is noted in the membrane. These changes result in an increased cell surface area associated with the target cells or thin macrocytes that are so characteristic of liver disease. The loss of sialic acid from the red cell surface may contribute to impaired viability of the cell.[378] Bile duct obstruction leads to an increase in the activity of neuraminidases, enzymes that remove sialic acid. However, it is not proven that such abnormalities shorten red cell survival.[351]

In spur cell hemolytic anemia, the erythrocyte membrane accumulates excess cholesterol without a corresponding increase in lecithin, resulting in the characteristic morphologic abnormality. This change is accompanied by pronounced reduction in erythrocyte survival, probably because the distorted cells are less deformable than normal and thus become trapped by splenic macrophages. Passage through the spleen causes loss of cell surface with transformation of echinocytes to acanthocytes,[366,375] but in fact, the spleen is not required for development of spur cells.[379,380] Splenectomy may ameliorate severe hemolysis.[366] The mechanism whereby the red cell lipid pattern becomes altered is not well understood. One possible factor is an alteration in the cholesterol-to-phospholipid ratio in high-density plasma lipoproteins, because mature erythrocytes are unable to synthesize lipids and depend largely on plasma lipids for replenishment.[381] In addition, the process of red cell phospholipid repair appears to be defective in spur cell anemia.[382,383] Phospholipid biosynthesis is inhibited and therefore cannot compensate for the increased membrane cholesterol characteristic of liver disease. Other potential contributors to altered erythrocyte membrane lipids in liver disease are changes in plasma lecithin-cholesterol acyltransferase activity, retention of lytic bile acids,[382] and an increase in the intrinsic proteolytic activity of the membrane.[384]

Zieve syndrome has been mentioned earlier. It has been proposed that the transient hemolytic anemia in this syndrome is caused by the lytic action of certain plasma lipids.[354] However, hypertriglyceridemia by itself does not cause hemolysis[353,376,377]; erythrocyte lipids in these patients are similar to those described in patients with only a modest hemolytic component[377]; and hemolytic anemia may occur in patients with acute fatty liver disease even if plasma triglyceride levels are not increased.[352] Alcohol-induced vitamin E deficiency with decreased polyunsaturated fatty acids in membrane lipids may play a role in some patients[353]; similar findings have been reported in vitamin E-deficient children.[385]

Erythropoiesis

In addition to the shortened erythrocyte survival, the marrow response to the anemia in patients with liver disease may be inadequate. Plasma iron turnover, red cell iron utilization, and erythrocyte iron turnover were normal or reduced in the majority of patients in one series, whereas these parameters were increased two- to threefold in another.[96,386] The presence or absence of complications may explain such discrepancies. Alcohol, in particular, depresses erythropoiesis, and if the patient is studied before the effects of alcohol ingestion subside, marrow function appears depressed.[360]

Serum from cirrhotic patients can suppress hematopoietic colony formation in vitro,[387] and cytokines implicated in inhibition of erythropoiesis have been found to be increased in patients with liver disease.[388] Dyserythropoiesis with morphologic abnormalities and intramedullary hemolysis has also been reported in severe liver disease.[389] It has been suggested that extrarenal Epo by the liver is abnormal in patients with liver disease, but in fact, the expected inverse relationship between hemoglobin and Epo production has been found to be preserved in liver disease and to result in levels appropriate for the degree of anemia.[66,390]

ANEMIAS ASSOCIATED WITH ENDOCRINE DISORDERS

A mild to moderate anemia commonly accompanies disorders affecting the thyroid, adrenals, parathyroids, gonads, or pituitary. It is usually not associated with symptomatology (other than that associated with the underlying endocrinopathy) and in fact may reflect a physiologically appropriate hemoglobin concentration because the hormone deficiency often results in reduced oxygen requirements. The anemia is therefore "adaptive."[391] In consultative hematology practice, these individuals present as referrals for evaluation of moderate anemia with normal iron, B_{12}, and folate studies, generally with a question from the referring doctor of whether marrow examination is required. The endocrine disorder is typically undiagnosed at time of referral.

Hypothyroidism

Anemia is observed in 21% to 60% of hypothyroid patients and is more common in hypothyroid men than in hypothyroid women.[392] The frequency of anemia was 39% in patients with subclinical hypothyroidism, and 43% in patients with overt hypothyroidism in one series.[393] The anemia observed may be normocytic and normochromic, hypochromic and microcytic, or macrocytic. The last category comprises roughly one-third of anemic patients in most reported series; the frequency of the other two morphologic types varies considerably in different reports (Table 41.4).[391,394,395–397]

The uncomplicated anemia of hypothyroidism is either normocytic or slightly macrocytic, as is suggested by the predominance of these findings in most series.[392,395,396] Hypochromic microcytic anemia found in association with hypothyroidism should

TABLE 41.4

INCIDENCE OF VARIOUS TYPES OF ANEMIA MORPHOLOGIES IN PATIENTS WITH MYXEDEMA

Type of Anemia	Reference 396 (%)	Reference 391 (%)
Normocytic, normochromic	4	13.5
Hypochromic, microcytic	14	4.5
Macrocytic	13	8
All anemias	31	26

be considered iron deficiency until proven otherwise.[391,392,396] Biochemical markers of iron deficiency are present: The microcytic anemia responds (at least in part) to iron therapy, even if thyroid hormone is not administered, but does not typically respond to thyroid hormone without iron.[392] Iron deficiency in hypothyroidism may be normocytic, so an important step is to determine the serum iron, transferrin, and ferritin concentrations. Hypothyroid individuals are more likely to become iron-deficient because of predisposition to menorrhagia[397] and achlorhydria[396] and because thyroid hormone itself may be essential for normal iron absorption.[391] Severely macrocytic anemia usually results from complicating deficiency of vitamin B_{12}[396] or folate.[395]

When patients with iron, folate, or vitamin B_{12} deficiency are excluded, the remaining individuals should be considered to have "uncomplicated anemia of hypothyroidism," which is a manifestation of the hormone deficiency itself.[395,396] All or nearly all children with anemia and hypothyroidism have the uncomplicated form of the syndrome.[398] Anemia usually affects children whose height is below the third-percentile. The anemia usually is mild, with the hematocrit rarely falling below 0.35. The plasma volume often is decreased, which tends to make the reduction in hematocrit less than might be expected for a given decrease in red cell mass.[396,399] The degree of anemia is related to both the severity and the duration of the hypothyroidism.[400] The hematocrit declines for as long as 6 months after thyroidectomy in previously euthyroid subjects, even though the basal metabolic rate remains at a stable reduced level.

The MCV may be increased in hypothyroid patients, even in the absence of anemia (350). Anisocytosis, poikilocytosis, and other red cell morphologic abnormalities are uncommon, but acanthocytes are apparent in ~20% of patients.[391] Usually, the leukocyte and platelet counts are within the normal range, although both may be slightly reduced.[400] The bone marrow may be mildly hypoplastic, but the myeloid-to-erythroid ratio is not significantly altered.[401,402] Hemoglobin A_2 levels are reduced slightly.[403]

Pathogenesis

The anemia of hypothyroidism results from decreased red cell production. Erythrocyte survival is normal or even slightly prolonged in humans,[396,404] but plasma iron transport and erythrocyte iron turnover rates are reduced, indicating subnormal red cell production.[221,404] As noted earlier, the anemia of hypothyroidism is considered "adaptive"—that is, a physiologic adjustment to the reduced needs of the organism for oxygen.[391] Epo secretion is reduced in hypothyroid patients,[405] and 2,3-DPG levels are not increased[406] as occurs in most anemic and hypoxic states. Thyroid hormones can enhance erythropoiesis in vitro and presumably in vivo as well.[407] The observation that the noncalorigenic D-isomer of triiodothyronine can stimulate erythropoiesis without altering oxygen consumption has been cited as evidence of a hormonal effect that is not oxygen-dependent.[408]

The response of anemia of hypothyroidism to thyroid hormone is gradual. No striking reticulocytosis occurs, and the hematocrit returns to a normal value only gradually over approximately a 6-month period (range, 3 to 12 months).[392,396] The MCV almost always decreases, regardless of its initial value or the presence or degree of anemia, and stabilizes after 4 to 6 months or more.[409]

Hyperthyroidism

A mild anemia with no other apparent etiology occurs in 10% to 25% of patients with hyperthyroidism.[410,411] Anemia is primarily observed in individuals with severe or prolonged hyperthyroidism.[410] More typically, the hemoglobin value falls somewhat but remains within normal limits.[410] The anemia of hyperthyroidism is in many ways the mirror image of that observed in hypothyroidism. MCV is either normal or modestly decreased and, consistent with the comparison to hypothyroidism, may be decreased even in the absence of anemia.[410] Hemoglobin A_2 levels are slightly increased but not as much as in thalassemia.[403] Both the anemia and the microcytosis are corrected when the hyperthyroidism is successfully treated; on average, the hemoglobin increases 0.5 g/dl, and the MCV increases 6 fl.

The pathogenesis of anemia and microcytosis of hyperthyroidism is not well understood. Plasma volume may be increased, suggesting dilution.[399] Erythropoiesis usually is accelerated but ineffective.[411,412] Some (but not all) investigators report increased levels of erythrocyte 2,3-DPG.[406,413–415] Such a change would reduce oxygen affinity and improve oxygen delivery, thereby compensating for the reduced hemoglobin level. Increased plasma Epo levels have been reported[416]—the opposite of what has been described for hypothyroidism.

Adrenal Insufficiency

Although anemia (in the sense of a decreased red cell mass) is common and probably nearly universal in adrenal insufficiency, it may be masked by the dehydration characteristic of this syndrome.[417,418] In a series of patients with untreated Addison disease, the average blood hemoglobin level was 13.2 g/dl (range, 9.4 to 18.0 g/dl).[419] The red cells were normocytic and normochromic. After institution of hormone replacement, the average hemoglobin fell to 10.7 g/dl and the hematocrit from 0.42 to 0.33, presumably reflecting the expansion of plasma volume associated with clinical improvement. Later in the course of the disease, reticulocytosis and a return to normal hemoglobin levels occurred.[419] Pernicious anemia is observed in 3% to 16% of cases of nontuberculous adrenal insufficiency and may complicate 13% of adrenal insufficiency cases associated with the polyglandular autoimmune syndrome type I.[420,421]

Androgen Deficiency

After puberty, values for the hematocrit, blood hemoglobin concentration, and red cell count average ~10% to 13% higher in men than in women.[422] In castrated men, these values fall to within the normal female range.[423,424] This is almost certainly due to a difference in Epo production,[425] although the relationship between hemoglobin and Epo concentration does not differ between the sexes. After the sixth decade, male hemoglobin values fall back toward those observed in women.[422,426] The anemia in these patients is corrected by androgen replacement.

The differences in red cell parameters between the sexes are accounted for chiefly by the stimulating effect of androgens on erythropoiesis. In addition, some observers suggest that estrogens exert a suppressive effect. Thus, castration of male rats precipitates a decrease in hemoglobin, whereas castration of female rats brings about an increase.[427,428] The administration of androgens to castrated males restores male values for hemoglobin concentration. Androgens can also stimulate erythropoiesis in normal subjects (see Chapter 44). In normal men, testosterone enanthate

induced an average red cell mass increase of 1.7 to 2.3.[429] The increase in hematocrit was of smaller magnitude (from 0.456 to 0.494), probably because the plasma volume also increased. Androgens act by increasing renal synthesis of Epo.[430,431] Estrogens produce anemia when given in large amounts to rats.[432,433] It has been suggested that this effect results from suppression of hepatic synthesis of Epo, but it may also simply represent opposition to androgen effects in general.

Hypopituitarism

Moderately severe anemia is a well-recognized feature of pituitary insufficiency, regardless of cause. In an extensive review of cases of Simmonds disease in the first half of the 20th century, the average blood hemoglobin concentration was ~10 g/dl, with similar values reported in patients with hypopituitarism that arose from neoplasms.[434–436] Anemia is also evident in prepubertal pituitary dwarfs but tends to be underappreciated because of contracted plasma volume.[437,438] The anemia usually is normocytic and normochromic, and the red cells appear normal morphologically. In some patients, slight hypochromia or macrocytosis has been observed[435,439]; however, complicating deficiencies of iron or folate were not excluded. Results of kinetic studies demonstrate reduced red cell production.[437]

The anemia of hypopituitarism results chiefly from deficiencies of the hormones of target glands controlled by the pituitary, especially the thyroid and adrenal hormones, but also from a deficiency of androgens. In addition, lack of other pituitary factors, such as growth hormone,[437,440] prolactin,[441] or factors characterized less clearly,[442] may be of importance. The interrelations of these various hormones have been studied experimentally in animals, especially the rat. In this species, hypophysectomy results in a moderately severe, slightly hypochromic and microcytic anemia[440,443] associated with a pronounced decrease in erythroid elements in the bone marrow.[444] No hemolysis has been reported. Combined adrenalectomy and thyroidectomy results in an anemia that is similar, but not identical, to that noted after hypophysectomy.[440,445]

As suggested for the anemia of hypothyroidism, panhypopituitarism probably produces its effects on erythropoiesis chiefly by reducing tissue oxygen consumption.[440] The organism reacts to this decreased need for oxygen by secreting less Epo, and the red cell mass diminishes until a new equilibrium between oxygen supply and demand is established. This hypothesis is supported by the observations that (a) tissue oxygen consumption is low in the hypophysectomized rat, even if the red cell mass is restored to normal levels[440]; (b) once equilibrium is established, the marrow of the hypophysectomized animal responds to hypoxia, bleeding, or cobalt administration[440,446]; (c) correlation between oxygen consumption and rate of erythropoiesis is apparent in hypophysectomized animals given thyroxine or 2,4-dinitrophenol[441]; and (d) erythrocyte 2,3-DPG levels, which increase when tissue oxygen delivery is compromised, are normal in patients with panhypopituitarism.[447]

Treatment with a combination of thyroxine, cortisone, and growth hormone corrects both the anemia and the marrow hypoplasia[440] and is more effective than any single hormone by itself. In one reported case of panhypopituitarism secondary to craniopharyngioma, anemia persisted and progressed despite replacement hormone therapy. Administration of rhEpo (6,000 IU/day) was followed by correction of the anemia, with the blood hemoglobin level rising from 6 g/dl to normal over a 3-month period.[448]

Hyperparathyroidism

Secondary hyperparathyroidism as a contributor to anemia of renal failure has been discussed earlier. Anemia is a rare complication of primary hyperparathyroidism.[449,450] At one institution, 17 of 332 patients (5.1%) with primary hyperparathyroidism were anemic, with hematocrit values ranging from 0.23 to 0.37.[451] None had leukopenia or thrombocytopenia. The anemia was normocytic and normochromic, and no reticulocytosis was evident. Five patients had bone marrow examinations. Four of these patients had 25% or more of their marrow replaced by fibrosis. Anemic patients appeared to have relatively severe hyperparathyroidism as judged by the presence of bone cysts, subperiosteal bone resorption, and particularly high values for serum calcium, alkaline phosphatase, and parathyroid hormone. The hematocrit increased in all seven patients who underwent parathyroidectomy; in six patients, it became normal.[451]

The cause of the anemia in these patients remains obscure. Although renal failure and gastrointestinal bleeding occur in association with hyperparathyroidism, they could not be implicated as an etiologic factor in this group of anemic patients, nor was incidental iron deficiency evident. Some authors conclude that parathyroid hormone decreases proliferation of erythroid precursors in culture.[251] Marrow fibrosis may also be a result of excess hormone levels.[252,253] Myelofibrosis is a common finding in bone marrow biopsy specimens, but the usual morphologic signs of myelophthisis are lacking.[450]

When hyperparathyroidism is secondary to renal disease, it is difficult to ascertain the relative importance of the hormone excess versus the Epo deficit characteristic of renal failure as a contributor to the observed anemia. Of note, however, is that medical treatment of hyperparathyroidism with vitamin D_3 can bring about improvement in anemia and decreased requirement for Epo in some patients.[323]

Anorexia Nervosa

Anemia is observed in as many as 84% of patients with anorexia nervosa admitted to the hospital.[452,453,454] A moderate degree of leukopenia or thrombocytopenia may also be observed. The peripheral blood smear shows a striking composite process, and bone marrow examination shows gelatinous transformation with necrosis, as well as decreased cellularity in most cases.[453–455] These are essentially the findings observed in starvation, and they return to normal with improved nutrition.[453–455] Hemolytic anemia has also been reported in anorexia nervosa.[456] This was presumed to be a complication of hypophosphatemia (see Chapter 32).

CHAPTER 42

ANEMIAS DURING PREGNANCY AND THE POSTPARTUM PERIOD

Robert T. Means, Jr.

OVERVIEW/EPIDEMIOLOGY

By the second trimester of pregnancy, at least a mild degree of maternal anemia (defined as a hemoglobin concentration or hematocrit below the lower limit of normal for healthy adult females) is almost universal.[1] Significant anemia (defined as a hemoglobin concentration <10 g/dl) occurs with a prevalence ranging between 2% and 26%, depending upon the population studied.[2–4] In all populations, but particularly in the less-developed countries of the world, anemia is a major contributor to maternal and fetal morbidity and mortality.[2–6]

Anemia in pregnancy represents a combination of various potential etiologies. The common underlying mechanism, encountered routinely, is a consequence of the physiology of pregnancy itself (*physiologic anemia of pregnancy*). Superimposed on this can be deficiency of nutrients (typically in the context of a preexisting deficiency exacerbated by childbearing), hemolysis, or marrow failure syndromes. It should also be remembered that pregnant women remain susceptible to etiologies of anemia unrelated to their pregnancy.[7] In some cases, such as sickle cell anemia, the underlying condition has major implications for the management of pregnancy.

MATERNAL ERYTHROPOIESIS

There is an increase in maternal erythropoiesis during the third trimester preceded by an increase in serum erythropoietin concentrations, presumably on the basis of reduced oxygen delivery to maternal renal tissues during the late second and early third trimesters.[8] Similarly, serum erythropoietin concentrations are elevated in fetuses with anemia, and correlate with hypoxemia.[9]

The biology of erythropoietin and erythropoiesis in the fetus is discussed in Chapter 43. Erythropoietin is also present in human breast milk in concentrations of 10 to 20 mU/ml, essentially the same as in amniotic fluid.[10] Erythropoietin concentrations in the mother's milk do not correlate with erythropoietin concentrations in her blood. In fact, over the first weeks of lactation, maternal serum erythropoietin concentrations fall, whereas milk erythropoietin concentrations increase, reaching the highest concentrations in women breast-feeding for a year or more. The source of erythropoietin in breast milk appears to be mammary gland epithelium. Erythropoietin in human breast milk, like that in amniotic fluid and colostrum, is relatively protected from proteolytic digestion in the fetal and neonatal gastrointestinal tract.[10]

PHYSIOLOGIC ANEMIA OF PREGNANCY

Expansion of the plasma volume is the cause of the physiologic anemia of pregnancy (Table 42.1). Expanding the plasma volume reduces the volume-dependent indicators of anemia (the hematocrit, the blood hemoglobin concentration, and the circulating erythrocyte count) but does not reduce the absolute amounts of hemoglobin or of erythrocytes in the circulation as a whole. The mechanisms underlying these changes are uncertain. It has been speculated that the physiologic anemia of pregnancy serves the purpose of reducing maternal blood viscosity, thereby enhancing placental perfusion and facilitating oxygen and nutrient delivery to the fetus. Beginning in approximately the sixth week of pregnancy, the plasma volume increases disproportionately to the red cell mass. Plasma volume generally reaches a maximum value at approximately 24 weeks' gestation[11] but may continue increasing as late as the 37th week.[12] At its peak, the plasma volume is about 40% higher among pregnant women than among nonpregnant women.[13,14] The reduction in the hematocrit, hemoglobin concentration, and circulating erythrocyte count generally occurs by the seventh to eighth week of pregnancy,[11,14] and continues until a new equilibrium is reached at the 16th to 22nd week.[13,15] As a result of this new physiologic equilibrium, it has been suggested that a hemoglobin concentration <11 g/dl in the late first trimester and <10 g/dl in the second and third trimesters are the lower limits below which a cause other than the physiologic anemia of pregnancy should be sought.[16] In patients with β-thalassemia trait who have only modest anemia at baseline, hemoglobin concentration may drop significantly after the first trimester of pregnancy.[17]

During pregnancy, a 15% to 25% increase in the red cell mass generally occurs but is concealed by the dilutional effect of the increase in plasma volume.[12,13] A greater increase in red cell mass occurs if the mother takes iron supplements.[1] Ferrokinetic studies demonstrate accelerated erythropoiesis during pregnancy, supporting the concept of an increase in red cell mass.[18,19] Choi and Pai investigated erythropoiesis during pregnancy among 342 women by examining reticulocyte subpopulations using flow cytometry and also by measuring serum transferrin receptor concentrations. They found no differences between prepregnancy and those during the first and second trimesters. However, during the third trimester of pregnancy, reticulocyte maturity index and serum transferrin receptor concentrations increased twofold. After delivery these values decreased, falling to nonpregnant values about 5 weeks after delivery. They concluded that maternal erythropoiesis increases late in gestation and returns to normal by about 1 month after delivery.[20]

Maternal plasma volume generally decreases during the final weeks of pregnancy, and consequently the hematocrit, hemoglobin, and circulating erythrocyte count increase.[21,22] However, studies of maternal blood volume in late pregnancy yield conflicting results depending on whether the patient is supine or in the decubitus position, and the effects of the gravid uterus

TABLE 42.1

FEATURES OF THE PHYSIOLOGIC ANEMIA OF PREGNANCY

Plasma volume begins to increase during the sixth week of pregnancy.
There is no significant increase in erythrocyte production during the first trimester.
Dilutional anemia is first apparent by the seventh to eighth week.
Increase in erythrocyte production is apparent during the second trimester.
Lowest hemoglobin explainable by dilutional effect (the physiologic anemia of pregnancy) is 11 g/dl in the first trimester and 10 g/dl in the second and third trimesters.
Physiologic anemia of pregnancy is normochromic, is normocytic, does not worsen during the third trimester, and does not require additional evaluation or specific treatment.

compressing blood vesssels are an additional source of variation. As a result, the results observed may represent only variations within the error of measurement or random occurrences.[13,21,23] The maternal blood volume generally returns to prepregnancy levels within 1 to 3 weeks after delivery, in part reflecting blood loss at delivery.[19,24,25]

IRON DEFICIENCY DURING PREGNANCY

The physiologic anemia of pregnancy is normochromic and normocytic. Therefore, if a pregnant woman has a microcytic hypochromic anemia, nonphysiologic causes must be considered. Iron deficiency is common in women of childbearing age and is certainly the most common cause of nonphysiologic anemia during pregnancy.[1] It is particularly common in economically and socially disadvantaged populations.[26,27] The prevalence of iron deficiency ranges from 16% to 55% in pregnant women during the third trimester. This partially reflects utilization of iron by the fetus, and partially reflects pre-existing iron deficiency.[1,26,28] In a Cochrane review, Milman et al. observed that among fertile women, 20% have presumed iron reserves of >500 mg (defined as a serum ferritin concentration >70 μg/L), which is stated as the required minimum during pregnancy; 40% have iron stores of 100 to 500 mg (defined by a serum ferritin concentration 30 to 70 μg/L), and 40% have undetectable iron stores (serum ferritin <30 μg/L).[29] The fetus is a privileged recipient of the nutrients required for hemoglobin synthesis. Thus, the hemoglobin concentration of infants born to mothers who have severe iron deficiency anemia is normal, and the serum iron, transferrin saturation, and serum ferritin levels are unrelated to maternal iron status.[30–32]

In a study by De Leeuw et al., 84% of women not supplemented with oral iron lacked stainable iron in bone marrow aspirates after delivery at term, whereas 81.5% of women treated with iron had stainable iron present at term.[1] The demand for absorbed iron increases from 0.8 mg/day in early pregnancy to 7.5 mg/day in late pregnancy. An iron supplement of 65 mg/day beginning at or before 20 weeks' gestation generally is adequate to prevent iron deficiency during pregnancy.[29]

There is evidence that the risks of premature delivery, low birth weight, and infant death are increased by severe iron deficiency. However, it is difficult to distinguish the effects of the iron deficiency itself from the conditions that produced the deficiency. A large case–control study from Venezuela indicated that maternal iron deficiency was associated with increased risk of premature delivery (risk ratio, 1.70; 95% confidence interval, 1.18 to 2.57).[33] However, when Mahomed reviewed 20 trials evaluating the issue of iron supplementation in pregnancy for the Cochrane database, he concluded that iron supplementation during pregnancy resulted in a substantial reduction in women with anemia (a hemoglobin below 10 g/dl late in pregnancy) but had no detectable effect on maternal or fetal outcome.[34] Thus, whether maternal iron deficiency adversely influences pregnancy is controversial. In fact, it is not entirely clear whether maternal iron deficiency reduces the fetal iron supply. Harthoorn-Lasthuizen et al. found no significant differences in iron status of neonates born to iron-deficient versus iron-replete women and concluded that the fetal iron supply is not negatively influenced by iron deficiency in the mother.[35] In contrast, Turgeon O'Brien et al. reviewed medical records of 202 pregnant women to examine the association of low- and high-ferritin levels and anemia with pregnancy outcome.[36] They observed an inverse relationship between first-trimester anemia and birth weight, but they observed no relationship in the second and third trimesters. They suggested that maternal iron deficiency in early pregnancy was associated with poor fetal weight gain but that maternal iron deficiency later in pregnancy was not. During iron deficiency, the placenta becomes hypertrophied, a possible cause of maternal hypertension. A specific variant of pica, namely (ingestion of baking powder) can lead to symptoms suggesting preeclampsia.[37]

Recombinant erythropoietin administration, combined with iron replacement, has been reported to be an effective treatment for moderate and severe iron deficiency anemia during pregnancy,[38,39] although a meta-analysis of this topic suggests that the benefits from erythropoietin are relatively modest.[40]

The usual criteria for diagnosing iron deficiency are valid during pregnancy (see Chapter 23), including a reduced mean corpuscular volume (MCV), a reduced serum transferrin saturation to ≤15%, and a reduced serum ferritin concentration. Measurement of serum transferrin receptors may be useful in complicated situations in which inflammatory disease makes the serum ferritin value less reliable.[41] Interpretation of serum iron values can be complicated during pregnancy: Even in apparently iron-replete women, serum iron levels progressively decline, and values for serum total iron-binding capacity and free erythrocyte protoporphyrin increase,[1,42] findings that usually indicate iron deficiency. Expression of the iron-regulatory peptide hepcidin appears to be suppressed during preganancy, consistent with an increased iron demand.[43]

Dietary supplementation with 78 mg of elemental ferrous iron daily during pregnancy increased the hematocrit, hemoglobin concentration, and red cell mass, with the red cell mass rising to nearly twice that found in similar, apparently healthy women not supplemented.[1] At term, the mean hemoglobin concentration averaged 12.4 g/dl in those who received the supplement and 10.9 g/dl in those who did not. In Bantu women, whose diet is habitually high in iron, a significant change in serum iron does not occur, and iron deficiency anemia does not develop during pregnancy.[44] Some have recommended that all pregnant women receive iron supplements beginning at 18 to 20 weeks' gestation in doses ranging from 30 to 60 mg/day,[26] whereas others recommend that iron supplementation be provided selectively. A typical regimen in this second circumstance is as follows: No iron supplementation if the serum ferritin concentration is >70 μg/L; low-level iron supplementation (40 mg elemental iron/day) if serum ferritin is between 30 and 70 μg/L; and 80 to 100 mg elemental iron/day in women with lower serum ferritin concentrations.[45]

Actual iron deficiency anemia should be treated as in individuals who are not pregnant (see Chapter 23). Constipation may be an especially problematic side effect in pregnant women; therefore, gradual increases in dose until fully therapeutic levels are achieved and an emphasis on taking medication with meals are particularly important precautions. Rarely, parenteral treatment may be necessary.

DEFICIENCY OF FOLATE AND OTHER NUTRIENTS DURING PREGNANCY

Macrocytic anemia of pregnancy is typically megaloblastic and in most cases results from deficiency of folic acid.[46–49,50] In a study from India, macrocytic anemia in pregnancy carried a more negative prognosis for both mother and child than did iron deficiency.[51] Megaloblastic anemia during pregnancy begins most often in either the third trimester or shortly after delivery.[52] Folate requirements increase during pregnancy, and the diets of many pregnant patients are insufficient to meet the increased need.[53,54] Although folate deficiency occurs most often in economically deprived patients, this consequence of inadequate eating habits is not confined to the poor.[52–55] Particularly in pregnant adolescents, the diet may provide an inadequate source of folate, regardless of economic status.[54] In uncomplicated pregnancies, the gastrointestinal absorption of dietary folate (polyglutamate) and of folic

acid (monoglutamate) is normal.[56,57] Folate deficiency during pregnancy is relatively common, although its frequency depends on the population studied. The prevalence varies from 1% to 50% of pregnant patients.[48,52,55,58] In North America, the prevalence is 1% to 4%.[50] Not all patients in whom the serum concentration of folate is low develop megaloblastic anemia. In those who do, often the serum folate concentration was low earlier in pregnancy.[52]

Pregnant women often have no symptoms with folate deficiency anemia and may be found to have blood hemoglobin levels of 6 to 9 g/dl in the third trimester or postpartum. Folate deficiency is clearly associated with fetal neural tube defects and cleft palate, but these defects are established very early in fetal development, long before maternal megaloblastic anemia is detected.[50] The association between low serum folate during the first trimester of pregnancy and fetal neural tube defects has been known for over 25 years.[50] Lumley et al. reviewed this issue for the Cochrane database, examining four trials involving 6,425 women treated with folate or placebo.[59] Preconceptional folate supplementation reduced the incidence of neural tube defects to a relative risk of 0.28 (95% confidence interval, 0.13 to 0.58). Folate did not increase miscarriage, ectopic pregnancy, or stillbirth. Multivitamins without folate did not prevent neural tube defects, and adding multivitamins to folate supplementation did not produce additional preventive effects. Thompson et al. reported an unexpected but significant reduction in childhood acute lymphoblastic leukemia among offspring of women supplemented with folate during pregnancy.[60]

An association between bacteriuria and folate deficiency was noted in pregnant patients. In experimental systems, infection may induce folate-deficient megaloblastic anemia. Malabsorption (see Chapter 36) may be associated with megaloblastic anemia of pregnancy, even in nontropical areas.[50]

In rare cases, folate-deficient pregnant patients develop erythroblastopenia and bone marrow changes morphologically simulating acute leukemia.[61] Application of current molecular, immunologic, and cytochemical tools for diagnosing leukemia will avoid a mistaken diagnosis.

Megaloblastic anemia during pregnancy, as in the nonpregnant patient, is suggested by an increased MCV with oval macrocytes and hypersegmented granulocytes on blood smear, but a bone marrow examination can be done if doubt exists. Folate deficiency must be distinguished from vitamin B_{12} deficiency. The latter is rare in pregnancy, and the distinction can often be made on clinical grounds, especially on the basis of a careful nutritional history.

Folate is transported across the placenta against a concentration gradient. Infants born to mothers with the megaloblastic anemia of pregnancy have no anemia and no biochemical evidence of folate deficiency.[62] The concentration of vitamin B_{12} also is two to three times higher in cord blood than in maternal blood.[63] Nevertheless, this nutritional advantage is insufficient to protect the infant if the mother is vitamin B_{12} deficient and if the sole source of nutrition is the mother's milk. Megaloblastic anemia accompanied by irreversible neurologic damage has been documented in breast-fed infants of vegan mothers[64,65] and in breast-fed infants of mothers with subclinical pernicious anemia.[66,67]

Dietary supplementation with approximately 0.3 mg of folic acid daily during pregnancy reduces the occurrence of megaloblastic anemia to approximately 0.7% of all pregnant women,[49,68,69] whereas a supplement of only 0.1 to 0.2 mg/day is not adequate to maintain serum folic acid concentration at normal levels.[70,71] A supplement of 0.45 mg/day results in supranormal values for serum folate,[69,71] but, even with this amount of supplementation, megaloblastic anemia may occur in a pregnant patient in whom the course is complicated by urinary tract infection, hemolysis, or hemorrhage.[71] Nevertheless, because true pernicious anemia caused by a lack of intrinsic factor and vitamin B_{12} does occur in pregnant patients,[72] the considerations regarding masking of pernicious anemia with folate doses of 0.40 mg/day or more apply (Chapter 36). Both the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists recommend daily supplements of 0.4 mg of folic acid for pregnant women at low risk for neural tube defects; for pregnant women with a history of previous pregnancies associated with neural tube defects or at otherwise high risk, 4 mg of folic acid daily is recommended.[73–75] For patients not at high risk for neural tube defects but at increased risk for folate deficiency, such as those with chronic hemolytic anemia, the supplement may be increased to 1 mg/day.[50]

For established deficiencies, the regimen described in Chapter 36 should be followed. If the possibility of vitamin B_{12} deficiency cannot be excluded, vitamin B_{12} injections should be added to the regimen.

Anemia due to zinc deficiency has been associated in some studies with fetal growth restriction, congenital abnormalities, and neurodevelopmental delay. Iodine deficiency during pregnancy is very uncommon in developed countries but can result in fetal wastage, preterm delivery, and neonatal hypothyroidism. Deficiency of magnesium, selenium, copper, and calcium has also been associated with complications of pregnancy and fetal development.[76,77] In a study in Nepal, vitamin A supplementation reduced maternal mortality, and suggested that vitamin A influences the synthesis of erythropoietin and thus might decrease maternal anemia, although other studies carried out in pregnant women in Africa have not confirmed this.[78–80]

MATERNAL ANEMIA ASSOCIATED WITH PRENATAL INFECTIONS

Most clinically significant infections of the fetus are viral or protozoal, but generally these conditions result in minimal evidence of infection in the mother. Specifically, women carrying a fetus infected with cytomegalovirus, toxoplasmosis, rubella, herpes simplex, or parvovirus B19 generally have no anemia related to the infection. However, certain infectious diseases during pregnancy do result in maternal anemia. For example, intestinal helminth infections, common in certain parts of the world, produce or exacerbate iron deficiency during pregnancy, resulting in anemia. Nurdia et al. reported that 70% of 442 pregnant women from Central Java, Indonesia, had either *Trichuris trichiura*, *Necator americanus*, or *Ascaris lumbricoides* detected during pregnancy.[81] They observed a significant negative association between hookworm infection and serum ferritin in the first trimester and suggested that anthelminthic therapy should be given to infected women before conception as a means of improving their iron status. Similarly, Torlesse and Hodges reported that anthelminthics were useful in Sierra Leone, reducing the decline in hemoglobin concentration during pregnancy by more than 6.5 g/L.[82]

Syphilis generally does not lead to anemia in pregnancy. Mavrov and Goubenko, from Ukraine, reported on 155 pregnant women with syphilis. They observed that 78% of the women remained asymptomatic throughout pregnancy, although placental and fetal/neonatal pathology were found in about half of cases.[83]

Malaria can cause maternal and fetal anemia.[84] This is a significant issue in the less-developed countries of the world. Standard methods of diagnosing malaria are often ineffective during pregnancy.[84] The anemia is mild in most neonates with malaria, but with a marked placental accumulation of parasites, intrauterine growth retardation can be significant.[85] Steketee et al. reviewed studies between 1985 and 2000 and summarized the risk of neonatal anemia, low birth weight, and infant mortality associated with maternal malaria. Indeed, maternal malaria was associated with substantial risks for anemia (population attributable risk, 3% to 15% increased), low birth weight (8% to 14% increased risk), and infant mortality (3% to 8% increased risk).

They estimated that each year 75,000 to 200,000 infant deaths are associated with maternal malaria.[86] More recent studies from Nigeria, Benin, and India have shown similar results.[87–89]

HEMOLYTIC ANEMIA IN PREGNANCY

Pregnancy-induced Hemolytic Anemia

A variety of hemolytic anemia syndromes can occur in pregnant women just as in nonpregnant women. In fact, pregnancy can exacerbate underlying autoimmune hemolytic anemia.[90] Thus, hemolytic anemia is not particularly uncommon in obstetric practice. However, a rare entity has been described in which an idiopathic hemolytic anemia occurs during pregnancy, resolves completely after pregnancy, and recurs during subsequent pregnancy (Table 42.2). The pathogenesis of this anemia is not known. Terms for the condition include *idiopathic autoimmune hemolytic anemia of pregnancy*, *unexplained hemolytic anemia associated with pregnancy*, and *pregnancy-induced hemolytic anemia*. The condition is not homogeneous. In the cases reported by Ng et al. from Kuala Lumpur and Benraad et al. from The Netherlands,[91,92] women had immunoglobulin G warm antibodies and were successfully treated with glucocorticoids. In some cases, a positive direct antiglobulin (Coombs) test is not found.[93–95] The majority of cases have no identifiable immune mechanisms and have a variable response to glucocorticoids.[96–98]

This pregnancy-induced hemolytic anemia becomes apparent in the third trimester of pregnancy and in most cases remits completely within 2 months of delivery, sometimes taking as long as 4 or 5 months. The anemia is usually very severe, even life threatening to mother and fetus. Corticosteroids and intravenous immunoglobulin (IVIG) have been reported to be successful in some cases, but many of the women have been treated with repeated erythrocyte transfusions. Generally, the transfused donor cells have a shortened survival. Neonates born to women with pregnancy-induced hemolytic anemia generally have transient hemolysis, lasting 1 to 2 months; severe jaundice requiring neonatal exchange transfusion has not been reported.

Autoimmune Hemolytic Anemia during Pregnancy

In cases of autoimmune hemolytic anemia during pregnancy, whether idiopathic or of an identified variety, the degree of hemolysis is generally more severe in the mother than that in the fetus.[99] However, therapy that ameliorates the maternal disease (such as corticosteroids or IVIG) often does not protect the fetus. This is in contrast to autoimmune thrombocytopenia during pregnancy, in which maternal and fetal platelet counts are likely to be concordant.

TABLE 42.2

FEATURES OF IDIOPATHIC PREGNANCY-INDUCED HEMOLYTIC ANEMIA

There is no identifiable mechanism.
Anemia becomes apparent in the third trimester.
Anemia remits completely within 2 mo of delivery.
Anemia generally recurs in subsequent pregnancies.
Anemia is usually severe, even life threatening.
Corticosteroids and intravenous immunoglobulin are sometimes helpful.
Erythrocyte transfusions are the mainstay of treatment for severe anemia.
Donor cells have a shortened survival.
Neonates generally have transient nonsevere hemolysis.

HELLP Syndrome

Preeclampsia is characterized by gestational hypertension and proteinuria or pathologic edema; eclampsia is complicated by the additional occurrence of seizures.[100,101] Preeclampsia and eclampsia are systemic diseases involving the kidney, liver, heart, and central nervous system. Hematologic complications have been recognized for some time and include microangiopathic hemolytic anemia with characteristic fragmented red blood cells (RBCs) in the peripheral blood, thrombocytopenia, and well-defined abnormalities of the coagulation system.[102,103] This subset of patients with severe preeclampsia/eclampsia is considered to have HELLP syndrome, characterized by hemolysis (H), elevated liver (EL) enzymes, and low platelet (LP) counts (Table 42.3).[104,105]

It is thought that RBC fragmentation and thrombocytopenia associated with HELLP are a result of a number of interrelated, largely mechanical factors, including endothelial damage, vasoconstriction coupled with hypertension, and the deposition of fibrin in injured vessels. Women with preeclampsia have abnormalities in coagulation, including signs of chronic intravascular coagulation,[106] shortened platelet lifespan,[103,107] decreased plasma antithrombin III activity,[108,109] abnormalities in circulating fibrinogen multimers[110] and increased fibrin deposition within the kidney and the liver.[111,112] Increased rates of factor VIII consumption have been reported by some although not all investigators.[113–115] Patients with preeclampsia have decreased hemopexin relative to healthy pregnant mothers.[116] Women with preeclampsia also have higher circulating levels of the endogenous vasoconstrictor endothelin and other abnormalities of endothelial function.[117–120] Patients with preeclampsia have an imbalance of placental prostacyclin and thromboxane production that favors vasoconstriction.[121]

TABLE 42.3

MAJOR CLINICAL CHARACTERISTICS OF HELLP SYNDROME, TTP, AND HUS

Clinical Features	HELLP Syndrome	TTP	HUS
Target organ/ system involved	Liver	Neurologic	Renal
Gestational age	Second to third trimester	Second trimester	Postpartum
Platelets	Decreased	Decreased	Decreased
PT/PTT	Normal	Normal	Normal
Hemolysis	Present	Present	Present
Fibrinogen	Normal	Normal	Normal
Creatinine	Normal/ increased	Increased	Increased
Liver enzymes	Increased	Normal	Normal
ADAMTS-13	Mild–moderate	Severely	Variable; typically severely
	Decreased	Decreased/ absent	Decreased

HELLP, hemolysis (H), elevated liver (EL) enzymes, and low platelet (LP) counts; HUS, hemolytic-uremic syndrome; PT, prothrombin time; PTT, partial thromboplastin time; TTP, thrombotic thrombocytopenic purpura.
Modified from Saphier CJ, Repke JT. Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome: A review of diagnosis and management. Semin Perinatol 1998; 22(2):118–133.

HELLP syndrome reportedly occurs in 20% of women with severe preeclampsia and 10% of women with eclampsia.[122] The median gestational age at presentation is 32 to 34 weeks, with a range of 24 to 39 weeks.[123] Clinical findings at presentation include malaise, right upper quadrant tenderness, hypertension, and edema. Most women with HELLP syndrome are not anemic at presentation, although they may drop their hemoglobin out of proportion to the volume of blood lost at delivery.[123]

Laboratory features include elevated liver enzymes (i.e., alanine aminotransferase [ALT] and aspartate aminotransferase [AST]), thrombocytopenia with $<100{,}000/\mu l$ in most patients, and evidence of compensated hemolysis. The latter is probably the most specific abnormality associated with HELLP syndrome, but sometimes difficult to detect. The peripheral blood smear usually reveals schistocytes and there also may be burr cells and polychromatophilia.[123] In one study, however, schistocytes were seen in only a small fraction of patients and it was proposed that the fragmented cells may have been removed by the spleen.[124] Hemoglobinemia and hemoglobinuria occur in <10% of cases. The one consistent abnormality noted in women with HELLP syndrome is a decreased serum haptoglobin in virtually all patients, and this may be considered to be a highly sensitive test to detect this RBC abnormality when only a few schistocytes are present on smear.[124] Patients with HELLP syndrome have been reported to have mild to moderate reduction in the von Willebrand factor cleaving protease ADAMTS-13 compared to nonpregnant women or women experiencing an uncomplicated pregnancy. These reduced levels were not due to inactivating antibodies.[125] Severely reduced ADAMTS-13 levels would suggest a diagnosis of thrombotic thrombocytopenic purpura (TTP) rather than HELLP.[126] TTP is also distinguished from HELLP by an increased lactate dehydrogenase (LDH)/AST ratio.[127]

The management of pre-eclampsia with HELLP syndrome is a matter of some obstetric debate, and is beyond the scope of this chapter. In general, the issues relate to immediate delivery or close observation, and these in turn are governed by maternal clinical status and fetal gestational age.[123,128] The most common approach is to deliver the fetus as soon as possible or, if it is likely that there is fetal lung immaturity because of gestational age, steroids are administered to the mother for 2 to 3 days, and then the infant is delivered. It is intriguing that a small but significant fraction of women (30% in one study) spontaneously improves without more aggressive intervention.[129] In contrast to TTP, there currently are no data indicating a role for plasmapheresis.

One of the most serious complications is hepatic rupture, with 50% maternal and 60% to 70% fetal mortality. Other complications include disseminated intravascular coagulation, renal failure, pulmonary edema, and placental abruption.[105] Overall, maternal mortality ranges from 0% to 4% in different series.[123] Hematologic and chemical abnormalities resolve within a few days of delivery. Neonatal mortality is 5% to 20%,[105,123] and this is more a reflection of fetal age rather than any specific complication of maternal HELLP issues.

Pregnancy-associated Thrombotic Thrombocytopenic Purpura and Hemolytic-uremic Syndrome

In most reported studies of thrombotic microangiopathy with pregnancy, TTP and hemolytic-uremic syndrome (HUS) have been distinguished on the basis of the predominant symptomatology, neurologic or renal. TTP most commonly occurs antepartum, with a significant majority of cases presenting before 24 weeks' gestation. Postpartum TTP is uncommon.[130] HUS, on the other hand, typically occurs after a normal delivery and a symptom-free interval, and is characterized by acute-onset renal failure and microangiopathic hemolytic anemia.[106,128] Hypertension is almost always found. A small fraction (10% to 15%) of HUS and TTP patients have signs of preeclampsia. Sometimes TTP/HUS is not correctly diagnosed until the patient, thought to have preeclampsia, has an atypical prolonged recovery in the postpartum period.[131]

Laboratory results show the expected hemolytic anemia with many RBC fragments. Severe thrombocytopenia usually is present. Fibrin breakdown products are often increased, but the findings of other coagulation studies usually are normal.[106] In postpartum HUS azotemia is the rule, but is rare in TTP.

In an extensive case review, the overall maternal mortality was 44%. The mortality rate was reduced to 0% with plasma therapy, but was 68% if plasma therapy was not instituted.[106,131,132,133,134] The pregnancy should not be terminated because this does not cure the disease, and the fetus may survive with successful therapy. The presence of severely reduced ADAMTS-13 activity at the outset of pregnancy in any woman with a history of TTP should suggest a need for plasma exchange during pregnancy.[126]

BONE MARROW FAILURE SYNDROMES ASSOCIATED WITH PREGNANCY

Aplastic Anemia/Pure Red Cell Aplasia

Pregnancy may occur in patients with existing bone marrow failure syndromes,[135,136,137] although this is uncommon and requires cooperation between a high-risk obstetrics expert and a hematologist experienced with bone marrow failure syndromes. Predictors of a poor outcome include thrombocytopenia and aplastic anemia associated with paroxysmal nocturnal hemoglobinuria.[136] Even more uncommon is aplastic anemia that develops during pregnancy. Whether this is a coincident association in most cases is unclear: The observation that approximately up to 25% of these individuals experience a spontaneous remission after delivery suggests that it is not coincidence.[138,139] Patients are generally managed with supportive care during pregnancy, and receive specific immunosuppressive therapy subsequently if necessary.

Pure red cell aplasia may also have its initial onset in pregnancy. These patients should be managed with supportive care also, and the majority will experience a remission after delivery. In some cases, subsequent pregnancies are associated with recurrence.[140,141,142]

Sideroblastic Anemia

There have been a number of case reports and small series of sideroblastic anemia with onset during pregnancy. Some cases appear to represent a coincident association with idiopathic sideroblastic anemia,[143] whereas others appear to be pregnancy induced, and may recur with subsequent pregnancies.[144,145] A pregnancy-associated syndrome with morphologic features of both sideroblastic anemia and amegakaryocytic thrombocytopenia has been described, which responds to immunosuppression, but may also undergo spontaneous remission after delivery.[146]

POSTPARTUM ANEMIA

Postpartum anemia is common, particularly among low-income women. Studying nearly 60,000 women who were enrolled in the Special Supplemental Nutrition Program for Women, Infants, and Children, Bodnar et al. reported an overall incidence of postpartum anemia of 27%. However, rates reached 48% among non-Hispanic black women. Prenatal anemia was the best predictor

of postpartum anemia. Maternal obesity, multiple births, and formula feeding also predicted postpartum anemia.[27]

Peripartum hemorrhage is an obvious and common cause of postpartum anemia. An estimated blood loss at delivery in excess of 500 ml is claimed to be a good predictor of postpartum anemia.[147] Unsuccessful vacuum extraction can cause peripartum hemorrhage and subsequent postpartum maternal anemia. Sheiner et al. evaluated over 2,100 cases of delivery by vacuum extraction in Israel between 1990 and 1998[148] and reported that 5.4% of all deliveries were complicated by unsuccessful extraction, with a subsequent cesarean section. Postpartum anemia was much more common in the women following unsuccessful vacuum extraction than in those in whom cesarean sections were not preceded by attempts at vacuum extraction. Maternal blood loss during and after the unsuccessful vacuum extraction procedures was suggested as the cause.

Hemorrhage occurring a week or more after delivery, so-called secondary postpartum hemorrhage, has a high morbidity rate. Hoveyda and MacKenzie analyzed 132 consecutive women presenting with secondary postpartum hemorrhage over a 3-year period at Barrett Maternity Hospital, Northampton, United Kingdom.[149] They observed this complication in just under 1% of women and found that most presented in the second week after delivery. Histories of either primary postpartum hemorrhage or manual removal of the placenta were the only significant risk factors identified. Eighty-four percent of these women were rehospitalized, 63% required surgery, and 17% received blood transfusions.

Peripartum hemolysis is another cause of postpartum anemia. Hemolytic reactions have been described in women receiving second- and third-generation cephalosporins, such as cefotetan, administered prophylactically for cesarean section.[150,151]

Recombinant erythropoietin has been used to treat postpartum anemia. Meta-analysis suggests that although erythropoietin treatment is safe and tends to be associated with a more rapid rise in hematocrit, it may not reduce the need for transfusion.[152] Similarly, intravenous iron administration for postpartum anemia is associated with a more rapid hemoglobin increment than oral iron.[153] However, the relative safety compared to oral iron is not established.[154]

CHAPTER 43

ANEMIAS UNIQUE TO THE FETUS AND NEONATE

Robert D. Christensen, Robin K. Ohls

INTRODUCTION

The reference ranges used to define normal hematocrit, hemoglobin, erythrocyte count, and the erythrocyte indices, change considerably during fetal life as well as in the weeks after birth.[1,2] Consequently, the laboratory findings that define anemia in a fetus or neonate are highly dependent on the gestational and postnatal age. Once anemia is recognized in a fetus or neonate, the differential diagnosis used to seek for the cause is unique from that at all other ages. In this chapter we display the pertinent reference ranges and review the underlying differences in erythropoiesis, erythrocyte structure, function, and metabolism that make anemias in the fetus and neonate so unique.

ERYTHROPOIETIN BIOLOGY IN THE FETUS AND NEONATE

Erythropoietin has both erythropoietic effects and nonerythropoietic effects during human fetal and neonatal development (Table 43.1).[3,4] Although initially described by, and principally known for, its actions on erythroid progenitors, erythropoietin is also an important physiologic growth factor for fetal small intestinal villous enterocytes and neurons.[4,5,6,7]

Erythropoietin is a constituent of amniotic fluid, in concentrations of 25 to 40 mU/ml. A normal human fetus swallows 200 to 300 ml of amniotic fluid per kilogram body weight per day, and thus swallows 10 to 15 U of erythropoietin/kg/day.[8] In humans, erythropoietin does not cross the placenta from maternal to fetal circulations, and it appears that the source of the erythropoietin in amniotic fluid is not the maternal circulation. In the second and third trimesters, amniotic fluid is largely derived from fetal urine, with minor constituents from fetal tracheal effluent and the placenta and fetal membranes. However, erythropoietin in amniotic fluid does not appear to come from fetal urine. The fetal kidney makes little erythropoietin before delivery, and the first-voided urine of neonates generally has no detectable erythropoietin.[8] Studies using in situ hybridization and immunohistochemistry indicate that the source of erythropoietin in amniotic fluid is largely maternal: from mesenchymal and endothelial cells in the deciduae and from the amnion.[8]

Erythropoietin is present in human colostrum and breast milk in concentrations of 10 to 20 mU/ml.[4,5,6,7,8,9] Erythropoietin concentrations in mother's milk do not correlate with erythropoietin concentrations in her blood. In fact, over the first weeks of lactation, maternal serum erythropoietin concentrations fall, whereas milk erythropoietin concentrations increase, reaching the highest concentrations in women breast-feeding for a year or more. The source of erythropoietin in breast milk appears to be mammary gland epithelium.[7,8]

Erythropoietin in human amniotic fluid, colostrum, and breast milk is relatively protected from proteolytic digestion in the fetal and neonatal gastrointestinal tract.[8] Rather than being absorbed from the gastrointestinal track into the blood, the erythropoietin swallowed by the fetus and neonate binds to erythropoietin receptors on the luminal surface of villous enterocytes, where it serves topically as a growth and development factor. Indeed, experimental animals artificially fed formulas devoid of erythropoietin have retarded villous development, a condition that can be remedied by enteral recombinant erythropoietin and blocked by antierythropoietin antibody.[4,5,6,7,8,9]

Erythropoietin is produced by cells in the developing central nervous system and is present in relatively high concentrations in fetal cerebrospinal fluid (CSF).[10–15] Among newborn infants, the highest concentrations of erythropoietin in the CSF are seen in the most premature neonates, and by several years of age CSF erythropoietin concentrations are generally below 1 mU/ml.[5] Erythropoietin receptors are expressed on human fetal neurons,[10–15] and at least small quantities of recombinant erythropoietin, administered intravenously, cross the blood–brain barrier and appear in the CSF fluid.[16] Erythropoietin in the central nervous system is a neuroprotectant from hypoxia. Erythropoietin production increases rapidly in the brain during hypoxia, and when erythropoietin binds to receptors on neurons, antiapoptotic activity is induced. Cell culture systems and whole animal models illustrate a marked neuroprotective effect of erythropoietin.[17] The clinical utility of recombinant erythropoietin as a neuroprotectant is a topic of recent and ongoing studies.[18,19,20–21,22]

The liver is the primary site of erythropoietin production in the fetus. The kidney does not become the primary site until several months after birth. In the human fetus, the kidney produces about 5% of the total erythropoietin during mid-gestation. The developmental mechanisms regulating the switch in erythropoietin production from the liver to the kidney are not completely known but may involve developmental expression of transcription activators such as hypoxia inducible factor and hepatic nuclear factor 4, or developmental methylation of promoter and enhancer regions. Alternatively, the switch might involve the GATA transcription factors, particularly GATA-2 and GATA-3, which are negative regulators of erythropoietin gene transcription.

Erythropoietin ameliorates experimental damage to the placenta and fetal liver induced by lipopolysaccharide.[23] Elevated concentrations of erythropoietin in fetal blood and/or amniotic fluid may indicate fetal hypoxia, and although erythropoietin may have a protective role for some fetal cells, such as neurons, placental, hepatic, and intestinal villous cells, it might also be a marker for poor neurodevelopmental outcome on the basis of severe or chronic hypoxia.[23–25,26]

TABLE 43.1

ACTIONS OF ERYTHROPOIETIN IN THE HUMAN FETUS

Site of Erythropoietin Production	Mechanism of Erythropoietin Delivery to Target Cells	Actions at Target Cells
Hepatocyte/hepatic macrophages	Paracrine	Erythropoiesis/ angiogenesis
Glia	Paracrine	Neural migration
Glia	Paracrine	Neural protection from hypoxia
Decidua and amniotic membranes (amniotic fluid)	Swallowed by fetus	Small bowel villous development
Mammary epithelia (breast milk)	Swallowed by neonate	Small bowel villous development

NORMAL ERYTHROCYTE VALUES DURING HUMAN FETAL DEVELOPMENT

Normal ranges for erythrocyte values of the human fetus and neonate are generally not available. This is because blood is not drawn on healthy neonates to establish such ranges. Instead, reference ranges are used, consisting of the 5th to the 95th

percentile values compiled from laboratory tests performed on neonates who were thought to have minimal pathology relevant to the laboratory test, or pathology unlikely to affect the test results significantly. The premise on which the reference range concept is based is that these values approximate normal ranges, although they were admittedly obtained for a clinical reason and not from healthy volunteers.[1,2]

Circulating erythrocytes in the mid- and third trimester fetus have features reminiscent of what is called "stress erythropoiesis in adults. These features include marked anisocytosis, poikilocytosis, macrocytosis, and a relatively high percentage of nucleated erythrocytes. Marrow cellularity in the fetus is relatively high, and because the available marrow space is fully cellular, the fetus and newborn infant have little marrow reserve on which to call. Erythroid precursors account for 30% to 65% and myeloid cells 45% to 75% of nucleated marrow cells at birth.[27] The myeloid to erythroid ratio at birth is approximately 1.5:1. Marrow cellularity decreases after birth, attaining a density that is normal for adults by 1 to 3 months.[28] Initially, this decrease in cellularity results from a rapid decline in red cell precursors. At 1 week of age, erythroid elements account for only 8% to 12% of nucleated cells, and the myeloid to erythroid ratio exceeds 6:1. The normal adult proportion of myeloid to erythroid precursors is not established until the third month. Both the percentage and absolute number of lymphocytes increase during the first 2 months, so that by 3 months of age, they constitute nearly 50% of marrow nucleated cells. Differential counts of bone marrow aspirates from preterm infants are the same as those for term infants.[29]

Normal reference ranges for the hemoglobin concentration on the day of birth, at gestational ages ranging from 22 to 42 weeks, are shown in Figure 43.1. The reference ranges gradually increase during this period in utero, and there are no differences between genders.[30] After birth, the anatomic site of blood sampling to measure the hemoglobin and hematocrit influences the test result.[1,2,31] Perfusion of small vessels in the extremities can be relatively poor, particularly during hypotension or skin cooling, resulting in increased transudation of fluid and hemoconcentration. Consequently, the hemoglobin concentration and packed cell volume of capillary blood are 5% to 10% higher than those of venous blood.[2] The difference between capillary and venous values is greatest at birth but disappears by 3 months of age. The discrepancy is greatest in preterm infants and in those with hypotension, hypovolemia, and acidosis.[32] Differences can be minimized, but not fully resolved, by warming the extremity before sampling, obtaining freely flowing blood, and discarding the first few drops. The interpretation of serial observations necessitates the consistent use of one site of blood sampling.

Hemoglobin concentrations increase during the first hours after birth attributable in part to a shift of fluid from the intravascular compartment but also to the transfusion of fetal red cells from the placenta at the time of birth.[2] After the first day, the reference ranges for hemoglobin and hematocrit gradually decrease, as shown in Figure 43.2 (term and late preterm neonate) and Figure 43.3 (preterm neonates).

The mean corpuscular volume (MCV) at birth is highly dependent on gestational age, as shown in Figure 43.4.[33] Values below the 5th percentile are seen in neonates with α-thalassemia trait or hereditary spherocytosis.[34,35,36] A low MCV at birth due to fetal iron deficiency is less common, but this can occur with chronic fetomaternal hemorrhage or twin-to-twin transfusion syndrome. The mean corpuscular hemoglobin (MCH), like the MCV, is high at birth, by adult standards, and is highly dependent on gestational age. In contrast, the mean corpuscular hemoglobin concentration (MCHC) does not change with gestational age and should be in the range 33 to 35 g/dl in all neonates whether born prematurely or at term. An MCHC value >36 to 36.5 g/dl can suggest hereditary spherocytosis, particularly if accompanied by an MCV below the reference range for gestational age.[35,36]

Reticulocytosis and normoblastosis reflect the accelerated nature of fetal erythropoiesis. Reticulocyte counts at birth are approximately 5%, with a range of 4% to 7%.[2] Counts in preterm infants are slightly higher, averaging 6% to 10%. Reticulocytes remain elevated for the first 1 to 2 days of life, then drop abruptly to 0% to 1%.

Nucleated red blood cells (NRBC) are seen regularly on blood smears during the first day of life. The reference ranges for NRBC, according to gestational age at birth, are shown in Figure 43.5.[37] Elevations in NRBC in preterm infants correlate with adverse outcomes of intraventricular hemorrhage (IVH) and periventricular leukomalacia.[37,38] Elevations in NRBC in term infants correlate with hypoxic ischemic encephalopathy and with adverse neurodevelopmental outcomes.[37,38]

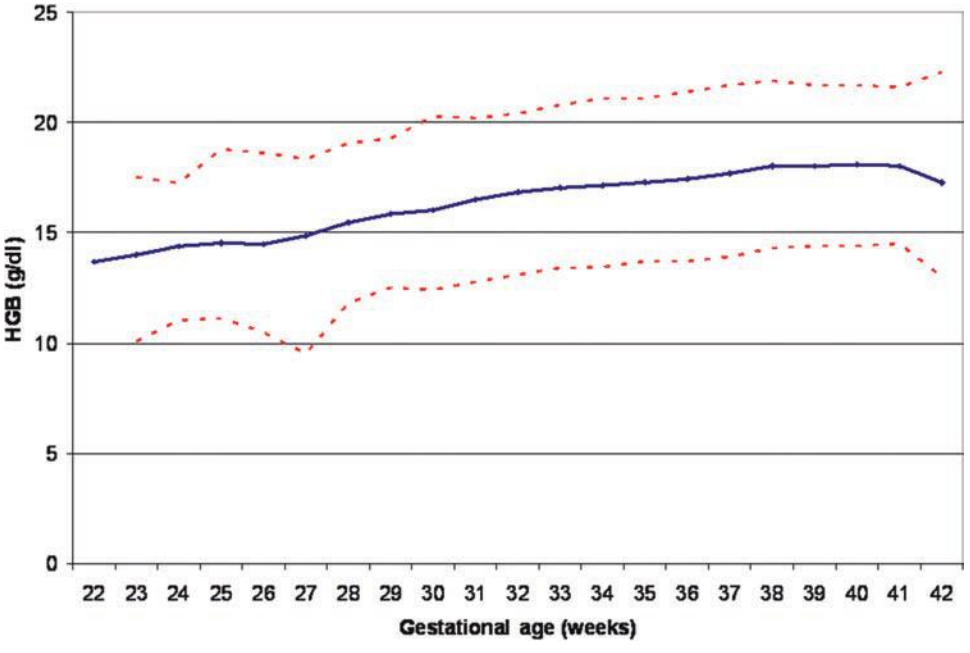

FIGURE 43.1. Reference ranges for blood hemoglobin concentration at birth. Values are shown from 24,416 subjects after 22 to 42 weeks gestation. The solid line shows the mean value and the dashed lines show the 5% and the 95% reference range. (From Jopling et al. Reference ranges for hematocrit and blood hemoglobin concentration during the neonatal period; data from a multihospital healthcare system. Pediatrics 2009;123;e333–e337.)

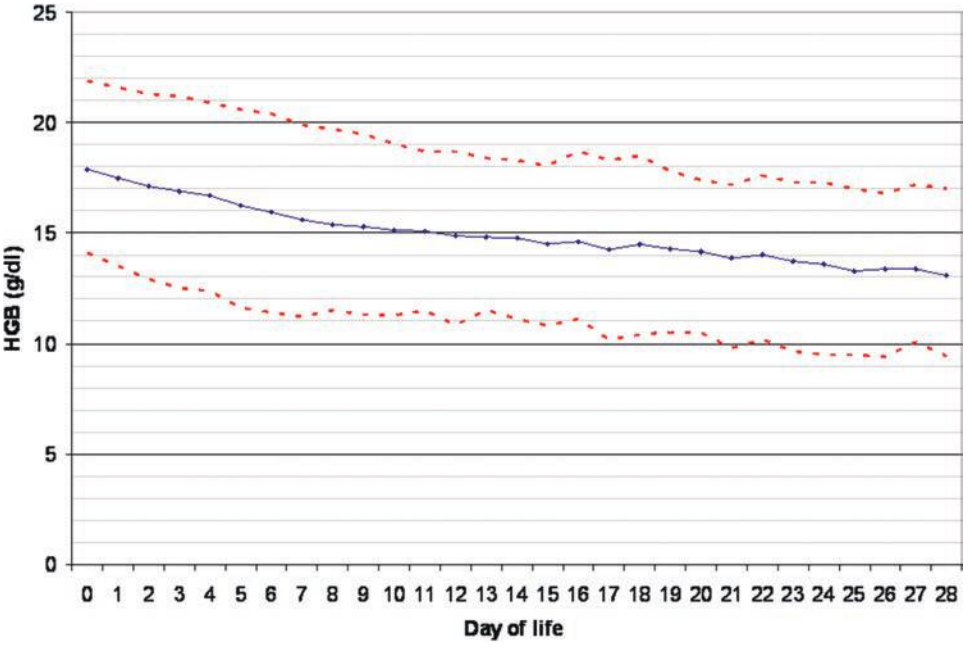

FIGURE 43.2. Reference ranges for blood hemoglobin concentration of term and late preterm neonates during the first month after birth. The solid line shows the mean value and the dashed lines show the 5% and the 95% reference range. (From Jopling et al. Reference ranges for hematocrit and blood hemoglobin concentration during the neonatal period; data from a multihospital healthcare system. Pediatrics 2009;123;e333–e337.)

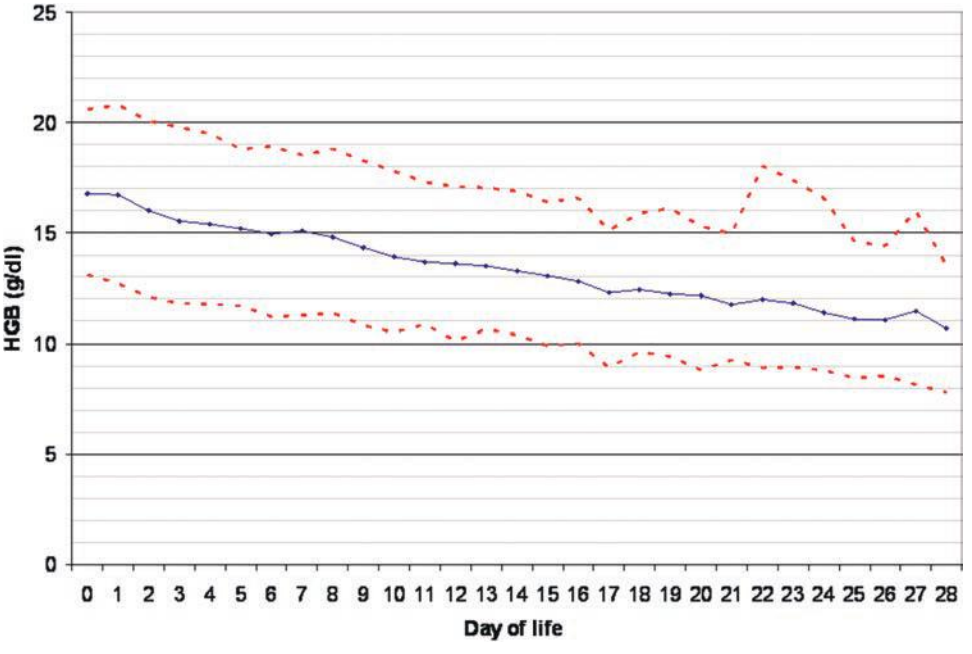

FIGURE 43.3. Reference ranges for blood hemoglobin concentration of neonates 29 to 34 weeks gestation during the first month after birth. The solid line shows the mean value and the dashed lines show the 5% and the 95% reference range. (From Jopling et al. Reference ranges for hematocrit and blood hemoglobin concentration during the neonatal period; data from a multihospital healthcare system. Pediatrics 2009;123;e333–e337.)

Red cell morphology in the newly born preterm or term neonate is characterized by macrocytosis and poikilocytosis. Target cells and irregularly shaped cells are particularly prominent. A high proportion of stomatocytes is noted when viewed by phase contrast microscopy.[39] Similarly a high proportion of siderocytes (3.16% vs. normal male adult mean of 0.09%) are seen.[40] Differential staining of red cells for fetal hemoglobin (HbF) provides a demonstration of the switch in hemoglobin synthesis that precedes birth: the younger macrocytes contain a minimal amount of HbF, whereas the smaller older cells are rich in HbF.[41]

Variations in red cell size and shape are somewhat greater than those observed in term infants, and cytoplasmic vacuoles are evident in nearly one-half of all cells when viewed by using interference-contrast microscopy. Red cell survival is shorter in preterm than in term infants. For infants who undergo exchange transfusion or multiple transfusions, both erythropoietin concentrations and reticulocyte counts are lower at any given hemoglobin concentration.[42] It had been assumed that oxygen delivery is decreased in newborns because of the presence of a high-affinity hemoglobin, but a leftward shift in the hemoglobin–oxygen dissociation curve due to high levels of HbF might actually better maintain oxygen delivery during episodes of severe hypoxemia.[43]

The capacity of a fetus or neonate to deliver oxygen to tissues is better estimated by the circulating red blood cell volume than by the hematocrit or hemoglobin concentration. However, measuring the circulating red blood cell volume in a fetus or neonate is particularly difficult. Therefore, either the hematocrit or the hemoglobin is often used in making transfusion decisions. Mock

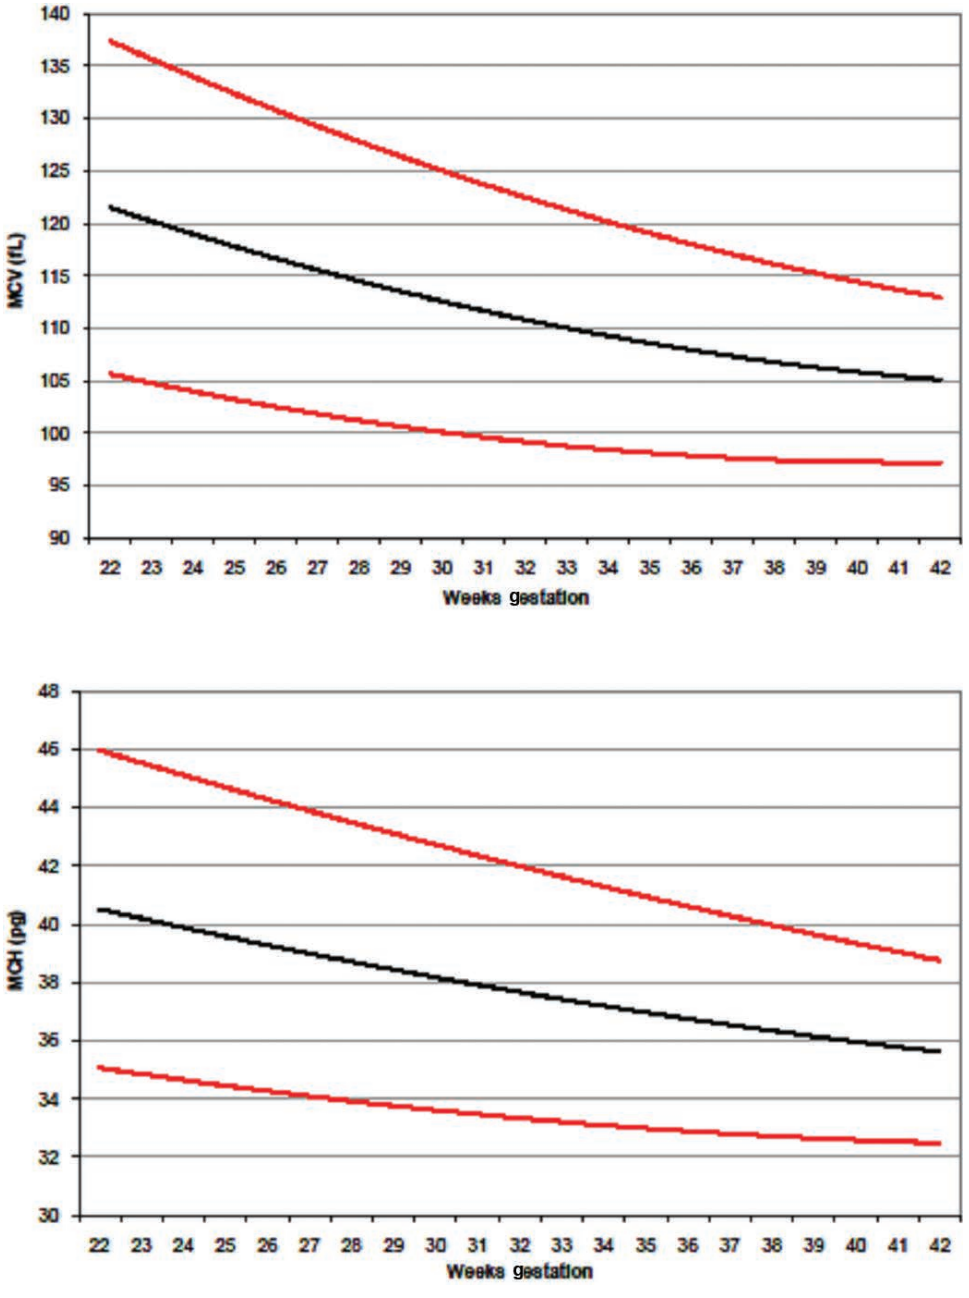

FIGURE 43.4. Reference ranges for mean corpuscular volume (MCV) upper panel, and mean corpuscular hemoglobin (MCH) on the day of birth. Values are shown from subjects after 22 to 42 weeks gestation. The solid line shows the mean value and the dashed lines show the 5% and the 95% reference range. (From Christensen et al. The erythrocyte indices of neonates, defined using data from over 12,000 patients in a multihospital healthcare system. J Perinatol 2008;28:24–28.)

et al. used a nonradioactive method, based on in vivo dilution of biotinylated RBC enumerated by flow cytometry, to estimate the correlation between hematocrit and circulating RBC volume in infants below 1,300 grams, between 7 and 79 days of life. They found that venous hematocrit values correlated highly with the circulating erythrocyte volume ($r = 0.907$; $p < 0.0001$).[44]

Neonates have a shorter red cell survival than do children and adults.[45] The life span of red cells from term infants is estimated to be 60 to 80 days with use of the ^{51}Cr method and 45 to 70 days using methods involving ^{59}Fe.[45] Fetal studies using [14C] cyanate-labeled red cells in sheep revealed an average red cell life span of 63.6 ± 5.8 days.[46] The mean red cell life span increased linearly from 35 to 107 days as the fetal age increased from 97 days (mid-gestation) to 136 days (term).

Neonatal red cells transfused into adults have a similarly short survival,[47] indicating that factors intrinsic to the newborn red cell are responsible. Also, adult red cells survive normally in newborn recipients.[48] The life span is not parametrically distributed, in that most cells are destroyed before the mean survival is reached. Shortened red cell survival as well as demands imposed by an expanding red cell mass account for erythropoietic rates at birth that are three to five times higher than those of normal adults.

The abrupt transition from the uterus to an oxygen-rich environment triggers responses that have a profound effect on erythropoiesis. During the first 2 months of life, the infant experiences both the highest and lowest hemoglobin concentrations occurring at any time in development. Although quite variable, erythropoietin levels at birth usually are well above the normal adult range. Erythropoietin levels fall in the immediate postnatal period, with a half-life of 2.6 ± 0.5 hours in infants with polycythemia and 3.7 ± 0.9 hours in infants born to mothers with preeclampsia.[49] By 24 hours, the erythropoietin value is below the normal adult range, where it remains throughout the first month. The decrease in erythropoietin is followed by a decline in the number of bone marrow precursors[50] and a fall in the reticulocyte count.

The combination of shortened cell survival, decreased production, and growth-related expansion of the blood volume is responsible for a progressive fall of the hemoglobin concentration

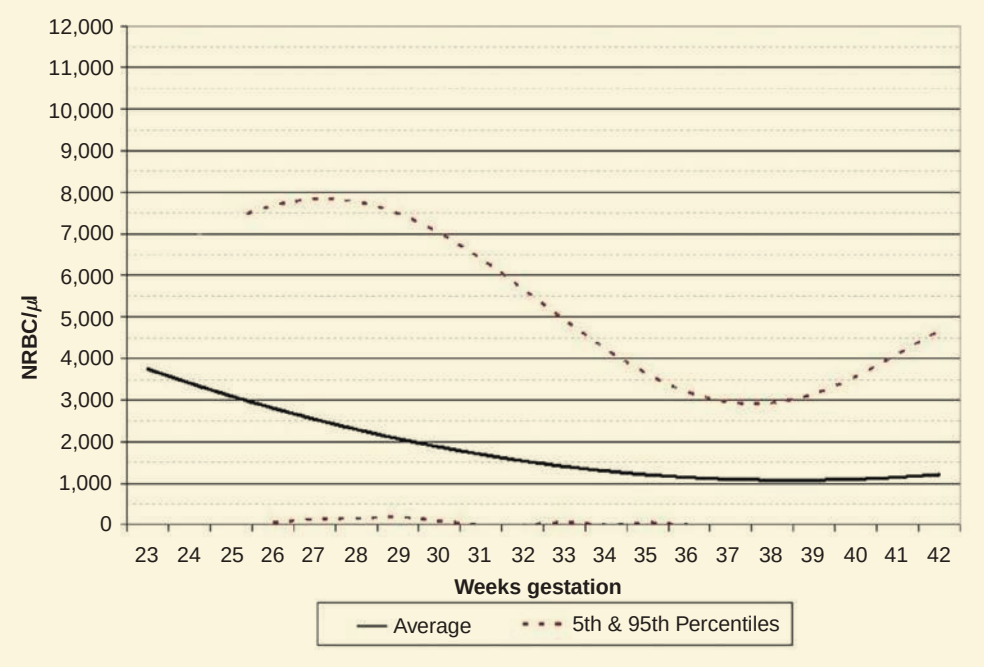

FIGURE 43.5. Reference ranges for blood concentrations of nucleated erythrocytes on the day of birth. Values are shown from subjects after 23 to 42 weeks gestation. The solid line shows the mean value and the dashed lines show the 5% and the 95% referenc range. (From Christensen et al. Neonatal reference ranges for blood concentrations of nucleated red blood cells. Neonatology 2010;99:289–294.)

to a mean of approximately 11 g/dl at 2 months of age.[51] The lower range of normal for infants of this age is approximately 9 g/dl. This nadir is called *physiologic anemia*, because it is not associated with apparent distress and is not prevented with nutritional supplements. Stabilization of the hemoglobin concentration is heralded by an increase in reticulocytes at 4 to 8 weeks.[50] Thereafter, the hemoglobin concentration rises to a mean level of 12.5 g/dl, where it remains throughout infancy and early childhood.

At term, the placenta and umbilical cord contain 75 to 125 ml of blood, or approximately one fourth to one third of the fetal blood volume. The umbilical arteries constrict shortly after birth but the umbilical vein remains dilated, and blood flows in the direction of gravity. Infants held below the level of the placenta can receive half of the placental blood volume (30 to 50 ml) in 1 minute. Conversely, infants held above the placenta can lose 20 to 30 ml of blood back into the placenta per minute.[52] The blood volume of infants with early cord clamping averages 72 ml/kg, whereas the volume of infants with delayed cord clamping averages 93 ml/kg. Linderkamp et al. compared postnatal alterations in blood viscosity, hematocrit, plasma viscosity, red cell aggregation, and red cell deformability in the first 5 days in full-term neonates with early (less than 10 seconds) and late (3 minutes) cord clamping.[53] The residual placental blood volume decreased from 52 ± 8 ml/kg of neonatal body weight after early cord clamping to 15 ± 4 ml/kg after late cord clamping. The neonatal blood volume was 50% higher in the late cord-clamped infants than in the early cord-clamped infants.

It is possible to promote placental transfer of blood to preterm infants by delaying the clamping of the umbilical cord for 30 seconds. In fact transfer of about 10 ml/k body wt can be expected using this method.[54] In a randomized trial by Mercer et al., this maneuver of delayed cord clamping among infants <1,500 grams birth weight resulted in less IVH and less late-onset sepsis.[55] An alternative approach involves "milking or "stripping of the umbilical cord after delivery, while the placenta is still attached to the uterus. This maneuver moves fetal blood toward the fetus before the umbilical cord is clamped. Delayed clamping and cord stripping are roughly equivalent means of providing a small transfusion before birth of a very low birth weight (VLBW) infant, thereby reducing the odds that a donor blood transfusion will be needed during the first days after birth when phlebotomies for laboratory tests commonly result in transfusions to replace the rapidly depleted red cell mass.[56–58]

FETAL AND NEONATAL ERYTHROCYTE MEMBRANE AND METABOLISM

The erythrocyte membranes of neonates differ slightly from those of adults.[59] The percentage of spectrin dimers and the spectrin tryptic peptide patterns are the same as in adult cells[60] but neonatal cells have more immunoreactive myosin.[61] The quantity and distribution of lipids differ in several respects from adult red cells. Total lipid, phospholipid, and cholesterol are increased out of proportion to the surface area of newborn red cells.[62,63] Neonatal cells also exhibit increased endocytosis in response to membrane-active agents, suggesting that the membranes of neonatal cells are less stable and are capable of greater reorganization.[59]

Antigen expression differs from that of adult cells. The A, B, S, and Lutheran antigens are present in decreased amounts. Replacement of the i antigen with its adult counterpart I requires its conversion from a linear polylactosamine to a branched polylactosamine.[59] Reduced A and B antigenicity may result in part from decreased branching and increased stimulation of glycoproteins on neonatal red cells.[64]

At term, red cell deformability and viscoelastic properties are normal.[65] Similarly, osmotic fragility of erythrocyte from preterm neonates is similar to or even slightly less fragile than erythrocytes of term neonates. However, preterm neonates may have a small subpopulation of cells that are more susceptible to hemolysis, giving preterm infants a greater tendency to develop hemolytic jaundice.[66]

Increased concentrations of certain erythrocyte enzymes in neonates can be explained by the young mean age of red cells. The increase in glycolytic enzymes is comparable in magnitude to that observed in high-reticulocyte adult blood.[67,68] Increased glycolytic enzyme activity, in turn, is responsible for increased consumption of glucose and galactose and increased levels of adenosine triphosphate (ATP).[69] Unique metabolic characteristics of neonatal erythrocytes are summarized in Table 43.2.

TABLE 43.2

METABOLIC CHARACTERISTICS OF FETAL/NEONATAL RED BLOOD CELLS

Metabolic characteristics explained by young mean cell age
Increased enzyme activity
Hexokinase
Aldolase
Triosephosphate isomerase
Phosphoglycerate mutase
Pyruvate kinase
Lactate dehydrogenase
Glucose-6-phosphate dehydrogenase
6-Phosphogluconate dehydrogenase
Glutathione reductase
Glyoxalase I and II
Galactokinase
Galactose-1-phosphate uridyl transferase
Increased glucose and galactose consumption
Increased levels of ATP
Metabolic characteristics distinctive for neonatal red cells
Embden-Meyerhof pathway
Increased activity of phosphoglycerate kinase, enolase, glucose phosphate isomerase, and glyceraldehyde-3-phosphate dehydrogenase
Decreased activity of phosphofructokinase
2,3-Diphosphoglycerate instability
Pentose phosphate pathway and glutathione metabolism
Decreased glutathione peroxidase and glutathione synthetase
Glutathione instability
ATP and phosphate metabolism
ATP instability
Decreased phosphate uptake, slower incorporation of phosphate into ATP and 2,3-diphosphoglycerate
Nonglycolytic enzymes
Decreased enzyme activity
Carbonic anhydrase
Catalase
Cholinesterase
Adenylate kinase
Phosphoribosyl transferase
Cytochrome b_5 reductase

ATP, adenosine triphosphate.

The activities of four enzymes in the Embden-Meyerhof pathway—phosphoglycerate kinase, enolase, glucose phosphate isomerase, and glyceraldehyde-3-phosphate dehydrogenase—are increased out of proportion to cell age.[70,71] The activity of phosphofructokinase, a rate-controlling enzyme in glycolysis, is only 40% to 70% of that in adult red cells of comparable age.[68,69,71] Low levels of phosphofructokinase may produce a block in glycolysis, resulting in the accumulation of glucose-6-phosphate and fructose-6-phosphate and a decrease in the amounts of 2,3-diphosphoglycerate (2,3-DPG) and phosphoenolpyruvate.[71] Decreased activity of phosphofructokinase is probably explained by accelerated decay of a less stable fetal isoenzyme.[72] Neonatal red cells contain a homotetramer of liver-type phosphofructokinase subunits rather than the heterotetramer of liver and muscle subunits present in adult cells.[73] Differences in the relative proportions of isoenzymes have also been described for hexokinase and enolase.[74] The concentration of 2,3-DPG falls rapidly during short periods of incubation,[69] apparently because of accelerated breakdown. Preterm infants have lower 2,3-DPG concentrations than term infants. These concentrations gradually increase with gestation.[75,76] Concentrations can be increased with the use of erythropoietin, thereby shifting the oxygen dissociation curve to the right.[77]

The activities of two key enzymes of the pentose phosphate pathway, glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase, are increased by virtue of a young mean red cell age.[68,69] The response of the pentose phosphate pathway to oxidant stimuli is normal, and the level of reduced glutathione is equal to or greater than that found in adults.[70] Despite this, newborn cells exhibit glutathione instability, increased Heinz body formation, and a propensity to increased methemoglobin generation, all indicative of greater susceptibility to oxidant-induced injury.[67] The basis for this oxidant vulnerability is not known. Although red cells of the newborn infant have low levels of activities of both glutathione peroxidase[78] and glutathione synthetase,[79] no apparent relationship exists between these deficiencies and oxidant vulnerability.[80] Other factors that have been implicated in attempts to explain metabolic differences include deficient catalase activity, decreased numbers of membrane sulfhydryl groups,[81] greater residual membrane hemoglobin,[82] and other plasma factors.[83,84] Studies evaluating the antioxidant capacity of preterm red cells and plasma from infants with respiratory distress syndrome reported no difference in activity between sick and well preterm infants, and antioxidant activity appeared intact. The study did not provide convincing evidence of oxidative damage and diminished antioxidant defenses in preterm infants with neonatal respiratory distress syndrome.[85]

Although elevated at birth, the red cell ATP level falls rapidly during short periods of incubation. The uptake of labeled orthophosphate by cord blood cells is slower than that by adult cells, resulting in delayed incorporation of phosphate into ATP and 2,3-DPG.[86] This disturbance in energy metabolism has been held responsible for accelerated potassium loss during incubation. Neonatal erythrocytes have increased rates of endocytosis compared to adult erythrocytes; these rates gradually decrease to adult levels with prolonged incubation.[87] In septic neonates, ATP concentration in red blood cells was significantly lower than in neonates with respiratory distress syndrome and controls, whereas the 2,3-DPG concentration was increased.[88]

The activity of a number of nonglycolytic enzymes differs in neonatal red cells compared to adult red cells. Carbonic anhydrase,[86] catalase,[89] acetylcholinesterase,[90] adenylate kinase,[90] hypoxanthine-guanine-phosphoribosyl transferase,[91] and cytochrome b_5 reductase[92] are all less active than in adult red cells. Differences in carbonic anhydrase activity have been exploited by using this enzyme to lyse selectively any contaminating maternal cells from samples of mixed fetal and maternal cells obtained for the prenatal diagnosis of hemoglobinopathies.[93] Reduced activity of cytochrome b_5 reductase, the enzyme responsible for methemoglobin reduction, contributes to the infant's vulnerability to methemoglobinemia. This enzyme exists in both soluble and membrane-bound forms. The membrane-bound form is the precursor enzyme that is posttranslationally processed to a smaller soluble form, probably by a calmodulin-dependent endogenous protease.[94] Neonatal red cells have membrane-bound cytochrome b_5 reductase activity comparable to that of adult cells but are limited in their ability to convert membrane-bound enzyme to the soluble form.

Cord blood contains HbF (α_2, γ_2), HbA (α_2, β_2), and HbA2 (α_2, δ_2), with HbF constituting the major fraction (50% to 85%) at term. Because of this, hemoglobinopathies involving β-chain synthesis, such as sickle cell disease and β-thalassemia, do not present in the neonatal period. The G-γ to A-γ ratio at birth is approximately 3:1, in contrast to a ratio of 2:3 in adults.[95]

HbA accounts for 15% to 40% of the hemoglobin at term and HbA2 is present in only trace amounts (mean, 0.3%), but increases slowly after birth, reaching the normal adult level (2% to 3%) by 5 months. The level of HbF at birth is influenced by a number of variables, the most significant of which is gestational age. Premature infants have more HbF and postmature infants less (Fig. 43.6).[95] Neonates who have survived chronic intrauterine hypoxia, such as occurs with maternal heart and lung disease, have higher levels of HbF. The switch from γ-chain synthesis to β-chain synthesis appears to be developmentally programmed. Neither intrauterine transfusion nor neonatal exchange transfusion affects the synthetic rates of β- and δ-chains.[96]

HbF has an affinity for oxygen that is greater than that of HbA.[97] The oxygen tension at which the hemoglobin of cord blood is 50% saturated is 19 to 21 mm Hg, 6 to 8 mm Hg lower than that of the hemoglobin of normal adult blood. This shift to the left of the hemoglobin–oxygen dissociation curve results from poor binding of 2,3-DPG by HbF.[98] The position of the oxygen dissociation curve is determined by both the percentage of HbA and the red cell content of 2,3-DPG.[99] As the relative proportion of HbA increases, the oxygen dissociation curve shifts by approximately 4 to 6 months of age to a position that is normal for the adult (Fig. 43.7). The increased oxygen affinity of HbF confers a physiologic advantage to the fetus in facilitating the transfer of oxygen from mother to fetus.

HbF is resistant to alkali denaturation, and unlike HbA is not eluted from fixed blood smears immersed in an acid buffer.[100] This property permits the differential staining of HbF and HbA, a technique used to detect fetal cells in the maternal circulation.

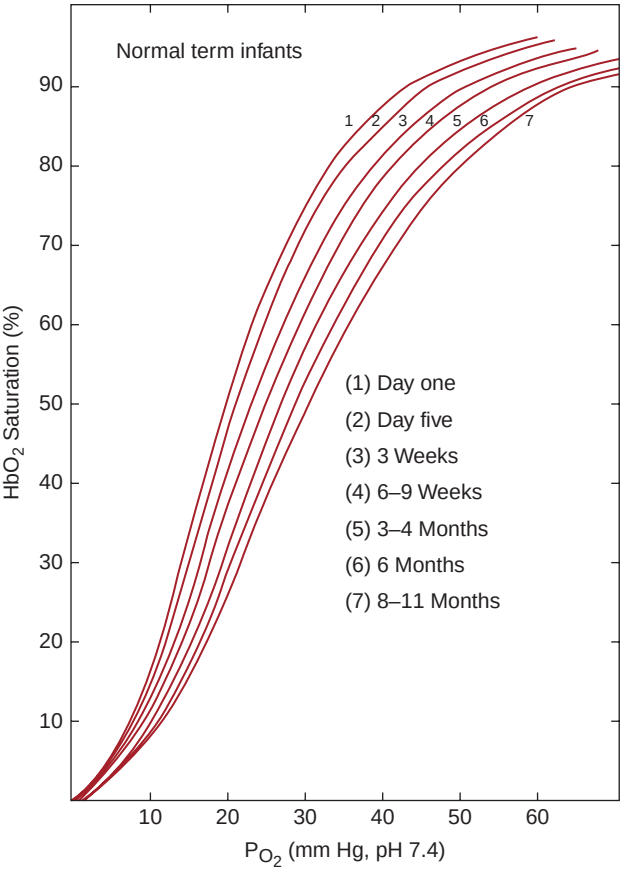

FIGURE 43.7. Oxygen dissociation curves of blood from term infants at different postnatal ages. (From Oski FA, Delivoria-Papadopoulos M. The red cell 2,3-diphosphoglycerate, and tissue oxygen release. J Pediatri 1970;77:941–956, with permission.)

FETAL AND NEONATAL ANEMIA DUE TO HEMOLYSIS

Bilirubin is effectively cleared from fetal blood by the placenta and is metabolized by the maternal liver.[101] As a result, fetal hemolytic disease does not present with significant jaundice immediately at birth. However, after birth the products of heme catabolism must be processed by the neonate's liver, which is limited in its ability to metabolize bilirubin efficiently, in part because of a relative deficiency of the cytoplasmic acceptor protein ligandin, and in part because of decreased activity of uridine diphosphoglucuronyl transferase.[102]

Causes of hemolytic disease in the newborn are noted in Table 43.3. Worldwide, isoimmunization caused by maternal–fetal blood group incompatibility is the most common cause of hemolytic anemia. Antigens in the ABO, MN, Rh, Kell, Duffy, and Vel systems are well developed on fetal red cells during early intrauterine life.[103] They are present in the fifth to seventh gestational week and remain constant through the remainder of intrauterine development. Other antigens, such as the Lutheran and XgA systems, develop more slowly but are present at birth, unlike Lewis antigens, which develop after birth. By 2 years of age, red cell and plasma antigens have developed a pattern that is seen throughout the remainder of life.[104]

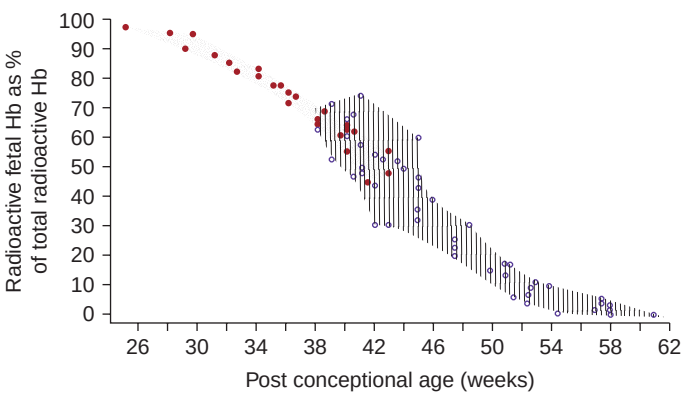

FIGURE 43.6. Decline in fetal hemoglobin synthesis as a function of gestational age. Solid dots represent cord blood samples from preterm infants, open circles are samples from term infants. (From Bard H. The postnatal decline of hemoglobin F synthesis in normal full-term infants. J Clin Invest 1975;55:395–398, with permission.)

Although A and B antigens are present early in utero, A and B isoagglutinin production occurs later during the second and third trimesters.[104] By 30 to 34 weeks gestation, about one half of all fetuses have some measurable anti-A or anti-B antibodies. The fetal production of such antibodies is not related to maternal blood type, rather, intrauterine exposure to gram-negative organisms whose antigens are chemically related to those of blood groups A and B act as a potent stimulus for antibody development. Isoimmunization due to Rh or ABO incompatibility is the most common cause of hemolytic disease in the newborn period. ABO incompatibility represents a spectrum of hemolytic disease in newborns.

Fetuses with hemolytic anemia due to anti-Kell antibody have lower reticulocyte counts and total serum bilirubin levels than comparable anti-D anemic fetuses.[105] The level of hemolysis caused by anti-Kell antibodies is less than that caused by anti-D antibodies, but fetal erythropoiesis is blunted because Kell sensitization results in both suppression of fetal erythropoiesis and hemolysis. Anti-Kell antibodies cause fetal anemia by suppressing erythropoiesis at the level of erythroid progenitors.

TABLE 43.3

CAUSES OF HEMOLYTIC DISEASE IN NEWBORNS

- Immune-mediated
  - Rh incompatibility (anti-D antibody)
  - ABO, c, C, e, E, G incompatibility
  - Minor blood group incompatibility:
  - Fya (Duffy), Kell group, Jka, MNS, Vw
  - Drug-induced (penicillin, α-methyldopa, cephalosporins)
  - Maternal autoimmune hemolytic anemia
  - Non-Immune mediated
- Congenital erythrocyte enzyme defects
  - Glucose-6-phosphate dehydrogenase deficiency
  - Pyruvate kinase deficiency
  - Hexokinase deficiency
  - Glucose phosphate isomerase deficiency
  - Pyrimidine 5′ nucleotidase deficiency
- Hereditary erythrocyte membrane disorders
  - Spherocytosis
  - Elliptocytosis
  - Stomatocytosis
  - Pyropoikilocytosis
  - Other membrane disorders
- Infection
  - Bacterial sepsis (*Escherichia coli*, group B streptococcus)
  - Parvovirus B19 (can present with hydrops fetalis)
  - Congenital syphilis
  - Congenital malaria
  - Congenital TORCH infections (toxoplasmosis, rubella, cytomegalovirus, disseminated herpes)
  - Other congenital viral infections
- Hemoglobin defects
  - α-Thalassemia syndromes
  - γ-Thalassemia syndromes
  - α- and γ-Chain structural anomalies
  - Macro- and microangiopathic hemolysis
  - Cavernous hemangiomas
  - Arteriovenous malformations
  - Renal artery stenosis or thrombosis
  - Other large vessel thrombi
  - Severe coarctation of the aorta
  - Severe valvular stenoses
- Other causes
  - Disseminated intravascular coagulation
  - Hypothyroidism
  - Galactosemia
  - Lysosomal storage diseases
  - Prolonged metabolic acidosis from metabolic disease (amino acid and organic acid disorders)

High titers of anti-C antibody have been associated with neonatal hemolytic disease.[106] However, routine screening of anti-C titers during pregnancy is not warranted, because antibody titers do not accurately reflect the severity of hemolytic disease.[107] C(w) is a low-frequency antigen in the Rh blood group system with a prevalence of about 2% among Caucasian populations. Anti-C(w) is not too uncommon in pregnancy (0.1% incidence), but clinically significant hemolytic disease of the newborn is very unusual.[108]

FETAL AND NEONATAL ANEMIA DUE TO HEMORRHAGE

Hemorrhage can occur at any time during the prenatal, perinatal, and postnatal periods (Table 43.4).

Prenatal Hemorrhage

Small numbers of maternal and fetal erythrocytes cross the placental barrier during pregnancy. The volume of fetal blood identified in the maternal circulation, at delivery, is generally on the order of 0.01 to 0.1 ml. However, approximately 1 in 400 pregnancies is associated with a fetal to maternal hemorrhage of 30 ml or more, and approximately 1 in 2,000 pregnancies are associated with a potential fetal transplacental hemorrhage of 100 ml or more.[109] To detect and quantify fetal–maternal hemorrhage, flow cytometric–based methods, quantifying erythrocytes with HbF in the maternal circulation, are more sensitive than the Kleihauer–Betke.[109] Significant fetal–maternal hemorrhage has been described following maternal trauma,[110] but most cases have no identified antecedent.

Term neonates born after a large fetomaternal hemorrhage present with pallor and tachypnea but they generally have minimal to no requirement for supplemental oxygen. Hemoglobin concentrations can be extremely low at birth, between 4 and 6 g/dl, and a significant metabolic acidosis is often present as a result of poor perfusion.

Twin–twin transfusion occurs in 5% to 30% of monochorionic twin gestations and involves placental anastomoses that allow net transfer of blood from one twin to the other.[111] The perinatal mortality rate can be as high as 70% to 100%, depending on severity

TABLE 43.4

CAUSES OF HEMORRHAGE IN THE FETUS/NEONATE

- Prenatal
  - Chronic and/or acute twin-to-twin transfusion syndrome
  - Chronic and/or acute fetal–maternal hemorrhage
  - Hemorrhage into amniotic fluid after periumbilical blood sampling
  - Traumatic amniocentesis
  - Maternal trauma
  - Trauma after external cephalic version
- Perinatal
  - Placental abruption
  - Placenta previa
  - Vasa previa
  - Trauma or incision of placenta during cesarean section
  - Ruptured normal or abnormal (varices, aneurysms, hematoma) umbilical cord
  - Placental hematoma
  - Velamentous insertion of the cord
  - Nuchal cord
- Postnatal
  - Subgaleal hemorrhage
  - Cephalohematoma
  - Hemorrhage associated with disseminated intravascular coagulation/sepsis
  - Intraventricular/intracranial hemorrhage (prematurity, trauma, isoimmune thrombocytopenia)
  - Organ trauma (liver, spleen, adrenal, renal, gonadal)
  - Pulmonary hemorrhage
  - Iatrogenic blood loss (phlebotomy, central line accidents)

and timing of presentation. Approximately 70% of monozygous twin pregnancies have monochorionic placentas.[112] Although vascular anastomoses are present in almost all such cases, not all of those develop twin–twin transfusion.

Acute twin–twin transfusion generally results in twins of similar size but with hemoglobin concentrations that vary by more than 5 g/dl. In chronic twin–twin transfusion, the donor twin becomes progressively anemic and growth retarded, whereas the recipient becomes polycythemic, macrosomic, and sometimes hypertensive. Both can develop hydrops fetalis; the donor twin becomes hydropic from profound anemia, and the recipient from congestive heart failure and hypervolemia. The donor twin often has low amniotic fluid volumes, whereas the recipient twin has increased amniotic fluid.

Chronic twin–twin transfusion can be diagnosed by serial prenatal ultrasounds measuring cardiomegaly, discordant amniotic fluid production, and fetal growth discrepancy of >20%. Percutaneous umbilical blood sampling can determine if hemoglobin concentration differences of greater than 5 gm/dl exist between the two fetuses.[113] After birth, the donor twin may require transfusions and can also experience neutropenia, hydrops from severe anemia, growth retardation, congestive heart failure, and hypoglycemia. The recipient twin is often the sicker of the two. Problems include hypertrophic cardiomyopathy, congestive heart failure, polycythemia, hyperviscosity, respiratory difficulties, hypocalcemia, and hypoglycemia. Neurologic evaluation and imaging are helpful because of the risk of neurologic cerebral lesions in 20% to 30% of both twins.[114]

Prenatal treatment for twin–twin transfusion consists of close monitoring and reduction amniocenteses to decrease uterine stretch and prolong the pregnancy. Treatment in utero using laser surgery to ablate bridging vessels has become more common in the past decade. Most recent reports conclude an improvement in fetal survival using selective laser ablation.[115,116,117]

Perinatal Hemorrhage

Obstetric complications, such as placenta previa, abruption, incision or tearing of the placenta during cesarean section, and cord evulsion, can result in significant neonatal blood loss. Placental abruption involves premature separation of the placenta from the uterus and occurs in 3 to 6 per 1,000 live births.[118] Risk factors for abruption include cigarette smoking, prolonged rupture of the membranes, chorioamnionitis, hypertension (before pregnancy and pregnancy-induced), and advanced maternal age.[119–121] The incidence of abruption increases with lower gestational age, and abruption can be a cause of preterm delivery.[120] Mortality ranges from 0.8 to 2.0 per thousand births, or 15% to 20% of the deliveries in which significant abruption occurs.

Placenta previa involves part or all of the placenta overlying the cervical os. Maternal risk factors for developing a placenta previa are essentially the same as those for abruption.[122,123] Vasa previa (anomalous vessels overlying the internal cervix os) can be made with transvaginal color Doppler, and should be suspected in any case of antepartum or intrapartum hemorrhage. Although vasa previa is uncommon (1 in 3,000 deliveries), the perinatal death rate is high, ranging from 33% to 100% when undetected before delivery.[124]

Infants born after placental abruption or previa can be hypovolemic due to prenatal hemorrhage. Although the majority of the blood loss is maternal, loss of fetal blood can also occur, thus in neonates born after abruption or previa it is important to monitor blood pressure, hemoglobin/hematocrit, and tissue perfusion.

Cord rupture can occur during delivery due to traction on a shortened, weakened, or otherwise abnormal umbilical cord. Cord aneurysms, varices, and cysts can all lead to a weakened cord. Cord infections (funisitis) can also weaken the cord and increase the risk of rupture. Hematomas of the cord occur infrequently (1 in 5,000 to 6,000 deliveries) and can be a cause of fetal blood loss and fetal death. Hematomas of the cord can be diagnosed in utero by ultrasound and differentiated from other lesions of the placenta and cord.[125]

Velamentous insertion of the umbilical cord occurs when the cord enters the membranes distant from the placenta, and is present in approximately 0.5% to 2.0% of pregnancies. These vessels are more likely to tear, even in the absence of traction or trauma. The fetal mortality is high in this condition, because rapid detection is difficult.[126]

Postnatal Hemorrhage

Loss of fetal blood during delivery can occur into the placenta. The fetal–placental–umbilical cord unit contains about 120 ml/kg of blood, at term. After delivery, but before the umbilical cord is severed, blood in this unit can flow predominantly toward or away from the neonate. A fetoplacental hemorrhage can occur when the neonate is held significantly higher than the placenta after birth, for instance, on the mother's abdomen. It has been suggested that neonates can lose 10% to 20% of their blood volume when born with a tight nuchal cord, which allows blood to be pumped through umbilical arteries toward the placenta, while constricting flow back from the placenta to the baby, through the umbilical vein, which is more easily constricted due to its thin wall structure. However, in a study of over 200,000 deliveries, those with a tight nuchal cord (6.7%) did not have outcomes different from those with loose nuchal cords or with no nuchal cords.[127] On that basis, it is not clear that tight nuchal cords typically cause clinical problems.

Hemorrhage into the subgaleal space can be a life-threatening neonatal complication.[128] However, the spectrum of severity ranges widely, from a small asymptomatic hemorrhage to a massive one causing hypovolemic shock. Associations are well known between vacuum or forceps-assisted delivery and subgaleal hemorrhage, but some cases occur when neither vacuum nor forceps were applied. In 38 neonates recently reported with a subgaleal hemorrhage, 21 occurred after vacuum, two after forceps, four after vacuum followed by forceps, and 11 when neither vacuum nor forceps were used. Thirty-five were admitted to an intensive care unit. Transfusions were given to 13, but no transfusions were given in the group where neither vacuum nor forceps was used, suggesting their hemorrhages were less severe.[128]

Anemia appearing after the first 24 hours of life in a nonjaundiced infant can be a sign of hemorrhage. Visible hemorrhages, such as a cephalohematoma, as well as internal occult hemorrhages, can occur. Breech deliveries may be associated with renal, adrenal, or splenic hemorrhage into the retroperitoneal space. Delivery of macrosomic infants, such as infants born to diabetic mothers, can result in hemorrhage. Infants with overwhelming sepsis can bleed into soft tissue and organs, such as liver, adrenal glands, and lungs.

The liver in a neonate is prone to iatrogenic rupture, resulting in a high morbidity and mortality.[129] Infants may appear asymptomatic until the liver ruptures and hemoperitoneum occurs. This can occur in term and preterm infants[130] and has been associated with chest compressions during cardiopulmonary resuscitation. Surgical intervention involving vascular tamponade has been reported to save some infants; however, the mortality remains high.[131]

Splenic rupture can result from birth trauma or as a result of distention caused by extramedullary hematopoiesis. Abdominal distension and discoloration, scrotal swelling, and pallor are clinical signs of splenic rupture; these signs may also be seen with adrenal hemorrhage or hepatic rupture.[132] Other rare causes of postnatal hemorrhage include hemangiomas of the gastrointestinal tract,[133] vascular malformations of the skin, and hemorrhage into soft tumors, such as giant sacrococcygeal teratomas or ovarian cysts.

FETAL AND NEONATAL ANEMIA DUE TO CONGENITAL INFECTION

Neonatal bacterial sepsis can cause anemia on the basis of hemolysis, DIC, and/or hemorrhage. Neonates with sepsis are generally jaundiced and have hepatosplenomegaly. Some bacterial organisms responsible for neonatal sepsis produce hemolytic endotoxins that result in accelerated erythrocyte destruction.[134]

Congenital infections due to cytomegalovirus, toxoplasmosis, rubella, syphilis, and herpes simplex can also cause hemolytic anemia. Fetal and neonatal infection with parvovirus B19 can cause severe anemia, hydrops, and fetal demise.[135] The fetus or neonate generally presents with a hypoplastic anemia, but hemolysis can occur as well. The virus replicates in erythroid progenitor cells and results in red cell aplasia. In utero transfusions for hydropic fetuses can be successful. Intrauterine fetal infusion of B19 IgG-rich high titer gammaglobulin has been reported to be successful.[136]

Other fetal infections associated with neonatal anemia include malaria and HIV. Congenital malaria is seen rarely in the United States, generally in large cities where imported cases of malaria are increasing. In certain African countries, congenital malaria has been reported in up to 20% of neonates.[137] Congenital HIV infection in a neonate is generally asymptomatic. However, infants born to mothers on zidovudine can have a hypoplastic anemia due to suppressive effects of the drug on fetal erythropoiesis.[138]

ANEMIA OF PREMATURITY AND OTHER HYPOPROLIFERATIVE DISORDERS

Impaired erythrocyte production can occur in a fetus or neonate for a variety of reasons. Lack of an appropriate or sufficient marrow environment (as seen in osteopetrosis), lack of specific substrates or their carriers (e.g., iron, folate, vitamin B_{12}, or transcobalamin II deficiency), and lack of specific growth factors (e.g., decreased erythropoietin production or abnormalities in Epo receptors) can be causative.

Anemia of Prematurity

Infants delivered before 32 completed weeks gestation typically develop a transient and unique anemia knows as the *anemia of prematurity*.[139] During the first week or two after birth, while in an intensive care unit, anemia secondary to phlebotomy loss is common.[140] However after this period has passed, a second anemia is sometimes seen; it is characterized as a normocytic, normochromic, hyporegenerative anemia, with serum erythropoietin concentrations significantly below those found in adults with similar degrees of anemia.[141] This anemia is not responsive to the administration of iron, folate, or vitamin E. Some infants with the anemia of prematurity are asymptomatic, whereas others have clear signs of anemia that are alleviated by erythrocyte transfusion. These signs include tachycardia, rapid tiring with nipple feedings, poor weight gain, increased requirements for supplemental oxygen, episodes of apnea and bradycardia, and elevated serum lactate concentrations.[139–141]

The reason preterm infants do not significantly increase serum erythropoietin concentration during this anemia is not known.[142] Indeed, it is unclear whether production of erythropoietin does in fact increase, yet the serum concentration does not. Certainly their erythroid progenitors are sensitive to erythropoietin,[143,144] and concentrations of other erythropoietic growth factors appear to be normal.[145]

The molecular and cellular mechanisms responsible for the anemia of prematurity are multifactorial, and include the transition from fetal to adult hemoglobin, shortened erythrocyte survival, and hemodilution associated with a rapidly increasing body mass.[139,140] It is unknown whether preterm infants rely on erythropoietin produced by the liver (the source of erythropoietin in utero), or that produced by the kidney, or a combination of the two. Regardless of the mechanism responsible for the anemia of prematurity, exogenous erythropoietin administered to preterm infants accelerates effective erythropoiesis.[146,147] A meta-analysis of studies evaluating the use of "late erythropoietin administration to prevent and treat the anemia of prematurity reveals a positive effect on decreasing transfusion requirements in preterm infants.[148] In addition, beneficial neurodevelopmental effects of recombinant erythropoietin administration have been reported in preterm infants.[17,18,19,20,149,150]

Pharmacokinetic studies of darbepoetin, the long-acting erythropoietic stimulator, have been conducted among neonates with the anemia of prematurity, with the speculation that less frequent dosing and cost savings might render darbepoetin a more attractive alternative than recombinant erythropoietin for treating the anemia of prematurity.[151,152,153,154] Following subcutaneous and intravenous dosing, darbepoetin has a considerably shorter terminal half-life in neonates than in adults (Table 43.5). Intravenous dosing appears to be as effective as subcutaneous dosing.[153] Newer, long-acting Epo mimetics, such as CERA (continuous erythropoiesis receptor agonist), have yet to be studied in neonates, but may hold promise as potential agents to decrease transfusions and provide neuroprotection. Although a minimal number of clinical studies evaluating darbepoetin administration to preterm infants have been published, numerous RCTs evaluating Epo administration to preterm infants have consistently shown evidence of increased erythropoiesis and a decrease in transfusions.[141]

A consistent finding in the largest RCTs has been an elevation in hematocrit among Epo-treated infants compared with placebo/controls, despite the implementation of strict transfusion guidelines aimed at maintaining hematocrits in a similar range. For those neonatal practitioners electing to maintain hematocrits at higher levels, the use of Epo can gain a "buffer" of 4% to 6% hematocrit points, decreasing the number of transfusions given. This may benefit preterm infants in a number of ways, given recent studies that have reported associations between RBC transfusions and necrotizing enterocolitis (NEC)[155] and between RBC transfusions and IVH.[156,157]

Other Hypoproliferative Anemias

During the neonatal period, hypoproliferative anemias are rare, with the exception of the anemia of prematurity, which is common (Table 43.6). The hypoproliferative anemia Diamond-Blackfan syndrome can be diagnosed at birth, but characteristically is not recognized until after 2 to 3 months of age. In fact, 10% to 25% of infants with Diamond-Blackfan syndrome have at least a mild anemia at birth.[158] Severe anemia with hydrops has been

TABLE 43.5

TERMINAL T ½ OF DARBEPOETIN AMONG ADULTS, CHILDREN, AND NEONATES AFTER SUBCUTANEOUS OR INTRAVENOUS DOSING

	After Subcutaneous Dosing (hours)	After Intravenous Dosing (hours)
Adults	49	25
Children	43	22
Neonates	22	10

TABLE 43.6

SYNDROMES ASSOCIATED WITH FETAL/NEONATAL ANEMIA

Genetic Syndrome	Phenotypic Features	Genotypic Features
Adenosine deaminase deficiency	Autoimmune hemolytic anemia, reduced erythrocyte adenosine deaminase activity	AR, 20q13.11
Congenital dyserythropoietic anemias	Type I (rare): megaloblastoid erythroid hyperplasia and nuclear chromatin bridges between nuclei; type II (most common): "hereditary erythroblastic multinuclearity, positive acidified serum (HEMPAS) test, increased lysis to anti-i; type III: erythroblastic multinuclearity ("gigantoblasts), macrocytosis	Type I: 15q15.1-q15.3; type II: 20q11.2; type III: 15q21
Diamond-Blackfan syndrome	Steroid-responsive hypoplastic anemia, often macrocytic after 5 mo of age	AR; sporadic mutations and AD inheritance described; 19q13.2, 8p23.3-p22
Dyskeratosis congenita	Hypoproliferative anemia usually presenting between 5 and 15 yr of age	X-linked recessive, locus on Xq28; some cases with AD inheritance
Fanconi pancytopenia	Steroid-responsive hypoplastic anemia, reticulocytopenia, some macrocytic RBCs, shortened RBC lifespan. Cells are hypersensitive to DNA cross-linking agents	AR, multiple genes: complementation; group A: 16q24.3; B:; C: 9q22.3; D2: 3p25.3; E: 6p22-p21; F: 11p15; G: 9p13
Osler hemorrhagic telangiectasia syndrome	Hemorrhagic anemia	AD, 9q34.1
Osteopetrosis	Hypoplastic anemia from marrow compression; extramedullary erythropoiesis	AR: 16p13, 11q13.4-q13.5; AD: 1p21; lethal: reduced osteoclasts
Pearson syndrome	Hypoplastic sideroblastic anemia, marrow cell vacuolization	Pleioplasmatic rearrangement of mitochondrial DNA; X-linked or AR
Peutz-Jeghers syndrome	Iron-deficiency anemia from chronic blood loss	AD, 19p13.3
X-linked α-thalassemia/mental retardation (ATR-X and ATR-16) syndromes	ATR-X: hypochromic, microcytic anemia; mild form of hemoglobin H disease ATR-16: more significant hemoglobin H disease and anemia are present	ATR-X: X-linked recessive, Xq13.3; ATR-16: 16p13.3, deletions of α-globin locus

AD, autosomal dominant; AR, autosomal recessive; RBC, red blood cell.

reported in conjunction with this syndrome. Aase syndrome, another congenital hypoplastic anemia syndrome involving marrow and skeletal anomalies,[159] is sometimes classified as a variant of Diamond-Blackfan syndrome. Congenital dyserythropoietic anemia is a rare disorder marked by ineffective erythropoiesis, megaloblastic anemia, and characteristic abnormalities of the nuclear membrane and cytoplasm seen on electron microscopy. Fanconi pancytopenia rarely is manifested during the neonatal period. This autosomal-recessive disorder is characterized by marrow failure and congenital anomalies, including abnormalities in skin pigmentation, gastrointestinal anomalies, renal anomalies, and upper limb anomalies.[160] Approximately one third of patients have no obvious congenital anomalies, and anemia is less common than thrombocytopenia and leukopenia. Five genetic phenotypes of Fanconi pancytopenia have been reported, and two of the genes have been cloned.[161] Cells are hypersensitive to DNA cross-linking agents such as diepoxybutane and mitomycin C. The diepoxybutane test represents a sensitive and specific diagnostic test. When Fanconi anemia is recognized in a neonate, it is generally on the basis of the congenital anomalies and not the hematologic abnormalities. However, congenital thrombocytopenia, manifested during the immediate newborn period, progressing to pancytopenia has rarely been reported.[162] Erythropoietin concentrations are usually elevated, and HbF production is increased. A significant percentage of patients develop myelodysplastic syndrome or acute myelogenous leukemia later in life. Treatment of Fanconi pancytopenia includes androgen therapy, and, in many cases, bone marrow transplantation has been successful.

Autosomal-recessive osteopetrosis is a rare disorder characterized by osteoclast dysfunction, resulting in a decreased bone marrow space.[163] Developmental delay, ocular involvement, and neurodegenerative findings occur in association with hypoplastic anemia. Patients are generally treated with hematopoietic stem cell transplantation, but they are particularly susceptible to posttransplantation complications after myeloablation, and reduced-intensity conditioning programs may be helpful.[164]

Pearson syndrome is a congenital hypogenerative anemia that can progress to pancytopenia, and additionally affects the exocrine pancreas, liver, and kidneys.[165] Patients with this syndrome can present during the neonatal period, but typically do so later in infancy, often in the first year of life. Presenting features include failure to thrive, with anemia, neutropenia, and/or thrombocytopenia. The marrow examination typically shows characteristic vacuoles within erythroid and myeloid precursors, hemosiderosis, and ringed sideroblasts. The syndrome is caused by a loss of large segments of mitochondrial DNA.[166,167]

CONSIDERATIONS REGARDING ERYTHROCYTE TRANSFUSION IN THE NEONATAL PERIOD

Transfusion of banked donor erythrocytes can be life saving for small and ill neonates with severe anemia or hemorrhage. However, risks of transfusions exist and must be weighed against potential benefits each time a transfusion is considered. Two transfusion risks are highly unique to VLBW(<1,500 g) infants. The first is an association between RBC transfusions administered in the first few days after birth and the subsequent occurrence of a grade 3 or 4 IVH.[156,157,167] The second is an association between RBC transfusions administered during the third to fourth week and the subsequent occurrence of NEC.[155,167–171,172] Much remains to be discovered about the pathogenic links between transfusions and these adverse outcomes, and more work is needed to establish whether transfusions are causatively associated with these adverse outcomes or are co-variables.[168]

Means of avoiding transfusion among VLBW infants are listed in Table 43.7 and include: (1) Delay clamping of the umbilical cord, (2) strip or milk the cord, (3) draw all initial laboratory tests from fetal blood in the placenta and thereby draw no blood from the neonate, (4) reduce phlebotomy losses in the first days and weeks, (5) adopt written transfusion guidelines, (6) remove unnecessary indwelling catheters, (7) use an early dose(s) of erythropoietin or darbepoetin, and (8) optimize nutrition.

The idea of sterilely salvaging anticoagulated fetal blood from the umbilical cord and placenta at the time of birth, for a subsequent autologous transfusion for small or sick neonates has had limited study.[173–176,177] Harvesting cord blood from term pregnancies for stem cell transplantation is successful and popular.[176] However, harvesting from extremely preterm deliveries has practical limitations that have prevented this from becoming routine practice.[177] A few reports have used a modification of this practice for transfusion immediately after birth, aimed at immediate volume expansion of ill and small neonates.[178,179–181] Most such reports describe processing and storing the fetal blood in case a transfusion is needed in the subsequent days or weeks. Reports from Japan[182] and Germany[183] describe successful cord/placental blood transfusion for neonates with surgical problems. Earlier studies by Golden et al. demonstrated bacteriologic safety of this practice when the blood is used within 4 hours of delivery.[174–175] As better means are developed for harvesting, storing, and administering autologous fetal blood from extremely preterm deliveries, the benefits of using this blood, rather than donor blood, for early transfusions might outweigh the risks.[184,185–186]

The recent use of bi- or multiprobe near infrared spectroscopic (NIRS) monitoring in the NICU has provided new evidence of a benefit of RBC transfusions in selected patients.[187] Tissue oxygenation is estimated by NIRS on the basis of different near infrared light absorbance by oxyhemoglobin versus deoxyhemoglobin. Unlike pulse oximetry, NIRS evaluates hemoglobin oxygen saturations deeper in the tissue, about 2 cm below the skin surface, thus reflecting values from mixed arteriolar, venous, and capillary sources. When oxygen delivery to tissues becomes limited by anemia, oxygen extraction increases and venous oxygen saturation falls.[187]

Van Hoften et al. used NIRS monitoring to evaluate 33 preterm neonates before, during, and after a clinically ordered transfusion of 15 ml/kg RBC infused over a period of 3 hours.[188] They found that regional cerebral tissue oxygen saturation and the fractional tissue oxygen extraction correlated with the pretransfusion hemoglobin level, with lower hemoglobin levels predicting a lower cerebral oxygen tension. Their data supported the conclusion that a blood hemoglobin concentration <9.7 g/dl in a preterm infant corresponds with diminished cerebral oxygenation, and that erythrocyte transfusion improves this parameter. Dani et al. from Florence, Italy reported on 15 preterm infants using similar methodology, and came to a similar conclusion, that in neonates with a hemoglobin below about 6 g/dl, transfusion can often increase cerebral, splanchnic, and renal oxygenation.[189] Bailey et al. applied biprobe NIRS monitoring during a 20-minute period just before a clinically ordered RBC transfusion; 40 such measurements (each integrated over 30 seconds) were made.[190,191] One probe on the forehead was intended to assess cerebral and one on the abdomen to assess splanchnic changes. The measurements from each site were averaged into a ratio of oxygen saturations measured from the cerebral and splanchnic sites. The ratios were expressed as a SCOR (splanchnic–cerebral oxygenation ratio). Ratios were correlated with independent means of judging whether the transfusion actually provided a benefit. A SCOR at or below 73% (meaning the average oxygenation in the splanchnic circulation was ≤73% of the cerebral circulation) performed well in identifying the neonates who were likely to benefit from a transfusion.

With recent technological and other creative advances, it is becoming clear that NICU transfusions should not be ordered simply on the basis of the hemoglobin/hematocrit values. Better practice guidelines will likely consider NIRS and other measures of oxygen delivery to determine transfusion need.

TABLE 43.7

STRATEGIES FOR REDUCING ERYTHROCYTE TRANSFUSIONS AMONG VERY LOW BIRTH WEIGHT NEONATES

1. Delay clamping of the umbilical cord by 45 to 60 sec after birth, with the neonate in a position lower than the placenta.
2. Strip or milk the umbilical cord at birth, moving additional blood from the placenta and umbilical cord into the neonate, before the umbilical cord is clamped.
3. Draw all initial laboratory blood tests (blood culture, CBC, etc.) using fetal blood in the umbilical cord/placenta, thereby initially drawing no blood from the neonate.
4. Develop a consistent approach to minimizing phlebotomy losses in the first days and weeks.
5. Adopt written transfusion guidelines.
6. Remove indwelling catheters once they are not critically needed.
7. Early dose(s) of recombinant erythropoietin or darbepoetin.
8. Optimize nutrition.

CHAPTER 44

ERYTHROCYTOSIS

Robert T. Means, Jr.

DEFINITIONS AND TERMINOLOGY

The terms *polycythemia* and *erythrocytosis* are often used as if they are interchangeable; in fact, they describe related but distinct findings that usually, but not always, coexist. *Polycythemia* ("many cells") describes an increase in the total quantity or volume (mass) of red blood cells in the body without any implication regarding leukocytes or platelets. An increase in the *concentration* of erythrocytes, however, whether measured as number of cells, hemoglobin (Hb), or packed cell volume (PCV, hematocrit), is more correctly designated *erythrocytosis*. Erythrocytosis may be the result of an increase in the red cell volume or mass (polycythemia; also called *absolute erythrocytosis*) or the result of a reduced plasma volume (called *relative* or *spurious* polycythemia or erythrocytosis), which produces an increase in red cell concentration that does not reflect an increase in the quantity of red cells in the body.

Despite the precision with which these terms are defined, opportunities for confusion abound. *Polycythemia vera* (also called *polycythemia rubravera*) is a myeloproliferative disorder associated with trilineage marrow hyperplasia and characterized by an increased red cell mass, usually in association with leukocytosis and thrombocytosis. The outdated term *erythremia* refers to this disease (see Chapter 82). Some patients who do not have this myeloproliferative disease are described as having polycythemia vera simply because they have an elevated red cell mass (i.e., their polycythemia is "true" ["vera"]). Confusion on this point is frequently encountered in consultative hematology practice.

PATHOLOGIC PHYSIOLOGY

Red cell survival in polycythemic states is typically normal, implying that increased red cell mass reflects increased erythropoiesis. As the red cell mass rises, the total blood volume typically increases: the variability of changes in plasma volume means that the degree of increase is unpredictable.[1]

The clinical manifestations of erythrocytosis are related in part to the disorder responsible for erythrocytosis (e.g., thrombosis in patients with polycythemia vera,[2] hypertension in relative polycythemia,[3] etc.). In addition, the increased blood volume and increased blood viscosity that occur in association with polycythemia themselves produce certain symptoms and signs; these are related to the degree of the increase and the resulting effects on blood flow and oxygen transport.[4] Thus, the "ruddy cyanosis" seen in patients with polycythemia vera is a consequence of dilatation of cutaneous vessels by expanded blood volume and sluggish local circulation caused by increased blood viscosity.[5,6,7] Headache, dizziness, tinnitus, a full feeling in the head, and a bleeding tendency may develop in patients with erythrocytosis and expanded blood volume regardless of the basic cause.[8–11] These symptoms usually are relieved by normalization of the hematocrit.

Blood Viscosity and Oxygen Transport

Viscosity is an intrinsic characteristic of a liquid and represents the tendency of that liquid to resist changes in shape. The viscosity of blood is a result of the interaction of several factors, including the red cell concentration by volume, the physical characteristics (deformability, aggregability, and size) of red cells, the plasma volume, plasma proteins, platelet count, and leukocyte number and character.[12] In this chapter, the red cell concentration by volume is referred to as the *hematocrit*, reflecting common usage. Other authors, particularly those studying rheology and oxygen transport, refer to this parameter as the *volume of packed red blood cells* or PCV. As discussed below, the blood viscosity affects the oxygen content and delivery. This section focuses primarily on the contribution of red cell concentration to viscosity and oxygen transport; more complete discussions are available elsewhere.[12]

The rate of flow of a liquid through a tube of fixed length is directly related to the pressure gradient across that length of tube and to the radius raised to the fourth power (r^4) and inversely related to the viscosity of that liquid (Poiseuille's law).[9,10,13,14] Determinations of the effects of erythrocytosis on blood viscosity were largely made by determining the flow rate of venous blood through an 18-gauge needle under known pressure and thus calculating viscosity.[14] The values thus determined are only an approximation of the in vivo situation. Poiseuille's law is strictly applicable only to fluids that maintain constant viscosity under differing flow rates; this is not the case with blood (Fig. 44.1).[13,14] As the velocity of flow (indicated by the shear rate) increases, the viscosity at any given hematocrit decreases.[14] Other factors that interact with the hematocrit to contribute to viscosity are the mean erythrocyte corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH).[15,16,17] At any given hematocrit, decreased MCV or MCH (or both) is associated with increased viscosity, especially at low flow rates.[16,17] This is a clinically significant observation, because iron deficiency (low MCV) with a normal Hb

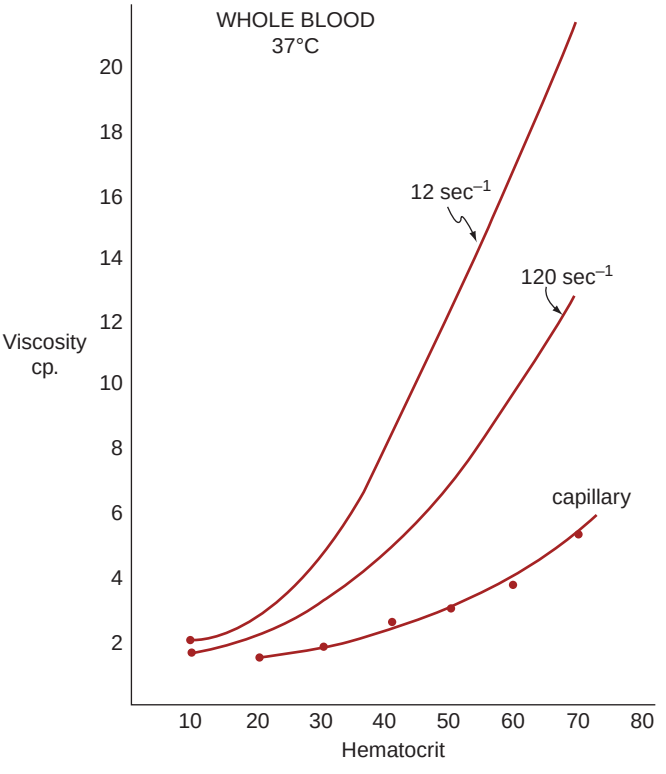

FIGURE 44.1. Relation of volume of packed red cells (hematocrit) to blood viscosity in centipoise (cp) as measured in a capillary viscosimeter compared with that calculated for shear rates of 120 sec^{-1} (ascending aorta) and 12 sec^{-1} (medium arteriole). (From Wells RE Jr, Merrill EW. The variability of blood viscosity. Am J Med 1961;31:505, with permission.)

or hematocrit is a common endpoint of the treatment of polycythemia by phlebotomy.

It is noted above that the model for determining blood viscosity represents a somewhat artificial system: calculated values probably exceed those existing in vivo.[13] However, studies of cerebral blood flow in patients with erythrocytosis of various etiologies have demonstrated the clinical effects of an elevated hematocrit on in vivo blood flow.[18,19,20,21] Cerebral blood flow in patients with erythrocytosis was significantly reduced compared to controls whether it was due to an elevated red cell mass,[19] due to reduced plasma volume,[20,21] or of unknown etiology[18] (Table 44.1). Hematocrit reduction, either by venesection[18,19,20,21] or by volume expansion,[21] improved cerebral blood flow.

The determination of blood viscosity values at different hematocrits allows the estimation of blood flow rates under different conditions. As Poiseuille's law predicts (and the data in Table 44.1 imply), blood flow decreases linearly with increasing viscosity.[22] The rate of oxygen transport can then be calculated from the blood flow rate and oxygen content. At a given vessel size and pressure gradient, the predicted relation of oxygen transport to hematocrit is expressed by an arch-shaped curve (Fig. 44.2A).[14,22,23] At low hematocrits, the reduced Hb content of blood translates into reduced oxygen content. At elevated hematocrits (>0.5 to 0.6), increased viscosity reduces oxygen transport despite increased blood oxygen content. Optimal oxygen transport would be predicted to occur in the normal hematocrit range.[22–26] Experiments in normovolemic dogs (Fig. 44.2B, dashed line) support this prediction.[23]

The differences in oxygen transport observed between normovolemic and hypervolemic dogs at different hematocrits (Fig. 44.2B) reflect the probable situation occurring in patients with erythrocytosis due to an expanded red cell mass (polycythemia). In polycythemia, the associated hypervolemia permits an oxygen transport curve that is similar to that of normovolemic patients but which is elevated and shifted to the right.[23,26] Therefore, in patients with tissue hypoxia, polycythemia is beneficial because it leads to hypervolemia and increases oxygen transport (compare oxygen transport at hematocrit 0.6 on the hypervolemic and normovolemic curves in Fig. 44.2B). In contrast, in patients who have a normal or decreased total blood volume (as in relative or spurious polycythemia), erythrocytosis has an adverse effect on oxygen transport.

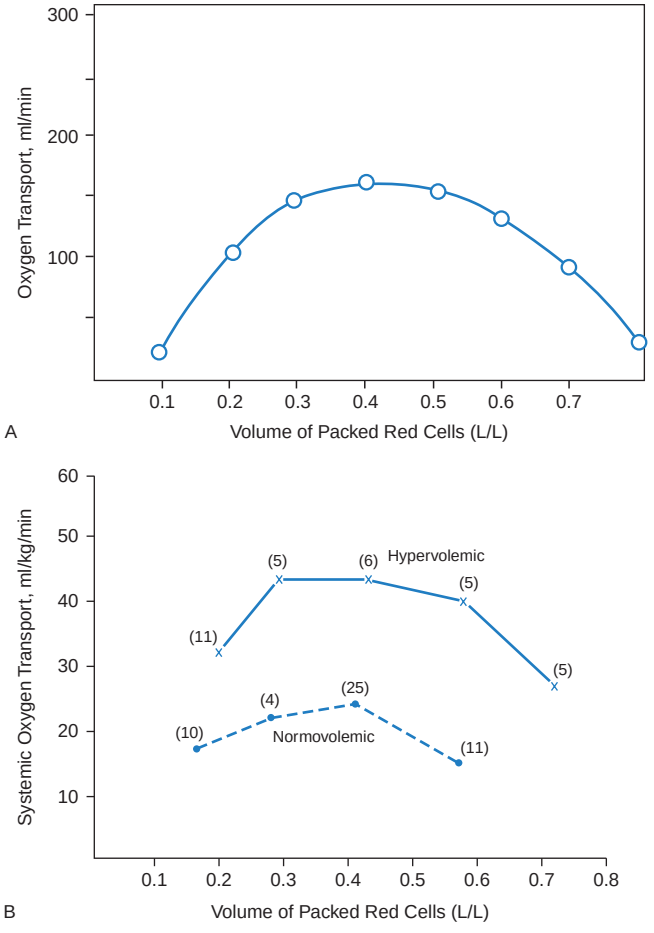

FIGURE 44.2. Arterial oxygen transport at different volumes of packed red cells and thus different viscosity values. A: Values in curve were calculated from blood viscosity values as measured by Pirofsky.[9] **B:** Systemic oxygen transport as calculated from cardiac output measured in normovolemic and hypervolemic dogs. Relation to Treatment of Polycythemia

The considerations noted above are of interest in understanding not only the pathophysiology of the different etiologies of erythrocytosis, but also their treatment. Patients with polycythemia vera have no need for increased tissue oxygen transport. In some areas where fixed vessel diameter (from arteriosclerosis) limits increased blood flow, however, the additional impeding effect of increased blood viscosity may limit oxygen transport and result in local tissue ischemia. Phlebotomy can bring about a significant clinical benefit (see Chapter 82). When treating by phlebotomy, however, blood volume should not be reduced too greatly at any one episode, especially in patients with known symptoms of cardiovascular disease (angina pectoris, transient ischemic attacks). This is particularly true early in the course of therapy, when hematocrit (and consequently viscosity) is highest.[27] Rather, time should be allowed for hemodilution to occur between phlebotomies; in emergencies, the blood volume should be maintained by infusing saline or some other plasma expander.[6] A concern is that the patient not suddenly be shifted from the hypervolemic, erythrocytosis–beneficial curve to the normovolemic, erythrocytosis–adverse curve. Another concern is that a sudden fall in blood volume from any cause, such as dehydration or acute hemorrhage, may result in local ischemia because increased cardiac output cannot compensate immediately for the effects of high viscosity. In patients with congestive heart failure, the need for reduction of blood viscosity may be urgent, because the ability to increase cardiac output to compensate for the increased blood viscosity has been compromised. The oxygen–Hb dissociation curve is shifted to the right in such patients.[28]

In contrast to polycythemia vera, patients with polycythemia due to tissue hypoxia may benefit from an increased hematocrit.

TABLE 44.1

EFFECT OF ERYTHROCYTOSIS ON CEREBRAL BLOOD FLOW

Etiology of Erythrocytosis (No. of Patients)	Reference	CBF (ml/100 g/min)	Percent Normal CBF
Polycythemia[16]	19	37.9 ± 11.2	54.8 ± 16.2
Mixed[39]	18	41.4 ± 10.5	63.6 ± 16.2
Relative polycythemia	20		
High-normal red blood cell mass[21]		45.8 ± 10.9	66.8 ± 15.9
Low plasma volume[18]		48.8 ± 12.9	71.1 ± 18.8
Relative polycythemia[5]	21	40.7 ± 5.4	59.9 ± 7.8

Note: Values expressed as mean ± standard deviation.

Reduced arterial oxygen saturation means that blood oxygen transport is less efficient at particular Hb or hematocrit levels. Therefore, the curves for oxygen transport would be shifted closer to the origin than those noted in situations in which Hb oxygenation is normal (Fig. 44.2B). In the presence of decreased arterial oxygen saturation, tissue hypoxia may persist even when erythrocytosis is marked. The main advantage to decreasing blood viscosity and blood volume in hypoxic (secondary) polycythemia is to decrease the cardiac workload. One would predict that in such situations an increase in tissue oxygen transport and clinical improvement should result from phlebotomy; results show that this is the case.[29] Again, especially early in the course, phlebotomy with preservation of an expanded blood volume may be beneficial.[6,27] To achieve the best balance between increased cardiac work and decreased tissue hypoxia in patients with hypoxemic erythrocytosis, some authors suggest that the hematocrit be maintained between 0.50 and 0.55;[6,29] however, the subjective symptomatology of the patient is usually the best guide.[22]

CLASSIFICATION AND APPROACH TO THE PATIENT WITH ERYTHROCYTOSIS

An increase in hematocrit (erythrocytosis) may result from decreased plasma volume or from *polycythemia*, which is an increase in the absolute quantity of red cells or red cell mass. The various forms of erythrocytosis are listed in Table 44.2. They are classified according to red cell mass (relative erythrocytosis or polycythemia vs. actual polycythemia). Polycythemia, in turn, is divided into primary polycythemia (*polycythemia vera* and *familial primary polycythemia/primary proliferative polycythemia*) and polycythemia driven by erythropoietin production (*secondary polycythemia*). The secondary polycythemic syndromes are divided into those that represent a response to tissue hypoxia (physiologically appropriate) and those driven by erythropoietin not produced in response to tissue hypoxia (physiologically inappropriate).

TABLE 44.2

CLASSIFICATION OF ERYTHROCYTOSIS

Relative Erythrocytosis or Polycythemia (Spurious Polycythemia)

Hemoconcentration

Spurious polycythemia (Gaisböck syndrome)

Polycythemia (Absolute Erythrocytosis)

Primary polycythemia
- Polycythemia vera
- Primary familial polycythemia

Secondary polycythemia
- Secondary to decreased tissue oxygenation (physiologically appropriate polycythemia or hypoxic erythrocytosis)
  - High-altitude erythrocytosis (Monge disease)
  - Pulmonary disease
    - Chronic cor pulmonale
    - Ayerza syndrome
  - Cyanotic congenital heart disease
  - Hypoventilation syndromes
    - Primary alveolar hypoventilation
    - Pickwickian syndrome, Ondine curse
    - Positional desaturation
    - Sleep apnea
  - Abnormal hemoglobins
    - Inherited
    - Acquired: Drugs and chemicals, carboxyhemoglobin
  - Familial polycythemia
- Secondary to aberrant erythropoietin production or response (physiologically inappropriate polycythemia)
  - Tumors, cysts, hemangiomas, and so forth
  - Androgen abuse
  - Erythropoietin abuse
  - Familial polycythemia
- Idiopathic polycythemia

An approach to the evaluation of the patient with erythrocytosis is outlined in Figures 44.3 and 44.4. Although actual polycythemia can usually be differentiated from relative polycythemia on clinical grounds (as described below), an assessment of the red cell mass is the initial step in evaluation. Traditionally, this has been done by measurement of red cell mass and blood volume by isotope labeling. Normal values are presented in Table 44.3, but considerable variation exists from one subject to another in red cell, plasma, and total blood volume, even when expressed as milliliters per kilogram (ml/kg) body weight. This variation results, in part, from differences in body fat content[31–34]; blood volume is more closely related to lean body mass[33] than to weight or surface area. It has been proposed that a red cell mass of at least 125% of that predicted should be considered as indicating polycythemia.[35] It has been a common practice at many to measure either plasma volume or red cell volume and, from one of these determinations, to calculate total blood volume on the basis of the relative amounts as indicated by a hematocrit determination. In the view of most,[36,37,38] but not all,[15] investigators, this practice is associated with an increased chance of error; measuring red cell mass and plasma volume separately is preferable. It must be emphasized that blood volume measurements do not differentiate between secondary polycythemia and polycythemia vera; they are useful only in distinguishing absolute from relative erythrocytosis.

However, availability of actual red cell volume measurement has become limited to a small number of large medical centers with special expertise. Surrogate measures based on Hb or hematocrit are now the routine basis for distinguishing relative and actual polycythemia. In men with a hematocrit > 0.60 or women with a hematocrit > 0.55, there is reported to be >99% likelihood that the red cell mass is elevated.[39] In its 2007 criteria for the diagnosis of polycythemia vera, the World Health Organization (WHO) uses an Hb concentration of >18.5 g/dl in men or 16.5 g/dl in women to define an elevated red cell mass.[40] In a comparative study, the hematocrit 0.60/0.55 standard was reported to identify elevated red cell mass more accurately than the Hb concentration 18.5/16.5 g/dl standard.[41] It should be noted that in certain circumstances of severe hemoconcentration (e.g., in the systemic capillary leak syndrome[42]), Hb concentrations or hematocrits in this range may be observed in patients with a normal red cell mass. Such patients typically exhibit anasarca and other physical findings suggestive of severe intravascular volume depletion and redistribution of intravascular volume.

The goal of the approach outlined in Figures 44.3 and 44.4 is initially to distinguish spurious (relative) polycythemia from actual polycythemia, then to distinguish polycythemia vera from secondary polycythemia and primary proliferative polycythemia, to rule out other primary polycythemia, and finally to identify the etiology of secondary polycythemia. The characteristics of polycythemia vera are outlined in Chapter 82; the other polycythemic syndromes are discussed below. A certain number of patients are not readily classified as having either polycythemia vera or secondary polycythemia. These patients fall into a category called (for want of a more physiologic term) *idiopathic polycythemia* or *idiopathic erythrocytosis* and appear to represent a heterogeneous group of disorders (see below).

The diagnostic approach to polycythemia has been substantially altered by the observation that more than 95% of patients with polycythemia vera express a mutation in the *JAK2* gene in which phenylalanine is substituted for valine at position 617.[43–45] *JAK2* V617F mutation-negative polycythemia vera patients have been reported to have mutations in other exons of *JAK2*.[46]

Men				
Sea level				
Wennesland et al.[34]	199	28.3 ± 2.8	34.4 ± 4.0	—
Huff and Feller[31]	42	28.3 ± 4.1	33.5 ± 5.2	61.5 ± 8.6
Weil et al.[30] 1,600 m[b]	16	27.1 ± 3.7	33.0 ± 5.3	60.0 ± 8.6
Weil et al.[30] 3,100 m[b]	19	26.8 ± 3.2	31.9 ± 3.6	58.7 ± 5.8
Weil et al.[30]	39	31.8 ± 6.7	35.2 ± 5.3	66.8 ± 8.5

[a]Red blood cell volume measured by ^{51}Cr method. Other values calculated without correction for trapped plasma.
[b]Only values of which we are aware at altitudes significantly above sea level. They may be somewhat low for unknown reasons; the packed cell volumes at 1,600 m were the same as at sea level, a finding that contradicts an earlier author's own large experience.

It is tempting to regard the *JAK2* mutation in polycythemia vera as conceptually analogous to the *bcr/abl* mutation in chronic myelogenous leukemia; however, the *JAK2* V617F mutation is also found in other myeloproliferative disorders.[44] Its implications are discussed in more detail in Chapter 82, but in terms of differential diagnosis, it should be regarded as a marker of a myeloproliferative state. Polymerase chain reaction–based assays for *JAK2* V617F versions of this test are widely available through reference laboratories in the United States and Europe at costs in the $300 to $500 range. As the role of *JAK2* assessment in the approach to myeloproliferative disorders continues to expand, increasing numbers of medical centers are developing in-house tests for *JAK2* V617F.

The WHO criteria for the diagnosis of polycythemia vera requires evidence of an increased red cell mass, and a *JAK2* or other functionally similar mutation and one minor criterion; or evidence of an increased red cell mass and all three minor criteria.[40] The minor criteria are a serum or plasma erythropoietin concentration below the range of normal for the laboratory; a bone marrow examination exhibiting the characteristic features of a myeloproliferative disorder (hypercellularity with trilineage hyperplasia, clustered pleomorphic megakaryocytes, and no features of inflammation) and the formation of erythroid colonies in vitro in the absence of added erythropoietin ("endogenous erythroid colonies"[EECs]).[40] Although these tests can be evaluated in any order desired, ease of test access would suggest that erythropoietin concentration be ordered first, followed by marrow evaluation if necessary. In a *JAK2* mutation-positive patient, either a characteristic erythropoietin concentration or a characteristic marrow would permit the diagnosis of polycythemia vera. In a *JAK2* mutation-negative patient, absence of both a characteristic erythropoietin concentration and a characteristic marrow would rule out the diagnosis. EEC assays, a hallmark of myeloproliferative disorders in general,[47,48] are not readily available outside of research laboratories, which limits their diagnostic practicality.

The roles of erythropoietin levels and EEC assays in the differential diagnosis of erythrocytosis are most strongly supported by their association with the WHO diagnostic criteria; as stand-alone tests in individual cases, utility is less clear.[49,50,51] Although mean serum erythropoietin concentration in the subset of patients with polycythemia vera is significantly lower than that observed in secondary polycythemia, there is considerable overlap, making it less useful for individual cases. This would be expected physiologically. A patient with secondary polycythemia due to tissue hypoxia would have an elevated serum erythropoietin level until the hematocrit was sufficiently high to oxygenate tissue adequately; then the erythropoietin concentration would be expected to decrease. The intermittent nature of detection of an elevated serum erythropoietin concentration in secondary polycythemia has been described,[52] as has the failure of serum erythropoietin concentrations to predict clinical course in idiopathic erythrocytosis.[53] Studies have been reported demonstrating that polycythemia vera and secondary polycythemia can be distinguished based on the serum erythropoietin response to phlebotomy: after phlebotomy, serum erythropoietin levels increase in secondary polycythemia but remain stable in polycythemia vera.[49] EECs corresponding to erythroid burst-forming units were observed in 12 of 17 polycythemia vera patients, 3 of 11 secondary polycythemics, 1 of 6 relative polycythemics, and 1 of 11 normal individuals in one series.[54]

Soluble transferrin receptors are typically elevated in all forms of polycythemia and thus do not distinguish polycythemia vera and secondary polycythemia.[55]

As a general approach to the evaluation of erythrocytosis, all patients with presumed polycythemia should undergo *JAK2* V617F testing. If the clinical features are suggestive of a secondary etiology of polycythemia, patients who do not show a JAK2 mutation should follow the process outlined in Figure 44.4. Individuals without a documented JAK2 mutation but in whom suspicion of a myeloproliferative disorder is high, should be investigated for minor WHO criteria (Fig. 44.3).

RELATIVE POLYCYTHEMIA

Lowered fluid intake, marked loss of body fluids, or a combination of both causes a decrease in plasma volume and may produce a relative erythrocytosis. The decrease in plasma volume may result from any cause of intravascular fluid loss, insensible fluid loss, persistent vomiting, severe diarrhea, copious sweating, postoperative complications, or shift of fluid into the extravascular space ("third spacing")[3,37,42,56] or may be an effect of high altitude.[53] In severe burns, plasma loss leads to hemoconcentration.

Chronic relative polycythemia or erythrocytosis has been variously referred to as *Gaisböck syndrome*,[57] *"stress" erythrocytosis*,[3] *benign polycythemia*,[52,56] *benign erythrocytosis*,[58] *spurious polycythemia*,[59,60] *pseudopolycythemia*,[61] and *apparent polycythemia*.[62] The last three terms are the most accurate: in the absence of an elevated red cell mass, there is no polycythemia. In one series of 215 patients referred with a diagnosis of polycythemia vera,[63] 18 (8.3%) were believed to have chronic relative erythrocytosis, possibly caused by "stress."[3] Patients with relative polycythemia or erythrocytosis are typically male; the mean age at diagnosis is less than is seen in patients with polycythemia vera.[62] Obesity is typically described as an associated feature,[3] although not all studies support this association.[64] Other features reported to be strongly associated with relative polycythemia are hypertension and smoking;[62,64,65] associations with alcohol abuse and renal disease are occasionally reported.[62,63] It is probable that this syndrome is not a true clinical entity.[60] The red cell mass values generally accepted as normal at sea level, or at any given altitude, represent the mean ±2 standard deviations. Thus, on the basis of the normal frequency distribution curve for this physiologic parameter, the values in 2.5% of the population are above this range. The individuals in this group should not be regarded as necessarily abnormal.[66]

The optimal management of relative polycythemia is unknown. As noted previously, phlebotomy increases cerebral blood flow even in patients with relative polycythemia; whether it is of

symptomatic benefit is less clear.[20,21] It should probably be avoided. Theoretic arguments can be made that contracting the blood volume further in these patients who already are normovolemic or slightly hypovolemic may impair tissue perfusion. Satisfactory control of hematocrit can be obtained in at least two thirds of patients by reduction of excess weight, improved hypertension control, avoidance of diuretics, and reduction if not cessation of smoking.[64] Potentially leukemogenic cytoreductive therapy, such as radioactive phosphorus or oral chemotherapeutic agents, is probably never indicated.

Some types of high-affinity Hbs (Heathrow,[67] Pierre-Benite,[68] Rahere[69]) may show relative polycythemia.

POLYCYTHEMIA (ABSOLUTE ERYTHROCYTOSIS)

Primary Polycythemia

Polycythemia Vera

Polycythemia vera is discussed in Chapter 82.

Primary Familial Polycythemia ("Chuvash Polycythemia")/Primary Proliferative

Polycythemia familial erythrocytosis or *polycythemia* is a term used to describe instances in which two or more members of a family have polycythemia, do not have polycythemia vera, and have no identifiable "secondary" causes.[70] This finding can result from a constellation of pathophysiologic mechanisms, including abnormalities of oxygen–Hb interaction, or idiopathic constitutive erythropoietin secretion. These syndromes are discussed under etiologies of secondary polycythemia, below.

Primary familial polycythemia is a term used to describe a syndrome observed in families with abnormalities of the erythropoietin receptor, resulting in hypersensitivity to erythropoietin and consequent erythrocytosis.[71,72,73] This particular autosomal dominant trait does not necessarily confer an adverse prognosis early in life: the propositus of the first such family described was an Olympic gold medalist in cross-country skiing.[71] However, these individuals are at increased risk for thrombotic and vascular mortality later on. A variant of this syndrome occurs with high frequency among the people of the Chuvashia region of the former Soviet Union.[74] These individuals appear to have a mutation in the oxygen-sensing pathway regulating erythropoietin production, typically involving von Hippel-Lindau protein, and also in the response of erythroid progenitors to erythropoietin.[75–78] This effect on erythropoietin signaling appears to be mediated by loss of *JAK2* regulation of erythropoiesis.[79] As in other patients with familial erythrocytosis due to aberrant erythropoietin signaling, Chuvash polycythemia patients have increased risk for vascular disease.[80] Isolated cases with similar mechanisms are referred to as *primary proliferative polycythemia*.

Secondary Polycythemia (Physiologically Appropriate [Hypoxic])

Insufficient oxygen supply to the tissues may result from any of the following, alone or in combination: (a) decreased ambient oxygen pressure (e.g., high altitude); (b) pulmonary diffusion or mixing abnormalities; (c) right-to-left cardiopulmonary shunts, as in cyanotic congenital heart disease; (d) hypoventilation; or (e) altered oxygen-carrying affinity of Hb. In all of these disorders, insufficient tissue oxygenation leads to increased erythropoietin production and a consequent increase in red cell mass (see Chapter 6).

High-altitude Erythrocytosis

In 1890, Viault showed that erythrocytosis develops during sojourn at high altitude.[81] He found erythrocyte counts of 7.5 to 8.0 $\times$ 10^{12} cells/L not only in natives of the Peruvian Andes working in a mine at an altitude of 4,392 m above sea level, but also in himself and in a traveling companion, although his blood count in Lima (160 m above sea level) had been normal. On a Mt. Everest expedition, researchers demonstrated that red cell volume and values of total Hb rose progressively as higher altitudes were attained; at 19,000 feet (5,800 m), mean values were 49% above those at sea level. The increase in total blood volume was partially masked by reductions in plasma volume.[82,83] A sharp increase in erythropoietin production occurs within the first week of high-altitude exposure and is associated with mobilization of iron stores and evidence of iron-deficient erythropoiesis.[84] Mechanisms of adaptation to living at high altitude apparently are multiple and differ between ethnic groups.[85,86]

The rapid ascent to high altitude is accompanied by symptoms of fatigue, dizziness, pulsating headache, anorexia, nausea, vomiting, insomnia, and irritability, a syndrome well known to mountain climbers and residents of high altitudes and referred to as *acute mountain sickness* or *acute altitude disease*.[87–90] The symptoms first appear some 4 to 6 hours after reaching a high altitude but may be delayed for as many as 96 hours, suggesting that the pathogenesis represents more than simple hypoxia. The incidence is greatest in younger persons, in those flying to high altitude, or in those who climb fast and spend few nights acclimatizing. Gender, the weight of the load carried, and recent respiratory infection do not appear to affect the incidence.[88] Severity is greatest in the young and in less-experienced climbers and correlates with the speed of ascent and the altitude reached.[91] Thus, all persons develop symptoms if they are suddenly transported from sea level to 15,000 feet (4,570 m) or higher, whereas a few develop symptoms at 8,000 to 10,000 feet (2,400 to 3,000 m).[83] After 4 to 8 days, acclimatization usually occurs, and symptoms remit spontaneously.[88,92] In some individuals, however, symptoms may progress to cerebral confusion, coma, and even death related to pulmonary edema unless the subject is returned to low altitude.[87,93]

The pathogenesis of acute mountain sickness may involve hypoxia and subsequent excessive secretion of antidiuretic hormone and adrenal steroids with resulting fluid retention, increased blood volume, and finally cerebral edema, pulmonary congestion, or both.[94–97,98] The incidence and severity of symptoms can be considerably reduced or prevented by appropriate treatment.[99]

The events associated with acclimatization after arrival at high altitude are not understood completely but probably include the following:

- An increase in erythrocyte 2,3-biphosphoglycerate (BPG) levels and a shift to the right in the oxygen–Hb dissociation curve, thus allowing better tissue delivery of oxygen despite decreased arterial oxygen saturation.[86,100–102] The increase in 2,3-BPG appears to compensate for the left shift in the curve that results from the initial hypocapnia and increase in arterial pH.[100,103]
- Increased erythropoietin production with subsequent increase in iron mobilization, reticulocytosis, and increase in red cell mass and blood volume.[104]
- Correction of the initial excessive antidiuretic hormone and adrenal steroid secretion and return to the normal diurnal variation of plasma steroid levels.[98]

The final result is a new equilibrium at decreased oxygen saturation and carbon dioxide tension with increases in alveolar ventilation, respiratory frequency, and red cell mass.[92] These manifestations of acclimatization are quickly lost on descent to sea level, even after many years of residence at high altitude.

In some individuals, however, after a few or many years of good adaptation, excessive erythrocytosis develops, and arterial oxygen saturation may fall to as low as 60% (normal, 81%).

An incapacitating illness characterized by alveolar hypoventilation develops. This entity is known as *chronic mountain* or *altitude sickness* or *Monge disease*.[105] Diminished mental acuity, headaches, dyspnea, fatigue, reduced physical fitness, nausea, vomiting, diminution of visual acuity, dizziness, tinnitus, vague or even excruciating pains in the extremities, paresthesias, and cough are characteristic symptoms. If the condition advances, symptoms include incessant dyspnea, aphonia, profound lethargy, and even coma. The face is bluish violet or almost black, the eyelids are edematous and bluish, the sclerae are intensely colored by distended capillaries, the tongue is thick, the hands are enlarged and turgid, the fingers are clubbed, and dependent edema may be observed. The thorax is more barrel-shaped than in healthy inhabitants of the same region and altitude. Hypotension is often present. The spleen and the liver are infrequently enlarged, unless cardiac failure ensues.

Erythrocytosis is more marked than in normal residents of high altitudes, with hematocrits up to 0.84 L/L and Hb values as high as 28.0 g/dl. MCV is normal or slightly increased, and the mean corpuscular hemoglobin concentration (MCHC) is normal. Normal reticulocyte and leukocyte counts are usually observed. Hyperbilirubinemia owing to unconjugated bilirubin may be pronounced. Red cell turnover is greater in these individuals than in normal residents of high altitudes. Platelet counts usually are normal or high, yet epistaxis is common, and hemoptysis, bleeding of the gums, and purpura may occur. Red cell volume is greatly increased (88 to 95 ml/kg body weight). The results do not appear to be completely explainable by differences in erythropoietin production.[105–110]

Affected individuals usually are in the fourth to sixth decade of life. Remissions and relapses are described. Ascent to still higher altitudes aggravates symptoms, whereas descent to sea level relieves them. Cardiac impairment does not appear until late in the disease course, and death occurs more often from hemorrhage, pulmonary tuberculosis, or bronchopneumonia than from cardiac insufficiency.

At first, the disease was considered a distinct entity. It has been suggested that the disease is an exaggeration of the process of acclimatization and aging, because patients with chronic mountain sickness had Hb concentrations within the normally distributed values for large groups of native residents. Support for this suggestion comes from the observation that chronic lung disease increases the likelihood of chronic mountain sickness.[111] Chronic mountain sickness has not been reported to occur in natives of the Himalayas.[112] This may reflect in part occupational differences, namely mining, and a consequently high incidence of chronic lung disease in the Andes as compared with the pastoral occupation of the Sherpas. Investigation of selective gene expression in populations in whom chronic mountain sickness is prevalent, may further enhance understanding of this syndrome.[113,114,115]

Differentiation of chronic mountain sickness from other causes of hypoxic polycythemia should not be difficult. Cases of congenital or acquired cyanotic heart disease can be distinguished by the cardiac findings. Polycythemia vera is not altered by increased ambient oxygen tension, whereas in Monge disease, descent to sea level produces complete relief of symptoms, together with a pronounced reduction in the blood volume and restoration of normal blood counts.[116]

Pulmonary Disease

A variety of diseases, such as chronic obstructive pulmonary disease, diffuse pulmonary infiltrates (fibrous or granulomatous), kyphoscoliosis, and multiple pulmonary emboli, leads to erythrocytosis as the result of inadequate oxygenation of the blood circulating through the lungs. Not all patients with lung disease and decreased arterial oxygen saturation, however, have elevated Hb or hematocrit levels,[117,118] and only in approximately 50% is an increase in red cell mass noted.[119] The reason for this suboptimal response to hypoxia is not clear, but it does not appear to result from a decrease in erythropoietin production or the presence of chronic infection.[117,118,120] When polycythemia occurs, it usually is associated with increased MCV, reduced MCHC,[119] and normal MCH[120] values. The red cell morphology changes have been attributed to increased water uptake by the cell, which in turn may result from carbon dioxide retention.[117] If polycythemia is present, it is corrected by chronic oxygen administration.[121]

Vascular malformations in the lung may also be associated with erythrocytosis.[122,123] Pulmonary arteriovenous fistulae should be suspected when a murmur is heard in a lung field in association with erythrocytosis.

Chronic Cor Pulmonale

The clinical picture of chronic cor pulmonale varies, but oxygen deficiency with arterial desaturation and elevated pulmonary artery pressure is of central importance.[124,125] Polycythemia with its associated increase in blood viscosity and volume appears to be the physiologic price of a compensatory mechanism progressively extended to the point at which it is more injurious than beneficial.[126] As in less severe pulmonary disease, the MCV of the red cells tends to be elevated, whereas the MCHC generally is decreased.[127]

Cyanotic Heart Disease

Marked degrees of polycythemia may be seen in patients with a partial shunt of the blood from the pulmonary circuit. Hematocrit levels greater than 0.60 are not uncommon. The most frequent defects producing such polycythemia are pulmonary stenosis (usually with defective ventricular or atrial septum, patent foramen ovale, or patent ductus arteriosus), persistent truncus arteriosus, complete transposition of the great vessels, and the tetralogy of Fallot (pulmonary stenosis, defective ventricular septum, dextroposition of the aorta, right ventricular hypertrophy). Individuals with such defects exhibit evidence of disturbed cardiorespiratory function, marked cyanosis, clubbing of the fingers and toes, and sometimes stunted growth.

The total plasma volume may be reduced to below normal levels, but the increase in the size of the red cell mass is so great that the total blood volume usually is higher than normal.[128] Erythroid hyperplasia is observed in the marrow.[129,130]

The general consensus is that low oxygen tension resulting from shunting of unoxygenated blood through or around the lungs with consequent desaturation of the arterial blood stimulates erythropoietin production. With successful operative intervention, this value may be significantly corrected, with resolution of polycythemia.

Acquired Heart Disease

In 1901, Abel Ayerza described a syndrome characterized clinically by slowly developing asthma, bronchitis, dyspnea, right-sided heart failure, and severe cyanosis with associated polycythemia.[131] The striking degree of cyanosis led Ayerza to describe these patients as “black cardiacs.” It was subsequently demonstrated that the unifying feature of these patients was not pulmonary disease but rather pulmonary arterial hyperplasia, leading to pulmonary hypertension and consequent right-sided heart failure.[132] In all forms of acquired heart disease, any erythrocytosis that may develop is correlated to some extent with the degree of cardiopulmonary decompensation. It is typically minimal. Polycythemia is reportedly accompanied by evidence of intensified erythropoiesis in the bone marrow, an increase in red cell mass, and some macrocytosis.[131]

Hypoventilation Syndromes

Polycythemia is found occasionally in patients who exhibit no evidence of pulmonary disease or cardiovascular shunts. The primary defect in at least some of these patients appears to be an inadequate ventilatory drive from the respiratory center in the brain.[126,133] A similar defect has been reported in patients with the *Pickwickian syndrome*, so called because of the description of Joe, the hypersomnolent fat boy, in Dickens's *The Pickwick Papers*.[134] In the setting of extreme obesity, these patients exhibit somnolence, cyanosis, and hypercapnia and may develop periodic respiration, ultimately with right ventricular failure. Voluntary hyperventilation alleviates the hypercapnia, and in many patients, loss of weight restores normal alveolar ventilation and reverses the syndrome.[135,136] Alveolar hypoventilation and erythrocytosis, however, do not develop in all obese individuals; it appears that only in the presence of an insensitive respiratory center does a massive panniculus limit respiratory function and result in alveolar hypoventilation, hypoxemia, and hypercapnia.[137] In some patients, the decreased ventilatory drive is of unknown cause or is a result of idiopathic disease of the medullary respiratory center (Ondine curse)[133,138]; other etiologies include bulbar poliomyelitis, vascular thrombosis, or previous encephalitis.[126,137] In any case, the consequent hypoxemia results in elevated levels of erythropoietin and erythrocytosis, with hematocrits reported as high as 0.75^8.

Patients with polycythemia and positional arterial oxygen desaturation have also been reported.[139] Whether this results from alveolar hypoventilation while supine or from shunting through an arteriovenous malformation while upright is unclear.[140] Obstructive sleep apnea has been associated with polycythemia (presumably due to episodic erythropoietin secretion during apneic episodes) in some[141] but not all[142] reports.

Abnormal Hemoglobins

Inherited Abnormalities of Hemoglobin

Certain mutant Hbs are characterized by increased oxygen, and patients who carry such Hbs tend to develop erythrocytosis.[143–145,146] More than 200 high-affinity Hbs have been characterized, of which roughly half produce significant erythrocytosis.[147] Oxygen–Hb dissociation curves are shifted dramatically to the left in individuals carrying these abnormal Hbs. The degree of left shift can be quantified by determining the P_{50} (i.e., the oxygen pressure at which Hb is half-saturated). The normal value in whole blood is 23 to 29 mm Hg at standard pH, temperature, CO_2 content, and barometric pressure. The whole-blood P_{50} is almost invariably decreased in patients with a high-affinity Hb; most values fall between 9 and 21 mm Hg. In a few instances, the P_{50} has been normal, or nearly so, in whole blood (e.g., HbG Norfolk[148]), necessitating the measurement of the oxygen dissociation curve of the purified Hb to demonstrate the defect. The approach to the diagnosis of high-affinity Hb variants, the characteristics of patients with representative mutations, and the molecular pathology are discussed in Chapter 35.

The most important physiologic consequence of increased oxygen affinity is that release of oxygen is impaired at partial pressure of oxygen values normally found in tissues. Uptake of oxygen in the lungs is enhanced, but this effect is relatively unimportant, because normal Hb is nearly completely saturated in the lungs under the usual physiologic circumstances. As previously noted, however, the increased affinity may confer some advantages when environmental oxygen is low, such as at high altitudes.

Individuals with high-affinity Hbs are not at a disadvantage under hypoxic conditions. They tolerate ascent to high altitudes as well as or better than normal subjects and thus appear to be preadapted to hypoxic stresses. Under such conditions, the enhanced oxygen loading seems more important than the impaired delivery. Similarly, exercise tolerance appears unimpaired.[149] There is no evidence that oxygen delivery to the heart is defective in patients with high-affinity Hbs. Although myocardial infarctions and other findings of atherosclerotic cardiovascular disease are reported in these patients, it is unclear whether this is an actual association or simply reflects the high frequency of atherosclerosis in the general population.[150–152]

High-affinity Hbs appear to exert no adverse effects on fetal development in utero. Theoretically, oxygen delivery to a developing noncarrier fetus might be impaired when the mother is a carrier, because the normal differential in oxygen affinity between fetal and adult Hb (which is in favor of the developing fetus) would be narrowed. However, only in the family with Hb Yakima was there a suggestion that spontaneous abortions occurred at an increased rate.[153,154] In contrast, normal pregnancy outcomes were recorded for mothers carrying the severe high-affinity variants Hb Bethesda, Hb Osler, and Hb Little Rock.[154] Evidently, maternal and fetal polycythemia and increased uterine and fetal blood flow compensate for the theoretic deficit in placental oxygen transport. There are no data addressing whether carrier fetuses have a developmental advantage over noncarriers born to these mothers; however, in dizygotic twins born to a mother with Hb Osler, the carrier twin developed more fully than the noncarrier as measured by the ponderal index (weight/length^3).[154]

It has been suggested that the homozygous state for high-affinity Hbs would be incompatible with life because of insufficient oxygen release to tissue. This may be true; however, at least four patients with abnormal Hb levels approximating those that would be observed in homozygotes have been described with no apparent ill effects (Hb Abruzzo,[155] Hb Crete,[156] and Hb Headlington[157]). The unusually high proportion of abnormal Hb was clearly due to concurrent β-thalassemia in two cases[157] and probably in the others as well.

No treatment is indicated for most patients with high-affinity Hbs. Their erythrocytosis is a compensation for a physiologic state and should be regarded as "normal for them." In the rare patient with erythrocytosis and associated symptoms, phlebotomy may be used, but caution must be used to avoid lowering the hematocrit to a point at which oxygen delivery is impaired.[158] A reasonable approach is probably to phlebotomize the individual patient to the highest hematocrit at which he or she is no longer symptomatic rather than to a specific number.[149,158,159] Certainly, reducing blood Hb concentrations to normal levels would be undesirable. Cytoreductive agents should not be used for treatment.

Acquired Abnormalities of Hemoglobin

Moderate elevations of carboxyhemoglobin in erythrocytes shift the oxygen dissociation curve. In heavy smokers, carboxyhemoglobin concentration may reach sufficiently high levels (4.0% to 6.8%) to produce polycythemia.[160,161] In the older literature, polycythemia in association with phosphorus poisoning has been described, although it may have been merely relative erythrocytosis resulting from acute liver damage. Although certain drugs and chemicals (e.g., nitrites, nitrates, aniline dyes, sulfonamides, and nitrobenzene) produce toxic levels of methemoglobin, sulfhemoglobin, or both in the blood of even normal persons,[162–167] erythrocytosis apparently has not been described in patients with toxic methemoglobinemia.

Familial Polycythemia (Physiologically Appropriate)

Familial defects in 2,3-BPG metabolism (e.g., BPG mutase deficiency[168] or elevated erythrocyte adenosine triphosphate[169]), which would have the effect of shifting the oxygen dissociation curve to the left, provide other physiologically appropriate (tissue hypoxia) reasons for polycythemia. A specific pyruvate kinase

mutation resulting in higher than normal enzyme activity and decreased 2,3-BPG causing erythrocytosis has been described as well in association with erythrocytosis.[170]

Secondary Polycythemia (Physiologically Inappropriate [Normoxic])

Unlike patients with physiologically appropriate secondary polycythemia, individuals with inappropriate polycythemia receive no benefit from the higher red cell concentrations. Treatment should be aimed at correcting the underlying disease; phlebotomy can be considered in the symptomatic.

Aberrant Erythropoietin Secretion

Erythrocytosis has been described in association with a variety of neoplasms, cysts, vascular abnormalities, and endocrinologic disorders. In the syndromes discussed in the preceding section, erythrocytosis was secondary (i.e., driven by increased erythropoietin); however, this erythropoietin secretion and the consequent erythrocytosis were physiologic responses to tissue hypoxia. In this section, disorders in which erythropoietin-driven erythrocytosis bears no relation to physiologic requirements are reviewed (Table 44.4).

Renal Disorders

Renal cell carcinoma (hypernephroma) is one of the disorders most frequently associated with erythrocytosis. Erythrocytosis is observed in 0.9% to 1.6% of patients with renal cell carcinoma (approximately one fourth as frequent a finding as anemia).[171] Elevated serum erythropoietin levels, however, are observed in more than 60% of patients.[172] Erythrocytosis also has been reported in patients with renal sarcoma, hemangioma, adenoma,[173] Wilms tumor,[153,174] renal cysts, hydronephrosis,[175–177] horseshoe kidney,[175] and polycystic kidneys.[173] Renal artery stenosis has also been reported in association with erythrocytosis.[178]

Erythrocytosis in renal cell carcinoma is attributed to constitutive erythropoietin production by the tumor. Erythropoietin messenger RNA can be demonstrated in renal carcinoma cells.[179] It is assumed that this is also the mechanism by which other parenchymal renal diseases produce erythrocytosis. Hydronephrosis and anatomic abnormalities probably produce erythrocytosis by increasing pressure on erythropoietin-producing cells in the renal parenchyma.[180] Significant and measurable concentrations of erythropoietin (sometimes >100 mU/ml) can be detected in fluid aspirated from renal cysts associated with polycythemia. Production of erythropoietin in renal cell carcinoma is said to predict a good response to therapy.[181] Management of erythrocytosis in these patients should be directed at treatment of the responsible renal lesion with phlebotomy as an adjunct, when necessary.

Erythrocytosis is also observed in patients after renal transplantation.[182] This phenomenon is associated with elevated serum erythropoietin; the source of erythropoietin is presumed to be the transplant recipient's native kidneys.[183,184] Effective therapeutic modalities include phlebotomy, angiotensin-converting enzyme inhibitors, and theophylline.[185–187]

Liver Diseases

During fetal development, the liver contributes to erythropoietin production (Chapter 6); hepatic disease, like renal disease, may be associated with erythropoietin production and polycythemia. Erythrocytosis has been identified in persons with hepatocellular carcinoma with incidence 2.5% to 10.0%.[188,189] When measured, red cell mass has been shown to be increased,[190] and elevated serum erythropoietin levels have also been described.[191] As with renal cell carcinoma, erythropoietin production by the tumor has been demonstrated.[192,193,194] Remission of erythrocytosis may be observed after successful tumor treatment.[193,194]

Erythrocytosis has also been reported with hepatic hamartomas and tumors metastatic to liver,[173] as well as hepatic angiomas[195] and hemangiosarcomas.[196] Polycythemia has been reported in the early stages of viral hepatitis.[197,198] Cirrhosis is occasionally listed in texts as associated with erythrocytosis, but this apparently does not occur except in the setting of another disease, such as cirrhosis with hepatocellular carcinoma.

TABLE 44.4

DISORDERS ASSOCIATED WITH NORMOXIC SECONDARY POLYCYTHEMIA

Renal Disease
Renal cell carcinoma
Renal sarcoma[a]
Renal adenoma[a]
Renal hemangioma[a]
Wilms tumor[a]
Solitary renal cysts
Polycystic kidney disease
Hydronephrosis
Horseshoe kidney[a]
Renal artery stenosis[a]
Postrenal transplantation
Hepatic Disease
Hepatocellular carcinoma
Hepatic hamartoma[a]
Hepatic metastases[a]
Hepatic angiosarcoma[a]
Hepatic angioma[a]
Viral hepatitis[a]
Vascular cerebellar tumors
Other Neoplasms
Uterine leiomyomata
Uterine fibroid tumors[a]
Cutaneous leiomyomata[a]
Meningioma[a]
Placental trophoblastic tumors[a]
Chronic lymphocytic leukemia[a]
Systemic amyloidosis[a]
Atrial myxoma[a]
Endocrine Disorders
Cushing syndrome
Primary aldosteronism
Virilizing ovarian tumors
Bartter syndrome[a]
Pheochromocytoma[a]
Other
Human immunodeficiency virus infection[a]

[a]Polycythemia infrequently reported.

Cerebellar Vascular Tumors

The association of erythrocytosis with vascular tumors of the cerebellum is well established.[173,199] Elevated serum erythropoietin

levels and tumor production of erythropoietin have been demonstrated,[200–202] but abnormalities in Von Hippel-Lindau protein are observed as well.[203–205] Correction of erythrocytosis may be observed after effective therapy and erythrocytosis may return with recurrence of the tumor.[173]

Leiomyoma and Fibroid Tumors of the Uterus

Several cases in which large leiomyomas and fibroid tumors of the uterus were associated with erythrocytosis have been reported.[206,207] Erythrocytosis tends to subside after effective therapy and is also associated with production of erythropoietin by tumor.[207,208] Cutaneous leiomyomata have also been associated with erythrocytosis.[209]

Other Neoplasms

Rare instances of erythrocytosis in association with a variety of other tumors have been reported, but some of these associations may be coincidental.[173] However, erythropoietin synthesis by tumor cells has been clearly demonstrated in a patient with meningioma.[210] Erythrocytosis has also been reported in rare patients with chronic lymphocytic leukemia,[211] systemic amyloidosis,[212] placental trophoblastic tumors,[213] and atrial myxomas.[214]

Endocrinologic and Other Disorders

Erythrocytosis has been reported in association with a number of endocrinologic disorders, including Cushing syndrome, primary aldosteronism,[215] virilizing ovarian tumors,[216] Bartter syndrome,[217] and pheochromocytoma.[218,219] In the latter disorder, tumor erythropoietin production has been reported.[220]

There have been a number of reports describing small numbers of patients with human immunodeficiency virus infection and polycythemia.[221,222–226] It is unclear if there is an actual pathophysiologic association or if this is coincidental.

Drug-induced Erythrocytosis

Anabolic and androgenic steroids may be abused by both recreational and professional athletes for purposes of improving performance.[227] A consequence of androgen administration, either medicinal or extralegal, may be erythrocytosis.[228,229,230] In some cases, the degree of erythrocytosis may be severe.

Recombinant human erythropoietin has also been abused by athletes (particularly those in endurance sports) to increase the red cell mass and thus oxygen-carrying capacity.[231,232,233] As indicated earlier in Figure 44.2, this may backfire if the athlete becomes hypovolemic as a result of exertion. Cases of surreptitious erythropoietin self-administration resulting in accelerated hypertension and unstable angina have been reported.[234] A perceived advantage of erythropoietin over androgens for this purpose is the inability to distinguish endogenous from exogenous erythropoietin as well as the lack of hepatic toxicity. Newer approaches that allow discrimination between exogenous recombinant erythropoietin and endogenous erythropoietin may make this practice less frequent.[235,236,237,238]

Familial Polycythemia (Physiologically Inappropriate)

Kindreds that exhibit an autosomal recessive erythrocytosis associated with increased erythropoietin production have been described.[239]

Idiopathic Polycythemia

The term *idiopathic polycythemia* (or *erythrocytosis*) refers to patients who have an elevated red cell mass of unknown etiology after appropriate investigation. It would include most of the patients formerly categorized as "benign erythrocytosis." The existence of this group, which is estimated to contain 20% to 30% of patients evaluated for polycythemia,[141] essentially represents a failure to categorize all polycythemic patients correctly.

Of 25 patients reported in one series, 12 were found to have elevated erythropoietin levels and were therefore assumed to represent patients with secondary polycythemia; these patients tended to be younger than the patients with normal erythropoietin levels.[139] Progenitor culture studies were not helpful in subcategorizing the group in this particular study.[139] Some studies have reported endogenous colony-formation studies to be useful and serum erythropoietin levels not helpful,[50] whereas others have reported the opposite.[240]

Kiladjian et al. treated 39 patients with idiopathic erythrocytosis with pipobroman and compared their clinical course to 140 concurrently treated polycythemia vera patients.[241] The risk of leukemia, thrombosis, and myelofibrosis was the same in the two groups. This study confirms that the idiopathic erythrocytosis group contains a certain number of polycythemia vera patients; however, it does not provide a way to identify individuals who do not have a myeloproliferative disorder and therefore should not be exposed to leukemogenic agents.[241]

Because this category probably represents a mixed bag, including early polycythemia vera, mild secondary polycythemia, and normal individuals at the higher end of the bell-shaped curve for red cell mass,[64] a cautious approach is warranted. Observation may be the most reasonable intervention; this may be the patient subset in which otherwise low-yield studies, such as erythroid progenitor studies, are likely to be useful. Periodic retesting for the *JAK2* V617F mutation or other *JAK2* mutations may also be useful, although a study that addressed this question found that less than 2% of idiopathic erythrocytosis patients studied exhibited the mutation.[242]

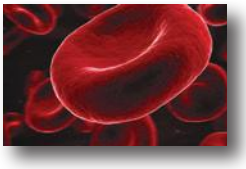
PART V

Disorders of Hemostasis and Coagulation

SECTION 1 INTRODUCTION



CHAPTER 45

DIAGNOSTIC APPROACH TO THE BLEEDING DISORDERS

George M. Rodgers, Christopher M. Lehman

Except for that which occurs during menstruation, spontaneous bleeding is abnormal. Surprisingly, little blood is lost, even after large injuries, because of the efficiency with which vascular integrity is normally maintained and the rapidity with which it is restored after injury. In general, these phenomena reflect the functional effectiveness of normal hemostasis (see Chapters 17 through 19). It must be recognized, however, that the adequacy of hemostasis is only relative, and despite the presence of normal vessels, platelets, and coagulation factors, bleeding can occur as the result of localized pathologic processes.

The 11 chapters in Part V deal with disorders that result from abnormalities of the hemostatic process. This chapter is a summary of the diagnostic approach to these disorders and includes a brief discussion of laboratory methods for their study. In subsequent chapters, individual disorders are considered in six categories: thrombocytopenia (Chapters 46 through 49), bleeding disorders caused by vascular abnormalities (Chapter 50), thrombocytosis (Chapter 51), disorders of platelet function (Chapter 52), inherited coagulation disorders (Chapter 53), and acquired coagulation disorders (Chapter 54). The pathophysiology of thrombosis and the principles of antithrombotic therapy are summarized in Chapter 55.

CLINICAL EVALUATION OF THE BLEEDING PATIENT

A careful evaluation of the patient presenting with a bleeding disorder can often provide valuable clues as to whether the abnormality resides in the vessels, platelets, or the process of blood coagulation; a carefully obtained history can usually establish whether the disorder is inherited or acquired; and the physical examination may reveal findings such as the characteristic skin lesions of hereditary hemorrhagic telangiectasia, which alone may provide the diagnosis of a previously perplexing bleeding problem. Results of the clinical evaluation should lead to a rational and efficient laboratory investigation.

It is important to ask specific questions about bleeding because people with normal hemostasis may believe they bleed excessively.[1] Certain questions may discriminate between those with normal and abnormal hemostasis, including whether excessive bleeding occurs after tooth extraction or small cuts, whether spontaneous bruising or muscle bleeding occurs, or whether the patient has ever been transfused or treated with blood products.[1]

MANIFESTATIONS OF DISORDERED HEMOSTASIS

Certain signs and symptoms are virtually diagnostic of disordered hemostasis. They can be divided arbitrarily into two groups: those seen more often in disorders of blood coagulation and those most commonly noted in disorders of the vessels and platelets. The latter group is often called *purpuric disorders* because cutaneous and mucosal bleeding usually are prominent. The clinical findings that are most valuable in distinguishing between these two broad categories are summarized in Table 45.1. Although these criteria are relative, they provide valuable clues to the probable diagnosis if they are applied to the predominant clinical features in a given patient.

TABLE 45.1

CLINICAL DISTINCTION BETWEEN DISORDERS OF VESSELS OR PLATELETS AND DISORDERS OF BLOOD COAGULATION

Finding	Disorders of Coagulation	Disorders of Platelets or Vessels
Petechiae	Rare	Characteristic
Deep dissecting hematomas	Characteristic	Rare
Superficial ecchymoses	Common; usually large and solitary	Characteristic; usually small and multiple
Hemarthrosis	Characteristic	Rare
Delayed bleeding	Common	Rare
Bleeding from superficial cuts and scratches	Minimal	Persistent; often profuse
Sex of patient	80%–90% of inherited forms occur only in male patients	Relatively more common in females
Positive family history	Common	Rare (except von Willebrand disease and hereditary hemorrhagic telangiectasia)

Bleeding into Skin and Soft Tissues

Petechiae are characteristic of an abnormality of the vessels or the platelets, such as thrombocytopenia, and are exceedingly rare in the coagulation disorders. These lesions are small capillary hemorrhages ranging from the size of a pinhead to much larger (Fig. 45.1). They characteristically develop and regress in crops and are most conspicuous in areas of increased venous pressure, such as the dependent parts of the body and areas subjected to pressure or constriction from girdles or stockings. In patients with scurvy, petechiae may be distributed around hair follicles in the "saddle area" of the thighs and buttocks (see Fig. 50.5). Petechiae must be distinguished from small telangiectasias and angiomas. Vascular structures such as telangiectasias or angiomas blanch with pressure, whereas petechiae do not.

In the purpuric disorders, petechiae commonly are associated with multiple superficial ecchymoses, which usually develop without perceptible trauma but seldom spread into deeper tissues. Small isolated ecchymoses are commonly noted in apparently normal women, especially on the legs, and in small children.

Although large superficial ecchymoses may be seen in association with the coagulation disorders, the most characteristic lesion is the large spreading hematoma (Fig. 45.2). Such hematomas may arise spontaneously or after trivial trauma and often spread to involve an entire limb by dissecting within muscles and deep fascial spaces, often with minimal discoloration of the overlying skin.

Hemarthrosis

Hemorrhage into synovial joints is virtually diagnostic of a severe inherited coagulation disorder, most commonly hemophilia A or hemophilia B, and is rare in disorders of the vessels and platelets or in acquired coagulation disorders. This disabling problem often develops with pain and swelling as chief symptoms but without discoloration or other external evidence of bleeding (see Fig. 53.3). Subperiosteal hemorrhages in children with scurvy and swollen painful joints that may develop in some patients with allergic purpura occasionally may be confused with hemarthrosis.

FIGURE 45.2. Large dissecting hematoma of thigh in a patient with hemophilia. A. The lesion resulted from a slight bump to the inguinal area and spread to involve the entire thigh. (Courtesy of Dr. John Lukens.)

Traumatic Bleeding

The unavoidable traumas of daily life and even minor surgical procedures are a greater challenge to hemostasis than any test yet developed in the laboratory. In contrast to "spontaneous" bleeding manifestations, bleeding after trauma in a person with a hemorrhagic diathesis differs in a quantitative way from that which would normally be expected in terms of the amount, duration, and magnitude of the inciting trauma. Such variables are extremely difficult to assess accurately by taking the patient's history. The amount of blood lost may be exaggerated by the patient. The need for transfusions and the number administered may serve as a rough guide. The patient's statement concerning the duration of bleeding is more reliable. Detailed inquiry as to past injuries and operations must be made because the patient is likely to forget procedures or injuries that were uncomplicated and to dwell on those in which bleeding was a problem. Whether reoperation was required for prolonged bleeding after tooth extraction or other minor surgical procedures may be helpful in identifying a patient with abnormal hemostasis.

In individuals with a coagulation disorder, the onset of bleeding after trauma often is delayed. For example, bleeding after a tooth extraction may stop completely, only to recur in a matter of hours and to persist despite the use of styptics, vasoconstrictors, and packing. The temporary hemostatic adequacy of the platelet plug despite defective blood coagulation may explain this phenomenon of delayed bleeding, as well as the fact that patients with coagulation disorders seldom bleed abnormally from small superficial cuts such as razor nicks. In contrast, posttraumatic or postoperative surgical bleeding in thrombocytopenic patients usually is immediate in onset, as a rule responds to local measures, and rarely is as rapid or voluminous as that encountered

in patients with coagulation disorders. However, it may persist for hours or days after surprisingly small injuries.

Valuable information often is obtained from a careful review of dental procedures, because most patients have had one or more teeth extracted at some time during their lives. The amount of bleeding normally encountered varies greatly, but as a rough guide, uncomplicated extraction of a single molar tooth may result in brisk bleeding for up to 1 hour and slight oozing for up to 2 days in normal persons.[2] Typically, bleeding is more profuse from upper than from lower sockets and is more extensive after extraction of molar teeth, particularly impacted third molars, than after removal of other teeth. In patients with inherited coagulation disorders, the shedding of deciduous teeth often is uncomplicated.

The response to trauma is an excellent screening test for the presence of an inherited hemorrhagic disorder, and a history of surgical procedures or significant injury without abnormal bleeding is equally good evidence against the presence of such a disorder. The removal of molar teeth is a major challenge to hemostasis, as is a tonsillectomy, and it is a rare hemophiliac, however mildly affected, who can withstand these procedures without excessive bleeding.

Miscellaneous Bleeding Manifestations

Despite the fact that structural causes for bleeding (such as polyps, varices, and tumors) are commonly seen in patients with hematuria, hematemesis, and melena, bleeding from these sites may also be associated with both purpuric and coagulation disorders. Severe menorrhagia may be the sole symptom of women with von Willebrand disease (vWD), mild thrombocytopenia, or autosomally inherited coagulation disorders. Recurrent gastrointestinal bleeding or epistaxis in the absence of other bleeding manifestations is common in hereditary hemorrhagic telangiectasia. A coagulation disorder or a disorder of platelet function should be considered if protracted hematuria is the only symptom.

Bleeding into serous cavities and internal fascial spaces often occurs in patients with inherited coagulation disorders and may create serious diagnostic problems. In hemophilia, retroperitoneal hemorrhage or bleeding into the psoas sheath may mimic appendicitis, and hemorrhage into the bowel wall may be confused with intestinal obstruction. Signs and symptoms simulating a variety of acute intra-abdominal disorders also may be seen in association with allergic purpura. Bleeding into the central nervous system may complicate thrombocytopenia and may occur after minor trauma in patients with coagulation disorders. Multiple small retinal hemorrhages are common in patients with thrombocytopenia and other purpuric disorders but are uncommon in those with inherited coagulation disorders; large hematomas of the orbit may be seen in the latter group. The coexistence of bleeding and thromboembolic phenomena or bleeding from previously intact venipuncture sites is suggestive of diffuse intravascular coagulation (DIC). Protracted wound healing, wound dehiscence, and abnormal scar formation have been described in inherited afibrinogenemia, the dysfibrinogenemias, and in factor XIII deficiency.[3] Hemoptysis rarely is associated with hemorrhagic disorders.

CLINICAL FEATURES OF INHERITED BLEEDING DISORDERS

An inherited bleeding disorder is suggested by the onset of bleeding symptoms in infancy and childhood, a positive family history (particularly if it reveals a consistent genetic pattern), and laboratory evidence of a single or isolated abnormality, most commonly the deficiency of a single coagulation factor.

Age at Onset: Bleeding in the Neonate

Birth and the neonatal period provide unique challenges to the hemostatic mechanism,[4] and bleeding during the first month of life often is the first evidence of an inherited disorder of hemostasis. Small cephalohematomas and petechiae are common in the newborn as a result of the trauma of delivery. Large cephalohematomas that progressively increase in size may result from hemophilia but are more common in association with acquired bleeding disorders such as hemorrhagic disease of the newborn (see Chapter 54). Bleeding from the umbilical stump and after circumcision is common in the acquired coagulation disorders, and it also occurs in the inherited coagulation disorders,[5] with the exception of hypofibrinogenemia, dysfibrinogenemia, and factor XIII deficiency. The onset of bleeding from the umbilical cord may be delayed in these latter disorders. In the evaluation of bleeding in the neonate, the clinician should remember that hematochezia and hematemesis may originate from swallowed blood of maternal origin. Simple tests to distinguish such maternal blood from fetal blood have been described.[5]

Many infants with inherited coagulation disorders do not bleed significantly in the neonatal period. Less than one-third of patients with hemophilia A and B and only 10% of those with other inherited coagulation disorders have hemorrhagic symptoms during the first week of life. In such patients, the disorder may become clinically silent for a time. Hematomas may first be seen only when the child becomes active. Hemarthrosis commonly does not develop until a child is 3 or 4 years of age.

A mild inherited hemorrhagic disorder may be difficult to distinguish from the insidious onset of an acquired defect. Patients with mild inherited coagulation disorders may enter adult life before characteristic bleeding manifestations occur. These patients and those with some forms of inherited thrombocytopenia and disordered platelet function often describe a history of posttraumatic bruising and hematoma formation that they have come to accept as normal. In hereditary hemorrhagic telangiectasia, the lesions become more prominent with advancing age and may not be symptomatic until middle age. Similarly, in patients with Ehlers-Danlos syndrome, bleeding may not be a problem until adult life.

Family History

The family history is of great importance in the evaluation of bleeding disorders. In disorders inherited as autosomal dominant traits with characteristic symptoms and high penetrance, such as hereditary hemorrhagic telangiectasia, an accurate pedigree spanning several generations can often be obtained. The presence of typical bleeding manifestations in male siblings and maternal uncles is virtually diagnostic of X-linked recessive inheritance, which characterizes hemophilia A and hemophilia B. In such X-linked traits, the family history also may be helpful in a negative sense—that is, it may clearly exclude the disorder in certain offspring, such as the sons of a known hemophiliac. Details of the various genetic patterns that may be encountered are discussed in the chapters that deal with these conditions.

The limitations of the family history, however, are greater than is commonly realized. Hearsay history is difficult to evaluate, and it is often impossible to assess the significance of easy bruising or to differentiate between manifestations of a generalized bleeding disorder and more common localized lesions, such as peptic ulcer and uterine leiomyomas. A negative family history is of no value in excluding an inherited coagulation disorder in an individual patient. As many as 30% to 40% of patients with hemophilia A have a negative family history.[6] The family history usually is negative in the autosomal recessive traits, and consanguinity, which is commonly present in these kindreds, is notoriously difficult to document or exclude.

CLINICAL FEATURES OF ACQUIRED BLEEDING DISORDERS

Generalized bleeding may be a prominent feature of a wide variety of acquired disorders that encompass virtually the entire field of medicine. Bleeding manifestations usually are less severe than in the inherited forms, and the clinical picture often is dominated by evidence of the underlying disorder rather than by bleeding alone. In the neonate, for example, DIC usually is associated with significant complications such as sepsis, hypoxia, acidosis, or problems related to prematurity. The physician should suspect sepsis or occult thrombosis in any sick neonate with unexplained thrombocytopenia.[5] Multiple hemostatic defects commonly are present in patients with acquired hemorrhagic diseases, which often include thrombocytopenia and significant coagulation abnormalities. In contrast, a single abnormality usually is found in patients with inherited hemorrhagic disorders.

In general, the emphasis of the study of the acquired bleeding disorders should be on the patient, not on the laboratory. A thorough history and the physical examination often reveal the cause of thrombocytopenia, such as a drug or acute leukemia. In most vascular disorders, including senile purpura, allergic purpura, scurvy, and amyloidosis, the history and physical examination are of primary diagnostic importance, and the laboratory has little to offer.

Drug History

The importance of exhaustive interrogation regarding drug use and chemical exposure cannot be overemphasized. The list of drugs associated with thrombocytopenia (see Table 47.6) or vascular purpura grows longer each year. Less common but more serious is drug-induced aplastic anemia, which may present initially with bleeding. Many commonly used drugs, notably aspirin, impair platelet function and produce abnormal findings on laboratory tests that often lead to expensive and unnecessary additional laboratory studies. The same drugs may provoke bleeding when administered to patients with pre-existing hemostatic defects such as hemophilia A. Drug ingestion also may produce coagulation abnormalities, and drugs that potentiate or antagonize the anticoagulant effects of coumarin derivatives may lead to bleeding or erratic laboratory control. The surreptitious ingestion of such agents is not uncommon.

Results of various coagulation tests may be abnormal in a surprisingly large percentage of hospitalized patients because of heparin that is administered therapeutically or is used in small amounts to maintain the patency of indwelling venous catheters, venous pressure lines, arteriovenous shunts, and various pumps and infusion machines. The partial thromboplastin time (PTT), in particular, may be greatly prolonged in patients who have received even a minute amount of this anticoagulant. Such coagulation abnormalities often are confused with DIC, inhibitors of factor VIII, and other serious coagulation disorders, and they commonly lead to repeated, and usually useless, coagulation studies. A thorough bedside inventory often is required to find out that heparin is indeed responsible. Prolongation of the thrombin time associated with a normal reptilase time or direct assay of heparin provides laboratory evidence of heparin contamination.

LABORATORY METHODS FOR STUDY OF HEMOSTASIS AND BLOOD COAGULATION

No single test is suitable for the laboratory evaluation of the overall process of hemostasis and blood coagulation, but methods of varying complexity and use are available for assessing various components and functions individually. The emphasis of the following discussion is on methods that are simple and widely available in most laboratories. The interpretation of the most commonly used tests and the range of values obtained in normal subjects with representative techniques are summarized in Table 45.2. Definitive coagulation methods usually require a specially equipped laboratory and trained personnel, and are discussed here from a general standpoint only. Additional comments concerning the use and limitations of the various methods are included in chapters dealing with individual disorders.

TABLE 45.2

INTERPRETATION OF COMMON TESTS OF HEMOSTASIS AND BLOOD COAGULATION

Test	Normal Range[a] (±2 SD)	Common Causes of Abnormalities
Platelet count		
Phase microscopy	140,000–440,000/μl	Thrombocytopenia, thrombocytosis
Automated	177,000–406,000/μl	
Partial thromboplastin time (activated)[b]	26–36 sec[55,c]	Deficiencies or inhibitors of prekallikrein; high-molecular-weight kininogen; factors XII, XI, IX, VIII, X, and V; prothrombin or fibrinogen; lupus inhibitors; heparin; warfarin
Prothrombin time[b]	12.0–15.5 sec[66,c]	Deficiencies or inhibitors of factors VII, X, and V; prothrombin or fibrinogen; dysfibrinogenemia; lupus inhibitors; heparin; warfarin
Thrombin time[b]	14.7–19.5 sec	Afibrinogenemia, dysfibrinogenemia, hypofibrinogenemia, and hyperfibrinogenemia; inhibitors of thrombin (heparin) or fibrin polymerization (fibrin degradation products, paraproteins)
Fibrinogen assay[b]	150–430 mg/dl[70]	Afibrinogenemia, dysfibrinogenemia, and hypofibrinogenemia; inhibitors of thrombin or fibrin polymerization
Factor VIII assay[b]	50–150 U/dl	Hemophilia A and von Willebrand disease; acquired antibodies to factor VIII
Fibrin degradation product assay	0–5 μg/ml[80]	Disseminated intravascular coagulation; fibrinogenolysis; thrombolytic drugs, liver disease; dysfibrinogenemia
D-dimer assay	0–0.4 μg/ml	Disseminated intravascular coagulation; recent surgery; pregnancy; thromboembolism

[c]Significant variations depending on reagents and technique.

Tests of Vascular and Platelet Phases

Bleeding Time

Hemostasis in a small superficial wound, such as that produced when measuring the bleeding time, depends on the rate at which a stable platelet plug is formed and, thus, provides a measure of the efficiency of the vascular and platelet phases. However, it does not discriminate between vascular defects, thrombocytopenia, and platelet dysfunction. The bleeding time leaves much to be desired in terms of reproducibility, because no two skin areas are exactly the same and it is impossible to produce a truly standard wound.[7]

Older studies using the bleeding time test supported the view that this test might be helpful in predicting bleeding in individual patients.[8] More recent studies suggest that a bleeding time result is determined not only by platelet number and function, but also by hematocrit,[9] certain components of the coagulation mechanism,[10,11] skin quality,[12] and technique.[13] A careful analysis of this literature indicates that there is no correlation between a skin template bleeding time and certain visceral bleeding times,[13,14] and that no correlation exists between preoperative bleeding time results and surgical blood loss or transfusion requirements.[15]

A clinical outcomes study reported that discontinuation of the bleeding time in a major academic medical center had no detectable adverse clinical impact.[16] A position paper of the College of American Pathologists and the American Society of Clinical Pathologists concluded that the bleeding time was not effective as a screening test, and that a normal bleeding time does not exclude a bleeding disorder.[17] Patients thought to have a platelet-type bleeding disorder based on their personal or family history (or both) should be evaluated for vWD and the inherited qualitative platelet disorders, using assays discussed in the section Platelet Function Assays. Newer assays that may be useful in screening patients for platelet dysfunction are also discussed in the section New Assays of Platelet Function.

Platelet Enumeration

Platelets are considerably more difficult to count than erythrocytes or leukocytes. This difficulty is to be expected in view of the small size of these cells and their tendency to adhere to foreign surfaces and to aggregate when activated.

In general, techniques for platelet counting may be classified into two groups: hemacytometer or direct methods, in which whole blood is diluted and the platelets are counted in much the same way as leukocytes or erythrocytes, and fully automated electronic methods. Virtually identical values for the normal range of the platelet count have been obtained with modern methods, as summarized in Table 45.2.

An estimate of platelet numbers in a well-prepared blood smear by an experienced observer is a valuable check on the platelet count as determined by any method. In general, when a blood smear is examined at 100 × power, each platelet counted/field represents approximately 10,000 platelets × 10^9/L. Consequently, a normal blood smear should demonstrate, on average, at least 14 platelets/high-power field.

Instruments for totally automated platelet counting are widely used. Details of automated cell counters are discussed in Chapter 1. When automated methods are used, various nontechnical factors may produce falsely low platelet counts.[18] These factors include platelet agglutinins,[19] abnormal amounts of plasma proteins in various paraproteinemias, previous contact of platelets with foreign surfaces such as dialysis membranes,[20] large or giant platelets, platelet satellitism,[21] lipemia,[22] and ethylenediaminetetra-acetic acid (EDTA)–induced platelet clumping,[23] a phenomenon that may produce platelet clumps of sufficient size to artifactually increase the leukocyte count.[24] Spuriously high platelet counts may result from the presence of microspherocytes,[25] fragments of leukemic or red blood cells,[26] and Pappenheimer bodies.[27] Special technical modifications and the use of careful manual counting methods may be required to eliminate these artifacts and to obtain accurate platelet counts.

Platelet Volume Measurements

The widespread availability of particle counters in the clinical laboratory permits the accurate measurement of platelet volume on a routine basis. Mean platelet volume (MPV) is increased in disorders associated with accelerated platelet turnover as the result of large numbers of megathrombocytes[28] or in patients with Bernard-Soulier syndrome. Normal or decreased values for MPV usually are obtained in patients with disorders associated with deficient platelet production, in some patients with sepsis,[29] and in people with certain big-spleen syndromes.[30]

Some authors suggest that increased MPV provides evidence of accelerated platelet production and may be interpreted in the same way as the reticulocyte count. The method is difficult to standardize, however, and when determined on routinely collected specimens by automated counters, it is affected by numerous variables pertaining to specimen collection, anticoagulant, temperature, and duration of storage.[31] In view of these problems and the difficulty in interpreting platelet size heterogeneity under normal and abnormal conditions,[32] these measurements should be interpreted with caution.

The presence of microcytic platelets in patients with some inherited thrombocytopenias such as Wiskott-Aldrich syndrome is reliably reflected by MPV measurements. On the other hand, giant platelets associated with Bernard-Soulier syndrome may be counted as leukocytes or erythrocytes and may not be reflected in the MPV.

Platelet Function Assays

Since the 1960s, platelet aggregation using platelet-rich plasma has been the standard method to assess platelet function. This method uses aggregometers, which are modified nephelometers that permit measurement of changes in optical density of a platelet suspension under conditions of constant temperature and continuous agitation (Fig. 45.3). Most instruments measure

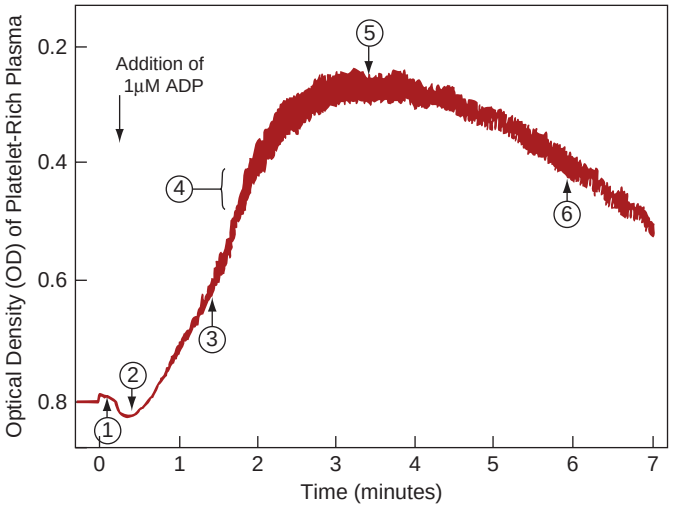

FIGURE 45.3. The interpretation of aggregometer tracings. Tracing of platelet aggregation produced by a low concentration of adenosine diphosphate (ADP), illustrating normal changes in optical density (OD)—that is, *(1)* a slight decrease caused by dilution with aggregating agent; *(2)* a transient increase caused by initial platelet swelling or shape change; *(3)* a rapid progressive decrease as platelet aggregates form, the size of which is roughly proportional to the amplitude of the oscillations in the tracing *(4)*. The OD then reaches a nadir *(5)* from which maximal aggregation as a percentage of the initial OD may be calculated as follows: maximal aggregation (%) = OD at T0—minimum OD/OD at T0. After this *(6)*, a slow increase in OD caused by disaggregation occurs under some conditions.

a combination of light scatter and absorption. Instruments have been developed that permit both nephelometric and photometric measurements and the simultaneous measurement of aggregation and nucleotide release.[33]

Platelet aggregation usually is studied in suspensions of citrated platelet-rich plasma, in which the size and dimensions of the stirring bar, variations in plasma citrate concentration attributable to variations in hematocrit, the pH, and the nature of the buffers are important variables. Platelet suspensions usually are prepared by differential centrifugation, but methods that use albumin density gradient centrifugation and gel filtration have also been described.[34] Although harvesting platelets from the blood of thrombocytopenic patients is difficult, testing such platelets in the aggregometer is reproducible in suspensions containing as few as 50,000 platelets/μl. Methods for the study of platelet aggregation in whole blood[35,36] also have been described. Interfaced computer systems have been developed for calculating and expressing platelet function data.[37]

Adenosine diphosphate (ADP) in concentrations of 5 μmol/L or higher produces platelet aggregation directly that is independent of the release of platelet-contained ADP.[38] Various other aggregating agents act mainly by inducing the release reaction, such as a suspension of connective tissue particles (collagen), epinephrine and norepinephrine, and thrombin. With epinephrine (5 μmol/L), a weak primary aggregating effect usually can be clearly distinguished from the subsequent release reaction, which produces a secondary wave of aggregation. Such primary and secondary waves of aggregation also may be seen with carefully titrated amounts of ADP (0.2 to 1.5 μmol/L).[38]

Ristocetin is an antibiotic that induces platelet agglutination (platelet metabolic activity not required) in the presence of von Willebrand factor (vWF). Patients deficient in vWF (vWD) or in the receptor for vWF (Bernard-Soulier syndrome) have an abnormal ristocetin response. Ristocetin is tested in concentrations of 0.6 to 1.2 mg/ml; the lower concentrations are helpful in identifying specific variants of vWD, type 2B and platelet-type vWD (see Chapters 52 and 53).

The release reaction is measured only indirectly by routine aggregometry—that is, the aggregation associated with the release of ADP from the platelets (release-induced aggregation or secondary aggregation). Methods for the quantitation of various substances released from platelets have been described. For example, the amounts of ADP or serotonin released/unit of time serve as indices of dense body release[39]; the amount of various hydrolytic enzymes or platelet factor 4 released is a measure of the extent of α-granule release.[40] Suggested guidelines for standardization of platelet aggregation methods have been proposed.[41,42]

Sensitive methods have been developed for the determination of platelet-derived substances in plasma that may serve as markers of intravascular platelet activation,[43] including platelet factor 4, β-thromboglobulin, stable prostaglandins (6-keto prostaglandin $F_1\alpha$ and thromboxane A_2), and leukotrienes.[43] These measurements may have diagnostic value in thromboembolic disorders and syndromes characterized by intravascular platelet aggregation.

New Assays of Platelet Function

An appreciation of the limitations of the bleeding time test has led to the development of newer assays to evaluate platelet function.[44] Some of these are point-of-care tests. The clinical use and predictive value of these tests to identify patients with hemostatic disorders remain to be established. One assay, the platelet function analyzer (PFA-100), has been investigated for several years, and many published reports using this assay are available. In this method, citrated blood samples are exposed to high shear rates in a capillary flowing through an aperture within a membrane coated with collagen and either ADP or epinephrine.[45] The closure time to hemostatic plug formation within the aperture is the endpoint of the test. A large study using the PFA-100 found that prolonged closure times could be attributed to specific quantitative or qualitative abnormalities in platelet function or vWF (or both) in 93% of patients tested.[46] However, the International Society on Thrombosis and Haemostasis has taken the position that the PFA-100 is insufficiently sensitive and specific to be used as a screening device for platelet disorders.[47] It has been suggested that optimal use of the PFA-100 in evaluation of hemostasis would use an algorithmic approach, evaluating not only PFA-100 closure times, but also a complete blood count, blood smear, and assays for vWD and platelet aggregation to further evaluate abnormal closure times. A recent addition to the PFA repertoire is the INNOVANCE PFA P2Y test designed to assess P2Y12-receptor blockade.

Several additional platelet function analyzers are available on the market, though they are not as well studied as the PFA-100.[48] The ICHOR II-Plateletworks system (Helena Laboratories, Beaumont, TX) compares impedance-derived platelet counts in samples with and without added platelet agonists to assess platelet function. This system has historically been used to evaluate cardiopulmonary bypass patients, but more recently has been applied to patients undergoing coronary stent placement. The Impact-R (Matis Medical, Beersel, Belgium) is an automated cone-and-plate research analyzer that assesses platelet adhesion and aggregation on a polystyrene surface under laminar flow conditions. The VerifyNow system analyzes platelet agonist-induced aggregation of fibrinogen-coated microparticles to assess platelet function. Agonist cartridges are designed to evaluate the effects of aspirin, clopidogrel, and GPIIb/IIIa platelet receptor inhibitor administration on platelet function. Platelet mapping, a modification of thromboelastography, measures the platelet contribution to clot strength in the presence of specific agonists.[49] To date, no platelet function analyzer assay has been sufficiently studied or validated to warrant routine clinical use.[48,50,51]

Tests of Coagulation Phase

In general, meticulous performance of coagulation tests is more important than the exact technique chosen. Blood samples obtained by traumatic venipunctures or from indwelling catheters often are inadequate for coagulation studies.[52] A poorly collected blood sample is a far more common cause of inaccurate results than is technical error.

With the exception of one assay for fibrin degradation products (FDPs), all coagulation tests are performed on citrated plasma, most commonly obtained using blue-top vacuum blood collection tubes that pull in nine parts of blood to one part citrate. The International Society for Thrombosis and Haemostasis recommends the routine use of 3.2% sodium citrate. A pool of freshly frozen citrated plasma from several normal donors is a suitable control for screening procedures in most laboratories. Lyophilized control plasma and borderline abnormal control plasmas are available commercially to standardize coagulation assays and to provide reference standards.

The citrate ion does not enter the erythrocyte. Consequently, the plasma citrate concentration is abnormally high when blood with a high hematocrit (>55%) is collected in usual concentrations of this anticoagulant. This may produce artifactual prolongation of one-stage screening tests of coagulation, such as the PTT.[53] To obtain interpretable data on such samples, tubes containing citrate concentrations appropriate for the hematocrit must be prepared by removing an aliquot of the citrate anticoagulant contained in standard blue-top tubes.

Activated Partial Thromboplastin Time

The activated partial thromboplastin time (PTT) is a simple test of the intrinsic and common pathways of coagulation. When a mixture of plasma and a phospholipid platelet substitute is recalcified,

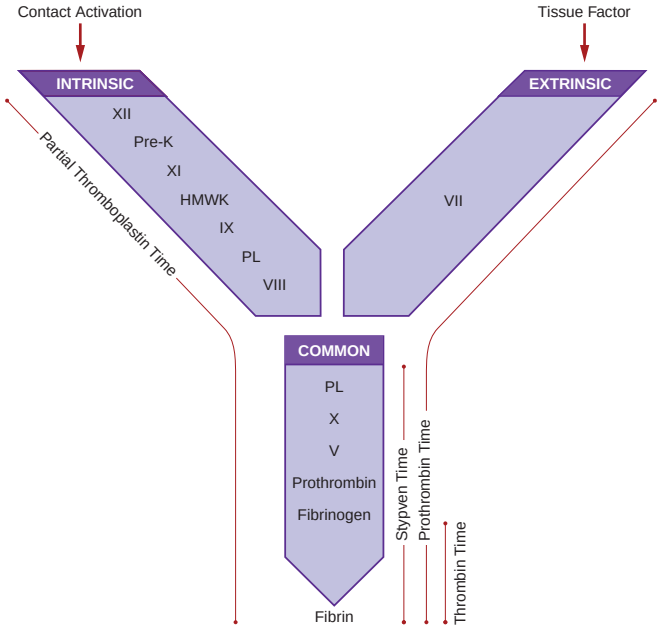

FIGURE 45.4. The interpretation of common screening tests of blood coagulation. Coagulation factors are indicated within arrow-shaped blocks, which represent the major pathways of coagulation. Screening tests are indicated at the side of these blocks in relation to pathways and coagulation factors measured by each. HMWK, high-molecular-weight kininogen; PL, phospholipid; Pre-K, prekallikrein.

fibrin forms at a normal rate only if the factors involved in the intrinsic pathway (prekallikrein, high-molecular-weight kininogen, and factors XII, XI, IX, and VIII) and in the common pathway (factors X and V, prothrombin, and fibrinogen) are present in normal amounts (Fig. 45.4). Platelet substitutes of various kinds may be used, such as chloroform extract of brain[54] and other crude cephalin fractions as well as soybean phosphatides (inosithin). In the PTT, such platelet substitutes are provided in excess, and the test is unaffected by the number of platelets remaining in the plasma (unless the sample contains antiphospholipid antibodies). Platelet substitutes are only partial thromboplastins, however, and they are incapable of activating the extrinsic pathway, which requires complete tissue thromboplastin (tissue factor). Thus, the PTT bypasses the extrinsic pathway and is unaffected by a deficiency of factor VII. The PTT assay is used to detect factor deficiency, screen for the lupus anticoagulant, and monitor heparin anticoagulation.

The PTT is somewhat more sensitive to deficiencies of factors VIII and IX than to deficiencies of factors XI and XII or factors involved in the common pathway,[55,56] but with most techniques, the test usually yields abnormal results if the plasma level of any of the essential factors is <15% to 30% of the normal value. The PTT thus detects some mild coagulation disorders. However, the ability to detect mild factor deficiency is reagent-dependent, and certain PTT reagents may not detect factor deficiency as low as 5% to 10%.[57] As is the case with all one-stage tests, the PTT may be shortened by high levels of a single factor, most commonly factor VIII. Thus, a short PTT may signify any of the various hypercoagulable states (see Chapter 55),[58] and high levels of any of the factors involved in the intrinsic or common pathways of coagulation may mask deficiencies of other factors.[59]

In the original method, contact activation was provided by the glass tube, but the addition of activators, such as ellagic acid, or particulate silicates, such as Celite or kaolin, provides more optimal and standardized contact activation and represents a significant improvement over the original nonactivated test.[60,61] The PTT is the routine assay currently used to evaluate intrinsic coagulation. The PTT of plasma deficient in prekallikrein (Fletcher factor) is abnormal when it is determined by standard methods using particulate activators such as Celite or kaolin.[62] This abnormality is minimized or abolished by protracted contact activation (15 minutes[63]), as compared with 2 to 3 minutes used in the standard technique. The PTT may yield normal results in prekallikrein deficiency when soluble activators such as ellagic acid are used.[63] A large recent pediatric reference interval study found no significant differences between adult PTT values and those of children ages 7 to 17 years.[64]

Whereas increased PTT values may suggest a bleeding disorder, shortened PTT values have been found to be independent predictors of an increased risk of death, thrombosis, bleeding, and morbidity.[58,65] The use of the PTT in the control of heparin therapy and in detection of the lupus anticoagulant is discussed in Chapters 55 and 54, respectively.

Prothrombin Time

The production of fibrin by means of the extrinsic and common pathways (Fig. 45.4) requires tissue factor and factor VII, in addition to factors X and V, prothrombin, and fibrinogen. These pathways are measured by the prothrombin time (PT),[66] in which plasma is recalcified in the presence of excess tissue factor. This test does not require contact activation and bypasses the intrinsic pathway and the factors involved therein. Because tissue thromboplastins contain phospholipids that act as platelet substitutes, the test is unaffected by platelet numbers. Of the five coagulation factors measured by the PT (factors V, VII, and X, prothrombin, and fibrinogen), three (prothrombin and factors VII and X) are vitamin K–dependent and are decreased by coumarin-like drugs. As a result, the PT is the test used most widely for controlling oral anticoagulant therapy. The PT usually is prolonged if the plasma levels of any of the requisite factors are <10% of normal, and it is more sensitive to deficiencies of factors VII and X than to deficiencies of fibrinogen and prothrombin. The PT also is prolonged by inhibitors of any of the essential factors and by heparin (unless heparin neutralizers are present in the PT reagent), but it is less sensitive to the anticoagulant action of heparin than is the PTT. A large pediatric reference interval study found that children ages 7 to 17 years have PT values ~1 second longer than normal adults.[64]

Various modified techniques and thromboplastins,[67] including recombinant human thromboplastins,[68] have been developed to improve the use of the PT in the control of coumarin anticoagulant therapy (see Chapter 55). Use of the international normalized ratio in monitoring oral anticoagulation therapy is the recommended format (discussed in Chapter 55). The PT performed with bovine brain thromboplastin is abnormal in patients with certain genetic variants of factor IX deficiency but is normal in patients with the more common form of this disorder. The venom of the Russell viper contains an enzyme that initiates coagulation by the direct activation of factor X and does not require factor VII. The one-stage "prothrombin time" performed with this venom (the Stypven time) thus distinguishes between deficiency of factor VII and deficiency of factor X (Fig. 45.4).

Assay of Plasma Fibrinogen

Several accurate methods are available for the quantitative assay of plasma fibrinogen, a measurement of great clinical importance that should be available in all laboratories. Fibrinogen may be converted into fibrin, which is quantitated by gravimetric, nephelometric,[69] or chemical[70] methods. An immunologic[71] method has also been described. Kinetic techniques based on the thrombin time, however, are simple to perform, and they have been widely adopted.[72] Both gravimetric methods and those based on the thrombin time underestimate fibrinogen in the presence of high concentrations of FDPs; technical modifications designed to avoid these problems have been proposed.[73] Some nephelometric

methods appear to be minimally affected by FDP. Modified methods that eliminate interference by heparin,[74] as well as automated techniques, have been described. Marked differences in fibrinogen levels obtained by gravimetric and immunologic methods and those obtained by functional techniques are found in patients with the inherited dysfibrinogenemias. Reference values to identify patients with dysfibrinogenemia have been reported.[75]

Thrombin Time and Related Techniques

When thrombin is added to plasma, the time required for clot formation is a measure of the rate at which fibrin forms (Fig. 45.4). This test (thrombin time) yields abnormal results when the fibrinogen level is <70 to 100 mg/dl, but it is unaffected by the levels of any of the other coagulation factors[76]; it is greatly prolonged by heparin. The thrombin time may also be prolonged by a qualitatively abnormal fibrinogen (dysfibrinogen), elevated levels of fibrin (fibrinogen)-degradation products, certain paraproteins, and hyperfibrinogenemia. The thrombin time and modifications thereof are technically simple, can be performed quickly, and are valuable, particularly in the diagnosis of DIC. The reptilase clotting time is similar to the thrombin time in principle, but coagulation induced by this enzyme, which is prepared from snake venom, is unaffected by the presence of heparin.

Tests for Fibrin (Fibrinogen)-degradation Products and D-Dimer

Fibrin (fibrinogen)-degradation products (FDPs) are protein fragments of varying sizes that result from the proteolytic action of plasmin on fibrin or fibrinogen (see Chapter 18).[77] Plasma levels of these fragments are commonly increased in association with DIC and fibrinogenolysis, disorders in which their presence is of considerable diagnostic significance. Quantitative assays for FDP are based on several principles, such as the agglutination of latex particles coated with antifibrinogen antibody,[78] immunodiffusion,[79] and red cell hemagglutination inhibition.[80] Serum containing rheumatoid factor[78] or residual fibrinogen may yield false-positive results in some assays.[81]

None of the aforementioned methods distinguishes between fibrin degradation products and fibrinogen degradation products; to make this distinction, measurement of the DD-dimer or even more sophisticated methods are required.[82] Extremely sensitive methods for the measurement of fibrinopeptides and specific FDP, such as the DD-dimer,[83] DDE-trimer, or B-β 15-42–related peptide, are useful as indices of DIC and as markers of subtle activation of coagulation in vivo (see Chapter 54).

Unpolymerized fibrin monomer is commonly present in the blood of patients with DIC. Various techniques (paracoagulation techniques) for demonstrating such monomers have been described; these range from the ethanol gelation test,[84] which is insensitive, to various protamine gelation techniques,[85] which are highly sensitive but nonspecific. Cryofibrinogen, which may be demonstrated in some cases of DIC, also may signify the presence of fibrin monomers. All of these assays to diagnose DIC have been supplanted by the D-dimer test.[83] The use of D-dimer tests to exclude venous thromboembolism is discussed in Chapter 55.

Tests for Factor XIII Activity

The principle of the factor XIII screening test is that clots cross-linked by factor XIII resist denaturation by high concentrations of urea or acid. Deficiency of factor XIII results in premature clot lysis.[3] Patient plasma is recalcified to induce a clot; the clot is then suspended in 5 mol/L urea (or 1% monochloroacetic acid) for 24 hours. Clot stability is examined visually after 24 hours of incubation. Because this assay is a screening test, abnormal results should be repeated and confirmed using a quantitative factor XIII method, such as measuring factor XIII–dependent incorporation of labeled amines into substances such as fibrinogen or casein.[86]

Tests for Fibrinolysis

The plasma euglobulin fraction contains plasminogen activators and fibrinogen. Most of the major antiplasmins are removed in the pseudoglobulin supernatant fluid. The rate of lysis of a fibrin clot prepared from the euglobulin fraction (the euglobulin clot lysis time) thus provides a measure of fibrinolysis in the absence of major inhibitors and is a measure of the activity of plasminogen activators.[87]

Tests for fibrinogenolysis and assays for individual components of the fibrinolytic enzyme system, including plasminogen,[88] free plasmin,[89] and antiplasmins, are available. Routine coagulation assays for plasminogen activators and plasminogen activator inhibitors typically involve enzyme-linked immunosorbent assay (ELISA) methods.[90,91] Blood collection methods, timing, processing, and determination of assay-specific reference ranges are critically important in accurate evaluation of fibrinolysis parameters.[90,91]

Moderate concentrations of ε-aminocaproic acid (4×10^{-4} mol/L) inhibit plasminogen activators but not free plasmin. Thus, a shortened euglobulin lysis time in the presence of such concentrations of ε-aminocaproic acid indicates the presence of free plasmin, as in association with fibrinogenolysis (see Chapter 54). Fibrinolysis in heated fibrin plates also measures free plasmin[92] because plasminogen activators are thermolabile.

Bioassays for Coagulation Factors

Bioassays for coagulation factors are usually based on the familiar screening tests, such as the PT and PTT. In principle, the extent to which an unknown sample corrects the abnormality in plasma with a known deficiency is assumed to be proportional to the content of the deficient factor in the sample. The results of coagulation assays may be expressed in terms of units, which equal the amount of a given factor that is present in 1 ml of normal pooled or reference plasma. Alternatively, plasma levels of various factors may be expressed as a percentage of normal. Thus, plasma levels of various coagulation factors typically range from 50 to 150 U/dl, or 50% to 150% of normal.

One-stage methods for factors VIII and IX, which are based on the PTT and use substrate plasma from patients with severe inherited deficiencies (<1% of normal) of these factors, are somewhat simpler to perform than comparable two-stage methods. However, two-stage methods are more specific than one-stage methods, particularly in patients with intravascular coagulation and liver disease,[93] presumably because the two-stage methods are less affected by the presence of activated coagulation factors or traces of thrombin that increase the activity of factors V and VIII. One study found that for detecting low factor VIII levels, the clot-based assay was better than the chromogenic assay, while for elevated factor VIII levels, the chromogenic assay was preferred.[94] Plasmas deficient in specific factors are available commercially. Modifications that do not depend on natural substrates have been developed, including techniques for the assay of prothrombin[95]; factors V,[96] VII, and X combined; and factors VIII,[97] IX,[98] X,[99] and XI.[100] Details of coagulation assay methodology have been summarized.[101]

Tests for Inhibitors of Coagulation

Abnormalities in any test of coagulation, if caused by deficiency of an essential factor, are corrected by the addition of small amounts of normal plasma. If the abnormality is caused by the presence of one of the various inhibitors of coagulation rather than a deficiency of an essential factor, the opposite is true: Small amounts of

the patient's plasma impair coagulation in normal samples. These tests are called *mixing studies* or *inhibitor screens*. This phenomenon is the essence of all screening tests for inhibitors, most of which are based on one-stage coagulation techniques, such as the PT and PTT.[102] The presence of heparin may be confirmed in various ways, including use of thrombin time and reptilase time assays, correction by protamine sulfate, or direct assays for activity of heparin or low-molecular-weight heparin.[101]

Tests for Physiologic Inhibitors of Coagulation

Several methods have been described for the assay of physiologic inhibitors of coagulation,[103] such as antithrombin,[104] heparin cofactor II, protein C,[103,105] and protein S.[106,107] Both immunologic and functional assays are available for many of these components.[103] Quantitative assays of such physiologic inhibitors may yield valuable information in patients with certain thromboembolic disorders (see Chapter 55).

Automated Coagulation Methods

Numerous instruments are available to detect automatically the endpoint of blood coagulation. These devices operate on a variety of principles: mechanical detection of the onset of fibrin formation, photometric recording of clot opacity, or the rate of fibrin polymerization. Such instruments are helpful in the performance of one-stage screening tests, such as the PT and PTT, especially if a large number of tests must be done daily.

Totally automated methods for performing coagulation tests are widely used. Automated instrument platforms have been developed to perform a large variety of coagulation methods with significant cost savings, permitting more laboratories to do comprehensive coagulation testing.[108] A College of American Pathologists Web site has summarized coagulation instrumentation (www.cap.org; see vendor surveys at the CAP Today link).

The *thromboelastograph*, an instrument that demonstrates changes occurring during blood coagulation and fibrinolysis, has been used by some investigators. Different coagulograms are described in association with various bleeding disorders and hypercoagulable states.[109] However, this is not a commonly used method to diagnose coagulation abnormalities in most laboratories. Its primary use is as a point-of-care instrument in the surgical setting.[44]

The activated clotting time (ACT) is a whole blood clotting assay now used primarily as a point-of-care test. The ACT measures the clotting time for a whole blood sample after addition of particulate (contact) activators such as kaolin or Celite; thus, this assay measures the intrinsic pathway of coagulation. The ACT is used mostly to monitor anticoagulation in the setting of cardiopulmonary bypass, cardiac catheterization, or dialysis. The ACT is preferable to the PTT in certain settings that require high-dose heparin, such as cardiopulmonary bypass.[110]

Other point-of-care coagulation instruments are being used in the setting of outpatient or home-based oral anticoagulation monitoring. Numerous studies have found that these instruments are at least as effective in providing safe and efficacious anticoagulation as is provided by physicians with standard laboratory anticoagulation testing.[111]

Chromogenic and Fluorometric Techniques

Artificial peptides release chromogenic substances or fluorophores when they are enzymatically cleaved.[112,113] The hydrolysis of such peptides by activated coagulation factors provides a novel means for assessing various coagulation reactions.[114] Such chromogenic and fluorometric techniques have been developed for the assay of prothrombin and factors VII, IX, and X[115]; antithrombin[116]; α_2-antiplasmin; heparin; urokinase[117]; kallikrein[118]; plasmin; and other components of the fibrinolytic enzyme system.[119] Assays also have been developed for coagulants that do not have enzymatic activity, such as cellulose sandwich fluoroimmunoassays for vWF antigen[120] and solid-phase front-surface fluorescence detection methods for factors VIIIc and IX.[121] These methods appear to be intrinsically more precise and may be less time-consuming than traditional coagulation methods, and instruments designed specifically for their performance are available. Chromogenic and fluorometric assays are expensive, however, and at present are used mainly in research and in large reference coagulation laboratories.

INITIAL LABORATORY EVALUATION

Primary Screening Tests

The initial laboratory study of the bleeding patient should be guided by the information obtained from the clinical evaluation. In many cases, however, the routine use of a small battery of screening tests has merit because it usually saves time, and the results direct the course of further study. It is generally agreed that the most essential information usually can be obtained from the three tests summarized in Table 45.3, which, in view of their availability, simplicity, and low cost, are well suited to serve as primary screening tests. The platelet count provides the most reliable and reproducible test of primary hemostasis. The PTT measures all of the coagulation factors involved in the intrinsic and common pathways (Fig. 45.4) and generally is accepted as the best single screening test for disorders of blood coagulation. When supplemented with the PT, which assesses the extrinsic as well as the common pathway, the abnormality usually can be localized to one of the three pathways and the factors involved therein (Fig. 45.4 and Table 45.3). The results of these three tests thus provide a presumptive diagnosis, which can then be clarified further by the confirmatory methods summarized in the next section. The bleeding time test has been omitted from this evaluation because of its nonspecificity in the general clinical setting.[13,16] The definitive laboratory diagnosis of individual bleeding disorders is discussed in Chapters 46 through 54.

It is important to realize that patients with mild bleeding disorders (factor VIII, IX, or XI deficiency) may have normal PTT values, because most PTT reagents do not detect mild deficiency states (factor levels of 20% to 30%).[57] Consequently, if the clinical suspicion is high, specific factor assays for these disorders should be performed, even if the initial evaluation suggested in Table 45.3 is not productive.

CONFIRMATORY TESTS

Thrombocytopenia

Thrombocytopenia, like anemia, is a symptom, not a diagnosis. It is the most common of the acquired bleeding disorders. Additional laboratory tests usually are not indicated merely to confirm the presence of thrombocytopenia (Table 45.3), but are helpful in establishing the mechanism for thrombocytopenia. It is useful, however, to examine the thrombocytopenic patient's blood smear to exclude pseudothrombocytopenia that may be seen in a small number of patients.[18,19] The differential diagnosis of thrombocytopenia is discussed at length in Chapters 46 through 49. One approach to evaluating thrombocytopenia is shown in Figure 45.5.

von Willebrand Disease

von Willebrand disease is the result of an abnormality in primary hemostasis combined with mild to moderate deficiency of

TABLE 45.3

PROFILES OF HEMOSTASIS SCREENING TESTS IN PATIENTS WITH BLEEDING DISORDERS

Prothrombin Time	Activated Partial Thromboplastin Time	Platelet Count	Differential Diagnosis
↑	—	—	Common
			Acquired factor VII deficiency (early liver disease; early vitamin K deficiency; early warfarin therapy)
			Rare
			Factor VII inhibitor; dysfibrinogenemia; some cases of DIC; inherited factor VII deficiency; certain factor X variants
—	↑	—	Common
			Deficiency or inhibitor of factors VIII, IX, or XI; vWD; heparin
			Rare
			Lupus inhibitor with qualitative platelet defect; certain factor X variants
↑	↑	—	Common
			Vitamin K deficiency; liver disease; warfarin; heparin; superwarfarin
			Rare
			Deficiency or inhibitor of factors X or V, prothrombin, or fibrinogen; lupus inhibitor with hypoprothrombinemia; DIC; dysfibrinogenemia; primary fibrinolysis
↑	↑	↓	Common
			DIC; liver disease
			Rare
			Heparin therapy with associated thrombocytopenia
—	—	↓	Common
			Increased platelet destruction; decreased platelet production; hypersplenism; hemodilution
			Rare
			Certain inherited platelet disorders (Wiskott-Aldrich syndrome, Bernard-Soulier syndrome)
—	—	↑	Myeloproliferative disorders
—	—	—	Common
			Mild vWD; acquired qualitative platelet disorders (uremia, antiplatelet medications)
			Rare
			Inherited qualitative platelet disorders; vascular disorders; fibrinolytic disorders; factor XIII deficiency; autoerythrocyte sensitization; dysfibrinogenemia; mild factor deficiency (VIII, IX, XI); disorders of platelet procoagulant activity

↑, increased; ↓, decreased; —, normal; DIC, disseminated intravascular coagulation; vWD, von Willebrand disease.
Note: The differential diagnosis of bleeding disorders suggested by results of the prothrombin time, partial thromboplastin time, and platelet count is listed for each profile. This table includes the differential diagnosis of hemostasis screening test results in patients with a history of bleeding. Consideration of patients with abnormal coagulation tests and negative bleeding histories is not included in this table.
Modified from Rodgers GM. Common clinical bleeding disorders. In: Boldt DH, ed. Update on hemostasis. New York: Churchill Livingstone, 1990:75–120.

factor VIIIc (see Chapter 53). In the classic case, the results of screening tests reveal a normal platelet count and a prolonged PTT (Table 45.3). In many patients, however, the PTT will be normal. Furthermore, the results of all of the laboratory tests tend to fluctuate from time to time.[122] If the clinical suspicion is high, initial laboratory studies directed at excluding vWD should be performed, because vWD is more common than the inherited disorders of platelet function (Fig. 45.6). Useful tests include bioassay of factor VIII (VIIIc), immunoassay of vWF antigen, and measurement of ristocetin cofactor activity. In many cases, the diagnosis of vWD requires repeated testing.

Another available test to evaluate patients for vWD is multimeric analysis of vWF. Patient plasma is separated by agarose electrophoresis, and vWF is identified by immunologic methods. The patient's multimeric pattern is compared to that of normal plasma. A more detailed description of this test is given in Chapter 53.

Qualitative Platelet Disorders

Symptoms of mucocutaneous bleeding in the presence of a normal number of platelets and normal results of coagulation tests (Table 45.3) are presumptive evidence of a disorder of platelet function (see Chapter 52). Inherited forms are uncommon, but bleeding caused by platelet dysfunction may be an important complication in patients with various acquired disorders, such as uremia. Commonly available confirmatory tests occasionally provide useful information regarding platelet dysfunction. Various morphologic abnormalities of the platelets may be seen on the blood smear. Strikingly large platelets are characteristic of certain inherited disorders, such as Bernard-Soulier syndrome. A markedly elevated platelet count is present in the myeloproliferative disorder, essential thrombocytosis.

Definitive methods for the study of platelet dysfunction are time-consuming and technically difficult. The absence of platelet aggregation by ADP, collagen, and epinephrine is characteristic of Glanzmann thrombasthenia. Deficient secondary wave aggregation is associated with various disorders of the release reaction, such as inherited deficiency of storage nucleotides, uremia, and aspirin ingestion. Abnormal responses to ristocetin indicate vWD or Bernard-Soulier syndrome.

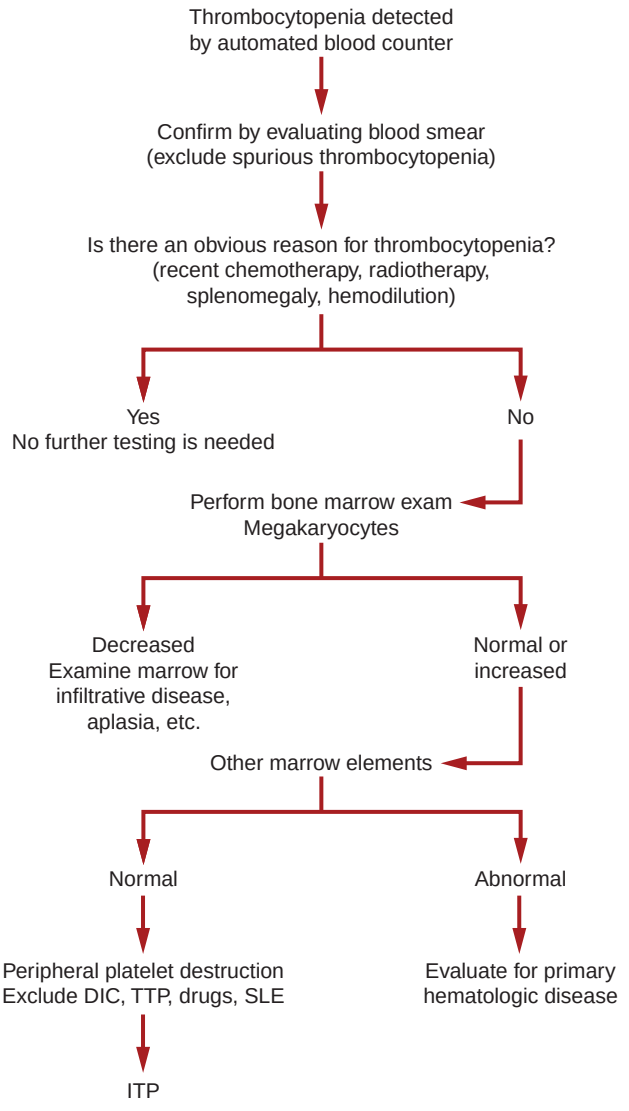

FIGURE 45.5. An approach for evaluation of thrombocytopenia. The necessity to do a bone marrow examination in the evaluation of idiopathic thrombocytopenic purpura (ITP) is controversial. ITP is a diagnosis of exclusion. DIC, disseminated intravascular coagulation; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura. (Redrawn from Kjeldsberg C, ed. Practical diagnosis of hematologic disorders, 4th ed. Chicago: ASCP Press, 2006:319.)

Disorders of the Intrinsic Pathway of Coagulation

Disorders of the intrinsic pathway of coagulation are characterized by a prolonged PTT and a normal PT (Table 45.3). Inherited forms include deficiencies of factor VIII or IX (hemophilia A and B), prekallikrein, high-molecular-weight kininogen, factor XI, or factor XII (Fig. 45.7). Factor XII (Hageman factor) deficiency and deficiencies of prekallikrein or high-molecular-weight kininogen can be excluded readily, because they are not associated with excessive clinical bleeding. Distinguishing between deficiencies of factors VIII, IX, and XI is done by performing specific assays for these factors. Screens (mixing studies) should also be performed to exclude antibodies to the intrinsic factor under study. If a factor VIII inhibitor is identified, the titer should be quantitated (see Chapter 54). An algorithm approach for evaluating bleeding patients with an isolated, prolonged PTT is shown in Figure 45.8.

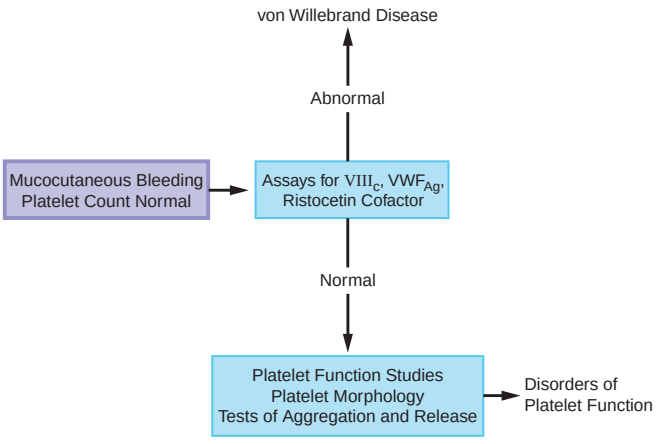

FIGURE 45.6. Laboratory diagnosis of von Willebrand disease (vWD) and platelet dysfunction. The initial evaluation reveals mucocutaneous bleeding symptoms in a patient with a normal platelet count (block on left). In vWD, the partial thromboplastin time also may be prolonged because of deficiency of factor VIIIc. Additional tests (blocks) and a suggested sequence for their performance are indicated as a flow diagram. Some patients with vWD may have normal assays for factor VIIIc, von Willebrand factor Ag (vWF$_{Ag}$), and ristocetin cofactor activity. These patients may be diagnosed by abnormal ristocetin-induced platelet agglutination when aggregation studies are performed or by multimeric analysis of vWF. For patients with normal studies for vWD and platelet dysfunction who are strongly suspected of having an inherited disorder, von Willebrand studies should be repeated.

Acquired coagulation disorders associated with a prolonged PTT and a normal PT include the lupus inhibitor and antibodies to factor VIII. Prolongation of the PTT is commonly the result of heparin administration or poorly collected blood samples.

Disorders of the Common Pathway of Coagulation

Prolongation of the PTT and PT in a patient with an inherited bleeding disorder indicates a deficiency of one of the factors in the common pathway—factor X, factor V, prothrombin, or fibrinogen, or a dysfibrinogen (Table 45.3 and Fig. 45.7). Such isolated deficiencies are exceedingly rare. On the other hand, deficiency of one or more of these factors is associated with additional abnormalities in the intrinsic and extrinsic pathways in many of the common acquired coagulation disorders, such as vitamin K deficiency, liver disease, and DIC. A prolonged PT usually suggests an acquired disorder (excluding the rare cases of inherited factor VII deficiency) and usually is associated with a complex abnormality involving multiple pathways, such as DIC.

When confronted with this combination of findings, the first step should be to exclude or to identify an abnormality of fibrinogen. This may be accomplished by determination of the plasma fibrinogen level and tests for increased amounts of D-dimer or FDP. The most helpful ancillary procedures are the platelet count and examination of the blood smear for schistocytes. The laboratory findings characteristic of DIC are summarized in Chapter 54.

Inherited disorders associated with a low fibrinogen level include afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia (see Chapter 53). In certain dysfibrinogenemias, large amounts of unclotted fibrinogen remain in the serum and are detected by tests for FDP.

Inherited deficiencies of factor V, factor X, and prothrombin can be diagnosed by specific factor assays.

Disorders of the Extrinsic Pathway of Coagulation

A prolonged PT and a normal PTT (Table 45.3) suggest an isolated deficiency of factor VII, which is rare and may be the

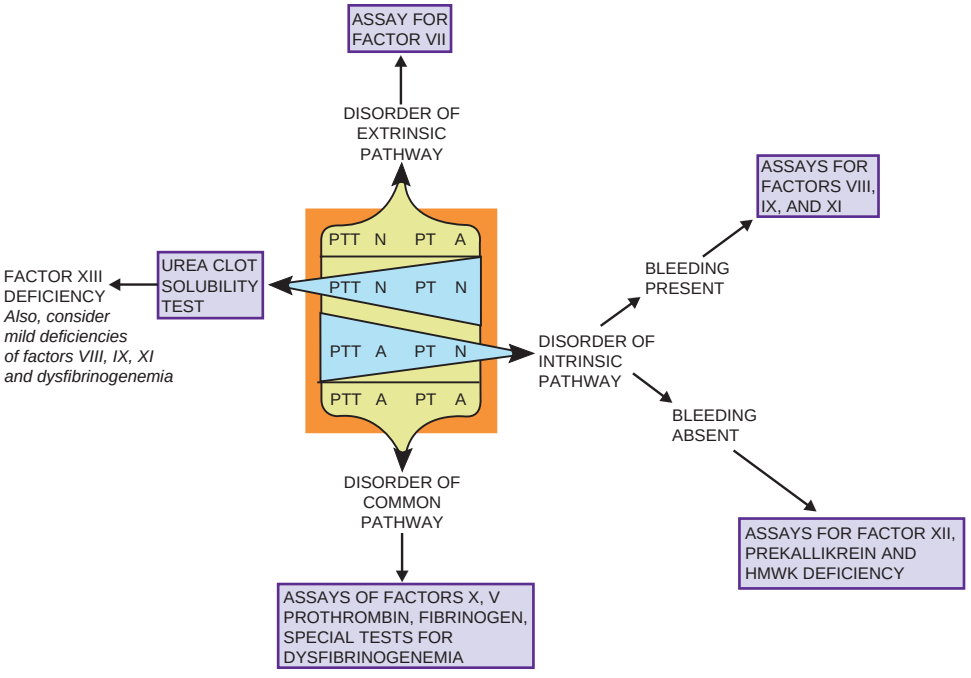

FIGURE 45.7. Laboratory diagnosis of inherited coagulation disorders. Results of primary screening tests of coagulation (activated partial thromboplastin time [PTT], prothrombin time [PT]) are summarized in the center block. Additional tests (blocks) and a suggested sequence for their performance are presented as a flow diagram. A more complete list of the differential diagnosis of bleeding disorders is presented in Table 45.3. A, abnormal; HMWK, high-molecular-weight kininogen; N, normal; PTT, partial thromboplastin time.

result of an inherited or an acquired abnormality (Figs. 45.7 and 45.9). Less commonly, inhibitors of factor VII have been reported (see Chapter 54). Additionally, certain cases of DIC or dysfibrinogenemia may present with isolated prolonged PT values.[123] Because factor VII is essential only in the tissue factor–activated extrinsic pathway of coagulation, the Stypven time is normal in patients with factor VII deficiency.

Disorders in Which Results of Primary Screening Tests Are Normal

Screening tests usually yield normal results in patients with bleeding disorders related to vascular abnormalities (Tables 45.3 and 45.4). The diagnosis is usually made from the associated clinical findings that are often characteristic, such as the skin lesions of

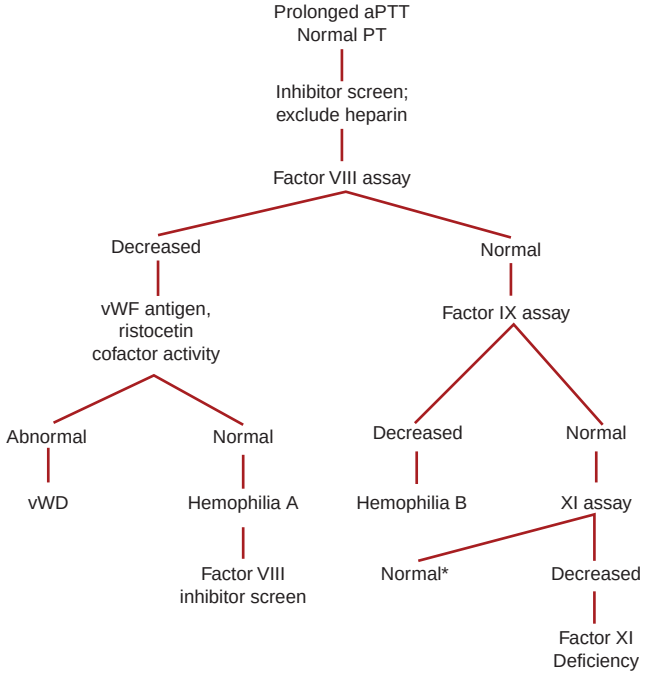

FIGURE 45.8. Evaluation of a patient with bleeding and an isolated, prolonged partial thromboplastin time (PTT). *Asterisk* indicates that patients with clinical bleeding but normal studies should be evaluated further for lupus anticoagulants associated with either platelet dysfunction or thrombocytopenia. PT, prothrombin time; PTT, activated partial thromboplastin time; vWD, von Willebrand disease; vWF, von Willebrand factor. (Redrawn from Kjeldsberg CR, Perkins SL, eds. Practical diagnosis of hematologic disorders, 5th ed. Chicago: ASCP Press, 2010:349.)

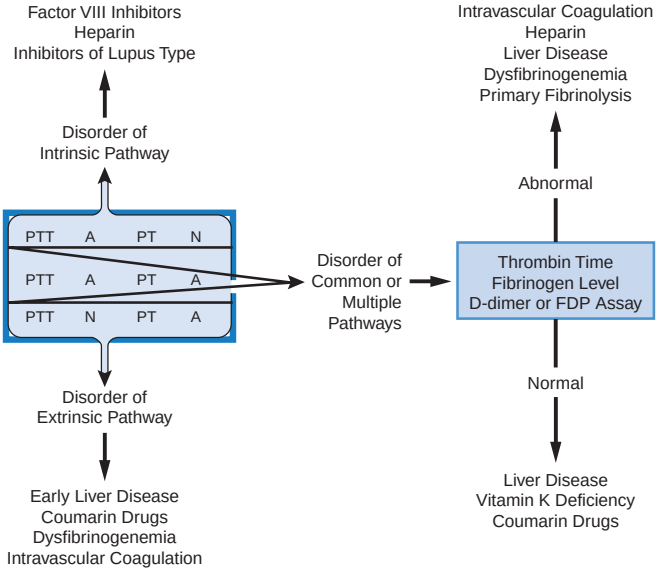

FIGURE 45.9. Laboratory diagnosis of acquired coagulation disorders. Results of primary screening tests of coagulation (partial thromboplastin time [PTT], prothrombin time [PT]) are summarized in the left-side block. Additional tests (right-side block) and a suggested sequence for their performance are presented as a flow diagram. Because of the complexity of acquired coagulation disorders and great variations in the results of laboratory tests that may be encountered in the various disorders and in individual patients, this diagram should be regarded as a general guide only. A more complete list of the differential diagnosis of bleeding disorders is presented in Table 45.3. A, abnormal; FDP, fibrin degradation products; N, normal.

TABLE 45.4

BLEEDING DISORDERS IN WHICH THE RESULTS OF PRIMARY SCREENING TESTS MAY BE NORMAL

von Willebrand disease
Mild inherited coagulation disorders, particularly factor XI deficiency
Heterozygous carriers of inherited coagulation disorders
Factor XIII (fibrin-stabilizing factor) deficiency
Some forms of dysfibrinogenemia
Disordered platelet function, particularly deficient release reaction; Scott syndrome
Hereditary hemorrhagic telangiectasia
Allergic and other vascular purpuras
α_2-Plasmin inhibitor deficiency
Elevated levels of plasminogen activator

hereditary hemorrhagic telangiectasia, allergic purpura, scurvy, and senile purpura. The results of screening tests also are normal in factor XIII (fibrin-stabilizing factor) deficiency, a disorder in which the diagnosis is made by the demonstration of characteristic clot solubility in urea or monochloroacetic acid.

Although abnormal in the typical case, the results of screening tests may be normal or equivocal in patients with mild coagulation disorders (including heterozygous carriers), certain disorders of platelet function, mild forms of vWD, and dysfibrinogenemia or abnormal fibrinolysis.[101,124] More definitive tests are required to establish the diagnosis in these patients (Table 45.4). An increasing number of reports have indicated that many bleeding patients with normal screening studies have disorders of platelet procoagulant activity, such as Scott syndrome.[125]

There are patients with a significant bleeding history in whom the results of detailed studies of hemostasis and blood coagulation are normal. Some have disorders of hemostasis that cannot be detected by methods currently available. The clinical management of these cases requires great care, and the fact that a clear-cut history of bleeding is always more significant than negative laboratory data cannot be overemphasized. Trauma may be denied in physically abused patients and may be self-inflicted in psychotic or neurotic patients.

PREOPERATIVE HEMOSTASIS EVALUATION

The value of obtaining routine screening tests before surgical procedures has been debated for years.[126] The screening tests for hemostasis are not totally satisfactory in detecting all mild hemostatic defects. Nevertheless, routine preoperative laboratory screening is of great value in certain high-risk patients who have disorders that predispose them to unexpected postsurgical bleeding, even from limited biopsy procedures. Important in this category are patients with liver disease, biliary obstruction, renal disease (particularly if complicated by azotemia), myelofibrosis, polycythemia vera, and other myeloproliferative disorders, particularly those associated with thrombocytosis and those with paraproteinemias. Included in this list should be all patients scheduled to undergo procedures involving the use of extracorporeal circulatory devices.

One approach to the question of preoperative hemostasis screening tests is to balance the financial costs of laboratory testing with the extent of surgery to be performed and with the amount of bleeding that can be safely tolerated. This approach makes the patient's hemostasis history particularly important.

TABLE 45.5

GUIDELINES FOR PREOPERATIVE HEMOSTASIS EVALUATION

Level	Bleeding History	Surgical Procedure	Recommended Hemostasis Evaluation
I	Negative	Minor	None
II	Negative	Major	Platelet count, PTT
III	Equivocal	Major, involving hemostatic impairment	PT, PTT, platelet count, factor XIII assay, euglobulin clot lysis time
IV	Positive	Major or minor	Level III tests; if negative, then factors VIII, IX, and XI assays, thrombin time, α_2-antiplasmin assay; consider von Willebrand disease and platelet aggregation testing; consider specific tests for uncommon disorders listed in Table 45.3

PT, prothrombin time; PTT, activated partial thromboplastin time.
Note: Information in this table is a revision based on the suggested preoperative guidelines for hemostasis testing by Rapaport.[126] The bleeding time is omitted as a hemostasis test because of more recent appreciation of its weakness as a useful test. Comprehensive testing should be performed on level IV patients.
Modified from Rodgers GM. Preoperative hemostasis screening. In: Kjeldsberg CR, Perkins SL, eds. Practical diagnosis of hematologic disorders, 5th ed. Chicago: ASCP Press, 2010:373.

Patients scheduled for minor surgical procedures (dental, skin biopsy) do not need routine hemostasis screening tests if they have a negative history. In contrast, patients undergoing neurosurgery or other procedures that may induce a hemostatic defect (use of a bypass pump) or patients with a positive bleeding history need a hemostasis evaluation by the laboratory. Table 45.5 summarizes the recommendations of Rapaport in evaluating preoperative patients.[126]

EVALUATION OF THE NEONATE

Laboratory investigation of hemostasis and blood coagulation in the neonate and infant differs from that just outlined in several respects.[127] First, the quantity of blood that can be obtained is limited, and often, the venipuncture is difficult. Various microtechniques and modifications of standard coagulation techniques that involve the use of capillary blood have been developed to circumvent this problem.[128] Second, in terms of adult norms, the results of some tests are abnormal, even in healthy full-term infants (Table 45.6). Such physiologic abnormalities presumably are the result of deficiencies of the vitamin K–dependent factors and of additional abnormalities in the contact phase of coagulation and in the thrombin–fibrinogen reaction.[4,129]

The PT may be prolonged but often is normal if vitamin K is administered to the infant or mother.[129] Abnormalities of the thrombin time and the PTT are present in many normal neonates. These findings usually disappear within 2 to 6 months.[4] These abnormalities and moderate deficiencies of the vitamin K–dependent factors (prothrombin; factors VII, IX, and X; and proteins C and S) are more pronounced in the premature than in the full-term infant, and they are inversely proportional to gestational age and birth weight. Levels of factors VIII and V as well as antithrombin may be low in extremely premature infants.[130] Factor VIII levels and the ratio of vWF_{Ag} to VIIIc are higher in term infants than in adults or older children.

Levels of factor V are normal in both neonates and thriving premature infants.[129,131] Levels of antithrombin and other physiologic inhibitors of coagulation and of factor XIII are below adult norms in term neonates.[132] Significant abnormalities of platelet

[d]Results are of antigenic assays; all other results are of functional assays.

[e]Gender-specific reference ranges are given for protein S for children ages 7–9 years and older.

aggregation and of the results of other platelet function tests may be seen in normal neonates.[133] The newborn also is abnormally susceptible to drugs that impair platelet function, including those transferred placentally from the mother. The platelet count in term infants, as well as in thriving premature infants, is within the range found in adults and older children. Table 45.6 summarizes coagulation reference ranges in newborns, children, and adults.

CHAPTER 46

THROMBOCYTOPENIA: PATHOPHYSIOLOGY AND CLASSIFICATION

George M. Rodgers

PATHOPHYSIOLOGY

Thrombocytopenia may be defined as a subnormal number of platelets in the circulating blood. It is the most common cause of abnormal bleeding. Despite the number and diversity of disorders that may be associated etiologically, thrombocytopenia results from only four processes: artifactual thrombocytopenia, deficient platelet production, accelerated platelet destruction, and abnormal distribution or pooling of the platelets within the body (Fig. 46.1). The changes in the basic parameters of thrombopoiesis that are characteristic of each of these processes are summarized in Table 46.1.

Artifactual Thrombocytopenia

Artifactual thrombocytopenia, or falsely low platelet counts, occurs ex vivo when platelets are not counted accurately. This mechanism should be considered in patients who have thrombocytopenia but no petechiae or ecchymoses. Although inaccurate counting may occur in the presence of giant platelets[1] or with platelet satellitism,[2] the most common cause of artifactual thrombocytopenia is platelet clumping (pseudothrombocytopenia).[3] Platelet clumping in pseudothrombocytopenia appears to be caused by anticoagulant-dependent platelet agglutinins that are immunoglobulins (Igs) of IgG, IgA, or IgM subtypes. Although clumping is most commonly seen when blood is collected into ethylenediaminetetraacetic acid anticoagulant, other anticoagulants may cause clumping, even hirudin or Phe-Pro-Arg chloromethyl ketone.[4] Platelet clumping is also time-dependent and varies with the type of instrumentation used for automatic counting.[4] There is evidence that the autoantibodies bind to glycoprotein IIb/IIIa,[5] and in one study, there was over 80% concordance between the presence of anticardiolipin antibody and platelet agglutinins in individual patient plasmas.[6] These autoantibodies have no known associations with disease or drugs and have been noted in some patients for over 10 years.[7]

Accelerated Platelet Destruction

Accelerated platelet destruction is the most common cause of thrombocytopenia. It leads to stimulation of thrombopoiesis and, consequently, to an increase in the number, size, and rate of maturation of the precursor megakaryocytes (Fig. 46.1).[8] When the rate of platelet destruction exceeds this compensatory increase in platelet production, thrombocytopenia develops. "Compensated" platelet destruction without thrombocytopenia also may occur in patients with prosthetic heart valves and in patients with idiopathic thrombocytopenic purpura after splenectomy.[9–11]

Platelet destruction may result from both intracorpuscular defects and extracorpuscular abnormalities. Intracorpuscular defects are rare but have been demonstrated in certain forms of hereditary thrombocytopenia, such as Wiskott-Aldrich syndrome (see Chapter 49).[12] In such disorders, the survival of affected platelets is shortened in the circulation of both the patient and normal recipients. Platelets injured by either intracorpuscular or extracorpuscular processes usually are removed from the circulation by the spleen, liver, and reticuloendothelial system. Platelet destruction most often is the result of extracorpuscular factors; various immunologic phenomena are the most common. Immunologic platelet destruction is discussed in Chapter 47.

Platelet consumption in intravascular thrombi or on damaged endothelial surfaces is another cause of thrombocytopenia. This occurs in disseminated intra vascular coagulation (see Chapter 54) and in thrombotic thrombocytopenic purpura (see Chapter 48) and other microangiopathic processes. Thrombocytopenia caused by other nonimmunologic platelet destruction is discussed in Chapter 49.

Deficient Platelet Production

Deficient platelet production may result from any of a number of processes. Those that depopulate the stem cell or megakaryocyte

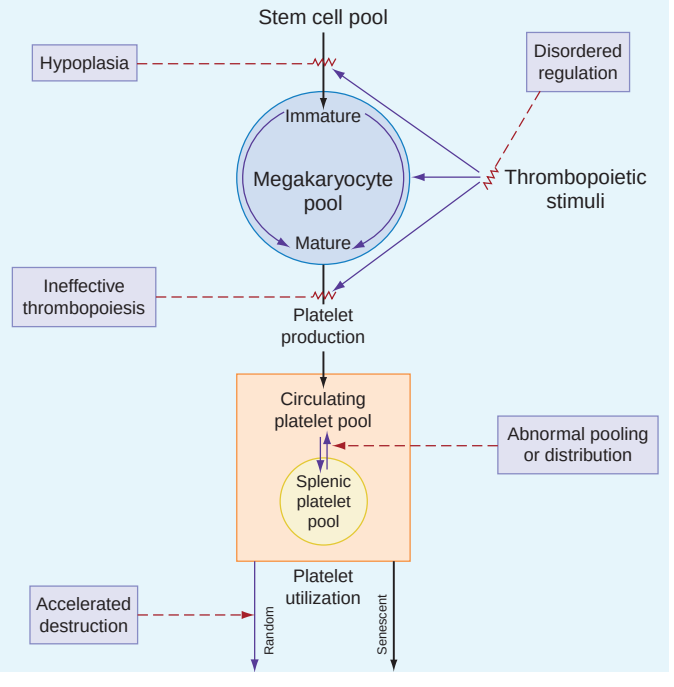

FIGURE 46.1. The pathophysiology of thrombocytopenia. A simplified diagram of the biodynamics of the megakaryocyte–platelet system (*solid lines*) and the mechanisms (*dashed lines*) by which pathologic processes (*shaded blocks*) produce thrombocytopenia.

TABLE 46.1

THROMBOKINETIC PATTERNS IN VARIOUS FORMS OF THROMBOCYTOPENIA

Measurement	Decreased Production		Accelerated Destruction[c]	Abnormal Pooling
	Hypoproliferation or Hypoplasia[a]	Ineffective Thrombopoiesis[b]		
Total megakaryocyte mass[d]	Decreased	Increased	M increased	V increased
Megakaryocyte number	Decreased	M increased	Increased	V increased
Megakaryocyte volume	Increased	Normal or V decreased	Increased	V increased
Platelet turnover rate or production rate[e]	Decreased	Decreased	Increased	V increased
Total platelet mass	Decreased	Decreased	Decreased	? Normal
Splenic platelet pool	Decreased	Decreased	Decreased[f]	Increased
Platelet survival	Normal	V shortened	Shortened	V shortened

M, markedly; V, variably.
[a]Includes myelophthisic processes.
[b]Mainly in megaloblastic hematopoiesis; component of accelerated destruction present in some cases.
[c]Minor component of ineffective thrombopoiesis present in some cases.
[d]Equated to total thrombopoiesis.
[e]Equated to effective thrombopoiesis.
[f]Not representative of sequestered antibody-sensitized platelets.
Based on Harker LA. Megakaryocyte quantitation. J Clin Invest 1968;47:452–457; Harker LA. Thrombokinetics in idiopathic thrombocytopenic purpura. Br J Haematol 1970;19:95–104; and Harker LA, Finch CA. Thrombokinetics in man. J Clin Invest 1969;48:963–974.

compartments are the most common, such as marrow injury by myelosuppressive drugs or irradiation and aplastic anemia. Deficient platelet production also may be the consequence of disordered proliferation within a precursor compartment of normal or even increased size. For example, in disorders characterized by megaloblastic hematopoiesis, hypertrophy of the precursor compartment occurs in response to thrombopoietic stimuli, but thrombopoiesis is ineffective and platelet production is insufficient. Rarely, abnormalities of the processes that normally regulate thrombopoiesis appear to underlie deficient platelet production, such as deficiency of thrombopoietin and cyclic thrombocytopenia.

Abnormal Pooling

Abnormal pooling or abnormal in vivo distribution of an essentially normal total platelet mass may produce thrombocytopenia. This type of thrombocytopenia is seen in the various disorders associated with splenomegaly (see Chapter 49), in which platelet production is normal or even increased, but most of the platelets are sequestered in the vastly enlarged extravascular splenic pool. Thrombocytopenia may also be caused by dilution of platelets when patients are massively transfused during blood loss. A discussion of various forms of thrombocytopenia attributable to deficient or ineffective thrombopoiesis or abnormal platelet pooling is included in Chapter 49.

CLASSIFICATION

A classification of thrombocytopenia based on pathophysiologic criteria is presented in Table 46.2. It should be recognized that multiple pathogenetic factors may simultaneously or sequentially play a role in the production of thrombocytopenia.

Methods for the measurement of serum thrombopoietin concentrations or reticulated platelets have been reported. These techniques may both elucidate the pathophysiology of thrombocytopenia in various disease states and determine the mechanism of thrombocytopenia in individual patients. Reticulated platelets can be identified with fluorescent dyes that bind to nucleic acids,

TABLE 46.2

PATHOPHYSIOLOGIC CLASSIFICATION OF THROMBOCYTOPENIA

Artifactual thrombocytopenia

Platelet clumping caused by anticoagulant-dependent immunoglobulin (pseudothrombocytopenia)
Platelet satellitism
Giant platelets

Decreased platelet production (see Chapter 49)

Hypoplasia of megakaryocytes
Ineffective thrombopoiesis
Disorders of thrombopoietic control
Hereditary thrombocytopenias

Increased platelet destruction

Caused by immunologic processes (see Chapter 47)
- Autoimmune
  - Idiopathic
  - Secondary: Infections, pregnancy, collagen vascular disorders, lymphoproliferative disorders, drugs, miscellaneous
- Alloimmune
  - Neonatal thrombocytopenia
  - Posttransfusion purpura

Caused by nonimmunologic processes
- Thrombotic microangiopathies
  - Disseminated intravascular coagulation (see Chapter 54)
  - Thrombotic thrombocytopenic purpura (see Chapter 48)
  - Hemolytic-uremic syndrome (see Chapter 48)

Platelet damage by abnormal vascular surfaces (see Chapter 49)
Miscellaneous (see Chapter 49)
- Infection
- Massive blood transfusions

Abnormal platelet distribution or pooling (see Chapter 49)

Disorders of the spleen (neoplastic, congestive, infiltrative, infectious, of unknown cause)
Hypothermia
Dilution of platelets with massive transfusions

especially RNA. Measurement of the percentage of reticulated platelets identifies platelets that have recently been released from the bone marrow. There is an increased percentage of reticulated platelets in patients with thrombocytopenia caused by increased destruction and a normal to reduced percentage of reticulated platelets in patients with deficient production.[13,14] The sensitivity and specificity of this method of distinguishing between these categories are reported to be more than 95%.[15]

CHAPTER 47

THROMBOCYTOPENIA CAUSED BY IMMUNOLOGIC PLATELET DESTRUCTION

Meghan S. Liel, Michael Recht, David C. Calverley

Immune thrombocytopenia (ITP) occurs when platelets undergo premature destruction as a result of autoantibody or immune complex deposition on their membranes. Although this disorder was previously known as *idiopathic thrombocytopenic purpura*, it is now correctly termed ITP because this nomenclature more clearly reflects the immune-mediated mechanism of the disease.[1] In this chapter, both primary and secondary types of ITP are discussed (Table 47.1). Human immunodeficiency-virus–related autoimmune thrombocytopenia, which is also in major part a result of the deposition of autoantibody or immune complexes, or both, on the platelet surface, is discussed in Chapter 64.

The diagnosis of ITP is primarily a diagnosis of exclusion, because currently available clinical assays for platelet-associated antibodies or serum antiplatelet antibodies/immune complexes are neither specific nor sensitive enough for routine clinical use. These disorders are characterized by peripheral thrombocytopenia (confirmed by examination of the peripheral smear), with a normal or increased number of megakaryocytes present on bone marrow examination, and absence of splenomegaly. Those patients who have no identifiable underlying cause, which might include infections, collagen vascular diseases, lymphoproliferative disorders (chronic lymphocytic leukemia or lymphoma), or drugs, are diagnosed as primary ITP. In some instances, ITP may be the presenting manifestation of an underlying disease, and additional manifestations appear weeks to months later.

PRIMARY IMMUNE THROMBOCYTOPENIA

Primary ITP refers to thrombocytopenia in which apparent exogenous etiologic factors are lacking and in which diseases known to be associated with secondary thrombocytopenia have been excluded. This syndrome has been recently reviewed.[2–6]

Acute ITP and chronic ITP differ in incidence, prognosis, and therapy (Table 47.2). These differences illustrate the wide spectrum of disorders that by definition are included in the syndrome, but many clinicians have long believed that acute ITP and chronic ITP are fundamentally different disorders.

Incidence

The annual incidence of ITP in the United States is estimated to be 1.6/10,000.[7] *Acute ITP,* defined as thrombocytopenia occurring for <6 months and usually resolving spontaneously, most often affects children and young adults. The incidence peaks in the winter and spring, following the incidence of viral infections.[8,9] Acute ITP is most common between 2 and 6 years of age. Approximately 7% to 28% of children with acute ITP develop the chronic variety.[9–11] Chronic ITP, lasting >6 months and requiring therapy to improve the thrombocytopenia, occurs most commonly in adults. In chronic ITP in adults, the median age is usually 40 to 45 years,[12,13] although in one large series of patients, 74% of 934 cases were younger than age 40 (range, 16 to 87 years of age).[14] The ratio of females to males is nearly 1:1 in acute ITP[9–11,15] and 2 to 3:1 in chronic ITP.[13,14]

Pathophysiology

The syndrome of ITP is caused by platelet-specific autoantibodies that bind to autologous platelets, which are then rapidly cleared from the circulation by the mononuclear phagocyte system via macrophage Fcγ receptors predominantly in the spleen and liver[16] (Fig. 47.1). The ITP antibody does not fix complement in vitro when tested by the usual techniques, but activation of components of complement on the platelet surface may be demonstrated.[17,18]

A compensatory increase in platelet production takes place in most patients in response to the autoantibody-mediated platelet destruction described above. In others, however, platelet production appears to be impaired as a result of either intramedullary destruction of antibody-coated platelets by marrow macrophages or the inhibition of megakaryopoiesis. Autoantibodies from ITP patients have been shown to inhibit production of megakaryocytes in vitro, and megakaryocyte apoptosis has also been observed in this setting.[19–21] Turnover studies have shown platelet production to be reduced or inappropriately normal in around two thirds of ITP patients.[22,23,24] In one study, megakaryocytes were small in patients with anti-gpIb/V/IX autoantibodies and increased in size and cytoplasmic area in patients with anti-gpIIb/IIIa autoantibodies,

TABLE 47.2

FEATURES OF ACUTE AND CHRONIC IMMUNE THROMBOCYTOPENIA

Feature	Acute ITP	Chronic ITP
Peak age of incidence	Children, 2–6 y	Adults, 20–40 y
Sex predilection	None	3:1 female to male
Antecedent infection	Common 1–3 wk before	Unusual
Onset of bleeding	Abrupt	Insidious
Hemorrhagic bullae in mouth	Present in severe cases	Usually absent
Platelet count	<20,000/μl	30,000–80,000/μl
Eosinophilia and lymphocytosis	Common	Rare
Duration	2–6 wk; rarely longer	Months or years
Spontaneous remissions	Occur in 80% of cases	Uncommon

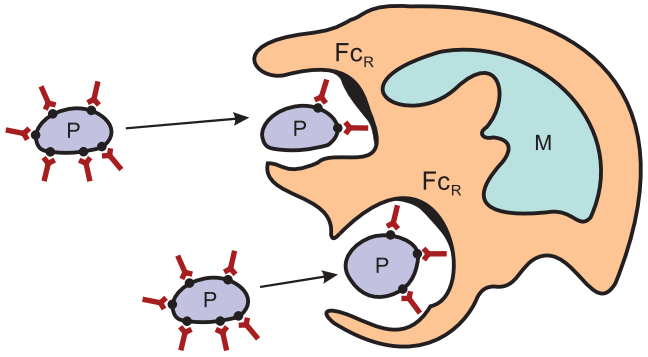

FIGURE 47.1. Antiplatelet antibody–induced destruction of platelets (P) in chronic immune thrombocytopenia. Immunoglobulin binds to platelet-associated antigen, resulting in phagocytosis by macrophages (M). Antiplatelet antibody–coated platelets bind to macrophages through macrophage Fc receptors (FcR). •, platelet membrane antigen; γ, platelet autoantibody.

suggesting that the anti-gpIIb/IIIa autoantibody impairs platelet production.[25] Megakaryocyte colony formation (colony-forming unit megakaryocyte) is increased in acute ITP.[26,27] In chronic ITP, decreased megakaryocyte colony formation has been reported.[28]

Consistent with findings of inappropriately low platelet production in ITP, plasma levels of endogenous thrombopoietin have not been found to be elevated in ITP.[29,30] This differs from impaired platelet production settings such as following chemotherapy.[29–31] This may be a result of clearance of thrombopoietin by the megakaryocyte and platelet mass.[32]

Platelet Antibodies

In 1951, Harrington and colleagues first reported that the infusion of plasma from patients with ITP predictably induced thrombocytopenia in normal recipients.[33] Shulman and colleagues then demonstrated that the responsible factor was an immunoglobulin (Ig) of the IgG class that was species-specific and could be removed from serum by absorption to and elution from normal human platelets.[34] In addition, the platelet-depressing factor produced effects in vivo that were quantitatively and qualitatively similar to those produced by known platelet antibodies. In 1982, van Leeuwen first identified platelet membrane glycoprotein IIb/IIIa as a dominant antigen by demonstrating that the autoantibodies eluted from ITP platelets bound to normal platelets but not to platelets from patients with Glanzmann thrombasthenia.[35] Increased quantities of IgG have been demonstrated on the platelet surface in ITP, and the rate of platelet destruction is proportional to levels of such platelet-associated Ig.[36,37] Autoantibodies are readily found in plasma or platelet eluate in patients with active disease, but are infrequently found in patients in remission.[38,39] Disappearance of the antibodies correlates with the appearance of normal platelet counts.[38]

The antiplatelet antibodies and platelet antigens involved in ITP have been extensively studied (Table 47.3). Antiplatelet autoantibodies bind to many of the major platelet membrane glycoproteins through the Fab portion of the molecule[40,41] (Fig. 47.2). Platelet gpIIb/IIIa was the first platelet antigen detected, and microtiter assays using platelet monoclonal antibodies to gpIb and gpIIb/IIIa later demonstrated that platelet autoantibodies bind to both major platelet membrane glycoproteins.[42,43,44] Serum autoantibodies can react with IIb or IIIa or the intact IIb/IIIa complex.[44–55] Platelet autoantibody binding to gpIbα has been reported, but data indicate that the majority of Ib/V/IX autoantibodies are directed to the complex.[56,57] Some autoantibodies react with gpIV and $\alpha_2\beta_1$, although the plasma from these patients usually also contains autoantibodies reacting with one of the other two major platelet membrane antigens.[57] Serum antibodies to P-selectin (CD62P) and $\alpha_v\beta_3$ have been detected as well, but their clinical significance is unknown.[58,59]

TABLE 47.3

CHARACTERISTICS OF PLATELET AUTOANTIBODIES IN PRIMARY IMMUNE THROMBOCYTOPENIA

		Comments
Ig subtype	IgG, IgA, IgM[a]	IgG and IgA have equal frequency
Antigen specificity	gpIIb/IIIa, Ib/V/IX	Most common antigens
	gpIa/IIa, IV	Never only antigen if positive
	Granule membrane protein-140	One patient reported
	Glycosphingolipid	Rare; unclear pathogenetic importance
	Cardiolipin	Common; ?pathogenetic importance
Presence of antibody		
Plasma	85% of patients	
Platelet eluate	75% of patients	
Complement fixation by antibody	Rare	Unresolved importance
Circulating immune complexes	Rare	Unresolved importance

gp, glycoprotein; Ig, immunoglobulin.
[a]IgM is never present as the only antiplatelet Ig in an individual patient.

Antibodies in ITP sera have also been demonstrated to bind to glycosphingolipids[60,61] and cardiolipin.[62–65] Although two studies identified antiphospholipid antibodies (lupus anticoagulant activity or anticardiolipin antibodies) in 46% and 38%, respectively, of ITP patients at diagnosis, there was little clinical evidence that they played a role in the pathogenesis of the disease or affected outcome.[66,67]

The presence of antibodies against multiple antigens is seen in most patients.[68] Once destruction of platelets within antigen-presenting cells occurs, this generates a series of neoantigens that in turn results in sufficient antibody to cause thrombocytopenia. This phenomenon is termed *epitope spread*.[69] Plasma autoantibodies and autoantibodies eluted from platelets in the same patient may have slight differences in antigen specificities within a membrane glycoprotein complex.[49] There is evidence from two studies that the specific β_3 antigen epitope in any given patient to which anti-gpIIIa autoantibodies are directed may influence the clinical presentation and course of the disease.[49,70] Whether these findings can be generalized to other ITP autoantibody epitopes is unknown.

Autoantibodies bind to platelets and cause thrombocytopenia primarily by shortening platelet survival. However, rare autoantibodies have also been reported that bind to glycoproteins and activate platelets.[71–75] Additionally, one patient with an anti-gpIIIa antibody was reported to have developed an antibody-related defect in aggregation and adhesion.[76]

The incidence of serum autoantibodies to platelet gpIIb/IIIa is the same in the acute and chronic forms of childhood ITP (68% vs. 62%, respectively).[77] The presence of anti-gpIIb/IIIa, therefore, does not predict which children will develop the chronic form of the disease, and, in fact, these data provide evidence that the mechanism may be the same in both acute and chronic forms of ITP.

The role of cell-mediated immunity in ITP remains uncertain, although data from patients with ITP suggest that T lymphocytes

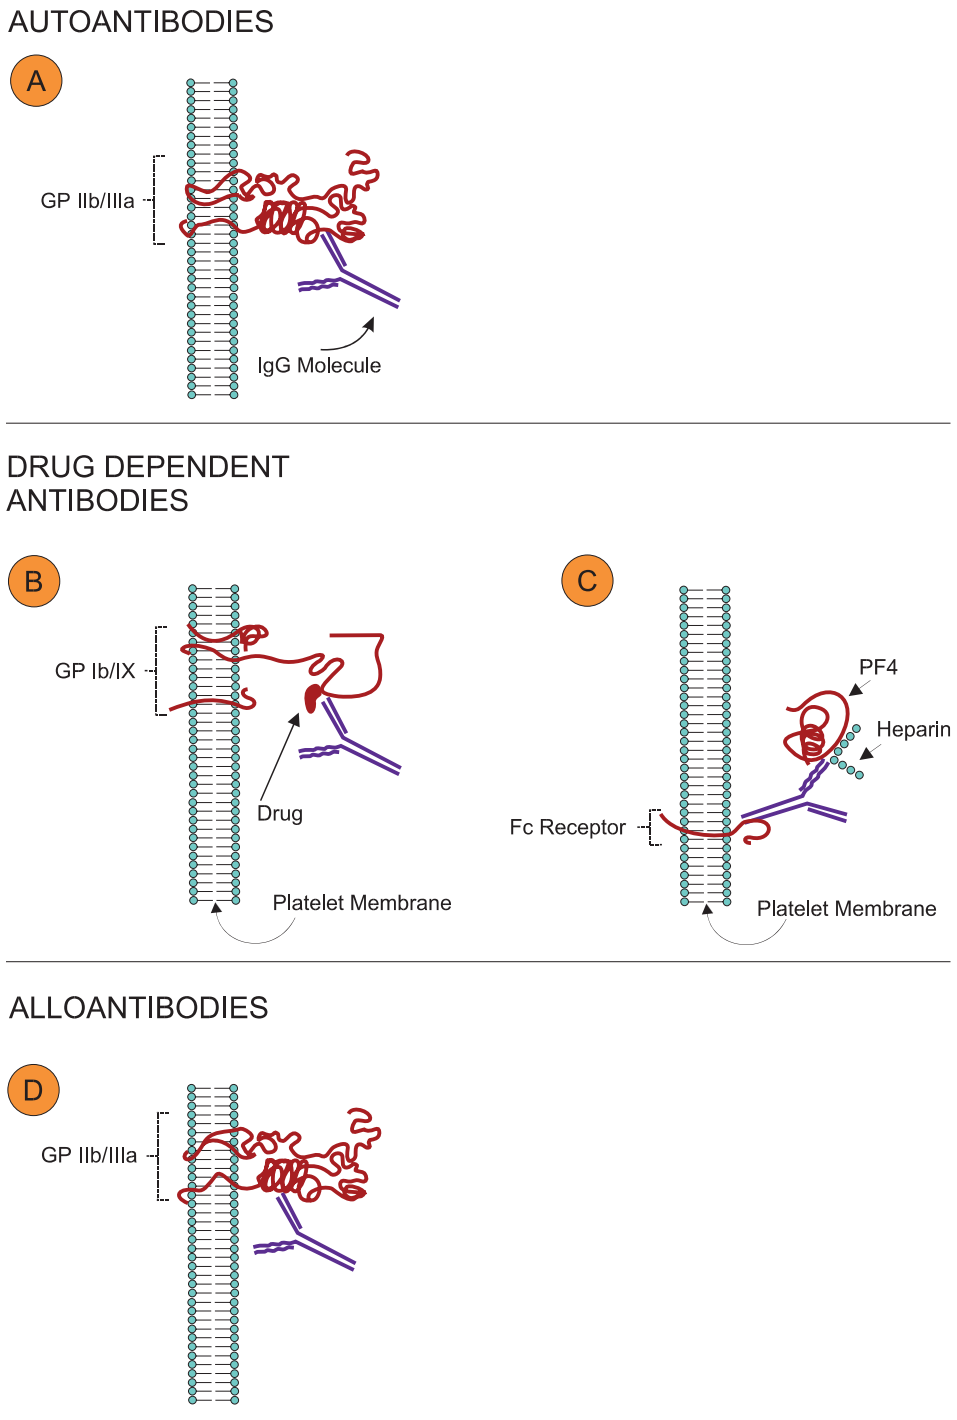

FIGURE 47.2. Types of antibody-mediated platelet destruction. A: Platelet autoantibodies bind to variable external and internal platelet epitopes. **B:** Quinine/quinidine-dependent antibodies. The antibody target is a complex of drug and glycoprotein (GP) (usually gpIb/V/IX or gpIIb/IIIa). **C:** Heparin-dependent antibodies. The antigen–antibody complex (target: platelet factor 4 [PF4]/heparin) activates platelets by the binding of immunoglobulin G (IgG) to Fc γRIIA on platelets. **D:** Platelet alloantibodies bind to platelet tertiary conformational epitopes on the platelet membrane. (Modified from Kelton, reference 40.)

demonstrate phenotypic and functional abnormalities. Platelet reactive T-cell clones can be identified from the peripheral blood of adults and peripheral blood and spleens of children with chronic ITP, suggesting that autoreactive peripheral T lymphocytes may mediate or participate in disease pathophysiology.[53,78,79] Adults with ITP often have increased numbers of HLA-DR$^+$ T cells, increased numbers of soluble interleukin-2 receptors, and a cytokine profile suggesting the activation of precursor and mature helper T-cells.[79] CD3$^+$ T cells from ITP patients in one DNA microarray study had increased expression of genes involved in cell-mediated cytotoxicity and, in addition, cytotoxic cell-mediated lysis of autologous platelets was shown in active ITP.[80]

Platelet Survival

Platelet survival, measured using ^{51}chromium- or ^{111}indium-labeled platelets, is shortened in ITP, and the survival time can range from 2 to 3 days to a matter of minutes.[22,23,24,80–89] Using ^{111}indium-labeled autologous platelets, some investigators found an inverse correlation between venous platelet count and platelet survival,[86] whereas others have not.[87] These study differences may relate to the types of patients included, as patients with mild to moderate thrombocytopenia have a longer measured platelet survival than patients with severe thrombocytopenia.

Splenic sequestration and destruction account for the shortened survival in most patients,[90,91] but the liver and the reticuloendothelial cells of the bone marrow can play a major role in the sequestration of antibody-coated platelets, especially in patients with very low platelet counts or continued thrombocytopenia after splenectomy.[22,23,86] Patients with severe thrombocytopenia have been found to have elevated levels of macrophage colony-stimulating factor[92] and increased in vitro monocyte-platelet rosette formation.[93] The spleen has also been implicated as a site of antibody formation.[94,95] In a pathologic study of 83 spleens that had been removed after patients did not respond to steroid therapy, investigators found splenic weights of <300 g, prominent secondary lymphoid follicles (28%), foamy macrophages (67%), and megakaryocytic extramedullary hematopoiesis (60%).[96] These pathologic changes reflect the two major pathogenic roles of the spleen: Antiplatelet antibody production and macrophage-mediated platelet destruction.

Clinical Picture

Immune Thrombocytopenia in Children

In children with acute ITP, the onset of the disorder usually is sudden (Table 47.2). A history of infection preceding the onset of bleeding has been documented repeatedly.[97,98] In one series, such infections were noted within 3 weeks of the onset of ITP in 84% of cases.[8,9] Varicella zoster virus and Epstein-Barr virus are the most frequently identifiable viruses, although nonspecific unidentified viral infections predominate.[99] Acute ITP may also occur after vaccination.[100] Although it is most common between 2 and 5 years of age, ITP occurs in all pediatric age groups.[101] The severity of ITP in infants is similar to that in older children, but compared to older children, a relatively small percentage of infants develop chronic ITP. A male preponderance was observed in the infant population in two studies.[101,102] Even though thrombocytopenia is likely to be severe, the bleeding manifestations of acute ITP in children usually are mild,[103] and intracranial hemorrhage occurs in <1% of patients. The rare adult with the acute form of the disorder, however, may suffer hemorrhage and a more fulminant course. Acute ITP in children usually is self-limited; spontaneous remissions occur in as many as 90% of patients.[8,9] The duration of the disease ranges from a few days to a few months, with an average of 4 to 6 weeks.[104] The favorable prognosis of ITP in children reflects the preponderance of the acute form of the disease in this age group. Children with thrombocytopenia of >6 months duration are classified as chronic ITP, although spontaneous remissions may still occur in an occasional child after 6 months.[105,106] Fever of mild degree has been reported, and the spleen tip may be palpable in up to 10% of patients, but this is believed to be the same incidence as is seen in normal children.[107] The spleen is usually of normal weight in those patients who proceed to splenectomy.[97]

Immune Thrombocytopenia in Adults

In adults, the onset of the chronic form of the disorder usually is insidious (Table 47.2). A long history of hemorrhagic symptoms of mild to moderate severity is often described by the patient, but antecedent infections or fever are uncommon. Patients with chronic ITP usually have a fluctuating clinical course. Episodes of bleeding may last days or weeks and may be intermittent or even cyclic. Spontaneous remissions are very uncommon in adults, with an estimated occurrence of <5%.[13,14,108–110] Most spontaneous remissions occur early; however, remissions have been described after 6 months in a small number of patients.[13] Relapses in some cases are associated with vaccination.[111] Often the clinical course is surprisingly benign.

Bleeding Manifestations

The hemorrhagic manifestations of ITP are of the purpuric type. Patients with only ecchymoses and petechiae have "dry" purpura; those with mucous membrane bleeding in addition to skin manifestations have "wet" purpura.[112] Platelet counts are usually lower and the complication rates higher in those with wet purpura. In a series of 712 patients reported by the Israeli ITP study group, 82% of all patients had bleeding limited to the skin, although 43% of adult women reported menometrorrhagia.[98]

In general, the severity and frequency of hemorrhagic manifestations correlate with the platelet count (Fig. 47.3).[113] Bleeding after trauma without spontaneous hemorrhage is usual in mildly affected patients with platelet counts >50,000/μl. Thrombocytopenia associated with counts between 10,000 and 50,000/μl results in spontaneous hemorrhagic manifestations of varying severity, such as ecchymoses and petechiae. Patients with platelet counts <10,000/μl are at risk for serious morbidity and mortality from bleeding, although the mortality rate is actually quite low.[114] Patients who have an increased risk of bleeding include those with a history of bleeding, those with additional bleeding diatheses, and patients >60 years of age.[12,114] Older patients have also been reported to have an increased incidence of major, life-threatening bleeding.[12,115,116]

Skin and Mucous Membranes

Spontaneous bleeding into the skin in the form of petechiae is characteristic. These lesions are minute, red to purple hemorrhages that range in size from that of a pinpoint to that of a pinhead (Fig. 47.4). They are flat, do not blanch with pressure, and appear and regress, often in crops, over a period of days. They are most conspicuous in areas of vascular stasis, such as the areas below tourniquet sites, the dependent portions of the body (especially around the ankles), and areas subjected to constriction from belts or stockings, as well as on skin surfaces over bony prominences. The presence of petechiae on the face and neck is unusual, except as the result of coughing.

Ecchymoses may develop on any skin surface. In ITP, they are seldom associated with subcutaneous hematomas and infrequently spread or dissect into deeper or adjacent structures. Large, purple, superficial ecchymoses may be seen, particularly on the back and thighs. Circular ecchymoses often surround even atraumatic venipuncture sites, but external bleeding from such sites is uncommon. Hemorrhagic vesicles or bullae may be seen inside the mouth and on other mucous surfaces. The bullae probably are the result of severe acute thrombocytopenia rather than a specific feature of any particular pathogenetic form.

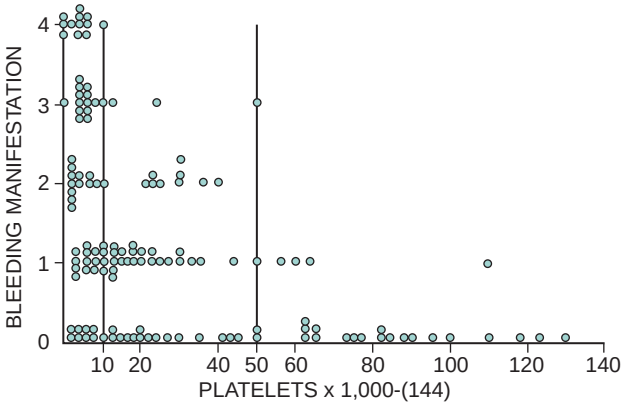

FIGURE 47.3. Bleeding manifestations in relation to platelet count in patients with primary immune thrombocytopenia. Bleeding manifestations (or duration) are graded from 0 to 4, as follows: 0, no bleeding; 1, minimal, resulting from trauma; 2, spontaneous, but self-limited; 3, spontaneous, requiring special attention (e.g., nasal packs); and 4, massive uncontrolled or poorly controlled. (From Lacey and Penner, reference 113.)

FIGURE 47.4. Petechiae. Pinpoint, nonblanching erythematous capillary bleeding sites are most common in dependent body areas or pressure points.

Gingival bleeding and epistaxis are common. The latter usually responds for a time to conservative measures, such as nasal packing or tamponade, often to recur intermittently. Epistaxis may originate from lesions resembling petechiae in the nasal mucosa. Such lesions also may be found in the mucous membranes of the throat and mouth, sometimes in the absence of cutaneous hemorrhage. In many patients, discrete bleeding points cannot be identified.

The genitourinary tract is a frequent site of bleeding. Menorrhagia may be the only symptom of ITP and may appear for the first time at puberty. Hematuria also is a common symptom, the blood coming from the kidneys, the bladder, or the urethra, although bleeding into the kidney parenchyma is rare. Gastrointestinal bleeding is usually manifested by melena or, less often, by hematemesis.

Central Nervous System

Intracranial hemorrhage is the most serious complication of ITP. Fortunately, it is rare, affecting 1% to 2% or less of patients with severe thrombocytopenia.[9,117] The hemorrhages usually are subarachnoid, often are multiple, and vary in size from petechiae to large extravasations of blood. Numerous small hemorrhages often are seen in the retina; subconjunctival hemorrhage may also occur.

Bleeding after Trauma

Excessive bleeding often follows tooth extractions, tonsillectomy, or other operations or injuries and may first suggest the diagnosis of ITP. In contrast to the hereditary coagulation disorders, such traumatic bleeding is seldom voluminous or rapid. Slow persistent oozing may occur after trivial cuts, razor nicks, and scratches. Delayed bleeding and spontaneous hemarthrosis, which are characteristic of the hereditary coagulation disorders, are extremely rare in ITP.

Laboratory Findings

Blood

The mean platelet count of patients at the time of diagnosis of ITP is 25 to 30,000 and severe thrombocytopenia (<10,000) is frequently seen.[117,118] Abnormalities in platelet size and morphologic appearance are common. The platelets often are abnormally large (3 to 4 μm in diameter) and reveal more than normal variation in size and shape. Abnormally small platelets and platelet fragments ("microparticles") also are evident and may represent the equivalent of microspherocytes and schistocytes.[119–122] Although megakaryocyte fragments may be apparent in routine blood smears, quantitative studies reveal subnormal numbers of these fragments.[123]

Estimates of mean platelet volume (MPV) and the extent of platelet size heterogeneity (platelet distribution width) by means of automated particle counters may, if present, provide useful information in the evaluation of patients with ITP.[124] The presence of numerous megathrombocytes results in high MPV values.[125] Platelet distribution width also is increased, presumably reflecting an abnormal degree of platelet anisocytosis.[126] The exact mechanism underlying such megathrombocytosis is still uncertain, but it may be the result of accelerated platelet production in response to platelet destruction. When MPV is increased in patients with ITP, it is typically inversely correlated in a nonlinear manner with the platelet count. In contrast, low MPV values have been reported in association with big spleen syndromes[126] and some myeloproliferative disorders, after chemotherapy with cytotoxic drugs, and in patients with septic thrombocytopenia.[127]

Significant abnormalities in the other blood counts should prompt a thorough evaluation for other causes of thrombocytopenia as these findings are unusual in ITP. Anemia, if present, is proportional to the extent of blood loss and is usually normocytic. If bleeding has been severe and long-standing, iron deficiency anemia may occur. Occasionally, recent severe hemorrhage may produce reticulocytosis and moderate macrocytosis. Antiplatelet antibodies in patients with ITP do not usually cross-react with erythrocytes, although erythrocyte fragmentation, presumably the result of weak complement activation, may occur.[121] Patients may also have a positive direct Coombs test and autoimmune hemolytic anemia; the combination is known as *Evans syndrome*.[128,129]

The total leukocyte count and the differential count usually are normal. Eosinophilia has been noted, particularly in children, but this finding is by no means consistent. Lymphocytosis with abnormal cells resembling those characteristic of infectious mononucleosis also has been reported.[130,131]

Tests of hemostasis and blood coagulation reveal only changes attributable to thrombocytopenia, such as a prolonged bleeding time. The results of tests of blood coagulation, including prothrombin time, partial thromboplastin time, and fibrinogen, are normal in patients with uncomplicated thrombocytopenia. Slight increases in the levels of fibrinogen degradation products have been demonstrated in the plasma of some patients with ITP.[132] Plasma levels of glycocalicin, a portion of platelet membrane gpIb, may be high in patients with ITP and other forms of platelet destruction. As noted previously, concentrations of thrombopoietin are not significantly increased in ITP.

Bone Marrow

ITP causes no characteristic bone marrow changes; therefore, bone marrow examination should not be routine. The American Society of Hematology (ASH) guidelines for management of ITP recommend against bone marrow biopsy in both children and adults with history, physical exam, CBC, and peripheral smear typical of ITP.[5] However, bone marrow aspiration may be helpful in the differential diagnosis of ITP in patients who have atypical findings that may suggest some of these other etiologies.

In patients with ITP, alterations in the bone marrow are usually limited to the megakaryocytes, although normoblastic hyperplasia may develop as a result of blood loss. The leukocytes are essentially normal with the exception of occasional eosinophilia.[133]

Megakaryocytes usually are increased in size[134] and are increased or normal in number,[135,136] the numbers correlating roughly with the MPV. Morphologic abnormalities of these giant cells are present in most patients with ITP. "Smooth" forms with single nuclei, scanty cytoplasm, and relatively few granules are common. Presumably, they represent the results of markedly

accelerated platelet production and the presence of many young forms.[137,138] The changes just summarized are similar to those found in most forms of thrombocytopenia caused by accelerated platelet destruction and are not characteristic or diagnostic of ITP.

Antiplatelet Antibodies

Primary ITP is a diagnosis of exclusion and relies on clinical impression. A number of different types of antiplatelet antibody tests have been developed and reported through the years.[36,139–146] Most of these tests were quite cumbersome and therefore never became available for routine testing. These tests measured different types of Ig, including serum antiplatelet antibodies, platelet-associated surface Ig, or total platelet Ig and are now generally regarded as unreliable.[147] The platelet Ig is released, along with other α-granule proteins, such as platelet factor 4 and β-thromboglobulin, during platelet activation and secretion. It is presumed that some of these released proteins bind to the platelet surface. These observations make it difficult to use either the platelet-associated IgG assays or the total platelet Ig assays for the diagnosis of ITP.[148]

In a more recent generation of antiplatelet antibody assays, monoclonal antibodies for the specific platelet membrane glycoproteins that are implicated in ITP are used in antigen-capture–type assays (also called *glycoprotein immobilization assays*).[149] Studies have identified a specificity of 78% to 93%.[150,151] However, the sensitivity (49% to 66%) is not high enough to exclude the presence of ITP if the test is negative.[68,151,152] None of these tests is in routine clinical use, and experts disagree on their role in the diagnosis of ITP. Future direction might include the use of flow cytometry in the diagnosis and follow-up of autoimmune thrombocytopenia.[153]

Differential Diagnosis

The initial step in the evaluation of a thrombocytopenic patient is inspection of the peripheral blood smear to confirm the decreased platelet count.[154] Thrombocytopenia may be produced artifactually by clumping of the platelets in the blood sample caused by ethylenediaminetetra-acetic acid–associated platelet agglutinins (pseudothrombocytopenia),[155,156] or the platelets may be unavailable for counting because they are bound in rosette formation to the surface of white blood cells in the venous blood sample ("platelet satellitism").[157,158]

The diagnosis of ITP is usually a diagnosis of exclusion based on a demonstration of peripheral thrombocytopenia, with a history, physical examination, and complete blood count that do not suggest another cause for the thrombocytopenia. Splenomegaly suggests that the thrombocytopenia may be a result of hypersplenism related to the presence of a separate underlying disease associated with splenic enlargement.

The initial manifestations of acute leukemia, myelodysplastic syndrome,[159,160] myelophthisic processes, and aplastic anemia may mimic ITP. These other types of underlying hematologic disorders are suggested by anemia out of proportion to blood loss and by changes in the leukocytes not attributable to either hemorrhage or complicating infection. Although not routinely recommended for the diagnosis of ITP, bone marrow aspiration may be helpful in the differential diagnosis of ITP in patients who have atypical findings that may suggest some of these other etiologies.

The presence of schistocytes in the blood smear suggests that thrombocytopenia may be associated with a microangiopathic process (see Chapter 48). In thrombotic thrombocytopenic purpura (TTP) or hemolytic-uremic syndrome (HUS), thrombocytopenia is associated with laboratory manifestations of hemolysis, including elevated levels of lactate dehydrogenase and indirect bilirubin.[161] Patients may also have transient, multifocal neurologic signs or symptoms, renal insufficiency, and/or fever in TTP, or renal insufficiency alone in HUS. After a diagnosis of ITP, the next essential step is to distinguish between primary ITP purpura and secondary forms of ITP purpura, such as human immunodeficiency virus, hepatitis C, or *Helicobacter pylori* infections; collagen vascular diseases such as systemic lupus erythematosus (SLE); lymphoproliferative disorders such as chronic lymphocytic leukemia; and drug ingestion. The ASH guidelines recommend considering testing all adults with a new diagnosis of ITP for hepatitis C and HIV as treatment plans differ in these settings.[5] The importance of careful inquiry regarding drug ingestion or exposure to toxic substances cannot be overemphasized, because thrombocytopenia attributable to drugs or toxins often is indistinguishable from ITP.[162] The development of thrombocytopenia in an adult, in particular, should arouse suspicion of a pharmacologic etiology, because many of the drugs associated with thrombocytopenia are used more often by adults than by children. It is also essential to eliminate the possibility that the thrombocytopenia is secondary to heparin administration. ITP may be produced by heparin administered in any dose and by any route of administration, including heparin-bonded catheters.[163] Finally, the antiphospholipid antibody syndrome is a disorder that may be associated with thrombocytopenia. In the usual case, this presentation may be associated with thromboembolic manifestations, anticardiolipin antibodies, and coagulation inhibitors of the lupus type (see Chapter 54).

Treatment of Primary Immune Thrombocytopenia

Many of the treatment recommendations for ITP are based on expert opinion rather than high-level evidence from randomized controlled trials. The ASH has published a practice guideline on ITP.[5,164,165] The reader is referred to this practice guideline for specific questions regarding the treatment of patients with ITP.

Children

Childhood ITP is usually benign and self-limited. Therefore, treatment is not required for most patients. Treatment is reserved for patients with severe thrombocytopenia (<20,000/μl) and bleeding, or patients who remain thrombocytopenic for >6 months, that is, those with chronic ITP (Table 47.4).[166] Treatment guidelines recommend observation for all children with no or mild bleeding, regardless of platelet count.[5] Although the greatest

RECOMMENDATIONS FOR INITIAL TREATMENT OF IMMUNE THROMBOCYTOPENIA (IVIG) PATIENTS WITH PLATELET COUNTS <20,000–30,000/μl[a]

	Children	Adults
Asymptomatic	None	Steroids (preferred) or IVIG
Minor purpura Mucosal membrane bleeding that may require clinical intervention	None IVIG or steroids	Steroids (preferred) or IVIG) IVIG and/or steroids
Severe, life-threatening bleeding	Steroids and IVIG Hospitalization Consider platelet transfusion and other measures	Steroids and IVIG Hospitalization Consider platelet transfusion and other measures

[a]The current ASH guidelines recommend treatment for adults with platelet counts of <30,000/μl.

fear in the acute form is intracranial hemorrhage, several large studies show that even with low platelet counts (<30,000/μl) life-threatening bleeding and intracranial hemorrhage are rare (<0.5%).[166,167]

Treatment guidelines for pediatric ITP recommend first-line treatment with either a single dose of intravenous immunoglobulin (IVIG) (0.8 to 1 g/kg) or a short course of steroids.[5] Several multicenter randomized trials have been performed in high-risk patients with acute ITP to define whether treatment is associated with a prompt increase in platelet counts. These clinical trials demonstrated that treatment with either oral prednisone or IVIG was associated with a more rapid rise in platelet count to >20,000/μl than either no therapy or treatment with anti-D.[168,169] Only IVIG shortened the time to reach a platelet count >50,000/μl. More recently, children with platelet counts <10,000/μl or counts of 10,000 to 29,000/μl and mucosal bleeding were studied in a prospective randomized clinical trial, and IVIG raised platelet counts faster than three corticosteroid regimens.[170] Therefore, IVIG should be preferentially used if a rapid rise in platelet count is desired.

Treatment of children who develop persistent ITP or are unresponsive to initial treatment is evolving. Splenectomy remains a standard given high response rates; however, many experts recommend delaying splenectomy for at least 12 months given the frequency of spontaneous remission.[5] Rituximab treatment has been used in children and adolescents in a small study comprised of 36 patients with chronic ITP.[171] In contrast to observations in adults, the median time to response was 1 week (range 1 to 7 weeks), and the overall response rate was 31%. Outcome was not associated with age, prior pharmacologic response, prior splenectomy, duration of disease, screening platelet count, refractoriness, or IgM reduction. Therefore, rituximab may be considered as an alternative to splenectomy in children with chronic ITP or in patients with persistent bleeding despite first-line treatments.[5] High-dose dexamethasone (0.6 mg/kg/day) may also be considered in patients who are unresponsive to initial therapy based on small studies showing a 25% response rate in refractory patients.[172]

Adults

Patients with chronic ITP may have mild thrombocytopenia that can be followed without treatment. The incidence of bleeding is correlated with the platelet count; therefore, patients with platelet counts >50,000/μl rarely have spontaneous bleeding and may require treatment only if extensive operative procedures are planned. Patients with platelet counts <20,000 to 30,000/μl or significant mucosal membrane bleeding with platelet counts <50,000/μl are usually treated[5] (Table 47.4 and Fig. 47.5).

No prospective studies on long-term prognosis of ITP after treatment are reported. However, it has been reported that most adult patients have a good response to treatment (without necessarily returning to normal platelet counts) and have no excess mortality when compared to the general population.[173] A small group of patients who had severe thrombocytopenia after 2 years of primary and secondary therapies had a mortality risk of 4.2 (95% confidence interval, 1.7 to 10.0) resulting from both bleeding and infectious complications related to therapy.

ITP is uncommon in elderly patients; only 30% of patients in reported series are >45 years of age.[133,174] However, these patients may be more refractory to therapy[115] and appear to have a higher incidence of hemorrhagic complications than younger patients.[12] Guthrie and colleagues reported a 52% incidence of life-threatening or fatal bleeding in their series of 40 patients

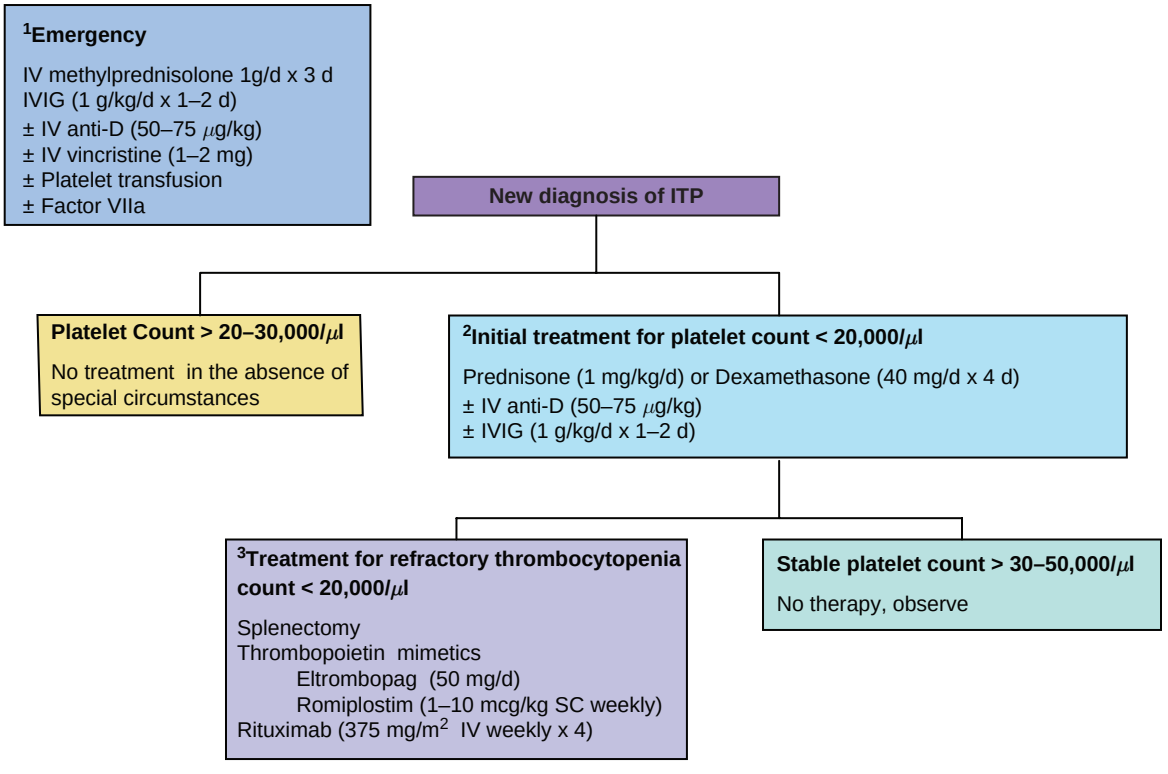

FIGURE 47.5. Therapy of adult immune thrombocytopenia (ITP). (1) Minimal emergency therapy includes intravenous (IV) methylprednisolone and intravenous immunoglobulin (IVIG). Intravenous anti-D and platelet transfusions may be given as needed. All three modalities given prior to transfusions may help preserve platelet longevity in the circulation and repeated or continuous platelet transfusions may be required in urgent situations. (2) Initial treatment of ITP typically consists of steroids (prednisone or dexamethasone) with the goal of attaining a platelet count of >30,000/μl and cessation of bleeding. IVIG or anti-D may be used if steroids are contraindicated or the patient has persistent thrombocytopenia despite steroids. (3) Thrombocytopenia recurs in most adults as corticosteroids are tapered. Treatment options for refractory ITP include splenectomy, thrombopoietin mimetics, and rituximab. (Modified from Cines and Bussel, reference 459.)

older than age 45 years.[115] This risk of fatal bleeding in patients with platelet counts that are chronically <30,000/μl is estimated at 0.4% per year for patients <40 years of age and 13.0% per year for patients >60 years of age.[175]

First-line Treatment

Initial treatment for adult patients with newly diagnosed ITP is typically steroids. Other options that increase the platelet count rapidly include IVIG and anti-D. The most recent ASH guideline recommends use of these alternative first-line therapies in patients with contraindications to steroids.[5] Patients with life-threatening bleeding may require parenteral glucocorticoids and IVIG followed by platelet transfusions,[176] plasmapheresis,[177] or even emergency splenectomy as first-line treatment. Standard ITP treatments and their dosing schedules are shown in Table 47.5.

Steroids

Steroids are the conventional first-line therapy for adult ITP. Dameshek first reported his experience with prednisone therapy in 1958,[178] when 30 consecutive patients with acute (N = 11) or chronic (N = 19) ITP were treated with 20 to 150 mg/day of prednisone. Twenty-two of the patients demonstrated an increase in platelet count to normal after an average interval of 22 days and then were maintained on 2.5 to 15.0 mg/day of prednisone. In eight patients, prednisone was discontinued without relapse.

Numerous retrospective studies of steroid treatment in both children and adults with ITP have been reported.[13,14,97,98,104,108–110,133,174,179–182] The criteria for inclusion of patients in the individual studies and the criteria for response to treatment vary significantly among the reports; therefore, it is difficult to combine the data accurately. However, some useful observations can be made. Complete (CR) and partial (>50,000/μl) responses (PR) in patients treated with prednisone (usually, 1 mg/kg/day as starting dose) average 65% to 85%, but sustained responses after discontinuation of the drug occur in only 25% or less of patients.[183,184] Platelet counts usually increase within 1 week in responding patients and have usually reached peak values by 2 to 4 weeks. Patients who have not had any response by 4 weeks are unlikely to respond to prednisone and therefore should be considered for other forms of treatment. No pretreatment patient characteristics have predicted a patient's response to steroids.

Several prospective randomized steroid treatment trials in patients with ITP have been reported. Bellucci and colleagues randomized patients between low (0.25 mg/kg/day) or high (1.0 mg/kg/day) prednisone for 3 weeks, with taper and discontinuation by the end of the fourth week.[185] If bleeding continued, patients could be increased from low dose to high dose, or a second 4-week course could be given. CR, defined as a platelet count >100,000/μl for at least 6 months, was seen in 74% of children and 41% of adults. CRs or PRs occurred in 83% of children and 59% of adults. No significant differences were seen between low- and high-dose regimens in either age group. Mazzucconi and colleagues randomized patients between prednisone 0.5 mg/kg/day and 1.5 mg/kg/day.[186] The response rates in adults were not significantly different between patients treated with low- versus high-dose steroids: 30% and 34% CR, respectively. In children, however, the rates were 64% for low-dose versus 81% for high-dose prednisone. Therefore, there is evidence to support the use of lower doses of steroids in adults than have conventionally been used at the beginning of treatment. However, based on the opinion of an expert panel convened by the ASH, high-dose prednisone (1 mg/kg/day) is recommended as appropriate initial treatment in ITP patients with platelets <30,000/μl, including asymptomatic patients.[5,164,165]

Another prospective randomized, controlled trial compared prednisone (1 mg/kg/day) to IVIG (400 mg/kg/day for 4 days), or to both in a small number of patients.[187] A platelet count >50,000/μl was achieved in 82%, 54%, and 92% of patients, respectively. The median times to peak platelet counts were 8.5, 7.0, and 7.0 days. These authors concluded that there was no advantage for IVIG over conventional corticosteroid treatment. In another recent randomized control trial, platelet counts >50,000/μl were achieved more quickly in patients receiving IVIG than in those receiving intravenous methylprednisolone, but long-term outcomes were the same.[188]

There are also several studies that have evaluated the role of high-dose dexamethasone in the initial treatment of ITP. This protocol was initially developed because of concern regarding long-term side effects of daily prednisone use. Initial trials showed that using 40 mg of dexamethasone daily for 4 consecutive days results in an initial response in 85% of patients.[189,190] Additional work has shown that repeating dexamethasone bursts may provide long-term disease control in some patients. Mazzucconi and colleagues treated newly diagnosed patients with ITP with dexamethasone 40 mg daily for 4 days, repeating these cycles every 14 days for 4 cycles.[191] A total of 85% of patients responded with 65% achieving a CR. Relapse-free survival at 15 months was 81% indicating that many of these patients may be long-term responders.

There are conflicting opinions regarding the choice of prednisone versus dexamethasone for first-line treatment of ITP. The writers of the 2011 ASH guidelines favor longer-term prednisone over dexamethasone[5] but other experts in the field think that either is reasonable.[192]

The mechanism of action of steroids in ITP involves both direct and indirect effects on thrombocytopenia. Steroids ameliorate thrombocytopenia directly by several mechanisms. Steroids may (a) decrease consumption of antibody-coated platelets by the spleen[193–195] or bone marrow, (b) reduce antibody production by the spleen,[94,196] (c) decrease antibody production by the bone marrow,[197] and/or (d) increase marrow platelet production by undetermined mechanisms.[198]

There is little doubt that corticosteroids in high doses ameliorate splenic sequestration of antibody-coated platelets. Corticosteroids decrease antibody-coated red blood cell sequestration in guinea

TABLE 47.5

THERAPEUTIC AGENTS AND THEIR DOSING SCHEDULES

Agent	Dose and Schedule
Anti-D immunoglobulin	50–75 μg/kg IV, repeated at 3-week intervals as indicated
Cyclophosphamide	150 mg daily for up to 8 wk
Colchicine	200 mg daily for up to 4 wk
Dexamethasone	40 mg daily for 4 d, repeated every 14 d for 4 cycles
Danazol	400 mg twice daily for 1 mo or longer
Eltrombopag	50 mg daily. Must be continued indefinitely.
IVIG	1 g/kg IV for 1–2 d, repeated every 2 to 4 wk as indicated
Prednisone	1 mg/kg daily for up to 28 d, then taper to lowest dose possible
Rituximab	375 mg/m^2 IV weekly for 4 doses
Romiplostim	1–10 mcg/kg subcutaneous injection weekly. Start at 1 mcg/kg and titrate based on platelet count. Must be continued indefinitely.
Vincristine	2 mg at 5- to 7-day intervals for 2 or more doses
Vinblastin	7.5 mg at 5- to 7-day intervals for 3 or more doses

Modified from Narang et al.[460]

pig spleens by decreasing Fcγ receptor proteins on macrophages,[199] and in vivo and in vitro data support a similar action of steroids in humans.[90,91,194,200,201] Corticosteroids also decrease monocyte Fc receptors in autoimmune hemolytic anemia.[202] This down-regulation of monocyte/macrophage Fc receptors may account for the early effects of steroid treatment on platelet counts. Chronic corticosteroid treatment is associated with a decrease in antibody production, but this usually occurs after several weeks of high-dose steroids. Steroid treatment also results in increased platelet production in some ITP patients,[198] an effect that may be secondary to reduction of the antiplatelet Ig effect on thrombopoiesis, reduction in intramedullary destruction of antibody-coated platelets before their release into the circulation, or decreased antibody synthesis by bone marrow lymphocytes.

In addition to these direct effects on thrombocytopenia, steroids also act on endothelial cells to reduce bleeding. Experimental evidence indicates that thinning of the endothelium with development of endothelial fenestrations occurs in both animal models and humans with ITP, suggesting that platelets play a role in normal endothelial homeostasis.[203,204] Clinically, steroids are known to ameliorate the purpuric bleeding in ITP patients before the platelet count actually increases. Experimentally, investigators have demonstrated that 3 days after steroid therapy in rabbits and 4 days after steroid therapy in patients, the endothelial thinning reverts toward normal, providing a scientific explanation for this clinical observation.[204,205] This endothelial effect may in part be explained by the observation that when endothelial cells are cultured with steroids, cell morphology is altered, with greater confluence and increased protein synthesis and content.[206]

Intravenous Immunoglobulin

The intravenous administration of polyvalent Ig (IVIG), first used in 1981,[207] may induce remissions in patients with life-threatening bleeding or in patients with refractory ITP. IVIG therapy has proved most effective in infants and small children,[208,209] an age group in which the response is difficult to evaluate because of the frequency of spontaneous remissions. In adults this regimen has produced relatively less impressive long-term results,[210–213] although an occasional patient enters complete remission after the initial treatment and a series of booster doses.[214,215,216,217] In a review of 28 published reports of IVIG in 282 adults, 64% of patients had a peak platelet count >100,000/μl, and 83% had peak platelet counts >50,000/μl[218] after the initial infusion. Platelets may begin to rise after 2 days and usually reach peak levels by 1 week after treatment.

Regimens of 400 mg/kg/day for 5 days versus 1,000 mg/kg/day for either 1 or 2 days,[219,220] have been equally effective in randomized trials, and doses of 0.5 g/kg are as effective as 1.0 g/kg for maintenance therapy.[221] These doses produce significant increases in serum and platelet levels of IgG.[209,214,216] In a randomized controlled trial, one dose of 1,000 mg/kg was superior to 500 mg/kg in raising platelet counts to >80,000/μl by day 4.[220] Most of these patients were being prepared for splenectomy or delivery.

Several mechanisms are thought to be involved in the beneficial effects of IVIG. They include Fc receptor blockade of reticuloendothelial cells,[214,216,222–225] effects on B cells and antibodies[226–231] and anti-inflammatory effects.[232,233] No evidence exists that reduction of antiplatelet antibodies accounts for the acute effects of therapy.[232]

Therapy with IVIG remains expensive. The rapid nature of the response to treatment makes it an ideal agent for treatment of patients for life-threatening bleeding or before surgery [234,235]; however, the role of IVIG in long-term therapy remains uncertain. The major side effect of treatment is headache, although some patients also develop fever, myalgias, and skin rashes.[234] There are also reports of acute renal failure occurring in up to 7% of patients, especially older patients and those with diabetes, or baseline increases in creatinine (or both).[236,237] The patients may be oliguric, and most demonstrate peak creatinine levels by day 5 after the IVIG infusion. Hemodialysis may be required acutely, and several patients required chronic dialysis. The volume of fluid required for IVIG administration can also be a major problem in some older patients with co-morbidites such as congestive heart failure.

Anti-D

Intravenous Rho (D) immune globulin (anti-D) has been studied in children and adult ITP as an alternative to IVIG.[238,239,240] The mechanism of action is unknown; however, it is believed that the antibody coats the red blood cells of Rh-positive patients and either blocks the reticuloendothelial clearance of platelets or modulates the immune system, resulting in an increase in the platelet count.[240,241] Although infusion of both IVIG and anti-D slow the Fcγ-receptor–mediated destruction of antibody-coated platelets, responses to anti-D appear to uniquely correlate with polymorphisms specific to the FcγRIIa and FcγRIIIa receptors.[242] This is characterized by increases in the plasma levels of IL-6, tumor necrosis factor-α, monocyte-chemoattractant protein-1, and IL-10 that are specific to IV anti-D infusions compared with IVIG.

Children respond better than adults, and nonsplenectomized patients respond better than splenectomized patients to anti-D.[241,243] The platelet count does not begin to increase for 48 to 72 hours, so it may not be as effective for the treatment of life-threatening bleeding compared with IVIG. The effect lasts for several weeks to a month, and patients respond well to retreatment. They may respond to intramuscular injections given weekly as maintenance.[244] Occasionally, patients have a sustained remission.[245] Most patients exhibit a modest decrease in hemoglobin, and most have subclinical signs of mild hemolysis,[243] with decreased haptoglobin, increased lactate dehydrogenase, and increased indirect bilirubin. Red cell survival is only modestly reduced.[246] No correlation has been found between the amount of hemolysis and the platelet response, leading some investigators to question the proposed effect on reticuloendothelial blockade.[247] Reinfusion of autologous red blood cells that have been opsonized with anti-D has produced both complete and partial remissions in a small number of patients, even after splenectomy.[248] With respect to anti-D dosing, early studies in adults receiving 25 to 50 μg/kg/day showed an increase in platelet count of >20,000/μl in 79% of patients. However, the platelet count did not increase for >72 hours, which made this treatment approach less efficient for bleeding patients.[249] More recent studies have shown a more rapid increase of the platelet count within 24 hours and a longer duration of the increase when using a higher dose of 75 μg/kg compared with 50 μg/kg.[250] Anti-D therapy now carries a black box warning that requires observation of the patient for 8 hours after administration due to the risk of intravascular hemolysis and disseminated intravascular coagulation.[251]

Treatment of Chronic Primary Immune Thrombocytopenia

Many adult patients with ITP, even if they initially respond to steroids, will develop chronic ITP. Chronic ITP is defined as ITP lasting longer than 12 months.[1] Patients who are asymptomatic and have platelet counts between 30,000 and 50,000/μl may be managed with careful observation.[164,184] Symptomatic patients with platelet counts <30,000/μl who had an initial response to steroids can be retreated with prednisone and then tapered to find the minimum dose that can maintain the patient hemorrhage-free, even if the platelet count is not >30,000/μl. If patients can be maintained on 10 mg every other day, additional treatment may not be

indicated. Some patients observed for years with platelet counts of 10,000/μl have had no significant bleeding other than ecchymoses or petechiae, even without steroid therapy.[252] Splenectomy has been the traditional therapy for refractory cases of ITP. There are more options now with accumulating evidence regarding the role of rituximab and thrombopoiesis-stimulating agents.

Splenectomy

Patients with severe thrombocytopenia (<10,000/μl) who do not respond to steroids (administered for up to 4 weeks) or who relapse during steroid tapering, and patients with platelet counts of <30,000/μl for periods up to 3 months, should be considered for splenectomy.[5] Most patients demonstrate a response to steroids within 2 to 4 weeks, but a late response is rarely seen. Therefore, the best time for splenectomy in a patient who does not respond to steroid therapy must be determined individually.

Sustained CRs to splenectomy (variously defined as platelet counts of 100,000 to 150,000/μl) have been reported in ~50% to 80% of patients, depending on the series.[252–256,257,258–265] After the operation, the platelet count may increase rapidly, often within 24 to 48 hours, and may reach levels as high as 1 million/μl or even higher in approximately 10 days.[97] Operative mortality is <1%, and perioperative bleeding is rare.[13,14,98,108,109] Platelet transfusions are usually given only if the patient has bleeding after the spleen has been removed. Postsplenectomy infections are also rare, especially if patients have received immunization to encapsulated organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*) before splenectomy. Laparoscopic splenectomies in ITP patients are as successful as conventional splenectomies, although patients occasionally may require conversion to an open procedure.[266,267] Therapeutic responses are reported also when splenic ultrasound,[267] splenic radiation,[268,269] or partial splenic embolization[270] was used instead of splenectomy.

Patients who do not respond to splenectomy or who relapse after an initial response to splenectomy should be studied for the presence of accessory spleens.[262,271–275] The incidence of accessory spleens found at the time of the original splenectomy ranges from 15% to 20%.[257,262] The incidence of accessory spleens in patients who relapse after splenectomy may be as high as 50%,[133,263,264] and surprisingly, the majority of these patients demonstrate postsplenectomy changes (i.e., Howell–Jolly bodies) on their peripheral blood smears. Relapse secondary to an accessory spleen may occur weeks to years after the initial splenectomy. Scanning methods have varying sensitivities; conventional ^{99m}technetium scans, ^{99m}technetium scans using heat-denatured red blood cells, or computed tomography scans can be used. Accessory spleens as small as 0.5 cm have been found when ^{111}indium scans were performed preoperatively and isotope detector probes were used intraoperatively to detect all accessory splenic tissue.[257] A review of 56 published cases demonstrated a 73% excellent therapeutic response and a 27% moderate response to accessory splenectomy.[257]

The effectiveness of splenectomy in the therapy for ITP is attributed to removal of the organ that is primarily responsible for the destruction of antibody-sensitized platelets. The increase in platelet count correlates with an increase in platelet survival, whereas platelet production remains unchanged.[198] The removal of the spleen may also result in a reduction of antibody production, but this effect is probably of minimal significance in view of the immediate favorable responses to splenectomy. No factors have consistently predicted a response to splenectomy; age, concentration of platelet-associated IgG, the time between diagnosis and splenectomy, the patient's response to steroids, IVIG or intravenous anti-D, and the peak postoperative platelet count have all been studied.[256,276–280] The site of platelet sequestration, based on preoperative ^{51}chromium- and ^{111}indium-labeled platelet survival studies, may be predictive of response,[260,281] but these techniques are seldom used.

Rituximab

Rituximab, an anti-CD20 monoclonal antibody, has produced CRs or PRs in approximately 60% of patients.[282–285,286] Rituximab causes selective B-cell lysis in vitro and B-cell depletion in vivo.[287] Involved mechanisms of action include apoptosis, antibody-dependent cell-mediated cytotoxicity, and/or complement-dependent cytotoxicity. Recovery of B-cell counts usually occurs by 6 to 12 months after completion of treatment.

Most of the patients in the studies of rituximab in ITP had relapsed or refractory disease, and some had undergone splenectomy. The majority of studies have used the standard treatment dose of 375 mg/m^2 weekly for four weekly doses;[286] however, published reports have shown that lower doses are effective as well.[288] The side effects were mild and seen most commonly after the first infusion. The long-term safety profile of rituximab is felt to be favorable. Only one case of progressive multifocal leukoencephalopathy, a rare but fatal consequence of rituximab administration, has been reported in a patient with ITP.[289] There are two different response patterns, early versus late.[290] Patients with an early response to four weekly infusions had an increasing platelet count after the first or second infusion and peaked between weeks 6 and 10. Late responders had no rise of their platelet count during treatment but increased their platelet count between weeks 6 and 8, with the peak occurring shortly thereafter. In one study, the B-cell count in patients who responded was lower than in patients who did not have a response.[285]

A recent meta-analysis of studies employing rituximab in the treatment of refractory/relapsed patients consisted of 299 patients described in 15 reports.[291] The overall response rate was 55%, of which 38% of patients achieved a CR, which was defined as a platelet count of at least 100,000 to 150,000/μl. In addition, 17% of the patients achieved a PR, which was defined as a platelet count of >50,000 and <100,000/μl. The median duration of response was 74 weeks (24 to 120 weeks) and in PR patients was 55 weeks (12 to 160 weeks). CR in splenectomized patients (62%) was higher than in nonsplenectomized patients (available from five studies, n = 126).[272] Another recent meta-analysis showed similar results with 43.6% of patients achieving a CR (>150,000/μl) and 62.5% of patients achieving a PR (>50,000/μl).[286]

Longer-term studies have shown that prolonged disease responses are less common. Patel et al. reported that with 2.5 years of follow-up 1 in 6 patients remained in remission.[292] Most patients with relapse can be retreated with rituximab with success.[293] The role of rituximab as part of first-line therapy for ITP is currently under investigation[294] but is not considered a standard of care.

Thrombopoiesis-stimulating Agents

Thrombopoiesis-stimulating agents (thrombopoietin mimetics) are another, recently approved treatment option for management of refractory ITP. There are two currently available thrombopoiesis-stimulating agents, eltrombopag and romiplostim. They have both been the subject of randomized controlled trials in refractory ITP.

Eltrombopag, an oral agent, is a peptide that interacts with the transmembrane domain of the thrombopoietin receptor thereby stimulating differentiation and proliferation of megakaryocytes in the bone marrow. The most common side effects are mild elevation in liver enzymes and nausea/vomiting.[295] In a study published in 2009, 114 patients with refractory ITP were randomized to eltrombopag versus placebo in a 2:1 randomization.[295] After 6 weeks of follow-up, 59% of patients in the eltrombopag arm versus 16% in the placebo arm had achieved a platelet count >50,000 and less bleeding was observed in the eltrombopag arm.

Platelet counts dropped again within 2 weeks of discontinuing therapy. A phase III study (RAISE) in patients with chronic ITP published in 2011 showed similar results.[296] After two weeks of therapy, median platelet counts in the eltrombopag group were 53,000 to 73,500 versus 17,500 to 23,000 in the placebo arm. Patients in the eltrombopag arm had less bleeding and were more successfully tapered off their other ITP treatments.

Similar results have been seen with romiplostim. Romiplostim is an injectable thrombopoeitin mimetic that is given once per week. It is a thrombopoietin mimetic peptide (peptibody) which binds to the thrombopoeitin receptor. In a randomized study published in 2008, patients with ITP were randomized in a 2:1 fashion to romiplostim versus placebo.[297] In splenectomized and nonsplenectomized patients, 79% and 88% of patients receiving romiplostim achieved a platelet count >50,000. Only a very low number of patients in the placebo arm achieved this threshold (14% of nonsplenectomized patients, 0% of splenectomized patients). This correlated with decreased use of other ITP therapies. The most common side effects are arthralgias, fatigue, and nausea.[298] Serious adverse events are rare. Additional trials have shown that romiplostim is safe and effective for prolonged use[299] and that decreased bleeding is observed in patients receiving romiplostim due to higher platelet counts.[300] With prolonged use patients do still require regular platelet monitoring as the dose required may vary over time.[299] As with eltrombopag, indefinite treatment is required as platelet counts fall quickly when treatment is discontinued.

There has been some concern regarding increased marrow fibrosis in patients receiving eltrombopag or romiplostim. Preclinical data showed increased fibrosis in the marrow of rats treated with romiplostim.[301] This appeared to be dose dependent and decreased after the treatment was discontinued. In the same paper, a retrospective review of clinical trials using romiplostim was performed.[301] Reticulin deposition was noted in 10 of 271 patients; however, most patients did not have bone marrow biopsies performed. In 5 patients who had pretreatment bone marrow biopsies, reticulin deposition increased in 4 patients. In all patients, reticulin staining decreased when romiplostim was discontinued. In 10 patients followed prospectively with serial bone marrow biopsies, only 1 of 10 patients treated developed new reticulin fibrosis on treatment. Similar findings are seen with eltrombopag. The clinical significance of this finding is unclear.

Although the thrombopoietin mimetics are effective in both splenectomized and nonsplenectomized patients, expert panels recommend that they be reserved for patients with refractory ITP after splenectomy and patients with contraindications to splenectomy.[5] This recommendation is based on concerns regarding the requirement for indefinite treatment which is accompanied by significant cost and risk of long-term toxicities that have not yet been identified.

Immunosuppressive Drugs

Immunosuppressive therapy for ITP has yet to be evaluated thoroughly; the overall effectiveness of these potent drugs is variable, and remissions achieved have been short-lived. Poor results were reported in children.[302] Favorable results are nevertheless noteworthy, because they were obtained in refractory patients who had not responded to splenectomy or steroids.[303]

Preliminary reports of successful treatment in refractory patients have been published using high-dose methylprednisolone[234,304] and cyclophosphamide-based combination chemotherapy.[305] Cyclophosphamide alone, either daily oral or pulse intravenous therapy, induced remissions in 16% to 55% of patients.[14,303,306–308] However, this drug must be administered for several weeks before the platelet count rises and often must be continued for an indefinite period to maintain the remission, and side effects such as leukopenia and alopecia often are significant. Azathioprine, cyclosporin A, mycophenolate mofetil, actinomycin, and other immunosuppressive agents, either alone or in combination with corticosteroids, have variable success.[309–315] Vincristine and vinblastine, administered intravenously at weekly intervals, may be as effective as cyclophosphamide but act more rapidly, often increasing the platelet count within 7 days.[316–320] In addition to their suppressive effects on cellular and humoral immune responses, these agents increase platelet production in both animals and normal human subjects.[321,322] In ITP, their mechanism of action has been postulated to be inhibition of microtubule-dependent events required for monocyte–macrophage function.[323]

Other Proposed Therapies

A number of other therapies have been reported to be successful in single case reports or in small series of patients. Danazol, an attenuated androgen, has been effective in increasing platelet counts in patients with ITP in doses ranging from 50 mg/day[324] to 800 mg/day.[325–327] The mechanism of action is postulated to be a danazol-induced reduction of Fc receptors on phagocytic cells.[328] Long-term results indicate a final response rate of >40% at a median follow-up of 10 years with a reasonable safety profile.[329] Recombinant α-interferon can increase platelet counts in up to 50% of patients when injected subcutaneously three times a week, and some responses were durable after stopping treatment.[330,331]

Supportive Measures

Physical activity should be restricted to minimize the hazards of trauma, particularly head injury. Drugs, such as nonsteroidal anti-inflammatory drugs, that impair platelet function should be avoided. Blood loss should be treated as indicated, and platelet concentrates should be administered in the presence of significant bleeding.[332] However, transfusions typically produce only a slight and transient increase in the platelet count, no doubt because of the rapidity with which they are destroyed in vivo.[333] Platelet transfusions, nevertheless, may produce some increase in platelet numbers in many patients,[334] often diminish bleeding for a time, and can be effective in the management of serious complications such as subarachnoid hemorrhage. They should be reserved for such life-threatening emergencies or for the immediate preoperative treatment of patients with serious hemorrhage before splenectomy. A single large dose of IVIG followed by a platelet transfusion can be effective in arresting hemorrhage in some critically ill patients.[235] In most patients with platelet counts >50,000/μl, preoperative platelet transfusions are not indicated. Platelet transfusions should be avoided in patients with chronic ITP because of subsequent development of alloantibodies. Exchange plasmapheresis may be valuable in critically ill patients and may be particularly effective in children.[335–337] Anovulatory hormones are useful when menorrhagia is a major complaint. Because of the risk of septicemia, polyvalent pneumococcal vaccine, *Haemophilus influenzae* B vaccine, and quadrivalent meningococcal polysaccharide vaccine should be administered at least 2 weeks before elective splenectomy in both adults and children.[338]

Immune Thrombocytopenia in Pregnancy

Both ITP and non-ITP may occur during pregnancy.[339,340] Thrombocytopenia was present in 7% of women when they were admitted to hospital for a full-term delivery in a prospective 7-year study of 15,741 mothers and 15,932 newborns.[341–343] Most platelet counts were between 100,000 and 150,000/μl, and 1% of women had platelet counts <100,000/μl. Thrombocytopenia was detected incidentally in the majority of women, and only 0.01% of their infants had fetal platelet counts <50,000/μl. None of the infants had hemostatic impairment, and most mothers had normal or near-normal platelet counts by discharge. If the

mothers had an obstetric or medical complication, the incidence of thrombocytopenia (<50,000/μl) in the infants was 0.35%. It is unclear when the incidental thrombocytopenia (called *gestational thrombocytopenia*) developed during pregnancy, and the etiology of this mild abnormality is likewise unknown. Antiplatelet antibody testing was not sufficiently specific to differentiate patients with gestational thrombocytopenia from those with ITP.[344] Among those with maternal thrombocytopenia, 74% have incidental thrombocytopenia, and only 4% have ITP.[345] It is therefore recommended that healthy women who have a platelet count of 70,000 to 150,000/μl at delivery require no specific treatment, and the mode of delivery should be determined only by obstetric indications.

A recent retrospective 11-year analysis of obstetric patients with ITP examined 92 women with ITP during 119 pregnancies.[346] For most women, the pregnancy was uneventful, although women had moderate to severe bleeding in 25 pregnancies (21.5%). Women in 37 pregnancies received treatment to increase platelet counts. During delivery, 44 women received epidural analgesia without complications, with most having a platelet count between 50,000 and 149,000/μl. Most deliveries were vaginal (82.4%). Bleeding was uncommon at delivery. In most settings epidural analgesia is held if platelets are less than 80 to 90,000/μl.

Platelet autoantibodies in pregnant patients with ITP cross the placenta and can produce thrombocytopenia and clinical bleeding in the infant. During pregnancy, both maternal and infant health must be considered, and management of women with ITP diagnosed before or during the pregnancy is therefore more difficult and still controversial.[345,347] Women with severe thrombocytopenia should be treated with IVIG or the lowest dose of steroids needed to maintain a platelet count >50,000 to 60,000/μl; it must be noted, however, that when mothers have been treated during pregnancy, changes in their platelet counts do not correlate with the fetal platelet counts when these have been sampled before and after treatment.[348] When betamethasone or placebo was given for 4 weeks before delivery in a randomized trial, no differences were seen in either the maternal or infant platelet counts or the incidence of bleeding at delivery.[349] Splenectomy during pregnancy may have higher complication rates, but it is not contraindicated. IVIG can be used before delivery to increase the platelet count rapidly. The safety of other forms of therapy used in nonpregnant ITP patients is uncertain.

At the time of delivery, it must be decided whether to deliver the infant by cesarean section or by vaginal delivery. When 474 infants were analyzed from series reported over a 20-year period, 10% of infants had platelet counts between 50,000 and 100,000/μl, and 15% had platelet counts <50,000/μl.[350] Intracranial hemorrhage occurred in 3%, but no significant association existed between intracranial hemorrhage and mode of delivery. More recent data indicate that morbidity and mortality in infants with neonatal thrombocytopenia is lower than originally reported. Burrows and Kelton published a systematic review of pregnancy in patients with ITP, selecting only those series with more than 10 patients and those that included fetal platelet counts and infant outcome.[351] They reported 288 live births and an incidence of fetal thrombocytopenia of 10% with platelet counts <50,000/μl and 4% with platelet counts <20,000/μl. There were no deaths and no cases of intracranial hemorrhage, and there was no difference in morbidity between cesarean sections and vaginal births. During the decade from 1990 to 2000, these cumulative totals from 13 prospective studies were 9% and 4%.[345] Minor bleeding complications occurred in 3% of infants, and 2% had major bleeding complications.

Many studies have been done to determine maternal characteristics that may correlate with severe thrombocytopenia in the newborn[345] and to help with decisions regarding method of delivery. To date, only the birth of a previously affected infant correlates with the incidence of neonatal thrombocytopenia. Other variables that were analyzed, such as the mother's platelet count or prior splenectomy, were predictive in some studies but not in others. Fetal platelet counts might be able to predict newborn risks of bleeding, but scalp-vein platelet counts can be artifactually low, and the incidence of complications associated with percutaneous umbilical blood sampling is higher than the incidence of postnatal major bleeding. In all these reports, it was also noted that the infant platelet count could fall for several days after delivery. It is therefore currently recommended that the mode of delivery should be determined solely by obstetric indications.[5]

SECONDARY AUTOIMMUNE THROMBOCYTOPENIC PURPURA

Autoimmune thrombocytopenia can be associated with drugs and with several common diseases (i.e., collagen vascular disease, infections, lymphoproliferative disorders, and Graves disease). Secondary ITPs are discussed separately because of their unique features and the issues of diagnosis and management. ITP associated with human immunodeficiency virus infection is discussed in Chapter 64.

Autoimmune Thrombocytopenic Purpura Secondary to Drugs

Numerous drugs have been associated with ITP. In some cases, the evidence associating a given drug to ITP is circumstantial. However, a systematic review is available in which specific criteria were established to determine the likelihood of drug-induced ITP due to specific drugs (Table 47.6).[162,352–354] The most common drugs with level 1 evidence are quinidine, quinine, rifampin, trimethoprim-sulfamethoxazole, danazol, methyldopa (Aldomet), acetaminophen, and digoxin. The most common drugs with level 2 evidence are gold, procainamide, carbamazepine, hydrochlorothiazide, ranitidine, and chlorpropamide. Heparin, which causes ITP in as many as 1% of patients, is discussed in Chapter 55.

Pathophysiology

Drug-induced platelet antibodies are the result of an idiosyncratic reaction that develops in only a small percentage of persons exposed to a drug. This ranges from an estimated 38 cases per 1 million exposures for trimethoprim-sulfamethoxazole to as many as 1 in 100 patients for gold salts, and 3 in 100 patients for true immune-mediated heparin-induced thrombocytopenia.[355,356,357] It is not clear whether there are predisposing risk factors for most of the drugs that cause ITP, although evidence suggests that the risk of developing antibodies to gold salts depends on host HLA type, with the majority of patients studied expressing HLA-DR3 antigen.[357]

Drug-induced antibodies may be complement- or noncomplement-activating antibodies that react with platelets, in either the absence (autoantibodies) or presence of drugs. The most completely studied antibodies are those that develop in response to quinidine/quinine and heparin.[40] Most nonheparin drug-induced antibodies bind specifically to platelet membrane glycoproteins in the IIb/IIIa or the Ib/V/IX complex through the Fab portion of the antibody molecule (Fig. 47.2B). In contrast, antibodies to heparin bind to a heparin–platelet factor 4 complex, and the immune complex then binds to the platelet membrane via the Fc portion of the antibody molecule (Fig. 47.2C).

Most of the drug-induced antibodies are developed in response to the parent drug, and drug-dependent antibodies can be demonstrated in a variety of in vitro tests. In some cases, however, these tests are negative when the parent compound is present but positive if known metabolites are used instead of the

TABLE 47.6

DRUGS ASSOCIATED WITH IMMUNE THROMBOCYTOPENIA AND CRITERIA FOR THEIR CLASSIFICATION

Level 1[a]		Level 2[b]
Acetaminophen	Iopanoic acid	Acetazolamide
Alprenolol	Isoniazid	Ampicillin
Aminoglutethimide	Levamisole	Captopril
Aminosalicylic acid	Linezolid	Carbamazepine
	Lithium	
Amiodarone	Meclofenamate	Chlorpropamide
		Filgastrim (G-CSF)
Amphotericin B	Mesalamine	Fluconazole
Amrinone	Methicillin	Glibenclamide
Atorvastatin	Methyldopa (Aldomet)	Gold
	Methylprednisolone	
Cephalothin	Minoxidil	Hydrochlorothiazide
Chlorothiazide	Nalidixic acid	Ibuprofen
Chlorpromazine	Naphazoline	Oxyphenbutazone
Cimetidine	Nitroglycerine	Oxytetracycline
Danazol	Novobiocin	Phenytoin
	Orofiban	
Deferoxamine	Oxprenolol	Procainamide
Diatrizoate meglumine/ diatrizoate sodium	Pentoxifylline	Ranitidine
	Piperacillin	Sulindac
Diazepam	Quinidine	Ticlopidine
Diazoxide	Quinine	Trastuzumab
Diclofenac	Rifampin	
Diethylstilbestrol	Sulfasalazine	
Difluormethylornithine	Sulfasoxazole	
Digoxin	Tamoxifen	
Ethambutol	Thiothixene	
Haloperidol	Tolmetin	
Indinavir	Trimethoprim-sulfamethoxazole	
Interferon-α	Vancomycin	

Criteria[a,b]
1. The candidate drug preceded thrombocytopenia, and recovery from thrombocytopenia was complete and sustained after the drug was discontinued.
2. The candidate drug was the only drug used before the onset of thrombocytopenia, or other drugs were continued or reintroduced after discontinuation of the candidate drug with a sustained normal platelet count.
3. Other etiologies for thrombocytopenia were excluded.
4. Re-exposure to the candidate drug resulted in recurrent thrombocytopenia.
[a]Level 1 evidence met criteria 1–4.
[b]Level 2 evidence met criteria 1–3.
Modified from publications by George et al. (references 162, 352–354).

parent compound. Antibodies against drug metabolites have been reported with acetaminophen, para-aminosalicylic acid, naproxen, and trimethoprim-sulfamethoxazole.

Clinical Features

Drug-induced thrombocytopenia is associated with a heterogeneous clinical picture and varying degrees of bleeding. Thrombocytopenia and bleeding usually appear abruptly and may be severe. Mucosal membrane bleeding from all sites and oral hemorrhagic bullae may occur, and patients often develop fever, chills, nausea, vomiting, and fatigue as part of a prodrome to the bleeding.

Severe thrombocytopenia usually develops within hours in sensitized patients ingesting quinidine or quinine; however, a minimum of 6 to 7 days is required to initiate a primary immune response in individuals taking the drug for the first time. Some patients do not develop thrombocytopenia for months or years, a characteristic that seems to be more dependent on the host than the type of drug. The amount of drug that is required to cause thrombocytopenia is quite variable; however, even the amount of quinine present in a gin and tonic (15 mg) is sufficient to produce severe thrombocytopenia and bleeding in a patient who has been previously sensitized to quinine ("cocktail purpura").[358] After the drug is stopped, platelet counts return to normal within days and usually are normal by 1 week. Thrombocytopenia induced by gold salts resolves more slowly, usually over weeks or months, because gold remains in the tissues.

Diagnosis

It is often difficult to make a definite diagnosis of drug-associated ITP because either the patient has taken the medication intermittently or a hospitalized patient is receiving more than one drug that may cause thrombocytopenia. Although it may be possible to demonstrate drug-dependent antibodies against the parent drug or its metabolites, this type of testing is beyond the scope of hospital laboratories. The readministration of the suspected drug in an attempt to confirm an etiologic relationship is not recommended as a routine diagnostic measure. Most of the level 1 drugs listed in Table 47.6 were demonstrated to cause immune-mediated thrombocytopenia because of patient response to an inadvertent in vivo challenge.

A detailed history, including all prescribed drugs, over-the-counter medications, and any herbal supplements, is of great benefit. Complete data from all English-language articles describing patients with assumed drug-induced thrombocytopenia have been catalogued on the Internet (http://www.ouhsc.edu/platelets/ditp.html).

Treatment

Ordinarily, no therapy is needed, because withdrawal of the offending drug is followed by recovery. IVIG and plasmapheresis may be helpful if life-threatening bleeding occurs. Many patients are treated with corticosteroids, and a normal platelet count is usually restored within 1 week. The major exception is gold-induced thrombocytopenia, which may persist for weeks or even months. British anti-Lewisite (dimercaprol) may accelerate the excretion of gold and speed recovery.[359]

Autoimmune Thrombocytopenia in Systemic Lupus Erythematosus

Thrombocytopenia may complicate collagen vascular diseases and other disorders associated with disordered immunologic responses such as thymoma[360] and myasthenia gravis.[361–363] In most instances, the ITP in SLE appears to result from immunologic platelet injury and is identical to primary ITP in most respects.

From 5% to 15% of patients with ITP fulfill the criteria for diagnosis of SLE at the time of presentation.[364,365] Other patients have a positive antinuclear antibody test when they are first diagnosed with ITP, and a small number of them may develop SLE within several years. Patients with high-titer antinuclear antibody in a speckled pattern and antibodies against native DNA and other nuclear antigens are the patients most likely to develop SLE.[366–369] SLE is a chronic and debilitating disease, so it is important to identify such patients so therapy can be directed at all aspects of the autoimmune disease.

ITP in SLE patients may be the result of either specific platelet autoantibodies or immune complex deposition on platelets. Only

a few studies have been reported in which the newest platelet antigen-capture autoantibody tests have been used, and in these patients, platelet autoantibodies to platelet membrane glycoproteins have been detected.[370–373] Thrombocytopenia correlates with SLE disease activity[374] but not the presence of antiphospholipid antibodies.[375–377] These antibodies, which may be present in SLE or in otherwise healthy patients, also bind to platelet membrane gpIIb/IIIa or Ib/IX/V.[372,373] It is unclear, however, whether they are specific to these glycoproteins or cross-reactive.

Patients with ITP and SLE should be treated the same as patients with primary ITP, even though there are conflicting reports on the success rate of splenectomy in this population.[378,379]

Immune Thrombocytopenia in Other Disorders

ITP has been reported in association with a number of other medical conditions, including infections, neoplasms, and thyroid disease, and it is unknown whether this increased platelet destruction involves antibody binding, immune complex deposition, and/or antibody-mediated complement activation.

ITP has been documented in patients with infectious mononucleosis, cytomegalovirus, varicella or zoster,[380–383] hepatitis C,[384,385] tuberculosis,[386] and human immunodeficiency virus infections (discussed in Chapter 64). During the last several years, ITP was also reported in patients with *H. pylori,* particularly in Europe and Japan. Platelet counts may or may not normalize with treatment directed only at *Helicobacter*.[387–390,391,392–395] The ASH guidelines recommend that *H. pylori* infection be considered in all adults with ITP for whom eradication therapy would be undertaken if testing were positive.[5]

ITP is a well-known complication of chronic lymphocytic leukemia,[396] although it is not as frequent as autoimmune hemolytic anemia in these patients. It has also been reported in patients with other lymphoproliferative disorders including Hodgkin disease.[397–400] Thrombocytopenia in patients with a variety of solid tumors has also been thought to most likely be immune-mediated.[401,402]

Thrombocytopenia may accompany Graves disease and Hashimoto thyroiditis,[403–406] but it is not certain that it is immunologically mediated. Platelet-associated IgG has been increased when studied,[406] but there may also be an element of enhanced reticuloendothelial phagocytosis.

ALLOIMMUNE THROMBOCYTOPENIA

Platelets express membrane-associated epitopes as a result of polymorphisms in discrete regions of the platelet membrane surface glycoproteins.[407] No natural antibodies to human platelet antigens are known. Acquired platelet alloantibodies are of clinical importance in three circumstances: (a) Neonatal alloimmune thrombocytopenia (NAIT), which is the result of the placental transfer of alloantibodies formed by the mother to incompatible fetal platelet antigens;[408] (b) posttransfusion purpura (PTP), a rare disorder in which the transfusion of platelet-containing blood products provokes the formation of alloantibodies that act as autoantibodies;[409] and (c) passive transfer of platelet alloantibodies after transfusion from a multiparous or multiply transfused donor.[410–413]

Neonatal Alloimmune Thrombocytopenia

Pathophysiology

Immunologic thrombocytopenia in the newborn may result from the placental transfer of platelet antibodies formed as the result of active immunization of the mother by fetal platelet antigens. Pathophysiologically, such NAIT is similar to erythroblastosis fetalis. Thus, as a consequence of the inheritance by the fetus of platelet antigens lacking in the mother, alloantibodies are formed in the maternal circulation and cross the placenta, producing thrombocytopenia in the fetus. Antibodies can be detected as early as the 19th week, and thrombocytopenia has been found in utero by 20 weeks' gestation.[414] Immunization to human platelet alloantigen (HPA)-1a (PL^A, Zw^A)[415,416,417] or HPA-5b (Br^A, Zav, Hc)[418,419] is most common; however, other antigens have been detected and found to be responsible for occasional cases of NAIT (Fig. 47.2D).[415,416,417–426] One of the largest studies to date examined maternal sera for platelet-reactive antibodies in mothers of infants suspected of NAIT. Maternal HPA-1a (Pl^{A1}) alloimmunization accounted for 79% of confirmed NAIT cases.[427] The overwhelming majority of platelet polymorphisms found to date are caused by a single base-pair mutation leading to a single amino acid substitution in the polypeptide chain of the specific glycoprotein.[428] Rarely, HLA antibodies are responsible.[415,418]

Alloimmunization to platelet antigens commonly develops during the first pregnancy and then recurs in >80% of patients during subsequent pregnancies. However, not all mothers who are missing the antigens presented by the fetus develop antibodies, and not all fetuses and neonates develop thrombocytopenia in spite of antibody development.[418] HPA-1 mismatch is present in 1 in 50 births, yet NAIT occurs in only 1 in 1,000 to 2,000 births.[414,416,417,429] Maternal HLA Class II determinants appear to be important. A high incidence of maternal allotypes HLA-DR3 and HLA-DRw52a has been demonstrated in mothers isoimmunized to fetal alloantigen HPA-1,[417,430] and a high incidence of HLA-DR6 has been reported in mothers sensitized to PLA-5b.[418]

Clinical Features

Infants with NAIT are born with signs of purpura and severe thrombocytopenia. Thrombocytopenia usually is present at birth, but the platelet count may fall further during the postpartum period. Intracranial hemorrhage occurs in 20% to 30%, with one half of the episodes occurring in utero.[431] An overall mortality rate of 6% to 14% has been reported.[416,419,420] Thrombocytopenia usually resolves after 10 to 14 days. Platelet antibody titers during the second half of the pregnancy appear to correlate with the risk of thrombocytopenia or bleeding, or both, in NAIT.[432,433]

Laboratory Diagnosis

When infants are born with platelet counts <20,000 μl, NAIT must be suspected. Maternal plasma should be studied with paternal or neonatal platelets as targets; maternal (antigen-negative) platelets and paternal plasma are appropriate negative controls. NAIT is diagnosed when platelet antigen incompatibility is found between the parents, maternal antipaternal platelet antibodies are present, and the antibody detected corresponds to the incompatibility of platelet antigens that have been noted.

Treatment

Severely thrombocytopenic children should be treated aggressively with IVIG and platelet transfusions of compatible irradiated platelets. Maternal platelets are usually obtained by pheresis, concentrated, irradiated, and transfused. Interestingly, a recent retrospective study reported that transfusion of platelet concentrates from random donors is an appropriate strategy in the management of unexpected severe NAIT predominantly in first pregnancies, pending the availability of compatible platelets.[434]

Prevention of NAIT In women with no personal or family history of NAIT, screening by platelet typing is currently not recommended.[435] Maternal platelet antigen typing has been recommended for those with a sister whose pregnancy was complicated by NAIT or if personal or family history is suggestive of NAIT

(e.g., neonatal thrombocytopenia of undetermined origin or fetal or neonatal intracranial hemorrhage of undetermined origin). In these cases, maternal and paternal platelet typing is performed simultaneously in order to look for incompatibility in the PHA-1 antigen system. Screening studies to detect neonatal thrombocytopenia during the first pregnancy have been limited to patients with known PL^{A1} incompatibility and an HLA allotype associated with an increased incidence of antibody formation.[417] However, after the birth of one child with NAIT, subsequent pregnancies should be evaluated antenatally.

When maternal and paternal platelet typing document a risk of NAIT, after the index case, over 85% of that couples' subsequent fetuses will be at risk for NAIT. In the absence of any intervention, thrombocytopenia in the second affected fetus is always as or more severe than in the previous fetus/infant.[436] Because of the high risk of in utero bleeding, the majority of which include intracranial hemorrhage, initiating therapy antenatally, rather than waiting until birth, has become standard. Previously, it was recommended that fetal platelet typing[402,422–425] and platelet counts should be obtained at 20 weeks' gestation.[401,426] If platelet incompatibility is noted and the infant is thrombocytopenic, in utero platelet transfusions or maternal treatment with IVIG should be instituted and maintained during the pregnancy.[401,427,428] In the United States, the most common therapies include infusion of IVIG and/or oral prednisone.[437] Combination therapy with IVIG plus steroids may lead to higher platelet counts in women with a previous child with intracranial hemorrhage or a current fetus with platelet counts $<20{,}000/\mu l$.[431] Fetal platelet transfusions have been advocated. However, because of the risk of fetal mortality, this has become a therapy of last resort, to be used only if IVIG or prednisone are ineffective.[438] There is no consensus on whether fetuses affected by NAIT or at risk for NAIT should be delivered by cesarean section.[439]

Because the use of serial fetal blood sampling procedures is clearly associated with an increased risk of fetal morbidity and mortality, some practitioners prefer to avoid performing fetal blood sampling and choose to treat empirically. The precise role of this invasive procedure remains to be determined.[440,441] Studies of the cost-effectiveness of empiric treatment versus treatment directed by fetal blood sampling favored empiric treatment, decreasing perinatal deaths although increasing the number of infants with long-term neurologic deficits.[441] Follow-up studies of children after antenatal treatment for alloimmune thrombocytopenia show that general health and neurodevelopmental outcome is comparable to that of the general population. However, significantly more infections and hearing problems were observed in children who were not exposed to maternal IVIG treatment in comparison to children who were exposed to IVIG treatment or the normal population.[442]

Posttransfusion Purpura

Alloantibodies that develop as a result of transfusion of incompatible platelets are responsible for the destruction of the transfused platelets. This is a frequently encountered problem in patients who have received multiple platelet transfusions. Rarely, however, severe thrombocytopenia in the recipient—that is, destruction of host platelets—is produced by the transfusion of incompatible platelets, and this potentially fatal reaction is known as PTP.[443,444,445] PTP is characterized by abrupt onset of thrombocytopenia and bleeding that occurs ~1 week after the transfusion of packed red blood cells. PTP has also been described after the transfusion of other blood components, including plasma.[446]

The syndrome occurs most commonly in multiparous women who have been sensitized by pregnancy; however, previously transfused patients may also develop PTP. The antibody most commonly develops against PL^{A1} (HPA-1a) in PL^{A2} (HPA-1b) homozygous recipients, but the Bak (HPA-3a/HPA-3b), Pen (HPA-4a/HPA-4b), Br (HPA-5a/HPA-5b), and Nak[a] polymorphisms have been implicated as well[409,444,445,447–450] (Table 47.7). The diagnosis of PTP is a clinical one, and physicians must therefore consider this diagnosis in any patient who develops thrombocytopenia within 3 to 14 days after transfusion of any blood product.

TABLE 47.7

PLATELET ALLOANTIGENS IMPLICATED IN THE DEVELOPMENT OF POSTTRANSFUSION PURPURA

Serologic Designation	Alternative Designation	Phenotype Frequency	Antigen Location
PL^{A1} (HPA-1a)	Zw^a	0.96–0.99	gpIIIa
PL^{A2} (HPA-1b)	Zw^b	0.27	gpIIIa
Bak^a (HPA-3a)	Lek^a	0.78–0.89	gpIIb
Bak^b (HPA-3b)	Lek^b	0.50–0.70	gpIIb
Pen^a (HPA-4a)	Yuk^b	0.99	gpIIIa[a]
Pen^b (HPA-4b)	Yuk^a	0.01	gpIIIa[a]
Br^b (HPA-5a)	Zav^b	0.99	gpIa
Br^a (HPA-5b)	Zav^a	0.18–0.20	gpIa

gp, glycoprotein; HPA, human platelet alloantigen.
[a]Antigen appears to be distinct from PL^{A1} (HPA-1a).
Modified from McCrae and Herman.[409]

The pathophysiology of this rare but severe thrombocytopenia is still uncertain, but several hypotheses have been proposed: (a) Autologous platelets are destroyed because of binding of immune complexes to their surface; (b) recipient platelets acquire the phenotype of the donor's platelets because they bind soluble antigens from the transfused blood product, and the platelets are then destroyed by alloantibodies; and (c) exposure to foreign platelets in transfused products induces the formation of autoantibodies to the recipient's platelets.[409,451,452]

PTP is self-limited, resolving within 1 to 3 weeks in most patients. Treatment with steroids, plasmapheresis, or IVIG may shorten the period of thrombocytopenia. Plasmapheresis is effective in 80% of patients,[446,453–455] but IVIG, in doses of 2 g/kg over 2 days, may be preferable because plasmapheresis requires central venous access with large-bore catheters and places the patient in danger of significant bleeding.[456–458] Platelet transfusions should be reserved for life-threatening hemorrhage, because patients often develop a febrile reaction and an increase in platelet count is infrequent.

CHAPTER 48

THROMBOTIC THROMBOCYTOPENIC PURPURA, HEMOLYTIC-UREMIC SYNDROME, AND RELATED DISORDERS

Han-Mou Tsai

The various forms of thrombocytopenia discussed in this chapter share the common features of thrombocytopenia and hemolysis with characteristic schistocytes on blood smears (microangiopathic hemolytic anemia, MAHA) (Fig. 48.1). It is believed that thrombocytopenia results from consumption of platelets, whereas erythrocyte fragmentation and hemolysis are due to mechanical injury of the red blood cells by abnormal levels of shear stress.

Fragmentation of the red blood cells occurs in two types of clinical conditions: vascular devices such as prosthetic heart valves, ventricular assist devices, and extracorporeal oxygenator and microvascular stenosis.

In the absence of mechanical devices, fragmentation of the red blood cells signifies stenosis in the arteriolar microvasculature. This is because wall shear stress, determined by blood viscosity, flow rate, and the inverse of the luminal diameter to the third order, is at its highest in the arterioles and may be further increased to exceed the threshold level of red cell fragmentation when the lumen is narrowed. Furthermore, the red cells are likely to be entrapped in the presence of microvascular stenosis. The combination of abnormal shear stress and cell entrapment accounts for red cell fragmentation in patients with arteriolar stenosis. Due to their lower shear stress profile, it is unusual that stenosis in the venules, veins, or arteries is sufficient to cause red cell fragmentation.[1]

Arteriolar stenosis may result from one of five different types of pathology (Fig. 48.1): (1) von Willebrand factor (vWF)–platelet thrombosis, as typically observed in patients with thrombotic thrombocytopenic purpura (TTP) due to severe ADAMTS13 (a disintegrin and metalloprotease with thrombospondin type 1 motif, member 13) deficiency; (2) platelet fibrin thrombosis, as exemplified in patients with disseminated intravascular coagulopathy (DIC) but also may occur in a variety of other conditions; (3) tumor cell invasion of the microvasculature in patients with metastatic neoplasm; (4) microvascular vasculitis, as occasionally observed in patients with systemic lupus erythematosus and related autoimmune disorders or certain types of infections such as Rocky Mountain spotted fever and anthrax; and (5) thrombotic microangiopathy (TMA), as observed in patients with the typical shiga toxin–associated hemolytic-uremic syndrome (stx-HUS) following *Escherichia coli* infection, pneumococcal HUS, or atypical hemolytic-uremic syndrome (aHUS) due to defective regulation of the alternative complement pathway.

A comprehensive classification of microangiopathic disorders is listed in Table 48.1. This classification includes four groups: TTP, TMA due to defective complement regulation (aHUS), TMA due to other mechanisms, and MAHA due to other types of pathology. In TMA, organ dysfunction may result from thrombotic stenosis, which causes thrombocytopenia and MAHA; non-thrombotic stenosis, which causes MAHA but not thrombocytopenia; and/or abnormal vascular permeability, which causes tissue edema and cavitary effusions but not thrombocytopenia or MAHA. Due to multiple pathogenetic pathways, organ dysfunction or clinical disease severity in patients with aHUS or other types of TMA does not always closely correlate with thrombocytopenia or MAHA. TTP, stx-HUS, and aHUS are further discussed in this chapter.

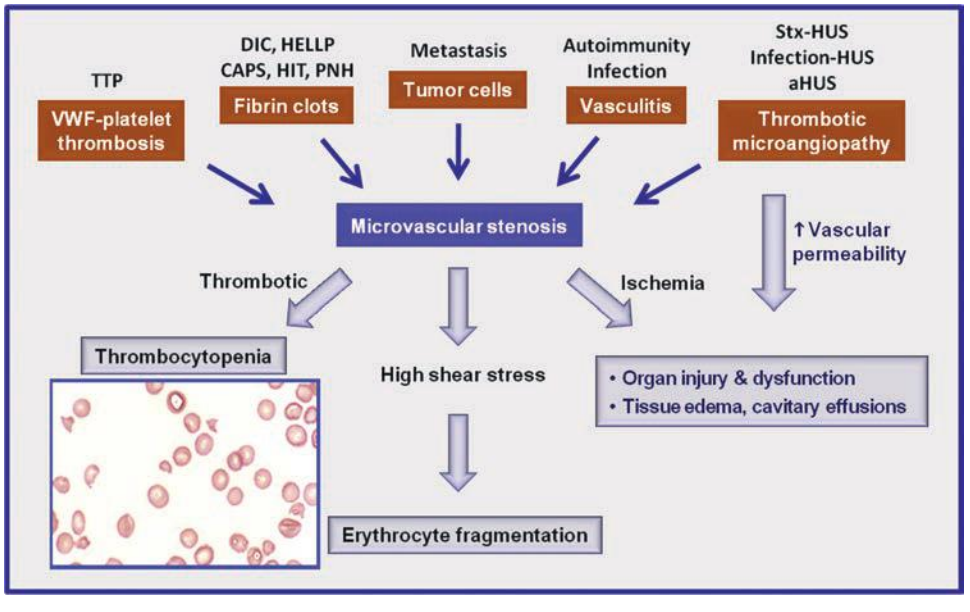

FIGURE 48.1. A scheme depicting how different types of pathology may lead to microvascular stenosis and the syndrome of thrombocytopenia and microangiopathic hemolysis (MAHA). Thrombotic microangiopathy may also lead to tissue edema and organ dysfunction by increasing vascular permeability. DIC, disseminated intravascular coagulopathy; CAPS, catastrophic antiphospholipid antibody syndrome; HELLP, hemolysis with elevated liver enzymes and low platelets; HIT, heparin-induced thrombocytopenia; HUS, hemolytic-uremic syndrome; PNH, paroxysmal nocturnal hemoglobinuria; Stx-HUS, shiga toxin–associated hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

TABLE 48.1

CLASSIFICATION OF MICROANGIOPATHIC DISORDERS

I. TTP: a disease with propensity to microvascular thrombosis due to ADAMTS13 deficiency
- Acquired: autoimmune inhibitors of ADAMTS13
- Hereditary: mutations of ADAMTS13

II. aHUS: a disease with propensity to TMA due to defective complement regulation

A: Idiopathic aHUS
- – Mutations or genetic variants of CHF, MCP, CFI, CFB, C3, THBD, etc.
- – Autoantibodies to CFH, with or without CFHR1 genomic deletion

B: Co-morbidity as a trigger of aHUS presentation in patients with the disease
- – Pregnancy, IV contrast, pancreatitis, infection, inflammation, surgery, trauma, etc.

C: Co-morbidity causing defective complement regulation (e.g., CFH autoantibodies)
- – Hematopoietic stem cell therapy
- – Suspected, but not yet proven: HIV infection, systemic autoimmune diseases, drugs, etc.

III. TMA via other mechanisms
- Shiga toxin-associated HUS: Shiga toxin-producing *E. coli* or *Shigella dysenteriae*
- Microbial neuraminidases causing T-antigen activation (e.g., *Streptococcus pneumonia* or *influenza virus*)
- Angiogenesis inhibitor: e.g., bevacizumab
- Undefined mechanisms: hematopoietic stem cell therapy, HIV infection, systemic autoimmune diseases, drugs (e.g., gemcitabine, mitomycin, quinine, calcineurin inhibitors*, cocaine, etc.) , severe hypertension**

IV. Other types of pathology
- Microvascular thrombosis comprised of fibrin and platelets
  - – DIC, CAPS, HELLP syndrome, HIT, PNH, etc.
- Vasculitis:
  - – Autoimmune diseases (e.g., systemic lupus erythematosus)
  - – Infectious diseases (e.g., Rocky Mountain spotted fever, anthrax)
- Intravascular clusters of neoplastic cells
- Intravascular devices:
  - – Ventricular assist device, extracorporeal membrane oxygenator, prosthetic heart valves, etc.

ADAMTS13, a disintegrin and metalloprotease with thrombospondin type 1 motif, member 13; aHUS, atypical hemolytic-uremic syndrome; CAPS , catastrophic antiphospholipid antibody syndrome; CFB, complement factor B; CFH, complement factor H; CFHR1, complement factor H-related protein 1; CFI, complement factor I; DIC, disseminated intravascular coagulopathy; HELLP, hemolysis with elevated liver enzymes and low platelet count; HUS, hemolytic-uremic syndrome; HIT, heparin-induced thrombocytopenia; MCP, membrane cofactor protein (CD46); PNH, paroxysmal nocturnal hemoglobinuria; THBD, thrombomodulin; TMA, thrombotic microangiopathy; TTP, thrombotic thrombocytopenic purpura; vWF, von Willebrand factor.
*Some patients are found to have aHUS with defective complement regulation.
**Severe hypertension may be a consequence of aHUS rather than cause of thrombotic microangiopathy

ACQUIRED THROMBOTIC THROMBOCYTOPENIC PURPURA

The current definition of TTP is based on the demonstration of autoimmune inhibitor for acquired TTP and genetic mutation of the ADAMTS13 gene for hereditary TTP. By this definition, TTP is a disease that is prone to, but does not always have, microvascular thrombosis, thrombocytopenia, microangiopathic hemolysis, or organ dysfunction.

This definition is different from the conventional diagnosis of TTP as a clinical syndrome. It requires the demonstration of ADAMTS13 inhibitors or mutations and encompasses patients who are asymptomatic and patients who do not have thrombocytopenia or microangiopathic hemolysis.

The problem of conventional TTP diagnosis based solely on clinical features is most clearly illustrated by the vast difference in the prevalence of severe ADAMTS13 deficiency among the patients in the Canadian Apheresis Group trial on the efficacy of plasma therapy and the patients in the Oklahoma TTP registry. Severe ADAMTS13 deficiency was detectable in more than 76% of the patients in the Canadian Apheresis Group trial, yet in less than 15% of the patients in the Oklahoma registry.[1–3] Indeed, many clinical series of 'TTP' or 'TTP/HUS' included patients with atypical HUS or other causes of microangiopathic hemolysis, resulting in confusion in the diagnosis and management of patients presenting with microangiopathic hemolysis and thrombocytopenia.

Pathology

The pathology of TTP, as first described by Moschcowitz in 1925[4], is quite distinctive: widespread hyaline thrombi in the terminal arterioles and capillaries, accompanied by no or little endothelial injury or inflammation (i.e., microangiopathy) (Fig. 48.2A). The thrombi are present most extensively in the heart, pancreas, spleen, kidney, adrenal gland, and brain (mainly cerebral cortex) and are composed primarily of platelets and vWF (Fig. 48.2B).[5,6,7] Small amounts of fibrin may be present surrounding or sometimes penetrating the amorphous or granular material. Glomerular microthrombi are usually spotty, and cortical necrosis of the kidney is uncommon in TTP. Fibrinoid necrosis and vascular or perivascular inflammatory cell infiltration are characteristically absent or minimal.

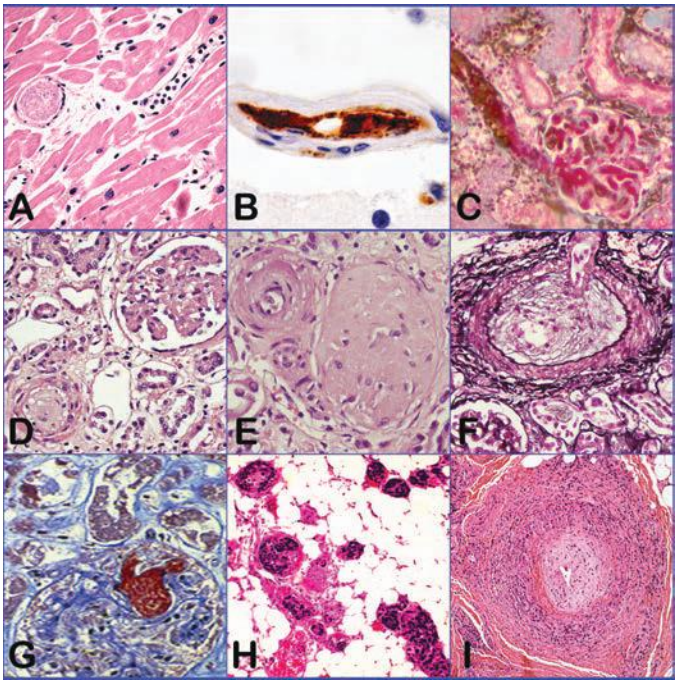

FIGURE 48.2. Histopathology and histochemistry of thrombotic thrombocytopenic purpura (TTP) and other microangiopathic disorders. A: TTP (heart); **B:** TTP (brain); **C:** shiga toxin–associated hemolytic-uremic syndrome (HUS) (kidney); **D–F:** atypical HUS (kidney); **G:** disseminated intravascular coagulopathy (DIC) (kidney); **H:** tumor cell invasion of microvasculature in metastatic neoplasm (soft tissue); **I:** proliferative vasculitis of lupus causing microvascular stenosis (soft tissue). The endothelial cells and the vessel wall are intact in TTP and DIC. All images are H&E stains except panel B (immunohistochemical stain for vWF, brown), panels C and G (fibrin stain of Carstair), and panel F (Jones silver stain).

In chronic cases, the thrombi may be infiltrated by fibroblasts or converted to subendothelial deposits by proliferating endothelial cell lesions. Pseudoaneurysmal dilatation may also be present upstream of the stenosis or occlusion.

In the literature, some investigators have suggested that endothelial cell injury is prominent in TTP. A review of the clinical features in those reports suggests that those patients likely had shiga toxin–associated or atypical HUS rather than TTP.

Pathophysiology

Historically two schemes have been proposed to account for the microvascular thrombosis in TTP: endothelial cell injury and uncontrolled platelet aggregation. The scheme of endothelial cell injury is not consistent with the absence or paucity of microangiopathy in TTP patients. The predominance of vWF and platelets in the thrombi and the integrity of vascular endothelial cells suggest that thrombosis results from dysregulation of vWF-platelet interaction in TTP.

vWF, a plasma glycoprotein derived primarily from vascular endothelial cells, supports platelet adhesion and aggregation at sites of microvascular injury under high shear stress conditions. Deficiency in vWF causes defective microvascular hemostasis and a bleeding diathesis in patients with von Willebrand disease.

vWF is synthesized in vascular endothelial cells as a disulfide-bonded polymer that is converted to a series of multimers in the circulation (Fig. 48.3). This conversion is mediated by repetitive cleavage at the Tyr1605-Met1606 bond by ADAMTS13.

vWF exists in a compact form with its cleavage sites and platelet binding sites cryptic. This explains why in a test tube vWF is not susceptible to cleavage by ADAMTS13 and is inactive in aggregating platelets. High levels of shear stress induce a conformational change of vWF, exposing its binding sites for platelet receptors (Fig. 48.4A). Due to its large molecular size and responsiveness to shear stress, vWF is uniquely capable of supporting platelet adhesion and aggregation under high shear stress conditions.

In the circulation, the activation of vWF by shear stress is prevented by ADAMTS13, which cleaves vWF whenever its cleavage sites are exposed by shear stress. The process of proteolysis is repeated during each cycle of circulation through the microvasculature, thereby converting vWF from a large polymer to a series of multimers while maintaining vWF in its compact inactive configuration (Fig. 48.4B).

A disruption in this proteolytic regulation of vWF occurs in TTP, in which ADAMTS13 deficiency, due to genetic mutation or autoimmune inhibitors, leads to incessant unfolding and activation of vWF by shear stress, resulting in vWF-platelet binding and microvascular thrombosis (Fig. 48.4C). This explains why a severe deficiency of ADAMTS13 can lead to microvascular thrombosis characteristic of TTP.

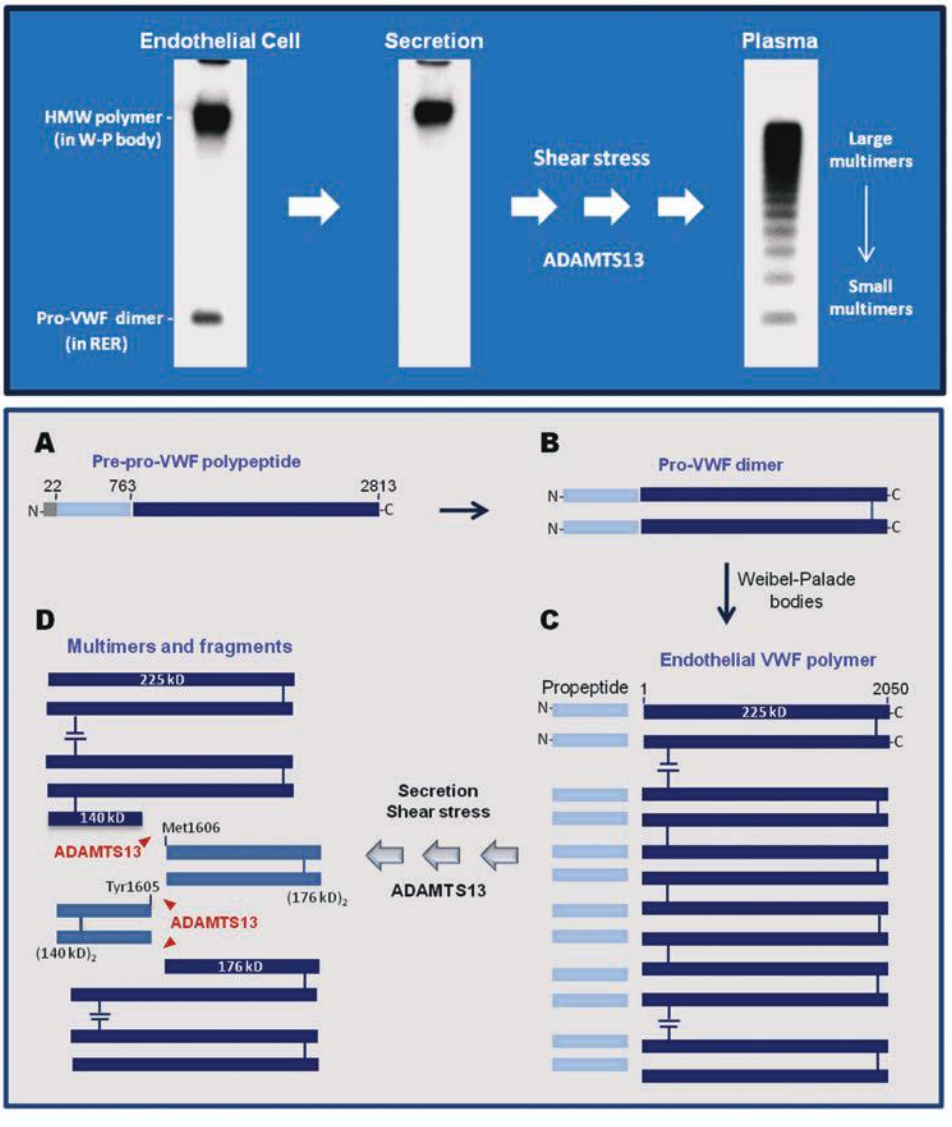

FIGURE 48.3. Gels and schemes depicting how VWF multimers are generated in the circulation. Upper panel: gels showing von Willebrand factor (vWF) polymer and multimers. In vascular endothelial cells vWF exists in two forms, a dimer of pro-vWF polypeptide in the rough endoplasmic reticulum (RER) and a polymer of mature vWF polypeptide in the Weibel-Palade bodies. Only the vWF polymer is secreted. Under the high shear stress conditions of the microcirculation, the vWF polymer is cleaved by ADAMTS13. A repetition of this process converts a vWF polymer to a series of multimers in normal plasma. vWF is separated by SDS-agarose gel electrophoresis and visualized with a radio-labeled antibody to vWF. Lower panel: a scheme of vWF biosynthesis and proteolysis. **A:** Pre-pro-vWF with 2,813 amino acid residues. **B:** A dimer of pro-vWF with disulfide bonds near the C-terminus. **C:** In the Weibel–Palade bodies, a vWF polymer is formed through disulfide bonding near the N-terminus of vWF dimers and cleavage of the propeptide. **D:** Under the high shear stress conditions of the microcirculation, vWF is cleaved at the Tyr1605-Met1606 bond, generating dimers of the 140 kD and 176 kD fragments and a series of progressively smaller multimers.

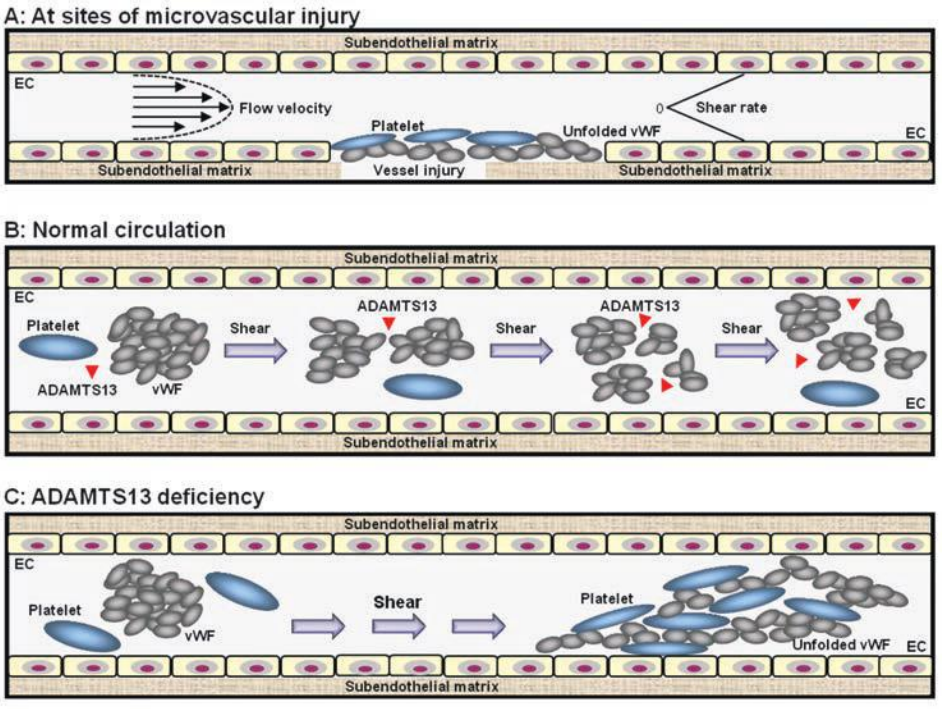

FIGURE 48.4. A scheme depicting how ADAMTS13 deficiency leads to von Willebrand factor (vWF)-platelet aggregation and microvascular thrombosis seen in thrombotic thrombocytopenic purpura (TTP). A. The responsiveness of vWF to shear stress allows it to be activated at sites of microvascular injury to support platelet adhesion and aggregation. **B.** In the circulation, vWF-platelet aggregation is prevented by ADAMTS13, which cleaves vWF whenever its cleavage sites are exposed by shear stress. This process maintains vWF in its compact inactive configuration while its size becomes progressively smaller. **C.** In the absence of ADAMTS13, vWF is relentlessly activated by shear stress, leading to vWF-platelet aggregation and microvascular thrombosis of TTP. Thrombosis increases the shear stress in the microcirculation, leading to further cycles of vWF-platelet aggregation.

Observations in patients with TTP reveal that vWF-platelet aggregation and thrombosis does not occur when the plasma ADAMTS13 activity level is greater than 10% of normal. On the other hand, a patient with ADAMTS13 activity less than 10% may be asymptomatic and may have a normal platelet count. This is because other factors such as platelet number, vWF level, shear stress profile in the circulation, and modifiers of vWF response to shear stress such as thrombospondin[8] may affect the propensity to vWF-platelet aggregation when ADAMTS13 is deficient.

Distinction between Thrombotic Thrombocytopenic Purpura Disease and Its Complications

A patient with autoimmune inhibitors or genetic mutations of ADAMTS13 may be completely asymptomatic and have normal blood counts. Such asymptomatic individuals are considered to have TTP, the disease, and are prone to the development of microvascular thrombosis causing clinical features such as thrombocytopenia, microangiopathic hemolysis, neurologic deficits, and injury of other organs.

Animal Models of ADAMTS13 Deficiency

Animal models of severe ADAMTS13 deficiency have been created in mice by inactivation of the ADAMTS13 gene and in baboons by infusion of an inhibitory ADAMTS13 antibody.[9,10,11] In both models, thrombi comprising vWF and platelets ensue in the arterioles. The findings in these animal models support the role of ADAMTS13 deficiency in causing microvascular thrombosis of TTP. Nevertheless, some mouse strains are phenotypically free of thrombosis. The difference in phenotypic severity among the mouse strains highlights the principle of epistasis in which the composition of other genes modifies the expression of a molecularly defined disease.

Interactions between von Willebrand factor and ADAMTS13

The vWF polypeptide comprises a series of homologous domains. The cleavage site of vWF, Tyr1605-Met1606, is located in the A2 domain, sandwiched between the A1 domain, which contains epitopes interacting with the platelet glycoprotein Ib, and the A3 domain, where a collagen-binding epitope is located (Fig. 48.5). This topographic arrangement facilitates the regulation of platelet thrombus formation, as cleavage of vWF at the A2 domain disengages the platelet from the vessel wall.

Structural studies confirm that shear stress induces vWF cleavage by altering the conformation of vWF.[12,13] Narrow-angle neutron scattering studies of vWF in guanidine hydrochloride, which also promotes vWF cleavage by ADAMTS13,[14] or after exposure to shear stress, shows that conformational change at the subdomain level is sufficient for proteolysis to occur.[15,16] Unfolding of vWF to extended configurations at the multimeric level is not necessary for proteolysis.

ADAMTS13, comprising 1,427 amino acid residues, is a member of the ADAMTS metalloprotease family, which shares a conserved domain structure of metalloprotease (MP)-disintegrin (Dis)-thrombospondin type 1 repeat (TSR)-cysteine rich region (Cys) and spacer (Spa) domains. ADAMTS13 contains 7 additional TSR downstream of the Spa domain, followed by two unique CUB (complement C1r/C1s, Uegf, Bmp1) domains (Fig. 48.5).

ADAMTS13 is synthesized primarily in the stellate cells of the liver.[17,18] ADAMTS13 may also be expressed, albeit at much

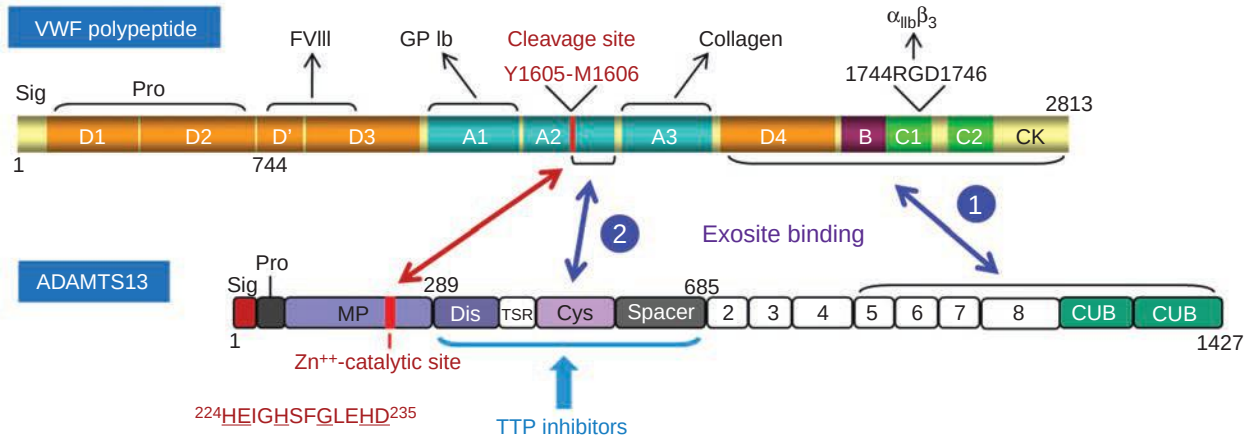

FIGURE 48.5. A scheme depicting the domain structures of von Willebrand factor (vWF) and ADAMTS13 and their interactions. The cleavage of vWF by ADAMTS13 involves exosite and catalytic interactions. It is believed that the exosite binding 1 occurs constitutively, whereas exosite binding 2 occurs only when the sequence in the A2 domain downstream of the scissile bond Tyr1605-Met1606 is exposed by shear stress. The exosite bindings orient the catalytic site of ADAMTS13 to attack the scissile bond of vWF (double-arrowhead red line). The inhibitors of thrombotic thrombocytopenic purpura (TTP) patients target the exosites of ADAMTS13 downstream of the metalloprotease domain.

lower levels by at least one to two orders, in the spleen and other organs. The localization of its biosynthesis to the stellate cells instead of hepatocytes may be instrumental in maintaining the ADAMTS13 activity in patients with hepatic insufficiency, as the stellate cells react to liver injury by activation and proliferation. The expression of ADAMTS13 in hepatic stellate cells and endothelial cells may be down-regulated by cytokines such as IFN-γ, TNF-α, and IL-4.[19]

Expression of ADAMTS13 has been described in the renal glomerular podocytes and endothelial cells and vascular endothelial cells in culture.[20,21] The ADAMTS13 expressed in renal glomeruli may cleave vWF before it is neutralized by autoantibodies, accounting for the generally milder renal injury observed in acquired versus hereditary TTP.

The metalloprotease domain of ADAMTS13 contains a catalytic 224–HEIGHSFGLEHD–235 module characteristic of the ADAMTS proteases (conserved residues are underlined). Structural analysis has identified three surface exosites of ADAMTS13 in the Dis, Cys, and Spa domains that react with discrete epitopes of the vWF A2 sequence around and downstream of the Tyr1605-Met1606 scissile bond.[22,23]

The exosite bindings greatly enhance the efficiency of catalytic reaction between ADAMTS13 and vWF. The vWF scissile bond and the exosite binding sites of the vWF A2 domain are normally cryptic, only exposed by tensile force to initiate interaction with ADAMTS13. Another exosite in the TSR5-CUB region of ADAMTS13 may interact with a constitutively exposed epitope in the N-terminal D4-CK region of vWF. This C-terminal binding may facilitate the interaction of the exosites upstream.

Alteration of von Willebrand factor Multimers in Thrombotic Thrombocytopenic Purpura

The involvement of vWF in the pathophysiology of TTP was first suggested by the intriguing observation that large multimers disappear during acute crisis of chronic relapsing TTP and yet ultra-large multimers are present during remission.[24]

The complexity of vWF multimers in TTP is due to two opposing processes acting upon plasma vWF in patients with ADAMTS13 deficiency: deficiency of ADAMTS13 leading to the presence of ultra-large multimers; and the activation of vWF by shear stress leading to the consumption and depletion of ultra-large and large multimers.

Three types of vWF multimer abnormalities are observed in TTP (Fig. 48.6). A shift of vWF to ultra-large forms occurs when ADAMTS13 activity is <20% to 30%; at this stage, no platelet thrombosis occurs (lane 1). The ultra-large and large multimers are partially depleted when ADAMTS13 is <10% and vWF-platelet aggregation begins to occur (lane 2). The ultra-large multimers are depleted and the large multimers are further decreased or depleted in patients presenting with extensive thrombosis and severe thrombocytopenia (lane 3).

The vWF changes in TTP are a dynamic process, as the multimers in a plasma sample represent a snapshot of the balance of the two changes acting in opposite directions. Transition from one multimer pattern to another occurs swiftly during the course of the disease, reflecting the changes in ADAMTS13 level and the process of vWF-platelet aggregation.

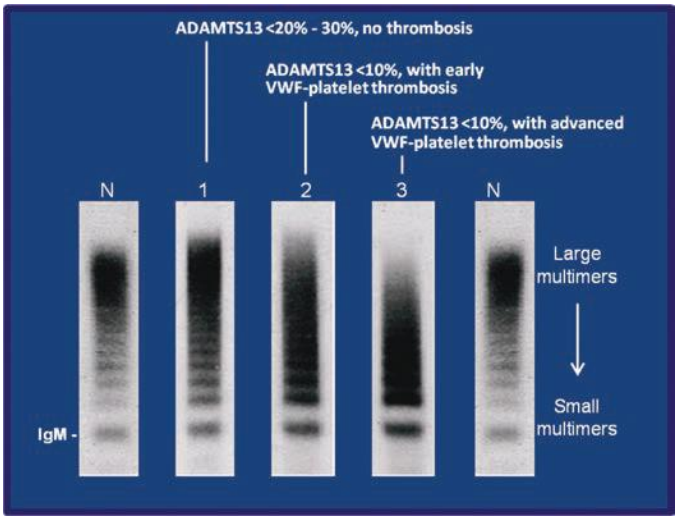

FIGURE 48.6. von Willebrand factor (vWF) abnormalities in thrombotic thrombocytopenic purpura (TTP) reflect the balance of underlying ADAMTS13 deficiency and vWF-platelet thrombosis. Three types of vWF abnormalities are detected in TTP during its course: Lane 1: A shift of vWF to ultra-large forms occurs when ADAMTS13 activity is <20%–30%. Lane 2: The ultra-large and large multimers are decreased when ADAMTS13 is <10%, and vWF-platelet aggregation begins to occur. Lane 3: The ultra-large multimers are depleted and the large multimers are further decreased in patients presenting with extensive thrombosis and severe thrombocytopenia.

In other types of microangiopathic hemolysis such as shiga toxin–associated or atypical HUS, depletion of the large vWF multimers also occurs. In these conditions, the loss of large multimers is due to excessive cleavage of vWF by ADAMTS13 under abnormal shear stress conditions.[7]

Other Pathogenic Mechanisms in Thrombotic Thrombocytopenic Purpura

Various hypotheses have been proposed to explain the thrombosis of TTP, including defects in fibrinolytic activity[25] or prostacyclin homeostasis,[26] increased circulating thrombomodulin, abnormal tissue plasminogen activator or plasminogen activator inhibitor-1 levels,[27] antiendothelial cell antibodies,[28–30] immune complexes,[31] platelet aggregating proteins,[32] anti-CD36 antibodies,[33] calcium-dependent cysteine proteases,[34] endothelial cell apoptotic factors,[35] and activation of the complement system.[36] These observations are preliminary, represent secondary changes, or are not specific for TTP.[37–41] Immune complexes and activation of the complement system detected in patients with TTP may result from ADAMTS13 binding with its antibodies.

Causes of ADAMTS13 Deficiency

Severe ADAMTS13 deficiency results primarily from autoimmune inhibitors of the protease,[42] although in a small number of patients the deficiency is the consequence of homozygous or, more commonly, compound heterozygous mutations of the ADAMTS13 gene.[43]

The ADAMTS13 activity level is also decreased in various pathologic conditions such as sepsis, malarial infection, multiorgan failure, major surgery, DIC, metastatic neoplasm, and pregnancy.[44–49,50,51] In these conditions, the decrease in ADAMTS13 levels is mild to moderate, and generally not sufficient to cause platelet aggregation. Yet the decrease induced by infection, surgery, or pregnancy may be sufficient to precipitate vWF-platelet aggregation and thrombosis in patients with pre-existing ADAMTS13 mutations or inhibitors, giving rise to the suspicion that these conditions cause TTP.

The ADAMTS13 activity is also less stable in pathologic samples, yielding falsely low ADAMTS13 levels if the samples are not properly handled.

Autoimmune Inhibitors of ADAMTS13

In patients with acquired TTP, which accounts for >95% of TTP cases, deficiency of ADAMTS13 results from autoimmune inhibitors of the ADAMTS13 protease.[52] In most cases of acquired TTP the causes of the autoimmunity are unknown. It is speculated that an otherwise innocuous infection may induce autoimmune reaction to ADAMTS13 in genetically susceptible individuals. Indeed 10% to 40% of TTP patients exhibit positive autoimmune reactions to other antigens, suggesting they have defective immune regulation. Deranged immune regulation is consistent with the finding that the HLADRB1*11 allele is overrepresented among patients with acquired TTP.[53]

Ticlopidine therapy increases the risk of developing ADAMTS13 antibodies by 50- to 300-fold.[54,55] The antibodies occur between 2 to 8 weeks after institution of ticlopidine therapy, respond to plasma exchange and discontinuation of the culprit drug, and generally do not recur. Although another anti-platelet thienopyridine, clopidogrel, has also been implicated,[56] an association between clopidogrel and TTP has not been confirmed.

HIV infection has been associated with TTP.[57] It is estimated that the risk is increased by 35-fold among patients not being treated with antiretroviral therapy. This higher risk may be related to the predisposition of HIV-infected individuals to autoimmunity.

An ADAMTS13 polymorphism (R1060W) is reportedly more prevalent in acquired TTP patients than in the population, raising the speculation that certain ADAMTS13 polymorphisms may predispose the affected individuals to develop ADAMTS13 inhibitors.[58] The validity of this association remains to be confirmed.

ADAMTS13 Mutations

DNA sequence analysis reveals that hereditary TTP patients have compound heterozygous or, less commonly, homozygous mutations of the ADAMTS13 gene on chromosome 9q34.[59] More than 80 mutations, including nonsense, missense, frame-shifting insertion or deletion, and splicing mutations, have been detected in patients with hereditary TTP.

Only a few mutations have been detected in seemingly unrelated families. One mutation, 4143insA, has been detected in at least 15 patients in central-northern Europe, Turkey, and Australia that appear to share a common haplotype.[60]

More than 25 polymorphisms have also been detected in the coding sequence of ADAMTS13. One polymorphism, P475S, common among Japanese (5%), Koreans (4%), and Chinese (1%), makes the ADAMTS13 variant more susceptible to inhibition by urea,[61–63] which is used in some ADAMTS13 assays.[64] It yields falsely low ADAMTS13 activity levels if urea-based assays are used.[65] Certain *cis*-combinations of polymorphisms or mutation-polymorphism may result in severe ADAMTS13 deficiency.[66]

Characteristics of the Inhibitors

In most patients the levels of the ADAMTS13 inhibitors are low (<10 U/ml), and often further decrease to undetectable levels after a few weeks or months. Occasionally the inhibitor level may surge to very high levels.

The ADAMTS13 inhibitors of TTP are primarily IgG, with IgA and IgM antibodies detectable infrequently.[67] The VH1-69 germline heavy chain gene appears to be used most frequently in producing the ADAMTS13 antibodies.[68] All four subclasses of IgG have been detected, although IgG4 appears to be the most prevalent, detectable in ≥90% of the patients according to one study.

Targets of the ADAMTS13 Inhibitors

The cysteine-rich region and spacer domain are an integral part of the epitopes of ADAMTS13 reacting with the inhibitors of TTP patients. ADAMTS13 variants truncated upstream of the cysteine-spacer domain, but not those truncated downstream, exhibit markedly decreased but detectable vWF cleaving activity that is not suppressible by the inhibitors of patients with TTP.[69] This decreased activity is consistent with the existence of critical exosites in the deleted domains. Such nonsuppressible ADAMTS13 species may be exploited to overcome the therapeutic difficulty posed by ADAMTS13 inhibitors.

Further mapping studies show that residues R660, Y661, and Y665 in the spacer domain are critical for binding with vWF A2 domain sequences.[70] They are also the target of TTP inhibitors. Substitution of residues Arg660, Tyr661, or Tyr665 in ADAMTS13 with Ala abolishes the binding targets of ADAMTS13 inhibitors. Intriguingly, two vWF variants with substitutions of these three residues exhibit increased vWF cleaving activity by several fold. Such "super" variants of ADAMTS13 may be potential candidates as a replacement therapy for patients with TTP, although immune responses to these foreign proteins may be a concern.[71]

Some studies found that TTP antibodies may also target other epitopes downstream of the spacer domain. However, it remains unclear whether these antibodies contribute to ADAMTS13 deficiency in TTP patients.[72]

Clinical Presentation

The incidence of TTP is estimated to be 2 to 15 cases per 1×10^6 person-years.[3,48,49] The broad range of the observed incidence

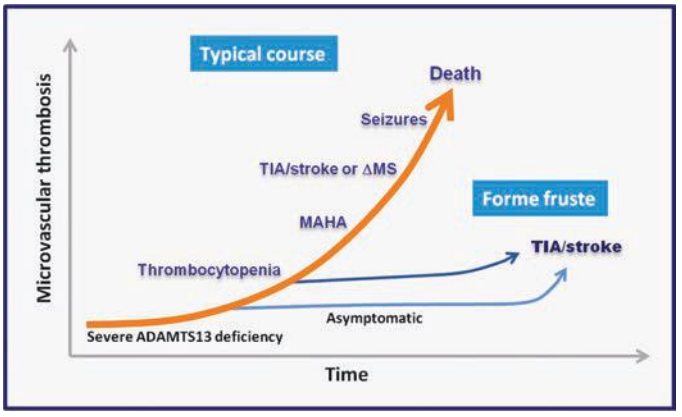

FIGURE 48.7. Progression of thrombotic complications in thrombotic thrombocytopenic purpura (TTP). When ADAMTS13 decreases below the threshold level, microvascular thrombosis begins to occur. In most patients, TTP evolves progressively from ADAMTS13 deficiency to thrombocytopenia, microangiopathic hemolytic anemia (MAHA), fleeting neurologic deficits (TIA), stroke, altered mental status, seizures, and death if it is not treated. Occasionally, a patient may be detected at the thrombocytopenia stage when a CBC is ordered for other reasons. TTP may also present in forme fruste, with microvascular thrombosis causing TIA or stroke before thrombocytopenia or MAHA occurs. ΔMS, altered mental status.

rates is likely due to differences in demographics, particularly the prevalence rate of HIV infection in the population.

Acquired TTP primarily affects adolescents and adults, with median and mode ages between 30 and 40 years, although TTP may occasionally affect children <10 years of age. In most clinical series, the female-to-male ratio is 2 to 3:1.

Many patients present with the triad of thrombocytopenia, microangiopathic hemolytic anemia (MAHA), and neurologic deficits or the triad with fever and renal dysfunction (pentad); neither is invariably present or specific for the diagnosis of TTP. In a typical case, the course of TTP begins with the appearance of ADAMTS13 inhibitors, which progressively decrease the plasma ADAMTS13 level, eventually leading to microvascular thrombosis, thrombocytopenia, microangiopathic hemolysis, and organ dysfunction (Fig. 48.7).

The duration of asymptomatic ADAMTS13 deficiency is quite variable, ranging from a few days to years. Serial monitoring of patients with a history of acquired TTP suggests that the plasma ADAMTS13 activity level may fluctuate for weeks to months before decreasing to less than 10% of normal and causing thrombosis. Thrombocytopenia is detectable when platelet consumption exceeds compensatory platelet production.

The stage of thrombocytopenia without overt hemolytic anemia may last for days to months, and the course of TTP at this stage is not invariably downhill; some patients may spontaneously revert to a normal platelet count. The patients at this stage may be given the incorrect diagnosis of immune thrombocytopenic purpura (ITP). On the other hand, infection, surgery, or pregnancy may worsen microvascular thrombosis in patients with subclinical ADAMTS13 deficiency, giving rise to the clinical impression that TTP is triggered by these events. Neurologic complications typically, albeit not invariably, present later, when thrombocytopenia is profound and microangiopathic hemolysis is evident.

Most of the patients have no other significant medical history and begin to notice ill-defined symptoms such as headache, dizziness, and fatigue that are often considered insignificant until more serious complications such as profound fatigue, focal neurologic deficits, syncope, mental status changes, or seizures ensue. Less frequently, a patient may present with abdominal pain, nausea, and vomiting, with or without pancreatitis, or chest pain due to myocardial infarction, or even sudden death.

Advanced renal failure causing oliguria, anuria, fluid retention, electrolyte abnormalities, or uremia is rare in acquired TTP. The creatinine generally increases only minimally. When advanced renal failure occurs in a patient with acquired TTP, it is likely due to other causes.

Thrombotic Thrombocytopenic Purpura without Microangiopathic Hemolysis or Thrombocytopenia

Thrombocytopenia and microangiopathic hemolysis are not invariably present at the time of acute presentation (Fig. 48.7). Relapse of TTP is also increasingly diagnosed before microangiopathic hemolysis ensues.

Until recently, TTP presenting with acute stroke or transient ischemic attack without overt microangiopathic hemolysis was diagnosed only in retrospect after the patients went on to develop thrombocytopenia and microangiopathic hemolysis. ADAMTS13 assays greatly facilitate the diagnosis of atypical TTP.

Hereditary Thrombotic Thrombocytopenic Purpura

Also known as Schulman-Upshaw syndrome or chronic relapsing TTP, hereditary TTP is rare, accounting for <5% of all TTP cases.[73,74] Because the diagnosis is not recognized in milder cases, the incidence is likely higher than presently appreciated.[75]

Hereditary TTP typically has its initial manifestations during the neonatal period, but historically is often not recognized until later in life.[76,77] Some of these patients have siblings who died before birth presumably due to TTP complications. Milder cases may present with thrombotic complications or have their disease recognized later in their life.[76–78]

In a typical case, the affected neonate is born with meconium stain or presents within a few hours after birth with neonatal distress, jaundice, and thrombocytopenia. Hemolysis may not be severe and schistocytes on blood smears may be overlooked. Occasionally, serious complications such as seizures and mental obtundation may occur.

The symptoms typically improve immediately after blood transfusion or exchange transfusion performed unknowingly for thrombocytopenia or hyperbilirubinemia. Consequently, the neonates may be discharged from the hospital without a correct diagnosis, only to present with complications of the disease weeks or years later.

Like most genetic disorders, hereditary TTP varies in its severity. Many patients with hereditary TTP invariably develop hematologic or other complications if not treated regularly with plasma infusion every 2 to 4 weeks. Others have no or only subtle symptoms and maintain normal or mildly subnormal platelet counts and develop more serious complications only intermittently. The severity may also vary during the lifetime of individual cases, with or without apparent exacerbating conditions such as pregnancy.

The thrombotic process may cause focal neurologic deficits, seizures, pancreatitis, or renal failure.[79,80] Of the patients not receiving regular plasma infusion, 10%–20% of the cases develop at least one episode of acute renal failure requiring dialysis during their course. The renal failure is reversible if the patients promptly receive plasma infusion. Chronic renal failure occurs in approximately 10% of the patients not being regularly treated with plasma infusion, likely a result of cumulative microinfarcts in the kidney.

The propensity to acute and chronic renal disease in hereditary TTP is quite different from its rarity in acquired TTP. It is speculated that local expression of ADAMTS13 in renal glomerular podocytes and endothelial cells[20] may provide protection against vWF-platelet aggregation before its activity is suppressed by the inhibitors. Such protection is not present in patients with genetic ADAMTS13 mutations. Rarely renal failure may occur because the patient also has concurrent atypical HUS.[81]

Laboratory Findings

In de novo TTP cases presenting at the emergency service, the diagnosis is typically raised by the laboratory findings of severe

thrombocytopenia and hemolysis with the presence of schistocytes on blood smears. The haptoglobin level is decreased or undetectable. Other common laboratory tests for assessment of hemolysis, including reticulocyte count, LDH, and indirect bilirubin are often but not invariably abnormal. In chronic cases, hemolytic anemia may predominate, as active platelet consumption is masked by compensatory thrombopoiesis.

As mentioned above, a patient with TTP may have no symptoms or may present with acute focal neurologic deficits without thrombocytopenia and/or microangiopathic hemolysis. Therefore, absence of thrombocytopenia or microangiopathic hemolysis in laboratory tests does not exclude the diagnosis of TTP.

Hematuria and proteinuria reflect renal glomerular thrombosis. The increase in the creatinine level is minimal in most cases. This is consistent with the pathologic findings that the kidney is minimally affected and its architecture is well preserved in TTP patients at autopsy.

Overt renal failure causing hypertension, fluid retention, electrolyte derangement, oliguria, or anuria favors the diagnosis of typical or atypical HUS over autoimmune TTP, unless there is a concurrent renal disorder. As mentioned above, acute and chronic renal failure may occur in patients with hereditary TTP.

Imaging studies such as CT or MRI are often requested for neurologic dysfunction. In most cases, the studies yield negative results or reveal only subtle ischemic changes, although occasionally a TTP patient may present with macrovascular ischemic strokes detectable by conventional imaging studies. It is speculated that in such cases the macrovascular thrombosis may result from thrombotic injury of the vasa vasorum.

The literature includes reports of "TTP" case series with a high percentage showing abnormal CT or MRI findings. However, a review of cases in these reports reveals that most of these patients likely had typical or atypical HUS rather than TTP.

Abnormal electrocardiograms with nonspecific ST-T wave changes and elevated CPK or troponin levels are common. Occasionally thrombosis may affect large coronary arteries leading to myocardial infarction. Cardiac arrhythmia is uncommon. Electromechanical dissociation, heart failure, or pulmonary infiltrates or hemorrhage occur in advanced, pre-terminal cases.

The amylase and lipase levels may be elevated. Abnormal liver function is rare. Abdominal CT scans may detect focal pancreatitis, intestinal wall or mesenteric thickening, or stranding due to ischemia or infarction.

ADAMTS13 Activity Levels

Among patients presenting with thrombocytopenia and microangiopathic hemolysis, only TTP patients have severe ADAMTS13 deficiency (less than 10%), whereas patients with other disorders have detectable ADAMTS13 levels (Fig. 48.8). ADAMTS13 may be detectable if the assay is performed after the patients receive plasma or blood transfusions. The ADAMTS13 activity level remains decreased in most patients during their remission, suggesting that the autoimmunity is active. Severe ADAMTS13 deficiency provides the diagnosis of TTP in the patients with comorbidities in whom the diagnosis would otherwise be difficult to make.

The assay used to obtain the data presented in Figure 48.8 uses purified vWF as the substrate and SDS-PAGE to detect the proteolytic products. This assay is technically demanding and not practical for use in clinical laboratories. Various assays using vWF peptides spanning the scissile bond have been developed for analysis of ADAMTS13 activity in clinical laboratories. The assays differ in their performance and reliability and may not provide a definitive diagnosis or exclusion of TTP.[82,83,84–88]

Because some clinical assays may yield falsely high or low values of ADAMTS13, the diagnosis of TTP requires corroboration of the ADAMTS13 test results with clinical and other laboratory data.

ADAMTS13 Inhibitors

Inhibitors of ADAMTS13, measured by mixing patient and normal plasma samples, are detectable in 80% to 90% of the acquired TTP patients. A negative test for ADAMTS13 inhibitors does not exclude the presence of ADAMTS13 inhibitors. In such patients, the presence of inhibitors may be inferred if the increase of the ADAMTS13 activity level is less than expected after plasma therapy, or if the ADAMTS13 activity recovered to >10% during remission.

ADAMTS13 Antibody and Antigen Assays

Assays have been developed to measure ADAMTS13 antigen and antibody levels in enzyme-linked assay formats. These solid-phase microtiter plate-based assays have limited utility in practice. The antigenic assay detects free ADAMTS13 as well as ADAMTS13/

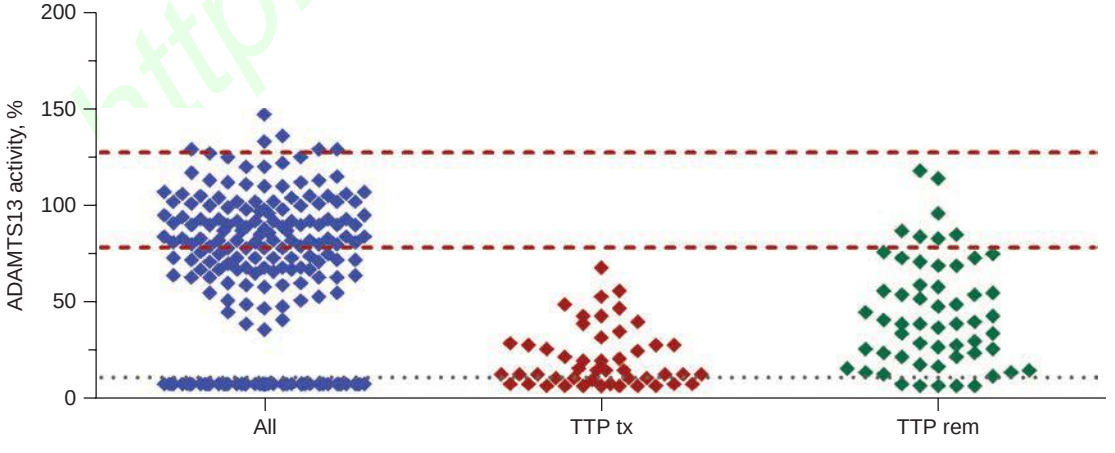

FIGURE 48.8. Plasma ADAMTS13 activity is undetectable in patients with thrombotic thrombocytopenic purpura (TTP). Patients (338 cases) presenting with thrombocytopenia and microangiopathic hemolysis segregate in two nonoverlapping groups based on their plasma ADAMTS13 activity levels. Severe ADAMTS13 deficiency defines the diagnosis of TTP in 219 patients (65%), of which 191 had autoimmune ADAMTS13 inhibitors and 28 had genetic mutation as the cause of the deficiency. ADAMTS13 activity is detectable in some patients after receiving plasma or blood transfusion (TTP tx). During remission, (TTP rem) most patients continue to have decreased ADAMTS13 activity levels, consistent with the chronic nature of their disease. The two upper dashed lines encompass the normal range of plasma ADAMTS13 activity. The lowest line marks the detection limit of the assay at 10%.

inhibitor complex, yielding low ADAMTS13 antigen levels in <50% of TTP patients.[89] The ADAMTS13 antibody assay is highly sensitive (>90%) for acquired TTP but may yield false-positive results in 5% to 10% of individuals without ADAMTS13 antibodies.[90,91]

ADAMTS13 Activity Levels during Plasma Therapy and Remission

ADAMTS13 activity assays are used not only for initial diagnosis of TTP, but are also used to assist management during plasma therapy and clinical remission.[43]

In general, vWF-platelet aggregation does not occur when ADAMTS13 activity is >10% of normal. Thus, in a patient with persistent thrombocytopenia or declining platelet counts, an ADAMTS13 activity >10% of normal, either at initial presentation or during plasma therapy, precludes TTP as the cause of the low platelet count, and requires a search for other causes.

At the end of plasma therapy and during remission, persistently low (<10%) or steadily declining ADAMTS13 levels connote a high risk of immediate or impending relapse.

Hereditary Thrombotic Thrombocytopenic Purpura

The ADAMTS13 activity level should be ≤10% and the inhibitor and antibody tests should be negative in patients with hereditary TTP. Falsely-positive antibody results may cause confusion. Improvement of the ADAMTS13 level to greater than 10% during remission excludes the diagnosis of acquired TTP.

Familial studies may be performed to show that the parents have partial ADAMTS13 deficiency.[59] In practice, familial studies may be limited in the power to distinguish carriers from normal individuals.

Differential Diagnosis

Although the diagnosis of TTP depends on the demonstration of severe ADAMTS13 deficiency, it is essential to exclude other causes of microangiopathic hemolysis as listed in Table 48.1. On the other hand, the presence of a co-morbidity does not preclude the diagnosis of TTP.

A complete history and physical examination should be accompanied by appropriate laboratory tests such as ELISA or PCR tests for shiga toxins in the stool; blood or viral cultures or PCR analysis for pneumococcal or other bacterial or viral infections; autoimmune serology tests for lupus, scleroderma, and related autoimmune disorders; coagulation profile such as PT, PTT, fibrinogen, D-dimer assays, and additional clotting factor assays for disseminated intravascular coagulopathy; MRI for mental status changes; CT scan or other imaging studies and tissue biopsies for metastatic neoplasm; and flow cytometry for paroxysmal nocturnal hemoglobinuria.

Advanced renal failure, hypertension, and complications of abnormal vascular permeability such as brain edema, pleural or pericardial effusions, pulmonary edema, acute respiratory distress syndrome, ascites, and anasarca are rare in TTP. Any of these complications at presentation or during the course favors the diagnosis of thrombotic microangiopathy due to atypical HUS or other etiologies.

Management and Prognosis

Prompt plasma exchange is critical to prevent serious complications or death from TTP. The principles of management for patients with TTP are summarized in Table 48.2.

Plasma Therapy

Before plasma exchange or infusion was introduced in the 1970s,[92,93] more than 90% of patients died after presenting with symptomatic TTP. Plasma exchange and plasma infusion are the only therapies with proven efficacy for TTP presenting with thrombocytopenia and microangiopathic hemolysis.[2] With these treatments, a mortality rate of 10% to 20% and 40% to 50% is expected, respectively.

Plasma exchange is typically performed daily at 1–1.5 total plasma volumes until the platelet count is normal, then gradually tapered to ensure the platelet count is stable before the therapy is discontinued. It is believed that plasma exchange therapy removes antibodies and replenishes the deficient ADAMTS13.

Serial analysis shows that the plasma ADAMTS13 activity level often fluctuates in the first several weeks before it gradually stabilizes to a steady-state level. This explains why the response to plasma therapy may be unsteady for weeks to months and why it is important to monitor the blood counts closely after plasma exchange therapy is tapered.

ADAMTS13 levels persistently less than 10% of normal at the end of plasma therapy indicate a high risk of early relapse. On the other hand, a measurable ADAMTS13 level at the end of plasma therapy does not preclude the possibility that levels will subsequently decrease and cause later relapse. Thus, serial ADAMTS13 analysis is more informative than single tests.

Plasma infusion has the advantage that it does not require a large venous catheter and special equipment. Its efficacy is limited by the risk of fluid overload. Plasma infusion is used primarily as an emergent substitute until plasma exchange is instituted.

Cryoprecipitate-depleted plasma has been advocated as a more effective alternative of fresh-frozen plasma because it lacks large vWF multimers.[94,95] However, two small randomized-controlled trials failed to demonstrate that the use of cryoprecipitate-depleted plasma is superior to fresh-frozen plasma as initial replacement therapy.[96,97]

TABLE 48.2

PRINCIPLES OF MANAGEMENT FOR THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP)

- High index of suspicion is essential for patients presenting with thrombocytopenia or TIA/stroke.
  - Some patients may not have thrombocytopenia or microangiopathic hemolysis at presentation.
- Prompt treatment is critical to prevent serious complications and death.
- Daily plasma exchange is the therapy of choice for acquired TTP presenting with active thrombosis.
- Plasma infusion is used as an emergent substitute until plasma exchange is available.
- ADAMTS13 activity assay should be obtained before the patients receive any blood products.
- The diagnosis should be re-assessed during the course of therapy.
- Monitoring of ADAMTS13 during plasma therapy and remission may help clinical assessment.
  - For patients with persistent thrombocytopenia, ADAMTS13 >10% should suggest other causes of thrombocytopenia.
  - Monthly ADAMTS13 monitoring may detect impending relapses.
- Rituximab therapy should be considered for patients
  - Unable to wean off plasma exchange due to persistent and severe ADAMTS13 deficiency.
  - With persistent and severe ADAMTS13 deficiency during clinical remission.
  - Exhibiting a trend of declining ADAMTS13 levels.
- Hereditary TTP
  - Plasma infusion is effective for patients presenting with acute symptoms.
  - Plasma exchange is used if the patient has renal failure or fluid overload.
  - For most patients, plasma therapy every 2–3 wk prevents acute crisis, strokes, and renal failure.

Acquired TTP is a chronic autoimmune disease punctuated with episodes of acute exacerbation. The ADAMTS13 level during clinical remission is quite variable, ranging from normal to undetectable. Normal ADAMTS13 activity levels during remission do not preclude the risk of future relapses. Serial monitoring may detect trends of declining ADAMTS13 levels before the patients develop symptomatic relapses, providing a window for immunosuppressive intervention before a relapse occurs.[43]

Immunosuppressive Therapy

Plasma therapy does not address the underlying ADAMTS13 autoimmunity of TTP. Patients are able to achieve sustained remission primarily because the inhibitors spontaneously decrease, allowing the recovery of the ADAMTS13 activity above the threshold level. Nearly all patients will experience at least one relapse in their later lives. Some patients develop refractory disease after years of quiescent periods or several sporadic relapses.

For patients who cannot be weaned off plasma exchange due to persistent ADAMTS13 deficiency, suppression of B-cells with rituximab, a chimeric monoclonal antibody to CD20, induces clinical remission in approximately 70% to 90% of the patients.[98,99–101] Rituximab increases the ADAMTS13 level by suppressing, but not necessarily eliminating, the ADAMTS13 inhibitors. A small increase in the ADAMTS13 activity level to 10% or higher is sufficient to induce clinical remission, allowing the patient to be weaned off plasma therapy. Rituximab is less effective in patients with high ADAMTS13 inhibitor levels.

Rituximab may decrease the risk of immediate relapse in patients with severe ADAMTS13 deficiency entering or during remission.[102,103,104,105] It may also be used pre-emptively to avert relapses in patients exhibiting a trend of declining ADAMTS13 activity levels during remission.[43] The efficacy of rituximab lasts for several months to a few years, with a median remission duration ~1.5 years. Patients may be re-treated with rituximab when their plasma ADAMTS13 activity begins to show a steady decline. The major side effects of rituximab include allergic reaction and reactivation or exacerbation of viral infections such as hepatitis B and progressive multifocal leukoencephalopathy.

Cyclosporin may be efficacious, but the experience of using cyclosporine in TTP patients remains limited.[106] Splenectomy, which decreases the number of B-cells and immunocytes, has been recommended for patients unable to be weaned off plasma exchange or who experience frequent relapses.[107] With rituximab demonstrating high response rates, splenectomy is performed less frequently. Other immunosuppressive therapies that have been used in TTP include corticosteroids, vincristine, cyclophosphamide, and azathioprine. These therapies are generally less effective than rituximab and more likely to cause serious side effects.

Antiplatelet Agents

For most patients, adding antiplatelet drugs such as aspirin, dipyridamole, ticlopidine, or clopidogrel is unlikely to improve the response to plasma therapy. These drugs may prevent relapses in patients whose ADAMTS13 levels are low enough to cause platelet thrombosis. Nevertheless, the response to antiplatelet therapy is unreliable.

Hereditary Thrombotic Thrombocytopenic Purpura

Hereditary TTP responds to 7.5–10 ml fresh-frozen plasma per kilogram of body weight. Plasma exchange therapy is reserved for patients with renal failure. Inasmuch as thrombotic complications are unpredictable and may result in serious sequelae such as chronic renal failure or strokes, maintenance plasma therapy is recommended for most patients with hereditary TTP. The regimen should be tailored to prevent not only acute symptomatic crisis but also the development or progression of chronic organ injury. To achieve these goals, maintenance of normal platelet counts is recommended. Most patients require fresh-frozen plasma every 2 weeks to achieve and maintain normal platelet counts and prevent acute exacerbations. For patients not receiving maintenance therapy, serial monitoring of CBC, renal function, and urinalysis is recommended.

Special Considerations: Thrombotic Thrombocytopenic Purpura in Pregnancy

An association between pregnancy and TTP has been suspected, but never confirmed. Because TTP affects women in their reproductive years, it may occur co-incidentally during pregnancy. Patients presenting with TTP during pregnancy should be treated as other patients with plasma exchange, and with tapering of the treatment to be guided by serial ADAMTS13 levels.

A more difficult challenge is counseling and management of women with a history of TTP who desire pregnancy. Pregnancy progressively decreases ADAMTS13 levels by 30% at term, and by nearly 65% if the pregnancy is complicated with preeclampsia or the HELLP (hemolyis, elevated liver enzymes, and low platelet count) syndrome. Pregnancy also increases plasma vWF levels. Therefore, pregnancy may lead to exacerbation of TTP in patients with pre-existing ADAMTS13 deficiency. Microvascular thrombosis increases maternal and fetal morbidity and mortality, and therefore every effort should be made to prevent thrombosis and thrombocytopenia during pregnancy.

For women with a history of acquired TTP and low ADAMTS13 levels during their remission, pregnancy is not advised, as it involves real risks that cannot be reliably predicted or easily managed. ADAMTS13 levels may decrease to cause maternal TTP relapses. It may also cause fetal complications without overt maternal relapses.

If pregnancy is inevitable, rituximab may be an option to pre-emptively increase ADAMTS13 levels before pregnancy occurs. Rituximab is a class C drug for pregnancy, based on the adverse effect of lymphocytopenia observed in animal reproductive studies. In theory, its deleterious effects may last for 12 months. There are no adequate and well-controlled studies in humans. Rituximab use during pregnancy has been reported in a woman without causing adverse consequences. Thus, potential benefits may warrant use of the drug in pregnant women despite the theoretical risks.

Serial monitoring of ADAMTS13 levels is essential in pregnant patients. If ADAMTS13 exhibits a trend of decrease toward 10% of normal, pre-emptive plasma exchange or infusion therapy is used to prevent TTP relapses and fetal complications.

Patients with genetic ADAMTS13 mutations should receive adequate maintenance plasma therapy titrated to prevent thrombocytopenia and thrombosis. Some women with milder forms of hereditary TTP may become pregnant without knowing the diagnosis of the disease. These patients may develop thrombocytopenia that is often incorrectly attributed to immune thrombocytopenia or gestational thrombocytopenia, only to develop TTP exacerbation or fetal complications as the pregnancy progresses. A positive family history, a high index of suspicion, and liberal use of ADAMTS13 assays may help identify such patients for correct diagnosis and management.

Novel Therapeutic Modalities

Recombinant ADAMTS13 is under development for replacing deficient ADAMTS13 in patients with TTP. Truncated variants of ADAMTS13 or variants with substitutions at the residues critical for interaction with inhibitors may circumvent the difficulties posed by inhibitors. However, immunogenicity is a concern for variant ADAMTS13 molecules with substituted amino acid.

N-acetylcysteine, presently used for acetaminophen liver toxicity and chronic lung disease, decreases the size of vWF by reducing the disulfide bonds of vWF multimers.[108] It may be an attractive therapy for TTP if its vWF-reducing activity is confirmed in human subjects.

Inhibitors of vWF-platelet aggregation such as the anti-vWF aptamer ARC1779[107] or nanobody ALX-0081[109] may prevent microvascular thrombosis in TTP patients. These drugs may best serve as a short-term measure to prevent serious complications or death before ADAMTS13 levels are raised by plasma replacement therapy or rituximab.

SHIGA TOXIN–ASSOCIATED HEMOLYTIC-UREMIC SYNDROME

First described by Gasser et al. in 1955,[110] typical HUS refers to the constellation of renal failure, microangiopathic hemolysis, and thrombocytopenia following a bout of hemorrhagic diarrhea. This is a relatively uncommon disease but often draws public attention during outbreaks of food-borne illness.

Etiology

It is estimated that approximately 90% of North American and European children with HUS have infection with shiga toxin–producing *E. coli* (STEC) of the enterohemorrhagic serotype, typically serotype O157:H7. In the United States, approximately 4,000 cases of *E. coli* O157:H7 infections are diagnosed annually, with 15% of them developing the complication of HUS. STEC of non-O157 serotypes and even *Shigella dysenteriae* serotype I have also been implicated in causing HUS.

The offending organisms share the capacity of producing powerful shiga toxins, which are encoded by phage DNA and comprise several genotypes.[111] Most HUS cases are caused by shiga toxin genotype 2 or 1+2. With more laboratories conducting the shiga toxin assays, increasing numbers of non-O157 *E. coli* serotypes such as O26:H11, O103:H2, O111:H8, and O145:H28 are detected.

Enteropathogenic *E. coli* has a reservoir in bovine intestine and is transmitted by meat, milk, or water contaminated with ruminant feces. Most cases of shiga toxin–associated HUS result from ingestion of contaminated food such as beef, leafy vegetables, dairy, fruits, nuts, sprouts, poultry, or water. Other modes of transmission include direct animal contact and person-to-person contact during the acute diarrheal phase. Very low infectious doses (<100 organisms) are sufficient to cause clinical disease. Outbreaks account for only 20% of the cases. Approximately 50% of the cases occur during the summer months.

The outbreaks in Germany, France, and other countries in 2011 were due to contamination with *E. coli* O104:H4, which evolved from an unusual progenitor of enteroaggregative *E. coli* through acquisition of a stx2-encoding prophage and a plasmid encoding a CTX-M-15 extended-spectrum beta-lactamase (ESBL) gene.[112,113,114,115]

Many strains of STEC have not been associated with hemorrhagic diarrhea or HUS, indicating that other virulence factors of the organisms are also critical for pathogenesis. The expression of additional genes on a chromosomal locus of enterocyte effacement pathogenicity island, including intimin encoded by the *eae* gene for intimin attachment, has a strong association with the risk of HUS.[116]

STEC is one of the surveillance infections conducted by the Foodborne Disease Active Surveillance Network (FoodNet).

Pathology

The pathology of shiga toxin–associated HUS is quite different from that of TTP, as it is dominated by glomerular endothelial cell swelling or necrosis and subendothelial expansion in the kidney.[117,118] Fibrin-platelet thrombi are commonly present in glomerular loops and hila and may be seen extending into small and medium-sized arteries, including the interlobular arteries (Fig. 48.2C). Neutrophil infiltration may be present. Extensive thrombosis may result in renal cortical infarcts.

Other organs such as brain, heart, intestinal tract, and pancreas may also be affected, either with edema due to abnormal vascular permeability or with ischemic injury due to microvascular stenosis or thrombosis.

Pathophysiology

It is believed that injury of the kidney and other organs is a consequence of the cytotoxic effect of shiga toxins on vascular endothelial cells.[119,120,121] A shiga toxin molecule comprises an A-subunit and a pentameric B-subunit. The shiga toxin molecule binds via its B-subunit to globotriaosylceramide (Gb3) expressed on the membrane lipid rafts of renal microvascular endothelial or other target cells. This binding is followed by internalization of the A-subunit via endocytosis. After proteolysis, a smaller fragment of the A-subunit is generated that is capable of disrupting the 60s ribosomes, blocking protein synthesis in the target cells. The sensitivity of endothelial cells may be enhanced by cytokines such as IL-1 and TNF-α released in response to endotoxins.

Additional studies suggest that shiga toxins may also alter the expression of vasoactive factors (e.g., endothelin and nitric oxide) and adhesive proteins (e.g., vWF, $\alpha_v\beta_3$, PCAM-1, and P-selectin), or activate the alternative complement pathway.[122,123,124,125] However, it is not clear whether the high concentrations of shiga toxins used in these studies are pathophysiologically relevant.

The cytotoxicity of shiga toxins leads to endothelial cell swelling, abnormal vascular permeability, and cell death. Endothelial cell disruption exposes the underlying thrombogenic glomerular basement membrane, triggering the activation of the coagulation cascade and subsequent thrombosis. Thrombosis leads to ischemic organ injury, thrombocytopenia, and abnormal shear stress causing red cell fragmentation. Vascular stenosis may also result from endothelial swelling and subendothelial expansion, causing tissue ischemia and red cell fragmentation without increasing platelet consumption. The microangiopathy may also increase vascular permeability, leading to brain edema, pleural or pericardial effusion, ascites, mesenteric or intestinal edema, and anasarca that do not correlate with thrombocytopenia or microangiopathic hemolysis.

Clinical Presentation

There is a spectrum of illness following ingestion of STEC, ranging from no symptoms to self-limited gastroenteritis, the HUS and death.

Symptomatic STEC infection leads to HUS in up to 15% of cases.[111,126] Diarrhea and other gastrointestinal symptoms develop between 2 and 12 days after ingestion of pathogenic *E. coli*. Bloody diarrhea develops 1 to 3 days later.

Symptoms and signs of HUS begin to manifest as the diarrhea begins to improve. Risk factors for HUS after infection with shiga toxin–producing *E. coli* include young or old age, long duration of diarrhea, elevated leukocyte count, antimicrobial or antidiarrheal drug use, and bloody diarrhea.[127]

The onset of hemolysis and renal failure may be dramatic, with sudden pallor, abdominal pain, vomiting, and the appearance of dark-red or nearly black urine. These manifestations may quickly lead to oliguria or even anuria. On the other hand, mild or incomplete HUS with thrombocytopenia but no anemia or azotemia is almost as frequent as the complete form of HUS.

Extrarenal complications occur in approximately 50% of patients, and may include pancreatitis, glucose intolerance,

colonic necrosis and perforation, myocardial infarction, congestive heart failure, pericardial or pleural effusion, and acute respiratory distress syndrome.[128]

Neurologic complications including irritability, confusion, transient paralysis, seizures, and coma are the most serious and often result from cerebral edema of thrombotic microangiopathy. Hemorrhagic or thrombotic stroke is quite infrequent. Elderly individuals, especially frail nursing home residents, are more likely to experience cardiovascular and neurologic complications and death.[129]

Laboratory Findings

Hematologic findings are similar to those of TTP, although the severity of thrombocytopenia is more variable and does not always reflect the severity of the clinical status. The anemia often is severe and may be accompanied by moderate polymorphonuclear leukocytosis. Hemoglobinemia may be marked. The prothrombin time and partial thromboplastin time usually are normal or minimally prolonged; fibrin degradation products or D-dimer tests are frequently elevated.[130] Serum haptoglobin levels are typically undetectable. The bilirubin level is usually elevated. The liver transaminases and amylase may also be elevated.[131] The blood urea nitrogen and serum creatinine levels may be quite high. The urine usually contains hemoglobin and hemosiderin in addition to albumin. Microscopically, erythrocytes, leukocytes, and casts are seen.

CT and MRI studies of the brain in patients with neurologic complications may reveal various abnormalities including restricted water diffusion; edema or posterior reversible encephalopathy syndrome (PRES); contrast enhancement; or hemorrhage in the basal ganglia, thalamus, cerebellum, or brainstem.[132] The lesions are most commonly due to abnormal vascular permeability and may resolve on follow-up examinations and are not necessarily associated with a poor long-term neurologic outcome. Similar lesions are also often detected in patients with atypical HUS.

With perhaps rare exception, patients with shiga toxin–associated HUS have normal or slightly decreased ADAMTS13 activity levels and no inhibitory antibodies.[7] Large vWF multimers may be decreased as abnormal shear stress in the microcirculation augments proteolysis of vWF by ADAMTS13.[7]

Diagnosis, Management, and Prognosis

Conventionally, *E. coli* O157:H7 is detected by plating fresh feces on sorbitol–MacConkey agar. Direct detection of shiga toxins by ELISA or PCR analysis is more sensitive and also detects non-O157:H7 serotypes.[133]

No specific treatment is available for shiga toxin–associated HUS. Early and careful management of acute renal failure and hypertension and the judicious use of packed red cell transfusions appear to constitute the safest and most effective approach to the management of HUS in children.

Plasma therapy is of no or little benefit in children.[134] Because of the excellent results achieved in the treatment of TTP and difficulty in distinguishing HUS from TTP, adult patients are often treated with plasma exchange, although evidence in support of this practice remains circumstantial.[135]

Recently, based on laboratory observations of complement activation by shiga toxin and endothelial P-selectin,[122] eculizumab, a humanized monoclonal antibody of C5 originally approved for patients with paroxysmal nocturnal hemoglobinuria and aHUS, was used in three patients with severe shiga toxin–associated HUS.[136] The patients promptly improved. This could represent a major therapeutic advance if its efficacy is reproduced in other trials.

Certain antibiotics such as ciprofloxacin may induce the expression of shiga toxins.[126,137,138] Antibiotic usage increases the risk of HUS following *E. coli* O157:H7 infection.[139] Until future investigation shows otherwise, bactericidal antibiotics and antimotility drugs should be avoided in patients with shiga toxin–associated colitis.

Approximately 50% of patients with shiga toxin–associated HUS require dialysis. The usual indications for dialysis support include fluid overload unresponsive to diuretics, a rapidly rising creatinine value, anuria for more than 24 hours, severe electrolyte imbalance, and serious clinical signs of uremia.

Direct person-to-person transmission occurs during the acute diarrheal phase. In some cases, excretion of the microorganisms may persist for several months. Contact isolation and frequent hand washing are recommended to minimize the spread of infection.

The overall mortality in children with epidemic HUS is 12% (range 0 to 30%). The majority of patients recover without serious consequences. Long-term renal injury such as decreased glomerular filtration rate, proteinuria, hypertension, or renal failure may be present in as many as 1 of every 4 survivors.[140,141] However, this risk is quite variable. Some patients may develop irritable bowel syndrome.[142] Young women may also be at higher risk of pregnancy-related hypertension, presumably due to subclinical kidney injury.[143] A few patients may require long-term dialysis or renal transplantation therapy. Shiga toxin–associated HUS is not expected to recur following renal graft transplantation.

ATYPICAL HEMOLYTIC–UREMIC SYNDROME

aHUS originally referred to the constellation of acute renal failure, microangiopathic hemolysis, and thrombocytopenia in children without a prodrome of hemorrhagic diarrhea or another apparent cause. It is now recognized that aHUS may present in adults as frequently as in children, although most of the adult patients have been given the diagnosis of TTP. Most patients with aHUS have defects in regulating the alternative complement pathway.[144] Defective complement regulation is also found in women with pregnancy-associated aHUS.[145] Preliminary evidence suggests that some of the patients with other co-morbidities such as bone marrow/hematopoietic stem cell transplantation also have defective regulation of the alternative complement pathway.[144] In such patients, aHUS is believed to be induced by the co-morbidity. In addition, severe hypertension may be a complication of aHUS instead of a cause of microangiopathic hemolysis as previously believed.

Because of overlapping clinical features, aHUS is not distinguished from TTP in many reports. In fact, most patients with the so-called "TTP without severe ADAMTS13 deficiency" really have aHUS instead of TTP. Interpretation of reports in the literature is difficult when the case definitions do not provide a clear distinction between TTP and aHUS. A comparison of the distinctive features of TTP and aHUS is summarized in Table 48.3.

Pathology

Although aHUS and TTP share the common features of thrombocytopenia and microangiopathic hemolysis, they are quite different pathologically.

In aHUS, the affected glomerular capillaries, arterioles, and interlobular small arteries typically exhibit endothelial cell swelling or death and subendothelial expansion due to edema and/or hypercellularity, often but not invariably accompanied by thrombosis.[146] The glomerular tufts may show mesangiolysis. Late changes may show double basement membranes, mesangial cell proliferation with expansion of the matrix and interstitial fibrosis. The lesions often include admixtures of acute and chronic changes (Fig. 48.2D–F). The prominence of chronic changes in

patients at their first presentation suggests antecedent subclinical injury.

The pathology of thrombotic microangiopathy may also be demonstrable, albeit less conspicuously, in other organs. More common is tissue edema in the brain, lung, gastrointestinal tract, mesentery and cutaneous soft tissues. Fluid accumulation may be present in the pericardial, alveolar, pleural, or peritoneal space. These changes result from abnormal vascular permeability and are uncommon in patients with TTP.

Molecular Pathogenesis

The complement system, an important part of the innate host defense against invading microorganisms, may be triggered by immune complexes or microbial lectins. The alternative pathway, via complement factors B, D, and P, amplifies complement activation by promoting the generation of alternative C3b and C5b convertases (Fig. 48.9). Complement factor H (CFH), factor I (CFI), membrane cofactor protein (MCP, or CD46), thrombomodulin (THBD), and possibly complement factor H-related proteins 1–5 (CFHR1–5) are involved in regulating self-perpetuating complement activation.

Genetic mutations of the alternative complement activators or regulators have been found in approximately 50% of aHUS patients, with a higher prevalence among patients with a family history (75%) than in patients without a family history (40%). The molecular defects include inactivating mutations of CFH (25%), MCP, CFI, and THBD (5% to 10% each); gain-of-function mutations of activators C3 (5% to 10%) and CFB (a few pedigrees).[144,147,148] Additionally, antibodies to CFH are detected in 5% to 10% of the cases, often with concurrent homozygous or heterozygous genomic deletion of CFHR1.[149,150]

The genetics of aHUS are more complex than involvement of single genes. Compound mutations are present in 10% or more of the patients. Atypical HUS may only develop in patients with more than one variant of the activators or regulators.[151] Analysis of single nucleotide polymorphisms (SNP) of complement activators and regulators demonstrates that the risk of aHUS is significantly increased or decreased with certain SNPs and haplotypes of CFH, CD46, CFHR2, CFHR4, and intergenic CR1-CD46.[152] Laboratory studies have demonstrated that certain combinations of common variants (complotype) of the complement activators and regulators increase the risk of the disease.[153]

Complement factor H-related proteins 1–5 (CFHR1–5) are the products of a series of genes located immediately downstream of the CFH gene, that are mapped to a region of chromosome 1q containing multiple retrotransposon sequences. Genomic deletion of CFHR1 and CRFR3 is detected in only 3% of the control population, but is present in 28% of aHUS patients.[150,154,155] Further analysis intriguingly reveals that genomic CFHR1 deletions are present in 90% of patients with CFH autoantibodies and 20% of patients with CFI mutations, but not different from its background prevalence in patients with other or no mutations.[156] The presence of CFHR1 deletion markedly increases the severity of aHUS in patients with CFI mutations.[157] CFHR1 may block the binding between CFH and its antibodies in autoimmune aHUS patients.[144,158]

The genetic lesions of complement regulation affect the prognosis of aHUS. Long-term survival without advanced renal failure is approximately 80%–90% for patients with only mutations affecting MCP, and is 20%–30% for patients with mutations of CFH.

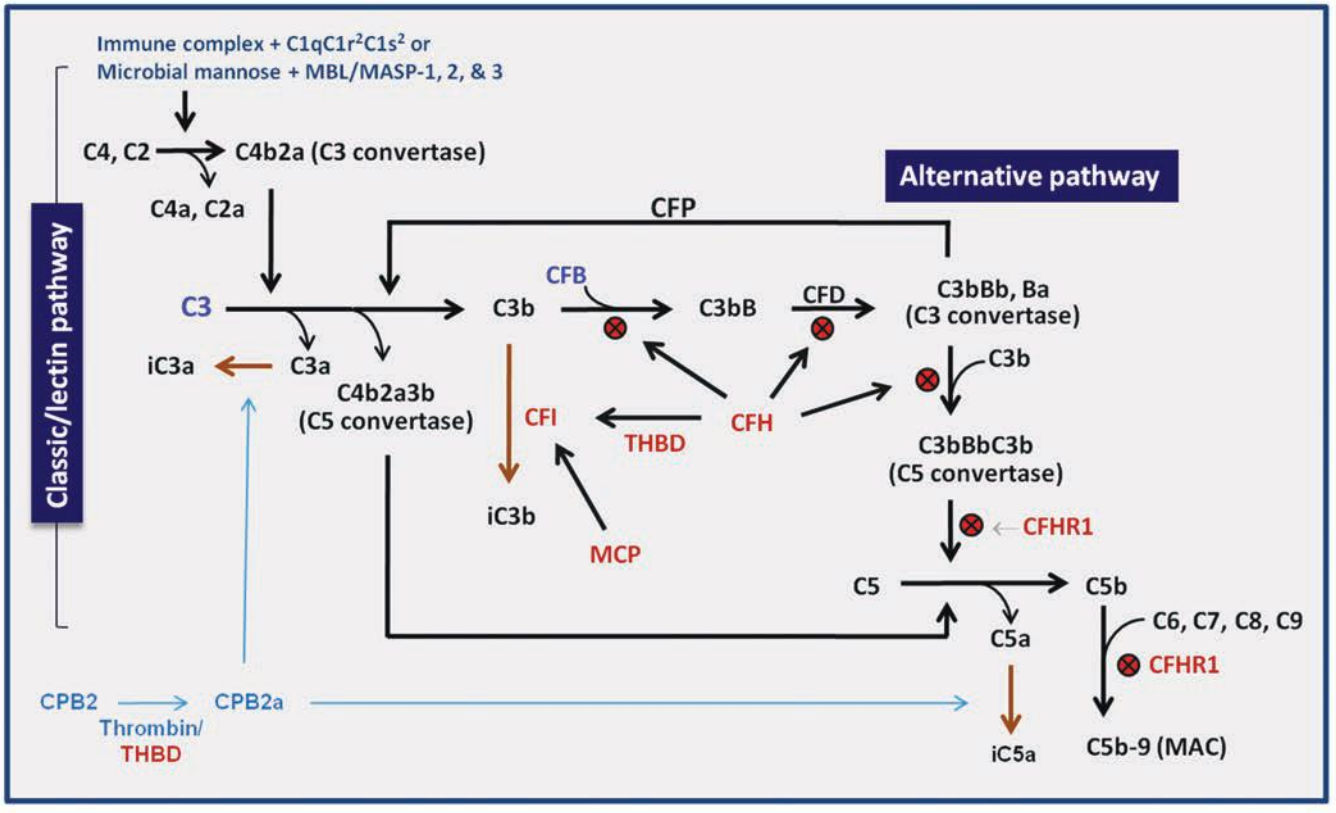

FIGURE 48.9. A scheme of the complement system highlighting the alternative pathway and its regulators (in red). Complement factor I is a plasma serine protease which, with the help of complement factor H (CFH) or membrane cofactor protein (MCP), cleaves C3b to its inactive form (iC3b). CFH also regulates other steps in the alternative pathway. Thrombomodulin (THBD) augments the cofactor activity of CFH and promotes the activation of carboxypeptidase B2 (CPB2) by thrombin, thereby accelerating the inactivation of C3a and C5a. CFB, complement factor B; CFHR1, complement factor H related protein 1; CPB2a, activated CPB2; iC3a, inactivated C3a; iC3b, inactivated C3b; iC5a, inactivated C5a; CFD, complement factor D; CFP, complement factor P; MBL, mannose binding lectin; MASP, mannose binding lectin associated protease.

More than 50% of patients with CFI mutation have concurrent mutations affecting other complement activator or regulatory proteins. Concurrence mutations increase the risk of serious aHUS complications.[157]

As a consequence of the complexity in its genetics, atypical HUS due to complement mutations is transmitted as an autosomal dominant trait with incomplete and variable penetrance, which is greater than 50% with CFH and MCP mutations, but much lower with mutations of the other proteins.

Pathophysiology

The clinical features of aHUS are the consequence of microvascular stenosis, thrombosis, and abnormal vascular permeability resulting from uncontrolled activation of the complement system.

When the complement system is triggered by infection or other factors, defective regulation of the alternative pathway leads to unrelenting generation of complement activation products, including C3a, C5a, and C5b–9 (membrane attack complex, MAC). It is believed that C5b–9 causes direct injury of vascular endothelial cells, whereas C3a and C5a may cause abnormal vascular permeability (Fig. 48.10).

Endothelial cell injury and disruption expose the prothrombotic components in the subendothelium, leading to the activation of the coagulation system, microvascular thrombosis, thrombocytopenia, and ischemic organ injury. Microvascular thrombosis also creates abnormal levels of shear stress, causing fragmentation of the red blood cells.

Endothelial injury causes cell swelling, subendothelial edema, and cellular proliferation. These changes may directly result in marked luminal stenosis (Fig. 48.2E,F) and ischemic organ injury. Vascular stenosis also increases the shear stress and causes microangiopathic hemolysis without concurrent thrombocytopenia. Abnormal vascular permeability may lead to tissue edema and organ dysfunction without concurrent thrombocytopenia or microangiopathic hemolysis. The combination of multiple pathophysiology pathways explains why microangiopathic hemolysis, thrombocytopenia, and organ dysfunction do not always closely correlate with each other in patients with aHUS.

Other Phenotypes of Complement Dysregulation

Excessive complement activation is also associated with the phenotype of mesangiocapillary or membranoproliferative glomerulonephropathy type 2 (dense-deposit disease).[159,160,161,162,163] Occasionally, a patient may present with HUS, evolving to renal failure with histopathologic features of mesangiocapillary glomerulonephropathy later in life.[164]

Complement dysregulation is also associated with age-related macular degeneration. The Y402H polymorphism in the short consensus repeat-7 (SCR-7) of CFH has been linked to age-related macular degeneration among European patients.[165,166,167] More than 20 cases of CFI deficiency have been described from 19 pedigrees linked to increased risk of pyogenic infection.[168] Uncontrolled complement activation also underlies the mechanism of hemolysis in patients with paroxysmal nocturnal hemoglobinuria.[169]

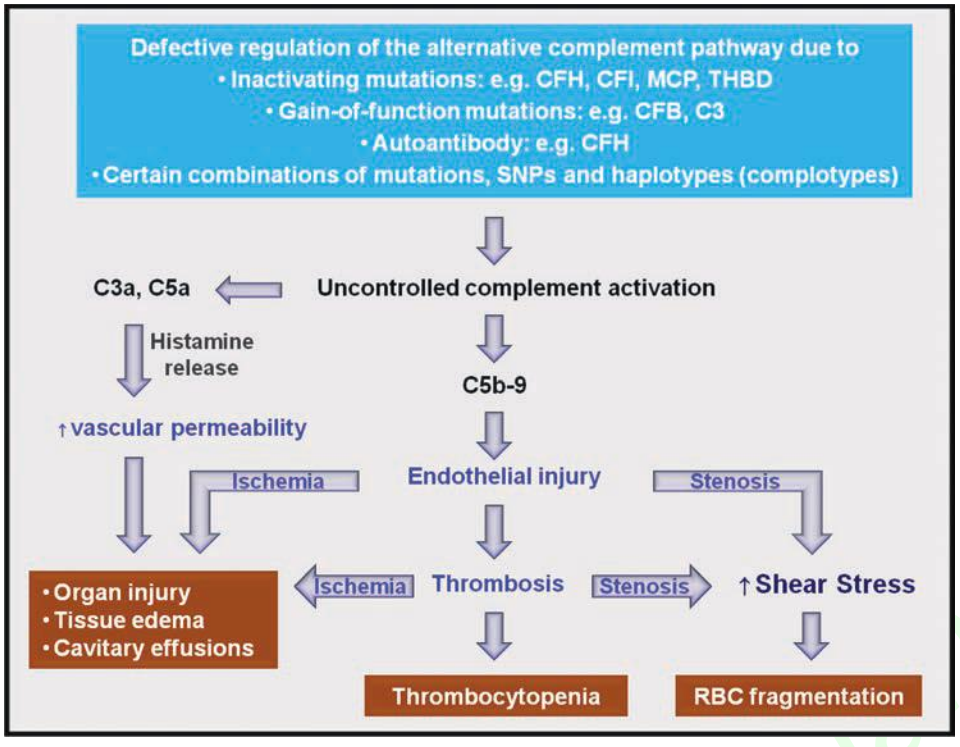

FIGURE 48.10. A scheme depicting how defective regulation of the alternative complement pathway may lead to atypical hemolytic-uremic syndrome (aHUS). Four types of molecular defects have been detected in patients with aHUS, in which organ dysfunction may result from ischemic injury or interstitial tissue edema. Consequently, it is not unusual that a patient with aHUS may continue to deteriorate neurologically due to brain edema while the platelet count is stable or increasing. CFB, complement factor B; CFH, complement factor H; CFI, complement factor I; MCP, membrane cofactor protein; THBD, thrombomodulin.

Clinical Presentation

The prevalence of aHUS has been estimated at 3 per million children. Atypical HUS is likely to be as common as TTP in adults. Both males and females are equally affected.

The onset of an acute aHUS crisis may occur spontaneously or after trigger of stress conditions such as infection, surgery, trauma, inflammation, pancreatitis, intravenous contrast agents, or pregnancy. Although renal failure, microangiopathic hemolysis, and thrombocytopenia are its common features, aHUS is a systemic disease affecting multiple organs.

Gastrointestinal symptoms such as abdominal pain, bloody or nonbloody diarrhea, nausea, and vomiting are the most common acute presenting symptoms of aHUS. Some patients have recurrence of these symptoms for months to years before the diagnosis is recognized.

Laboratory tests may reveal elevated pancreatic enzymes such as amylase or lipase, diabetes mellitus, and/or abnormal liver function tests.

Imaging studies may reveal thickening, edema, and/or ischemic changes of the intestinal or bronchial wall, mesenteric edema, ascites and pancreatitis.

Headache and waxing and waning mental status changes are common. Impaired vision due to exudative or hemorrhagic retinopathy, seizures, and coma may ensue as the disease progresses. Focal neurologic deficits may occur although these are not as frequent as in patients with TTP.

The most common findings in brain imaging studies are cerebral edema or posterior reversible encephalopathy syndrome (PRES), a reflection of abnormal vascular permeability. Ischemic changes or overt infarction may be present, but are less common. Many of these changes may not be detectable with computerized tomography.

The severity of anemia and thrombocytopenia are quite variable in aHUS. Petechiae or other bleeding symptoms may occur but are uncommon. Rising platelet counts alone should not be taken as indication of disease improvement or remission.

Chest pain, dyspnea, respiratory failure, or congestive heart failure may result from pleurisy, pericarditis, airway edema, noncardiogenic pulmonary edema, or myocardial injury, which are detectable with chest radiograms, CT imaging, echocardiography, and EKG. Troponin and CPK levels may be elevated. Hypertension may be severe but often labile. Cardiac arrhythmias may lead to sudden death.

Proteinuria, hematuria, and renal function impairment are common. Hematuria is microscopic in most cases but may be gross occasionally. The severity of renal failure is variable. Some patients may present with very mild elevation of creatinine, and others present with anuric renal failure requiring dialysis support. Occasionally, a patient presents with aHUS only after receiving a renal graft for end-stage renal failure.

Diagnosis

No simple tests exist at this time for the diagnosis of defective alternative complement regulation. The C3 level is decreased in approximately 30%–50% of the patients. The C4 level is decreased in less than 10% of the cases. These changes are not specific for aHUS. In patients with mutations of CFH or CFI, the antigen levels of the affected proteins are decreased in approximately 30% of the cases.

Mutation analysis detects abnormalities in approximately 50% of the patients. Because compound mutations are common, all genes known to be involved in alternative complement regulation need to be analyzed. CFH antibodies are detected by ELISA in 5% to 10% of patients with aHUS. The genetics of aHUS also involve SNPs, haplotypes, and combinations of common or uncommon variants of complement activators or regulators. Due to its complexity and incomplete understanding of pathogenic mechanisms, genetic study is not required for the diagnosis of aHUS.

Presently the diagnosis of aHUS relies on a process of exclusion (Fig. 48.11). aHUS is suspected in patients presenting with the constellation of microangiopathic hemolysis, any degree of renal function impairment and thrombocytopenia, and the diagnosis is

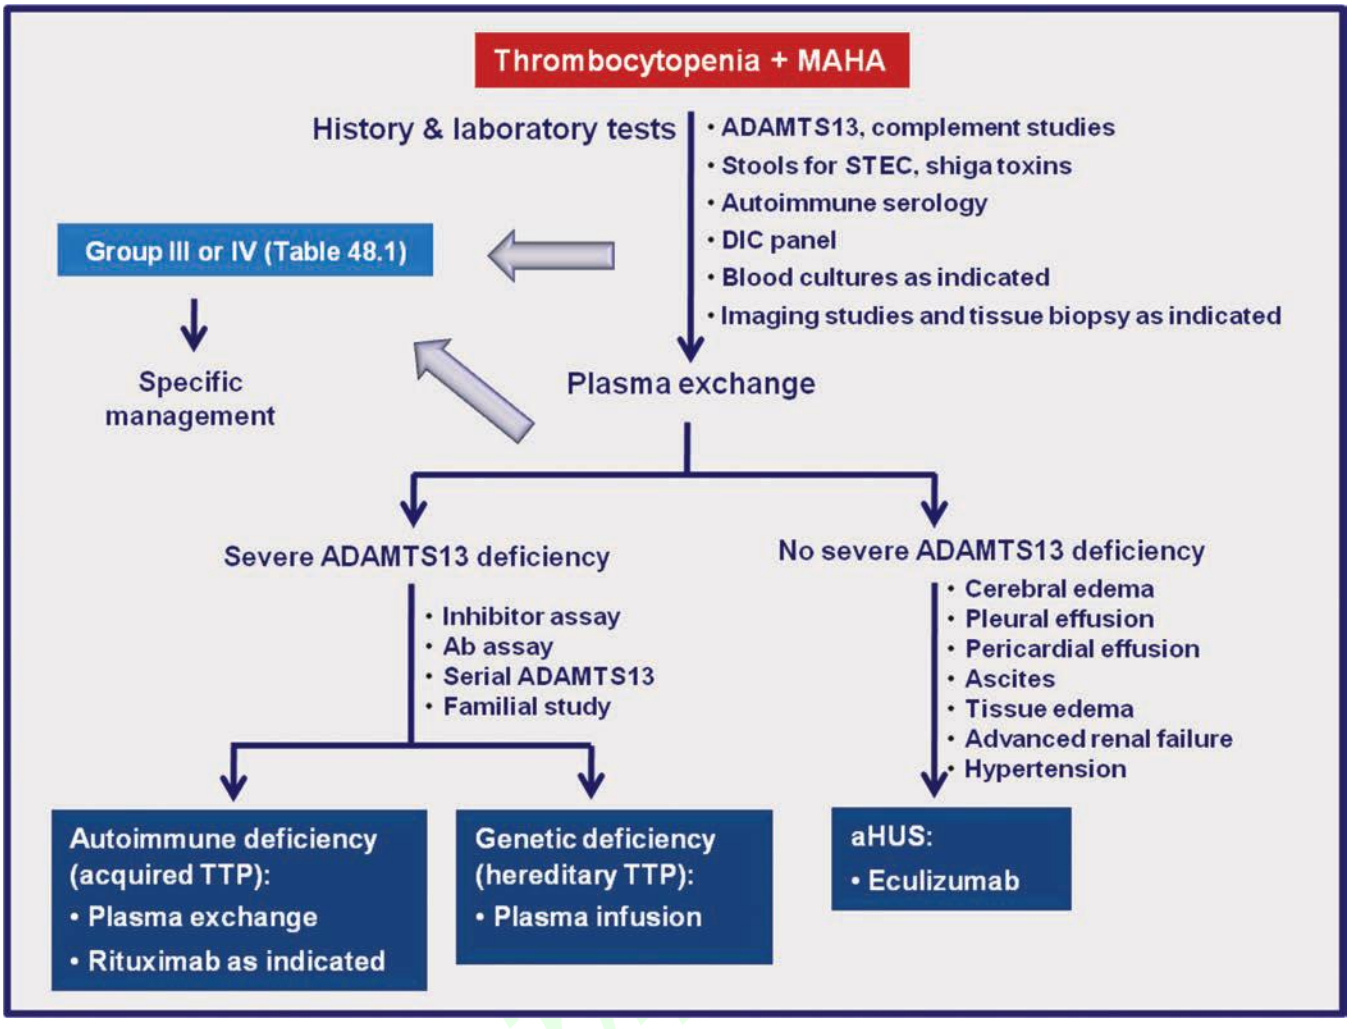

FIGURE 48.11. A scheme summarizing the current approach to patients presenting with thrombocytopenia and microangiopathic hemolytic anemia (MAHA). The patients should be empirically treated with plasma exchange unless history, physical examination, and laboratory tests strongly indicate otherwise. The indication of plasma exchange should be continually reassessed based on the evolution of clinical course and laboratory test results. Until ADAMTS13 assays are proven to be reliable, an ADAMTS13 level >10% should be correlated with clinical findings of advanced renal failure and/or abnormal vascular permeability for exclusion of thrombotic thrombocytopenic purpura (TTP). The role of eculizumab for treatment of shiga toxin–associated hemolytic-uremic syndrome (HUS) or other thrombotic microangiopathy of Group III disorders (Table 48.1) remains uncertain. DIC, disseminated intravascular coagulopathy.

presumed after exclusion of TTP and groups III and IV disorders listed in Table 48.1.

aHUS needs to be distinguished from TMA via other mechanisms such as shiga toxins or microbial neuraminidases. Shiga toxin assays are indicated for patients presenting with diarrhea. Blood cultures or viral studies are indicated for patients with suspected systemic infections. There is insufficient knowledge to determine how frequent TMA occurs in patients with hematopoietic stem cell therapy, systemic autoimmune diseases, HIV infection, or various classes of drugs. Patients with autoimmune diseases may also develop MAHA due to vasculitis, which requires tissue biopsy for diagnosis. aHUS needs to be distinguished from hemolysis with elevated liver enzymes and low platelets (HELLP) syndrome and preeclampsia in women during pregnancy. Contrary to what is commonly believed, severe hypertension may be a consequence of aHUS rather than a cause of MAHA. The diagnosis of aHUS in patients without both MAHA and overt renal failure is more challenging and requires a high index of suspicion. The presence of hypertension, pleural or pericardial effusions, ascites, mesenteric or intestinal wall edema, anasarca, airway edema, acute respiratory distress syndrome, exudative retinopathy, brain edema, or posterior reversible encephalopathy syndrome (PRES) by CT or MRI strongly favors the diagnosis of aHUS over TTP.

Management

The principles of management for patients with aHUS are summarized in Table 48.4. Traditionally, aHUS patients were treated with plasma exchange. This practice was an extension of plasma exchange therapy for TTP, but its efficacy has never been rigorously investigated. It appears to be effective in a fraction of patients with aHUS.

Plasma Therapy

Many patients improve following the institution of plasma exchange therapy. Some patients deteriorate and even die after exhibiting an initial response. Others relapse after the therapy is discontinued, but do not respond to its reinstitution. Thus, the outcome with plasma therapy is uncertain for individual patients.

Knowledge of the molecular defects of aHUS may potentially predict which patients are likely to benefit from plasma exchange therapy. Plasma exchange or even plasma infusion is most likely

TABLE 48.4

PRINCIPLES OF MANAGEMENT OF ATYPICAL HEMOLYTIC-UREMIC SYNDROME (aHUS)

- Atypical HUS is a systemic disease
  - Gastrointestinal symptoms of nausea, vomiting, abdominal pain, diarrhea are common complaints.
  - Cardiopulmonary symptoms of chest pain and dyspnea may occur
  - Neurologic abnormalities such as headache, somnolence, confusion, seizures, or visual defects may occur.
  - Advanced renal failure, hypertension or complications of abnormal vascular permeability[a] favors the diagnosis of aHUS over TTP.
  - Renal failure may be minimal or mild in some cases.
- Atypical HUS is a diagnosis of exclusion
  - TTP should be excluded with ADAMTS13 assays.
  - Stx-HUS should be excluded with stool shiga toxin assays for patients with diarrhea.
  - Other causes of MAHA should be excluded with history, coagulation tests, autoimmune serology, microbiology, and/or tissue biopsy as indicated.
  - Acute presentation of atypical HUS may be triggered by a co-morbidity (Table 48.1).
- Plasma exchange is the initial choice of therapy until TTP is excluded
- Eculizumab is the treatment of choice for aHUS
  - Improvement in thrombocytopenia and mental status change is evident after one or two doses of eculizumab.
  - Recovery of renal function may occur slowly over many months.
  - Vaccination is critical for prevention of meningococcal sepsis.
- Long-term therapy with eculizumab should be considered for patients who
  - have more than minimal renal dysfunction, or
  - are predisposed to relapse with serious complications.
- If eculizumab is discontinued, close monitoring is indicated for early detection of relapse or organ injury. Follow-up evaluation should include
  - Symptoms, physical findings, blood pressure.
  - CBC, renal function and hemolysis markers.

Stx-HUS, shiga toxin–associated hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura
[a]As reflected by cerebral edema, posterior reversible encephalopathy syndrome, pleural or pericardial effusion, pulmonary edema, acute respiratory distress syndrome, ascites, or soft tissue swelling.

to benefit patients with deficiency of plasma proteins such as CFH or CFI, but not patients with defective membrane-bound proteins such as MCP. Intensive plasma exchange may be effective for patients with gain-of-function C3 or CFH mutations, or CFH antibodies. For patients with multiple mutations or unknown mutations, it is impossible to predict whether they will respond to plasma therapy.

Some patients develop end-stage renal failure, months to years after plasma exchange is discontinued, without ever experiencing acute symptomatic relapses of aHUS. Thus, long-term maintenance plasma therapy is often needed for responsive patients to prevent relapses or progression of kidney injury. Long-term plasma therapy is technically demanding, poses a major stress on the patients, and its optimal regimen can only be determined empirically at best.

Eculizumab

A major advance in the treatment of aHUS is eculizumab, a humanized monoclonal antibody to C5 originally approved in 2007 for the treatment of paroxysmal nocturnal hemoglobinuria. Based on two prospective studies of 37 adult and adolescent patients, and a retrospective study of 19 pediatric patients,[170] the U.S. Food and Drug Administration and European Medicines Agency approved eculizumab in 2011 for the treatment of childhood and adult aHUS.

In the clinical trials, patients without identifiable mutations also responded to eculizumab, suggesting that defective regulation of the alternative complement pathway plays a pathogenetic role in most if not all patients of aHUS without identifiable molecular defects.

With eculizumab, clinical improvement in mental status, gastrointestinal symptoms, and increase in the platelet count are often apparent after one or two weekly administrations. Renal function improvement may be slow but continues for many months. Long-term eculizumab therapy may lead to gradual recovery of renal function, allowing some patients to come off dialysis therapy.

The aims of eculizumab therapy for aHUS include prevention of death, and avoidance of aHUS relapse. To achieve these aims, eculizumab should be instituted as soon as the diagnosis is reasonably established and TTP is excluded.

Atypical HUS is a chronic disease that often continues to cause subclinical injury of the kidney and other organs even in the absence of overt symptoms, thrombocytopenia, or microangiopathic hemolysis. Long-term eculizumab therapy should be considered for patients who are close to requiring renal replacement therapy and patients whose aHUS, if left untreated, may cause severe hypertension or other serious extra-renal complications. If eculizumab is discontinued, close monitoring of clinical status, blood pressure, blood counts, and renal function is indicated for early detection of aHUS relapse or progressive organ injury.

Eculizumab is well tolerated with minor adverse reactions. It is important to note that eculizumab therapy may predispose patients to fulminant *Neisseria meningitides* infections. Patients should be given meningococcal vaccination and take prophylactic antibiotics until 2 weeks after the vaccination. Patients should also carry an identification card to facilitate emergency management of any infectious complications. Concern of serious infection has prompted some physicians to recommend long-term prophylactic antibiotic therapy.

The efficacy of eculizumab for patients with thrombotic microangiopathy in association with a co-morbidity such as those in Table 48.1 (group III), but no identifiable molecular defects in complement regulation has not been extensively investigated. Preliminary experience suggests that it is effective in some, if not all of such patients.

Eculizumab has been used in a small number of patients during pregnancy without causing adverse effects to the mother and fetus.[171,172]

Eculizumab versus Plasma Exchange Therapy

Compared to plasma exchange, eculizumab offers several advantages: the high efficacy of eculizumab is documented in clinical trials; it is expected to be effective for aHUS irrespective of the underlying molecular defects; and it is easier to administer, particularly for long-term maintenance therapy.

In contrast, the efficacy of plasma exchange has never been rigorously investigated in patients with aHUS; treatment failure is not uncommon; and plasma exchange requires a venous catheter that is inconvenient, uncomfortable, and carries the risk of infection or thrombosis.

Renal Transplantation

Due to high rates of disease recurrence, aHUS patients, except those with mutations of membrane proteins such as MCP, have a very high risk (>80% to 90%) of graft failure following kidney transplantation.

Previously, combined kidney and liver transplantation was performed based on the rationale that restoration of normal CFH in the circulation by the transplanted liver would prevent recurrence of aHUS and renal graft failure. However, because the complement system is triggered during major operations, the procedure was associated with a very high risk of morbidity and mortality. Pre-operative plasma exchange was advocated to prevent these complications.

Patients with mutations of membrane cofactor protein are expected to be cured, at least from the renal perspective, by a kidney allograft. Nevertheless, graft failure may occur if the donor is a family member who also carries the molecular trait, or if the patient carries other unidentified mutations. Due to the incomplete phenotypic expression of aHUS, family members of aHUS patients should not be organ donors. Extra-renal complications of aHUS may continue to occur after kidney transplantation. Maintenance eculizumab therapy is indicated for such patients.

If a patient with aHUS is to receive kidney transplantation, the patient should be treated with eculizumab prior to the operation.[173,174] Eculizumab should be continued postoperatively to prevent recurrence of the disease causing acute complications and graft failure. Because chronic eculizumab therapy is expected to be quite effective in preventing relapse of aHUS or organ injury, concurrent liver transplantation is no longer necessary.

Prognosis

Historically, approximately 10% to 30% of aHUS patients treated with plasma exchange died during their acute presentation. The overall risk of death or end-stage renal failure was ~60%. The risk was the highest (70% to 80%) for patients with CFH mutations, compound mutations, or CFI mutation with CFHR1 deletion, and the lowest mortality (10% to 20%) occurred in patients with MCP mutations.

Many of the patients never develop recurrence of overt thrombocytopenia or microangiopathic hemolysis while they progress to advanced renal failure. The absence of hematologic relapse leads to erroneous reports in the literature that "TTP" patients without severe ADAMTS13 are less likely to relapse and have a better long-term prognosis than those with severe ADAMTS13 deficiency. Eculizumab is expected to suppress systemic complications and prevent renal function, deterioration, and death.

PLATELET AND RED CELL DAMAGE BY ABNORMAL VASCULAR SURFACES

Platelets are subject to damage by interactions with "nonphysiologic" surfaces within the vascular system. Pathologic alterations of vessels that may produce such platelet damage include stenotic and roughened heart valves,[175] extensive atherosclerosis, metastatic cancer, and kidney disease associated with severe vascular changes in renal vessels.[176] An increasing number of surgical techniques involve the implantation of devices containing foreign material within the vascular system. Such circulatory prostheses include cardiac valves, vascular grafts of many types, indwelling catheters,[177] intra-aortic balloon pumps,[178] extracorporeal membrane oxygenators (ECMO),[179] and ventricular assist devices (VAD).[180] Extensive efforts have been made to render such materials nonthrombogenic, but most of these devices produce varying degrees of platelet destruction as well as hemolysis.[181]

Bleeding during cardiopulmonary bypass surgery appears to be multifactorial, including operative factors, dilution of clotting factors, inadequate neutralization of heparin, thrombocytopenia, platelet dysfunction,[180] and enhanced fibrinolysis. Hemodilution leads to a rapid reduction in platelet counts by as much as 50% shortly after cardiopulmonary bypass surgery begins. The platelet function defect is maximal during cardiopulmonary bypass surgery and usually disappears within 24 hours of surgery. The nature of the platelet defect is controversial. Investigators report partial platelet degranulation, circulating activated platelets by flow cytometry, and defects in platelet membrane glycoprotein Ib/IX and IIb/IIIa.[182,183] Efforts to minimize platelet and coagulation abnormalities in association with cardiac surgery include higher heparin doses to suppress thrombin generation,[184] heparin-coated circuit,[185] miniaturized closed circuit,[186] and off-pump operations.[187] Avoidance of cardiotomy suction, perhaps in combination with a direct thrombin inhibitor such as bivalirudin as the anticoagulant, may substantially minimize activation of the coagulation system.[188] Bleeding is often reduced by infusion of normal platelets, 1-deamino-8-d-arginine vasopressin, epsilon aminocaproic acid, or aprotinin.[189,190,191,192] However, indiscriminate prophylactic platelet transfusion is ineffective and may increase the risk for adverse outcomes. A higher risk of end-organ damage has been observed with aprotinin, but not with tranexamic acid or aminocaproic acid.[193] Nitric oxide plus iloprost may reduce the deleterious effects of cardiopulmonary bypass on platelets and even reduce post-operative bleeding.[194]

Red cell fragmentation and intravascular hemolysis are common in patients with left ventricular assist devices (LVAD), extracorporeal membrane oxygenator, or prosthetic heart valves. In such patients, monitoring of plasma hemoglobin concentration is recommended, as an increase in plasma hemoglobin level may herald intradevice thrombosis or malfunction. Analysis of vWF may also demonstrate a decrease in the normal large multimers in patients with LVAD.[195,196–199] Such vWF multimer changes, presumably due to excessive proteolysis induced by abnormal shear stress profiles, are more profound in patients with nonpulsatile than pulsatile devices. The vWF changes alone may not be sufficient to cause bleeding; yet they may contribute to the bleeding diathesis induced by anticoagulation or antiplatelet therapy, other hemostatic defects such as thrombocytopenia and platelet function defects, and acquired angiodysplasia of the gastrointestinal tract.[200]

MISCELLANEOUS FORMS OF NONIMMUNOLOGIC PLATELET DESTRUCTION

Extensive burns are associated with mild to moderate thrombocytopenia that results from nonimmunologic platelet destruction.[201] Thrombocytopenia may become severe and bleeding may develop when complications of sepsis or disseminated intravascular coagulation develop. Thrombocytopenia has been well described after hepatic cryotherapy[202] and in moderate hypothermia treatment.[203,204]

Certain drugs may produce thrombocytopenia by nonimmunologic phenomena. Ristocetin, an antituberculous agent no longer used clinically, promotes the attachment of vWF to its platelet receptor and initiates direct platelet-to-platelet interaction by means of an agglutination phenomenon. Studies of ristocetin-induced platelet aggregation have provided much information concerning von Willebrand disease.

Oxaliplatin may cause thrombocytopenia by causing liver injury and portal hypertension, leading to splenomegaly and hypersplenism.[205] Protamine may produce reversible sequestration of platelets in the liver,[206] but seldom is the cause of significant thrombocytopenia. Aggregation of platelets independent of immune mechanisms plays a role in type 1 heparin-induced thrombocytopenia. Thrombocytopenia is a common feature of post-decompression sickness in divers and has been attributed to intravascular platelet aggregation.[207]

CHAPTER 49

MISCELLANEOUS CAUSES OF THROMBOCYTOPENIA

Archana M. Agarwal, George M. Rodgers

This chapter summarizes miscellaneous forms of congenital and acquired thrombocytopenia (Table 49.1), including thrombocytopenia attributable to deficient platelet production, associated with abnormal platelet pooling in the spleen, and resulting from dilution with massive transfusions.

CONGENITAL THROMBOCYTOPENIA

Hereditary thrombocytopenias have been well documented and may be inherited as an autosomal dominant trait, an autosomal recessive trait, or an X-linked recessive trait. Bleeding can be mild, and in some instances the affected family members are virtually asymptomatic, being identified only through incidental platelet counts or family studies after the identification of the propositus. It is important to recognize these mild forms of familial thrombocytopenia because, although they may resemble autoimmune thrombocytopenic purpura, patients do not respond to steroid treatment or intravenous immunoglobulin, and this therapy may be harmful. These disorders can be classified according to platelet size (Table 49.2).

Autosomal Recessive Thrombocytopenias

Congenital Amegakaryocytic Thrombocytopenia

The presence of severe thrombocytopenia, absence of megakaryocytes in the bone marrow, and absence of any physical anomaly in an infant characterize congenital amegakaryocytic thrombocytopenia (CAMT).[1] Because of the recessive nature of the disease, family history is usually negative, with both parents having normal platelet counts and function. Patients with CAMT have markedly elevated serum levels of thrombopoietin (TPO)[2] and mutations in the *c-mpl* gene. Multiple mutations in the *c-mpl* gene have been reported, including deletions, nonsense mutations, and missense mutations. Many of the patients studied are compound heterozygotes with one mutation inherited from each parent.[3,4,5] Because patients with CAMT develop progressive bone marrow aplasia during the course of the disease, it is likely that Mpl signaling is essential for the production of mature megakaryocytes as well as maintenance of the hematopoietic stem cell population.[6]

Further subgrouping of CAMT patients into two groups has been proposed based on their clinical course: Group CAMT I, with a more severe type of thrombocytopenia with constantly low platelet counts and an early onset of pancytopenia; and group CAMT II, which is characterized by a transient increase in platelet counts during the first year of life and a later or no development of pancytopenia.[4] The type of *mpl* mutation determines the clinical course of CAMT; a total loss of the TPO receptor due to homozygous nonsense mutations, deletions, and frameshift mutations causes the more severe form of disease found in CAMT I patients. In contrast, the transient increase in platelet counts and the later development of pancytopenia in patients with homozygous or compound heterozygous missense mutations are the result of a residual function of the TPO receptor.[7] Hematopoietic stem cell transplant is the only curative treatment for these patients, and matched sibling transplants have been successful.

Thrombocytopenia with Absent Radius Syndrome

The thrombocytopenia with absent radius (TAR) syndrome is a congenital malformation syndrome characterized by bilateral absence of the radii but with thumbs present, hypomegakaryocytic thrombocytopenia, and a number of additional features including skeletal and cardiac anomalies.[8,9] Among the skeletal anomalies, bilateral absence of the radii may be accompanied by ulnar or humeral anomalies, and the most severe cases exhibit phocomelia. Lower limb involvement is variable and includes dislocation of the patella and/or of the hips, absent tibiofibular joint, and lower limb phocomelia. Among the cardiac anomalies, tetralogy of Fallot and atrial septal defects are common.[10,11] Studies have noted a high incidence (62%) of cow's milk intolerance, which presents as persistent diarrhea and failure to thrive.

TABLE 49.1

MISCELLANEOUS CAUSES OF THROMBOCYTOPENIA

Congenital Thrombocytopenia
- Autosomal recessive thrombocytopenias
  - Congenital amegakaryocytic thrombocytopenia
  - Thrombocytopenia with absent radius (TAR) syndrome
  - Bernard-Soulier syndrome
- Autosomal dominant thrombocytopenias
  - MYH9-related disorder
    - May-Hegglin anomaly
    - Sebastian anomaly
    - Fechtner anomaly
    - Epstein anomaly
  - Familial platelet disorder with predisposition to acute myelogenous leukemia
  - Mediterranean macrothrombocytopenia
  - Paris-Trousseau syndrome (in association with deletion of *FLI1* gene)
  - Autosomal dominant thrombocytopenia with linkage to human chromosome 10 (THC2)
  - Gray platelet syndrome
  - Amegakaryocytic thrombocytopenia with radial-ulnar synostosis (ATRUS) syndrome
  - Variant von Willebrand disease (type 2b and platelet-type) (see Chapter 53)
- X-linked thrombocytopenia
  - X-linked microthrombocytopenia (*WAS* gene mutation)
  - X-linked macrothrombocytopenia with dyserythropoiesis (*GATA-1* mutation)
- Others
  - 22q11 deletion syndrome (DiGeorge Syndrome)

Acquired Thrombocytopenia
- Thrombocytopenia caused by deficient platelet production
  - Acquired pure amegakaryocytic thrombocytopenic purpura
  - Chemical and physical agents that produce generalized bone marrow suppression
    - Drugs that selectively suppress the megakaryocyte
    - Drugs that cause ineffective thrombopoiesis
- Thrombocytopenia caused by abnormal platelet pooling
- Thrombocytopenia caused by hypothermia
- Thrombocytopenia associated with infections
  - Thrombocytopenia associated with viral infections
  - Thrombocytopenia associated with bacterial and protozoal infections
- Thrombocytopenia after massive blood transfusions

TABLE 49.2

CLASSIFICATION OF INHERITED THROMBOCYTOPENIA BY PLATELET SIZE (MPV)

Low MPV	Normal MPV	Increased MPV
Wiskott-Aldrich syndrome	ATRUS syndrome	MYH9-related disorders
	Thrombocytopenia with absent radius syndrome	Mediterranean macrothrombocytopenia
	Congenital amegakaryocytic thrombocytopenia	Bernard-Soulier syndrome
	Familial platelet disorder with predisposition to AML	GATA-1 mutation
	THC2	Gray platelet syndrome
	X-linked thrombocytopenia with GATA-1 mutation	Paris-Trousseau syndrome
		vWD type 2B
		Platelet type vWD
		22q11 deletion syndrome

GATA-1 mutation platelets may have normal or increased MPV.
AML, acute myelocytic leukemia; ATRUS, amegakaryocytic thrombocytopenia with radial-ulnar synostosis; MPV, mean platelet volume; THC2, autosomal dominant thrombocytopenia with incomplete megakaryocyte differentiation and linkage to chromosome 10; vWD, von Willebrand disorder.
Adapted from Drachman JG, Inherited thrombocytopenia: when a low platelet count does not mean ITP. Blood 2004;103:390–398; Lambert MP. What to do when you suspect an inherited platelet disorder. Hematology Am Soc Hematol Educ Program 2011; 2011: 377–383.

An episode of thrombocytopenia may be precipitated by introduction of cow's milk and relieved by its exclusion from the diet.[12]

These patients have elevated serum TPO levels and normal *c-mpl* and *HOX* genes. However, they have a profound defect in megakaryocyte differentiation and platelet production and no response of megakaryocytes to TPO.[13,14,15] There may be a slight increase in platelet count in response to recombinant human erythropoietin.[16] Although specific microdeletion of chromosome 1q21.1 has been reported in the majority of individuals with TAR syndrome, it is not the disease-causing mutation.[17] Compound inheritance of a rare null mutation in exon-junction complex subunit RBM8A has been found to be the cause of TAR syndrome. RBM8A controls the production of the protein Y14, and its low level is responsible for the cause of low platelets.[18]

Diagnosis is rarely difficult because of obvious morphologic abnormalities in association with thrombocytopenia. Prenatal diagnosis has been described by ultrasonographic detection of morphologic abnormalities and detection of low fetal platelet counts.[19,20,21] Congenital rubella and some variants of Fanconi syndrome should be excluded. Platelet counts gradually increase during the first 2 years of life. The degree of thrombocytopenia is usually greatest at the time of birth; platelet transfusions are frequently required and are effective. Thrombocytopenia becomes less severe during the first year of life, and most affected individuals with TAR do not require platelet transfusions after infancy.[10,22]

Bernard-Soulier Syndrome

Bernard-Soulier syndrome is an autosomal recessive bleeding disorder associated with deficiency of platelet membrane proteins GPIb, GPIX, and GPV. This results in abnormal platelet interaction with ligands of these receptor proteins, which include thrombin, von Willebrand factor (vWF), P-selectin, and leukocyte integrin $\alpha_M\beta_2$, in addition to causing thrombocytopenia. This topic is described in more detail in Chapter 52.

Autosomal Dominant Thrombocytopenia

A number of families have been described who have autosomal dominant inheritance of isolated mild thrombocytopenia characterized by normal platelet survival and a normal number of bone marrow megakaryocytes, a constellation of findings that suggests ineffective thrombopoiesis.[23,24,25] Thrombocytopenia (platelet counts between 20,000 and 100,000/μl) or a history of increased bruisability is apparent early in life, and examination of the peripheral blood smear demonstrates platelet macrocytosis (mean platelet volume >10 μm^3). Splenic size is always normal. Platelet aggregation abnormalities have been described in some families, but platelet membrane glycoproteins (GPs) have been normal when studied.[24]

MYH9-related Disorders

A group of autosomal dominant macrothrombocytopenias caused by mutations in the *MYH9* gene with variable penetrance and expression has been defined.[26–29] These include May-Hegglin anomaly, Sebastian syndrome, Epstein syndrome, and Fechtner syndrome. These disorders are defined by the presence of mutations involving the *MYH9* gene located at chromosome 22q12.3–13.1 and include single nucleotide changes, in-frame deletions or duplications, and frameshift and nonsense mutations.[30] The *MYH9* gene encodes nonmuscle myosin heavy chain IIA (NMMHC-IIA).[31] NMMHC-IIA is part of the nonmuscle myosin IIA hexamer that is a component of the contractile cytoskeleton in megakaryocytes, platelets, and other tissues. Thrombocytopenia is usually mild and derives from complex defects of megakaryocyte maturation and platelet formation. More specifically, these mutations likely affect the platelet release from the mature megakaryocytes.[30] All of these *MYH9* gene mutation–related disorders have macrothrombocytopenia, leukocyte inclusion bodies (Döhle body–like inclusions) and can have various combinations of hereditary nephritis, deafness, and cataracts (Table 49.3). Sometimes, the inclusions are rarely appreciated on conventional May-Grunwald-Giemsa staining, especially in patients with mutations at codon 702 because of their low RNA content. These cases can be diagnosed by the use of immunofluorescence assays.[32] Thrombocytopenia is generally mild to moderate. Peripheral blood smears reveal enlarged platelets with frequent giant platelets.

Clinically, patients have a mild platelet-type bleeding disorder. May-Hegglin anomaly and Sebastian syndrome both have macrothrombocytopenia and granulocyte inclusions, but ultrastructural analysis of the Döhle-like inclusions demonstrates diagnostic differences between these two syndromes, and both types of inclusions can also be distinguished from Döhle bodies seen in acute infection. Patients with Fechtner syndrome and Epstein syndrome have hearing disability and nephritis. In Fechtner syndrome, cataracts are also present.[33] These two disorders result from allelic mutations at amino acid 702, which cause conformational changes to the myosin head.[31,34,35,36] Diagnosis is suggested by detection of macrothrombocytopenia and the presence of one or more of the above-mentioned clinical features. Döhle-like inclusion bodies within neutrophils on May-Grünwald-Giemsa-stained peripheral blood are highly suggestive of an *MYH9*–related disorder. Abnormal staining of neutrophil inclusions with anti-NMMHC-IIA may offer greater sensitivity. Definitive diagnosis requires the demonstration of a causative mutation within the *MYH9* gene.[31] Treatment options for bleeding include platelet transfusion, allogeneic stem cell transplantation, or use of a thrombopoietic drug (eltrombopag).[37]

Platelet-type von Willebrand disease is another autosomal dominant disorder associated with hereditary thrombocytopenia, characterized by abnormal binding of large vWF multimers to platelets. This intrinsic platelet defect results in mild thrombocytopenia, increased ristocetin-induced platelet aggregation, and a selective

TABLE 49.3

SYNDROMES CAUSED BY *MYH9* GENE DEFECTS

Syndrome	Macrothrombocytopenia	Döhle-like Bodies	Nephritis	Deafness	Cataracts
May-Hegglin	Yes	Yes	No	No	No
Sebastian	Yes	Yes	No	No	No
Fechtner	Yes	Yes	Yes	Yes	Yes
Epstein	Yes	Yes	Yes	Yes	No

loss of high-molecular-weight vWF multimers from the plasma. This disorder resembles type 2b von Willebrand disease (see Chapter 53).

Familial Platelet Disorder with Predisposition to Acute Myelogenous Leukemia

Familial platelet disorder with predisposition to acute myelogenous leukemia (FPD/AML) is an autosomal dominant disorder characterized by moderate thrombocytopenia, a defect in platelet function, and predisposition to develop myeloid malignancy.[38] The defect in platelet function is manifested by prolonged bleeding times and abnormal platelet aggregation. Expansion of megakaryocyte progenitors in the bone marrow or peripheral blood cells reveals diminished megakaryocyte colony formation. Bone marrow from affected patients shows decreased megakaryopoiesis. Linkage analysis of several pedigrees affected by FPD/AML has led to identification of germline heterozygous mutations in the hematopoietic transcription factor AML1, also known as RUNX1 and CBFA2. These mutations include missense, frameshift, and nonsense mutations and a large intragenic deletion.[39,40] CBFA2 is a transcription factor that trans-activates the expression of a spectrum of genes required for normal development of hematopoietic cells. Mutation of CBFA2 has been implicated in the pathogenesis of human leukemias resulting from somatically acquired chromosomal translocations.[41] Normal megakaryopoiesis requires TPO binding to the Mpl receptor. In FPD/AML, CBFA2 mutation leads to diminished Mpl receptor expression, resulting in impaired TPO signaling leading to thrombocytopenia. Consequently, serum TPO levels are usually elevated in these patients.[42]

Mediterranean Macrothrombocytopenia

A relatively common and mild form of macrothrombocytopenia has been described in a group of 145 apparently healthy subjects from Italy and the Balkan peninsula. Because this abnormality was not detected in control subjects from northern Europe, the condition was named Mediterranean macrothrombocytopenia.[43] Linkage analysis localized the gene mutation to the short arm of chromosome 17, in an interval containing the *GPIbα* gene. GPIbα, together with other proteins, constitutes the plasma vWF receptor, which is altered in Bernard-Soulier syndrome. Sequencing of the gene identified a mutation of GPIbα (Ala156Val) shared by 10 of 12 pedigrees studied.[44] These data demonstrate that for most families with Mediterranean thrombocytopenia, the genotype and phenotype are equivalent to that of a carrier of Bernard-Soulier syndrome. Clinically, patients have a mild bleeding diathesis, usually diagnosed after incidental discovery of thrombocytopenia. Peripheral blood shows platelets that are larger than normal.

Paris-Trousseau Syndrome (in Association with Deletion of the FLI1 Gene)

Paris-Trousseau syndrome (PTS) is an inherited disorder characterized by several congenital anomalies including dysmegakaryopoiesis with two morphologically distinct populations of megakaryocytes and giant α-granules in a low percentage of platelets. These features occur in association with deletion of the long arm of chromosome 11 at 11q23.3 (which includes the *FLI1* gene), a region that is also deleted in Jacobsen syndrome (a variant form of PTS). Clinical features include a combination of mild to moderate psychomotor retardation, trigonocephaly, facial dysmorphism, cardiac defects, and thrombocytopenia.[45,46] Hematologic history, biologic data, ultrastructural, and molecular investigations were reported from a case series of 10 patients.[47] Thrombocytopenia is chronic, with mild clinical bleeding. Peripheral blood smears and electron microscopy show abnormal platelets with giant granules. Bone marrow findings consist of dysmegakaryopoiesis with many micromegakaryocytes. Abnormal α-granules are not seen in the bone marrow and cultured megakaryocytes. Platelets have a normal lifespan in the circulation. The number of megakaryocytes in the bone marrow is increased, accompanied by impaired maturation. Together these findings suggest that platelet release is substantially impaired. PTS occurs as a result of hemizygous loss of the *FLI1* transcription factor gene, which has been shown to be critical for megakaryocyte differentiation and release of platelets. *FLI1* shows monoallelic expression during a brief window in megakaryocyte differentiation. This monoallelic expression explains the dominant inheritance pattern of PTS despite the presence of one normal *FLI1* allele.[48,49]

Autosomal Dominant Thrombocytopenia with Incomplete Megakaryocyte Differentiation and Linkage to Chromosome 10

The genetic defect for this autosomal dominant thrombocytopenia has been mapped to a region on the short arm of chromosome 10 (10p11–12).[50] This disorder is characterized by moderate thrombocytopenia, abnormal platelet size, and incomplete differentiation of megakaryocytes. Clinical features consist of mild to moderate bruising but absence of major bleeding even with minor surgery and childbirth, suggesting that the residual platelets have normal hemostatic function. However, platelets are deficient in GPIa and α-granule content. Morphologically, the platelets appear normal. Bone marrow examination reveals impaired megakaryocyte maturation and small megakaryocytes. Colony assay on bone marrow and peripheral blood cells reveal expanded progenitors across all hematopoietic lineages, and tremendously increased expansion of immature megakaryocytes (CFU-Mk). Serum TPO level is only moderately elevated and is usually lower than expected for the degree of thrombocytopenia.[51]

Recently, mutations in *ANKRD26* were identified in the original patients and in several additional families around the world; these mutations accounted for 10% of patients in an inherited thrombocytopenia database.[52] The term "thrombocytopenia 2" (THC2) has been applied to this disorder.

Gray Platelet Syndrome

The gray platelet syndrome for which both autosomal recessive and autosomal dominant inheritance have been described is characterized by macrothrombocytopenia with bleeding tendency, myelofibrosis, and classical abnormal platelet morphology.[53] The α-granules are absent or greatly reduced, giving the platelets a gray color on Wright-Giemsa stain. The α-granules are the principal storage site for hemostatic proteins such as fibrinogen, vWF, thrombospondin, and factor V and for growth factors such as platelet-derived growth factor and transforming growth factor-β.[54] One result of absence of α-granules is a continued leakage of growth factors and cytokines into the marrow, causing myelofibrosis.

Amegakaryocytic Thrombocytopenia with Radial-Ulnar Synostosis Syndrome in Association with HOXA11 Mutation

Homeobox genes encode regulatory proteins that are critical to bone morphogenesis as well as hematopoietic differentiation and proliferation.[55] This defect is the first reported germline HOX gene mutation associated with a human nonneoplastic hematologic disorder, and only the third HOX gene implicated in a human disorder.[56] *HOXA11* is suggested to be endogenously expressed in very early hematopoietic precursor cells and involved in regulation of megakaryocytic differentiation.[57] Clinical features consist of CAMT, aplastic anemia, proximal radial-ulnar synostosis, clinodactyly, syndactyly, hip dysplasia, and sensorineural hearing loss.[58] Platelet transfusions are effective as initial symptomatic management. The only definitive treatment is hematopoietic stem cell transplantation.[59]

X-linked Thrombocytopenia

X-linked Microthrombocytopenia (WAS Gene Mutation)

Wiskott-Aldrich syndrome (WAS), originally described in 1937, is now known as an X-linked hereditary disorder associated with combined immunodeficiency, thrombocytopenia, small platelets, eczema, and an increased risk of autoimmune disorders and cancers. It has a broad range of phenotypes.[60] At one end of the clinical spectrum, patients exhibit platelet abnormalities only, and at the other end, patients manifest thrombocytopenia, eczema, and immune abnormalities with progressive T-cell lymphopenia, and increased susceptibility to infection. The severe form of WAS and its milder manifestations—X-linked thrombocytopenia and X-linked neutropenia—are caused by mutations in the gene for the WAS, located at Xp11.22–p11.23 and cloned in 1994.[61,62,63,64] The *WAS* gene is composed of 12 exons and encodes a polypeptide of 502 amino acids. Most mutations consist of single-nucleotide substitutions, small insertions and deletions, and splice-site mutations, and these are distributed throughout the coding region and the intron–exon junctions.[65] Even within families, the same genotype can be associated with varying phenotypes. Measurement of the WAS protein (WASP) is now possible, making diagnosis less difficult.[66] The mature WASP contains numerous protein-interacting domains and appears to provide a critical link between the cellular cytoskeleton and signal transduction pathways. WASP is a key regulator of actin polymerization in hematopoietic cells. It has five well-defined domains that are involved in signaling, cell locomotion, and immune synapse formation. WASP facilitates the nuclear translocation of nuclear factor κB and has been shown to play an important role in lymphoid development and in the maturation and function of myeloid monocytic cells.[67]

Megakaryocyte mass is normal or increased in WAS. Platelet differentiation and production are normal, and platelets produced in vitro are normal in size. These observations suggest that increased destruction in the spleen is responsible for both the thrombocytopenia and decreased platelet size. Management of patients with WAS is challenging; however, early diagnosis is very important for prophylaxis and treatment.[68] Splenectomy definitely improves platelet counts in these patients, which frequently return to normal, suggesting a role of the reticuloendothelial system in platelet removal. Notably, antiplatelet antibodies are not present.[69] The only curative therapy remains hematopoietic stem cell transplantation, which corrects both thrombocytopenia and immunodeficiency. The administration of WAS gene corrected autologous hematopoietic stem cells may represent an alternative treatment option.[60]

X-linked Macrothrombocytopenia with Dyserythropoiesis (GATA-1 Mutation)

The X-linked gene *GATA-1* regulates the expression of a large number of genes in multiple cell types.[70,71] GATA-1 transcription factor contains both DNA binding and transactivation activity within three functional domains: Two zinc fingers (known as the N finger and the C-finger) and an N-terminal activation domain. The C-finger is responsible for binding of GATA-1 to typical GATA-binding sites (WGATAR consensus). The N terminus of GATA-1 constitutes an activation domain, as defined by the ability of this region to confer transcriptional activation in reporter assays in fibroblasts.[72] Taken together, these domains act in a manner similar to a multitude of transcription factors that bind DNA and activate transcription of target genes. In addition to binding DNA, the N finger has a second essential function, recruitment of the co-factor Friend of GATA-1 (FOG-1).[73] FOG-1, as is GATA-1, is primarily expressed in hematopoietic cells, and is absolutely essential for the development of red blood cells and megakaryocytes. Five germline mutations of *GATA*-1 that cause X-linked disorders have been described, and all cluster in the N-terminal zinc finger.

GATA-1 mutation–associated thrombocytopenia is clinically distinguished from WAS by the presence of large or normal-sized platelets and the absence of immunodeficiency, eczema, and lymphomas.[74] Thrombocytopenia is more severe (10,000 to 40,000/μl). Clinically, bleeding and bruising in affected individuals are severe, and platelet aggregation studies have shown that platelet function is also diminished.[75] The bone marrow is hypercellular, with dysplastic features in the erythroid and megakaryocytic lineages.[76]

Others

22q11.2 Deletion Syndrome (DiGeorge Syndrome)

This relatively common genetic disorder occurs in 1:4,000 live births, and in addition to thrombocytopenia, is associated with cardiac abnormalities, velofacial anomalies, hypocalcemia, immune defects, and a variety of other features.[77] One particular gene in the region of 22q11-*TBX1* is likely responsible for cardiac defects.[77] The macrothrombocytopenia seen in this disorder is mild.[74]

ACQUIRED THROMBOCYTOPENIA

Deficient Platelet Production

Deficient platelet production may result from three mechanisms: Hypoplasia or suppression of the precursor megakaryocytes; ineffective thrombopoiesis despite a normal precursor mass; or, rarely, deficiency or aberration of thrombopoietic control mechanisms.

Acquired Amegakaryocytic Thrombocytopenic Purpura

Acquired amegakaryocytic thrombocytopenic purpura (AATP) is a rare cause of thrombocytopenia associated with decreased or absent megakaryocytes in otherwise normal bone marrow. The prevalence is possibly higher than reported, as many cases are underdiagnosed or misdiagnosed as immune thrombocytopenia.

The differential diagnosis of patients with severe thrombocytopenia and isolated amegakaryocytosis includes a misdiagnosis of immune thrombocytopenic purpura, as mentioned above; ethanol use or drug ingestion; immune suppression associated with diseases such as systemic lupus erythematosus; and prodromal manifestations of acquired aplastic anemia, myelodysplastic disorders, or acute leukemia.[78,79] Thrombocytopenia and amegakaryocytosis caused by chemotherapy or postradiation therapy should be apparent.

The pathogenesis of AATP is uncertain. AATP can occur individually or as a component of aplastic anemia secondary to exposure to environmental agents such as viruses (cytomegalovirus [CMV], parvovirus B19), and certain toxins such as benzene.[78,80] Both cell-mediated suppression of megakaryopoiesis and the role of humoral immunity in AATP have been proposed, but the exact role of either remains unclear. A marked increase of T-activated suppressor cells ($CD8^+/DR^+$) in association with AATP has been reported.[81] AATP has also been associated with high levels of anti-TPO IgG antibodies.[82] No cytogenetic abnormality has been shown to be consistently associated with AATP.[83] A defect in cytokine-mediated regulation of megakaryopoiesis is another proposed mechanism leading to AATP, but conclusive data are lacking.

Patients with AATP do not have a palpable spleen. The platelets are usually small or normal in size. An increased mean red cell volume is a common finding. In most patients, an etiology cannot be determined, and empirical therapy is necessary. Platelet transfusions should be used to treat bleeding and may be required prophylactically in some patients. Although there are occasional spontaneous remissions, most sustained remissions have occurred in patients receiving immunosuppressive therapy. Treatment with intravenous immunoglobulin, prednisone, cyclophosphamide, and vincristine has not been efficacious in AATP. Myeloablative chemotherapy (busulfan and cyclophosphamide) followed by allogeneic bone marrow transplant from a fully HLA-matched sibling is effective.[84] Danazol has been reported to be effective in two cases of AATP.[85] Antithymocyte globulin (ATG) alone,[86] rituximab,[87] azathioprine,[88] and cyclosporine alone or in combination with ATG, have been shown to be very effective in treatment of AATP.[83,89,90] The role of recombinant interleukin-11 (IL-11, a thrombopoietic growth factor) in AATP is uncertain. The availability of thrombopoietic drugs,[91] may offer another treatment option for AATP patients.

Chemical and Physical Agents That Produce Generalized Bone Marrow Suppression

Ionizing radiation, alkylating agents, antimetabolites, and cytotoxic drugs may produce thrombocytopenia as the result of predictable suppression of the marrow. The mechanisms by which these agents act are well defined, and thrombocytopenia is a common complication when they are used in immunosuppression and cancer chemotherapy. In addition, many drugs, such as chloramphenicol, produce marrow hypoplasia as a result of idiosyncratic reactions. The pathophysiology in these cases is poorly understood.

Agents that produce thrombocytopenia may damage other bone marrow precursors as well as megakaryocytes, and the usual picture is one of diffuse bone marrow hypoplasia and pancytopenia. Rarely, only thrombocytopenia may be present. Platelets often are the last cell type to return to normal after recovery from bone marrow hypoplasia; in some patients, thrombocytopenia may persist indefinitely.

Drugs That Selectively Suppress the Megakaryocyte

Chlorothiazides. Chlorothiazides and various congeners may produce thrombocytopenia by one of at least two mechanisms: by the formation of platelet antibodies or by a poorly understood suppression of thrombopoiesis.[92] The latter action is by far the most common. Evidence of marrow suppression is largely indirect.[79] Serologic tests for platelet antibodies usually yield negative results. Diminution in the number of megakaryocytes has been observed in infants born of mothers who were taking these drugs, but few instances of megakaryocytic hypoplasia have been documented in adults. Mild asymptomatic thrombocytopenia may occur in as many as 25% of patients taking these agents, an observation that implies that thrombocytopenia may be a pharmacologic rather than an idiosyncratic effect. Recovery from thrombocytopenia associated with the use of thiazide drugs is slow, and thrombocytopenia usually can be reproduced only by readministration of the drug for a protracted period.

Estrogens. Estrogenic hormones appear to affect platelet kinetics in animals both by facilitating reticuloendothelial phagocytosis and by impairing thrombopoiesis. Neither effect has been convincingly demonstrated in humans, but several instances of "amegakaryocytic" thrombocytopenia have been reported after the administration of diethylstilbestrol. In one patient, thrombocytopenia recurred when the hormone was readministered.[93]

Ethanol. Ethanol can suppress platelet production, a phenomenon that may be a common cause of mild thrombocytopenia in the alcoholic patient. In most reported cases, nutritional factors, folate deficiency, and splenomegaly were excluded, but patients did have evidence of impaired hepatic function. Platelet counts $<100{,}000/\mu l$ occur in as many as 26% of acutely ill alcoholics.[94,95] The experimental administration of ethanol produces thrombocytopenia with decreased platelet survival and platelet turnover.[96] Bleeding is rare, and when ethanol is withdrawn, the platelet count begins to increase in 2 to 3 days and returns to normal or supranormal levels in 2 to 3 weeks.[95] Several patients developed venous thromboembolic disease when platelet counts reached values $>500{,}000/\mu l$.[97]

Pathophysiologic studies in alcohol-induced thrombocytopenia reveal accelerated platelet destruction and a subnormal compensatory increase in thrombopoiesis. Platelet function abnormalities have also been described. The bone marrow usually reveals normal numbers of megakaryocytes. Studies using mice and guinea pig megakaryocytes demonstrate that the effect of ethanol is primarily on the maturing megakaryocytes, a finding consistent with ineffective thrombopoiesis.[98] Several cases of bone marrow hypoplasia secondary to consumption of excessive alcohol have also been described. Colony-forming unit (CFU) granulocyte-macrophage–derived colony formation in one of these patients was inhibited by much lower concentrations of ethanol than that of normal volunteers.[99]

Drugs That Cause Ineffective Thrombopoiesis

Ineffective thrombopoiesis may play a role in several different types of thrombocytopenia. Thrombocytopenia is a consistent feature of megaloblastic hematopoiesis that results from deficiency of vitamin B_{12} or folic acid. Although seldom severe and rarely of clinical significance, this form of thrombocytopenia results from a distinctive abnormality of platelet production called *ineffective thrombopoiesis*. This abnormality was first demonstrated in thrombokinetic studies and is characterized by diminished platelet production despite the presence of an increased megakaryocyte mass. Thus, it is analogous to ineffective erythropoiesis,

which is also characteristic of the megaloblastic anemias. Platelet production, whether calculated per megakaryocyte or per nuclear unit, is diminished. Although the number of megakaryocytes increases in response to thrombopoietic stimuli, the normal concomitant increase in their volume does not occur. This phenomenon presumably results from impaired DNA synthesis and the consequent limitation in nuclear endoreduplication. In stained smears, the megakaryocytes often appear hyperlobulated, and circulating platelets are abnormally large.[100] Moderate shortening of platelet survival and, rarely, hypoplasia of the megakaryocytes may be important contributory factors in the production of thrombocytopenia in some cases.

Thrombocytopenia Caused by Abnormal Platelet Pooling

The splenic pool normally contains approximately one third of the total platelet mass, and this pool may increase in size as a result of disorders that are associated with splenomegaly, such as cirrhosis with portal hypertension, sarcoidosis and other granulomatous infections, Gaucher and other lipid-storage diseases, leukemias and lymphomas, and Felty syndrome.[101,102,103] This shift of platelets into the spleen may result in thrombocytopenia in the circulating blood despite a normal or even increased total platelet mass. The clinical picture in hypersplenic thrombocytopenia is usually dominated by the underlying disease, and numerous other hematologic abnormalities, such as neutropenia, anemia, and coagulation defects, may also be present.

The pathophysiology of thrombocytopenia in disorders associated with splenomegaly is not completely understood. Rat spleens demonstrate large numbers of platelets adherent to reticuloendothelial cells.[104] It is also hypothesized that the splenic pool increase may occur because of very slow passage of platelets through the tortuous splenic vasculature. The platelets in the splenic pool are in equilibrium with the circulating pool and can be mobilized with an infusion of epinephrine or during plateletpheresis.[105,106,107] This is in contrast to the irreversible thrombocytopenia caused by splenic removal of damaged or antibody-coated platelets in disorders such as autoimmune thrombocytopenic purpura. There is some evidence for accelerated platelet destruction in many instances of thrombocytopenia associated with disorders of the spleen.[108,109] Survival of isotopically labeled platelets is shortened in some patients with cirrhosis and portal hypertension, even though the major mechanism of thrombocytopenia in these patients appears to be splenic pooling.

The usual laboratory findings are pancytopenia with mild thrombocytopenia and a normal or moderately increased number of megakaryocytes in the bone marrow. Platelet counts in cirrhotic patients have been as low as 20,000/μl, although thrombocytopenia of this severity is uncommon. Patients with hypersplenism have smaller platelets than those with autoimmune thrombocytopenia, so platelet sizing may provide a means of differentiating between thrombocytopenia related primarily to immunologic platelet destruction and that related to big-spleen syndromes. In general, the severity of the thrombocytopenia correlates poorly with the size of the spleen, but it is nonetheless difficult to entertain a diagnosis of thrombocytopenia caused by abnormal splenic platelet pooling in the absence of significant splenic enlargement.[110]

Therapy is seldom indicated for thrombocytopenia alone, but splenectomy, embolic occlusion of the splenic vasculature, and splenic damage secondary to infusion of radiolabeled particles can improve the thrombocytopenia and sometimes alleviate the pancytopenia completely.[108,111,112,113,114,115,116] Patients with thrombocytopenia secondary to cirrhosis with portal hypertension may benefit from portocaval shunts or transjugular intrahepatic portosystemic shunts.[117,118]

Thrombocytopenia Caused by Hypothermia

In humans, mild reversible thrombocytopenia is a predictable consequence of surgical hypothermia below 25°C.[119,120] Thrombocytopenia has also been noted after hypothermia caused by environmental exposure.[121] Finally, thrombocytopenia occurs in almost all patients undergoing one- or two-cycle cryotherapy for hepatic metastases from colorectal adenocarcinoma.[122]

Adhesion of platelets to subendothelium is mediated through an interaction of the platelet GP Ib–IX–V complex and subendothelial vWF. The GP Ib–IX–V complex comprises four transmembrane polypeptide chains, GPIbα, GPIbβ, GPIX, and GPV. Lipid rafts (also known as glycolipid-enriched membranes) are dynamic assemblies of cholesterol and sphingolipids that are more ordered in structure than the rest of the plasma membrane.[123] Receptor clustering is an essential feature of signaling through lipid rafts and occurs in platelet membrane at lower temperatures.[124] A subset of the GP Ib–IX–V complex is constitutively associated with lipid rafts in unstimulated platelets.[125] Upon exposure to cold, the cooled platelets irreversibly reorganize vWF receptors (the $[GPIb\alpha\beta IX]_2V$ complex) into clusters on the platelet surface. The hepatic macrophage integrin receptor Mac-1 (CD11b/CD18) recognizes clustered GPIbα, leading to phagocytosis of cooled platelets. Cooling, however, does not grossly impair the interaction between GPIb and activated vWF, implying that the hemostatic and clearance functions of GPIb are distinct.[126,127]

Thrombocytopenia Associated with Infections

Purpura was recognized as a manifestation of pestilential fevers 2,000 years ago. Several factors are now known to cause bleeding in association with infections, of which thrombocytopenia is the most common.

Thrombocytopenia Associated with Viral Infections

Viruses may produce thrombocytopenia by several different mechanisms: Impaired platelet production as a result of invasion of megakaryocytes by the virus, impaired platelet production caused by toxic effects of viral proteins on progenitor cells, viral-induced hemophagocytosis, destruction of circulating platelets by the virus, and increased platelet destruction caused by binding of viral-induced autoantibodies or viral antigen–antibody complexes.

The administration of live measles vaccine produced significant yet subclinical thrombocytopenia in most normal children.[128] Degenerating vacuolated megakaryocytes were evident 3 days after administration of the vaccine. The nadir of the platelet count occurred 7 days after vaccination. There are now several reports of thrombocytopenia occurring after immunization with measles–mumps–rubella vaccine, monovalent measles vaccine, and measles–mumps vaccine.[129] Thrombocytopenia has been severe (<20,000/μl), and some patients have had significant hemorrhagic complications. The majority of the patients have been <2 years of age, but the age range was 1 to 40 years.[130] Thrombocytopenia after vaccination for hepatitis A and B and varicella has also been noted.[131,132,133] Children with neonatal infections with mumps and rubella are often thrombocytopenic,[134,135] and hepatomegaly and splenomegaly may also be present. CMV infection is usually asymptomatic in immunocompetent adults. However, there are reports of severe thrombocytopenia and even thrombocytopenia with hemolysis.[136,137] It is unclear whether the thrombocytopenia is caused by a direct cytopathologic effect of the virus on megakaryocytes, viral-induced hemophagocytosis, or immunologic destruction.

Parvovirus B19 is the etiologic agent responsible for erythema infectiosum. It is also cytotoxic to erythroid progenitors and can cause aplastic crises in patients with hemolytic anemia and chronic bone marrow failure in immunocompromised hosts. Thrombocytopenia may occur in some of these patients,

and recent studies demonstrate cytotoxic effects of viral nonstructural-1 proteins on megakaryocytes.[138,139,140]

Thrombocytopenia has been reported following the administration of adenoviral gene transfer vectors.[138,141] The interaction between adenovirus and platelets leads to platelet activation and rapid exposure of P-selectin on the platelet surface. P-selectin interacts with major P-selectin ligand on leukocytes, leading to the formation of platelet–leukocyte aggregates.[142] Adenovirus also activates endothelial cells either directly or indirectly through activated platelets. It is followed by increases in total amounts of vWF and of ultralarge vWF multimers in plasma as well as an increase in the number of circulating endothelial cell–derived microparticles. Endothelial cell activation and the associated up-regulation of adhesion molecules (VCAM-1) contribute to leukocyte and/or platelet leukocyte aggregate rolling and transendothelial migration, a critical process for tissue macrophage influx. This is followed by removal of activated platelets by tissue macrophages.

Thrombocytopenia Associated with Bacterial and Protozoal Infections

Thrombocytopenia commonly is associated with septicemia resulting from both Gram-negative and Gram-positive bacteria. This complication is particularly common in infants and children, and the presence of unexplained thrombocytopenia, particularly in this age group, should always alert the physician to the possibility of septicemia. The etiology of thrombocytopenia may be multifactorial. Thrombocytopenia may be caused by disseminated intravascular coagulation (DIC), and the diagnosis of DIC may be apparent when coagulation studies are performed. Thrombocytopenia has also been described in patients with Gram-negative or Gram-positive septicemia, and 46% of these patients had elevated platelet-associated immunoglobulin G without evidence of DIC. These studies were interpreted as demonstrating the presence of platelet destruction caused by splenic destruction of immune complex–coated platelets. These data must be reinterpreted with third-generation immune complex capture assays that can better define platelet autoantibodies and immune complexes.

Platelet adherence to damaged vascular surfaces may also account for thrombocytopenia in certain bacterial infections, such as meningococcemia. Endotoxins, exotoxins, or platelet-activating factor may damage platelets, resulting in increased clearance. Patients with sepsis syndrome may develop hemophagocytic histiocytosis with phagocytosis of platelets, white cells, and platelets in bone marrow histiocytes.[143]

Thrombocytopenia may also be caused by direct platelet toxicity caused by the microorganism. Thrombocytopenia occurs in >80% of patients with malaria, and platelets from malaria patients have been demonstrated to contain plasmodia.[144] Significant ultrastructural changes in platelets of patients with malaria are present, and the extent of abnormal findings correlates with the level of parasitemia.[145]

The pathophysiology of thrombocytopenia in malaria has recently been studied in a mouse model of experimental malaria induced by *Plasmodium berghei*. Signaling through multipotent immunomodulator CD40L and its receptor CD40, expressed on activated platelets, initiates the caspase cascade, resulting in apoptosis of the platelet and the formation of platelet microparticles.[146] Early depletion of platelets leads to an altered immune response with significantly decreased levels of proinflammatory cytokines, such as interferon-γ and interleukin-2 (IL-2), as well as increased levels of IL-10, indicating a role for platelets in the regulation of pathogenic cytokines and cell-mediated immune responses.[147] Cell-mediated rather than the humoral immune response has been shown to play a major role in development of thrombocytopenia.[148]

Theoretically, any bacterial or protozoal infection can be associated with thrombocytopenia that is caused by one of the mechanisms hypothesized in this chapter. There are reports of thrombocytopenia in Lyme disease and *Mycoplasma pneumoniae* infections, a manifestation of these infections that appears to be uncommon.[149,150]

Patients with thrombocytopenia associated with infection should be tested for the presence of DIC. At this time, no other clinically available tests can be used to define the precise etiology in patients without evidence of DIC. The most important therapy for infection-related thrombocytopenia is that directed at the underlying infection. Platelet transfusions, with or without intravenous IgG, can be used to control bleeding until antimicrobial therapy is effective.

Thrombocytopenia after Massive Blood Transfusion

Massive blood transfusion is defined as complete replacement of a patient's blood volume within 24 hours, usually 10 units of packed red blood cells for an average-sized adult. Because packed red blood cells do not contain a significant number of functional platelets and do not replace labile clotting factors, there has been concern about the incidence of developing hemostatic abnormalities and clinical bleeding in patients given only packed red blood cells.

Some studies demonstrate a correlation between the number of units of packed red blood cells transfused and both reduction in platelet counts ("dilutional thrombocytopenia") and increases in prothrombin and partial thromboplastin times. However, significant changes (platelets, 50,000 to 100,000/μl) are not apparent until patients have received >15 units of blood.[148,149]. *Severe thrombocytopenia,* defined as a platelet count <50,000/μl, is most common in patients receiving >20 units of blood.[151,152] Microvascular bleeding occurs in 20% to 60% of patients who are massively transfused, but neither the platelet count nor changes in coagulation studies can be used to predict which patients will bleed.[153] Although bleeding appears to be more dependent on thrombocytopenia than on coagulation abnormalities, prophylactic administration of platelets was no more effective than equivalent volumes of prophylactic fresh-frozen plasma infusions in preventing bleeding.[154] Therefore, it is recommended that platelet and plasma replacement during massive transfusions be guided by serial monitoring of platelet counts, prothrombin time, and partial thromboplastin time, and that platelet counts be kept >75,000/μl and prothrombin time and partial thromboplastin time <1.5 times normal.[152] The coagulopathy associated with massive blood transfusion is discussed further in Chapter 54.

CHAPTER 50

BLEEDING DISORDERS CAUSED BY VASCULAR ABNORMALITIES

George M. Rodgers, Matthew M. Rees

This chapter discusses causes of bleeding that are not the result of thrombocytopenia, coagulation factor deficiency, or qualitative platelet defects. Bleeding disorders caused by these various "vascular" abnormalities represent a heterogenous group of diseases, and in considering the differential diagnosis, it is convenient to consider cutaneous causes, connective tissue abnormalities, vascular lesions, and intravascular causes.

CLINICAL APPROACH TO THE PATIENT

The initial approach to the bleeding patient is discussed in Chapter 45. When considering "vascular" causes of bleeding, the appearance of the lesions (petechiae vs. more extensive ecchymosis, size, shape, color), location and pattern of involvement, associated features (fever, ulcers, scars, livedo reticularis), and the clinical setting are helpful clues. Table 50.1 lists some common physical finding patterns helpful in considering the differential diagnosis of vascular disorders.

Purpura is the term used to describe the skin lesions that develop when red blood cells extravasate from capillaries. Purpura refers to either pinpoint lesions called petechiae or more widespread lesions known as ecchymoses. Purpura can be differentiated from other erythematous lesions by the use of diascopy, which is the application of a glass slide to the border of the lesions. True purpura does not blanch with pressure.[1]

MECHANICAL PURPURA

External pressure such as blunt trauma results in ecchymoses when the force is sufficient to disrupt vascular integrity and allow extravasation of red blood cells. The size of the resulting lesion is dependent on the durability of the tissue traumatized, the vascularity of the region, the density of the surrounding tissue, and the time elapsed.[2,3] The extent of bruising can increase over time, and tracking through tissue planes can occur, resulting in bruises in areas remote from the area of trauma.[4] The color of the lesion is in part dependent on the location of the red cells—lesions near the surface have a more reddish color, and deeper lesions appear bluish. This finding is due to optical scattering in the dermis, and the fact that blue wavelengths scatter and reflect more than red.[5] Bruises change color with time, and the color of bruise has been used to determine the age of lesions. However, evidence suggests that there is more variability in color changes than previously recognized.[4,6]

Mechanical purpura can be seen on occasion with minor trauma such as blood pressure cuff monitoring in anticoagulated patients[3] or even vigorous scratching. Young adults playing active sports such as basketball can develop calcaneal petechiae resulting from relatively minor, but repetitive, heel trauma.[7] Periorbital, face, or neck purpura can occur after a sudden increase in intravascular pressure with a Valsalva maneuver[8] and has been described after bungee jumping.[9]

Suction purpura occurs when negative pressure is applied to the skin in sufficient force to result in extravasation of erythrocytes. Young healthy people develop petechiae with 350 to 400 mm Hg negative pressure, but the required amount of pressure to induce purpura decreases with age to as low as 100 mm Hg.[10] The application of rubber suction devices to the forehead can result in circumscribed purpura. This seems to occur mostly when new parents apply children's suction toys to their foreheads and has been termed *cyclops purpura*.[11] A similar, relatively common cause of suction purpura is seen in adolescents who place a drinking glass over their chin and suck out the air to form a vacuum, ultimately causing chin or perioral purpura.[12] Adolescents are also prone to develop small purpuric lesions in the neck region from "hickeys" or "love bites," another form of suction purpura.

Large areas of contusions develop with blunt force injuries. Certain patterns of contusion can help identify the type of device causing the injury. Skin bruises corresponding to the sites of seat belts are known as "seat belt mark" signs. It is important to recognize these, as the presence of this sign should alert physicians to the higher likelihood of internal injuries.[13] A direct blow from a linear or cylindric object causes parallel lines ("tram-line" appearance) with central clearing, as the blood beneath the site of highest impact is displaced laterally. Similarly, a bruise in the shape of a circle with central clearing may occur as a result of a blow from the circular edge of a pipe or spherical objects.[14] Caution, however, should be used in interpreting these types of bruises, as simple bruises can sometimes occur with "ring resolution."[15] Circular contusions 1 to 1.5 cm in diameter may be due to fingertip pressure and grab marks or bite marks, and they show semicircular arch contusions, but are highly variable.[14] Certain bruising patterns can suggest child or elder abuse, but results should be interpreted carefully.[16,17]

Larger ecchymotic areas also may demonstrate other patterns that can be a clue to underlying pathology. The well-known Cullen sign refers to bluish discoloration around the umbilicus, and Grey-Turner sign is flank ecchymosis. Both may indicate hemorrhagic pancreatitis or a rectus sheath hematoma.[18] Scrotal ecchymosis may be a clue to intraperitoneal hemorrhage, and perianal ecchymosis has been described as a manifestation of aneurysmal rupture into the sigmoid mesocolon.[19,20] "Raccoon eyes" and mastoid ecchymosis (Battle sign) may indicate a basilar skull fracture after head trauma.[21] Ecchymosis occurring in patients with swollen calves suggests a ruptured popliteal cyst with gravitational spread of the bruise down to the ankle and occasional linear appearance ("tide mark" appearance) with sparing of the foot and lower ankle due to the pressure of footwear.[22]

STRUCTURAL MALFORMATIONS OF VESSELS

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT) was first described in 1864 by Sutton[23] and later recognized and reported by Rendu,[24] Osler,[25] and Weber,[26] and it is thus also known as Osler-Weber-Rendu syndrome. It is an autosomal dominant disorder characterized by multiple telangiectatic lesions involving the skin and mucous membranes associated with epistaxis and other bleeding complications. HHT has an estimated prevalence of 1 in 8,000,[27] with complete penetrance by 40 years of age.[28]

Genetic studies have identified several mutations responsible for the vascular malformations. Mutations in the endoglin gene on chromosome 9 (HHT1) or in the activin receptor–like kinase

TABLE 50.1

COMMON PHYSICAL FINDINGS AND ASSOCIATIONS OF VASCULAR DISORDERS

Pattern and Usual Location	Etiology	Associated Features
Subconjunctival and axillary petechiae	Fat emboli	Dyspnea
Periorbital, facial, and neck petechiae	Valsalva maneuvers	
Periorbital ecchymosis ("black eye")	Trauma; in penetrating globe injuries without periorbital trauma, suggests posterior rupture	
"Raccoon eyes"	Basilar skull fracture	
"Battle sign" (mastoid ecchymosis)	Basilar skull fracture	
Palatal petechiae	Viral upper respiratory infection	
Ecchymosis of limbs and face of infant	AIHE	Inflammatory edema
Eyelid and periorbital edema and purpura, often after dependency; purpura in other areas with minimal trauma	Amyloid	
Glove and stocking petechiae with areas of confluence and sharp line of demarcation between normal and abnormal areas	PPGSS	
Palm and sole petechiae	Rat bite fever and other infections	
Purpuric lesions on the forearm in elderly patients	Solar or steroid purpura	
Bluish discoloration of the umbilicus (Cullen sign)	Hemorrhagic pancreatitis or rectus sheath hematoma	
Flank ecchymosis (Grey-Turner sign)	Hemorrhagic pancreatitis	
Periumbilical purpura with "thumbprint" signing	*Strongyloides* infection	
Scrotal/perineal ecchymosis	Intraperitoneal hemorrhage or iliac aneurysmal rupture (rupture into sigmoid mesocolon)	
Telangiectatic lesions along the face, lips, nares, tongue, and nail beds	HHT	
Lower extremity palpable, nonblanching purpura	Vasculitis	
Perifollicular lower extremity, with areas of confluence	Scurvy	Gingival, intramuscular bleeds
Urticarial lesions followed by purpura	Urticarial vasculitis	
Proximal thigh involvements often with a "kissing" or symmetric lesion	Calciphylaxis	
Mucosal oozing and easy bruising	EDS	Skin hyperextensibility, joint immobility
Hemorrhagic bulla	Bacterial infections (*Clostridium, Vibrio, Aeromonas*); hypersensitivity to insect bites, snakebites; pemphigus	
"Tram lines"	Blunt force with cylindrical or linear object	
"Ring" bruises	Blunt force with circular end or sphere; may also be seen in normal bruise resolution	

AIHE, acute infantile hemorrhagic edema; EDS, Ehlers-Danlos syndrome; HHT, hereditary hemorrhagic telangiectasia; PPGSS, papular-purpuric gloves and socks syndrome.

(*ALK1*) gene on chromosome 12 (HHT2) account for ~85% of the cases. Currently more than 500 mutations in the ALK1 or endoglin genes have been identified, and each family studied appears to have a unique mutation.[27] Endoglin is an integral membrane glycoprotein expressed on endothelial cells in arterioles, venules, and capillaries. This glycoprotein and ALK1 serve as a binding protein for transforming growth factor-β (TGF-β). TGF-β regulates many transcriptional targets and plays a crucial role in vascular development and homeostasis. Recently identified mutations in the MADH4 gene abnormalities are associated with juvenile polyposis and HHT,[29] and linkage studies suggest additional mutations exist on other chromosomes.[30,31] An HHT mutation database is available at http://www.hhtmutation.org.

The mechanisms by which these genetic defects result in telangiectatic lesions have not been identified. Ultrastructural analysis of cutaneous HHT lesions suggests that postcapillary venule dilation is the earliest identifiable morphologic abnormality.[32,33] As the venules enlarge, they become convoluted and interconnect with arterioles through capillary segments. The capillary segments eventually disappear, and direct arteriolar-venular communications are established (Fig. 50.1). An infiltrate of mononuclear cells appears in the perivascular region of the HHT lesions.

The bleeding manifestations are thought to occur because of mechanical fragility of these vessels. Common abnormalities in the hemostatic system do not seem to represent a major factor in the underlying bleeding tendency. HHT patients manifest a variety of other complications including shunting, emboli, and thrombosis.

Clinical Manifestations

The cutaneous lesions usually appear in affected persons by 40 years of age, and they increase in number with age. The lesions measure 1 to 3 mm in diameter and are sharply demarcated in appearance (Fig. 50.2). They blanch with pressure, but the blanching may be incomplete as a result of "strangulation" of coiled loops of vessels.[34,35] The telangiectatic lesions are most commonly found on the face, lips, nares, tongue, nail beds, and hands. Some patients have only a few lesions, necessitating a thorough search in anyone suspected of having HHT. Bleeding from these cutaneous telangiectasias is uncommon and rarely of clinical importance. One report suggests that capillaroscopy of the dorsal hands can detect morphologic changes in the skin microcirculation, including microscopic telangiectatic lesions, but the clinical utility of this is undefined.[36]

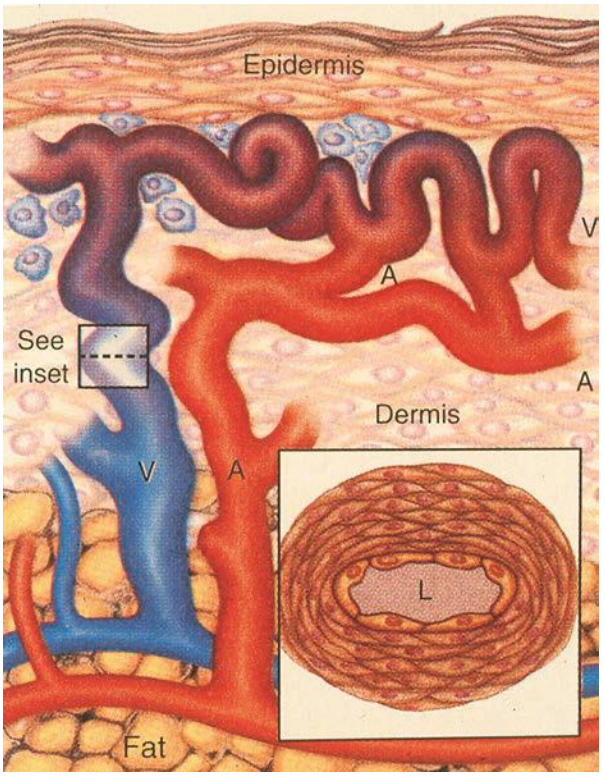

FIGURE 50.1. Arteriovenous malformations in hereditary hemorrhagic telangiectasia. In a fully developed cutaneous telangiectasia, the venule (V) and its branches have become dilated and convoluted throughout the dermis. The connecting arterioles (A) have also become dilated and communicate directly with the venules without intervening capillaries. A perivascular infiltrate is present. The thickened wall of a dilated postcapillary venule is also shown. L, lumen of the vessel. (From Guttmacher AE, Marchuk DA, White RI. Hereditary hemorrhagic telangiectasia. N Engl J Med 1995;333:918–924, with permission.)

Epistaxis is the presenting complaint in up to 90% of patients with HHT. This symptom results from bleeding telangiectatic lesions over the inferior turbinates and nasal septum. Symptoms usually occur before 35 years of age and are highly variable. Approximately one-third of patients have mild symptoms requiring no treatment, and another third have moderate symptoms requiring only outpatient treatment. The remaining third have severe symptoms often requiring inpatient treatment, transfusions or chronic iron replacement therapy, and surgery.[35] The nosebleeds may become more difficult to control as the patient ages.

FIGURE 50.2. Telangiectasias of the tongue and lower lip in a patient with hereditary hemorrhagic telangiectasia. (From Guttmacher AE, Marchuk DA, White RI. Hereditary hemorrhagic telangiectasia. N Engl J Med 1995;333:918–924, with permission.)

Pulmonary arteriovenous malformations (PAVMs) occur in 30% of patients with HHT, and 85% to 90% of people with PAVM are found to have HHT.[32,34,35,37] Genetic linkage studies have found that patients with endoglin mutations have significantly higher rates of PAVMs (40%) than HHT patients with other mutations (14%).[38,39] The PAVMs are primarily located in the lower lung lobes and are multiple. These PAVMs may result in a significant right-to-left shunt, and patients may develop dyspnea, cyanosis, clubbing, fatigue, decreased exercise tolerance, migraine headaches, and polycythemia. Paradoxic emboli can occur and result in brain abscesses, transient ischemic attacks, and strokes. The prevalence of cortical infarcts has been reported to be as high as 14% in patients with a single PAVM and increases to 27% in patients with multiple PAVMs.[40] These lesions may also bleed and result in hemoptysis or hemothorax; pregnant women with PAVMs appear to be at increased risk.[41]

The detection of PAVMs may be difficult in patients with few or no symptoms. Physical examination may uncover an end-inspiratory bruit.[34] A chest radiograph may detect a coin lesion but often misses smaller lesions. Gravitational shifts in blood flow to the lung bases result in increased right-to-left shunting in the sitting or standing position. Physiologic tests such as measuring O_2 saturation in the supine and standing position (on room air and 100% O_2) can detect the positional change in shunting and can be used to screen patients for PAVMs. However, the best screening test for PAVM appears to be contrast echocardiography.[42] Patients with a positive screening test should undergo an unenhanced spiral computed tomography (CT) to confirm and further characterize the PAVM.[43] Pulmonary angiography is a less sensitive study but is necessary in treatment planning.

Approximately 20% of patients with HHT develop significant upper and lower gastrointestinal (GI) tract hemorrhage. Bleeding is rare before the fifth decade of life. Approximately 40% of the bleeding episodes occur from upper GI tract lesions, whereas only 10% occur in the colon, and a full one-half are indeterminate after evaluation.[35] Spontaneous regression of GI bleeding is rare, and steady progression or chronic intermittent bleeding is the norm.

Hepatic involvement occurs in 70% of patients, but symptoms and complications are rare.[44] Patients may have hepatomegaly, a hepatic bruit or thrill, or elevated liver function studies.[45] Types of intrahepatic shunting include hepatic artery to hepatic vein (arteriovenous), hepatic artery to portal vein (arterioportal), and portal vein to hepatic vein (portovenous). These shunts can lead to clinical complications of high-output heart failure, portal hypertension, encephalopathy, biliary ischemia, and nodular regenerative hyperplasia. The dominant type of shunt identified on multiphasic CT does not correlate strongly with the clinical syndrome.[46] Nodular regenerative hyperplasia is found with a 100-fold increased prevalence compared to the general population, and along with portal hypertension can lead to a misdiagnosis of cirrhosis (pseudocirrhosis).[44] It is important to consider this diagnosis in the setting of a liver mass, as biopsy should generally be avoided when suspected. Additionally, if patients with known focal nodular hyperplasia are being treated with estrogen or progesterone therapy, close monitoring is indicated with discontinuation of hormones in the case of symptomatic tumor enlargement.[44] Hepatic AVMs can be detected by dynamic CT,[45] color Doppler ultrasound, magnetic resonance imaging/magnetic resonance angiography (MRI/MRA), or celiac angiography. CT evidence for AVMs includes both the characteristic heterogenous enhancement of the entire liver as well as a dilated common hepatic artery.[46]

The neurologic manifestations of HHT result from PAVM in up to two-thirds of cases.[32] The remainder of the neurologic symptoms are the result of cerebrovascular telangiectasias, AVMs, aneurysms, and cavernous hemangiomas. Ten to twenty percent of patients with HHT have cerebral AVM, but only 10% of people who have cerebral AVM are found to have HHT.[47] The cerebral

TABLE 50.2

CURACAO CRITERIA FOR THE DIAGNOSIS OF HEREDITARY HEMORRHAGIC TELANGIECTASIA (HHT)

1. Epistaxis—spontaneous and recurrent
2. Telangiectasias—multiple, at characteristic sites (lips, oral cavity, fingers, nose)
3. Visceral lesions—with or without bleeding (gastrointestinal, pulmonary, cerebral, hepatic)
4. Positive family history—a first-degree relative with HHT

The presence of three of the above criteria indicate definite HHT; the presence of two criteria are suspicious for HHT.
From Shovlin CL, Guttmacher AE, Buscarini E, et al. Diagnostic criteria for hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber Syndrome). Am J Med Genet 2000;91:66–67.

AVMs are often multiple.[47] The annual risk of bleeding from cerebral AVM is low, reported as 0.41% to 0.72%/year (compared to 2% to 4% risk for sporadic, non-HHT AVM).[47,48] MRI is recommended for detecting these lesions.[41]

The clinical diagnostic criteria (Curacao criteria) are listed in Table 50.2.[49] Genetic testing is now available, but requires sequencing the entire coding regions of ALK1 and endoglin, and is complex and expensive.[27] Consultation with a medical geneticist is recommended.

Management

Asymptomatic patients with HHT should be screened with a thorough history, careful physical exam, complete blood count (CBC), and stool guaiac studies. A brain MRI to screen for cerebral AVMs is recommended, and contrast echocardiography to screen for PAVMs should be performed in all patients at least once after the age of 10. Children younger than 10 should be screened with oxygen saturations in the sitting and supine position every 1 to 2 years, with further testing for saturations <97%.[41] Hepatic AVM screening is controversial, but if considered, an ultrasound is the preferred study.[44]

Recurrent epistaxis can be a perplexing problem, and few trials exist that compare various treatment modalities. Recent efforts to classify the nasal vasculature pattern[50] and develop an epistaxis severity scoring system should pave the way for randomized trials of the various approaches. Prophylactic measures include humidification and saline nose drops. Nasal trauma from vigorous nose blowing, straining, and finger manipulation should be avoided. Antihistamines should also be avoided to prevent drying of the nasal mucosa. Mild bleeding can be treated with absorptive packing and direct pressure. Cautery is commonly used to stop persistent bleeding, but repeated cauterizations can result in necrosis and septal perforation, and should be avoided.[51] Fibrin glue spray was of benefit in a small study.[52] The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser system has been shown to be effective treatment for epistaxis, and analysis of the vascular pattern appears to correlate with the success rates of laser therapies.[50] Argon plasma coagulation also appears promising, and application of topical estrogens may be useful.[53] Arterial embolization or ligation is effective in some patients. Septal dermoplasty is a technique of removing diseased nasal mucosa and the subepithelial telangiectasias and replacing abnormal tissue with an enduring barrier. In refractory cases, rhinotomy with forehead flap reconstruction may be required.[54] The use of estrogen and e-aminocaproic acid is discussed in the following section.

PAVMs are treated with transcatheter embolotherapy[55,56] to diminish the risk of paradoxic emboli and other complications. PAVMs with feeder artery diameters >3 mm should be treated. This procedure is effective at decreasing the right-to-left shunt and improving oxygen saturation, and it has a low complication rate. In cases in which embolotherapy is technically difficult, surgical resection should be used. After embolotherapy or surgery, small AVMs may enlarge and become clinically significant. For this reason, patients should undergo screening helical CT scans every 5 years.[32] Because brain abscesses and septic emboli occur in 1% to 20% of patients with HHT and PAVM, these patients should receive prophylactic antibiotic therapy before dental or surgical procedures.[57]

Bleeding GI vascular malformations can be treated with endoscopic thermal devices including bipolar electrocautery and laser techniques. The mucosa coagulates and sloughs, leaving a small ulcer in the place of the vascular lesion.[58] The ulcer re-epithelializes over the next few days. These treatments are rarely effective for the long term, however, because new lesions continue to develop and small intestinal lesions are not accessible. Estrogen and progesterone have been effective in decreasing the bleeding episodes.

Cerebral AVMs have been treated with surgery, stereotactic radiosurgery, and embolotherapy. A follow-up angiogram should be repeated at 1 year, followed by periodic MRI. Hepatic malformations resulting in high-output heart failure, portal hypertension, or cholangitis should be treated with intensive medical management. Refractory cases have been treated with transcatheter embolization, but the complication rate is significant.[59] The mortality rate of this procedure in HHT has been calculated to be as high as 25% to 40%.[58] Consensus recommendations suggest that the procedure be used only "as a last resort in patients who are not candidates for liver transplant," and should be absolutely avoided in patients with biliary signs or symptoms.[44] Other treatments that have been successfully used include hepatic artery ligation for localized vascular malformations[59] and liver transplant in patients with extensive lesions.[60]

Medical Therapy

Observations in the 1950s that epistaxis decreased during pregnancy and increased after menopause led to the use of estrogens as therapy for HHT. Estrogens in large doses result in metaplasia of the nasal mucosa, resulting in thick layers of squamous epithelium, and electron microscopy studies indicated that estrogen re-established endothelial cell continuity.[61] A small randomized trial of 3 months' duration showed no benefit in reducing the number of bleeding episodes with estradiol valerate.[62] However, another author reported 100% success in an uncontrolled series of 67 consecutively treated patients who continued with high-dose estrogen therapy.[61] Several case reports and one small randomized controlled trial evaluated the use of low-dose estrogen–progesterone combination therapy in patients with severe GI bleeding. The bleeding episodes and transfusion requirements significantly diminished in treated patients.[63] Patients on tamoxifen have also been noted in case reports to have decreased episodes of bleeding. Recent reports suggest that either oral or intranasal tranexamic acid may be useful.[64–66]

Several intriguing case reports describe regression of telangiectatic lesions and decreased bleeding in patients treated for unrelated reasons with interferon, sirolimus, and bevacizumab,[67,68,69] suggesting a possible role for angiogenic inhibitors in managing HHT.

Virtually all patients with HHT have iron deficiency anemia. The treatment of iron deficiency anemia in this setting usually requires more than oral iron replacement. Patients with significant blood loss and anemia who do not respond or do not tolerate maximal doses of oral iron should be given intravenous iron therapy. Three products are recommended for parenteral iron therapy: low-molecular-weight iron dextran, iron gluconate, and iron sucrose.[70] Patients who have toxicity with iron dextran should receive one of the other products. With the currently available options for iron replacement in anemic HHT patients, red cell transfusion should rarely be necessary.

Genetic counseling should be part of the treatment, and referral to a designated HHT center should be considered in most cases. Seventeen U.S. and Canadian HHT centers currently exist and are listed on the HHT Foundation International, Inc. Web site (www.hht.org). Additional centers exist in Europe, South America, Israel, and Asia. A recent review summarizes all aspects of HHT diagnosis and management.[71]

Vascular Malformations

Vascular malformations result from localized errors of angiogenic development. The underlying molecular genetics of angiogenesis are complex (see Chapter 19). Mutations in angiogenic pathways can result in a variety of malformations, including capillary or venous angiomas, cerebral cavernous malformations (CCMs), and AVMs, either as isolated or multifocal lesions. Bleeding problems occur from rupture or leakage from these vascular anomalies, and the clinical sequelae depend on their location.

Skin lesions are the most common vascular malformation and include a variety of birthmarks. Hemoptysis can result from pulmonary vascular anomalies including AVM and a rare disease known as pulmonary capillary hemangiomatosis. Hematuria may rarely be due to genitourinary AVMs or hemangiomas.

GI bleeding may be due to vascular malformations such as the blue rubber nevus syndrome, gastric antral vascular ectasia, telangiectasias, and AVM. GI angiodysplastic lesions deserve special attention, given their frequency. They appear to be due to degenerative dysplasia and are the most frequent cause of obscure GI bleeding. The cause is thought to be intermittent obstruction of the submucosal veins where they penetrate the muscular layers of the colon, ultimately leading to dilated, tortuous submucosal veins and venules.[72] Small intestinal angiodysplastic lesions can be particularly hard to detect, but wireless capsule endoscopy can facilitate this diagnosis. Endoscopic-based therapy or surgery may be required for treatment. This disorder is frequently associated with aortic stenosis, and there are reports of cessation of bleeding after aortic valve repair. Continuous estrogen–progestin treatment is not useful in the prevention of rebleeding from GI angiodysplasia.[73]

Central nervous system vascular lesions include AVMs, berry aneurysms, and cavernomas. Bleeding from these lesions may account for 30% of spontaneous intraparenchymal lobar bleeds.[74] Autopsy studies show the presence of intracranial aneurysms in 1% to 5% of the adult population, and 20% to 50% of these aneurysms rupture. They are sporadically acquired, but patients with autosomal dominant polycystic kidney disease may have up to a 40% incidence. Screening is recommended for families with two immediate relatives with intracranial aneurysms and all patients with autosomal dominant polycystic kidney disease. Histologically, there is a decrease in the tunica media causing structural defects, leading to aneurysmal dilatation at branch points at the base of the brain. Rupture leads to subarachnoid hemorrhage with symptoms ranging from headache and nuchal rigidity to drowsiness, stupor, and coma.[75]

CCMs are vascular lesions characterized by abnormally enlarged capillary cavities without intervening brain parenchyma. The most common presentation is with seizures and cerebral hemorrhage. Sporadic and familial forms exist, with the familial form showing autosomal dominant inheritance with incomplete penetrance. The familial forms usually have multiple CCM lesions. Three CCM loci have been identified, and the clinical and neuroradiologic features compared.[76] CCM3 carriers have an earlier age of onset of cerebral hemorrhage. CCMs are not usually visible on angiography, but T1- and T2-weighted images on MRI show characteristic findings.

Patients with brain AVMs present between the ages of 10 and 40. The risk of bleeding in patients with untreated AVMs is 2.8% per year, but varies between 1% in low-risk patients to 30% in high-risk patients.[77] Genetic abnormalities have been identified in CCMs; these defects result in abnormal blood vessel architecture, and interestingly, may be reversible by statin therapy (reviewed in Ref. 78).

Other Vasculopathies

Amyloidosis

Patients with multiple myeloma or systemic amyloidosis may have light chain deposits in the cutaneous blood vessels. These vessels are particularly fragile, and purpura can occur as a result of minor trauma ("pinch purpura"). The eyelids and periorbital regions are particularly prone to developing purpura (Fig. 50.3), and a classic sign is postproctoscopic periorbital purpura occurring after proctoscopies (for diagnostic rectal biopsies done in the past) or after Valsalva maneuvers. Purpura also commonly develops in other flexural skin areas such as the nasolabial folds, neck, axillae, and umbilicus.[79] Biopsies of the cutaneous vascular lesions demonstrate amyloid deposits in the dermis and subcutaneous tissues, and inflammatory cells are scarce. The diagnosis and treatment of these disorders are discussed in detail in Chapter 99.

Moyamoya Disease

Moyamoya disease is a chronic cerebral vasculopathy initially described in Japan. The disease is characterized by occlusion of the terminal portion of the internal carotid arteries, or the proximal aspects of the middle or anterior cerebral arteries. An abnormal vascular network of collaterals develops in the regional area of occlusion. Cerebral infarcts are common in children, but adults have a higher propensity for intracranial hemorrhage. The risk of bleeding appears to be highest in adult Asians. Features of moyamoya phenomenon differ in U.S. patients, with women aged 30 to 50 most commonly affected, predominantly with ischemic symptoms.[80] The etiology is unknown, and diagnosis rests on characteristic angiographic findings.

Cerebral Small Vessel Disease

Cerebral small vessel disease usually refers to arterioles $<100\ \mu m$ in size consisting of an internal elastic membrane and a tunica media one to two layers thick, or small arteries measuring 100 to 400 μm in size with tunica media composed of smooth muscle cells three to four layers thick. These vessels are usually end arteries. A constellation of syndromes is now recognized as causing cerebral small vessel disease, and these are mostly characterized

FIGURE 50.3. Periorbital purpura in a 58-year-old woman with immunoglobulin A κ plasma cell dyscrasia associated with secondary amyloidosis. (This photograph was kindly provided by Drs. Theresa Scholz and Pamela Nemzer, Department of Dermatology, University of Utah Health Sciences Center.)

by recurrent ischemic strokes with progressive cognitive impairment. Bleeding, however, is a recognized complication of most of these disorders, and it is important to recognize that many disorders have a substantially increased risk of bleeding with anticoagulants.

Degenerative cerebral microangiopathy is characterized by lipohyalinosis of small vessels associated with aging and increasing in severity with vascular risk factors such as hypertension, diabetes, and hyperhomocystinemia. The vessel walls thicken due to sclerosis, hyalinosis, and lipid deposition. Most of the bleeding appears to occur at or near the bifurcation of affected arteries where prominent degeneration of the media and smooth muscles is most appreciated. Occlusion leads to lacunar infarcts, and rupture can lead to cerebral microbleeds and lobar intracranial hemorrhages.

Cerebral amyloid angiopathy typically presents with lobar hemorrhages in patients older than 70 years, and is due to several types of mutations that lead to the accumulation of *b*-amyloid material in the media and adventitia of small cortical and leptomeningeal vessels. This leads to a "vessel in vessel" appearance on pathology studies. Because of the higher risk of bleeding, strict avoidance of anticoagulation and antiplatelet agents are recommended.

Cerebral autosomal dominant arteriopathy with stroke and ischemic leukoencephalopathy (CADASIL) is a cerebral vasculopathy occurring in patients usually between the ages of 40 and 60. Patients present with subcortical strokes and a slowly progressive dementia and may have mood disorders, migraine headaches, and in the later stages, pseudobulbar palsy. The diagnosis is suggested by a characteristic finding of widespread leukoencephalopathy on MRI. White matter lesions located in the temporal poles of the brain are considered pathognomonic for CADASIL syndrome.[81] Recent studies suggest that cerebral microbleeds are found in 31% to 69% of patients with CADASIL syndrome and intracranial hemorrhaging occurs in 25% of patients.[82] The vascular defect lies in the smooth muscle cells, with electron microscopy showing exocytosis of granular osmophilic material from the vascular smooth muscle cells and pericytes.

Type 4 collagen is a component of the vascular basement membrane in the brain, and recent mouse studies indicate that mutations can lead to microvascular fragility and result in intracranial hemorrhage. Some familial forms of intracerebral hemorrhage also appear to be due to mutations in the COL4A1 gene.[83]

BLEEDING DUE TO DISORDERS OF PERIVASCULAR TISSUE

Ehlers-Danlos Disease

The Ehlers-Danlos syndromes (EDSs) are a group of rare connective tissue disorders caused by abnormalities of collagen synthesis or processing. The prevalence is estimated to be 1 in between 10,000 and 20,000 births. A simplified classification system has identified six major types of EDS and their genetic defects.[84,85] The clinical features include hyperextensible, fragile skin associated with joint hypermobility. The majority of patients with EDS also report a history of excessive bruising and bleeding.[86] Other bleeding manifestations may include subcutaneous nodular hematomas, mucosal oozing after dental procedures, hemoptysis, and GI bleeding. In most patients, screening tests show no hemostatic abnormalities, and the bleeding is thought to result from abnormalities in the perivascular collagen leading to fragility of the subcutaneous vessels. However, several authors have noted abnormal bleeding times and platelet function studies, as well as factor deficiencies in individual patients.[86,87]

Certain types of EDS have an increased risk of major bleeding. In particular, vascular EDS (type IV) has unique clinical features

FIGURE 50.4. "Papyrus" scarring and thin skin with petechiae in a patient with Ehlers-Danlos syndrome. (From Anstey A, Mayne K, Winter M, et al. Platelet and coagulation studies in Ehlers-Danlos syndrome. Br J Dermatol 1991;125:155–163, with permission.)

of interest to hematologists. This disorder is due to quantitative or qualitative defects in type 3 collagen, which is particularly abundant in the arterial wall[88,89] and intestine. Patients with this disorder are prone to develop arterial aneurysms and dissections, significant bleeding from spontaneous rupture of medium-sized abdominal arteries, and intestinal rupture.

Carotid-cavernous fistula is another well-documented complication, and clinical diagnosis is based on the findings of pulsatile exophthalmia, tinnitus, thrill, and headache. In addition to vascular abnormalities, patients with vascular EDS have characteristic facial features (prominent eyes, thin nose, small lips, and lobeless ears)[90] and thin translucent skin with a conspicuous venous network. Papyrus scarring (Fig. 50.4) may be present, but patients usually have minimal joint hypermobility (often limited to the hands) or skin hyperextensibility. Median life expectancy is 48 years with one-fourth of the patients developing complications by age 20, and 80% developing complications by age 40.[91] The diagnosis can be confirmed by skin fibroblast cultures with biochemical analysis of type 3 collagen with or without screening for COL3A1 mutations. If vascular EDS is suspected but the above tests are negative, patients should be screened for TGF-β receptor gene mutations, as clinical features overlap with the newly described Loeys-Dietz syndrome (see below).

Patients with EDS, particularly vascular EDS, should generally avoid contact sports and isometric exercise and are advised to avoid medications with antiplatelet properties.[88] Arterial rupture should be considered in the differential diagnosis when these patients present with new-onset symptoms such as abdominal pain. Diagnostic procedures that involve arterial puncture are relatively contraindicated because of a high incidence of complications.[88,92] If surgery is mandatory, extreme care should be used in the manipulation of vascular tissues. Postpartum hemorrhage is a major risk for pregnant patients with EDS, and the management of pregnancy has been reviewed in case reports.[93,94] Patients with vascular EDS can develop uterine or vessel rupture in the peripartum period, and should be followed in high-risk centers.[91] Genetic counseling and referral to the Ehlers-Danlos National Foundation (www.ednf.org) should be considered.

Marfan Syndrome

Marfan syndrome is a genetic disorder with characteristic ocular, skeletal, and cardiovascular abnormalities, affecting 1 in 5,000 individuals. Easy bruisability has been reported but does not seem to be a major feature of the Marfan syndrome.[95] However, the risk of postpartum hemorrhage is reported to be increased.[96]

The basic defect is due to a mutated fibrillin gene on chromosome 15.[97] Fibrillin is a component of extracellular microfibrils

associated with elastin, and is necessary for connecting and anchoring tissue. Fibrillin was recently found to be important as a TGF-β receptor binding protein, holding TGF-β in an inactive complex. Dietz's group discovered that blocking TGF-β in affected mice prevents some of the developmental abnormalities (including aneurysms), suggesting that certain clinical manifestations are due to excess levels of TGF-β.[98] Further studies, in fact, showed that some families diagnosed with Marfan syndrome and familial thoracic aneurysms have a missense mutation in the TBF-β receptor 2, and this syndrome is now known as the Loeys-Dietz syndrome.[98,99]

Loeys-Dietz Syndrome

The pathogenesis of Loeys-Dietz syndrome has been described.[100] Patients with Loeys-Dietz syndrome have a phenotype characterized by hypertelorism, bifid uvula or cleft palate, and arterial tortuosity with vascular aneurysms, resulting in dissections and arterial rupture. The severity of the craniofacial abnormalities appears to correlate with the outcome.[98] The natural history of Loeys-Dietz varies from Marfan syndrome and EDS, with median survival of 37 years (vs. 48 and 70 years, respectively), but with a much lower complication rate after vascular surgery. It is of note that childhood aortic dissections occurred in patients with aortic diameters <5 cm, and it is recommended that repair occur when the maximum dimension of the ascending aorta exceeds the 99th percentile in children.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is an autosomal dominant disease characterized by brittle bones with pathologic fractures as a result of a deficiency in bone matrix. Approximately 95% of cases are caused by mutations in the genes COLA1 and COLA2, which code for the pro-α1(1) and pro-α2(2) peptides of type 1 collagen.[101] There are two α_1-chains and one α_2-chain in each type 1 collagen, and many different mutations in the genes coding for these subunits have been characterized. Eight clinical types of OI are currently recognized.[101] Approximately 25% of patients have been noted to bruise easily; this tendency appears to vary with the clinical type.[102] Skin contains predominantly type 1 collagen, and bruising is thought to be the result of defective supporting structures. The ecchymoses are generally mild and insignificant compared to the broader clinical picture. Recent reports describe patients with extradural hematomas, subdural hematomas, and retinal bleeds after minor trauma in patients with OI, occasionally being misinterpreted as child abuse.[103,104] Excessive bleeding from wound sites after surgery has also been described.[105] Recombinant factor VIIa and desmopressin have been reported to be useful in postoperative bleeding in case reports.[106,107] The Osteogenesis Imperfecta Foundation can be accessed at http://www.oif.org.

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is an inherited connective tissue disorder that results in calcification of elastic fibers,[108] especially in the internal elastic lamina of medium-sized arteries. The basic genetic defect is now known to be a variety of loss of function mutations in the gene encoding the transmembrane transporter protein ABC-C6.[109] This protein is in the multiple drug resistance family of proteins and may function as an efflux pump, but it is not yet known what the substance transported is or how the mutation causes the disease. It is possible that this defect could result in accumulation of compounds that could lead to the calcification of the elastin fibers.[109]

Patients with pseudoxanthoma elasticum have skin that becomes grooved and thickened over time and has been described as resembling Moroccan leather.[110] Other cutaneous features include the development of yellow cutaneous plaques usually in the neck or axillary region or in other flexural sites. Cardiovascular disease results from calcification of the arterial internal elastic lamina. Criteria for the diagnosis of pseudoxanthoma elasticum have been published.[108] Bleeding can result when the calcified vessels rupture. The manifestations include bruising, epistaxis, and bleeding from the uterus, bladder, and joints. GI bleeding occurs in 13% of patients, usually between 20 and 30 years of age, and is usually of gastric origin. Treatment should include the avoidance of gastric irritants and careful control of hypertension and hypercholesterolemia. Regular ophthalmology evaluations are also recommended, as is the avoidance of antiplatelet agents and trauma. First-degree relatives should be screened. The National Association for Pseudoxanthoma Elasticum can be contacted at http://www.pxenape.org/.

Scurvy

Humans require vitamin C in the diet to promote the peptidyl hydroxylation of procollagen. In the absence of vitamin C, collagen strands are weakened as a result of abnormal triple helical structures. The abnormal collagen results in defective perivascular supportive tissues, which predispose to capillary fragility and delayed wound healing.[111,112]

The clinical manifestations of scurvy depend on the severity of vitamin C deficiency. Patients classically develop perifollicular petechiae (Fig. 50.5).[111] The petechiae can coalesce and form purpura, particularly in a "saddle" distribution, and patients may develop gingival or intramuscular hemorrhage. Up to 75% of patients have a multifactorial normochromic, normocytic anemia. Other manifestations include peripheral edema and fatigue.

Patients at risk for scurvy include elderly edentulous patients who cook for themselves, alcoholics, mentally ill patients, and people on unusual diets. The treatment is replacement of ascorbic acid in doses of 200 mg/day.[111,113]

Steroid-induced Purpura

Patients on chronic steroids develop thinning of the connective tissues, and minor trauma can result in extensive purpura, especially in older patients. Avoidance of trauma is the best prophylaxis for bleeding in these patients.

Solar Purpura

Senile purpura or solar purpura is a common phenomenon first described in 1817 by Bateman. The lesions are typically located

FIGURE 50.5. Perifollicular hemorrhages and corkscrew hairs in a patient with scurvy. (From Ghorbani AJ, Eichler C. Scurvy. J Am Acad Dermatol 1994;30:881–883, with permission.)

FIGURE 50.6. Senile purpura (also known as Bateman purpura) in a 70-year-old man. (This photograph was kindly provided by Dr. Kappa Meadows, Department of Dermatology, University of Utah Health Sciences Center.)

on the extensor surfaces of the forearms and dorsum of the hands and occur without recognized preceding trauma (Fig. 50.6).[114] The prevalence in hospitalized patients older than 65 years of age is approximately 5% but increases exponentially with age to include up to 30% of men 90 years of age or older.[115] The skin in elderly people is thin as a result of loss of subcutaneous fat and changes in both the amount and quality of collagen. Skin lesions are thought to develop by incidental lateral displacement of slack skin with resulting capillary shearing. The lesions tend to last longer than other purpuric lesions and do not generally undergo the changes in hue that other ecchymotic lesions do.[114] Hemostasis tests are normal, and no treatment other than reassurance is indicated.

VASCULITIS

The nomenclature of the vasculitides is quite confusing, but an international consensus conference has developed a system based on vessel size. This classification system recommends abandoning the term *hypersensitivity vasculitis* in favor of *microscopic polyangiitis* for small vessel vasculitides with few or no immune complexes and *cutaneous leukocytoclastic* vasculitis for small vessel vasculitis with isolated skin involvement.[116]

Cutaneous Leukocytoclastic Vasculitis

Leukocytoclastic vasculitis is characterized by immune complex deposition in postcapillary venules resulting in an inflammatory infiltrate, red cell extravasation, fibrinoid necrosis of the vessel wall, and fragmentation of nuclei (leukocytoclasis). The lesions typically develop 7 to 10 days after exposure to the offending antigen.

Palpable purpura is the classic clinical finding associated with cutaneous small vessel vasculitis. The lesions are the result of extravasation of erythrocytes into the inflamed dermis; therefore, the lesions do not blanch with pressure. The lesions range in size from pinpoint to several centimeters in diameter and are most prominent on the lower legs. The diagnosis should be confirmed by skin biopsy. Evaluation for the etiologic agent can be challenging and requires a detailed history to identify causative agents (Table 50.3).[117,118] Helpful laboratory studies include CBC, blood cultures, serum protein electrophoresis, cryoglobulins, hepatitis screen, rheumatoid factor, antinuclear antibody, antineutrophil cytoplasmic antibodies (ANCAs), and complement. Systemic involvement should be determined by the history and physical as well as urinalysis, chest radiography, and electrocardiography.

TABLE 50.3

ETIOLOGIES OF LEUKOCYTOCLASTIC VASCULITIS

Underlying disorders
Malignancy (leukemia, lymphoma, myeloma, cryoglobulinemia)
Autoimmune disease (systemic lupus, ulcerative colitis, periarteritis nodosa, Sjögren syndrome, viral hepatitis, primary biliary cirrhosis, etc.)
Infections (viral, bacterial, mycobacterial, fungal)
Drugs/chemicals
Penicillin, aspirin, phenothiazines, tetracycline, retinoids, colony-stimulating factors, contrast dye, insecticides, herbicides
Idiopathic

Antineutrophil Cytoplasmic Antibody–Positive Vasculitis

A major advance in understanding and classifying the vasculitides has been the recognition of ANCAs in specific vasculitic syndromes. Patients with ANCA-associated small vessel vasculitis include three major categories, which are histologically identical. Speed in the diagnosis of ANCA-associated small vessel vasculitis is critical, as early treatment with immunosuppressive drugs can prevent life-threatening organ damage.[117]

Wegener granulomatosis is distinguished by necrotizing granulomatous inflammation and pulmonary, upper respiratory, and renal involvement. Vascular inflammation in these areas can cause epistaxis, hemoptysis, and hematuria. Churg-Strauss disease is defined by the presence of necrotizing granulomas with asthma and eosinophilia. Vasculitis affects the nerves, GI tract, and skin primarily. Microscopic polyangiitis is recognized by the characteristic histology with the absence of asthma and granulomas. This vasculitis typically occurs in males older than 50 years of age. Prodromal symptoms include fever, myalgias, and arthralgias. Microhematuria, proteinuria, and oliguric renal failure may develop, and 30% to 40% of patients develop cutaneous lesions (splinter hemorrhages, palpable purpura). Pulmonary involvement occurs in one-third of patients.

Cryoglobulinemia

Essential cryoglobulinemic vasculitis is a vasculitis with cryoglobulin immune deposits. Cryoglobulins are immunoglobulins (Igs) that form a precipitate in cooled serum. They were first described by Wintrobe and Buell in 1933.[119] The cryoglobulins can precipitate in dermal vessels and result in leukocytoclastic vasculitis[120] and palpable purpura. When the cryocrit is significantly elevated (e.g., in lymphoproliferative diseases), hyaline thrombi can form and result in vasculopathy without associated vasculitis.[120]

Clinically, patients develop crops of purpuric macules, papules, and patches most prominently over the lower extremities that are occasionally associated with burning or pruritus. Cutaneous infarcts and petechiae are also occasionally present. Only rarely are these symptoms precipitated by exposure to cold; more commonly, prolonged standing or exercise is the inciting event. Systemic manifestations of cryoglobulinemia include arthralgias, asthenia, neuropathy, and renal disease.[120] Cryoglobulinemia is further discussed in Chapter 101.

Hypergammaglobulinemic Purpura

Hypergammaglobulinemic purpura (HP) is a syndrome first described by Waldenström in 1943; this disorder is characterized by polyclonal hypergammaglobulinemia associated with recurrent

attacks of palpable or nonpalpable purpura.[121] The syndrome has a marked predilection for women. The onset is often in the third and fourth decades of life, but young children and octogenarians have also been reported to develop this syndrome.[122] The attacks of purpura are often sudden in onset and sometimes occur after prolonged standing, exercise, dancing, wearing tight-fitting clothes (e.g., jeans), and alcohol ingestion.[122,123] Some patients have premonitory symptoms such as stinging, itching, or mild pain before the development of purpura. The purpura typically involves the lower extremities and is palpable in approximately 75% of cases.[124] Associated systemic symptoms include arthralgias (particularly adjacent to the purpura), low-grade fever, and lower extremity edema. The purpura usually resolves over 2 to 10 days. Recurrences are common but highly variable. Some patients have up to four attacks per week; others have only rare recurrences.[124]

HP can be divided into primary and secondary forms. Primary HP occurs with no underlying disease process; secondary HP is identified when the typical symptoms of HP develop in patients with underlying diseases such as Sjögren syndrome, systemic lupus erythematosus, or other autoimmune, inflammatory, or neoplastic diseases.[123,124] The purpuric lesions can occur years before or after the diagnosis of autoimmune disease.

The laboratory features of HP include hypergammaglobulinemia, elevated erythrocyte sedimentation rate, mild anemia, and mild leukopenia. Both primary and secondary HP have a high prevalence of positive rheumatoid factor (88% to 100%).[123,124] Anti-Ro antibodies are similarly elevated in both primary HP and HP associated with Sjögren syndrome[122] and in up to 100% of HP associated with systemic lupus.[124] Histopathologically, the lesions show inflammation of the superficial dermal vessels with an early neutrophil infiltrate followed by a mononuclear cell infiltrate and varying degrees of leukocytoclasis. Skin biopsies are often positive under direct immunofluorescence for IgM and IgG. Circulating immune complexes have also been identified.[121,124]

Treatment in the past has been described as unsatisfactory.[123] However, a recent prospective, nonrandomized trial of 17 patients suggests that milder cases respond to indomethacin or hydroxychloroquine (200 mg twice daily) and more severe cases respond to prednisone at doses more than 20 mg/day.[124] Plasmapheresis results in only temporary relief of symptoms.[125]

A relative deficiency of IgG_2 has been reported in some patients despite the hypergammaglobulinemia. IgG subclass determination should be considered in HP patients with recurrent infections.[126]

Urticarial Vasculitis

Patients who present with purpura after resolution of urticaria may have urticarial vasculitis. Typically, the urticarial lesions burn, sting, or itch and last longer than 24 hours. The trunk and proximal extremities are affected more than the distal extremities. Residual hyperpigmentation may be present after resolution of the skin lesions. The pathogenesis appears to be due to immune complexes that activate complement and lead to mast cell degranulation. Patients with normal complement levels usually have minimal, if any, systemic involvement, whereas patients with depressed complement levels may have more severe disease.[127] Hypocomplementemic urticarial vasculitis is due to anti-C1q precipitins.

Acute Infantile Hemorrhagic Edema

Acute infantile hemorrhagic edema is a leukocytoclastic vasculitis confined to the skin in infants 4 to 24 months of age. Patients present with the dramatic onset of ecchymotic purpura involving the limbs and face with inflammatory edema in an otherwise healthy child. Spontaneous and complete resolution occurs in 1 to 3 weeks. Pathology shows leukocytoclastic vasculitis. Perivascular IgA deposits are often identified, and some authors consider this disorder to be a variant of Henoch-Schönlein purpura (HSP).[128]

Henoch-Schönlein Purpura

HSP is an acute vasculitic syndrome with features of colicky abdominal pain, nephritis, arthritis, and palpable purpura. The manifestations of the syndrome were initially described by Schönlein in 1837 and further developed by Henoch in 1874.[129,130] The disease occurs primarily in children, with a peak incidence occurring between 4 and 11 years of age. There appears to be a seasonal variation, with most reported cases occurring from fall to spring and a paucity of cases in the summer.[129,131] Many of the cases occur after upper respiratory infections. Epidemiologic studies generally suggest that HSP occurs as sporadic cases, but clustering does occasionally occur. In 1987, a series of 20 cases occurred in Connecticut in a 5-month span and were found to be clustered in one ethnic group.[132] This space–time clustering suggests a possible role for an infectious agent in precipitating the disease. Other infections, medications, insect bites, and malignancy have also been described as potential precipitating factors.

Biopsies of the superficial dermis and bowel in HSP show an acute vasculitis of precapillary arterioles and postcapillary venules. Immunofluorescent staining commonly shows IgA deposits in the walls of the arterioles of both the involved and noninvolved skin.[133] In patients with renal involvement, a proliferative and necrotizing vasculitis is described, and IgA deposits are found in the glomerular mesangium.[134] Circulating immune complexes containing IgA are detected in approximately 70% of patients shortly after the onset of purpura, followed by the appearance of complement and IgA, IgM, and IgG immune complexes later in the disease course.[135] A variety of genetic polymorphisms that may predispose patients to developing HSP have been investigated.[136]

The onset of symptoms is usually acute, with fever and palpable purpura involving the extremities and buttocks.[129,130] The purpuric lesions appear in symmetric crops with a predilection for extensor surfaces of the extremities (Fig. 50.7). They are most abundant around the knees, ankles, and elbows.[130] A transient oligoarticular arthritis involving the large joints occurs in approximately 40% of cases, and the pain is often out of proportion to the physical findings. Renal involvement is manifest as proteinuria or hematuria. The renal abnormalities are almost always transient in younger children, but up to 20% to 25% of older children and adults have progressive renal disease.[129,137] Poor prognostic factors for renal disease include nephrotic syndrome and >50% glomerular crescent formation on renal biopsy.[138]

FIGURE 50.7. Lower extremity palpable purpura in a patient with Henoch-Schönlein purpura. (From Van Hale HM, Gibson LE, Schroeter AL. Henoch-Schönlein vasculitis: direct immunofluorescence study of uninvolved skin. J Am Acad Dermatol 1986;15:665–670, with permission.)

Diffuse, crampy abdominal pain occurs in more than one-third of the cases and may occur before the characteristic purpura. The abdominal pain can be severe enough to mimic a surgical abdomen, and appears to be due to submucosal bleeding, edema, and ulcerations. Because abdominal pain is common, it is important to be aware that rare complications requiring surgery do occur, and include intussusception, perforation, and bowel necrosis.[139] An abdominal ultrasound should be considered in the evaluation of abdominal pain, as other studies may miss ileoileal intussusception. GI bleeding presenting as melena or hematochezia can occur and is occasionally severe. Scrotal involvement is not uncommon, affecting up to 20% males, and can mimic testicular torsion.[140]

Criteria for the classification of HSP have been published.[129] The presence of two of the following four criteria can usually accurately differentiate HSP from other forms of vasculitis: Palpable purpura, age of onset 20 years or younger, acute abdominal pain, and biopsy showing granulocytes in the walls of arterioles or venules. A biopsy is not required in children with the classic presentation of HSP. The prognosis depends in part on the age at presentation. Children usually recover completely from HSP, but relapses may occur over a 3- to 6-week period before complete resolution of symptoms.[129] Adults have more severe disease at presentation, with a worse renal prognosis.[141]

Supportive care alone is used to treat mild cases. Steroids may be useful to alleviate symptoms in severe cases, but do not prevent renal complications from developing.[142] Nonsteroidal anti-inflammatory drugs are beneficial for symptom relief in some patients, and plasmapheresis is of reported use with renal involvement.[143] Patients with crescentic nephritis are treated with methylprednisolone, immunosuppressive drugs, plasmapheresis, and renal transplant.

Serum Sickness

Serum sickness is a specific clinical syndrome with systemic features and immune complex-induced vasculitis. The clinical syndrome typically occurs 7 to 12 days after administration of heterologous serum. The features include fever, urticaria, palpable purpura or other rash, and lymphadenopathy.[144] The purpura is caused by immune complex deposition, and skin biopsies show a necrotizing angiitis. Drugs such as cefaclor, penicillin, hydralazine, sulfonamides, and thiazide diuretics have been associated with serum sickness-like reactions.

PURPURA ASSOCIATED WITH INFECTION

Infectious agents can cause petechiae, purpura, and diffuse bleeding manifestations through a variety of mechanisms including disseminated intravascular coagulation, vasculitis, septic emboli, vascular toxins, and direct vascular or endothelial invasion.[145] Certain clinical syndromes in the latter two categories are considered here. Septic emboli are briefly discussed under the section on vascular obstruction.

Acute Febrile Illness with Petechiae

Petechiae are often associated with acute febrile illnesses in children and immediately raise the concern for possible meningococcemia. Although a florid meningococcal infection may be instantly recognizable, children who present with small skin hemorrhages and fever, but who are not acutely ill, can be a diagnostic challenge. Petechiae that are present only above the nipple line in the distribution of the superior vena cava are often due to the coughing or vomiting that accompanies the acute infection. Bacterial agents such as streptococcal infections, pneumococcus, and *Haemophilus influenzae* may cause fever and petechiae. Viral illnesses due to enterovirus and adenovirus are well-known causes of fever and petechiae as well. To help clinicians distinguish between the agents responsible (and to avoid missing an early meningococcal infection), algorithms have been developed.[146,147]

Papular-purpuric Gloves and Socks Syndrome

Patients with sharply demarcated purpura involving the hands and feet may have a syndrome known as papular-purpuric "gloves and socks" syndrome as shown in Figure 50.8. This syndrome was initially described in 1990[148] and has been confirmed in several other reports.[149] Patients are usually adolescents or young adults that present in the spring or summer with pruritic edema and erythema of the hands and feet. Petechiae and confluent purpura follow, with a relatively sharp demarcation at the wrists and ankles. Oral mucosal involvement is common, and patients may have other systemic signs or symptoms including lymphadenopathy, fever, elevated liver function studies, and cytopenias. Rare presentations may include a perioral petechial rash or more generalized petechial eruption.[150] The syndrome is self-limited and usually resolves within 1 to 2 weeks. The etiologic agent is usually parvovirus B19, but cytomegalovirus, hepatitis B, measles, rubella, and human herpesvirus 6 have also been implicated. Immunohistochemical studies show viral invasion of endothelial and epidermal cells.[151]

Rickettsial Diseases

Rickettsiae infection results in damage to the endothelial cell with a characteristic multifocal lymphohistiocytic immune response causing increased vascular permeability, decreased perfusion, and activation of coagulation.

Rocky Mountain spotted fever is transmitted by the bite of ixodid ticks and, therefore, has a peak incidence in the United States in May, June, and July. The incubation period is 2 to 14 days (mean, 7 days), and symptoms usually include the sudden onset of fever, chills, headache, and myalgia. A pink macular rash develops on the wrists, hands, and ankles and spreads to cover most of the body. After 2 to 7 days, the lesions become petechial, and hemorrhagic areas may coalesce to form large areas of ecchymosis. The major complications are a result of vascular injury, and multiple organs may become involved. Diagnosis is based on serologic studies showing a rise in antibody titers or biopsy of the skin lesions with immunofluorescent identification of the organisms. Treatment is with a tetracycline or chloramphenicol.

Other rickettsial diseases such as Mediterranean spotted fever, Asian tick typhus, and Queensland tick typhus are generally milder and have an eschar (tache noire) at the site of the primary tick bite. The treatment is the same as for Rocky Mountain spotted fever.[152]

Brazilian Purpuric Fever

Brazilian purpuric fever is a disease of pediatric patients that usually begins with purulent conjunctivitis followed 7 to 16 days later by acute onset of fever, bacteremia, petechiae purpura, and vascular collapse. The etiologic agent is *H. influenzae* biogroup aegyptius. The purpuric tendency appears to be due to direct invasion of endothelial cells with subsequent vascular damage.[153]

Rat Bite Fever

Rat bite fever is an acute illness caused by rodent bite or exposure due to organisms that are part of their normal oral flora. Over 200 cases have been reported in the United States.[154] Most U.S. cases are caused by *Streptobacillus moniliformis*, whereas cases in Asia are due to *Spirillum minus*. The onset of symptoms

FIGURE 50.8. Skin lesions of hands and feet associated with papular-purpuric gloves (A) and socks syndrome (B). (From Harms M, Feldmann R, Saurat J-H. Papular-purpuric "gloves and socks" syndrome. J Am Acad Dermatol 1990;23:850–854, with permission.)

is usually within 1 week of the bite but can occur several weeks after the wound has healed. Initial symptoms include abrupt onset of fever, chills, headache, malaise, and cough followed in 75% by morbilliform or petechial rash involving the palms and soles. Hemorrhagic vesicles on the peripheral extremities may be particularly suggestive of the diagnosis.[154] Migratory polyarthritis develops in 50% of patients with the *Streptobacillus* type. The case mortality rate if untreated is 10%. Treatment is with procaine penicillin, tetracycline, or streptomycin.

Strongyloides

Strongyloides stercoralis is endemic to parts of South America, Central Africa, South East Asia, and the Southern United States (particularly Kentucky and Tennessee).[155] Disseminated strongyloidiasis can occur in patients receiving chemotherapy or steroids, and in otherwise immunocompromised patients. Periumbilical purpura that resembles "multiple thumbprints" has been described,[156] and it appears to be associated with a poor prognosis. More diffuse purpura may develop as well. Biopsy of the skin lesions frequently reveals larva.[157] Other bleeding manifestations include alveolar hemorrhage and GI bleeding.

Vibrio vulnificus

An increasing number of infections caused by *Vibrio vulnificus* are being reported in the United States, particularly in Gulf coastal communities. The consumption of raw oysters is one of the primary mechanisms of infection along with localized wound infections due to exposure to infected salt water. Almost all patients are immunocompromised because of liver disease, diabetes, hemochromatosis, or steroid use.[158] Patients present with abrupt onset of fever, chills, hypotension, and the development of hemorrhagic bullae. These bullae can develop into necrotic ulcers. The hemorrhagic complications appear to be due to a secreted metalloprotease, which has prothrombin-activating and fibrinolytic activities.[159]

Hemorrhagic Fever Viruses

The hemorrhagic fever viruses are a diverse group of small RNA viruses with a lipid envelope. The clinical presentations vary, but symptoms usually begin with fever, headache, and myalgias progressing to generalized malaise. These symptoms last 3 to 4 days and are followed by petechiae, mucosal bleeding, and GI tract hemorrhage. However, infection of the endothelium may be common to all,[160] and direct disruption of endothelial cells may occur. Some of the viruses have almost no cytopathologic effect; however, others are highly destructive to the endothelial cells. Activation of immune cells with the release of cytokines and chemokines that target endothelial cells is another suggested mechanism of damage.[161] Release of tissue factor from damaged cells can trigger coagulation abnormalities,[162] and varying degrees of thrombocytopenia and disseminated intravascular coagulation are present and contribute to the bleeding diathesis.

The major etiologic agents and the distinctive clinical features are outlined in Table 50.4.[163] A high index of suspicion is required to diagnose hemorrhagic fever virus. Risk factors for naturally occurring cases include foreign travel, handling of animal carcasses, contact with sick animals or people, and arthropod bites within 21 days of the onset of symptoms. Lack of identifiable risk factors should raise the suspicion of a bioterrorist attack.

Rapid diagnosis is currently available only by sending clinical specimens to the Centers for Disease Control and Prevention or the U.S. Army Medical Research Institute of Infectious Disease in Frederick, Maryland. Suspected cases should be reported immediately to the health department. Protective measures from nosocomial spread should be followed.

PURPURA ASSOCIATED WITH VASCULAR OBSTRUCTION

Although oversimplified, it is often convenient to think of some disorders as causing purpura by intravascular obstruction with subsequent hemorrhage due to necrosis, vasculitic injury, or consumptive coagulopathy. Table 50.5 lists disorders that can be grouped together as causing abruptly decreased blood flow with

TABLE 50.4

HEMORRHAGIC FEVER (HF) VIRUSES

Viral HF	Cytopathic Effect	Endothelial Cell Infection	Cytokine Activation	Disseminated Intravascular Coagulation
South American HF	±	++	++++	No
Lassa fever	±	++	+++	No
Rift Valley fever	++++	?	?	Yes
Crimean Congo HF	+	+	?	Yes
Hantavirus pulmonary syndrome	0	++++	++++	No
Filovirus HF	+++	+++	+++	Yes
Yellow fever	++	?	?	No

0, no effect; ±, negligible effect; +, through; ++++, minimal to major effect; ? = unknown.

TABLE 50.5

CLASSIFICATION OF BLEEDING DISORDERS ASSOCIATED WITH VASCULAR OBSTRUCTION

Vascular Obstruction Component	Disease Examples
Thrombus	Warfarin-induced skin necrosis, disseminated intravascular coagulation
Emboli	
Thromboemboli	Atrial fibrillation
Septic emboli	Endocarditis
Marantic emboli	Sterile endocarditis
Cholesterol emboli	Invasive vascular procedures, warfarin blue-toe syndrome
Immunoglobulins	Waldenström macroglobulinemia, myeloma
Plasma proteins	Cryoglobulinemia
Fibrin	Cryofibrinogenemia
Red cells	Polycythemia
Platelets	Thrombocytosis, heparin-induced skin necrosis
Fat	Fat emboli syndrome

subsequent bleeding. Note that cold agglutinins are not included because necrosis and bleeding are not expected complications.

Cryofibrinogenemia

Cryofibrinogens are cold-precipitable plasma proteins that dissolve as plasma is rewarmed. The proteins are distinct from cryoglobulins, which precipitate on cooling of serum (after the plasma proteins have been removed). Approximately 3% to 13% of hospitalized patients have detectable cryofibrinogens when appropriate assays are used.[164,165] Cryofibrinogens can be associated with underlying malignancies or inflammatory processes (secondary cryofibrinogenemia) or be present as an isolated finding (essential cryofibrinogenemia).

Although patients with cryofibrinogenemia are often asymptomatic, they may present with symptoms of lower extremity or acral ulcers, cold intolerance, cutaneous purpura, livedo reticularis, gangrene, or Raynaud phenomenon.[166] Paradoxic bleeding may occur and appears to be proportional to the cryocrit.[165] Many patients have an elevated total fibrinogen level.[164] It is hypothesized that the abnormal cryofibrinogen is due to high levels of α_1-antitrypsin and α_2-macroglobulin that inhibit plasmin, resulting in decreased fibrinolysis.[165] The cutaneous lesions develop as a result of fibrin thrombi obstructing the small and medium-sized dermal vessels.[166] Biopsies from the edge of ulcers show eosinophilic thrombi with sparse lymphocytic infiltrate.[167] Leukocytoclastic vasculitis has also been described.[168] To measure cryofibrinogens, blood should be anticoagulated with ethylenediaminetetraacetic acid, citrate, or oxalate. The sample should be maintained at 37°C until centrifuged, and the separated plasma should be chilled at 4°C for 72 hours. Chilling the sample in this way increases the sensitivity for detection. The cryocrit is expressed as a percentage of the plasma sample volume.

Cryofibrinogenemia may be asymptomatic and require no treatment. Mild cases can be treated with avoidance of cold, and procedures that include cooling. Patients with more severe symptoms are usually treated with streptokinase, other fibrinolytic agents, or plasmapheresis. A small clinical trial and case reports have suggested that stanozolol, an androgenic steroid with fibrinolytic activity, can produce excellent results.[166,169] Immunosuppressant agents have been reported to be effective in some patients.[167] Heparin use is discouraged.[165]

Cholesterol Embolization Syndrome

Cholesterol embolization syndrome is an increasingly recognized disorder caused by dislodged cholesterol crystals from atherosclerotic plaques. This occurs after vascular procedures or can be due to warfarin (blue-toe syndrome) and results in renal insufficiency, peripheral emboli, and possibly GI or central nervous system involvement. Livedo reticularis is the most common skin finding and can be best appreciated with the patient in the upright position. Cyanosis, purpura, ulcers, and gangrene can all occur.[170] Biopsies of the cutaneous lesions, including livedo reticularis, demonstrate thrombi with cholesterol "clefts," since the cholesterol is dissolved during fixation.

Fat Emboli Syndrome

Fat emboli syndrome is poorly understood. It is characterized by hypoxemia, tachypnea, petechiae, and changes in mental status occurring after long bone and pelvic fractures or intramedullary fixation. It may result from release of fat from bone marrow resulting in diffuse microvascular fat emboli. Although embolization of fat is common after trauma, only a few patients develop the fat emboli syndrome. Pulmonary dysfunction typically occurs 12 to 24 hours after fracture or operative fixation and is

manifested as hypoxemia and tachypnea. The delay in symptoms suggests the role of a biochemical reaction leading to lung toxicity. Forty percent of patients develop petechiae, particularly in the axilla and subconjunctiva 24 to 48 hours after the event. Up to 70% of patients develop mental status changes.[171] Fat droplets can be identified on bronchoalveolar lavage, and fat globules have been identified in pulmonary capillary blood obtained through a wedged pulmonary artery catheter.

Silicone Embolism Syndrome

Liquid silicone is an inert material used in illegal subcutaneous injections for breast augmentation and other cosmetic procedures. A recent review of the literature showed many similarities with the fat emboli syndrome in 33 patients. The most common symptoms are respiratory distress and hypoxemia occurring within 72 hours of the procedure with fever, alveolar hemorrhage (64%), and petechiae (18%). Six patients presented with neurologic symptoms occurring during or several hours after the injections and all patients deteriorated rapidly. Transbronchial biopsies show vacuolated globular deposits of silicone in the interstitial capillaries.[172]

Septic Emboli

Calciphylaxis

Calciphylaxis is a small vessel vasculopathy characterized by calcifications of the tunica media of small to medium-sized cutaneous and subcutaneous vessels. The vasculopathy leads to development of tissue ischemia, necrosis of the skin and subcutaneous fat, and sometimes deeper tissues. Patients typically have end-stage renal disease and are on hemodialysis, but the disorder has now been described in a variety of other conditions. Clinically, painful dusky, purple-hued subcutaneous nodules and induration occur on the trunk, buttocks, or proximal extremity, and can progress to necrotic ulcers with eschars. In retrospective review, obesity, liver disease, steroid use, calcium phosphate product of >70 mg^2/dl, and an aluminum >25 ng/ml were identified as risk factors. The diagnosis is usually made by biopsy of one of the lesions showing calcification of the tunica media with intimal proliferation and microthrombosis. Treatment involves lowering the calcium phosphate product when elevated by using sevelamer hydrochloride as a substitute for calcium phosphate binders, and decreasing the phosphate intake and calcium in the dialysate bath. Elevated parathyroid levels can be managed with calcimimetic agents or parathyroidectomy. Wound management is of key importance, as sepsis is the leading cause of death.[173]

Livedoid Vasculopathy

Livedoid vasculopathy is a cause of lower extremity purpura progressing to shallow ulcerations that heal with atrophic hypopigmented scarlike plaques (atrophie blanche). Biopsy of the lesions shows hyaline vascular changes with intraluminal thrombosis. It is associated with multiple coagulation abnormalities.[174]

PURPURA ASSOCIATED WITH SKIN DISEASES

Pigmented Purpuric Dermatitis

Pigmented purpuric eruptions encompass a group of related skin diseases that have in common the clinical appearance of red-brown skin pigmentation (caused by hemosiderin deposits) associated with purpura or petechiae. These lesions tend to develop on the lower extremities of middle-aged people and are usually chronic. Histologically, there is a mononuclear upper dermal infiltrate without evidence of leukocytoclasis. Extravasated red blood cells are present around the capillaries, and hemosiderin deposits are found in older lesions. Six skin diseases are commonly classified as pigmented purpura. In Schamberg progressive pigmentary dermatosis, the lesions appear as orange-brown patches of skin with "cayenne pepper spots" at the borders or within the lesion (Fig. 50.9). Majocchi purpura annularis is distinguished by an annular 0.5- to 2.0-cm patch of reddish-brown macules. Eczematoidlike purpura has a seasonal pattern and appears as pinpoint lesions that spread rapidly over 2 to 4 weeks and develop a slight scale. The lesion in pigmented purpura lichenoid dermatitis (Gougerot-Blum purpura) is a reddish-brown macule with telangiectasias. These lesions tend to coalesce and form plaques. Itching purpura presents with an acute onset of pigmented macules associated with severe pruritus. Lastly, lichen aureus is described as "grouped copper-orange to purple lichenoid papules forming an irregular, usually singular, plaque."[175] The etiology of pigmented purpura is unknown, but some degree of venous stasis is apparent in many patients and may be a factor in its development. The importance of these lesions is to differentiate them from other causes of chronic purpura with hemosiderin deposits such as purpura associated with abnormal proteins. The lesions may clear in up to two-thirds of patients with long-term follow-up.[176] Some patients with longstanding pigmented and purpuric dermatitis develop mycoses fungoides, and the differentiation between mycoses fungoides and pigmented purpuric lesions can sometimes be difficult.[177]

FIGURE 50.9. Skin lesions associated with Schamberg progressive pigmentary dermatosis. Note the irregular patches of punctate hemorrhagic lesions with yellow-brown discoloration of hemosiderin deposits. (From Sherertz EF. Pigmented purpuric eruptions. Semin Thromb Hemost 1984;10:190–195, with permission.)

Pigmented purpuric eruptions have been described in children[178] (Fig. 50.10), and may be familial. Treatment in the past has been with fluorinated steroids, but recently, psoralen

FIGURE 50.10. Pigmented purpura in a child. (This photograph was kindly provided by Drs Payem Tristani-Firouzi and Sheryll Vanderhooft, Department of Dermatology, University of Utah Health Sciences Center.)

plus ultraviolet light of A wavelength has been found to be effective in some cases.[179]

Purpuric Contact Dermatitis

Purpura can be a presenting sign of allergic contact dermatitis and is often due to textile dyes in clothing. This diagnosis should be considered in patients who develop purpura only in areas of skin contact with clothing. Several allergens in textile dyes have been identified.[180] Other reported antigens include benzoyl peroxide, epoxy resin, and agave sap.[181]

Drug Reactions

Drug reactions can cause nonthrombocytopenic purpura by a number of different mechanisms, including leukocytoclastic vasculitis, serum sickness, and, occasionally, a pigmented purpura. Some of the drugs associated with pigmented purpuric dermatosis include acetaminophen, aspirin, glipizide, hydralazine, meprobamate, dipyridamole, creatine, thiamine, interferon, injected medroxyprogesterone acetate, and infliximab.[182] A fixed drug reaction can occur, with an isolated purpuric-appearing lesion occurring in a location without preceding trauma (Fig. 50.11).

FIGURE 50.11. A fixed drug eruption lesion. This 30-year-old woman developed this thigh lesion after taking ibuprofen. (This photograph was kindly provided by Dr. Pamela Nemzer, Department of Dermatology, University of Utah Health Sciences Center.)

PSYCHOGENIC PURPURA

Autoerythrocyte Sensitization

Autoerythrocyte sensitization is a rare disorder characterized by recurrent spontaneous ecchymotic lesions in patients with otherwise normal hemostasis. The syndrome was first described in 1955 by Gardner and Diamond after their discovery that intradermal injections of autologous red blood cells reproduced the skin lesion.[183] Since the original description, more than 200 cases have been described, with the largest series collected by Ratnoff.[184]

The cutaneous lesions are usually preceded by localized symptoms, including pain and a burning or stinging sensation in the involved area. The area then becomes erythematous, raised, and warm, and within hours, ecchymoses occur in the inflamed area. The ecchymoses can range in size from 1 to 2 cm to extensive involvement of the trunk or an extremity. The erythema and swelling usually subside within 48 hours of the development of ecchymoses. The lesions can recur weeks to years later. The ecchymotic lesions are usually only one symptom among many. Patients commonly have systemic symptoms including headaches, paresthesias, syncopal episodes, abdominal pain, nausea, vomiting, chest pain, dyspnea, dysuria, and arthralgia.

Autoerythrocyte sensitization typically affects adolescent to middle-aged females who have significant underlying emotional problems. Patients are commonly found to suffer from depression, anxiety, and inability to handle hostile feelings, as well as hysterical and masochistic character traits. They have often sustained significant physical and emotional trauma in the past, and up to two-thirds of the patients describe significant emotional stress present at the time the initial purpuric lesions develop.

The skin lesions can classically be reproduced in most patients with the intradermal injection of 0.1 ml autologous whole blood, packed red blood cells, or red cell stroma. However, this test has limited sensitivity, and some authorities recommend using clinical criteria to diagnose this disorder.[185] No specific therapy is of proven value in psychogenic purpura. Psychotherapy appears to be beneficial in some younger patients but is less effective in the older population.[186]

Autosensitivity to DNA

A similar syndrome of recurrent ecchymoses after a prodrome of localized itching was described in 1961 by Levin and Pinkus.[187] This patient developed the typical skin lesions described above after the intradermal injection of frozen and thawed buffy coat leukocytes or purified calf thymus DNA. There are few data concerning the emotional background of these patients. Since the initial description, a few other cases have been reported, but some of these also had a positive reaction to intradermal injection of blood or washed red cells. Chloroquine can induce remissions, and cyproheptadine was useful in one patient.[188,189,190]

Factitious Purpura

Self-inflicted ecchymoses can be difficult to diagnose. This disorder should be considered when there is a clear secondary gain present, when the lesions only occur in accessible areas, or when ecchymotic lesions assume unusual shapes. Circular, well-circumscribed lesions around the upper limbs and breasts may be a result of sucking of the skin.

Religious Stigmata

Purpuric religious stigmata are bruises that allegedly occur spontaneously and resemble the wounds of the crucified body of Christ. The phenomenon usually occurs in women, and many have belonged to a religious order. The etiology is unknown.[184]

CHAPTER 51

THROMBOCYTOSIS AND ESSENTIAL THROMBOCYTHEMIA

George M. Rodgers, Robert T. Means, Jr.

The normal reference interval for platelet counts in adults approximates 150,000 to 450,000/μl; patients with platelet counts higher than the upper limit of normal have thrombocytosis, which can be broadly classified as reactive (secondary), essential (clonal or primary), or inherited (Table 51.1). Routine screening of healthy individuals has identified persons with asymptomatic thrombocytosis; some of these people will have essential thrombocythemia (ET).[1] In contrast, hospitalized patients with elevated platelet counts usually have reactive thrombocytosis (RT).[2] At least 90% of all patients with thrombocytosis have RT due to an underlying clinical disorder.[3] It is important to distinguish ET from RT or inherited thrombocytosis because patients with the former disorder may be at risk of ischemic or bleeding complications, or evolution to myelofibrosis or acute leukemia, whereas patients with the latter disorders usually require only treatment of their underlying medical condition, with minimal or no treatment in the case of inherited thrombocytosis.

REACTIVE (SECONDARY) THROMBOCYTOSIS

Epidemiology and Pathophysiology

A retrospective Turkish survey of the incidence and etiology of thrombocytosis over a 5-year period demonstrated that of 124,340 patients who had platelet counts determined, 2,000 patients (1.6%) had at least one platelet count ≥500,000/ml.[4] RT was identified in 96.7% of these 2,000 patients, with infection being the most common cause of RT.[4] Another survey found that tissue injury (surgery) was the most common cause of RT.[5]

Increased thrombopoiesis seen in infectious, inflammatory, or malignant disorders results from cytokines and other acute-phase response mediators active in these circumstances. Mediators that have been linked to RT include interleukin (IL)-6[6] and thrombopoietin (TPO).[6,7] TPO may act as an acute-phase protein in some, but not all circumstances.[7] Both thrombocytosis[8] and thrombocytopenia[9] have been reported in iron-deficiency anemia. Patients with solid tumors (e.g., lung, ovarian cancers) have a 30% to 40% incidence of thrombocytosis.[3,6] Extreme thrombocytosis may occur after splenectomy[3] or in patients with hyposplenia or asplenia.[10]

TABLE 51.1

CLASSIFICATION OF THROMBOCYTOSIS

Reactive (Secondary)	Clonal (Primary)	Inherited
Infection	Essential thrombocytosis	*THPO* mutations
Inflammation	Other myeloproliferative neoplasms:	*MPL* mutations
Malignancy	Polycythemia vera	
Iron deficiency	Chronic myeloid leukemia	
Hemolytic anemia	Myelofibrosis	
Post-splenectomy	Myelodysplasia	
Recovery from thrombocytopenia		
Tissue injury:		
Surgery		
Burns		

MPL, thrombopoietin receptor gene; *THPO*, thrombopoietin gene.

Treatment

Although no trials have formally addressed the need for treating RT, the general recommendation is not to treat the elevated platelet count, either with antiplatelet or with myelosuppressive therapy.[3] However, there are case reports describing thrombotic events in RT patients[11] and studies identifying a thrombosis risk in hospitalized patients or cancer patients with RT.[12] In general, these patients have well-established cardiovascular risk factors, such as smoking,[11] diabetes, older age, and the like, or they have venous thromboembolism risk factors such as cancer,[12] or as seen in a hospitalized population. One approach may be that when RT is encountered in such patients with cardiovascular risk factors, antiplatelet therapy can be considered. Hospitalized patients with RT should receive venous thromboembolism prophylaxis, and primary therapy for all RT patients should focus on treating the underlying disorder.

Inherited Thrombocytosis

Inherited thrombocytosis is suspected in patients with a lifelong history of asymptomatic thrombocytosis, especially if other family members are also affected. The genetic mutations in inherited thrombocytosis are heterogeneous and may or may not involve mutations in the thrombopoietin gene (*THPO*) or its receptor (*MPL*).[3] At least four different mutations in *THPO* associated with increased TPO production and inherited thrombocytosis have been described in European and Japanese kindreds.[13] Thrombocytosis was inherited in an autosomal dominant manner in all four families. The TPO molecule in these patients is normal, and increased translation appears to explain elevated levels of TPO in these patients.[13] At least three different *MPL* mutations have been linked to inherited thrombocytosis; affected kindreds are of European, African-American, Arabic, and Japanese ancestry.[13] Approximately 7% of African-Americans are heterozygous for the MPL-Baltimore mutation.[14] Thrombocytosis in patients with *MPL* mutations appears to result from either constitutive receptor activation or reduced receptor binding affinity for TPO.[13]

Clinical findings in patients with inherited thrombocytosis can be classified by whether the patients have *THPO* or *MPL* mutations. In general, those with *THPO* mutations have elevated TPO levels and mild splenomegaly, but a low incidence of vascular complications and low risk of evolution to acute leukemia and myelofibrosis,[13] although development of bone marrow disease was described in two family members with inherited thrombocytosis due to *THPO* mutations.[15] Some patients with *MPL* mutations and inherited thrombocytosis have been reported to experience thrombosis, splenomegaly, and myelofibrosis, but these complications have not been reported in African-American patients with MPL-Baltimore.[13]

Clonal Thrombocytosis Other Than Essential Thrompocythemia

Clonal or primary thrombocytosis includes not only ET (discussed later) but also a prominent feature of the other myeloproliferative neoplasms and certain myelodysplastic syndromes. Between 35% and 50% of patients with chronic myeloid leukemia (CML), polycythemia vera, or myelofibrosis may have elevated platelet counts.[5,16] The diagnosis, clinical aspects, and management of these disorders are discussed in Chapters 81 to 83.

Clonal thrombocytosis is also seen in myelodysplastic syndromes associated with certain cytogenetic features (trisomy 8,[17] 5q- syndrome,[18] and chromosome 3 abnormalities[19]), as well as the presence of ringed sideroblasts.[20] However, the frequency of thrombocytosis in myelodysplasia is lower than in the myeloproliferative neoplasms. Myelodysplastic syndromes are discussed in Chapter 79.

DIFFERENTIAL DIAGNOSIS AND CLINICAL APPROACH TO THROMBOCYTOSIS

When evaluating a patient with thrombocytosis, the key consideration is to exclude ET and CML[21] from reactive or inherited thrombocytosis and other disorders. Thrombocytosis may be a presenting feature of CML.[21] Inasmuch as CML patients are at risk of conversion to acute leukemia, and there is targeted therapy for CML, BCR-ABL, and cytogenetic testing is important in patients with thrombocytosis who do not have inherited or reactive etiologies. Patients with RT usually will have major symptoms of an underlying inflammatory, infectious, or malignant disorder. However, patients with occult malignancy may initially present without obvious cancer symptoms. Post-splenectomy thrombocytosis will usually be obvious, but patients with asplenia or hyposplenia will be identified by observing Howell-Jolly bodies on the blood smear and by abdominal imaging showing a vestigial spleen or no splenic tissue. The World Health Organization (WHO) criteria for ET are discussed in the next section, and focus on distinguishing essential thrombocytosis from the other myeloproliferative neoplasms. These criteria provide no direct definitions of RT. Thus, the physician is left with practical clinical criteria to suggest an RT if a patient does not have an obvious underlying disorder. Such criteria might include the presence of fever, an elevated C-reactive protein or erythrocyte sedimentation rate, a blood smear showing reactive or toxic changes in the leukocytes, the presence of iron deficiency, or the post-splenectomy state.[3,5]

One approach to the evaluation of thrombocytosis is shown in Figure 51.1. Inherited thrombocytosis can be rapidly excluded if there is no life-long history of thrombocytosis and the family history is negative. Patients who may possibly have inherited thrombocytosis can be further evaluated with testing for *THPO* and *MPL* mutations. Because >90% of patients with thrombocytosis will have a reactive etiology,[3,4,5] significant effort should be made in excluding secondary thrombocytosis before considering testing for myeloproliferative neoplasms, including ET.

ESSENTIAL THROMBOCYTHEMIA

Definition

ET is a clonal myeloproliferative disorder characterized by excessive production of platelets that is independent of usual drivers of thrombocytosis. This thrombocytosis is in many ways analogous to the erythrocytosis characteristic of the related disorder, polycythemia vera. This "family resemblance" between what we now

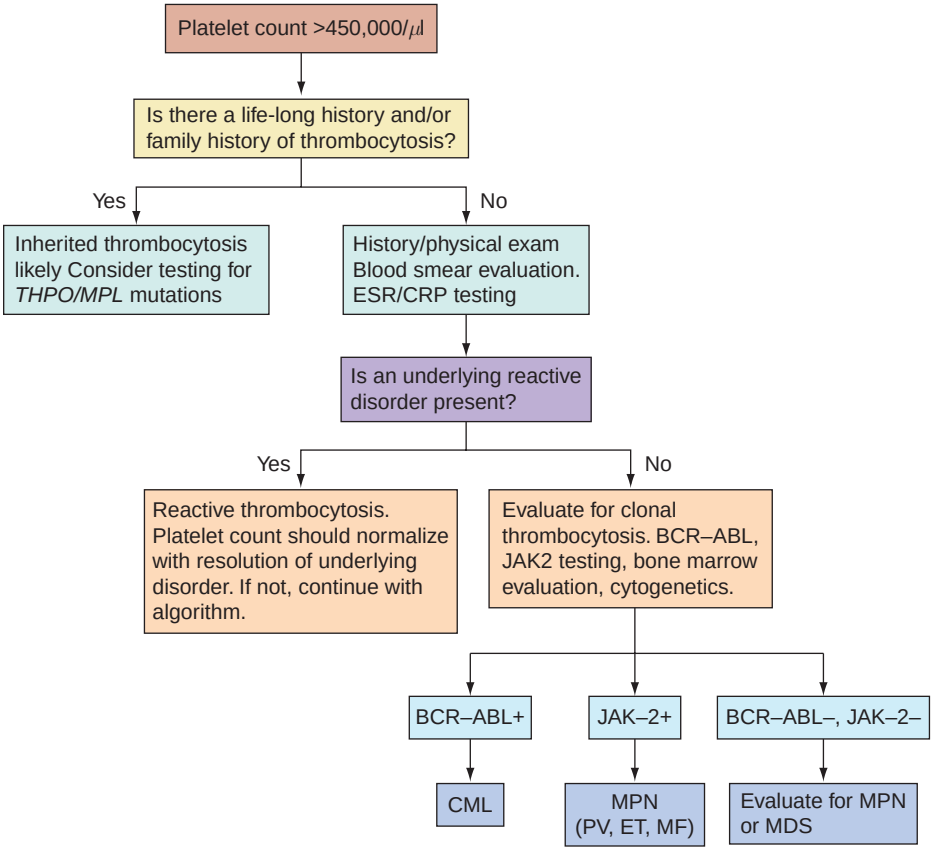

FIGURE 51.1. An approach to evaluating thrombocytosis. A life-long personal history and family history of thrombocytosis would suggest a diagnosis of inherited thrombocytosis. If that diagnosis is excluded, reactive etiologies should next be considered. If an underlying cause is identified and is treatable, thrombocytosis should resolve with appropriate therapy. If neither inherited nor reactive thrombocytosis is likely, testing for clonal thrombocytosis should be performed; this should include BCR-ABL and JAK2 testing. The appropriate tests include bone marrow evaluation and cytogenetics for myeloproliferative neoplasms and myelodysplasia. CML, chronic myeloid leukemia; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; MF, myelofibrosis; ET, essential thrombocytosis; MDS, myelodysplasia; *MPL*, thrombopoietin receptor gene; MPN, myeloproliferative neoplasms; PV, polycythemia vera; *THPO*, thrombopoietin gene.

recognize as *BCR/ABL*-negative myeloproliferative disorders was initially pointed out by William Dameshek more than 60 years ago.[22]

Epidemiology

Evolving diagnostic criteria (discussed below) make it difficult to characterize the incidence and prevalence of ET. In studies published between 2001 and 2008, an incidence of 1.5/100,000 was reported.[23,24] Prevalence based on insurance claims data in the northeastern United States has been reported to be 24 cases/100,000 population.[25] However, these reports antedate the 2008 revision of the WHO diagnostic criteria for ET, which includes a lower platelet threshold and could potentially alter the reported prevalence and incidence.

The median age at diagnosis is in the mid-50s in large reported series, and females represent 60% to 70% of cases.[26,27] Cases have been reported in children but are uncommon.[28–30] First-degree relatives of ET patients have an increased risk of ET.[31]

Risk for developing ET appears to be associated with environmental factors linked to other myeloid neoplasms, such as radon and gamma irradiation.[32,33] Hairdressers, electricians, and farmers appear to be at increased risk to develop ET compared to other occupations, although it should be remembered that these risks are still quite low.[32,33]

Diagnostic Criteria

For many years, the diagnosis of ET was based on the demonstration of significant sustained thrombocytosis (typically greater than 600×10^9/L) in the absence of a reactive etiology.[34] However, the observation that a specific gain-of-function mutation in Janus-associated kinase 2 (*JAK2*V617F) is found in virtually all cases of polycythemia vera and in most cases of ET,[35,36] provided an additional positive criteria for the diagnosis of ET.

The 2008 revision of the WHO criteria for the diagnosis of ET is shown in Table 51.2.[34] The first criterion represents a reduction in the threshold for thrombocytosis from 600×10^9/L to what is in essence the upper limit of the normal platelet count and addresses concerns that the higher threshold prevented the detection of early disease.[37–39] The second criterion requires demonstration of the characteristic bone marrow morphology of ET.[40]

As discussed earlier in this chapter, a number of other myeloid neoplasms may be associated with thrombocytosis. This is particular true when employing the lower platelet threshold of the 2008 criteria. Polycythemia vera is excluded by the absence of an elevated hematocrit or hemoglobin concentration with adequate iron stores demonstrated on a Prussian blue-stained marrow specimen or a normal serum ferritin: if iron stores are absent, a trial of iron replacement that does not elevate the hematocrit or hemoglobin above normal is required.[34] Primary myelofibrosis is excluded by the absence of excessive reticulin deposition on the marrow biopsy. Chronic myelogenous leukemia is excluded by the absence of the *BCR/ABL* mutation. Myelodysplastic syndromes and other myeloid neoplasms are excluded by absence of characteristic marrow abnormalities, such as ringed sideroblasts.[41]

In the absence of the *JAK2*V617F mutation, exclusion of nonclonal reactive processes remains a key element of the diagnosis of ET. Etiologies of RT specifically cited in the criteria that should be excluded by history or laboratory studies include iron deficiency, previous splenectomy, recent surgery, active inflammation, connective tissue disorders, metastatic cancer, and lymphoproliferative diseases.[34] In polycythemia vera, mutations of *JAK2* in exons other than the site of the V617F mutation have been found in a significant number of *JAK2*V617F-negative cases.[42] Similar findings have not been reported for ET.

The 2008 revised criteria have generally performed well in validation studies,[43,44] although at least one study suggests that they function poorly in distinguishing ET from early stage primary myelofibrosis.[45] They also may be of less utility in children with ET, who are often polyclonal and *JAK2*V617F-negative.[46,47]

TABLE 51.2

WORLD HEALTH ORGANIZATION DIAGNOSTIC CRITERIA FOR ESSENTIAL THROMBOCYTHEMIA

Diagnosis requires meeting all four criteria

1. Sustained platelet count ≥450×10^9/L
2. Bone marrow biopsy specimen showing proliferation mainly of enlarged mature megakaryocytes; no significant increase or left shift of neutrophil granulopoiesis or erythropoiesis
3. Not meeting criteria for polycythemia vera, primary myelofibrosis, chronic myelogenous leukemia, myelodysplastic syndrome, or other myeloid neoplasm (details discussed in text)
4. Demonstration of *JAK2*V617F or other clonal marker; or, in the absence of a clonal marker, no evidence for reactive thrombocytosis. However, the presence of a condition associated with reactive thrombocytosis does not exclude essential thrombocytosis if first three criteria are met

Modified from Tefferi et al., Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. Blood 2007;110:1092–1097.

Pathophysiology

In polycythemia vera, in vitro studies of erythroid progenitors have shown hypersensitivity to erythropoietin or erythropoietin independence,[48] as well as hypersensitivity to other growth factors such as IL-3 or granulocyte–macrophage colony stimulating factor (GM-CSF).[49,50] In an analogous manner, megakaryocyte progenitors from ET patients have been reported to show a similar response pattern to IL-3, GM-CSF, and/or IL-6 in vitro.[51,52] Such studies provide some rationale for a proposed hypothesis that inflammation may be a driver of clonal evolution in ET.[53]

However, the primary focus of pathophysiologic investigation in ET is on specific mutations found in myeloproliferative disorders and their contributions to its pathogenesis. The involved or potentially involved genes include *JAK2, ASXL1* (additional sex combs-like 1), *CBL* (Casitas B-lineage lymphoma), *DNMT3A* (DNA methyl transferase 3α), *EZH2* (enhancer of zeste homolog 2), *IDH1* (isocitrate dehydrogenase 1) and *IDH2, LNK* (lymphocyte specific adaptor protein), the TPO receptor/ligand *MPL* (myeloproliferative leukemia virus), *SF3B1* (splicing factor gene B1), *NF1* (nuclear factor 1), *SUZ12* (suppressor of zeste 2 homolog), and *TET2* (ten-eleven translocation oncogene family member 2).[54,55,56] Brecqueville and colleagues studied several of these genes in 53 ET patients. A total of 70% of patients had mutations in one or more of the genes studied (Table 51.3).[54]

*JAK2*V617F is the most common mutation found in ET, and is detected in 50% to 75% of patients.[54,57,58] As Table 51.3 indicates, it may occur alone or with other mutations. As noted earlier, *JAK2*V617F is a gain-of-function mutation resulting in constitutive activation of signaling through the JAK/STAT pathway.[36] Expression of *JAK2*V617F in hematopoietic progenitors in vitro or in whole animals leads to a myeloproliferative disorder phenotype resembling polycythemia vera.[59–61] It has been proposed that the extent of the *JAK2*V617F allele burden distinguishes ET from polycythemia vera.[62] However, *JAK2* mutations do not appear to be universally present in ET, and data from other myeloproliferative disorders suggest it is a late pathogenetic event.[63] The precise mechanistic contributions of *JAK2* mutations to ET pathogenesis, their interactions with other genes and significant hematopoietic

TABLE 51.3

FREQUENCY OF SPECIFIC GENE MUTATIONS IN 53 ESSENTIAL THROMBOCYTHEMIA PATIENTS

Gene	Percent
JAK2 V617F	65
Isolated mutation	55
Concurrent with *ASXL1*	2
Concurrent with *TET2*	8
ASXL1	4
Isolated mutation	2
Concurrent with *JAK2*V617F	2
CBL	2

TET2	8
Concurrent with *JAK2*V617F	8

DNMT3A, IDH1, IDH2, MPL, NF1, and *SUZ12* mutations were not found in ET patients, although *MPL* and *SUZ12* mutations were detected in post-ET myelofibrosis patients. Abbreviations per text.
Data from Brecqueville et al., Mutation analysis of *ASXL1, CBL, DNMT3A, IDH1, IDH2, JAK2, MPL, NF1, SF3B1, SUZ12,* and *TET2* in myeloproliferative neoplasms. Genes Chromosomes Cancer 2012;51:743–755.

proteins such as *ASXL1,*[55] *TET2,*[64] and Mpl,[65] remain to be clarified.

Clinical and Laboratory Features

Most ET patients are asymptomatic at time of presentation,[44] although some may be diagnosed after a thrombotic event or in the course of evaluation of vasomotor symptoms such as dizziness and headache, which may reflect vascular occlusion.[66,67] Erythromelalgia (burning dysesthesia in the fingers or toes relieved almost instantly by aspirin) is a characteristic symptom of myeloproliferative thrombocytosis, whether from ET or polycythemia vera.[68] Distal ischemia ("blue toes syndrome"[69]) and cutaneous changes such as livedo reticularis or ulceration [70] are occasionally found; frank limb gangrene is fortunately rare.[71,72]

Presenting blood counts and physical examination results from three series are shown in Table 51.4.[27,44,66] Although hemoglobin concentration and white blood cell counts are typically normal, anemia and/or leukocytosis $> 15 \times 10^9$/L may be found in 15% to 20% of patients.[27] The white blood cell differential is usually normal but may show the basophilia, eosinophilia, or left-shift characteristic of myeloproliferative disorders. Splenomegaly, whether palpable or radiographic, is found in fewer than 25% of cases without transformation to myelofibrosis.[27,44,66]

The characteristic bone marrow feature is proliferation of large, mature-appearing megakaryocytes (Fig. 51.2). Marrow cellularity is increased in approximately a third of cases,[44] but is otherwise normal. The presence of significant reticulin deposition, dyserythropoiesis, or dysmyelopoiesis should raise suspicion for other diagnoses.

Patients with ET exhibit evidence of aspirin-reversible increased platelet activation in vivo (increased circulating levels of beta thromboglobulin, platelet factor 4, and thrombomodulin and increased urinary thromboxane B2 excretion), whereas paradoxically exhibiting defective platelet function in vitro, both by classic platelet aggregation or platelet function analyzer (PFA)-100 studies.[73,74,75] Some ET patients with platelet counts $> 1{,}000 \times 10^9$/L develop a bleeding diathesis due to an acquired type 2 von Willebrand syndrome which is reversed by platelet reduction.[73]

Splenomegaly present, %	23	18	11

Median values from the USA and Spanish series; mean values from Japanese series.
[a]Patients with leukemic transformation excluded.

Natural History and Prognosis

The median overall survival of ET patients appears to exceed 22 years and does not significantly differ from that of the age-adjusted general population (Fig. 51.3).[26] A plurality (40%) of deaths is unrelated to ET; the next greatest contributor is thrombosis (26%). Solid tumors (14%) are the next most common cause of death, followed by leukemia, either de novo or post-myelofibrotic (8%) and myelofibrosis (4%).[26] Compared to polycythemia vera patients, the 15-year cumulative risks of thrombosis (27% vs. 17%), leukemia (7% vs. 2%) and myelofibrosis (6% vs. 4%) are lower in ET patients.[26]

Reported risk factors for overall survival include age >60 years, history of thrombosis, anemia, and leukocytosis $>15 \times 10^9$/L; age, anemia, and platelet count $>1{,}000 \times 10^9$/L, are reported risk factors for leukemic transformation.[27] Studies have reported that *JAK2*V617F-negative ET patients have a lower arterial thrombotic risk than *JAK2*V617F-positive ET patients.[76] In contrast, the *JAK2*V617F allele burden itself may or may not predict a greater thrombotic diathesis.[76,77] Among *JAK2*V617F-negative ET patients, the presence of other markers of clonality such as mutations in human androgen receptor (HUMARA), *TET2, ASXL1,* or *MPL,* predicts an increased thrombotic risk.[78]

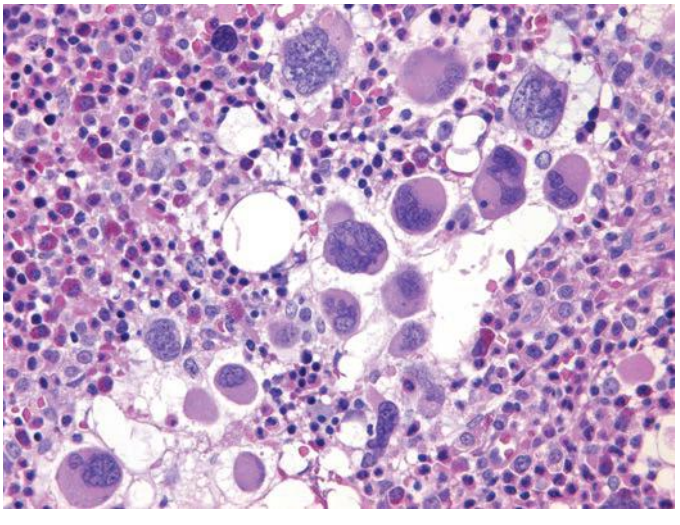

FIGURE 51.2. Characteristic megakaryocyte proliferation in a marrow specimen from an essential thrombocythemia (ET) patient.

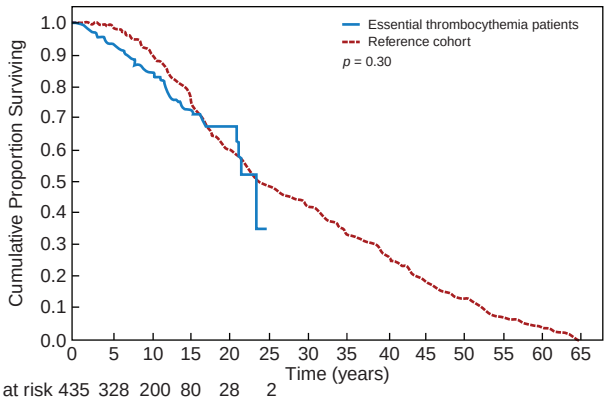

FIGURE 51.3. Survival curves of 435 patients with essential thrombocythemia, compared with life expectancy of the general population. From Passamonti et al., Life expectancy and prognostic factors for survival in patients with polycythemia vera and essential thrombocythemia. Am J Med 2004;117:755–761, with permission.

The standard model for thrombotic risk in ET has two components: age >60 years and history of thrombosis. The absence of both denotes low risk, and the presence of either denotes a high risk of thrombosis.[79] A model proposed more recently, the International Prognostic Score for ET-thrombosis (IPSET-thrombosis), incorporates the two elements of the standard model as well as the presence of cardiovascular risk factors and *JAK2*V617F mutation status.[80] The IPSET-thrombosis model defines low, intermediate, and high risk categories. Approximately half the patients in the low risk category from the standard model are relocated to the intermediate category in the IPSET-thrombosis model, whereas the standard model high risk patients are distributed essentially evenly between the three IPSET-thrombosis categories.[80] The two models are outlined in Table 51.5.

TREATMENT

The goal of treatment in ET is the prevention of thrombotic events, the primary cause of morbidity and mortality.[26] Therefore, treatment strategy is based on thrombotic risk stratification.[79,81,82] At present, only the standard risk stratification model has been validated as a guide to therapy. Low risk patients can be managed with low dose aspirin or, under some circumstances, observation only. Cytoreduction of the platelet count is recommended for high risk patients.[81,82]

The IPSET-thrombosis model has not been prospectively validated as a guide to therapy, but the developers of the model have suggested that cytoreductive therapy be considered in any patient with a history of thrombosis and in older patients with cardiovascular risk factors and/or *JAK2*V617F mutation. Aspirin therapy is recommended for younger patients without a thrombosis history but with either cardiovascular risk factors and/or *JAK2*V617F mutation.[80]

The bleeding associated with acquired von Willebrand syndrome in ET can be resolved by reduction of the platelet count to a value approximating normal.[83]

TABLE 51.5

PROGNOSTIC MODELS FOR THROMBOTIC RISK IN ESSENTIAL THROMBOCYTHEMIA

Standard Model[79]	
Age > 60 years	
History of thrombosis	
Low risk: Neither factor	
High risk: One or both factors	
IPSET-Thrombosis Model[80]	
Age > 60 years	1 point
Cardiovascular risk factors[a]	1 point
History of thrombosis	2 points
*JAK2*V617F mutation present	2 points
Low risk: 0 or 1 point	
Intermediate risk: 2 points	
High risk: ≥ 3 points	

[a]Cardiovascular risk factors include diabetes, hypertension, and/or tobacco use.

Aspirin

Aspirin therapy, usually at 100 mg/day or less, is generally well tolerated in ET patients, with a low risk of bleeding.[84] Antiplatelet agents such as aspirin reduce the risk of venous thrombosis in ET patients with the *JAK2*V617F mutation, and the risk of arterial thrombosis in patients with cardiovascular risk factors. Its benefits in other low risk patients are unclear.[85] Aspirin and antiplatelet agents should be avoided in patients with a history of bleeding. Although markedly elevated platelet counts are not a risk factor per se for aspirin-induced bleeding,[85] acquired von Willebrand syndrome may be unmasked by aspirin in patients with platelet counts greater than $1{,}000 \times 10^9$/L.[73] Many physicians regard it as prudent to assess von Willebrand factor activity prior to initiating aspirin in such patients.[83]

Cytoreductive Therapy

Hydroxyurea

Hydroxyurea is considered the first-line cytoreductive agent in ET.[81,82,86,87] Some of the beneficial effects of hydroxyurea in ET and other myeloproliferative disorders may reflect reduction of leukocytosis and leukocyte-platelet interaction.[88] The extent to which hydroxyurea reduces *JAK2*V617F expression in ET patients is disputed.[89,90,91,92]

Anagrelide

The platelet-reducing drug anagrelide is a reasonable second choice for patients intolerant of, or unresponsive to, hydroxyurea.[93,94] As a first-line agent in ET, anagrelide has been reported to be non-inferior to hydroxyurea.[95] Unlike hydroxyurea, it does not affect leukocytosis.

Interferon

Administration of recombinant interferon can also be considered in patients refractory to hydroxyurea or to both hydroxyurea and anagrelide.[96–98] The systemic side effects and need for subcutaneous injection limit its acceptability to some patients.[99] High risk pregnant females with ET can be successfully managed with interferon.[100]

Other Agents/Modalities

Busulphan is an agent of established efficacy in myeloproliferative disorders such as ET,[82,101] however, its risk profile as an alkylating agent makes it less attractive than hydroxyurea, anagrelide, or interferon. Apheresis can utilized to obtain rapid reduction in the platelet count in emergencies associated with severe thrombocytosis such as bleeding with acquired von Willebrand syndrome or limb gangrene or in preparation for surgery, but should be

accompanied by cytoreductive drugs.[83] *JAK2* inhibitors currently available appear to be of primary benefit in post-ET myelofibrosis rather than in ET itself.

Post-essential Thrombocythemia Myelofibrosis

Myelofibrosis may be a late complication of ET, with an incidence of approximately 1.6 per thousand person-years of follow-up and is the cause of death in approximately 4% of ET patients.[26] Patients may develop transfusion-dependent anemia and/or thrombocytopenia, and symptomatic splenomegaly. JAK2 inhibitors appear to have benefit in the management of cytopenias and splenomegaly in myelofibrosis.[102–104] In general, management follows the pattern outlined for primary myelofibrosis in Chapter 83.

CHAPTER 52

QUALITATIVE DISORDERS OF PLATELET FUNCTION

Thomas J. Kunicki, Diane J. Nugent

Much of our current understanding of normal platelet structure–function relationships has been derived from the study of patients with congenital platelet disorders. These syndromes are the subject of excellent recent reviews.[1–5]

NORMAL PLATELET FUNCTION: A SUMMARY

When a blood vessel is damaged, circulating platelets interact with components of the extracellular matrix, particularly collagen, and a complex series of receptor–ligand interactions ensue that ultimately lead to the formation of a stable platelet plug or thrombus (Fig. 52.1). This process is a continuum of at least three phases that we can describe as *initiation*, *extension*, and *consolidation*, each of which entails the cooperation of a different group of receptors.

In the *initiation* phase (Fig. 52.2), plasma von Willebrand factor (VWF) binds to collagen via its A3 domain and becomes structurally altered such that its A1 domain then binds to the platelet membrane receptor glycoprotein Ib–IX–V complex (GPIb complex). This association is a requisite step in the adhesion of platelets to exposed thrombogenic surfaces at sites of vessel wall injury or in regions of atherosclerotic plaque rupture. Concurrently, a more stable platelet monolayer is formed on the collagen surface mediated predominantly by the platelet-specific receptor GP VI (GPVI) and platelet integrin $\alpha_2\beta_1$.

The engagement of these receptors enhances platelet activation leading to the *extension* phase (Fig. 52.3), mediated largely by the conversion of prothrombin to thrombin at the activated platelet surface and the secretion of active compounds from platelet granules (α-granules and δ-granules) that can further stimulate platelets. One of these, adenosine diphosphate (ADP), plays a particularly important role in the platelet response, binding to its cognate platelet receptors to augment platelet activation. The activated platelet also produces and/or releases additional agonists, including the agonist thromboxane A2 (TXA2). Most of the receptors involved in the events of the *extension* phase are members of the G protein-coupled receptor family.

In the *consolidation* phase (Fig. 52.4), platelet–platelet cohesion (aggregation), mediated by the binding of fibrinogen and/or VWF to the activated platelet integrin $\alpha_{IIb}\beta_3$ (GPIIb-IIIa), together with the assembly of a fibrin network, results in the generation of platelet-rich aggregates or thrombi. Further complexity is inherent in this final phase of platelet plug formation, and current research indicates an essential role for outside–in signaling through integrins and via receptor tyrosine kinases, including members of the Eph kinase family.

Inherited or acquired defects that affect any phase of this complex process can result in excessive thrombosis or bleeding. Hereditary disorders can be divided into groups (Table 52.1), based on whether they predominantly influence the initiation, extension, or consolidation phases of platelet-dependent hemostasis. Platelet dysfunction can also be a manifestation of many acquired disorders, and these are also discussed in this chapter.

DIAGNOSIS AND CLASSIFICATION OF PLATELET DYSFUNCTION: AN ALGORITHM

The preliminary diagnosis of platelet dysfunction must be made on the basis of patient history, and the diagnosis then confirmed by specific laboratory tests of platelet function. A practical algorithm for this purpose, depicted in Figure 52.5, is reproduced with permission from the excellent review by Bolton-Maggs et al.[5]

Bedside Exam and Patient History

An accurate and detailed patient and family history is a key element in the assessment of platelet disorders. One should bear in mind that bleeding histories are subjective and that bleeding can be variable, often evolving or decreasing throughout a person's lifetime. In particular, children may not have yet had enough hemostatic challenges to develop a strong clinical. The subjectivity of the oral history is reflected in a recent statistic that at least one quarter of persons who complain of serious bleeding do not have a bleeding disorder, whereas at least one third of persons who

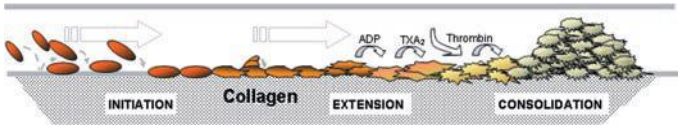

FIGURE 52.1. Platelet thrombus formation. The formation of a platelet thrombus can be envisaged as occurring in three distinct phases. The *initiation* phase entails the transient tethering of the platelet followed by a firmer adhesion to components of the matrix, leading to platelet activation. In the *extension* phase, the activated platelets synthesize and/or release from granule stores potent agonists, such as adenosine diphosphate (ADP) or thromboxane A2 (TXA2). These augment platelet activation. At the same time, the procoagulant platelet surface facilitates the formation of thrombin, which is itself a potent platelet agonist. In the *consolidation* phase, platelet–platelet cohesion (platelet aggregation) mediates the formation of the stable platelet plug.

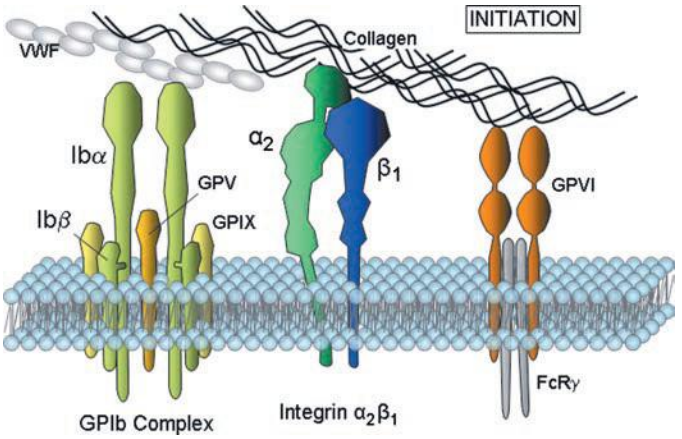

FIGURE 52.2. Initiation of platelet adhesion by matrix components, particularly collagen. Platelets employ a number of collagen receptors. These include VWF-mediated binding of collagen to the glycoprotein Ib (GPIb) complex (a heptamer composed of GPIbα, GPIbβ, GPV, and GPIX), the direct engagement of collagen by the integrin $\alpha 2\beta 1$ and GPVI/FcRγ. Engagement and clustering of GPVI initiates tyrosine phosphorylation of FcRγ by a Src family kinase (SFK). The tyrosine kinase Syk then binds and is activated, in turn activating phospholipase Cγ, which then initiates phosphoinositide hydrolysis, secretion of ADP, and the production of TXA2. ADP and TXA2 augment platelet activation by binding to their respective platelet receptors.

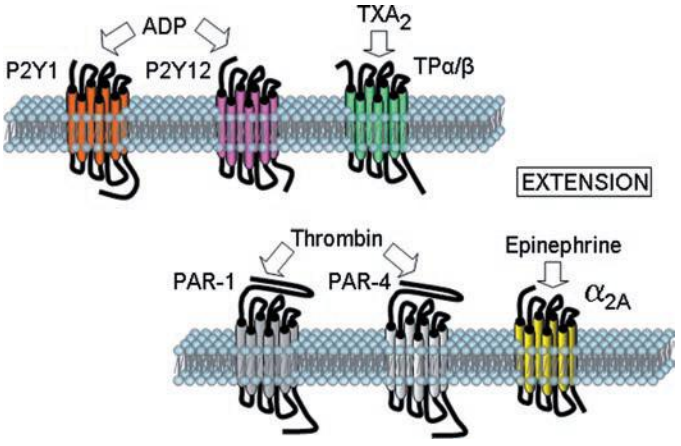

FIGURE 52.3. The extension phase of platelet plug formation accelerates and augments the activation of the platelet and is mediated largely by G protein-coupled receptors, including: the purinogenic receptors P2Y1 and P2Y12, which are bound by ADP; the α and β isoforms of the thromboxane A2 (TXA2) receptor TP; the protease-activated receptor (PAR) family members PAR1 and PAR4, that are recognized by thrombin; and the α2A-adrenegic receptor that is specific for epinephrine.

have no bleeding can be shown to have von Willebrand disease (vWD) or a platelet disorder.[6]

To overcome the subjectivity of a history for superficial mucocutaneous bleeding, the International Society on Thrombosis and Hemostasis (ISTH) suggests that bleeding should be considered clinically significant when there are two or more distinct bleeding sites such as the skin, nose, gums, vagina, gastrointestinal tract, or genitourinary tract. This includes either spontaneous bleeding or provoked bleeding, such as that which might result from dental work, parturition, trauma, or surgery. In addition, a bleeding history involving only a single site should be considered significant when it is so severe as to warrant blood transfusions. Finally, a single bleeding symptom that recurs on three or more unrelated and separate occasions should also be considered significant.[7,8]

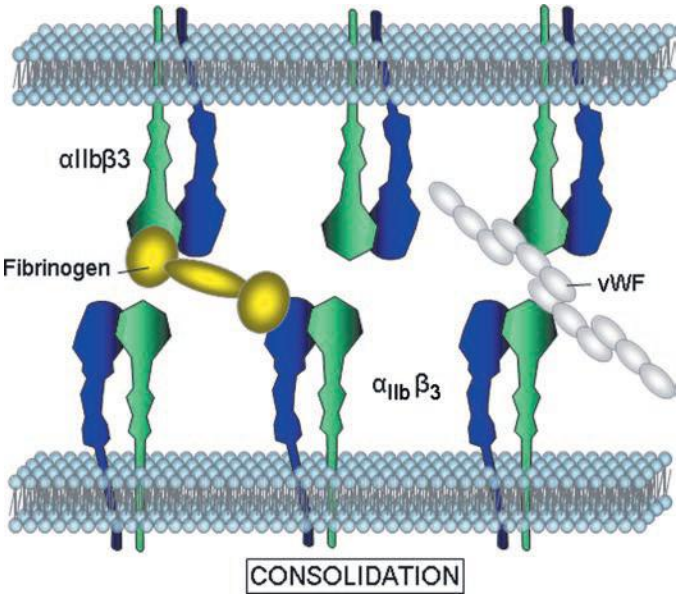

FIGURE 52.4. The consolidation phase of platelet thrombus formation occurs through the bridging of adjacent integrin αIIbβ3 complexes by fibrinogen or VWF, as well as other adhesive proteins.

TABLE 52.1

DISORDERS OF PLATELET FUNCTION

- **Hereditary platelet dysfunction**
  - **Initiation phase**
    - Bernard-Soulier syndrome
    - GPVI deficiency
  - **Extension phase**
    - Secretion disorders/granule deficiencies
      - α-Granule abnormalities (gray platelet syndrome)
      - δ-Granule (dense body) abnormalities
      - Hermansky-Pudlak syndrome
      - Chediak-Higashi syndrome
      - Wiskott-Aldrich syndrome
      - α/δ-Granule deficiency
    - Defects of signal transduction and secretion
      - Impaired liberation of arachidonic acid
      - Cyclooxygenase deficiency
      - Thromboxane synthetase deficiency
      - Thromboxane A_2 receptor abnormalities
    - Defects in calcium mobilization
    - Defects of platelet procoagulant activity
  - **Consolidation phase**
    - Glanzmann thrombasthenia
  - **Miscellaneous**
    - Hereditary macrothrombopathy/sensorineural hearing loss
- **Acquired disorders of platelet function**
  - **Drug-induced platelet dysfunction**
    - Analgesics
    - Antibiotics
    - Cardiovascular drugs
    - Psychotropic drugs
  - **Secondary platelet dysfunction**
    - Uremia
    - Paraproteinemia
    - Myeloproliferative disorders

A number of quantitative approaches to assess the relative severity of patient bleeding have been proposed, some including a normalization based on patient age.[9,10] However, such approaches work best for a comparison of cohorts of related individuals with comparable bleeding disorders, such as families of patients with vWD.

The distinction between normal individuals and those with bleeding disorders is not always clear cut. Care should be taken in all patients to note the use of medicines, either "over the counter," herbal, or prescription, that are known to influence platelet function. This is particularly true of medications such as aspirin, other nonsteroidal anti-inflammatory drugs (NSAIDs), ticlopidine or clopidogrel, integrin αIIbβ3 antagonists (e.g., Abciximab, tirofiban, and eptifibatide), epoprostenol, statins, cilostazol, sildenafil, fluoxetine, and large doses of various β-lactam antibiotics (penicillins > cephalosporins).[7]

Bleeding manifestations typical of platelet dysfunction include: (1) Unexplained or extensive bruising; (2) epistaxis, particularly if lasting more than 30 minutes, causing anemia or admission to hospital; (3) menorrhagia, particularly if this has been present since the menarche; (4) oral cavity bleeding; (5) bleeding during

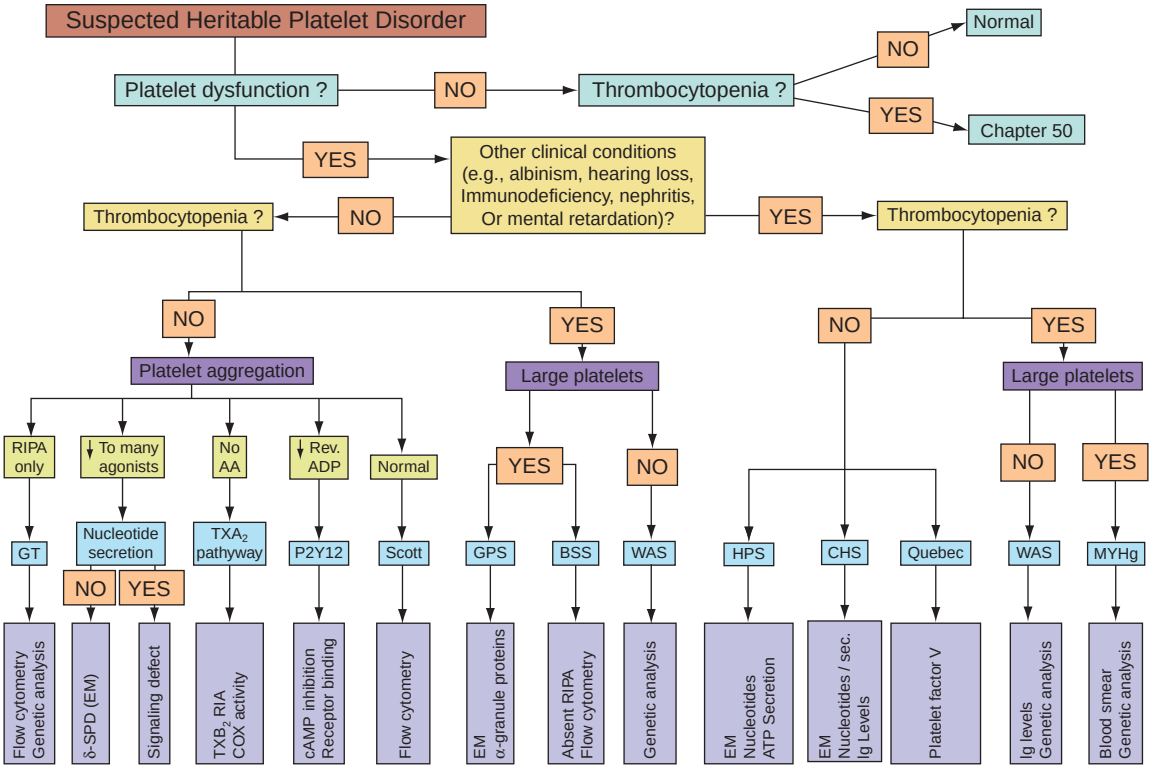

FIGURE 52.5. A scheme for the analysis of patients with suspected hereditary platelet dysfunction. In order to establish a precise diagnosis, specific laboratory tests are needed to establish a defect in platelet number or function. Generally, an automated full blood count, blood film, platelet aggregometry, and quantification of platelet nucleotides are necessary. The purpose of this algorithm is to assist the investigator in the systematic interpretation of laboratory results. To complete a diagnosis, specialty analyses may be necessary, and these are included for the specific disorder. Such assays might include flow cytometry to measure expression of surface glycoproteins, such as αIIb or β3 (GT), GPIb or GPIX (BSS). In addition, quantitation of annexin V binding (Scott syndrome) and genetic analyses to identify specific gene mutations might be needed: αIIb or β3 (GT), WAS (WAS and XLA) and MYH9. Certain disorders can be caused by mutations in more than one gene (e.g., HPS and BSS), so genetic analysis has not been considered as a definitive test in all cases. The algorithm includes the most frequent or best characterized heritable platelet disorders. Symbols and abbreviations: ↓, reduced aggregation; AA, arachidonic acid; BSS, Bernard-Soulier Syndrome; CHS, Chediak-Higashi syndrome; COX, cyclooxygenase; δ-SPD, dense-granule disorder; EM, electron microscopy; GPS, gray platelet syndrome; GT, Glanzmann thrombasthenia; HPS, Hermansky-Pudlak syndrome; MYH9, *MYH-9*–related disorder; P2Y12, deficiency of P2Y12 ADP receptor; QBS, Quebec platelet syndrome; Rev., reversible aggregation; RIA, radioimmunoassay; RIPA, ristocetin-induced platelet aggregation; Sec., secretion; TXA2, thromboxane A2; WAS, Wiskott-Aldrich syndrome. childbirth; (6) bleeding following invasive procedures; and (7) bleeding following dental extraction.

Severe platelet dysfunction is present from early childhood onward. Following delivery of an affected infant one may find intracranial and/or subdural hemorrhage, excessive bleeding from the umbilical stump or after circumcision, or easy bruising after handling. As the infant becomes more mobile, easy or extensive bruising following relatively mild trauma can be indicative of platelet dysfunction. Prolonged epistaxis is a common finding throughout childhood and can even become life threatening. In adults, menorrhagia and bleeding during childbirth are common and potentially serious, whereas bleeding following any invasive procedure should be anticipated.[5]

Mild platelet dysfunction is more likely to manifest itself at any age most commonly following a definable hemostatic challenge, such as surgery or dental extractions. Easy bruising is a very nonspecific symptom, and many cases are difficult to distinguish from what would otherwise be considered a normal response.

Consanguinity increases the likelihood of an autosomal recessive platelet disorder, and a family history is invaluable in establishing the diagnosis of inherited platelet dysfunction.

Laboratory Assessment

A number of laboratory-based evaluations are critical for an accurate diagnosis of platelet dysfunction.

Whole Blood Platelet Count

A key element in assessing platelet dysfunction is an accurate whole blood platelet count. Automated counts should be viewed as provisional. Inasmuch as macrothrombocytes or platelet aggregates created inadvertently during blood processing will not be counted, the whole blood platelet count should be confirmed by an optical method.

Global Coagulation Tests

To rule out abnormalities in clotting factors, all patients should have a prothrombin time, activated partial thromboplastin time, and thrombin time performed. Laboratories should determine their own age-related normal range. It is also critical to investigate all patients for VWD, which is far more common than platelet function disorders and creates a similar bleeding phenotype.

Bleeding Time

The bleeding time is historically a common measure of platelet function. However, because the test is poorly reproducible, time consuming, and insensitive, the bleeding time has gradually fallen out of favor as a clinically useful test.[11] In cases of mild platelet dysfunction, the bleeding time is often normal or minimally prolonged; [11] in severe cases, it will usually be prolonged.

Unfortunately, the bleeding time does not correlate well with the in vivo bleeding tendency within individual patients, and an accurate bleeding history is considered by many to be a more valuable screening test. Nonetheless, a prolonged bleeding time should be considered sufficient grounds to perform additional tests of platelet function.

Platelet Function Analyzer-100

The platelet function analyzer-100 (PFA-100) measures the rate of thrombus formation under high shear in citrated whole blood that is perfused through a membrane aperture coated with collagen/epinephrine or collagen/ADP. The closure time (CT) will be significantly prolonged in Glanzmann thrombasthenia (GT) and Bernard-Soulier syndrome (BSS) using either ADP/collagen or epinephrine/collagen membrane cartridges.[12,13] Consequently, the PFA-100 can be used to screen patients to exclude these diagnoses.

The PFA-100 may be sensitive to platelet storage pool disease (SPD), primary secretion defects, the Hermansky-Pudlak syndrome (HPS), and the Quebec syndrome. However, because false-negative results occur in patients with all of these disorders, there are those who question its usefulness as a screening tool.[12,14] The PFA-100 is affected by platelet count and hematocrit, and is dependent on normal VWF levels and naturally occurring (genetic) differences in platelet membrane GPVI or $\alpha 2\beta 1$ expression.[13,14,15]

Platelet Aggregation

Platelet aggregation in platelet-rich plasma remains an important test in the analysis of platelet function. The typical agonists that are used to induce platelet aggregation are ADP, epinephrine, collagen, arachidonic acid (AA), ristocetin, the TX receptor agonist U46619, thrombin or the thrombin receptor-activating peptide. Because the level and/or activity of each of the receptors for the agonists can vary among normal subjects, it is recommended that dose–response curves to each agonist be obtained from the patient under study and compared to a reference range obtained from multiple normal subjects.[16] When thrombin is the agonist, an inhibitor of fibrin polymerization, such as glycine–proline–arginine–proline peptide, must be added to the PRP, or alternatively, plasma-depleted washed platelets must be used.

Platelet aggregation is sensitive to platelet count, and at counts $\leq 120{,}000/\mu l$, the response to some agonists will be impaired. In thrombocytopenic samples, the best options are to adjust a control sample to the same count as the patient or to perform studies on washed platelets where the platelet number can be normalized. Consideration should also be given to more specialized tests, such as a measure of P-selectin expression or integrin $\alpha IIb\beta 3$ activation by flow cytometry. The expected aggregation responses associated with specific diagnoses are covered in the appropriate sections.

Adenine Nucleotide Content and Release

Measurement of platelet adenosine nucleotide (ADP and adenosine triphosphate [ATP]) content and release can be used in the diagnosis of storage pool and release defects.[17] A finding of normal platelet aggregation does not exclude the diagnosis of SPD. It is recommended that patients suspected of having platelet dysfunction should have both platelet aggregation and adenine nucleotide release performed, unless it is certain that the laboratory performing the platelet aggregation assays can demonstrate that their assay conditions are sensitive to defects in platelet nucleotide amount or release.

Platelet nucleotide content and release varies with age. Ideally, age-related normal ranges should be established for total and released levels of ATP and ADP and their ratios. Platelet aggregation, nucleotide content, and nucleotide release in children over 12 months of age do not differ significantly from adult values, whereas collagen-induced platelet nucleotide release has been shown to be reduced in neonates compared with children older than 1 year. Agonist-induced secretion of platelet granule contents has been shown to be reduced in both term and premature babies due to immature signal transduction pathways.[18,19]

Flow Cytometry

Flow cytometry is routinely used to measure platelet surface receptor density, platelet activation, α-granule release, procoagulant phospholipid expression, and microvesicle production.[20,21] A common application of flow cytometry is the assessment of GPIb complex and integrin $\alpha IIb\beta 3$ expression in the diagnosis of BSS and GT. Individuals who are heterozygous for these disorders are also readily distinguished. An important benefit of flow cytometry is the small quantities of blood required, an attractive feature in young children or thrombocytopenic individuals.

Electron Microscopy

Transmission electron microscopy (TEM) of fixed/embedded platelet thin sections can be performed by a limited number of specialized personnel, but is critical in the assessment of platelet granule defects and changes in platelet ultrastructure (e.g., in the evaluation of patients with *MYH-9* defects). Whole-mount EM can be used to quantitate δ-granule content because this is readily identified in unstained preparations.[22]

Additional Assays

Several additional assays are available in specialized laboratories that can provide further information relevant to the diagnosis of the particular platelet disorder, including analysis of receptor expression, specific molecular or genetic defects, protein phosphorylation, formation of signal transduction intermediates, or a characterization of the platelet proteome. The utility of these tests in clinical diagnoses is currently under intense investigation.

Overview of Treatment Options for Platelet Disorders

Although the number of clearly identifiable platelet dysfunction syndromes is growing, our choice of treatment options remains limited. Minor membrane bleeding may be controlled with topical agents in the nasal or oral cavities with antifibrinolytic agents. Epsilon-aminocaproic or tranexamic acids will decrease blood loss associated with epistaxis or menorrhagia. Some patients may benefit from Stimate as documented by DiMichele and Hathaway,[23] whereas others actually bleed more with this agent due to the fibrinolysis induced by this medication. For this reason many centers recommend the use of Stimate in conjunction with Amicar or Cyklokapron.

In the case of menorrhagia, hormonal suppression is the mainstay for women who do not wish to undergo endometrial ablation for hysterectomies. In combination with antifibrinolytics and Stimate, even severe bleeding may be controlled; however, more aggressive therapy including platelet infusion may be required to control bleeding before these agents take effect.

Platelet transfusion may pose a dilemma to those physicians wishing to avoid alloimmunization in patients who may require multiple transfusions throughout their lifetimes to control hemorrhage. This is particularly true for those patients who are lacking membrane GPs, such as $\alpha IIb\beta 3$ or GPIb. In this setting patients are at risk of developing isoimmunization, making antibodies against the "foreign" proteins that they lack and thus becoming refractory to all subsequent platelet transfusions.

Although rare, this creates a significant challenge in patients who require frequent platelet infusions to control life-threatening bleeding. Patients with GT have not only developed antibodies to αIIb and/or β3 but also demonstrated anti-idiotypic antibodies that bind to fibrinogen, thus creating a hemorrhagic disorder far worse than the underlying platelet dysfunction. In general, physicians avoid platelet transfusion apart from cases of severe hemorrhage. Isoimmunization appears to be rare in Glanzmann but the risk of alloimmunization is still a major concern, therefore leukocyte depletion of transfused platelets is recommended to decrease the frequency of sensitization.

Activated recombinant Factor VII (rFVIIa) has been used to slow or arrest bleeding associated with platelet dysfunction.[24] Dosages have varied widely but many patients have responded to this regimen when others have failed. Used in combination with antifibrinolytics, minor bleeding can be controlled in certain patients. This treatment is often used prior to platelet transfusion in order to avoid blood product exposure and isoimmunization.

For those patients who present with recurrent life-threatening bleeds, bone marrow transplant or stem cell infusion following immune ablation is recommended before the patients have extensive blood product exposure.[25] Successful transplantation with normal stem cells represents long-term cure for these patients. Although complications related to stem cell transplantation cannot be overlooked, successful engraftment essentially eliminates the significant risk of mortality related to hemorrhage in patients with severe disorders.

Patients with rare platelet dysfunction syndromes are now included in many of the rare bleeding disorder international and regional registries that will aid physicians in understanding the natural course, optimal therapy, and life expectancy for each of the syndromes listed below, as well as the numerous platelet disorders that have yet to be defined. Definitive molecular and biochemical diagnoses will dictate appropriate therapy in these patients. With improvement in platelet function measurement and proteomic approaches one should see significant improvement in early diagnosis and medical management.

HEREDITARY DISORDERS OF PLATELET FUNCTION

Defects in the Initiation Phase: Bernard-Soulier Syndrome

BSS is a rare disorder first described in 1948 as "dystrophie thrombocytaire hemorrhagipare congenitale" caused by abnormal expression or activity of the platelet GPIb complex.[26]

Etiology

BSS platelets have a quantitative or qualitative abnormality of the membrane GPIb complex, a heptamer composed of four leucine-rich GP that are the products of distinct genes (Fig. 52.2). The prominent member of the complex, GPIb, is a heterodimer composed of disulfide-bonded GPIbα and GPIbβ subunits. GPIb then forms a noncovalent complex with GPIX, and two GPIb-IX trimers then associate noncovalently with one molecule of GPV. The amino-terminal type A domain of GPIbα binds directly to VWF, mediating normal platelet adhesion during the initial phases of primary hemostasis, whereas BSS platelets do not adhere to the extracellular matrix when perfused at a high shear rate.[27] The defect in the GPIb complex also explains the failure of affected platelets to agglutinate in the presence of ristocetin, even in the presence of normal plasma or VWF.

Mutations in the gene for GPIbα, GPIbβ, or GPIX, but not GPV, have been shown to result in decreased expression of the GPIb complex and the BSS. Defects range from virtually absent GPIb to variant forms in which patients retain measurable amounts of apparently dysfunctional GPs.[1]

BSS is usually inherited as an autosomal-recessive disorder, and consanguinity is common in reported kindreds. Heterozygotes typically have "giant" platelets and reduced levels of the GPIb complex and may or may not be symptomatic.

Clinical Features

Bleeding symptoms are usually evident shortly after birth or in early childhood. The clinical manifestations include purpura, epistaxis, gingival bleeding and menorrhagia, and more rarely gastrointestinal bleeding, major hematomas, or hematuria. Severe bleeding episodes can result from trauma and surgical procedures, such as tonsillectomy, appendectomy, splenectomy, oral surgery, and menses. However, individual bleeding can vary substantially in severity and frequency.

Laboratory Findings

The typical laboratory findings include an increased bleeding time, mild thrombocytopenia, giant platelets on blood smear, and defective adhesion to collagens in vitro. Platelet morphologic abnormalities are a hallmark of BSS, featured by large platelets with a diameter as high as 10 μm. A defective platelet agglutination in response to ristocetin, as measured by aggregometry in vitro, is a unique characteristic of BSS that differentiates this syndrome from other rare inherited disorders that are also associated with macrothrombocytopenia, such as the *MHY9*-related disorders.[1] A firm diagnosis requires the combined findings of increased bleeding times, macrothrombocytopenia, defective ristocetin-induced agglutination, and low or absent levels of platelet GPIb-V-IX (CD42a-d) by flow cytometry.

In bone marrow aspirates, megakaryocytes are normal or increased in number, but they reveal no characteristic morphologic abnormalities when viewed by light microscopy. Electron microscopic studies have revealed abnormalities of the dense tubular system and vacuolization of the demarcation membrane system.[28]

Management

Therapeutic approaches include both general and specific treatment of bleeding. Patients should be warned to avoid trauma and antiplatelet medication, such as aspirin, and to maintain proper dental hygiene. Females may benefit from contraceptive therapy once they reach puberty. Treatment of bleeding or prophylaxis during surgical procedures usually requires blood or platelet transfusion with the associated risk of developing antiplatelet alloantibodies. Desmopressin and rFVIIa administration have been shown to shorten the bleeding time in some patients. In rare cases of life-threatening bleeding, a bone marrow or umbilical cord hematopoietic stem cell transplantation may be considered.[29] Responses to antifibrinolytic agents are more variable, and the administration of adrenal corticosteroids and splenectomy are usually ineffective.

Platelet-reactive isoantibodies have been generated by BSS who have received multiple blood or platelet transfusions.[30] These antibodies produce a particularly severe clinical complication because they will bind to and may neutralize the function of GPIb on transfused platelets. This results in impaired adhesion of the transfused platelets. The presence of such antibodies can be established by a finding of impaired in vitro aggregation of normal platelets induced by ristocetin and bovine VWF in the presence of patient plasma. Alloimmunization is also a common side effect of multiple platelet transfusions, and this may necessitate the subsequent use of HLA-matched platelets.

Variation in the Initiation Phase: Collagen Receptor Polymorphisms

A lifelong bleeding disorder and the unique absence of in vitro platelet aggregation to collagen have been associated with a deficiency of either of the collagen receptors, integrin $\alpha 2\beta 1$ or GPVI,[1] yet specific gene defects have not been identified. Careful evaluation is needed to establish a specific molecular defect in either receptor.

The Integrin $\alpha_2\beta_1$

Among normal individuals, platelet $\alpha_2\beta_1$ levels can vary up to tenfold and correlate with differences in adhesiveness to type-I or type-III collagens and genetic variants of the $\alpha 2$ subunit gene *ITGA2*. We identified several single nucleotide polymorphisms (SNPs) within the coding sequence of the α_2 gene *ITGA2* that correlate with platelet $\alpha_2\beta_1$ density[31] and define six major *ITGA2* haplotypes.

Clinical Relevance of α_2 Polymorphisms

In VWD, platelet adhesive functions are impaired due to the decrease in functional VWF multimers in plasma and platelets. Inheritance of the *ITGA2* haplotypes associated with lower $\alpha 2\beta 1$ density will increase the risk of bleeding in patients with either type I and type2 VWD.[9,10]

The association of *ITGA2* haplotypes with risk for arterial thrombosis has been studied in acute coronary syndromes, diabetic nephropathy, and stroke. Although several studies have found that the inheritance of high-density *ITGA2* haplotypes correlates with increased thrombosis, this association is not a consistent observation.[32]

Platelet Glycoprotein VI

GPVI is a major platelet GP (60 to 65 kDa) that has been confirmed as an important receptor for collagen since the initial identification of a patient with a mild bleeding disorder whose platelets lacked GPVI and exhibited defective collagen-induced responses.[33] Autoantibodies against GPVI can cause substantial shedding of this receptor through metalloproteinase cleavage.[34,35]

Glycoprotein VI Polymorphism

Aside from isolated cases of GPVI defects, it is important to note that there is variation in platelet GPVI content among normal healthy subjects,[36] which is directly proportional to normal variation in mean platelet volume.[37] This variation is manifested in a significant difference in prothrombinase activity induced by GPVI-specific agonists such as the snake venom protein convulxin or collagen-related peptide (CRP).[36] The direct association between platelet $\alpha_2\beta_1$ density and GPVI content is also attributable to variation in mean platelet volume, which has a proportional effect on levels of other receptors, including αIIbβ3.[37] Variation in GPVI content represents yet another genetically controlled risk factor predisposing individuals to hemorrhagic or thromboembolic disorders.

Defects in the Extension Phase

Secretion Defects: Storage Pool Disease

SPD is a heterogeneous group of congenital disorders that have in common a deficiency of granules or their constituents that results in a defect in ADP release from activated platelets and abnormal secretion-dependent platelet aggregation.[1] Defective platelet secretion can result from the absence of or defects in one or both of the dominant types of platelet granules: The α-granule or the δ-granule (dense body). Thus, three subgroups of SPD are now distinguished. The isolated deficiency of α-granules (α-SPD) has been studied for several years and is more commonly known as the Gray platelet syndrome (GPS)[38]; the exclusive abnormality of dense-granules (δ-SPD) can be congenital or acquired, as in myeloproliferative syndromes or rheumatologic disorders; [17] and abnormalities of both α- and δ-granules are classified as $\alpha\delta$-SPD.[17]

α-Granule Storage Pool Disease: Gray Platelet Syndrome

GPS is a very rare disorder with less than 100 cases reported worldwide and is characterized by a selective deficiency in the number and content of α-granules.[17,38] The formation of α-granules in immature megakaryocytes proceeds normally, but the granule number then decreases during maturation, and the mature megakaryocytes are left with only small abnormal granules that are few in number. Some of the normal protein constituents of α-granule membranes, such as GPIV, integrin αIIb-β3, and P-Selectin remain in the abnormal granules and will be normally redistributed during platelet activation. The defect is limited to megakaryocytes and platelets. Recent evidence suggests that GPS is associated with mutations in *NBEAL2* (neurobeachin-like 2 gene), which encodes a protein containing a BEACH domain that is predicted to be involved in vesicular trafficking and may be critical for the development of platelet α-granules.[39–41]

Several proteins are synthesized but not stored properly in the abnormal α-granules. These include platelet factor 4, β-thromboglobulin, fibrinogen, fibronectin, vWF, platelet-derived growth factor, and thrombospondin. Other organelles, such as lysosomal granules, mitochondria, and δ-granules (dense bodies) are present in normal numbers, and δ-granules contain normal amounts of adenine nucleotides and serotonin.

Clinical Features

GPS is inherited as an autosomal trait and is associated with mild to moderate thrombocytopenia (20,000 to 150,000/μl) and moderately enlarged platelets.[17,38] The bleeding time is usually prolonged, and platelet survival may be shortened, but splenomegaly is not common. As in other platelet function defects, a history of mild bleeding is the norm, and treatment is seldom required. The bone marrow exhibits normal megakaryocyte numbers and increased reticulin, occasionally around clusters of megakaryocytes, but myelofibrosis is not a feature of this disorder. In Wright-stained blood smears, the platelets appear large, misshapen, agranular, and gray. In electron photomicrographs, an almost total lack of α-granules is evident in platelets and in megakaryocytes.

When analyzed by EM, it is the only disorder that is characterized by the selective absence of platelet α-granules. Megakaryocytes show defective α-granule biogenesis, with impaired uptake and storage of endogenously synthesized proteins, such as platelet factor 4, β-thromboglobulin, or VWF, and defective sequestration of exogenous proteins, such as fibrinogen, albumin, or factor V. On the other hand, in the platelet, the α-granule marker P-selectin is retained and is redistributed to the surface upon activation. Both autosomal recessive and autosomal dominant inheritance have been reported, implicating more than one gene in the etiology of the disease. Myelofibrosis of bone marrow is an additional feature that is attributed to the spontaneous release of platelet-derived growth factor and transforming growth factor-β1 from megakaryocytes.

Laboratory Findings

Gray platelets have a normal aggregation and release in response to AA or ionophore and generate TX normally. Platelet aggregation induced by ADP, epinephrine, thrombin, or collagen is variably affected. Release from dense bodies usually is subnormal,

particularly when induced by thrombin. Abnormal calcium influx and mobilization from intracellular stores have also been reported. The platelet count is often reduced and can be as low as 50,000 per μl. By EM, the platelets have reduced numbers or a complete absence of α-granules.

Management

Because of the rare nature of α-granule disorders, there is not a very extensive clinical database upon which to make generalizations about effective treatment of the bleeding problem. However, these patients should be managed in the same manner as other patients with mild bleeding disorders. In the case of major bleeding or surgical challenge, they may require platelet transfusion.

Isolated δ-Storage Pool Disease

δ-SPD is characterized by easy bruising, mucocutaneous bleeding, and excessive post-operative and post-partum hemorrhage.[17]

Clinical Features

The symptoms can become more severe if the patient ingests aspirin or other antiplatelet agents, and patients with SPD should be advised to avoid such drugs. Platelet counts are typically normal, and the bleeding time is usually prolonged. The platelets are morphologically normal on Wright-stained smears, but they are deficient in dense bodies by EM. The diagnosis of δ-SPD must be made by the finding of a decrease in dense granule constituents and/or EM to demonstrate the absence of dense granule-limiting membranes and contents. The most consistent finding is that adenine nucleotides are reduced with an increased ratio of ATP to ADP and normal levels of lysosomal enzymes.

The platelet content of serotonin, however, can be variably reduced. Whole-mount EM recognizes calcium, but it cannot differentiate the absence of a dense granule from the absence of its calcium. Dense granules can also be quantitated by fluorescent microscopy because, whether full and empty, δ-granules take up the fluorescent dye quinacrine (mepacrine).[42]

Laboratory Findings

Because of the defect in δ-granules and the decreased level of ADP, primary aggregation responses in vitro are normal, but secondary aggregation may be diminished. Typically, there is an impaired response to collagen and a deficient secondary wave with ADP, epinephrine, and low concentrations of thrombin, but ristocetin aggregation is normal. Although this functional defect is often encountered in this disorder, it cannot be relied upon as a diagnostic criterion. The platelets are also deficient in serotonin, calcium, and pyrophosphate, which are stored in the δ-granules.[17]

The bleeding time is increased, with normal platelet counts and morphology. Subsets of patients have been identified who have a prolonged bleeding time, decreased dense bodies, and ADP release but normal platelet aggregation. The diagnosis of δ-granule SPD can best be made following a combination of studies, including bleeding time, platelet aggregation, an assessment of storage pool adenine nucleotides, thrombin-induced radioactive serotonin uptake and release, and TEM.

There is suggestive evidence that δ-SPD is inherited as an autosomal dominant characteristic, but neither the causative gene nor the molecular nature of the basic defect have yet been determined.

Management

To treat the symptoms of SPD, desmopressin (DDAVP) can normalize the bleeding time in some patients, often within 1 hour after infusion.[23] This treatment is particularly effective in improving hemostasis after procedures.

Combined αδ-Storage Pool Disease

In αδ-SPD, which is much less common than isolated δ-SPD, δ-granules and/or their contents are uniformly decreased, and the deficiency of α-granules and/or their constituents can vary.[17] Platelets in these patients form significantly smaller thrombi in flowing blood than is seen with platelets from patients with δ-SPD. The defects are also not uniformly among the platelet population, such that α-granules and δ-granules may be completely absent in one portion of the population yet present in nearly normal levels in another.[43]

The mode of inheritance appears to be autosomal dominant, but a basic molecular defect and a genetic basis have not yet been determined.

Animal Models and Etiology

The comparative study of granule deficiencies in the mouse or rat can provide clues to understanding the etiology of SPD. For example, the gunmetal mouse[44] and the fawn-hooded hypertensive rat[45] are characterized by reduced platelet α- and δ-granules, a disorganization of megakaryocyte internal membranes, and impaired α-granule protein retention. Mutations in *RabggtA* result in defective geranylgeranyl transferase, which catalyzes the attachment of lipid geranylgeranyl groups to *Rab* proteins.[44] *Rab* proteins are small guanosine triphosphatases (GTPases), which split GTP to provide energy for membrane fusion events and for attachment to cytoskeletons. By analogy, it is possible that mutations in the human gene *RABGGTA* are also responsible for human αδ-SPD, but this remains to be proven.

Clinical Features

Bleeding in this disorder is clinically similar to bleeding in δ-SPD and GPS, and is manifested by a prolonged bleeding time with normal platelet counts.[17] Except for their bleeding tendency, patients with αδ-SPD appear otherwise healthy.

Laboratory Findings

Defects in secondary platelet aggregation are typical, and defects in primary aggregation are even more extreme than seen in δ-SPD. Because of variability, in vitro platelet aggregation in αδ-SPD is not an appropriate diagnostic criterion, and an accurate diagnosis requires measurement of δ- and a-granule constituents and/or EM of platelet organelles. The lysosomal enzyme content of αδ-SPD platelets is normal.

Management

Because of the few numbers of patients with combined αδ-SPD, there is little clinical information upon which to develop a treatment scheme. However, this disorder can likely be managed in the same manner as the isolated δ-SPD (see above).

Quebec Platelet Syndrome (Factor V Quebec)

The Quebec platelet syndrome is an extremely rare, autosomal dominant disorder that was originally identified by the finding of low levels of platelet α-granule factor V but normal plasma factor V.[1,17] It is characterized by protease-related degradation of many platelet α-granule proteins, including P-selectin. The α-granule ultrastructure is normal. Increased expression of α-granule urokinase-type plasminogen activator is thought to lead to spontaneous intracellular activation of the fibrinolytic pathway resulting in the generation of plasmin, which cleaves multimerin that would otherwise stabilize factor V.[46]

Clinical Features and Laboratory Findings

Many cases may go undiagnosed because there are no characteristic morphologic features or platelet aggregation abnormalities. The main laboratory finding is defective procoagulant activity,

reflected by a failure to assemble the prothrombinase complex. A related defect, platelet Factor V New York, is also characterized by decreased levels of platelet Factor V, although there is no indication of Factor V proteolysis, as in Factor V Quebec.[47]

Management

The Quebec platelet syndrome is unresponsive to platelet transfusions. It is the current opinion that fibrinolytic inhibitors are the most effective means to control bleeding.[48] Otherwise, treatment should be similar to that given to patients with bleeding disorders.

Hermansky-Pudlak and Chediak-Higashi Syndromes

The HPS and Chediak-Higashi syndrome (CHS) are rare autosomal recessive disorders that have in common platelet dense granule deficiency, albinism, and lysosomal granule defects.[49]

Hermansky-Pudlak Syndrome

HPS is as an autosomal-recessive trait that has a worldwide distribution but is most prevalent in Puerto Rico.

Etiology

The genetic causes of HPS are diverse. Mutations in at least seven genes have been linked to this disease, and the absence of platelet dense bodies is thought to result from a defect in organelle development.[50]

Clinical Features and Laboratory Findings

A diagnosis of HPS is based on the presence of oculocutaneous albinism and absent platelet dense bodies on whole-mount EM.[51] Typical findings are a lifelong history of easy bruising; minor bleeding episodes, such as mucus membrane bleeding; epistaxis, and metromenorrhagia. Many patients will require whole blood or platelet transfusions when bleeding symptoms become more severe. Pulmonary fibrosis and inflammatory bowel disease, associated with infiltration of ceroid-pigmented reticuloendothelial cells in the lung and colon, have been reported in several cases of this syndrome.[52] In platelet aggregation assays, there is an absence of the secondary wave in response to ADP and epinephrine, and the response to collagen is also abnormal. Usually, the template bleeding time will also be longer than normal.

Management

Localized and limited treatment of the bleeding symptoms is the norm in HPS.[49,53] The albinism necessitates skin and eye protection, and the bleeding can be controlled topically with thrombin and Gelfoam. Prophylactic use of intravenous 1-desamino-8-D-arginine vasopressin or Stimate is recommended for procedures such as tooth extractions or biopsies. Menstrual bleeding can be regulated by birth control pills. In the event of major surgeries or severe bleeding episodes, platelet or red blood cell transfusions may be required.

Chediak-Higashi Syndrome

SPD also may be associated with the CHS.[1,54] In addition to defective platelet dense granules and oculocutaneous albinism, CHS is also characterized by immune deficiency and progressive neurologic dysfunction. In CHS patients, the granule abnormalities are not restricted to the megakaryocyte lineage, and numerous cell types exhibit giant cytoplasmic inclusions that are enlarged vesicles.

Etiology

Numerous cases of CHS have been reported to result from mutations in the lysosomal trafficking regulator gene (*LYST*) located on chromosome 1q42.1-42.2. Mutations in the LYST protein can be associated with defective natural killer cell function.[55] However, LYST mutations cannot be identified in all CHS patients, suggesting the existence of causative defects in other genes.[56] Several proteins are known to interact with LYST, including the SNARE complex protein HRS, signaling protein 14-3-3, and casein kinase II.[57] It has been proposed that LYST may be an adaptor protein that brings into close proximity proteins that mediate intracellular membrane fusion reactions. Along this vein, LYST contains several consensus motifs that play distinct roles in vesicle transport and fusion.

Clinical Features and Laboratory Findings

Platelet counts are normal prior to development of the accelerated phase. The dense granule defect results in mucocutaneous bleeding and a prolonged bleeding time. The secondary wave of platelet aggregation is impaired, there is an increased ATP-to-ADP ratio, decreased platelet serotonin, and decreased platelet calcium. Some patients have a normal number and shape of dense bodies, but most often there is an absence of or marked reduction in dense bodies.

Management

Prior to the accelerated phase, hemostatic problems can be treated as in the case of other mild platelet disorders. With time, infections and a lymphoproliferative accelerated phase are serious developments that can result in death within the first decade.[1,54] Although experience is still limited, hematopoietic cell transplantation is a potentially effective therapy for correcting and preventing hematologic and immunologic complications of CHS.[58]

Griscelli Syndrome

Mutations in *RAB27A*, a gene for a small GTPase involved in vesicular transport and organelle dynamics, are considered to be the cause of GS.[59] The ashen mouse with mutated *RAB27A* is a model of GS and exhibits a reduction in the number of platelet dense granules. However, the hemostatic phenotype of these mice is affected by the genetic background, and it is likely that additional modifier gene polymorphisms have an important influence on the hemostatic phenotype.

Clinical Features and Laboratory Findings

GS is a rare autosomal recessive disorder in which patients present with abnormal pigmentation, immunodeficiency, and development of the accelerated phase.[60] GS patients have no obvious bleeding prior to the accelerated phase, and it has not been firmly established that there is a characteristic platelet dense granule defect. Hypopigmented hair with a silvery-gray sheen and pigment clumps is a characteristic of GS, but these are larger and less homogeneously distributed than one sees with CHS patients. The giant cytoplasmic granules typical of CHS cells are not seen in GS cells.

Management

Like CHS, the disease is usually fatal by the first decade of life. The same management as observed with CHS will likely be effective in patients with Griscelli syndrome.[1,54]

Paris-Trousseau (Jacobsen) Syndrome

The Paris-Trousseau (Jacobsen) syndrome is an autosomal dominant disorder characterized by thrombocytopenia, a history of relatively mild bleeding, the presence of giant α-granules in a minor proportion of platelets, and two morphologically distinct populations of megakaryocytes in the bone marrow, some of which exhibit signs of abnormal maturation. Additional congenital abnormalities include mental retardation, cardiac abnormalities, and cranio-facial abnormalities. This is an extremely rare disorder, and only 10 childhood cases have been reported.[61]

These patients have deletions of the long arm of chromosome 11q that include the gene *FLI1*, which encodes a transcription factor that plays a critical role in normal megakaryocytopoiesis. Thus, the hemizygous deletion of *FLI1* generates a subpopulation of megakaryocyte progenitors that fail to differentiate normally, forming small immature megakaryocytes that undergo massive lysis.[62] Those platelets with giant α-granules fail to release their contents normally upon stimulation.

Arthrogryposis-Renal Dysfunction-Cholestasis Syndrome

The gene VPS33B encodes a protein that is involved in protein trafficking. A mutation of the gene is the cause of ARC syndrome.[63] ARC is an autosomal recessive disorder with multiple systemic abnormalities, one of which is platelet dysfunction is caused by a deficiency in platelet α-granules.[64] This disorder is diagnosed by severe distinguishing features other than the platelet dysfunction, and affected individuals usually do not survive their first year.

Inherited Disorders of Primary Membrane Receptors

Congenital Defects of P2Y12

The adenine nucleotides ADP and ATP are both released from platelet δ-granules during activation induced by a variety of agonists, and both can augment or modulate the platelet functional response through autocrine and paracrine mechanisms by binding to platelet purinergic receptors.[65]

Two platelet purinergic receptors are specific for ADP, the Gq-protein–coupled receptor P2Y1 and the Gi-protein–coupled receptor P2Y12. One receptor, the P2X1 ion channel, is bound by ATP. The P2Y and P2X receptors operate in a temporally distinct manner and selectively trigger distinct intracellular signaling pathways. Recent advances in our understanding of P2Y receptor physiology suggest that these receptors are a potentially relevant target of antithrombotic therapy. P2Y1 mediates ADP-induced intracellular calcium ion mobilization and shape change, and P2Y12 is coupled to adenylyl cyclase inhibition and is responsible for ADP-induced macroscopic platelet aggregation.[66]

At the same time, we have only a perfunctory understanding of the function of P2X1 in platelet activation. It is known, however, that P2X1 function is linked to calcium ion influx.[66]

Etiology

P2Y12 defects are inherited as autosomal recessive traits,[67] and heterozygous individuals display a mild abnormality in platelet function similar to that observed in patients with SPD. In two cases, different homozygous frameshift mutations cause premature termination of translation. In another case, one allele presented a reading frameshift caused by the deletion of two nucleotides, whereas the other case had a normal coding sequence but a reduced expression, possibly resulting from another mutation in a regulatory region of the gene.[68]

Clinical Features and Laboratory Findings

A limited number of patients have been described with congenital abnormalities of P2Y12 resulting in bleeding diatheses and abnormalities of platelet function.[4] The common clinical findings in these patients are a lifelong history of mucosal bleeding, easy bruising and/or excessive post-operative bleeding, and mildly to severely prolonged bleeding times. Laboratory findings were a weak and rapidly reversible primary wave of aggregation induced by ADP and abnormal aggregation induced by collagen, arachidonate, and TXA2 analogs. Aggregation induced by high concentrations of thrombin was normal. ADP-induced shape change is normal, but ADP fails to inhibit the expected normal rise in cAMP levels seen after stimulation with prostaglandin E1.

Management

Inasmuch as there are generally no serious side effects, DDAVP is recommended for prophylaxis and treatment in these patients.[23]

Thromboxane A2 Receptor

Defective TXA2 receptor function is characterized by impaired platelet aggregation in response to the TXA2 analog U46619, a variable response to other agonists comprising a reduced primary wave and absent secondary wave, and defective secretion.[69]

Epinephrine Receptor

A selective absence of an aggregation in response to adrenaline has been reported as a heritable trait in association with easy bruising and reduced expression of platelet α2-adrenoceptors.[70,71] However, the aggregation response to adrenaline among normal individuals is itself quite variable, and a relative decrease in the aggregation response to adrenaline may represent the lower segment of a common asymptomatic population variant.[72]

Inherited Defects in Signal Transduction Pathways

Cyclooxygenase Defects

Defects in platelet cyclooxygenase (COX) or TX synthase[73] give the same laboratory findings as seen in TXA2 receptor defects (see above), but can be distinguished from the latter by the preservation of platelet aggregation in response to prostaglandin-H2 or the TXA2 analog U46619.

Scott Syndrome

Scott syndrome is a rare autosomal recessive disorder characterized by a defect in calcium-induced phospholipid scrambling and prothrombin conversion on platelets and other blood cells.[74]

When Scott platelets are activated, phosphatidylserine is not transported from the inner to the outer phospholipid leaflet of the membrane. The binding of factor Va–Xa and factor VIIIa–IXa complexes is impaired, resulting in decreased thrombin generation and impaired platelet-dependent fibrin formation on subendothelium. It has been reported that Scott syndrome may be explained, at least in part, by mutations in an ATP-binding cassette transporter A1 implicated in the exofacial translocation of phosphatidylserine.[75]

Additional Defects

Patients have been described with: A lineage-specific Gαq subunit deficiency and impaired αIIbβ3 activation; reduced Gαi1 expression and signaling; defective calcium ion mobilization and an abnormal response to ionophore A23187; a reduced production of inositol 1,4,5-triphosphate and phosphatidic acid, diminished plekstrin phosphorylation and defective phospholipase C activation; and a specific defect in phospholipase Cβ2 expression.[76] Pseudohypoparathyroidism type 1b, which is associated with a mild bleeding disorder, is caused by a defect in the heterotrimeric G protein subunit Gsα, which regulates adenylyl cyclase.[77]

Defect in the Consolidation Phase: Glanzmann Thrombasthenia

GT is an autosomal-recessive disorder characterized by defective in vitro platelet aggregation and a lifelong bleeding tendency due

to quantitative or qualitative abnormalities of the platelet GPIIb-IIIa,[2] also known as the integrin αIIbβ3.

Etiology

A qualitative or quantitative defect of either GPIIb or GPIIIa is the basic biochemical basis for GT. GPIIb-IIIa is a calcium-dependent heterodimer that binds preferentially to fibrinogen or vWF, but also to fibronectin or vitronectin. The genes for GPIIb and GPIIIa are distinct but are physically located within 1 Mb of each other on the long arm of chromosome 17 (17q21-22). A genetic defect in either GPIIb or GPIIa can inhibit synthesis of that subunit and/or prevent normal assembly and processing of the functional receptor. This results in the lack of a fibrinogen receptor and defective fibrinogen binding after platelet activation. Platelet aggregation, which requires this protein, is therefore deficient or completely absent.

A continually maintained database is accessible on the Internet (https://haemgen.haem.cam.ac.uk/thrombogenomics/) which contains a list of over 100 mutations that give rise to GT. The αIIb and β3 genes (*ITGA2B* and *ITGB3*, respectively) are both affected, and although post-translational defects predominate, reduced mRNA stability can also be a cause. Integrin synthesis occurs in the megakaryocytes with αIIbβ3 complex formation in the endoplasmic reticulum. Noncomplexed or incorrectly folded gene products fail to undergo processing in the Golgi apparatus and are rapidly degraded intracellularly.[78]

In GT, isoantibodies specific for the deleted GPs have been demonstrated in the blood of multiply transfused patients,[2] and these can reproduce the thrombasthenic defect in normal transfused platelets.

Clinical Features

Thrombasthenia is inherited as an autosomal-recessive trait, and consanguinity is common within affected kindreds, resulting in geographic clusters of patients.[2] Hemorrhagic symptoms occur only in patients homozygous for GT mutations, whereas the heterozygous condition is mostly asymptomatic, even though platelets from heterozygotes have only one half the normal level of αIIbβ3. The sites of bleeding in GT are clearly defined: Purpura, epistaxis, gingival hemorrhage, and menorrhagia are nearly constant features; gastrointestinal bleeding and hematuria are less common but can cause serious complications. Bleeding at menarche is severe enough to require transfusions in most patients. Deep visceral hematomas, a characteristic of coagulation disorders such as hemophilia, are not usually seen in GT. Bleeding symptoms normally manifest rapidly after birth, even if most patients are diagnosed before the age of five. Epistaxis is a common cause of severe bleeding, and is typically more severe in childhood. In general, the bleeding tendency in GT decreases with age. Post-traumatic and post-operative hemorrhage can be serious, and pregnancy and delivery represent a severe hemorrhagic risk, because bleeding may not always be preventable by platelet transfusions. Although GT can be a severe hemorrhagic disease, the prognosis is excellent with careful supportive care. Death from hemorrhage in diagnosed patients is rare unless associated with trauma, other disease (e.g., cancer), or chronic isoimmunization.

Laboratory Findings

A prolonged bleeding time, deficient clot retraction, and deficient platelet aggregation with ADP, collagen, epinephrine, or thrombin are typical findings. Ristocetin-induced aggregation, on the other hand, and coagulation tests are normal. Thrombasthenic platelets are present in normal numbers and are morphologically normal when viewed by light microscopy.

Management

With GT patients, it is important to anticipate bleeding risks before performing procedures, and because the risk for bleeding is so unpredictable, it is prudent to administer prophylactic platelet transfusions even in the absence of a prior history of bleeding.

Localized bleeding can be treated by limited measures, such as fibrin sealants or topical thrombin and antifibrinolytic agents (ε-aminocaproic acid, tranexamic acid). Epistaxis and gingival bleeding can be controlled by nasal packing or the application of gel foam soaked in topical thrombin. The risk of gingival bleeding can be minimized by regular, proper dental care. When tooth extractions must be performed or when hemorrhage accompanies the loss of deciduous teeth, bleeding can be significantly reduced by the application of individually prepared plastic splints that provide physical support for hemostasis.

Severe menorrhagia is common and can be effectively treated with high doses of progesterone, followed by maintenance treatment with birth control pills. Severe gastrointestinal bleeding is an isolated but severe problem. Iron deficiency anemia can develop insidiously with gingival oozing or minor menorrhagia. Confronted with a severe bleeding episode or as prophylaxis for invasive procedures, most GT patients receive blood transfusions, regardless of bleeding history.[79] Transfusions should be continued until wound healing is complete. However, a significant number of transfused patients can develop HLA-specific alloantibodies or GPIIb-IIIa-specific isoantibodies, which seriously complicate transfusion therapy and limit future treatment. Isoantibodies can block normal transfused platelet aggregation and/or lead to the rapid removal of transfused platelets by immune mechanisms. It is not yet possible to predict the propensity of individual GT patients to develop such antibodies. Antibodies may be successfully removed prior to surgery by immunoadsorption on Protein A Sepharose, but this is a complex procedure restricted to specialized centers.[80]

Pregnancy and delivery represent a severe hemorrhagic risk. Platelet transfusions are required not only prior to delivery, but afterward as well. Successful delivery by cesarean section, with platelet transfusions, has been reported.

The use of rFVIIa (NovoSeven®; NovoNordisk A/S, Malov, Denmark) is an alternative approach for early cessation of bleeding in GT, especially in the case of patients who have developed antibodies and/or have a history of transfusion refractoriness.[81] It seems that rFVIIa enhances deposition of αIIbβ3-deficient platelets on the subendothelial matrix through an interaction with fibrin formed by the increased thrombin generation[82] leading to increased clot stability.[83] However, some question the efficacy of rFVIIa in children with GT.[84]

In a few GT patients, the bleeding symptoms have been considered sufficiently serious to warrant allogeneic bone-marrow transplantation.[85]

Additional Hereditary Defects of Platelet Function (with Thrombocytopenia)

MYH-9-related Thrombocytopenia Syndromes

MYH-9-related disorder encompasses autosomal dominant macrothrombocytopenia syndromes previously classified as May-Hegglin anomaly, Sebastian, Fechtner, and Epstein syndromes and certain inherited thrombocytopenias that have in common mutations within *MYH9*, the gene for nonmuscle myosin heavy chain II-A (NMMHC-IIA).[86]

Etiology

NMMHC-IIA is part of the nonmuscle myosin IIA hexamer that is a component of the contractile cytoskeleton in megakaryocytes, platelets, and other many other cell types. Mutations of *MYH9*

that give rise to *MYH-9*-related disorder disrupt the stability of the nonmuscle myosin IIA hexamer or its association with regulatory proteins. This results in defective megakaryocytopoiesis that leads to thrombocytopenia. Additional platelet function defects arise from abnormal shape change or impaired expression of the GPIb complex.[87] As in many other inherited hematologic disorders, incomplete penetrance accounts for a poor correlation between the *MYH9* genotype and clinical phenotype as well as variability in phenotype among individuals with identical mutations.[86]

Clinical Features

Patients with *MYH-9*-related disorder present with bleeding, sensorineural hearing loss, glomerulonephritis, and/or eye abnormalities. The severity of the bleeding symptoms is out of proportion to the moderately decreased platelet count, suggesting the concurrence of a platelet function defect. Life-threatening bleeding has been reported, but is the exception. The combination of macrothrombocytopenia and one or more of the recognized clinical features of *MYH-9*-related disorder is strong evidence for this diagnosis.

Laboratory Findings

Platelet counts are normally from 20,000 to 130,000/μl, and are associated with an increased mean platelet volume and a conspicuous population of very large platelets. The presence of Dohle-like bodies within neutrophils on stained peripheral blood smears is highly suggestive of *MYH-9*-related disorder. An abnormal staining of neutrophil inclusions with antibodies specific for NMMHC-IIA is a more sensitive index of the syndrome, but a definitive diagnosis must be based on the identification of a causative mutation within *MYH9*.

Management

The symptoms of *MYH-9*-related disorders are highly variable, and therefore treatment of individual patients should be guided as much as possible by personal and family history.[5] In general, management would be the same as for other mild platelet disorders.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disease characterized by microthrombocytopenia, eczema, and immunodeficiency.[1] The *WAS* gene encodes the WAS protein (WASP), and mutations in *WAS* result in decreased or absent expression of WASP, a key regulator of actin polymerization in hematopoietic cells playing a role as an adapter protein. The reduction in or absence of WASP results in premature proplatelet formation in the bone marrow and the microthrombocytopenia characteristic of WAS.

Etiology

WAS arises from mutations in *WAS,* the gene for the protein WASP that is expressed in all hematopoietic cell lineages. Isolated X-linked thrombocytopenia (XLT) is also caused by mutations in *WAS* and is a variant of the same disease but generally lacks severe immune deficiency.[88]

Clinical Features

Infants with WAS often present with bruising and purpura in the neonatal period with an increased risk of intracranial hemorrhage. Gastrointestinal bleeding or prolonged bleeding after circumcision may be a presenting feature. Eczema develops during the first year of childhood and can varying in severity, from widespread and debilitating in children with "classic" WAS to mild or absent in those with the XLT. Infections begin in the first 6 months of life. Bacterial infections occur more often, particularly otitis media and respiratory tract infections, whereas severe viral infections and opportunistic infections occur less frequently. In the XLT phenotype, eczema and infection do not occur. With increasing age, hemolytic anemia and vasculitis become the most frequent manifestations of the autoimmune component of this disease.[89] Another life-threatening complication of WAS is malignancy, usually but not exclusively lymphoreticular in origin.

Laboratory Findings

Thrombocytopenia (ranging from 5,000 to 50,000/μl) with small platelets is evident at birth. Despite normal bone marrow megakaryocyte numbers and morphology, there may be ineffective thrombocytopoiesis with reduced platelet survival.

Management

The management of WAS should address bleeding manifestations, recurrent infections, eczema, autoimmune disorders, and the risk of malignancy. When available, bone marrow or stem cell transplant is the treatment of choice as early as possible. Proper management is benefited by a multidisciplinary approach, which should include an immunologist. When transfusion is necessary, HLA-compatible and irradiated platelets should be used in order to avoid sensitization. Because of the immune deficiency, platelets to be transfused should always be irradiated and certified free of cytomegalovirus. Splenectomy can result in an increase both in platelet number and size, but the risk of sepsis is increased post splenectomy, and a risk–benefit analysis of this operation must be considered for individual patients. Splenectomy does not influence the development of malignancy or autoimmune disorders, and it may thus be more successful in the milder phenotype of XLT.

ACQUIRED DISORDERS OF PLATELET FUNCTION

Drug-induced Platelet Dysfunction

An adult patient that presents with a normal platelet count, mucocutaneous bleeding, and a negative family history, defined as no bleeding among first degree relatives, should be evaluated for an acquired disorder. Although inherited platelet disorders are rare, acquired disorders of platelet function are encountered frequently.

A diverse variety of medications, from ionophores to ADP analogs, certain systemic diseases, and various procedures can induce platelet dysfunction (Table 52.2). Even common dietary substances, such as garlic or fish oil, can impair platelet function.[90] This chapter focuses on commonly used drugs that can impair platelet function at therapeutic doses. Other drugs that are used to treat thromboembolic disorders are discussed in detail in Chapter 62.

The extent of platelet dysfunction produced by drugs in healthy individuals is usually not clinically significant. On the other hand, patients with coagulation disorders, uremia, thrombocytopenia, and patients receiving heparin or Coumadin as anticoagulant

TABLE 52.2

DRUGS AFFECTING PLATELET FUNCTION

Analgesics
Aspirin
Nonsteroidal anti-inflammatory drugs
Acetaminophen
Antibiotics
β-Lactams: Penicillins, cephalosporins
Cardiovascular drugs

therapy, can exhibit serious bleeding when they receive a drug that attenuates platelet function. In addition, the inherent variation in platelet reactivity among normal indviduals[91] can greatly influence the susceptibility of an individual to the antiplatelet effects of dietary supplements or drugs.

Aspirin

Aspirin inhibits platelet function via irreversible acetylation of platelet COX-1 and the resulting inhibition of TXA2 synthesis. A single high dose of aspirin (e.g., 325 mg or more) or consecutive smaller doses (e.g., 81 mg) taken for 3 or more days will produce essentially complete inhibition of TXA2 production. The hemostatic risk following aspirin is predictable, with a 5% to 10% incidence of minor bleeding and a 1% to 2% incidence of major bleeding, i.e., requiring hospitalization or red cell transfusion.[92]

In ex vivo whole blood perfusion assays, aspirin-treated platelets will adhere normally to denuded arterial segments or collagen-coated surfaces, but they fail to form thrombi due to inhibition of aggregate formation. By EM, one notes an inhibition of organelle centralization that normally follows platelet stimulation by collagen. In platelet aggregation assays, aspirin-treated platelets exhibit decreased responses to collagen and an absence of the secondary wave of aggregation that is normally induced by epinephrine and low concentrations of ADP, which is reflected in a marked reduction in the release of δ-granule ADP, ATP, and serotonin.

Individual differences in platelet responsiveness to aspirin have been noted. In some normal individuals, aspirin ingestion can modestly elevate the bleeding time and have a small impact on platelet aggregation in vivo, more so in men than in women, but in certain patients with otherwise minor platelet dysfunction, the bleeding time can be markedly prolonged and platelet aggregation severely impaired after aspirin ingestion. The search for a genetic basis for this difference in aspirin sensitivity is a hotly contested area of investigation.

Other Nonsteroidal Anti-inflammatory Drugs

NSAIDs reversibly inhibit platelet COX-1, and normal platelet function is gradually restored when these drugs are stopped. For example, ibuprofen (600 mg daily) will prolong PFA-100 CTs, but these will conform to baseline within 24 hours after drug intake is ceased.[93] It is uncommon to see clinical bleeding in normal individuals as a result of an NSAID, but gastrointestinal bleeding due to gastric ulceration is not uncommon. Paradoxically, ibuprofen can also exhibit a prothrombotic effect if it is ingested within 2 hours of taking aspirin, inasmuch as it can transiently block acetylation of the COX-1 target site.

Cyclooxygenase-2 Inhibitors

COX-2 inhibitors provide the anti-inflammatory effects of COX blockade without affecting platelet function. COX-2 is expressed in endothelial cells, fibroblasts, and monocytes and is up-regulated in response to growth factors, cytokines, endotoxin, and hormones. Even though COX-2 inhibitors have no direct effect on platelets, they increase the risk for thrombosis and cardiovascular disease because they inhibit vascular (endothelial) cell synthesis of prostacyclin, a natural inhibitor of platelet activation and thrombosis.[94]

P2Y12 Antagonists

Platelet responses to natural agonists are normally enhanced by the binding of released ADP to platelet purinogenic receptors. The thienopyridines clopidogrel and ticlopidine bind irreversibly to the platelet purinogenic receptor P2Y12 and thereby inhibit platelet responses induced by both exogenous ADP and ADP released from platelet δ-granules. However, clopidogrel has replaced ticlopidine as the preferred medication because the latter is associated with potentially life-threatening hematologic side effects (thrombotic thrombocytopenic purpura, agranulocytosis, and aplastic anemia). Steady-state inhibition of platelet function occurs after 3 to 5 daily doses of 75 mg clopidogrel, but it can be achieved sooner with a 300-mg loading dose. Even though clopidogrel has a greater effect than aspirin on the bleeding time,[95] there is no greater risk of bleeding in vivo. The combination of clopidogrel and aspirin is currently used to prevent or treat arterial thrombosis.[96] The effect of clopidogrel on platelet function is irreversible, such that after cessation of clopidogrel, platelet function returns to roughly 50% of normal levels by 72 hours, and its effect is completely reversed by 7 days.[97]

Antibiotics

Large doses of various β-lactam antibiotics (penicillins more often than cephalosporins) can cause clinical bleeding, abnormal platelet function in vitro, and increased bleeding times, because of a nonspecific effect on ligand–receptor interactions.[98] The effect on platelet function can be manifested by a dose-dependent reduction in platelet aggregation in vitro to ADP, epinephrine, and collagen. The clinical effect is exaggerated in hypoalbuminemic patients because the level of free drug is increased and thus more interact with the platelet surface. β-Lactam compounds influence clinical bleeding when there is co-existing hemostatic defect, such as in uremia, thrombocytopenia, or vitamin K deficiency.

β-Lactams appear to modify the platelet membrane and decrease agonist binding. The effect can become event after several days of treatment and will not resolve until 7 to 10 days after discontinuation. Moxalactam and cefotetan can produce clinical bleeding as a result of both platelet dysfunction and the N-methythiotetrazole side-chain effect on vitamin K–dependent clotting factor synthesis.[99,100]

Integrin $\alpha IIb\beta_3$ Antagonists

Specific inhibitors of integrin αIIbβ3 are potent inhibitors of platelet function, and three are currently approved by the FDA: Abciximab is a chimeric human–mouse monoclonal Fab fragment; tirofiban is an arginine–glycine–aspartate-based peptidomimetic; and eptifibatide (integrelin) is a synthetic cyclic heptapeptide based on the lysine–glycine–aspartate motif of the snake venom disintegrin barbourin.

These antagonists, which inhibit platelet aggregation effectively because they prevent fibrinogen and VWF binding to αIIbβ3, are used commonly in patients undergoing percutaneous coronary intervention (PCI), concurrently with heparin and other antiplatelet therapy such as aspirin. Bleeding is a common side effect of these antagonists and occurs in ~10% of recipients, but intracranial bleeding (<0.5%) and death due to bleeding (<0.1%) are rare. The duration of the antiplatelet effect of these drugs varies: Although unbound abciximab is cleared rapidly, elimination of bound drug is significantly slower and some residual receptor blockade (~25%) can be detected for up to 7 days; the inhibitory effects of the other two small molecules are directly proportional to their elimination half-life and usually disappear within hours of drug removal.[101]

Uremia

Patients with uremia are at risk for bleeding complications because of a number of factors that include minor coagulation abnormalities, platelet dysfunction, thrombocytopenia, or the widespread use of medications that compromise hemostasis.[102] Defects in all stages of platelet hemostasis including adhesion, secretion, and aggregation have been noted in studies of platelet function in uremic patients.

Factors That Influence Hemostasis

Nitric oxide is a potent modulator of vascular tone that limits platelet adhesion to the endothelium and platelet–platelet interaction by increasing the formation of cGMP,[103] and enhanced nitric oxide synthesis has been demonstrated in uremic patients. The inhibition of nitric oxide formation in a rat model of uremia completely normalized the bleeding tendency in rats.[104]

Additional platelet changes have been noted. Deficient platelet stores of ADP and serotonin have been described in uremic platelets, suggesting that these platelets have an acquired storage pool deficiency. Elevated cAMP levels may be responsible for an acquired defect of COX activity with reduced ability to synthesize TXA2. Alterations in intraplatelet calcium mobilization have also been reported and theorized to be associated with uremic bleeding.[105]

In uremic patients, integrin αIIbβ3 has a reduced ability to bind both VWF and fibrinogen,[106] most likely due to a conformational change in this integrin. Hemodialysis improved fibrinogen binding, leading to the hypothesis that a dialyzable toxic substance is responsible in part for altered platelet function. Uremic substances that inhibit platelet function in concentrations detectable in uremic plasma include: Urea, guanidine-succinate, parathyroid hormone, phenol, and tryptophan products.[107] Small peptides containing the RGD that could potentially inhibit αIIbβ3 function accumulate in uremic patients due to reduced clearance.[108]

The Effects of Anemia

Anemia predisposes uremic patients to bleeding complications.[109,110] When the hematocrit is reduced, platelets travel closer to the center of the vascular lumen and are thus less likely to interact with the subendothelium. In addition, red blood cells release ADP and TXA2 which enhances platelet aggregation.[111] Hemoglobin also scavenges nitric oxide and therefore a reduced hematocrit would be associated with enhanced nitric oxide activity and promoting platelet inhibition and vasodilatation. Finally, significant anemia in current vintage dialysis populations often co-occurs with other major problems such as iron deficiency, malnutrition, and inflammation in the sickest patients. This may further confound observational studies of bleeding risk in current dialysis patients.

Secondary Effects of Medications

The bleeding risk in uremic patients is increased by exposure to antiplatelet agents and anticoagulants, including aspirin, αIIbβ3 antagonists, heparin, and warfarin.[112]

Clinical Features

The bleeding sites in the uremic patient are gastrointestinal and intracranial. Through gastrointestinal bleeding, chronic renal failure patients may lose 4 to 6 times as much blood per day as normal individuals through peptic ulcer disease, gastric bleeding, telangiectasias in the stomach, duodenum, jejunum, and colon, and duodenitis and esophagitis.[113] In a long-term follow study of 1,609 chronic hemodialysis patients, there was a tenfold higher incidence of intracerebral hemorrhage compared to the general population.[107]

Laboratory Findings

Platelet aggregation to exogenous agents is often but not always defective, such that the sensitivity to aggregating concentrations of collagen, ADP, and epinephrine is decreased, and TXB_2 generation and δ-granule ADP content are reduced relative to control platelets.[104]

Management

The most effective treatment of uremic bleeding includes hemodialysis and peritoneal dialysis,[114] although a transient worsening of platelet function may be encountered immediately following.[115] When platelet function was prospectively evaluated after renal transplantation, platelet aggregation, F-actin, and platelet cytoskeletal abnormalities were completely normal by 8 weeks after renal transplant.

Red blood cell transfusions and/or administration of erythropoietin (rHUEPO) have been observed to decrease bleeding, shorten the bleeding time, and increase platelet adhesiveness when given to hemodialyzed patients.[116] However, some patients may become hypercoagulable.

Administration of DDAVP can shorten the bleeding time and is effective for short-term control of bleeding in some uremic patients as a result of changes in vWF activity.[117]

Cardiovascular disease is common in patients with chronic renal insufficiency and end-stage renal disease. Antiplatelet medications are associated with an increased risk of bleeding, compared to the risk associated with their use in patients who do not have end-stage renal disease. Among patients undergoing PCI and treated with abciximab, those with renal insufficiency had a greater tendency of major bleeding.[118]

Paraproteinemias

Bleeding is a common complication of paraproteinemias associated with multiple myeloma, Waldenstrom macroglobulinemia, monoclonal gammopathies, and even polyclonal hypergammaglobulinemia.[119,120] The etiology is complex, but various mechanisms have been proposed, such as thrombocytopenia or platelet dysfunction, inhibitors of specific coagulation factors, circulating monoclonal proteins that bind to and promote clearance of coagulation factors, and hyperviscosity syndrome.

Clinical Features and Laboratory Findings

Hematologic findings that are limited to purpura and mucocutaneous bleeding are most often encountered in patients with IgA myeloma and macroglobulinemia. Platelet dysfunction likely results from nonspecific binding of immunoglobulins to the platelet surface.[121]

Myeloproliferative Disorders

Chronic myeloproliferative disorder (MPD) defines a group of Philadelphia chromosome-negative disorders that includes essential thrombocythemia (ET), polycythemia vera (PV), and agnogenic myeloid metaplasia and chronic idiopathic myelofibrosis.[122] Various platelet defects have been reported in patients with MPD, including defective platelet aggregation and secretion, subnormal uptake of serotonin, abnormal expression of Fc receptors, specific defects in integrin αIIbβ3 expression or activity, and an acquired SPD.

Etiology

Vainchenker et al. showed that acquired JAK2 V617F mutation in hematopoietic precursors causes PV.[123] The V617F mutation results in the loss of inhibitory activity of the JH2 pseudokinase segment of JAK2 leading to enhanced activity of the JH1 kinase of JAK2, which renders hematopoietic precursors hypersensitive to thrombopoietin, erythropoietin (EPO), insulin growth factor 1, stem cell factor, and granulocyte colony-stimulating factor. The result is a trilinear myeloproliferation that explains the common proliferative features of ET, PV, and MF.[124,125]

Clinical Features and Laboratory Findings

Microvascular disturbances in ET and PV, including erythromelalgia, and atypical and typical transient cerebral, ocular, and coronary ischemic attacks, are caused by platelet-mediated transient and occlusive thrombosis in the end-arterial circulation.[122] An inconsistent pattern of laboratory abnormalities has been encountered, with poor correlation between lab results and bleeding severity. As in MDS and acute leukemia, platelet dysfunction appears to result from defective megakaryocyte maturation and/or thrombopoiesis.

The endogenous synthesis of TXA2 by platelets, reflected by the stable urine metabolite TXB2, is increased in ET and PV patients.[126] This increased biosynthesis of TXA2 is a reflection of spontaneous platelet activation in vivo.[126,127]

Management

Correction of hematocrit to normal by phlebotomy will reduce the major arterial and venous thrombotic complications, but fail to prevent the platelet-mediated microvascular circulation disturbances in PV patients because thrombocythemia persists. Complete relief and prevention of microvascular and major thrombosis in ET and PV patients, in addition to phlebotomy, are obtained by treatment with aspirin but not with warfarin.[122]

CHAPTER 53

INHERITED COAGULATION DISORDERS

Jerry S. Powell, George M. Rodgers

Inherited disorders of coagulation result from the deficiency or functional abnormality of one of the plasma proteins involved in providing normal coagulation.[1] There are other proteins that regulate the kinetics of coagulation, and abnormalities in one of these proteins usually result in increased risk of thrombosis; these proteins will not be covered in this chapter. If von Willebrand disease (vWD) is included, the inherited coagulation abnormalities (Table 53.1) are common; for example, vWD may affect up to 1% of the population. The other inherited coagulation disorders occur less often.

Since the purpose of the coagulation cascade is to rapidly produce fibrin to form a clot, the clinical manifestation of any deficiency or functional abnormality in any coagulation protein will be similar, i.e., clinical bleeding, with greater bleeding associated with more severe deficiency. Therefore, the manifestations and complications of clinical bleeding will be described in this chapter in the section on hemophilia A. A recent review of treatment of hemophilia A has been published with proposed algorithms for therapy.[2]

TABLE 53.1

INHERITED DISORDERS OF COAGULATION

X-linked recessive traits
Hemophilia A
Hemophilia B (i.e., CRM^+ and CRM^- variants; hemophilia B_m, B Leyden, etc.)
Autosomal recessive traits
Factor XI deficiency
Prothrombin deficiency
Factor V deficiency
Factor VII deficiency
Factor X deficiency (i.e., Prower variant, Stuart variant, Friuli variant, others)
Afibrinogenemia
Hypofibrinogenemia
Factor XII deficiency
Factor XIII deficiency
Autosomal dominant traits
von Willebrand disease
Dysfibrinogenemias
Combined abnormalities
Associated with factor VIII deficiency (i.e., factor V deficiency, hemophilia B, factor XI deficiency, factor VII deficiency, von Willebrand disease, dysfibrinogenemias, platelet dysfunction)
Involving vitamin K–dependent factors (i.e., factors II, VII, IX, and X; factors IX and XII; others)
Miscellaneous
Prekallikrein deficiency
High-molecular-weight kininogen deficiency
Deficiency of physiologic inhibitors (i.e., α_2-antiplasmin, abnormal α_1-antitrypsin [antithrombin Pittsburgh])

CRM, cross-reacting material.

NOMENCLATURE

Historically, the best known inherited coagulation disorder is hemophilia, which dramatically manifested itself in the royal families of Europe in the 20th century, following a spontaneous mutation that apparently arose in Queen Victoria in England. The international Roman numeral designations for these disorders are summarized in Table 18.1. Like abnormal hemoglobins, qualitatively abnormal fibrinogens are designated by the name of the city in which they were first discovered, as in *fibrinogen Paris*.

PRINCIPLES OF PATHOPHYSIOLOGY

With the exception of fibrinogen and prothrombin, the coagulation factors are trace proteins. Clinical laboratory measurements of their activity depend on bioassays, which detect both quantitative absence of a specific factor and a qualitative functional abnormality in a factor that is present in normal amounts. Further laboratory testing is required to determine the actual concentration of the protein, usually by enzyme-linked immunoabsorbent assay (ELISA) methodology. Thus, for example, in hemophilia A, the bioassay measures *factor VIII coagulant activity* (factor VIIIc) and refers to the functional property of the factor VIII molecule that corrects the coagulation defect of patients with hemophilia A. The amount of protein measures the amount of antigen by ELISA and is referred to as *factor VIIIAg* (Table 53.2). Many hemophilia treatment centers currently proceed to determine the genotype for individual persons with inherited coagulation disorders; such analysis is helpful to predict the severity of the clinical phenotype, to predict the risk of inhibitor development, and to aid in family counseling.

Most qualitative abnormalities in coagulation factors result in loss of function of the protein in the coagulation cascade. However, some mutations produce qualitative abnormalities that result in "gain of function." Such factors are called *abnormal* or *aberrant factors* to distinguish them. The most clearly defined disorders of this type are the dysfibrinogenemias, in which the abnormal fibrinogen typically is not completely nonfunctional, but may also inhibit the function of normal fibrinogen. Other disorders characterized by aberrant coagulation factors include the B_m variant of hemophilia B and some of the variants of prothrombin deficiency. Aberrant procoagulant proteins also may be synthesized in acquired deficiencies of the vitamin K–dependent factors (see Chapter 54). An example of a "gain of function" mutation for factor IX was described recently, factor IX Padua, in which a leucine was substituted for arginine at position 338 (R338L) and, despite a normal concentration of factor IX protein in plasma, the factor IX clotting activity was eight times normal, resulting in clinically significant thrombosis.[3]

TABLE 53.2

NOMENCLATURE FOR FACTOR VIII AND VON WILLEBRAND FACTOR

Definition	International Nomenclature
Protein lacking or aberrant in hemophilia A	Factor VIII
Functional property of factor VIII that is deficient in hemophilia A and measured using coagulation assays	Factor VIIIc
Antigenic property of factor VIII that is measured by immunoassays in which homologous antibodies are used	Factor $VIII_{Ag}$
Protein required for normal platelet adhesion that is aberrant or deficient in von Willebrand disease	von Willebrand factor (vWF)
Antigenic property of vWF that is measured by immunoassays in which heterologous antibodies are used	vWF antigen (vWFAg)
Property of vWF required for platelet agglutination by ristocetin	Ristocetin cofactor activity (vWF:RCo)

Note: This table is based on recommendations of the International Committee on Thrombosis and Haemostasis.
From Marder VJ, Mannucci PM, Firkin BG, et al. Standard nomenclature for factor VIII and von Willebrand factor: a recommendation by the International Committee on Thrombosis and Haemostasis. Thromb Haemost 1985;54:871–872; and Mazurier C, Rodeghiero F. Recommended abbreviations for von Willebrand factor and its activities. Thromb Haemost 2001;86:712.

HEMOPHILIA A

Hemophilia A refers to the inherited coagulation disorder characterized by deficiency of function of the coagulation protein called factor VIII. Except for vWD, it is the most common inherited coagulation disorder, and is X-linked. As the most common bleeding disorder, historians assume that it is the severe and often fatal hemorrhagic diathesis that affected the male children of certain families and that was well recognized in antiquity, as noted in the writings of Rabbi Simon ben Gamaliel (2nd century A.D.) in the Talmud, and those of Maimonides, the Hebrew physician and philosopher, and Albucasis, the Arab (twelfth century).[4] Complete monographs have reviewed the early literature.[5] However, the bleeding disorder that occurred in males throughout the royal families of Europe due to a mutation that arose with Queen Victoria, long assumed to be the more common hemophilia A, turned out, after extensive medical forensic investigation, to be hemophilia B.[6]

Pathophysiology

The hemostatic abnormality in hemophilia A (factor VIII deficiency, classic hemophilia) is a deficiency or functional abnormality of the plasma protein factor VIII. It normally circulates in the plasma bound to a much larger molecule, vWF. The half-life of factor VIII in the absence of vWF is much shorter, as seen in individuals with the vWF Normandy mutation, resulting in loss of the protein sequences for the binding interaction site between factor VIII and vWF, and causing low levels of factor VIII and clinical bleeding that appears similar to the bleeding seen in patients with hemophilia A. The production of vWF is coded by an autosomal gene, and this protein is qualitatively normal and is present in normal or increased amounts in patients with hemophilia A (Fig. 53.1).[7,8] The function of the coagulation protein factor VIII is to serve (when activated) as a cofactor for the serine protease enzyme factor IX, and accelerate the reaction as part of the coagulation cascade. No other function for factor VIII has been clearly characterized.

Incidence

Hemophilia A has been recognized in all areas of the world and in all ethnic groups. Estimates of its incidence approximate 1 in 5,000 males, or 1 in 10,000 persons.[9,10] A population-based study of the southeastern United States by the Centers for Disease Control and Prevention found that 11 cases per 100,000 persons had hemophilia A and that the prevalence was similar among different racial groups.[11] This same survey estimated that in 1994, there were 13,320 cases of hemophilia A in the United States.[11]

Genetics

Hemophilia A is a classic example of an X-linked recessive trait. In such a disorder, the defective gene is located on the X chromosome[12]; the factor VIII gene maps to Xq28, on the distal end of the long arm of the X chromosome. In males who lack a normal allele, the defect is manifested by clinical hemophilia (Fig. 53.2; generation I, number 1). The affected male does not transmit the disorder to his sons (generation II, numbers 4 and 5) because

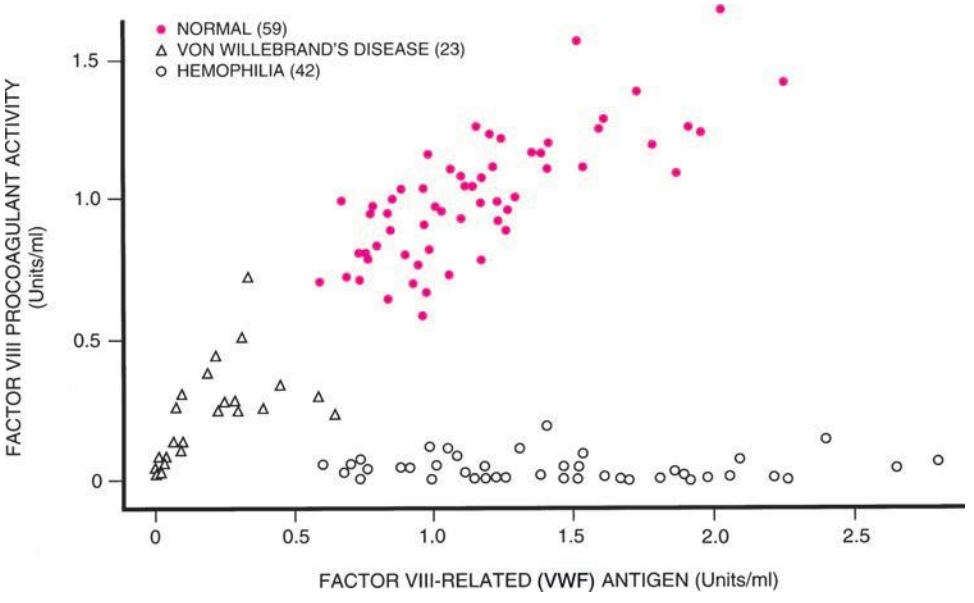

FIGURE 53.1. The relationship of factor VIII procoagulant activity and factor VIII–related antigen (von Willebrand factor [vWF]) in the plasma of normal subjects and patients with hemophilia or von Willebrand disease. (From Hoyer LW. The factor VIII complex: structure and function. Blood 1981;58:1–13, with permission.)

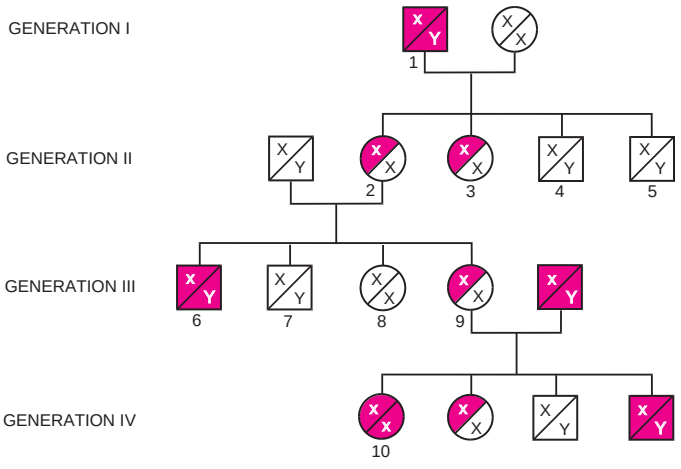

FIGURE 53.2. The inheritance of hemophilia A and hemophilia B. The pedigree is hypothetical. *Squares* indicate male; *circles* indicate female; *fully shaded squares* or *circles* indicate affected members; *half-shaded circles* indicate carriers. X, normal X chromosome; x, abnormal X chromosome.

his Y chromosome is normal. However, all of his daughters are obligate carriers of the trait because they inherit his X chromosome (generation II, numbers 2 and 3). Most of these women are unaffected clinically because of the presence of a normal allele from the mother. The female carrier transmits the disorder to half of her sons (generation III, numbers 6 and 7) and the carrier state to half of her daughters (generation III, numbers 8 and 9). Due to Lyonization of the X chromosome, if the normal factor VIII allele is inactivated more often by chance, then some of the carrier females may have clinical bleeding. The severity of their bleeding depends on their factor VIII activity level; and, rarely, a woman can have very low factor VIII activity and present with symptoms of moderate or even severe hemophilia.

The severity of bleeding varies in different kindreds, and closely depends on the particular genetic defect. Since the same gene defect is present in the kindred, each of the affected males will have very similar clinical phenotypes.[13] As expected, hemophilia A has been observed several times in twins.[14] Occasionally, however, the coinheritance of other genetic defects can influence the clinical symptoms of hemophilia A patients. An example is the coinheritance of the factor V Leiden mutation (discussed in Chapter 55) with hemophilia A. These patients have a milder clinical phenotype than expected for the same molecular defect in factor VIII.[15] The coinheritance of the factor V Leiden mutation or other prothrombotic risk factors in children with severe hemophilia A may delay the first symptomatic bleeding event.[16]

Intriguing, and yet to be fully explained, is the fact that in over a third of families with hemophilia A, there is no evidence or history of abnormal bleeding in other members of the family.[17,18] This percentage is consistent with the Haldane hypothesis, which predicted that maintenance of a consistent frequency of a genetic disorder in the population would require that approximately one-third of cases result from spontaneous mutation. In other instances, neonatal deaths or the passage of the trait through a succession of female carriers may explain the negative family history. For practical purposes, therefore, a negative family history is of little value in excluding the possibility of hemophilia A. Mutations that cause hemophilia A originate in males at least threefold more often than in females.[19] The large size of the factor VIII gene (186 kb), the presence of hot spots (e.g., CpG dinucleotides), and the fact that the X chromosome is unpaired in males may predispose for the factor VIII gene to undergo spontaneous mutation.[20,21,22,23]

Nearly 3,000 individuals with hemophilia have had their factor VIII genes analyzed; this genetic information is collected in the Hemophilia A Mutation Database (HADB, formerly the Hemophilia A Mutation, Structure, Test and Resource Site[HAMSTeRS] database).[21] The genetic defects of hemophilia A encompass deletions, insertions, and mutations throughout the factor VIII gene.[24] Point mutations involving CpG dinucleotides are especially common. Approximately 5% of patients with hemophilia A have large (>50 nucleotides) deletions in the factor VIII gene.[25]

Approximately 45% of severe hemophilia A cases result from a major inversion of a section of the tip of the long arm of the X chromosome, one breakpoint of which is situated within intron 22 of the factor VIII gene.[26] This common inversion is associated with severe hemophilia A, and a higher incidence of inhibitor formation. It is presumed that in the absence of homologous X chromosome pairing during male meiosis, an intrachromosomal recombination event occurs on the single X chromosome, resulting in this inversion. This event typically occurs in the father of the mother of a child with severe hemophilia A, and often leads to relief of guilt feelings in the mother, as the genetic mutation is not "her fault." Another common inversion (intron 1) accounts for 5% of patients with severe factor VIII deficiency.[27] Thus, two inversions of the factor VIII gene are seen in nearly one-half of all severely affected patients with hemophilia A. In contrast, point mutations are most likely found in patients with mild to moderate hemophilia A.[28] The first case of hemophilia A caused by unequal homologous Alu/Alu recombination has been reported.[29] Because there are ~50 Alu repeats in the factor VIII gene, it is possible that many cases of hemophilia may result from this mechanism.[29] More than 95% of hemophilia A patients have mutations detected.[22,30,31] Approximately 2% of hemophilia A patients have no detectable mutations in the coding region of the factor VIII gene.[32] These results indicate that a substantial number of families with severe hemophilia A can undergo accurate gene tracking and carrier analysis. The intron 1 and 22 inversions responsible for 50% of severe hemophilia A cases can be sought using long and inverse polymerase chain reaction (PCR) techniques. Various algorithmic approaches to rapid laboratory genetic testing have been described,[30,33,34] and a recent method of performing linkage analysis of hemophilia A in families in whom mutations could not be identified has been reported.[35]

There is a strong association between genetic mutations that lead to absence of large portions of the factor VIII protein and the development of antibodies to therapeutic factor VIII infusions. These antibodies generally develop within the first 50 infusions of factor VIII, as expected when the immune system detects a protein to which it has not been exposed previously.

Variants

Hemophilia A with autosomal dominant transmission has been reported; however, it is important to distinguish these "variant hemophilia A patients" with negative X-linked transmission from patients with variant vWD (type 2N, vWD Normandy), an autosomal vWD subtype caused by defective factor VIII binding to vWF and with a clinical picture similar to hemophilia A.[36]

Carrier Detection

Despite the high rate of spontaneous de novo mutations in hemophilia A, detection of females who are carriers is important. When the family history of a patient suggests risk for being a carrier, then coagulation-based assays are performed, followed by DNA testing. The daughter of a man with hemophilia is an obligate carrier, whether she has symptomatic bleeding or not. Similarly, if a female has two sons with hemophilia, then she is likely a carrier; if she has one son with hemophilia and a family history of hemophilia, then she is likely a carrier; but if she has one son with hemophilia and a negative family history, then the odds are approximately 67% that she is a carrier. A number of specialized laboratories perform molecular testing for the factor VIII gene. It is most efficient and less expensive if the DNA of the relative with hemophilia is available to identify the specific genetic mutation in that kindred; then only that specific mutation is evaluated in the potential carrier.[37]

Coagulation-based Assays

Coagulation-based assays may be useful in confirming or excluding the carrier state, although they have limitations. The regularity with which the abnormal factor VIII gene is suppressed by the normal allele in female carriers of hemophilia varies because of the phenomenon of random X chromosome inactivation (the Lyon hypothesis). Thus, although the mean concentration of factor VIIIc in the plasma of heterozygous female carriers is ~50% of that in normal women,[13,38] observed values scatter widely around this mean and often overlap with those found in the normal population. This is a result, in part, of the large error of assay methods and the wide range of factor VIIIc levels in normal subjects.

Although the demonstration of low levels of factor VIIIc by means of the usual assay methods strongly suggests the presence of the carrier state, the converse statement cannot be made with equal certainty—that is, the presence of normal levels of factor VIIIc does not reliably exclude the carrier state.[39] Furthermore, pregnancy and hormonal medications may increase the levels of factor VIIIc in female carriers.[40] Normal women and carriers with blood types A, B, or AB have higher levels of factor VIIIc and vWFAg than those with blood type O.[41]

The use of immunoassays for vWF has improved carrier detection in hemophilia A.[42] These methods allow measurement of levels of vWF, which are normal[43] or increased in carriers of the disorder, despite mild but variable deficiencies of factor VIIIc. Results obtained when a bioassay and an immunoassay are performed on the same sample, and the ratio of VIIIc to vWF is computed, differentiate between the carrier population and the normal population with minimal overlap.[44] This ratio normally ranges from 0.74 to 2.20 and was found to be from 0.18 to 0.90 in obligatory carriers. The overall detection rate ranged from 72% to 94% in such obligatory carriers[46] and from 48% to 51% in women without hemophilic sons or fathers.[42] In the latter group (possible carriers), 50% would be predicted to be carriers. Abnormally low ratios of VIIIc:vWF (false positives) have been encountered in an occasional normal subject,[43,45] which may be attributable to nonspecific variables such as stress.[46] Pregnancy and the use of oral contraceptives, blood type,[41] or contamination of plasma samples with thrombin[46] or other proteolytic enzymes may produce falsely high ratios (false negatives) in documented obligatory carriers. Linear discriminant analysis[47] has been recommended for the expression and analysis of such laboratory data. The carrier detection rates using standardized assays with discriminant analysis exceed 90%.[48]

DNA-based Assays

Molecular analyses of the factor VIII gene identify mutations in 97% of hemophilia A patients. Based on the frequency of the intron 22 inversion, severe hemophilia A patients should be initially screened for this defect. Inversion-negative patients and those with mild or moderate hemophilia A should have systematic sequencing of the factor VIII promoter, exons, and splice junctions performed. Such an approach has been reported to identify mutations in 97% of hemophilia A patients.[30]

DNA-based assays have been adapted for prenatal diagnosis,[49] and for pre-implantation genetic diagnosis in association with in vitro fertilization. One commonly used method is to obtain chorionic villi samples during the eleventh to twelfth gestational week and perform direct genotype testing.[50] Alternatively, genetic linkage analysis of polymorphisms can be performed. The subject of genetic counseling in hemophilia has been reviewed.[51]

Hemophilia in the Female

Hemophilia has been well documented in human females.[44,52] The most common form is that seen in a minority of heterozygous carriers, discussed previously, in whom X chromosome inactivation may occur at an unusually early stage of embryogenesis, resulting in unusually low levels of factor VIII.

A second cause of female hemophilia is a mating between an affected male and a carrier female (Fig. 53.2; generation IV, number 10).[53] One-half of the female offspring of such a match would inherit two abnormal X chromosomes, one from the father and one from the mother. Such homozygous female hemophilia was once thought to be lethal and to inhibit the development of the embryo. That this is not true was first suggested by the successful experimental production of hemophilia in female dogs. Homozygous hemophilia is now well authenticated in several women[53,54] and resembles the disorder seen in affected males in all respects.

Clinical Manifestations of Hemophilia

Prior to effective replacement therapy, the life expectancy for a child born with severe hemophilia was less than 20 years. These boys would die from exsanguinating hemorrhage after a trivial traumatic injury, from spontaneous internal bleeding or from spontaneous intracranial hemorrhage. It is dramatic that a boy born today with severe hemophilia A can expect to have a normal life expectancy.

However, the most characteristic bleeding manifestations in hemophilia are spontaneous bleeding in weight-bearing joints, leading to severe hemarthrosis. The frequency and severity of these joint bleeds are related to the functional activity level of factor VIII in plasma[8,55] (Table 53.3). Three categories of severity have been defined by a consensus committee on the basis of FVIII activity levels (Table 53.3).[56] Severe hemophilia (factor VIII level <1 IU/dl) is manifested clinically by repeated and severe hemarthroses, resulting almost invariably in crippling arthropathy in the absence of replacement therapy; such severe cases often are called *classic hemophilia*. Moderate hemophilia (factor VIII level of 1 to 5 IU/dl) is associated with less frequent and less severe hemarthroses and seldom results in serious orthopedic disability. In mild hemophilia (factor VIII level of 6 to 40 IU/dl), hemarthroses and other spontaneous bleeding manifestations may be absent altogether, although serious bleeding may follow surgical procedures or traumatic injury.[57] As indicated in Table 53.3, most patients with hemophilia A have severe disease. However, one epidemiologic survey reported variable differences in the incidence of severity between individual states within the United States; for example, 13% of hemophilia cases were of moderate

TABLE 53.3

PREVALENCE AND SEVERITY OF HEMOPHILIA A AND HEMOPHILIA B IN THE UNITED STATES

Factor VIII or IX Level (IU/dl)	Clinical Picture[a]	Incidence (%)[b]	
		Hemophilia A	Hemophilia B
<1	Severe, spontaneous bleeding	70	50
1–5	Moderate bleeding with minimal trauma or surgery	15	30
6–40	Mild bleeding with major trauma or surgery	15	20

[a]The criteria for classifying hemophilia severity are taken from White GC, Rosendaal F, Aledort M, et al. Definitions in hemophilia. Thromb Haemost 2001;85:560.
[b]Incidence figures are for the United States in 1989 and were provided by the National Hemophilia Foundation (Courtesy of Kathleen F. Cortes, PhD).

severity in Massachusetts, whereas 35% of cases in Georgia were classified as moderate severity.[11]

Hemarthrosis

Hemarthrosis is the most common manifestation of the inherited coagulation disorders (Fig. 53.3). Joint bleeding and the consequent damage to weight-bearing joints remain the most common debilitating symptom in severe hemophilia.

Pathophysiology

Bleeding presumably originates from the synovial vessels and develops spontaneously or as the result of imperceptible or trivial trauma. Spontaneous joint bleeding in the absence of identifiable mild trauma is unusual in patients with moderate hemophilia and very rare in patients with mild hemophilia. Hemorrhage occurs into the joint cavity or into the diaphysis or epiphysis of the bone. In the acute stage, the synovial space is distended with blood. Muscular spasm further increases the intrasynovial pressure. Hemorrhage into the periarticular structures is a common complicating feature that occurs most often around small joints. The inflammatory response to joint bleeding is highly variable and not well studied. However, in many patients permanent joint damage, detectable by MRI, appears to occur after only one or two minor bleeds into a single joint.[58]

The joint may regain normal function after the first few episodes of hemarthrosis. More often, however, the absorption of intraarticular blood is incomplete, and the acute bleeding leads to chronic inflammation of the synovial membrane with the development of long-term damage to the joint. Sometimes, the joint remains swollen, tender, and painful for months, and in this setting may often suffer episodes of rebleeding. Such a joint is often termed a "target joint," and should be treated aggressively with physical therapy and appropriate factor replacement to interrupt the vicious cycle of inflammation, swollen synovium, and recurrent bleeding. Release of inflammatory cell proteolytic enzymes initiates destruction of cartilage and bone.[59]

Acute hemarthroses almost invariably recur from time to time. With each recurrence, the synovium becomes progressively more thickened and vascular; folds and villi, which predispose to synovial injury during even minimal activity, may form. Proliferating synovium often fills and distends the joint, which remains swollen and enlarged in the absence of bleeding or pain (chronic proliferative synovitis).[60] Together with the weakening of the periarticular supporting structures, this process predisposes the joint to recurrent episodes of bleeding. Repeated episodes of hemarthrosis, with the associated subchondral and synovial ischemia, result in progressive loss of hyaline cartilage, particularly at the margins of the joint. Large punched-out areas of destruction are sometimes produced by subchondral hemorrhages and, in the cancellous structure of the bone, cavitation may be caused by intraosseous hemorrhage. Through disuse, diffuse demineralization of the involved bones also may occur. Subperiosteal hemorrhages are not common.

The terminal stage of hemarthrosis is called *chronic hemophilic arthropathy*.[61] It is manifested by fibrous or bony ankylosis of larger joints; complete destruction may take place in the smaller articulations because of the weaker joint structure and the thinner cortices of the smaller bones. Other permanent sequelae of hemarthrosis include atrophy and proliferation of bone, roughening of the articular surfaces with lipping and osteophyte formation, bone necrosis and cyst formation, stunted growth as the result of interference with the nutrition of the bone, and accelerated development and overgrowth of the epiphyses caused by excessive blood flow (Figs. 53.3 and 53.4). Chronic hemophilic arthropathy is less common now because of widespread use of prophylactic replacement therapy and improved availability of factor replacement therapy.

Magnetic resonance imaging is superior to standard radiography for assessment of early arthropathy.[62] A scoring system for magnetic resonance joint evaluation has been reported[62] (Table 53.4).

It should be emphasized that with modern prophylactic therapy of regular factor infusions to maintain the plasma factor concentration above 1% of normal, boys are now reaching adolescence and young adulthood with essentially normally functioning joints. However, such a program of regular infusions with currently available factor therapies requires intensive medical and family support.

Clinical Presentation

Most persons with severe hemophilia report a characteristic warm, tingling sensation before the onset of symptoms of joint bleeding and hemarthrosis; this is called the *aura*. The earliest definite symptom is pain, which in the acute form may be excruciating. Physical examination reveals muscle spasm and limited motion of the affected joint. If therapy is not initiated immediately, typically within approximately 30 minutes, then the joint may progress so that it is warm and grossly distended and discolored,

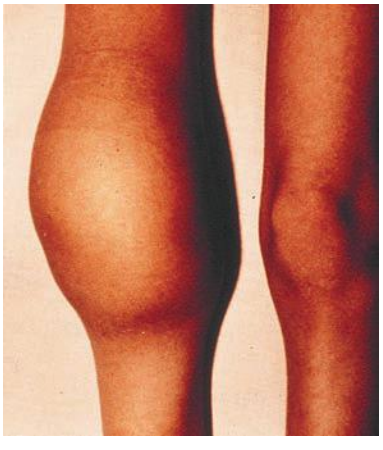

FIGURE 53.3. Hemophilic arthropathy. This figure illustrates the sequelae of recurrent joint bleeding.

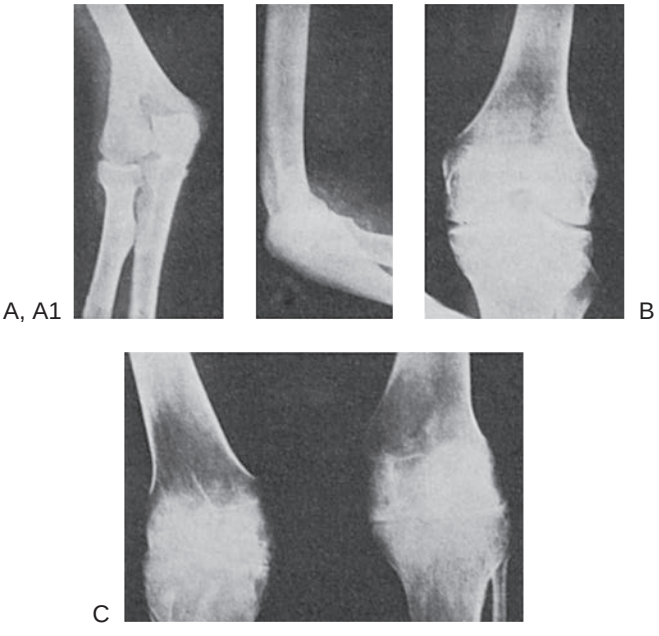

FIGURE 53.4. Elbow and knee joints in a patient with hemophilia A. Thickening of synovium with deposition of calcium is shown in **(A)** and **(A1)**; increased intercondylar notch is shown in **(B)**; increased density and decreased interarticular space are shown in **(A)**, **(B)**, and **(C)**; and lipping along the borders of the joint surfaces is shown in **(C)**.

TABLE 53.4

SCORING SYSTEM FOR HEMOPHILIC ARTHROPATHY USING MAGNETIC RESONANCE IMAGING

Score	Abnormalities on Imaging
0	None
I	Minimal hemosiderin
II	Large amount of hemosiderin and cartilaginous erosion
III	Cartilage destruction, bone erosion, subchondral cysts
IV	Osteoarthritis with or without ankylosis

but external evidence of bleeding may be minimal or absent in chronically damaged large joints because of thickening of the articular capsule. Generally, only one joint is involved at a time, although bleeding may develop simultaneously in two or more joints. The weight-bearing joints are most commonly affected and the knees are the joints most often severely affected. However, because of the success of total knee and total hip replacement surgeries, the ankles are the most commonly affected joints that lead to chronic problems that interfere with quality of life for persons with severe hemophilia.

Subcutaneous and Intramuscular Hematomas

Large ecchymoses and subcutaneous and intramuscular hematomas were common in hemophilia A prior to the use of regular infusion therapy, reflecting the substantial amounts of time patients had factor levels less than 1% of normal. With modern treatment protocols designed to keep plasma levels above 1% of normal, and immediate home infusion when a bleeding episode occurs, the frequency of large soft tissue bleeds has decreased dramatically. Such hemorrhages, when not treated promptly, characteristically spread within fascial spaces and dissect deeper structures (see Fig. 45.2). Subcutaneous bleeding may be extensive. When not treated promptly with factor infusion, the bleeding continues; and at the site of origin, the tissue is hard, indurated, raised, and purplish black. From this center, the hemorrhage extends in all directions, with each successive concentric extension less deeply colored. The point of origin of the hemorrhage may be absorbed entirely while the margin is still progressing. Intramuscular and subcutaneous hematomas may produce leukocytosis, fever, and severe pain in the absence of significant discoloration of the overlying skin.

Hematomas may produce serious consequences from the compression of vital structures. Bleeding into the tongue, throat, or neck may develop spontaneously and is especially dangerous because it may compromise the airway with surprising rapidity.[63] Gangrene may result from pressure on arteries; and the development of compartment syndrome and, if not promptly treated, ischemic contractures are common sequelae of hemorrhage into the calves or forearms. Peripheral nerve lesions of varying severity are common complications of untreated hemorrhage into joints or muscles. Hemophilic cysts are discussed in the section Special Aspects of Treatment.

Psoas and Retroperitoneal Hematomas

Spontaneous hemorrhage into internal fascial spaces and muscles of the abdomen is common in severe hemophilia A,[64] reflecting plasma factor levels less than 1% of normal. Bleeding into or around the iliopsoas muscle produces pain of progressively increasing severity and tenderness; when it occurs on the right side, it may closely simulate acute appendicitis. Femoral nerve involvement may be partial or complete, with the development of pain on the anterior surface of the thigh. The psoas sign is positive, and the hip is held in partial flexion. Paresthesias, partial or complete anesthesia, and, ultimately, weakness or paralysis of the thigh extensors with eventual muscular atrophy may ensue. Retroperitoneal hemorrhage and intraperitoneal hemorrhage also are common. Computed tomography may be helpful in the diagnosis of these hematomas.[64] Prompt factor infusion is critical to normalize coagulation and should be continued until the hematoma has resolved completely, as any residual hematoma is at higher risk for rebleeding and pseudocyst formation.

Gastrointestinal and Genitourinary Bleeding

Hemorrhage from the mouth, gums, lips, frenulum, and tongue is common and often serious. The eruption and shedding of deciduous teeth usually occur without abnormal bleeding, but may occasionally be accompanied by hemorrhage that lasts for days or weeks if not treated. Epistaxis occurs in many patients and may be of exsanguinating proportions.

Hematemesis, melena, or both are not uncommon. The source of the bleeding is usually the upper gastrointestinal tract. In most patients in whom bleeding is persistent or recurrent, it originates from a structural lesion, most commonly a peptic ulcer or gastritis. Hemorrhage may be accompanied by abdominal pain, distention, increased peristalsis, fever, and leukocytosis. Intramural bleeding into the intestinal wall may result in intussusception or obstruction.

Hematuria is more common than gastrointestinal bleeding, but it is less often the result of a demonstrable pathologic condition in the genitourinary tract. The bleeding may arise in the bladder or in one or both kidneys and may persist for days or weeks.[65] When clots form, ureteral colic may develop. Typically, the hematuria resolves after factor infusion, but if persistent, then a short course of prednisone may prove helpful to shorten the course of hematuria.[66]

Traumatic Bleeding

Patients with coagulation disorders seldom bleed abnormally from small cuts such as razor nicks, reflecting the normal function of platelets, as measured by platelet function tests. All laboratory assays of platelet function are normal in patients with severe hemophilia A. After larger injuries, however, hemorrhage out of proportion to the extent of the injury is characteristic. The bleeding reflects both increased acute bleeding rates beyond what is expected after the trauma, and persistent bleeding as slow continuous oozing occurs for days, weeks, or months. Such traumatic bleeding may be massive and life-threatening unless coagulation replacement therapy is provided by immediate factor infusion.

Delayed bleeding is common. Thus, although hemostasis after an injury or a minor surgical procedure may appear to be adequate, hemorrhage, often of sudden onset and serious proportions, may develop several hours or even days later. This phenomenon apparently occurs because the processes of primary hemostasis are only temporarily effective. Delayed bleeding may occur in patients with mild hemophilia and is a significant hazard after minor surgical procedures, particularly those performed on an outpatient basis, such as tooth extraction and tonsillectomy.

Venipuncture, if skillfully performed, is without danger for the person with severe hemophilia, primarily because of the elasticity of the venous walls. If venipuncture is traumatic, digital pressure on the puncture site or a pressure dressing may prevent further complications. Subcutaneous, intracutaneous, and small intramuscular injections seldom produce hematomas if firm finger pressure is maintained for at least 5 minutes. Large intramuscular injections should be avoided. Vaccination using intramuscular injections is acceptable with minimal increase in bleeding risks.

Other Clinical Aspects

Infants usually are asymptomatic because they are insulated from trauma.[67] However, trauma during birth or afterwards may trigger

life-threatening bleeding. Infants of women who are known carriers may be at risk during delivery, and instrumentation during vaginal delivery should be avoided. Currently, the usual standard of care is to avoid testing the infant in utero due to the risks inherent in current techniques available to test the fetus, and to allow normal vaginal delivery with back-up Caesarean section available if any difficulties arise during birth. Typically, hematomas are seen first when children become active, and hemarthroses seldom develop until they begin to walk. Occasionally, evidence of the disorder is not seen until patients reach teenage years or young adult life. Spontaneous hemorrhage may be cyclic in nature. Petechiae, which are characteristic of disorders of platelets and blood vessels, are rare in patients with hemophilia but have been noted in severely affected patients during an exacerbation of bleeding. Hemorrhage from the umbilical cord or stump is unusual, but prolonged bleeding after circumcision is common and brought hemophilia to the attention of the ancient Hebrews. Pulmonary and pleural bleeding are uncommon, although mediastinal and pleural shadows have been noted radiographically and presumably originate from fresh or old hematomas. Intraocular hemorrhage is uncommon, but bleeding into the orbit and conjunctiva occurs often. Spontaneous rupture of the spleen has been reported. Intracranial bleeding is discussed in the section Special Aspects of Treatment. The website for the National Hemophilia Foundation is www.hemophilia.org and contains useful information and links to more detailed information on this bleeding disorder.

Course and Prognosis

In recent years, the prognosis in severe hemophilia has improved dramatically. With modern therapy using regular factor infusions to maintain adequate plasma factor concentrations to prevent nearly all spontaneous bleeding episodes, a person born with severe hemophilia A can expect to live an essentially normal lifespan. No other genetic disease has made such dramatic progress in the past 50 years. It is not yet clear whether hemophilia protects older hemophilia patients from thromboembolic disorders,[68] atherosclerosis,[69] or cardiovascular diseases. Despite the lack of stringent prospective clinical studies for this emerging problem of aging patients with severe hemophilia and other medical problems, reviews of current practice and expert opinion on how to treat aging patients with severe hemophilia have been published.[70,71,72,73]

Laboratory Diagnosis

The activity of the various coagulation factors is expressed in terms of units, defined as the activity present in 1 ml of fresh plasma from normal donors. The concentration of all coagulation factors in normal pooled plasma is thus 1 IU/ml or 100 IU/dl, or 100% activity. It should be noted that the activity levels in blood bank plasma are somewhat lower, approximately 80 IU/dl because of the dilution with anticoagulant.

Routine clinical laboratory tests (noncoagulation) are normal in patients with hemophilia A. The presence or absence of anemia or of signs of blood regeneration depends on the severity and frequency of bleeding, as in any individual patient. Neutrophilia may accompany severe hemorrhage, and the destruction of red blood cells in the hematoma may be reflected in elevated LDH, AST, or bilirubin. As in other instances of posthemorrhagic anemia, the bone marrow reflects the response to blood loss.

Screening Tests of Hemostasis and Coagulation

The partial thromboplastin time (PTT) usually is prolonged in patients with hemophilia A (Table 53.5). The biochemical conditions for most laboratory assays of PTT are set so that the PTT is abnormal if the factor VIII level is <25% of normal; however, some PTT reagents are insensitive to mild factor VIII deficiency.[74] Therefore, in most situations the abnormality of the PTT can be

TABLE 53.5

LABORATORY FINDINGS IN COMMON INHERITED COAGULATION DISORDERS

Disorder	Partial Thromboplastin Time (PTT)	Prothrombin Time	Thrombin Time	Ancillary Tests
Hemophilia A	A	N	N	vWF antigen and activities are normal or increased, ratio VIIIc:vWF is low.
Hemophilia B[a]	A	N[a]	N	—
von Willebrand disease[a,b]	A or N	N	N	vWF antigen and VIIIc are usually low, ratio VIIIc:vWF is variable; ristocetin-induced platelet aggregation and ristocetin cofactor activity are usually diminished.

Dysfibrinogenemia[a]	vA	vA	A[c,d]	Hypofibrinogenemia,[e] reptilase time is prolonged,[a] fibrin(ogen) degradation products levels are increased.[a]
Hypoprothrombinemia[a]	A	A	N	Two-stage assay is abnormal.[f]
Factor V deficiency	A	A	N	—
Factor VII deficiency[a]	N	A	N	Stypven (Russell viper venom) time is normal.
Factor X deficiency[a]	A	A	N	Stypven time is abnormal.
Factor XI deficiency	A	N	N	—
Factor XII deficiency	A	N	N	—
Factor XIII deficiency	N	N	N	Clot solubility tests are abnormal.

A, abnormal; N, normal; v, variable; vWF, von Willebrand factor.
Certain PTT reagents may not detect mild deficiency of factors VIII, IX, and XI.
[a]Findings are significantly different in some variants.
[b]Coagulation abnormalities are caused by deficiency of factor VIIIc.
[c]Patient's plasma may inhibit normal coagulation.
[d]Abnormality may be corrected by increasing calcium concentration and may be magnified by diluting the thrombin solution.
[e]Abnormality varies depending on technique.
[f]Results of one-stage techniques may be uninterpretable.

normalized by mixing the patient's plasma with normal plasma in a ratio of 1:1; and this test, called a mixing study, is routinely used to detect whether neutralizing factor VIII antibodies are present. The platelet count usually is normal, but may be elevated in the stress reaction to hemorrhage.

Factor VIIIc Assays

Assay of factor VIII is a simple technique, but requires trained and experienced technicians, as the results are sensitive to errors in laboratory technique, or to errors in proper handling of the blood specimen. In clinical practice, if the laboratory results do not seem to fit the clinical picture, then most clinicians will repeat the laboratory test, and/or discuss the results with the laboratory personnel. Two-stage methods,[75] one-stage methods,[76] and micromethods[77] are suitable for diagnosis. The one-stage techniques are used most widely because they are simple to perform. They require either a supply of plasma from a known individual with severe hemophilia, which is available commercially, or artificial substrate plasma. Two-stage assays detect approximately 20% more factor VIII than do one-stage methods,[78] and they are less subject to variables[79] such as fluctuations attributable to contaminating traces of thrombin or other proteolytic enzymes.

The World Health Organization makes international standards, but many laboratories purchase commercial secondary standards that are calibrated to the international standard. Under most circumstances, a pool of citrated plasma carefully collected from normal subjects and frozen in individual laboratories also serves as an acceptable standard.

The factor VIII assay has a large potential for error, even in expert hands. Therefore, when borderline values are obtained, the assay should always be repeated. Extensive studies of the many variables of the factor VIII assay have been reported.[80–83]

In the clinical setting of delivery of a boy with a question of hemophilia A, assays for both factor VIII and vWF may be carried out with reasonable accuracy on material obtained by fetoscopy—that is, mixtures of blood and amniotic fluid[84] or unmixed fetal blood.[85]

The availability of a new recombinant form of factor VIII (B domain–deleted factor VIII, Xyntha) raised concerns about accurate laboratory monitoring of patients receiving this product.[86] Chromogenic substrate assays or typical one-stage PTT assays using physiologic phospholipids are needed to quantitate factor VIII levels accurately in patients receiving B domain–deleted factor VIII.[87] Alternatively, a standard one-stage PTT assay using B domain–deleted factor VIII as the assay standard would be appropriate. The use of concentrate standards (rather than plasma standards) diluted in factor VIII–deficient plasma has been proposed as a solution to resolve discordant results using different assay methods.[88]

Analysis of appropriate methods for laboratory assays of factor VIII activity levels after therapeutic infusions of the newer factor VIII products with extended half-life will be an important part of the small phase III clinical trials initiated in 2012.[89] The Scientific Subcommittee on Standards of the International Society of Thrombosis and Haemostasis is involved in defining appropriate standards for these new products.

Factor VIIIAg (cAg) Assays

Highly specific but complicated assays using immunoradiometric methods and ELISA techniques[90] are available to measure factor VIIIAg (VIIIAg). The latter methods use liquid- and solid-phase principles and both natural factor VIII antibodies and monoclonal antibodies. The results of both of these techniques demonstrate the absence of factor VIIIAg in most severely affected hemophiliacs and correlate well with factor VIIIc measurements in most cases. Results are more variable when mild hemophiliacs are tested. In most series, ~10% of patients have detectable levels of factor VIIIAg and a low VIIIc-to-VIIIAg ratio (the CRM-positive variant). Immunoassays for vWF are discussed in the section Laboratory Diagnosis.

Differential Diagnosis

The diagnosis of hemophilia A is seldom difficult, especially in the severely affected patient with repeated and often serious hemorrhagic manifestations, including such characteristic signs as hemarthrosis. Typically the PTT is abnormal and leads to specific assays for clotting factor activity and mixing studies to rule out neutralizing inhibitors of coagulation activity. Hemarthrosis with significant orthopedic disability is rare in patients with coagulation disorders other than hemophilia A or B.

In patients with mild forms of the disorder, however, failure to recognize the existence of the disease or to make the correct diagnosis is more likely. Such patients rarely have a history of spontaneous bleeding, and the family history tends to be vague or negative. A history of abnormal bleeding after minor trauma may be difficult to establish due to variability in bleeding. Occasionally, mild hemophilia A may present with a normal PTT when the factor VIII activity assay result is greater than 25%; thus a normal PTT may be misleading. It must be emphasized that individuals with mild hemophilia are still at risk for hazardous hemorrhage after trauma or during surgical procedures.[91,92] A survey of hemophilia carriers found that mild reduction in factor VIII or IX levels (41 to 60 IU/dl) was associated with excessive bleeding.[93] A normal PTT value, therefore, cannot be relied on to exclude the possibility of hemophilia. In the mildly affected patient, specific factor assays must be performed to confirm or exclude the diagnosis of hemophilia.

The results of screening tests (Table 53.5) usually are sufficient to exclude the possibility of acquired hemorrhagic disorders associated with serious bleeding. Such disorders are seldom associated with a prolonged PTT and a normal prothrombin time (PT), a combination that strongly suggests an inherited disorder or an inhibitor. Among the inherited disorders characterized by this combination of findings (hemophilia A, hemophilia B, and deficiencies of factors XI, XII, prekallikrein, and high-molecular-weight kininogen [HMWK]), deficiency of the latter three factors can be readily excluded because their deficiency is not associated with excessive clinical bleeding. Factor XI deficiency in males may mimic mild hemophilia, and hemophilia B is clinically identical to hemophilia A. Both factor XI deficiency and hemophilia B must be distinguished from hemophilia A in the laboratory using specific factor activity assays. The best way to accomplish this goal in evaluating patients with an isolated prolonged PTT is by performing specific assays of these three factors in the order of their statistical frequency—that is, VIII, IX, and XI. A PTT mixing study should also be performed to exclude an inhibitor. A definitive diagnosis is of great importance because specific products are used to treat each of these disorders.

Severe vWD in males may be indistinguishable from mild hemophilia A. Confirmatory tests for vWD are needed to make this distinction. Patients with the uncommon type 2N vWD may also be clinically indistinguishable from patients with hemophilia A. This diagnosis is important to establish, because therapeutic infusions of recombinant factor VIII (r-FVIII) would be ineffective due to the shortened half-life of factor VIII resulting from the absence of effective binding to von Willebrand protein. An X-linked family history of bleeding supports a diagnosis of hemophilia A in these patients, and an autosomal recessive family history of bleeding supports a diagnosis of type 2N vWD. Statistically, one would expect a rare family that might carry both genetic disorders; clearly that situation may be problematic to resolve without additional genetic testing.

Bleeding manifestations in hemophilia may simulate a variety of conditions. However, serious confusion results only when the

correct diagnosis has not been considered and appropriate laboratory studies have not been ordered. Thus, a deep hematoma may be mistaken for a suppurative condition, and surgical drainage may be attempted. Bleeding into a small joint may produce a clinical and radiologic picture suggestive of sarcoma; when larger joints are involved, findings simulate tuberculosis, arthritis, or Perthes disease. Bleeding elsewhere may suggest local causes such as kidney tumor, pulmonary disease, or peptic ulcer. For example, blood clots due to hemophilia bleeding in the renal collection system might appear as masses on a CT scan and be confused with cancer, leading potentially to inappropriate invasive procedures to obtain tissue for cancer diagnosis.

Intra-abdominal bleeding raises particularly serious diagnostic and therapeutic problems in the patient with hemophilia, even when the hemophilia condition has been accurately diagnosed. Thus, hemorrhage into the psoas, when on the right side, may simulate acute appendicitis so closely that, in the opinion of many experienced clinicians, there is no reliable clinical means to differentiate between the two diagnoses. A retroperitoneal hematoma may be mistaken for an appendiceal abscess. Intraperitoneal hemorrhage and bleeding into and around other viscera may simulate perforating peptic ulcer, bowel obstruction, or virtually any acute intra-abdominal condition. Computed tomography scanning and sonography may be particularly helpful in differentiating between intra-abdominal conditions that require surgical intervention and retroperitoneal and psoas hemorrhages. In any case, early therapeutic infusion of factor VIII will prevent further bleeding and carries no additional risk for the individual with hemophilia. Therefore, when there is a question and further diagnostic tests are planned, factor VIII should be administered first and promptly before the diagnostic tests are performed.

HEMOPHILIA B

Hemophilia B was recognized as a separate disorder from hemophilia A in 1947.[94] Hemophilia B (Christmas disease, factor IX deficiency) was established as different from hemophilia A by Aggeler et al. in 1952.[95,96] Hemophilia A is approximately 5 times more common than hemophilia B.[18] A 1994 survey estimated that there were 3,640 cases of hemophilia B in the United States.[11] As expected, it appears that the severity of hemophilia B is a consequence of the plasma factor IX concentration, and that for any particular plasma concentration, the clinical severity is similar for hemophilia A and B. However, in contrast with hemophilia A, most of the genetic causes of hemophilia B are not large deletions or inversions; therefore in many patients there is some antigenic protein, and often some low level of function of the mutated protein. Consequently, the clinical phenotype is often less severe. As with hemophilia A, hemophilia B is classified as severe, moderate, or mild based on the percentage of functional factor IX in coagulation activity assays. In addition, because of the presence of low levels of factor IX protein in more patients with hemophilia B, there are fewer persons with hemophilia B that develop neutralizing inhibitors (approximately 3% versus more than 25% in hemophilia A).

Historically, when plasma from patients with hemophilia B was tested against autologous antibodies, three distinct groups were defined: A cross-reactive material (CRM)-positive variant, the most common form; a CRM-negative variant; and a third form of the disorder in which antibody neutralization was variable in extent and was approximately proportional to coagulant factor IX activity (the CRM-reduced variant).[97] These distinctions are only of historical interest now.

In a disorder called *hemophilia B Leyden*,[98] the clinical manifestations tend to diminish during puberty in association with a rise in the factor IX level from as low as 1 IU/dl in childhood to levels of 20 IU/dl or more in adult life. The Leyden variant is characterized as CRM-negative at birth but becomes CRM-positive or CRM-reduced with advancing age.[98] The genetic basis for factor IX Leyden is that mutations occur in the factor IX gene promoter region; this region contains an androgen response element that, with age, stimulates factor IX gene transcription and protein synthesis.[99]

In another variant of hemophilia B, the PT is prolonged when performed with ox brain thromboplastin.[100] This disorder has been called *hemophilia* B_m and is characterized by the presence in the plasma of CRM that neutralizes both autologous and heterologous antibodies to factor IX.[101] The degree of abnormality of the ox brain PT is proportional to the plasma level of CRM in both affected males and carrier females. This variant results from mutations in the carboxy terminus of the factor IX molecule, resulting in a factor IX molecule that interacts abnormally with ox brain thromboplastin.

Numerous factor IX mutations have been recognized.[22,102] Factor IX purified from the plasma of affected members of one kindred did not fragment normally when activated in vitro (hemophilia B Chapel Hill).[101] The molecular defect was found to be a substitution of histidine for arginine at position 145, a defect that inhibits cleavage by factor XIa.[103] Studies of factor IX obtained from another family[104] revealed biochemical abnormalities identical to those characteristic of the descarboxy analog of this factor that is found in vitamin K deficiency or produced by coumarin drugs. Such molecules lack Ca^{2+}-binding sites and do not undergo conformational changes induced by Ca^{2+}. Another report concerns a unique variant with deficient Ca^{2+} binding and an abnormally high-molecular-weight (factor IX Zutphen).[105]

Genetics

Hemophilia B is inherited as an X-linked recessive trait, but the locus on the X chromosome of the gene controlling factor IX production is remote from that involved with factor VIII biosynthesis.[106] Factor IX levels <10% have been documented in a few women, including some with chromosomal abnormalities.[107–109] Ten useful polymorphisms have been described that are associated with the factor IX gene.[49] An updated listing of mutations is available at www.kcl.ac.uk/ip/petergreen/haemBdatabase.html. Unlike hemophilia A, the spontaneous mutation rate is low,[17] and most patients with hemophilia B have positive family histories.

Factor IX defects may be severe, moderate, or mild. Severe defects result from large gene deletions, nonsense mutations, and inversions; these defects are associated with absence of factor IX protein. Milder gene defects such as splice-site or missense mutations result in a dysfunctional protein with some residual activity. Missense mutations account for ~80% of mutations in severe hemophilia B patients.[22,110–112]

Detection of Carriers

Detection of heterozygous carriers of hemophilia B involves the same principles and limitations as described for hemophilia A. Carrier detection based on coagulation assay alone usually is more reliable than is the case with hemophilia A.[113] Thus, in one series of 45 obligatory carriers, the mean factor IX level in the plasma was 33 IU/dl; 40 from the group had levels <50 IU/dl, and 10 had levels <25 IU/dl. As a consequence of these low levels of factor IX, abnormal hemorrhage is not uncommon in carriers of hemophilia B.

Results of immunoassays of factor IX and the ratio of factor IX–related antigen to coagulant factor IX levels in the carrier population overlap with the normal population to a considerable degree, particularly in the CRM-positive variants.[114,115] Such studies provide a lower overall detection rate among obligatory carriers of hemophilia B than is the case with hemophilia A.[114,115] Levels of factor IX–related antigen obtained by immunoassay

are significantly increased by the use of oral contraceptives. The use of DNA probes[116] and monoclonal immunoassays[117] provide highly accurate methods for determining carrier status. Rapid carrier testing using allele-specific microarray methods has been described. This method permits detection of a majority of common factor IX mutations in a single assay.[118] Prenatal diagnosis of hemophilia B has been successful in the CRM-negative variants.[119] Modern methods for prenatal diagnosis use genetic testing and are quite reliable.[120,121] Determination of carrier status is based on several factors, including pedigree analysis, factor IX assay results, and genotype.[122]

Clinical Features

Severely affected patients (those with factor IX activity levels <1 IU/dl) are less common than in hemophilia A (Table 53.3), but the clinical manifestations of the two disorders are identical for the same activity levels of the coagulation factors. Specific factor assays are necessary to distinguish between hemophilia A and hemophilia B. Mild factor IX deficiency should always be considered in the differential diagnosis of patients with coagulation-type bleeding and normal routine coagulation test results (PT, PTT).[123] Many PTT reagents do not detect mild factor IX deficiency (factor IX levels of 20% to 30%).[74]

Laboratory Diagnosis

The laboratory diagnosis of hemophilia B involves the same approach and methods as those described for the recognition of hemophilia A (Table 53.5). The screening tests reveal similar abnormalities in the two disorders, except that the PT is abnormal in the B_m variant when either ox brain or Thrombotest is used as the thromboplastin.

Hemophilia A may be easily distinguished from hemophilia B by a specific factor assay. One-stage and two-stage assays for factor IX use the same principles as those discussed for factor VIIIc. Sensitive immunoassay methods for factor IX have been developed.[124]

VON WILLEBRAND DISEASE

The historical confusion that has surrounded the pathogenesis of vWD is apparent from the many names that have been applied to this disorder. These designations include *angiohemophilia, vascular hemophilia, pseudohemophilia, constitutional thrombopathy,* and *idiopathic prolonged bleeding time*. von Willebrand first recognized the disorder in a 1926 study of the inhabitants of the Åland Islands.[125] Three cardinal manifestations of this bleeding disorder are mucocutaneous hemorrhage rather than hemarthrosis and deep-muscle bleeds; autosomal dominant inheritance, rather than sex-linked as seen in hemophilia A; and prolonged bleeding time. Evaluation of one large kindred revealed variable severity of bleeding symptoms, with some obligate heterozygote carriers being asymptomatic. von Willebrand thought that the hemostatic defect resulted from combined defects in platelet function and vascular endothelium. The discovery that plasma from normal volunteers or patients with hemophilia A corrected the hemostatic defect of vWD suggested that a plasma protein distinct from factor VIII caused vWD. In 1972, von Willebrand factor (vWF) was purified. Genetic variants were correlated with various vWF structural abnormalities, and demonstration of the heterogeneous nature of vWD was furthered by development of vWF multimer analysis by gel electrophoresis.[126] In its most common form (type 1), the disorder is characterized by mild mucocutaneous hemorrhage, which is attributable to deficiency of both vWF and factor VIIIc. The disorder is not homogeneous, however, in part because of the multiple physiologic functions played by vWF. The recognition of a number of variants, together with the demonstration of multiple genetic patterns, suggested that vWD is very heterogeneous. However, all forms of vWD can be traced to insufficient amounts of vWF or defective function of this protein. Recent reviews of this area have been published,[127,128] and a consensus document on vWD sponsored by the National Institutes of Health reviewed all aspects of the disorder.[129,130]

Incidence

Epidemiologic studies indicate that vWD is the most common bleeding disorder, affecting about 1% of the population.[131] The high incidence of the disease is not limited to certain ethnic groups [131,132]; however, only a fraction of people come to medical attention because of bleeding symptoms. This may be because of either the relatively mild nature of the disease in many affected individuals, or a lack of recognition by patients of excessive bleeding in response to either physiologic challenge (e.g., heavy menstrual bleeding) or trauma.

Nomenclature

The identification of numerous variants of vWD has led to attempts to simplify classification of this disorder. An updated classification system has been proposed (Table 53.6).[128] Quantitative defects are divided into partial deficiency (type 1) and severe deficiency with virtually complete absence of vWF (type 3). The qualitative defects (type 2) are divided into four categories according to the nature of the defect of vWF function. Type 2A refers to variants with impaired interaction between vWF and platelets, resulting from a deficiency of intermediate- and high-molecular-weight multimers of vWF. Type 2B refers to variants in which vWF exhibits increased affinity for its receptor, platelet GPIb. Paradoxically, bleeding in these patients develops as a result of clearance of larger vWF multimers and platelets from the circulation. Type 2M refers to variants with defective interaction between vWF and the platelet GPIb receptor that is not due to deficiency of high-molecular-weight multimers of vWF from plasma, but rather results from defects within the GPIb-binding domain of vWF. Finally, variants of vWD in which decreased affinity of vWF for factor VIII results in depressed plasma factor VIII levels are classified as type 2N.[128] Thus, six major categories of vWD are defined, each having distinct pathophysiology.

TABLE 53.6

REVISED CLASSIFICATION OF VON WILLEBRAND DISEASE

Revised Type	Features
1	Partial deficiency of vWF
2	Qualitative vWF defects
2A	vWF variants with loss of high-molecular-weight multimers and decreased vWF-dependent platelet adhesion
2B	vWF variants with loss of high-molecular-weight multimers caused by increased affinity for platelet glycoprotein Ib
2M	vWF variants with decreased vWF-dependent platelet adhesion not associated with the loss of high-molecular-weight multimers
2N	vWF variants with decreased binding affinity for factor VIII
3	Severe deficiency of vWF

vWF, von Willebrand factor.

Genetics

A gene on chromosome 12 codes for the synthesis of the vWF macromolecule. The genetic message is composed of 52 exons covering a span of 158 kb.[132,133] The vWF gene encodes for a protein with multiple copies of homologous motifs, including three "A," three "B," two "C," and four "D" motifs (see Fig. 53.5). These motifs in turn encode protein domains that subserve the various functions of vWF. The A1 domain contains binding sites for platelet GPIb, ristocetin, and collagen,[134,135] the A2 domain contains a protease-sensitive domain that may have a role in regulating vWF function,[136] the A3 domain contains a second collagen-binding domain,[135] the C1 domain has an RGD sequence capable of interacting with platelet glycoprotein IIb/IIIa, and the D′ and D3 domains contain a factor VIII–binding sequence.[135]

vWD appears to be inherited by multiple genetic mechanisms (Table 53.7). The most common form of the disorder (type 1 vWD) accounts for ~70% of all cases of vWD. Diagnostic criteria for type 1 vWD have been proposed,[128] including a history of bleeding symptoms, a positive family history of bleeding symptoms, and bleeding that is attributable to quantitatively low vWF levels. Population screening suggests that the prevalence of vWD may be as high as 1% of the population, but only a minority of these patients subsequently present with clinically significant bleeding.[137] vWD is inherited as an incompletely dominant autosomal trait with variable penetrance, even among members within a single kindred. Because of variable penetrance and expression of vWD, only ~33% of children may be affected. Figure 53.6 illustrates one of the original pedigrees described by von Willebrand.

Twin studies demonstrated that ~60% of the variation in vWF level and ~50% of the variation in factor VIII level is attributable to genetic factors.[138] Genetic loci outside of the vWF gene contribute to variation of vWF level. Individuals with blood group O have vWF levels that are on average 30% lower than those of people with blood group A, B, or AB,[139] and it is likely that carbohydrate groups attached to vWF play a subtle role in clearance of vWF from plasma.[140,141] In addition, variation in expression of levels of other hemostatically active proteins, such as variation in the level of platelet adhesion receptors, may modulate the severity of symptoms conferred by vWF deficiency.[142] vWF levels are under hormonal and other controls, which further complicates disease expression. Variation in levels of as much as 20% has been reported with menstrual cycle, with levels lowest in the early follicular phase (before day 7 of the cycle); and levels increase with age, rising ~15% for each decade increase in age.[143] As will be discussed later, the criteria for diagnosing quantitative vWD deficiency, and the specificity of historic bleeding, have introduced controversy in what constitutes type 1 vWD and have led to the potential for the new diagnostic entity of "low vWF".[137,144]

Mild to moderate quantitative deficiency of vWF characterizes patients with type 1 vWD, whereas virtual absence of vWF characterizes type 3 disease. Two large studies of families with a diagnosis of type 1 vWD and genetic evaluation of patients with type 3 disease have begun to shed light on the genetics of quantitative vWF deficiency.

Very low vWF levels in the range of 5 to 20 IU/dl tend to be highly inheritable and are frequently associated with "dominant negative"–acting mutations. Mutations in these patients with type 1 vWD appear to be different than those with type 3 disease, such that type 1 disease is not simply explained by being heterozygous for a type 3 allele. Genetic defects associated with these more severe type 1 phenotypes encode amino acid changes that in turn lead to defects in protein expression. Mechanisms responsible for decreased plasma vWF level include reduced secretion related to impaired intracellular transport of vWF subunits, increased clearance from the circulation, or accelerated catabolism as a result of increased susceptibility to degradation by ADAMTS13. Changes that were most likely to cause a "dominant negative" mechanism

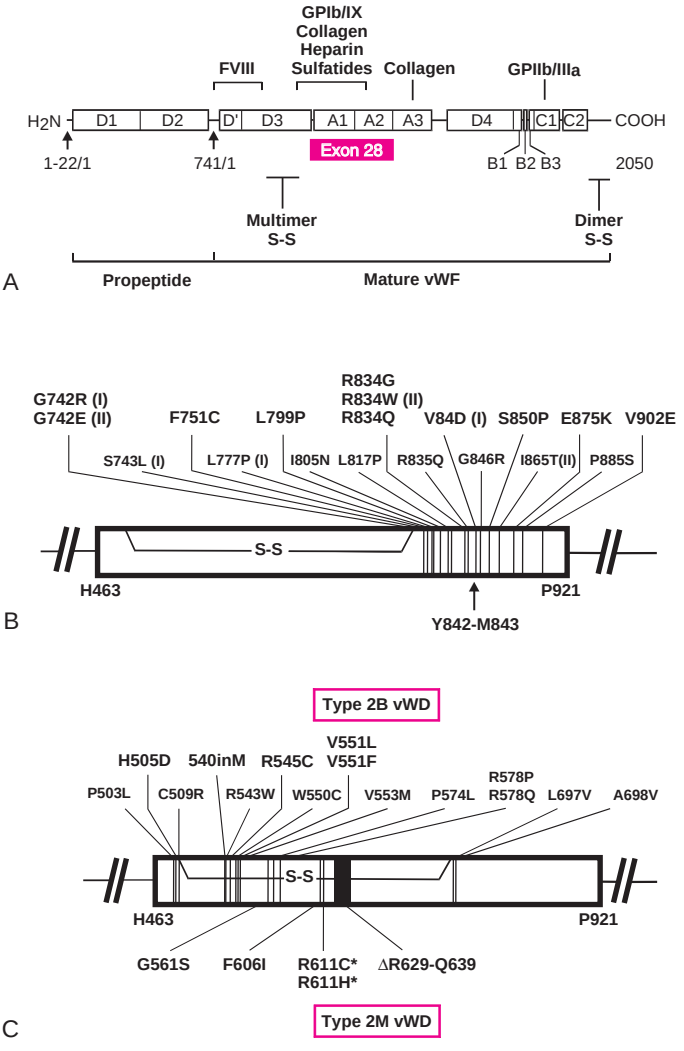

FIGURE 53.5. A: Structure and functional domains of von Willebrand factor (vWF). The open rectangles indicate domains of pre–pro-vWF. The first 22 amino acids of pre–pro-vWF are the signal sequence. The left arrow identifies the site of cleavage of the signal peptide, resulting in pre-vWF monomers. Pro-vWF monomers form dimers, and the vWF propeptide (vWAgII) is cleaved from mature vWF (right arrow indicates cleavage site). Dimer S–S and multimer S–S indicate locations of disulfide bonds that covalently link monomeric vWF into dimers and dimeric vWF into multimers, respectively. The red rectangle identifies exon 28, which encodes the A1 and A2 domains of mature vWF. Functional domains are identified above the open rectangles. The factor VIII binding site is located in the D′and D3 domains in the amino-terminal 272 amino acids of mature vWF. The A domains of vWF contain the binding site for the platelet glycoprotein (gp) Ib/IX complex, as well as binding sites for heparin, collagen, and sulfatides. The gpIIb/IIIa complex binding site of activated platelets is located at the carboxy-terminal portion of the C1 domain and contains the Arg–Gly–Asp sequence. The numbers below the open rectangles indicate amino acid numbers: Signal peptide, 22 amino acids; propeptide (vWAgII), 741 amino acids; mature vWF, 2,050 amino acids. **B:** Mutations associated with type 2A von Willebrand disease (vWD). The open rectangle represents vWF exon 28 encoding domains A1 and A2. The arrow indicates the site of proteolysis seen in type 2A vWD. Mutations are identified using the single-letter code for amino acids. I and II identify group I and group II missense mutations that result in impaired synthesis of vWF or increased sensitivity to proteolysis in plasma, respectively. The disulfide bridge shown represents the boundary of the Cys 509–Cys 695 loop in the A1 domain. Type 2A vWD mutations associated with defective vWF multimerization are not shown in this figure; these latter mutations occur in the propeptide (vWAgII) D1 and D2 domains. **C:** Mutations associated with types 2B and 2M vWD. The large open rectangle represents exon 28, which encodes domains A1 and A2 of vWF. The mutations responsible for type 2B vWD are shown above the rectangle. Most type 2B mutations lie between residues 540 and 578 of mature vWF. The mutations responsible for type 2M vWD are shown below the rectangle. Asterisks identify mutations that reduce the platelet-dependent function of vWF and vWF multimeric size. Δ indicates deletion of an amino acid sequence. TABLE 53.7

FEATURES OF COMMON VARIANTS OF VON WILLEBRAND DISEASE

Features	Type 1	Type 2A	Type 2B	Type 3	Platelet Type
Inheritance	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal recessive	Autosomal dominant
Factor VIIIc in plasma	Normal or reduced	Normal or reduced	Normal or reduced	Markedly reduced	Normal or reduced
vWF antigen	Normal or reduced	Normal or reduced	Normal or reduced; increased affinity for platelets	Markedly reduced	Normal or reduced; increased affinity for platelets
Ristocetin cofactor activity	Normal or reduced	Reduced	Normal or reduced	Markedly reduced	Reduced or normal
vWF multimeric analysis	Normal (plasma and platelets)	Absence of large and intermediate-sized multimers in plasma	Absence of large multimers from plasma; normal in platelets	Small multimers or absent multimers in plasma and platelets	Reduction in large multimers caused by "consumption" by platelets
Ristocetin-induced platelet aggregation	Normal or diminished	Diminished	Increased aggregation at low ristocetin concentrations	Markedly diminished	Hyperaggregation with patient's platelets, normal plasma, and low concentration of ristocetin
vWF in platelets	Normal or reduced	Normal or absence of large and intermediate-sized multimers	Normal	Absent	Normal
Ancillary findings	DDAVP usually produces significant increase in plasma VIIIc and vWF	DDAVP produces rise in factor VIIIc, but functional vWF increase is variable and may be of short duration	Variable response to DDAVP, with intravascular platelet aggregation and thrombocytopenia in some cases; ristocetin-induced platelet aggregation enhanced in presence of patient's plasma; cryoprecipitate does not aggregate platelets in vitro unless ristocetin is added	Response to DDAVP lacking; endothelial vWF absent	Transfusion of vWF or DDAVP may produce intravascular platelet aggregation and thrombocytopenia; cryoprecipitate produces in vitro platelet aggregation

DDAVP, 1-deamino-8-d-arginine vasopressin; vWF, von Willebrand factor.

are often missense mutations that change the number of cysteine residues in the vWF protein. Although such changes probably affect vWF synthesis and trafficking in the cell, at least one common mutation (Tyr1584Cys) also results in enhanced degradation by ADAMTS13.[145,146] One non–cysteine-related mutation is seen in vWD Vicenza. In these patients, a mutation encoding for Arg1205His results in accelerated clearance of plasma vWF, with levels of vWF in the range of 15 IU/dl. With DDAVP stimulation, timed plasma sampling revealed that the released vWF had a circulation half-life that was approximately one-sixth of normal.[147] Several other similar mutations have recently also been described.[148]

At higher levels of vWF, linkage of the vWF level to the vWF gene is found less often. The recent European type 1 vWF cohort study demonstrated this observation. Almost all families with vWF levels <30 IU/dl showed linkage to the vWF gene, but the proportion fell to only 51% with vWF levels >30 IU/dl.[98] These data were corroborated in the Canadian study.[146]

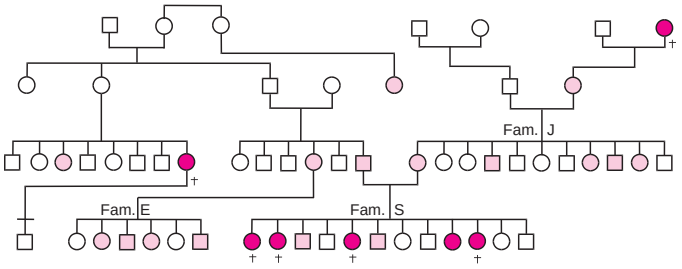

FIGURE 53.6. Pedigree of patients described by von Willebrand. Three families are emphasized: S, E, and J. Clinical details of bleeding events in these families have been reported. *Open circles* indicate female nonbleeders, open squares indicate male nonbleeders. *Shaded circles* and *squares* indicate female and male bleeders, respectively. *Solid symbols* indicate family members who experienced severe bleeding, and crosses indicate family members who experienced hemorrhagic deaths. (Modified from von Willebrand EA. Über hereditäre pseudohämophilie. Acta Med Scand 1931;76:521–550, with permission of the publisher.)

Complete absence of vWF is responsible for the most extreme form of vWD, and this is classified as type 3 vWD.[128] As one might predict, a large variety of genetic abnormalities scattered throughout the vWF gene have been reported in families with type 3 vWD. These have included large gene deletions, small gene deletions, frame-shift mutations, splice-site mutations, nonsense mutations, and point mutations.[149]

Type 2 vWD is characterized by production of a qualitatively defective protein, and the genetics of these variant forms is more straightforward than that of type 1 vWD. In families affected by types 2B and 2M, as well as in the majority of families with type 2A vWD, inheritance is autosomal dominant. Rare cases of type 2A disease are transmitted in an autosomal recessive fashion, as are most cases of type 2N disease. vWF gene sequencing studies combined with vWF mutation-expression analysis has revealed that single missense point mutations underlie the majority of type 2 disorders.[128] Type 3 vWD is also inherited as a recessive trait and occurs when both copies of the vWF gene are defective. In type 3 disease, gene abnormalities include large or partial gene deletions, disruption of orderly messenger RNA transcription (frame-shift mutation, splice-site, or nonsense mutation), and missense mutation. For patients with recessively inherited vWD phenotypes (type 2N, type 3, or some rare type 2A), genetic analysis may reveal either homozygous or compound heterozygous gene abnormalities. Members of the International Society of Thrombosis and Hemostasis maintain a database of vWD mutations (www.vwf.group.shef.ac.uk).

Pathophysiology

The basic defect in vWD is a deficiency or abnormality of vWF function. vWF is synthesized in endothelial cells and

megakaryocytes.[134] The primary transcription product is 2,813 amino acids in length and undergoes extensive further processing, including dimerization and polymerization, to form very-large-molecular-weight "multimers".[134] Multimerization and intracellular trafficking of vWF through the endoplasmic reticulum and Golgi apparatus and into storage granules is directed by the vWF propeptide (vWFpp). vWFpp is cleaved off the "mature subunit" after multimer assembly. Large vWF multimers, which may exceed 20 million daltons in size, are stored in endothelial cells in Weibel-Palade bodies and in platelet α-granules.

The majority of circulating vWF is present in plasma, with a concentration of ~10 μg/ml. The circulating half-life of plasma vWF is ~8 to 12 hours. Approximately 15% of circulating vWF is present intracellularly within platelets. Ultralarge multimers released from endothelial cells into the plasma are further degraded to smaller multimers through the activity of a "vWF cleaving protease".[136] The cDNA sequence identified this protein to be the thirteenth member of the ADAMTS family (a disintegrin-like and metalloproteinase with thrombospondin type 1 motifs, ADAMTS13).[150,151] vWF is cleaved between tyrosine 1605 and methionine 1606 located in the A2 domain.[152] High shear stress and tethering of vWF by platelets most likely enhance exposure of the cleavage site.[153] The physiologic importance of enzymatic degradation of vWF after release is demonstrated clinically by the association of an inherited form of thrombotic microangiopathy (Schulman-Upshaw syndrome) with congenital absence of the protein due to defects of the ADAMTS13 gene,[150] and the observation of plasma deficiency of the protein with presence of autoantibody in most patients with sporadic thrombotic thrombocytopenic purpura.[154] Endothelial cell stores of vWF can be released therapeutically with administration of desmopressin.[155]

vWF is required for normal platelet adhesion (see Chapter 17), and also acts as a carrier of factor VIII in the plasma. When vWF is deficient or aberrant, both factor VIII deficiency and abnormalities in the early steps of primary hemostasis result. vWD is thus manifested as a multifaceted hemostatic defect. Both abnormalities—factor VIII deficiency and abnormal primary hemostasis—give rise to characteristic and distinct laboratory abnormalities, and both defects contribute to the bleeding tendency.

Abnormalities of Primary Hemostasis

Convincing evidence exists that the platelets, although intrinsically normal, do not adhere to subendothelium normally in the setting of deficient or defective vWF.[156] This abnormality is well demonstrated by methods that measure platelet adhesion to subendothelial surfaces under flow conditions (the Baumgartner technique). The physiologic stimulus for interaction of vWF with platelets is not completely defined, but tethering of vWF on exposed subendothelial cell matrix or shear stress may cause vWF to undergo conformational change. Results of experimental studies suggest that in the absence of vWF, platelet adhesion to collagen in a flowing stream of blood may be particularly deficient at high rates of shear, when only a short time is available for formation of a platelet–collagen bond.[157] Deficient platelet plug formation has been observed directly in experimental wounds.[158] In vitro, the interaction of vWF with the platelet GPIb receptor can be induced by addition of the antibiotic ristocetin, by the snake venom protein botrocetin, or by subjecting platelets to high shear stress in the presence of vWF. For the effective support of platelet adhesion, vWF is multimerized into long chains (strings), which can exceed 2 μm in length. Plasma vWF demonstrates a spectrum of sizes; however, the longest vWF multimers are the most efficient at supporting platelet adhesion.[134]

Abnormalities of Secondary Hemostasis

A second function of vWF is as a molecular chaperone for factor VIII, increasing the plasma half-life of factor VIII approximately fivefold.[159] This effect may occur through protection of factor VIII from activated protein C–mediated degradation.[160] Furthermore, the binding of vWF to subendothelium at sites of vascular injury could serve to co-localize factor VIII, where it can participate in its role in the regulation of hemostasis on the activated platelet membrane.[134] It is generally thought that whereas vWF is synthesized in endothelial cells and megakaryocytes, factor VIII is synthesized by hepatocytes. When the drug desmopressin (DDAVP, 1-deamino-8-D-arginine vasopressin) is administered to normal subjects or individuals with mild quantitative deficiency of vWF or factor VIII, levels of both molecules rise. Studies of hemophilia patients and patients with type 3 vWD on replacement therapies suggest that both vWF and factor VIII must be endogenously synthesized in order for there to be coordinated release after DDAVP. The cell responsible for that coordinated synthesis remains controversial.

Response to Transfusion

When blood products containing the vWF–factor VIII complex are infused into patients with hemophilia A, peak levels of factor VIIIc are present immediately after the infusion; this activity then declines rapidly, with an overall half-life of 8 to 10 hours (Fig. 53.7). Twenty-four hours later, factor VIIIc activity is minimal. This response is highly predictable and is discussed in a later section concerning replacement therapy for hemophilia A. In most patients with vWD, the infusion of normal vWF–factor VIII complex produces an initial rise in factor VIIIc that is predicted from the preinfusion level and the amount of factor infused. This is followed by a sustained but variable rise in factor VIIIc activity that reaches a plateau about 24 hours later and may persist for 48 to 72 hours. This phenomenon is highly variable and irregular; in some patients, a rapid initial fall of factor VIIIc is followed by a secondary rise in activity. This disproportionate response to transfused factor VIII has been called the secondary transfusion response, a feature that is apparently unique to vWD. Various hypotheses have been advanced to explain the disproportionate response to transfusion described above. The leading hypothesis is that the infused vWF results in stimulation of increased factor VIII release into the plasma with the attachment of the newly released factor VIII onto infused vWF.[161]

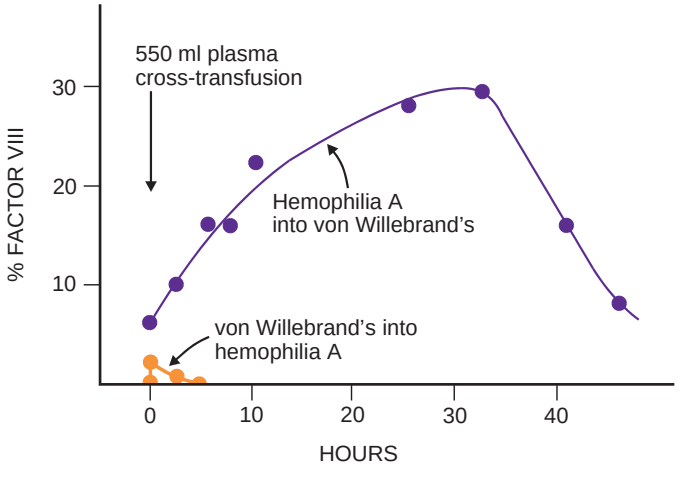

FIGURE 53.7. The phenomenon of new factor VIII synthesis in patients with von Willebrand disease (vWD) who receive plasma transfusion. *Open circles* indicate changes in the plasma factor VIII levels of a patient with vWD after infusion of plasma from a patient with severe hemophilia A. A significant and sustained increase in the factor VIII levels of the recipient was observed even though no active factor VIII was present in the infused plasma. *Solid circles* indicate effects of infusing plasma from a patient with vWD into a patient with severe hemophilia A. The factor VIII level in the infused plasma was 15% of normal. Note the slight and transitory effects. (From Shulman NR, Cowan DH, Libre EP, et al. The physiologic basis for therapy of classic hemophilia (factor VIII deficiency) and related disorders. Ann Intern Med 1967;67:856–882, with permission.)

Transfusions of blood products containing vWF shorten the bleeding time to a variable degree in patients with vWD. This corrective effect seldom persists for more than a few hours, even after massive transfusions that raise vWF to high levels. The correction of the bleeding time apparently requires the large molecular forms of vWF that are present in cryoprecipitate and select intermediate-purity factor VIII concentrates,[162] but that are completely absent from monoclonally purified or recombinant concentrates of factor VIII.[163] Failure of the skin template bleeding time of patients with vWD to show sustained correction with appropriate replacement therapy has been noted, and does not necessarily predict defective surgical hemostasis. This apparent paradox may be a result of sensitivity of the bleeding time test to platelet α-granule vWF, which is not replenished during vWF replacement therapies.[164]

Clinical Manifestations

The bleeding manifestations in vWD are heterogeneous but consistent with the dual roles of vWF in supporting both primary and secondary hemostasis. Thus, in the mild forms of vWD, the clinical picture is dominated by cutaneous and mucosal bleeding, which appears to be mainly the result of disordered primary hemostasis. In the most severe forms of the disorder, in which factor VIII levels are low, hemarthroses and dissecting intramuscular hematomas may develop. As in mild classic hemophilia, serious hemorrhage resulting from traumatic injuries or after surgical procedures is a significant hazard in severe vWD. Petechiae are rare, but hematoma formation and the extent of bruising are excessive compared with the inciting trauma.

The bleeding manifestations in the usual patient with type 1 vWD are mild, however, and many patients are virtually asymptomatic. The disorder may be symptomatic at any age, but it is not always recognized. Easy bruising is common in vWD, but it is not specific. Mucosal bleeding is particularly common. Childhood epistaxis, a life-long history of easy bruising, bleeding with dental extraction, heavy menstrual bleeding or anemia attributed to excessive menstrual blood losses, or postpartum hemorrhage are all included in the spectrum of vWD symptomatology. Systemic bleeding disorders are often not considered in women with menorrhagia,[165] but clinical studies reveal that the prevalence if vWD is significant in individuals who present with this complaint.[166] Angiodysplasia of various vascular beds, particularly those in the gut, has been demonstrated in some patients with vWD and may be an important contributory factor in chronic gastrointestinal bleeding.[167] In type 1 vWD, symptoms usually become milder during pregnancy or with estrogen therapy, when the vWF and factor VIIIc levels rise significantly.[40] The disorder may also decrease in severity with advancing age. Bleeding manifestations tend to be more prominent in patients with more severe quantitative deficiency and in patients with qualitative (type 2) defects.

While eliciting the history of bleeding, one should bear in mind that women are often inaccurate assessors of whether their menstrual flow is normal or excessive. Supplemental questioning regarding the frequency of changes of menstrual protection, and questions regarding a history of iron deficiency anemia and transfusion, may be informative. Retrospective studies of women with vWD show that abnormal bleeding can often be traced to menarche.[168] Family history also may provide important clues to a diagnosis. The physician should specifically seek a history of the response to hemostatic challenge, such as dental extraction, tonsillectomy, surgical procedures, menstruation, peripartum hemorrhage, and transfusion. A model questionnaire with a scoring system has been published.[169] Coexistent conditions or drug effects can strongly influence the severity of bleeding symptoms. Risk of hemorrhage may increase in patients with concomitant liver disease, uremia, gastrointestinal ulcer, or angiodysplasia. Excessive bleeding in response to challenge with aspirin may also point toward a bleeding disorder, but this history is not specific for vWD. Valproic acid use can result in lower vWF activity levels, as may hypothyroidism and valvular heart disease. Conversely, oral contraception frequently ameliorates menorrhagia.[127]

Laboratory Diagnosis

Criteria for the laboratory diagnosis of vWD are imperfect. One goal of applying a series of laboratory evaluations is to exclude other causes of bleeding. When specifically considering vWD, the laboratory evaluation may be complicated. Even with the more elaborate confirmatory tests now available, the diagnosis of this disorder may be difficult and may require repeated observations over a period of time. Both vWF and factor VIII are "acute-phase reactants," increasing with stress, trauma, estrogen therapy, or pregnancy, such that levels may fluctuate from time to time. Evaluation of a patient at a time remote from acute infection, pregnancy, or strenuous activity is preferable. However, pregnancy and acute-phase reaction are unlikely to obscure diagnosis in patients with more severe quantitative deficiency or qualitative defects.

Diagnosis of vWD is complicated, because of both the breadth of vWF functions and the spectrum of disorders that constitutes vWD. Consequently, a battery of studies should be considered to evaluate a patient conclusively for vWD.[134] Screening tests such as bleeding time, Platelet Function Analyzer-100 (PFA-100), and PTT lack sensitivity; specific tests such as those for vWF antigen, vWF activity, and factor VIII level are preferred. Correlating the values of these various quantitative assays with each other, or obtaining qualitative tests such as vWF multimer analysis or low-dose ristocetin–induced platelet aggregation, may provide important clues toward a diagnosis of type 2 vWD (Table 53.7).

Bleeding Time and Platelet Function Analyzer-100

The template bleeding time, the Ivy bleeding time, or technical modifications thereof may be useful in detecting the abnormality characteristic of vWD. However, the bleeding time may be normal in many patients with vWD.[170] Consequently, the bleeding time adds to the diagnosis of vWD if it is prolonged, but otherwise may have little clinical utility in the diagnosis and management of patients with vWD. The bleeding time may not improve following replacement therapy with vWF, and monitoring is generally not recommended,[171] because surgical bleeding can generally be prevented by replacement of plasma vWF.

Standardization issues, inconvenience, and residual scarring of patients are some of the issues that have fostered development of in vitro tests to replace the bleeding time. The PFA-100 evaluates platelet adhesion and aggregation to collagen in a whole-blood assay under high shear conditions.[172] Citrate-anticoagulated whole blood is aspirated through an aperture in a collagen-coated membrane, and the device measures the time from first flow until flow ceases as the "closure time." PFA-100 closure times are sensitive to multiple factors, including vWF function, platelet count, platelet function, and hematocrit. Initial studies using the PFA-100 in patients with diagnosed vWD indicated that the assay was sensitive to most forms of vWD. However, when the closure time test was applied in clinical settings where patients were referred for evaluation of bleeding symptoms, the sensitivity of the PFA-100 for diagnosis of vWD ranged from 62% to 80%, with specificity ranging from 84% to 89%.[173,174] In addition, the closure time may remain normal in acquired vWD despite a very reduced plasma vWF level, because the platelet vWF level may remain normal. The PFA-100 closure time may also be normal in patients with type 2N vWD, in which the major defect is low factor VIII levels. As with the bleeding time, correction of plasma vWF level in the absence of concomitant correction of the platelet vWF may be insufficient to correct the closure time, so this test may not be very helpful for perioperative monitoring of patients on replacement therapy.[175,176]

Partial Thromboplastin Time and Factor VIIIc Assay

Among the simple screening tests (Table 53.5), the PTT may be abnormal, reflecting reduced levels of factor VIIIc. Plasma levels of factor VIIIc vary greatly in this disorder and range from as low as 3 IU/dl in patients with type 3 vWD to normal levels in patients with mild type 1 vWD. Because factor VIIIc deficiency is often mild in patients with vWD, a diagnosis of vWD may be missed by the routine screening PTT. Consequently, a specific assay is required to reliably detect factor VIIIc deficiency in patients with vWD.

von Willebrand Factor Immunoassay

The immunoassay of vWF is a quantitative measure of vWF protein that is one of the most sensitive methods available for the diagnosis of vWD.[177] A variety of methods have been used, all of which depend on antibodies specific to vWF. The electroimmunodiffusion method of Laurell was initially widely used because it was simple to perform, but ELISA or automated assays using related methodologies have now largely replaced this technique. Average levels of vWF antigen (vWF:Ag) obtained by different laboratories will vary, but a level of ~45 to 50 IU/dl is the lower limit of normal reported by many laboratories. The ratio of factor VIII to vWF also varies by laboratory but normally ranges from ~0.7 to 2.2 (Fig. 53.1). Plasma levels of vWF:Ag are regulated to some extent by carbohydrate residues attached to the protein; ~25% lower vWF antigenic levels have been noted in patients with blood type O compared to patients with other blood types.[139] The contribution of blood group O is more marked in patients with mild quantitative vWF deficiency, where the low vWF level is less likely to be related to abnormalities of the vWF gene.[145,146] Whether these patients actually have vWD type I is subject to debate, and the role of blood group in the diagnosis of vWF deficiency remains to be resolved.[128] Patients with type 2 vWD may have normal vWF:Ag levels, emphasizing the need to use more than just a vWF antigen assay to evaluate a patient for vWD.

von Willebrand Factor Functional Assays

vWF has multiple functions, and assays have been devised to specifically evaluate many of these. The function most often clinically assessed is its ability to interact with platelets. An assay that evaluates the ability of vWF to interact with collagen has also been proposed as a functional assay. The relevance of collagen-binding activity analysis is questioned for routine screening, and collagen-binding activity assay has not gained widespread acceptance in the United States.[178] Finally, vWF binding of factor VIII can be assessed in special circumstances when questioning whether mild factor VIII deficiency is due to failure of vWF chaperone function. vWF functional assay generally correlates well with vWF:Ag in patients with quantitative disorders of vWF. Observing a discrepancy between vWF function and vWF:Ag provides a useful clue for qualitative defects, provided that the testing laboratory uses the same control plasma for determining both assays.[179]

Ristocetin Cofactor Activity and Ristocetin-induced Platelet Aggregation

The assay for ristocetin cofactor activity (vWF:RCo) is a quantitative technique for estimating the ability of vWF in patient plasma to bind target platelets that are specially prepared or preserved for use in the assay.[180] Ristocetin induces an activated conformation of vWF such that it will then bind platelets via the platelet GPIb receptor, mimicking the in vivo sequence of events that allows interaction between subendothelial tissue–bound vWF and platelets. Quantitation of vWF:RCo is held to be the single most sensitive and specific assay for vWD by multiple authorities.[181–183] vWF:RCo activity is adversely affected by loss of the larger-molecular-weight vWF multimers. The discrepancy between vWF:RCo and vWF:Ag that is observed in qualitative defects characterized by loss of both the intermediate- and higher-molecular-weight multimers (such as type 2A vWD) is thought to result from this. Ristocetin cofactor activity is also generally utilized to follow a vWD patient's response to therapeutic interventions. However, obtaining typical ristocetin cofactor activity is a time-consuming procedure, and assay standardization remains somewhat problematic. Automation of the vWF:RCo assay has resulted in a clinically more available, but less sensitive technique, which requires modification to detect levels below ~10 to 20 IU/dl. Simpler ELISA-based methods using monoclonal antibody to the GPIb-binding domain of vWF have been explored for estimating vWF activity.[184] Unfortunately, commercial functional epitope assays have not performed sufficiently well to allow them to replace vWF:RCo assay,[185,186] and these assays do not measure the increased functionality of the larger vWF multimers directly.

Ristocetin-induced platelet aggregation (RIPA) is a distinct test from ristocetin cofactor activity. RIPA is a qualitative test that involves evaluating the rate or extent of agglutination of patient-derived platelet-rich plasma in response to the addition of the antibiotic ristocetin. The concentration of vWF and platelets present in the test plasma, as well as the amount of ristocetin added, affect RIPA. The assay is relatively insensitive to mild deficiency of vWF, but decreased aggregation response is observed in both more severe deficiency and in patients with Bernard-Soulier syndrome (in which platelets are missing the GPIb receptor). Titrating down the amount of ristocetin added in the assay may be of specific interest in defining variants of vWD in which there are "gain of function" mutations (type 2B and platelet-type [pseudo] vWD). These two conditions are characterized by increased sensitivity of patient vWF or platelets to the effect of ristocetin.[128] However, insensitivity of patient samples to low-dose ristocetin aggregation is seen in occasional patients with type 2B vWD in whom there is marked reduction in the amount of high- and intermediate-molecular-weight multimers, and genetic analysis may be required to distinguish some cases of type 2B from type 2A vWD. In addition, low-dose ristocetin aggregation of patient-derived platelet-rich plasma cannot differentiate type 2B vWD from the rarer platelet-type (pseudo) vWD, and mixing studies using patient plasma and donor platelets have been devised to help make that distinction at the phenotypic level.[187]

von Willebrand Collagen–binding Activity

vWF contains collagen-binding sites in both the A1 and A3 domains of the vWF protein, and collagen-binding activity (vWF:CB) may be an important function that allows vWF to adhere to platelets at sites of vascular injury. Like ristocetin cofactor activity, vWF:CB is dependent on multimer size, with the larger multimers binding collagen more avidly. The assay is generally done in an ELISA format, in which type I and/or type III collagen is plated into microtiter wells, and the amount of vWF captured is assayed.[188] vWF:CB correlates well with vWF:Ag in normal individuals and those with quantitative deficiency of vWF, and discrepant results are indicative of vWD subtypes that are characterized by deficiency of larger vWF multimers. A single case of vWD characterized by mutation of the vWF A3 domain with isolated loss of collagen-binding function despite the presence of a normal multimer distribution has been described.[189] Although some studies suggest that vWF:CB testing complements assays of vWF:Ag and vWF:RCo in distinguishing type 1 vWD from type 2A and 2B variants, the role of vWF:CB testing in routine clinical practice remains to be determined.[127,178,190]

Assay of von Willebrand Factor's Ability to Bind Factor VIII

Factor VIII binding by vWF (vWF:FVIIIB) can be measured in a few reference coagulation laboratories, and is indicated for the evaluation of patients suspected of having factor VIII deficiency on the basis of defective vWF chaperone function (type 2N vWD).[191] In this ELISA format assay, ELISA plate wells are coated with antibody to vWF in order to capture vWF from patient plasma. After washing patient-derived factor VIII from the well, the ability of patient-derived vWF to capture r-FVIII is assessed using a chromogenic or immunoassay for factor VIII, and the quantity of patient-derived vWF:Ag in the well is quantified by standard ELISA technique. The calculated ratio of captured r-FVIII to vWF:Ag is expected to be in the normal range when testing plasma from a patient with hemophilia A, whereas it will be abnormally low in the rare cases of type 2N vWD.[192]

Multimeric Analysis of von Willebrand Factor

Normal vWF in plasma consists of a complex series of multimers, ranging in size from about 500 to 20,000 kDa. vWD initially diagnosed by abnormal assays for factor VIIIc, vWF antigen, or ristocetin cofactor activity should be further characterized by multimeric analysis. In this test, the spectrum of vWF molecular sizes of the patient's vWF is assessed by size-based separation of vWF multimers via agarose gel electrophoresis, and vWF multimers are imaged by immunologic methods coupled to autoradiography or other detection methods.[193] Multimer analysis is characterized as either "low-resolution" (which differentiates the largest multimer forms from the intermediate and smaller forms), or "high-resolution" (which resolves each multimer band into three to five satellite bands), which inform on the activity of ADAMTS13 on plasma vWF. Multimer analysis will confirm the presence of the entire spectrum of vWF multimers in normal individuals and those with type 1 vWD, and allows identification of the loss of intermediate- or high-molecular-weight multimers of vWF as is characteristic of the type 2A and type 2B qualitative defects.[193] Unfortunately, the distinction between type 2A and type 2B vWD is not always possible using multimer analysis alone, necessitating further testing. Multimeric analysis is a very labor-intensive test and is usually performed only in coagulation reference laboratories. The multimeric composition of plasma from normal subjects and patients with vWD is shown in Figure 53.8. This methodology has been reviewed.[194]

Genetic Testing in von Willebrand Disease

Direct mutational analysis by vWF gene sequencing, allele-specific PCR, or restriction enzyme analysis is useful in confirming a diagnosis of type 2 variant vWD.[195] The functional domain structure of the vWF gene results in clustering of the various type 2 vWD defects in limited areas of the vWF sequence.[128] vWF exon 28 encodes for the A1 loop of vWF responsible for the interaction of vWF with platelet GPIb, and vWD variants characterized by defects of this interaction (types 2B and 2M) are encoded by genetic mutations clustered in this exon.[196] Exon 28 also encodes the A2 domain, which contains the ADAMTS13-sensitive bond tyrosine1605–methionine 1606. Mutations that increase the susceptibility of this bond to cleavage by ADAMTS13 underlie a high fraction of type 2A vWD (previously classified as 2A, subtype 2). Less commonly, type 2A vWD results from a defect of the multimerization process. The carboxy terminus of the vWF peptide (encoded by exons 51 to 52) is involved in initial vWF dimer formation in the rough endoplasmic reticulum. The vWFpp (encoded by exons 3 to 17) directs further multimerization via cross-linkage of the amino-terminal D′ and D3 of the mature vWF protein (encoded by exons 18 to 28). As one might expect, type 2A vWD on the basis of failure of multimerization (previously classified as 2A, subtype 1) has been attributed to genetic abnormalities in each of these regions of the genome. Mutations responsible for defective interaction of vWF with factor VIII (type 2N vWD) are predominantly clustered in exons 18 to 20, which encode for the factor VIII–binding domain of vWF; however, rare cases have been attributed to mutations in exons 24 and 25. An online database of defects found in vWD patients can be accessed at www.vwf.group.shef.ac.uk. Figure 53.5 shows the location of these various genetic abnormalities schematically. Rapid, complete vWF gene sequencing has been reported.[197]

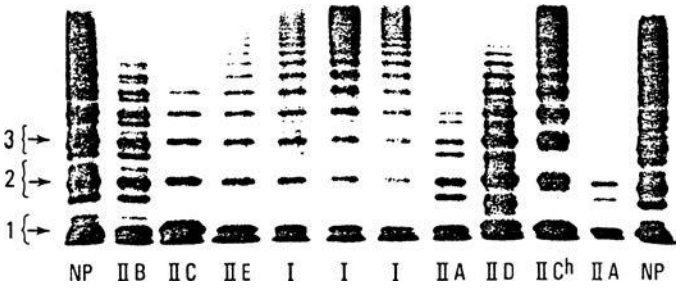

FIGURE 53.8. Multimeric composition of von Willebrand factor from normal plasma and that from types I, IIA, IIB, IIC, IID, and IIE von Willebrand disease (vWD), as well as from a type IIC heterozygote (IICh). Using the revised classification scheme, these types would correspond to 1, 2A, 2B, 2A, 2A, and 2A, respectively. The three brackets include the smallest normal oligomers, with arrows pointing to the central predominant band in each. In type 1 vWD, the relative concentration of large multimers varies. (From Zimmerman TS, Ruggeri ZM. von Willebrand disease. Hum Pathol 1987;18:140–152, with permission.)

Genetics of Type 1 and Type 3 vWD

Mild to moderate quantitative deficiency of vWF characterizes patients with type 1 vWD, whereas virtual absence of vWF characterizes type 3 disease. Genetic analysis is not generally required to make these diagnoses, but may provide useful additional information concerning pathogenesis of a patient's condition, responsiveness to DDAVP, or risk for alloantibody formation. In distinction from type 2 vWD, genetic defects underlying quantitative vWF deficiency are distributed throughout the vWF gene, complicating evaluation. In addition, for families with patients who demonstrate normal multimer structure and higher vWF levels, the chances of finding linkage to the vWF gene are reduced,[145,146] and family members are usually asymptomatic.[137] Type 3 patients with large gene deletions are particularly prone to develop anti-vWF alloantibodies after treatment with vWF-containing concentrates.

Type 1 von Willebrand Disease and "Low von Willebrand Factor"

Patients with bleeding attributed to decreased production of qualitatively normal vWF are classified as having type 1 vWD. Most patients with vWD (70% to 80%) fall into this category.[134] The majority of patients have a mildly symptomatic disorder, but bleeding may increase with physical trauma, surgery, or during menstruation. vWF levels are low, with concordant reduction of vWF:Ag and vWF:RCo (and vWF:CB, if that is measured). Factor VIII levels are generally equal to or higher than vWF levels, and all vWF multimers should be present if that analysis is performed as part of the patient evaluation. The diagnosis of type 1 vWD may be simpler in an individual with mucosal bleeding symptoms, a strong family history of similar symptoms, and quantitative vWF level (vWF:Ag and/or vWF:RCo) <30 IU/dl. Although not required for a diagnosis of type 1 vWD, the probability of finding linkage of the phenotype to the vWF gene in such an individual would be high, such that both therapeutic choices and genetic counseling would be straightforward.

Unfortunately, many factors make the diagnosis of type 1 vWD difficult.[144] Mild bleeding symptoms are common in hemostatically normal people (see Chapter 45). In addition, the relative risk of bleeding for individuals with only modest reductions in vWF level appears to be minimal. Finally, because of the strong influence of blood group on vWF levels, there is a high prevalence of blood group O among individuals with mildly depressed vWF levels. These observations have led to the recent proposal of the concept of "low vWF".[137,144] The term "low vWF" could be applied to patients with vWF levels below the normal reference range but above some lower limit. A recently convened "expert group" brought together by the National Heart, Lung and Blood Institute is considering this proposal.[129] Studies of families of patients with a diagnosis of type 1 vWD suggest that linkage to the vWF gene is less often seen when the vWF level rises above 30 IU/dl, suggesting that this might be a candidate for the lower limit of the "low vWF" category.[145,198] Empiric therapy to raise vWF levels in patients with "low vWF" at times of hemostatic challenge would be reasonable for patients with a history of bleeding, but the genetic counseling issues would clearly be different.[144]

On the other hand, two population-based studies have shown that "low vWF" causes increased bleeding.[199,200] These latter studies would suggest that abnormally low ristocetin cofactor activity, and not the presence of a mutation, should primarily be used to identify bleeders.

Type 3 von Willebrand Disease

Type 3 vWD is the most severe form of vWD, because it results from complete failure of vWF synthesis. This bleeding disorder is generally diagnosed during infancy. Hematoma formation is common, epistaxis may be life-threatening, and hemarthrosis may occur as a result of the low factor VIII levels that are seen in this condition. Plasma from patients with type 3 vWD contains virtually no detectable vWF, and vWF is not present in either platelets or endothelial cells. Factor VIII level is generally in the range of 1 to 10 IU/dl, similar to that seen in moderate to mild hemophilia A. Multimeric analysis of the little vWF present yields variable results, in some cases revealing only small multimers.[193] Type 3 vWD is rare, with an estimated frequency of 1 in a million people.[201] Genetic analysis reveals either homozygous or compound (double) heterozygous defects of the vWF gene, with gene deletions, frame-shift mutations, missense mutations, or nonsense mutations. Careful laboratory evaluation of the parents of patients with type 3 disease may reveal mild quantitative deficiency of vWF. In a review of 117 obligate heterozygotes, the mean plasma vWF level was 45 IU/dl, with a range from 5 to 130 IU/dl.[144] Parents are frequently asymptomatic, consistent with the impression that type 3 disease is inherited as a recessive trait. Consanguinity is common in kindreds with this variant. In some patients with type 3 vWD, large gene deletions have been identified on one or both vWF alleles.[128,202] Such patients are at increased risk of developing inhibitory alloantibodies to vWF after transfusion therapy.[202]

Because these patients lack vWF in their endothelial cells and platelets, there is no rise in vWF level in response to DDAVP. For replacement therapy, these patients require vWF-containing concentrates. This is usually provided in the form of specific intermediate-purity factor VIII concentrates that have been documented to contain intact vWF.[155] Because these patients possess a normal *factor VIII* gene but are missing the vWF chaperone, posttransfusion factor VIII recovery and survival may be longer in a patient with type 3 vWD than in a patient with hemophilia A, owing to endogenous factor VIII production. Although life-threatening bleeds require immediate replacement of both vWF and factor VIII, replacement with vWF alone may be sufficient if therapy is begun 12 to 24 hours before elective surgery.[203]

Qualitative Defects of von Willebrand Factor

Several subsets of patients with vWD differ substantially from those with the common quantitative deficiency states (Table 53.6).[128] Classified as type 2 variants, these qualitative defects of vWF are less common, but they may represent up to 20% to 25% of cases of vWD. Type 2 forms of vWD are suspected when the severity of the patient's symptoms seems in excess of the observed vWF and factor VIII levels, when there is discordant reduction between vWF antigen and vWF functional activity or factor VIII assay, or when there is concomitant vWF deficiency and thrombocytopenia. Discrimination between qualitatively normal and abnormal vWF can be difficult; however, when the ratio of vWF:RCo to vWF:Ag or vWF:CB to vWF:Ag is found to be <0.6, dysfunctional vWF should be considered. The sensitivity and specificity of such ratio screening depends to a large extent on the expertise and precision of the laboratory performing the assays, but the predictive value of ratios decreases when the level of vWF antigen is <20 IU/dl. Examining the structure of patient vWF may provide further definition of the nature of the qualitative defect. This can be demonstrated by vWF multimer analysis. If required, further information is provided by supplemental studies of vWF function, or via genetic analysis of the vWF gene (Fig. 53.5).[126,128,193] Type 2 defects were initially classified using a Roman numeral system, but further understanding of the genetics of vWD led to the consolidation and reclassification into types 2A, 2B, 2M, and 2N,[128] based on the nature of the vWF functional defect. In addition to the well-defined variants described in this chapter, other forms of vWD continue to be described.

Type 2A von Willebrand Disease

vWD with defective interaction of vWF with platelets due to deficiency of intermediate- and high-molecular-weight forms of vWF is classified as type 2A vWD.[128] This form of the disorder is generally inherited as an autosomal dominant trait,[204] and it accounts for the majority of patients with type 2 defects. Levels of factor VIIIc and vWF:Ag in the plasma may be normal or reduced. The vWF activity as assayed by either vWF:RCo or vWF:CB is significantly lower than vWF:Ag because of the absence of the larger multimers (which are more potent in their ability to interact with platelet GPIb and collagen). Analysis of vWF multimers reveals a relative reduction in intermediate- and high-molecular-weight species.[127] Protein studies followed by genetic analysis of the basis of type 2A vWD revealed multiple mechanisms for the generation of this disorder.[205–207] In some patients, there is failure to synthesize full-length multimers (type 2A, subgroup 1). Mutations associated with impaired vWF multimerization have been localized to the vWFpp (formerly called type IIC), the region of the mature vWF protein associated with the amino terminus area of multimer formation (formerly called type IIE), and the carboxy terminus region that is involved in initial dimer formation (formerly called type IID). Subtle abnormalities uncovered by high-resolution multimer analysis or genetic evaluation can be used to distinguish these subtypes of type 2A vWD. The spectrum of multimers released into plasma after DDAVP administration would not be expected to improve significantly in these patients whose defects prevent normal multimer assembly.

A second group of type 2A patients has been described in whom there is excessive catabolism of fully multimerized vWF after vWF is released into the plasma. These patients demonstrate mutations in exon 28, encoding the A1 and A2 regions of vWF. These mutations allow increased proteolysis of multimerized vWF by ADAMTS13. Again, high-resolution multimer gel studies may be informative by demonstrating increased "satellite" band intensity, which accumulates as a result of excessive ADAMTS13 activity. Because intracellular vWF is protected from cleavage by ADAMTS13, these patients may demonstrate very transient

improvement in both vWF:RCo and multimer spectrum after DDAVP administration.

Inheritance of type 2A vWD is generally autosomal dominant, with the majority of cases caused by mutations clustered in the region of exon 28, which encodes the vWF A2 homologous repeat (Fig. 53.5).[128] Rare recessive forms of type 2A vWD have been reported with some multimerization defects (formerly called types IIC and IID).

Because of the underlying structural abnormality of the vWF produced in these patients, neither stress nor pregnancy significantly increases the functional amount of vWF protein in the plasma. As noted above, the administration of DDAVP does not result in a significant rise in vWF:RCo in patients with type 2A vWD, in which the underlying mechanism is defective multimerization or transport, but a very short-lived correction may be observed in patients with mutations associated with increased vWF cleavage by ADAMTS13.

Type 2B von Willebrand Disease

Type 2B vWD is a paradoxical bleeding disorder, characterized by increased interaction of patient vWF with platelets which is demonstrated in vitro in the presence of low doses of ristocetin. Increased in vivo interaction of the larger multimers of type 2B vWF with platelets is thought to result from mutations that either allow increased access of platelets to the A1 loop of vWF or that stabilize that interaction.[127] This may in turn allow increased generation of vWF–platelet complexes, which are subsequently cleared from circulation, resulting in thrombocytopenia.

This bleeding disorder is characterized by deficient vWF function attributable to mild reduction of vWF:Ag, a somewhat more marked deficiency of vWF:RCo activity (and vWF:CB, if measured). Multimeric analysis reveals a deficiency of the highest-molecular-weight vWF multimers. Measurements of factor VIIIc are variable. Many patients with the type 2B variant have mild persistent thrombocytopenia.[208] The platelet count may fall further during physiologic stresses, pregnancy, in association with surgical procedures, or after the administration of DDAVP.[209]

Additional laboratory evaluation is required to support a diagnosis of type 2B vWD. In most cases, multimeric analysis reveals absence of higher-molecular-weight forms of plasma vWF, but distinction of type 2B from type 2A vWD is not possible by multimeric analysis alone. To show the distinct "gain in function" in type 2B disease, RIPA studies are done to reveal enhanced interaction of patient vWF and platelets with low doses of the drug. Finally, to differentiate the more common type 2B vWD from the rare platelet-type (pseudo) vWD, one should prove that the defect resides in vWF. This is done either through performing mixing studies of patient plasma with donor platelets[187] or by analysis of the patient's vWF gene.

Type 2B vWD is inherited as an autosomal dominant trait. A small cluster of mutations within the portion of vWF exon 28 that encodes the vWF A1 domain that interacts with platelet GPIb accounts for all the cases of type 2B vWD that have been reported (Fig. 53.5).[128]

Recent studies evaluating a large number of patients with type 2B vWD mutations revealed diversity in laboratory findings.[210] Not all patients had reduced vWF:RCo activity or abnormal multimeric analysis, and not all patients had thrombocytopenia.[210] Type 2B patients with normal multimers did not develop thrombocytopenia.

Type 2M von Willebrand Disease

The type 2M vWD variant is defined by diminished platelet-dependent vWF function that is not attributed to deficiency of vWF multimers.[128] Thus, these patients have an initial laboratory profile that in many ways is similar to that of patients with type 2A vWD, revealing variable deficiency of vWF:Ag but disproportionately decreased interaction of vWF with platelets in the presence of ristocetin as measured by vWF:RCo assay. Factor VIII level is proportionate to the vWF:Ag, and the platelet counts are normal. What differentiates type 2M vWD from the type 2A patients is that the vWF multimeric analysis is normal (and, if measured, the vWF:CB is usually similar to the vWF:Ag). Type 2M vWD is inherited as an autosomal dominant trait, and, when investigated, mutations have been found in the region of exon 28 that encodes the A1 domain of vWF. Unlike the type 2B mutations, 2M mutations cause impairment of the binding of vWF to the GP1b receptor and have been shown to be localized to an alternative area in the A1 domain (Fig. 53.5).[196]

One case classified as a type 2M defect was described in which the vWF interaction with collagen was defective. In that case, a mutation in the A3 domain that contributes to the interaction of vWF with collagen was found.[189]

Type 2N von Willebrand Disease

Mutations affecting the association of vWF with factor VIII can result in "autosomal hemophilia" in which factor VIII levels are significantly reduced relative to vWF.[128] Affected patients have factor VIII levels in the range of 5 to 30 IU/dl, attributed to mutations at the factor VIII–binding site near the amino terminus of the vWF subunit.[211] Indeed, genetic studies indicate that the majority of mutations underlying type 2N vWD involve vWF exons 18, 19, and 20, which encode the bulk of the factor VIII–binding domain of vWF. The other functions of vWF in patients with type 2N vWD are qualitatively normal, and thus vWF laboratory parameters (vWF:Ag, ristocetin cofactor activity, etc.) are usually normal (unless there is coinheritance of type 1 vWD). This variant was originally named vWD Normandy but has been renamed type 2N vWD in the revised classification.[128] The factor VIII–binding defect in these patients is inherited in an autosomal recessive manner, and thus affected patients must inherit 2N alleles from each of their two parents, or inherit type 1 vWD from one parent while inheriting a 2N allele from the other. Patients with factor VIII deficiency and a bleeding disorder that is not clearly transmitted as an X-linked disorder or who demonstrate an unexpectedly short in vivo survival of infused factor VIII should be evaluated for type 2N vWD.[212] Diagnosis requires performance of an assay that assesses the interaction of factor VIII with vWF,[191,192] or genetic studies of the vWF gene. A survey of almost 400 unrelated patients with either hemophilia A or type 1 vWD indicated a prevalence of type 2N vWD in these patient populations of 3% and 1.5%, respectively.[213] Consideration of this diagnosis is important because both therapy and genetic counseling are distinct from that of mild hemophilia A.

Platelet-type (Pseudo) von Willebrand Disease

Platelet-type (pseudo) vWD resembles type 2B vWD in most respects, except that the basis for platelet-type vWD is a structural defect in platelet GP1b[214] rather than a defect of vWF (thus platelet-type [pseudo] vWD is a form of platelet dysfunction). However, as with type 2B vWD, a genetic defect results in increased interaction between GP1b and vWF. Phenotypically, platelet-type (pseudo) vWD is manifested by mild thrombocytopenia, a prolonged bleeding time, and variable deficiency of plasma vWF and factor VIIIc. The reductions in plasma vWF and factor VIIIc may be a result of the attachment of these proteins to platelets that are subsequently removed from the circulation. This "consumption" of vWF and platelets results in preferential loss of high-molecular-weight multimers from patient plasma.[214] In vitro platelet aggregation studies reveal platelet agglutination at unusually low concentrations of ristocetin. Spontaneous intravascular platelet clumping may also occur. Platelet-type (pseudo) vWF is inherited as an autosomal dominant trait in most families.[214,215]

Distinction of platelet-type vWD from type 2B vWD is based on showing that the enhanced interaction of platelets with vWF is either platelet-based or resides in the plasma phase (type 2B vWD).[216] This can sometimes be demonstrated through low-dose ristocetin–based agglutination assays using mixtures of normal donor and patient samples, or genetic analysis can be used. To date, all cases of platelet-type vWD have been traced to genetic variations of platelet GPIbα.[217] These include missense mutations that alter the amino acid sequence from Gly233 to Met 239. This region of the protein adopts a β-sheet conformation after interaction with vWF, and these mutations may function to stabilize this conformation.[218] In addition, a 27-bp gene deletion that encodes for deletion of proline 421 through serine 429 has been shown to underlie platelet-type vWD in one kindred. Thus, genetic analysis of the GPIbα gene could confirm a diagnosis of platelet-type vWD in cases in which phenotypic studies were unsuccessful.

CLINICAL DISORDERS OF THE FIBRINOGEN MOLECULE

The clinical disorders of fibrinogen are complex, and depending on the types of mutation may present with bleeding or with thrombotic symptoms, or both. These disorders can be divided based on whether the defect is predominantly a quantitative or qualitative abnormality of the fibrinogen molecule.[219,220] Quantitative abnormalities are disorders associated with the complete absence of fibrinogen (afibrinogenemia) or with low levels of fibrinogen (hypofibrinogenemia). Qualitative abnormalities are disorders resulting from synthesis of an abnormal fibrinogen molecule (dysfibrinogenemia) with altered functional properties.[219,220–222] Dysfibrinogenemia may be asymptomatic and identified only through laboratory studies, or it may be associated with either hemorrhagic or thrombotic consequences.

Fibrinogen is a 340-kDa plasma protein that circulates at a concentration of 1.5 to 3.5 mg/ml. It is a symmetric disulfide-linked dimer with a central E domain linked via "coiled coil" peptide chains to outer D domains.[223] Each half-molecule consists of a set of three different peptide chains, termed Aα, Bβ, and γ, which are linked at their amino termini by disulfide bonds to form the E domain. The D domains are formed by disulfide linkages near the carboxy termini of the peptides. Fibrinogen is synthesized in hepatocytes[224] by coordinated expression of three separate genes on chromosome 4.[225] The rate-limiting step in fibrinogen synthesis is transcription of the Bβ gene. Fibrinogen is an acute-phase reactant, and levels may rise considerably with inflammation. The circulation half-life of plasma fibrinogen is ~4 days. Fibrinogen participates in multiple physiologic processes, including fibrin clot formation mediated by the enzymatic activities of thrombin and factor XIIIa, and cohesion of activated platelets through interaction with the GP IIb/IIIa receptor. Fibrinogen also acts as a plasma carrier for factor XIII. Fibrinogen physiology has been reviewed.[223]

The congenital disorders of fibrinogen associated with afibrinogenemia and hypofibrinogenemia are reviewed in the next section, followed by a discussion of the dysfibrinogenemias. Afibrinogenemia is a very uncommon condition. The first case was described in 1920 (reviewed in Ref. 226), and ~300 cases have been reported since then (see database at isth.org). Congenital hypofibrinogenemia was first reported in 1935 (reviewed in Ref. 227), and at least 40 cases have been reported in the literature. However, it is likely that many of the cases of hypofibrinogenemia were actually cases of dysfibrinogenemia with a reduced level of circulating clottable fibrinogen. Congenital disorders of fibrinogen are rare, and, in practice, most commonly observed disorders are acquired as a result of liver disease or consumptive processes.

Pathogenesis of Quantitative Fibrinogen Disorders

In congenital afibrinogenemia and hypofibrinogenemia, defects in synthesis, secretion, or intracellular processing of the final gene product result in deficiency of plasma fibrinogen.[228] When newly synthesized fibrinogen is not secreted, the protein may accumulate in the rough endoplasmic reticulum of hepatocytes or other cells, resulting in amyloid-like accumulations.[229] In both afibrinogenemia and hypofibrinogenemia, the fibrinolytic system and other coagulation pathways are completely normal. Similarly, there is no evidence of blood coagulation activation, which could cause consumption, or degradation of the fibrinogen molecule. The fibrinogen gene locus is located on chromosome 4; it contains three distinct genes that encode for the Aα, Bβ, and γ peptide chains that compose the fibrinogen molecule.[230] The inheritance pattern of afibrinogenemia is autosomal recessive in nature,[227] and many reported cases are the result of consanguineous relationships between asymptomatic parents with symptomatic homozygote offspring. The molecular basis for quantitative fibrinogen disorders has been reviewed.[231] Genetic defects are scattered throughout the three fibrinogen genes that code for the three polypeptide chains—Aα, Bβ, and γ. Multiple genetic defects have been reported, including deletions, point mutations, missense mutations, and uniparental isodisomy.[231] Deletion of an 11-kb region of the fibrinogen α gene appears to be a recurrent finding in unrelated families from both Europe and the United States.[232] A database of genetic defects that have been identified in patients with congenital fibrinogen abnormalities is accessible at www.geht.org/databaseang/fibrinogen. An unexpectedly large number of individuals with congenital fibrinogen disorders have been described in southern Iran.[233]

Afibrinogenemia

Inherited afibrinogenemia is a rare autosomal recessive disorder, with an estimated frequency of 1 in a million individuals.[232] It is somewhat of an anomaly that patients who are afibrinogenemic have little hemorrhage, despite the fact that their blood cannot clot normally. This may in part be due to the presence of functional vWF, which allows platelet adhesion and aggregation, with the formation of loose thrombi even in the absence of fibrinogen.[234] A similar phenotype was recently described for afibrinogenemic mice created by gene-targeted knockout.[235] In patients with afibrinogenemia, life-threatening hemorrhages do occur, but in many situations the bleeding is not as severe as is seen in hemophilia. The diagnosis is often made early in infancy, when prolonged umbilical stump bleeding occurs.[236] A major cause of death is intracranial hemorrhage during infancy or childhood.[237] The clinical manifestations include mucosal membrane bleeding, such as epistaxis, menorrhagia, or gastrointestinal hemorrhage. A review of the cases entered into the North American Rare Bleeding Disorder Registry indicated that most bleeding events were triggered by trauma, with only 20% to 30% occurring spontaneously.[238]

Increased incidence of first-trimester abortion, placental abruption, and postpartum hemorrhage have been observed in patients with afibrinogenemia.[239] Fetuses of female afibrinogenemic patients rarely reach full term unless replacement therapy is given.[240] Although 20% of afibrinogenemic patients are affected with hemarthrosis, the severity is generally less than that seen in patients with hemophilia. Replacement therapy for patients with afibrinogenemia is available,[241,242] although there may be some concern with increased risk of thrombosis during therapy. Transgenic afibrinogenemic mice demonstrate abundant thrombus formation in a vascular injury model.[234] The basis for this is not well understood, but may be in part related to the fact that fibrinogen has non–substrate-binding sites for thrombin that

could potentially modulate thrombin availability to activate platelets.[243] Patients with congenital hypofibrinogenemia do not typically have any spontaneous bleeding unless the fibrinogen level is <50 mg/dl. These patients may actually have hypodysfibrinogenemia, which is discussed in a later section of this chapter.

Laboratory Diagnosis

Screening coagulation tests from afibrinogenemic and hypofibrinogenemic patients typically show a marked prolongation of all tests where the endpoint is the appearance of fibrin clot, as severe fibrinogen deficiency renders plasma nonclottable. These tests include the PT, PTT, thrombin clotting time, and reptilase time. These test abnormalities, when due to functional deficiency of clottable fibrinogen, are usually corrected when patient plasma is mixed with normal plasma.[244] A diagnosis of afibrinogenemia depends on the specific finding of undetectable fibrinogen antigen in the plasma of these patients. Platelet fibrinogen is also absent. Mild thrombocytopenia has been reported in some afibrinogenemic patients, but typically the platelet count is usually not lower than 100,000/μl.[245] The bleeding time is prolonged in approximately one-third of patients with afibrinogenemia, presumably caused by the failure of platelets to aggregate in the absence of plasma or platelet fibrinogen. These abnormalities are correctable by infusion of plasma,[246] or more recently therapeutic concentrates of fibrinogen.[241,242] Furthermore, afibrinogenemic patients who undergo hypersensitivity reaction skin testing do not typically show an induration response to allergens. They show only erythema because the later phases of the hypersensitivity reaction depend on the deposition of subcutaneous fibrin.[247]

Differential Diagnosis and Therapy of Afibrinogenemia

Congenital quantitative defects in fibrinogen must be carefully distinguished from acquired quantitative defects in the fibrinogen molecule, which are often seen in the setting of liver disease or disseminated intravascular coagulation. Acquired hypofibrinogenemia has been reported after therapy with l-asparaginase, which impairs hepatic synthesis of fibrinogen,[248] and in patients with aplastic anemia treated with antithymocyte globulin and corticosteroids.[249] In the absence of purified fibrinogen concentrates, cryoprecipitate administration is used for replacement therapy for patients with severe afibrinogenemia. Prophylactic therapy is recommended only for pregnant patients, or patients with a history of central nervous system (CNS) hemorrhage.[236] Replacement therapy is indicated for any episode of acute active bleeding, preoperatively, and in pregnant patients. Fibrinogen levels between 50 and 100 mg/dl are usually adequate for normal hemostasis.[236] Levels >100 mg/dl are recommended for maintenance during pregnancy, based on empiric clinical observations.[236] Weekly infusions are recommended, but one should be aware that fibrinogen requirements may rise significantly around the time of parturition, and that levels as high as 150 mg/ml may be helpful to avert abruption.[250] Each bag of cryoprecipitate contains ~250 mg of fibrinogen, and one bag of cryoprecipitate typically raises plasma fibrinogen levels of an adult by ~10 mg/dl; thus 5 to 10 bags of cryoprecipitate are usually sufficient in the average adult patient. Because the fractional catabolic rate of fibrinogen is 25% per day, acute-care patients should receive one-third of their loading dose daily for as long as fibrinogen support is desired.[241,242,251] There are plasma concentrates of fibrinogen now available that may provide advantages over the use of cryoprecipitate.[252,253] Measurement of plasma fibrinogen levels after infusion is recommended to confirm that a patient has obtained the desired therapeutic effect. The complications of replacement therapy in afibrinogenemia include allergic reactions, development of antifibrinogen antibodies, and anaphylaxis.[254] Thromboembolic complications following cryoprecipitate infusions include deep venous thrombosis and pulmonary emboli; the risk of these complications may be increased when an inhibitor of fibrinolysis or oral contraceptive therapy is also administered.[255,256] Low-molecular-weight heparin in combination with fibrinogen replacement has been used to avoid these thromboembolic complications.[257] Antifibrinolytics alone may be sufficient to prevent bleeding from mucosal sites, but caution should be exercised in patients with a personal or family history of thrombosis.

Dysfibrinogenemia

The first reported case of dysfibrinogenemia mediated by a qualitatively abnormal fibrinogen molecule occurred in 1965, and since that time >300 families have been reported with this disorder.[220–222] The molecular genetic basis of fibrinogen dysfunction has been fairly well established in many families that have been studied. However, uncertainty persists concerning the linkage of genetic defects of fibrinogen and the disease phenotype expressed by patients, as environmental factors and other concomitant genetic abnormalities may be influencing disease manifestations.[258] There is an intriguing report of an increased association of dysfibrinogenemia with chronic thromboembolic pulmonary hypertension.[259] A database containing an updated list of the genetic defects associated with dysfibrinogenemia is accessible at http://site.geht.org/site/Pratiques-Professionnelles/Base-de-donnees-Fibrinogene/Database-English-Version/Fibrinogen-variants-Database-_79_.html.

Molecular Basis of Dysfibrinogenemia

The reported abnormalities in the fibrinogen molecule include defects in each of the major steps of fibrin formation and stabilization. The conversion of fibrinogen to an insoluble fibrin clot requires that the molecule first be cleaved by thrombin between arginine 16 and glycine 17 of the Aα chain to release fibrinopeptide A, and between arginine 14 and valine 15 of the Bβ chain to release fibrinopeptide B. This produces a fibrin monomer capable of undergoing the second step, fibrin polymerization. Once these molecules polymerize, they are stabilized by the action of factor XIIIa. Fibrinogen also supports the hemostatic process through interaction with platelets during platelet cohesion (aggregation). Finally, during the process of wound healing and tissue remodeling, the fibrin clot undergoes fibrinolysis by concerted activities of plasminogen and plasminogen activators. Fibrinogen dysfunction may affect any of these various steps of fibrin clot formation, platelet interaction, or lysis. It is therefore expected that the dysfibrinogenemias can be associated with abnormal clinical bleeding, thrombotic tendency, disorders of wound healing, or no clinically apparent disease. Domain location of a mutation does not necessarily predict the associated disease phenotype. Defects of fibrinopeptide release have been associated with both hemorrhagic and thrombotic complications. Similarly, disruption of D–D interactions have been associated with both bleeding and thrombosis. Patients who have heterozygous dysfibrinogenemia typically have ~50% of normal fibrinogen levels, which should be adequate for hemostasis. Clottable fibrinogen protein measurements may not be a reliable indicator of plasma fibrinogen concentration, because functionally abnormal molecules are not always incorporated into the clot. An abnormal fibrinogen may inhibit the conversion of normal fibrinogen to fibrin, so the tendency for many of these patients to bleed is higher than one would suspect. Hypodysfibrinogenemia occurs when an abnormality of the fibrinogen molecule results in decreased secretion or increased clearance of the protein. More than 20 families have been reported with hypodysfibrinogenemia. Autosomal amyloidosis has been attributed to genetic disorders of fibrinogen, as well as to genetic disorders of several other proteins (including transthyretin, gelsolin, apolipoprotein A, and lysozyme).

Hereditary renal amyloid disease has been associated with genetic defects of the Aα chain, and renal amyloid has recurred in renal transplants. Hepatic amyloid disease has also been attributed to abnormalities of fibrinogen.[230,260]

Dysfibrinogenemia is typically inherited as an autosomal dominant trait with high levels of penetrance. Most of these patients are heterozygotes, but a few homozygotes and some rare compound heterozygotes have been reported in the literature. Approximately 40% of dysfibrinogenemic patients are asymptomatic, and 45% to 50% have a bleeding disorder.[261] The remaining 10% to 15% have either a thrombotic disorder (venous or arterial) or both bleeding and thrombotic tendencies. The bleeding associated with dysfibrinogenemia is generally mild and includes soft tissue hemorrhage, easy bruising, and menorrhagia. Although intraoperative and postoperative bleeding have been reported, most bleeding is not life-threatening.

There are only a few families in which a thrombotic tendency can be unambiguously associated with dysfibrinogenemia, and criteria for making this association have been proposed. These criteria include a demonstrated molecular defect, thrombosis at an early age or in multiple family members, presence of no other predisposing factor for thrombosis, strong association between the fibrinogen defect and thrombus complications within a family, and association of the same molecular defect with thrombosis in another, unrelated kindred.[262] The true prevalence of thrombosis among patients with dysfibrinogenemia is unknown. Studies indicate a distinct thrombotic tendency in individuals with dysfibrinogenemia related to defects in the α-C domain of the Aα chain of fibrinogen, especially if new cysteine residues are encoded that can become disulfide-linked to albumin. In contrast, dysfibrinogenemic patients with defective cross-linking experience primarily defective wound healing.

Laboratory Diagnosis of Dysfibrinogenemia

The thrombin clotting time remains a sensitive screening test for dysfibrinogenemias,[244] and the PT appears to be more sensitive than the PTT to the effects of dysfibrinogenemia. In some cases, clot formation may be absent. Reptilase is a snake venom enzyme that differs from thrombin in that it cleaves only fibrinopeptide A of fibrinogen. The reptilase time is often more prolonged than the thrombin clotting time, especially in patients who have defective fibrinopeptide A release. Some dysfibrinogenemias exhibit a very short thrombin clotting time, and these patients may have thrombotic complications. The fibrinogen concentration can be either low or normal in these patients. Most patients with dysfibrinogenemia have a significant discrepancy between the level of clottable fibrinogen and that detected by immunologic methods. Criteria for diagnosing dysfibrinogens using ratios of immunologic and functional fibrinogen assays have been reported,[263] but the sensitivity and specificity of these criteria are not well characterized. The euglobulin clot lysis time is a crude measure of fibrinolytic potential, and may be helpful in detecting abnormal fibrinogens that show increased susceptibility to fibrinolysis. For example, with fibrinogen St. Louis,[264] the euglobulin clot lysis time is shortened, and fibrinogen degradation products are elevated in the plasma. Laboratory testing for fibrinogen abnormalities has been reviewed.[265]

The diagnosis of inherited dysfibrinogenemia must be distinguished from hypofibrinogenemia, which is either acquired or congenital in nature. Acquired dysfibrinogenemia occurs typically in the setting of severe liver disease,[266] and the suspicion can be readily investigated by evaluation of liver function tests. Acquired dysfibrinogenemias are also associated with malignancies that produce an abnormal fibrinogen molecule, such as some hepatomas (see Chapter 54), multiple myeloma,[267] and renal cell carcinoma,[268] as well as autoimmune disorders. An algorithm has been proposed for the orderly evaluation of patients in whom dysfibrinogenemia is a consideration.[244]

Acquired inhibitors to fibrin formation that interfere with fibrinogen-to-fibrin conversion may also be confused with dysfibrinogenemia. These acquired inhibitors include heparin-like molecules, elevated levels of fibrin split products, and antibodies at concentrations such as may occur in macroglobulinemia, multiple myeloma, or other disorders that interfere with fibrin polymerization.[269] Acquired antibodies against the fibrinogen molecule are quite rare but have been reported in association with a variety of diseases.[270,271]

Therapy

The majority of patients with dysfibrinogenemia do not require any specific therapy. Any bleeding complications that develop can be managed with transfusion of either plasma or cryoprecipitate. The role of the newer fibrinogen concentrates in treating patients with dysfibrinogenemia has not been clarified through appropriate clinical trials yet. Antifibrinolytic drugs have been used in some patients but should be especially avoided in patients who have thrombotic tendencies. Patients who have repeated venous thrombotic episodes may actually require long-term antithrombotic therapy. A patient with life-threatening thrombophilic manifestations was successfully managed with plasma exchange prior to surgery,[272] but one wonders whether simple anticoagulation therapy would have been sufficient to provide a satisfactory outcome. In women with dysfibrinogenemia, recurrent miscarriages may be prevented using prophylactic cryoprecipitate, and successful pregnancy outcomes in such cases have been reported.[236]

FACTOR XIII DEFICIENCY

The initial hemostatic plug is not sufficient to prevent blood loss unless it is stabilized by the action of plasma factor XIII (fibrin-stabilizing factor). A complex set of reactions among thrombin, fibrin, and plasma factor XIII is necessary for clot stabilization (see Chapter 18). When fibrin begins to polymerize after thrombin cleaves the fibrinopeptides, a complex forms between thrombin and fibrin, which promotes the conversion of factor XIII to factor XIIIa. Fibrin is the main catalytic substrate for factor XIIIa.[273] Factor XIIIa transforms the unstable, noncovalently associated fibrin clot to a stable covalently cross-linked set of fibrin fibers that are mechanically stronger, more rigid, and more elastic. A cross-linked fibrin clot is more resistant to mechanical as well as enzymatic degradation by plasmin than uncross-linked fibrin because α_2–plasmin inhibitor is also cross-linked to fibrin to inhibit plasmin activity. Factor XIIIa is a transglutaminase that catalyzes the formation of intermolecular γ-glutamyl-ε-lysyl covalent (isopeptide) bonds between the γ chains and α chains of fibrin strands within the clot. Cross-linkage of γ-chain Gln 398 and Lys 406 residues appears to occur earlier, with α-chain linkages between Gln 328 and 366 with Lys 508, 556, and 562 occurring more slowly.[273] In addition, several other plasma and extracellular matrix proteins are linked to the fibrin clot through the action of factor XIII. Cross-linking of thrombin-activatable fibrinolysis inhibitor into fibrin clots further increases the resistance of the clot to plasmin degradation.[273] Cross-linkage of fibrin to adhesive proteins such as vWF, fibronectin, thrombospondin, and vitronectin may improve adhesion to vessel walls and may play a role in cell migration during wound healing. In fact, fibronectin is the second most abundant material in the fibrin clot, accounting for 4% of the total protein.[274]

The importance of factor XIII function in normal health is emphasized by the clinical scenarios characteristic of inherited and acquired deficiency of factor XIII. In the following section, the pathogenesis, molecular genetics, clinical laboratory, diagnostic, and therapeutic elements of the diagnosis and treatment of factor XIII deficiency are discussed.

Pathogenesis

In 1944, Robbins postulated that a deficiency of fibrin-stabilizing factor, which later became known as factor XIII, would produce a serious bleeding disorder.[275] However, it was not until the first case of factor XIII deficiency was described in 1960 that the severe nature of this bleeding disorder was recognized.[276] During the last five decades, >200 cases of congenital factor XIII deficiency have been reported in the literature.[277] It is estimated that ~1 person in every 1 million to 5 million people has factor XIII deficiency. The disorder is inherited as an autosomal recessive trait.[236,277]

The factor XIII molecule is present in both plasma and in blood platelets and monocytes. The plasma concentration of factor XIII is 14 to 28 μg/ml. Approximately half that concentration circulates within blood platelets. Tissue-based factor XIII resides in monocyte/macrophages. Structurally, platelet and monocyte factor XIII consists of only A dimers, present within the cytoplasm of both platelets and megakaryocytes. The plasma factor XIII molecular complex is a heterotetramer, containing two of each of the A and B subunits. The A subunit mediates factor XIII function, containing an activation peptide, calcium-binding site, and enzymatic domain with an active site sulfhydryl residue that is characteristic of this class of enzymes.[278] The three-dimensional structure for the A subunit has been determined by x-ray crystallography.[273] The majority of the A subunit in circulation is derived from cells of marrow origin.[279] The B subunit of plasma factor XIII is synthesized in the liver and probably associates with the A subunit in the plasma phase after release from the hepatocyte. The B subunit appears to promote stabilization of the A subunit in plasma and may play an important role in regulating both the localization of the A subunit to the fibrin clot and thrombin-dependent activation of the protein. Two distinct forms of factor XIII deficiency have been described, based on whether the A and B subunits are absent or present.[273] In type I deficiency there is absence of the B subunit, with resultant decreased concentration of the A subunit in plasma, but platelet A subunit content is maintained. In type II deficiency, the A subunit is absent and the B subunit is present.

Molecular Genetics

Since the protein was initially described in human serum in 1944, both the A and B subunits have been purified, and cDNA sequence and gene structure have been established.[273] The A subunit is encoded on chromosome 6, containing 15 exons and spanning a region of 160 kb. A common genetic polymorphism of the A subunit has been described that results in Val34 replacement by Leu just three amino acid residues from the site of cleavage of the activation peptide. This polymorphism may influence factor XIII activation and has been investigated in reference to risk for myocardial infarction.[280] The B subunit is encoded by chromosome 1.[281] Because the mode of inheritance of factor XIII deficiency is autosomal recessive in nature, only homozygotes or compound heterozygotes are clinically symptomatic. The homozygotes reported in the literature are often children of consanguineous marriages.[282]

In the cases reported to date, factor XIII deficiency is more frequently attributed to mutation of the gene encoding the A subunit, confirming the functional importance of this subunit. To date, over 70 mutations have been described.[277] The majority of defects observed are "point mutations" resulting in stop codons, missense errors, or frame-shifts and small deletions. Inherited deficiency of the factor XIII A chain is not restricted to any specific ethnic group.[283]

Factor XIII B chain deficiency is a very rare autosomal recessive disorder, with very few reported cases in the literature.[284] One unique patient displayed a complete absence of the B chain and a shortened half-life of the A chain. Interestingly, this B chain–deficient patient had many of the same symptoms as an A chain–deficient patient. The ability of the B chain to promote A chain binding to the fibrinogen molecule may account for this clinical finding.[285] Only ~5 mutations have been reported in the B chain gene.[277]

Clinical Aspects

Clinically affected factor XIII–deficient patients typically have plasma levels that are <1% of normal,[273] with bleeding attributed to accelerated fibrin clot degradation. The bleeding phenotype in patients with inherited factor XIII deficiency is unusually severe. Abnormal bleeding manifests shortly after birth, when bleeding from the healthy umbilical cord remnant occurs.[286] This has been a prominent feature, reported in up to 80% of cases,[282] but this complication was observed in only 22% of the 34 cases reported to the North American Rare Bleeding Disorders Registry.[238] Umbilical stump bleeding is an uncommon presentation for other congenital bleeding disorders. Rebleeding at circumcision is also common. Other bleeding manifestations in these patients include soft tissue hemorrhage, hemarthrosis, hematomas, and the development of large pseudocysts.[286] The most life-threatening complication of factor XIII deficiency is spontaneous intracranial hemorrhage. Intracranial hemorrhage is more prevalent in factor XIII deficiency than in other inherited bleeding disorders. Approximately 25% of factor XIII–deficient patients experience intracranial hemorrhage.[287] Bleeding is usually spontaneous, and prevention of intracranial hemorrhage forms the basis for the recommendation of prophylactic therapy of factor XIII–deficient patients. Surgery in these patients is often complicated by abnormal wound healing and excessive postoperative bleeding, which can occur either immediately or later. Delayed bleeding may occur several days after surgery or tissue injury, and patients may experience cycles of repetitive bleeding that span weeks to months. Poor wound healing is reported in ~20% of patients with factor XIII deficiency. The affected males in some families also have oligospermia, resulting in infertility. Furthermore, infertility in affected females results from spontaneous abortions. Females with this deficiency cannot carry a pregnancy to term unless plasma factor XIII levels are maintained at levels that prevent bleeding.[288] The manifestations of factor XIII deficiency vary greatly among patients and may not necessarily present as bleeding symptoms. It has been hypothesized that heterogeneity of genetic defects underlying the deficient state accounts for the clinical variability in disease expression.[289] Factor XIII–deficient mice display a similar phenotype to the human condition.[290]

Differential Diagnosis

Congenital or acquired factor XIII deficiency must be considered when a patient has a major bleeding disorder and all of the initial screening laboratory tests are normal, including PT, PTT, and platelet count. Bleeding can occur spontaneously or after major surgery. It remains imperative in the adult to exclude both inherited and acquired factor XIII deficiency, because patients can develop antibodies to factor XIII that interfere with fibrin stabilization. Specific antibodies to factor XIII were reported in patients taking isoniazid, phenytoin, procainamide, penicillin, and valproic acid.[273] Factor XIII antibodies also occur in association with autoimmune disease, in patients with monoclonal gammopathy, or as an idiopathic occurrence. Acquired factor XIII deficiency has been reported in Henoch-Schönlein purpura, liver disease, Crohn disease, and ulcerative colitis.[273]

Laboratory Diagnosis

The PT and PTT assays are normal (Table 53.5). The solubility of a fibrin clot in 5M urea or 1% monochloroacetic acid (clot stability assay) is the most useful screening test for factor XIII deficiency.

In these conditions, clots formed in the absence of factor XIII activity dissolve within 60 minutes.[273] In contrast, normal clots covalently modified by factor XIIIa remain insoluble for at least 24 hours. This is a qualitative assay, and as little as 5% of the normal factor XIII activity level can render a clot insoluble in urea. Unfortunately, clot stability testing is not well standardized. If clot solubility is found, a mixing study with normal plasma is recommended to exclude factor XIII inhibitor. Deficiency of α_2-antiplasmin may also cause a bleeding disorder with normal coagulation screening studies and increased urea clot solubility; a specific assay for α_2-antiplasmin should be considered, to exclude this possibility.[291] Quantitative measurements of factor XIII activity can also be done, and these tests are useful to confirm factor XIII deficiency that is suspected based on an abnormal qualitative clot solubility assay. Specialized laboratories may measure either ammonia production (an end product of the factor XIIIa reaction)[292] or the incorporation of fluorescent or radioactive amines (such as dansylcadaverine) into proteins such as casein.[293] However, the most sensitive and specific measurement of factor XIIIa activity remains the functional assay measuring the stability of a covalently cross-linked fibrin clot.[294] Finally, immunologic based assays that detect factor XIII antigen are available, such as ELISAs specific for either the A or B subunits of factor XIII.[273] Results of immunologic assays correlate with factor XIII activity assays, but immunologic assays are not widely available.

PROTHROMBIN DEFICIENCY

Inherited prothrombin deficiency is an exceedingly rare, autosomal recessive bleeding disorder, with a frequency of <1 in 1 million.[295] To date, <40 mutations have been identified from <100 reported cases (Ref. 296, isth.org database). As with some of the other factor deficiencies, the frequency of prothrombin deficiency is greater in countries where consanguineous marriages occur. Phenotypically, prothrombin deficiency is classified as either *hypoprothrombinemia* (type I), distinguished by reduced prothrombin activity and reduced prothrombin antigen, or *dysprothrombinemia* (type II), distinguished by reduced prothrombin activity but normal prothrombin antigen.

Pathophysiology

Similar to deficiencies of the other vitamin K–dependent coagulation factors, prothrombin deficiencies result from mutant prothrombins that are either CRM-negative (hypoprothrombinemia) or CRM-positive (dysprothrombinemia). The CRM-negative form may be more common, is a product of missense, nonsense, insertion, or deletion mutations, and is characterized by a true deficiency of prothrombin, with a strong correlation between functional assays and immunoassays. The CRM-positive form is a product of missense mutations and is characterized by antigenically competent prothrombin, usually in quantities much greater than the associated functional activity.

By convention, these mutant prothrombins have been named according to the proband's origin, e.g., prothrombin Cardeza.[297] The prevalence of prothrombin deficiency in Puerto Ricans led to the recent description of several unrelated families of Puerto Rican ancestry having a common mutation, prothrombin Puerto Rico I, with characteristics of both hypoprothrombinemia and dysprothrombinemia.[298] Dysprothrombins with amino acid substitutions at or near the factor Xa cleavage sites inhibit activation to thrombin.[299,300] Amino acid substitutions elsewhere in prothrombin can affect the function determined by that region, including the catalytic domain (Quick II,[301] Molise, Perijé[302]), and fibrinogen-binding (Quick I[303]). Figure 53.9 summarizes some of these mutant prothrombins and their concomitant functional abnormalities.

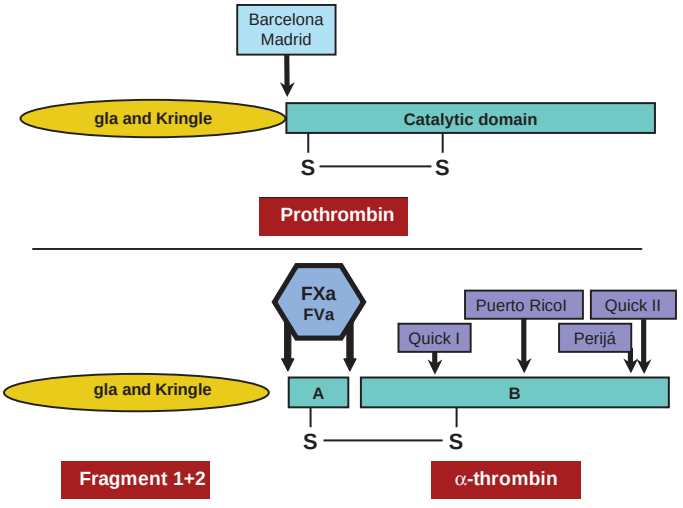

FIGURE 53.9. Schematic representation of prothrombin activation by prothrombinase (i.e., factors Xa, Va, and a negatively charged phospholipid surface) and sites of certain prothrombin mutations leading to inherited prothrombin deficiency. The fragment 1 + 2 domain contains γ-carboxyglutamic acid (gla) residues responsible for Ca^{2+}-dependent binding of prothrombin to cellular membranes. Prothrombins Barcelona and Madrid have a mutation at the factor Xa cleavage site (Arg271Cys), preventing activation to thrombin. The remaining depicted mutations are within the catalytic site/regulatory elements of α-thrombin. Prothrombin Quick I results in decreased proteolytic activity toward fibrinogen, as well as reduced abilities to release fibrinopeptide A, aggregate platelets, and stimulate the release of prostacyclin from human endothelial cells; prothrombins Perijé and Quick II result in decreased proteolytic activity due to alterations within the primary binding pocket; and prothrombin Puerto Rico I results in decreased activation to thrombin, possibly due to the removal of a salt bridge linking the A and B chains of thrombin.

Clinical Features

Epistaxis, menorrhagia, and posttraumatic bleeding are the most common complaints. Hemarthroses and muscle hematomas have also been reported.[295] The extent of prothrombin deficiency does not necessarily correlate with clinical bleeding. Although hemostasis can be maintained by prothrombin levels >25% of normal, significant bleeding is usually seen when prothrombin levels are <2% of normal.[304] Of the severe prothrombin deficiency patients reported to the Rare Bleeding Disorders Registry, 20% experienced intracranial bleeding.[238] Prothrombin-deficient heterozygotes have 40% to 60% of normal prothrombin activity; compound heterozygotes and homozygotes usually have <10% of normal prothrombin activity.[305] As of yet, no human cases of total prothrombin deficiency have been reported. Based on studies with knockout mice, such a complete deficiency is thought to be incompatible with life, leading to a loss of vascular integrity, arrested development, and tissue necrosis, ultimately resulting in embryonic or neonatal lethality.[306] This effect is thought to result from a developmental activity of thrombin on yolk sac vasculature. The genetic elimination of prothrombin in an adult mouse model was also not compatible with survival.[307]

Laboratory Diagnosis

A summary of laboratory findings in prothrombin deficiency is included in Table 53.5. Prothrombin deficiency is associated with normal thrombin times but prolonged PT and aPTT, which can be corrected in mixing studies. Specific factor assays for prothrombin are used in diagnosis. Acquired prothrombin deficiency, caused by either vitamin K deficiency or an antiprothrombin antibody associated with antiphospholipid antibodies, should be considered before making the diagnosis of inherited prothrombin deficiency. Fresh-frozen plasma (FFP) and prothrombin complex concentrates (PCCs) are used to treat prothrombin deficiency, as outlined later, in Table 53.8.

TABLE 53.8

REPLACEMENT THERAPY IN OTHER INHERITED COAGULATION DISORDERS

Disorder	Therapeutic Product	Loading Dose	Maintenance Dose
von Willebrand disease	Humate-P[a]	40–60 IU/kg	40–50 IU/kg every 12–24 h for up to 7 d
	Cryoprecipitate[b]	Not required	1 bag/10 kg daily
Fibrinogen deficiency	Cryoprecipitate	1–2 bags/10 kg	1 bag/10 kg every other d
	Purified fibrinogen[c]	50–100 mg/kg	20 mg/kg every other d
Prothrombin deficiency	Fresh-frozen plasma[d]	15 ml/kg	5–10 ml/kg daily
Dysprothrombinemia	Purified prothrombin complex[e]	20 IU/kg	10 IU/kg daily
Factor V deficiency	Fresh-frozen plasma	20 ml/kg	10 ml/kg every 12–24 h
Factor VII deficiency	Fresh-frozen plasma[d]	20 ml/kg	5 ml/kg every 6–24 h
	Purified prothrombin complex[e]	30 IU/kg	10–20 IU/kg every 6–24 h
Factor X deficiency	Fresh-frozen plasma[d]	15–20 ml/kg	5–10 ml/kg daily
	Purified prothrombin complex[e]	15 IU/kg	10 IU/kg daily
Factor XI deficiency	Fresh-frozen plasma[d]	15–20 ml/kg	5 ml/kg every 12–24 h
Factor XIII deficiency	Fresh-frozen plasma[f]	5 ml/kg every 1–2 wk	Not usually required

Note: The replacement therapy regimens suggested in this table are for major bleeding or surgical prophylaxis. Patients with minor bleeding may require lower dosages of these replacement products. Confirmation of hemostatic levels of the appropriate coagulation factor being replaced should be done, with dosage adjustments performed as needed.
[a]Labeled in ristocetin cofactor units. Alphanate and Wilate can also be used to treat von Willebrand disease.
[b]Recommended only if purified factor replacement therapy is not available.
[c]Not routinely available in the United States.
[d]Plasma after removal of cryoprecipitate is satisfactory.
[e]Prothrombin complex concentrates are thrombogenic and should be used only for major bleeding or major surgery. Antifibrinolytic drugs (ε-aminocaproic acid, tranexamic acid) should not be used in conjunction with prothrombin complex concentrates.
[f]A factor XIII concentrate is now available in the United States. See text for details.

FACTOR V DEFICIENCY

Inherited factor V deficiency, also known as *labile factor deficiency, proaccelerin deficiency,* and *parahemophilia,* is a rare autosomal recessive bleeding disorder first described by Owren,[308] with an estimated frequency of 1 in 1 million.[295] To date, >100 mutations have been identified from >200 reported cases,[309,310,311] and a database at isth.org lists >120 factor V mutations. As with some of the other factor deficiencies, the frequency of factor V deficiency is greater in countries where consanguineous marriages occur.[295] Phenotypically, factor V deficiency is classified as either type I, distinguished by reduced factor V activity and reduced factor V antigen, or type II, distinguished by reduced factor V activity but normal factor V antigen.

Pathophysiology

The majority of factor V deficiencies result from a failure to either synthesize or secrete factor V. The mutants responsible for these deficiencies are CRM-negative (type I); CRM-positive factor V mutations (type II) have also been detected.[312] The CRM-negative form is a product of missense, nonsense, insertion, or deletion mutations and is characterized by a true deficiency of factor V, with a strong correlation between functional assays and immunoassays. Factor V New Brunswick, a CRM-positive form, is caused by a missense mutation and is characterized by antigenically competent factor V with reduced activity, most likely due to reduced stability of factor Va.[313,314]

By convention, many of these mutant factor Vs have been named according to the proband's origin, e.g., factor V Stanford[315] and factor V Ogden.[316] Factor V Quebec is associated with a moderate reduction in plasma factor V levels and a severe reduction in platelet factor V, but also other α-granule proteins, including multimerin (a factor V carrier molecule within platelets), and is thus more properly considered a platelet disorder.[317] Approximately 20% of the circulating pool of factor V is contained within platelets. This platelet pool of factor V and low levels of tissue factor pathway inhibitor seen in factor V deficient patients may explain the milder bleeding phenotype in this bleeding disorder.[310]

Clinical Features

Epistaxis, menorrhagia, and posttraumatic bleeding are the most common complaints. Trauma-induced hemarthroses and muscle hematomas have also been reported.[295] Gastrointestinal or CNS bleeding is observed very rarely. Although neonatal bleeding has seldom been observed, factor V deficiency has been associated with other congenital abnormalities.[318] Hemostasis can be maintained by factor V levels >10% to 20% of normal, but moderately severe bleeding is usually seen when factor V levels are <10% of normal. Factor V–deficient heterozygotes have 40% to 60% of normal factor V activity; compound heterozygotes and homozygotes usually have <10% of normal factor V activity. Bleeding symptoms may correlate better with platelet factor V content rather than the plasma factor V level.[317]

A genetic model of factor V deficiency utilizing factor V–knockout mice underscores the importance of factor V in not only hemostasis but development, as fetal loss in utero is markedly increased.[319] Based on these knockout-mouse studies, complete factor V deficiency is apparently incompatible with life, but <0.1% of normal factor V activity is sufficient to rescue completely deficient mice.[320] As of yet, no human cases of total factor V deficiency have been reported, and even patients with a homozygous or compound heterozygous factor V deficiency usually have some residual factor V activity.

Laboratory Diagnosis

A summary of laboratory findings in factor V deficiency is included in Table 53.5. Factor V deficiency is associated with

normal thrombin times but prolonged PT and aPTT, which can be corrected in mixing studies. A PT–based factor V assay or an ELISA can be used to verify quantitative reductions in factor V. Good results have been obtained using aged oxalated or ethylenediaminetetraacetic acid plasma as a factor V–deficient substrate,[321] as well as artificially depleted substrate plasmas. Acquired factor V deficiency, caused by liver disease, disseminated intravascular coagulation, or antibodies to factor V, should be excluded before making the diagnosis of inherited factor V deficiency. Upon confirmation of factor V deficiency, however, a specific assay for factor VIII should also be performed to rule out the rare combined factor V/factor VIII deficiency,[322] treatment of which entails a different replacement therapy. Currently, FFP is used to treat factor V deficiency, as outlined later, in Table 53.8.

FACTOR VII DEFICIENCY

Factor VII deficiency was first described in 1951 by Alexander et al. under the name *serum prothrombin conversion accelerator* (SPCA) deficiency. Approximately 200 cases of true factor VII deficiency have been reported, and the population prevalence is estimated to be 1 in 500,000,[295] making it the most common of the "rare bleeding disorders." Also known as *stable factor* or *proconvertin deficiency,* the condition is inherited as an autosomal recessive trait that produces severe deficiency in the homozygote and mild deficiency, usually without clinical manifestations, in the heterozygote. As in other rare bleeding disorders, it is more common in cultures where consanguineous marriage is practiced.

Pathophysiology

Factor VII is secreted as a single-chain proenzyme glycoprotein of ~50 kDa by hepatocytes. Factor VII has the shortest plasma half-life of all coagulation factors (~5 hours), and its plasma concentration is very low, ~500 ng/ml.[323] Factor VIIa is detectable in trace amounts in normal plasma,[324] and sensitive assays indicate that ~1% of circulating factor VII is in the activated form.[324] The circulating half-life of activated factor VIIa is approximately 2.5 hours.[325] Tissue factor increases the rate of activation of factor VII significantly,[324] and current theory is that coagulation is initiated in the presence of tissue factor that is exposed at sites of vascular injury or contributed by blood monocytes.[326]

The factor VII gene includes nine exons and spans 128 kb on chromosome 13.[327] It is located just upstream of the factor X gene. In a mouse knockout model in which factor VII is completely lacking, fatal hemorrhage occurs perinatally.[328] In humans, factor VII deficiency occurs as a recessive trait resulting from homozygous or compound heterozygous mutations. Many mutations of the factor VII gene have been reported, with >200 mutations listed in 2012 in a database at isth.org. Most reported genetic defects are single-base substitutions, including missense, splice-site, and nonsense mutations. Most mutations affect only a few patients, but one mutation (Ala242Val) was detected in 23 "apparently" unrelated Jews in Israel.[329] More extended haplotype testing suggests a "founder effect".[329] Although Dubin-Johnson syndrome is associated with factor VII deficiency,[330] the genetic defect underlying that syndrome is located on chromosome 10, and the association of Dubin-Johnson syndrome and factor VII deficiency may simply reflect a high consanguinity rate in one population.[291] Combined deficiency of factor VII along with the other vitamin K–dependent coagulation proteins or as a deficiency with a single other coagulation protein has been reported in rare families (see below).

Clinical Features

Only severe factor VII deficiency is associated with hemorrhagic symptoms, and heterozygous carriers are asymptomatic. Factor VII levels do not completely correlate with the severity of symptoms, and this may in part reflect heterogeneity in the molecular basis of factor VII deficiency or the tissue factor–containing reagents used to quantify the factor VII activity level in patients.[331] However, patients with levels of >10 to 15 IU/dl rarely manifest bleeding.[332] Patients with levels between 5 and 10 IU/dl tend to have milder symptoms, such as epistaxis, gingival bleeding, or genitourinary and gastrointestinal bleeding. Patients with levels <1 IU/dl may have symptoms similar to patients with hemophilia A or hemophilia B, with spontaneous joint and deep-muscle bleeding, but some patients with factor VII levels of <1 IU/dl have been asymptomatic. Bleeding into the CNS is particularly common, being observed in 15% to 60% of patients with factor VII levels <2 IU/dl.[333] CNS bleeds often present during the neonatal period, and the risk of recurrence is high enough that prophylaxis with factor replacement therapy should be considered in patients who present with this complication.[334] The severity of bleeding after trauma or surgical procedures varies to a surprising degree in this disorder, with oral and urogenital cavity procedures being particularly troublesome, possibly reflecting the high local fibrinolytic activity in these regions of the body. Prior clinical bleeding symptoms are an important prognostic factor predicting surgical bleeding complications in patients with factor VII deficiency.

Some reports indicate that patients with factor VII deficiency may also be more prone to various thromboembolic manifestations.[335] The explanation for this phenomenon is unknown, but thrombophilic markers have been observed in most of these cases.[336]

Laboratory Diagnosis

In factor VII deficiency, normal results are obtained with coagulation tests that bypass the extrinsic pathway of coagulation and factor VII (Table 53.5), that is, the PTT, thrombin time, and, if tested, the Stypven (Russell viper venom) time. Thus, a diagnosis of factor VII deficiency is suspected in a patient with a life-long history of bleeding when there is an isolated prolonged PT and normal PTT. The PT will correct on 1:1 mixing of patient plasma with normal plasma, but a diagnosis of factor VII deficiency requires a specific factor VII assay for confirmation. Use of human thromboplastin in the PT assay is recommended. A factor VII mutation (factor VII Padua) has been described in African-American patients who are asymptomatic; this defect results in low factor VII activity levels when rabbit brain thromboplastin is used, but normal factor VII activity when human thromboplastin is used.[337] Confirmation of low factor VII antigen level can be obtained by ELISA assay. Levels of factor VII in heterozygous carriers overlap the normal range. Before making a diagnosis of factor VII deficiency, one should exclude causes for acquired abnormalities such as vitamin K deficiency, liver disease, or warfarin therapy. Also, rare conditions such as combined deficiency of all vitamin K–dependent factors, and combined factor VII and factor X deficiency should be considered. Autoantibody directed to factor VII occurs, but few case reports have been published.

Phenotypically, patients have been characterized by evaluating plasma levels of factor VII antigen (or CRM). CRM-negative patients have low factor VII antigen as a result of the lack of synthesis or increased factor clearance, whereas CRM-positive patients produce factor VII that is detected antigenically but is structurally abnormal and with deficient function. CRM-reduced individuals presumably represent a combination of these two entities. Further complexity of the factor VII–deficient phenotype is introduced because of insensitivity of some factor VII activity assays to low levels of factor VII or from variability in assays that is introduced by the use of varying animal sources of tissue thromboplastin.

Treatment of factor VII deficiency with recombinant human factor VIIa, plasma, or PCCs is discussed later in this chapter. Although the necessity for correcting factor VII deficiency has

been questioned,[338] patients who have factor VII deficiency and a history of excessive clinical bleeding should be given replacement therapy before surgery. Numerous clinical reviews confirm that the patient's clinical bleeding history is the best predictive parameter of bleeding risk.[339] It has been reported that patients with factor VII deficiency who have factor VII levels >10% when assayed using human thromboplastin reagents have minimal bleeding symptoms.

FACTOR X DEFICIENCY

Inherited factor X deficiency, first described in the Prower[340] and Stuart[341] kindreds, is a rare autosomal recessive bleeding disorder with an estimated frequency of 1 in 1 million.[295] Factor X deficiency represents ~10% of all rare bleeding disorders. To date, >100 mutations have been identified,[342,343,344] with the majority being missense mutations.[345] As with some of the other factor deficiencies, the frequency of factor X deficiency is greater in countries where consanguineous marriages occur.[295] Phenotypically, factor X deficiency is classified as either type I, distinguished by reduced factor X activity and reduced factor X antigen, or type II, distinguished by reduced factor X activity but normal factor X antigen.

Pathophysiology

The CRM-negative form is a product of missense, insertion, or deletion mutations, and is characterized by a true deficiency of factor X, with a strong correlation between functional assays and immunoassays. The CRM-reduced and -positive forms are products of missense mutations and are characterized by low to normal levels of antigenically competent factor X but with disproportionately reduced factor X activity. Deletion mutations result in premature termination and thus the loss of the factor X catalytic domain, whereas missense mutations may affect not only the catalytic domain, but phospholipid binding, activation, secretion, or even synthesis of factor X. By convention, these mutant factor Xs have been named according to the proband's origin, e.g., factor X San Antonio I,[346] factor X Friuli,[347] and factor X St. Louis II.[348]

Clinical Features

The symptoms of factor X deficiency tend to be the most severe of the inherited coagulation deficiencies. Epistaxis, menorrhagia, and posttraumatic bleeding are common complaints, and hemarthroses and hematomas have been reported in two-thirds of factor X–deficient patients.[295] Umbilical stump, gastrointestinal, and CNS bleeding are also frequently observed. Heterozygotes generally appear asymptomatic, as hemostasis can be maintained by factor X levels >10% of normal. On the other hand, compound heterozygotes and homozygotes with factor X levels <1% of normal suffer from severe bleeding. Experiments utilizing factor X–knockout mice resulted in either neonatal death or postnatal death, caused by intraabdominal or intracranial bleeding.[349]

Laboratory Diagnosis

A summary of laboratory findings in factor X deficiency is included in Table 53.5. Factor X deficiency is associated with normal thrombin times but prolonged PT, aPTT, and often Stypven (Russell viper venom) time, particularly among the CRM-negative variants. Unfortunately, factor X–deficiency variants have been described with isolated prolonged PT or aPTT values.[350,351] Upon ruling out other inherited bleeding disorders, a factor X–specific assay can be used to verify factor X deficiency. Acquired factor X deficiency, caused by liver disease, warfarin therapy, amyloidosis,[352] or antibodies to factor X, should be excluded before making the diagnosis of inherited factor X deficiency. Currently, FFP or PCCs are used to treat factor X deficiency, as outlined in Table 53.8.

FACTOR XI DEFICIENCY

Factor XI deficiency (plasma thromboplastin antecedent deficiency) was first recognized by Rosenthal et al. in 1953[353] and was called *hemophilia C*. Factor XI deficiency is transmitted as an incompletely recessive autosomal trait manifested either as a major defect in homozygous patients with factor XI levels <20 IU/dl or as a minor defect in heterozygous patients with levels ranging from 30 to 65 IU/dl.[354] The incidence of this disorder varies widely, with estimates of frequency in the general population being 1 in 1 million persons. A particularly high frequency of the disorder exists in people of Jewish extraction,[354,355,356] with an estimated gene frequency of 5% to 11% in Ashkenazi Jews.[357] Up to 0.3% of this population is homozygous for factor XI deficiency.[357]

Factor XI deficiency has been reported to result from three major types of mutations: Type I mutations result in disruption of splicing; type II mutations result in a stop codon and nonfunctional molecule; and type III mutations result in amino acid substitutions and a dysfunctional molecule.[358] Patients with type II mutations have the greatest bleeding tendency.[359] Type II and III mutations are most common in Ashkenazi Jews. The type II mutation is also common in Iraqi Jews,[360] who may represent the ancient gene pool of Jews.[361]

A more recent classification scheme for factor XI–deficiency cases that are CRM–negative includes three mechanistic categories: (a) Mutations that reduce or prevent polypeptide synthesis, (b) mutations resulting in polypeptides that fail to form intracellular dimers, and (c) mutations resulting in polypeptides that form dimers that are not secreted.[362] Mechanism (c) may account for some kindreds with apparent autosomal dominant factor XI deficiency.[363] In general, most factor XI mutations result in decreased factor XI protein proportionate to factor XI clotting activity. Over 100 factor XI mutations have been reported[364,365] (database at isth.org).

Clinical Features

The clinical manifestations of factor XI deficiency are extremely variable and generally milder than those of hemophilia A or B.[355,364,366] As a rule, spontaneous bleeding is rare, and hemorrhage usually occurs only after trauma or a surgical procedure. The extent of factor XI deficiency may not correlate with bleeding.[355,364,366] Hemarthrosis is uncommon, but delayed bleeding is a particularly treacherous feature in some patients,[353,367,368] especially for surgical procedures involving tissues rich in fibrinolytic activity.[236] Mild factor XI deficiency may be associated with Noonan syndrome[369] and Gaucher disease.[370] Hemorrhagic manifestations may be absent in certain patients,[371] especially in those with type I mutations. Approximately one-half of heterozygous factor XI–deficient patients have a bleeding tendency.[372] Factor XI deficiency should be considered in female patients with menorrhagia.[373] In one study of women with menorrhagia, the prevalence of factor XI deficiency was 4%.[168]

Laboratory Diagnosis

In the homozygous form of factor XI deficiency,[374] the PTT is prolonged. In most of these patients, factor XI levels in the plasma are in the range of 3 to 15 IU/dl. In people with the mild form of the disorder, the PTT often is normal because most PTT reagents are insensitive to mild factor XI deficiency.[74,236] Abnormalities in the plasma of such mildly affected patients may be removed by freezing. Specific factor assays are used to diagnose

factor XI deficiency. The bleeding time and thrombin time are normal. Factor XI deficiency has also been reported in combination with inherited factor IX deficiency (type VI familial multiple factor deficiency).[376] Treatment of factor XI deficiency is discussed later in this chapter in the section "Plasma".

FACTOR XII DEFICIENCY

Factor XII deficiency was discovered by Ratnoff and Colopy during routine preoperative coagulation studies on John Hageman, an adult who had no evidence or history of abnormal bleeding.[376,377,378] The disorder, subsequently named *Hageman factor deficiency,* is inherited as an autosomal recessive trait. Factor XII deficiency has been identified in 1.5% to 3.0% of a healthy blood donor population.[379]

Pathophysiology

The plasma of most patients with factor XII deficiency does not contain material that reacts with antibodies to this factor. Radioimmunoassays with heterologous antibodies have demonstrated antigenic material identical to normal factor XII in only 2 of 42[380] and 2 of 31[381] separate kindreds. One large study of 31 factor XII–deficient kindreds identified most mutations in the serine protease domain.[381]

Clinical Features

Factor XII deficiency usually is not associated with hemorrhagic manifestations.[376,382] It is noteworthy that myocardial infarction and thrombophlebitis have been observed in patients with severe factor XII deficiency,[383] and that Hageman died of thromboembolic complications.[384] It was originally thought that factor XII deficiency might actually predispose to thrombosis, possibly as the result of deficient activation of fibrinolysis.[385] However, more recent surveys indicate that factor XII deficiency is not associated with an excessive risk of thrombosis [68,386,387]; thrombotic events in factor XII–deficient patients may be explained by the presence of other prothrombotic gene defects in these patients.[388]

In vitro experiments suggest that factor XII has a central role in the initiation of the intrinsic pathway of coagulation and mediates a variety of other processes such as fibrinolysis, complement activation, inflammation, and chemotaxis.[382,389] The physiologic importance of these factor XII–mediated phenomena remains obscure, because patients with even severe deficiency of this proenzyme reveal no evidence of deficiency or aberrance of host defenses.

The discrepancy between in vitro evidence of grossly abnormal blood coagulation and the absence of hemorrhagic manifestations in factor XII deficiency poses a fundamental question regarding the role of the intrinsic coagulation pathway in hemostasis and the significance of laboratory measurements of coagulation. Alternative mechanisms for initiation of coagulation are discussed in Chapter 18.

Results of an animal model of arterial thrombosis have again raised the question of whether factor XII has a role in thrombosis.[390] When factor XII–deficient mice were exposed to arterial vascular injury, defective platelet-rich thrombosis was observed, a defect that was corrected by administration of exogenous factor XII.[390] Results from a mouse stroke model indicate that factor XII deficiency protects affected mice from ischemic brain injury.[391] Although a large body of clinical evidence suggests that factor XII is not important for hemostasis, the animal model data suggest that factor XII is important for pathologic (arterial) thrombosis, perhaps by factor XII_a–mediated factor XI activation.[392]

Laboratory Diagnosis

Factor XII–deficient patients typically present with a negative history of clinical bleeding and an isolated, prolonged PTT that corrects with mixing with normal plasma. The coagulant effects of contact activation are diminished or absent in plasma from subjects with factor XII deficiency.[393] Normal levels of factor XII range from 50 to 150 IU/dl. As with factor XI, accurate assays of factor XII depend on a source of deficient substrate plasma. Laboratory demonstration of the heterozygous state is difficult. The mean level of factor XII in the plasma of carriers is ~50% of normal, but observed values are distributed in a bimodal manner, an observation interpreted as suggesting the presence of multiple abnormal alleles.[394]

PREKALLIKREIN DEFICIENCY

An additional abnormality of the intrinsic pathway of coagulation was defined and named *Fletcher factor deficiency* by Hathaway in 1965.[395] In 1972, Wuepper et al. established that Fletcher factor was identical to plasma prekallikrein, a protein that had been studied for many years in terms of its role in inflammation.[396] The convergence of these two avenues of research demonstrated that prekallikrein, in addition to its role in inflammation and chemotaxis, is essential for the optimal activation and fragmentation of factor XII in the early steps of coagulation.[389]

Pathophysiology

Prekallikrein deficiency apparently is inherited as an autosomal recessive trait,[395] although genetic information is scanty. ~80 cases have been reported.[397] Heterozygotes with ~50% of normal plasma levels of prekallikrein can be identified. The disorder is associated with the absence of antigenically competent prekallikrein in most cases.[398]

Clinical Features

Prekallikrein deficiency, like factor XII deficiency, is not associated with abnormal bleeding. Studies of affected patients revealed variable deficiencies in stress-induced fibrinolysis, chemotaxis, immediate and delayed inflammatory responses, and responses to preformed permeability–enhancing activity.[399] These abnormalities are not associated with any apparent deleterious effects. Most patients with prekallikrein deficiency are of African ancestry.[400] Prekallikrein deficiency is not associated with an excessive risk of thrombosis.[68]

Laboratory Diagnosis

Prekallikrein deficiency is associated with a moderate prolongation of the PTT. The PT and thrombin time are normal. The time required for release of vascular plasminogen activators in vivo after venous occlusion is prolonged.[401] The disorder is characterized by abnormally slow contact activation. Thus, the PTT may be normalized by prolonged incubation (10 to 15 minutes) of plasma with particulate activators.[395,402] This phenomenon appears to result from autoactivation of factor XII.[403] Specific assays for prekallikrein are based on traditional coagulation techniques and chromogenic substrate assays.[404]

HIGH-MOLECULAR-WEIGHT KININOGEN DEFICIENCY

A unique inherited coagulation abnormality associated with deficiencies of kinin formation and fibrinolysis was described in three unrelated kindreds in 1975. The disorder received the names

of the affected families (Fitzgerald trait,[405] Williams trait,[406] Flaujeac trait, and Fujiwara trait[407]) and has subsequently been found to be the result of deficiency of HMWK. Patients with this disorder are asymptomatic. The data suggest that HMWK functions in its nonactivated form as a cofactor, binding prekallikrein and factor XI to anionic surfaces, accelerating their activation by surface-bound factor XIIa (see Chapter 18).

Pathophysiology

Deficiency of HMWK appears to be inherited as an autosomal recessive trait.[366] Mildly affected heterozygotes have been identified in some families. Detailed biochemical studies of five kindreds revealed considerable heterogeneity.[406,408] Thus, HMWK levels in the plasma ranged from nil[406] to 50 IU/dl.[405] With the exception of the Fitzgerald kindred, associated deficiencies in low-molecular-weight kininogen have been demonstrated in all families. Variable deficiency of prekallikrein also was present in the Williams, Fitzgerald, and Fujiwara kindreds; prekallikrein levels were normal in the Flaujeac kindred. Immunologic studies revealed the absence of kininogen antigen in the homozygotes and 50% of normal levels in the heterozygotes.[409] The associated prekallikrein deficiency also apparently is of the CRM-negative type.[409] The absence of the stabilizing effects of HMWK may lead to accelerated degradation and deficiency of prekallikrein in this disorder.[409] HMWK deficiency is not associated with excessive clinical bleeding or thrombosis. There is limited information on the genetic basis for HMWK deficiency.[410–412]

Laboratory Diagnosis

Deficiency of HMWK is manifested by an isolated, prolonged PTT. The PTT assay results are abnormal whether particulate or soluble contact activators are used, and values are not normalized by prolonged incubation of the plasma with particulate activators.

MISCELLANEOUS INHERITED COAGULATION DISORDERS

Combined Defects

Of unusual interest are reports concerning the presence of combined deficiencies of two or more coagulation factors. Deficiency of factors V and VIII, and combined deficiency of various vitamin K–dependent factors appear to be the most common combined deficiency disorders.[413] Several other combined coagulation defects have been described (Table 53.1).

Deficiency of Factors V and VIII

Combined deficiency of factors V and VIII, reported in <200 patients, is inherited as an autosomal recessive trait.[414] This combined defect manifests clinically with mild mucosal and cutaneous bleeding. Severe posttraumatic and postsurgical bleeding is common (e.g., after tooth extractions).[414] Hemarthrosis is rare. Laboratory findings in homozygous patients include a prolonged PTT and PT and levels of factor VIIIc and Vc that average 15 IU/dl. Levels of factor VIIIAg (VIIIcAg) and VAg are low and are proportional to those obtained by coagulation measurements.[415]

Linkage analysis of combined factor V and VIII deficiency to chromosome 18q excluded all known hemostasis proteins, suggesting that the basis for the disease is a defect affecting a process common to the biosynthesis of factors V and VIII. Indeed, subsequent studies by two groups identified the genetic basis for most patients with the disorder as mutations in the endoplasmic reticulum–Golgi intermediate compartment protein 53 (also known as lectin mannose-binding type 1 [LMAN1]). Other patients with this combined defect have mutations in another protein termed multiple coagulation factor deficiency-2 (MCFD2).[416–418] LMAN1 and MCFD2 form a complex that acts as a receptor (chaperone) or cargo receptor for transport of several secreted proteins, including factors V and VIII.[417,419] Still other patients with combined factors V and VIII deficiency have been identified[417] who appear to have unique mutations.

Combined Deficiency of Factors II, VII, IX, and X

Combined deficiency of factors II, VII, IX, and X is an autosomal recessive coagulation disorder that has been identified in only a small number of patients.[238,413,420,421] In addition to affecting levels of the vitamin K–dependent factors, skeletal abnormalities may also be seen, resulting from effects on bone Gla proteins.[422] Levels of the vitamin K–dependent proteins range from <12% to 50% of normal; thus, clinical bleeding manifestations may vary widely. Both the PT and PTT are prolonged. Measurement of serum warfarin levels may be necessary to exclude surreptitious anticoagulant use. Mutations in the γ-glutamyl carboxylase gene have been identified in a few patients with this disorder,[423–425] and another group has identified a second gene locus (vitamin K epoxide reductase complex, subunit 1 [*VKORC1*]) causing this defect.[426] Some patients have clinical improvement and correction of the coagulopathy with vitamin K therapy.[420,424]

ABNORMALITIES OF PROTEASE INHIBITORS

Rare abnormalities of three plasma antiproteases, which are associated with bleeding, are described in this section. Other, more numerous abnormalities of the components of the antiprotease system and the fibrinolytic enzyme system that may be associated with thrombosis are discussed in Chapter 55.

α_2-Antiplasmin Deficiency

Severe bleeding, including hemarthrosis, was associated with deficiency of α_2-antiplasmin in several kindreds.[427,428–431] This disorder appears to be inherited as an autosomal recessive trait, in which heterozygotes have detectable deficiencies of this antiprotease but only mild bleeding. CRM-positive and CRM-negative forms have been identified.[430] A report published in 2008 identified 15 cases; seven cases had genetic abnormalities defined.[432] Most cases had mutations in exon 10, which is the location of the active site, and the plasminogen-binding site.[431,432]

Bleeding presumably is the result of premature lysis of hemostatically important fibrin plugs caused by unregulated plasmin activity. The laboratory findings are variable. Hypofibrinogenemia and increased clot solubility in urea have been reported. Fibrinogen degradation product levels and platelet counts were normal in most cases.[430] When assayed qualitatively by fluorometric or photochromogenic techniques, α_2-antiplasmin levels usually are <10 IU/dl. Treatment of bleeding episodes with tranexamic acid and other antifibrinolytic agents may be helpful.

Plasminogen Activator Inhibitor-1 Deficiency

Deficiency of plasminogen activator inhibitor (PAI)-1 is associated with a moderate bleeding disorder.[433] Only ~10 to 20 families have been reported.[434] One study investigated a large kindred with multiple family members who were homozygous for this disorder.[435] Homozygous patients, but not heterozygous patients, exhibited clinical bleeding.[435] The null gene mutation responsible for PAI-1 deficiency was identified in this kindred.[435] Other cases have been described.[436] The basis of the bleeding is similar to that described for α_2-antiplasmin deficiency: Excessive plasmin activity, caused in this case by excessive activation of plasminogen.

Laboratory screening studies are typically normal, but the euglobulin clot lysis time is shortened. It is recommended that measurement of PAI-1 antigen and activity in both serum and plasma be done to screen for PAI-1 deficiency.[435] The in vitro activities and clinical relevance of PAI-1 have been reviewed.[437]

α_1-Antitrypsin Pittsburgh

A life-long hemorrhagic diathesis in a 14-year-old boy was associated with a unique qualitatively abnormal form of α_1-antitrypsin (antithrombin III Pittsburgh).[438,439] This disorder is the result of the substitution of a single amino acid (arginine for methionine at position 358 in the α_1-antitrypsin molecule).[439] This site corresponds to the P1 residue or "bait" amino acid of the molecule, and the substitution produced a mutation of α_1-antitrypsin, a weak antiprotease with little affinity for thrombin, into a potent antithrombin that impaired blood coagulation to a significant degree. The mutant molecule also is a potent inhibitor of factor XIa, factor XIIf, and kallikrein, a property lacking in the normal molecule.[440] The plasma concentration of the abnormal molecule increased after trauma, possibly as the result of an acute-phase response. The patient ultimately died of bleeding. A second family was reported with the disorder; it is inherited in an autosomal dominant manner.[441] Other amino acid substitutions at position 358 have been produced artificially by genetic engineering.[442]

TREATMENT OF INHERITED COAGULATION DISORDERS

The principal treatment for the inherited coagulation disorders is replacement therapy—that is, the intravenous administration of the required factor in the form of blood products derived from normal people or animals, or recombinant coagulation proteins.[443] Estrogens may be useful in treating female patients with vWD.[444] Topical hemostatics (thrombin) may be temporarily effective in small injuries or nose bleeds, and certain other treatments such as DDAVP and inhibitors of fibrinolysis are useful adjunctive therapy under specific circumstances such as dental surgery.[445]

Replacement Therapy

The objective of replacement therapy is to obtain a concentration of the required factor at the bleeding site such that coagulation may become hemostatically effective. The pharmacokinetic (PK) properties of the various coagulation factors (Table 53.9) and clinical assessment of the severity of the hemorrhagic risk are important considerations in determining appropriate doses and duration for therapy. Replacement products are dosed on the basis of actual body weight (Tables 53.8 and 53.10) or plasma volume. This latter method may be more precise in patients who do not have a normal plasma volume because of bleeding. In one such method, blood volume is considered to be 7% of body weight; plasma volume is then calculated using the patient's hematocrit. Next, the therapeutic objective is assessed (e.g., the desired incremental increase in factor VIII level). For example, if a patient with severe hemophilia A (<1% factor VIII) has a plasma volume of 3,000 ml and requires major surgery, the target factor VIII level should be 100% of normal. Infusion of 3,000 IU of factor VIII would result in a calculated peak factor VIII level of 1 IU/ml (100% of normal). Peak factor levels should be monitored to determine whether the expected response was achieved, and then further dosage adjustments can be calculated if necessary. Subsequent doses are scheduled according to the predicted half-life of the factor, with laboratory tests to verify actual levels when appropriate. Case reports and clinical experience detailing management of hemophilia A during surgery have been published.[446,447,448,449,450]

TABLE 53.9

BIODYNAMIC PROPERTIES OF COAGULATION FACTORS OF CONCERN IN REPLACEMENT THERAPY

Disorder	Hemostatic Level (IU/dl)[a]		Biologic Half-life (h)
	*	+	
Hemophilia A (factor VIII deficiency)	25–30		12
Hemophilia B (factor IX deficiency)	20–60		20–24
Fibrinogen deficiency	100 mg/dl	>100 mg/dl	77–106
Prothrombin deficiency	40–50		72–96
Factor V deficiency	10–30	12	15–36
Factor VII deficiency	10–20	25	4–7
Factor X deficiency	10–40	56	32–48
Factor XI deficiency	20–30	26	40–80
Factor XIII deficiency	10	31	280
von Willebrand disease	20–50		20–40

[a]Patients undergoing major surgery or experiencing major bleeding should receive dosages to achieve higher factor levels; for example, patients with hemophilia A should have replacement such that factor VIII levels approach 100% of normal. For patients with factor XIII deficiency and major trauma, plasma factor XIII levels of at least 25% should be achieved.
*Data in this table are taken from Teruya J, Ramsey G. Blood components for hemostasis. Lab Med 2001;32:31–35.
+Data taken from Peyvandi F, Palla R, Menegatti M, et al. Coagulation factor activity and clinical bleeding severity in rare bleeding disorders: results from the European Network of Rare Bleeding Disorders. J Thromb Haemost 2012;10:615–621.

Hemostatic Levels

The *hemostatic level* may be defined as the lowest plasma concentration of a given coagulation factor that is required for normal hemostasis (Table 53.9). This value was determined by purely empiric means—that is, by measurement of the blood levels of the deficient factor at which bleeding appeared to stop in patients with one of the inherited coagulation disorders during the course of replacement therapy. Such estimates obviously may be inaccurate. In patients with hemophilia A, the hemostatic level of factor VIIIc is ~25 to 30 IU/dl; in those with hemophilia B, values range from 20 to 60 IU/dl. However, for patients with major trauma or those undergoing surgery, higher plasma levels of these coagulation proteins should be achieved (i.e., 100% for factors VIII or IX; 25% to 50% for factor XIII).

In Vivo Recovery and Survival of Infused Coagulation Factors

When a coagulation factor is infused intravenously into a recipient who is deficient in that factor, the levels present in the circulation after intravascular mixing usually are significantly lower than those that would be expected from mere dilution in the recipient's plasma. That this initial in vivo recovery of infused coagulation factors (Table 53.9) is <100% presumably is the result of loss of these proteins from the intravascular space. The adsorption of coagulation factors by platelets and various cell and vascular surfaces may also be involved. The initial recovery of infused coagulation factors is difficult to quantify and ranges from nearly 100% for factor XI to as low as 30% for factor IX. Typically, because the range of in vivo recovery in a population is so variable, clinicians will determine the in vivo recovery for each individual by laboratory testing of blood samples drawn 10 to 20 (peak level) minutes after the therapeutic infusion.

TABLE 53.10

REPLACEMENT THERAPY IN HEMOPHILIA A AND HEMOPHILIA B

		Minor Bleeding (i.e., Uncomplicated Hemarthroses; Hematomas in Noncritical Areas; Hematuria; Dressing Changes;[a] Arthrocentesis;[a] Removal of Sutures and Drains[a])		Major Bleeding (Hematomas in Critical Locations; Traumatic Injuries; Multiple Tooth Extractions; Major Surgical Procedures)	
Disorder	**Therapeutic Product**	**Loading Dose**	**Maintenance Dose**	**Loading Dose**	**Maintenance Dose**
Hemophilia A (factor VIII deficiency)	Cryoprecipitate[b]	Not required	1.25–1.75 bags/10 kg every 12 h for 1–3 d	3.5 bags/10 kg	1.75 bags/10 kg every 8 h for 1–2 d; every 12 h thereafter
	Purified factor VIII[c]	Not required	10–15 IU/kg every 12 h for 2–4 d	30–40 IU/kg	30–40 IU/kg every 12 h
Hemophilia B (factor IX deficiency)	Prothrombin complex[b,c]	20–30 IU/kg	15 IU/kg every 24 h for 2–4 d	40–60 IU/kg	20–25 IU/kg every 24 h
	Purified factor IX[c,d]	20–30 IU/kg	15 IU/kg every 24 h for 2–4 d	60–70 IU/kg	20–40 IU/kg every 24 h

Note: Because weight-based calculations may not correctly predict plasma volumes in bleeding patients, confirmation of the hemostatic level of the coagulation factor being replaced should always be performed for patients with major bleeding indications, with appropriate dosage adjustments performed based on these results.
[a]Single dose of 15 IU/kg or equivalent amounts of concentrated product usually are sufficient.
[b]Recommended only if purified factor replacement therapy is not available. Antifibrinolytic therapy should not be used with prothrombin complex concentrates.
[c]Initial in vivo recovery of active factor varies somewhat depending on preparation.
[d]Recombinant factor IX may require higher doses.

After in vivo mixing is complete, the activity of most coagulation factors in the plasma declines in a biphasic manner—that is, an initial rapid loss of activity is followed by a more gradual decline (Fig. 53.10).[451] The first or rapid phase presumably is the result of diffusion into extravascular pools. This diffusion half-life ranges from minutes for factor VII to several hours for factor VIII. In general, it is the rapidity of this first phase, together with the initial in vivo recovery of the particular factor, that determines the necessity for and the size of the preliminary or loading dose of therapeutic product.

The second or slow phase of the survival curve presumably is the result of degradation and reflects the true biologic half-life of the infused factor (Table 53.9; Fig. 53.10). This parameter, together with the hemostatic level for the factor of concern, is the main determinant of the frequency of administration and the size of the maintenance dose of therapeutic product. For example, ~80% of factor VIII infused is initially recovered in the circulation; its initial (diffusion) and subsequent (biologic) half-lives are ~6 and 12 hours, respectively.[452] Thus, in the treatment of patients with hemophilia A, doses are administered every 8 to 12 hours. In patients with hemophilia B, the initial recovery of factor IX is 50% or less; its initial and subsequent half-lives are ~3 and 24 hours, respectively.[453] Hence, larger doses are required initially, but dosing is usually once a day to maintain adequate hemostasis. After a large loading dose or after several courses of therapeutic product have been administered, the survival curves of infused coagulation factors become nearly monophasic, presumably because extravascular spaces and the other mechanisms that remove infused coagulation factors from the circulation are saturated. New factor VIII and factor IX products currently in small phase III clinical trials have extended half-lives, so it will be important during these clinical trials to determine the appropriate initial dosing and dosing intervals for each of the new products.[89,454,455]

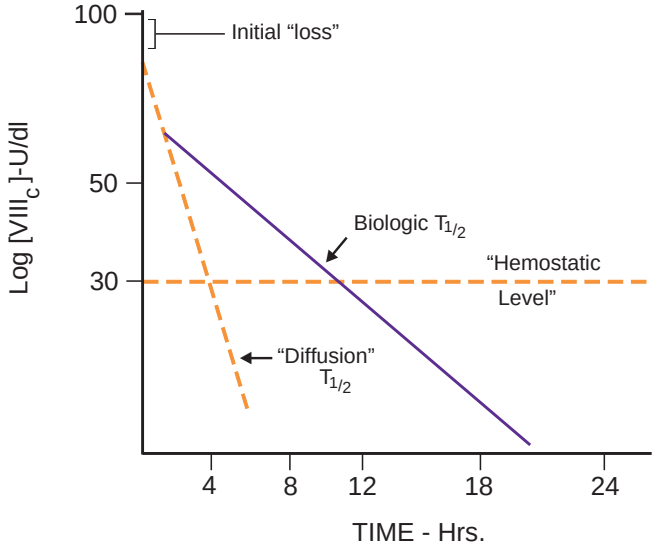

FIGURE 53.10. Biodynamics of factor VIII. A hypothetical survival curve obtained in a patient with severe hemophilia A after transfusion of sufficient factor VIII to increase the plasma factor VIIIc level to 100 IU/dl is shown. $T_{1/2}$, half-life.

Products

Before 1960, plasma was the only agent generally available for the treatment of the inherited coagulation disorders. Tremendous progress has been made in treating congenital coagulation disorders, primarily through development of effective therapeutic products. It should be noted that the life expectancy of a boy born in 1960 with severe hemophilia A was approximately 20 years, and now the life expectancy is essentially normal with modern therapeutic products and the comprehensive care of hemophilia treatment centers.[456] Tables 53.11 to 53.16 summarize therapeutic choices available to treat certain inherited bleeding disorders.

Plasma

Although most current replacement therapies of coagulation factor deficiencies involve sterile purified concentrates or recombinant proteins, plasma therapy is still important in treating some deficient states such as factor XI deficiency. FFP is usually preferred for therapeutic purposes. For factor VIII and fibrinogen deficiencies, and vWD, the appropriate coagulation factors are concentrated in cryoprecipitate. Both the rate of administration and the total dose of plasma administered are limited by the possibility of acute or chronic circulatory overload. The volume expansion

resulting from even moderate doses of plasma also limits the blood levels of the missing coagulation factor that can be attained. As a consequence, therapy with plasma alone can be expected to increase the levels of a deficient factor no more than 20 IU/dl above baseline values. When plasma is the only therapeutic agent available, plasmapheresis may be of adjunctive value.[457] A sterile solvent-detergent–treated plasma preparation is available,[458] but activity of certain coagulation proteases and inhibitors in this product is not equivalent to that of FFP.[459,460] Better preparations of solvent-detergent–treated plasma are available in Europe and are in clinical trials for the U.S. A British guideline for the use of FFP and cryoprecipitate has been published.[461]

Purified or Concentrated Coagulation Factors

Cryoprecipitate

A major advance in the therapy of hemophilia A was the demonstration by Pool et al. that cold insoluble material obtained from plasma contains high concentrations of factor VIII and fibrinogen.[462] Cryoprecipitate, which for many years was discarded during clarification of plasma, is prepared by slowly thawing rapidly frozen plasma at 2–4°C, then harvesting the precipitate by centrifugation. Cryoprecipitate prepared from 200 ml of fresh plasma (1 unit) contains 50 to 120 units of factor VIII, ~250 mg of fibrinogen, and therapeutically useful amounts of factor XIII and vWF that are rich in high-molecular-weight multimers. Cryoprecipitation provides 7- to 20-fold purification of factor VIII with respect to plasma and can be carried out by means of a closed double-bag system, even in small blood banks without special equipment. With the widespread availability of modern therapeutic products to treat hemophilia A and vWD, cryoprecipitate is now used primarily to treat hypofibrinogenemia.

Purified Factor VIII

Among the many methods developed to purify factor VIII, several are suitable for the large-scale production of concentrates of the human protein for therapeutic use, and sufficiently robust to attain in vivo factor VIIIc levels as high as 100 IU/dl in hemophilic patients without significant expansion of the plasma volume. Most plasma-derived factor VIII concentrates contain vWF but lack the high-molecular-weight vWF multimers found in cryoprecipitate or plasma.

Nearly all individuals with severe or moderate hemophilia require frequent therapeutic intravenous infusions and therefore,

TABLE 53.16

COMPARISON OF MISCELLANEOUS ANTIHEMOPHILIC AGENTS

Agent	Manufacturer/ Site	Method of Viral Depletion or Inactivation	Labeled Uses	AWP per Unit	Miscellaneous
Factor VIIa, Recombinant (Novoseven RT, Recombinant)	Novo Nordisk A/S Denmark	• Chromatographic purification	• Surgical prophylaxis and treatment of bleeding in patients with hemophilia A with inhibitors to Factor VIII • Surgical prophylaxis and treatment of bleeding in patients with hemophilia B with inhibitors to Factor IX • Surgical prophylaxis and treatment of bleeding in patients with acquired hemophilia • Surgical prophylaxis and treatment of bleeding in patients with congenital Factor VII deficiency	$1.67	• Contains mouse, hamster, and bovine proteins • Contains sodium chloride, calcium chloride dihydrate, glycylglycine, polysorbate-80, mannitol, sucrose, and methionine • RT formulation is stable at room temperature
Factor XIII, human (Corifact, human plasma-derived)	CSL Behring, GmbH Germany	• Aluminum hydroxide adsorption • Vitacel defibrination • Ion exchange chromatography • Heat treatment at 60°C for 10 h	• Routine prophylaxis in patients with congenital Factor XIII deficiency	$9.36	• Contains human albumin, glucose, and sodium chloride • Maintain trough Factor XIII activity levels between 5% and 20%
Anti-inhibitor Coagulant Complex (Feiba NF, human plasma-derived)	Baxter Healthcare Corporation, USA	• Nanofiltration • Vapor heat treatment • DEAE-Sephadex adsorption	• Surgical prophylaxis and treatment of bleeding in patients with hemophilia A and hemophilia B with inhibitors to Factor VIII or Factor IX	$2.17	• Contains Factor II, IX, and X (mainly inactivated), Factor VII (mainly activated), trisodium citrate, and sodium chloride • Generally used in patients with Inhibitor titers >5 Bethesda Units

as the concentrated factor products became available in the late 1970s most patients learned how to administer these infusions themselves at home.

Unfortunately, before the mid-1980s, the risk of viral transmission accompanied the use of these concentrated preparations, because they were prepared from large plasma pools and specific virucidal treatment was not used. The risk of virus transmission has been greatly diminished by serologic testing of the plasma for viruses and by sterilization of the concentrate by solvent-detergent treatment and/or heat sterilization.[463] High-potency preparations of factor VIII can be obtained by affinity chromatography using monoclonal antibodies. Therapeutic products of r-FVIII, activated factor VII, and factor IX are available for clinical use.[464] The initial (first-generation) r-FVIII products contain human albumin. Second-generation products eliminated albumin, but human and/or animal protein components are utilized in the manufacturing process. Third-generation products have removed all exogenous human and animal proteins from the manufacturing process. Other recombinant factor products are in development or in clinical trials in 2013, including products with extended half-life for factors VIII, IX, and VII.

Although modern production methods have reduced the risk of transmitting lipid-enveloped viruses (e.g., human immunodeficiency virus [HIV] and hepatitis B and C), transmission of non–lipid-enveloped viruses, such as hepatitis A and parvovirus B19, has been reported with sterilized plasma–derived products.[465–467] Tables 53.11, 53.13, and 53.14 summarize information on currently available products used to treat hemophilia A and hemophilia B.

Prothrombin Complex Concentrates, Factor IX, and Factor VII (VIIa)

The vitamin K–dependent factors (prothrombin; factors VII, IX, and X; and proteins C and S) are avidly absorbed by aluminum hydroxide or barium sulfate and can be readily concentrated by elution therefrom. This simple procedure is the starting point for several methods of preparing therapeutically useful concentrates of these proteins[468] (Table 53.15).

Concentrates of vitamin K–dependent coagulation factors contain small but significant amounts of activated coagulation factors that may be thrombogenic when administered in large doses or for extended periods of time. The thrombogenicity of such concentrates varies from preparation to preparation and from lot to lot and has been variously attributed to thrombin, factor VIIa,[327] factor Xa,[469] factor IXa,[470] and coagulant phospholipids.[471] Attention has been directed to the serious and even fatal thromboembolic complications of these products, including disseminated intravascular coagulation.[469,472] Such complications are particularly common in infants and in patients with liver disease,[473] as discussed in Chapter 54. The availability of monoclonally purified and recombinant factor IX products has led to decreased use of PCCs in the treatment of hemophilia B.[474–476] PCCs are now used primarily to treat patients with inhibitors to factor VIII, a condition in which the presence of thrombogenic proteins is clinically useful.[477–479] PCCs are also useful in treating deficiencies of prothrombin and factors VII and X. PCCs also are used for reversal of the anticoagulation effects of warfarin or the new oral anticoagulants when bleeding occurs, although their usefulness with the latter is controversial.[480,481]

When treating hemophilia B with replacement factor IX products, it should be noted that factor IX distributes to both intravascular and extravascular compartments. Consequently, loading doses required to achieve 100% of the normal plasma factor IX level are usually 1.5 to 2.0 times greater than those calculated from the patient's plasma volume. Thus, when purified factor IX products are used, twice the calculated amount of factor IX should be given for the initial dose. On the other hand, PCCs are thrombogenic, and when these products are used to treat patients with hemophilia B, the dosage should be reduced below that given when the purified products are used.

Recombinant factor VIIa is being used primarily for treatment of bleeding episodes in patients with hemophilia with inhibitors,[482] but also in patients with bleeding due to refractory thrombocytopenia, platelet dysfunction, factor VII deficiency (discussed in the section Factor VII Deficiency), or severe liver disease (discussed in Chapter 54).

Detailed summaries of prior and current coagulation factor products have been published recently.[2,483,484] A summary of the biologic properties of the new factor products in clinical trials in 2013 has also been published.[485]

Adjunctive Therapies

A congener of vasopressin, DDAVP, was originally developed for the treatment of diabetes insipidus. Its extrarenal actions stimulate vascular endothelial cells to release several proteins, including vWF in amounts sufficient to raise the plasma levels of this protein and associated factor VIII two to five times (Fig. 53.11).[486] This effect is therapeutically useful in most patients with type 1 vWD[487] and in some patients with mild hemophilia A,[488] and it is particularly useful because the biohazards of blood products are avoided. Excellent responses were obtained in the prevention of bleeding after minor surgical procedures, such as tooth extractions, and in some major surgical procedures.[489,490] It has been noted that young boys with mild to moderate hemophilia A have a lower response rate to DDAVP; the response rate of these patients improves later in life, and nonresponder children are candidates for retesting when they are older.[491]

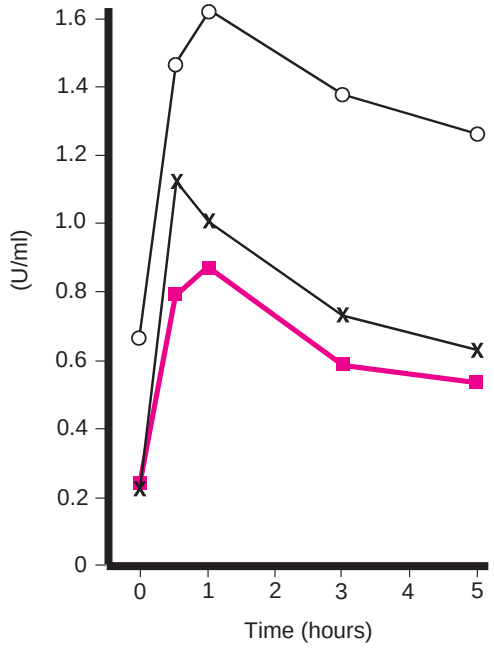

FIGURE 53.11. The response to desmopressin infusion (0.3 μg/kg body weight) in a hemophilic patient. *Open circles* indicate von Willebrand factor antigen, *solid boxes* indicate factor VIIIc activity, and *crosses* indicate factor VIIIc antigen. (From de la Fuente B, Kasper CK, Rickles FR, et al. Response of patients with mild and moderate hemophilia A and von Willebrand disease to treatment with desmopressin. Ann Intern Med 1985;103:6–14, with permission.)

The vWF released in response to DDAVP is rich in high-molecular-weight multimers[492] that increase adhesion and spreading of platelets at injury sites. This effect may explain the therapeutic efficacy of the drug in several disorders of platelet function, including uremia.[493]

DDAVP has also been reported to be clinically useful in patients with hemophilia B.[494] Although factor IX levels are minimally increased by DDAVP, the improved PTT values in hemophilia B patients given DDAVP associated with increases in factor VIII and vWF activity probably account for drug efficacy. Another group found DDAVP useful in hemophilia B patients when combined with antifibrinolytic therapy.[495]

DDAVP also induces the release of endothelial cell–derived plasminogen activators and has produced exaggerated fibrinolytic phenomena in several rare cases. For this reason, it is sometimes given with ε-aminocaproic acid (EACA) or other fibrinolytic enzyme inhibitors. Compared to vasopressin, DDAVP is markedly less potent as a pressor agent, but does retain significant antidiuretic activity. Neither effect has proved to be a major problem in its therapeutic use, but most experienced clinicians use caution when treating patients with hypertension or congestive heart failure. Reports of hyponatremia and seizures in children less than 2 years of age have led to cautious use of DDAVP in this population. Serum sodium should be monitored in adults who receive more than 3 or 4 sequential doses of DDAVP because of the side effect of hyponatremia, and in these patients water restriction is advised. DDAVP should not be administered more than once a day, and repeated doses of DDAVP may produce progressively diminishing amounts of vWF (tachyphylaxis), presumably because of exhaustion of stored vWF. DDAVP is available in a formulation for parenteral use or by the nasal spray Stimate.[490,496] DDAVP can be given parenterally (0.3 μg/kg, up to a maximal dose of 20 to 24 μg).[497] Physicians should be aware that two DDAVP nasal sprays are available, and that only the nasal spray with the higher DDAVP concentration (Stimate, 1.5 mg/ml) is effective in treating vWD. DDAVP should be used cautiously in older patients with vascular disease because of the potential risk of drug-induced thrombosis.[497–499]

Increasing use of DDAVP has revealed certain limitations of this hemostatic drug. One report in adult patients indicated that ~20% of patients experienced toxicity with DDAVP, including nausea and headache, and symptomatic hyponatremia was seen in ~5% of patients.[496] These side effects may be minimized with water restriction. Limitations of DDAVP in the pediatric population have been summarized.[500]

Inhibitors of fibrinolysis, such as EACA or tranexamic acid, may diminish bleeding from mucosal membranes where the concentrations of fibrinolytic enzymes are high, in patients with inherited coagulation disorders: For example, with bleeding in the mouth, tongue, tonsils, and pharynx, and with bleeding associated with operative dental procedures.[501] These drugs act to protect labile hemostatic plugs from fibrinolytic degradation. The use of EACA alone has been effective in the treatment of patients with mild hemophilia A (plasma levels of factor VIII >5 IU/dl)[502] and those with other mild inherited coagulation disorders such as vWD or factor XI deficiency. Some clinicians have used EACA as an adjunct to single-dose[503] or various other factor replacement regimens. EACA should be administered in oral doses (pills or syrup) of 6 g every 6 hours to adults and 100 mg/kg every 6 hours to children, for 3 to 4 days after tooth extraction. Doses of as little as 1 g every 6 hours may be as effective in most adult patients. The drug can be given intravenously (1 g/hour) for patients who cannot swallow. Hematuria or abnormal renal function is a contraindication to the use of this drug because of the hazard of intrarenal or ureteral obstruction by blood clots.[504] EACA also should not be given to patients with disseminated intravascular coagulation or active hepatitis, or to patients receiving PCCs, although an EACA mouthwash can be used with these latter drugs.[501,505]

Tranexamic acid is now available; the recommended adult dosage is two 650 mg tablets orally three times daily. These drugs may be teratogenic and should be used with caution in pregnant women.

MAJOR AND MINOR BLEEDING

General treatment guidelines for patients, including newborns with hemophilia and other bleeding disorders, have been published.[73,505,506] Additional detailed guidelines are available on the National Hemophilia Foundation's website, www.hemophilia.org, under Medical and Scientific Advisory Council (MASAC) recommendations.

For purposes of replacement therapy, the various bleeding manifestations commonly encountered in the inherited coagulation disorders are often divided subjectively into major and minor bleeding. Manifestations falling into the minor category include bleeding associated with uncomplicated hemarthrosis, symptomatic hematomas in noncritical areas, and minor traumatic injuries, as well as such therapeutic procedures as minor dental procedures, arthrocentesis, and dressing changes. Small cuts and scratches, removal of stitches or drains, superficial ecchymoses, and small hematomas may require no replacement therapy.

Major bleeding is by definition life-threatening and includes hematomas in critical locations and bleeding resulting from traumatic injuries, particularly those in which external blood loss is significant. Major bleeding occurs in surgical procedures, including tonsillectomy and the extraction of molar teeth. In the treatment of major bleeding, general guidelines recommend that the in vivo levels of the missing factor should be maintained above 60% to 80% to provide effective hemostasis until bleeding has stopped and appropriate healing has occurred so that there is no risk of rebleeding. In bleeding of a particularly critical nature, such as intracranial hemorrhage, or for the prevention of excessive bleeding during neurosurgery, factor levels should be maintained at 100% of normal.

Hemophilia A Minor Bleeding

DDAVP is effective in the treatment of minor bleeding manifestations in individuals with hemophilia A with baseline factor VIIIc levels >5 IU/dl, if patients have been previously demonstrated to respond to DDAVP with therapeutic levels of factor VIIIc after administration of DDAVP.[489,490] Side effects are more prominent if the total dose exceeds 24 μg. Both parenteral and intranasal administration produce significant increases in factor VIIIc and vWF.[507] Repeated doses of DDAVP at approximately daily intervals may produce useful increments of factor VIII in many patients. At least 24 hours should elapse before repeat administration of the drug in order for the endothelial cell stores of vWF to be replenished. Patients should be tested before surgery for their response to DDAVP by documenting adequate hemostatic levels of factor VIII levels 30 to 60 minutes after treatment, to ensure that the drug will be effective in appropriate responders. Only small amounts of factor VIII are produced by DDAVP in persons with severe hemophilia, and the use of this drug in patients with factor VIII levels <5 IU/dl is seldom useful and therefore is not recommended, even for minor bleeding manifestations. EACA (6 g orally every 6 hours) or tranexamic acid (25 mg/kg orally every 6 to 8 hours) has been administered together with DDAVP in an attempt to minimize fibrinolysis.[501] For maximal effectiveness, antifibrinolytic drugs should be started 24 hours prior to surgical procedures.

Although effective in minor bleeding, plasma or cryoprecipitate is not currently recommended for use in the treatment of patients with hemophilia A. Factor VIII concentrates are widely available and are the most useful therapeutic products. The regimens summarized in Table 53.10 illustrate one approach to treating hemophilia A. For some minor bleeding manifestations, treatment for a minimum of 3 days is required, but in most cases, a single dose of 10 to 15 IU/kg of factor VIII is usually sufficient.[508] In the treatment of minor bleeding, loading doses are not required, and laboratory monitoring of in vivo factor VIII levels is unnecessary. The minor bleeding treatment regimens summarized in Table 53.10 typically result in peak factor VIII levels of ~30%. Occasionally, if the minor bleeding episode is not treated promptly and bleeding is prolonged, then a hematoma may form, and often additional doses of factor products at higher doses are needed to prevent continued bleeding around the hematoma and potential pseudocyst formation. It is generally recommended in such cases of delayed treatment that full (100%) doses be administered to maintain adequate hemostatic levels until the hematoma is completely resolved.

Hemophilia A Major Bleeding

To treat major bleeding in patients with hemophilia A, sufficient factor VIII must be given often enough to ensure that the blood level does not fall to <30 to 50 IU/dl for any length of time. Most experienced clinicians target trough levels of more than 50% IU/dl until bleeding has stopped and substantial healing has taken place. Maintenance doses usually are administered every 8 to 12 hours. Regimens of continuous infusion of factor VIII are being used with increasing frequency during hospitalization, and have been shown to save total factor use by as much as 30%.[509,510–513] The administration of 2 IU/kg/hour of factor VIII produces a mean factor VIIIc level in the plasma of ~50 IU/dl and appears to be more cost-effective than twice-daily intravenous bolus treatments.[514] Continuous infusion also has the advantage of maintaining a consistent, therapeutic factor level. It is important to note that the treatment of postsurgical or major traumatic hemorrhage in patients with mild hemophilia A requires nearly as much therapeutic product as is needed for the severely affected patient. Many authors recommend treatment for 10 to 14 days after major surgical procedures, whereas others administer the full doses indicated in Table 53.10 for 10 days and continue half-doses for longer periods as healing continues and the patient is undergoing increasingly active physical therapy, especially after major orthopedic surgeries.

Determination in the laboratory of the in vivo levels of factor VIIIc is recommended during the treatment of patients with major hemorrhage. Incidents of unexpected subtherapeutic responses to infused factor VIII have been reported.[515] The use of the PTT to guide factor VIII replacement therapy is not recommended, because the results of these tests may be normal at levels of factor VIII that do not provide adequate hemostasis.[74]

von Willebrand Disease

In a disease as heterogeneous as vWD, decisions about treatment begin with accurate diagnosis (including vWD subtype) and complete evaluation. Fortunately, in many patients with vWD, bleeding manifestations are mild, and replacement therapy is seldom required. Unlike the situation in hemophilia, in which there is a close correlation between factor levels and clinical outcome, treatment decisions are more complicated in vWD because it is unclear which measurement (vWF, factor VIII, or platelet function) correlates best with the severity of bleeding or clinical outcome.[127] Many experts recommend following vWF:RCo and factor VIII levels,[516] but little information exists about the level of vWF:RCo that is critical for control of mucosal bleeding or the prevention of surgical bleeding. Bleeding times may not normalize, but a normal bleeding time is not required for a satisfactory response, and monitoring of bleeding time is not recommended.[155] Therapeutic goals include resolution of active bleeding and prevention of excessive bleeding in response to invasive procedures or trauma.

Unlike the situation with hemophilia A or B, chronic prophylaxis therapy is rarely required, but should be considered in patients with type 3 vWD who have recurrent gastrointestinal or joint hemorrhage.

The spectrum of therapeutic interventions in vWD includes desmopressin (DDAVP), concentrate infusion, and adjunctive therapy with medications that modulate bleeding symptoms by affecting either menstrual pattern or fibrinolysis. Dosing recommendations in vWD are empiric. In the case of a patient with major surgery or trauma, one recommendation is that clinicians attempt to bring the vWF (and factor VIII) level to near 100 IU/dl, and maintain it >40 to 50 IU/dl for the first 3 to 5 days, after which one recommended goal is to maintain the factor VIII level at >40 IU/dl for a total of 7 to 10 days or until healing is completed.[155] In surgical settings, monitoring of factor levels seems prudent, but monitoring of the bleeding time is discouraged, as surgeries have been done successfully in patients with type 3 vWD in the face of only partial correction of bleeding time.[155]

DDAVP is the mainstay of treatment for patients with mild forms of type 1 vWD.[155] The dosage, route of administration, and contraindications described under the discussion of hemophilia A also apply to the use of the drug in vWD. vWF and factor VIII levels generally increase by two- to fourfold over baseline. Because responsiveness to therapy between patients is variable, a test dose given at the time of diagnosis or before elective surgery is advised. Obtaining both vWF:RCo and factor VIII levels 1 hour after DDAVP administration is recommended in order to confirm a patient's responsiveness. It may also be informative to obtain a second sample between 2 and 4 hours after DDAVP to confirm that vWF has the expected 8- to 10-hour half-life after release.[147] Concerns regarding tachyphylaxis, hyponatremia, and rare thrombotic complications are similar to those when treating patients with hemophilia A. Note that whereas patients with type 1 vWD are likely to have a satisfactory response, patients with non–type 1 vWD respond poorly or unpredictably to DDAVP. Type 3 patients have essentially no endogenous vWF synthesis, and are DDAVP-nonresponsive. In one large series of patients with type 2B vWD, the platelet count fell from an average of 86,000 to 60,000/μl after administration of this drug.[210] Because thrombocytopenia may worsen after administration of DDAVP to patients with type 2B vWD and the platelet-type form of the disorder, patients with these variants should not be treated routinely with DDAVP.[155] However, some authors report good-responder type 2B vWD patients who received DDAVP.[517] Response in type 2A vWD is variable and may be of shorter duration than in type 1 patients, because of increased vWF proteolysis. Similarly, factor VIII levels may rise in response to DDAVP in patients with type 2N vWD, but because of the deficient factor VIII–stabilizing activity of vWF in this variant, levels of factor VIII then fall at an accelerated rate.[518] Because of interindividual variability, a documented therapeutic response to DDAVP should be obtained before surgical prophylaxis with the drug, to ensure adequate hemostasis postoperatively. It is recommended that this DDAVP trial be performed at the time of diagnosis of vWD.

Transfusion therapy with plasma-derived products is the therapy of choice in DDAVP-unresponsive patients who require factor support. In order to treat both the factor VIII deficiency and the defect in primary hemostasis seen in patients with severe vWD, it is generally necessary to give a product with factor VIII activity that also contains high-molecular-weight multimers of vWF. The concentrations of vWF and factor VIII in FFP are insufficient for appropriate therapy. Cryoprecipitate contains ~80 to 100 units/bag, 5 to 10 times the concentration of these factors compared to plasma. Cryoprecipitate has a small residual risk of viral transmission and is not currently suited for virus-inactivation therapy; consequently, pathogen-inactivated, intermediate-purity factor VIII concentrates with demonstrated preservation of vWF multimers are the preferred replacement product. At the time of this writing, three commercial plasma-derived products were licensed in the United States for this indication (Humate-P, manufactured by CSL Behring and known as Haemate-P in Europe; Wilate, manufactured by Octapharma; and Alphanate SD/HT, manufactured by Grifols) (Table 53.12). Several other commercial products have been developed and are currently licensed in other countries. A Canadian multicenter study confirmed "excellent" or "good" outcomes in 97% of patients treated with Humate-P, with a median recovery of 1.23 IU/kg per IU/kg infused.[519] Similarly, Alphanate was shown to ultimately control all bleeding episodes in one large multicenter trail.[520] Alphanate is currently not licensed for treatment of vWD; it is labeled only in factor VIII units, but vWF:RCo has been reported to be ~50% lower than the labeled factor VIII content.[520] A PK clinical trial compared Wilate vs Humate-P and found similar PK parameters for the two products; however, Wilate achieved a 1:1 ratio for vWF:factor VIII, suggesting simpler dosing of Wilate.[521] A chromatographically purified vWF concentrate with minimal factor VIII (Wifactin) has been evaluated in type 3 vWD. After infusion, factor VIII levels rise slowly and peak ~6 to 8 hours later. These data imply that if type 3 patients are to be pretreated for surgery with a pure vWF-containing concentrate, either concomitant factor VIII will need to be administered, or the surgery should be scheduled for 6 to 8 hours after the vWF administration.[155,203] Very-high-purity plasma-derived factor VIII concentrates and r-FVIII concentrates are essentially devoid of vWF, and they should not be used to treat vWD.

Suggested doses and target factor levels for treatment of vWD patients have been published.[129,522] Recommended doses in ristocetin cofactor units are similar to factor VIII doses, because both have similar in vivo recovery (~2 IU/dl rise in plasma concentration for each IU/kg of factor administered). Monitoring response to therapy with both factor VIII and vWF:RCo is appropriate. Although vWF levels can be expected to fall between doses of vWF-containing concentrate, which has a half-life of 8 to 10 hours, factor VIII levels may continue to rise in response to the patient's endogenous factor VIII production. Avoidance of unusually high factor VIII levels is suggested in order to minimize venous thrombotic risk.[523]

Platelets are estimated to contain ~15% of the total body vWF. Some authors suggest using platelet transfusion in patients with severe vWD who exhibit bleeding despite plasma factor VIII concentrate therapy.[155] Thrombocytopenia may be exacerbated by the administration of normal exogenous vWF in platelet-type (pseudo) vWD,[524] but not in type 2B vWD. Patients with platelet-type vWD should receive platelet transfusions for significant bleeding or surgery.

Adjunctive therapy for vWD patients with menorrhagia usually takes the form of oral contraception or other hormonal intervention.[155] Antifibrinolytic therapy and DDAVP have also found a role in control of menorrhagia[501,525] and oral bleeding. Doses of intranasal DDAVP administered every 12 to 24 hours for up to 3 days, or ε-aminocaproic acid up to 5 g three times per day, or tranexamic acid, have been reported to be useful in control of menorrhagia,[127] but toxicity profiles should also be considered. Failure of medical therapy may lead to surgical approaches, such as endometrial resection or even hysterectomy.

Pregnancy is a special situation for patients with vWD. vWF levels generally improve in patients with type 1 vWD as pregnancy proceeds, but improvement is less likely in type 2A vWD, and thrombocytopenia may actually worsen in patients with type 2B and platelet-type (pseudo) vWD variants. Current information indicates that the patient's factor VIIIc at delivery predicts the risk of bleeding, with a factor VIII level <50% of normal at term being associated with excessive bleeding.[526] If sufficient factor VIII levels are achieved, aggressive surgical hemostasis and efficient uterine contraction should prevent peripartum bleeding. Thus, factor levels should be determined before delivery. If sufficient

factor VIII levels are not achieved before delivery and the patient is known to respond to DDAVP, this drug can be given to the mother immediately postpartum. If the patient does not respond to DDAVP, then vWF/factor VIII concentrate should be administered peripartum. Although endogenous vWF levels rise during pregnancy in patients with type 1 vWD, the vWF levels fall quickly after parturition, and patients should be advised to report late bleeding. DDAVP or replacement therapy may be useful to prevent late bleeding in patients with vWD. Finally, unlike type 1 vasopressin agonists, DDAVP has little or no oxytocic activity, and some authorities have advocated prophylactic use before invasive diagnostic or surgical interventions in pregnant vWD patients.[155]

Alloantibodies to vWF develop in a minority of patients with type 3 vWD after replacement therapy. The risk appears to be highest in patients with large gene deletions. Administration of vWF-containing concentrates to these allosensitized patients has been associated with anaphylactic reactions. Alternative therapies that have been successful include high-dose r-FVIII administered by continuous infusion at doses of 700 to 900 IU/kg/day,[127] or recombinant factor VIIa. Patients with acquired vWD (see Chapter 54) have broader therapeutic options, because DDAVP and replacement therapy may have some efficacy, as would treatment of the underlying disease process.

Hemophilia B Treatment

Most of the guidelines for replacement therapy of patients with hemophilia A apply to the treatment of those with hemophilia B (Table 53.10). Because of the low initial in vivo recovery and the rapid initial disappearance of factor IX from the circulation, higher initial doses are recommended, even for the treatment of minor bleeding. In patients with hemophilia B, purified factor IX concentrates or recombinant factor IX products are recommended for the treatment of major or minor hemorrhage because of the thrombotic potential of PCCs[469,472] (Table 53.14). One disadvantage of recombinant factor IX compared to plasma-derived factor IX is a lower in vivo recovery of recombinant factor IX (~30% lower than predicted), perhaps related to different posttranslational modifications of the recombinant protein.[527] Higher doses of recombinant factor IX need to be given routinely to achieve similar therapeutic levels, and monitoring factor IX levels with this product should be done routinely,[528] especially in young children.[529] These concerns about in vivo recovery do not seem to apply to the new extended half-life factor IX products in clinical trials in 2013.[454,455,530]

An unusual complication of hemophilia B therapy is anaphylaxis. These patients typically have severe factor IX deficiency with complete gene deletions.[531,532] The anaphylaxis typically occurs with the first or second administration of factor IX, and essentially never with subsequent infusions if the initial doses are tolerated well. These patients rarely respond to immune-tolerance induction, and should be treated with either PCCs or recombinant factor VIIa (see Chapter 54).

Gene Therapy for Hemophilia

Gene therapy for the inherited bleeding disorders is now promising, after many years of frustrating failures.[533–535] A major success was recently published involving patients with severe factor IX deficiency.[536] Six of six subjects with severe hemophilia B were treated with adeno-associated viral vector carrying a normal factor IX gene, and have had factor IX levels of 2% to 4% for many months. While this is encouraging, there need to be additional studies with more subjects to evaluate safety and efficacy of gene therapy in hemophilia.[537] Work with the factor VIII gene for viral delivery is more complex because of its much larger size. Viral and nonviral constructs containing genes for factor VIII or factor IX have been used, as well as modified retrovirus, adenovirus, or adeno-associated virus vectors. Sustained partial correction of factor VIII or factor IX deficiency has been seen with gene transfer in animal models, and it is expected that with additional work, these encouraging results will be seen in patients also. A major focus of gene therapy research is to develop a gene delivery system that is efficient, safe, nonimmunogenic, and provides long-term gene expression.[538,539] The promise for gene therapy lies in the fact that if gene therapy could increase endogenous factor VIII or factor IX levels only from <1% to 1 to 2 IU/dl, this incremental change would dramatically alter the clinical course and treatment of patients with severe hemophilia. Significant questions about potential risks associated with gene therapy, including inflammatory responses, inhibitor development, oncogenesis, and germline mutations will need to be addressed as further clinical trials are undertaken.[540]

Factor VII Deficiency

Unlike in patients with severe hemophilia A or B, bleeding in a patient with factor VII deficiency undergoing surgery is variable, so multiple issues should be considered in the perioperative care of factor VII–deficient patients,[541–543] including the individual patient's prior experiences and symptomatology: Patients with a history of hemarthrosis or CNS hemorrhage are at a higher risk for bleeding complications. The oral and urogenital tracts are areas of high local fibrinolytic activity. The minimum factor VII level required for surgical hemostasis is not known; patients with levels <3 IU/dl are at high risk for bleeding, whereas patients with levels of 15 to 25 IU/dl are less likely to develop bleeding complications associated with surgery. Finally, one should consider the logistics of therapy, because factor VII has a short half-life, possibly as short as 3.5 hours. Volume overload is likely, as plasma is commonly used as a source for factor replacement, and the safety profile of the various factor VII–containing products varies.

Traditionally, FFP, PCCs, or plasma-derived factor VII concentrate has been used for factor VII replacement therapy, and more recently, recombinant human activated factor VIIa (rFVIIa) has been the recommended product.[544–550] In general, doses of between 15 and 30 μg/kg of rFVIIa were administered at intervals of 4 to 6 hours. The half-life of recombinant factor VIIa is between 2.5 and 3 hours, and the roles of continuous factor infusion and laboratory monitoring remain to be defined in treating factor VII-deficient patients.[551] Antibody to factor VII has developed in response to therapy in some individuals with congenital factor VII deficiency.[551] Although serious thrombotic events have been reported when rFVIIa has been used in an attempt to control bleeding in the setting of acquired coagulopathy,[552] only three reports of serious thrombotic complications were collected in a recent review of rFVIIa use to treat congenital factor VII deficiency. Furthermore, at least two of those three cases were managed using higher doses of rFVIIa than are recommended here. The risk of thrombosis should be considered when rFVIIa is being used, especially when treating a condition that itself is associated with thrombosis, such as orthopedic surgery.[553]

Although the half-life of factor VII is short, both factor VII and, more recently, rFVIIa infusions have been successful in chronic infusion prophylaxis programs to prevent spontaneous CNS and joint bleeding. Factor VIIa was administered every other day or twice weekly, suggesting that an additional mechanism of action independent of the short plasma half-life was operative in these cases.

Although it is no longer the "product of choice," plasma can be used for replacement therapy for factor VII in emergency situations when other products are not available. Plasma has the disadvantage of posing a large volume load and has potential for viral transmission. For patients treated with plasma, a loading dose of 15 to 20 ml/kg, followed by 4 to 6 ml/kg every 6 hours for 7 to 10 days has been recommended. Plasma exchange therapy has been used in some patients to avoid volume overload.[554] PCCs

have been used, but they too are not the product of choice. PCCs carry some thrombotic risk, which may be associated with the generation of unnecessarily high levels of other activated vitamin K–dependent coagulation proteins.[555] This is especially a problem with extended PCC use or use of PCCs in the setting of liver disease. Those products are not generally labeled with their factor IX content, but the factor VII content is usually available from the manufacturer. Recovery studies indicate that an administered factor VII dose of 1 IU/kg will raise the patient's plasma factor level by ~2 IU/dl. If it is available, the use of purified factor VII concentrate might decrease the thrombotic risk associated with the use of less-specific PCCs. A heat-treated intermediate-purity factor VII concentrate (manufactured by Immuno A.G.) had been used for treatment of acute bleeds, perioperative prophylaxis, and for prevention of recurrent CNS hemorrhage. Factor VII levels rose ~2.33 IU/dl for each IU/kg infused, and the factor VII half-life was ~6 hours. Despite the short half-life of factor VII, infusions as infrequent as once per week were successful in preventing recurrent intracranial bleeding.[336] For replacement therapy in a surgical setting, factor-level monitoring is recommended, to ensure that perioperative factor levels are >25 IU/dl.

Factor XIII Deficiency Treatment

Therapy for congenital factor XIII deficiency is based on the principle that only a small quantity of factor XIII must be present in human plasma to promote normal hemostasis.[556] The long half-life of factor XIII (estimated as being between 9 and 19 days in the literature [557]) makes prophylactic therapy both practical and highly advisable given the high frequency of intracranial hemorrhage.[284] This long half-life may not be present in some situations in newborn infants with severe FXIII deficiency.[588] FFP and factor concentrates have been used successfully to prevent factor XIII–associated bleeding, and these remain the treatment of choice. Pasteurized factor XIII concentrate that contained only the A subunit prepared from human placenta has been replaced by plasma-derived preparations that contain both A and B subunits.[559] A plasma-derived factor XIII preparation is available (Corifact, CSL Behring, Table 53.16) to treat congenital factor XIII deficiency. Recommended dosing is 40 IU/kg every 4 weeks with dose adjustments based on achieving a trough level of 5% to 20%. Two other preparations that have been used therapeutically are Fibrogammin-P, which is licensed in several countries (but not the United States or Canada), and a factor XIII preparation from Bio Products Laboratory that has been used in the United Kingdom. Kinetic studies with Fibrogammin-P indicate a mean recovery of 65% and a plasma half-life of ~5 to 11 days.[560,561] A recombinant factor XIII concentrate composed of the A subunit has been developed and is currently undergoing clinical investigation.[562] Recommended dosing for factor XIII concentrate is 10 to 20 IU/kg body weight every 4 to 6 weeks for prophylaxis against unprovoked bleeding. It is strongly recommended that all patients with severe factor XIII deficiency be placed on life-long prophylaxis in order to prevent the devastating complication of intracranial hemorrhage. Prophylactic therapy of affected patients undergoing surgery may actually require more intensive replacement therapy. If concentrates are unavailable, patients can be given either FFP or cryoprecipitate.[563] A typical plasma dose is 10 to 20 ml/kg body weight, every 4 to 6 weeks. Cryoprecipitate at a dose of 1 bag per 10 to 20 kg of body weight every 3 to 4 weeks is an alternative therapy that has the advantage of requiring transfusion of a smaller volume. It is recommended that factor XIII levels be kept between 25% and 50% of normal to achieve normal hemostasis following major trauma in these patients; doses of concentrate recommended are 35 IU/kg preoperatively, followed by 10 IU/kg/day for 5 more days. Affected patients with a history of spontaneous abortions can complete a normal pregnancy when they are managed with prophylactic FFP or factor XIII concentrates. Factor XIII levels fall during pregnancy, and replacement therapy is recommended every 21 days.[564] Monitoring of factor XIII trough levels may also be helpful. Formation of antibody inhibitors to factor XIII after replacement therapy appears to be rare.

In acquired factor XIII deficiency, >50% of patients need aggressive therapy. The most useful therapy for patients who have acquired inhibitors to factor XIII remains plasma exchange with or without immunosuppression with cytotoxic drugs. In addition, infusions of platelets can be given with occasional success, because platelets contain large amounts of factor XIII. Alternatively, replacement therapy with a factor XIII concentrate can be considered.

Treatment Considerations for Miscellaneous Disorders

Therapeutic regimens recommended for the treatment of patients with any of the less common inherited coagulation disorders are summarized in Table 53.8.

The management of major bleeding caused by deficiencies of prothrombin and factor X has been facilitated by the availability of PCCs (Table 53.15). The majority of these plasma-derived products contain three factors (prothrombin, factor IX, and factor X), but four-factor concentrates are also available.[481] Factor IX content has generally been used to label the potency of these concentrates, but factor content of the other vitamin K–dependent factors relative to the factor IX content is often available, either in published reports[481] or from the manufacturer. The currently available PCC products are subjected to virus-attenuation steps to inactivate hepatitis B, hepatitis C, and HIV. However, the thrombogenicity of these products remains a concern,[469,472] and concomitant use of antifibrinolytics may increase that risk. In the absence of a specific factor concentrate, plasma transfusion may also be used to replace vitamin K–dependent coagulation factors.

There are few data on which to base recommendations on treating the rare bleeding disorders. It is estimated that 1 IU/kg of infused PCC will raise the prothrombin level by 1 IU/dl. Relatively low levels of prothrombin are required for normal hemostasis, and target values of 40 to 50 IU/dl are recommended for surgery. The half-life of prothrombin is ~72 hours, so infrequent postoperative infusions, every 2 to 3 days, is reasonable.[565] Guidelines for the treatment of factor X deficiency vary. The biologic half-life of factor X is 20 to 40 hours. Calculation of the factor X dose is based on the empiric observation that for each 1 IU/kg infused, factor X levels rise ~1.5 IU/kg. Factor X levels varying from 5 IU/dl to as high as 40 IU/dl have been recommended for surgery; however, levels >20 IU/dl were suggested by the United Kingdom Haemophilia Centre Doctors' Organisation.[236] Monitoring of the factor level achieved is prudent.

There are currently no factor V concentrates, so patients with factor V deficiency who require replacement therapy are treated with transfusions of plasma. Target levels of factor V recommended before surgery vary. The United Kingdom Haemophilia Centre Doctors' Organisation recommend target levels >15 IU/dl, whereas others have suggested levels of 25 to 30 IU/dl.[236] The half-life of plasma factor V is reported to be 12 to 36 hours. In the United States, some blood collection organizations are moving away from production of FFP, toward production of plasma that is separated and frozen within 24 hours after collection (FP-24). Although factor V has been called "labile factor," levels of factor V in FP-24 are only modestly reduced compared to those in FFP.[566] In addition, factor V appears to be relatively stable in "thawed plasma" held up to 5 days in transfusion service refrigerators at 0–4°C.[567] Loading plasma doses of 20 ml/kg are often given, followed by maintenance infusions of 3 to 6 ml/kg every 12 hours. Cryoprecipitate does not contain sufficient factor V to be used as an alternative to plasma. If adequate factor V levels cannot be achieved by simple transfusion, exchange transfusion may be

tried. Finally, in the setting of acquired factor V autoantibody, platelet transfusion has been used successfully. Similarly, platelet transfusion might hold some promise in treatment of a patient with congenital factor V with alloantibody.[236]

Patients with factor XI deficiency usually respond well to FFP. A solvent-detergent plasma preparation has been developed[568] and may be the desired therapy not only for factor XI deficiency, but for other factor deficiencies for which sterile concentrates are not available. Unfortunately, some of the factor XI concentrates were shown to be thrombogenic in early clinical studies,[236] and their clinical utility may be limited by this toxicity.

Cryoprecipitate is used in replacement therapy for afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia. When a sterile, nonthrombogenic fibrinogen concentrate becomes routinely available, it should replace cryoprecipitate for treating these latter disorders. Such a product is in clinical trial.[241] Fibrinogen replacement therapy has been reviewed.[241]

SPECIAL ASPECTS OF TREATMENT

Hemarthrosis

All patients with hemarthrosis should receive adequate replacement therapy in order to prevent the development of permanent disability due to repeated bleeding into a joint. Pain usually is relieved promptly and is a reliable index of the therapeutic response. Supportive therapy follows the acronym of RICE: Rest through immobilization, ice to cool the inflammation and reduce the swelling, compression to reduce the swelling and bleeding, and elevation to reduce the swelling. The administration of analgesics that do not interfere with platelet function is appropriate to relieve the pain of bleeding into the joint.

Arthrocentesis usually is unnecessary if therapeutic infusion is accomplished early, but it may be of significant benefit when the joint is severely distended or when resolution of the hemarthrosis is delayed despite adequate replacement therapy.[569] Large volumes of blood seldom can be aspirated, but even a small volume may relieve symptoms. If arthrocentesis is performed, it should be done immediately after the administration of a therapeutic dose of factor.

Early physiotherapy aimed at restoring the full range of motion of the affected joint should be instituted as soon as the acute stage of hemarthrosis has resolved. More energetic physiotherapeutic techniques should be carried out only in conjunction with an adequate course of replacement therapy. Various orthopedic devices (orthotics), such as braces and removable bivalve plaster casts, which provide additional support for chronically injured joints, have proved useful in reducing the frequency of recurrent hemarthrosis, particularly in the knee and ankle joints.[570] For pain management of hemophilic arthropathy, nonsteroidal antiinflammatory agents may be helpful.[571] In particular, salsalate (Disalcid) or choline magnesium trisalicylate (Trilisate) or the newer cyclo-oxygenase-2 inhibitors (Celebrex) may be useful in patients with bleeding disorders, because these drugs have antiinflammatory activity but do not impair platelet function.[572,573]

Regular infusions of factor concentrates may prevent or significantly delay progression of hemophilic arthropathy. A randomized clinical trial in boys demonstrated the markedly better results of a prophylaxis program versus episodic treatment on long-term joint function.[58] This study demonstrated a significant reduction in joint damage and other bleeding episodes in the prophylaxis group. Similar results would be expected in adult patients also, but have not yet been demonstrated in a rigorous clinical trial.

Prophylaxis therapy is regarded as optimal treatment for patients with severe hemophilia. One report compared two prophylaxis regimens for hemophilia A—standard prophylaxis (20 to 40 IU/kg every other day) vs. PK-tailored prophylaxis (20 to 80 IU/kg every third day). Annualized bleeding rates, factor consumption, and adverse events were similar.[574]

Reconstructive surgical procedures are available to improve the function of chronically damaged joints.[61,575,576] Favorable results have been reported with total knee arthroplasty in several series.[576] Long-term follow-up (>5 years) indicates adequately functioning prostheses and persistent pain relief in most patients. Synovectomy is effective in reducing the frequency of hemarthrosis that cannot be controlled by replacement therapy.[577] Radioisotopic synovectomy is also effective therapy for hemophilic arthropathy.[578] A review of the literature on radioisotopic synovectomy indicates that ~80% of patients benefit from the procedure,[579] but an updated safety review identified two patients who subsequently developed acute lymphocytic leukemia.[580] While not statistically significant, this report raises a safety question, and until more data and long-term follow-up is obtained, radioisotopic synovectomy should be considered carefully in the context of each patient's needs.

Hemophilic Cysts

Hemophilic cysts are very rare with modern treatment, but once were a serious complication that developed in patients with severe hemophilia A or B that had recurrent bleeding with inadequate treatment. Also known as *hemophilic pseudotumors,* such cysts are gradually expanding blood-filled loculations that apparently originate from hemorrhages into confined subperiosteal, tendinous, or fascial spaces. The osmotic pressure created by breakdown products of blood in such confined spaces may produce further influx of fluid; this, together with recurrent bleeding, explains the progressive increase in the size of the cyst and its ability to erode contiguous structures. Such cysts most commonly develop in the thigh and may destroy bone as well as the soft tissues as they increase in size. Hemophilic cysts are readily prevented, but difficult to treat. Although long-term replacement therapy combined with x-ray treatment has been successful in a few cases,[581] hemophilic pseudocysts may require radical surgical procedures such as extensive resections or amputations. Even with optimal supportive therapy, these procedures often are unsuccessful and may be complicated by infection. Surgical and nonsurgical approaches to manage pseudotumors have been reviewed.[582,583] The modern use of home prophylaxis has made pseudotumors an unusual complication of hemophilia, although they still occur in parts of the world that do not have access to prophylaxis treatment of hemophilia.

Intracranial Bleeding

Despite the widespread use of prophylaxis programs, hemorrhage, including intracranial hemorrhage, remains a leading cause of death among persons with hemophilia.[584] After the neonatal period, intracranial hemorrhage affects 3% to 10% of hemophilia patients not receiving prophylaxis.[585] An estimate of the incidence of intracranial hemorrhage placed the risk at 1 in 200 per year, proportional to the time spent with factor levels below 1 IU/dl.[585] A mortality survey for hemophilia A for the years 1995 to 1998 found that hemorrhage was the listed cause of death for 22% of hemophilia A patients who died during that time period.[11] Approximately 50% of cases are associated with head injury[586]; the etiology is not apparent in 38% of cases (spontaneous cases).[587] Bleeding may be subdural, epidural, or intracerebral. Subarachnoid bleeding occurs least commonly, but it carries the best prognosis. Hemorrhage also may develop in the spinal cord or spinal meninges. In cases associated with head trauma, the presence of a lucid interval and the absence of localizing neurologic signs at the time of presentation are commonly seen.[587]

Significant head injury must be treated early and intensively in patients with inherited coagulation disorders. Those with

hemophilia A and B should immediately receive sufficient factor product to raise the plasma level of deficient factor to 100 IU/dl. Samples for essential coagulation studies should be drawn before administration of replacement therapy, but treatment should not be delayed while waiting for results of these studies. Radiologic procedures, such as computed tomography scanning, should be performed after the therapeutic product is administered. If it is performed expertly, lumbar puncture usually can be carried out without serious risk, but many clinicians prefer to wait until replacement therapy has been given. In one series, replacement therapy given within 6 hours of head injury prevented any intracranial bleeding.[588]

In cases involving major cranial trauma, if neurologic signs or symptoms develop, or if intracranial bleeding is confirmed radiologically or otherwise, the administration of factor VIII or factor IX concentrates should continue on a schedule in doses sufficient to keep the nadir levels of the deficient factor >30 IU/dl. Treatment should be maintained for 10 to 14 days.[587] Before the widespread use of factor VIII concentrates, the mortality rate after intracranial bleeding was greater than 70%.[586] For treatment of patients who have suffered from an episode of spontaneous intracranial hemorrhage, most experts recommend prophylaxis therapy so that the factor level rarely is below 1 IU/dl, as the risk of recurrence is significantly higher in such patients. It is expected that the morbidity and mortality of intracranial bleeding will be reduced further with the increased use of the extended half-life factor products currently in phase 3 clinical trials.

Viral Transmission from Past Factor Concentrates: HIV and Hepatitis C

Acquired immunodeficiency syndrome (AIDS) was first recognized in 1978 and was found to be transmitted in blood products in the early 1980s,[589] infecting approximately 70% of persons with severe hemophilia using factor concentrates prior to 1984. HIV transmission through factor concentrate was reduced to zero after 1985, through the development of factor concentrates including virucidal steps in the manufacturing process, the institution of stringent donor testing, and the availability of recombinant products. Improvements in therapy for HIV have allowed many persons with hemophilia to become long-term survivors, although there remain many seropositive patients who have not progressed to AIDS.

In the United States mortality survey of hemophilia A patients between 1995 and 1998, liver disease was listed as a cause of death in 15% of patients.[590] It is estimated that approximately 90% of persons with severe hemophilia who used factor concentrates prior to 1984 were infected by the hepatitis C virus transmitted in the factor concentrate.[591] Nearly 20% of these individuals were able to eradicate the virus, thus becoming hepatitis C antibody positive, but hepatitis C virus negative. However, for other patients, the hepatitis C virus has progressed inexorably with many dying from chronic liver disease. Liver biopsies confirmed the presence of chronic active hepatitis in many patients.[592] The disorder is usually the result of persistent infection with the hepatitis C virus, but may be complicated in some individuals by coinfection with hepatitis B.[593,594] A prospective study of U.S. hemophilia patients found that 66% of the hepatitis C–infected hemophilia patients also had HIV infection,[591] and that coinfection was associated with a five- to sixfold increase in end-stage liver disease. Modern manufacturing methods render factor concentrates free of hepatitis C virus and other lipid-enveloped viruses. No hepatitis C viral transmission has been connected with factor concentrates since 1986. Patients who are seronegative for the hepatitis A and B viruses should receive immunizations for these viruses. However, standard solvent-detergent–inactivated products may still transmit non–lipid-enveloped viruses such as parvovirus,[595] hepatitis A,[596] and other viruses.[597] An unresolved issue is the transmission potential of the agent that causes Creutzfeldt-Jakob disease, but the manufacturers of plasma-derived factor concentrates have taken steps to reduce the risk of transmitting this agent also.[598–600]

Antibodies to Coagulation Factors

A major problem with current therapeutic products in hemophilia A is the development of neutralizing antibodies (inhibitors) to factor VIII. This complication is less common in patients with hemophilia B and other inherited coagulation disorders. Such antibodies may seriously complicate the treatment of these patients (see Chapter 54).

Home Treatment Programs

In general, current recommended therapy of hemophilia is replacement therapy or prophylaxis treatment to prevent any spontaneous bleeding episodes, rather than treating bleeding episodes after they occur, termed "on demand." A prospective randomized clinical trial has demonstrated that joint damage is minimized if treatment is begun immediately after the onset of symptoms.[58] The availability of factor VIII concentrates that are stable in home refrigerators led to the development of various early home-care programs.[601] Parents and patients are trained to administer the product at the first sign of bleeding. Such programs have resulted in decreased bleeding episodes and improved preservation of joint function.[602,603] Typical prophylactic regimens are 25 to 40 IU/kg of factor VIII three times per week for hemophilia A, and 25 to 40 IU/kg of factor IX twice per week for hemophilia B. Such therapy usually maintains the trough factor level at or above 1% of normal. In older hemophilia patients with significant joint arthropathy, higher doses often are needed, while in younger patients with essentially normal joints, the lower factor doses are sufficient. A 30-year follow-up report confirmed the efficacy of prophylaxis.[604] An economic analysis of prophylaxis found that although higher costs were associated with prophylaxis programs, the approach was justified on medical grounds.[605] It is recommended that patients begin prophylaxis soon after the first joint bleed.[606]

In 2013 there were at least 3 new factor VIII products and 3 factor IX products with extended half-lives in clinical trials. There have been no safety issues demonstrated so far in this clinical trial experience. These new products should dramatically improve the treatment of patients with hemophilia by simplifying prophylaxis regimens.

Dental Care

Special attention should be given to preventive dental care in patients with coagulation disorders, so as to minimize the complications, expense, and hazards of operative dental procedures. The extraction of even a single tooth usually requires replacement therapy. Most authorities recommend that dental procedures in patients with inherited coagulation disorders be carried out under cover of replacement therapy and antifibrinolytic therapy.[502]

THE FUTURE IN HEMOPHILIA TREATMENT

After the devastating epidemics in the hemophilia community caused by HIV and hepatitis C, it was a major step forward to have available recombinant products for treatment of hemophilia in the early 1990s. Now, 20 years later, several new products are in clinical trials that promise major advances in hemophilia treatment. Factor VIII and factor IX have been available as recombinant proteins for nearly 20 years, but due to their relatively short

half-lives, still require frequent intravenous infusions in order to maintain clotting factor concentrations in plasma to avoid the risk of spontaneous bleeding. The longer half-life factor VIII and factor IX products will change treatment paradigms. In addition, there are efforts to provide other coagulation proteins as recombinant therapeutic products. Finally, there are renewed efforts in gene therapy for hemophilia, with better and safer viral vectors.

CHAPTER 54

ACQUIRED COAGULATION DISORDERS

George M. Rodgers

Abnormalities in blood coagulation may complicate a large number of disorders (Table 54.1). In contrast to inherited disorders in which deficiency or abnormality of a single factor is characteristic, the acquired forms usually are associated with multiple coagulation abnormalities, and the disorder often is complicated by thrombocytopenia, deficient platelet function, and abnormal inhibitors of coagulation. Because of the compound nature of the hemostatic defect, the severity of bleeding often correlates poorly with the results of laboratory tests in patients with acquired coagulation disorders, and replacement therapy may be ineffective. With some notable exceptions, however, bleeding usually is less severe than in the inherited forms, and the clinical picture often is complicated by signs and symptoms of the underlying disease.

DEFICIENCIES OF VITAMIN K–DEPENDENT FACTORS

Prothrombin; factors VII, IX, and X; and proteins C and S are synthesized by the liver by a process that depends on vitamin K (see Chapter 18 and Fig. 54.1).[1,2] When stores of this vitamin are deficient or abnormal, hypofunctional analogs of these factors are synthesized, which inhibit normal coagulation. These descarboxy analogs of the vitamin K–dependent factors do not bind to cellular phospholipid surfaces and, therefore, do not participate in cell-associated coagulation reactions. This may occur in disorders in which intake or absorption of vitamin K is deficient and in disorders that impair the biosynthetic capacity of the liver (Fig. 54.1). A similar coagulation abnormality may be produced by anticoagulant drugs such as coumarin and indanediones, which antagonize the action of vitamin K (see Chapter 55).

Vitamin K Deficiency Bleeding (Hemorrhagic Disease of the Newborn)

Hemorrhagic disease of the newborn is the result of vitamin K deficiency in the neonate; this phrase was first used more than 100 years ago.[3] The preferred term is *vitamin K deficiency bleeding* (VKDB) *in infancy* as proposed by a consensus committee.[4] Formerly a major cause of bleeding, this disorder is now uncommon because of the routine administration of vitamin K at birth[5]; however, it is still encountered in economically deprived populations.

Pathophysiology

The normal newborn has a moderate deficiency of the vitamin K–dependent coagulation factors. The plasma levels of these factors normally fall even further during the first 2 to 5 days of life, rise again when the infant is 7 to 14 days old, and attain normal adult levels later in life (see also Table 45.6). The deficiency of the vitamin K–dependent coagulation factors that is present at birth, as well as the slow rate at which adult levels are attained, presumably is the result of intrinsic "liver immaturity;" neither of these physiologic phenomena is affected by vitamin K administration.[6] On the other hand, the diminution in levels of these factors that occurs at age 2 to 5 days is prevented by vitamin K administration because it is the result of a transitory physiologic deficiency of this vitamin. Factors that further diminish the amount of vitamin K available at this juncture and those that further impair the synthetic capacity of the liver predispose neonates to hemorrhagic disease of the newborn. These factors are (a) prematurity, (b) inadequate dietary intake, (c) delayed gut colonization by bacteria, (d) various obstetric and perinatal complications, and, possibly, (e) maternal deficiency of vitamin K.

Prematurity often has been associated with VKDB.[7] Levels of the vitamin K–dependent factors at birth are approximately proportional to gestational age and birth weight.[8] In premature infants, the physiologic immaturity of the liver is marked, and the response to vitamin K that is present is subnormal.

Most factors associated with deficient intake of vitamin K also delay the colonization of the gut by bacteria. These factors include delayed feeding, breast-feeding, vomiting, severe diarrhea, and antibiotics, including those present in maternal milk. Human milk and colostrum are poor sources of vitamin K,[6] and reliance on breast milk as the sole source of nutrients in the neonatal period is an important factor in many cases of VKDB.[5]

Coumarin and indanedione drugs cross the placenta and may produce hemorrhagic disease in the newborn.[9] Infants born of mothers who were taking diphenylhydantoin or other anticonvulsants, including barbiturates, or salicylates have developed a syndrome similar to VKDB.[10] Treatment of the mother with vitamin K during the last trimester may prevent this complication.

Clinical Features and Laboratory Diagnosis

VKDB etiology is considered idiopathic (no cause other than breast-feeding) or secondary (malabsorption of vitamin K, liver

TABLE 54.1

ACQUIRED COAGULATION DISORDERS

Deficiencies of vitamin K–dependent coagulation factors
- Hemorrhagic disease of the newborn (vitamin K deficiency bleeding)
- Biliary obstruction (gallstone, strictures, fistulas)
- Malabsorption of vitamin K (sprue, idiopathic steatorrhea, celiac disease, ulcerative colitis, regional enteritis, gastrocolic fistulas, *Ascaris* infestation)
- Nutritional deficiency
- Drugs
  1. Pharmacologic antagonists of vitamin K (coumarins, indandiones, others)
  2. Those that alter gut flora (broad-spectrum antibiotics, sulfonamides)
  3. Miscellaneous (cholestyramine)

Liver disease (see Table 54.3)

Accelerated destruction of coagulation factors
- Disseminated intravascular coagulation (see Table 54.4)
- Fibrinolysis (liver disease, thrombolytic agents, tumors, after surgery)

Inhibitors of coagulation
- Specific inhibitors (antibodies) (see Table 54.6)
- Antiphospholipid–protein antibodies (see Table 54.7)
- Miscellaneous (antithrombins, paraproteinemias)

Miscellaneous
- After massive transfusion
- After extracorporeal circulation
- Drugs (antibiotics, antineoplastic agents, others)
- Other disorders (polycythemia vera, congenital heart disease, amyloidosis, nephrotic syndrome, Sheehan syndrome, Gaucher disease, leukemia, others)

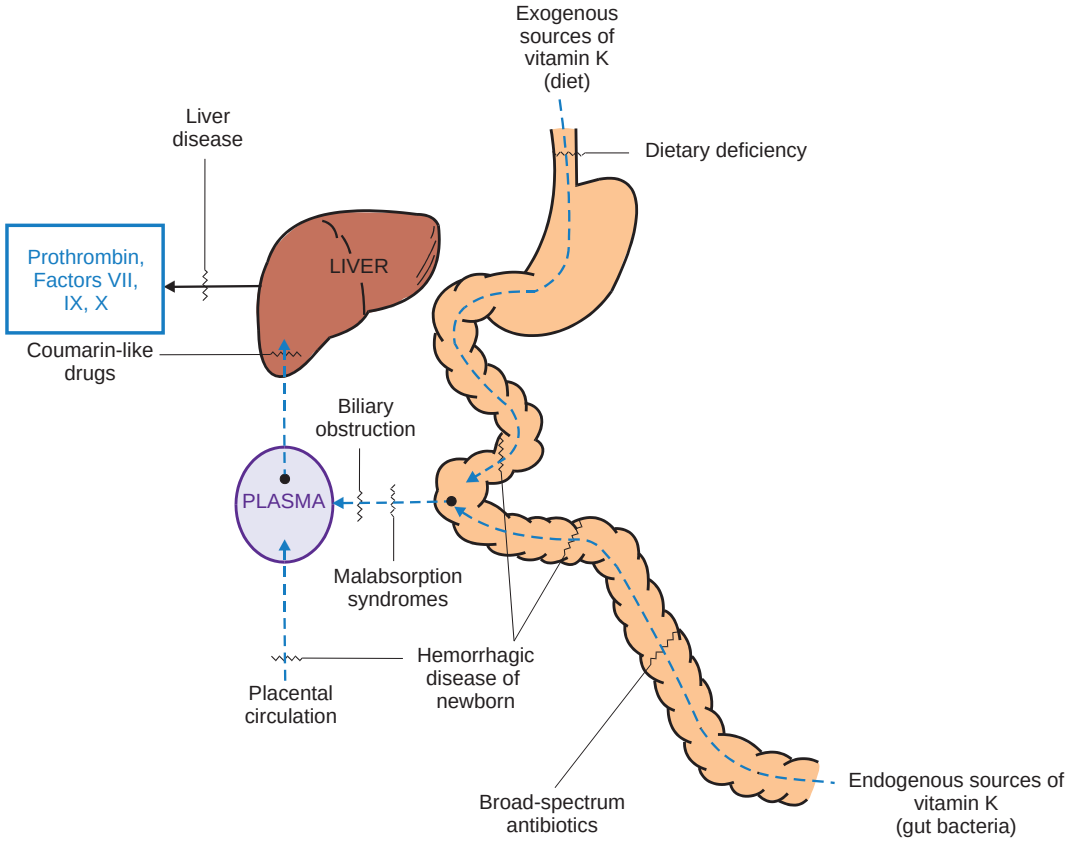

FIGURE 54.1. Etiologies of vitamin K deficiency. Sources of vitamin K include the diet and gut bacterial synthesis. Processes leading to vitamin K deficiency are indicated with a solid line ending in a squiggle.

disease, drugs).[4] VKDB can also be classified in terms of age of onset: Early (onset <24 hours of age), classic (onset usually between 3 and 5 days), and late (onset on or after 8 days). Early VKDB is uncommon and usually results from placental transfer of maternal drugs that antagonize vitamin K in the newborn. Late VKDB occurs almost exclusively in breast-fed infants who may also have hepatobiliary disease.[4]

Bleeding in classic VKDB is severe.[3] The most common manifestations are melena, large cephalohematomas, and bleeding from the umbilical stump and after circumcision. Generalized ecchymoses, often without petechiae, intracranial bleeding, and large intramuscular hemorrhages also may develop.[3,6]

Laboratory diagnosis is relatively simple (Table 54.2), but physiologic differences in the results of various coagulation tests in normal neonates must be kept in mind (see Table 45.6). In infants with VKDB, the prothrombin time (PT) always is prolonged. The partial thromboplastin time (PTT) is also prolonged. Specific factor assays reveal deficiencies of prothrombin; factors VII, IX, and X; and proteins C and S. The presence of normal antigenic levels of the vitamin K–dependent factors may be demonstrated by immunoassays.[11] Factors V and VIII, as well as fibrinogen, are present in normal amounts. The consensus committee recommends diagnosing VKDB with a prolonged PT value, a normal fibrinogen level, and a normal platelet count.[4]

The clinician should not assume that bleeding in the neonate is invariably the result of vitamin K deficiency.[4] In the differential diagnosis of VKDB, virtually all causes of bleeding, particularly thrombocytopenia (see Chapter 46) and disseminated intravascular coagulation (DIC) must be considered.[12] The inherited coagulation disorders (see Chapter 53) also may produce serious hemorrhage in the neonatal period, but significant prolongation of the PT is not found in the most common forms, for example, hemophilia A and hemophilia B. Umbilical bleeding and hemorrhage after circumcision are relatively less common in the inherited coagulation disorders than in VKDB.

Treatment

Vitamin K_1 (0.5 to 1.0 mg given intramuscularly) is dramatically effective in the treatment of VKDB[13]; the 0.5-mg dose appears to be more than adequate.[14] Shortening of the PT may be expected within 6 hours, and normal neonatal levels of the vitamin K–dependent factors usually are attained within 24 hours of administration. An American Academy of Pediatrics consensus report has summarized recommendations of vitamin K therapy for prevention of early and late VKDB.[15] Larger (2 mg) or repeated (every 4 to 8 hours) doses of vitamin K_1 may be required to counteract the effects of coumarin drugs in infants.[6] The response in premature infants to vitamin K_1 usually is incomplete. The administration of large doses of vitamin K may produce hemolysis, hyperbilirubinemia, and even kernicterus in the neonate. These complications appear to be associated more commonly with the synthetic derivatives than with vitamin K_1, but even the latter may be dangerous in large doses.[6]

In severe cases of VKDB, the transfusion of plasma may be helpful.[6] Concentrates of vitamin K–dependent coagulation factors are effective but have led to thrombosis and intravascular coagulation in some infants, particularly in premature infants. This result has been attributed to immaturity of the hepatic clearance functions and physiologic deficiency of antithrombin.

Because VKDB is primarily a disease of breast-fed infants,[16] VKDB can be prevented by the administration of vitamin K to the mother before delivery. Most authorities, however, recommend administering vitamin K_1 to the infant. This procedure is now routine in most nurseries. Many pediatricians also recommend the

prophylactic administration of vitamin K_1 to infants 1 to 5 months of age, especially those who are breast-fed or who have a disorder that may impair vitamin K absorption.[17] The usual dosage in such older infants is 50 to 100 μg daily or 1 mg monthly.

Most pediatricians would attribute the decrease in incidence of VKDB in recent years to the prophylactic administration of vitamin K. There is widespread consensus on continuing vitamin K prophylaxis to newborns.[3,15] A prospective population study in the United Kingdom found that with prophylaxis, VKDB in newborns is rare,[18] whereas in developing countries, prophylaxis is not frequently used, and VKDB is common.

Other Causes of Vitamin K Deficiency

Obstruction of the biliary tract, either intrahepatic or extrahepatic, produces vitamin K deficiency because of the absence of bile salts in the gut. Complete obstruction may lead to severe coagulation abnormalities and bleeding within 2 to 4 weeks. This was a major obstacle to surgical procedures on the biliary tract before the discovery of vitamin K.

Most malabsorption syndromes and various other chronic gastrointestinal disorders also may give rise to vitamin K deficiency. Such disorders include celiac disease, sprue, gastrocolic fistulas, ulcerative colitis, regional enteritis, extensive gut resections, protracted diarrhea of any cause, *Ascaris* infestations, and cystic fibrosis. The last named disorder often is complicated by liver disease.[11] Severe abnormalities of coagulation and bleeding are less common in association with these disorders than with biliary obstruction, presumably because absorption of vitamin K is seldom completely deficient.

Because vitamin K normally is available from two independent sources (Fig. 54.1), neither nutritional deficiency nor gut sterilization alone produces deficiency of a degree that results in significant coagulation abnormalities. In normal adults, the daily oral intake of vitamin K must be reduced to 20 μg or less for several weeks to produce significant hypoprothrombinemia.[1] However, vitamin K deficiency is more common than is usually realized in hospitalized patients with poor or negligible oral food intake, especially if they are also taking antibiotics.[19,20] Significant coagulation abnormalities may arise with surprising rapidity

in such patients, and when unsuspected, they may be confused with DIC or may first be revealed by serious, unexpected postoperative hemorrhage. Antimicrobial agents presumably impair vitamin K production by inhibiting the synthesis of menadiones by gut bacteria, but they may also directly affect carboxylation reactions.[21,22] Vitamin K deficiency also may result from use of drugs other than antimicrobial agents, such as cholestyramine,[23] which acts by binding bile salts, or mineral oil and other cathartics when used for protracted periods. Vitamin E may antagonize the metabolic action of vitamin K and potentiate the action of coumarins.[6] When taken in large doses, this vitamin may prolong the PT.[24] Antibiotic therapy, poor diet, or any of the aforementioned disorders may predispose patients to coumarin toxicity (see Chapter 55).[25] Large doses of aspirin, as given to treat rheumatic disorders or in amounts associated with overdosage of the drug, may also induce vitamin K deficiency.[26]

Treatment

In adults, the parenteral administration of 10 mg of vitamin K_1 abolishes coagulation abnormalities within 12 to 24 hours if they are the consequence of a deficiency of this vitamin. Failure of vitamin K to normalize the PT is evidence for the presence of a complicating process, such as liver disease or DIC, or superwarfarin ingestion.[27] The synthetic vitamin K_3 (menadiones) may be absorbed in the absence of bile salts and in various malabsorption syndromes. However, these congeners of vitamin K have a more transient effect than the natural forms of this vitamin and offer minimal therapeutic advantage in the usual case. Replacement therapy with fresh frozen plasma or prothrombin complex concentrates (PCCs) is effective in the treatment of emergent vitamin K deficiency.

Intravenous administration of vitamin K may produce hemolytic anemia in patients with inherited deficiencies of various red cell enzymes, and may be associated with a risk of anaphylaxis.[28] Malnourished patients receiving broad-spectrum antibiotic therapy should receive vitamin K prophylactically, 5 mg twice weekly, orally or subcutaneously.[29]

Commercially available rodenticides (super-warfarins) that exhibit long-acting vitamin K antagonism have been associated with significant bleeding disorders when these compounds have been ingested by humans.[27] These drugs are chemically distinct from warfarin, are 100 times more potent than warfarin, and can induce vitamin K deficiency lasting for months. In 1995 alone, more than 13,000 people were exposed to these agents and treated.[30] Initial treatment of these patients may require up to 100 mg of vitamin K daily to normalize vitamin K metabolism.[30]

LIVER DISEASE

Virtually every hemostatic function may be impaired in patients with severe hepatic disease (Table 54.3)[31,32,33] as the result of failure of both the biosynthetic and clearance functions of the liver. The pathophysiology of some of these abnormalities is tied to thrombocytopenia (see Chapter 46), platelet dysfunction (see Chapter 52), intravascular coagulation and fibrinolysis, and the effects of products of fibrinogen catabolism on hemostasis (see below).

Pathophysiology

Thrombocytopenia

Patients with significant liver disease have portal hypertension, splenomegaly, and splenic sequestration of platelets, contributing to thrombocytopenia. The liver is also the major site of production of thrombopoietin, the principal humoral factor involved in megakaryocyte maturation and platelet formation (see Chapter 15).

TABLE 54.3

ABNORMALITIES OF HEMOSTASIS AND COAGULATION IN LIVER DISEASE

Deficient biosynthesis
Of fibrinogen; prothrombin; coagulation factors V,[39] VII, IX, X, XI, XII, XIII; prekallikrein; high-molecular-weight kininogen
Of antiplasmins,[58] antithrombin,[57] proteins C and S
Aberrant biosynthesis
Of abnormal fibrinogen,[41,45] factor V
Of abnormal inhibitory analogs of prothrombin, factors VII, IX, and X[46]
Deficient clearance
Of hemostatic "products" (e.g., fibrin monomers, fibrin[ogen] degradation products, platelet factor-3)
Of activated coagulation factors (IXa, Xa[158], XIa)
Of plasminogen activators[49]
Accelerated destruction of coagulation factors
Disseminated intravascular coagulation[64,65,66]
Abnormal fibrinolysis[50]
Thrombocytopenia
Hypersplenism (portal hypertension)
Folic acid deficiency
Chronic ethanol intoxication
Disseminated intravascular coagulation
Platelet dysfunction
Acute and chronic ethanol intoxication
Effects of products of fibrinogen degradation[51]
Uremia
Miscellaneous
Inhibition of coagulation by products of fibrinogen degradation[53,54]
Loss or consumption of coagulation factors in ascitic fluid[68]

Recent studies have evaluated whether deficient levels of thrombopoietin occur in liver disease. Results indicate that thrombocytopenia in liver disease is not explained by deficient hepatic production of thrombopoietin.[34,35] However, there is a correlation between the extent of liver disease and platelet expression of the thrombopoietin receptor, c-Mpl,[35] and this reduced expression may contribute to thrombocytopenia. Additionally, increased thrombopoietin degradation by platelets sequestered in the spleen may also contribute to thrombocytopenia in these patients.[36]

Deficient or Aberrant Synthesis of Coagulation Factors

In patients with liver disease, all coagulation factors except factor VIII may be deficient as a consequence of synthetic failure of the hepatic cells. Failure of biosynthesis of coagulation factors often correlates with the severity of hypoalbuminemia, but exceptions to this rule are common. Deficiencies of prothrombin; factors VII, IX, and X; and proteins C and S result mainly from synthetic incompetence. For example, factor VII expression in liver biopsies from patients with liver disease decreases as the severity of hepatic dysfunction increases.[37] Impaired carboxylation of precursors may contribute to the defect.[11] Superimposed vitamin K deficiency may result from a poor diet or malabsorption caused by insufficient production of bile salts or by exocrine pancreatic insufficiency.[38] The failure of these coagulation abnormalities to respond to vitamin K administration provides good evidence of hepatic cell dysfunction.

Factors V, XI, and XIII are synthesized by the liver but are not vitamin K–dependent[39]; all of these factors may be deficient in patients with severe liver disease. Plasma levels of factor XII, prekallikrein (Fletcher factor), and high-molecular-weight kininogen (Fitzgerald factor) also may be low in association with liver disease. Deficiencies of these latter three factors do not contribute to a bleeding diathesis.

Hypofibrinogenemia rarely may result from deficient hepatic biosynthesis[39,40] or may be the consequence of fibrinogenolysis or DIC, as discussed subsequently. In many patients with liver disease, prolongation of the thrombin time can be significant in the absence of hypofibrinogenemia or increased levels of fibrin(ogen) degradation products (FDPs).[41] This apparently is the result of a qualitatively abnormal fibrinogen that is synthesized by the diseased hepatic cell. Such acquired dysfibrinogenemia has been reported in most forms of liver disease, ranging from mild acute hepatitis to acute hepatic necrosis and cirrhosis.[42] Fibrin monomer polymerization is delayed,[43] and the abnormal fibrinogen molecule acts as an antithrombin.[41] Additionally, this hepatic disease dysfibrinogen may have an abnormally high content of sialic acids[44] and may produce a structurally defective fibrin clot.[45] Acquired dysfibrinogenemia, abnormal inhibitors of fibrinolysis, and the presence within the plasma of descarboxy analogs of prothrombin[46] have been reported in patients with hepatomas.[47] Hepatoma-associated dysfibrinogens have also been noted to have an increased carbohydrate content.

Plasma levels of factor VIIIc usually are elevated in both parenchymal and cholestatic liver disease.[48] Studies in patients with cirrhosis indicate that elevated plasma factor VIII levels are not due to increased transcriptional activity of factor VIII in the liver, but instead likely result from increased liver synthesis of von Willebrand factor (vWF) and decreased levels of lipoprotein receptor–related protein. Both of these latter proteins regulate plasma factor VIII levels.[48]

Fibrinogenolysis and Fibrinolysis

Endogenous plasminogen activators normally are removed from the circulation by the liver. In patients with severe liver disease, however, they may circulate for an abnormally long time and lead to the chronic or intermittent activation of the fibrinolytic enzyme system.[49,50] This process may be a contributory factor in the pathogenesis of hypofibrinogenemia in patients with liver disease. It also leads to the production of large amounts of FDP, which persist in the circulation for abnormally long periods because of deficient hepatic clearance, and may impair blood coagulation and platelet function.[51] Such proteolytic activity also may produce a shift in the mean molecular weight of circulating fibrinogen from the normal species to a less reactive species of lower molecular weight,[52] thereby contributing to the "antithrombins of liver disease."[53,54]

The incidence of hyperfibrinolysis was surveyed in patients with cirrhotic and noncirrhotic liver disorders.[55] Hyperfibrinolysis, as measured by a shortened euglobulin clot lysis time, was present in approximately 30% of cirrhotic patients but not present in noncirrhotic patients.[55] The role of thrombin-activatable fibrinolysis inhibitor deficiency in liver disease in contributing to hyperfibrinolysis has been studied; thrombin-activatable fibrinolysis inhibitor levels are reduced in liver disease, with lower levels seen in more severe liver disease.[56] However, there was no association of low thrombin-activatable fibrinolysis inhibitor levels with hyperfibrinolysis, even in cirrhotic patients. These studies suggest that hyperfibrinolysis is not common in liver disease, even in cirrhosis.[55,56]

Plasma levels of antithrombin,[57] antiplasmin,[58] and plasminogen[59] are subnormal in patients with liver disease. These abnormalities are of uncertain clinical importance.

Intravascular Coagulation

Severe liver disease theoretically predisposes individuals to the development of DIC because DIC is associated with deficient hepatic clearance of activated coagulation factors and other coagulant substances. The in vivo turnover rates of prothrombin,[60] fibrinogen,[61] plasminogen,[60] and antithrombin[57] often are accelerated in patients with cirrhosis. Plasma levels of fibrinopeptide A are elevated in most patients with cirrhosis.[62] All of these abnormalities may be normalized in some cases by the administration of heparin.[63] It has been hypothesized that accelerated catabolism of coagulation factors in these disorders is the result of DIC. The nature of the initiating process is unclear, but one suggestion is that DIC is activated by hypoperfusion of the congested portal bed.[40] Indirect evidence suggests that in severe liver disease, activators of coagulation, possibly endotoxin, may originate in the gut.

Low-grade DIC or localized intravascular coagulation indeed may occur in association with severe liver disease, but overt DIC is responsible only rarely for bleeding in the absence of other etiologic factors that trigger this process, for instance, sepsis, shock, and cancer.[64,65] This conclusion is supported by findings in patients with stable cirrhosis that demonstrated no increased levels of markers of activation of coagulation, such as prothrombin fragment 1+2, thrombin–antithrombin complex, and so forth.[66]

Evidence for accelerated fibrinogen turnover in ascitic fluid suggests that the loss or consumption of coagulation factors in peritoneal fluid may be a contributory factor in the coagulopathy of chronic liver failure. Shunting of ascitic fluid into the venous circulation by means of LeVeen shunts consistently produces coagulation abnormalities consistent with DIC in cirrhotic patients.[67] Although this phenomenon usually is attributed to intravascular coagulation, evidence shows that it may result in part from the presence of plasminogen activators and active plasmin[68] or collagen[69] in peritoneal fluid.

A transitory coagulation disorder that resembles intravascular coagulation with active fibrinolysis has been documented during liver transplantation procedures. Coagulation abnormalities disappear promptly if the graft is successful.[70] The complex coagulopathy seen with liver transplantation has been reviewed.[71]

Clinical Manifestations

In view of the numerous hemostatic abnormalities associated with severe liver disease, it is surprising that many patients do not bleed abnormally. Gastrointestinal hemorrhage is the most common bleeding manifestation, but it almost always originates from a local lesion, such as esophageal varices, peptic ulcer, or gastritis. The degree to which coagulation abnormalities contribute to such bleeding is uncertain. In one large series, gastrointestinal bleeding was not significantly more severe or protracted in patients with coagulation abnormalities than in those without them.[72] In another study, serious hemorrhage occurred only in patients with prolonged PTs and significant factor IX deficiency.[73] Moderate generalized bleeding manifestations, such as recurrent ecchymoses and epistaxis, are not uncommon, and severe generalized bleeding may complicate surgical procedures, including biopsies, tooth extractions, and other minor procedures.

The above-mentioned paradox of the lack of bleeding in many patients with severe liver disease despite multiple hemostatic abnormalities has been explored.[74] An emerging concept is that coagulation in liver disease patients is "rebalanced" due to parallel reductions in both procoagulant and anticoagulant factors. Standard coagulation tests (such as the PT) do not measure major in vivo regulators of coagulation such as thrombomodulin and may not adequately reflect hemostasis in these patients.[32,74] This new paradigm has implications for managing the coagulopathy of liver disease.

Laboratory Diagnosis

The laboratory findings in liver disease vary with the cause and severity of the underlying disorder and range from a slight prolongation of the PT in anicteric hepatitis to the findings summarized in Table 54.2, which are seen in severe decompensated cirrhosis. In cirrhosis, coagulation abnormalities correlate with the presence of portal hypertension and may be minimal in inactive cirrhosis; thrombocytopenia alone is common in association with portal hypertension. Acute fibrinogenolysis is significantly more common in patients with cirrhosis[55] than in those with acute hepatocellular disease, such as hepatitis, although elevations of FDP are consistently found in people with chronic aggressive hepatitis.[42] Coagulation abnormalities are seldom marked in biliary cirrhosis, and some patients with this disorder have abnormally high levels of prothrombin and factors VII and X. Hemostatic abnormalities of any sort are rare in metastatic liver disease. In acute liver failure, the PT value has prognostic value and is indicative of the need for liver transplantation.[75] The spectrum of coagulation abnormalities in liver disease has been reviewed.[31]

Although screening tests of coagulation are almost invariably performed before liver biopsy, they apparently are of little value in predicting hemorrhage after this and other minor surgical procedures.[32,74,76,78] Similarly, the bleeding time test is of little clinical use in predicting bleeding.[79] Many physicians use the international normalized ratio (INR) as a substitute coagulation test for the PT.[80] When measured with a sensitive thromboplastin, the INR can quantitate vitamin K deficiency due to liver disease, but it should not be interpreted as in patients receiving warfarin.[80]

Treatment

Not all patients with the coagulopathy of liver disease require hemostatic correction before procedures such as liver biopsy. A retrospective study looked at the PT ratio (patient PT/mean of reference range PT) and degree of thrombocytopenia to determine the necessity of plasma and platelet transfusion.[81] In patients with platelet counts of 50,000/μl or greater, there was no increased bleeding with liver biopsy compared with patients with normal platelet counts. With regard to elevated PT values, if the PT ratio was <1.5, no increased bleeding was observed.[81] Therefore, patients with moderate thrombocytopenia and mild liver disease coagulopathy do not need routine hemostatic correction with blood products. One exception to this recommendation is patients with a diagnosis of malignancy, who may have a higher bleeding risk, possibly due to chronic DIC and elevated FDP levels.[81] On the other hand, a British guidelines committee on the use of plasma products suggests that "patients with liver disease and a PT more than 4 seconds longer than control are unlikely to benefit from FFP."[82] This recommendation is based on expert opinion.

Elevated FDP levels may be a significant hemostasis risk factor in liver disease. High levels of FDP may impair platelet function and fibrin monomer polymerization. The thrombin time can screen for the latter defect. A prolonged thrombin time in a patient with a normal functional fibrinogen level and high FDP levels, who is not receiving heparin, may constitute a significant bleeding risk, especially in the setting of moderate thrombocytopenia.

Vitamin K_1, in a dose of 10 mg, produces some improvement in the coagulation abnormalities in approximately 30% of patients with liver disease,[73] but the PT often becomes prolonged again after an initially favorable response. Patients with severe liver disease have minimal or no response to vitamin K therapy.

Replacement therapy with fresh frozen plasma is indicated only in the presence of serious bleeding or before surgical procedures, and its effect is often disappointing in patients with liver disease.[73] Reasons for this may include the short in vivo half-life of factor VII, hypervolemia, the loss of transfused factors into ascitic fluid, and the fact that the in vivo recovery of transfused factor IX is significantly lower than that of other factors, even in the absence of liver disease. Concentrates of vitamin K–dependent coagulation factors (PCC) have been used in the replacement therapy of bleeding in patients with liver disease with variable success but, in several cases, have led to thromboembolic complications and DIC.[83] Thrombosis presumably develops because such concentrates contain trace amounts of activated coagulation factors, particularly factors IXa and Xa,[83,84] that normally are not cleared from the circulation by the diseased liver and because of antithrombin deficiency, which is commonly present. Newer PCCs are becoming available; these also contain proteins C and S in addition to the procoagulant vitamin K–dependent factors. These products have not been well studied in liver disease coagulopathy, but appear to be effective in reversing warfarin coagulopathy.[85] Fresh frozen plasma is the preferable treatment option, but the effects of even maximum doses (20 to 30 ml/kg of body weight) often are transitory. Cryoprecipitate is useful to maintain fibrinogen levels over 100 mg/dl. A controlled trial found that 1-desamino-8-d-arginine vasopressin (DDAVP) is not helpful in management of variceal bleeding in cirrhotic patients.[86]

Recombinant factor VIIa (rVIIa) is a potential therapy for liver disease patients with significant coagulopathy. However, the drug is not indicated for use in variceal bleeding, partial hepatectomy, or liver transplantation.[87] Disadvantages of rVIIa include its high cost and risk of DIC and thromboembolic complications.

Even though heparin administration may normalize fibrinogen catabolism, little evidence is cited that it decreases the duration or severity of bleeding in patients with low-grade DIC and severe liver disease. However, heparin may be useful in conjunction with PCC therapy. In this setting, the addition of small amounts of normal plasma and heparin to vials of these thrombogenic concentrates inactivates activated proteases and minimizes the thrombotic risks of these concentrates.[88]

Correction of thrombocytopenia may be difficult in patients with severe liver disease. One promising intervention is the use of synthetic thrombopoietins and thrombopoietin mimetic agents. Eltrombopag is approved to treat thrombocytopenia in chronic hepatitis C patients who receive interferon therapy.

For patients requiring liver biopsy who are deemed "high risk" from the hemostasis perspective, the transjugular approach should be considered.

DISSEMINATED INTRAVASCULAR COAGULATION

The syndrome of DIC (defibrination syndrome, consumption coagulopathy) has been one of the most intensively studied subjects in hematology. This large body of information has been summarized in many detailed reviews and monographs.[89–91] A consensus definition of DIC has been proposed: "DIC is an acquired syndrome characterized by the intravascular activation of coagulation with loss of localization arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction."[90]

Etiology and Incidence

DIC has been well documented in association with the disorders summarized in Table 54.4. Several retrospective studies suggest that DIC remains a relatively uncommon entity, but in one large general hospital, its overall incidence was 1 in 1,000 admissions.[92] The most prevalent etiologic factor was infection,[92] but in another study, more than 50% of cases were obstetric patients.[93] A Japanese study found that in a hospital population, 45% of DIC cases were associated with malignancy.[94] In many of the disorders listed in Table 54.4, DIC develops only in an occasional case. Thus, it is rare in heatstroke,[95] autoimmune disorders,[96] and hemolytic anemias.[97] DIC is present in most cases of venomous

TABLE 54.4

ETIOLOGIES OF DISSEMINATED INTRAVASCULAR COAGULATION

Obstetric complications

Abruptio placentae,[188] septic abortion and chorioamnionitis, amniotic fluid embolism, intrauterine fetal death, miscellaneous (degenerating hydatidiform moles and leiomyomas, postpartum hemolytic-uremic syndrome, abdominal pregnancy, tetracycline-induced hepatorenal failure, fetomaternal blood passage, saline-[194] and urea-induced[195] abortions)

Infections

Viral (herpes, rubella, smallpox, acute hepatitis, Reye syndrome, cytomegalic inclusion disease, various epidemic hemorrhagic fevers, others)

Rickettsial (Rocky Mountain spotted fever, others)

Bacterial (meningococcemia, septicemia, particularly that due to Gram-negative organisms, many others)

Mycotic (histoplasmosis, aspergillosis)

Protozoal (malaria, kala-azar, trypanosomiasis)

Neoplasms

Carcinomas[98] (prostate, pancreas, breast, lung, ovary, many others)

Miscellaneous (metastatic carcinoid, rhabdomyosarcoma, neuroblastoma, others)

Disorders of the hematopoietic system

Acute leukemia (promyelocytic[219], other types)

Intravascular hemolysis (transfusion of incompatible blood, paroxysmal nocturnal hemoglobinuria[607], fresh-water submersion[608])

Histiocytic medullary reticulosis

Vascular disorders

Malformation (giant hemangiomas [Kasabach-Merritt syndrome][225], aneurysms, coarctations of the aorta and other large vessels, Takayasu aortitis, large prosthetic arterial grafts,[609] cyanotic congenital cardiac lesions)

Collagen-vascular disorders[610]

Hypoxia and hypoperfusion, myocardial infarction, cardiac arrest,[611] various forms of shock, hypothermia

Massive tissue injury

Large traumatic injuries and burns, extensive surgical intervention,[612] extracorporeal circulation, fat embolism[613]

Miscellaneous

Acute iron toxicity, head trauma,[614] snakebite,[231] anaphylaxis, concentrates of vitamin K–dependent coagulation factors,[83] heatstroke,[95] allograft rejection, graft versus host disease, severe respiratory distress syndrome, diabetic acidosis,[615] status epilepticus,[616] acute pancreatitis,[617] homozygous deficiency of protein C[618]

snakebite, which is probably one of the most common causes of the disorder worldwide.

Pathophysiology

Mechanisms by Which Disseminated Intravascular Coagulation Is Initiated

The pathophysiology of DIC is complex. The mechanisms that activate or "trigger" DIC act on processes that are involved in normal hemostasis, namely, the processes of platelet adhesion and aggregation and contact-activated (intrinsic) and tissue factor–activated (extrinsic) pathways of coagulation (Fig. 54.2). These mechanisms have in common the capacity, in terms of either the magnitude or the duration of the activating stimulus, to exceed normal compensatory processes. Thrombin is persistently generated, and fibrin is formed in the circulating blood. Fibrinogen, various other coagulation factors, and platelets are consumed. The fibrinolytic

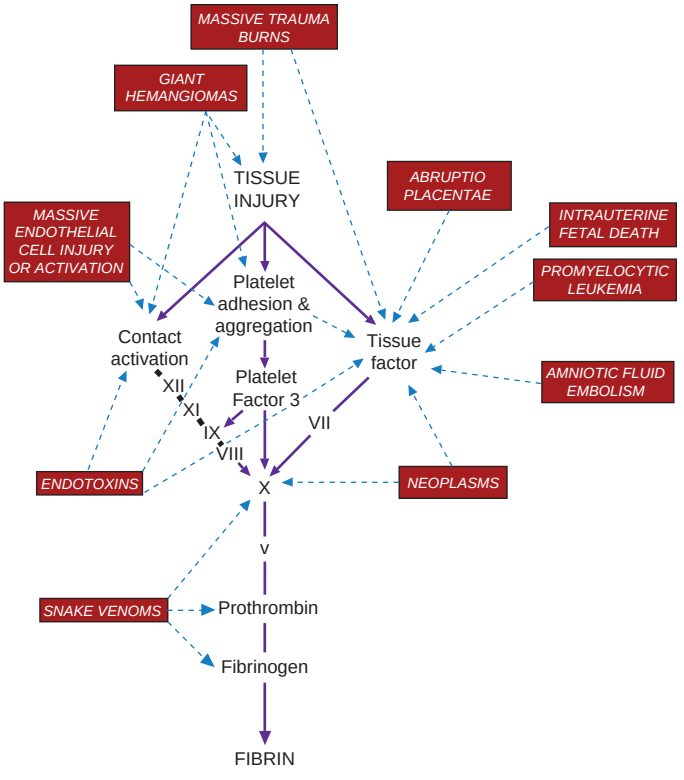

FIGURE 54.2. Initiating mechanisms of disseminated intravascular coagulation (DIC). The *solid arrows* indicate normal hemostatic pathways, and *dotted arrows* indicate pathways by which certain disorders associated with DIC initiate or promote the coagulopathy of DIC. Initiation of coagulation by expression of tissue factor activity is probably the most important mechanism triggering DIC.

mechanism is activated, and large amounts of FDP are produced, which further impair hemostatic function. Bleeding, shock, and vascular occlusion commonly supervene and produce profound alterations in the function of various organ systems. Normal compensatory processes may become impaired, creating a self-perpetuating "vicious cycle." The ultimate outcome is determined by a dynamic interplay between the various pathologic processes and compensatory mechanisms, in other words, fibrin deposition versus fibrinolysis; depletion versus repletion of coagulation factors and platelets; and production versus clearance of fibrin, FDPs, and other products of coagulation (Fig. 54.3). In most forms of DIC, the initiating factors are multiple and interrelated. For example, in meningococcemia, endothelial cell injury may lead to expression of tissue factor and to collagen exposure; the latter then initiates platelet adhesion, aggregation, and thrombosis.

Tissue Factor

The exposure of procoagulant tissue extracts to blood is a major contributory factor in most forms of DIC and is of major pathogenetic importance in cases associated with abruptio placentae, intrauterine fetal death, acute promyelocytic leukemia, amniotic fluid embolism, massive trauma, and various neoplasms.[98] The active component of such extracts is tissue factor (thromboplastin); that is, tissue factor interacts with factor VIIa to activate the extrinsic pathway of coagulation.

In abruptio placentae[99] decidual fragments, serum-containing activated coagulation factors, and other substances from the placental site enter the intervillous "maternal lake" and, hence, the venous circulation. This process is initiated by rupture of the basal decidual plate.

In amniotic fluid embolism, relatively weak thromboplastins that increase in potency with gestational age[100] and large

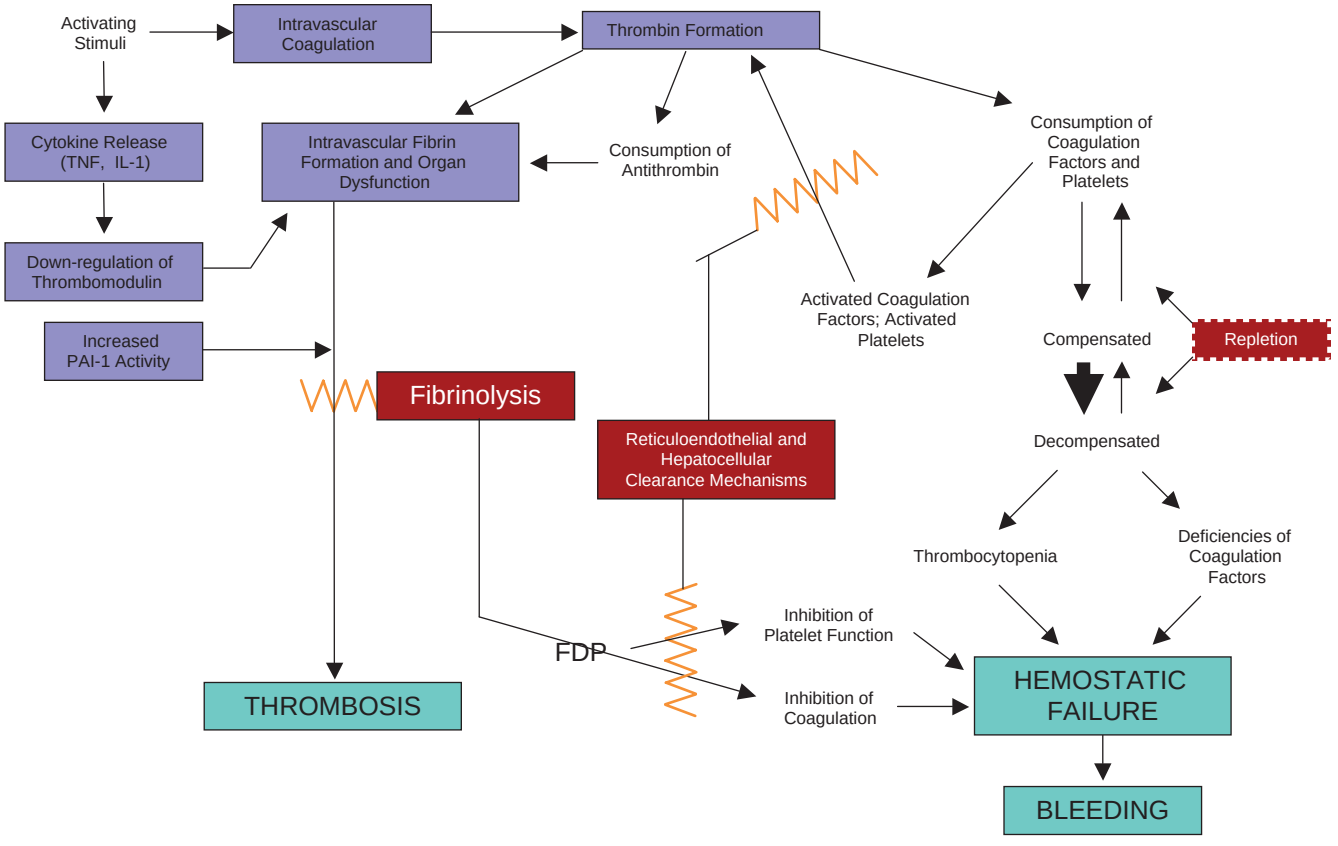

FIGURE 54.3. Pathophysiology of disseminated intravascular coagulation (DIC). The critical event in DIC is the generation of thrombin in an unregulated fashion. The clinical consequences of thrombin production depend on the rate of thrombin formation as well as underlying host factors (marrow reserve of platelet production, liver function). Patients with adequate compensatory responses (ability to enhance platelet or coagulation factor production, fibrinolysis, intact clearance mechanisms) may have minimal symptoms, whereas other patients with defective compensatory responses may bleed, thrombose, or both. Increased levels of cytokines occur (TNF, IL-1) that contribute to the proinflammatory state by down-regulating thrombomodulin activity; this leads to enhancement of intravascular fibrin formation and organ dysfunction. Major compensatory factors that influence clinical events are indicated in colored blocks. The zig-zag line indicates interruption of an adverse clinical event by a compensatory factor. FDP, fibrin(ogen) degradation product; IL-I, interleukin-1; PAI-1, plasminogen activator inhibitor-1; TNF, tumor recrosis factor.

amounts of particulate matter enter the circulation suddenly. In intrauterine fetal death, thromboplastic substances from the dead fetus are slowly but continuously absorbed, producing a picture of chronic but progressive DIC.

In neoplasms, tumor microemboli and tumor "vesicles"[101] are thought to enter the circulation and act as thromboplastins.[98,102] Tumor cell surface expression of tissue factor has been demonstrated.[103] Some neoplasms may secrete a factor X activator.[104]

DIC in association with acute leukemia presumably results from the formation or release of tissue factor by leukemic cells.[105] Additional leukocyte enzymes such as elastase may contribute to DIC and fibrin(ogen)olysis by proteolysis of coagulation zymogens and fibrinogen.[106] Malignant promyelocytes, as seen in promyelocytic leukemia, express high levels of annexin II, a phospholipid-binding protein and receptor for plasminogen and tissue plasminogen activator.[107] This overexpression of annexin II results in enhanced plasmin production and increased fibrinolytic activity.[107] The granules of various "blast" forms contain tissue factor, with the promyelocyte containing particularly high concentrations.[105]

In DIC associated with massive trauma,[108] major surgical procedures, or large burns, damaged tissue expressing tissue factor activity presumably is a major initiating factor. In such cases, additional abnormalities and complications are important contributory factors, such as "hypercoagulability," azotemia, shock, intravascular hemolysis, massive transfusions of stored blood, septicemia, and hypoxia. Cerebral trauma of sufficient magnitude to produce significant brain destruction induces a brief episode of DIC, which, although transitory, may be significant in that it may perpetuate cerebral bleeding.[109]

Monocyte-associated Procoagulants

It has been known for many years that monocytes and tissue macrophages may, when suitably activated, express substances capable of initiating blood coagulation.[110] This phenomenon is thought to be of importance in inflammation and in tissue localization of infectious agents and tumors. It has become apparent that "recognition-coupled" responses of the monocyte–macrophage system[111] may be important in triggering DIC in association with meningococcemia[112] and other forms of septicemia, certain forms of leukemia, major transfusion reactions, and anaphylaxis. The best defined model of this process is the induction of tissue factor by monocytes exposed to endotoxin[113] or immune complexes.[114] Other substances that may induce monocyte procoagulant activity include anaphylatoxins[115] and cytokines.[116] Most of these substances induce the formation of monocyte coagulants only in the presence of T lymphocytes[117] and the complement system.[115] A prothrombinaselike activity[118] and a specific activator of factor X[119] also are formed by appropriately conditioned monocytes.

Vascular Endothelium

In addition to monocytes or macrophages, vascular endothelium can be induced to express tissue factor activity in the setting of experimental DIC.[120] Endothelium can also be down-regulated in

terms of anticoagulant properties (e.g., thrombomodulin activity, fibrinolysis) by stimuli relevant in the pathogenesis of DIC (see Chapter 19). This altered endothelium is referred to as *activated*; properties of activated endothelium include conversion of the normally anticoagulant phenotype to a procoagulant phenotype, expression of adhesion molecules, production of inflammatory mediators, and production of vasoactive agents.[121] Many of these pathologic events are amplified by endothelial cell protease-activated receptors (PARs) (see Chapter 19). Vascular endothelium may also promote coagulation by formation of thrombogenic microparticles, which express anionic phospholipid.[122] Microparticles in DIC may also originate from platelets or granulocytes.[123]

Thrombin generation caused by activation of factor XII in DIC appears to be less important than that initiated by tissue factor.[124] Contact activation, instead, appears critical in mediating DIC-associated hypotension.[125]

Role of Cytokines

Although there are numerous etiologies for DIC (Table 54.4), a common pathway for activation of coagulation by these disorders is cytokine release.[89] Important mediators include endotoxin, interleukin-1 (IL-1), IL-6, IL-8, platelet activating factor, and tumor necrosis factor (TNF). TNF and IL-1 both increase monocyte and endothelial cell tissue factor activity and inhibit protein C activation. Elevated levels of IL-8 correlate with sepsis mortality and DIC.[126]

Infections

DIC often accompanies septicemia as a result of bacteria that possess potent endotoxins. This correlation has led to the intensive study of the effects of endotoxin on the hemostatic mechanism. Purified endotoxin produces several effects that may lead to DIC, namely, activation of factor XII,[127] platelet aggregation, inhibition of fibrinolysis, leukocyte aggregation, direct endothelial injury,[128] cellular induction of tissue factor activity,[129] and impairment of compensatory clearance functions. Many of these phenomena may be mediated by the interaction between endotoxin and monocytes, as discussed earlier.

Shock, Hypoperfusion, and Hypoxemia

Shock may favor the development of DIC by potentiating various activating stimuli that ordinarily would not exceed the capacity of compensatory processes and may perpetuate DIC after a transient activating stimulus has been dissipated. Hypoperfusion, even of normal vessels, acidosis, and hypoxemia produce hypercoagulability and favor intravascular platelet aggregation. Furthermore, splanchnic hypoperfusion impairs reticuloendothelial and hepatic clearance functions and is present in virtually all forms of shock. Shock also may impair hepatic synthesis of coagulation factors and thus contribute to the coagulation defect in DIC. Activated neutrophils may generate oxygen radicals and proteases to alter vascular permeability. Vascular injury may also occur with ischemia/reperfusion that elicits inflammatory responses.

DIC in association with giant hemangiomas (Kasabach-Merritt syndrome)[130] or with aneurysms of the aorta or other large vessels[131] has been attributed to hypoperfusion and stasis in local vascular beds. In Kasabach-Merritt syndrome, large gaps in the endothelium that expose subendothelial collagen and other fibers, together with the induction of thromboplastic substances by poorly supported, recurrently injured vessels within the tumor, also may be important factors leading to the initiation of DIC.

Miscellaneous Activating Stimuli

Snake venoms contain enzymes that may trigger coagulation in unique ways. Such venoms may produce defibrination without affecting other coagulation factors, such as ancrod, an enzyme purified from the venom of the Malayan pit viper (*Agkistrodon rhodostoma*). Other venoms contain thrombinlike enzymes or substances that specifically activate factor X or prothrombin.[132] Crude venoms also contain substances that act as thromboplastins and produce intravascular red cell hemolysis and massive vascular damage.[133] An inventory of the biochemical properties of snake venoms and their constituent enzymes has been summarized elsewhere.[134,135]

Consumption of Coagulation Factors and Impaired Anticoagulant Pathways

DIC constitutes a model of accelerated turnover of various coagulation factors, the levels of which at any time are determined by the size of the plasma pool and the differences between the rates at which they are being destroyed and replenished. Results of quantitative studies have demonstrated accelerated turnover rates for platelets, fibrinogen,[136] and prothrombin. Numerous factors complicate a simple kinetic approach. For example, the depletion of plasma fibrinogen induces a compensatory release of large amounts of fibrinogen into the circulation, possibly from the hepatic–lymphatic system, and also increases the rate of fibrinogen synthesis. Other complexities include impaired hepatic synthesis of coagulation factors and the phenomenon of postdepletion "rebound" and "overshoot."[137]

Generalizations based on the consumption of coagulation factors during in vitro coagulation are not always consistent with laboratory findings in patients with DIC. Plasma levels of factors that are normally consumed, such as fibrinogen, prothrombin, and factors V and XIII, often are reduced in severe DIC, but factors that normally are not consumed also may be deficient, such as factors VII, IX, and X. Prothrombin, which is consumed completely during coagulation in vitro, often is at a normal level in patients with DIC. Significant hypoprothrombinemia must reflect either massive and protracted activation of coagulation or complicating factors, because in animals, severe depletion of platelets, fibrinogen, and factors V and VIII results from activation of only 10% of plasma prothrombin.[138]

Proteins other than coagulation factors may be depleted as a result of DIC; those of potential importance include antithrombin,[139] α_2-antiplasmin,[140] and plasminogen.[141] Plasminogen has great avidity for fibrin and may co-precipitate in fibrin thrombi. In experimental animals, depletion of tissue plasminogen activator, as well as plasminogen, can be produced by the protracted infusion of tissue factor.

Antithrombin is the principal inhibitor of thrombin activity; low levels of antithrombin in DIC result from consumption due to persistent neutralization of thrombin, degradation by elastase released from activated neutrophils, and decreased hepatic synthesis. Other natural anticoagulant pathways—the protein C pathway and tissue factor pathway inhibitor—are also diminished in DIC.[142] Proinflammatory cytokines (TNF, IL-1) down-regulate endothelial cell thrombomodulin activity, resulting in decreased levels of activated protein C (APC). Low levels of APC not only fail to inhibit activation of coagulation (by inactivating factors V_a and $VIII_a$), but also contribute to failure to down-regulate inflammation. Thus, impairment of the protein C pathway in DIC contributes to the procoagulant and inflammatory phenotype seen in the disorder.

The numerous and diverse defense processes that are mediated by factor XIIa are activated in DIC, including the complement system and the kallikrein system. It has been suggested that the hypotensive effects of bradykinin may explain the conspicuous presence of hypotension in patients with DIC triggered by activation of factor XII,[143] for example, that associated with endotoxemia.

Consumption of Platelets

In DIC, the platelet count often is depressed out of proportion to the severity of coagulation abnormalities. Thrombocytopenia may result from processes other than the consumption of platelets in

thrombotic lesions. These processes include adhesion to denuded or damaged endothelial cell surfaces and intravascular aggregation with subsequent sequestration, which may be caused by endotoxin, antigen–antibody complexes, thrombin, particulate matter, and, possibly, fibrin–FDP complexes.

All of these agents initiate the platelet release reaction, which may produce a population of partially activated platelets that are depleted of storage nucleotides (acquired storage pool disease). Partially activated platelets may contribute to impairment of clearance functions. Epinephrine and serotonin are released from the platelets and may reach extremely high concentrations in hypoperfused vascular beds. This process may produce sustained constriction of the afferent renal arteriole and may predispose to cortical necrosis. Serotonin also may produce pulmonary and cerebral hypoperfusion.

A mouse model of DIC investigated the role of PARs in mediating the endothelial cell and platelet response to activation of coagulation. In this model of endotoxemia, activation of coagulation occurred, but knockout of PARs failed to improve survival or thrombocytopenia. Although this model may not be extrapolated to human DIC, the possibility is suggested that PARs may not mediate the DIC response, and that thrombocytopenia in DIC may result from mechanisms other than thrombin activation.[144]

Intravascular Fibrin Formation

The formation of fibrin, in the form of small strands and "microclots", is the immediate result of DIC; the ultimate consequence of this process is determined by a balance between the rate of fibrin formation and the rate of its clearance from the circulation or lysis by the fibrinolytic enzyme system.

Erythrocytes are injured mechanically during passage through fibrin networks in the microcirculation. Such microangiopathic hemolysis leads to the production of schistocytes and microspherocytes. Erythrocyte damage in metastatic carcinoma appears to be caused mainly by fibrin strands that form around tumor cell emboli as a result of low-grade DIC.[145] It should be noted that red cell fragmentation is not seen in all patients with DIC.[146]

Fibrinolysis

Fibrinolysis is present in virtually every patient with DIC, but it generally plays a homeostatic rather than a pathologic role. In the setting of DIC, this "secondary fibrinolysis" is an appropriate response to persistent thrombin generation. Fibrinolysis may be activated by several mechanisms. The major endogenous source of plasminogen activators is in the vascular endothelium of the microcirculation, and in DIC, such activators, especially tissue plasminogen activator, are apparently released as a result of thrombin formation and fibrin deposition on endothelial surfaces, endothelial injury, or hypoxia. Many of the thromboplastic substances that initiate DIC, such as tumor tissues and extracts of leukemic cells, also contain plasminogen activators. The release of plasminogen activators from platelets and leukocytes also may be significant. Finally, factor XIIa activates plasminogen by interacting with normal proactivators and the kinin system.[147]

Fibrinolysis must be distinguished clearly from the process of fibrinogenolysis, in which fibrinogen and other coagulation factors are proteolytically destroyed in the circulation. Fibrinogenolysis may be an inappropriate response in DIC associated with amniotic fluid embolism,[148] heatstroke,[95] and, rarely, carcinoma. It is uncommon in other forms of DIC; when present, it is usually transitory and overshadowed by marked fibrinolysis. Disorders in which fibrinogenolysis arises in the absence of DIC (primary fibrinolysis) are discussed elsewhere in this chapter.

Following the initial enhanced fibrinolytic response to DIC, suppression of fibrinolysis occurs due to elevated levels of plasminogen activator inhibitor-1; this inhibition of fibrinolysis was associated with a poorer clinical outcome.[149]

Fibrin(ogen) Degradation Products

The stepwise process by which fibrin is degraded proteolytically and the biologic effects of the various products of the process (FDPs) are discussed in Chapter 18. These protein fragments act as antithrombins,[53,54] inhibit fibrin polymerization, produce a structurally defective fibrin polymer,[150] and may impair platelet[51] and reticuloendothelial clearance functions. The presence of large amounts of FDP in the circulation is a major factor in the production of hemorrhage in many patients with DIC.

The infusion of large amounts of FDP (fragment D) into rabbits produces changes that resemble the posttraumatic respiratory distress syndrome in humans.[151] This observation suggests that large amounts of FDP may directly damage the pulmonary vasculature, leading to respiratory distress syndrome, which has been reported in association with DIC and the use of thrombolytic agents.[152] The smallest FDPs are peptides of 3,000 to 4,000 molecular weight that inhibit smooth muscle contractility, an effect that may explain the frequency of uterine inertia in abruptio placentae.[153]

In DIC, a large amount of fibrin remains in a soluble state as a consequence of the formation of complexes between fibrin monomers, various FDPs, and fibrinogen. This solubility has been regarded as a final defense against vascular occlusion. In vitro, the complexes dissociate in the presence of alcohol or protamine sulfate to form gels or precipitates of various types (paracoagulation).

Impairment of Clearance Mechanisms

The numerous processes that normally remove procoagulant material from the circulation are of the utmost importance in DIC because of the presence of massive amounts of both activators and products of coagulation. Most of the products of intravascular coagulation (prothrombinase, platelet factor-3 activity, various types of FDPs and complexes thereof[154,155]), as well as various initiators of the process (tissue fragments, endotoxin, antigen–antibody complexes, tissue factor, and red cell stroma), are removed from the circulation by the reticuloendothelial system[156] (Fig. 54.3). The Kupffer cells of the liver[157] and splenic macrophages are of particular importance. In certain forms of DIC, large amounts of relatively inert particulate matter (e.g., amniotic fluid embolism) place an additional burden on the reticuloendothelial system. The hepatic cells are of primary importance in the clearance of activated coagulation factors (IXa, Xa,[158] and XIa).

Investigators have suggested that various substances saturate and produce an "autoblockade" of reticuloendothelial and hepatic clearance functions in DIC in a manner comparable to that produced experimentally in the Shwartzman reaction.[156,159] This blockade may be an important pathophysiologic factor, particularly in perpetuating DIC after a transient activating stimulus. Shock and endotoxemia, both of which produce significant hepatic hypoperfusion, may contribute indirectly to autoblockade of clearance functions.

Chronic or "Compensated" Disseminated Intravascular Coagulation

Certain forms of DIC result from a weak or intermittent activating stimulus. In such patients, destruction and production of coagulation factors and platelets are balanced (Fig. 54.3). The pathophysiology of such chronic, subacute, or "compensated" DIC is fundamentally the same as that in the acute case. Nevertheless, the distinction is valuable because the clinical picture and laboratory findings in the chronic form are quite variable and may be diagnostically confusing.

Chronic DIC has been described in many patients with intrauterine fetal death or giant hemangiomas (Kasabach-Merritt syndrome) and in many cases of adenocarcinoma.[98] Other etiologic factors that may produce chronic DIC include various forms of vasculitis, acute leukemia, aneurysms, hemangiomatous transformation of the spleen, and renal allograft rejection.

In cancer patients, a virtually continuous spectrum of clinical and laboratory features has been described; these range

from recurrent venous thrombosis or arterial embolism[98] with high levels of platelets and coagulation factors to acute DIC with severe hemorrhage.[98] The clinical and experimental evidence is incontrovertible that pregnancy, the best studied form of hypercoagulability, is associated with an increased propensity for the development of DIC.[160,161] Indeed, even normal pregnancy has been suggested as a form of low-grade "physiologic" DIC,[160] which, at term, becomes overt for a short time. Thus, transitory but significant elevations of FDP and corresponding diminution in fibrinogen levels are observed regularly during the first 4 hours after delivery.[160] This may be triggered, in part, by the release of tissue factor into the circulation.

Clinical Features

The major clinical features of DIC are bleeding, often of serious magnitude and abrupt onset; a variable element of shock that is often out of proportion to apparent blood loss; and symptoms of hypoperfusion of various vascular beds. Acute renal failure is common, and thromboembolic manifestations often are noted.[162] Any of these features or signs and symptoms of the underlying disorder may predominate in a given case.

Evidence of major organ dysfunction is a common finding in patients with DIC, most often including signs, symptoms, and laboratory evidence of abnormal pulmonary, renal, hepatic, and central nervous system function. Although virtually all of these manifestations have been attributed to the underlying DIC, the clinical manifestations that have been described usually were the result of the underlying disorder. For example, one study observed that patients with DIC due to aortic aneurysm had laboratory features of DIC but minimal clinical manifestations. Patients with DIC due to obstetric disorders all had bleeding, but only 20% had organ dysfunction. In contrast, of patients with DIC due to sepsis, only 15% had bleeding, but 76% had organ failure.[94] These results suggest that marked heterogeneity exists in clinical manifestations of DIC, and that the etiology of DIC is a major predictor of clinical events.[94]

In this section, the clinical manifestations and diagnosis of DIC are discussed in general terms. Various specific clinical features and details regarding treatment of the most common forms follow in a separate section.

Acute Disseminated Intravascular Coagulation

Bleeding manifestations of virtually every kind have been described, and they may evolve rapidly in the patient with acute DIC. Generalized ecchymoses, petechiae, and bleeding from previously intact venipuncture sites or around indwelling intravenous needles or catheters are noted in many patients. Large, spreading, hemorrhagic skin lesions often are superimposed on familiar exanthems in patients with rickettsial and viral infections. "Geographic" acral cyanosis is a prominent feature in some patients. Large, sharply demarcated ecchymotic areas may result from thrombotic occlusion of dermal vessels and may progress to skin infarction. Such infarcts are particularly common in patients with purpura fulminans (Fig. 54.4) and are seen also in coumarin-induced skin necrosis and inherited homozygous deficiency of protein C (see Chapter 55). In patients with meningococcemia, cutaneous hemorrhage may be striking. Bleeding from apparently normal gingivae, epistaxis, gastrointestinal bleeding, pulmonary hemorrhage, and hematuria are common. In patients who develop DIC after surgical procedures, alarming hemorrhage may develop around drains and tracheostomies, and accumulations of blood may be concealed in serous cavities.

Chronic Disseminated Intravascular Coagulation

Superficial but extensive ecchymoses of the extremities, often without petechiae, may develop intermittently or may persist.

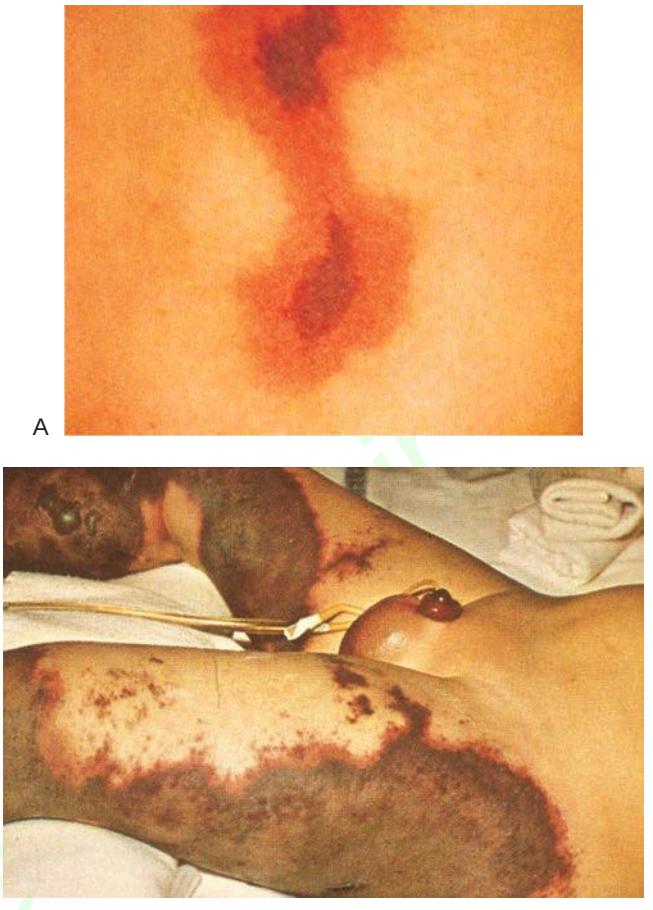

FIGURE 54.4. Purpura fulminans in infection-associated disseminated intravascular coagulation. Early lesions **(A)** are circumscribed; progressive lesions **(B)** may become necrotic. (From Dudgeon DL, Kellogg DR, Gilchrist GS, et al. Purpura fulminans. Arch Surg 1971;103: 351–358; copyright 1971, American Medical Association.)

Recurrent episodes of epistaxis or more serious internal mucosal bleeding may punctuate the course. Trousseau sign (recurrent migratory thrombophlebitis in association with cancer) in most instances is a manifestation of chronic DIC. More serious hemorrhagic manifestations may develop as the underlying disease progresses or may arise with dramatic suddenness after surgical procedures such as a prostatectomy. Acute DIC may be heralded by further thrombophlebitis or pulmonary emboli. In some patients, evidence of vascular obstruction (e.g., impairment of renal function, confusion, transitory neurologic syndromes, or repeated episodes of cerebral thrombosis) may develop with minimal bleeding.

Laboratory Diagnosis

The laboratory findings in DIC are summarized in Table 54.2. Contrary to what is commonly assumed, they may be quite variable. The plasma fibrinogen level, PTT, PT, platelet count, and estimates of FDP or D-dimer are the cornerstones on which the diagnosis of DIC is based. These simple tests should always be performed first. Additional information may confirm, but seldom refutes, the diagnosis of DIC if typical abnormalities are demonstrated by these tests. Laboratory data may change with remarkable rapidity in DIC, based on disease progression or therapy.

Laboratory data must be interpreted with caution. Levels of platelets and various coagulation factors, fibrinogen, and factor VIII, in particular, may be elevated in many of the conditions associated with DIC, including pregnancy. Thus, a fibrinogen level of 200 mg/dl, although within the normal range determined in

healthy subjects, may represent a significant decrease in a patient whose baseline level was 800 mg/dl due to acute-phase changes.

The best test for diagnosing DIC is the D-dimer assay. The semiquantitative method is sensitive,[163] and D-dimer values >2,000 ng/ml have been reported to be consistent with DIC.[164] More sensitive, quantitative D-dimer assays are now available; one study reported that a sensitive D-dimer assay result <8.2 μg/ml optimized sensitivity and negative predictive value in patients with DIC.[165]

A new test, measurement of the biphasic waveform in the PTT assay, has been reported to precede development of DIC and to predict DIC better than the D-dimer assay.[166] The biphasic waveform results from the formation of a precipitate on plasma recalcification; the precipitate contains very-low-density lipoprotein complexed with C-reactive protein. If confirmed in clinical outcome studies, this assay may be a useful addition to laboratory tests for DIC.

Basic Blood Examinations

In patients with DIC, routine hematologic tests may reveal evidence of acute bleeding, accelerated red cell destruction, or signs of the underlying disease. Examination of the blood smear reveals schistocytes in approximately 50% of cases,[93,146] but the degree of schistocytosis bears no necessary correlation with other facets of the disorder. More subtle evidence of intravascular hemolysis often is found, such as increased serum levels of lactic acid dehydrogenase and diminished haptoglobin levels. Rarely, massive intravascular hemolysis with hemoglobinemia and hemoglobinuria is noted.[144]

Thrombocytopenia is an early and consistent sign of acute DIC, and the consideration of this diagnosis in the presence of a persistently normal platelet count is difficult. Platelet counts in the range of 50,000 to 100,000/μl are the usual finding, but thrombocytopenia may be severe.

Coagulation Defect

The PTT, PT, and thrombin time are prolonged in most patients with acute DIC. Early in the course of the disorder and in chronic DIC, the PTT may be normal or even shorter than normal, which may be the result of the procoagulant effects of activated coagulation factors or elevated factor VIII levels.

Occasionally, one can follow the process of DIC from its inception, and specific assays for various coagulation factors obtained at the time of diagnosis reveal a variable and rapidly changing picture. The plasma levels of fibrinogen and of factors V and XIII usually are significantly depressed; fibrinogen and factor V are the most consistently affected.[167] The level of factor X may be lower than that of other "stable" factors (factors VII, IX, and XI), which usually are present in normal amounts.[167] In many patients, particularly those with abruptio placentae, normal prothrombin levels are maintained,[99,167] but marked hypoprothrombinemia often is present in those with septic DIC.[168]

The levels of factors VIII, IX, and XI as determined by one-stage assays may fluctuate widely as the result of the presence of activated factors[169] such as thrombin and factor Xa.[162] This problem is minimized in two-stage assays.[167] Levels of factor VIIIc often are normal or increased, particularly when assayed by two-stage techniques.[170] In many patients, the levels of coagulation factors tend to "overshoot" after repletion. As a consequence of the inhibitory effects of FDPs, the thrombin time may be prolonged out of proportion to the reduction in the fibrinogen level.

Tests for Fibrinolysis: Fibrin Monomers, Fibrin(ogen) Degradation Products, and D-Dimer

In most patients with DIC, FDP levels as determined by quantitative methods, such as red cell hemagglutination inhibition or latex agglutination, are 25-μg fibrinogen "equivalents"/ml or higher.[167] All methods are most sensitive to large or "early" FDPs. These fragments, particularly fragment X, retain thrombin-binding sites or may form a complex with fibrinogen and consequently be removed during the preparation of serum for FDP tests. This phenomenon or the presence of only small FDPs may explain the normal levels of FDPs in some patients with otherwise typical DIC. Fibrinopeptide A and certain fibrinogen fragments that are formed by the lysis of cross-linked fibrin, such as the DD-dimer and the DD-dimer–E complex, can be demonstrated by using special techniques. These latter FDPs provide direct evidence of the action of thrombin on fibrinogen and provide a means of differentiating fibrin degradation products from fibrinogen degradation products.[171,172]

The simplicity, specificity, and sensitivity of the D-dimer test have led many laboratories to replace less sensitive or less convenient tests for DIC with the D-dimer test. Because false-positive results may be seen with FDP latex agglutination tests in patients with dysfibrinogenemia, the D-dimer test may be more specific in diagnosing DIC, especially in distinguishing the coagulopathy of liver disease from DIC.[65,163,173] False-positive D-dimer latex agglutination tests may occur in patients with elevated levels of immunoglobulin M (IgM) (rheumatoid factor).

"Paracoagulation" techniques are simple to perform, but they are less specific than tests for FDPs. The results of the ethanol gelation test, in particular, often are negative in DIC. To the contrary, results of protamine gelation tests usually are positive,[174] but abnormal results are obtained in numerous other disorders, including many that commonly are associated with DIC.

Other Laboratory Findings

Plasma levels of fibrinopeptide A[175] and the rate of incorporation of ^{14}C-labeled glycine ethyl ester into soluble "circulating fibrin"[176] are exceptionally sensitive indicators of DIC and may be abnormal even in patients with normal levels of FDP. Levels of antithrombin,[177] α_2-antiplasmin, and proteins C and S may be diminished in some cases.

Other parameters of activation of coagulation and fibrinolysis have been studied in DIC, especially in sepsis. Thrombin–antithrombin III (TAT) complexes and plasmin–α_2-antiplasmin (PAP) complexes are often elevated in sepsis-associated DIC. Assays such as TAT and PAP complexes may have prognostic significance in DIC, as may other coagulation parameters, including plasminogen activator inhibitor type-1, vWF antigen, and α_2-antiplasmin.[178] In a primate model of Gram-negative sepsis, a number of molecular markers of coagulation were investigated for their use in monitoring DIC.[179] Markers such as soluble thrombomodulin and soluble fibrin monomer are useful in assessing the status of microvascular injury.

The clinical role of these assays in diagnosing or managing DIC patients at this time is uncertain. The best test for diagnosis and monitoring DIC appears to be a sensitive D-dimer assay; the PTT waveform analysis may also prove to be a useful test. The International Society on Thrombosis and Haemostasis (ISTH) has proposed clinical and laboratory criteria to better define the spectrum of DIC cases.[90,180]

Differential Diagnosis

The syndrome of DIC is seldom difficult to recognize. Problems arise when the diagnosis simply is not considered or in chronic forms, when the underlying coagulation disorder may be masked by features of the basic disease or by thromboembolic complications.[181]

Two disorders, however, produce laboratory abnormalities that resemble DIC: Severe liver disease, which is common, and primary fibrinogenolysis or "pathologic" fibrinolysis, which is rare (Table 54.2).

In patients with primary fibrinogenolysis, the following conditions may be evident: Hypofibrinogenemia; increased levels

of FDP; abnormalities of the PTT, PT, and thrombin time; and deficiencies of factors V and VIIIc. The euglobulin lysis time is significantly and persistently shortened, often in association with plasminemia. However, the platelet count usually is normal, the D-dimer level should be normal or only minimally elevated, and protamine sulfate tests should be negative. Hypoprothrombinemia and deficiencies of stable coagulation factors VII, IX, X, and XI are rare. Thus, routine coagulation tests should be able to distinguish DIC from primary fibrinogenolysis.

In patients with liver disease, coagulation abnormalities and thrombocytopenia may originate from many pathologic processes (Table 54.3). Chronic or intermittent fibrinogenolysis with high levels of FDP is common, particularly in patients with cirrhosis. In such patients, the exclusion of the diagnosis of DIC may be difficult. Factor VIIIc levels usually are elevated when liver disease is severe, and the levels of factors VII and IX typically are low. A helpful test in discriminating between the coagulopathy of liver disease and DIC is the D-dimer test, the results of which should be abnormal in DIC but normal in liver disease (unless additional disorders coexist[65,173]).

DIC, particularly that associated with carcinoma, may be confused with various microangiopathic hemolytic anemias, such as thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome; in these disorders, the clinical picture may resemble that of DIC in many respects. High levels of FDP may be encountered in patients with microangiopathic hemolytic anemias, but significant coagulation abnormalities are not commonly present. Many other disorders may produce slight to moderate elevations of FDP: For example, pulmonary embolism and chronic renal disease with uremia.

Moderate thrombocytopenia is a common consequence of the use of extracorporeal circulatory devices, and coagulation abnormalities often are noted immediately after their use because of the presence of residual heparin. Heparin levels also may rise several hours later (the rebound phenomenon). In such patients, the presence of thrombocytopenia together with the effects of heparin may be confused with DIC; similar difficulties may arise after hemodialysis. Even the small amounts of heparin required to irrigate indwelling catheters, or to contaminate Hickman catheters, are a common cause of "pseudo-DIC."

Treatment

DIC always is the end result of a serious underlying disorder. Although the patient may benefit greatly from the replacement of depleted coagulation factors and platelets, correction of the syndrome depends on prompt and energetic treatment of the primary disorder. This—not the therapeutic measures described in this section—remains the cornerstone of therapy.

Anticoagulants

Heparin is a specific activator of the physiologic antithrombin system and thereby inhibits a number of proteolytic enzymes, including factors IXa and Xa and thrombin (see Chapter 55). The therapeutic efficacy of heparin is unquestionable in some animal models of DIC, but assessment of its effectiveness in humans has proved more difficult. In view of the complexity of DIC, inhibition of coagulation alters only one facet, albeit a fundamental one, of the pathophysiologic cycle. Recent appreciation of the role of anticoagulation and inflammatory pathways has led to consideration of novel therapies, including replacement of anticoagulant proteins such as antithrombin and APC.[142]

In patients with chronic DIC, the results of heparin therapy usually are favorable and may be dramatic. In most patients, heparin would not be expected to alter ultimate mortality because of the nature of the underlying diseases; however, this drug typically does reduce the severity of bleeding and thromboembolic manifestations and produces parallel improvement in the abnormalities of laboratory test values. Elevated levels of D-dimer and FDPs drop rapidly, and accelerated fibrinolysis, if present, disappears after the administration of heparin, often before the coagulation defect has been alleviated. The response of the platelet count to heparin therapy for DIC is slow and often erratic.

In patients with acute DIC, particularly that associated with sepsis, the results of heparin therapy have been less encouraging.[182] Most clinicians are reluctant to use heparin in patients with acute DIC. Because baseline PTT values are usually prolonged in acute DIC, heparin levels may be required to monitor therapy (see Chapter 55).

Replacement Therapy with Platelets and Coagulation Factors

Many patients with DIC ultimately receive large amounts of blood products, even though evidence is only anecdotal that they are necessary or therapeutically effective.[183] The major aim of replacement therapy with blood products in DIC is to replenish fibrinogen. This goal is best accomplished by the administration of cryoprecipitate, each unit of which contains approximately 250 mg of fibrinogen.[184] The amount of cryoprecipitate given should be sufficient to elevate the plasma fibrinogen level to at least 100 to 150 mg/dl. As a general guide, 3 g of fibrinogen can be expected to raise the plasma level of an adult patient approximately 100 mg/dl. Fibrinogen administration probably should be restricted to the occasional patient with hypofibrinogenemia and significant bleeding, in whom DIC is self-limited or has been controlled by heparin therapy (e.g., in intrauterine fetal death before surgical intervention). Sterile fibrinogen concentrates are not yet available for routine therapeutic use in the United States.

Patients with DIC, bleeding, and platelet counts $<50{,}000/\mu l$ should be considered for platelet transfusion. Due to the acquired storage pool defect seen with DIC, as well as FDP inhibition of platelet function, DIC patients may require a higher platelet count for adequate hemostasis than patients with thrombocytopenia in the absence of platelet dysfunction.

The availability of purified, sterile antithrombin concentrates has led to its investigation in treating DIC. As seen in most studies,[185] although antithrombin concentrates can normalize plasma levels of this protein in patients with DIC and improve hemostasis parameters, consistent clinical benefit in terms of survival is not evident. A large clinical trial demonstrated that high-dose antithrombin therapy in patients with sepsis had no effect on mortality.[186] A post hoc analysis of this clinical trial indicated that high-dose antithrombin therapy may be effective in improving survival in the subset of patients with severe sepsis and high risk of death, especially if concomitant heparin treatment is avoided.[187] Prospective studies will be important to confirm this subgroup analysis.

Other Therapeutic Measures

Treatment of shock should be immediate and vigorous in all patients with DIC. Packed erythrocytes should be given promptly if indicated. The indiscriminate use of ε-aminocaproic acid (EACA) and other antifibrinolytic drugs should be discouraged. Because of the potential risks, fibrinolytic enzyme inhibitors should be administered only to carefully selected patients, that is, those in whom DIC has resulted from a transitory stimulus or has been arrested by heparin administration and in whom fibrinogenolysis or inappropriate fibrinolysis, hypofibrinogenemia, and adequate renal function have been clearly documented. The therapeutic use of EACA in fibrinogenolysis and appropriate dosage schedules are discussed elsewhere in this chapter.

Specific Features of Various Forms of Disseminated Intravascular Coagulation

Obstetric Disorders

Abruptio Placentae

DIC complicates abruptio placentae in approximately 10% of cases[188] in which fetal compromise occurs. Shock develops rapidly, but vaginal bleeding may be minimal or absent for a time and bears little relationship to the extent of abruption. Brisk external hemorrhage may originate from episiotomies and lacerations, and large amounts of blood may be concealed behind the placenta and within the wall of the uterus. Severe placental abruption associated with fetal death is often linked with DIC.[189]

Hemorrhage is the major factor leading to shock and renal complications in abruptio placentae, and the most essential therapeutic measures are the vigorous treatment of blood loss and the prompt evacuation of the uterus. Extensive replacement therapy seldom is required. Often, fibrinogen replacement is given if immediate surgical treatment is necessary. Fibrinogen replacement may be most useful in patients with fetal death requiring cesarean delivery. If the coagulation defect and thrombocytopenia are severe or persist for an unusually long time, the administration of platelets, fibrinogen in the form of cryoprecipitate, and fresh frozen plasma[190] may reduce hemorrhage. Most obstetricians do not administer heparin because it may increase bleeding and because rapid spontaneous remission of DIC is usual when the uterus is evacuated.

Intrauterine Fetal Death

In the event of intrauterine fetal death, definite laboratory abnormalities are not seen until the dead fetus has been retained for ≥5 weeks[188]; plasma levels of FDPs then begin to rise, and the platelet count and fibrinogen level gradually decline. Bleeding may be inconspicuous, but a progressive loss of renal function is not uncommon. In most women in whom delivery of the dead fetus is induced promptly according to usual obstetric practice, bleeding is not serious, even in the presence of low-grade DIC. Operative intervention is dangerous when hypofibrinogenemia is severe, and such patients should receive heparin until safe fibrinogen levels are restored.[191] If immediate surgery is imperative, heparin administration should be followed by platelet replacement and enough fibrinogen, in the form of cryoprecipitate, to produce plasma fibrinogen levels of 150 mg/dl or greater.[192]

Amniotic Fluid Embolism

In women who survive amniotic fluid embolism (mortality rate of up to 80% in early studies), DIC with severe hemorrhage may develop within 1 to 2 hours.[162,193] More recent surveys indicate a mortality rate of 20% to 30%[194]; 50% of patients with amniotic fluid embolism had DIC.[188] Often, the syndrome is complicated by significant fibrinolysis and even fibrinogenolysis.[148] Hypoxia and other sequelae of pulmonary vascular obstruction dominate the clinical picture and usually determine the outcome. The release of serotonin and other vasoactive substances from platelets may contribute to the profound pulmonary vasoconstriction.

Miscellaneous Obstetric Disorders

Intravascular coagulation has been documented after abortions induced by intra-amniotic injection of hypertonic saline solutions[194] and hypertonic urea,[195] but it apparently does not complicate abortions performed by suction curettage or those induced by prostaglandin $F_2\alpha$.

Disseminated Intravascular Coagulation in Neonates and Infants

Several disorders unique to the neonate and infant may be associated with DIC (Table 54.2).[196] The transplacental passage of thromboplastins or other procoagulant substances has been the apparent cause of DIC in neonates born of mothers affected with DIC owing to abruptio placentae, eclampsia, or septicemia. Asphyxia may be a common precipitating factor for DIC in these disorders.[197] Bacterial infection and generalized viral infections (e.g., herpes simplex, cytomegalic inclusion disease, and rubella), acidosis, and hypoxia are more common causes of DIC in infants than in adults.[198] DIC secondary to giant hemangiomas and purpura fulminans has been reported in neonates.

Management of septic DIC in the neonate should emphasize treatment of underlying infection. A controlled study that compared treatment with heparin, extensive replacement therapy with blood products, and supportive care only revealed no significant differences in outcome for the three groups.[199] A more recent study confirms that clinical trials in neonatal sepsis have not identified a beneficial therapy.[200]

The diagnosis seldom is difficult, but DIC must be distinguished from septic shock, endotoxin shock, or simple thrombocytopenia, all of which may develop independently of DIC in severe infections.[201]

In many patients, no additional measures other than treating infection and shock (if present) are required. No evidence has been cited that heparin has diminished mortality.[168] In one series, the alleviation of septic shock appeared to be more important in the ultimate prognosis than did correction of the coagulation abnormalities.[168] Recombinant APC (r-APC) was demonstrated in one study to reduce mortality in adult patients with sepsis[202]; however, a Cochrane database review of the effects of r-APC in neonates with sepsis concluded that there were insufficient data to support the use of the drug in the pediatric setting.[203] Subsequent studies in adult patients demonstrating no clinical benefit of r-APC in sepsis led to withdrawal of this drug.

Purpura Fulminans

The hemorrhagic manifestations of purpura fulminans develop several days after an acute infection; these are most commonly scarlet fever or various viral respiratory diseases. Purpura fulminans is most common in children but is also well documented in adults. The most common manifestations are symmetric ecchymoses of the lower extremities and buttocks, sharply circumscribed infarcts of the skin and genitalia, and gangrene of the extremities that often involves the digits symmetrically.[204] These ecchymotic lesions often become necrotic, ultimately forming blood-filled bullae (Fig. 54.4). Petechiae are rare. Fever and prostration are seen, but visceral lesions, including renal involvement, are relatively uncommon.

The mortality rate associated with purpura fulminans ranges from 18%[205] to 40% to 70%.[206] Heparin in therapeutic doses has often proved therapeutically effective, and it has been suggested that poor results obtained previously with this anticoagulant reflect late treatment of moribund patients. In patients with purpura fulminans, relapses are particularly common after cessation of heparin therapy,[205] and the administration of this anticoagulant, possibly in reduced doses, should always be continued for 2 to 3 weeks. The subject of purpura fulminans diagnosis and treatment has been recently reviewed.[207] Evidence that purpura fulminans may be a manifestation of homozygous protein C deficiency is discussed in Chapter 55. The efficacy of protein C in patients with sepsis and purpura fulminans is discussed below.

Neoplastic Disorders

Carcinoma

In patients with DIC associated with carcinoma, the clinical picture is quite variable and often consists of a combination of bleeding and thromboembolic phenomena, including arterial embolism.[98,102,103] The association of chronic DIC,

thromboembolism, and cancer is often called *Trousseau syndrome*.[98] Laboratory findings are variable. Evidence of chronic DIC, hypercoagulability, or acute DIC may be found. In a study of more than 1,000 patients with solid tumors, 7% were diagnosed with DIC using standard coagulation tests (platelet count, fibrinogen, D-dimer, FDPs).[208] Risk factors associated with the occurrence of DIC included older age, male gender, advanced disease, breast cancer, and necrosis of the tumor specimen.[208]

One reason for the variability in cancer patients having venous thromboembolism relates to the histology of the malignancy. Analysis of a very large database of Medicare patients with cancer identified tissue-specific differences in thrombotic risks among cancers.[209] Those cancers with a high risk of thrombosis included uterine, brain, leukemia, ovary, and pancreas (twofold or greater risk), whereas prostate, liver, head or neck, bladder, and breast cancer had less than a onefold risk (compared to noncancer patients).[209]

DIC in association with carcinoma resolves with effective treatment of the underlying tumor. Heparin or low-molecular-weight heparin (LMWH) in therapeutic doses has proved effective in controlling the hemorrhagic and thromboembolic symptoms.[98,102,210] There is a suggestion in the literature that the use of LMWH therapy is associated with improved mortality in cancer patients. A large European study of patients with noncurable solid tumors evaluated the survival effects of a LMWH (nadroparin) given in therapeutic dose for 2 weeks followed by half-dose for 4 weeks.[211] There was significant improvement in survival in the LMWH group with minimal toxicity.[211] The basis for this antitumor activity of LMWH may not relate to anticoagulant activity.[212] A recent Cochrane literature review of the effects of anticoagulation on cancer patient survival found improved survival after 24 months, but not 12 months.[213]

A significant minority of patients with cancer and thrombosis will experience recurrent thrombosis with oral anticoagulation[98] and will benefit from long-term heparin or LMWH.[214] Based on these data, optimal anticoagulant therapy for cancer patients with thrombosis is LMWH. In the case of DIC associated with prostate cancer, adjunctive therapy with ketoconazole[215] or antiandrogens[216] may be useful.

An animal model of cancer has provided evidence that tumors may activate coagulation through overexpression of the MET oncogene.[217] When MET-induced carcinogenesis was established in mice, a hypercoagulable state resulted. Inhibition of the activated MET oncogene may be a potential therapeutic target in patients with cancer and DIC. The spectrum of mechanisms of thrombosis in Trousseau syndrome has been reviewed.[218]

Acute Promyelocytic Leukemia

DIC has been reported in association with all forms of acute leukemia, but it is most common in the "hypergranular" promyelocytic variety,[219] in which it may occur in 60% to 100% of cases. The cause of the coagulopathy is multifactorial: Tissue factor is present in the granules of the abnormal promyelocytes[105] as well as leukocyte proteases, including elastase.[220] Enhanced fibrinolysis also results from increased promyelocyte expression of annexin II, a receptor for plasminogen and tissue plasminogen activator.[107] Additionally, the malignant promyelocytes contain plasminogen activators.[221] The clinical picture usually is one of chronic progressive DIC with a significant fibrinolytic component that may antedate the other manifestations of the disease. Acute fulminant DIC may develop spontaneously or may be triggered by the administration of chemotherapeutic agents, which cause the release of thromboplastic contents of the promyelocytes.

In some patients with acute leukemia, accelerated fibrinolysis is a conspicuous finding. In one study, depletion of α_2-antiplasmin developed during induction of chemotherapy, a finding that was more predictive of bleeding complications than traditional indices of DIC, such as levels of fibrinogen, antithrombin, and plasminogen.[222] This study suggests that "unregulated" fibrinolysis, by destroying functional hemostatic plugs and depleting fibrinogen, may be more important than DIC in some cases.

In the past, heparin has produced clear-cut remissions in patients with chronic forms of DIC associated with acute leukemia. An earlier approach[220] recommended fibrinogen replacement therapy for fibrinogen levels <100 mg/dl and platelet transfusion for platelet counts <20,000/μl. Fresh frozen plasma is given to patients with prolonged PT and PTT values who are bleeding. If the fibrinogen level is difficult to maintain over 100 mg/dl, or if FDP levels are rising, heparin is infused at 500 U/hour.[220] When α_2-antiplasmin levels are below 30% of normal, EACA or another antifibrinolytic agent should be added to this regimen,[222] and α_2-antiplasmin levels should be monitored during induction of chemotherapy.

A newer approach that has virtually replaced the need for heparin and antifibrinolytic agents in the treatment of acute promyelocytic leukemia is the early administration of all-trans retinoic acid.[223] However, these patients still may require replacement therapy for hypofibrinogenemia and thrombocytopenia.[223] Current protocols for acute promyelocytic leukemia combine all-trans retinoic acid and combination chemotherapy (or arsenic trioxide) to ameliorate the coagulopathy; all-trans retinoic acid is more effective than chemotherapy alone in improving the coagulopathy.[224]

Kasabach-Merritt Syndrome (Giant Hemangiomas)

The severity and incidence of DIC tends to parallel the size of the vascular tumors in the Kasabach-Merritt syndrome.[225] Platelet consumption, activation of coagulation, and microangiopathic red cell destruction take place mainly within the hemangioma ("sequestered" or localized intravascular coagulation), but laboratory evidence of DIC in the general circulation usually is clear-cut.[130,225] Recurrent bleeding from the surface of the tumor is the major hemorrhagic manifestation; in the presence of DIC, this bleeding may be intractable. Periodic swelling of the lesions often is observed. This phenomenon may be a consequence of intermittent obstruction of blood outflow from the hemangioma and may provoke serious hemorrhage. Irradiation and corticosteroids have produced favorable results in a few cases, but surgical removal of the tumors has ultimately been required in most patients.[225] Interferon-α has been successful in large numbers of patients; this cytokine probably acts as an antiproliferative/antiangiogenic agent.[225] Antifibrinolytic therapy has been reported to be useful in controlling the coagulopathy.[226,227] Other useful therapies include cryoprecipitate and platelets for replacement therapy to correct a severe coagulopathy. The use of heparin therapy is uncertain.[225]

For patients with aneurysms associated with DIC, LMWH has been reported to be useful in resolving the coagulopathy.[228]

Shock and Massive Trauma

Heparin therapy may be hazardous for patients with massive injuries. Even in the face of DIC, intensive supportive care and replacement therapy with plasma and platelets are the mainstays of treatment.[229]

Hemolytic Transfusion Reactions

DIC is present in many patients with hemolytic transfusion reactions. Severe, acute hemolytic transfusion events are triggered by antigen–antibody reactions that initiate complement activation and activation of coagulation. These reactions are usually a result of ABO incompatibility. These patients may experience not only DIC, but also shock and renal failure. Primary therapy is directed to control of hypotension and restoration of renal blood flow. Fluid, diuretics, and dopamine may be useful therapies. Heparin therapy for DIC in hemolytic transfusion reactions is controversial.[230]

Snakebite

DIC associated with snakebite differs from the usual form of the syndrome in several respects. Hemorrhage may be relatively inconspicuous,[231] even in the presence of incoagulable blood. When present, it is mainly the result of a vascular toxin. Platelets often are spared, although the venom of the timber rattlesnake (*Crotalus horridus horridus*) contains a unique serine protease that acts as a potent platelet activator.[232] In some cases, a disorder manifested mainly by brisk fibrinolysis in the absence of evidence of DIC has been described.[233] The specific coagulopathy seen in individual patients in large part depends on venom constituents present in the particular snake species. Detailed lists of venom constituents affecting hemostasis have been published.[132,134,135]

The treatment of snakebite involves the administration of specific antivenom and intensive supportive care. Heparin therapy has proved marginally effective at best.[231,234] In general, it is not indicated when specific antivenom is available. Cryoprecipitate should be given to maintain the fibrinogen level over 100 mg/dl.

Pathology

The fatality rate associated with DIC is up to 60%.[235] In many cases, death is attributed to bleeding or thrombosis. Mortality increases with age, underlying co-morbidities, the number of clinical manifestations, and the severity of laboratory abnormalities.

The deposition of fibrin in small vessels represents the ultimate result of DIC. In many patients, fibrin can be formed and lysed without significant vascular occlusion. Indeed, at autopsy, fibrin thrombi in some subjects were absent or were demonstrated only with special stains or by electron microscopy. This may result from postmortem lysis or from deposition of thin films of fibrin on the vast endothelial surface and on the erythrocytes. The localization of fibrin thrombi varies somewhat with the cause of DIC. The kidney is the single most common site of fibrin thrombi. Renal lesions range from patchy tubular necrosis to massive bilateral cortical necrosis and have been attributed to a sieving effect of the renal microvasculature. Nonthrombotic endocarditis and pulmonary hyaline membranes have been found in many patients,[98,236] especially those with cancer.

Emerging Therapies for Disseminated Intravascular Coagulation

The recognition of pathogenic mechanisms critical in initiation or progression of DIC has led to investigation of new therapeutic agents in animal models of DIC and clinical trials in humans. For example, protease inhibitors such as aprotinin[237] or gabexate[238] have been studied. However, survival advantages have not been shown with these agents. Similarly, high-dose antithrombin replacement therapy had no effect on mortality in patients with severe sepsis.[186]

The key role of tissue factor in triggering DIC[239] has led to studies in which neutralizing antibodies to this procoagulant were found to prevent lethal septic shock in animal models.[240,241] Two published clinical trials in sepsis patients used tissue factor pathway inhibitor as therapy; there was no significant benefit observed.[242]

The role of protein C in ameliorating the mortality of sepsis has also been demonstrated; neutralization of protein C activity in an animal model exacerbated the lethal response,[243] and infusion of protein C[244] or APC [243] prevented the lethal response in humans with meningococcemia or in a primate model, respectively. APC had previously been demonstrated to improve survival in sepsis[202]; subsequent studies demonstrated no clinical benefit of the drug, and it is no longer available.

PRIMARY FIBRINOLYSIS (FIBRINOGENOLYSIS)

Fibrinolysis is an appropriate response to thrombosis and necessary in the re-establishment of blood flow. This localized response, termed *physiologic fibrinolysis*, is discussed in Chapter 18. The term *pathologic fibrinolysis* has been used indiscriminately to refer to any situation in which in vitro evidence of fibrinolysis was associated with bleeding. In retrospect, it seems probable that fibrinolysis in many cases was secondary to DIC and that in others it represented an essentially physiologic response to anoxia, shock, or stress. In fibrinogenolysis, on the other hand, the proteolytic destruction of fibrinogen and other proteins occurs in the general circulation, and severe bleeding may develop. The pathophysiology of fibrinogenolysis may represent a disproportionate or "inappropriate" response to underlying DIC or may result from a defective fibrinolytic mechanism that may be inherited or acquired.

Etiology

Fibrinogenolysis may complicate various disorders, among which severe liver disease[49] is the most common. Fibrinogenolysis is a predominant laboratory feature in several patients with disseminated neoplasms,[245–247] especially urogenital neoplasms.[248] The mechanism for enhanced fibrinolysis in these patients is probably increased tumor cell secretion of plasminogen activators such as urokinase.[246] Fibrinogenolysis and marked fibrinolysis rarely complicate the immediate puerperium,[192,193] and they have been reported in association with acute promyelocytic leukemia.[220,221] Enhanced fibrinolysis has also been associated with cardiac bypass surgery[249] and aortic clamping during vascular surgery.[250] Inherited deficiency of plasminogen activator inhibitor type-1[251] or α_2-plasmin inhibitor[252] also results in hyperfibrinolysis and a bleeding tendency.

Pathophysiology

Fibrinogenolysis is a consequence of the generation of plasmin within the general circulation (plasminemia). Potent plasmin inhibitors (antiplasmins) normally neutralize free plasmin rapidly (see Chapter 18); the result is that the proteolytic effects of this enzyme normally are restricted to fibrin. Fibrinogenolysis occurs only when the neutralizing capacity of the antiplasmins is exceeded.

The proteolytic action of plasmin is nonspecific. In addition to fibrin and fibrinogen, this enzyme may degrade factor VIIIc, factor XIII, other coagulation factors, and a wide variety of other plasma proteins, such as complement and various hormones. Free plasmin also may activate bradykinin, a phenomenon that may underlie the marked hypotension present in some patients with fibrinogenolysis. Thus, *pathologic proteolysis* is an appropriate synonym for *fibrinogenolysis*.

Fibrinogenolysis is activated by mechanisms that are remarkably similar to those that initiate DIC. Therefore, tumor tissue contains plasminogen activators in addition to tissue factor.[246] The secretion of these activators into the circulation may rapidly activate most of the circulating plasminogen.

Hypoxia and hypoperfusion may lead to plasminogen activation and, occasionally, to fibrinogenolysis. However, in many of these patients, bleeding is minimal; when present, it cannot be clearly related to the presence of fibrinogenolysis. In these patients, fibrinogenolysis probably is a nonspecific, essentially physiologic response. Fibrinogenolysis may also result from therapy with thrombolytic agents, as discussed in Chapter 55.

Clinical Features and Laboratory Diagnosis

The clinical picture in most reported cases of fibrinogenolysis is similar to that of DIC. The usual laboratory findings are

summarized in Table 54.2 and are discussed in an earlier section of this chapter. Hypofibrinogenemia may be seen. The PTT, PT, and thrombin time may be prolonged because of the anticoagulant effects of FDPs. Moderate concentrations of EACA (4×10^{-4} mol/L) inhibit plasminogen activators but not free plasmin. Thus, the euglobulin lysis time, which invariably is shortened in patients with fibrinogenolysis, is unaffected by the addition of EACA if free plasmin is present. Among the coagulation factors, factors V and VIIIc are the most sensitive to the proteolytic action of plasmin; factor XIII also is deficient in some patients. The plasma levels of other factors (e.g., factors VII and IX), including some that are degraded by plasmin in vitro, usually are normal in patients with fibrinogenolysis. Depletion of plasminogen and α_2-antiplasmin and the presence of α_2-antiplasmin–plasmin complexes in the plasma also may be demonstrated in many patients with fibrinogenolysis and in those with DIC and active fibrinolysis.[253]

The standard FDP test does not discriminate between fibrinogen degradation products and fibrin degradation products. Measurements of fibrinopeptide A and the D-dimer, which is a specific indication of degraded cross-linked fibrin, yield normal results in fibrinogenolysis. Thus, patients with hypofibrinogenemia, prolonged PT and PTT values, elevated FDP levels, and a normal D-dimer may have primary fibrinogenolysis. In the absence of intravascular coagulation, paracoagulable complexes containing fibrin monomers do not form in plasma; thus, plasma protamine gelation tests are negative in fibrinogenolysis. Assays for plasminogen and for the various inhibitors of the fibrinolytic enzyme system may reveal a pattern of depletion. In addition to normal results for D-dimer, patients with fibrinogenolysis have normal platelet counts or mild thrombocytopenia with bleeding out of proportion to the reduction in platelet count.[246]

Treatment

Antifibrinolytic agents would seem therapeutically desirable in the treatment of fibrinogenolysis; however, these drugs are hazardous in the presence of DIC. EACA and tranexamic acid are specific and potent inhibitors of fibrinolysis and fibrinogenolysis.[254] In low concentrations (10^{-4} mol/L), EACA inhibits plasminogen activation competitively; in high concentrations (0.06 M), it inhibits plasmin directly in a noncompetitive manner. The clinical effectiveness of this drug is dramatic in carefully selected patients.[255] For severe bleeding, EACA should be administered intravenously (0.1 g/kg every 6 hours, up to 24 g/day), or intravenous doses of 1 g/hour, after a 5-g loading dose. The drug can also be given orally. The total dosage should not exceed 24 g in a 24-hour period. Tranexamic acid is a newer antifibrinolytic agent that, like EACA, possesses the ability to bind to the lysine-binding sites of plasminogen, thereby preventing plasmin that is generated from binding to fibrin. The oral dosage of tranexamic acid is 25 mg/kg, three or four times daily. The intravenous dosage is 10 mg/kg given three or four times daily.

Because antifibrinolytic agents are potentially dangerous drugs in the presence of DIC,[256] the diagnosis of DIC should be excluded in these patients using a specific test, such as D-dimer, before administering these agents. Patients with DIC and a substantial secondary fibrinolytic component should be considered for heparin therapy before administration of antifibrinolytics.[248]

Patients with hormone-refractory prostate cancer and fibrinogenolysis have been reported to benefit from docetaxel, with resolution of bleeding symptoms and laboratory evidence of hyperfibrinolysis.[257]

Pathologic Inhibitors of Coagulation

Circulating anticoagulants are pathologic endogenous inhibitors that can act at any stage in the process of coagulation. Most are antibodies that act as specific inhibitors, inactivating a single coagulation protein. The clinical and laboratory manifestations resemble the corresponding inherited coagulation disorders in many respects. Antibody disorders with wider effects on the coagulation system are sometimes seen, especially in the antiphospholipid–protein antibody (APA) disorders. Other inhibitors of coagulation often have heparinlike activities and are much less common.

Antibodies to Factor VIII

Factor VIII is the most common target of monospecific acquired anticoagulant antibodies. Conditions that are associated with monospecific factor VIII antibodies are outlined in Table 54.5. Factor VIII inhibitors are termed alloantibodies when they appear in treated hemophilia patients and autoantibodies when they appear in nonhemophilia patients.

Alloantibodies in Hemophilia A

Frequency of Inhibitors

Prospective studies suggest a higher incidence of inhibitors than that historically appreciated[258–260] (up to 45%), even in patients treated with traditional factor VIII concentrates. However, many patients have only transient inhibitors, and perhaps only 5% to 10% of hemophiliacs have persistent inhibitors.[261] As a consequence, initial concerns based on historical prevalence controls suggesting that newer factor VIII concentrates, such as those purified by monoclonal antibody affinity chromatography or produced by recombinant technology, might be inducing an increased percentage of inhibitors appear to be allayed. In fact, continued longitudinal surveillance of patients receiving such products indicates a similar or perhaps lower incidence of clinically significant persistent inhibitor induction.[262,263] Those at high risk of development of inhibitors include patients with severe hemophilia A whose factor VIII mutation prevents factor VIII synthesis (nonsense mutation or intron 22 inversion), or patients with mild or moderate hemophilia A whose factor VIII mutation in the A2 domain or near the junction of the C1–C2 domains results in an abnormal factor VIII molecule.[261] This latter mutation results in a factor VIII molecule identified by the patient's immune system as abnormal. Other factors affecting the risk of inhibitor development include the patient's human leukocyte antigen (HLA) class II haplotype, the type of factor VIII therapy used,[261] African-American

TABLE 54.5

Medications: penicillin, sulfa antibiotics, chloramphenicol, phenytoin
Idiopathic

ancestry,[264,265] periods of intensive therapy,[266] and early use of factor VIII at the time of a major bleed or surgery.[267] Additional reports have confirmed these conclusions in patients with mild to moderate hemophilia.[268,269] A more recent literature meta-analysis observed that use of recombinant factor VIII products was associated with an almost twofold increase in inhibitor development compared to plasma-derived factor VIII products,[270] and an initial study identifies an increased risk of inhibitor development with second-generation full-length recombinant products.[270a] A provocative study reported that patient age at initiation of therapy was an independent risk factor for inhibitor development.[271] Patients beginning therapy before 6 months of age had three times the rate of inhibitors than patients beginning therapy after 1 year of age.[271] If these data are confirmed, exposure of hemophilia A patients to factor VIII should be delayed, and patients should be treated with other products during the first year of life (such as rVIIa). A United Kingdom epidemiology study reported that there is a biomodal distribution of factor VIII antibodies in hemophilia A patients, with peaks in early childhood and >60 years of age.[272] The genetic and immunologic aspects of induction of antifactor VIII alloantibodies have been reviewed.[267,273]

Induced Antibody Titer

It is recognized, particularly in patients with mild hemophilia, that 50% to 75% of inhibitors are subclinical, occur relatively early (median of 10 days) after product exposure, are of low titer, are transient, and often resolve even with continuing product exposure.[260,262] Hemophiliacs with inhibitors can be categorized as either strong or weak responders to administered factor VIII. Once an antibody has developed in a hemophiliac, further administered factor VIII may act as an inducing antigen. Additionally, it has been appreciated that certain factor VIII products, depending on the manufacturing process, may be immunogenic in hemophilia A patients.[261,270,270a]

Autoantibodies to Factor VIII in the Nonhemophilic Patient

It is estimated that acquired factor VIII autoantibodies are seen in 1 to 2 persons per million population annually.[274] Monospecific antibodies to factor VIII can arise spontaneously in association with various autoimmune and chronic inflammatory diseases, such as systemic lupus erythematosus (SLE), rheumatoid arthritis, and ulcerative colitis.[275,276] Antibodies to factor VIII can develop in the puerperium,[277] usually appearing at term or within several months after parturition in association with a first pregnancy. The antibody may disappear spontaneously in postpartum patients after 12 to 18 months. Reappearance during subsequent pregnancy seems to be very unusual, and in those patients who have persistent antibodies, remission can occur during a subsequent pregnancy.[278] Acquired hemophilia may also be seen in association with hematologic malignancies and solid tumors;[279–281] certain medications such as penicillin,[282] sulfa antibiotics, chlorpromazine, and phenytoin[283]; and dermatologic conditions such as psoriasis and pemphigus vulgaris.[284] Most often, acquired factor VIII antibodies are idiopathic, particularly in older persons without apparent underlying disease.[276,284]

Pathophysiology of Development of Antibodies to Factor VIII

The immunologic mechanism that underlies inhibitor induction in a select minority of patients with hemophilia A and the corresponding presumed lack of immunologic tolerance is unclear. Although inhibitor induction is more common in more severely affected patients, inhibitors are also seen in mild hemophilic patients.[268,285] In patients with severe hemophilia, major deletions, the intron 22 inversion, nonsense mutations, and early initiation of replacement therapy are risk factors for antibody development.[261,264,276] Underlying genetic susceptibility factors have been suggested by studies of brother pairs with a significant predisposition to the development of inhibitors.[286] Specific associations between factor VIII genotype and HLA class II phenotype have been made,[287] but the associations are weak. Genetic influences on inhibitor development are postulated to be additive and polygenic.[287] Mutations resulting in a major loss of factor VIII gene coding information and a lack of circulating factor VIII antigen are associated with a high incidence of inhibitor formation.[288] For example, a high frequency (70%) of inhibitor development is seen in patients with either large, multidomain deletions or nonsense mutations in the factor VIII A3 domain.[289] Fewer patients with other gene defects (missense point mutation) form inhibitors. However, the presence of inhibitors is not consistent, even in a given family with similar factor VIII mutations, suggesting that other factors contribute to induction of factor VIII antibodies.[261] A clinical prediction score to identify the risk of untreated hemophilia A patients to develop an inhibitor has been reported.[290]

Another hypothesis as to how inhibitors to factor VIII might occur is that these antibodies arise from the expansion of preexisting natural factor VIII clones that possess neutralizing properties[291]; such antibodies have been identified from the IgG fraction of plasma from normal people.[291] Clonal expansion of antifactor VIII antibodies may be modulated by the presence of anti-idiotypic antibodies.[292]

Characteristics of Factor VIII Inhibitory Antibodies

The majority of antibodies to factor VIII are IgG immunoglobulins that appear to be specific for the coagulant subunit of the factor VIII complex (VIIIc).[293,294] Common epitopes for allo- and autoantibodies include those in the A2 domain, the C2 domain, or both.[295] Typically, hemophilic alloantibodies recognize both domains,[296] whereas autoantibodies recognize the C2 domain more frequently than the A2 domain.[295] Circulating factor VIII immune complexes have been identified in plasma from patients with acquired hemophilia A with autoantibodies.[297] IgA or IgM inhibitors are rare, as are antibodies that inhibit both VIIIc and vWF. The factor VIII inhibitory antibody subunits in hemophilia A show limited heterogeneity[298] but are not truly monoclonal. In nonhemophiliacs, antibodies to factor VIII more often reveal normal heterogeneity of their subunits. Antibodies to factor VIII are disproportionately often of the IgG_4 subclass and do not fix complement.

Antibodies inactivate factor VIII in a time- and temperature-dependent process,[299] the kinetics and stoichiometry of which are variable. Two types of antibody inhibition are described[300]: Type I inhibitors completely inhibit factor VIII activity following second-order kinetics (linear time course of inactivation); these antibodies are seen in hemophilia patients.[301] Type II inhibitors have complex kinetics and do not completely inhibit factor VIII activity; these are autoantibodies seen in nonhemophilic patients.[302] The type II inhibition phenomenon may produce aberrations in the assay system and may explain certain puzzling laboratory features in atypical cases, such as detectable factor VIII clotting activity in a patient with a high-titer inhibitor.[303] A report on alloantibody inhibition of factor VIII activity indicated that certain alloantibodies possess catalytic activity that can proteolyze factor VIII.[304]

Laboratory Evaluation

Simple mixing techniques based on the PTT usually suggest the presence of an inhibitor. Factor VIII levels usually are undetectable in severely affected patients but may be detectable in patients with autoantibodies. Specific tests for antibodies involve the demonstration of progressive and time-dependent inactivation of factor VIII in vitro by the plasma or serum of the patient. Methods

for detecting low-titer inhibitors and for quantifying the levels of antibody have been devised,[305] and standardized inhibitor units (the Bethesda unit in the United States[306] and the Oxford unit in Britain[307]) have been defined. In the Bethesda assay, in vitro tests are performed at 37°C using 2-hour incubation mixtures of various dilutions of patient plasma with normal plasma. The inhibitor titer is the reciprocal of the dilution of inhibitor plasma that neutralizes 50% of normal factor VIII activity. Because the Bethesda assay may underestimate the inhibitor titer in acquired hemophilia, it is recommended that the titer should be calculated from the lowest dilution that results in 50% residual factor VIII activity after the incubation period.[308] The New Oxford method measures residual activity at 37°C after a 4-hour incubation. A Bethesda unit is generally equivalent to 1.21 Oxford units. The standard Bethesda assay does not control pH, permitting variable low-level inactivation of factor VIII by nonimmunologic mechanisms. The Nijmegen modification controls pH, thus improving classification of positive and negative samples.[306] The Nijmegen modification of the Bethesda assay has been endorsed by the ISTH.[309] Additional improvements in this assay have been described.[310] Although an inhibitor unit does not imply that any specific number of factor VIII units infused into the patient will neutralize any specific number of inhibitor units, the titer provides a general estimate of the initial likelihood of response to infusion of factor VIII products.

Clinical Manifestations

The bleeding manifestations resulting from antibodies to factor VIII are often similar to those seen in hemophilia A.[275,284] Prolonged or unexpectedly severe hemorrhage may occur after comparatively trivial trauma, postoperatively, or postpartum. Soft tissue or muscle hematomas, hematuria, and spontaneous and intractable epistaxis seem relatively common. For unknown reasons, hemarthrosis is relatively less common in acquired hemophilia than in congenital hemophilia A. Figure 54.5 illustrates soft tissue hematomas occurring in a nonhemophilic patient with an acquired inhibitor to factor VIII. When antibodies arise in patients with mild hemophilia A, bleeding typical of severe deficiency may develop; more significantly, the bleeding may be refractory to replacement therapy. This condition may have serious consequences, and fatal events are seen in 10% to 20% of clinically symptomatic patients.[275,311] Antibodies to factor VIII arising during pregnancy may cross the placenta.

Treatment

The treatment of bleeding in patients with antibodies to factor VIII presents several challenges.[312,313] No adequate randomized trials have been conducted to evaluate different forms of therapy or to investigate the timing and sequence of their application; therefore, practical treatment decisions are somewhat arbitrarily based on estimates of benefits and risks deduced from retrospective literature review and consideration of each patient's circumstances and co-morbidities. A consensus group from the United Kingdom and an international panel have published guidelines on treatment of inhibitors in patients with hemophilia,[314, 314a, 315] and a literature review of acquired hemophilia therapy options has summarized treatment recommendations.[316] An algorithm that has some general applicability is shown in Figure 54.6. As a first step, basic clinical information should be obtained, including whether the inhibitor arose in the setting of hemophilia or is acquired; the severity of bleeding; anticipated surgical procedures; inhibitor titer and persistence; prior inhibitor response and relation in time to previous factor infusions; possible triggering events such as recent medication exposure or pregnancy; and the presence of other diseases. For example, the mere presence of an inhibitor may in itself not warrant immediate therapy because many inhibitors are present in low titer and are often transient. Spontaneous remissions may occur in a significant number of patients, particularly if the inhibitor develops during the puerperium.[276] At the other end of the spectrum, an unfortunate clinical scenario might involve significant spontaneous clinical hemorrhage, a persistent high-titer inhibitor, and incidental co-morbidities such as cardiac, hepatic, or renal insufficiency. Principles of management include stopping bleeding using bypass therapy, eradication of the inhibitor with immunosuppression, and recognizing and treating any underlying disorder that may have triggered autoantibodies to factor VIII.

In patients with low-titer inhibitors who do not have any clinical bleeding and for whom no surgical procedures are foreseen, the most reasonable approach may be to monitor the abnormal laboratory finding. Steroids and cytotoxic therapy (usually cyclophosphamide) are usually ineffective when inhibitors arise in patients with congenital hemophilia A, but they are effective in the setting of nonhemophilic patients.[275,316] Cyclosporin has also been used to treat acquired antibodies to factor VIII.[317] Procedures or medications (antiplatelet drugs) that would increase hemostatic risks should be avoided, and ancillary local therapeutic measures to control minor bleeding are recommended and may in themselves be sufficient. For patients with minor bleeding who have residual factor VIII activity >5% of normal, DDAVP therapy may be helpful (0.3 μg/kg, up to 24 μg maximal dose).[273,318] Antifibrinolytic therapy, such as the administration of EACA or tranexamic acid, may be helpful, especially for oral or nasal bleeding; however, this therapy should be used cautiously in muscle bleeds because it appears to be less effective, and it should not be used in conjunction with PCCs, activated PCCs (APCCs), or rVIIa.

The inhibitor titer and its prior response to factor VIII infusion may be of particular use in guiding therapeutic decisions (Fig. 54.6). As a rule, replacement therapy with factor VIII in the usual doses is ineffective. If clinical bleeding mandates active therapy, patients with a low Bethesda titer (<5 U/ml), particularly if they are known to be low responders, usually respond to high-purity or recombinant human factor VIII[314] given as a large initial 150 U/kg bolus followed by a continuous infusion of 1,000 U/hour. The therapeutic response to human factor VIII should be clinically assessed; factor VIII levels and repeat assays of inhibitor titer response may be helpful. Therapy with human factor VIII is seldom successful in patients with high-titer antibodies (>5 Bethesda U/ml), high-affinity antibodies, and infinite coagulation times.

As an alternative, particularly in patients with high-titer inhibitors or a history of an anamnestic response, or routinely in medical centers that prefer to reduce the uncertain risk of inducing an increased inhibitor titer, the use of inhibitor-bypassing products may be useful. These include the PCCs, APCCs, and rVIIa. The best-studied treatment options are FEIBA (factor VIII inhibitor bypassing activity) and rVIIa.[316] There is no consensus as to the best therapeutic approach between these options.[319]

FIGURE 54.5. Soft tissue hemorrhage in a 76-year-old man with a high-titer factor VIII inhibitor. This patient has a history of ischemic cardiomyopathy and diabetes and developed spontaneous extremity bruising as shown. The antihuman factor VIII antibody titer was 10 Bethesda units. (Courtesy of Alan Grosset.)

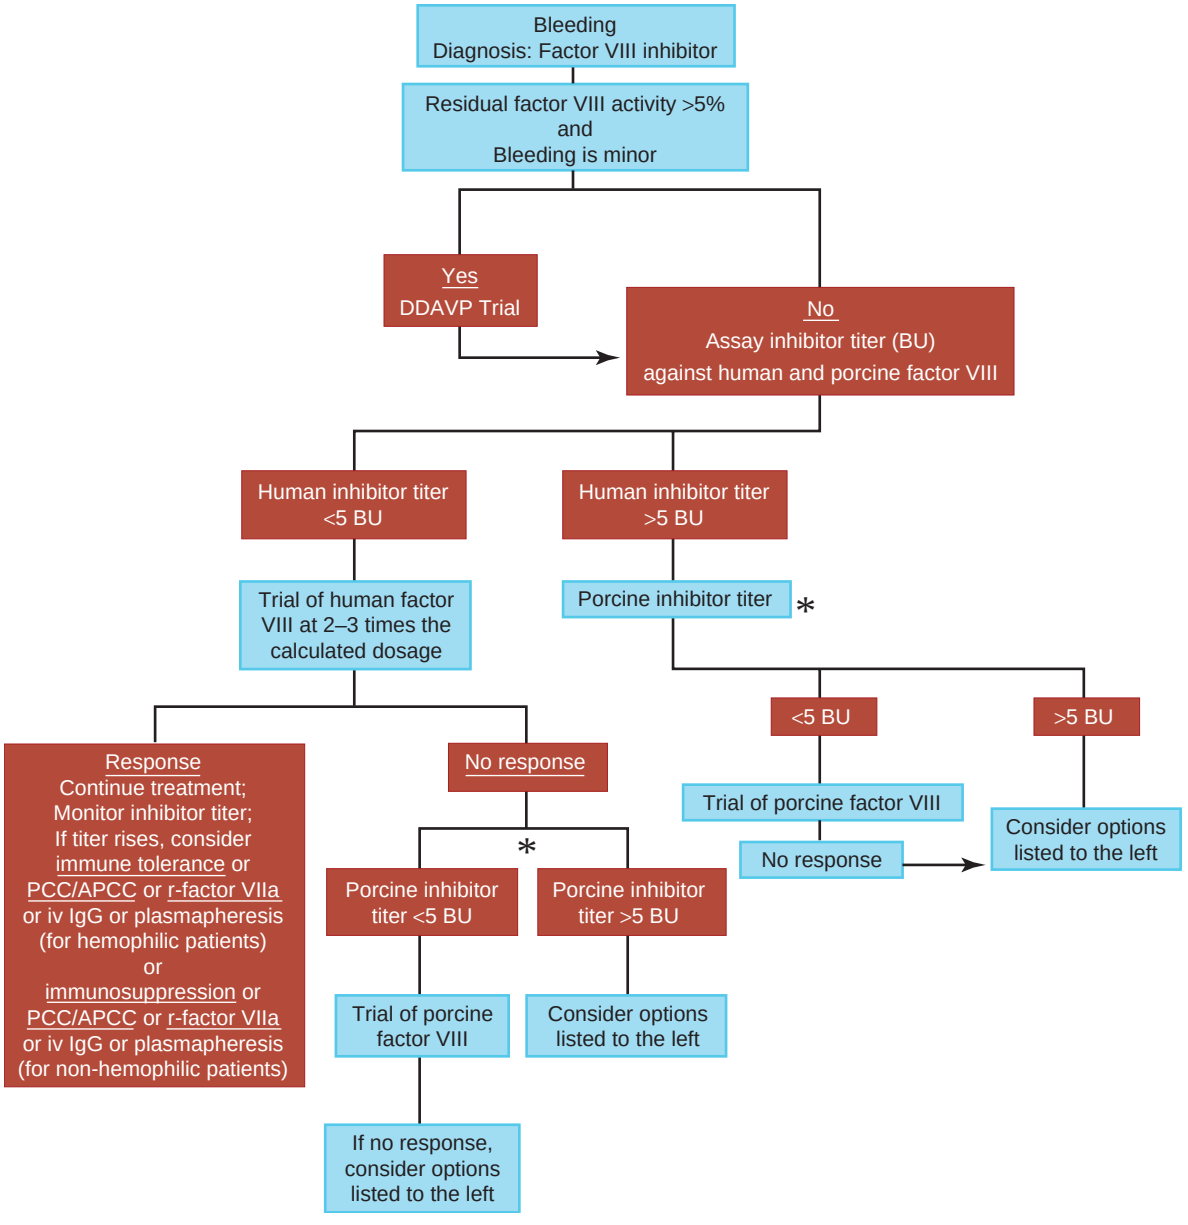

FIGURE 54.6. A strategy for management of factor VIII inhibitors in hemophilic and nonhemophilic patients. Key decisions are based on antihuman and antiporcine factor VIII inhibitor titers. Multiple options for patients not responding to human or porcine factor VIII are available. BU, Bethesda units; DDAVP, 1-desamino-8-D-arginine vasopressin; PCC/APCC, prothrombin complex concentrate/activated prothrombin complex concentrate. The underlined options are preferred. Immunosuppression options include rituximab, steroids, and cytotoxic drugs. *As of early 2013, porcine factor VIII was not routinely available, so testing porcine inhibitor titers should not be done. If a recombinant porcine product becomes available, then these tests will be relevant. (Information in this figure is from the literature, including Morrison AE, Ludlam CA. Acquired haemophilia and its management. Br J Haematol 1995;89:231–236.)

A literature review of efficacy and safety of FEIBA and rVIIa in treating bleeding events in acquired hemophilia indicates "indistinguishable" efficacy between the two products[316]; if one agent is not successful in stopping bleeding, the other agent should be used. A typical dose for FEIBA in this indication is 75 U/kg every 8 to 12 hours. Both therapies (FEIBA, rVIIa) are associated with thrombosis.[316]

rVIIa is a treatment option for inhibitor patients.[320,321] This drug was originally thought to exert activity by binding to tissue factor at sites of vascular injury to initiate coagulation. More recent data indicate that at the pharmacologic concentrations of factor VIIa achieved during rVIIa therapy, there may be platelet-dependent, tissue factor–independent mechanisms to mediate hemostasis.[322] The standard dose of rVIIa is 90 μg/kg every 2 hours for serious bleeding[323] or 90 μg/kg every 3 hours for mild to moderate bleeding in home treatment.[324] Recent trial data indicate that a single rVIIa dose of 270 μg/kg is effective home treatment for hemarthroses.[325] Continuous infusion of rVIIa is also effective, targeting factor VII levels to 30 to 40 U/ml.[326] rVIIa, like FEIBA therapy, is associated with potential thrombotic complications; a comparative evaluation of the thrombotic event rate of rVIIa versus FEIBA revealed that rVIIa was associated with approximately threefold more thrombotic events than APCC.[327] FEIBA has been successfully used as a prophylaxis therapy for hemophilia patients with inhibitors.[328]

There are few studies directly comparing the efficacy of rVIIa versus FEIBA or other activated PCCs in inhibitor patients with serious bleeding. These products have similar efficacies,[316,329,330] and consensus recommendations generally include multiple treatment options.[314,331,332] For patients refractory to both drugs used as single agents, sequential therapy with FEIBA and rVIIa has been reported.[333]

Another potentially useful product in inhibitor patients is porcine factor VIII. Obtaining an antiporcine antibody titer is useful, but as a rule of thumb, the initial antiporcine titer is often 5% to 10% of the antihuman titer. However, the antiporcine titer may rapidly rise after administration of porcine factor VIII. For these reasons, porcine factor VIII is usually reserved for one-time use.[332] Some investigators consider porcine factor VIII to be the therapy of choice for patients with factor VIII antibodies in which the antibody has minimal cross-reactivity to porcine factor VIII,[334] and consensus groups consider porcine factor VIII an appropriate treatment option.[314,331] Porcine factor VIII is currently unavailable in the United States; however, a recombinant B-domain-deleted porcine factor VIII product is in clinical trials.

Long-term eradication of antibodies to factor VIII requires immunosuppressive therapy. Numerous treatment options exist.[316] A literature review[335] of the efficacy of intravenous Ig in the treatment of acquired factor VIII antibodies found a cumulative response rate of only 12%, suggesting that other modalities should be attempted first for these patients.

Standard immunosuppression should be reserved for patients with autoantibodies because this therapy is rarely beneficial in the alloimmune setting. Corticosteroids (e.g., prednisone in doses of 1.0 to 1.5 mg/kg/day) produced improvement in approximately 50% of patients when administered on a long-term basis,[275] with the best results obtained with nonhemophilic patients. Similar therapeutic responses have been reported when immunosuppressive drugs, such as cyclophosphamide (2 to 3 mg/kg/day), were administered alone or with prednisone.[316,336] Remission of bleeding and reduction of antibody titer have been well documented, but total suppression of the antibody is rare.

Rituximab, a monoclonal antibody to the CD20 antigen on B cells, has been reported to be effective in case series of patients with acquired factor VIII antibodies,[316,337,338] and a United Kingdom practice guideline recommends rituximab as second-line therapy if patients have not responded to steroids and cyclophosphamide.[314]

One aggressive treatment regimen for acquired hemophilia combined protein A immunosorption, factor VIII, intravenous IgG, and immunosuppression; this regimen resulted in abolition of antibody levels within 3 days and a complete response rate of 88%.[339] This aggressive regimen should be considered for patients with severe, life-threatening bleeding.[316] Cyclosporin A has been reported to be useful in patients failing first-line eradication therapy.[316]

In many patients with hemophilia A who have developed alloantibodies to factor VIII, infused factor VIII provokes a rapid increase in the antibody titer. However, in many of these patients, the administration of large doses of factor VIII for periods of months to years may produce immune tolerance (IT) to factor VIII. An international registry of patients treated with this approach reported that approximately 70% of patients achieved long-lasting tolerance.[340] A 1997 update of this registry indicated that 52% of patients were successfully treated with IT.[341] Several IT regimens have been summarized.[342] The registry data suggest that success of inducing tolerance is greatest in patients given more than 100 U/kg/day factor VIII who had an initial inhibitor titer of <10 Bethesda U before starting IT.[340,341] Data from the North American Immune Tolerance Registry have been reported; the overall success rate was 70%.[343] The cost effectiveness of IT therapy has been demonstrated.[344]

The International Immune Tolerance Study compared high-dose (200 U/kg daily) versus low-dose (50 U/kg daily) factor VIII. Both dosage regimens were equivalent in terms of inducing tolerance; however, the low-dose regimen was associated with more bleeding.[345] The use of factor VIII products that contain vWF may be more effective in IT induction.[346] The topic of IT induction in hemophilia A and B patients has been recently reviewed.[347]

Monospecific Antibodies to Other Coagulation Factors

Table 54.6 summarizes certain conditions associated with antibodies to other coagulation factors.

Factor IX

Inhibitors of factor IX have been demonstrated in approximately 5% of patients with hemophilia B[348,349] and rarely in previously normal persons (acquired hemophilia).[350] Hemophilia B patients who acquire antibodies to factor IX often have gross

TABLE 54.6

ACQUIRED DISORDERS ASSOCIATED WITH DEFICIENCY OF A SINGLE COAGULATION FACTOR

Deficient Factor	Specific Inhibitors[a]	Other Disorders
Fibrinogen	Hereditary afibrinogenemia[386]; lupus erythematosus; liver disease	—
Prothrombin	Previously normal persons[387]	Lupus inhibitors[389]
Factor V	Previously normal persons;[357] often associated with streptomycin;[357] rarely in inherited factor V deficiency; postoperative patients who received bovine thrombin[361,362,363,364–366]	Chronic myelocytic leukemia[620]
Factor VII	Bronchogenic carcinoma,[398] acquired immunodeficiency syndrome[399]	Aplastic anemia,[593] liposarcoma[594]
Factor VIII (VIIIc)	Hemophilia A;[258,259] puerperium;[277] inflammatory disorders; drug reactions; in absence of underlying disease[275]	—
von Willebrand factor	Previously normal persons; lymphoproliferative disorders;[372–376,377,378] rarely in von Willebrand disease; thrombocytosis	Wilms tumor[619]
Factor IX	Hemophilia B;[348,349] rarely in previously normal persons[350]	Nephrotic syndrome;[587] Sheehan syndrome[591]; Gaucher disease[592]
Factor X	—	Amyloidosis;[577–583] upper respiratory infection;[394] other associations[584]
Factor XI	Lupus erythematosus; rarely in inherited factor XI deficiency and chronic lymphocytic leukemia; previously normal persons[392]	—
Factor XII	Lupus erythematosus, rarely	Nephrotic syndrome; chronic myelocytic leukemia
Factor XIII	Previously normal persons, often associated with isoniazid;[381] rarely in inherited factor XIII deficiency;[380] other associations[597]	Acute and chronic leukemia;[595] Crohn disease[596]

[a]Evidence suggests these inhibitors are antibodies. In patients with inherited deficiencies of the various factors, their development usually is related to transfusion of blood or blood products.

gene deletions.[351] In contrast to antibodies to factor VIII, factor IX antibodies act instantaneously. One series of eight hemophilia B inhibitor patients found that antibodies typically were IgG_1 and IgG_4, and that the antibodies targeted the Gla domain and protease domain epitopes of factor IX.[352] rVIIa[353] or IT therapy[343] has been used to treat these patients, although IT for hemophilia B inhibitor patients may be less effective than for hemophilia A inhibitor patients.[354] PCCs are also a treatment option.[355] Patients with antibodies to factor IX may experience anaphylaxis when treated with factor IX–containing products[354]; rVIIa may be the appropriate therapy for this patient group. A British consensus group has published guidelines on treating factor IX inhibitor patients,[314,314a] and an ISTH registry of factor IX inhibitor patients has been established.[356]

Factor V

Inhibitors of factor V[357] have developed spontaneously in previously normal older persons after administration of streptomycin,[358] gentamicin, or penicillin and after surgical procedures. More rarely, factor V inhibitors have been associated with tuberculosis, femoral fracture, and bullous pemphigoid. These antibodies are usually of IgG isotype. An Australian survey estimated the annual incidence of factor V inhibitors at 0.29 cases per million population,[359] and a Singapore incidence rate was 0.09 cases per million person years.[360] Alloantibodies to factor V may occur in factor V–deficient patients who receive blood products.[361]

Over the past 30 years, an iatrogenic coagulopathy has been identified: The occurrence of antibodies to thrombin and factor V in patients treated with bovine thrombin during surgery.[361,362,363] The antithrombin antibody neutralizes bovine thrombin and therefore can prolong the thrombin time when bovine thrombin is used for this test.[364,365] However, no clinically significant hemostatic defect appears to result from this single laboratory abnormality. Some patients acquire additional antibodies to human factor V, which may result in significant factor V deficiency and bleeding.[364,365] In a large surgical series of patients exposed to bovine thrombin, more than 95% of patients developed antibodies to bovine thrombin or factor V, and 50% of these patients had antibodies cross-reacting to human coagulation proteins.[366] These latter patients have a bleeding risk.[366]

In contrast to most other specific inhibitors, antibodies to factor V seldom produce serious hemorrhage.[361,367] Patients with alloantibodies to factor V typically have significant bleeding.[366] Patients with antibody recognition of the C2 domain of factor V have also been reported to have a significant bleeding risk. A literature review identified a bleeding mortality rate of 12% in patients with factor V antibodies not due to exposure to bovine factor V or noninherited acquired factor V antibodies.[360] In several patients with severe hemorrhage, platelet transfusions were therapeutically more effective than plasma.[360,363,368] This clinical benefit of platelet transfusions likely relates to platelet α-granule content of factor V which is released at sites of bleeding to improve local hemostasis. Plasmapheresis,[369] immunosuppression, and intravenous IgG[370] have been reported to be effective in resolving antibodies to factor V. In some cases, these antibodies resolve spontaneously.[366]

A small number of patients have been described with thrombosis symptoms associated with factor V antibodies. These patients may[357] or may not[361,371] have coexisting antiphospholipid antibodies.

von Willebrand Factor

Acquired von Willebrand disease (vWD) has been reported in association with a variety of disorders, primarily including patients with lymphoproliferative disorders, myeloproliferative disorders, solid tumors, autoimmune disease, aortic stenosis, and artificial heart devices. An international registry identified lymphoproliferative and myeloproliferative disease as accounting for more than 60% of acquired vWD.[372] A literature review concluded that most cases of acquired vWD result from an antibody that recognizes high-molecular-weight multimers of vWF and mediates subsequent antigen–antibody clearance.[373] Another mechanism for the development of this disorder includes adsorption of vWF by tumor cells[374] or platelets. Acquired vWD has also been reported in patients with aortic stenosis[375] and in patients with ventricular-assist devices and artificial hearts.[376] In these cardiac conditions, vWF is subjected to shear stress and proteolysis.[375,376] Ristocetin co-factor activity is usually decreased, whereas factor VIII activity may be normal.[373] In most patients, the hemostatic abnormalities disappear when the underlying disorder is treated.[377] For patients with acquired vWD resulting from a lymphoproliferative disorder or monoclonal gammopathy, intravenous Ig may be effective.[378] The consensus group recommends a trial of DDAVP as initial therapy[379]; DDAVP failures are then treated with vWF concentrates (e.g., Humate-P or Wilate).[372] Intravenous Ig is reserved for those patients having no success with DDAVP and vWF concentrates.[372] For patients with acquired vWD associated with monoclonal gammopathy of uncertain significance, a trial comparing DDAVP and vWF concentrates versus intravenous Ig found that the latter treatment provided a sustained response compared to DDAVP/vWF concentrates.[379]

Factor XIII

Inhibitors of factor XIII have been described after transfusions in patients with inherited deficiency of this proenzyme and in previously normal persons.[380] Many of the latter group had received isoniazid,[381] and it was suggested that this drug may alter factor XIII in such a manner that it becomes antigenic.[382] These inhibitors may recognize the zymogen, impair the activation of factor XIII by thrombin, or be directed against the cross-linking sites of fibrin, or to the B-subunit.[383,384] Therapeutic options include factor XIII replacement therapy (plasma, cryoprecipitate), rVIIa, as well as inhibitor eradication options (steroids, cyclophosphamide, rituximab, etc.).[384] A factor XIII concentrate, Fibrogammin, if available, may also be useful.[384] A survey of hemophilia treatment centers reported that ~38% of inherited factor XIII–deficient patients developed antibodies as a treatment complication[385]; these patients may require bypassing agents to treat bleeding.

Fibrinogen and Prothrombin

A precipitating antibody to fibrinogen has been demonstrated after transfusions in patients with hereditary afibrinogenemia.[386] Acquired hypofibrinogenemia is usually seen in acute DIC. Dysfibrinogenemia may occur in patients with liver disease or hepatoma, or in plasma cell disorders (discussed in the section "Deficient or Aberrant Synthesis of Coagulation Factors"). Antibodies to prothrombin have also been reported.[387] An unusual case of an autoantibody to prothrombin was described; the antibody induced protease activity from the zymogen, leading to neutralization by antithrombin.[388] Acquired hypoprothrombinemia usually occurs in the setting of the lupus anticoagulant (LA) when patients have antibodies to prothrombin that clear prothrombin activity from blood.[389]

Factor XI

A survey of prevalence of acquired inhibitors to factor XI in patients with inherited factor XI deficiency found that ~5% of patients with severe deficiency developed antibodies after plasma therapy.[390] Of those factor XI–deficient patients homozygous for a null allele, one third developed antibodies.[390] A combination of

low-dose rVIIa and tranexamic acid was reported to be safe and effective for such patients requiring surgery.[391] Specific inhibitors of factor XI have been described primarily in association with autoimmune disease.[392,393]

Factor X

Antibodies to factor X are very uncommon and may be associated with upper respiratory tract infections,[394] either viral or mycoplasma; however, in these cases, inhibitors to factor X have been directly proved infrequently. Bleeding has been controlled using PCCs,[395] or ivIgG and steroids.[396] Acquired factor X deficiency has been frequently reported in amyloidosis (discussed below).

Factor VII

Antibodies to factor VII are rare, with fewer than 20 cases reported in the English literature.[397] They have been reported in lung cancer[398] and human immunodeficiency virus infection,[399] and with no apparent disorder.[400] Immunosuppression has been used successfully in anecdotal case reports of autoantibodies to factor VII.[401]

Tissue Factor

Antibodies to tissue factor are very uncommon, with one group reporting two patients who developed antitissue factor antibodies after liver surgery.[402] Similar to patients who acquire antithrombin and antifactor V antibodies after use of topical bovine thrombin,[361,362,363,364] the patients who developed antitissue factor antibodies were both treated with a topical hemostatic agent prepared from bovine tissue that contained tissue factor. The antibodies to bovine tissue factor did not cause clinical bleeding but did prolong PT values.[402]

Antiphospholipid–Protein Antibodies: Lupus Anticoagulants and Anticardiolipin Antibodies

Historical Considerations and Nomenclature

The two best-known clinical types of APAs are traditionally called LA and *anticardiolipin* (aCL) *antibodies*. These antibodies are associated in some patients, but not in others, with clinical illness[403,404] of varying severity. Individual patients may manifest arterial or venous thromboembolic disease, recurrent pregnancy loss, thrombocytopenia or other cytopenias, and neurologic and skin abnormalities. The clinical importance, particularly of the LA or higher-titer aCL antibodies, has been increasingly recognized; these antibodies or their functional consequences are found in approximately 10% of patients with venous thromboembolic events.[405,406] Bleeding is quite uncommon, and when present, it is usually the result of severe thrombocytopenia, platelet dysfunction, hypoprothrombinemia, or the effects of an underlying disease. On the other hand, thrombosis and its many manifestations are common.

Synonyms for LA and aCL antibodies include *antiphospholipid* (aPL) *antibodies*, *APAs*, and *autoantibodies to phospholipid-binding plasma proteins*.[407] The associated clinical manifestations including thrombosis are variously called the *LA syndrome*, *antiphospholipid syndrome* (APS), or *antiphospholipid-protein syndrome*. APS without a known well-defined autoimmune disease is termed *primary APS* (PAPS). A few patients with APA develop an acute, severe, multiple-organ APS illness. These patients are designated as having *catastrophic APS* (CAPS).

The existence of these antibodies was first detected more than 50 years ago when it became apparent that approximately 15% of patients with active SLE have a false-positive Venereal Disease Research Laboratory (VDRL) test.[408] The VDRL test assesses antibody reactivity to "reagin" (antigen), an acidic-phospholipid complex that is chemically extracted from bovine heart tissue. Reagin consists of a mixture of lecithin, cholesterol, and cardiolipin. A nonspecific antibody reaction to reagin is also seen less often in other autoimmune disorders and in some apparently healthy patients. Other laboratory assays discussed in this section identified a family of antibodies that were initially thought to have direct specificity to various phospholipids, although it is now known that the antibodies recognize phospholipid–protein complexes. The proteins often serve a critical cofactor role,[409] and the antibodies collectively are thus most accurately called *APAs*.[410]

Coagulation assays are sensitive to some of these antibodies. Plasma samples from some patients with SLE, often those with the abnormal VDRL tests, show an in vitro inhibitor effect in several coagulation assays. This association gave rise to the term LA.[411] Most often, a prolonged PTT result that is not corrected on mixing with normal plasma is observed; other phospholipid-dependent assays, including the modified Stypven time (dilute Russell viper venom time [DRVVT]), are also affected.[367] Despite persistent clinical use, it is now known that most patients with an LA phenomenon do not have SLE. Moreover, clinical thrombosis is much more often seen than is bleeding with APS antibodies. Patients with SLE occasionally have inhibitors to other hemostatic factors,[412] but these inhibitors are not considered LAs.

In addition to the biologically false-positive VDRL results and the paradoxic in vitro lupus-anticoagulant effect, laboratory studies found a third phenomenon, initially detected by radioimmunoassay: Antibodies to cardiolipin.[413] In aCL-antibody assay systems, serum Igs bind to various anionic phospholipid–protein complexes, most commonly to cardiolipin in a coated microwell enzyme-linked immunosorbent assay (ELISA). The sensitivity and specificity of this assay are substantially higher than those of the VDRL. A phospholipid-binding protein, β_2-glycoprotein I ($\beta_2$gpI), has been identified,[414] and antibodies to this antigen can also be demonstrated in patients with APS.[415] Thus, the most useful assays to evaluate patients for antiphospholipid antibodies include the LA, aCL antibodies, and antibodies to $\beta_2$gpI.

Epitope Specificity

In these disorders, the antibodies were initially thought to react with anionic phospholipids directly, but the presence of specific plasma proteins associated with phospholipids is now known to be of great importance.[416] In the case of LAs, the seemingly paradoxic discordance between laboratory screening test results and clinical symptoms is frequently the consequence of antibodies that bind to a complex of phospholipid-bound prothrombin.[389,417] This antibody binding impairs the function of the standard prothrombin-binding synthetic anionic phospholipids[418] that are used routinely in the laboratory to replace platelets in phospholipid-dependent coagulation assays, such as the PTT. Other more natural phospholipids, or platelets themselves, are less affected by this phenomenon and are used in some assays as correction factors in mixing studies.

In the case of aCL antibodies, especially in autoimmune and drug-induced aCL, $\beta_2$gpI[419] serves as a mandatory protein cofactor.[414] Patient-derived antibodies directed against $\beta_2$gpI that have LA activity have also been reported.[420] $\beta_2$gpI is a 57-kD plasma protein with an uncertain physiologic role, but it is often considered a noncomplement member of the complement-control family of proteins, with structural similarity to complement factor H. A recent study reported that $\beta_2$gpI inhibited complement activation at the level of C3.[421] $\beta_2$gpI has a number of anticoagulant activities,[422,423] but inherited deficiency of $\beta_2$gpI has no thrombophilic association.[424] The antibodies in these settings are often of the IgG isotype, are relatively persistent and high in titer, are associated with an LA phenomenon in approximately 60% of patients, and are clearly associated with the clinical syndromes

discussed subsequently. IgM and IgA antibodies occur less often. aCL antibodies are not directed primarily against cardiolipin itself, but against epitopes formed after $\beta_2$gpI binds to anionic phospholipid membranes or anionic synthetic surfaces. One study observed that pathogenic antibodies targeted an epitope in domain 1 of $\beta_2$gpI, and that these antibodies had LA activity.[425] $\beta_2$gpI may also mediate aCL binding to endothelial cell membranes.[426] Other proteins have been occasionally implicated as possible obligatory cofactors, including annexin A5,[427] annexin A2,[428] factor Xa, protein C, protein S, and vimentin.[429] Anti-$\beta_2$gpI antibodies have been reported to induce acquired resistance to APC.[430]

It was previously thought that APA recognized neoepitopes of the above phospholipid-binding proteins expressed on cell-surface binding. Another hypothesis is that the true antibody target is an appropriate density ("clustering") of proteins bound to phospholipid surfaces, which is necessary for antibody recognition.[431] For example, based on in vitro data, it has been proposed that $\beta_2$gpI acts as an antigen in vivo only when the antigen ($\beta_2$gpI) clusters on membrane surfaces such as endothelium. When clustering occurs, this increased antigenic density allows antibody recognition to occur, leading to antibody binding and endothelial cell activation and potentially triggering cellular events resulting in thrombosis.[432] Figure 54.7 illustrates how this phenomenon might occur. Additional studies found that $\beta_2$gpI undergoes a conformational change (circular to "fishhook") upon cell binding to anionic phospholipids, leading to clustering[433] and antibody binding.[434] Involvement of the MyD88 signal transduction pathway in antibody-mediated endothelial cell activation has been described,[435] and others have reported involvement of the p38 mitogen-activated protein kinase pathway.[436] Receptors that have been described that could possibly mediate the APA response include a toll-like receptor on endothelium,[435] annexin A2, and apoER2′. The latter receptor has been demonstrated to promote leukocyte–endothelial cell adhesion and thrombosis by inhibition of endothelial cell nitric oxide synthase activity.[437] Other investigators have identified cell signaling through the toll-like receptor 4 mediated by a multiprotein complex as a pathway for endothelial cell activation by APS antibodies.[438]

In other settings, particularly those related to infection, the aCL antibodies are often of IgM isotype, are often of low titer and relatively transitory, and have no identified co-factor protein.[409] Although $\beta_2$gpI is an absolute protein co-factor requirement for aCL activity in autoimmune settings, it may, in contrast, be inhibitory in the infection-related circumstance.[409] The clinical association of IgM antibodies with thrombophilia is less strong,[439] particularly thrombosis occurring after drug administration,[440] although exceptions to this generalization have been noted.[441] The detection of subgroups of aPLs has been reviewed.[403]

Another key question related to the pathogenesis of APS is, how are antiphospholipid antibodies generated? One report found that only $\beta_2$gpI bound to phospholipids could be successfully presented to T lymphocytes to elicit a pathogenic immune response.[442] Oxidation of $\beta_2$gpI increases its immunogenicity, and patients with APS have increased amounts of oxidized $\beta_2$gpI.[443]

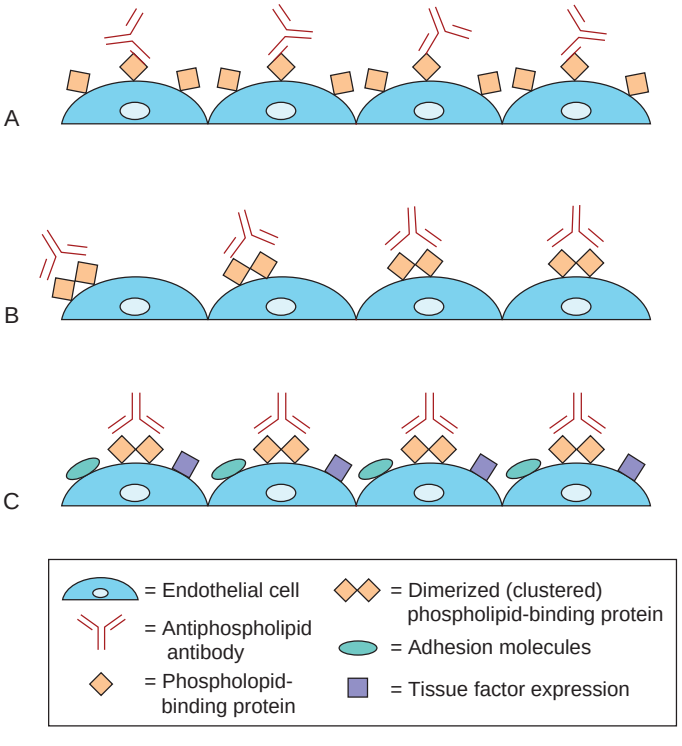

FIGURE 54.7. A proposed mechanism by which antiphospholipid antibodies induce endothelial cell activation and thrombosis. A: Endothelial cells express a phospholipid-binding protein (e.g., $\beta_2$gpI). In the absence of high antigenic density ("clustering"), antibody binding is inefficient. **B:** Endothelial cells display dimerized ("clustered") antigen, which allows for efficient antibody binding, resulting in endothelial cell activation and promotion of thrombosis **(C).**

Mechanism of Thrombosis

Potential mechanisms to explain how aPL induces thrombosis[405] include (a) endothelial cell activation, (b) oxidant-mediated vascular injury, (c) interference with the function of phospholipid-binding proteins in regulating coagulation, and (d) complement activation.[404] In the first hypothesis, aPL antibodies directly bind to endothelium to up-regulate expression of adhesion molecules and cytokine secretion.[403] In the second hypothesis, autoantibodies to oxidized low-density lipoprotein occur with aCL antibodies, and aCL antibodies recognize oxidized phospholipids and phospholipid-binding proteins.[444] In the third hypothesis, aPL antibodies may interfere with the anticoagulant functions of protein C or annexin V or enhance procoagulant activity.[403,427,428] In the fourth hypothesis, complement activation by aPL antibodies leads to neutrophil expression of tissue factor.[445]

Immunologic studies lend strong support for a direct pathophysiologic role of these antibodies in the clinically observed thrombotic syndromes.[446] In animal models using standardized vessel injury to induce thrombosis, either passively conferred APA[447] or active induction of antibody with either APA or $\beta_2$gpI[448] resulted in thrombosis; this suggested that APAs are not merely epiphenomena of thrombi arising for other reasons but, in some cases, play a direct role in initiation, propagation, or maintenance of thrombosis. Immunization of mice or rabbits with $\beta_2$gpI produces two populations of antibodies: One with specificity for $\beta_2$gpI alone without binding to phospholipids and the other with specificities for both cardiolipin and $\beta_2$gpI.[449] This dual specificity of antibodies is also seen with those aPLs that are present in patients with autoimmune diseases.

The concept of hexagonal phase configuration has been popularized. This configuration is thought to arise in vivo in response to membrane damage.[450,451] Normally, polar heads of phospholipids exist on the external surface, whereas in the hexagonal phase, lipid cylinders exist with internal aqueous channels formed by polar head groups.[452] LA and aCL may represent antibodies generated in response to these neoantigens. APAs have been generated in mice immunized with hexagonal phase phospholipid[453]; these antibodies reacted with cardiolipin and possessed functional LA activity.

The precise cause of thrombosis in APS is uncertain, and is likely multifactorial. Presumably, APAs act by interfering with coagulation,[404] possibly involving dysfunction or apoptosis[454] of endothelial cells, platelets, and coagulation proteins, and affect pregnancy outcome by interfering with embryo implantation and fetal development.[403]

Specific mechanisms of thrombosis that have been implicated include inhibition of APC,[404] acquired free protein S deficiency, platelet activation, and abnormalities in the antigenic levels or activity of endothelium-derived hemostatic factors, including inhibition of prostacyclin secretion, fibrinolysis, nitric oxide synthesis, or disruption of annexins A5 or A2.[404,427,428,437] The thrombogenicity of APAs may also result from their interference with endothelial cell phospholipids required for antithrombin and proteins C and S anticoagulant activity, and increased endothelial cell expression of the following procoagulants: Tissue factor, vWF, platelet-activating factor, and plasminogen activator inhibitor type-1.[403,404,455,456] Tissue factor was identified as a mediator of complement-induced APS fetal loss in a mouse model.[445,457]

Epidemiology and Clinical Associations

Young, apparently healthy control subjects are reported to have a prevalence of 1% to 5% of aPL antibodies.[458] In patients with systemic lupus, aPL occurs in 12% to 34%. After prolonged follow-up, APS may develop in more than 50% of patients with systemic lupus.[403]

LA and aCL antibodies have been reported in a variety of clinical disorders, including SLE and other autoimmune and connective tissue diseases, and in disorders that are unrelated to SLE (Table 54.7). The presence of phospholipid-binding antibodies could in some cases be an epiphenomenon. In other cases, APAs may be of profound direct etiologic relevance. In general terms, although there are individual patient exceptions, clinical symptoms are seen less often with aCL than with LA, particularly when APAs are associated with infection or medication, are of low titer, and are of IgM isotype.

Interpretation of estimates of APA frequency must consider the sensitivity of the diverse assay systems that have been used by investigators. Different LA assay systems have been tested with plasma samples from a rigorously defined group of patients with the antiphospholipid–protein syndrome, confirming the importance of variables such as the concentration and composition of phospholipids used in the assay,[459] phospholipid reagent conformation,[452] and so forth.

TABLE 54.7

CLINICAL DIAGNOSES ASSOCIATED WITH ANTIPHOSPHOLIPID–PROTEIN ANTIBODIES

Primary antiphospholipid–protein antibody syndrome	
	Autoimmune disorder with no apparent cause
Secondary autoimmune disorders	
	Systemic lupus erythematosus; other autoimmune and connective tissue diseases; drug induced: procainamide, hydralazine, quinidine, phenothiazines, penicillin
Malignancies	
	Leukemia, lymphoproliferative and plasmacytic disorders, solid tumors, essential thrombocytosis
Infections	
	Viral, bacterial, protozoal, fungal
Neurologic disorders	
Liver disease	
Valvular heart disease	
Peripheral arterial ddisease	
Chronic renal failure	
Sickle cell disease	
Ethylenediaminetetraacetic acid–dependent pseudothrombocytopenia	

In a large series of internal medicine patients, 7% were APA positive, and 2% fulfilled the criteria of antiphospholipid antibody syndrome.[460] The most commonly associated diseases were cancer and chronic or acute alcoholic intoxication. In another study, elevations of APA were found in approximately 20% of an unselected autopsy population, 10% of age- and sex-matched controls, and 2% of healthy normal subjects.[461]

Inhibitors of the lupus type originally were recognized in association with SLE.[367] The prevalence of LA in patients with SLE strongly depends on the type of LA assay system used; three standard PTT reagents detected LA in only 10% of SLE patients.[462] A modified PTT with a reduced concentration of phospholipid detected LA activity in approximately 50% of SLE patients.[462,463] The kaolin clotting time, a test similar to the PTT, detected LA in 70% of patients with SLE.[464] LA activity was associated with higher mortality in SLE patients.[465] APAs have been seen in other connective tissue disorders, including rheumatoid arthritis and Behçet syndrome.

APAs are present in many patients with malignancy.[466] APAs have been associated with monoclonal gammopathy of undetermined significance and Waldenström macroglobulinemia. APAs have been identified in liver disease, the prevalence increasing significantly as the liver disease progresses; APA positivity was as high as 80% in patients with alcoholic hepatitis or cirrhosis.[467] The antibodies have been found in many infections, including hepatitis C,[468] infection with human immunodeficiency virus,[469,470] human T-cell lymphotrophic virus-1–associated tropical spastic paraparesis, Q fever, and malaria.[471] Children with viral infections often acquire a transient LA effect.[462] Perhaps as a result of the structural changes in the red cell membrane with increased hexagonal-phase content, APAs are common in sickle cell disease.[472] Patients with transient ischemic attacks and cardiac valve lesions had a high incidence of APAs.[461] APAs have been seen in a variety of unrelated neurologic disorders.[473] Patients with essential thrombocytosis have an increased prevalence of APA and increased risk of thrombosis.[474]

Several medications are associated with APA, most often, phenothiazines such as chlorpromazine,[440] procainamide,[475] quinine and quinidine,[476] hydralazine, and penicillin.[477] APAs were common in patients with ethylenediaminetetraacetic acid–dependent pseudothrombocytopenia.[478] aCL antibodies can occur in both active and quiescent Crohn disease, usually without concomitant LA expression,[479] but their role in the thrombotic complications that can occur in the active phase of this disease is uncertain.

APA positivity is a common finding in patients with idiopathic thrombocytopenic purpura,[480] with either LA or elevated aCL antibodies in almost one half of patients. Moreover, APA levels were not influenced by immunosuppressive therapy with steroids and are not related to the activity of idiopathic thrombocytopenic purpura.

aCL antibodies and, less often, LA are seen in apparently healthy people,[458,481] especially in the elderly.[482] In studies of normal blood donors, 5% to 10% have aCL antibodies, often present transiently and in relatively low titer without a concomitant LA effect; these donors do not have an increased risk of developing thrombosis.[483] An inherited predisposition to the development of lupus inhibitors was suggested by their presence in two pairs of siblings[484] and in familial studies.[485] Further investigations have suggested associations with certain HLA types.[486,487]

Clinical Manifestations

Although LAs are immunologically distinct from aCL antibodies, clinical manifestations associated with each antibody appear to be similar. Clinical experience suggests that venous thrombosis is more likely associated with the LA, and arterial thrombosis is more likely associated with high-titer aCL antibodies. However,

a literature meta-analysis found that the LA was a stronger risk factor for all thrombosis.[488]

The antiphospholipid-antibody syndrome is characterized by the clinical events of pregnancy morbidity or thromboembolic disease (arterial, venous, or small vessel), or both (Table 54.8).[489] These clinical features are most highly associated with aPL antibodies in prospective studies.[489] Older definitions included immune thrombocytopenia as a clinical event, but the newer classification omits thrombocytopenia.[489] A wide variety of clinical features may be seen with APA.[404,489,490–492] However, many patients with APA are asymptomatic. A proportion of asymptomatic patients develop SLE[493] or other disorders.[494] The diverse clinical manifestations of APA are listed in Table 54.9.

Arterial and Venous Thromboembolic Disease

The most common clinical presentation of patients with LA or aCL antibodies, or both, is arterial or venous thromboembolism,[404,495,496] affecting up to 70% of patients in some series but averaging approximately 30% to 40% of patients in most studies.[463,496,497] The most common site is extremity deep vein thrombosis, but occasionally, unusual sites are involved, such as the axillary, retinal, and hepatic veins and cerebral venous sinus thrombosis.[498] Cerebral thrombosis, often heralded by repeated transient ischemic attacks, is a common arterial lesion.[404,499] Mesenteric artery occlusion, adrenal infarction, gastrointestinal ischemia or ulceration, and subclavian thrombosis with "pulseless" disease also have been described. Multiple cerebral infarcts with dementia in addition to coronary occlusions have occurred in unusually young age groups.[500] A paradoxic syndrome of cerebral infarction with concurrent severe thrombocytopenia and bleeding has been reported in several cases.[499] Antibodies to $\beta_2$gpI are highly associated with venous thrombosis,[501] and in other studies, assays for the LA correlated best with thrombosis, compared with assays for other APAs.[488,502] Another unusual ischemic syndrome associated with APA is avascular osteonecrosis.[503]

TABLE 54.8

CRITERIA FOR DIAGNOSIS OF THE ANTIPHOSPHOLIPID-ANTIBODY SYNDROME (APS)

Clinical Event	Laboratory Abnormality
Venous thrombosis	Positive lupus anticoagulant test (according to guideline in Table 54.11)
or	*or*
Arterial thrombosis	Positive anticardiolipin antibody test (moderate titer or high-titer IgG or IgM antibodies)
or	*or*
	Positive $\beta_2$gpI antibody test (titer >99th percentile, IgG or IgM antibodies)
	and
Small-vessel thrombosis	Laboratory abnormality should persist for two or more occasions at least 12 wk apart
or	
Complications of pregnancy	
One or more unexplained deaths of normal fetuses at or after 10 wk of gestation with normal fetal morphology	
One or more premature births of normal neonates before 34 wk of gestation	
Three or more unexplained consecutive spontaneous abortions before 10 wk of gestation, excluding anatomic, hormonal, and chromosomal abnormalities	

Note: A diagnosis of definite APS requires the presence of at least one clinical event and at least one laboratory abnormality.
Ig, immunoglobulin.
Criteria from Miyakis S, Lockshin MD, Atsumi T, et al. International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). J Thromb Haemost 2006;4:295–306.

TABLE 54.9

CLINICAL MANIFESTATIONS OF ANTIPHOSPHOLIPID ANTIBODIES

Asymptomatic

Arterial and venous thromboembolism

Avascular osteonecrosis

Hematologic

Cytopenias: thrombocytopenia, autoimmune hemolytic anemia, leukopenia

Coagulopathy: platelet dysfunction, prothrombin deficiency, lupus anticoagulant

Neurologic

Acute ischemia (cerebrovascular accident, transient ischemic attack, encephalopathy); severe migraine; multiple infarct dementia; cognitive dysfunction; seizures

Dermatologic

Livedo reticularis; acrocyanosis (distal cutaneous ischemia, ulceration, gangrene); widespread cutaneous necrosis; pyoderma gangrenosum–like skin lesions; anetoderma

Cardiopulmonary

Marantic endocarditis; myocardial ischemia and infarction; intracardiac thrombotic mass; peripheral arterial disease; thromboembolic and nonthrombotic pulmonary hypertension

Obstetric

Recurrent spontaneous abortion; intrauterine growth restriction; preeclampsia; chorea gravidarum; low Apgar scores; prematurity

Catastrophic antiphospholipid syndrome

Thrombocytopenia

Moderate immune thrombocytopenia is noted in approximately 50% of patients with lupus inhibitors, but in many cases, it apparently is the result of the underlying disorder.[504] Immune thrombocytopenia is no longer considered a clinical criterion for diagnosis of APS.[489] When bleeding occurs in patients with aPLs,[505] this is generally attributed to co-existent thrombocytopenia, platelet dysfunction,[506] prothrombin deficiency,[507] or other underlying coagulopathies. Other cytopenias may be associated with APA, including autoimmune hemolytic anemia and leukopenia.

Neurologic Syndromes

Various neurologic disorders have been linked with APA, including dementia, migraines, chorea, seizures, transverse myelopathy, Guillain-Barré syndrome, mononeuritis multiplex, transient global amnesia, and myasthenia gravis. Many of these disorders are not associated with ischemia or thrombosis, and the pathologic relationship of these disorders with APA is uncertain. A consensus statement on stroke and APS proposed criteria to determine the likelihood that APA is associated with ischemic stroke.[508] A literature survey determined that the presence of APA in patients with ischemic stroke did not predict recurrence of stroke or differential response to treatment, and that routine screening for APA in these patients was not warranted.[509]

Dermatologic Disorders

A variety of ischemic–dermatologic syndromes have been associated with aCL antibodies, including livedo reticularis,

acrocyanosis (distal cutaneous ischemia, ulceration, gangrene), widespread cutaneous necrosis, and pyoderma gangrenosum–like skin lesions.[489,510] Livedo reticularis is more prevalent among APS patients with systemic lupus, and in females.[489]

Cardiac Disorders

A high incidence of APA is seen in patients with peripheral arterial disease who experience an associated increased risk of early graft thrombosis.[511] This may justify routine testing for APA before reconstructive vascular surgery, with consideration of perioperative antiplatelet agents or anticoagulation. Some reports have noted the presence of APA in survivors of myocardial infarction.[512] A variety of valvular heart lesions is associated with APS.[489] The consensus group recommends that patients with biopsy-proven myocardial small-vessel thrombosis or those with intracardiac thrombi be considered for meeting criteria for APS. Coronary artery disease also fulfills the APS thrombosis criterion.[489]

Pulmonary Disorders

Ischemic and thrombotic pulmonary disease is linked to APA, including pulmonary embolism, pulmonary hypertension, intra-alveolar pulmonary hemorrhage, and adult respiratory distress syndrome.[513,514] The latter syndrome has been reported in patients with CAPS.[514]

Obstetric Aspects

APAs are associated with obstetric complications,[403,489,515,516,517] including intrauterine growth restriction, preeclampsia, chorea gravidarum, and, primarily, recurrent spontaneous fetal loss (RSFL). Pregnancy losses in women with aPLs are often caused by fetal death despite normal fetal karyotypes. Spontaneous fetal loss is perhaps most common in the first trimester, but paradoxically, early first-trimester pregnancy losses are relatively less common than in other patients with recurrent fetal loss.[518] The international consensus statement listed obstetric criteria for diagnosis of APA: (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation (with normal fetal morphology); (b) one or more premature births of a morphologically normal neonate before the 34th week of gestation because of preeclampsia, eclampsia, or placental insufficiency; or (c) three or more unexplained consecutive spontaneous abortions before the 10th week of pregnancy (with maternal anatomic or hormonal abnormalities, and paternal and maternal chromosomal causes excluded).[489]

There is a significantly increased incidence of elevated APA in women with a history of two or more miscarriages in the first trimester of pregnancy.[519] Women with a history of RSFL should be tested for both LA and aCL antibodies.[520] Repeat testing is important because only 66% of LA-positive, 37% of IgG aCL-positive, and 36% of IgM aCL-positive women had a positive test result on repeat evaluation. Laboratory screening for LA is confounded in pregnancy because altered coagulation factor concentrations in normal pregnancy may change the observed normal range of coagulation tests, including the PTT. In two studies, the DRVVT was the most frequently positive test for the LA in this population. Rigorous adherence to diagnostic criteria is particularly appropriate in pregnancy because treatment may require potentially hazardous antithrombotic therapy. Elevated maternal serum levels of α-fetoprotein[521] or human chorionic gonadotrophin[522] are common in women with aPLs and are significantly associated with fetal loss. Maternal APA testing may be appropriate if prenatal screening reveals an elevated human chorionic gonadotrophin level and ultrasonography demonstrates an otherwise normal singleton gestation.

It is generally considered not appropriate to screen for APA in asymptomatic pregnancies without a history of RSFL.[523] APAs were identified at the first pre-natal visit in almost 25% of healthy pregnant women.[524] LA appears to be much rarer than aCL antibodies in pregnancy.[525] It appears that women with isolated IgM aCL or with low levels of IgG aCL are a distinct group that is not at risk for APA-related complications beyond the risk conferred by their medical histories.[526]

Although the mechanism by which APA causes recurrent pregnancy loss has not been fully explained, these antibodies may induce intervillous thrombosis and intravillous infarctions, resulting in poor placental perfusion, and have been shown to affect cytotrophoblast tissue in vitro. The thrombotic phenomenon may be mediated by aPL antibodies interfering with trophoblastic annexin V.[404,527]

The role of inflammation and the complement pathway in APS-associated pregnancy complications was reported.[528] Anticoagulants that prevented complement activation (unfractionated or LMWH) were successful in preventing pregnancy loss in an animal model of APS; anticoagulants that did not inhibit complement activation (fondaparinux, hirudin) did not prevent pregnancy loss. These data suggest that the beneficial effects of anticoagulants in APS-associated pregnancy loss result from inhibition of complement activation.[528]

Catastrophic Antiphospholipid-antibody Syndrome

Some patients with APA develop an acute, severe, multiorgan illness[403,514,529] characterized by diffuse small vessel ischemia and occlusion with extensive tissue damage, including myocardial infarction, limb ischemia, DIC, and a high mortality rate of 50%.[530] The patients present with a dramatic illness, often without an obvious precipitating event, that prompts consideration of a wide differential diagnosis including severe lupus vasculitis, thrombotic thrombocytopenic purpura, or severe DIC. The syndrome is defined by clinical involvement of at least three different organ systems with histologic evidence of thrombosis.[529,530] Typically, small vessel thrombotic lesions occur, with common sites of involvement including the kidney, lung, central nervous system, heart, and skin.[529,530] In a larger series of CAPS patients, nearly one half of the cases had systemic lupus, and 40% had PAPS.[531] Precipitating factors for development of CAPS included infections, trauma/procedures, cancer, and subtherapeutic anticoagulation.[531] LA activity and, particularly, high aCL antibody titers are usually present. Central nervous system symptoms and hypertension are common, and leukocytosis and a significantly elevated sedimentation rate are often also present. The clinical manifestations of this syndrome can include all the symptoms and signs indicated in Table 54.9. Preliminary criteria for the classification and diagnosis of CAPS have been published.[529] Effective therapies include therapeutic anticoagulation, steroids, ivIgG, plasma exchange, and cyclophosphamide.[529] A literature review of rituximab use in CAPS found encouraging results.[532] A summary of CAPS registry cases reported that anticoagulation with steroids ± plasma exchange/ivIgG was associated with at least a 70% success rate.[533]

Laboratory Diagnosis of Antiphospholipid–Protein Antibodies

LA and high-titer aCL antibodies have similar clinical implications, although studies suggest a higher thrombotic risk in patients with the LA.[488,502] In patients with SLE, the LA is the best predictor for both venous and arterial thrombosis. The laboratory should perform both fibrin-based coagulation assays to detect LA and solid-phase ELISA assays for aCL and $\beta_2$gpI antibodies in patients suspected of having APA.

A considerable array of phospholipid-responsive laboratory tests, such as the PTT, dilute PTT, kaolin clotting time, and DRVVT, may serve to screen for the LA.[409] LA may be defined as an immunoglobulin (IgG, IgM, IgA, or a mixture) that interferes with one or more of these in vitro, phospholipid-dependent coagulation tests. A more recent definition of the LA would be antibodies to $\beta_2$gpI or to prothrombin that prolong phospholipid-dependent coagulation

assays. Coagulation tests that are phospholipid independent are not affected by LA. Unless concurrent additional factor deficiencies are present, the standard PT is usually normal because of the large amount of phospholipids in this reagent. No individual test seems to have a universal detection rate; this observation may reflect LA subtypes with distinct activities or the requirement of various co-factors. Consequently, it is recommended to perform at least two independent assays for the LA.[489,534] A simplified algorithm approach for diagnosis of the LA has been described that uses two assays, the DRVVT and a hexagonal phase assay.[535] Comparative studies suggest that activated PTT reagents with reduced levels or different types of phospholipids are more sensitive than routine PTT reagents.[409,536] Platelet-poor plasma should be used in these screening assays, particularly if frozen plasma samples are to be tested.[537] A recent update of LA guidelines has reviewed these issues.[538] Table 54.10 indicates some of the clinical and laboratory differences between specific anticoagulant antibodies to particular factors, such as factor VIII and LA. Other nonspecific anticoagulants are uncommon but include the heparinlike anticoagulants discussed in the section "Other Acquired Coagulation Disorders." Confirmatory tests for LA based on activated PTT or DRVVT include abnormal mixing studies with normal plasma and correction with mixing using phospholipids, such as lysed washed platelets (platelet neutralization procedure), or with added hexagonal-phase phospholipids.[539] A high concentration of liposomes prepared from rabbit brain extracts may achieve the most efficient correction of the defect,[540] but this method is not widely used. The College of American Pathologists has published detailed recommendations for LA testing,[541] and testing issues affecting the LA have been reviewed.[542]

Several clinical points are worth stating. The search for LA or aCL antibodies should not be abandoned even if normal plasma in a mixing study corrects the test patient plasma, particularly in a human immunodeficiency virus–positive population.[543] It is sometimes important for the clinician to discern the possible effect that heparin in the test patient plasma can have on the confirmatory laboratory assay; satisfactory correction procedures should be resistant to heparin, and many commercial LA reagents have heparin neutralizers. The ideal test to identify the LA is controversial; some investigators have reported the kaolin clotting time to be the most sensitive test.[536,544] On the other hand, some DRVVT assays are more able to identify LA associated with thrombosis.[545] A subgroup of patients with unexplained thrombosis with antibodies to phosphatidylethanolamine as the only abnormal APA test has been identified.[546] Optimal detection of the LA requires more than one of the phospholipid-dependent assays described earlier.[489,538,547] This latter suggestion is supported by reports that different phospholipid-dependent coagulation tests detect different populations of LA antibodies.[548] Table 54.11 summarizes the recommendations of an ISTH consensus group on laboratory diagnosis of LA.[489]

aPLs may also be detected by ELISA[489] or by radioimmunoassay. Commercial ELISA systems are reasonably well standardized. The aCL-antibody assay used to improve sensitivity and specificity has undergone several modifications. Using anti-$\beta_2$gpI–dependent assay systems is useful to discriminate between transiently positive aCL antibodies that are associated with infection, which characteristically do not have a $\beta_2$gpI cofactor requirement, and those aCL antibodies associated with an increased risk of thrombosis.[549] IgA aCL antibodies should not be considered a laboratory criterion for diagnosis of APS.[489]

Definitional standardization of the criteria for clinical and laboratory APA has been published.[403,489] For the diagnosis of APS, in addition to a clinical event (e.g., at least one venous, arterial, or small-vessel thrombosis, pregnancy morbidity/mortality), positive laboratory tests for LA, aCL, or $\beta_2$gpI antibodies (in medium or high titer) should be found on two occasions at least 12 weeks apart (Table 54.8). It is recommended that aCL antibodies be measured by a standardized ELISA for $\beta_2$gpI-dependent antibodies.[403,489] Although consensus criteria require persistence of the laboratory abnormality for at least 12 weeks, in clinical practice, a functional definition taking into account the number of clinical manifestations and the titer of aCL antibodies or positivity for the LA on even a single occasion may help categorize patients as having definite, probable, or doubtful APS and may direct immediate treatment options. A "triple positive"

TABLE 54.10

COMPARISON OF FACTOR VIII ANTIBODIES AND ANTIPHOSPHOLIPID–PROTEIN ANTIBODIES

Clinical Event or Laboratory Test	Factor VIII Antibodies	Antiphospholipid–Protein Antibodies
Bleeding	Often severe	Uncommon
Thrombosis	Rare	Common
Obstetric complications (abortion and intrauterine fetal death)	Rare	Common
Prothrombin time	Normal	May be prolonged
Thrombin time	Normal	Occasionally prolonged
Thrombocytopenia	Rare	Common
Inhibitory effect in plasma mixtures	Usually time dependent	Often is instantaneous; occasionally, mixing studies show time-dependent inhibition
Prothrombin level	Normal	Occasionally deficient
Factor VIII level	Deficient; one-stage assay curve is aberrant with low-affinity antibodies	Normal when assayed in a dilute system; all one-stage assay curves are aberrant
Anticardiolipin and $\beta_2$gpI antibodies	Rare	Common
Phospholipid or platelet correction of abnormal assay result	No	Usually

Ig, immunoglobulin.

TABLE 54.11

LABORATORY DIAGNOSIS OF LUPUS ANTICOAGULANT: INTERNATIONAL SOCIETY ON THROMBOSIS AND HAEMOSTASIS CRITERIA

- Prolongation of at least two phospholipid-dependent coagulation tests with the use of platelet-poor plasma (e.g., the activated partial thromboplastin time, dilute prothrombin time, dilute Russell viper venom time, kaolin clotting time). The DRVVT should be the first test considered.
- Failure to correct the prolonged coagulation time by mixing patient and normal plasma.
- Confirmation of lupus anticoagulant by demonstrating correction of the prolonged coagulation time by addition of excess phospholipids or freeze-thawed platelets.
- Exclusion of alternative coagulopathies using specific assays (e.g., factor VIII antibodies).

Diagnostic criteria from Levine JS, Branch DW, Rauch J. The antiphospholipid syndrome. N Engl J Med 2002;346:752–763; and Brandt JT, Triplett DA, Alving B, et al. Criteria for the diagnosis of lupus anticoagulants: an update. On behalf of the Subcommittee on Lupus Anticoagulant/Antiphospholipid Antibody of the Scientific and Standardisation Committee of the ISTH. Thromb Haemost 1995;74:1185–1190. Additional laboratory details and patient selection criteria are discussed in Pengo V, Tripodi A, Reber G, et al. Update of the guidelines for lupus anticoagulant detection. J Thromb Haemost 2009;7:1737–1740.

profile (positive results for all three assays: LA, aCL antibodies, and $\beta_2$gpI antibodies) has been identified as a strong independent risk factor for thrombosis.[550]

Even if the patient is asymptomatic, lupus inhibitors should always be identified correctly when discovered, even though costly and time-consuming laboratory study is required. If the cause for a prolonged PTT is not identified, the necessity for definitive laboratory evaluation almost invariably arises again, often in the context of an emergency. This may result in the unnecessary use of blood products and a delay of required surgical procedures.

Treatment of Antiphospholipid–Protein Antibody Syndrome

The optimal treatment of patients with APA syndrome is undefined, although randomized treatment trials are providing useful therapy recommendations. Depending on the clinical symptoms, patients with APA may need no treatment or may need anticoagulant or immunosuppressive therapy. Although spontaneous remissions are uncommon and aCL antibodies and LA can be associated with life-threatening thromboembolic events, only 10% to 15% of asymptomatic patients with APA develop these complications. Based on the uncertainty of predicting when thrombotic events might occur, as well as the risks of anticoagulation, most investigators do not treat asymptomatic patients prophylactically, with the possible exception of short-term intervention when additional thrombophilic hazards such as immobilization or surgery are anticipated.

Patients with significant thrombotic events (e.g., deep vein thrombosis, arterial ischemia, or fetal loss) are appropriate candidates for antithrombotic therapy. Two randomized trials investigated the optimal intensity of warfarin therapy in APS patients.[551,552] Both studies found that high-intensity warfarin (INR 3.1 to 4.0 or 4.5) was not superior to standard intensity warfarin (INR 2.0 to 3.0).[551,552] Long-term treatment with oral anticoagulation therapy is advised because of the high rate of recurrence even if the venous or arterial occlusion occurred many years previously.[553,554] Patients receiving oral anticoagulants had no recurrence over 8 years, whereas patients in whom anticoagulant drugs had been discontinued had a 50% probability of a recurrent venous thromboembolic episode after 2 years and an almost 80% probability of recurrence after 8 years.[555] This strategy is supported by a study that found that APS patients with thrombosis benefited from prolonged oral anticoagulation because persistent elevation of aCL levels predicted an increased risk of thrombosis recurrence and death.[556] Many investigators follow this approach,[404] unless all laboratory evidence of LA and aCL in patients in whom high titers were initially detected or in whom a thrombotic risk was attributed to APA has been continually absent for at least 6 months; no other thrombophilic risk is present; and close surveillance is feasible. An emerging treatment strategy in APS patients is to consider single-positivity test results for $\beta_2$gpI or aCL antibodies as a lesser risk for recurrent thrombosis, and perhaps less-intense or shorter duration treatment periods.[404]

A literature review of treatment for APS patients with ischemic stroke concluded that treatment with either aspirin or low-intensity warfarin (INR 2.0 to 3.0) is effective.[557] For noncerebral arterial thrombosis, combined therapy with low-intensity warfarin (INR 2.0 to 3.0) plus aspirin (81 mg) was recommended.[557]

A relatively new therapy for APS is hydroxychloroquine, an immunosuppressive agent used to treat patients with SLE. Hydroxychloroquine therapy decreases thrombosis risk in SLE patients,[558] perhaps by interfering with aPL antibody binding to phospholipid.[559]

Patients with the uncommon LA hypoprothrombinemia syndrome who either have bleeding or need surgery may benefit from steroid therapy or intravenous IgG.[560]

Patients with the LA and acute thrombosis pose difficulty in terms of monitoring heparin anticoagulation. The usually prolonged PTT value seen with the LA renders this test unreliable. These patients can be monitored using heparin assays, which are available by automated methodology (see Chapter 55). Alternatively, patients can be treated using a LMWH, without the necessity for laboratory monitoring (see Chapter 55).

In those patients with an LA and hypoprothrombinemia, or an LA that affects the PT, the use of the INR to monitor anticoagulation has been questioned. These patients may require monitoring with a test that is insensitive to the LA, such as a prothrombin–proconvertin assay or a chromogenic factor X assay.[561]

Corticosteroid use often diminishes or abolishes the coagulation abnormalities and immune thrombocytopenia of APA syndrome within a short time. However, for most patients, the role of steroids, other immunosuppressive agents, or aspirin is uncertain. Although immunosuppression with cyclophosphamide in pulse form is effective in reducing elevated antibody levels, there is often a rapid rebound to pre-treatment levels shortly after discontinuation of the therapy. Consequently, additional therapies with aspirin or steroids or more aggressive immunosuppression are not used unless recurrent thrombotic or ischemic events are seen despite optimal warfarin therapy. High-dose corticosteroid therapy has equivocal efficacy and considerable toxicity and is reserved for treatment of underlying co-morbid conditions such as active lupus and not for the laboratory phenomena of the antiphospholipid antibody syndrome itself.

In patients with CAPS who experience multisystem involvement, intensive treatment with corticosteroids, immunosuppression, intravenous IgG, or plasmapheresis may be useful.[530,532,533] In one literature analysis of CAPS therapy, the highest response to therapy occurred in patients treated with anticoagulation and steroids (64%).[531] Immune thrombocytopenia and autoimmune hemolytic anemia in patients with APA are treated similarly as in patients without APA.

Obstetric Treatment

Because the risk of pregnancy loss in women with APS and prior pregnancy loss may exceed 60%, a history of recurrent fetal loss is an indication for treatment during pregnancy. Antiplatelet agents such as aspirin 80 mg/day,[562] low-dose immunosuppressive agents such as prednisolone 10 mg/day,[563] or anticoagulants (heparin or LMWH) have all been used in an attempt to improve pregnancy outcome.[403,404] Several randomized studies have provided information about useful treatment strategies in pregnancy-associated APS (reviewed in References 403 and 564). Intravenous IgG is of no benefit in these patients, and heparin may be more effective than aspirin. A meta-analysis recommends that a combination of unfractionated heparin (5,000 U s.c. twice daily) and low-dose aspirin be used,[564] and a recent consensus guideline recommends "prophylactic or intermediate-dose unfractionated heparin or prophylactic LMWH combined with low-dose aspirin (75 to 100 mg/day)".[565]

Transfusion-associated Coagulation Abnormalities

The administration of blood products in a volume >1.5 times the patient's estimated blood volume or replacement of total blood volume in <24 hours constitutes massive blood transfusion.[566] Traditional resuscitation efforts were initiated with large volumes of crystalloid and packed red cell transfusions; a new paradigm is termed "damage control resuscitation" which includes administration of tranexamic acid for cases of uncontrolled hemorrhage, use of a massive transfusion protocol with fixed blood product

ratios, avoidance of large-volume crystalloid use, and usage of permissive hypotension.[567,568]

The importance of core body temperature on hemostasis parameters has been demonstrated; at a temperature of 33°C, platelet function is impaired. Below 33°C, both coagulation factor activity and platelet function are reduced.[569]

Bleeding Associated with Extracorporeal Circulation

Defective hemostasis with cardiopulmonary bypass is associated with multiple contributory causes, including hemodilution of coagulation factors, inadequate neutralization of heparin, acquired platelet dysfunction, and thrombocytopenia. These latter two defects are further discussed in Chapter 52. In general, extracorporeal-circulation–induced hemostatic defects may be ascribed to activation of platelets and coagulation proteins by artificial surfaces.

Platelet dysfunction (acquired storage pool defect) is considered the major hemostatic insult induced by bypass.[570] Although DDAVP was shown to reduce bleeding and transfusion requirements in these patients in earlier studies, subsequent trials indicated no benefit from DDAVP,[571] and routine DDAVP therapy may be hazardous in older patients with significant vascular disease.[572] Aprotinin should not be used in this setting.[573]

Drug-induced Coagulation Abnormalities

Broad-spectrum antibiotics, such as the β-lactam antibiotics, may induce a coagulopathy by inhibition of vitamin K synthesis by gut bacteria and direct inhibition of essential carboxylation reactions.[22] A number of antibiotics may also inhibit platelet function (see Chapter 52).

l-Asparaginase produces hypofibrinogenemia and deficiency of other coagulation factors.[574] Hematin produces a complex coagulopathy.[575] Valproic acid therapy has been associated with acquired vWD.[576]

Acquired Deficiencies of Single Coagulation Factors

An uncommon phenomenon is the development of deficiency of a single coagulation factor during the course of an acquired disorder (Table 54.6). Isolated deficiency of factor X is well documented in patients with primary amyloidosis and amyloidosis associated with multiple myeloma.[577] Factor X levels in these patients do not rise even after massive replacement therapy, and studies using ^{131}I-labeled factor X suggest that this proenzyme is bound to subendothelial amyloid fibrils in blood vessels.[578] A combined deficiency of factors IX and X in amyloidosis also has been reported.[579] In many patients, the hemostatic defect is complicated by other abnormalities, such as vascular infiltration, liver disease, high levels of antithrombins, and azotemia with platelet dysfunction.[580] Splenectomy abolished the factor X deficiency and produced complete remission of bleeding in several cases,[581] presumably because of extensive amyloid infiltration in the splenic vasculature. Chemotherapy with melphalan and prednisone may also resolve factor X deficiency in amyloidosis.[582] High-dose chemotherapy with stem cell transplantation is also effective therapy.[583] Factor X deficiency has also been associated with upper respiratory tract infections.[394] A detailed literature review of acquired factor X deficiency has been published.[584]

Hypoprothrombinemia has been reported as an isolated finding,[585] most commonly in association with LAs, as discussed previously. Deficiencies of prothrombin, factors IX and XII, plasminogen, and antithrombin have been reported in some patients with the nephrotic syndrome,[586–590] presumably as the result of massive protein loss in the urine. In one patient with Sheehan syndrome, a selective deficiency of factor IX responded to treatment with corticosteroids and thyroid replacement.[591] Isolated deficiency of factor IX in several patients with Gaucher disease also has been documented.[592] Acquired factor VII deficiency has been reported with aplastic anemia[593] and liposarcoma.[594]

Factor XIII deficiency has been associated with chronic myelocytic leukemia and with various forms of acute leukemia.[595] Factor XIII deficiency has also been associated with inflammatory bowel disease,[596] and isoniazid-induced antibodies to factor XIII have been reported.[381,382,597] Factor XII deficiency has been described in association with chronic myelocytic leukemia[598] and antiphospholipid antibodies.[599] Factor XI deficiency has been linked to Gaucher disease[600] and Ehlers-Danlos syndrome.[601] Factor V deficiency has been reported in chronic myeloid leukemia and in celiac disease. Acquired vWD was discussed earlier in the section on vWF.

Other Acquired Coagulation Disorders

Heparinlike anticoagulants have been reported in patients with hematologic malignancies (e.g., plasma cell dyscrasias[602] or leukemias[603,604] or solid tumors[605]). A prolonged thrombin time and normal reptilase clotting time are typically seen in these patients. Significant clinical bleeding may occur with heparinlike anticoagulants; a titrated protamine sulfate infusion may be helpful in these patients.

Malignancy may also be associated with other inhibitors of coagulation, including FDPs and paraproteins, dysfibrinogenemias, and specific antibodies to coagulation factors (discussed earlier). A monoclonal antithrombin antibody associated with bleeding has been reported in a patient with myeloma.[606]

CHAPTER 55

THROMBOSIS AND ANTITHROMBOTIC THERAPY

Robert C. Pendleton, George M. Rodgers

The term *thrombosis* refers to the formation, from constituents of the blood, of a mass within the venous or arterial vasculature of a living animal. Hemostatic thromboses, namely, self-limited and localized thromboses that prevent excessive blood loss, represent the body's natural and desired response to acute vascular injury. Pathologic thromboses such as deep venous thrombosis (DVT), pulmonary embolism (PE), coronary arterial thrombosis leading to myocardial infarction (MI), and cerebrovascular thrombotic occlusion represent the body's undesired response to acute and chronic perturbations of the vasculature, blood, or both. The terms *coagulated blood* and *clot* are not synonymous with thrombosis and refer to the formation of a solid mass of blood components outside of the vascular tree. Examples of clots include soft tissue, body cavity (e.g., peritoneal), and visceral hematomas. Coagulated blood best describes clots formed ex vivo.

Thrombosis of the veins and arteries, together with complicating embolic phenomena, is perhaps the most important cause of sickness and death in the developed countries of the world at the present time. Deaths from MI and thrombotic stroke consistently represent the major causes of death in the United States, numbering >700,000 people annually (almost 30% of all deaths) in a recent report.[1] Venous thromboembolic disease is the third most common cardiovascular disease, after atherosclerotic heart disease and stroke. It has been estimated that between 500,000 and 2 million venous thromboembolic events (VTE) including calf vein thrombosis, proximal DVT (e.g., lower extremity and pelvic veins), and PE occur annually in the United States alone.[2] The incidence of pathologic thrombosis, prevalence of disorders that predispose to thrombosis, and morbidity and mortality associated with thrombotic events all reflect the magnitude of the importance of the study of thrombotic mechanisms and development of effective antithrombotic and thrombolytic therapies.

In this chapter, the pathophysiology of arterial and venous thrombosis and mechanisms of action of antithrombotic pharmacologic agents including antiplatelet drugs, anticoagulants, and fibrinolytic agents are summarized and discussed. Inherited conditions that predispose an individual to thrombosis, also termed *hypercoagulable states,* and the management of venous thromboembolic disease are covered. The management of arterial thrombotic events is beyond the scope of this chapter, and the reader is referred to several excellent recent review articles.[3–5]

PHYSIOLOGY AND PATHOPHYSIOLOGY OF THROMBOSIS

The human hemostatic system consists of multiple independent, yet integrally related, cellular and protein components that function to maintain blood fluidity under normal conditions and promote localized, temporary thrombus (hemostatic thrombus) formation at sites of vascular injury. A normal hemostatic system is the human physiologic defense against exsanguination. An abnormal hemostatic system can result in pathologic bleeding, vascular thrombosis, or both.

The hemostatic system is comprised of six major components: Platelets, vascular endothelium, procoagulant plasma protein "factors," natural anticoagulant proteins, fibrinolytic proteins, and antifibrinolytic proteins. Each of these six hemostatic components must be present in fully functional form, in adequate quantity, and at the proper location to prevent excessive blood loss after vascular trauma and, at the same time, to prevent pathologic thrombosis. The hemostatic system is highly regulated and maintains a delicate balance between a prohemorrhagic state and a prothrombotic state. Any significant acquired or congenital imbalance in the hemostatic "scales" can lead to a pathologic outcome.

Normal hemostasis in response to vascular injury can be divided into two major processes of equal importance, known as primary and secondary hemostasis. *Primary hemostasis* comprises the reactions needed to form a platelet plug at a site of vascular damage, whereas *secondary hemostasis* comprises a series of reactions (coagulation cascade) needed to generate cross-linked fibrin required to stabilize the platelet plug and form a durable thrombus. Natural anticoagulants (antithrombin [AT] and activated protein C [APC]) function to confine thrombus formation to the sites of vascular injury and limit thrombus size to prevent vessel occlusion and flow interruption in the affected vessel. The activity of AT is greatly enhanced by endothelial cell heparan sulfate and pharmacologic heparins. The function of APC is enhanced by its cofactor, protein S. Physiologic fibrinolysis is initiated by endothelial-cell–derived tissue-type plasminogen activator (t-PA), which converts plasminogen to plasmin. Plasmin can degrade cross-linked fibrin, limit thrombus size, and help dissolve a thrombus once the vascular injury has been repaired. The fibrinolytic system is regulated and localized by antiplasmin and PA inhibitor (PAI)-1. Details of the hemostatic mechanisms and endothelial cell regulation of hemostasis are given in Chapters 18 and 19.

Specific alterations in the quantitative and qualitative status of any hemostatic cellular or protein element can lead to pathologic thrombosis. A marked increase in the platelet count (thrombocytosis) and accentuated platelet aggregation ("sticky platelet syndrome") are associated with thromboembolic events. Elevated levels of procoagulant factors such as fibrinogen, factors VIII, IX, XI, and VII, as well as resistance to inactivation of factor Va by APC, are recognized risk factors for vascular disease and thrombosis. Deficiency of a natural anticoagulant protein such as protein C, protein S, or AT is associated with venous thromboembolic disease. Deficiency of a fibrinolytic cascade component, such as t-PA or plasminogen, and excess plasma levels of the fibrinolytic inhibitor PAI-1 have been linked to hypercoagulability and thrombosis. It is the net balance between the participating and, at times, opposing groups of proteins and not the level of any individual factor that is most critical to hemostatic regulation.

VIRCHOW TRIAD

In the mid-19th century (1854), German pathologist Rudolph Virchow postulated that vascular obstruction was precipitated by, and thrombosis resulted from, three interrelated factors:

(a) "Decreased blood flow" (stasis of blood flow), (b) "inflammation of or near the blood vessels" (vascular endothelial injury), and (c) "intrinsic alterations in the nature of the blood itself" (hypercoagulability).[6] Many students of coagulation medicine, though, do not realize that Virchow actually recognized his "triad" as being the result of vascular occlusion, not necessarily as the original precipitant of vascular thrombosis. Nonetheless, the vascular, rheologic, and hematologic aspects of thrombosis known as the Virchow triad remain relevant and instructive today (Fig. 55.1).

Abnormalities of Blood Flow

Arterial thrombosis initially occurs under conditions of rapid blood flow (high shear stress), a condition in which von Willebrand factor (vWF) is critical for platelet adhesion.[7] Arterial thrombi usually are composed of tightly coherent masses of platelets, which contain small amounts of fibrin and a few erythrocytes and leukocytes. These thrombi are the classic "white thrombi," which resemble, in many respects, normal hemostatic plugs. As arterial thrombi enlarge, progressive or intermittent deposition of new layers of platelets and fibrin produces the characteristic lines of Zahn; partial or complete obstruction of blood flow may produce a "tail" of "red thrombus." The most serious consequences of arterial thrombosis are vascular occlusion with resultant ischemia and infarction of tissue and distal thrombus embolization.

Hypertension, turbulent blood flow at arterial branch points and at sites of focal atherosclerosis, and hyperviscosity may be contributory factors in certain forms of arterial thrombosis. Causes of plasma hyperviscosity that can precipitate thrombosis and exacerbate ischemia include acute myeloid leukemia, myeloproliferative syndromes such as polycythemia rubra vera, cryoglobulinemia, and the plasma cell dyscrasias, including multiple myeloma and Waldenström macroglobulinemia. Immunoglobulin (Ig) paraproteins produced by plasma cell dyscrasias can increase viscosity, and promote red blood cell agglutination.

Venous thrombosis typically develops under conditions of slow blood flow (low shear stress) and is augmented by further retardation and stagnation of flow caused by the developing thrombus itself. Right-sided heart failure, pre-existent venous thrombosis, extrinsic vascular compression by tumor, and chronic venous insufficiency all promote venous stasis, blood pooling, and a concentration of procoagulant factors.[8] The anatomic structure of venous valves results in retrograde eddy currents, which produce pockets of stasis even in normal veins.[9] The venous arcades in the soleus muscles of the calves may represent another site of physiologic venous stasis. These structures may enlarge and lose vascular tone with aging.[10,11] These facts may partially explain why DVT most commonly occurs in the valve cusps and veins of the pelvis and lower extremities, and why older age is an important risk factor for venous thrombosis.[12]

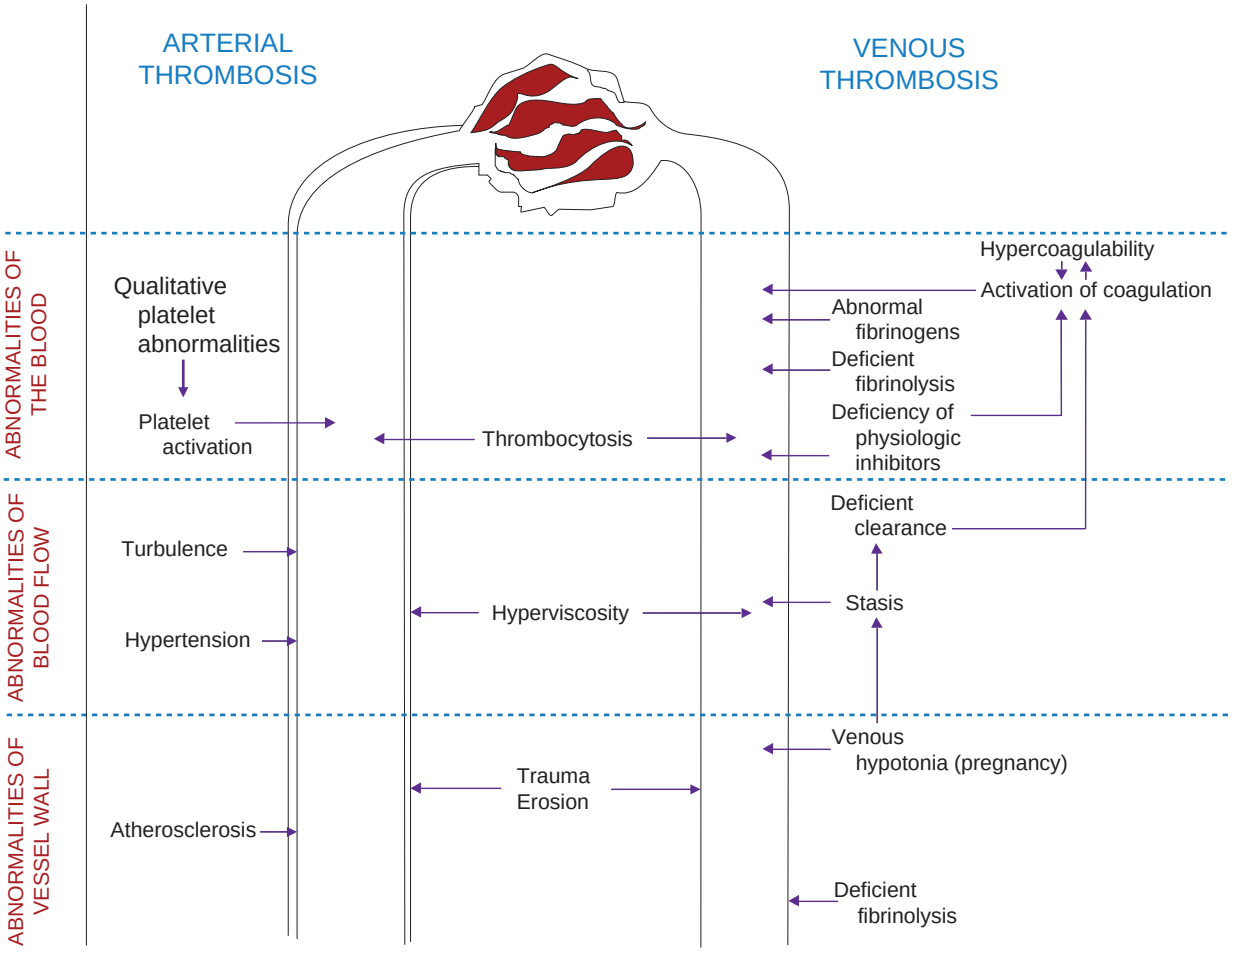

FIGURE 55.1. Pathophysiology of thrombosis. Factors implicated in the pathogenesis of arterial thrombosis (*left*) and venous thrombosis (*right*) are depicted. Examples of disorders leading to platelet activation and arterial thrombosis include atherosclerosis, the myeloproliferative disorders, heparin-associated thrombocytopenia/thrombosis syndrome, thrombotic thrombocytopenic purpura, and certain platelet polymorphisms. Examples of disorders leading to venous thrombosis in the category of deficiency of physiologic inhibitors include the inherited disorders, factor V Leiden, proteins C and S deficiencies, and AT deficiency. Many patients with thrombosis may have more than one of the risk factors listed. Estrogen therapy is a risk factor for venous thrombosis; its use is associated with activation of coagulation.

Venous thrombi are composed of large amounts of fibrin containing numerous erythrocytes. In these loose, friable masses (the red thrombus), the platelets and leukocytes are enmeshed in random fashion. Venous thrombi resemble blood clots formed in vitro, and they usually produce significant obstruction to blood flow from the outset, but their most serious consequence is embolization. Blood flow obstruction secondary to venous thrombosis itself promotes the further formation of thrombus. Results of studies of clots formed in a thromboviscometer at varying rates of shear suggest that the differences in the structure of venous and arterial thrombi may be mainly the result of the velocity of blood flow. The many and complicated rheologic factors that may be involved in thrombosis have been reviewed.[13] Although traditional teaching holds that risk factors for arterial and venous thrombotic disease are distinct, new epidemiologic data suggest that common risk factors exist for both disorders, and that appropriate management of thrombosis patients should address secondary prevention of both arterial and venous thrombosis.[14] The pathogenesis of venous and arterial thrombosis has been recently reviewed.[15]

Vascular Injury

Permanent and transient vascular injuries play major roles in the development of arterial thrombosis. Intraluminal vascular endothelial cell injury, atherosclerotic plaque rupture, hyperhomocysteinemia, arterial outflow obstruction, aneurysm formation, and vessel dissection are among the recognized risk factors for arterial thrombosis.[16] Arterial thrombosis usually begins with platelet adhesion to an abnormal vascular endothelial surface or exposed subendothelial constituent such as collagen. The adherent platelets become activated, leading to the release of α- and dense granule contents.[15] Platelet-dense granules (dense bodies) release adenosine diphosphate (ADP), adenosine triphosphate (ATP), calcium, and serotonin into the surrounding milieu, resulting in the recruitment and activation of additional platelets.[16] This release reaction and platelet synthesis of thromboxane A_2 (TxA_2) and other agonists induce the aggregation of more platelets and enlargement of the temporary platelet plug. In addition to the recruitment of additional platelets, the original nidus of adherent platelets provides a phospholipid surface rich in phosphatidylserine to support and concentrate the generation of thrombin and fibrin necessary to reinforce and stabilize the platelet plug.

New insights into arterial thrombus formation have been gleaned from experiments using confocal and wide-field microscopy to image real-time thrombus formation in live-mouse cremaster muscle arterioles.[17] Thrombosis is precipitated by laser-induced endothelial injury. These experiments demonstrated that the initiation of blood coagulation in vivo involves the initial accumulation of tissue factor (TF) on the upstream and thrombus–vessel wall interface of the developing thrombus. The TF is biologically active and is associated with intrathrombus fibrin generation. TF density is highest at the thrombus–vessel wall interface and is eventually observed throughout the thrombus. Leukocyte rolling is noted approximately 2 minutes after endothelial cell injury and correlates with P-selectin expression on the outer aspect of the thrombus. Minimal TF and fibrin are detected in platelet thrombi formed in mice lacking P-selectin or the P-selectin glycoprotein ligand, PSGL-1.

In venous thrombosis, the luminal surface of the vessel wall is usually histologically normal, and factors extrinsic to the vessel appear to have a major pathophysiologic role. Exceptions to this generalization are direct venous trauma, extrinsic venous compression, and vascular endothelial cell injury resulting from the toxic effect of cancer chemotherapy and excess levels of homocysteine. A limited quantity of activated platelets likely serves as a phospholipid surface to support local thrombin and fibrin formation. A generalized reduction in venous tone may be an important pathophysiologic factor in venous thrombosis in pregnant women and in women taking oral contraceptives.[18] vWF-mediated platelet adhesion was shown to be essential for venous thrombosis in an animal model.[19] Additional mechanisms may contribute to a prothrombotic state, including up-regulation of stress-response genes, endothelial cell activation, formation of neutrophil extracellular traps, and activation of the intrinsic coagulation pathway.[20]

Studies indicate that human platelets express TF pre-mRNA, and when activated, splice this message into mature mRNA which is expressed.[21] These results suggest that both platelets and the vessel wall may contribute to initiation of thrombosis.

Abnormalities of the Blood: Hypercoagulability

The term *hypercoagulable state* and its synonym *thrombophilia* refer to any inherited or acquired abnormality of the hemostatic system that places an individual at increased risk for venous or arterial thrombosis (or both). Blood from patients with active thrombosis or with a hypercoagulable state may clot at an abnormally rapid rate in vitro.[22] The concept of hypercoagulability has gained widespread acceptance, and it is generally appreciated that these hemostatic changes are important in the pathogenesis of thrombosis; however, whether testing for these disorders may be helpful in patient management is uncertain.[23,24,25]

Platelet Abnormalities

Although platelets may be incorporated into virtually any thrombus, they appear to be pathogenetically most important in arterial thrombosis. Increased platelet turnover (shortened platelet survival, compensated platelet destruction) occurs in vascular disease and thrombosis, including arterial and venous thrombosis, coronary artery disease, vasculitis, hyperhomocysteinemia, and valvular heart disease.[26–29] Increased platelet turnover can also be seen in patients with risk factors for vascular disease, including those who use tobacco and those with hyperlipidemia.[30,31] Increased platelet turnover and activation can reflect thromboembolic disease and also probably contribute to an exacerbation of thrombotic events.

As a consequence of platelet–vessel wall interactions in patients with vascular disease, platelet adhesion, activation, and aggregation occur, resulting in acquired storage pool disease and the presence in the blood of platelet-granule–derived proteins such as platelet factor-4 (PF4) and β-thromboglobulin.[32,33] Although elevated blood levels of these proteins indicate increased platelet turnover, improper blood collection technique may artifactually result in abnormal levels, and the clinical value of such testing is uncertain.

Vascular endothelium possesses multiple antiplatelet properties that may be important in preventing platelet adhesion, promoting vasodilation, and inhibiting platelet aggregation.[34,35,36,37] However, interruption of endothelial cell prostacyclin synthesis by aspirin does not result in a net thrombotic tendency. The potential role of hyperactive platelets in patients with thrombosis, as well as the use of platelet function testing in this setting, is somewhat controversial.

Because of the importance of vWF in mediating platelet adhesion to subendothelium, the role of vWF in human vascular disease has been a topic of investigation. An association between elevated plasma vWF levels and recurrent MI has been demonstrated, and vWF antigen is an independent predictor of coronary artery disease.[38]

Platelet polymorphisms have been evaluated as risk factors for arterial thrombosis. These include polymorphisms for glycoprotein (gp) IIIa (Pl^{A2}), gpIa (807 T allele), and gpIbα.[39] The Pl^{A2} polymorphism is linked with coronary artery disease; Pl^{A2}-positive platelets exhibit a lower threshold for activation and also have variable aspirin sensitivity.[39]

Coagulation Abnormalities

Coagulation disorders that can contribute to hypercoagulability can be divided into three risk-factor categories: Transient, inherited, and acquired.[40] *Transient risk factors* represent well-defined, temporary clinical circumstances that are associated with increased thrombosis risk both while they are present and for a short period after they have resolved. Examples include surgery, prolonged immobilization, oral contraceptive pill (OCP) use, hormone replacement therapy (HRT), pregnancy, cancer chemotherapy, and heparin-induced thrombocytopenia (HIT). *Inherited risk factors* represent genetic mutations and polymorphisms that result in deficiency of a natural anticoagulant (e.g., protein C, protein S, or AT), procoagulant factor accumulation (e.g., prothrombin G20210A), or coagulation factor resistance to inactivation by a natural anticoagulant (i.e., factor V G1691A, also known as factor V Leiden). These conditions are characterized by a disruption in the normally highly regulated coagulation mechanism, resulting in greater thrombin generation and an increased risk of clinical thrombosis. *Acquired risk factors* result either from medical conditions or from nonfamilial hematologic abnormalities that interfere with normal hemostasis or blood rheology. Examples include cancer, inflammatory bowel disease, nephrotic syndrome, vasculitis, antiphospholipid antibodies, myeloproliferative syndromes, paroxysmal nocturnal hemoglobinuria, and hyperviscosity syndromes. These acquired risk factors are distinct from transient risk factors by the fact that they represent alterations in hemostatic homeostasis as a result of disease or, for the most part, nonreversible processes. In contrast, transient risk factors result from either a therapeutic intervention or an adverse reaction to such an intervention. Hyperhomocysteinemia and increased factor VIII functional activity are examples of thrombosis risk factors that can be acquired in nature or have a genetic predisposition.[41,42] Age defies categorization but remains the single most predictable risk factor for thrombosis. The estimated baseline annual age-associated risk of VTE is 1 in 10,000 people <40 years of age, increasing to 1 in 100 people >75 years of age.[43–45]

Recent reports have focused on elevated levels of various coagulation factors, particularly fibrinogen and factors V, VII, VIII, X, and XI, that have been documented in patients with thrombosis and prethrombotic disorders, including pregnancy and use of estrogen-containing contraceptives.[46] Fibrinogen and factors V and VIII are acute-phase reactants, and their plasma levels may rise in patients with virtually any disorder associated with tissue damage or inflammation, including most thrombotic processes. Whether increased because of a genetic factor or an acute-phase reaction, excess procoagulant factor concentrations may tilt the hemostatic scales in favor of hypercoagulability and may be associated with an increased risk of thrombosis. Epidemiologic studies have identified dose-dependent elevations in plasma levels of vWF, fibrinogen, factor VII, factor IX, and factor XI as independent risk factors for cardiovascular disease.[47–50]

Fibrinolytic Abnormalities

Abnormal fibrinolysis has also been linked to vascular disease. Low fibrinolytic activity (measured by dilute clot lysis) was a significant determinant of coronary artery disease in the Northwick Park Heart Study, and elevated PAI-1 activity was associated with major ischemic events in other studies.[51,52] In the European Concerted Action on Thrombosis and Disabilities study, an increased incidence of vascular events was associated with higher baseline PAI-1 antigen concentrations ($p = .02$) and PAI-1 activity ($p = .001$).[53] Defects in endogenous fibrinolytic capacity have also been found in young patients with severe limb ischemia or unexplained arterial thromboembolism. Deficient t-PA release was found in 45% of such patients, and elevated levels of PAI-1 were found in 59%.[54] Excess PAI-1 resulting in impaired endogenous fibrinolysis has also been associated with venous thrombosis in select cases.[55]

ACTIVATION OF COAGULATION

Mechanisms leading to activation of coagulation in patients with thrombosis have been proposed. TF is thought to be the primary initiator of in vivo coagulation.[56,57] In the absence of TF expression, endothelial cells actively maintain thromboresistance. TF may be expressed in trace amounts during various physiologic processes, such as during normal parturition and after even minimal trauma, including minor head injuries. Immunologic injury of endothelium may lead to the exposure of TF.[58] Antibodies formed to exogenous heparin may bind to heparan sulfate on the endothelium, resulting in cell injury, the expression of TF, and the initiation of coagulation.[59] In a similar manner, endothelial cells may be induced to express TF by interleukin-1, homocysteine, tumor necrosis factor, and endotoxin.[60,61,62,63] TF antigen expression by endothelium has been demonstrated in pathologic primate and human tissues.[64,65,66] Activation of coagulation may also occur on monocytes, and platelets can be activated to mediate factor-Xa–catalyzed prothrombin conversion to thrombin.[67,68] Deficient hepatic clearance of activated coagulation factors may represent an important thrombogenic factor in premature infants and in patients with liver disease, especially after administration of prothrombin complex concentrates that contain trace amounts of activated vitamin-K–dependent coagulation factors.

Various other mechanisms may be responsible for low-grade in vivo coagulation under certain conditions. Certain tumor cells can promote thrombin generation directly, by producing TF, expressing the coagulation factor X activator known as *cancer procoagulant,* or displaying surface sialic acid residues that can support nonenzymatic factor X activation.[69,70] Tumor cells can also promote thrombin generation indirectly, by eliciting TF expression by monocytes and endothelial cells. Tumor-associated coagulation cascade activation can result in the generation of thrombin that can promote angiogenesis by signaling through protease-activated receptors PAR-1, PAR-3, and PAR-4. In addition to its normal role in coagulation, evidence is mounting that TF plays a direct role in growth, invasion, dissemination, and angiogenesis of tumors.[71,72] Clotting-independent signaling through the TF cytoplasmic tail can lead to vascular endothelial growth factor (VEGF) up-regulation. Because VEGF can promote TF up-regulation, the potential for a self-perpetuating proangiogenic amplification loop exists. The TF:factor VIIa complex can also activate PAR-2 directly in a manner that results in gene expression related to angiogenesis and cell migration.[72] Selected tumors may mediate an accentuation of platelet activation and accumulation, whereas other tumor cells may express surface phospholipid species such as phosphatidylserine, which can support prothrombin and factor X activation.[73]

A laboratory picture similar to that described in the hypercoagulable state may also be seen in patients with nonovert (compensated or chronic) disseminated intravascular coagulation (DIC).[74] In such patients, the prothrombin time (PT) and the activated partial thromboplastin time (aPTT) may be shortened because of the presence of traces of thrombin or other activated coagulation factors. These activated factors affect one-stage, but not two-stage, clot endpoint coagulation assays. High levels of factor V and factor VIII activity may reflect the presence of thrombin-activated forms of these factors in the circulation. Pregnancy, which can be regarded as a hypercoagulable state, has also been described as a physiologic form of nonovert DIC by some clinicians.[75] Pregnancy increases the risk of venous thromboembolism (VTE) approximately fivefold among the general population, and female patients who have experienced prior venous thrombosis have a threefold risk of venous thrombosis during pregnancy.[76] The use of estrogen-containing oral contraceptives and estrogen HRT is clearly associated with an increased risk of VTE.[77–79] A prospective study of these patients indicates that estrogens induce activation of coagulation as well as reduction in levels of natural anticoagulants

such as AT and protein S.[80] However, many patients who experience VTE while taking oral contraceptives have a common inherited thrombotic disorder, APC resistance (APC-R), or prothrombin G20210A.[81] Another report indicated that oral contraceptives induced "acquired APC-R" in women.[82] The relative risk of VTE in postmenopausal women using estrogen replacement is 2.14, and the risk is highest during the first year of use.[83] The thrombotic risk imparted by pharmacologic estrogens appears to dissipate following medication discontinuation.[84] One study found that transdermal estrogen products were safer than oral estrogens in women receiving HRT.[85] One literature review of hormonal therapy and venous thrombosis concluded that all oral estrogen-containing products used for contraception or HRT, as well as therapeutic doses of progesterone-only products increased thrombosis risk.[79] The risk of venous thrombosis is not clearly increased for the levonorgestrel-containing intrauterine device, transdermal estrogen, and tibolone.[79] Regarding the risk of thrombotic stroke and MI, a very large Danish study found that use of ethinyl estradiol increased risk by 0.9 to 2.3, depending on drug concentration in the contraceptive pill.[86] Table 55.1 summarizes acquired etiologies that predispose to thrombosis.

INHERITED THROMBOTIC DISORDERS

Several monographs and reviews have covered the topic of inherited thrombotic disorders in detail.[40,46,86,87,88] Table 55.2 summarizes the prevalence of selected inherited and acquired hypercoagulable states in different populations, whereas Table 55.3 summarizes the clinical presentations of venous thrombosis that may be suggestive of particular hypercoagulable states. Many patients who experience thrombosis are found to have a combination of defects, for example, APC-R plus use of oral contraceptive agents,[81] or a combination of inherited defects.[40]

TABLE 55.1

ACQUIRED DISORDERS PREDISPOSING TO THROMBOSIS

Vascular disorders
- Atherosclerosis
- Diabetes
- Vasculitis
- Prosthetic materials (grafts, valves, indwelling vascular catheters)

Abnormal rheology
- Stasis (immobilization, surgery, congestive heart failure)
- Hyperviscosity (polycythemia vera, Waldenström macroglobulinemia, acute leukemia, sickle cell disease)

Other disorders associated with hypercoagulability
- Cancer (Trousseau syndrome)
- Cancer chemotherapeutic agents, thalidomide, bevacizumab
- Oral contraceptives, estrogen therapy, selective estrogen-receptor modulators
- Pregnancy
- Infusion of prothrombin complex concentrates and recombinant factor VIIa
- Nephrotic syndrome
- Myeloproliferative disorders
- Paroxysmal nocturnal hemoglobinuria
- Inflammatory bowel disease
- Thrombotic thrombocytopenic purpura
- Disseminated intravascular coagulation
- Antiphospholipid antibody syndrome
- Heparin-induced thrombocytopenia/thrombosis
- Human immunodeficiency virus infection

TABLE 55.2

PREVALENCE OF SELECTED INHERITED AND ACQUIRED HYPERCOAGULABLE STATES IN DIFFERENT PATIENT POPULATIONS

Hypercoagulable State	General Population (%)	Patients with First Venous Thromboembolism (%)	Thrombophilic Families (%)
Factor V Leiden	3–7[a]	20	50
Prothrombin G20210A	1–3	6	18
Protein C deficiency	0.2–0.4	3	6–8
Protein S deficiency	N/A	1–2	3–13
Antithrombin deficiency	0.02	1	4–8
Mild hyperhomocysteinemia	5–10	10–25	N/A
Elevated factor VIII	11	25	N/A
Lupus anticoagulant	0–3	5–15	N/A
Elevated anticardiolipin antibodies	2–7	14	N/A

N/A, not available or unknown.
[a]Prevalence as high as 15% in northern Europe.

Although people with inherited hypercoagulable states are at a greater risk for developing a thrombotic event than those without such disorders, not all people with a well-defined hypercoagulable state develop an overt thrombosis, and not all people with thrombosis have an identifiable hypercoagulable state. Testing for an inherited hypercoagulable state is likely to uncover an abnormality in >60% of patients presenting with idiopathic (i.e., spontaneous or unprovoked) venous thrombosis.[89] Although the remaining

TABLE 55.3

CLINICAL PRESENTATIONS OF VENOUS THROMBOEMBOLISM THAT MAY SUGGEST CERTAIN HYPERCOAGULABLE STATES

Venous Thromboembolism Presentation	Hypercoagulable State
Cerebral vein thrombosis in women using oral contraceptives	Prothrombin G20210A mutation
Cerebral vein thrombosis in general	Paroxysmal nocturnal hemoglobinuria, essential thrombocythemia, antiphospholipid antibodies, antithrombin deficiency, PT G20210A mutation
Intra-abdominal vein thrombosis (inferior vena cava, renal vein, portal vein, mesenteric and hepatic veins)	Antiphospholipid antibodies, paroxysmal nocturnal hemoglobinuria, myeloproliferative syndromes, cancer, antithrombin deficiency
Warfarin skin necrosis	Protein C, protein S deficiencies
Unexplained recurrent fetal loss	Antiphospholipid antibodies; factor V Leiden
Recurrent superficial thrombophlebitis	Factor V Leiden, polycythemia vera, protein C, protein S, or antithrombin deficiency
Migratory superficial thrombophlebitis (Trousseau syndrome)	Adenocarcinoma (particularly of the gastrointestinal tract)
Neonatal purpura fulminans	Homozygous protein C or protein S deficiency

PT, prothrombin.

30% to 40% have unremarkable test results, this does not imply a true absence of a hypercoagulable state. Some of these individuals may have an acquired condition such as cancer or antiphospholipid antibodies, whereas others may have a disorder or genetic defect that has not yet been discovered or characterized.

Antithrombin Deficiency

AT, formally known as *AT-III,* deficiency was first described by Egeberg in 1965.[90] AT, a serine protease inhibitor, regulates coagulation by inactivating thrombin and other procoagulant enzymes, including factors Xa, IXa, XIa, and XIIa. As are most inherited thrombotic disorders, AT deficiency is inherited as an autosomal dominant disorder.[91,92] A blood bank survey reported that 1 in 600 people has AT deficiency.[93] The interactions of unfractionated and low-molecular–weight heparin (LMWH) with AT are discussed in the section "Heparin."

Pathophysiology and Genetics

Patients with AT deficiency may have either type I (quantitative deficiency) or type II (qualitative abnormality) disease. Type I AT-deficient patients usually have concordant reductions in AT measured by both immunologic and functional assays. Type II patients have reduced functional AT activity associated with normal amounts of AT protein. Plasma concentrations of the thrombin activation peptide, prothrombin fragment 1+2, are elevated in patients with AT deficiency, indicating persistent activation of coagulation as a result of deficient neutralization of factor Xa in these patients.[94]

The genetic basis for type I AT deficiency is either deletion of a gene segment or the occurrence of point mutations or deletions, resulting in a nonsense mutation and an incomplete protein. The genetic basis for type II AT deficiency is the occurrence of point mutations that do not impair synthesis of the protein, but that result in a dysfunctional protease inhibitor. A summary of AT mutations (>100) has been reported.[95] A database of AT mutations is located at: http://www1.imperial.ac.uk/departmentofmedicine/divisions/experimentalmedicine/haematology/coag/AT/. In general, mutant AT molecules exhibit deficient heparin binding, deficient protease inhibition, or both.

Clinical Aspects

AT deficiency is manifested primarily by recurrent VTE.[91,92] Almost every vein site has been reported to be involved with thrombosis in AT-deficient patients, including unusual sites such as mesenteric vessels.[96] Thrombosis may occur in the absence of precipitating factors or may result from events such as pregnancy, estrogen use, trauma, or surgery. AT deficiency can result in heparin resistance manifesting as a normal to minimally increased aPTT in patients receiving large doses of heparin.[97] However, most patients with AT deficiency do not exhibit heparin resistance, and most cases of heparin resistance are not due to AT deficiency. In family studies, venous thrombosis occurred in 85% of AT-deficient relatives before 55 years of age.[97] The estimated increased lifetime relative risk of venous thrombosis has been reported to be up to 40-fold.[98,99] An annual absolute risk of venous thrombosis of 27.5% has been reported in female carriers of AT deficiency who also use OCPs.[100] Early studies reported pregnancy-related venous thrombosis rates as high as 70% for AT-deficient women.[101,102] Most AT-deficient patients are heterozygotes and possess ~50% of normal activity levels. Although homozygotes have been reported in consanguineous kindreds, in general, homozygous type I AT deficiency is believed to be fatal in utero.[103]

Laboratory Diagnosis

Results of the PT and aPTT are normal in AT-deficient patients. A variety of commercial assays is available to measure AT levels, including functional and immunologic assays. Functional assays are preferable because they detect both type I and type II patients. One report found that 2% of patients with AT deficiency had type II disease.[104] Functional assays for AT measure heparin cofactor activity using a chromogenic substrate method to quantitate thrombin or factor Xa neutralization.[105] A potential disadvantage of functional AT assays is that plasma AT levels may be overestimated because of the presence of heparin cofactor II (HCII) in the sample. The use of bovine thrombin and a low heparin concentration (3 U/ml) in the assay system can minimize this problem.[106]

Immunologic assays for AT use Laurell rocket immunoelectrophoresis, microlatex-particle immunoassay, radial immunodiffusion, or enzyme-linked immunosorbent assay (ELISA) methods.[107] Ideally, patients should be evaluated for AT deficiency at a time when they are not receiving therapeutic heparin or oral anticoagulants, because heparin depresses AT levels, whereas long-term warfarin therapy increases plasma AT levels in some patients.[92,108] Laboratory tests for AT deficiency have been summarized.[109]

Treatment

Some AT-deficient patients may experience heparin resistance, requiring the administration of AT by using virally inactivated, plasma-derived, or transgenic AT concentrates, or fresh-frozen plasma. Supplemental AT may make it easier to achieve therapeutic anticoagulation with heparin in these patients.[110] Patients with recurrent thrombosis should receive long-term warfarin therapy at a dosage to maintain an international normalized ratio (INR) value of 2.0 to 3.0 (discussed in the section "Warfarin"). Patients with a single thrombotic event should receive at least 3 to 6 months of warfarin therapy and, because of an increased recurrence rate, should be considered for long-term therapy beyond 6 months. Patients with massive venous thrombosis or PE may be candidates for thrombolytic therapy. AT-deficient patients who become pregnant or who will undergo general surgery should be considered for anticoagulant prophylaxis, including AT concentrate administration.[110,111] Most asymptomatic patients should not be treated. The avoidance of estrogens should be considered in AT-deficient patients, who are not therapeutically anticoagulated.

Acquired Antithrombin Deficiency

AT deficiency is also associated with numerous disorders, including DIC, liver disease, nephrotic syndrome, and preeclampsia, and is seen in patients taking oral contraceptive agents and during pregnancy.[112–115] Although logic suggests that correction of AT deficiency might be clinically useful in disorders such as DIC or liver disease, there are no conclusive data supporting AT replacement therapy outside the setting of prophylaxis of high-risk patients, such as pregnant, AT-deficient patients.[116]

Heparin Cofactor II Deficiency

HCII is another heparin-dependent thrombin inhibitor, differing from AT in that a glycosaminoglycan other than heparin, dermatan sulfate, catalyzes this inhibitor of coagulation.[117] HCII deficiency is inherited as an autosomal dominant trait. Although there have been anecdotal studies of thrombosis associated with HCII-deficient kindreds, a larger study has concluded that HCII deficiency by itself may not be an inherited risk factor for thrombosis.[118–120] Commercial assays to measure HCII levels are available, but the clinical utility of such assays in routine evaluation of patients for inherited thrombosis is uncertain.

Protein C Deficiency

Protein C is a vitamin-K–dependent plasma protein that, when activated by the thrombin–thrombomodulin complex to APC,

inactivates factors Va and VIIIa to inhibit coagulation.[121] APC also possesses profibrinolytic activity that results from neutralization of PAI-3 activity.[122] Inherited deficiency of protein C and its association with thrombosis were first described by Griffin and coworkers in 1981.[123] Protein C deficiency was believed to be inherited in an autosomal dominant pattern with incomplete penetrance. More recent studies have suggested that protein C deficiency may be an autosomal recessive disorder and that coinheritance of another defect (particularly factor V Leiden) results in a high degree of penetrance that appears as the dominant inheritance in double-heterozygous carriers.[124,125]

Pathophysiology and Genetics

As with AT deficiency, patients with protein C deficiency may have type I (quantitative deficiency) or type II (qualitative abnormality) disease. Most patients are heterozygotes with ~50% of normal protein C levels. A hypercoagulable state can be demonstrated in nonanticoagulated protein-C–deficient patients using activation peptide (fragment 1+2) assays.[126]

In type I protein C deficiency, more than half of the gene mutations identified are missense mutations. Point mutations affecting protein function appear to be common in patients with type II protein C deficiency. At least 195 different gene abnormalities have been associated with both types of protein C deficiency.[127] Despite the clear association of protein C deficiency with thrombosis in large epidemiologic studies, there are also definitive data indicating that many protein-C–deficient patients are asymptomatic.[128] For example, one report found that heterozygous protein C deficiency occurred in approximately 1:250 subjects, whereas a large Scottish study estimated the prevalence to be approximately 1:500.[124,129] No patient in either study had a history of symptomatic venous thrombosis. These findings indicate that additional risk factors—acquired, genetic, or both—are necessary to provoke thrombosis in heterozygous protein-C–deficient patients. Indeed, in one study, up to 20% of symptomatic protein-C–deficient patients also had APC-R, supporting the concept that many patients with recurrent thrombosis have more than one risk factor.[125]

Clinical Aspects

Three clinical syndromes are associated with protein C deficiency: VTE in heterozygous adults, neonatal purpura fulminans in homozygous newborns, and warfarin-induced skin necrosis in certain heterozygous adults. The predominant clinical symptom of protein-C–deficient patients is recurrent VTE, although arterial thrombotic events, including stroke, have been reported.[130,131] As mentioned above, many patients are found to have risk factors other than inherited protein C deficiency on investigation, such as APC-R, use of oral contraceptive agents, and pregnancy. Protein C deficiency has also been linked to fetal loss.[132]

Neonatal purpura fulminans is seen in homozygous newborns of heterozygous parents. These children develop DIC at birth, associated with extensive venous or arterial thrombosis (or both) and very low levels of protein C (<5% of normal).[133] Warfarin-induced skin necrosis is an unusual syndrome seen in certain patients with heterozygote protein C deficiency.[134] Most patients who develop this syndrome have received large doses of warfarin in the absence of concomitant overlapping therapeutic parenteral anticoagulation. The basis for this syndrome is that warfarin therapy, especially in large loading doses, reduces protein C levels more rapidly than the vitamin-K–dependent procoagulant factors, leading to exacerbation of the basal hypercoagulable state and thrombosis.

In family studies, venous thrombosis occurred in 50% of protein-C–deficient relatives of affected probands before 40 years of age.[135] The estimated increased lifetime relative risk of venous thrombosis has been reported to be up to 31-fold.[98] As stated above, other studies did not detect an increased thrombosis risk in carriers of protein C deficiency. Differences in risk between family- and population-based studies can be in part explained by greater difficulty in obtaining reliable population-based estimates because of the overall low prevalence of this and other natural anticoagulant deficiencies. In studies of unselected patients with venous thrombosis, the odds ratio (OR) of having protein C deficiency is increased six- to ninefold compared to controls.[40,135–137] An annual absolute risk of venous thrombosis of 4.3% has been reported in women carriers of a natural anticoagulant deficiency such as protein C deficiency who also use OCPs.[100,138]

Laboratory Diagnosis

Patients with heterozygous protein C deficiency have normal PT and aPTT values, whereas patients with homozygous protein C deficiency have abnormal coagulation tests consistent with DIC. Because both type I and type II disorders may occur, functional assays are suggested to optimize identification of affected patients. Some investigators prefer the clot endpoint-based assay, because it measures complete function of the protein C molecule, including those patients with abnormal protein C molecules that possess normal activity by a chromogenic substrate assay. However, therapeutic heparin levels affect the clot-based assay. A College of American Pathologists' consensus conference on thrombophilia recommends use of the chromogenic substrate assay.[139] One report indicated that measurement of the ratio of protein C to protein S antigen was useful in identifying carriers of protein C deficiency.[140]

Protein C levels can also be measured by immunologic methods, including Laurell rocket immunoelectrophoresis and ELISA. However, immunologic assays may not detect type II patients and may overestimate protein C levels in warfarin-treated patients. Immunologic assays may be more useful in evaluating patients with homozygous deficiency and DIC.

Age-related changes occur with protein C levels.[141] Consequently, it is important to consider this when testing younger patients (<30 years); otherwise, normal subjects may be misclassified as protein C deficient.

A common problem faced by laboratories is measuring protein C levels in patients taking oral anticoagulants. Many clinicians forget that protein C is a vitamin-K–dependent molecule, and that otherwise hemostatically normal people taking warfarin may have low protein C levels. Griffin and coworkers suggested that protein C data be normalized against the level of another vitamin-K–dependent protein to distinguish inherited protein-C–deficient patients from normal subjects taking warfarin.[123] One author reported that using a ratio between protein C and prothrombin optimally categorized patients.[142] However, for this method to be useful, patients must be stably anticoagulated for at least 2 weeks, and the laboratory must obtain plasma samples and reference ranges from patients taking warfarin for reasons other than recurrent thrombosis. The consensus conference did not recommend assaying protein C levels in patients on oral anticoagulants.[139] Laboratory tests for protein C deficiency have been reviewed.[143]

Treatment

Many patients with protein C deficiency are asymptomatic, especially those identified in screening studies. Asymptomatic patients should not be treated but should be considered for prophylaxis when they experience high-risk procedures, such as surgery. Symptomatic protein-C–deficient patients should be anticoagulated with heparin and then considered for long-term secondary prophylaxis with warfarin at an INR of 2.0 to 3.0. Those patients with a single thrombotic event should receive at least 3 to 6 months of warfarin. Patients with more than one thrombotic event, patients with a single life-threatening thromboembolic event, and those with a significant family history of thrombosis should be

considered for long-term anticoagulation. Patients with massive thrombosis or PE may be candidates for thrombolytic therapy.

Infants with neonatal purpura fulminans should be treated with protein C replacement therapy. Protocols using a purified protein C concentrate or prothrombin complex concentrates have been described.[144,145] Use of the purified concentrate normalizes activation of coagulation in these homozygous patients.[146]

Acquired Protein C Deficiency

Because protein C is a vitamin-K–dependent protein, any disorder associated with vitamin K deficiency may result in protein C deficiency, including warfarin use, liver disease, and malnutrition.[147] Protein C levels are also reduced in DIC, presumably reflecting thrombin activation of the zymogen and consumption of APC.[148] Protein C levels may also be reduced in renal disease, especially the nephrotic syndrome.[149]

Protein S Deficiency

Protein S is a vitamin-K–dependent plasma protein that facilitates the anticoagulant activity of APC. Protein S deficiency in association with inherited thrombotic disease was first described by two groups in 1984.[150,151] As with AT and protein C deficiencies, protein S deficiency is inherited as an autosomal dominant trait. Many patients with a previous diagnosis of protein S deficiency actually have APC-R.[152,153] This diagnostic error results from interference in the functional protein S assay of patients with the inherited disorder, APC-R, and misclassification of patients. These patients have a "pseudo" protein S deficiency, often display a type II deficiency pattern, and have protein S activity levels that correlate with the APC ratio. Based on these reports and the high incidence of APC-R in the general population, the true importance of protein S deficiency in inherited thrombosis is uncertain.[152–154]

Pathophysiology and Genetics

As described for AT and protein C deficiencies, patients with protein S deficiency may have quantitative or qualitative disorders. Under normal circumstances, protein S exists in plasma in two forms: Bound to C4b-binding protein (60% of total protein S) and free (40% of total). Because only free protein S has APC co-factor activity, a revised classification system has been proposed for protein S deficiency.[155] Type I protein S deficiency is a quantitative disorder in which protein S functional activity, total antigen, and free antigen levels are equally reduced to ~50% of normal. Type IIa protein S deficiency is a deficiency of free protein S with preserved normal levels of total protein S. In type IIb protein S deficiency, the levels of both total and free protein S antigen are normal. Apparent type IIb protein S deficiency has been described in patients with APC-R.[154] An acquired type IIa protein S deficiency may result from excess levels of C4b-binding protein or the presence of free protein S inhibitory and clearing autoantibodies.[156] Almost 200 different mutations have been identified in the gene that codes for protein S.[95,157] A full listing of protein S gene mutations and polymorphisms can be found at www.ISTH.org.

As with protein C deficiency, many patients with protein S deficiency and thrombosis have additional risk factors. In one study, among patients with protein S deficiency, ~40% also had APC-R; of family members with thrombosis, 72% had both defects, whereas <20% of patients with single defects experienced thrombosis.[158]

Clinical Aspects

Like AT and protein-C–deficient patients, most patients with protein S deficiency and thrombosis have experienced VTE.[150,151] However, unlike most other inherited thrombotic disorders, up to 25% of patients with protein S deficiency may experience arterial thrombosis, including stroke.[131,159] As mentioned previously, many patients with protein S deficiency and thrombosis have other risk factors, including APC-R, estrogen use, or pregnancy.[158] Neonatal purpura fulminans, fetal loss, and warfarin-induced skin necrosis have also been associated with protein S deficiency.[132,160] In family studies, venous thrombosis occurred in 100% of protein-S–deficient relatives of affected probands by 70 years of age.[161] The estimated lifetime increased relative risk of thrombosis has been reported to be as high as 36-fold for protein S deficiency.[98]

Laboratory Diagnosis

Patients with heterozygous protein S deficiency have normal PT and aPTT values. The laboratory diagnosis of protein S deficiency is complicated by four factors: The levels of C4b-binding protein, the coexistence of APC-R in certain patients, elevated factor VIII activity levels, and warfarin therapy. C4b-binding protein is an acute-phase–reactant protein-S–binding protein, often elevated in thromboembolism, resulting in reduced free protein S levels from the patient's true baseline. Consequently, measurement of protein S levels in patients with acute thrombosis may yield misleading results. Similarly, false-positive results may be seen when functional protein S assays are performed on patients who have APC-R or factor VIII activity levels ≥250%.[155] Patients should not be assumed to have protein S deficiency (diagnosed by functional assay) until APC-R has been excluded. Lastly, because protein S is a vitamin-K–dependent protein, warfarin therapy and vitamin K deficiency pose the same difficulty as described for patients evaluated for protein C deficiency. Protein S levels may also be decreased in the setting of pregnancy but are not necessarily associated with thrombotic events.

Both functional and immunologic assays are commercially available to quantitate plasma protein S levels. Functional assays may be PT- or aPTT-based, measuring inhibition of factor Va by APC.[162] These assays have the advantage of measuring free protein S activity. Immunologic assays to measure either total (free plus C4b-binding–protein bound) or free protein S levels are available.[163,164] Immunologic assays may be useful in evaluating patients who have co-existing APC-R. Total protein S levels are measured by Laurell rocket immunoelectrophoresis or ELISA. In the interpretation of immunologic assays, one should consider the report that the mean plasma level of protein S antigen in males is higher than it is in females.[164]

Treatment

Asymptomatic patients should not be treated but should be considered for prophylaxis when they experience high-risk procedures such as surgery. Symptomatic protein-S–deficient patients should be anticoagulated as described for protein-C–deficient patients.

Protein Z Deficiency

Protein Z is a vitamin-K–dependent plasma protein that serves as a co-factor for activated factor X inhibition by the protein-Z–dependent protease inhibitor.[165] Reduced circulating levels of protein Z have been implicated in thrombosis.[166,167] Protein Z deficiency has also been linked to early and late fetal demise and intrauterine growth restriction.[167] Protein Z deficiency has also been found in the setting of acute coronary syndromes, whereas a deficiency state and the presence of a series of protein Z variants that modulate protein Z plasma levels have been associated with stroke.[167–170] Further data are required before routine protein Z testing can be recommended.

Activated Protein C Resistance (Factor V Leiden)

Before 1993, most patients with idiopathic venous thrombosis evaluated for inherited thrombosis were not given a diagnosis,

because AT, protein C, and protein S deficiencies together were found in <20% of patients. In 1993, Dahlback and colleagues in Sweden postulated that certain patients with recurrent thrombosis might have additional abnormalities of the protein C pathway, resulting in a hypercoagulable state.[171] They found that addition of APC to plasma obtained from patients with recurrent thrombosis did not prolong the aPTT to the same degree as that seen when APC was added to normal plasma.[171] These patients did not have any previously recognized inherited thrombotic disorder. The term *APC resistance* was used for these patients. Other investigators then used the aPTT-based APC screening test to examine other populations for this phenotype. APC-R was found in 20% to 60% of patients with recurrent thrombosis.[172–174] Like other inherited thrombotic disorders, APC-R was inherited in an autosomal dominant manner.

Pathophysiology and Genetics

APC inactivates factor Va in an orderly and sequential series of cleavages, first at Arg506, and then at Arg306 and Arg679.[175–177] Although the affected factor V cleavage site in APC-R is not directly responsible for complete inactivation of factor Va, APC cleavage at this site is necessary for subsequent proteolytic events. This "partial resistance" is explained by the fact that cleavage of factor Va by APC at Arg306 continues to occur, albeit at a slower rate.[178] In fact, factor V Arg506Gln (factor V Leiden) is inactivated 10 times more slowly than normal factor Va. This provides a pathophysiologic explanation for why factor V Leiden, although common, is a relatively weak risk factor for VTE. Because factor Va functions as a cofactor in the conversion of prothrombin to thrombin, the mutation results in greater amounts of factor Va being available for coagulation reactions, "shifting" the hemostatic balance toward greater thrombin generation.[95]

APC-R due to factor V Leiden is the most common inherited predisposition to hypercoagulability in Caucasian populations of northern European background.[95] Factor V Leiden follows a geographic and an ethnic distribution: The mutation occurs most frequently in northern and western Europe (the highest prevalences, 10% to 15%, have been reported in Cyprus, Sweden, and Turkey) but is rare in the Asian and African continents as well as in ethnic groups of Asian descent, such as Inuit Eskimos, Amerindians, Australian Aborigines, and Polynesians.[179] In the United States, factor V Leiden is most commonly seen in Caucasians (6.0%), with lower prevalences in Hispanics (2.2%), African and Native Americans (1.2%), and Asian Americans (0.45%).[180]

Factor V Leiden accounts for 92% of cases of APC-R, with the remaining 8% of cases resulting from pregnancy, oral contraceptive use, cancer, selected antiphospholipid antibodies, plasma glucosylceramide deficiency,[181–183] and other factor V point mutations. Therefore, the terms *factor V Leiden* and *APC-R* should not be considered synonymous; in fact, APC-R is an independent risk factor for VTE even in the absence of factor V Leiden.[184] It is estimated that the mutation arose in a single Caucasian ancestor some 21,000 to 34,000 years ago, well after the evolutionary separation of non-Africans from Africans (~100,000 years ago) and of Caucasoid (white Caucasians) from Mongoloid (Asians) subpopulations (~60,000 years ago).[185]

Clinical Aspects

Heterozygous carriers of factor V Leiden have a 2- to 10-fold increased lifetime relative risk of developing VTE.[98,138,172,186–190] This risk is further increased in combination with pregnancy (9-fold), OCP use (36-fold), and HRT (13- to 16-fold).[191–194] VTE is the most common clinical symptom of APC-R in patients who experience thrombosis. In general, there is a notable lack of association of APC-R with arterial thrombosis (exceptions discussed below).[188] Another clinical association with APC-R is recurrent miscarriage, with one study reporting that 20% of patients with second-trimester pregnancy loss have APC-R.[132,195] Factor V Leiden does not appear to be a cause of recurrent pregnancy loss occurring late in the first trimester.[195,196] Neonatal purpura fulminans has been reported in a patient with factor V Leiden who did not have protein C or S deficiency.[197] APC-R is also a common inherited risk factor for cerebral venous thrombosis.[198] The factor V Leiden mutation has also been identified in children who experience thrombosis.[199] However, this mutation does not appear to play a major role in the hypercoagulability of cancer.[200] An intriguing report has demonstrated that the factor V Leiden mutation is a risk factor for MI in young women; the combination of factor V Leiden with smoking increased the risk of MI more than 30-fold.[201] Factor V Leiden has also been associated with MI in individuals with coronary artery thrombosis in the absence of evidence of underlying fixed atherosclerotic lesions.[202]

There are conflicting data on the role of factor V Leiden heterozygosity as an independent risk factor for VTE recurrence.[203,204] Two studies ("positive studies") have found an increased risk of VTE recurrence compared to control subjects, with relative risk of 4.1 and 2.4, respectively. Six other studies ("negative studies") have found no such association.[205,206,207,208–210] The positive studies by Ridker et al. and Simioni et al. were prospective but included a small number of patients with factor V Leiden heterozygosity (14 and 41, respectively).[203,204] The Physicians' Health Study (by Ridker et al.) included only men.[203] Among the negative studies, four were prospective and two were retrospective.[205,206,207,208–210] Three of the prospective studies and the large retrospective cohort study by De Stefano et al. each included 80 to 112 patients with factor V Leiden heterozygosity.[205,206,208,210] A recent re-evaluation of the study by Simioni et al. did confirm the original study findings of increased relative risk of recurrent VTE in heterozygous carriers of factor V Leiden.[211] The PREVENT trial later demonstrated equivalent rates of recurrent VTE in patients with and without factor V Leiden.[212]

Homozygous carriers of the factor V Leiden mutation are estimated to have an 80-fold increased lifetime relative risk of VTE.[188] A more recent estimate, derived from a pooled analysis of a larger population, has confirmed an increased risk of VTE but of lower magnitude (10-fold).[191] The discrepancy is likely due to the very low prevalence of factor V Leiden homozygosity found in the healthy controls from the general population. Most homozygous carriers present with VTE before 40 years of age, but some can live thrombosis-free until the sixth or seventh decade of life or even remain asymptomatic for life.[213,214] The majority of VTE is situational, and women appear more likely to develop VTE than men, suggesting an important role of OCP use and pregnancy in triggering thrombosis.[213–215] Based on data from the first prospective Duration of Anticoagulation trial, the risk of VTE recurrence is significantly increased in homozygous factor V Leiden carriers (36.4% at 48 months) when compared to heterozygous carriers (16.1%) and controls (12.4%).[206]

Laboratory Diagnosis

The intense interest in this common inherited thrombotic disorder has focused substantial attention on laboratory methods for its diagnosis. Laboratory aspects of its discovery have been reviewed by Dahlback.[216] The disorder can be evaluated by coagulation assays that have as their basis inhibition of factor Va by APC and prolongation of the clotting time. Typically, APC is added to patient plasma, and a clotting assay is performed (usually the PTT), with results expressed as a ratio:

$$\frac{\text{Patient PTT} + \text{APC}}{\text{Patient PTT}}$$

Reference ranges are established for normal patients with and without addition of APC. Affected patients with mutant factor V have clotting times prolonged to a lesser extent (lower ratio) than

normals. Alternatively, a DNA test can be done to look specifically for the Arg506Gln mutation; this highly conserved point mutation is present in most patients with APC-R.

With properly collected plasma samples, the APC-R clotting test can correctly classify nearly 100% of patients, when normalized to a control plasma pool.[217] Predilution of the patient sample with factor-V–deficient plasma has improved the performance characteristics of most currently available commercial assays.[218] Samples from patients with baseline abnormal coagulation studies (e.g., anticoagulant therapy, lupus anticoagulants, liver disease) yield uninterpretable results. A TF-dependent factor V assay has been described that is useful in patients taking oral anticoagulants or with the lupus anticoagulant.[219] The polymerase chain reaction test for factor V Leiden uses the restriction enzyme *Mnl*I to digest a 267-base pair amplified fragment of patient DNA.[176] Consensus recommendations on methodologies to assay for factor V Leiden and APC-R have been presented.[220,221]

Treatment

Therapy of VTE in patients with APC-R is similar to that described for patients without an identified hypercoagulable state. Long-term secondary prophylaxis is not necessary for heterozygotes unless they experience more than one thrombotic event or experience life-threatening thromboembolism. Asymptomatic patients with APC-R should not be treated, but female patients with this disorder should be informed about the additional thrombotic risk associated with oral contraceptive use, pregnancy, and HRT.[82,222] Prophylaxis for high-risk situations, such as surgery, should be given. Homozygotes who experience VTE should be considered for long-term anticoagulation.

Prothrombin Mutations

The prothrombin G20210A mutation is the second most common inherited predisposition to hypercoagulability. Heterozygous prothrombin G20210A has been found in 18% of probands of thrombophilic families, 6% of unselected patients with deep vein thrombosis (DVT), and 2% of normal Caucasian individuals.[40,223]

More recently, a novel single-point mutation of the prothrombin gene at position 20209 has been reported in four unrelated patients, two of whom had a history of VTE and one of whom had a history of stroke.[224] Although the clinical significance of the prothrombin C20209T mutation is unknown, it may be underrecognized because it is not detected by the polymerase chain reaction/digestion assay commonly used for prothrombin gene mutation testing. Interestingly, all four reported individuals with prothrombin C20209T were African-Americans.

Pathophysiology and Genetics

Prothrombin G20210A is a single-point mutation (G-to-A substitution at nucleotide 20210) in the 3′ untranslated region of the prothrombin gene.[223] This autosomal dominant mutation results in elevated concentrations of plasma prothrombin.[223] In fact, the VTE risk increases as the plasma prothrombin level increases, with levels >115 IU/dl leading to a 2.1-fold increased relative risk of VTE.[223] The G20210A mutation leads to a "gain of function" of the prothrombin gene, perhaps by resulting in an altered polyadenylation pattern in mutant prothrombin mRNA.[225] An in vitro study of thrombin generation found that increasing prothrombin levels to 150% of normal resulted in enhanced thrombin activity.[226]

The mutation appears to follow a geographic and ethnic distribution, with the highest prevalence occurring, unlike factor V Leiden, in Caucasians from southern Europe (3%).[227] This prevalence is nearly twice that observed in northern Europe (1.7%).[227] Similar to factor V Leiden, the prothrombin G20210A mutation is also found in the Middle East and Indian regions, but it is virtually absent in individuals of Asian and African backgrounds.[227] These distributions provide support to the estimate that both mutations (factor V Leiden and prothrombin G20210A) originated relatively recently in the European founding population, after the evolutionary divergences of subpopulations. An evaluation of patients in northeast Ohio who underwent hypercoagulability evaluations revealed an equivalent prevalence of prothrombin gene mutations in whites and blacks.[224]

Clinical Aspects

Heterozygous prothrombin G20210A is associated with a two- to sixfold increased lifetime relative risk of VTE.[40,214,223,228] The risk appears to be further increased in combination with pregnancy (15-fold) and OCP use (16-fold).[191,229] The relative risk of cerebral vein thrombosis is increased 10-fold in women with this mutation who are not on OCPs, as opposed to 150-fold in OCP users.[230] Homozygosity for prothrombin G20210A has an estimated population prevalence of 0.014%, and homozygous carriers appear to have greater predisposition to develop early (before 40 years of age) idiopathic recurrent VTE than heterozygotes.[223,231,232]

The role of prothrombin G20210A as a risk factor for VTE recurrence is less controversial than it is for factor V Leiden, but data are also somewhat conflicting. Simioni et al., re-evaluating a prospective study from 1997, retrospectively determined patients' prothrombin G20210A mutation status and found that the hazard ratio of VTE recurrence was 2.4.[211] However, three prospective studies, which each included 28 to 52 patients, found no increased risk of recurrent VTE in heterozygous prothrombin G20210A carriers.[206,233,234]

A fourfold increased risk of MI has been demonstrated, particularly in young women carriers of this mutation. A large case-control study of >14,000 men, though, revealed no increased risk of stroke or MI associated with this abnormal prothrombin gene. The reasons for this apparent male/female disparity are unknown.[201,235]

Laboratory Diagnosis

The prothrombin G20210A and C20209T mutations can only be reliably and routinely identified using molecular biologic techniques. Measurements of functional prothrombin activity do not sufficiently differentiate between carriers and noncarriers of this gene mutation. Testing can be performed accurately despite concomitant treatment with any form of anticoagulation.

Treatment

Treatment paradigms for patients with prothrombin G20210A heterozygosity parallel those for patients with heterozygous factor V Leiden. Patients with concomitant prothrombin G20210A heterozygosity and factor V Leiden heterozygosity should be considered for long-term anticoagulation following a first thrombotic event.

Hyperhomocysteinemia

Homocysteine is a sulfhydryl amino acid formed during the conversion of methionine to cysteine. Hyperhomocysteinemia results when homocysteine metabolism is abnormal. Hyperhomocysteinemia has been identified as an independent risk factor for stroke, MI, peripheral arterial disease, and venous thrombotic disease.[236–238] Even mild to moderate hyperhomocysteinemia is a significant risk factor for vascular disease. However, lowering homocysteine levels with vitamin therapy has not resulted in improved outcomes in vascular disease and thrombosis.[239,240]

Pathophysiology and Genetics

The amino acid homocysteine is normally metabolized via the transsulfuration pathway by the enzyme cystathionine-β-synthase (CBS), which requires vitamin B_6 as co-factor, and via the

remethylation pathway by the enzymes methylenetetrahydrofolate reductase (MTHFR), which is folate dependent, and methionine synthase, which requires vitamin B_{12} as co-factor.[241,242] Inherited severe hyperhomocysteinemia (plasma level >100 μmol/L), as seen in classic homocystinuria, may result from homozygous MTHFR and CBS deficiencies and, more rarely, from inherited errors of cobalamin metabolism.[241,242] Inherited mild to moderate hyperhomocysteinemia (plasma level >15 to 100 μmol/L) may result from heterozygous MTHFR and CBS deficiencies, but most commonly results from the thermolabile variant of MTHFR (tlMTHFR) that is encoded by the C677T gene polymorphism.[241,242]

Acquired hyperhomocysteinemia may be caused by folate deficiency, vitamin B_6 or B_{12} deficiency, renal insufficiency, hypothyroidism, type II diabetes mellitus, pernicious anemia, inflammatory bowel disease, advanced age, climacteric state, carcinoma (particularly involving breast, ovaries, or pancreas), and acute lymphoblastic leukemia, as well as methotrexate, theophylline, and phenytoin therapy.[241,242]

The precise mechanisms underlying the thrombogenicity of homocysteine remain unclear. Several diverse mechanisms have been proposed, including endothelial cell desquamation, low-density lipoprotein (LDL) oxidation, promotion of monocyte adhesion to endothelium, and factor V activation and promotion of thrombin generation.[241,242,243] Homocysteine also enhances platelet aggregation and adhesiveness as well as turnover, presumably as a result of endothelial cell injury.[244] One study found that moderate hyperhomocysteinemia does not impair the activation of protein C by thrombin and does not impair the inactivation of factor Va by APC.[245]

Severe homocysteinemia usually results from homozygous CBS deficiency. The incidence of this disorder is ~1 in 335,000 live births. Classic symptoms for homozygous patients include premature vascular disease and thrombosis, mental retardation, ectopic lens, and skeletal abnormalities.[246] Heterozygous homocysteinemia has been recognized as a disease entity; this disorder may affect 0.3% to 1.0% of the general population.[246]

Clinical Aspects

Heterozygous carriers of the tlMTHFR mutation have normal plasma homocysteine levels unless folate levels are reduced.[247] More important, the majority of case-control studies have not demonstrated an increased VTE risk in homozygous carriers of the tlMTHFR, and the majority of individuals with hyperhomocysteinemia do not have the tlMTHFR polymorphism. Thus, characterization of the tlMTHFR polymorphism is not useful to determine an individual's VTE risk. VTE risk is most closely related to elevated fasting plasma homocysteine levels, regardless of etiology. Hyperhomocysteinemia (plasma level >18.5 μmol/L) has been associated with a two- to fourfold increased VTE risk.[248,249] It is interesting that, in the Physicians' Health Study, hyperhomocysteinemia (plasma level above the 95th percentile; 17.2 μmol/L) did increase the risk of idiopathic VTE (relative risk, 3.4) but not the risk of all (transient and idiopathic) VTE.[189]

The majority of reports linking hyperhomocysteinemia to thrombosis have focused on venous thromboembolic disease. Kottke-Marchant et al. compared 23 patients with documented arterial peripheral thrombosis to age- and sex-matched controls.[250] Elevated homocysteine levels (>13 μm/L) conferred an OR of 7.8 for thrombosis. Elevated homocysteine levels were found in 73% of cases versus 28% of controls. Only smoking and homocysteine level were independent risk factors for arterial thrombosis. Currie et al. evaluated homocysteine and cardiovascular risk factors in 66 adult patients with vascular disease. Hyperhomocysteinemia was identified in 29% of patients and was an independent risk factor for the failure of vascular procedures ($p = 0.006$).[251]

Laboratory Diagnosis

The initial step in the evaluation of the patient with suspected hyperhomocysteinemia involves measurement of fasting total plasma homocysteine (the sum of nonprotein-bound and protein-bound).[241] Many laboratories report homocysteine values in reference to published "normal" ranges such as 5 to 15 μm/L, but, ideally, a local, laboratory-specific normal range should always be established. A normal value in the nonfasting setting does not normally require repeating. Testing 2 to 8 hours after an oral methionine load (100 mg/kg) increases the sensitivity of detecting occult vitamin B_6 deficiency and obligate heterozygotes for CBS deficiency,[252] but methionine loading is not routinely recommended.[253] Vitamin B_{12} and folate deficiency do not affect post-methionine loading homocysteine values. In patients found to have elevated levels of homocysteine, testing for vitamin B_{12} deficiency is advocated to avoid missing subclinical deficiency before beginning oral folic acid therapy. Methodologies to measure homocysteine levels have been reviewed.[254]

Treatment

Folic acid supplementation is the mainstay of effective hyperhomocysteinemia therapy.[241] A recent meta-analysis of 1,114 patients enrolled in 12 randomized studies of vitamin supplementation to lower homocysteine levels demonstrated a 25% reduction in homocysteine levels, with similar effects across a dosage range from 0.5 to 5.0 mg daily.[255] The usual recommended dose is 0.4 to 1.0 mg daily. Whether patients who are not responsive to one dose benefit from an escalation in dose is unclear. Because patients with subclinical vitamin B_{12} deficiency may be prone to developing peripheral neuropathy if they receive folic acid supplementation alone, additional treatment with 0.5 mg/day of oral vitamin B_{12} has been advocated. In the same meta-analysis, an additional 7% reduction of homocysteine levels was noted with vitamin B_{12} supplementation.[255] Vitamin B_{12} administration results in normalization of homocysteine levels in B_{12}-deficient individuals. In these patients, a monthly intramuscular injection of 200 to 1,000 μg of vitamin B_{12} is considered adequate replacement. Vitamin B_6 supplementation did not appear to have any effect on homocysteine levels. Betaine, a nutritional supplement derived from beets, functions as an alternative methyl donor in the remethylation of homocysteine to methionine. Betaine has been used in individuals with homocystinuria and may facilitate homocysteine reduction in individuals who are not responsive to folate and vitamin B_6.[256]

Thrombotic events in hyperhomocysteinemic patients should be treated as described for other inherited disorders. An additional treatment strategy is to lower plasma homocysteine levels, with the hope of alleviating a risk factor for recurrent thrombosis. However, results of the Heart Outcomes Prevention Evaluation (HOPE)-2 trial and Norwegian Vitamin (NORVIT) trial do not support the utility of homocysteine lowering in patients with arterial disease.[257,258] In patients with a history of coronary artery, cerebrovascular, or peripheral artery disease, or diabetes with at least one risk factor for atherosclerosis, lowering plasma homocysteine levels with folic acid and B vitamins did not reduce risk for the composite endpoint of MI, stroke, or death from cardiovascular causes more than placebo despite a 22% reduction in plasma homocysteine.[257] In NORVIT, folic acid and vitamin B_{12}, with or without vitamin B_6, did not reduce risk for the composite endpoint of MI, stroke, or death from coronary artery disease in patients with an index MI.[258] Other clinical trials have also failed to show a cardiovascular benefit of lowering homocysteine levels.[239,240] Secondary analysis of the HOPE-2 trial regarding effects of vitamin therapy on VTE risk found that there was no significant risk reduction in VTE with vitamin therapy.[259] These trials yielding negative results with vitamin therapy raise questions about the utility of testing and treating homocysteinemia.

Increased Factor VIII Activity

It is now appreciated that elevated levels of procoagulant coagulation factors, in addition to deficiencies of natural anticoagulant proteins, are risk factors for VTE. Factor VIII levels >1.5 IU/ml (150%) are associated with a threefold and a sixfold greater relative risk of VTE when compared to levels <1.5 IU/ml (150%) and <1.0 IU/ml (100%), respectively.[260] VTE risk is increased 11–fold with levels >200%, but it does not appear to be accentuated by concomitant OCP use.[261,262] Elevated activity levels of factor VIII associated with VTE risk seem to be persistent and not solely attributable to acute-phase response.[263] Transiently elevated factor VIII levels associated with acute-phase protein release, though, may in part explain the hypercoagulability associated with inflammatory disorders such as inflammatory bowel disease and cancer. Individuals with plasma factor VIII activity >234% (above the 90th percentile cutoff point for the study population) have a 6.7-fold increased relative risk of recurrent VTE compared to those with activity levels of <120%.[42]

Because factor VIII is indeed an acute-phase reactant and its levels can be affected by many factors, including blood type and vWF concentration, determination of the true meaning of an elevated factor VIII level in an individual patient with VTE is challenging. In the study by Koster et al., in which blood samples for factor VIII activity were obtained a minimum of 6 months after the VTE, it was impossible to distinguish completely between inherited elevation and postthrombotic, transient elevation of factor VIII.[260] Nonetheless, the fact that an increased factor VIII level is prevalent in persons with VTE may, in fact, imply that elevated factor VIII is not only frequent, but also an important risk factor for VTE.[214] More recent studies support the concept that elevated factor VIII levels are a significant risk factor in asymptomatic individuals for both arterial and venous thrombosis.[264,264a] The College of American Pathologists' consensus conference recommendations are not to routinely measure factor VIII levels in patients with venous or arterial thrombosis.[265]

Increased Levels of Factors IX, X, XI, and XIII

The Longitudinal Investigation of Thromboembolism Etiology study investigated the possible role of elevated factors IX, X, XI, and XIII in VTE risk[266] and found that of these coagulation proteins, only elevated factor XI levels were associated with VTE risk. Elevated factor XI levels have also been linked to stroke[267] and coronary disease.[268] This effect of elevated factor XI levels may be mediated by increased fibrin formation and decreased fibrinolysis.[269]

Impaired Endogenous Fibrinolysis

The endogenous fibrinolytic system is comprised of plasminogen, PAs, and antifibrinolytic regulatory proteins. Intravascular plasminogen is converted to the active fibrinolytic enzyme plasmin primarily by t-PA derived from vascular endothelial cells and by urokinase-type PA (u-PA) from leukocytes. The principal physiologic inhibitor of t-PA is PAI-1, whereas plasmin itself is inactivated by circulating and thrombus-bound α_2-antiplasmin, and to a lesser extent, α_2-macroglobulin. Decreased endogenous fibrinolytic activity as a result of qualitative and quantitative abnormalities of plasminogen, an inadequate release of t-PA in response to vascular injury, and excessive production of PAI-1, such as is found in inflammatory and malignant diseases, can result in impaired endogenous fibrinolysis and accumulation of pathologic thrombus.[270]

Abnormal fibrinolysis was previously thought to account for a large proportion of patients with inherited thrombosis. However, the discovery of APC-R as a common inherited disorder and a literature review that concluded that a causal relationship between abnormal fibrinolysis and inherited thrombosis had not been clearly demonstrated diminished enthusiasm for routinely evaluating patients with recurrent thrombosis for abnormal fibrinolysis.[271] However, newer data from the Leiden Thrombophilia Study indicate that reduced plasma fibrinolytic potential is a risk factor for venous thrombosis,[272] and another group identified an elevated level of thrombin-activatable fibrinolysis inhibitor (TAFI) as a risk factor for recurrent venous thrombosis.[273] Additionally, elevated levels of α_2-antiplasmin are linked to increased risk of MI,[274] and elevated levels of PAI-1 are associated with venous thrombosis.[275]

Plasminogen Deficiency

Quantitative and qualitative abnormalities of plasminogen have been reported in patients with recurrent venous thrombosis.[276,277] Quantitative deficiency is inherited as an autosomal dominant disorder, whereas qualitative plasminogen defects (dysplasminogenemia) are usually inherited as autosomal recessive disorders. Dysplasminogenemia is more common in Japanese subjects, and a single mutation accounts for >90% of cases in this population.[278] Two reports have suggested that quantitative plasminogen deficiency[279] and dysplasminogenemia[280] may not be risk factors for thrombosis, and a recent large series of 50 patients with quantitative plasminogen deficiency found the major clinical manifestation to be ligneous conjunctivitis; venous thrombosis was not observed.[281] The College of American Pathologists Consensus Conference on Thrombophilia does not recommend routine assay for plasminogen deficiency in thrombophilia patients.[282]

Tissue Plasminogen Activator Deficiency

Defective synthesis or release of t-PA from the vessel wall represents a potential mechanism for thrombosis. Plasma t-PA activity is unstable, and for accurate assays, citrated plasma samples must be immediately acidified and red blood cells removed.[283,284] Addition of a platelet activation inhibitor to the blood collection tube may help reduce the release of platelet-derived PAI-1, which can interfere with t-PA activity quantification. A plasminogen-chromogenic substrate assay is used to measure t-PA activity; t-PA antigen can be measured by ELISA using citrated plasma. The CAP Consensus Conference on Thrombophilia does not recommend routine assay for t-PA deficiency in thrombophilia patients.[282]

Increased Plasminogen Activator Inhibitor-1 Levels

Increased levels of PAI-1 have been associated with venous or arterial thrombosis. Plasma PAI-1 activity is measured in citrated plasma using a back-titration method with single-chain t-PA.[285] Because blood fibrinolytic activity exhibits a diurnal rhythm (decreased fibrinolysis in the morning as a result of peak PAI-1 levels; increased fibrinolysis in the evening as a result of low PAI-1 levels), plasma samples should be obtained at standardized times, such as between 8:00 and 9:00 a.m..[286] In addition, because fibrinolytic component levels can be affected by acute-phase changes, patients should not be evaluated for abnormal fibrinolysis until 2 to 3 months after an acute thrombotic event.

In the European Concerted Action on Thrombosis and Disabilities study, an increased incidence of vascular events was associated with higher baseline PAI-1 antigen concentrations ($p = .02$) and PAI-1 activity ($p = .001$).[53] Elevated levels of PAI-1 may effectively reduce t-PA activity levels, thereby blocking the activation of plasminogen to plasmin and inducing impaired fibrinolysis that may ultimately lead to thrombosis. Theoretically, markedly elevated levels of PAI-1 might also impair attempts at pharmacologic thrombolysis in the setting of acute arterial and venous thrombosis.[287] Defects in endogenous fibrinolytic capacity have also been found in young patients with unexplained arterial thromboembolism. Deficient t-PA release was found in 45% of such patients, and elevated levels of PAI-1 were found in 59%.[54]

Similar defects have been detected in individuals with recurrent venous thrombosis.[275] It has been noted that patients who have undergone major surgical procedures might experience a transient "fibrinolytic shutdown" as a result of elevated PAI-1 levels as part of an acute-phase response.[288]

Avoidance of obesity and associated insulin resistance, correction of hypertriglyceridemia, cessation of smoking, and exercise may improve the innate fibrinolytic status.[53,289,290] Treatment of hypertension with angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists has been associated with significantly reduced PAI-1 production.[291,292] The lipid-lowering agent gemfibrozil has also been shown to decrease the PAI-1 synthesis rate.[293] Modest alcohol consumption and hormone replacement treatment in postmenopausal women also seem to be beneficial.[294,295]

Dysfibrinogenemia

The clinical and biochemical aspects of dysfibrinogens are reviewed in Chapter 53. In general, dysfibrinogens associated with thrombosis have as their molecular defect generation of an abnormal fibrin that is resistant to fibrinolysis. An updated summary of dysfibrinogen molecular abnormalities is presented at www.ISTH.org. Dysfibrinogenemia as a cause of inherited thrombosis is uncommon.

Certain patients with dysfibrinogenemia may have a prolonged PT; more typically, these patients are detected by prolonged thrombin and reptilase times, suggesting a defect in the conversion of fibrinogen to fibrin.[296] Confirmation of a dysfibrinogen can be done by simultaneous measurement of functional and immunologic fibrinogen levels. Typically, immunologic levels are found to be higher than levels measured by functional assay. Published data for the healthy population indicate that for fresh plasma samples, the ratio of immunologic to functional fibrinogen ranges from 1.12 to 1.65; ratios >1.65 are suggestive of dysfibrinogenemia.[297]

Another potentially useful test to evaluate patients for dysfibrinogenemia is the fibrinogen lysis time. This test requires partial purification of the patient's fibrinogen, followed by clotting and lysis in a standardized assay.[298] Dysfibrinogens may also result in a false positive test for fibrin(ogen)-degradation products (FDPs) as assayed by latex agglutination, because residual fibrinogen remains in serum after clotting and is detected by the antibody-coated latex beads. An algorithm for the laboratory diagnosis of dysfibrinogenemia has been reported.[299]

Thrombomodulin Deficiency

Thrombomodulin complexed with thrombin is required to activate protein C. In theory, thrombomodulin deficiency should result in hypercoagulability. A number of mutations in the thrombomodulin gene have been identified in patients with venous thrombosis and their families.[300] Routine laboratory testing for this disorder is not yet available, but an Italian study of thrombosis patients indicated that thrombomodulin deficiency is not a common cause of thrombosis.[301] Thrombomodulin gene mutations have been linked to MI.[302] In the prospective Atherosclerosis Risk in Communities study, soluble thrombomodulin levels had a graded inverse association with, and were a good predictor of, coronary artery disease.[303] The levels correlated in their extreme quartiles with the coagulation activation marker prothrombin fragment 1+2.[303]

Lipoprotein(a)

Lipoprotein(a) (Lp[a]) is a lipoprotein moiety similar to LDL cholesterol in core lipid composition, and it has apolipoprotein (apo) B-100 as a surface apolipoprotein. In addition, Lp(a) has a unique glycoprotein, apo(a), which is bound to apoB-100. Apo(a) is structurally similar to plasminogen but lacks fibrinolytic activity.[304] Lp(a) has both atherogenic and thrombogenic properties. Its thrombogenic effect is derived from stimulation of PAI-1 synthesis, promotion of intercellular adhesion molecule-1 expression by vascular endothelium, inhibition of both plasminogen and t-PA binding to fibrin, inhibition of plasminogen activation by t-PA, and competition with plasminogen for binding sites on endothelial cells and fibrin.[305] The cumulative effect is impaired activation of plasminogen to plasmin at the vessel wall, inhibition of fibrinolysis, and increased risk for thrombosis.

The exact mechanisms that control Lp(a) levels are unknown, but genetic factors that regulate hepatic synthesis of apo(a) are likely important. One's plasma Lp(a) level is stabilized during infancy and maintained throughout life.[306] Plasma concentrations >20 mg/dl seem to increase the risk of coronary artery disease, peripheral arterial occlusive disease (PAOD), and stroke.[305] Lippi et al. evaluated Lp(a) in 68 patients subjected to vascular and endovascular surgery.[307] Significant restenosis or reocclusion occurred in 23 (34%) patients. Lp(a) concentrations were significantly higher in those with restenosis and reocclusion compared with those in the no-restenosis group. Occlusive complications were unlikely to occur in patients with Lp(a) concentrations <5 mg/dl.[307] Different isoforms of the apo(a) component of Lp(a) have different atherogenic potential and possibly different thrombogenic potential.

Measurement of Lp(a) should be considered mainly in individuals with atherosclerosis in the absence of classic risk factors, rapidly progressive atherosclerotic lesions despite aggressive risk factor modification, and individuals with acute arterial thrombosis.[306,308] Because it is an acute-phase reactant, an elevated Lp(a) level must be carefully interpreted if drawn shortly after surgery, acute thrombosis, or acute coronary syndromes.[309]
