The NOTCH pathway is mutated in the majority of T-ALL patients. NOTCH1 is a regulatory protein that is important in many cell fate decisions, including commitment to T-cell lineage and choice of $\alpha\beta$ lineage.[251,252,253] It was first cloned from a t(7;9)(q34;q34) translocation occurring in a T-ALL patient that involved *NOTCH1* on chromosome 9q34 and the T-cell receptor β-chain gene on chromosome 7q34.3.[254] The t(7;9) translocation turned out to be rare in T-ALL but targeted sequencing revealed that over 60% of T-ALL patients have activating mutations in *NOTCH1*.[255] NOTCH1 is synthesized as a single polypeptide protein that is cleaved in the Golgi at site S1 into two subunits, the ligand-binding N^{EC} (extracellular) and N^{TM} (transmembrane), which bind noncovalently at the heterodimerization domain. Upon ligand binding to N^{EC}, N^{TM} is cleaved at site S2 by a metalloprotease, and cleaved at S3 by regulated intramembrane proteolysis catalyzed by a multiprotein enzyme, the gamma (γ) secretase.[256] The remaining intracellular portion, ICN1, translocates to the nucleus, where it acts as a transcriptional regulator with the DNA-binding protein CSL and with coactivators of the Mastermind-like family.[257] The majority of the activating mutations in *NOTCH1* found in T-ALL occur in the heterodimerization domain or in the PEST domain.[255] The PEST domain regulates the turnover of NOTCH1. Therefore, the heterodimerization domain mutants uncouple NOTCH1 activation from ligand binding and the PEST domain mutants increase NOTCH1 protein stability.[255] The NOTCH1/CSL complex has numerous transcriptional targets that affect diverse pathways required for cell transformation; among these, *MYC* and *HES1* appear to be important for T-cell leukemogenesis.[258,259,260,261] The *FBXW7* gene is mutated in T-ALL and fits into the NOTCH pathway since it encodes a component of a multiprotein E3 ubiquitin ligase that targets NOTCH1, MYC, and CCNE for degradation.[262,263,264] Inactivating mutations in *FBXW7* are present in 9% to 16% of T-ALL patients.[265,266] The unique proteolytic pathway leading to activated NOTCH1 can be targeted by small molecule inhibitors of the gamma-secretase enzyme that is required for S3 cleavage.[267,268,269] These inhibitors have been used in clinical testing; however, since NOTCH1 regulates cell fate decisions for intestinal epithelial cells, patients have experienced significant gut toxicity.[267]

Transcription Factors

TAL1 and LMO Factors

Class B bHLH transcription factors, *TAL (SCL)* (T-cell acute lymphoblastic leukemia 1/stem cell leukemia), *TAL2, LYL1,* and *OLIG2* are frequently deregulated in T-ALL.[241] The *TAL1* gene is deregulated in 25% of T-ALL. *TAL1* was originally cloned from a translocation, t(1;14)(p32;q11), present in 3% of patients with T-ALL.[270] In the translocation, the breakpoint is 5′ to the coding region of *TAL1* on chromosome 1, and the translocation places *TAL1* under the regulation of the T-cell receptor α/β genes on chromosome 14.[271,272] A second series of rearrangements that occurs in 26% of patients with T-ALL results in deletion of 90 to 100 kb of DNA from the 5′ upstream region of *TAL1,* placing the gene under the control of the upstream constitutively active *SIL* promoter.[273] In both cases, the coding region of *TAL1* is intact, unlike the fusion proteins that are usually expressed in other acute leukemias. Also, in some cases of T-ALL, overexpression of TAL1 occurs when there is no evident gene rearrangement by Southern blot analysis, suggesting a mutation in regulatory sequences.[274]

During development, TAL1 is expressed in early hematopoietic elements, in both the yolk sac blood islands and the definitive blood cells of the AGM region and fetal liver.[275] Postnatally, it is expressed in erythroid, megakaryocyte, and mast cell lineages, but not in T cells. In nonerythroid cells, TAL1 is expressed in stem cells but is not expressed as the cells differentiate; however, in erythroid cells, TAL1 expression increases with early erythroid differentiation but decreases with terminal differentiation.[276] The essential role of *TAL1* in hematopoietic development is demonstrated by mice made null for *Tal1;* embryonic lethality occurs due to a total deficiency in hematopoietic progenitors.[277,278] Conditional gene targeting experiments using the Lox-Cre system to delete *Tal1* in adult mice demonstrate that continued expression

TABLE 72.6

FUNCTIONAL CLASSES OF GENES MUTATED IN T-LYMPHOBLASTIC LEUKEMIA

Gene Class	Frequency (%)	Oncogene or Tumor Suppressor
Cell cycle genes	85	*CDKN2A, RB1, TP53, CDKN1B*
Notch and its targets	70	*NOTCH1, FBW7, MYC*
bHLH and partners	35	*TAL1, TAL2, LYL1, OLIG2, LMO1-3*
Homeobox genes	35	*TLX1, TLX3, HOXA* cluster, *MLL, CALM*
Other transcription factors and chromatin modifiers	5–15	*MYB, BCL11B, PHF6, EZH2*
Cytokine and signal transduction	5–15	*ABL1, FLT3, IL7R, JAK1, LCK, NRAS, IGF1R*

The frequency shown is the estimated mean of all the frequencies reported for each individual gene mutation in a given class.

of TAL1 is not necessary for maintenance of HSCs, but it is necessary for erythrocyte and megakaryocyte differentiation.[279]

TAL1, like LYL1, OLIG2, and TAL2, binds E-box sequences in DNA by heterodimerizing with class I bHLH transcription factors TCF3. Tandem E boxes or E-box GATA sequences can be bound by two TAL1/TCF3 heterodimers that are bridged by LIM-domain-only 1 or 2 (LMO1/2) proteins. Interestingly, *LMO1-3* genes are also important drivers of T-ALL which can be deregulated by chromosomal rearrangements with T-cell receptor genes and other mechanisms.[216,280,281] Other TAL1 protein partners include GATA1, LDB1, coactivators p300 and pCAF, and corepressors mSin3A and HDAC1.[282,283] Interestingly, LMO2 can be coimmunoprecipitated with TAL1 from T-ALL cell lines,[284] and mice overexpressing both Tal1 and Lmo2 develop T-ALL with shorter latency than transgenic mice overexpressing either gene alone, providing evidence for cooperativity.[285–287] The transcriptional targets of activation or repression by TAL1 that are required for T-ALL have not been fully elucidated.[288,289,290] Alternatively, TAL1 may act as a dominant negative inhibitor of the TCF3 transcription factors.[291,292] Human and murine T-ALLs induced by bHLH or *LMO* gene overexpression show repression of TCF3 target genes.[293] LYL1, OLIG2, and TAL2 may all behave similarly to TAL1 in that they cooperate with LMO proteins to regulate gene expression, although LYL1-overexpressing T-ALLs are more immature in the T-cell differentiation hierarchy than TAL1-overexpressing T-ALLs.[294,295,296,297] The expression of these bHLH genes was quantified in a large panel of T-ALLs showing mutually exclusive expression patterns, which also argues for functional redundancy in leukemia pathogenesis. Interestingly, LYL1 and TAL1 are also functionally redundant in the maintenance of adult hematopoietic stem and progenitor cells.[244,298]

Homeodomain Proteins

The homeobox genes are a major group of genes deregulated in T-ALL, mutually exclusive to the bHLH genes and LMO genes discussed above.[244] *TLX1* (*HOX11*) is overexpressed by chromosomal rearrangement or other mechanisms in 7% of T-ALL.[242,299] *TLX3* (*HOX11L2*) is deregulated most commonly by a t(5;14)(q35.1;q32) in 20% of adult T-ALL cases.[300,301] Finally, the *HOXA* gene cluster is deregulated in 5% of T-ALL cases by inv(7)(p15.2q34) and other transcriptional mechanisms.[302–304] TLX1-overexpressing T-ALLs have a distinctive block at the cortical stage of T-cell differentiation. Recent data using transgenic mice overexpressing *Tlx1* show that the protein may repress mitotic checkpoint genes, leading to aneuploidy, and may disrupt the normal factors needed for T-cell receptor α rearrangement.[305,306] MLL and its fusion partners *PICALM* and *MLLT10* are rearranged and overexpressed in 5% to 10% of T-ALL cases and may function by deregulating the expression of the *HOXA* gene cluster.[140,304,307,308]

Other transcription factors mutated in T-ALL include the *MYB* oncogene, which is duplicated in 8.4% of T-ALL cases as analyzed by array CGH and fiber FISH studies.[309,310] Array CGH, SNP arrays, and sequencing revealed deletion or missense mutation in the *BCL11B* gene in 9% of T-ALL patients.[311] *Bcl11b* knockout mice show major defects in T-cell differentiation consistent with a role in T-cell progenitor transformation.[312] Loss of function mutations were found in *PHF6,* a transcription factor gene encoded on Xq26. This finding was very intriguing in that the mutations were 10-fold more prevalent in males than females, which correlates with the higher prevalence of the disease in males; however, the *PHF6* mutations were highly concordant with *TLX* gene deregulation and uncommon in TLX-negative cases.[313] *EZH2* and *SUZ12* loss of function mutations occur in 25% of T-ALL cases. These two genes encode protein components of the PRC2. PRC2 is responsible for methylation of Lysine-27 on histone H3, a mark associated with silenced genes.[314]

Mutations in Signaling Pathways

T-ALL, like most acute leukemias, harbors mutations predominantly in transcription factors. These proteins are difficult therapeutic targets in comparison to cytokine receptors and signal transducing tyrosine kinases. The latter group of genes was very recently implicated in T-ALL with targeted sequencing approaches. For example, gain of function mutations in the *IL7R* gene have been described in 5% to 10% of T-ALL patients.[295,315,316] Some of the missense substitutions in *IL7R* introduce a cysteine residue in place of the wild-type amino acid in the JM domain. This creates a disulfide bond linking two receptors, resulting in constitutive phosphorylation of STAT5 and other downstream substrates.[316] The IL7R protein utilizes the nonreceptor tyrosine kinases, JAK1 and JAK3, for signal transduction, and these too are mutated in 5% to 10% of T-ALL cases.[295,317,318,319] *FLT3*-ITD mutations similar to those found in AML are also found in T-ALL. *NRAS* mutations have also been described in ~10% of patients.[181,320,321] The *ABL1* gene is amplified involving simple translocations and complex rearrangements in 5% to 10% of T-ALLs.[322] Mutations in signaling pathways are more common in early T-cell precursor ALL, a form of T-ALL that is resistant to induction chemotherapy and prone to relapse.[295,296]

Some of the oncogenes and tumor suppressor genes involved in T-ALL pathogenesis are also targeted by a group of microRNAs, offering yet another pathway toward regulation of expression.[323,324]

SUMMARY

This chapter has reviewed the major translocations found in acute leukemia, with a focus on understanding the function of the fusion proteins encoded by the translocated genes. In addition, genes that are common sites of point mutations or deletions in acute leukemia are reviewed. A major theme has been alteration of transcriptional regulation. A major focus of future research will be identification of downstream targets of these aberrant transcription factors. Study of the aberrant transcription factors resulting from translocations and mutations has increased our understanding of the importance of histone acetylation, deacetylation, and methylation in transcriptional regulation. Study of mutated tyrosine kinases present in leukemia led to the first specifically engineered kinase inhibitor for the therapy of CML and Ph^+ ALL. Kinase inhibitors have also been developed for the relatively common mutant FLT3 protein present in AML. This is a truly exciting time for hematologic oncology, where elucidation of the pathogenesis of acute leukemia is leading to development of new therapeutic agents. However, powerful genomic methods have revealed the incredible complexity of the mutational events necessary for the development of acute leukemia.

CHAPTER 73

DIAGNOSIS AND CLASSIFICATION OF THE ACUTE LEUKEMIAS AND MYELODYSPLASTIC SYNDROMES

Daniel A. Arber, Attilio Orazi

INTRODUCTION

The diagnosis and classification of acute leukemias and myelodysplastic syndromes (MDSs) has grown increasingly complex.[1,2] Cases can no longer be fully classified by the use of only morphologic evaluation and cytochemical studies. Historic information, such as the presence of Down syndrome, prior therapy, or prior MDS all impact the final diagnosis. Additionally, immunophenotypic studies are needed for many cases; and cytogenetic, with possible molecular genetic, studies are required for essentially all cases.

This increase in complexity in the evaluation of these neoplasms has resulted in more precise diagnostic categories and recognition that the broad categories of acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), and MDS actually represent heterogeneous groups of diseases. The newer disease categories are more predictive of outcome than older classification systems, in part because of their ability to separate disease groups within each category.[3–6] Unfortunately, many physicians continue to use older terminology for these diseases, relying on terminology from the French-American-British Cooperative Group (FAB) classification[7,8,9,10] of these neoplasms. While the FAB classification provided firm diagnostic criteria and useful terminology for communication of findings using the methods available at the time, its use is no longer appropriate. The third (2001) and fourth (2008) editions of the World Health Organization (WHO) classification of hematopoietic tumors have dramatically changed the approach to diagnosis of many of these neoplasms, and the WHO system should be considered the current standard of care. Modifications from the LeukemiaNet group and others will certainly continue to aid in the refinement of our classification systems.[11,12,13] This evolution from the FAB to the WHO is reminiscent of changes in lymphoma classification with evolution from the Rappaport[14] and Kiel[15] classifications to the Working Formulation[16] to the REAL[17] classification and finally to the WHO classification.[2,18] Perhaps because the changes in lymphoma classification were more stepwise with shorter time intervals between the changes than the leukemia classification changes, they have been more widely adopted. We no longer refer to diffuse large B-cell lymphoma as histiocytic lymphoma and should no longer refer to AML with t(8;21)q22;q22) as M2, or to B-lymphoblastic leukemia with *BCR-ABL1* as L2.

Several discoveries have impacted the classification of these neoplasms and many of them are covered in great detail in other chapters, but genetic discoveries associated with the acute leukemias and MDSs are probably the most significant. The finding of recurrent cytogenetic abnormalities with prognostic significance impacts all of these diseases.[19,20,21–24] While balanced translocations are more common in the acute leukemias, the presence of single and complex abnormalities in the MDS has helped define disease prognosis as well as defining a specific disease category of MDS with isolated del(5q).[5,6] The more recent discoveries of specific gene mutations have further impacted both acute leukemia and MDS diagnosis.[13,25–31] While many of these mutations have their greatest frequency in AMLs with a normal karyotype, others offer prognostic significance that complements other morphologic and karyotypic features.

The classification of AML and MDS has also been impacted greatly by the understanding of similarities between the two. The so-called myelodysplasia-related AML and de novo AML described by Head[32] helped lead to a new way of thinking about this disease; especially AML occurring in older patients.

This chapter will highlight key classification issues in the acute leukemias and MDSs, which are discussed in detail in the chapters that follow.

DIAGNOSTIC EVALUATION

The diagnostic approach to acute leukemia and MDSs still begins with a morphologic evaluation, but requires careful integration of the morphologic findings with clinical information and relevant laboratory data, including cytogenetic and molecular results.[33] Laboratory data, particularly results of a recent complete blood count (CBC) must be reviewed with the samples. Morphologic evaluation requires a well-stained (usually Wright-stained) peripheral blood (PB) smear prepared from a recent sample (less than 2 hours from procurement). A 200-cell manual differential count is required for PB smears. The bone marrow (BM) aspirate smears are best prepared at the bedside immediately after procurement and promptly stained. The review of BM aspirate smear includes a 500-cell differential count. In patients with inaspirable marrow, touch preparation of the BM biopsy can be used in lieu of an aspirate smear. The BM biopsy is usually stained with hematoxylin and eosin (H&E) or Giemsa and is useful in many settings.[34] The morphologic assessment allows for the appropriate use of ancillary tests in these disorders. Details of the ancillary tests used for the workup of the various diseases are provided in Chapters 2 through 4 and will not be repeated here.

Cytochemical studies are still performed at many institutions and can often provide quick general information about the cell type of an acute leukemia (myeloid versus myeloperoxidase negative), but because more detailed information can now be obtained by flow cytometry in the same time frame, the use of these less specific cytochemical studies has decreased. Immunophenotyping, usually by multicolor flow cytometry, is now standard for acute leukemias and is absolutely required to accurately diagnose the lymphoblastic leukemias and some AMLs.[7,11,12,35,36] In cases of acute leukemia with marrow fibrosis, as may occur with some acute megakaryoblastic leukemias and with acute panmyelosis with myelofibrosis (APMF) (see Fig. 73.1), paraffin section immunohistochemistry performed on a BM trephine biopsy is essential.[37] The use of flow cytometry immunophenotyping in the MDSs is the subject of much study, and many centers have incorporated this technique into the evaluation of patients with potential MDS not only to help quantitate blood and marrow blast cell percentages, but also to detect abnormal maturing cell populations.[11,38,39] These methods, however, do not replace morphologic evaluation, including morphologic blast cell counts on smears.

Cytogenetic studies should also be performed on all cases of suspected acute leukemia or MDS.[21,40,41] While specific gene mutations and some structural abnormalities will be missed by this method, karyotype analysis currently provides the best overall assessment of chromosomal abnormalities and should not be supplanted by other studies. Fluorescence in situ hybridization (FISH) or polymerase chain reaction (PCR) studies are often helpful to detect cryptic abnormalities that may be missed by karyotype analysis and are often added in panels for suspected

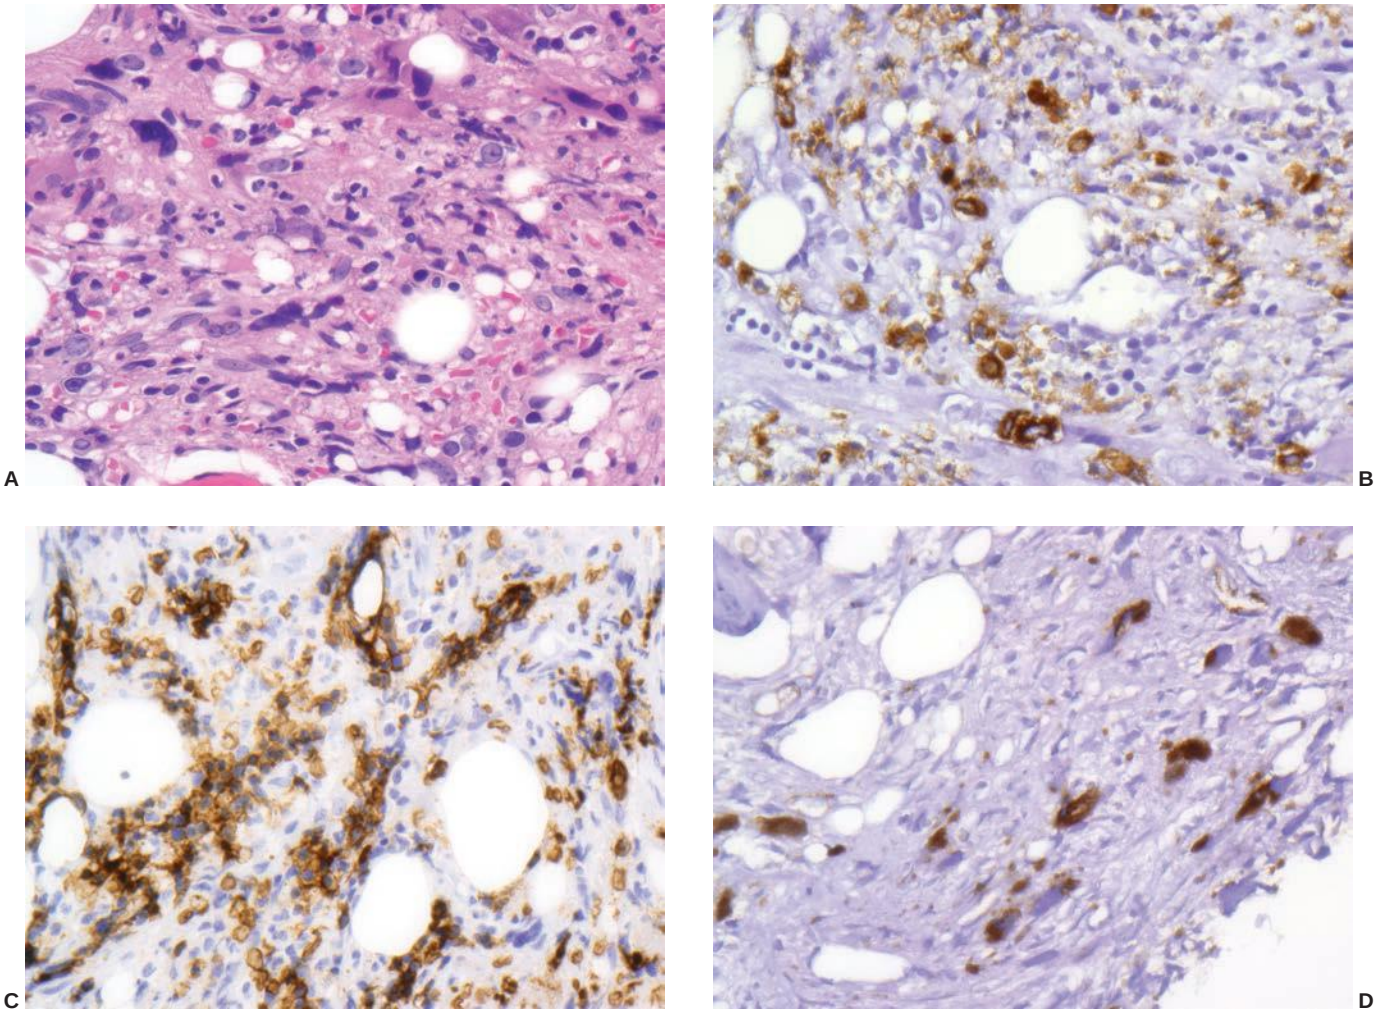

FIGURE 73.1 Acute panmyelosis with myelofibrosis illustrating the use of immunohistochemistry in diagnosis. The marrow is inaspirable due to marked marrow fibrosis **(A)** with a mixed cellular population that includes immature mononuclear cells. The cells show a mix of granulocyte precursors marking with myeloperoxidase **(B)**, erythroid precursors marking with glycophorin B **(C),** and immature megakaryocytes marking with von Willebrand's factor **(D)**.

acute leukemia or MDS.[42] Finally, molecular studies for specific gene mutations are now routinely performed on samples from patients with these disorders, but when each mutation is studied individually the specific tests performed should be ordered based on the findings of other studies. However, with the rapid growth of next-generation sequencing technology,[43] more cost-effective gene mutation panels will become available that may reduce the need for selective testing.

Once this broad array of studies is complete, the results should be incorporated into a single report with a final diagnosis. Because they cannot always be completed in the time interval needed to begin therapy, this approach requires the use of preliminary and amended reports. Because the WHO classification relies on use of cytogenetic studies and some prognostic risk groups are defined by mutation analysis, the diagnosis often needs to be refined, and thus amended, when these studies are complete.

MYELODYSPLASTIC SYNDROMES

Patients with MDS typically show persistent (>6 months) unexplained cytopenias. The majority of MDS patients present with anemia. Neutropenia and thrombocytopenia are less common presenting symptoms. The cytopenias are defined by a hemoglobin level of less than 10 g/dL, an absolute neutrophil count of less than 1.8×10^9/L, and a platelet count of less than 100×10^9/L.[33,44] Of note, CBC values higher than those listed above are not exclusionary for a diagnosis of MDS if definitive morphologic and/or cytogenetic findings are consistent with such a diagnosis. Since the presence of cytopenia(s) is required for the diagnosis, the most current and preferably previous CBCs have to be reviewed at the time of BM exam. Other pertinent data include medications, chemical exposure history, and previous and current illnesses, since all of these can cause morphologic dysplasia indistinguishable from MDS. Comorbidities associated with morphologic dysplasia are frequent in elderly patients affected by MDS, and include liver and kidney failure, autoimmune disorders, neoplasms, and systemic infections. In particular, morphologic evaluation is best performed when the patient is off medication.

Dysplastic features can be present in a single hematopoietic lineage (unilineage dysplasia) or involve all marrow populations (multilineage dysplasia) (Fig. 73.2). At least 10% of all cells in a given lineage (erythroid, myeloid, megakaryocytic) have to be dysplastic for establishing the presence of MDS-associated dysplasia. The majority of MDS subtypes show dyserythropoiesis. PB shows normocytic, normochromic, or macrocytic anemia with macroovalocytes. Microcytosis can be present in rare cases of MDS (e.g., cases associated with congenital or acquired alpha thalassemia).[45] The most common dysplastic features seen in erythroid precursors include nuclear abnormalities such as nuclear

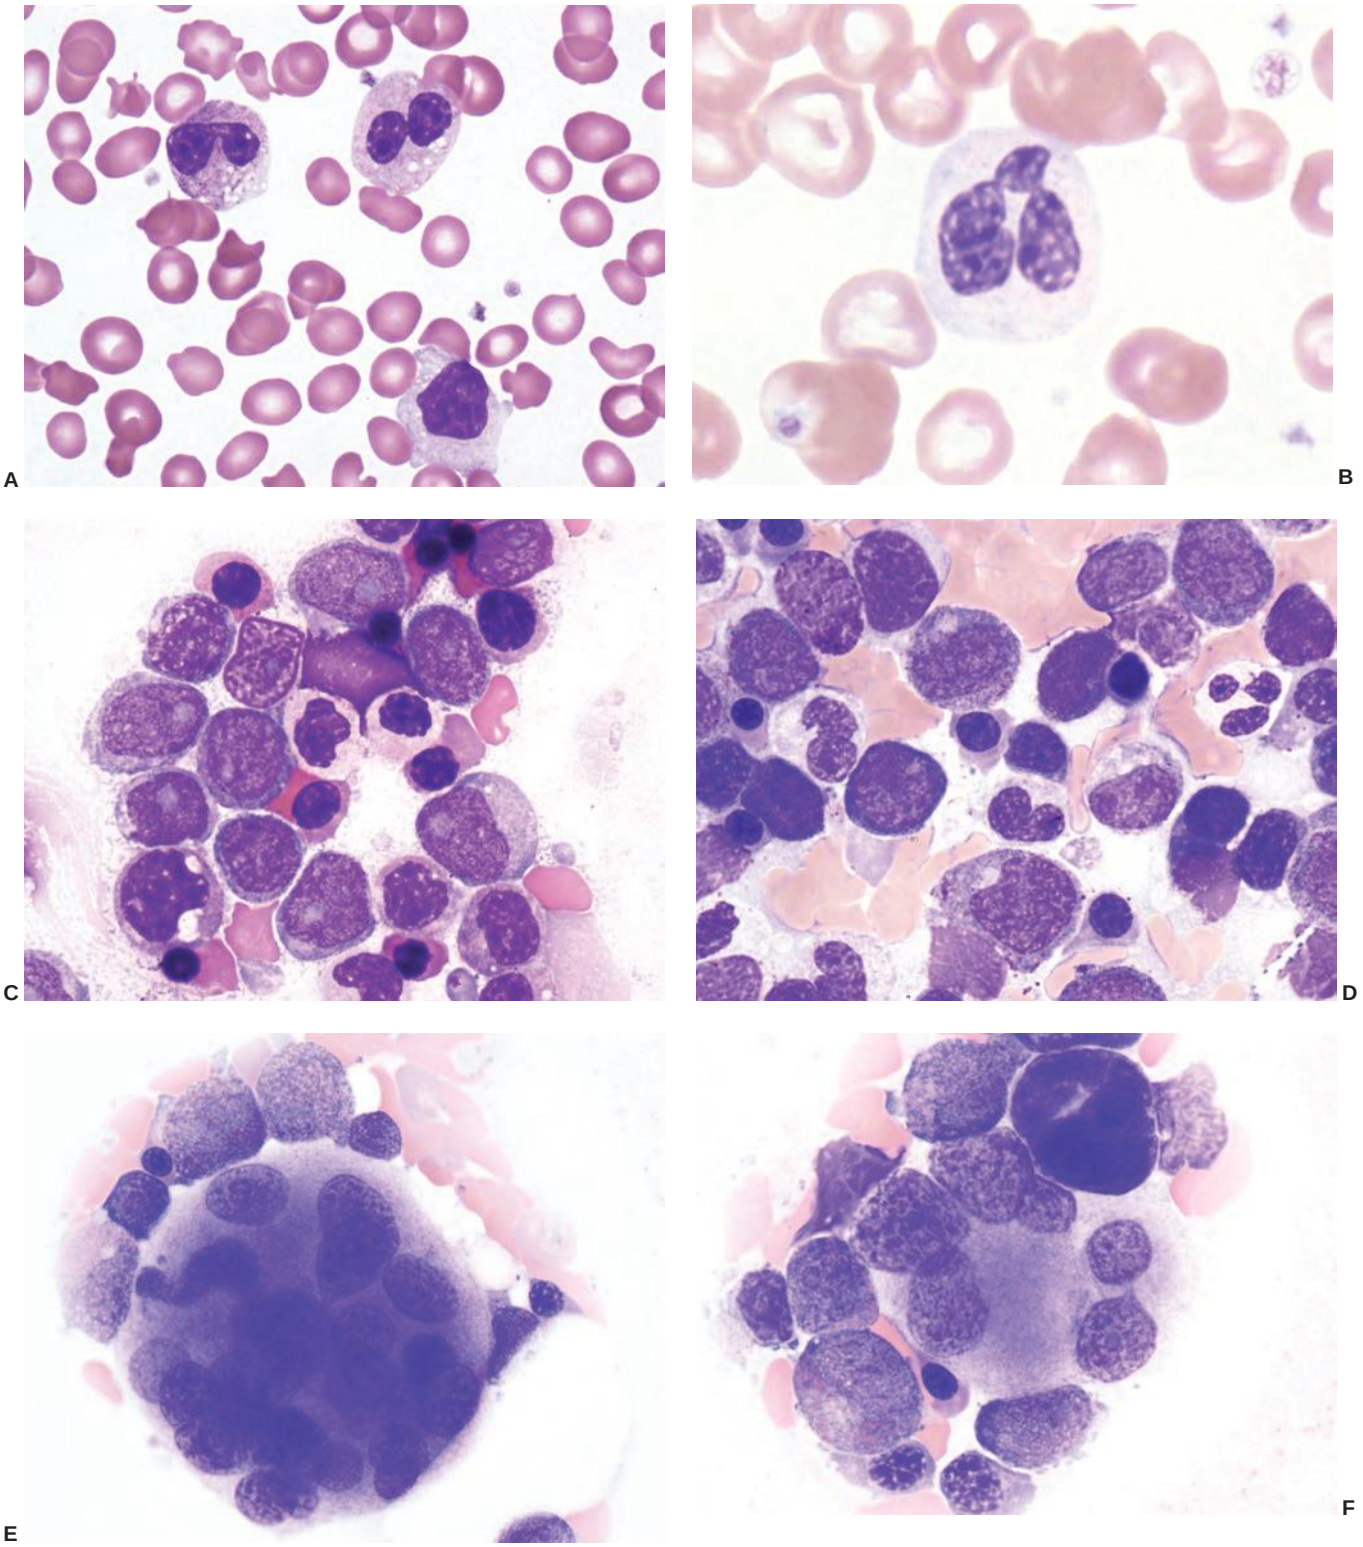

FIGURE 73.2 Dyspoietic changes in myelodysplastic syndrome and acute myeloid leukemia. Peripheral blood **(A, B)** and bone marrow **(C, D)** neutrophils may show cytoplasmic hypogranulation, clumped nuclear chromatin, and hyposegmentation, including pseudo–Pelger-Huët anomaly as shown in image **A.** Dyserythropoiesis may include nuclear-cytoplasmic asynchrony and irregular nuclear shapes in the marrow erythroid precursors **(C, D)**. Megakaryocyte changes include hypersegmented cells **(E)** and smaller, hypolobated cells **(F)**.

budding, nuclear fragmentation, irregular nuclear outlines, karyorrhexis, internuclear bridging, multinucleation, and megaloblastoid, coarsely condensed chromatin. Cytoplasmic vacuoles with coalescing vacuoles, defective hemoglobinization and increased numbers of ring sideroblasts can also be encountered. Similarly, dysgranulopoiesis is often manifested by abnormal nuclear features including hypolobation (pseudo-Pelger-Huët or monolobated neutrophils), hypersegmented and/or enlarged nuclei, nuclear sticks or fragments, macropolycytes, and abnormally condensed chromatin, which often coexists with nuclear hypolobation.

Cytoplasmic features of neutrophil dysplasia include hypogranulation, pseudo-Chediak-Higashi granules, and rarely Auer rods. Hypogranulation occurs frequently and is related to the defective formation of secondary granules. However, the evaluation of this feature is highly subjective and dependent on the staining quality. A well-stained segmented neutrophil or neutrophilic precursor with well-developed secondary granules present, preferably in the same microscopic field, can be used as an internal control. Megakaryocyte morphology can be evaluated using both aspirate smear and the histologic sections (biopsy or clot section) with careful examination of at least 30 megakaryocytes.[33,44] Dysplastic features include monolobated, hypolobated, and hyperlobated nuclei, and multiple, widely separated nuclei including "pawn-ball" forms. Normal size or small megakaryocytes with a single (nonlobated) eccentrically placed nucleus are common in 5q- syndrome and in cases with abnormalities of chromosome 3. The latter also shows typically numerous bilobated forms. Megakaryocytic dysplasia is often associated with thrombocytopenia and platelets of variable size, including large forms occasionally showing hypogranulation.

The biopsy allows for the evaluation of cellularity, architectural features, fibrosis, and the presence of previously undiagnosed focal lesions such as metastatic neoplasms or infections. In MDS marrows, the typical architectural organization is lost. Clusters of immature cells are frequently found in the center of the marrow space. This finding was originally termed abnormal localization of immature precursors and is more frequently seen in cases of high-grade MDS. The identification of blast clusters is facilitated by CD34 immunohistochemistry, which is also useful to determine the number of blasts in cases with inaspirable marrows. The presence of CD34 positive cell clusters is a prognostically significant finding that is predominantly seen in high-risk MDS.[46] The BM biopsy is necessary for the assessment of BM fibrosis by the Gomori silver impregnation method. Significant fibrosis occurs predominantly in high-risk and therapy-related MDS; however, it may also occur in low-risk disease. Finally, BM biopsy is critical for the exclusion of other hematologic and also nonhematologic diseases associated with unexplained cytopenia(s) which can clinically mimic MDS.

In addition to dysplasia, the evaluation of blasts constitutes a cornerstone of morphologic diagnosis of MDS. The optimal quality of BM aspirate and PB smears cannot be overemphasized.[33] The blast percentage is derived from the 500-cell differential count of marrow aspirate smear and 200-cell PB manual differential count. Both differential counts are essential for the subclassification of individual cases. The agranular and granular (type II and type III blasts), and, if present, monoblasts, promonocytes, and megakaryoblasts are included in the blast category.[47] In the absence of adequate BM aspirate smears due to causes such as an inaspirable marrow, careful inspection of the histologic material aided by a CD34 immunohistochemical stain can be used. The latter is particularly helpful in cases with significant marrow fibrosis or in hypoplastic marrows, which often yield hemodilute marrow aspirates.[48,49,50] Of note, blasts in MDS can be negative for CD34, therefore careful correlation with the visual blast identification is required in all cases. It is also important to emphasize that morphologic dysplasia is not equivalent to the diagnosis of MDS. Megakaryocytic and erythroid dysplasia are commonly seen in individuals in a variety of conditions. Nutritional deficiencies, heavy metal exposure, medications, and systemic diseases can produce morphologic changes resembling those seen in MDS. Therefore, as discussed previously, the correlation with clinical history is critical.

Cytogenetics is crucial and is also required for proper classification. The MDS-associated abnormalities are listed in Table 73.1. In addition, mutational analysis is becoming an important additional tool in the prognostic assessment of MDS[30,51]; but mutation studies are not routinely performed in the evaluation for MDS at this time.

TABLE 73.1

RECURRENT CHROMOSOMAL ABNORMALITIES AND THEIR FREQUENCY IN MYELODYSPLASTIC SYNDROME

Abnormality	Frequency (%)
Unbalanced	
+8	10
−7 or del(7q)	10
−5 or del(5q)	10
del(20q)	5–8
−Y	5
i(17q) or t(17q)	3–5
−13 or del(13q)	3
del(11q)	3
del(12q) or t(12q)	3
del(9q)	1–2
idic(X)(q13)	1–2
Balanced	
t(1; 3)(p36.3;q21.2)	1
t(2; 11)(p21;q23)	1
inv(3)(q21;q26.2)	1
t(6;9)(p23;q34)	1

The 2008 WHO classification further refined the criteria for diagnosis and classification of MDS, and seven categories are now recognized (Table 73.2). Cases currently recognized as refractory cytopenia with unilineage dysplasia (RCUD) were considered as refractory anemia (RA) or MDS, unclassifiable in the 2001 WHO classification. Such cases encompass patients with one isolated cytopenia or bicytopenia associated with unilineage dysplasia. An advantage of the new category of RCUD is that one can further specify the lineage: refractory anemia, refractory neutropenia, or refractory thrombocytopenia. Regardless of the lineage involved in RCUD, blasts are absent or represent less than 1% of the PB differential count. Patients with 1% blasts in PB or patients with unilineage dysplasia associated with pancytopenia are now classified as having unclassifiable MDS (MDS-U), owing to the uncertain but presumably more severe clinical significance of these findings.[2] Overall, the category of MDS-U is currently better defined and also includes cytopenic patients lacking significant dysplasia, but presenting with cytogenetic abnormalities considered presumptive evidence of MDS.

The 2008 WHO classification acknowledged a subset of pediatric patients with specific MDS features different from those commonly seen in adults, and included a separate category of childhood MDS termed refractory cytopenia of childhood. This category encompasses children with MDS that have persistent cytopenia with less than 2% blasts in the PB and less than 5% blasts in the BM.[52,53]

Some subtypes or presentations of MDS are more challenging and will be discussed in more detail. MDS-U includes cases which do not fulfill criteria of other MDS subtypes. MDS-U can be diagnosed in patients fulfilling the following criteria: (1) patients who fit the criteria for a diagnosis of RCUD or refractory cytopenia with multilineage dysplasia (RCMD), but in whom 1% blasts in the blood are found on at least two consecutive occasions; (2) patients with MDS with pancytopenia and morphologic dysplasia limited to one hematopoietic lineage; (3) patients with persistent cytopenias, no increase in blasts, and lacking diagnostic morphologic features of MDS (less than 10% dysplastic cells in any lineage), but with clonal cytogenetic abnormalities considered as a presumptive

TABLE 73.2

THE WHO 2008 CLASSIFICATION OF MDS

Subtype	Blood findings	Bone marrow findings
Refractory cytopenias with unilineage dysplasia (RCUD) Refractory anemia (RA) Refractory neutropenia (RN) Refractory thrombocytopenia (RT)	Unicytopenia or bicytopenia[a] No or rare blasts (<1%)	Unilineage dysplasia; ≥10% of the cells of the affected lineage are dysplastic <5% blasts <15% ring sideroblasts
Refractory anemia with ring sideroblasts (RARS)	Anemia No blasts	Erythroid dysplasia only <5% blasts ≥15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenia(s) No or rare blasts (<1%) No Auer rods $<1 \times 10^9$ L monocytes	Dysplasia in ≥10% of cells in two or more myeloid lineages <5% blasts No Auer rods ±15% ring sideroblasts
Refractory anemia with excess blasts-1 (RAEB-1)	Cytopenias <5% blasts No Auer rods $<1 \times 10^9$ L monocytes	Unilineage or multilineage dysplasia 5–9% blasts No Auer rods
Refractory with excess blasts-2 (RAEB-2)	Cytopenias 5–19% blasts ±Auer rods $<1 \times 10^9$ L monocytes	Unilineage or multilineage dysplasia 10–19% blasts ±Auer rods[b]
Myelodysplastic syndrome, unclassified (MDS-U)	Cytopenias No or rare blasts (≤1%) No Auer rods	Unequivocal dysplasia in <10% of cells in one or more myeloid cell lines <5% blasts
MDS associated with isolated del(5q)	Anemia No or rare blasts (<1%) Platelet count usually normal or increased	Normal to increased megakaryocytes with hypolobated nuclei <5% blasts Isolated del(5q) cytogenetic abnormality No Auer rods

[a]Bicytopenia may occasionally be observed. Cases with pancytopenia should be classified as MDS-U.

[b]If the diagnostic criteria for MDS are fulfilled and Auer rods are present, the patient should always be categorized as RAEB-2.

evidence of MDS. According to the 2008 WHO classification, if characteristic features of a specific subtype of MDS develop later in the course of the disease, the case initially classified as MDS-U should be reclassified accordingly. The prognosis of MDS-U varies and close follow-up is warranted.

MDS with fibrosis (MDS-F) is defined by the presence of significant fibrosis (at least 3+ reticulin fibrosis according to the Manoharan scoring system, or at least 2+ reticulin fibrosis according to the European consensus grading system).[44,54,55] In the past, select cases with 2+ reticulin fibrosis according to Manoharan scoring may have been classified as MDS-F. Approximately 10% to 15% of MDS patients show a significant increase in reticulin fibers and/or collagen fibrosis at presentation.[54] These patients are diagnosed with an MDS subtype according to the 2008 WHO classification, with the annotation to indicate the presence of fibrosis. The majority of MDS-F cases fall into the category of refractory anemia with excess blasts (RAEB). Therapy-related MDS cases frequently show significant marrow fibrosis, but are excluded from the MDS-F category in favor of placing them in a special entity of therapy-related myeloid neoplasms. The majority of MDS-F patients present with severe pancytopenia. Organomegaly is minimal or absent. The patients with MDS-F are reported to have shorter overall survival and disease-free survival times than those without fibrosis, even in the absence of excess blasts.[54,56,57] BM fibrosis is also associated with a poor outcome after BM transplantation.[58] BM and PB often show trilineage dysplasia with excess blasts. There is prominent dysmegakaryopoiesis, often associated with increased numbers of megakaryocytes. Cellular streaming is frequently seen on H&E biopsy section and is indicative of significant fibrosis. CD34 immunostaining may be helpful in assessing the number of blasts, since the aspirate smears are often inadequate in patients with fibrotic marrows. Differential diagnoses of MDS-F include other myelofibrotic myeloid neoplasms such as APMF, myeloproliferative, and myelodysplastic/myeloproliferative neoplasms. Similar to MDS-F, APMF, a subtype of AML-NOS (not otherwise specified), shows marked fibrosis, trilineage dysplasia, and dwarf megakaryocytes. The higher number of blasts (in the range of 20% to 25%), abrupt onset with fever and bone pain, and rapidly progressive course seen in APMF are helpful in establishing the definitive diagnosis.[37] Classic myeloproliferative neoplasms, such as primary myelofibrosis, can usually be easily distinguished from MDS-F by their morphologic characteristics (e.g., large-to-giant megakaryocytes with cloud-like nuclei, lack of other myelodysplastic features), and by the presence of significant splenomegaly.[33,59] Myelodysplastic/myeloproliferative neoplasms such as chronic myelomonocytic leukemia may show morphologic features similar to MDS, yet demonstrate laboratory and clinical features of a proliferative process such as elevated WBC and monocytosis.

Hypoplastic MDS (h-MDS), which is defined by its low marrow cellularity (cellularity of less than 20% for patients older than 70 years of age and less than 30% for individuals younger than 70 years), accounts for 5% to 10% of MDS patients.[2,60] Similar to typical cases of MDS, h-MDS is a disease of the elderly. It is more common in women. H-MDS has a prognosis and rate of transformation to AML similar to the corresponding

WHO-classified MDS subtypes. The major differential diagnosis of h-MDS is aplastic anemia.[60,61] The typically hemodilute marrow aspirates obtained from hypoplastic marrow limit the evaluation of cytologic features, and in this context the information derived from BM biopsy/clot section is of paramount importance. The majority of patients with h-MDS present with dyserythropoiesis and no increase in blasts, and are classified as RA.[60,61] Dysgranulopoiesis, dysmegakaryopoiesis, and increase in blasts occur less frequently. Patients with h-MDS can show mast cell hyperplasia, interstitial lymphocytosis, and lymphoid follicles. In the absence of significant multilineage dysplasia and/or increased blast population, the distinction from aplastic anemia can be challenging. The presence of megakaryocytes, increased reticulin fibers, and focally increased CD34 positive cells all suggest h-MDS. The immunohistochemical stains for CD34 and megakaryocytic antigens (CD42b and CD61) and reticulin stain are recommended to highlight the presence of these features.[60,61] Additional findings such as immunophenotypic abnormalities by flow cytometry or the presence of select cytogenetic markers such as losses of chromosomes 5 and/or 7, which are uncommon in aplastic anemia, are also helpful. The applications of novel technologies may help to better differentiate aplastic anemia from h-MDS, and aid in early detection of transformation in the former entity.[62] The diagnostic challenges might be related to the overlap in pathogenesis as demonstrated by the T-cell–mediated suppression of hematopoiesis or the coexistence of clones of paroxysmal nocturnal hemoglobinuria cells documented to occur in both diseases.[63]

Erythroid-predominant MDS (MDS-E) can also cause diagnostic difficulties. By definition, these patients have less than 20% of blasts both as enumerated from the total marrow cellularity and from the nonerythroid BM population. The latter is necessary to exclude a diagnosis of erythroleukemia. In MDS-E, similar to other cases of MDS, blasts are enumerated as a percentage of all BM cells and their number is used to classify cases into one of the MDS subtypes.[2,33] However, recent studies suggested that the alternative approach of calculating the percentage of blasts as a proportion of nonerythroid cells might provide a more accurate assessment of overall prognosis in MDS-E.[64] If blasts are calculated as a percentage of nonerythroid cells, the upgrade to a higher-risk subtype of MDS occurs mainly between the categories of RCMD and RAEB-1 and between RAEB-1 and RAEB-2. Changes from low-risk to high-risk MDS categories are exceedingly rare. Until more evidence is published, it is currently recommended to use the standard WHO criteria, using blast percentages based on all cells, to classify cases of MDS-E.

ACUTE MYELOID LEUKEMIA

The classification of AML has changed dramatically from the FAB classification[7,8,10,65] to the WHO classification.[2] While the FAB classification was based primarily on morphologic and cytochemical features of the blast cells, the WHO uses a combined approach in an attempt to define prognostically significant and biologically relevant disease groups. While many of the WHO categories rely heavily on cytogenetic findings, most still retain distinctive morphologic and immunophenotypic findings. The specific AML disease categories are listed in Table 73.3, and some of the distinctive morphologic and immunophenotypic features of specific types are illustrated in Figures 73.1, 73.3, and 73.4 and described in Table 73.4.

For most cases, a blast cell count of 20% or more in either the PB or BM aspirate is necessary for a diagnosis of AML. For cases with one of three recurring cytogenetic abnormalities (t(15;17)(q24.1;q21.1) *PML-RARA*; t(8;21)(q22;q22) *RUNX1-RUNXT1*; and inv(16)(p13.1q22) or t(16;16)(p13.1;q22) *CBFB-MYH11*), however, a diagnosis of AML can be made with a lower blast count. These low blast count cases are uncommon and still have abnormal blood and marrow findings. The detection of the cytogenetic abnormality would indicate AML over a diagnosis of MDS in these cases. Acute erythroid leukemia (erythroid myeloid type) is also diagnosed with less than 20% blood or marrow blasts (see below).

TABLE 73.3

2008 WORLD HEALTH ORGANIZATION CLASSIFICATION OF ACUTE MYELOID LEUKEMIA AND RELATED PRECURSOR NEOPLASMS

- AML with recurrent genetic abnormalities
  - AML with t(8;21) (q22;q22) (*RUNX1-RUNX1T1*)
  - AML with inv(16)(p13.1q22) or t(16,16) (p13.1;q22) (*CBFB-MYH11*)
  - Acute promyelocytic leukemia with t(15;17)(q24.1;q21.1) (*PML-RARA*)
  - AML with t(9;11)(p22;q23) (*MLLT3-MLL*)
  - AML with t(6;9)(p23;q34) (*DEK-NUP214*)
  - AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2) (*RPN1-EVI1*)
  - AML (megakaryoblastic) with t(1;22)(p13;q13) (*RBM15-MKL1*)
  - Provisional entity: AML with mutated *NPM1*
  - Provisional entity: AML with mutated *CEBPA*
- AML with myelodysplasia-related changes
- Therapy-related myeloid neoplasms
- AML not otherwise specified
  - AML minimally differentiated
  - AML without maturation
  - AML with maturation
  - Acute myelomonocytic leukemia
  - Acute monoblastic and monocytic leukemia
  - Acute erythroid leukemia
  - Acute megakaryocytic leukemia
  - Acute basophilic leukemia
  - Acute panmyelosis with myelofibrosis
- Myeloid sarcoma
- Myeloid proliferations related to Down syndrome
- Blastic plasmacytoid dendritic cell neoplasm

AML, acute myeloid leukemia.

The WHO classification defines AML types by recurring genetic abnormalities,[66] by recognizing cases related to MDS,[67] and by separating diseases related to prior therapy[68] or associated with Down syndrome.[69] Cases that do not fall into any of those groups are placed in the AML-NOS group[70] and can be subdivided by morphologic features. Many of these cases, however, have normal karyotypes, and the search for predictive markers to better categorize them is ongoing.[71]

AML with recurring genetic abnormalities was expanded in the 2008 WHO classification to include more disease groups and to attempt to incorporate disease-defining mutations. AML with mutated *CEBPA* and AML with mutated *NPM1* are provisional disease categories based on the hypothesis that these mutations are disease-defining events,[72–76] similar to the other recurring cytogenetic abnormalities in this category, and not merely secondary events that impact prognosis.

AML with myelodysplasia-related changes of the 2008 WHO classification (Table 73.5) is an expansion and revision of the category of AML with multilineage dysplasia in the 2001 classification.[3,67] The use of multilineage dysplasia as the sole source of classifying AML is controversial. Certainly cases of AML arising from MDS can lack sufficient background cells to diagnose multilineage dysplasia and the expansion of this category now allows cases to be diagnosed as AML with myelodysplasia-related changes by demonstrating the presence of multilineage dysplasia, presence of an MDS-associated cytogenetic abnormality (Table 73.6), a history of prior MDS or a myelodysplastic/myeloproliferative neoplasm, or a combination of such findings. This combined approach captures more cases of AML and defines a group with a particularly poor prognosis in adults.

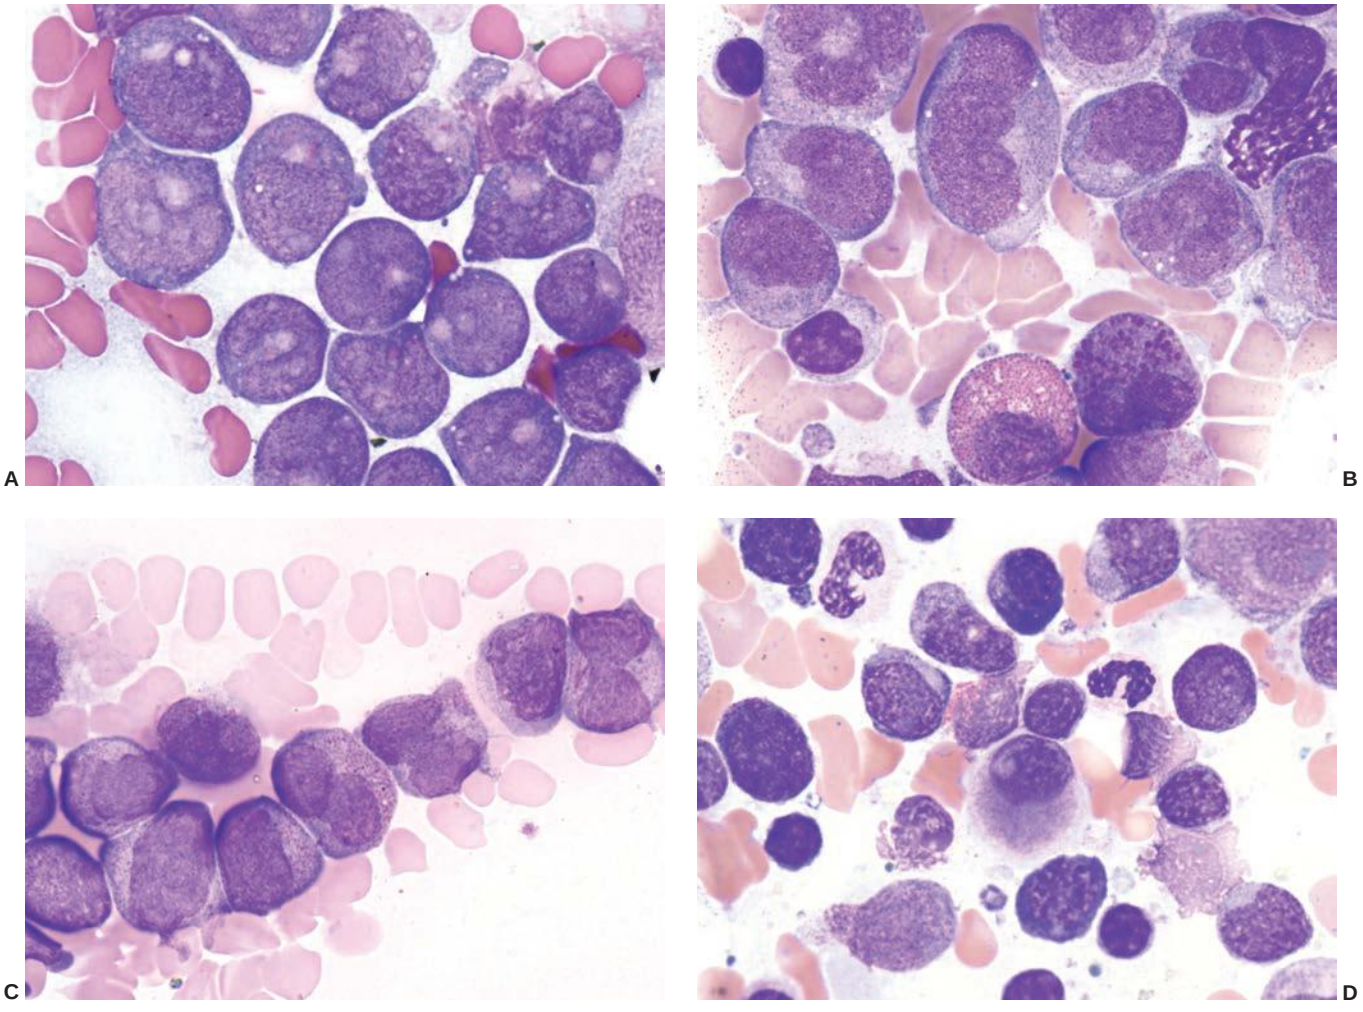

FIGURE 73.3 Morphologic features of more common acute myeloid leukemia types with recurrent cytogenetic abnormalities. A: Acute myeloid leukemia with t(8;21) (q22;q22) (*RUNX1-RUNX1T1*) with blasts containing abundant cytoplasm with large granules and perinuclear clearing (hofs). **B:** Acute myeloid leukemia with inv(16)(p13.1q22) or t(16,16) (p13.1;q22) (*CBFB-MYH11*) with an abnormal eosinophil containing large basophilic granules (lower right). **C:** Acute promyelocytic leukemia with t(15;17)(q24.1;q21.1) (*PML-RARA*) typically shows blasts with bilobed nuclei, cytoplasmic granules and Auer rods (far right). **D:** Acute myeloid leukemia with inv(3)(q21q26.2) (*RPN1-EVI1*) with background dyspoiesis and a small, monolobated megakaryocyte (center).

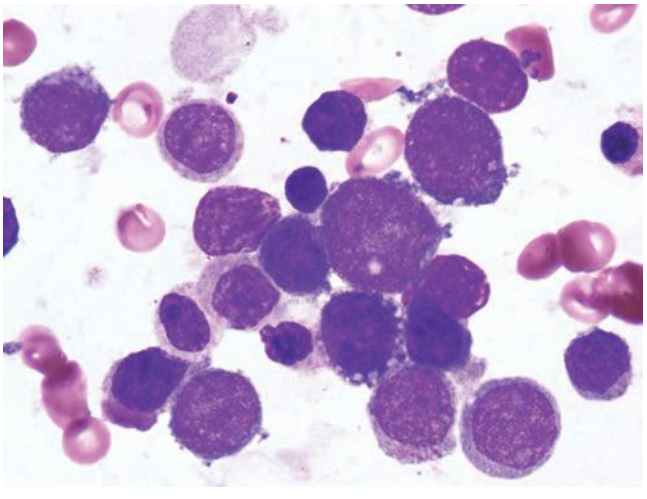

FIGURE 73.4 Acute erythroid leukemia, mixed myeloid erythroid type. Over 50% erythroid precursors are present in the bone marrow with dyspoietic changes that include cytoplasmic vacuolization (lower center). In addition, scattered blasts, which mark as myeloblasts, are present in the background (upper left and lower right) representing over 20% of the nonerythroid cells in the marrow.

Cases with a normal karyotype and no history, but the presence of multilineage dysplasia, defined as two or more cell lines with 50% or more dysplastic cells, is the major area of controversy. While some large series have failed to find prognostic significance for this group,[77,78] other studies find multilineage dysplasia to still independently predict a worse outcome compared to AML-NOS.[3,78]

Therapy-related myeloid neoplasms and the myeloid neoplasms associated with Down syndrome are also felt to be distinct from other AML types, and these also tend to show a continuum between cases with features of AML and MDS. For this reason, they are now considered separate disease entities, respectively, from the non-therapy or-Down-related leukemias.

The remaining cases are placed into the category of AML-NOS and this category includes many normal karyotype cases and cases that are diagnosed as AML with unique features. The subcategories of AML-NOS are probably of little significance, and mutation analysis is probably most important in this group. Selected mutations (*FLT3* and *KIT*) are included as prognostic markers for different AML types in the WHO classification. While the utility of *KIT* mutations is primarily in the core binding factor leukemias (those with t(8;21)(q22;q22) *RUNX1-RUNXT1*; and inv(16)(p13.1q22) or t(16;16)(p13.1;q22) *CBFB-MYH11*),[79] *FLT3* and *NPM1* mutations are prognostically predictive in most

TABLE 73.4

DISTINCTIVE CLINICAL, MORPHOLOGIC, AND IMMUNOPHENOTYPIC FEATURES OF ACUTE MYELOID LEUKEMIA CYTOGENETIC SUBTYPES

AML Subtype	Distinctive Features
AML with t(8;21) (q22;q22) (*RUNX1-RUNX1T1*)	Granular blasts with perinuclear hofs, large salmon-colored granules, aberrant CD19 expression on $CD34^+$ myeloblasts
AML with inv(16)(p13.1q22) or t(16,16) (p13.1;q22) (*CBFB-MYH11*)	Presence of abnormal eosinophils with basophilic granules
Acute promyelocytic leukemia with t(15;17)(q24.1;q21.1) (*PML-RARA*)	Bilobed nuclei with blasts lacking HLA-DR and usually CD34-negative
AML with t(6;9)(p23;q34) (*DEK-NUP214*)	Multilineage dysplasia and associated basophilia
AML with inv(3)(q21q26.2) or t(3;3) (q21;q26.2) (*RPN1-EVI1*)	Multilineage dysplasia and increased numbers of small mono- or bilobed megakaryocytes
AML (megakaryoblastic) with t(1;22) (p13;q13) (*RBM15-MKL1*)	Infant without Down syndrome with CD41+ and CD61+ blasts

AML, acute myeloid leukemia.

cases of AML-NOS.[28,72,73,80–84] In addition to the mutations included in the 2008 WHO classification, other mutations have been described and validated as potential prognostic markers.[27,85,86,87,88] Some of the most frequently occurring in AML include *DNMT3A*, *IDH1*, *IDH2*, *TET2*, *RUNX1*, *NRAS*, and *WT1*. Table 73.7 demonstrates one approach to combining cytogenetic studies and mutation analysis to develop prognostic categories in AML, but this approach will have to be frequently updated to include new discoveries.[85]

Categories of AML-NOS that offer the greatest diagnostic challenge are probably acute erythroleukemia and APMF. Acute erythroleukemia can be the pure erythroid leukemia with over 80% immature erythroid cells and no myeloblasts or a mixed myeloid erythroid type.[89] The latter type (Fig. 73.4) has 50% or more BM erythroid precursors; and of the nonerythroid marrow cells, 20% or more myeloblasts. The differential diagnosis of both types is with MDS, and both are probably closely related to aggressive MDS. APMF usually involves an inaspirable marrow with marked fibrosis and a mix of immature myeloid, erythroid, and megakaryocytic cells (Fig. 73.1).[37,90] This rare disorder is also difficult to distinguish from MDS-F and may be related to such proliferations.

TABLE 73.5

CRITERIA FOR DIAGNOSIS OF ACUTE MYELOID LEUKEMIA WITH MYELODYSPLASIA-RELATED CHANGES

1) At least 20% blasts in the blood or bone marrow

2) No history of prior cytotoxic therapy for other disease

3) Absence of a recurring chromosomal rearrangement as delineated in Table 73.3

AND, one or more of the following features:

1) Previous history of myelodysplastic syndrome or myelodysplastic/myeloproliferative disorder

2) Multilineage dysplasia (dyspoiesis in at least 50% of the elements from two or more lineages)

3) Presence of an MDS-associated cytogenetic abnormality (see Table 73.6)

MDS, myelodysplastic syndrome.

TABLE 73.6

CYTOGENETIC ABNORMALITIES SUFFICIENT TO DIAGNOSE ACUTE MYELOID LEUKEMIA WITH MYELODYSPLASIA-RELATED CHANGES WHEN ≥20% BLASTS ARE PRESENT IN BLOOD OR BONE MARROW IN THE ABSENCE OF PRIOR CYTOTOXIC THERAPY

Complex karyotype	≥3 unrelated chromosomal abnormalities, not including any rearrangements that would define a subtype of AML with recurrent cytogenetic abnormalities	
Unbalanced abnormalities	−7/del(7q) −5/del(5q) i(17q/t(17p) −13/del(13q)	del(11q) del(12p)/t(12p) del(9q) idic(X)(q13)
Balanced abnormalities	t(11;16)(q23;p13.3) t(3;21)(q26.2;q22.1) t(1;3)(p26.3;q21.1) t(2;11)(p21;q23)	t(5;12)(q33;p12) t(5;7)(q33;q11.2) t(5;17)(q33;p13) t(5;10)(q33;q21) t(3;5)(q25;q34)

In addition to new gene mutations, gene expression (i.e., *BAALC* and *ERG*), often altered by epigenetic changes in AML, is now recognized to have a prognostic impact on this disease.[91,92,93] Our understanding of the role of miRNAs and gene methylation in the diagnosis and prognosis of AML will also clearly grow in the near future.

ACUTE LYMPHOBLASTIC LEUKEMIA

The diagnostic approach to ALL has also changed dramatically over time. While the immunophenotype of ALL was not part of the FAB classification,[10] it is now essential for diagnosing these disorders. Also, the relationship between lymphoblastic lymphoma and ALL is now recognized, and these disorders are grouped together in the WHO classification.[94] Cases diagnosed in the past as ALL with a mature B-cell phenotype (FAB L3) are no longer considered as ALL and are best classified as leukemic variants of the mature B-cell lymphomas.

While morphologic evaluation is important in ALL to identify a blast cell proliferation, immunophenotyping must be performed because lymphoblasts cannot be distinguished reliably from undifferentiated myeloblasts by morphology alone. In fact some

TABLE 73.7

LEUKEMIANET PROGNOSTIC GENETIC CATEGORIES OF ACUTE MYELOID LEUKEMIA

Genetic Group	Subsets
Favorable	• t(8;21)(q22;q22); *RUNX1-RUNX1T1* • inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11* • Mutated *NPM1* without *FLT3*-ITD (normal karyotype) • Mutated *CEBPA* (normal karyotype)
Intermediate-I	• Mutated *NPM1* and *FLT3*-ITD (normal karyotype) • Wild-type *NPM1* and *FLT3*-ITD (normal karyotype) • Wild-type *NPM1* without *FLT3*-ITD (normal karyotype)
Intermediate-II	• t(9;11)(p22;q23); *MLLT3-MLL* • Cytogenetic abnormalities not classified as favorable or adverse
Adverse	• inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1* • t(6;9)(p23;q34); *DEK-NUP214* • t(v;11)(v;q23); *MLL* rearranged • −5 or del(5q); −7; abnl(17p); complex karyotype

B-lymphoblastic leukemia/lymphoma with t(v;11q23)(*MLL*)
B-lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22) (*ETV6-RUNX1*)
B-lymphoblastic leukemia/lymphoma with t(5;14)(q31;q32) (*IL3-IGH@*)
B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3) (*TCF3-PBX1*)
B-lymphoblastic leukemia/lymphoma with hyperdiploidy
B-lymphoblastic leukemia/lymphoma with hypodiploidy
T-lymphoblastic leukemia/lymphoma

lymphoblasts will contain cytoplasmic granules that may incorrectly suggest myeloid lineage.[95] Cytochemical studies are also not sufficient for such a diagnosis, because the absence of myeloperoxidase or Sudan black B by these methods does not exclude undifferentiated myeloblasts and the detection of PAS-positive granules in blasts is not specific for lymphoblasts.

The 2008 WHO classification (see Table 73.8) introduced cytogenetic subtypes of B-lymphoblastic leukemia and these studies are also essential for a complete diagnosis of ALL.[96] There are no specific morphologic features for these ALL types (Fig. 73.5), with the exception that the very rare ALL with t(5;14)(q31;q32) (*IL3-IGH@*) is associated with a marked proliferation of normal-appearing eosinophils.[97] While there are no specific morphologic features to most of these disorders, there are some characteristic immunophenotypic features that provide clues to the diagnosis, some of which are listed in Table 73.9. While many of these categories are defined by the detection of recurring cytogenetic abnormalities, the translocation of B-lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22) (*ETV6-RUNX1*) is cryptic,[98] and FISH or PCR testing must be performed to detect this category. Because this cytogenetic abnormality primarily occurs in children, routine molecular or FISH testing for this fusion is indicated in all pediatric B-ALL cases. Similarly, there are no morphologic clues to reliably distinguish T-lymphoblastic leukemia/lymphoma from B-lymphoblastic leukemia/lymphoma. Although nuclear convolutions are described as more common with a T-cell immunophenotype, this finding is not sufficiently reliable to replace immunophenotyping studies.

While mutations studies are not part of the 2008 classification of ALL, numerous genetic alterations have been described in recent years for this disease and will further impact classification. Interestingly, and in contrast to most mutations that are common in AML, many individual mutations in ALL have been shown not to have prognostic impact as a sole marker, but may define prognostic groups when they occur in combination.[99] *PAX5* mutations at 9p13 occur in approximately 30% of B-ALL cases and often occur in combination with other abnormalities; but this mutation alone does not appear to be clinically significant, and routine testing for this abnormality is probably not indicated. In contrast, deletions of *IKZF1* at 7p12 often occur in combination with *PAX5* mutations and are seen in over 80% of patients with B-ALL with t(9;22)(q34;q11.2)(*BCR-ABL1*). Even in the absence of the Philadelphia chromosome, children with this deletion (representing almost 30% of all Philadelphia chromosome negative ALLs in one study) have a poor outcome that is similar to B-ALL with t(9;22)(q34;q11.2). The poor prognosis of *IKZF1* deleted ALL appears to be independent of age, white blood cell count, or cytogenetic subgroup.[100,101] Mutations of *JAK2*, found in approximately 8% of B-ALL cases, in combination with *IKZF1* deletions are associated with an even worse prognosis.[102]

A new recurring cytogenetic abnormality, not included in the WHO classification, involves *CRLF2* located at Xp22.3/Yp11.3 and most often translocated with *IGH@*.[26,103] These translocations occur in 7% to 14% of B-ALL cases, but are associated with either ALL of Down syndrome or ALL in Hispanic patients. They are commonly associated with *JAK1* or *JAK2* mutations and *IKZF1* deletions and have a very poor prognosis.

In contrast to AML, there is no category of ALL for therapy-related disease. Despite this, it is now recognized that ALL may occur after cytotoxic therapy although the relationship to the prior therapy and the leukemia may be under-appreciated.[104,105] Most cases of therapy-related ALL are of precursor B lineage and some studies suggest that they are most often associated with *MLL* translocations involving 11q23.

Recurring cytogenetic abnormalities also occur in T-ALL, but are not included as diagnostic subcategories in the WHO classification. These translocations most often involve T-cell receptor genes at 7q32 (*TRB@*) and 14q11 (*TRA@, TRD@*) and *TLX1*, *TLX3* and *TAL1*, but many other genes may be involved in a smaller percentage of cases.[106,107] Prognostic significance has not been determined for many of these genetic changes, although *TLX1*

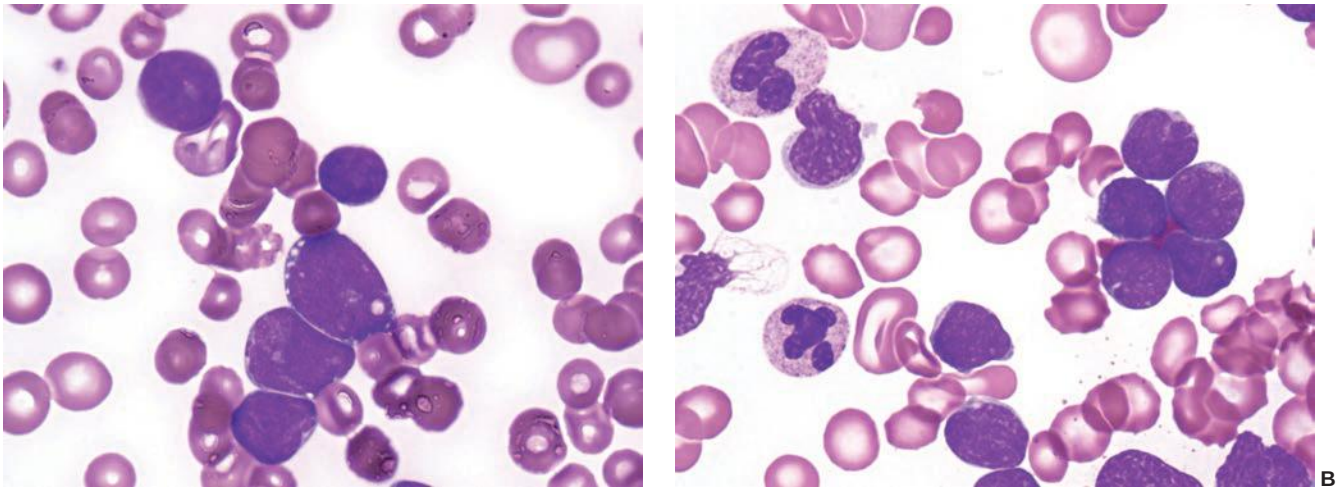

FIGURE 73.5 Acute lymphoblastic leukemia with blasts containing scant, agranular cytoplasm. The morphologic features are not specific and may also be present in minimally differentiated acute myeloid leukemia. Part **A** is from a case of B-lymphoblastic leukemia, while part **B** is from T-lymphoblastic leukemia; both showing similar morphologic changes.

TABLE 73.9

DISTINCTIVE CLINICAL, MORPHOLOGIC, AND IMMUNOPHENOTYPIC FEATURES OF B-LYMPHOBLASTIC LEUKEMIA CYTOGENETIC SUBTYPES

B-ALL Subtype	Distinctive Features
B-lymphoblastic leukemia/lymphoma with t(9;22)(q34;q11.2)(*BCR-ABL1*)	Precursor B-cell lineage with aberrant expression of CD13, CD33, CD38, and CD25
B-lymphoblastic leukemia/lymphoma with t(v;11q23)(*MLL*)	CD10-negative precursor B-cell lineage with aberrant CD15 expression
B-lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22) (*ETV6-RUNX1*)	Childhood leukemia with precursor B-cell lineage with CD34, bright CD10, and aberrant expression of CD13
B-lymphoblastic leukemia/lymphoma with t(5;14)(q31;q32) (*IL3-IGH@*)	Precursor B-cell lineage associated with marked eosinophilia
B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3) (*TCF3-PBX1*)	Precursor B-cell lineage lacking CD34 with cytoplasmic mu expression

B-ALL, B-cell acute lymphoblastic leukemia.

translocations appear to confer a good prognosis. Mutations are also common in T-ALL, with mutations of *NOTCH1* found in 50% to 60% of adult and pediatric disease.[106–110] Mutations of *FBXW7*, a gene involved in NOTCH signaling, occurs in 10% to 20% of cases.[108–110] Mutations of either gene appear to have some prognostic significance in children, at least predicting a favorable treatment response with protocols that include cranial irradiation, but appear to be of less significance in adult patients. *FLT3* mutations are rare in T-ALL, found in about 4% of cases.[111,112] However, these mutations are much more frequent in cases described as early T-cell precursor (ETP)-ALL. These cases are considered to represent a particularly high-risk type of T-ALL[111–113] that expresses CD7, but lacks CD1a and CD8, shows only weak expression of CD5, expresses CD34, HLA-DR, and CD117, and often expresses myeloid-associated antigens such as CD13, CD33, and CD65s. Some cases in the past were probably diagnosed as undifferentiated, mixed phenotype or biphenotypic acute leukemia. While often *FLT3* mutated, ETP-ALL typically lacks mutations of *NOTCH1* or *FBXW7*.[111]

ACUTE LEUKEMIAS OF AMBIGUOUS LINEAGE

Despite extensive immunophenotyping studies, a small subset of acute leukemias cannot be definitely classified as being derived from myeloid or lymphoid lineage.[114,115] These acute leukemias are either acute undifferentiated leukemias or mixed phenotype acute leukemias (MPAL) (Table 73.10). Acute undifferentiated leukemias have become extremely rare with modern immunophenotyping panels and are defined as lacking expression of markers specific for myeloid or lymphoid lineage. They often express non-specific markers such as HLA-DR, CD34, CD38, CD7 or TdT, but lack expression of cytoplasmic CD3, myeloperoxidase, cytoplasmic CD22, cytoplasmic CD79a, or strong expression of CD19, as well as markers of plasmacytoid dendritic cell tumors. No specific cytogenetic abnormalities are associated with these tumors.

The MPAL are slightly more common and are known by a variety of names that include mixed lineage acute leukemia, biphenotypic acute leukemia, and bilineal acute leukemia (Fig. 73.6). The diagnostic criteria for these disorders have been vague in the past, and the frequency of diagnosis has increased with the use of multicolor flow cytometry using large panels of antibodies. Lineage infidelity is common in acute leukemias, and determining how many aberrant markers are sufficient to make a diagnosis

TABLE 73.10

2008 WORLD HEALTH ORGANIZATION CLASSIFICATION OF ACUTE LEUKEMIAS OF AMBIGUOUS LINEAGE

Acute undifferentiated leukemia
Mixed phenotype acute leukemia with t(9;22)(q34;q11.2)(*BCR-ABL1*)
Mixed phenotype acute leukemia with t(v;11q23)(*MLL*)
Mixed phenotype acute leukemia, B/myeloid, NOS
Mixed phenotype acute leukemia, T/myeloid, NOS
Mixed phenotype acute leukemia, NOS—rare types

NOS, not otherwise specified.

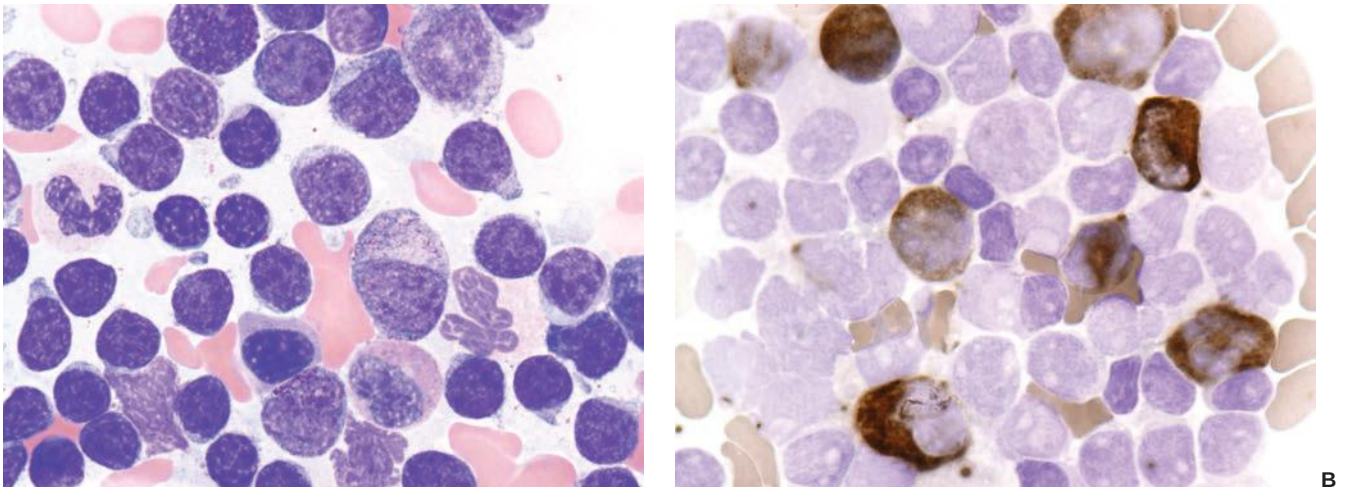

FIGURE 73.6 Mixed phenotype acute leukemia with a bilineal appearance. A mixture of small lymphocytes, small undifferentiated blast cells and larger blasts with granular cytoplasm are present **(A)**. The small blasts mark as B lymphoblasts, while the larger cells are myeloperoxidase positive by flow cytometry and cytochemistry **(B)**.

TABLE 73.11

EUROPEAN GROUP FOR THE IMMUNOLOGIC CLASSIFICATION OF LEUKEMIA (EGIL) SCORING SYSTEM FOR BIPHENOTYPIC ACUTE LEUKEMIA

Points/Lineage	B	T	Myeloid
2	CD79a Cytoplasmic IgM Cytoplasmic CD22	CD3 (membrane or cytoplasmic) TCR α/β TCR γ/δ	Myeloperoxidase
1	CD19 CD10 CD20	CD2 CD5 CD8 CD10	CD117 CD13 CD33 CD65s
0.5	TdT CD24	TdT CD7 CD1a	CD14 CD15 CD64

More than two points for an individual lineage is required.

of MPAL creates a challenge in many cases. A variety of diagnostic criteria have been proposed for these disorders, but the criteria proposed by the European Group for the Immunologic Classification of Leukemia (EGIL)[116,117] and the 2008 WHO[118,119] criteria are most often used, with the WHO criteria currently preferred. The EGIL criteria (Table 73.11) provided the ability to weight the significance of different markers and reduced the number of cases diagnosed as MPAL. However, as new markers became available, the scoring system became less useful and it was not clear that the criteria resulted in a biologically distinct disease entity.

The WHO criteria (Table 73.12) are actually simpler to use, based on fewer markers, and specify two cytogenetic abnormalities [t(9;22)(q34;q11.2) *BCR-ABL1*; t(v;11q23) *MLL* rearranged) that are often reported in cases of MPAL. The WHO definition of MPAL does not separate cases with a single blast cell population showing a mixed phenotype (biphenotypic) from cases with two distinct blast cell populations (bilineal), since there is great overlap between these case types with some presenting with one pattern and relapsing with another. While the two cytogenetic categories are similar to other acute leukemia categories in the WHO classification, it is not clear these MPAL variants are distinct from other acute leukemias with the same cytogenetic abnormality (i.e., MPAL with t(9;22)(q34;q11.2) *BCR-ABL1* versus ALL with t(9;22)(q34;q11.2) *BCR-ABL1*). The great variability of these disorders based on immunophenotype and recurring genetic changes suggests that immunophenotypic methods may not be the ideal means of classifying these tumors and future diagnostic methods may supplant this category in the future.

TABLE 73.12

2008 WORLD HEALTH ORGANIZATION CRITERIA FOR ASSIGNING LINEAGE FOR MIXED PHENOTYPE ACUTE LEUKEMIA

Lineage	Criteria
Myeloid	Myeloperoxidase or Monocytic differentiation (two or more: NSE, CD11c, CD14, CD64, lysozyme)
T lineage	Cytoplasmic or surface CD3
B lineage	Strong CD19 plus strong expression of at least one of CD79a, cCD22, CD10 or Weak CD19 plus strong expression of at least two of CD79a, cCD22, CD10

SUMMARY

The diagnostic evaluation for acute leukemia and MDSs has become increasingly complex. It requires careful coordination between the treating hematologist and hematopathologist to ensure that all sample types needed for diagnosis are collected and appropriately tested. Because the various tests needed for diagnosis and prognosis will be resulted at different times, consolidated reporting of all results using amended reports is suggested to ensure that all results are interpreted in the context of the entire specimen.

CHAPTER 74

ACUTE LYMPHOBLASTIC LEUKEMIA IN ADULTS

Steven E. Coutre

Acute lymphoblastic leukemia (ALL) is a neoplastic disorder that is rapidly fatal if untreated. In children, ALL is the most common malignancy, and considerable advances have led to the cure of most children with the disease. Historically, treatment outcomes in adults have not been as favorable. Although improved prognostic stratification has led to a better understanding of the biologic heterogeneity of the disease, targeted therapies exploiting these differences have not yet emerged as part of standard therapy for most patients. However, dramatic advances in whole genome sequencing as well as the development of novel immunotherapies promises to improve both the fundamental understanding of the biology of the disease and treatment outcomes.

The clinical onset of ALL is rarely insidious, and presenting signs and symptoms reflect bone marrow as well as extramedullary involvement by leukemia. Examination of the peripheral blood smear is often sufficient to establish the diagnosis of ALL, but additional clinical and laboratory tests are essential for formulating a treatment plan and provide important prognostic information. Current therapy for adults involves a scheduled sequence that starts with remission induction chemotherapy, followed by one or more cycles of intensification, prophylaxis of the central nervous system (CNS), and prolonged maintenance lasting 2 to 3 years. With this multiagent, multicycle approach, between 25% and 40% of adults with ALL are cured of their disease. Modifications to this general scheme, based on an appreciation of the high risk for disease relapse, have improved outcome for adult ALL patients who have the mature B-cell phenotype as well as those with the Philadelphia (Ph) chromosome. Age remains a significant limitation to treatment intensity as one third of adults with ALL are over the age of 60 years.

Most adult patients with ALL experience relapse of their disease. Successful treatment options for relapsed or refractory ALL are few.

HISTORICAL BACKGROUND

Only a few decades ago, ALL was an incurable disease in all but a small minority of patients. Progress in the treatment of pediatric ALL has been substantial. This is clearly illustrated in the results reported from a series of successive clinical protocols from St. Jude Children's Research Hospital.[1,2,3] Sequential treatment modifications in successive cohorts of children show a steady improvement in survival outcome as shown in Figure 74.1A. The initial clinical trials from 1962 to 1969 introduced multiagent chemotherapy regimens into pediatric ALL therapy. This proved superior to single-agent therapy, but, still, few children experienced long-term survival. The next era, from 1967 to 1979, saw effective prevention of leukemia relapse in sanctuary sites in the CNS through the use of cranial irradiation and intrathecal chemotherapy. Intensification of post-remission therapy with administration of non-cross–resistant drugs was responsible for improving survival in subsequent cohorts. With further refinements, as well as general improvement in supportive care, approximately 85% of children with ALL are now cured of the disease (Chapter 76).

The success demonstrated in the pediatric ALL trials led to similar approaches in the treatment of adults. As shown in Figure 74.1B, outcomes in consecutive cohorts of adults with ALL treated by the United Kingdom Acute Lymphoblastic Leukemia (UKALL) collaborative study group gradually improved as treatment was intensified and extended. Compared with the success in treating childhood ALL, however, the degree of improvement was only modest. The British Medical Research Council initiated the UKALL trials in 1971.[4] The first trial, UKALL I, evaluated CNS prophylaxis but only enrolled 16 adults. Subsequent trials examined both the addition of active agents and more sustained intensive post-remission therapy, and participation of adult patients progressively expanded. Survival for adults with ALL was still only 20% at the time the UKALL IX trial opened for patient accrual in 1980. It was the first trial in the series to enroll adults separately from children. UKALL IX and the subsequent trial, UKALL XA, saw further, although minor, incremental improvement in the survival rate but provided important systematic analyses of prognostic indicators based on clinical, immunophenotypic, and cytogenetic characteristics.[5] The subsequent study, UKALL XII/ECOG 2993, was the largest treatment study of newly diagnosed ALL in adults. It compared post-remission chemotherapy with autologous or related donor transplant. The complete remission (CR) rate was 90% in the 1,646 Philadelphia chromosome negative patients; overall survival at 5 years was 43% and 39% if all 1,913 eligible patients were included.[6] Patients up to age 50 were eligible for allogeneic hematopoietic stem cell transplantation (HSCT). Survival at 5 years was 54% for all Philadelphia chromosome-negative patients with a donor, versus 44% for those without ($P = 0.007$) and 63% versus 52% for standard risk patients ($P = 0.02$). There was no benefit to allogeneic transplant for high-risk Philadelphia chromosome-negative patients. Patients without a donor who underwent autologous transplant did no better than those who received chemotherapy alone. These series of studies, along with other national cooperative group studies have led to remarkably similar long-term survival rates among adults who receive chemotherapy without transplant. These outcomes are distinctly inferior to those achieved in the pediatric age group.[7–10]

PATHOPHYSIOLOGY

The cause of ALL is essentially unknown, and few clues can be derived from epidemiologic studies. The molecular pathogenesis of ALL is reviewed in Chapter 72. Points relevant to adult ALL concerning these issues are briefly highlighted here.

Epidemiology

The overall age-adjusted incidence of ALL in the United States based on the most recent National Cancer Institute (NCI) report (1975 to 2009) is 1.34 in 100,000.[11] The incidence of ALL in blacks is significantly less than in whites, 0.81 versus 1.34. There is a slight male predominance with a male to female ratio of 1.56:1.14. The majority of the approximately 6,000 new cases each year in the United States are diagnosed in persons younger than 20-years old with a peak between the ages of 2 and 5 years; the median age at diagnosis was 14 years in the NCI SEER Cancer Statistic Review between 2005 and 2009.[11] The incidence decreases sharply thereafter, a trend that continues through adolescence and adulthood until after age 50, when the incidence again starts to rise steadily (Fig. 74.2). Geographic differences in the incidence of ALL are reflected by higher rates in North America and Europe and lower rates in African and Asian populations.[12]

Etiology

The cause of ALL in adults is largely unknown.[13] Inherited factors and genetic predisposition syndromes are more relevant to childhood ALL. Survivors of the nuclear fallout from the atomic bombing in Hiroshima and Nagasaki have an overall relative risk of 9.1 for ALL, greater among those exposed in childhood, with the peak incidence occurring 6 to 7 years after radiation exposure.[14] Somewhat more relevant to adult ALL is the association between occupational exposure to low-dose ionizing radiation among nuclear workers in the United States and Europe and a slightly increased risk for leukemia, although findings were inconsistent across populations.[15–17]

Among chemical environmental exposures, high-level benzene exposure that occurred before contemporary occupational safety standards is generally accepted as a cause of bone marrow aplasia, chromosome damage, and leukemia.[18,19] Cigarette smoking was linked to a small increase in risk for ALL among persons older than 60 years in one report.[20] Secondary acute leukemias occurring after exposure to chemotherapeutic agents are usually myeloid, although rare cases of therapy-related ALL have been observed.[21–23]

Molecular Pathogenesis

Molecular abnormalities can be grouped according to the functional consequence of oncogenic mutation. Acquired constitutive activation of the ABL protein kinase by rearrangement with the *BCR* gene is an example of a mutation that confers a proliferative advantage.[24] The fusion gene is the consequence of the t(9;22)(q34;q11) balanced chromosomal translocation,

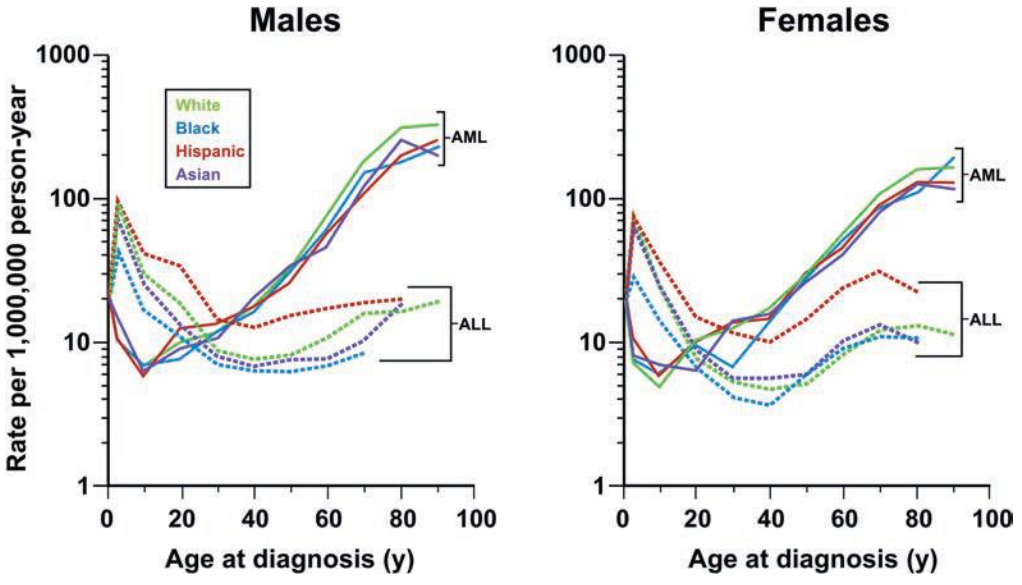

FIGURE 74.2. Age-specific incidence rates of acute lymphoblastic leukemia (ALL) (*dotted lines*) and AML (*solid lines*) according to sex and race/ethnicity, SEER-17, 2001 to 2007. which is the most common cytogenetic abnormality in adult ALL. ABL is a nonreceptor tyrosine protein kinase that enzymatically transfers phosphate molecules to substrate proteins, thereby activating downstream signal transduction pathways important in regulating cell growth and proliferation.[25] Other gene rearrangements result in loss- or gain-of-function mutations involving transcription factors that are important for normal hematopoietic development.[26] An example is the t(12;21)(p13;q22) chromosomal translocation, which juxtaposes the *ETV6* (*TEL*) and *RUNX1* (*AML*) genes.[27] Excluding numerical aberrations, *ETV6-RUNX1* is the most frequent cytogenetic abnormality in childhood ALL, although it is uncommon in adults. Another general mechanism of cancer formation involves loss or inactivation of tumor-suppressor genes, many of which have key regulatory functions in controlling cell cycle progression.[28] Examples are *p16*(*CDKN2A*) and *p15*(*CDKN2B*). Stock et al. investigated the incidence of cell cycle regulatory gene abnormalities in adult patients with de novo ALL treated by the Cancer and Leukemia Group B (CALGB) study group.[29] Deletions, microdeletions, and gene rearrangements involving *p16*(*CDKN2A*) and *p16*(*CKDN2B*) were common occurrences. Even more frequent was aberrant expression of *RB1* and *TP53*, two other tumor-suppressor genes. Concurrent abnormalities involving two or more of these genes were found in one third of adult ALL patients.

Aberrant expression of NOTCH1 has also been linked to ALL leukemogenesis. *NOTCH1* encodes a transmembrane receptor that regulates normal T-cell development. Upon proteolytic cleavage, NOTCH1 translocates to the nucleus and binds to a nuclear transcription factor, ultimately stimulating the transcription of target genes.[30] Although the association of a previously described t(7;9)(q34;q34.3) translocation, which fuses part of *NOTCH1* to the *TCRB* locus, is restricted to less than 1% of T-ALL, activating mutations of *NOTCH1* that produce aberrant NOTCH1 signaling independently of t(7;9) have been reported in over 50% of human T-ALL.[31] The exact mechanism for its role in leukemogenesis is not fully understood, although some evidence suggests that NOTCH contributes to TP53 suppression or nuclear factor-$\kappa\beta$ pathway activation, promoting deregulated T-cell proliferation.[32–34]

CLINICAL FEATURES

Although the clinical presentation is variable and may develop insidiously, virtually all adults diagnosed with ALL present with symptoms of only a few weeks duration. The symptoms generally reflect bone marrow failure or involvement of extramedullary sites by leukemia (Table 74.1). Up to one-half of patients with ALL have fever or documented infections. One third have bleeding symptoms at diagnosis, which is less frequent than in patients presenting with acute myeloid leukemia. Severe hemorrhage is uncommon.[34] Fatigue, lethargy, dizziness, or even dyspnea and cardiac angina may reflect anemia in adults with ALL. Marrow expansion by

leukemic blasts may produce bone pain and arthralgias, but marrow necrosis is much less frequently found in adults as compared with children who have ALL.[35] Approximately one half of adult patients have hepatomegaly, splenomegaly, or lymphadenopathy at diagnosis that can be appreciated on physical examination. Mediastinal masses are detected by chest radiographs or computed tomography scans primarily in patients with T-lineage ALL, who also frequently have pleural involvement and may complain of chest pain.[36] The fewer than 10% of ALL patients who have CNS involvement infrequently present with referable symptoms, such as headache, vomiting, neck stiffness, alteration in mental status, and focal neurologic abnormalities. Other sites of extramedullary involvement include testis, retina, and skin, although virtually any organ can be infiltrated by leukemic blast cells.

LABORATORY FEATURES

In addition to a complete medical history and physical examination, patients with ALL should have a battery of diagnostic laboratory tests to confirm the diagnosis, subcategorize the patient's disease for prognostic classification, and plan for appropriate therapy (Table 74.2). These studies include a complete blood count with examination of the peripheral blood smear, electrolyte measurements, creatinine, hepatic enzymes, uric acid, calcium, and albumin. Therapy-related declines in anticoagulation factors, including fibrinogen, occur with L-asparaginase, a drug commonly used in the treatment of ALL, and baseline levels should therefore be obtained. A mediastinal mass may be detected with a chest radiograph. A lumbar puncture for examination of the CSF to assess for leukemic involvement should be performed if patients present with neurologic symptoms. A bone marrow examination is mandatory and should include a complete cytogenetic assessment and immunologic phenotyping. Morphologic, cytogenetic, and immunophenotypic characteristics of ALL are detailed in Chapter 73. This section emphasizes features pertinent to adults diagnosed with the disease.

Routine Laboratory Evaluation

Routine laboratory evaluation reveals that a substantial number of adult patients with ALL have normal or only modestly elevated white blood cell (WBC) counts at the time of diagnosis (Table 74.3). Hyperleukocytosis (>100 × 10^9/L) occurs in approximately 15% of patients and may exceed 200 × 10^9/L. Some degree of anemia is present in the majority of adults. Approximately one third of patients have a platelet count less than 25 × 10^9/L, which is approximately the same proportion that present with bleeding symptoms. Circulating leukemic blasts may not be evident on examination of the peripheral smear in a significant number of patients. Coagulation parameters are typically normal, and disseminated intravascular coagulation is rarely observed.[37] Metabolic abnormalities, including hyperuricemia, can occur, especially in patients with rapidly dividing leukemia cells and high tumor burden.

TABLE 74.2

DIAGNOSTIC APPROACH FOR ADULT ACUTE LYMPHOBLASTIC LEUKEMIA

- Medical history
- Physical examination
- Laboratory studies
  - Complete blood count, peripheral smear, coagulation studies, fibrinogen level, serum chemistry (renal and hepatic function, electrolytes, calcium, phosphate, uric acid, LDH), ABO and Rh blood group, HLA typing
  - Appropriate cultures in the setting of fever
- Chest radiograph or computed tomography
- Cardiac assessment (EKG, ECHOcardiogram or MUGA)
- Lumbar puncture
- Bone marrow aspiration and biopsy
  - Immunophenotype analysis (± cytochemical stains); cytogenetic analysis (FISH probes for specific genes, translocations, and/or chromosome abnormalities); *BCR-ABL* molecular analysis (p190 and p210); minimal residual disease markers (by flow cytometry or PCR)
- Pregnancy test
- Information about fertility

Lumbar Puncture

A lumbar puncture is often performed at the time of diagnosis to examine the cerebrospinal fluid (CSF). CNS involvement is traditionally defined as greater than 5 WBC/μl of CSF with morphologically unequivocal leukemic blasts on the cytocentrifuged specimen.[38] Patients at risk for bleeding complications due to thrombocytopenia should be transfused to an adequate platelet count before the procedure. Whether to perform a lumbar puncture in patients with a high circulating blast count is controversial. This is due to concerns of iatrogenic "seeding" of the CNS with leukemic cells. Studies in pediatric ALL have shown that when the procedure is complicated by a traumatic tap, the finding of blast cells in the CSF occurs more frequently in children with higher presenting WBC count.[39] Among the patients who had traumatic lumbar punctures, those with leukemic blasts in the CSF were more likely to have subsequent CNS relapse.

Bone Marrow Evaluation

All patients with ALL should undergo a bone marrow aspiration and core biopsy procedure. The specimens must be submitted for histologic, cytogenetic, and immunophenotypic analysis. Morphologically, the marrow space is usually densely packed with leukemic blasts, which account for greater than 90% of nucleated cells in many adult ALL patients. As a result, the marrow biopsy sections are generally hypercellular, and, in 7% of adult patients with ALL, the normal marrow is completely replaced by leukemic blasts. This may prevent a successful aspiration, and a touch imprint of the biopsy tissue then becomes useful in evaluating cytologic features. Although increased reticulin deposits are common, marrow fibrosis is rarely present.[40,41]

Cytogenetics

Historically, poor chromosomal morphology in ALL made banding studies challenging, and karyotypic abnormalities were not reliably detected in early studies.[42] The implementation of modern metaphase spreading, banding, and molecular cytogenetic techniques now reveals prognostically significant abnormal karyotypes in the majority of adult patients with ALL.[43] These molecular techniques include fluorescent in situ hybridization using chromosome- and gene-specific probes for gene rearrangements that are difficult to identify, such as the t(12;21) chromosomal translocation.[44] Application of these sensitive methods has revealed, for instance, that the t(12;21) translocation is much less common in adults with ALL than in children.[45,46] Other age-related differences include fewer occurrences of numerical chromosome abnormalities and a higher incidence of the Ph chromosome in adults (Table 74.4).

Because of the profound prognostic implication of the Ph chromosome, molecular testing for the *BCR-ABL* gene rearrangement should be performed for all patients diagnosed with ALL.

The Ph chromosome was originally identified in a patient with chronic myeloid leukemia (CML), in whom the *BCR* and *ABL* genes juxtaposed within the so-called major breakpoint region.[24] This transcribes a 7-kb messenger RNA that is expressed as a 210-kd fusion protein, or $p210^{BCR\text{-}ABL}$. In ALL, a variant breakpoint location, which results in the smaller $p190^{BCR\text{-}ABL}$ oncoprotein, is commonly found.[47] A polymerase chain reaction (PCR) -based laboratory test capable of detecting both the $p210^{BCR\text{-}ABL}$ and $p190^{BCR\text{-}ABL}$ gene transcripts is now readily available to most clinicians and should always be performed in all newly diagnosed patients.

Immunophenotype

The primary basis of initial treatment strategies for ALL depends on antigenic parameters, and, hence, all patients should have their leukemic blasts characterized by immunophenotypic analysis. By current World Health Organization classification, the majority of adult ALL cases involve the precursor lymphoid neoplasms.[48] Approximately 70% of cases are B-cell ALL, and 25% are T-cell ALL. The remaining 5% are a mature B-cell neoplasm, Burkitt leukemia.[49] Compared with adults, children less often present with T-lineage ALL. There is also a slightly higher incidence of myeloid antigen expression in adult ALL patients, with reported incidences ranging from 15% to 54% compared with 4% to 35% in children.[50,51] Commonly detected myeloid antigens include CD13, CD15, and CD33.

Rare cases with co-expression of multiple lymphoid and myeloid antigens may be considered acute biphenotypic leukemia according to criteria suggested by a European group.[52] The clinical course appears to be poor; however, there is no uniform consensus on whether to manage these cases as acute myeloid or lymphoid leukemia.[53] The Royal Marsden Hospital group identified 25 acute biphenotypic leukemia patients whom they treated over a 7-year period.[54,55] The patients variably underwent remission induction with ALL-like regimens, AML-like regimens, or hybrid regimens containing elements of both with equal success, except for an excess of treatment-related mortality with the combined regimen. Overall survival was 39.4% at 2 years. They observed a high incidence of the Ph chromosome (41%) that partially accounted for the unfavorable outcome and emphasized the importance of aggressive risk-adapted therapy for these cases.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ALL in adult patients is rarely difficult. Most commonly, patients are diagnosed after an acute symptomatic presentation. ALL can be distinguished from the lymphocytosis, lymphadenopathy, and hepatosplenomegaly associated with viral infections and from lymphoma by the presence of leukemic blasts in peripheral blood or bone marrow specimens. This is followed by definitive diagnosis with immunophenotypic studies.

Difficulty may arise when patients present with an antecedent or overlapping period of pancytopenia before developing ALL, as has been sporadically reported.[56–59] It may be impossible to distinguish "aleukemic" pancytopenic ALL from aplastic anemia based on examination of the peripheral blood smear. Bone marrow evaluation and vigilant observation of the patient's clinical course are mandatory in these instances.

Patients in lymphoid blast crisis of CML are usually initially diagnosed in the chronic phase and later progress to acute leukemia. Characterization of the breakpoint region for Philadelphia-positive (Ph+) ALL patients is of no use in distinguishing de novo ALL from CML lymphoid blast crisis, as both $p190^{BCR\text{-}ABL}$ and $p210^{BCR\text{-}ABL}$ are found in even distribution in patients with Ph+ ALL.[60]

PROGNOSTIC FACTORS

Many clinical and biologic characteristics previously identified as prognostic factors for adult patients with ALL have lost predictive value as therapy has evolved and become more intensive. In contrast, age, WBC count at presentation, and immunophenotype remain strong predictors of disease-free and overall survival for Ph-negative patients.[61] (Table 74.5). More sophisticated assessment of the response to therapy, such as molecular detection of minimal residual disease (MRD), is becoming increasingly important in the management of adult ALL patients. The German Multicenter Study Group for Adult ALL (GMALL) prospectively assessed MRD evaluation in two consecutive trials.[62] The complete response rate was 89% after induction, but the molecular CR rate was only 70% in 580 evaluable patients. After consolidation molecular CR was highly predictive of continuous complete remission (CCR; 74% vs. 35%; $P < 0.0001$) and of overall survival (80% vs. 42%; $P = 0.0001$) compared with patients with molecular persistence. These results justify the routine assessment of MRD in the treatment of adult ALL and define a new high-risk group based on molecular persistence of disease.[63]

Clinical Features

Advanced age and high WBC count at the time of diagnosis have held up as significant adverse prognostic factors in all modern adult ALL multicenter collaborative trials.[5,7–9,61,64,65–73] Both advanced age and high WBC count were inversely correlated with more frequent occurrences of CR, longer duration of CR, or better overall survival in either the majority or all of the collaborative studies. Advanced age was variably defined as greater than 30 or 35 years. When included in multivariate analysis as a continuous variable, increasing age predicted worse outcome across the entire age range, making it difficult to choose a cut-off separating standard-risk from high-risk patients. The cut-off for high WBC count was either 30×10^9/L or 50×10^9/L. In the trial conducted by the CALGB study group, patients with advanced age (30 to 59 years) and high WBC count had an overall survival of 39% and 34%, respectively, compared with 69% and 59% for patients without these adverse prognostic factors.[7]

TABLE 74.5

PROGNOSTIC FACTORS FOR REMISSION DURATION IN ADULTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA (ALL)

Patient Features	Prognostic Factor
Age (y)	
<25, <35	Favorable
>35, >55, >70	Unfavorable
White blood cell count ($\times 10^9$/L)	
<30	Favorable
≥30 (≥100 for T cell)	Unfavorable
Immunophenotype	
Thymic T	Favorable
Early T (CD1a–, SCD3–)	Unfavorable
Mature T (CD1a–, SCD3+)	Unfavorable
Pro B (CD10–)	Unfavorable
Cytogenetics/Molecular genetics/ gene expression profiles	
Hyperdiploidy >50	Intermediate to favorable
Hypodiploidy <44	Unfavorable
9p abnormality	Intermediate to favorable
deletion 6q	Intermediate
Normal	Intermediate
Complex (≥ 5 abnormalities)	Unfavorable
B Lineage (e.g.,)	
t(12;21) (p13; q22) (*ETV6-RUNX1*)	Favorable
t(4;11) (q21; q23) (*MLL-AFF1*)	Unfavorable
t(1;19) (q23;p13) (*TCF3-PBX1*)	Unfavorable
t(9;22) (q34; q11) (*BCR-ABL1*)	Unfavorable[a]
IKZF1 deletions/mutations	Unfavorable
T Lineage (e.g.,)	
NOTCH1/FBXW7 mutations	Favorable
TLX1 or t(10;14) (q24; q11) (*TLX1-TCRA/D*)	Favorable
t(10;11) (p13; q14) (*PICALM-MLLT10*)	Unfavorable
t(5;14) (q35; q32) (*TLX3-BCL11B*)	Unfavorable
Response to therapy	
Complete remission within 4 wk	Favorable
Persistent minimal residual disease	Unfavorable

[a]Improved prognosis with tyrosine kinase inhibitors.

Laboratory Features

Immunophenotype

The major immunophenotypic subgroup with prognostic value and therapeutic importance is the mature B-cell neoplasm, Burkitt leukemia. Burkitt leukemia is characterized by strong expression of surface immunoglobulin in addition to other markers common to B-lineage ALL, including CD10, CD19, CD20, and CD22.[52] These patients respond poorly to standard ALL therapy, and outcome was dismal until brief, dose-intensified treatment programs were established as standard therapy.[74,75,76] The substantial improvement in survival that resulted has negated the adverse prognostic value of this feature if patients are optimally managed.

T-cell ALL is another formerly unfavorable prognostic subgroup that, due to changes in treatment approach, is no longer a poor risk feature.[77] In fact, with many modern treatment programs, the T-cell immunophenotype has become prognostically favorable.[7,68,78] High WBC count does not adversely affect survival in T-cell ALL unless the WBC is $>100 \times 10^9$/L.[66,67,79] In addition, more detailed examination of prospective immunophenotypic data collected by the CALGB identified a subset characterized by expression of fewer than three T-cell markers that had an unfavorable prognosis.[80] Leukemic blasts from these patients also infrequently expressed mature T-cell surface markers such as CD1a, CD2, CD3, CD4, and CD8, and, hence, would be consistent with the "early" T-cell ALL immunophenotype also reported to be unfavorable by the GMALL.[81,82] The distinction between early T-ALL (sCD3–, CD1a–), thymic T-ALL (sCD3–/+, CD1a+), and mature T-ALL (sCD3+, CD1a–) described by GMALL may serve as an example of a clinically significant, risk-adapted treatment stratification.[83]

Other immunophenotypic markers have variably been shown to have prognostic value but are less well established. CD34 is expressed more frequently in adults with B-lineage ALL and was reported to affect outcome by the CALGB adversely.[80] However, CD34 expression overlapped with both a high WBC and the presence of the Ph chromosome, and findings from other smaller series have yielded conflicting results.[84–88] Expression of myeloid antigen markers was slightly more frequent in B-lineage ALL than in T-lineage ALL but had no prognostic value in either instance.[64,80,89]

Cytogenetics

Unfavorable cytogenetic abnormalities in adult ALL include t(9;22)[*BCR-ABL*], observed in up to 30% of cases, t(4;11)(q21;q23)[*MLL-AFF1*], rare in adult ALL, t(1;19)(q23;p13)[*TCF3-PBX1*], also rare, and a hypodiploid karyotype, seen in 5% to 6%. Translocations involving chromosomal band 14q11 and abnormalities of the short arm of chromosome 12, including t(12;21)[*ETV6-RUNX1*], observed in 3% of cases, are favorable cytogenetic abnormalities. Results from collaborative studies providing karyotypic data generally indicate disease-free survival rates less than 25% for

patients with unfavorable abnormalities, as opposed to greater than 75% for those with favorable cytogenetic findings.[60,65,90–94] Additional reports from single institutions have provided similar outcome data.[95,96] Cytogenetic findings commonly identified in adult ALL with an intermediate prognosis include normal karyotype, hyperdiploidy, and abnormalities at 6q or 9p. The t(8;14)(q24;q32)[*MYC-IGH*] and other *MYC* gene rearrangements are associated with the Burkitt leukemia subtype and are not prognostically unfavorable markers with optimal treatment.

In the UKALL XII/ECOG 2993 trial, 41 patients (5%), without an established translocation, had a complex karyotype with 5 or more chromosomal abnormalities. Four patients were primary induction failures and 19 of 37 CR patients relapsed. All but 3 of these 19 patients relapsed within 2 years of diagnosis and 17 of the 19 died. EFS and OS were significantly inferior in this group. These results established complex karyotype as a poor prognostic indicator.[97]

Adult Ph-positive patients achieve CR rates comparable to Ph-negative ALL patients, but the remissions are short and survival poor with standard therapy. The most frequent translocation in adults involving the *MLL* gene, located at chromosome band 11q23, is t(4;11) and is also associated with poor survival.[94] The t(1;19) translocation results in the *TCF3-PBX* gene rearrangement, and patients with this abnormality were found to have a 3-year disease-free survival rate of only 20%.[92] Patients with hypodiploidy ranging from 30 to 39 chromosomes have a disease-free interval of only 2 to 4 months from the start of treatment.[92]

Deletions and translocations involving 12p include the *ETV6-RUNX1* gene rearrangement. *ETV6* gene rearrangements are much less frequent in adults than in children but are prognostically favorable in both. Translocations involving the *TCR-α/β* loci at chromosome 14q11 most frequently result in rearrangement with the *TLX1* (*HOX1)* gene at 10q24.[98] Adult ALL patients with t(10;14)(q24;q11) experience long survival, but this may reflect an association with T-cell ALL subtypes.[65,92]

Oncogenes

The absence of chromosomal abnormalities does not preclude the less conspicuous presence of aberrantly expressed oncogenes that promote leukemogenesis. Oligonucleotide microarrays, and more recently, next-generation sequencing technologies have led to a revolution in analysis of the leukemia genome and will undoubtedly add to cytogenetic profiling in the risk stratification of ALL. These are discussed in detail in Chapter 72. Using oligonucleotide microarrays, Ferrando et al. identified T-cell oncogenes—*TLX1, TLX3, TAL1,* and *LYL1*—that may have prognostic relevance in T-cell ALL.[99] These genes normally function as a homeobox gene (*TLX1*) or encode developmentally essential transcription factors (*TAL1, LYL1*) in normal thymocyte maturation. Their dysregulated expression is thought to foster leukemogenicity and can be detected as a signature genetic profile, which not only has the ability to provide insight into their pathogenetic heterogeneity, but also render important prognostic information. Overexpression of *TLX1*, present in approximately 30% of adult T-ALL cases, has been associated with a favorable prognosis, and in one study, demonstrated a leukemia-specific survival rate of 88% in *TLX1*-positive patients compared with 56% in *TLX1*-negative patients at a median follow-up of 4.7 years.[100] In contrast, the overexpression of *TAL1* or *LYL1* has been linked to poor response to treatment, and the predictive value of *TLX3*, another homeobox factor related to *TLX1,* is conflicting.[101,102]

Another mechanism for ALL leukemogenesis is the constitutive activation of tyrosine kinase via the *NUP214-ABL1* fusion episome. The juxtaposition of the two oncogenes leads to the familiar amplification of *ABL1* on the chromosome band 9q34. However, the *NUP214-ABL1* fusion escapes detection by conventional cytogenetics by virtue of its extrachromosomal position and requires molecular analysis for delineation. The fusion episome has been detected in approximately 6% of individuals with T-ALL.[103] Because of its sensitivity to abl tyrosine kinase inhibitors, the subset of T-ALL patients with this molecular feature is predicted to benefit from early identification.[104] The known presence of *TLX1* or *TLX3* may also merit exploration for the *NUP214-ABL1* fusion given their tendency for co-expression.[105]

Response to Therapy

Response to therapy can be assessed by determination of time to attainment of CR, quantitation of early leukemic blast clearance, or detection of MRD. These measurements provide a direct assessment of biologic susceptibility to antileukemic agents, and, as such, prognostic factors based on them have inherently high heuristic power. In addition, prospective evaluation of their utility as predictors of outcome in clinical trials has established that they also have high explanatory power. However, until recently, virtually all of the clinical studies measuring these outcomes have been performed in pediatric ALL. Assessments of response to therapy have become crucial prognostic factors in adult ALL, but remain underutilized in clinical practice. These should aid in refining prognostic models with the goal of improving outcome with risk-adapted therapy.

Early Complete Remission

Failure to achieve CR within 4 weeks of starting treatment or after one course of induction chemotherapy has been considered an independent unfavorable prognostic factor, confirmed in most adult ALL studies.[7,73] An exception is the international, multicenter UKALL XII/ECOG E2993 trial, which could not confirm its importance in its 1,500 patient cohort.[61] When significant, early CR held predictive value for standard ALL programs as well as for newer, dose-intensified treatment protocols.[5,67,78,106,107,108] Patients requiring greater than 4 weeks to achieve CR were at least twice as likely to relapse, depending on the study. In one study, patients who did not achieve CR by week 4 of induction had a 5-year disease-free survival of 0% as compared with 46% for the remainder of the complete responders.[78] In this study, the number of weeks required to achieve CR was only marginally worse than the Ph chromosome as an unfavorable variable.

Early Leukemic Blast Clearance

Evaluation for persistence of leukemic blasts at even earlier time-points, between days 7 and 21 of induction, has been firmly established as an important prognostic indicator for outcome in pediatric ALL.[109–111] Early persistence of leukemic blasts at 7 days after starting induction is thought to represent corticosteroid resistance.[112] In contrast, persistence at time-points after 21 days is considered a reflection of cytotoxic chemotherapy resistance. Numerous prospective studies in pediatric ALL have shown that a substantial unfavorable influence on outcome is associated with the morphologic detection of blood or marrow leukemic blasts persisting during induction therapy at day 7, day 21, or at other time-points in between. Persistence of leukemia was usually defined as the finding of greater than 1×10^9/L blast cells in a peripheral blood sample or leukemic blasts greater than 5% of normal cells in a marrow specimen.

Although pediatric protocols already incorporate early treatment response assessment by a day 7 or day 14 bone marrow examination into risk classification, similar data in adult ALL are limited.[113] Results from the few reported studies agree with findings from the pediatric experience. Sebban et al. prospectively evaluated persistence of marrow blasts, defined as greater than 5% of nucleated cells, at day 15 of induction for influence on outcome.[107] Among 437 adult ALL patients, one third were found

to have persistent blast cells. These patients were less likely to achieve CR after 4 weeks of therapy. Even among only the patients who achieved CR within 4 weeks, an otherwise favorable feature, those who had persistent blasts at day 15 fared significantly worse. Among all complete remitters, the 5-year disease-free survival was 34% for those who cleared marrow blasts at day 15, compared with 19% for those who did not. Annino et al. and the Italian collaborative study group evaluated the early corticosteroid response by giving a 7-day course of prednisone immediately before induction.[9] The pre-induction response was previously shown to have strong prognostic value in pediatric ALL.[114,115] In the adult ALL study, prednisone response was defined by reduction of peripheral blood blasts to less than or equal to 1×10^9/L. Lack of a prednisone response was found to affect overall survival negatively, as it did in the pediatric ALL studies, and, among CR patients, it also adversely influenced remission duration.

Minimal Residual Disease

MRD refers to the post-remission persistence of leukemia that cannot be detected by histomorphologic assessment. Immunophenotypic, cytogenetic, or molecular techniques can be used to detect MRD.[116] Samples from peripheral blood are generally one $\log_{10}$ less sensitive than bone marrow, perhaps as post-treatment *BCR-ABL* transcripts from peripheral blood clear more rapidly,[117] but may have comparable sensitivity in T-lineage ALL.[118,119,120] Fluorescence in situ hybridization is better than conventional banding analysis for detecting chromosomal translocations and numerical abnormalities, but both techniques are limited by low sensitivity.[121–124] Flow cytometry, used in four or more color combinations and taking advantage of new reagents, detects aberrant antigen expression on leukemic cells and can unambiguously distinguish one leukemic blast among more than 10^4 normal cells in 90% of all patients.[125,126] This level of sensitivity is sufficient for prognostically significant MRD detection.[127] Additionally, flow cytometry is rapid, reliable, and allows accurate quantitation, and the technical requirements for the assay are already in place at most centers, making it an attractive diagnostic tool. The most sensitive assays for detecting MRD, however, are based on PCR techniques, which can detect one leukemic blast in up to 10^6 normal cells. PCR targets using fusion gene transcripts such as *BCR-ABL*, *ETV6-RUNX1*, *AFF1-MLL*, and *E2A-PBX* are relatively standardized, but each alone can only be used for patient subsets.[128–130] PCR targets based on immunoglobulin and T-cell receptor gene rearrangements can be used to detect MRD in theoretically all patients, but lose sensitivity if consensus rather than patient-specific primers are used.[128,131] On the other hand, generating patient allele-specific primers requires DNA sequencing capability. Although a number of clinical studies have suggested the prognostic significance of threshold values of MRD,[132,133] early experience with accurate quantitation of leukemia-specific residual disease with the PCR assay was fraught with technical challenges, and standardization of assay sensitivity among testing facilities was of major concern.[130] Where available, however, real-time quantitative PCR technology utilizing newer automated methods has proven to be technically simple, yielding precise and consistent quantitation of residual leukemic clones, and is gaining widespread acceptance.[134,135] Information from pediatric ALL trials using PCR and flow cytometry in tandem may help determine more definitively the role of each for evaluating MRD.[136]

The prognostic utility of MRD detection was first described in studies conducted on children with ALL.[109,128,137] Three of the pediatric studies stand out for having large patient numbers, inclusion of both B- and T-lineage ALL, and for including patients with poor risk features.[127,132,133] The European studies were multicentered and used PCR detection of patient-specific antigen receptor gene rearrangement, whereas Coustan-Smith et al. used multicolor flow cytometry in an unselected patient cohort treated at the St. Jude Children's Research Hospital. MRD was determined at the end of induction and at various time-points thereafter. The testing was technically challenging, as 1,254 of 1,914 (66%) combined patients treated during the study period did not have suitable PCR targets, serial PCR performed, or an immunophenotype suitable for MRD assessment. Nonetheless, all three studies demonstrated an unfavorable influence of persistent MRD on relapse-free survival. By multivariate analyses in the St. Jude study, sequential detection of persistent MRD remained a poor prognostic marker after controlling for age, WBC count, and adverse cytogenetics including the Ph chromosome and *MLL* gene rearrangement.[127] Detection of MRD during maintenance therapy tended to have the strongest positive predictive value for relapse. Conversely, absence of MRD at the end of induction negated the unfavorable influence of persistent leukemic blasts at day 7 as a prognostic factor.

Studies assessing the predictive value of MRD in adult ALL have generally echoed findings of pediatric studies.[138–140] Mortuza et al. reported results for 66 Ph-negative adult B-lineage ALL patients treated at a single institution, for whom MRD was assessed with PCR using consensus immunoglobulin heavy chain gene primers.[138] Detection of residual leukemia at the 10^{-3} level, the limit of sensitivity of the assay, independently correlated with inferior disease-free survival when measured 3 to 5 months after induction therapy. The kinetics of MRD clearance has also gained much attention with respect to predicting relapse risk. Among the 196 standard-risk ALL patients monitored by quantitative PCR during their first year of treatment in the German Multicenter Acute Lymphoblastic Leukemia (GMALL) study, the 3-year relapse rate was 0% if MRD declined rapidly to lower than 10^{-4} at day 11, or below detection threshold at day 24, compared with a relapse rate of 94% if the MRD was at a level of 10^{-4} or higher until week 16.[141] Based on these results, they defined three risk groups based on MRD assessment in this otherwise homogeneous standard risk group. Scheuring et al. suggested that the magnitude and rate of *BCR-ABL* increase, as well as the absolute number of transcripts, could predict relapse within 2 months.[142] Another large cooperative group study reported that a 2-log reduction of MRD after induction, and a greater than 3-log reduction after consolidation therapy were associated with a 2-year actuarial probability of overall, disease-free, and relapse-free survival of 48%, 27%, and 38%, respectively, compared with 0% survival with smaller reductions.[143] The increasingly recognized prognostic significance of MRD has prompted a large cooperative group study to evaluate prospectively the utility of MRD in selecting patients for stem cell transplantation in first CR as a model for risk-adapted treatment strategy.[144]

PRIMARY THERAPY

Current management strategies for adult patients with ALL require a careful assessment of relapse risk at the time treatment is initiated. Most adult ALL patients have the precursor B-cell or T-cell subtype and can be managed with established treatment programs that start with remission induction, followed by blocks of intensification, CNS relapse prophylaxis, and prolonged maintenance therapy. With modern multiagent regimens, up to 90% of patients achieve CR, and 25% to 40% can be cured. The disease-free survival figure obviously needs improvement, and, hence, therapy should be tailored for patients who have an adverse prognostic profile. Risk-adapted therapy has proven remarkably effective for certain poor-risk groups, such as brief dose-intensive protocols for adult patients with Burkitt leukemia. Other patient groups known to have high risk for disease relapse should undergo allogeneic stem cell transplantation

(SCT) in first remission, given an available donor and eligibility status. Considerable clinical data suggest that this strategy has been effective, particularly with Ph+ patients. The ECOG/MRCXII trial also demonstrated the benefit of transplant in standard risk patients under age 50. Elderly ALL patients pose special treatment considerations that are discussed in this chapter. General issues relating to supportive care of the patient with leukemia are discussed in Chapter 69.

General Principles

On presentation, certain pre-treatment considerations should be addressed before initiating therapy. Leukemia therapy is guided by an estimate of relapse risk, although there is no formal risk assessment tool for adult ALL. In reviewing the list of agents used to induce remission and protect against relapse, it can be appreciated that the individual superiority of one drug over another in many instances has not been established. Complicating management decisions are similarly conflicting outcome results for SCT in first remission for high-risk patients, although the general consensus is that allogeneic SCT from a sibling donor is best therapy.

Pre-treatment Considerations

Attention should be paid to metabolic, infectious, and hematologic issues before starting leukemia-specific therapy. Hyperuricemia, hyperphosphatemia, and secondary hypocalcemia may be pronounced with high leukemic cell burden and require intravenous hydration, alkalinization, and administration of allopurinol. In addition to myelosuppression during intensive treatment blocks, ALL therapy suppresses cell-mediated immunity, and some protocols have provisions for prophylaxis against herpes simplex virus and *Pneumocystis jiroveci* infections.[106] The clinical consequences of hyperleukocytosis ($\geq 100 \times 10^9$/L) in adult ALL patients are not well understood. Patients with *MLL* gene rearrangements and Burkitt leukemia are at higher risk for hyperleukocytosis at presentation.[60] In children, pronounced hyperleukocytosis involving lymphoid blasts are better tolerated than myeloid blasts, as reflected by fewer complications attributable to leukostasis or hemorrhage.[145] In one series, leukapheresis for pediatric ALL patients having blast counts greater than or equal to 2×10^9/L led to outcomes equivalent to those for children who did not have this degree of hyperleukocytosis.[146] A similar policy is reasonable for adult ALL patients. Alternatively, immediate administration of prednisone or vincristine can rapidly reduce the circulating blast count. In an adult series, the WBC count dropped from greater than 100×10^9/L to less than 1×10^9 in 39% of patients given a 7-day course of prednisone immediately preceding remission induction chemotherapy.[9]

Risk Assessment Model

There are no useful clinical staging or prognostic scoring systems for adult ALL patients as there are for other hematologic malignancies, and there are no agreed-on uniform risk criteria as there are for pediatric ALL.[147–151] A prognostic model based on CALGB data suggested an additive effect of multiple adverse prognostic features on outcome, and, conversely, those without any poor prognostic factors did exceptionally well with few relapses.[7] Others have described similar analyses.[66,78] Based on these models and the current clinical evidence, a general framework for risk assessment may consider placing adults with ALL in different risk prognostic categories (Fig. 74.3). All patients with at least one established poor prognosis factor based on clinical, immunophenotypic, cytogenetic, or molecular features and response to induction therapy should be considered at high risk for relapse. Adding response to therapy, based on MRD detection, as a risk criterion for adapting therapy has been validated in several adult studies. In two consecutive GMALL trials (GMALL 06/99 and 07/03) involving 1,648 patients, prospective MRD evaluation was used at several time-points. MRD absence after consolidation therapy was highly predictive of continuous complete remission after 5 years (74% vs. 35%) as well as OS (80% vs. 42%). A multivariate analysis of prognostic factors, including age, immunophenotype, risk group, and MRD status after consolidation, found that only the MRD status was predictive of CCR after 5 years with a hazard ratio of 4.5 ($P < 0.0001$). Both age, with a hazard ratio of 1.3 ($P = 0.0007$), and MRD status, with a hazard ratio of 4.0 ($P < 0.0001$), influenced overall survival.[62]

In addition, patients with persistent MRD undergoing HSCT in first CR experienced higher rates of CCR than those without HSCT (66% vs. 11%), which led to better survival (54% vs. 32%). The Northern Italian Study Group also reported an advantage for patients positive for MRD treated with HSCT ($n = 36$) compared with non-HSCT ($n = 18$) with approximately 50% compared with 10% long-term disease-free survival.[152]

Remission Induction

The goal of remission induction therapy is hematologic complete remission (CR), as defined by the eradication of morphologically detectable leukemia cells in blood and bone marrow and the return of normal hematopoiesis. The importance of achieving CR after induction was highlighted in a study that demonstrated a 5-year overall survival rate of 45% in CR patients compared with 5% in patients who did not achieve CR.[61] Remission induction chemotherapy for adults with ALL is most commonly built around a backbone of vincristine and prednisone. Remission induction with these two drugs in combination produces CR in approximately one half of patients with de novo ALL. The CR rate improves to 70% to 85% when an anthracycline is added, which was proven in a landmark CALGB trial to be superior to vincristine and prednisone alone.[153] Induction failures are evenly divided between refractory disease and toxicity-related mortality.[5,7,9,66,78] The efficacy of various anthracyclines in adults, including daunorubicin, doxorubicin, zorubicin, and mitoxantrone, has been similar.[77,154–156]

Many alterations to the basic induction regimen have been evaluated.[82,157–160] A critical evaluation of the individual merits of these modifications is challenging. Improvement to CR rates that already exceed 80% would be difficult to detect at a satisfactory level of significance. Modern treatment protocols are complex, and it is difficult to attribute outcome results to any one component or to make comparisons of significant findings between any two trials. For example, some modern induction protocols also incorporate L-asparaginase, cyclophosphamide, or both, although neither has been proven by controlled trials to be beneficial in adult ALL when added to standard three-drug induction regimens. The one randomized trial with L-asparaginase found no improvement in frequency or duration of CR with the addition of L-asparaginase to doxorubicin, vincristine, and prednisone during induction.[161] Nonetheless, L-asparaginase has a mechanism of action that is close to being ALL-specific, causes minimal myelosuppression, and has been shown to be efficacious in pediatric ALL.[162] An Italian Gruppo Italiano Malattie Ematologiche dell' Adulto (GIMEMA) trial randomized adult ALL patients to induction with daunorubicin, vincristine, prednisone, and L-asparaginase with or without cyclophosphamide.[9] The rate and durability of remission, as well as overall survival, did not differ between the two randomized treatment groups or for any subtype analyzed. In contrast, other studies have suggested a benefit with the inclusion of cyclophosphamide during induction, especially for patients with T-cell ALL, and, conversely, worse outcome with its omission.[7,163]

Dose-intensified anthracycline and high-dose cytarabine induction regimens have been evaluated as alternatives to traditional

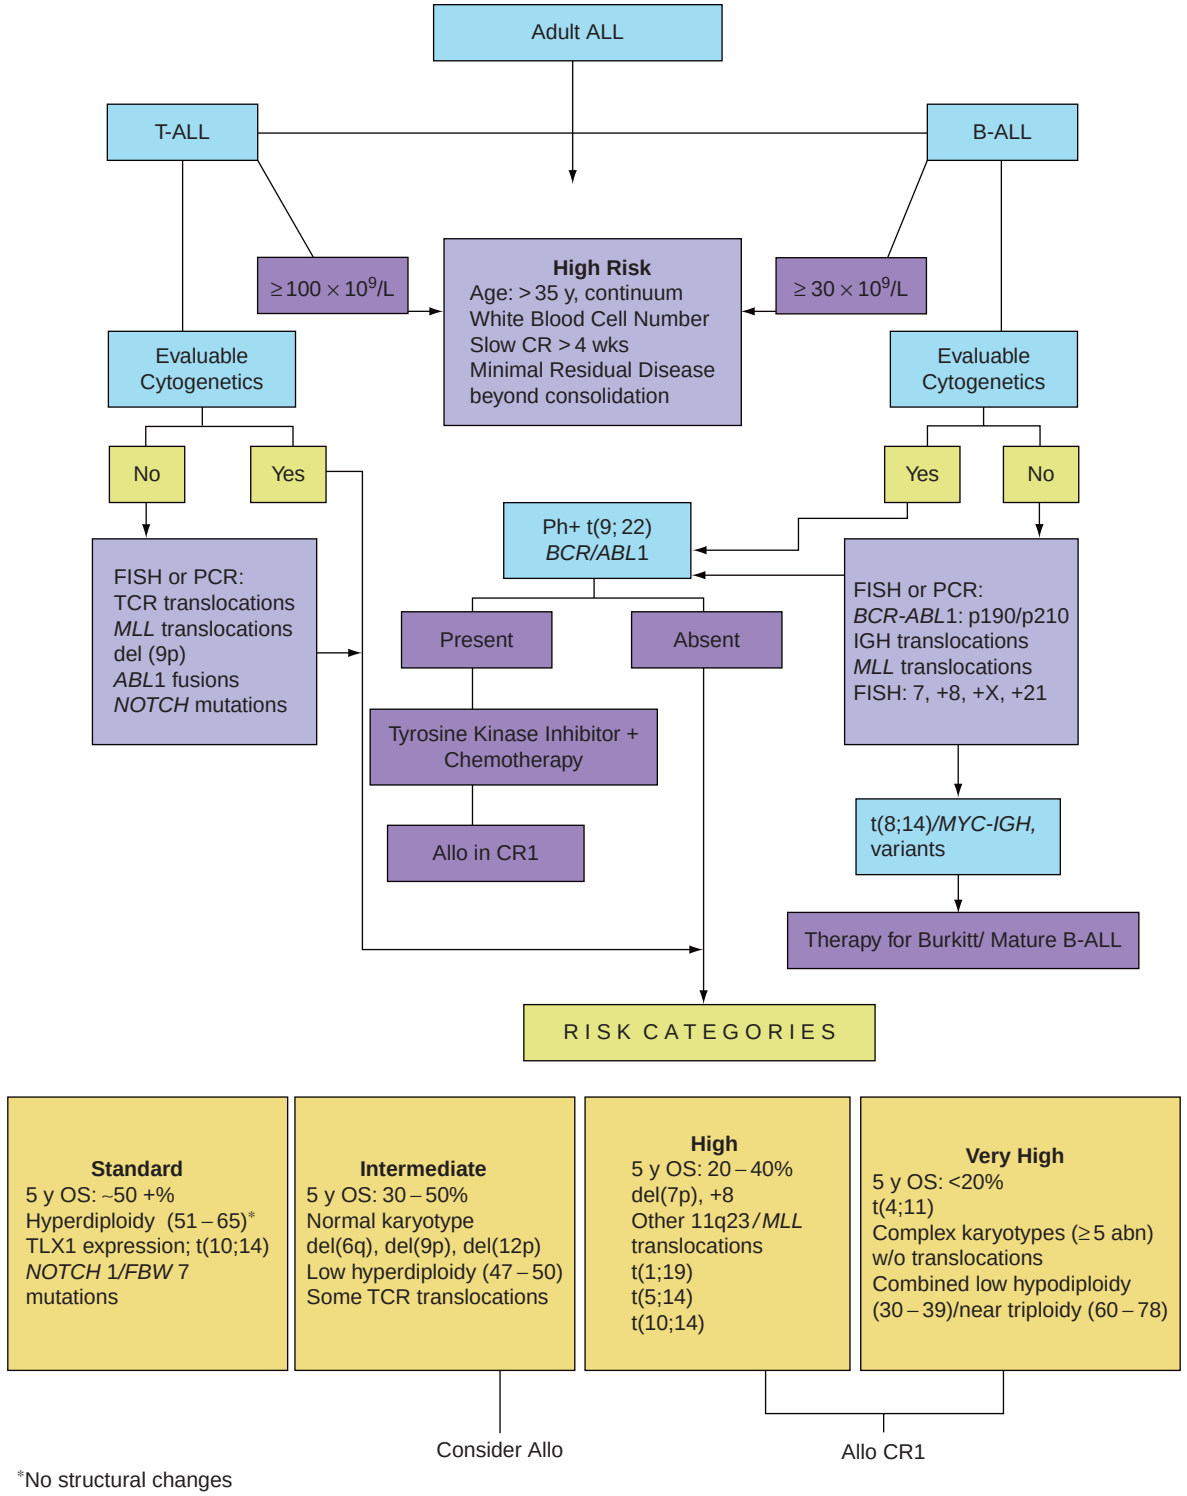

FIGURE 74.3. Risk assessment for adult acute lymphoblastic leukemia (ALL). Clinical, immunophenotypic, and cytogenetic features may be combined with the initial response criteria to classify patients into risk categories (Adapted from Pullarkat V, Slovak ML, Kopecky KJ, et al. Impact of cytogenetics on the outcome of adult acute lymphoblastic leukemia: results of Southwest Oncology Group 9400 study. Blood 2008;111:2563–2572.)

induction protocols. These treatment programs were intended to improve outcome by inducing rapid reduction of leukemic cell mass to achieve early CR.[164] Todeschini et al. generated considerable interest with reports from two sequential trials showing that dose escalation of daunorubicin to 225 mg/m^2 and, subsequently, to 270 mg/m^2 significantly improved disease-free survival.[165–167] Multicenter implementation of this protocol by the GIMEMA group, however, failed to reproduce the earlier experience based on an interim analysis of 460 of 501 total patients enrolled.[168] Weiss et al. investigated a different approach using high-dose mitoxantrone given with high-dose cytarabine during induction.[169,170] The results from their expanded randomized trial at seven study sites in the United States demonstrated improved remission (83% vs. 70%) and 5-year overall survival rates (35% vs.

22%), as well as less resistance and more activity in Ph+ disease, compared with a standard regimen,[171] establishing the activity of the combination of high-dose cytarabine and mitoxantrone in ALL. The standard L-20 regimen (vincristine, prednisone, cyclophosphamide, doxorubicin) used in this study did not use asparaginase during induction, and the results of the standard treatment arm are somewhat inferior to other contemporary regimens.

Dexamethasone has been substituted for prednisone in standard-risk pediatric patients in a large randomized trial.[172] The use of dexamethasone achieved a 34% reduction in relapse risk as well as a significant decrease in isolated CNS relapse. However, dexamethasone is associated with an increased risk of avascular necrosis in children. Current pediatric protocols use prednisone for all children >10 years old during induction and dexamethasone for those ≤10. This has not yet been studied in a comparable adult population.

Patients with Burkitt leukemia have poor initial responses to these conventional regimens and require special dose-intensified remission induction programs that are discussed below.[74,75,173,174,175]

Granulocyte colony-stimulating factor started after completion of the first few days of ALL induction chemotherapy did not improve survival or ultimate outcome in randomized trials. It did, however, shorten the duration of neutropenia by 5 to 6 days and appeared to reduce the incidence of associated complications, particularly infections.[64,176–178]

Intensification Therapy

Post-remission intensification or consolidation therapy after the attainment of CR is standard treatment for adult patients with ALL. This therapy refers to the administration of non-cross–resistant drugs aimed at eliminating residual leukemia to prevent relapse as well as the emergence of drug-resistant cells. Variably myelosuppressive doses of different drugs are given according to various schedules depending on the protocol. Due to the heterogeneity of approaches, it is difficult to assess the effect of any individual drug, and only a general assessment of the overall value of intensification can be made.

A randomized trial in childhood ALL clearly demonstrated that administration of both early (given immediately after CR) and late (week 20) intensification therapy was better than either early or late intensification alone and better than no intensification at all.[179] Two other pediatric trials confirmed the benefit of intensification.[180,181] Results from comparative trials in adults have been less clear and again highlight the difficulty of comparing findings from discordantly designed studies. The pediatric study was conducted by the British UKALL study group, which also enrolled adult patients in a concurrent trial using essentially identical treatment regimens.[5] There was a significant decrease in relapse incidence for adult patients who received the early intensification block, but this was not reflected by a statistically significant improvement in disease-free survival, possibly due to an increased number of deaths during remission. Likewise, two GIMEMA studies randomizing adult ALL patients to intensive versus standard consolidation and maintenance saw no advantage in disease-free survival for intensified post-remission treatment.[9,72] No benefit was observed with extending consolidation started early in the post-remission period from 1 month to 4 consecutive months.[182] Adding two myelosuppressive consolidation courses patterned after acute myeloid leukemia, "3 + 7" daunorubicin and cytarabine, to maintenance alone made no difference in the duration of remission.[183] Lastly, very late intensification given at 6 months or 11 months after CR, in two separate trials, led to no reduction in relapse compared with standard post-remission therapy alone.[184,185]

In contrast, clinical data from nonrandomized trials provide evidence that adult ALL patients benefit from intensification.[7,66,67] In the CALGB study, patients who achieved CR received two blocks of early intensification in addition to an 8-week late intensification therapy.[59] The reported medians of remission duration and survival, 29 months and 36 months, respectively, were substantially better than those observed in prior CALGB trials that did not use intensification blocks. Outcomes better than historical comparison groups were reported by the GMALL studies that consolidated remission patients with a late "re-induction" of drugs identical to initial therapy given 21 weeks after starting treatment.[7,63]

Maintenance Therapy

As with post-remission intensification, the value of long-term, continuous maintenance therapy for adult ALL has not been established by randomized trials as it has for pediatric ALL.[186] Patterned after the childhood ALL experience, maintenance therapy usually consists of daily 6-mercaptopurine and weekly methotrexate for a total treatment period of 2 to 3 years. There is no information from adult ALL trials regarding the proper duration of maintenance therapy, but children who receive less than 18 months of therapy have worse outcome. The addition of monthly pulses of vincristine and prednisone reduced relapses in controlled childhood ALL studies and has been adopted in some adult maintenance therapy regimens. From a mechanism-of-action perspective, it may be that long-term drug exposure is required to eradicate residual, slowly dividing, or drug-resistant ALL clones.[187] This could explain why maintenance is not necessary for optimally treated patients with Burkitt leukemia, which is a highly mitotically active leukemia.[2,74,75,173,174]

Relatively strong evidence that adult ALL patients benefit from maintenance therapy comes from a number of studies showing inferior outcome when prolonged maintenance was completely omitted.[154,188–190] The CALGB study was intended to evaluate the efficacy of mitoxantrone during induction and consolidation given over a 7- to 9-month period without maintenance.[154] Patient accrual on this trial was terminated at interim analysis because the median duration of remission (11 months) was much shorter than in previous protocols. Similarly, another American cooperative study group investigated high-dose cytarabine intensification followed by 8 cycles of multiagent consolidation.[189] Without maintenance, the median duration of remission was 10 months, and the disease-free survival at 4 years was only 13%.

Central Nervous System Therapy

CNS prophylaxis is essential in the treatment of ALL. Approximately one third of adult patients will eventually have CNS involvement at relapse without prophylactic therapy.[191,192] The advantage of CNS prophylaxis in adult ALL was established by the Southeastern Cancer Group in a randomized trial comparing cranial irradiation plus intrathecal methotrexate versus no prophylaxis.[193] CNS prophylaxis may involve combinations of intrathecal chemotherapy, cranial irradiation, and systemic administration of drugs with high CNS bioavailability, such as high-dose methotrexate and high-dose cytarabine. Although the best combination of modalities and the preferred timing have not been established in controlled trials, a number of different approaches have all proved equally effective. Intrathecal chemotherapy alone or high-dose chemotherapy alone, however, has been associated with poor protection from CNS relapse.[194,195] On the other hand, more aggressive approaches combining all three modalities do not yield clearly superior results.[66] Cranial irradiation between 1,800 and 2,400 cGy plus intrathecal methotrexate started after achievement of CR has been used as CNS prophylaxis in several studies, with CNS relapse rates between 0% and 11%.[7,69,78,163] Similar results were achieved in other studies that were able to omit cranial irradiation by starting intrathecal chemotherapy concurrent with induction and incorporating high-dose methotrexate, high-dose cytarabine, or both.[72,108,183]

Adult ALL patients with CNS involvement at diagnosis require additional CNS-directed therapy, as it can adversely affect survival. In the UKALL XII/ECOG 2993 trial evaluating post-remission therapies, overall survival at 10 years was inferior in patients with CNS disease at diagnosis compared to those without (34% vs. 29%, $P = 0.03$).[196] Up to 10% of adults present with CNS leukemia at the time of diagnosis.[7,67,156,195] Patients with Burkitt leukemia are at high risk for both CNS disease at presentation and subsequent CNS relapse.[74,75] The treatment of CNS leukemia has generally involved early and repeated dosing of intrathecal chemotherapy started during induction therapy.[67,78,106] Kantarjian et al. gave twice weekly alternating intrathecal methotrexate and cytarabine until the CSF showed no leukemic blasts, followed by the standard intrathecal prophylaxis regimen.[106] Linker et al. gave intrathecal methotrexate injections weekly for 10 weeks, then monthly for the remainder of the first year.[78] The cranial irradiation dose was also increased to 2,800 or 3,000 cGy when included as CNS prophylaxis during the treatment protocol.[67,78] With either approach, the presence of CNS leukemia did not adversely affect subsequent outcome.

Hematopoietic Stem Cell Transplantation

Allogeneic SCT in first remission improves outcome for adult ALL patients with high-risk features and should be pursued for all eligible patients. Outcome data from most uncontrolled individual trials indicate disease-free survival between 40% and 60% with matched sibling allogeneic SCT.[197–200,201] Some centers reported exceptionally impressive results. In a transplant study performed by Stanford University and the City of Hope National Cancer Center, high-risk inclusion criteria were defined as age greater than 30 years, a WBC count greater than 25×10^9/L, failure to achieve CR within 6 weeks of starting induction, or the presence of unfavorable cytogenetic abnormalities. Blume et al. initially reported a disease-free survival rate of 63%, which held up at 61% with longer follow-up of an expanded patient cohort, as reported by Chao et al.[197,198]

Registry data from the International Bone Marrow Transplant Registry (IBMTR) provide additional information. Registry data are useful in limiting the influence of selection bias and heterogeneity between patient groups at different institutions, especially when based on large patient numbers. Reporting on 243 adult patients with high-risk ALL undergoing sibling donor allogeneic SCT, the 5-year estimate of disease-free survival was 39%.[202] Treatment-related mortality (37%) exceeded disease relapse (30%) as the cause of treatment failure. In additional analyses by the IBMTR, patients were found to be half as likely to relapse if they developed either acute or chronic graft-versus-host disease.[203] Others have also described similar evidence for a significant graft-versus-leukemia effect, which may have contributed to the relatively low relapse rate, although to a lesser degree in comparison to chronic and acute myeloid leukemias.[204,205] Several comparisons of IBMTR data with outcome after standard therapy have been reported.[206,207,208] In these indirect comparisons with historical control groups, allogeneic SCT in first CR proved superior for survival due to protection from relapse.

The first study providing controlled outcome data for allogeneic SCT versus standard therapy was the French Leucémie Aiguë Lymphoblastique de l'Adulte (LALA)-87.[70,71,156] The study genetically randomized adult patients with ALL to sibling donor allogeneic SCT in first CR versus consolidation and maintenance chemotherapy, regardless of risk category. Risk categorization was based on criteria set by the German study group.[67,68] Allogeneic SCT was found to be significantly superior to standard therapy but only for high-risk patients. Disease-free survival at 10 years for these patients was 44% with allogeneic SCT versus 11% for conventional therapy. For standard-risk patients, disease-free survival with allogeneic SCT was similar (49%) but no better than conventional therapy (43%). The subsequent LALA-94 study also favored allogeneic SCT over standard chemotherapy for high-risk patients, with respective 5-year overall survival rates of 51% and 21%.[209] The benefit of allogeneic SCT from a related donor in first CR even in standard-risk patients was demonstrated in the UKALL XII/ECOG 2993 trial.[6]

Allogeneic SCT from unrelated donors for adults in first CR can be successfully performed. Various individual trials have been reported, as well as results reported to the National Marrow Donor Program (NMDP). When 64 patients with high-risk features, including the t(4;11) and t(1;19) translocations, received matched unrelated donor allogeneic SCT in first CR, transplant-related mortality was 54%, but relapse at 4 years was only 19%. Only 1 of 17 patients surviving beyond the first year had relapsed at the time of last follow-up.[210] Subsequently, Weisdorf et al. reported the outcome of 517 patients, ranging in age from 0 to 51 years, with high-risk ALL, including relapsed status and the t(4;11) and t(1;19) translocations, who received matched unrelated donor allogeneic SCT in first or second CR.[211] Transplant-related mortality was 42%, but relapse at 5 years was only 14% for those transplanted in first CR, and 25% for those in second CR. The 5-year probability of disease-free survival rates for those transplanted in first and second CR were 44% and 36%, respectively. Similarly, in a large European study, 5-year disease-free survival did not differ between patients receiving a graft from a matched related or unrelated donor as long as the SCT occurred in first CR (42% vs. 45%, respectively).[212] Treatment-related mortality also did not differ between the two donor types of SCT.

The role for autologous SCT as an option for post-remission therapy in high-risk ALL patients is difficult to evaluate. The French LALA-87 group performed a trial, parallel to the allogeneic SCT study that randomly assigned patients younger than 50 years who did not have a matched sibling donor to autologous SCT versus standard therapy, regardless of disease risk.[71,156] Conventional therapy was found to be equivalent to autologous SCT for standard-risk patients. For high-risk patients, autologous SCT and conventional therapy both proved equally ineffective, with 10-year disease-free survival rates of 10% and 16%, respectively. Patients on the SCT arm were transplanted after three consolidation courses, and the autografts were purged with monoclonal antibodies and complement or mafosfamide. The LALA-94 study compared the outcomes of high-risk ALL patients who were assigned to allogeneic SCT if they had an HLA-identical sibling, or randomized to autologous SCT versus standard therapy if they did not. Autologous SCT conferred no advantage over chemotherapy in this high-risk population, and the respective 5-year overall survival rates of 32% and 21% were not significantly different in statistical analysis.[207] In the UKALL XII/ECOG 2993 trial, conventional chemotherapy was superior to autologous transplant, with a 46% versus 37% 5-year survival.[6] Many autologous transplant studies compare individual trials with registry data and report significantly better results. Trials that compare registry data differ considerably from one another and from the French randomized studies with respect to timing of transplant, purging method, intensity of preparative regimen, and whether post-transplant maintenance therapy is given.[213,214] Taken together, disease-free survival for autologous SCT in first CR from individual trials ranges from 26% to 65%, a wide degree of variability likely reflecting the above considerations.[201,215] In some studies, transplant-related mortality approached 20% and seems high relative to contemporary experience with autologous SCT.[216–218]

A comparative analysis of data from two registries—the NMDP and the Autologous Blood and Marrow Transplant Registry—reported the outcomes of 517 patients who received matched unrelated donor allogeneic transplants and 195 patients who underwent autologous SCT. Transplantation-related mortality was higher after unrelated donor SCT (42%) compared with

autologous SCT (20%), but relapse rate was higher in the latter group (49%) compared with the former (14%). Five-year disease-free survival rates were similar (44% for unrelated donor SCT vs. 31% for autologous SCT) when transplanted in first CR or second CR (36% after unrelated SCT vs. 27% after autologous SCT). Net survival outcomes were, therefore, considered similar between the two transplant types, with the sole exception of a subset of patients with no high-risk features who enjoyed superior outcome with allogeneic compared to autologous SCT.[211] In contrast, a trial genetically randomizing adult patients in first CR to sibling donor allogeneic versus autologous SCT found the former superior by a substantial margin.[219] The French Groupe Ouest-Est des Leucémies et Autres Maladies du Sang (GOELAMS) trial prospectively compared matched sibling allogeneic SCT in first CR with unpurged autologous SCT following sequential re-induction in patients who had no HLA-matched sibling donor or who were older than 50 years. Matched-sibling SCT significantly improved the 6-year overall survival (75% vs. 40% after autologous SCT).[220]

Tailoring post-remission strategies in a risk-adapted manner has become an accepted approach in the management of patients with ALL. There is general agreement that, at least in the high-risk patient population, in whom conventional therapies are known to be inferior, expeditious administration of allogeneic transplantation with a matched related donor, whenever possible, can afford the best chance for long-term survival. In contrast, autologous transplant does not seem to be superior to standard chemotherapy approaches.

Adult B-Cell and T-Cell Acute Lymphoblastic Leukemia

Adult ALL patients with the B-cell or T-cell immunophenotype should enter into chemotherapy treatment programs that start with multiagent remission induction chemotherapy. Prophylaxis against CNS relapse is indicated for all patients. Standard-risk patients who achieve remission, who are the majority, should continue with intensification and maintenance therapy or consider allogeneic SCT. Patients at high risk for relapse are best managed with allogeneic SCT in first CR.

Modern adult ALL treatment regimens that have been established by major collaborative study groups are illustrated in Figure 74.4.[5,7,9,66,67] Clinical outcome results from adult trials are summarized in Table 74.6. Almost all modern multiagent, multiphasic adult ALL treatment protocols are variations on the same basic treatment theme.[6,9,73,77,78,152,156,161,183,209,220,221–227,228,229,230,231,232,233,234] Two exceptions are the GMALL B-NHL 86 and hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone) protocols, which are brief, intensive treatment regimens that have particularly improved outcomes for adult mature B-cell ALL. Although these protocols are further discussed separately in this chapter,[74,75] the hyper-CVAD regimen also has high activity in non-Burkitt B-cell ALL subtypes.[228] Maintenance thereapy, delayed intensive cycles, and rituximab (if CD20+) are added to HyperCVAD in pre-B ALL.[235]

The remission induction regimens are built around the four-drug combination of vincristine, prednisone, L-asparaginase, and an anthracycline, most commonly daunorubicin. The American CALGB 8811 and Italian GIMEMA 0288 protocols added cyclophosphamide to the induction regimen. For those who achieve remission, induction is followed by various intensification or consolidation treatment blocks, generally completed within 6 months of starting treatment. Prolonged maintenance with 6-mercaptopurine and methotrexate is continued for a total of 2 years of scheduled therapy. Intermittent pulses of vincristine and prednisone are also given during maintenance in the CALGB, GIMEMA, and the British UKALL protocols. Cranial irradiation is administered early in the German GMALL treatment program and during interim maintenance in the CALGB and UKALL programs, but omitted in the GIMEMA trial.

The CALGB 8811 trial was conducted between September 1988 and June 1991 at 25 institutions in the United States. Larson et al. reported the results of this study, which showed an 85% CR rate, median remission duration of 29 months, and disease-free survival of 46% but with relatively short median follow-up of 43 months.[7] Of these patients, 6% failed therapy due to death during induction, and an additional 7% due to refractory disease. Intensification of standard induction with cyclophosphamide was felt to contribute to favorable outcome with T-cell ALL but contributed to myelosuppression, requiring dose reduction in patients older than 60 years and hospital stays averaging 26 days during the induction phase. Prospective karyotype and immunophenotypic data were collected from patients on this and subsequent CALGB protocols for analysis of prognostic markers and were reported separately.[65,80]

The German GMALL 02/84 trial evaluated sequential blocks of intensive induction and consolidation therapy that extended for nearly a year before beginning maintenance. CNS therapy was aggressive and incorporated intrathecal chemotherapy and cranial irradiation, as well as systemic high-dose cytarabine and methotrexate. International application of this treatment protocol confirmed the high CR rate and disease-free survival of 39% that was reported by Hoelzer et al.[66,67,194,219,236–238]

The British UKALL XA trial was designed to evaluate the benefit of post-remission therapy with early and late intensification blocks. Results were reported by Durrant et al.[4] CR was achieved in 88% of adult patients, and disease-free survival at 5 years was 28%. As previously mentioned, there was a reduction in relapse for patients randomized to receive the early intensification block, but this did not lead to a superior disease-free survival rate. Additional analyses of this patient cohort describing clinical, immunophenotypic, and cytogenetic prognostic factors were detailed in separate reports.[69,93]

The GIMEMA 0288 trial tested the prognostic value of response to pre-induction prednisone and the efficacies of cyclophosphamide inclusion during induction followed by intensification of post-remission therapy. An 82% CR rate was observed in 794 adult patients with ALL, which was not better among patients randomized to receive cyclophosphamide during induction.[9] The response to prednisone was shown to have prognostic significance. Prednisone responders had an overall survival rate of 33% at 8 years compared with 17% among nonresponders. The disease-free survival rate was 29%, which was no better for patients who were randomized to an additional eight-drug consolidation after intensification, as opposed to proceeding directly to maintenance therapy.

In a single-institution study of 288 patients, dose-intensive hyper-CVAD courses alternating with high-dose methotrexate and cytarabine, with concomitant intrathecal CNS prophylaxis, achieved a CR rate of 92%. With a median follow-up of 63 months, the 5-year disease-free and overall survival rates were both 38%,[228] demonstrating activity comparable with other established protocols. A smaller single-institution study evaluated the outcome of 84 patients using an intensified and shortened chemotherapy regimen consisting of an induction program with daunorubicin, vincristine, prednisone, and asparaginase, followed by cyclical post-remission therapy with high-dose cytarabine/etoposide, high-dose methotrexate/6-mercaptopurine, and the four drugs used in induction,[239] along with intrathecal CNS prophylaxis. Despite eliminating prophylactic cranial irradiation and reducing the total dose of daunorubicin, the CR rate was 93%, and the 5-year disease-free survival rates for patients with B-lineage ALL, with and without high risk factors, were 34% and 66%, respectively.

Adult Mature B-Cell Acute Lymphoblastic Leukemia (Burkitt Leukemia)

The mature B-cell phenotype is found in 5% of adult ALL cases, and most are not cured with the majority of conventional ALL regimens such as those just described. Diagnosis is made by morphologic and immunophenotypic features, as has been discussed. Compared with other ALL subtypes, there is a more pronounced male predominance and higher incidence of extramedullary disease, including CNS involvement.[240–242] As is the case with other high-grade malignancies, the blast cells have a rapid doubling time, and vigorous supportive care must be pursued to prevent or treat tumor lysis syndrome.[243] The high proliferative rate exhibited by the leukemic cells served as the rationale for a treatment strategy based on repeated administration (hyperfractionation) of high-dose cyclophosphamide plus methotrexate, also given at high dose, which proved highly successful in pediatric studies.[173,244]

Adapted from Bassan R, Hoelzer D. Modern therapy of acute lymphoblastic leukemia J Clin Oncol 2011;29:532–543.

Studies performed by European and American groups have established that these brief, cyclical, dose-intensive protocols are the preferred approach to treating adult patients with mature B-cell ALL (Table 74.7).[74,75,76,245–247,248,249–252] Adapted from the pediatric regimens, the B-NHL 86 protocol was used by the German study group (Fig. 74.4) and the hyper-CVAD treatment program was evaluated at the M.D. Anderson Cancer Center. Both use alternating blocks of intensive chemotherapy given monthly for a total of 6 or 8 months without subsequent maintenance. The hyper-CVAD regimen rotated fractionated high-dose cyclophosphamide with high-dose methotrexate. The B-NHL 86 protocol gave high-dose methotrexate with every treatment block and alternated cyclophosphamide with ifosfamide. CNS prophylaxis with intrathecal chemotherapy was started early, but cranial irradiation was omitted in the hyper-CVAD protocol. Similar outcome was reported by both studies. Remarkably similar results were also reported by the CALGB, which implemented the German protocol in a study involving 24 adult patients, with the exception that excess neurotoxicity was reported by the CALGB.[246] By reserving intensive CNS prophylaxis for only high-risk individuals, however, the modified CALGB study was able to minimize neurologic toxicity without compromising efficacy.[76] Overall, with the use of such dose-intensive, short-duration combination chemotherapy treatment regimens, CR rates of 75% to 90% and overall survival rates of 50% to 70% have been achievable,[175,253] substantially improving the outcome in a highly aggressive disease once considered incurable.

There are currently no effective treatment options for mature B-cell ALL patients who have refractory or relapsed disease. From the recent studies, predictors for relapse or poor outcome include high WBC count (>50×10^9/L), severe anemia, older age, elevated LDH, and poor performance status.[74,75,245,247] In the report by Thomas et al., nine patients relapsed in CR, for whom the median remission duration was only 7 months. Progression after relapse was rapid, with two deaths occurring before treatment could be initiated. The remaining patients were resistant to salvage therapy that included re-treatment with hyper-CVAD. After relapse, the median survival for the group was 1 month.

Philadelphia Chromosome-positive Acute Lymphoblastic Leukemia

Ph+ ALL accounts for at least 20% of adult cases [60,254,255] and is associated with a poor prognosis.[256] Patients tend to be older and have a higher WBC count and are more likely to present with

hepatosplenomegaly and lymphadenopathy. Virtually all have the B-cell immunophenotype. Earlier experiences with standard ALL induction chemotherapy demonstrated that most achieved CR, but few were long-term survivors due to relapse. The median duration of survival ranged from 8 to 16 months, and disease-free survival did not exceed 10%.[65,91–93,257] The hyper-CVAD regimen led to improved response rates and duration of CR, but not to advantage in overall survival.[254] Incorporation of maintenance therapy to the regimen yielded potentially encouraging results for subtypes of adult ALL other than mature B-cell ALL but had no impact on survival for the 32 Ph+ patients in the series reported by Kantarjian et al.[106] In the LALA-94 and UKALLXII/ECOG 2993 trials the median OS was 5 months and the 5-year OS was only 3% to 6% in patients treated after relapse with Ph+ disease.[258]

Given the dismal prospect for long-term survival with combination chemotherapy alone, early allogeneic SCT in first CR has long been the recommended treatment for patients with Ph+ ALL. The benefits of transplantation derive from the intense myeloablative therapy combined with the graft-versus-leukemia effect.[259] Results vary from center to center, but with allogeneic SCT, 30% to 65% of Ph+ patients can expect long-term survival.[260–263] Registry data from the IBMTR show rates at 2 years of 38% for disease-free survival and 34% for relapse.[264] A large retrospective review of children who were Ph+, an equally unfavorable marker in pediatric ALL, suggested that allogeneic SCT substantially improved survival compared with chemotherapy alone.[265] In the prospective, multicenter LALA-94 trial of 154 patients with Ph+ ALL, both the absence of MRD and presence of allogeneic SCT were independent predictors of disease-free and overall survival.[266] In the study of 267 Ph+ ALL patients in the prospective multicenter trial UKALLXII/ECOG 2993, the actuarial 5-year relapse risk was lowest for those undergoing allogeneic SCT (32%) compared with those treated only with chemotherapy or with autologous SCT (81%).[258] Recipients of allogeneic transplants experienced higher event-free and overall survival rates at 5 years (36% and 42%, respectively) compared to their counterpart (17% and 19%, respectively).

The probability of cure, although small in this patient population, further diminishes with advanced disease. Among 38 patients studied by Chao et al., the disease-free survival for Ph+ ALL patients transplanted in first remission was 46% at 10 years, compared with 28% in those transplanted after relapse.[267] In another study of 127 patients with poor-risk cytogenetics, the National Marrow Donor Program reported that the overall survival at 2 years following matched unrelated SCT was 40% for patients in first CR, 17% in second or third CR, and 5% for primary refractory disease or relapse. The high treatment-related mortality associated with unrelated transplantation did not appear to overshadow the 37% disease-free survival at 2 years for patients in first CR.[210]

A paradigm shift in the treatment of Ph+ ALL patients has occurred with the introduction of the oral tyrosine kinase inhibitor imatinib mesylate, with a reported response rate of 70% as a single agent.[268] Although imatinib monotherapy in relapsed or refractory disease resulted in disappointingly poor durability,[269] immediate post-remission SCT [270] and integration into combination chemotherapy regimens have improved its therapeutic outlook. In the evaluation of concurrent hyper-CVAD and imatinib in 26 newly diagnosed Ph+ ALL patients, 96% achieved CR and five entered molecular remission, or RT-PCR negativity for the *BCR-ABL* transcript. Even without post-remission SCT, the 2-year disease-free survival rate was 87% for the combination imatinib–chemotherapy group compared with 12% to 28% with conventional chemotherapy regimens.[271] The value of incorporating imatinib into chemotherapy regimens in the treatment of newly diagnosed Ph+ or *BCR-ABL*–positive adult ALL patients was reiterated in another study that demonstrated a CR rate of 96%, molecular response exceeding 71%, and 1-year event-free and overall survival rates of 60% and 76%, respectively.[272] With a reduced risk of relapse compared with chemotherapy alone (3.5% vs. 42.3%) [273] and no adverse impact on subsequent SCT,[274] imatinib combined with chemotherapy can serve as a bridging strategy to SCT, the only known therapy with curative potential. When including imatinib, concurrent administration with chemotherapy appears to be superior to an alternating schedule,[275] and attention to CNS prophylaxis remains paramount given its poor CNS penetrance.[276]

The second-generation BCR-ABL tyrosine kinase inhibitors dasatinib and nilotinib have also shown efficacy when used either as single agents or in combination with chemotherapy in this patient population.[277,278] Dasatinib has been incorporated into

treatment programs for adults with Ph-positive ALL. In a phase II study of dasatinib with hyper-CVAD in previously untreated Ph-positive patients 94% of 35 patients achieved CR.[278] With a median follow-up of 14 months, median DFS and OS had not been reached. In another trial that involved initial treatment, dasatinib was given along with steroids to 53 newly diagnosed patients and all patients achieved complete hematologic response.[277] Although these results show that significantly less toxic regimens that include TKIs can achieve very high CR rates and survival has improved, the general recommendation is for eligible adult patients with Ph-positive ALL to undergo allogeneic SCT.

Ponatinib is the newest approved BCR-ABL inhibitor with activity against all known abl mutations including the resistant T315I mutation. A phase II trial consisted of 94 patients with CML lymphoid blast phase or Ph+ ALL, resistant or intolerant to other TKIs.[279] With a median follow-up of 12 months, the major hematologic responses were noted to be 35% and 33% in patients with resistance/intolerance to prior TKI and those with T315I mutation, respectively.

MRD following SCT for Ph+ ALL portends imminent relapse. Imatinib given in this setting was found to be effective in suppressing frank relapse in one study, inducing molecular negativity in 52% of 27 patients for the duration of treatment.[280] Relapse was observed if imatinib was unable to achieve molecular remission or in those who discontinued imatinib. Disease-free survival rates in those achieving molecular remission was 91% at 12 months and 54% at 24 months, compared with 8% at 12 months for those with remaining MRD.

Acute Lymphoblastic Leukemia in Elderly Patients

One third of adults diagnosed with ALL are older than 60 years according to US prevalence data.[281] Advanced age is itself an adverse prognostic factor for ALL, and survival decreases continuously with increasing age (Fig. 74.5). Although older age is independently predictive of inferior outcome, a number of factors can be identified that may account for the poor prognosis.[282–285] Elderly ALL patients tend to have worse performance status, in part, reflecting co-morbid medical conditions. As a result, these patients have limited tolerance for intensive therapy, which may contribute to a high rate of treatment-related mortality. In addition, aspects reflecting the underlying biology of the leukemia likely have an influence as well. Elderly patients are more likely to be Ph+, be underrepresented in the favorable T-cell subgroup, and have disease refractory to standard chemotherapy drugs used to treat ALL.

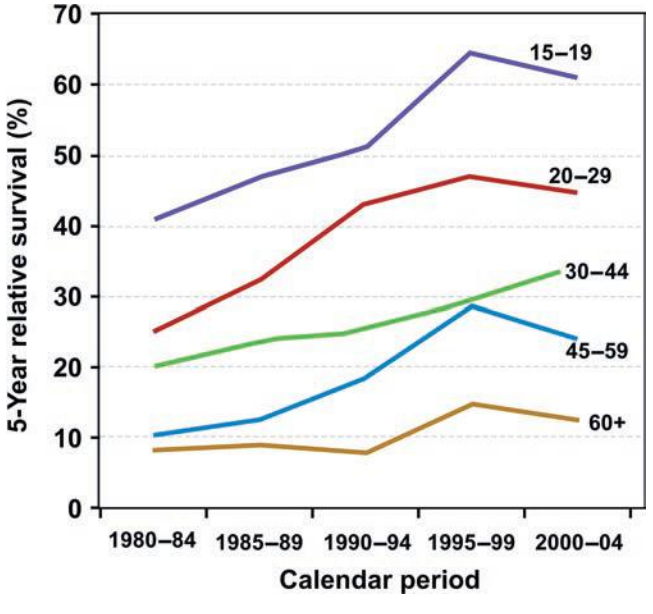

FIGURE 74.5. Five-year relative survival of patients with acute lymphoblastic leukemia (ALL) by major age groups in calendar periods from 1980–1984 to 2000–2004. (With permission from Pulte D, Gondos A, Brenner H. Improvement in survival in younger patients with acute lymphoblastic leukemia from the 1980s to the early 21st century. Blood 2009;113:1408–1411.)

At present, there is no satisfactory approach for managing elderly patients with ALL. Several groups have described treatment outcome for these patients, and the results are summarized in Table 74.8.[284,286–296] Elderly ALL patients given no therapy may not survive more than a few weeks.[287] Palliative therapy, usually moderate-dose prednisone and intermittent vincristine, has been used.[286] Modest responses were observed, with survival extending to a few months. A retrospective review of one cooperative group member institution's 13-year experience revealed that only one half of their ALL patients older than 60 years were enrolled in their active study protocol.[283] In these instances, risk-adapted therapy often meant limiting treatment intensity on a case-by-case basis. Many of these elderly patients were given ad hoc induction regimens of variably dosed vincristine and prednisone, with or without a third drug.[288,289,297] Complete responses were reported in up to 40%, but median survival remained only several months. Several groups uniformly treated fairly large cohorts (40 to 60) of elderly patients with "age-adjusted" chemotherapy programs.[291,292,298] Impressive CR rates were sometimes observed, and median survival extended to 12 to 14 months. The patient numbers were still small, and it is difficult to evaluate the influence of patient selection bias, as conflicting results have been reported by the same institution treating patients with essentially the same protocol.[291,292] Data from major collaborative groups treating selected, elderly ALL patients suggest that up to one half may achieve CR with intensive therapy.[290,293] Resistant disease and toxic deaths were frequent, but a median survival of 10 months may be reasonably expected.

Although the prognosis remains generally grim for elderly patients with ALL, new therapeutic options are becoming available to the subset with the worst prognosis, that is, those with Ph-positivity. Given the generally favorable toxicity profile of imatinib, a number of studies have embarked on the evaluation of its efficacy in elderly patients with Ph+ ALL. In a study of 12 patients, who were older than 60 and not eligible for intensive therapy, treatment with daily imatinib at 800 mg and prednisone, followed by single-agent imatinib consolidation therapy yielded a CR rate of 92%, whereas 67% remained in CR at a median follow-up of 7 months.[299] In the prospective, multicenter GMALL study, 32 elderly patients (median age, 67 years) with newly diagnosed Ph+ ALL were randomized to daily imatinib at 400 mg or age-adapted, multiagent induction chemotherapy followed by imatinib in consolidation and re-induction cycles. CR rates were 92% and 53%, respectively, with death and severe infectious complications during induction occurring only in the chemotherapy-assigned group.[300]

The accumulated literature is still sparse, and much remains to be learned about treating elderly patients with ALL. Ongoing evaluations of tyrosine kinase inhibitors, as well as the investigation of other new therapies, such as monoclonal antibodies and small molecule-based targeted approaches, are vital in the process of improving outcomes and the prognostic outlook for this growing demographic group. Elderly patients should be referred for investigational protocols at study centers whenever feasible.

SALVAGE THERAPY

The prospect of salvage therapy for refractory or relapsing disease will eventually have to be considered for most adult ALL patients. Primary resistance to induction chemotherapy reported by collaborative trials ranges from 8% to 15%.[5,7,9,66,73,78] Although most

[a]The top row involved induction with vincristine, daunoxome, and dexamethasone and was superior to the next row showing the results in elderly patients receiving GIMEMA ALL 0288 protocol.
[b]CR% was from 40 patients evaluable after induction.

patients achieve a first CR, only 20% to 40% become long-term survivors, and the principal cause of treatment failure is disease relapse. Although a second or salvaged CR can be obtained for a slight majority with chemotherapy, the durability of remission is likely short unless an allogeneic SCT is subsequently performed, and, even then, remission duration is limited for most patients.

Recent studies yield some insight into the biologic and clinical features of disease relapse in adult ALL patients. Thomas et al. reviewed the presenting characteristics at relapse in patients referred for therapy at a single institution over a 17-year period.[301] The duration of CR was less than 1 year in 61%. Essentially all patients had marrow relapses, although one third had concurrent extramedullary involvement, including CNS leukemia in 16%. In other studies, the cytogenetic, immunophenotypic, and molecular changes at relapse compared with initial presentation were examined.[302,303] Clonal cytogenetic changes were the most common finding. One half of the cytogenetic findings were believed to represent clonal evolution, and the remainder were karyotypic changes. Two entirely different abnormal karyotypes were never found. Immunophenotypic changes were twice as likely in patients with T-cell versus B-cell ALL and were marked by gain or loss of one or two antigens but no complete shift from B- to T-lineage ALL, or vice versa. Neither the presence of a karyotypic shift nor an immunophenotypic shift adversely influenced survival from the time of relapse. Patterns of persistence and clearance of BCR-ABL transcripts also characterize the assessment of MRD and appear to predict relapse in Ph+ ALL (see section on MRD).

Chemotherapy

Reinduction of remission, or attainment of a first CR for refractory patients, can be expected in slightly more than one half of patients with salvage chemotherapy. However, in the majority, remissions do not extend beyond 3 to 6 months, and long-term survival is well below 10% whether or not post-remission therapy is given. The numerous reports describing generally single-institution studies involving small numbers of patients have been exhaustively catalogued in excellent reviews.[304–306] In general, single-agent chemotherapy is inferior to multiagent protocols. Two or three drugs have been added to L-asparaginase or an anthracycline with good responses, but the best results are produced by combinations based on intermediate- to high-dose cytarabine. In one of the larger patient series, doxorubicin combined with vincristine and dexamethasone induced CR in 39% of 64 refractory patients.[307] Treatment failure was due to resistant disease in 41%, whereas induction mortality was only 6%, reflective of a correlation between toxicity-related death and antileukemic activity.

Salvage regimens based on high-dose cytarabine, which have been much more extensively studied, produce CR rates that vary widely but have occasionally exceeded 70%. Additional drugs have included anthracycline, mitoxantrone, and fludarabine. The hyper-CVAD regimen, which incorporates doxorubicin and high-dose cytarabine in addition to fractionated cyclophosphamide, was used to salvage 66 relapsed patients and induced remissions in 44%.[308] A separate study reported a more modest response, with a CR rate of 38%, in 29 patients with refractory or recurrent disease treated with high-dose cytarabine and a single high dose of idarubicin,[309] whereas standard-dose cytarabine and idarubicin led to a 30% CR rate in refractory patients in another study.[310] Hiddemann et al. reported a 50% CR rate in 24 refractory patients with the mitoxantrone and high-dose cytarabine two-drug combination.[311] Other studies with these two drugs have reported CR rates of 17% to 80%. Fludarabine is a purine analogue that enhances bioavailability of the active metabolite of cytarabine, and, as a salvage regimen, the combination yields CR in 30% to 83%, with the higher response rates reported when cytarabine was used at high rather than intermediate dose.[312–314]

In a large single-institution review, Thomas et al. described treatment outcome for 314 adult patients with relapsed or refractory ALL who received various salvage therapy regimens. Overall CR was achieved in 31%.[301] Patients with long first remissions received the customary front-line study salvage regimen, which

varied depending on the study period, whereas patients resistant to or relapsing on therapy were treated with new drug combinations. This approach to treatment regimen selection, based on timing of relapse and prior induction programs, can be regarded as reasonable recommendations for all adult ALL patients requiring salvage therapy. Patients with primary refractory disease and those with relapsed disease were found to achieve CR equally well. Death occurred without achieving remission in 21%. Patients with long first CR duration (>2 years) were more likely to achieve CR and have longer durations of second remission, a finding confirming observations made by other investigators.[315,316] For the entire group, the median durations of remission and survival from the start of salvage therapy were 6 months and 5 months, respectively. Although salvage regimens in resistant or relapsed disease offer only modest effects with short duration, they allow a bridge to HSCT, which has curative potential for select patients who achieve remission.

Novel Agents

The emergence of newer agents has rejuvenated some optimism that incremental improvements can still be effected in certain patient subgroups. Nelarabine was approved for the treatment of refractory or relapsed T-ALL or T-cell lymphoblastic lymphoma (T-LBL) in patients who have undergone at least two prior chemotherapy treatments. As a prodrug, it is converted to the deoxyguanosine analogue, 9-β-D-arabinofuranosylguanine (ara-G), which selectively induces apoptosis in T-cells by incorporating its phosphorylated form into DNA and inhibiting synthesis. Following a phase I study, which showed significant cytotoxicity against T-cells,[317] two phase II studies of single-agent nelarabine demonstrated CR rates of up to 23% in patients with refractory or relapsed T-ALL or T-LBL.[318,319] Neurotoxicity is the dose-limiting toxicity, for which close patient monitoring is strongly encouraged. There are ongoing trials incorporating nelarabine into frontline treatment protocols for T-cell disease including a very large Children's Oncology Group study, AALL0434.

Clofarabine is another deoxyadenosine analogue that was approved by the FDA for the treatment of pediatric patients (ages 1 to 21 years) with relapsed or refractory ALL. It demonstrated activity as a single agent, with a 30% overall response rate, in a phase II study of 61 heavily pre-treated children.[320] Pilot studies combined with cytarabine, or with epratuzumab, an anti-CD22 antibody are being explored in adult ALL.

Two promising antibody therapeutics offer great hope for improving outcomes in ALL. Inotuzumab ozogamicin is an anti-CD22-calecheamicin conjugate with significant activity, even in heavily pre-treated individuals.[321] In a phase II experience 49 previously treated patients received a 1-hour infusion of the study drug every 3 to 4 weeks for one to five courses. A CR was achieved in 9 patients with an additional 19 with a bone marrow complete response. Nineteen had resistant disease. Duration of response was short, with median overall survival of 5.1 months in all patients and 7.9 months in the 28 responding patients. Due to the significant efficacy observed, once-weekly dosing regimens are being pursued as are protocols incorporating inotuzumab in frontline regimens.

Blinatumomab is a bispecific single-chain antibody that binds both cytotoxic CD3 T lymphocytes and CD19 on the surface of the B-cell leukemic blast. In a phase II trial of B ALL patients with persistent or relapsed MRD, 80% of patients responded. With a median follow-up of 33 months, the hematologic relapse-free survival of the 20 evaluable patients was 61%.[322] These long-lasting remissions would be unusual for patients with MRD detectable disease. Another study included patients with overt hematologic relapse. Complete remission including MRD eradication was observed in 17 of 25 patients.[323] On the basis of this promising activity, additional trials are planned not only for recurrent disease but also in combination with chemotherapy as part of initial treatment regimens.

Although imatinib mesylate has begun to change the landscape of treatment options for Ph+ ALL by dramatically improving remission rates and overall outcome, emergence of drug resistance warns against complacency.[324] Among the several known mechanisms of imatinib resistance is the development of one of numerous kinase domain mutations of *BCR-ABL* which prevent imatinib from engaging and competitively inhibiting the kinase at the ATP-binding site.[325–328,329] Three other tyrosine kinase inhibitor compounds have since been developed that are active against the majority of the imatinib-resistant *BCR-ABL* mutants and promise significant antileukemic activity against *BCR-ABL*-positive leukemias. All have significantly increased potency compared with imatinib, but differ from each other in that nilotinib is a selective inhibitor of BCR-ABL,[330] whereas dasatinib and bosutinib are dual SRC-ABL kinase inhibitors.[331,332] Early phase studies showed promising activity against *BCR-ABL*−positive leukemia, with the exception of a single *BCR-ABL* mutation within the ATP-binding pocket of the tyrosine kinase, T315I, which confers a high degree of universal resistance to imatinib, nilotinib, bosutinib, and dasatinib.[332,333,334] Safety profiles were generally favorable. The main adverse effects for nilotinib were dose-dependent grade 3 or 4 thrombocytopenia and neutropenia, transient indirect hyperbilirubinemia, pruritis, and rash. Side effects associated with dasatanib included grades 3 and 4 thrombocytopenia and neutropenia, pleural effusions, diarrhea, peripheral edema, and headache; none were dose-limiting. The US FDA approved dasatinib for Ph+ ALL.[335] This approval included newly diagnosed patients, reflecting the unmet medical need in this difficult-to-treat population. Ponatinib was recently approved for these difficult-to-treat patients. Unlike the other abl inhibitors, ponatinib does not bind directly to the T315 abl active site.

Recent improvements in the outcomes for mature B-cell ALL do not obviate the need for novel salvage strategies for those with refractory or relapsed disease. In light of the highly expressed CD20 in mature B-cell ALL, recent studies have incorporated the monoclonal anti-CD20 antibody rituximab in intensive, multiagent chemotherapy regimens, yielding promising results (Fig. 74.4).[336] A total of 31 newly diagnosed patients were given rituximab on each of two noncontiguous days in four cycles of hyper-CVAD. Of the 23 evaluable patients, the CR rate was 86% for those less than 60 years of age and 100% for older patients. Compared with historical controls treated on hyper-CVAD alone, inclusion of rituximab led to a 2-year overall survival rate of 89% (versus 58%).

Stem Cell Transplantation

Given the dismal outlook for relapsed disease, allogeneic SCT should be attempted for all eligible adult ALL patients as soon as possible after second or salvaged remission is achieved. The logistics may be difficult given the narrow window before impending relapse. This was examined by Davies et al., who described finding matched related donors for only 35% of 115 consecutive relapsed ALL referrals to a single institution over a 2-year period.[337] An unrelated marrow donor search was initiated in most of the remainder, which was successful in another one third, but required a median of 10 weeks before a donor was identified. Overall, allogeneic SCT was not performed in the majority of the patients, and the reason in 19% was death before transplant despite all efforts to expedite SCT. This point was highlighted by a study at 12 GIMEMA institutions, which re-induced CR in 56% of adult ALL patients in first relapse with a combination of idarubicin and intermediate-dose cytarabine.[338] This was to be followed by a scheduled SCT that could not be performed in 44% due to relapse and in another 26.5% due to persistent infection acquired during induction.

Even if a patient is transplanted, the available data suggest that few will be effectively salvaged with allogeneic SCT. Outcome reported from individual trials indicates long-term disease-free survival in 15% to 45% after sibling donor allogeneic SCT in second or greater CR.[200,339,340] Registry data from the IBMTR show a 5-year disease-free survival estimate of 26%.[341] Unlike allogeneic SCT for adult ALL in first remission, however, relapse (52%) outranked treatment-related mortality (36%) as the cause of treatment failure.

Allogeneic SCT for active disease appears to yield inferior results. Results for individual trials reporting sibling-donor allogeneic SCT for untreated refractory or relapsed disease indicate disease-free survival of 12% to 43%.[340,342] The IBMTR reported a 4-year disease-free survival of 13% with 71% of patients relapsing.[341] In the study of imatinib therapy used as a bridge to SCT in relapsed or refractory Ph+ ALL patients, the disease-free survival at 12 months was 51% for patients transplanted in remission, compared with 8.3% at 7 months in those with active disease, further underscoring the importance of remission status at transplant on post-SCT survival.[270] Not surprisingly, worse outcomes characterized transplantation performed for advanced disease (in or after second CR) or with highest tumor burden (in relapse).[212]

Unrelated donor SCT is associated with a very high transplant-related mortality, compounding the difficulties of finding a matched donor. Based on registry data from the NMDP, transplant-related mortality was 75% for patients transplanted in second or greater CR and 64% for patients transplanted in relapse.[210] Another study, also based on NMDP data, demonstrated the significance of three factors in a multivariate analysis: unrelated donor transplantation, age greater than 20 years, and SCT performed between 1989 and 1995.[211] Recent advances in histocompatibility antigen matching based on molecular typing techniques may also improve transplant outcomes through a more precise selection of better-matched donors.[343]

A benefit from autologous SCT for patients in second or subsequent CR is difficult to determine. There are many individual studies, generally with short follow-up, reporting disease-free survival ranging from 10% to 31%.[216,344–347] Almost all failures are due to treatment relapse, however, and no study has demonstrated a disease-free survival plateau.

SUMMARY AND FUTURE DIRECTIONS

Considerable progress has been made in the management of ALL in adult patients. Multiagent induction chemotherapy induces CR in over 85% of adult ALL patients. With the institution of postremission therapy and prophylaxis against CNS relapse, up to 40% may be cured of the disease. There is no compelling reason to believe, however, that further modification of modern multiagent regimens with the addition of currently available chemotherapy drugs will lead to any substantial improvement in outcome for these patients, with the possible exception of nelarabine.

Tailoring therapy adapted for each individual patient on the basis of anticipated relapse risk is a strategy that has gained general acceptance. This approach has proved to be remarkably successful for two adult ALL subgroups, namely, those with Burkitt ALL and those with Ph+ ALL. Ongoing prospectively randomized clinical trials will establish the role of risk-adapted therapy for patients with high-risk features according to other criteria. Coupled with translational research, these trials will also help define the role of new technologies, such as whole genome sequencing and molecular MRD assessment, in refining and improving the ability to evaluate disease activity and relapse risk with greater accuracy.

Targeted molecular therapy, such as the small molecule inhibitors of the BCR-ABL tyrosine kinase, has emerged as an essential aspect of care in patients with Ph+ ALL. Whether the use of second-generation agents will translate into survival advantage remains to be seen. The success with improving outcomes for Ph+ ALL, although satisfying, is tempered by the fact that, at present, allogeneic SCT remains the only known viable intervention with curative potential for high-risk patients. Newer approaches with allogeneic SCT using dose-attenuated nonmyeloablative recipient conditioning are promising and can extend the procedure to patients who might otherwise not be eligible for conventional transplantation.[348,349] Clinical outcome data are not mature, however, and, at present, the procedure is still investigational.

Other targeted therapies, including monoclonal antibodies directed against surface antigens expressed by malignant cells and chimeric antigen receptor-modified T-cells targeted to B-cell–specific CD19 antigen, have proven extremely effective for other lymphoproliferative disorders and are currently undergoing clinical trials to assess their utility in ALL.[350] Discovery of additional, much-needed, state-of-the-art novel therapies depends upon the progressive understanding of the underlying biology and delineation of the critical molecular pathways that are responsible for ALL leukemogenesis.

CHAPTER 75

ACUTE MYELOID LEUKEMIA IN ADULTS

Ashkan Emadi, Maria R. Baer

Acute myeloid leukemia, acute myelogenous leukemia, and *acute nonlymphocytic leukemia* are equivalent terms for a hematopoietic neoplasm that is uniformly characterized by the presence of a malignant clone of myeloid cells in the bone marrow with maturation arrest at the level of blast. *Acute myeloid leukemia* (AML) is the term used in the World Health Organization (WHO) classification of the myeloid neoplasms[1,2,3] and is the current recommended term.[4]

AML may follow a myelodysplastic syndrome (MDS) (Chapter 79) or a myeloproliferative neoplasm (MPN; Chapters 80 through 83). AML should be distinguished from acute lymphoblastic leukemia (ALL; Chapter 74), in which blasts are of lymphoid rather than myeloid lineage. AML should also be distinguished from chronic myelogenous leukemia (CML; Chapter 81), in which, in the initial phase of the disease, myeloid cells are expanded but do not exhibit maturation arrest. In addition, CML is a uniform disease, whereas AML has heterogeneous clinical, morphologic, immunophenotypic, cytogenetic, and molecular features. Chapter 77 addresses presentation and therapy of AML in children. Chapter 78 addresses the biology, presentation, and management of the acute promyelocytic leukemia (APL) subtype of AML in adults and children.

AML occurs at any age, but is more common in adults, with increased frequency as age advances. Patients typically present with manifestations of anemia, neutropenia, and/or thrombocytopenia resulting from impaired hematopoiesis due to replacement or suppression of normal marrow elements by malignant blasts. The total white blood cell count is variable, ranging from leukopenia to hyperleukocytosis with an elevated blood blast count that represents a medical emergency.

The malignant cell in AML is a blast that most often shows myeloid or monocytic differentiation, but shows erythroid or megakaryocytic differentiation in approximately 5% to 10% of cases. The myeloid blast can be identified by the presence of granules and/or Auer rods by Wright Giemsa staining, by Sudan black, myeloperoxidase (MPO), chloroacetate esterase, or nonspecific esterase cytochemical staining, and/or by an immunophenotype demonstrating expression of myeloid antigens. Immunophenotyping by flow cytometry is currently in widespread use[4,5] and serves to define lineage in the absence of defining morphologic and cytochemical features.[6] In addition, ultrastructural features characteristic of AML may be demonstrated by electron microscopy,[7] although this modality is not generally a component of clinical diagnostics.

Immunophenotyping by flow cytometry has shown that AML is markedly heterogeneous, variably expressing antigens expressed on stem cells and on more mature myeloid cells, also with infrequent co-expression of lymphoid antigens.[8] Moreover AML generally exhibits aberrant patterns of antigen expression or co-expression in relation to normal myeloid cells.[9,10] Detection of aberrant phenotypes by flow cytometry has been applied toward monitoring of residual disease.[11]

Cytogenetic abnormalities are present in leukemia cells of most patients with AML,[12] and are currently the most powerful predictors of treatment outcome.[13,14] Because of the importance of cytogenetics in diagnosis and prognosis in AML, several recurrent cytogenetic abnormalties, including t(8;21)(q22;q22), inv(16)(p13.1q22), or t(16;16)(p13.1;q22), t(15;17)(q22;q12), t(9;11)(p22;q23), t(6;9)(p23;q34), inv(3)(q21q26.3), or t(3;3)(q21;q26.2) and t(1;22)(p13;q13), have been incorporated into the WHO classification of AML.[2] Moreover, cytogenetic abnormalities have been classified as favorable, intermediate, and unfavorable with regard to AML treatment outcomes,[13,14] and this information is used to assist in the choice of initial and subsequent therapies. New diagnostic tools, including fluorescence in situ hybridization (FISH), polymerase chain reaction (PCR), comparative genomic hybridization (CGH), and microarray analysis, have improved the sensitivity of detection of genetic abnormalities and the ability to subclassify AML and to detect residual disease. Diverse molecular abnormalities are also being demonstrated in AML and predict treatment response, particularly in AML with a normal karyotype. Molecular abnormalities are also serving as a basis for development of targeted therapies.

Advances in therapy have changed cure rates in AML from less than 20% in 1960 to 1980 to 40% to 70% for selected groups in the 2000s. The cure rate of APL is very high with the addition of all-trans-retinoic acid (ATRA) to chemotherapy and, in some regimens including in the relapse setting, use of arsenic trioxide (Chapter 78). For other types of AML, outcomes have improved significantly for younger, but not older, adult patients (Fig. 75.1). The highest cure rates have resulted from allogeneic stem cell transplantation (alloSCT) in first remission but, with improved survival of patients receiving high-dose cytosine arabinoside (cytarabine or ara-C) post-remission chemotherapy, the question of what is the best post-remission therapy in AML remains unanswered, and stratification based on patient and leukemia characteristics is indicated. Novel targeted approaches are currently being tested in AML, and their ultimate roles remain to be determined.

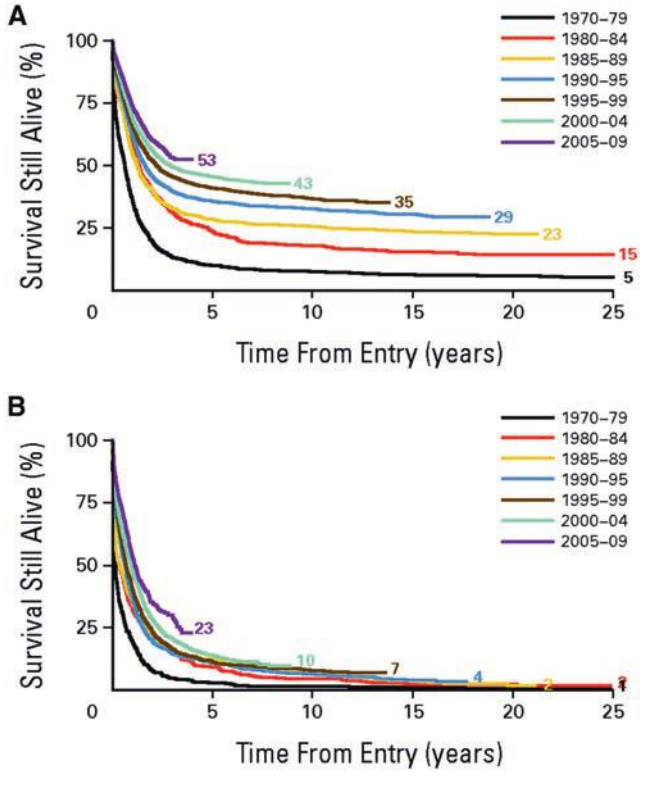

FIGURE 75.1. Change in overall survival of AML patients with time. A: Age 15 to 59 years. **B:** 60 or more years. (From Burnett A, Wetzler M, Löwenberg B. Therapeutic advances in acute myeloid leukemia. J Clin Oncol 2011:29(5):487–494.)

In this chapter, epidemiologic, clinical, biologic, cytogenetic, and molecular features of adult AML are addressed in the context of therapeutic principles and prognosis.

HISTORICAL PERSPECTIVE

The terms "weisses Blut" and "*leukämie*" were first used by Virchow in the middle of the 19th century, following initial descriptions of patients with an excess of white blood cells and splenomegaly at autopsy.[15,16] Ebstein introduced the term "acute leukemia" in 1889 to differentiate rapidly progressive leukemias from more indolent "chronic" leukemias. Naegeli identified the myeloblast in leukemia in 1900[17] and divided leukemias into "myeloid" and "lymphocytic." During the first half of the 20th century, most of the subcategories of AML were identified by light microscopy with the aid of cytohistochemical stains and were described based on resemblance to normal hematopoietic precursors. Reschad and Schilling described acute monoblastic leukemia in 1913;[18] DiGugliemo described acute erythroleukemia in 1917;[19] Von Boros and Karenyi described acute megakaryocytic leukemia in 1931;[20] and Hilstad described APL in 1957.[21]

The initial classification of AML developed by the French–American–British (FAB) cooperative group in 1976[22] was based on morphology. It was subsequently expanded to include new morphologic and immunogenotypic subsets, notably minimally differentiated disease with myeloid antigen expression.[6] The WHO classification, published in 1997 and updated in 2002 and 2008,[1,2,23,24] incorporates clinical and cytogenetic data, distinguishes therapy-related AML and AML with MDS-related changes from de novo AML, and uses several recurring structural cytogenetic abnormalities to define AML subtypes.

Numerous cytogenetic abnormalities, both structural and numerical, have been identified in AML, beginning with the t(8;21)[25] and t(15;17)[26] translocations. Several of these recurring abnormalities were incorporated into the WHO classification, serving to define new subtypes.[1,2,24] Cytogenetic findings in AML are the strongest predictors of treatment outcomes.[13,14,27,28,29,30,31–34] Structural cytogenetic abnormalities have been characterized at the molecular level, resulting in increased understanding of AML pathogenesis, and establishment of potential therapeutic targets, as well as molecular markers for quantitative monitoring of residual disease.[11] Increasing numbers of gene mutations are also being described in AML, also enhancing our understanding of its molecular pathogenesis, providing new prognostic categories,[35,36,37,38–41,42,43,44,45,46,47,48,49,50] and identifying new therapeutic targets.

The European LeukemiaNet has developed a new prognostic classification of AML incorporating cytogenetic and molecular data.[51,52]

Full sequencing of cytogenetically normal AML genomes was first reported in 2008[53] and 2009,[54] demonstrating 10 and 12 genes with acquired mutations, respectively. Finally, microRNAs, or small noncoding RNA molecules that hybridize to target messenger RNA species and regulate their translation, have also been found to have distinct expression patterns in AML, with prognostic significance, and may represent new therapeutic targets.[55,56,57]

EPIDEMIOLOGY

It is estimated that 13,780 individuals (7,350 men and 6,430 women) were diagnosed with AML and 10,200 died of AML in the United States in 2012.[58,59] Lifetime risk of AML based on rates from 2007 through 2009 is 0.39%, which means that 1 in 254 men and women born today will be diagnosed with AML during their lifetime.

TABLE 75.1

AGE DISTRIBUTION OF ACUTE MYELOID LEUKEMIA (AML) AT DIAGNOSIS

Age (Years)	AML Incidence (%)
<20	6.0
20 and 34	6.6
35 and 44	6.6
45 and 54	11.8
55 and 64	15.5
65 and 74	20.1
75 and 84	23.3
>85	10.2

The incidence of AML increases with age. AML accounts for 80% to 90% of cases of acute leukemia in adults, but less than 15% of cases of leukemia in children younger than 10 years and 25% to 30% in those between 10 and 15 years.[60,61] From 2005 through 2009, the median age at diagnosis of AML was 66 years.[62] Table 75.1 shows the age distribution for diagnosis of AML.[58]

The increased incidence of AML in the elderly is likely related to a combination of improved diagnosis, recognition of AML after MDS, and longer life expectancy, with consequent increased environmental exposures. Based on the number of patients diagnosed from 2005 through 2009 in 18 Surveillance Epidemiology and End Results (SEER) geographical areas, the age-adjusted incidence of AML is 3.6 per 100,000 subjects per year.[58] The incidence is higher in males than in females and higher in whites than in blacks (Table 75.2).[58,61] There is an increased risk for Eastern European Jews and a decreased risk for Asian populations.[63]

The overall 5-year relative survival for AML from 2002 through 2008 in 18 SEER geographic areas was 23.4%.[58] As with incidence, mortality rates in AML vary with age, gender, and race. Table 75.3 summarizes the age distribution of AML-related death.[58] The median age at death from AML was 72 years in 2005 to 2009,[64] and the age-adjusted mortality rate was 2.8 per 100,000 subjects per year.[58] Table 75.4 summarizes mortality rates by race and gender.[58] From 2002 through 2008, 5-year relative survival by race and sex was 21.3% for white men, 24.6% for white women, 23.2% for black men, and 24.8% for black women.[58]

RISK FACTORS

Risk factors for AML include both exposures that result in DNA damage, and congenital diseases and gene polymorphisms associated with impaired repair of DNA damage. Epidemiologic studies

have identified genetic, environmental, and occupational factors that may contribute to the pathogenesis of AML.[60,63,65] In addition, AML arising following cytotoxic therapy for prior malignancies or benign conditions, termed therapy-related AML (t-AML), is an increasing problem in the face of successful therapy for lymphomas and solid tumors, as well as leukemias, and decreasing the risk of this devastating complication is an important goal in the evolution of oncology treatment regimens and strategies.

Identified occupational, envitronmental, lifestyle-related, and medical risk factors for development of AML are discussed below. Multiple factors may contribute and interact. A recent case–control study of risk factors for de novo AML at MD Anderson Cancer Center demonstrated multiple factors, joint effects, and differences by sex and WHO subtype.[66] Heavy smoking (≥30 pack-years; odds ratio [OR], 1.86) and low-level (OR, 2.87) or moderate/high-level (OR, 4.13) occupational solvent exposure increased the risk of AML in men, whereas obesity (OR, 1.62) and low-level (OR, 2.73) or moderate/high-level (OR, 3.90) occupational solvent exposure increased the risk in women.

Occupational Exposures

Occupational exposures are risk factors for the development of AML. In recent literature, an increased risk of AML has been reported in workers manufacturing, or exposed to, rubber, paint, embalming fluids, pesticides, ethylene oxide, petroleum, poultry, munitions, automobiles, nuclear power, plastics and electrical wiring, as well as gasoline station attendants, beauticians, barbers, and cosmetologists.[67] Most of these reports are based on retrospective and cross-sectional studies, which makes establishing causal relationships difficult. Older literature also implicated employment in shoe-making, painting, furniture manufacturing or repair, paper mill, clothing or textile industry, chemical manufacturing, printing, nursing, and biologic laboratories,[67] and it can be speculated that enforcement of regulations pertaining to occupational exposures has altered the occupational risk profile. Of note, an association with hobbies, including artistic painting, car repair, ceramics or pottery, furniture repair, model building, photography, shooting or hunting, or wood working, has not been reported.[67–72]

The most fully characterized occupational exposure associated with AML is to the aromatic hydrocarbon benzene.[73–75] Benzene is absorbed through the skin and lungs and can accumulate in the body fat and neurologic tissues. Toxicity is related to cumulative dosage, and the risk of leukemia was high before safety controls were put into place in the workplace. Chromosome damage can occur at 1 to 10 ppm, and leukemogenic risk is considerable at 124 to 200 ppm. In surveys of factories in China, the leukemogenic risk was four to seven times higher in workers exposed to benzene than in the general population, and the average latency was 11.4 years.[76,77] A dose–response pattern was suggested, with the highest risk in Chinese workers exposed at constant levels of 25 ppm or higher.[77] Increased risk of AML with occupational exposure to benzene was confirmed in a recent systematic review and meta-analysis,[78] and occupational benzene exposure was found to be associated with specific aneuploidies.[79]

Environmental Factors

Ionizing radiation is carcinogenic primarily via induction of double-strand DNA breaks. The risk of leukemia correlates with radiation dosage and age at exposure, with a more rapid peak early in life (<15 years), as well as a more rapid decline than in those exposed at older ages (Fig. 75.2).[80]

Fallout from atomic tests and exposure to nuclear reactors has been a concern in the second half of the 20th century and the start of the 21st century. Atomic bombs were released over Hiroshima and Nagasaki in 1945, and an excess risk of leukemia was reported in 1952.[81] The excess relative rate, per Gray (Gy), of AML among Japanese atomic bomb survivors was best described by a quadratic dose–response function that peaked approximately 10 years after exposure, but with the effect persisting for more than five decades.[82] Whereas little radioactivity was released

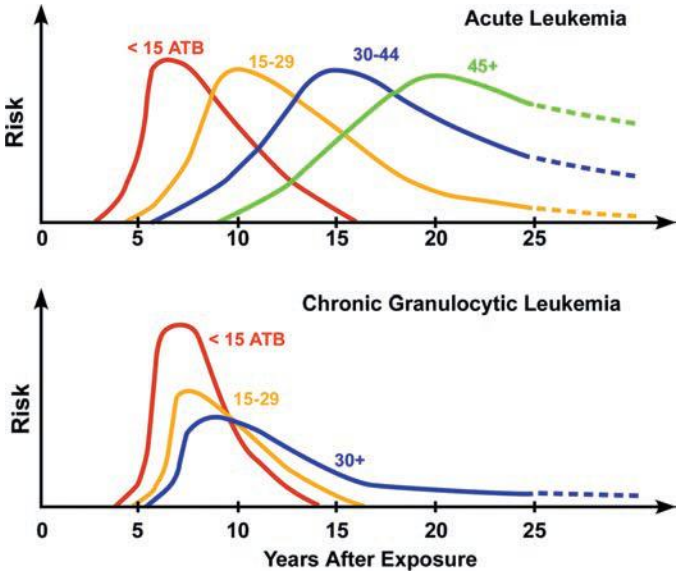

FIGURE 75.2. Effect of age at exposure and temporal pattern of developing leukemia according to cell type (acute vs. chronic granulocytic leukemia). ATB, at time of bomb. (From Okada S, Hamilton HB, Egami N, et al., eds. A review of thirty years of Hiroshima and Nagasaki atomic bomb survivors. J Radiat Res 1975;16(Suppl):1–164.)

into the environment at Three Mile Island, there was extensive exposure to radioactivity after Chernobyl,[83,84] and increased AML incidence has been reported in Chernobyl clean-up workers.[85] Of note, one Gray is the absorption of one joule of ionizing radiation energy, per kilogram of body matter.

Radon, cosmic radiation, and nonionizing radiation have been implicated as possible etiologic factors in AML but are unlikely to contribute a major risk.

Lifestyle-related Factors

Lifestyle-related risk factors for AML include smoking, obesity, and use of some hair dyes.

Smoking has been repeatedly identified as a risk factor for AML in an extensive literature.[86–92] Cigarette smoke contains more than 4,000 chemical compounds, of which 60 have been found to be carcinogenic and leukemogenic, including benzene, urethane, nitrosamines, and polyaromatic hydrocarbons such as benz[a]anthracene, benzo[a]pyrene, benzo[b]fluoranthene, benzo[c]phenanthrene, benzo[e]pyrene, and benzo[j]fluoranthene. Meta-analyses have estimated a relative risk for AML of 1.3 to 1.5 in smokers.[87,93] The risk of developing AML is two to three times higher in male smokers who have exceeded 20 pack-years.[86,94] Smokers of more than 40 cigarettes per day who develop AML have an increased incidence of unfavorable cytogenetic abnormalities, including –7/7q–.[88,92] In a recent case control study at MD Anderson Cancer Center, a history of heavy smoking was associated with AML in men, and current smoking was associated with an increased risk of AML in women, and there was a joint effect of smoking and solvent exposure.[66]

Obesity has been reported as a risk factor for AML.[66,95–97] In a large cohort of male US veterans, obesity was associated with a higher incidence of AML in both white and black populations.[96] Similarly, among over 40,000 women ages 55 to 69 years in the Iowa Women's Health Study, the risk of AML was increased among women who reported being overweight or obese (relative risk, 1.9; 95% confidence interval [CI], 1.0 to 3.4; relative risk, 2.4; 95% CI, 1.3 to 4.5; *P*(trend) = 0.006, respectively), compared with women of normal weight.[97] Findings were similar in a Canadian population.[95]

Finally, there is evidence of an association between use of permanent, but not nonpermanent, dark hair dye and AML.[98]

Therapy-related Acute Myeloid Leukemia

Antineoplastic therapy is associated with an increased risk of subsequent development of AML, and AML diagnosed following cytotoxic therapy for a prior malignant or benign condition is considered to be t-AML.

AML most commonly develops following treatment with alkylating agents or topoisomerase II inhibitors, but nucleoside analogs, antitubulins, and radiation are also associated with t-AML.[99,100,101]

Radiation used for medical purposes may be leukemogenic. Smith and Doll reported a fivefold increased risk of leukemia in patients with ankylosing spondylitis receiving a single dose of pelvic radiation; the risk peaked 3 to 5 years after radiotherapy.[102] A twofold increased risk has been reported after pelvic radiation for menorrhagia, a treatment commonly used during the 1930s and 1940s.[103] Small increases in risk have also been reported after radiation for tinea capitis[104] and peptic ulcer disease.[105]

t-AML presentation and treatment response differ based on the setting in which it arises and the likely causative agent. Most therapy-related leukemias occur 3 to 10 years after initial therapy, with a longer latency for alkylating agents (5 to 9 years) than for topoisomerase II inhibitors (6 months to 5 years).[99,101] Alkylating agents cause point mutations, as well as chromosome deletions and unbalanced translocations.[100] Topoisomerase II inhibitors result in loss of a critical enzyme involved in DNA replication, leading to balanced chromosomal translocations usually involving 11q23, and less frequently 21q22, with the formation of fusion genes.[106]

The prognosis for t-AML is poor, with a median survival of 7 to 10 months and usually less than 10% 5-year survival.[100] Patients with chromosome 5 and 7 abnormalities have the worst prognosis. Alkylating agent-associated t-AML, generally characterized by deletions or monosomies of chromosomes 5 and/or 7 or complex karyotypes, frequently evolves from t-MDS, and has a low complete remission rate and short disease-free and overall survival. In contrast, topoisomerase II-associated t-AML, most commonly with 11q23 translocations, is typically not preceded by t-MDS and has a high complete remission rate, but short disease-free and overall survival. More rarely, patients treated with antineoplastic agents may develop t-AML with t(8;21), inv(16), or t(15;17).[101,107] An early report suggests similar prognosis for t-AML and de novo AML with t(8;21) or inv(16),[108] whereas a more recent report suggests a worse outcome for t-AML than for de novo AML with t(8;21).[109]

Alkylating agent-asociated t-AML has been extensively described. Cumulative drug dose is a primary determinant in causing leukemia, and alkylators differ in their leukemogenicity. Mechlorethamine and melphalan are more leukemogenic than cyclophosphamide. Germline mutations in tumor suppressor genes (*NF-1*,*TP53*), genetic variations in enzymes (cytochrome P450, glutathione S-transferase, and NAD(P)H: quinone oxidoredutase 1) that are involved in drug metabolism, and genetic variations in genes such as *XRCC1* and *hMSH2*, encoding DNA repair proteins, can all contribute to an increased risk for t-MDS/t-AML.[110–112] Alkylating agent-associated t-AML was initially best characterized following treatment of Hodgkin lymphoma (HL), one of the first malignancies for which curative therapy was developed,[113–115] but has now been described after therapy of multiple neoplasms, including but not limited to breast cancer, multiple myeloma, ovarian cancer, and non-Hodgkin lymphoma (NHL),[101,116–118] as well as in nonneoplastic disorders such as collagen vascular diseases.[101]

In HL, radiation can be a contributing factor, but the risk in patients treated with radiation alone is usually less than 1.0%, compared to 1.5% to 5.0% for those who received both radiation therapy and chemotherapy, particularly when chemotherapy is administered as salvage therapy for relapse after radiation.[119,120] The risk of leukemia after HL ranges from an 11- to a 136-fold increase over that in the general population.[120] With the increased use of autologous transplantation as salvage therapy for lymphomas, t-MDS/t-AML is being recognized in 5% to 15% of patients and is associated with a poor prognosis.[101,121] The time of leukemia onset after alkylating agent exposure has ranged from 1 to 28 years and is most commonly in the 5- to 9-year range.[122] The risk is greater and the latency is shorter in older patients with HL (>50 years of age).[123] Splenectomy has been suggested as a contributing factor to leukemia in some, but not all, studies.[122,123] Elevation in the mean corpuscular volume (MCV) may be an early sign of development of myelodysplastic changes, and up to two thirds of patients who develop leukemia have a preceding myelodysplastic phase that lasts approximately 6 months.[122,124] Clonal cytogenetic abnormalities are often complex; the most common single abnormality is monosomy 7 (–7), followed by del(5q) and –5.[122]

Topoisomerase II inhibitors, particularly etoposide and teniposide, were recognized as leukemogenic agents in survivors of lung cancer,[125,126] germ cell cancer,[127] ALL,[128] neuroblastoma,[129] and osteosarcoma[130] in the 1980s. Large cumulative doses and prolonged courses have been implicated as increasing the risk of leukemia. The latency period is short, with most cases occurring between 6 months and 5 years after initial therapy. There is no myelodysplastic phase, and the majority of cases are myelomonocytic (FAB M4) or monoblastic (FAB M5). The most common cytogenetic abnormality involves a translocation of

the mixed lineage leukemia (*MLL*) gene at chromosome band 11q23.[122] Over 40 partner genes that encode different proteins are involved in *MLL* translocations. Patients with AML and 11q23 abnormalities after topoisomerase II inhibitors tend to be chemosensitive but are rarely long-term survivors because of a high relapse rate.[122]

Breast cancer is treated with both alkylating agents and topoisomerase II inhibitors, as well as antitubilins. Cytogenetic abnormalities in t-AML after breast cancer therapy are heterogeneous and include those associated with either alkylating agent or topoisomerase II inhibitor therapy.[131] Use of G-CSF has been implicated in increasing the risk of t-AML following breast cancer adjuvant therapy[131,132,133] and radiation therapy may also contribute.[131,134–136]

Nucleoside analogs have also been implicated in t-AML. Fludarabine in chronic lymphocytic leukemia is associated with t-AML, particularly when combined with chlorambucil[137] or mitoxantrone.[138] Nucleoside analogs are also associated with an increased risk of t-AML in Waldenström macroglobulinemia.[139] Azathioprine is associated with t-AML, frequently with chromosome 7 abnormalities, in patients with rheumatologic disorders and in solid organ transplant recipients.[140] 6-Mercaptopurine is also associated with t-AML.[141] In addition, MDS/AML with dysplasia and chromosome 7 abnormalities has been seen in patients treated for de novo AML and may represent t-MDS/t-AML associated with cytarabine.[142]

An increasing literature is also documenting t-MDS/t-AML occurring following therapy for APL with ATRA and diverse chemotherapy drugs. Many of these cases of t-MDS/t-AML have chromosome 5 and/or 7 abnormalities, but others have 11q23 translocations, and miscellaneous abnormalities are also seen.[143]

Although less leukemogenic than chemotherapy, radiation therapy is leukemogenic, as evidenced by an increased leukemia risk in patients receiving radiation in the past for ankylosing spondylitis,[102] menorrhagia,[103] tinea capitis[104] and peptic ulcer disease.[105] The risk of leukemia (latency period of 2 to 11 years) is approximately 2 times higher in patients who have received either radium implants or external beam radiation for cervical, ovarian, or endometrial cancer.[144–146] Similarly, a twofold increase in risk has been reported in breast cancer patients receiving adjuvant radiotherapy, compared to a tenfold increase in risk after chemotherapy; combined radiation and chemotherapy resulted in a seventeenfold risk.[131,136] Radiation therapy has been associated with only a small increase in risk of leukemia in patients with HL and NHL, unless the radiation is extensive and encompasses a large volume of bone marrow.[115,147]

In a recent report, patients who developed MDS/AML following radiation alone were found to have a lower incidence of high-risk karyotypes and longer survival than those who developed MDS/AML following chemotherapy or chemotherapy and radiation. Karyotypes did not differ from those in de novo MDS/AML, suggesting that post-radiation MDS/AML may not represent a direct consequence of radiation toxicity and may warrant a therapeutic approach similar to de novo disease.[148]

Medical exposure to radioactivity is leukemogenic. In a recent meta-analysis, the relative risk of leukemia in thyroid cancer survivors treated with radioactive iodine (RAI) was 2.5 (95% CI 1.13, 5.53, $p = 0.024$).[149] A standardized incidence ratio (SIR) of 5.68 (95% CI, 2.09 to 12.37) was recently reported in patients with low-risk (T1N0) well-differentiated thyroid cancer, with the excess risk of leukemia significantly greater in patients aged <45 years (*SIR* = 5.32; 95% CI, 2.75 to 9.30) than in older patients (*SIR* = 2.26; 95% CI, 1.43 to 3.39).[150] Increased leukemia risk has also been previously reported following therapy with radioactive phosphorus (^{32}P) for polycythemia vera, as well as following exposure to Thorotrast, a radioactive contrast agent containing thorium (^{232}Th).[151]

Chromosome Instability or Defective DNA Repair

The incidence of AML is increased in patients with syndromes characterized by chromosome instability or defective DNA repair,[152] notably Bloom syndrome,[59] an autosomal recessive disorder with excessive chromosomal breakage, including quadriradial formation, and increased sister chromatid exchanges, caused by alterations in a gene on chromosome 15q26.1 encoding a protein with helicase activity that is central to DNA repair.[153]

An increasing recent literature also associates polymorphisms in genes encoding detoxifying enzymes and DNA repair proteins with incidence of AML, as well as with treatment outcomes. Glutathione *S*-transferases (GSTs), including GSTM, GSTP, and GSTT, are detoxification enzymes involved in metabolism of carcinogens. A recent meta-analysis of the association of *GST* polymorphisms with risk of AML supported a significant risk of AML in the presence of null genotypes of *GSTM1* and *GSTT1*.[154] Associations with treatment outcomes were also suggested.[155,156]

Polymorphisms in the *RAD51* and *XRCC3* genes, encoding proteins involved in repair of DNA double-strand breaks via homologous recombination, have been associated with increased risk of development of AML, and the association is additionally strong for t-AML and in the setting of coincident polymorphic deletion of the *GSTM1* detoxification gene.[110] Other work implicates polymorphisms of the *XRCC1* gene, encoding a protein involved in base excision repair,[157] and of *RAD51*[111] in the risk of t-AML, and of polymorphisms in the xeroderma pigmentosum group D *(XPD)* DNA repair gene, encoding a protein involved in nucleotide excision repair, in AML with 5q and 7q chromosome deletions.[158] Additionally, *XPD* polymorphisms have been associated with AML treatment outcome, and *ERCC1* and *XRCC3* polymorphisms with treatment toxicities.[159]

Heritable Genetic Factors

Heritable syndromes associated with increased risk of AML are usually recognized in childhood and are discussed in Chapter 77. In addition to Bloom syndrome,[59] they include Fanconi anemia (FA),[160] familial platelet disorder (FPD),[161–163] Schwachman-Diamond syndrome,[164,165] amegakaryocytic thombocytopenia, which may be X-linked, as well as Blackfan-Diamond syndrome, familial aplastic anemia,[166] and Kostmann syndrome.[167] Severe congenital neutropenia (SCN), with mutations in the neutrophil elastase (*ELA2*) gene, when treated with G-CSF increases risk for AML, associated with acquired somatic mutations in the G-CSF receptor.[168]

Inherited mutations of tumor suppressor genes predispose patients to malignancies, including those of myeloid origin. The Li–Fraumeni syndrome, described in 1969, is an autosomal dominant cancer family syndrome with an increased risk for sarcomas, breast cancer, and other neoplasms, including leukemia, due to germline mutations in the *TP53* gene.[169,170]

CLINICAL PRESENTATION

AML presenting symptoms and signs are related to failure of normal hematopoiesis, resulting in anemia, neutropenia, and thrombocytopenia. The most common complaint is nonspecific fatigue or malaise that may have been present for several months. Pallor and weakness are caused by anemia. Fever is common and is the presenting feature in 15% to 20% of patients, often associated with sweats, and may result from infection secondary to neutropenia or from leukemia itself. Hemorrhagic signs and symptoms, including petechiae, epistaxis, and easy bruising, may be found in up to one half of patients at diagnosis. Petechiae correlate with the severity of thrombocytopenia, and ecchymoses with the presence

of disseminated intravascular coagulation (DIC), which is most common in APL, but also occurs in other AML subtypes. Weight loss is present in up to 50% of patients, but is usually not severe. Bone pain occurs in less than 20% of patients. Organomegaly and adenopathy have been reported in up to one half of patients with AML, but are less common than in ALL.

Leukemia Cutis

Leukemic skin infiltration, or leukemia cutis, occurs in up to 13% of patients with AML during the course of the disease, most commonly in those with a monocytic component. Skin lesions are often nodular and violaceous (Fig. 75.3), are painless, and may be widespread or localized. Widespread lesions are distinguished from other exanthems by being raised and palpable. Diagnosis is confirmed by biopsy. Skin lesions may precede the diagnosis of AML, or may occur concurrently with AML or as an extramedullary relapse. They are radiosensitive, but patients should usually be treated with systemic chemotherapy.[171] Benign skin lesions associated with AML include Sweet syndrome[172] and pyoderma gangrenosum.[173] These are painful and are responsive to corticosteroids. These diagnoses are also confirmed by skin biopsy. Leukemia cutis is frequently associated with involvement of other extramedullary sites, including the central nervous system (CNS).[171] Gum infiltration is also characteristic of acute monocytic leukemia (Fig. 75.4).

Myeloid Sarcoma

Myeloid sarcoma, or *granulocytic sarcoma*, *myeloblastoma,* or *chloroma* is an extramedullary tumor that occurs in 2% to 14% of cases of AML.[174–176] The term *chloroma* derives from a green appearance due to expression of MPO. The tumors are usually localized, frequently in bone, periosteum, soft tissues, lymph nodes, or skin. Common sites are the orbit and the paranasal sinuses, but other sites reported include the gastrointestinal tract, genitourinary tract, breast, cervix, salivary glands, mediastinum, pleura, peritoneum, and bile duct.[175] Myeloid sarcomas may occur at diagnosis of AML, may precede the diagnosis, or occur as an extramedullary relapse. They have also been seen in association with MDSs or MPNs and usually predict transformation to acute leukemia.[174–176] The diagnosis is suggested by presence of eosinophilic myelocytes in hematoxylin and eosin-stained biopsy sections. Imprint preparations can be helpful. The diagnosis can be made if Auer rods are detected or if myeloid origin is confirmed by cytochemical or immunohistochemical methods. Although granulocytic sarcomas are radiosensitive, systemic chemotherapy is warranted in most cases.[177]

Central Nervous System Leukemia

The incidence of CNS disease at diagnosis of AML is difficult to determine because lumbar puncture is not generally performed.[178] Meningeal disease has been reported to develop in up to 16% of adults with AML.[178] The increased use of high-dose cytarabine (HiDAC), which crosses the blood–brain barrier, lessens the risk of CNS leukemia in AML, as evidenced by a 2.2% incidence in a review of 410 patients from a single institution.[179] CNS disease is associated with hyperleukocytosis and the AMoL variants.[180] It is often asymptomatic, but may be associated with headache, nausea, and/or cranial nerve palsies, particularly V and VII. Ocular involvement may result in blindness and suggests meningeal involvement. Intracerebral masses were reported in FAB M4Eo in association with inv(16)(p13q22) and M5 subtypes,[181] but also appear to be less common with increased use of HiDAC. Prophylactic central nervous system (CNS) therapy is not given routinely to adult patients with AML, but some clinicians advocate prophylaxis in patients with AMoL or with presenting white cell counts greater than 100,000 cells/mm^3. Diagnostic lumbar puncture with prophylactic intrathecal chemotherapy may also be advocated prior to hematopoietic stem cell transplantation.

Other Organ System Involvement by Acute Myeloid Leukemia

Other organ systems may be involved. Cardiac abnormalities are usually related to electrolyte imbalances, particularly hypokalemia, but may result from direct involvement of the conduction system or infiltration of vessel walls.[175] Pulmonary symptoms occur in patients with leukostasis, infections related to neutropenia, or hemorrhage. Gastrointestinal symptoms also include infections, particularly perirectal abscesses and typhlitis, which is a necrotizing colitis related to leukemia infiltration of the bowel wall. Management of typhlitis is supportive, including antibiotics and nasogastric suction, but surgical intervention is sometimes unavoidable.[182] Obstructive jaundice has occurred secondary to myeloid sarcoma.

Hypocellular Acute Myeloid Leukemia

Hypocellular AML occurs in 5% to 10% of patients with AML and is defined by the presence of AML in a hypocellular bone marrow, with the definition of hypocellularity varying between 5% and 40%.[183] Hypocellular AML is typically seen in older patients, and should be distinguished from MDSs and aplastic anemia. Howe et al.

demonstrated a CR rate of 73% in a series of 29 patients with hypocellular AML.[184] Although hypocellularity alone should not exclude a patient from receiving chemotherapy, caution should be exercised in treating these patients, and transplantation strategies should be considered.

LABORATORY FINDINGS

Presenting blood counts vary widely among patients with AML.[185] The leukocyte count is elevated in more than half of patients, but is greater than 100,000 cells/mm^3 in less than 20%. Blasts are usually present in the peripheral smear or in a buffy coat smear. Auer rods and Phi bodies are considered pathognomonic of AML. *Phi bodies* are fusiform or spindle-shaped rods similar to Auer rods that require special stains for hydroperoxidases.[186]

Cytopenias result from hematopoietic failure and contribute to symptoms and signs. Anemia is common in AML and is predominantly normochromic and normocytic. Reticulocytopenia is generally present, but nucleated red blood cells may be seen. Neutropenia is present in most AML patients. A normal neutrophil count is more common in patients with monocytic variants of AML. Giant lysosomes are rarely noted in neutrophils of patients with AML; their presence has been called a *pseudo-Chédiak–Higashi syndrome*.[187] Thrombocytopenia is usually present and may be severe at diagnosis. Thrombocytosis is rarely identified, and is characteristic of AML with abnormalities of the long arm of chromosome 3, involving the *EVI1* gene.

DIC is more common in AML than in ALL, and is most common in APL (Chapter 78). DIC is seen at presentation in nearly all patients with APL, and its incidence in AML other than APL is in the 10% to 30% range.[188] The cause of DIC is thought to be the release of tissue factor-like procoagulants from the azurophilic granules within the leukemia cells. DIC is manifested clinically by bruising and, when severe, by bleeding from multiple sites. Laboratory findings include thrombocytopenia, hypofibrinogenemia, elevated fibrin split products, and deficiency of coagulation factors, including factor V and factor VIII.[189] Other mechanisms, such as excessive fibrinolysis and secretion of interleukin (IL)-1 by AML cells, may contribute to bleeding.[190]

Hyperuricemia is noted in up to 50% of patients with AML and can also be associated with tumor lysis, although the latter is more common in ALL.[191] Hydration and administration of allopurinol and/or recombinant urate oxidase (rasburicase) for markedly elevated uric acid levels or elevated uric acid levels with renal insufficiency, can prevent complications of tumor lysis, which may occur during induction chemotherapy, most often in the setting of hyperleukocytosis.

Serum lactate dehydrogenase (LDH) levels may be elevated, particularly in monocytic (FAB M4/M5) subtypes, but to a lesser degree than is observed in ALL.

Levels of lysozyme are elevated, particularly in variants of AML with a predominant monocytic component (FAB M4/M5). Excess lysozyme (muramidase) may cause proximal renal tubular damage, which results in hypokalemia. Other factors that can contribute to hypokalemia in AML include potassium uptake by rapidly proliferating cells, as well as medications, particularly diuretics and the antifungal antibiotic amphoterecin. Hyperkalemia can occur in association with hyperuricemia and tumor lysis. With improved agents to treat hyperuricemia, hyperphosphatemia with or without hypocalcemia is the most common abnormality associated with renal failure during induction therapy. Patients with AML may have hypocalcemia,[192] but hypercalcemia is very rare.[193]

Hyperleukocytosis, arbitrarily defined as a blood blast count greater than 100,000/mm^3, occurs most commonly in monocytic (FAB M4/5) AML and in AML with fms-like tyrosine kinase 3 internal tandem duplication (FLT3-ITD).[174,194] Hyperleukocytosis is a medical emergency because it is associated with leukostasis in the lungs and the CNS,[195] causing respiratory failure and intracerebral hemorrhage,[180,196–198] which are usually rapidly fatal. Pulmonary leukostasis is manifested by dyspnea, tachypnea, rales, interstitial infiltrates, and respiratory failure.[195,199] CNS leukostasis manifests as headaches, blurred vision, somnolence, obtundation, ischemic stroke, and intracerebral hemorrhage.[200] Spurious laboratory data associated with hyperleukocytosis include a falsely elevated platelet count because blast fragments are counted as platelets, pseudohypoxemia caused by oxygen consumption by leukemia cells, pseudohypoglycemia caused by glucose consumption by leukemia cells, hypophosphatemia, and falsely prolonged coagulation tests due to low plasma volume.[201–203] Artifactual lowering of the pO_2 and glucose may be prevented by placing blood samples on ice and performing the tests without delay.[174]

To decrease the risk of leukostasis in patients with hyperleukocytosis, the white blood cell count must be rapidly lowered. Therapeutic measures include leukapheresis, administration of large doses of hydroxyurea, and immediate initiation of induction chemotherapy.[174,198,204] Red cell transfusions should be minimized initially to avoid overcorrection of the hemoglobin level, because this may produce an increase in blood viscosity that can worsen leukostasis. A hemoglobin goal of 8 g/dl, but not higher, is generally appropriate. In contrast, platelet transfusions are needed to decrease the risk of hemorrhage, because the platelet count may be overestimated, as discussed above. In addition, leukapheresis exacerbates thrombocytopenia and patients may also have DIC. An initial platelet count goal of 50,000/mm^3 is generally reasonable. No controlled clinical trials have defined the optimal management of hyperleukocytosis, but retrospective data support the use of leukapheresis.[205] Leukapheresis is indicated urgently if symptoms of leukostasis are present.[196] Moreover, leukapheresis should be considered early to decrease the risk of leukostasis in patients with hyperleukocytosis, as the onset of leukostasis may be abrupt, and, once initiated, it may be fulminant and irreversible.[174] Studies suggest that leukapheresis is associated with decreased early mortality and improved complete remission (CR) rates, but not with improved survival.[197,198] Because leukapheresis is only a temporary measure to decrease the risk of leukostasis, hydroxyurea should also be administered, and chemotherapy should be initiated as rapidly as possible.[174]

BIOLOGIC FEATURES

Heterogeneity

AML is a complex and extremely heterogeneous neoplasm in all respects, including cytologic features, stage of differentiation, antigen expression, cytogenetic findings, gene mutations, gene expression, activation of signal transduction pathways, and response to treatment. Significant advances have been made in our understanding of the complex biology of AML, including identification and characterization of multiple interdependent pathogenetic phenomena and pathways. Increasingly sophisticated research techniques are being applied toward elucidating the complex biology of AML and developing more effective therapies.

Aberrant Immunophenotypes

In the majority of cases of AML, leukemia cells have immunophenotypes that distinguish them from myeloid progenitor cells found in normal marrow. Compared to normal bone marrow myeloid cell populations, AML cells exhibit asynchronous myeloid antigen expression, antigen overexpression, loss of antigen expression and co-expression of nonmyeloid antigens.[9] These findings are consistent with aberrant differentiation rather than arrest of normal differentiation. The ability to distinguish AML cells from normal marrow cells based on aberrant immunophenotypes has

formed the basis for flow cytometric analysis of AML in peripheral blood or marrows of patients with AML, as well as for detection of residual disease by flow cytometry.[206–208] Immunophenotypes remain abnormal at relapse, but commonly exhibit gain or loss of one or more antigens and/or changes in antigen density.[11,209]

Leukemogenesis

Leukemogenesis in AML is a heterogeneous, multistep process that results in maturation arrest, altered proliferation, and impaired apoptosis, mainly through genetic dysregulation. A "two-hit" model of leukemogenesis has been proposed for AML.[210] In this model, AML is the consequence of at least two classes of mutations. Class I mutations (e.g., *BCR–ABL, K-RAS, N-RAS, KIT, FLT3*) confer a proliferative and/or survival advantage, whereas Class II mutations (e.g., *CBFβ*-MYH11, *AML1-ETO*, *TEL-AML1*, and *PML-RARα* fusion genes) result in impaired cellular differentiation and apoptosis. Fusion genes such as *AML1-ETO* and *CBFβ*-MYH11, which are involved in the specific structural chromosomal abnormalities t(8;21) and inv(16), respectively, in AML, impair differentiation and apoptosis, but are insufficient to cause AML by themselves.[211,212] A second class of genetic changes, such as mutations in the receptor tyrosine kinases *FLT3*,[213] *KIT*,[214,215] or *N-RAS*,[213] which deregulate proliferation, are required for development of AML. The limitations of this hypothesis include: (1) lack of identifiable mutations in class I and class II in all cases of AML, (2) frequent epigenetic changes in AML, and (3) unexplained role of newly discovered alterations in metabolic pathways and enzymes such as isocitrate dehydrogenase (IDH) in AML pathogenesis.

Recent whole-genome sequencing of bone marrow and skin, paired with skin, from patients with AML evolving from MDS revealed persistence of an antecedent founding clone containing approximately 200 to 650 somatic mutations, accompanied by outgrowth or emergence of at least one subclone with several new mutations.[216]

Clonality

The clonal nature of AML is confirmed by the presence of clonal cytogenetic abnormalities in the majority of cases,[12] and has also been demonstrated by analysis of G6PD isoenzymes[217] and of restriction fragment length polymorphisms (RFLP).[218] Clonal abnormalities may be demonstrated in either a single cell line or in more than one cell line (such as myeloid and erythroid or myeloid and megakaryocytic), indicating that leukemic transformation can occur in either restricted-lineage or multipotential stem cells.[217,219] Whole genome sequencing demonstrated that irrespective of blast count, more than 80% of bone marrow cells in MDS and s-AML are clonal.[216]

Deep sequencing of genomes from AML patients at initial diagnosis and at relapse suggested two major clonal evolution patterns at AML relapse: (1) gain of new mutations by the founding clone in the primary tumor, or (2) expansion of a subclone of the founding clone surviving initial chemotherapy, with gain of additional mutations. Thus AML relapse is associated with new mutations and clonal evolution, perhaps due to the influence of chemotherapy on the founding clone.[220]

Leukemia Stem Cells

It is generally accepted that AML relapse is caused by survival and persistence of rare chemotherapy-resistant leukemia stem cells (LSC).[221] Transplantation of AML cells into immune-deficient mice demonstrated that LSCs are present at a frequency of one in 250,000 cells in the peripheral blood of AML patients, are usually enriched in the CD34+CD38− cell fraction,[222] and lack expression of CD71 and human lymphocyte antigen (HLA)-DR,[223] but express CD123.[224] These cells are primarily in the G0 phase of the cell cycle.[225] They are also characterized by activation of the transcription factor nuclear factor-κB (NF-κB), which is not activated in normal hematopoietic stem cells.[226] Finally, they express multiple multidrug resistance proteins, including P-glycoprotein (Pgp; MDR1; ABCB1) and breast cancer resistance protein (BCRP; MXR; ABCG2), as do normal hematopoietic stem cells.[227,228]

Substantial basic and translational research has been performed to better understand the biology of LSCs and ultimately to target them therapeutically.[229] LSCs cannot be distinguished from normal hematopoietic stem cells (HSCs) based on the the $CD34^+$ $CD38^-$ phenotype,[230] but intermediate levels of aldehyde dehydrogenase (ALDH) enzyme activity can distinguish $CD34^+CD38^-$ LSCs, capable of engrafting immunodeficient mice, from normal HSCs, which showed higher ALDH activity, and presence of $CD34^+CD38^-$ALDH intermedite leukemic cells in complete remission after induction chemotherapy was associated with subsequent relapse.[231] Moreover, using bioinformatic analysis, 42 and 121 genes were identified as LSC-related and HSC-related signatures, respectively, and 44 genes were found in both signatures and were designated as core-enriched HSC-LSC genes. When LSC- and HSC-related gene signatures were examined in 160 patients with cytogenetically normal AML, both signatures correlated negatively with overall survival even in patients with the prognostically favorable *FLT3* wildtype and *NPM-1* (nucleophosmin-1) mutant status.[230]

Hematopoietic Growth Factor Effects

The use of culture systems with phytohemagglutinin (PHA)-conditioned medium from peripheral blood leukocytes in the 1980s allowed growth of clonogenic cells in 80% to 90% of cases of AML,[232] likely because of the presence of hematopoietic growth factors. Leukemia cells, like normal cells, generally require growth factors for survival and proliferation. AML cells express receptors for a number of hematopoietic growth factors, including granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), interleukins 1, 3, 4, 6, and 9, Steel factor (KIT ligand), thrombopoietin (MPL ligand), and FLT3 ligand (FLT3L).[233–236] Growth factors predominantly cause proliferation, but may also inhibit apoptosis[235] and induce differentiation.[237] Growth factors may be produced by stromal cells or by AML cells themselves, resulting in paracrine or autocrine stimulation, respectively.[238,239] Patients whose AML cells exhibit autonomous growth in vitro have an inferior response to treatment,[240,241] and autonomous growth of AML cells is associated with other adverse disease characteristics, including unfavorable cytogenetic risk group,[242] multidrug resistance[243] and expression of antiapoptotic proteins.[244]

Proliferative Characteristics

The proliferative characteristics of AML cells, including the percentage of S-phase cells, the duration of S-phase, and the total cell cycle time, are highly variable,[245–247] and proliferation may be either slower or faster than that of normal myeloid cells. AML with a high or a low proliferative rate responds less well to chemotherapy than AML with an intermediate proliferative rate.[245] A high proliferative rate may be associated with marrow aplasia after chemotherapy, but rapid regrowth of leukemia,[246] whereas nonproliferative AML cells may be chemoresistant.[248] S-phase and total cell cycle times are longer in relapsed than in newly diagnosed AML.[245]

Resistance to Apoptosis

Resistance to apoptosis contributes to both leukemogenesis and drug resistance in AML.[249] Apoptosis occurs by two pathways,

both of which result in caspase activation: (1) receptor-mediated, involving the tumor necrosis factor (TNF) family of death receptors, and (2) mitochondrial-mediated, regulated by the BCL-2 family of proteins.[249] Chemotherapy kills malignant cells through activation of mitochondrial-mediated apoptosis, and altered apoptotic pathways are a mechanism of resistance to chemotherapy. AML cells overexpress BCL-2 and other anti-apoptotic proteins, including BCL-x(L), MCL-1, XIAP, and survivin,[250,251] which may be up-regulated by the effects of stromal cells[250] and cytokines.[252] Permeabilization of the mitochondrial outer membrane is blocked by higher levels of the antiapoptotic proteins BCL-2, BCL-x(L), and MCL-1, and facilitated by the proapoptotic proteins BAX or BAD. High BCL-2-to-BAX protein ratios in AML cells are associated with lower complete remission rates and shorter overall survival.[253] Expression of APAF-1, an important protein in the apoptosis machinery, is commonly silenced by methylation in AML cells, and may be restored by treatment with DNA methyltransferase inhibitors.[254] Expression of the multidrug resistance protein P-glycoprotein (ABCB1) may also inhibit AML cell apoptosis by a mechanism independent of drug efflux.[255]

Signal Transduction Pathway Activation

Activation of signal transduction pathways may result from mutations in gene encoding growth factor receptors such as *FLT3*, *KIT*, or *RAS*. In addition, aberrant activation of the PI3K/Akt/mammalian target of rapamycin (mTOR) signaling pathway is implicated in leukemogenesis in AML,[256–259] in the absence of consistent gene mutations. mTOR is constitutively activated in most AML cases,[256–258] but not in normal hematopoietic stem cells,[257] and P13K/Akt/mTOR pathway activation is associated with compromised apoptotic response mechanisms[260–262] and resistance to chemotherapy.[256,258–261] Thus PI3K/AKT/mTOR inhibitors have the potential to be both effective and selective in AML.[263,264] Multiple signal transduction pathways may be activated in AML and the number of pathways activated is associated with a progressively worse prognosis.[265]

Microenvironment

AML bone marrow exhibits increased microvessel density, compared to normal marrow,[266–268] and AML cells express vascular endothelial growth factor (VEGF), mRNA, and protein,[266] and may also express aberrant VEGF receptors.[269] VEGF can act via multiple paracrine,[270] as well as autocrine,[269] mechanisms to contribute to AML cell expansion and survival in the bone marrow microenvironment.[271,272] VEGF secretion is strongly correlated with expression of FLT3 and of FLT3 ligand.[273] Inhibition of FLT3 signaling with a small molecule FLT3 inhibitor, an antibody that blocks FLT3 ligand binding or FLT3 receptor siRNA decreases VEGF secretion. FLT3 is likely to induce VEGF secretion through the MAPK (mitogen-activated protein kinase) pathway via its activation of ERK1/2 (extracellular-signal regulated kinase-1 and -2) phosphorylation, rather than through AKT (protein kinase B) or STAT5 (signal transducer and activator of transcription-5),[273] suggesting novel treatment strategies.[274]

The chemokine stromal cell-derived factor-1 (SDF-1) regulates homing and engraftment of leukemia cells in the bone marrow microenvironment and stromal niche. SDF-1 and its receptor CXCR-4 (fusin, LESTR) are expressed by AML cells and promote AML cell survival[275] and stroma-mediated chemoresistance. CXCR-4 represents a novel therapeutic target[276] for AML, and CXCR4 inhibitors have been tested in combination with chemotherapy in preclinical and clinical studies, with the goal of inducing mobilization of AML cells into the circulation, with promising results.[277]

CYTOGENETIC AND MOLECULAR FINDINGS

Cytogenetics

Acquired chromosome abnormalities are present in AML cells in most patients and diverse recurrent abnormalities are strongly predictive of treatment outcomes. Cytogenetic abnormalities were first described in AML in the 1960s, and were found to be present in approximately one half of AML patients in the 1970s with development of chromosome banding techniques (Chapter 3). With technical improvements, recent series have reported abnormal karyotypes in 55% to 78% of adults with AML.[32,278] Approximately 55% of patients with AML have a single cytogenetic abnormality, including 15% to 20% with gain or loss of a single chromosome as the only change; the remaining 45% have two or more changes. The most common recurring cytogenetic abnormalities in AML include t(15;17), t(8;21), inv(16), +8, +21, del(5q), –7, 11q23 translocations, and 12p11–13 abnormalities.[32,278]

Correlation of cytogenetics and clinicopathologic data has led to the recognition of distinct subtypes of AML and has helped to identify prognostic groups (Table 75.5).[32,278] Techniques such as PCR, FISH, and CGH have allowed characterization of cytogenetic abnormalities at the molecular level, demonstrating frequent involvement of oncogenes and tumor-suppressor genes (Chapter 72).

The best described subtypes of AML are defined by recurring structural chromosomal abnormalities, which primarily consist of balanced translocations, occur more commonly in younger patients, tend to correlate with morphology, and are predictive of treatment outcomes. These include t(8;21), inv(16) or t(16:16), and t(15;17) and their variants. AML with t(8;21) tends to have blasts with maturation, often with azurophilic granules and occasionally with very large granules (pseudo-Chédiak–Higashi granules).[24] AML with inv(16) or t(16;16) is usually associated with monocytic differentiation and abnormal marrow eosinophils.[24,181] APL with t(15;17) and its variants is suggested by the presence of hypergranular promyelocytes in association with disseminated intravascular coagulopathy (DIC), but may also be present in a variant microgranular (hypogranular) subtype (Chapter 78). Other cytogenetic abnormalities associated with morphology in AML include 11q23 translocations with monoblastic features;[24,279] t(6;9) with marrow basophilia;[280]; abnormalities of 3q21-26 with abnormal platelets and thrombocytosis[281] and t(9;22), 14q32, or 11q23 with mixed lineage antigen expression.[282,283] t(8;21), inv(16) and t(15;17) are associated with favorable responses to chemotherapy, and 11q23 translocations, t(6;9), 3q21-26 abnormalities and t(9;22) with adverse treatment outcomes. AML with 11q23 abnormalities is associated with a high complete remission rate but short disease-free and overall survival, whereas the other unfavorable abnormalities are associated with low complete remission rates as well as short disease-free and overall survival.

11q23 translocations are common in t-AML arising following topoisomerase II therapy,[99,122] but they also occur de novo, and are associated with monocytic differentiation. 11q23 translocations are characterized molecularly by rearrangement of the *MLL* gene at 11q23. The frequency of *MLL* rearrangements is sevenfold higher (5.3% vs. 0.8%) in patients younger than 60 years of age. The molecular pathogenesis of *MLL* gene rearrangements probably involves aberrant nonhomologous end joining of DNA double strand breaks. The normal MLL protein is proteolytically cleaved and functions as a transcriptional repressor or activator. Chimeric proteins that are generated from *MLL* rearrangements include the N-terminal region of MLL, which is involved in protein–protein interactions and transcriptional repression, and their leukemogenic effects appear to occur via activation of clustered

TABLE 75.5

SELECTED PRIMARY CHROMOSOME ABERRATIONS IN ACUTE MYELOID LEUKEMIA

Type of Rearrangement	Genes Involved	Hematologic Clinical Features	Prognosis
t(1;3)(p36;q21)	*MEL1*	Preceded by MDS, M1, M4, dysmegakaryopoiesis	Poor
t(1;7)(q10;q10)		Preceded by MDS, M1, M4, genotoxic exposure	Poor
t(1;11)(p32;q23)	*AF1P, MLL*	M0, M5	Poor
t(1;11)(q21;q23)	*AF1Q, MLL*	M4, M5, infants	Poor
t(1;22)(p13;q13)	*RBM15, MKL1*	M7, thrombocytopenia, hepatosplenomegaly, bone marrow fibrosis	Poor
inv(3)(q21;q26);t(3;3)(q21;q26)	*EVI1, RPN1*	Preceded by MDS, M1, M4, M6, abnormal dysmegakaryopoiesis, thrombocytosis	Poor
t(3;5)(q25, 1;q35)	*MLF1, NPM*	M6, megakaryocytosis, Sweet syndrome	Intermediate to poor
t(3;12)(q26;p13)	*MDS1, EVI1-TEL*	Preceded by MDS, dysmegakaryopoiesis	Poor
t(3;21)(q26;q22)	*EVI1, MDS1, or EAP;AML1*	No FAB preference, genotoxic exposure	Poor
+4		M1, M2, M4; subcutaneous tumors	Poor
–5/del(5q)		No FAB preference, genotoxic exposure	Poor
t(5;17)(q35;q12)	*NPM, RAR-α*	M3	Poor
t (6;9)(p23;q34)	*DEK, CAN*	Preceded by MDS; M2 and M4, bone marrow basophilia	Poor
t(6;11)(q27;q23)	*AF6, MLL*	M4 and M5; localized infections	Poor
–7/del(7q)		No FAB preference; genotoxic exposure; prior MDS	Poor
t(7;11)(p15;p15)	*HOXA9, NuP98*	M2 with Auer rods	Intermediate
+8		M2, M4, and M5; can be preceded by MDS; no impact on prognosis when associated with good-risk cytogenetics	Intermediate to poor
inv(8)(p11q13)	*MOZ TIF2*	M5, acute mixed-lineage leukemia, erythrophagocytosis	Poor
t(8;16)(p11;q13)	*MOZ, CBP*	M5, erythrophagocytosis, DIC; mainly children	Poor
t(8;21)(q22;q22)	*ETO, AML1*	M2 with Auer rods, eosinophilia, myeloblastoma	Good
t(8;22)(p11;q13)	*MOZ, P300*	M5, can be therapy-related	Poor
t(9;11)(p21–22;q23)	*AF9, MLL*	M5	Intermediate
t(9;22)(q34;q11)	*ABL, BCR*	M1 and M2; biphenotypic, rare	Poor
t(10;11)(p11–15;q13–23)	*AF10, MLL*	M5	Intermediate to poor
t(10;16)(q22;p13)	*MORF, CBP*	M5, can be therapy-related	Poor
+11	*MLL*	M1, M2	Poor
t/del(11q23)	*MLL*	M5, biphenotypic, genotoxic exposure	Poor
t(11;16)(q23;p13)	*MLL, CBP*	M4, M5, infants	Poor
t(11;17)(q23;q25)	*MLL, AF17*	M2, M4, and M5	Poor
t(11;17)(q23;p21)	*PLZF, RAR-α*	M3	Intermediate
t(11;19)(q23;p13)	*MLL, ENL, ELL*	M4 and M5; biphenotypic	Poor
t/del(12p)		No FAB preference, genotoxic exposure	Poor
i(12)(p10)		Concurrent germ-cell tumors	Poor
t(12;22)(p13;q11)	*TEL, MNI*	Preceded by MDS, M1, M4, M7	Poor
+13		No FAB preference	Poor
t(15;17)(q22;q11)	*PML, RAR-α*	M3, M3v, DIC, Auer rods	Intermediate to poor
inv(16)(p13;q22), t(16;16), (p13;q22), del(16)(q22)	*MYH11, CBF-β*	M4Eo, central nervous system disease	Good
t(16;21)(p11;q22)	*FUS, ERG*	No FAB preference	Poor
i(17)(q10)		Preceded by MDS, no FAB preference	Poor
del (20q)		No FAB preference	Poor
+21		No FAB preference, MDS	Intermediate
+22		M4, can be associated with inv16; MDS	Intermediate

DIC, disseminated intravascular coagulation; FAB, French/Am British; MDS, myelodsplasia.
Note: See Chapter 72 for description of the genes and Mitelman F, Johansson B, Mertens F, eds., Mitelman database of chromosome aberrations in cancer. http://cgap.nci.nih.gov/chromosomes/mitelman.

homeobox (*HOX*) genes.[284] More than 40 different partner genes for *MLL* have been identified.[24] In t(9;11), t(10;11), and t(11;19), the amino terminus of the *MLL* gene is fused to one of three homologous genes, *AF9*, *AF10*, or *ENL*, from chromosomes 9q22, 10p12, and 19p13, respectively.[285] Survival of patients with de novo t(9;11) has varied among studies, with some groups placing it in an intermediate prognostic group whereas others have reported it as unfavorable.[29,278,286] De novo AML with t(6;11)(q27;q13) has a very poor prognosis.[287] Additional cytogenetic aberrations have been shown to modify the outcome of pediatric 11q23/*MLL*-rearranged AML.[288] AML patients with *MLL* gene rearrangement may have a better outcome with more intensive treatment regimens.

Structural abnormalities involving the long arms of chromosomes 5 and/or 7, monosomy 5 and/or 7, and complex karyotypes, defined by the presence of three or more unrelated numerical and/or structural abnormalities, are frequently seen in AML arising from prior MDS and in t-MDS/t-AML associated with alkylating agent therapy.[100,122] These abnormalities, whether in de novo AML or t-AML, are associated with low complete remission rates and short disease-free and overall survival. Other numerical chromosomal abnormalities associated with poor treatment outcome include +11, +13, and +21.

The monosomal karyotype (MK), recently defined by the presence of at least two autosomal monosomies or a single autosomal monosomy in combination with at least one structural abnormality, is associated with a particularly dismal prognosis, with a 4% ±1% 4-year overall survival, whereas the 4-year OS of patients with complex, but nonmonosomal, karyotypes was 26% ± 2%. In a subsequent Southwest Oncology Group study of 1,344 adult AML patients, MK was present in 13%, increased in incidence with age, being present in 4% of patients age 30 or younger, but 20% of those over age 60, comprised 40% of the unfavorable cytogenetic risk category, and was associated with a complete remission rate of only 18% and only 3% 4-year survival.[289] Transplantation resulted in limited improvement in outcome, with 25% 4-year OS in patients transplanted at the Fred Hutchinson Cancer Research Center.[290] Thus transplant is indicated when feasible, but improvement in outcome is modest.

Molecular Abnormalities

AML is characterized by recurrent gene mutations that confer constitutive or aberrant signaling through one or more pathways in the complex signaling network that regulates normal hematopoiesis. The therapeutic implications of targeting different signaling pathways have begun to be exploited in recent years, with several promising small molecules and biologic agents in development (see "Therapy" section). Moreover, prognosis in AML is increasingly able to be assessed by evaluating molecular markers including frequently detected gene mutations.[291] This can be particularly useful in dissecting the prognosis of AML with a normal karyotype.[49,292] In addition, overexpression of specific genes is associated with unfavorable treatment outcomes. Assays for gene mutations are more readily standardized and more widely applicable than assays measuring gene expression levels. The number of gene abnormalities described in AML continues to increase.

FLT3 is a receptor tyrosine kinase that is expressed on hematopoietic progenitor cells and is activated by binding of FLT3 ligand (FL), stimulating proliferation.[210] FL binds to the receptor and induces dimerization, tyrosine kinase activation, and receptor autophosphorylation, followed by initiation of the phosphorylation of downstream signaling proteins. FLT3 is expressed on AML cells in most cases of AML, and is mutated in 20% to 34% of patients with AML[35,36,37,293,294] resulting in constitutive activation.[210,293] *FLT3* mutations can be detected by genomic PCR amplification and gel electrophoresis. The most common mutation is a small in-frame internal tandem duplication (ITD) in the *FLT3* gene that results in duplication of an amino acid sequence within the juxtamembrane domain of the receptor, which disrupts the autoinhibitory activity of the juxtamembrane domain, resulting in constitutive tyrosine kinase activation (Fig. 75.5). Point mutations in the DNA sequence encoding the FLT3 activation loop, predominantly in the aspartic acid (D) residue at amino acid position 835, occur less frequently.[36]

FLT3 mutations activate similar transduction pathways as binding of FLT3 ligand to the wildtype receptor, including signal transducer and activator of transcription (STAT) 5 and the RAS/MAPK and PI3K/Akt pathways.[293,295–297] Other effects include myeloid maturation arrest by virtue of suppression of the C/EBPα and PU.1 transcription factors,[298] and antiapoptotic effects by virtue of phosphorylation of the proapoptotic protein BAD,[298,299] resulting in inactivation of its proapoptotic function.

FLT3 mutations are associated with higher peripheral blast counts, normal karyotype and FAB M5 disease. Presence of FLT3-ITD does not affect CR rate, but predicts high relapse rate and poor survival and is useful in stratifying patients with AML with a normal karyotype into poor risk groups.[35,37,293,300,301,302] *FLT3* point mutations are less prognostically unfavorable than *FLT3*-ITD.[303] *FLT3*-ITDs are of less prognostic significance in AML patients over age 70 years,[300, 304] likely because they occur in different patient populations than expression of MDR1/Pgp,[305] which is a strong adverse prognostic factor in older adult AML patients,[306] and because the prognosis of all AML patients over 70 years is poor.[307] Prognosis of patients with *FLT3*-ITD is further worsened by absence of the wildtype allele,[38] higher ITD to wildtype allelic ratio, larger size of the ITD[300] or presence of the ITD in CD34+CD33− precursors.[308] The role of transplantation

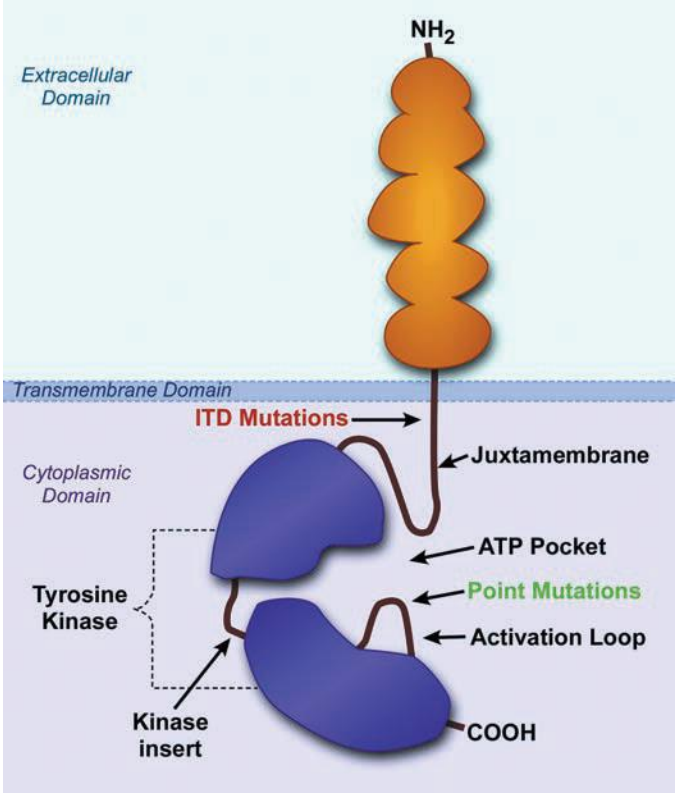

FIGURE 75.5. Simplified diagram of the FLT3 receptor: it contains 993 amino acids and consists of an extracellular ligand-binding domain with five immunoglobulinlike domains, a single transmembrane domain, and a cytoplasmic domain, which is comprised of a juxtamembrane domain followed by the tyrosine kinase domain. Internal tandem duplications (ITD) in the juxtamembrane domain and point mutations at aspartate 835 within the activation loop constitutively activate FLT3. (Drawing by Tim Gilfilen, Medical Art Group, Vanderbilt University.)

in overcoming the adverse prognosis associated with *FLT3*-ITD is under investigation (see "Stem Cell Transplantation" section). Several FLT3 inhibitors are currently being evaluated in clinical trials in AML (see "Therapy" section).

Recently several groups have focused on the important role of the FLT3 ligand (FL) in AML with *FLT3*-ITD. FL expression increases significantly during induction and consolidation chemotherapy, and AML blasts remain highly responsive to FL at relapse, suggesting a potential role of FL in promoting relapse.[309] A treatment strategy involving induction chemotherapy, stem cell transplantation, FLT3 inhibitors, and monoclonal antibodies against FL has therefore been proposed for AML with *FLT3*-ITD.[310]

Mutations of exon 12 of the nucleophosmin (*NPM* or *NPM1*) gene are the most common single gene mutations in AML, present in up to half of AML cases with normal karyotypes.[39,41,311] Nucleophosmin is a nucleocytoplasmic shuttling protein that regulates the p53 tumor suppressor pathway, and *NPM1* mutations in AML cells result in cytoplasmic localization of the protein, which can be demonstrated by immunohistochemistry.[312] *NPM1* mutations are found at diagnosis and remain stable throughout the disease course. These mutations are typically found in AML with a normal karyotype,[39–41,42,312,313] and are associated with prolonged event-free and overall survival.[42] Co-occurence of *NPM1* with *FLT3*-ITD mutations, but not with other mutations, negates their favorable prognosis,[39–41,45,302,314] (Fig. 75.6). The mechanistic role of *NPM1* in the pathogenesis of AML has not been fully elucidated. Perhaps due to favorable prognosis of *NPM1*-mutated AML, targeted therapies have not been investigated. Mutant *NPM1* transcript levels have been validated as a residual disease marker, with cumulative incidence of relapse after 4 years after double induction therapy 6.5% in patients who achieved RQ-PCR negativity compared with 53% in RQ-PCR–positive patients ($P < 0.001$); and with much better overall survival (90% vs. 51%; $P = 0.001$) in RQ-PCR–negative patients.[315]

Mutations in the *CEBPA* (CCAAT/enhancer binding protein-alpha) gene,[316] encoding a transcription factor that is essential for myeloid differentiation, are also a favorable prognostic factor in AML. These mutations are present in approximately 10% of AML patients overall and 15% of those with a normal karyotype,[46,48] and are correlated with a distinct DNA methylation profile. Mutations at the *CEBPA* C-terminus generate dysfunctional proteins, and frameshift mutations in the *CEBPA* N-terminus create a dominant negative shorter protein. Biallelic *CEBPA* mutations in AML are associated with better prognosis than for unmutated or monoallelic mutated AML.[50,317,318]

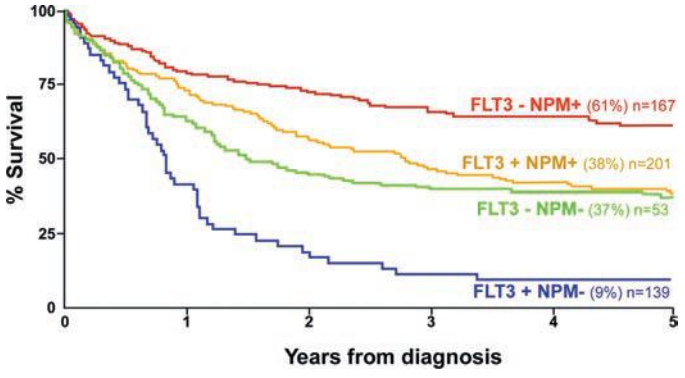

FIGURE 75.6. Clinical outcome in 550 AML patients with a normal karyotype according to FLT 3/ITD and NPM 1 mutant status. Both markers were prognostically significant predictors of survival ($p < 0.0001$), and together identified three prognostic groups: good (FLT3/ITD– NPM 1+), intermediate (FLT 3/ITD– NPM1– or FLT 3/ITD+ NPM1+), and poor (FLT 3/ITD + NPM1–). (With permission from Gale RE, Green C, Allen C, et al. The impact of FLT3 internal tandem duplication mutant level, number, size, and interaction with NPM1 mutations in a large cohort of young adult patients with acute myeloid leukemia. Blood 2008;111:2776–2784.)

Partial tandem duplication of the *MLL* gene (*MLL*-PTD), which is the gene at 11q23 that is involved in 11q23 chromosome translocations, was the first molecular abnormality to be identified in cytogenetically normal AML and to be associated with short disease-free survival,[319–321] although outcomes are better with recent regimens incorporating more intensive post-remission therapies.[322]

Overexpression of *ERG* (ets-related gene) adversely affects outcome in AML with a normal karyotype and can be detected in AML with complex karyotypes that have a cryptic amplification of chromosome 21.[323]

When expression of the *BAALC* (brain and acute leukemia, cytoplasmic) gene is dichotomized into high and low levels, high expression is associated with a higher rate of primary resistant disease and is an adverse prognostic factor for disease-free survival, cumulative incidence of relapse, event-free survival, and overall survival in AML with a normal karyotype, and predicts adverse prognosis independently from *FLT3* mutations.[324] High *BAALC* expression is also highly predictive of shorter disease-free and overall survival in normal-karyotype AML without *FLT3* or *CEBPA* mutations.[49] High *BAALC* expression is associated with *FLT3*-ITD, absent *FLT3*-TKD, wildtype *NPM1*, mutated *CEBPA*, *MLL*-PTD, and high *ERG* expression, but high *BAALC* expression independently predicted lower complete remission rates when adjusting for *ERG* expression and age, and shorter survival when adjusting for *FLT3*-ITD, *NPM1*, *CEBPA*, and white blood cell count.[325]

Overexpression of the *EVI1* (ectotropic viral integration site 1) gene on chromosome 3q26.2 has an incidence of approximately 11% and is seen not only in AML involving 3q26, including inv(3) and t(3;3), but also with other unfavorable karyotypes (e.g., –7/7q– and 11q23 abnormalities) and is associated with a poor prognosis.[326,327,328] *EVI1* is not overexpressed in AML with favorable-risk karyotypes or with *NPM1* mutations. Stem cell transplantation in first complete remission has a favorable impact on relapse-free survival of patients with AML overexpressing *EVI1* (20% to 40% versus 0%).

RAS mutations occur in 10% to 44% of AML, but rarely with *FLT3* mutations, and have not consistently predicted outcome.[36,329,300] Activation of the RAS/Raf/MEK/ERK pathway has also been demonstrated in AML, promoting AML cell survival and inhibiting apoptosis.[330,331]

TP53 mutations have a frequency of 10% in de novo AML, but much higher frequency (40% to 50%) in t-AML. They have been associated with abnormalities of chromosomes 5 and/or 7 and with worse overall survival in older patients.[300] *TP53* mutations, or *TP53* mutations and 17p-loss of heterozygosity combined, also have independent negative prognostic effects on survival in AML.[332]

Mutations in the *WT1* (Wilms tumor 1) gene occur in 5% to 10% of AML patients, with equal distribution in cytogenetically normal and abnormal AML groups.[291] There are reports of both positive[333] and negative[334] prognostic effects of *WT1* gene mutation in AML. *WT1* mutation in AML was found to be associated with overexpression of CD96, a leukemia stem cell–specific marker, and of genes involved in regulation of gene expression (e.g., *MLL*, *PML*, and *SNRPN*) and in proliferative and metabolic processes (e.g., *INSR*, *IRS2*, and *PRKAA1*).[335]

The *RUNX1* gene, located on chromosome 21 at band q22.12, encodes a transcription factor that is involved in benign and malignant hematopoiesis. The t(8;21) translocation, which is common in AML, results in a RUNX1 and ETO fusion protein. *RUNX1* mutations are identified in 5.6% to 13.2% of AML patients, and are more common in older patients and in men. They are associated with lower lactic dehydrogenase, FAB M0/M1 subtypes, and expression of HLA-DR and CD34, and with lack of CD33, CD15, CD19, and CD56 expression. *RUNX1* mutation is a poor prognostic factor, with resistance to chemotherapy and inferior event-free survival, relapse-free survival, and overall survival.[336,337,338]

The additional sex comblike 1 (*ASXL1*) gene encodes an enhancer of trithorax and polycomb proteins, which functions as a transcriptional activator or repressor in different cells. *ASXL1* mutations are present in AML and were found to be five times more common in older (≥60 years) patients (16.2%) than those younger than 60 years (3.2%; $P < 0.001$), and to be associated with wildtype *NPM1*, absence of *FLT3*-internal tandem duplication and mutated *CEBPA*, and with inferior complete remission rate and disease-free, overall, and event-free survival in older patients.[339]

TET hydroxylase enzymes are involved in DNA hypomethylation and demethylation by α-ketoglutarate-dependent conversion of 5-methylcytosine to 5-hydroxymethylcytosine (alcohol moiety), followed by further oxidation to 5-formylcytosine (aldehyde moiety) and to 5-carboxylcytosine (acid moiety), Figure 75.7,.[340–342] Mutations in the 10 to 11 translocation 2 (*TET2*) gene were identified with frequencies of 22% of myelomonocytic leukemia, 24% in secondary AML, 19% in MDSs, and 12% in MPNs.[343] Heterozygous *TET2* mutations were found in 7.6% of younger adult patients with AML and were not associated with favorable or unfavorable response to chemotherapy or with overall survival.[344]

Chromatin conformation can be affected at the DNA level by addition of a methyl group to the C-5 position of cytosine. Cytosine methylation occurs when the cytosine (C) is followed by a guanosine (G) in CpG pairs (p indicates phosphodiester bond). When CpG dinucleotides in the genome cluster together, they form CpG islands, which are located in proximity to gene promoter regions or in other intergenic areas. DNA methylation is catalyzed by the DNA methyltransferase (DNMT) family of enzymes which transfer a methyl group from S-adenosyl methionine to DNA. Hypermethylation of CpG islands in the promoters of tumor-suppressor genes is common in many cancers.

In 2010, Ley et al. found that 22% of 281 de novo AML cases had mutations in *DNMT3A* that could affect translation.[345] These mutations were seen predominantly in patients with intermediate-risk cytogenetic profiles, and not in patients with favorable-risk profiles. The precise effects of these mutations have not yet been elucidated. *FLT3*, *NPM1*, and *IDH1* mutations were significantly enriched in samples with *DNMT3A* mutations. *DNMT3A* mutations were independently associated with poor prognosis. *DNMT3A* mutations were associated with significantly shorter median overall survival (12.3 months vs. 41.1 months, $p < 0.001$).

Several subsequent studies have shown that *DNMT3A* mutations are frequent (approximately 20%) in older patients with normal karyotype AML and are associated with higher WBC and platelet counts, and concurrent mutations in the *NPM1*, *FLT3*, and *IDH1* or *IDH2* genes, and that they independently predict a higher relapse rate and shorter overall survival, but are not associated with a lower CR rate.[346–348,349]

Mutations in isocitrate dehydrogenase genes, *IDH1* and *IDH2* (m*IDH*), are present in 10% to 15% of de novo AML,[54] are most common in normal karyotype AML, and are an unfavorable prognostic factor according to most, but not all, studies.[350,351,352,353,354]

Although wildtype *IDH* in cytosol and mitochondria catalyzes the conversion of isocitrate to α-ketoglutarate (α-KG) with the production of NADPH, altered amino acids in m*IDH1* (R132) and m*IDH2* (R140 or R172) reside in the catalytic pocket and result in a neoenzymatic activity, converting α-KG to 2-hydroxyglutarate (2HG), with the consumption of NADPH.[355,356,357] The primary source for α-KG for these cells is glutamine, which is first converted to glutamate by glutaminase and subsequently to α-KG (Fig. 75.8).[358]

IDH1 and *IDH2* mutations in AML associate with specific cytosine methylation, and aberrant DNA hypermethylation is the dominant feature of *IDH1/2*-mutant AMLs.[359] 2HG, as the unique product of *IDH*-mutant enzymes, is a competitive inhibitor of multiple α-KG-dependent histone demethylases, prolyl hydroxylases, and TET hydroxylases (Fig. 75.7).[360,361] Expression of mutant *IDH1/2* and loss of *TET2* increase expression of stem cell markers and impair myeloid differentiation.[359]

KIT is a receptor tyrosine kinase, as is FLT3. *KIT* mutations have been described in approximately a third of cases of AML with t(8;21) or inv(16) in adults and their presence is associated with short disease-free survival in this otherwise prognostically favorable cytogenetic subset.[214,362,363,364,366] *KIT* mutations have been incorporated into the European LeukemiaNet prognostic classification.[51] KIT overexpression is also described in t(8;21) or inv(16) cases without *KIT* mutations.[214] KIT inhibitors are beginning to be tested in conjunction with chemotherapy in t(8;21) or inv(16) AML.

Patterns of microRNA expression are beginning to be described in AML, with potential prognostic significance;[55,56,57] microRNA expression may also be a future therapeutic target.

CLASSIFICATION OF ACUTE MYELOID LEUKEMIA

Morphologic Subtypes

The FAB classification identified eight subtypes of AML based on morphology and cytochemical staining, with immunophenotypic data in some instances (Chapter 73).[6] Four types (M0, M1, M2, M3) are predominantly granulocytic and differ according to the extent of maturation. M4 is both granulocytic and monocytic, with at least 20% monocytic cells, whereas M5 is predominantly monocytic (at least 80% monocytic cells). M6 shows primarily erythroid differentiation with dysplastic features including megaloblastic changes, and M7 is acute megakaryocytic leukemia (AMgL) identified by the presence of megakaryocyte antigens demonstrated by flow cytometry or immunohistochemistry, or of platelet peroxidase or a demarcation membrane system on ultrastructural studies. Problems with the FAB classification include interobserver variability, lack of definitive criteria for some cases of AML, and poor correlation with survival. In addition, correlations with immunophenotype, cytogenetic findings, and molecular abnormalities were not fully defined. Morphologic subtypes not precisely defined by the FAB include hypocellular AML and mixed lineage acute leukemia.[367] Eosinophilic leukemia, basophilic

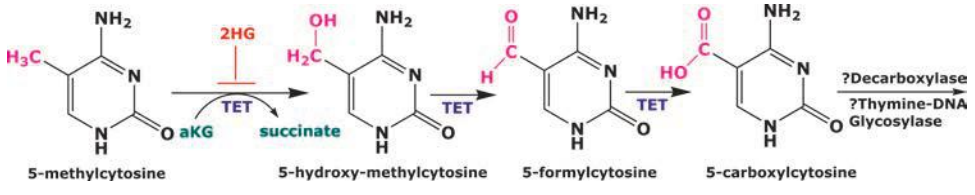

FIGURE 75.7. DNA demethylation reactions mediated by the effect of TET enzymes and 2-HG. 5-methylcytosine in DNA is partially converted to 5-hydroxymethylcytosine by the TET (10 to 11 translocation) dioxygenases. In DNA 5-hydroxymethylcytosines are oxidized to aldehyde (5-formylcytosine) and acid (5-carboxylcytosine) by TET enzymes. TET enzymes use α-KG as co-enzyme. 2-HG, produced by IDH mutant enzyme, inhibit these reactions mediated by TET enzymes. The ultimate outcome is aberrant hypermethylation of DNA. (Drawing by Ashkan Emadi, University of Maryland Greenebaum Cancer Center.)

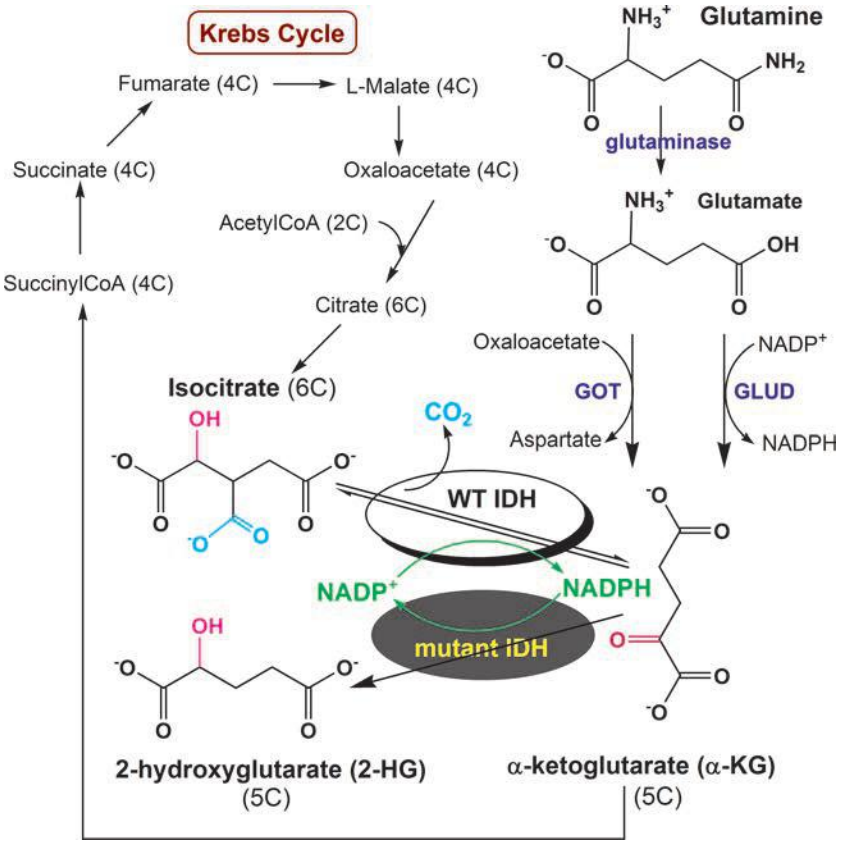

FIGURE 75.8. Chemical reactions that link glutamine to IDH enzymes. In normal cells, IDH catalyzes loss of one carboxyl (CO_2, *light blue*) group from isocitrate and oxidizes its hydroxyl group (OH, *pink*) to ketone. The product is α-KG. Under certain conditions, this reaction can be reversible. In cells with mutant *IDH*, α-KG cannot be converted to isocitrate, instead it is converted to a new molecule 2-HG, and as a result, α-KG is siphoned by the mutant enzyme. Glutamine is the primary source for α-KG, which is replenished via conversion of glutamine to glutamate by glutaminase. Glutamate can be converted to α-KG either by transamination or by oxidation processes. GOT, glutatamate oxaloacetate transaminase; GLUD, glutamate dehydrogenase. (Drawing by Ashkan Emadi, University of Maryland Greenebaum Cancer Center.)

leukemia, and mast cell leukemia are rare, overlap with myeloproliferative disorders, and are also not recognized by the FAB classification. The WHO classification recognizes chronic eosinophilic leukemia with the overlapping hypereosinophilic syndrome, and acute basophilic leukemia and the spectrum of mast cell disease, including mast cell leukemia.[24]

World Health Organization Classification

The WHO classification of acute leukemias and MDS evolved from the FAB classification, which is based on morphology, to also include clinical, immunophenotypic, and cytogenetic features.[1,3,24] The WHO recognizes five major categories: (a) AML with recurrent genetic abnormalities; (b) AML with multilineage dysplasia; (c) AML and MDS, therapy-related; (d) AML not otherwise categorized; and (e) acute leukemia of ambiguous lineage (Table 75.6). Additionally, the WHO classification defines AML by presence of 20% or more blasts, thus including cases with 20% to 30% blasts, which had been categorized as the refractory anemia with excess blasts in transformation subtype of MDS in the FAB classification. This change was made based on evidence that survival of patients with marrows with 20% or more blasts is similar to that of patients with marrows with 30% or more blasts.[368] In addition, in the WHO classification presence of recurrent cytogenetic abnormalities that are characteristic of AML, including (8;21)(q22;q22), inv(16)(p13;q22) or t(16;16)(p13q22), t(15;17)(q22;q12), or translocations or structural abnormalities involving 11q23 establishes the diagnosis of AML, even if the bone marrow contains less than 20% blasts.

AML with recurrent genetic abnormalities includes AML with t(8;21)(q22;q22), inv(16)(p13;q22), or t(16;16)(p13q22), t(15;17)(q22;aq12), or translocations or structural abnormalities involving 11q23. t(8;21) and inv(16) or t(16;16) typically occur in younger patients, have a relatively favorable response to therapy, and define the favorable category in cytogenetic classifications of AML. AML patients with 11q23 translocations include two clinical subgroups in particular: AML in infants and therapy-related leukemia, usually occurring after treatment with DNA topoisomerase II inhibitors. AML with recurrent genetic abnormalities is discussed in the "Clinicopathologic Syndromes" section in the context of the FAB morphologic subtype with which the abnormalities correlate and is also discussed in the "Cytogenetic Classification" section.

AML with multilineage dysplasia must have dysplasia in 50% or more of cells of at least two lineages. It is more common in older patients, frequently exhibits aberrant expression of CD56, CD7, or both, and is associated with unfavorable cytogenetic findings, including –7/del(7q), –5/del(5q), +8, +9, +11, del(11q), del(12p), –18, +19, del(20q) +21, and, less often, translocations involving 3q21 and 3q26 and t(1;7) (q10;p10). Abnormalities in the 3q26 region may be associated with increased platelet production. AML with multilineage dysplasia has a poor response to therapy.

AML not otherwise categorized includes AML that does not fulfill criteria for the other groups and essentially reflects the morphologic and cytochemical features and degree of maturation used in the FAB classification, with the exception that AML is defined by 20% (rather than 30%) or more blasts in the marrow. The abnormal promyelocytes in APL and the promonocytes in AML with monocytic differentiation are considered blast equivalents. In addition, AML not otherwise categorized includes acute basophilic leukemia, acute panmyelosis with myelofibrosis, and myeloid sarcoma.

Acute leukemia of ambiguous lineage is diagnosed when blasts lack sufficient lineage-specific antigen expression to classify them as myeloid or lymphoid and is discussed in the "Immunophenotypic Classification" section.

Immunophenotypic Classification

The nonlymphoid derivation of AML is confirmed by the presence of antigens expressed during myelomonocytic differentiation,

TABLE 75.6

CLASSIFICATION OF ACUTE MYELOID LEUKEMIA

Acute Myeloid Leukemia with Recurrent Genetic Abnormalities

Acute myeloid leukemia with t(8;21)(q22;q22), (*RUNX1—RUNX1T1;AML1/ETO*)

Acute myeloid leukemia with abnormal bone marrow eosinophils inv(16)(p13q22) or t(16;16)(p13;q22), (*CBFβ*/MYH11)

Acute promyelocytic leukemia, AML with t(15;17)(q22;q12), (*PML/RARα*) and variants

Acute myeloid leukemia with t(9;11)(p22;q23), (*MLLT3-MLL*)

Acute myeloid leukemia with t(6;9)(p23;q34), (*DEK-NUP214*)

Acute myeloid leukemia with inv(3)(q21q26.2) or t(3;3)(q21;q26.2), (*RPN1-EVI1*)

Acute myeloid leukemia (megakaryoblastic) with t(1;22)(p13;q13), (*RBM15-MKL1*)

Provisional entity: AML with mutated *NPM1*

Provisional entity: AML with mutated CEBPA

Acute Myeloid Leukemia with Multilineage Dysplasia

Following a myelodysplastic syndrome or myelodysplastic syndrome/myeloproliferative disorder

Without antecedent myelodysplastic syndrome

Acute Myeloid Leukemia and Myelodysplastic Syndromes, Therapy-Related

Alkylating agent-related

Topoisomerase type II inhibitor-related (some may be lymphoid)

Other types

Acute Myeloid Leukemia Not Otherwise Categorized

Acute myeloid leukemia minimally differentiated

Acute myeloid leukemia without maturation

Acute myeloid leukemia with maturation

Acute myelomonocytic leukemia

Acute monoblastic and monocytic leukemia

Acute erythroid leukemia

Acute megakaryoblastic leukemia

Acute basophilic leukemia

Acute panmyelosis with myelofibrosis

Myeloid sarcoma

Acute Leukemia of Ambiguous Lineage

including CD13 (My7), CD14 (Mo2), CD15 (My1, LeuM1), CD33 (My9), CD117 (KIT), and MPO; erythroid antigens (glycophorin A, CD71); and megakaryocytic antigens, including CD41 (platelet glycoprotein IIb/IIIa), CD42b (platelet glycoprotein Ib), CD61 (platelet glycoprotein IIIa), and factor VIII antigen.[369] The stem cell marker CD34 (My10, HPCA-1) is present on blasts in 40% to 65% of cases of AML.[370,371] Surface markers in most cases have not correlated well with the FAB classification or with prognosis.[372] More than 90% of cases of AML express CD33 or CD13, 80% to 90% express HLA-DR, and less than 25% express CD15; CD11b and CD14 are more variably expressed and tend to be present in monocytic (M4/M5) subtypes.[51] Some antigens have also been associated with morphologic and cytogenetic subsets: CD2 with M4Eo with 16q22 rearrangements;[373] absence of HLA-DR (major histocompatibility complex class II) and of CD34 with M3 [t(15;17)]; and presence of CD19 and CD56 with M2 with t(8;21).[10,374]

The morphologic associations and prognostic significance of surface markers have been variable; antigen expression should be interpreted only in the context of other clinicopathologic features. CD34 is expressed more often in less differentiated subtypes (M0, M1; M5, poorly differentiated) in many series;[375] it has also been described as more common in monocytic (M4/M5) than in granulocytic (M1, M2, M3) subtypes.[376] CD34 is generally a poor prognostic marker, particularly when observed in older patients, after MDS, or in association with expression of the multidrug resistance gene P-glycoprotein (Pgp; MDR-1; ABCB1),[375,377] but CD34 is also expressed in FAB M2 AML with the t(8;21) chromosomal translocation[378] and in FAB M4Eo with inv(16),[376] both of which have a favorable prognosis.

Lineage-specific antigen expression in the WHO classification is demonstrated in Table 75.7. Lymphoid antigens are expressed on blasts in 10% to 30% of cases of AML, and their expression has often been implicated as having prognostic significance, but their presence should be interpreted in the context of all available information.[379] Expression of CD19 (B-cell) is associated with a good prognosis when present in AML with t(8;21)[283] and a poor outcome when co-expressed with CD34 in the absence of favorable cytogenetics findings. CD7 (T-cell) is present in 15% to 20% of cases of adult AML and has been associated with a poor prognosis, usually with less differentiated subtypes (M0/M1) and expression of CD34, Pgp, or TdT.[380,381] CD56, a cell-surface glycoprotein identical to the neural cell adhesion molecule, is more commonly observed in patients with AMoL, t(8;21), and trisomy 8, and with expression of CD11b, CD14, and CD19,[382] and has been associated with shorter disease-free survival in favorable AML subtypes.[383]

Acute leukemias of ambiguous lineage are divided into three groups. Undifferentiated acute leukemias, the first group, lack morphologic or immunologic differentiating features. The blasts often express HLA-DR, CD34, and CD38 and may express TdT and CD7. Bilineage acute leukemia, the second group, has two

TABLE 75.7

LINEAGE-SPECIFIC ANTIGEN EXPRESSION IN THE WHO CLASSIFICATION

Myeloid	MPO (by flow cytometry, immunohistochemistry or cytochemistry) *or* monocytic differentiation (at least two of the following: NSE, CD11c, CD14, CD64, lysozyme)
T-lymphoid	Cytoplasmic CD3 (flow cytometry with antibodies to CD3 epsilon chain; immunohistochemistry using polyclonal anti-CD3 antibody may detect CD3 zeta chain, which is not T-cell-specific) *or* surface CD3 (rare in mixed phenotype acute leukemias)
B-lymphoid	Strong CD19 with at least 1 of the following strongly expressed: CD79a, cytoplasmic CD22, CD10, *or* weak CD19 with at least two of the following strongly expressed: CD79a, cytoplasmic CD22, CD10

populations of blasts expressing distinct lineage markers of myeloid or lymphoid origin or, less frequently, B- and T-cell lineage. In the third group, biphenotypic acute leukemia, blasts coexpress myeloid and lymphoid (B- or T-cell) antigens. Blasts very rarely express myeloid, B-, and T-cell antigens. Rearrangements of the T-cell receptor or the immunoglobulin chain genes are usually absent in AML with lymphoid antigen expression, although they have been described, usually in association with karyotypic abnormalities such as t(9;22), 11q23, or 14q32 translocations.[384–386] Up to 20% of patients with acute leukemia may have biphenotypic or mixed lineage features as detected by immunologic and molecular genetic techniques, but less than 4% of cases are unclassifiable.[24]

Cytogenetic Classification

Cytogenetic findings are the strongest predictors of AML treatment outcomes. AML has been divided into favorable, intermediate, and unfavorable subgroups based on cytogenetic findings in large series from multiple cooperative groups, with remarkably consistent findings. Cytogenetic classification of AML is discussed in the section, "Prognosis."

Molecular Classification

Cytogenetically normal AML is subdivided based on the presence of diverse mutations, which are detailed above and further discussed in the section, "Prognosis."

European LeukemiaNet Classification

In a 2010 publication, the European LeukemiaNet proposed a classification of AML that integrated cytogenetic and molecular data to define favorable, intermediate-I, intermediate-II, and unfavorable genetic groups.[51] This classification is being widely adopted, and the significance of additional and newly discovered molecular abnormalities is being described in the context of this classification.

CLINICOPATHOLOGIC SYNDROMES

The WHO classification recognizes four major categories of AML defined by specific genetic abnormalities, with multilineage dysplasia, therapy-related, and a not otherwise categorized group that retains the morphology-based FAB classification. In addition, acute leukemia of ambiguous lineage is included. Clinicopathologic syndromes of AML are discussed below.

Minimally Differentiated Acute Myeloid Leukemia (AML M0)

Criteria for FAB M0 were developed in 1991.[6,387] Immunophenotyping confirms the myeloid nature of blasts in M0, because morphology and cytochemistry are inconclusive. Blasts in M0 AML are agranular and lack Auer rods. By definition, the diagnosis of AML M0 requires less than 3% MPO-positive and Sudan black B-positive cells but more than 20% leukemia cells expressing myeloid antigens (CD13, 33, 117).[6,387] Of note, lymphoid-associated antigens, particularly T-cell type (CD2 and CD7) and TdT (30 to 50%), are commonly expressed in AML M0, but T-lymphoid–specific cytoplasmic CD3 (cyCD3) and B-lymphoid–specific cytoplasmic CD22 and CD79 (cyCD22, cyCD79) are absent.[388] M0 is characterized by a higher incidence of karyotypic abnormalities (70 to 75%) than other FAB subtypes.[389] AML M0 tends to occur in older patients (>60 years).[390] The CR rate and survival in AML M0 are generally poor, consistent with the association with unfavorable karyotypes.[391–393]

Acute Myeloid Leukemia Without Maturation (AML M1)

AML M1 is defined by a predominance (>90%) of myeloblasts without evidence of maturation (<10% promyelocytes or other, more mature, cells). The presence of Auer rods is variable. At least 3% of the blasts are reactive with Sudan black or MPO. The blasts express myeloid antigens. AML M1 makes up 10% to 20% of cases of AML and is more common in adults than in children; the median age is 45 to 50 years.[24] Constitutional symptoms are common, and hepatosplenomegaly and lymphadenopathy occur in up to one third of patients.[24] No specific cytogenetic marker has been associated with AML M1, but trisomies 11 and 13 have been reported in the immature myeloid leukemias, AML M0 and M1.[389]

Acute Myeloid Leukemia with Maturation and with t(8;21) (AML M2)

AML M2 is associated with t(8;21)(q22;q22) in 30% to 40% of cytogenetically abnormal cases.[24] Approximately 10% of all AML patients present with this syndrome; most are children and young adults. Myeloid sarcoma is common in this syndrome. AML with t(8;21) is typically associated with prominent Auer rods, marrow eosinophilia, and cytoplasmic globules and vacuoles (Fig. 75.9).

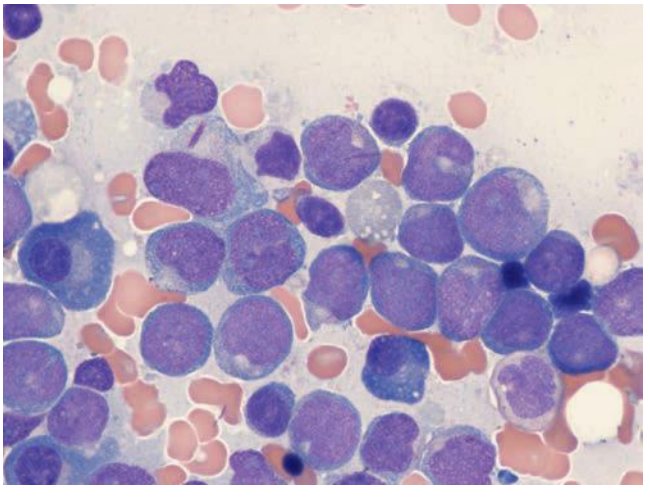

FIGURE 75.9. AML M2 with t(8;21), Wright-stained bone marrow smear. Blasts with maturing myeloid elements. (Courtesy of Dr. Qing Chen, Department of Pathology, University of Maryland.)

Immunophenotypic markers include the presence of myeloid antigens, increased expression of the natural killer cell-associated antigen CD56, and, less commonly, the B-cell antigen CD19.[394]

The two genes involved in t(8;21) are *AML1* (also known as *RUNX1, CBFα*, and *PEBP2α*B) at 21q22 and *ETO* (also called *CDR* and *MTG8*) at 8q22[395,396] (Chapter 72). They form a fusion gene on the derivative 8 chromosome, which may be detected even in patients in long-term remission, indicating its low value as a marker for minimal residual disease.[397] The *AML1* gene is also involved in t(3;21)(q26;q22), a rare balanced translocation observed in blast crisis of CML and in t-AML, and in t(12;21) with the *TEL* gene in ALL.[398]

The t(8;21) usually occurs in de novo AML and generally predicts a favorable outcome, with a high remission rate (CR rate of 86% to 95%) and long survival (5 years DFS of 57% to 71%), particularly after high-dose cytarabine (HiDAC) consolidation therapy.[399] Children and patients with leukocytosis (>20,000 cells/mm^3) or with extramedullary disease may have high relapse rates and inferior survival.[400] Mutations of the growth factor receptor *KIT* in AML1-ETO AML identify a subgroup of patients with a high white count (median 29,600/mm^3), a higher incidence of extramedullary disease (33%), and a poor prognosis.[364] Expression of the CD56 antigen on AML cells with t(8;21) is also associated with a shorter disease-free survival (DFS).[383] Because of high survival rates after multiple cycles of HiDAC consolidation, alloSCT is usually reserved for relapse.

Acute Promyelocytic Leukemia (AML M3)

See Chapter 78.

Acute Myelomonocytic Leukemia (AML M4) and Acute Myelomonocytic Leukemia with Eosinophilia (AML M4Eo) and Pericentric Inversion of Chromosome 16

AML M4 and M4Eo is present in approximately 5% to 10% of patients with AML in association with monocytosis and a myeloblastic/monoblastic infiltration of the bone marrow (Fig. 75.10). Organomegaly is common, with splenomegaly in 30% of patients. Hyperleukocytosis (>100,000 cells/mm^3) is present in 20% to 25% of patients.[24] Extramedullary disease with involvement of skin (scalp), ovaries, testicles, intestine, CNS, and particularly lymphadenopathy occurs in 20% to 30% of patients and may confer a worse prognosis.[401] The immature eosinophils have a monocytoid nucleus and a mixture of eosinophilic and large atypical basophilic granules. Staining with Sudan black, periodic acid-Schiff (PAS), and chloroacetate esterase with nonspecific esterase (double esterase) can identify the neoplastic cell. By flow cytometry, all cases of AML M4Eo express the panmyeloid marker CD13 and the stem cell antigen CD34, but there is variable expression of other myeloid/monocytic markers, including CD11b, CD11c, CD14, and CD33. There is also frequent expression of the T-lymphoid marker CD2, along with HLA-DR.

The syndrome associated with AML M4Eo was first described by Arthur and Bloomfield in 1983 in five patients with a deletion of the long arm of chromosome 16. In subsequent reports, the abnormality has been described in almost all patients as a pericentric inversion of chromosome 16, inv(16)(p13;q22), whereas a minority of patients have a balanced translocation between the two copies of chromosome 16, t(16;16)(p13.1;q22).[402] The prognosis of patients with t(16:16)(p13;q22) is similar to that of patients with (inv16)(p13;q22).[403] Cloning of the 16p and 16q breakpoints has identified the two genes involved: *MYH11*, which codes for smooth muscle myosin heavy chain, and core-binding factor (*CBF*) *β* (also known as *PEBP2β*), which codes for the *β* subunit of CBF, a heterodimeric transcription factor involved in murine leukemogenesis and in T-cell receptor gene

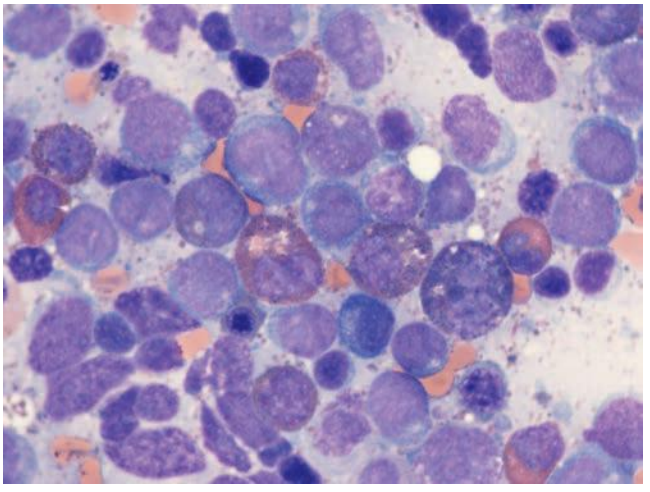

FIGURE 75.10. AML M4Eo with inv(16), Wright-stained bone marrow smear. In addition to myeloblasts and monoblasts, abnormal eosinophils with large basophilic granules are characteristic of this type of AML. (Courtesy of Dr. Qing Chen, Department of Pathology, University of Maryland.)

expression.[404,405] *CBFβ*-MYH11 fusion transcripts are detected by RT-PCR in typical AML M4Eo, but also in approximately 10% of patients with AML M4 without eosinophilia.[406]

The 81% to 93% CR rate and 48% to 63% DFS of AML with inv(16) or t(16;16) to conventional chemotherapy represent a better prognosis than for most other subtypes of AML.[399,407] Allogeneic transplantation is usually considered only in patients who relapse. AML with inversion 16 previously had a high risk of CNS relapse, but the use of HiDAC as consolidation therapy decreases the incidence of CNS disease and may serve as CNS prophylaxis. Multiple cycles of HiDAC consolidation are associated with better relapse-free survival (RFS) than a single cycle.[399] As with AML/ETO, the detection of *KIT* mutations is associated with an increased relapse rate.[366] Minimal residual disease (MRD) can be monitored by quantitative RT-PCR to identify patients at risk for relapse.[406,408,409] Carefully defined MRD cutpoints for persistent *CBFβ*-MYH11 transcript positivity were shown to be able to distinguish patients with significantly increased risk of relapse.[410]

Acute Monocytic Leukemia (AML M5a and M5b) and with 11q23 Abnormalities

AML M5 accounts for 2% to 10% of AML cases. M5 is subdivided into M5a, poorly differentiated (>80% monocytic cells including monoblasts), and M5b, well differentiated (80% monocytic, predominantly promonocytes and monocytes).[178] Patients with M5a tend to be younger (75% <25 years of age) than those with M5b, but both include a wide age range.[24] Monocytic precursors are recognized by their fluoride-inhibitable nonspecific esterase positivity and expression of CD14 and CD4 (dim expression) but not CD2. Monoblasts may be recognized by staining with antibodies to lysozyme and to CD68 (KP1).[24] There is cytogenetic heterogeneity in AML M5, but common findings include a normal karyotype (49%), 11q23 abnormalities (21%), and trisomy 8 (21%).[411] The incidence of 11q23 abnormalities is higher in AML M5a (31% to 33%) than in AML M5b (12% to 16%) and AML M4 (5%); they are found in less than 1% of all other FAB subtypes ($P < 0.0001$).[278,286,411] Trisomy 8 is more common in M5a than M5b, which has a normal karyotype in 71% of cases.[411] *FLT3* mutations are more common (29%) in M5b than M5a.[411]

Extramedullary disease occurs in over 50% of patients with AML M5 and is more common in AML M5 than in other subtypes of AML. It may include cutaneous lesions, gum infiltration,

testicular involvement, and CNS disease.[412,413] CNS involvement has been reported in 3% to 22% of patients.[412] Leukocytosis is a common finding, present in 10% to 37% of patients. The frequency of DIC is second only to that in APL, and DIC may be exacerbated when therapy begins. Elevated levels of lysozyme are found in more than two thirds of patients and may contribute to renal insufficiency or proteinuria. Results of several studies indicate that AML M5 is associated with poor prognosis, and specifically short disease-free survival.[412] On the other hand, ECOG reported no difference in CR rates for M5 patients (62%) compared to non-M5 patients (60%) and no difference in 3-year overall survival (31% vs. 30%).[414]

Erythroleukemia (AML M6)

Erythroleukemia accounts for 2% to 4% of cases of AML and is characterized by a prominent component of erythroblasts. Erythroid/myeloid leukemia (M6a) has 50% or more erythroid precursors in the nucleated population and 20% or more myeloblasts in the nonerythroid population. In the less common pure erythroid leukemia (M6b), 80% of the marrow cells are immature erythroids, without a significant percentage of myeloblasts. A third type (M6c) has been characterized by 30% or more nonerythroid blasts and 30% or more pronormoblasts.[415]

Morphologic findings in the peripheral smear may include schistocytes, teardrop forms, pincered red cells, and basophilic stippling.[416] Circulating erythroblasts are observed in one half of patients. The bone marrow is usually hypercellular with megaloblastic changes.[416] Erythroid precursors commonly have multinuclearity (65%), karyorrhexis (53%), morulae (25%), and/or cytoplasmic vacuolization (23%). The PAS reaction may stain abnormal erythroid cells in either a coarse globular (16%) or diffuse (57%) pattern. The most common immunophenotypic markers for erythroleukemia are glycophorin 7 and the transferrin receptor (CD71).

There is a bimodal age distribution for erythroleukemia, with a small peak below 20 years and a broader peak in the seventh decade.[415] In many series approximately one half of cases of erythroleukemia are therapy-related.[416] Cytogenetic abnormalities are found in over 70% of patients, and abnormalities of chromosomes 5 and 7 are common.[417–419]

The prognosis for erythroleukemia is generally poor, with a recent reported overall survival of 8 months,[420] but depends upon age, secondary leukemia, cytogenetic abnormalities, and subtype of erythroid leukemia. One report had a CR rate of 62% for de novo erythroleukemia but most series have CR rates in the 10% to 40% range, particularly in secondary erythroleukemia.[415] The CR rate in patients with 5q or 7q abnormalities is approximately 20% and the median survival is 4 months, compared to 18 months in the absence of these abnormalities.[421] Median survival was inferior in M6b (1.8 months) compared to M6a (18.8 months, $P < 0.002$) and M6c(7 months, $P < 0.01$).[422] Allogeneic SCT appears to confer the best long-term survival in erythroleukemia, particularly with unfavorable cytogenetics and/or therapy-related.[415]

Acute Megakaryocytic Leukemia (AML M7)

AML M7 was first described in 1931 and was added to the FAB classification in 1985.[423–425] There is a bimodal age distribution, with one peak in infancy and the other in older adults. Megakaryocytic AML represents 0.6% to 1.2% of cases of adult AML, compared to 3% to 10% of childhood AML. The median age for adult AML M7 is 51 to 58 years and there is a male predominance. Morphologically, AML M7 can be confused with the L2 subtype of ALL or with AML M1. Cytoplasmic blebs suggestive of megakaryocyte differentiation may be present on the blasts. The myeloid surface markers CD13 or CD33 may be expressed, and CD34 is often absent. The diagnosis depends on the expression of at least one platelet antigen (CD41, CD42b, CD61, or factor VIII-related antigen) on the leukemia cells. The bone marrow may be difficult to aspirate and over two thirds of patients will have significant fibrosis.

Cytogenetic abnormalities are more frequent (>90%) in AML M7 than in other subtypes of AML.[426] They are heterogeneous but differ between children and adults,[426] with adults typically having complex karyotypes.

Although data are limited, the clinical presentation of AML M7 is not substantially different from that of other subtypes of AML. Organomegaly is infrequent in adults. Cytopenias are usually present, but approximately 30% of patients have platelet counts above 100,000/μl.[178] Platelet function studies usually indicate impaired aggregation responses. Serum LDH levels are often elevated. Osteosclerotic and osteolytic lesions have been demonstrated radiographically.[178,427]

Prognosis in adult AML M7 is poor.[423–425] The CR rate is 43% to 50% and the median DFS is 6 to 10 months.[423–425] The ECOG series reported an inferior DFS in M7 compared to non-M7 AML (23 vs. 52 weeks, $P < 0.001$), and found M7 AML to be an independent adverse prognostic factor for DFS.[423] Because of the poor prognosis of adult AMgL, early allogeneic SCT should be considered.

Other Clinicopathologic Syndromes

Acute panmyelosis with myelofibrosis (APMF) was first described in 1963 by Lewis and Szur.[428] APMF is rare, representing less than 1% of AML, and has replaced acute myelosclerosis or acute myelofibrosis in the WHO classification.[428] The median age is 57 to 67 years and there is a male predominance. The onset is sudden and patients have pancytopenia with <5% blasts in the peripheral blood and no to minimal teardrop forms. There is no history of preceding myeloproliferative disorders and there is no, or minimal, splenomegaly. The marrow is hypercellular with various degrees of hyperplasia of the three cell lineages; clusters of late-stage erythroids may be prominent. Dysplastic changes, including hypolobated megakaryocytes with dispersed chromatin, are present. Clusters of immature cells are present, and the degree of marrow fibrosis is variable. If the proliferative process includes predominantly myeloblasts and fibrosis is present, the leukemia should be classified as AML of the appropriate cell types with "myelofibrosis." The main differential diagnosis is between APMF and AML M7.[428] There are fewer blasts in APMF and the blasts rarely express megakaryocytic antigens. Cytogenetic findings are not specific but are often complex and include abnormalities of 5q, 7, and 17p.[429] The prognosis of APMF is extremely poor, with a median survival of less than 2 months in some series.[428,430]

Acute basophilic leukemia is very rare, but is recognized as an independent entity by the WHO classification.[431] Cutaneous disease, organomegaly, lytic bone lesions, and symptoms of hyperhistaminemia may be present. Blasts have oval, round, or bilobed nuclei and variable numbers of coarse basophilic cytoplasmic granules. The characteristic cytochemical staining is metachromatic positivity with toluidine blue, diffuse acid phosphatase positivity, and, in some cases, block PAS positivity. Blasts often do not stain with Sudan black B, MPO, or nonspecific esterase. Blasts express the panleukocyte antigen CD45, the myeloid antigens CD13, CD33 and CD11b, and usually also CD9 and CD17, CD34, and HLA-DR. Involvement of 12p or t(6;9), which can occur in AML with increased basophils, has been reported.[431] Some cases may represent blast crisis of CML or de novo Ph+ acute leukemia. Prognosis is uniformly poor.[432]

The t(6;9)(p21;q34) is a rare variant of AML (<1%) that was initially described in a young age group (20 to 30 years of age) with basophilia and a poor response to therapy. It is usually of the FAB M2 or M4 subtype.[433] The genes involved are the *DEK* gene on chromosome 6p23 and the nucleoporin protein, *NUP214* (previously *CAN*) gene on chromosome 9p34.[434]

AML with abnormalities of the long arm of chromosome 3, inv(3)(q21q26) and t(3;3)(q21;q26), typically presents with a normal platelet count or thrombocytosis.[435] The critical gene involved at 3q26 is *EVI1* (ecotropic viral integration site 1),[436,437] and overexpression of EVI1 is found in 9% of AML without 3q26 abnormalities.[438] GATA2 (3q21) may also be overexpressed. The inv(3)(q21;q26) syndrome represents 1% to 3% of de novo AML, may also follow MDS, and has a poor prognosis. Abnormal megakaryocytes may be present.[439] Other rare balanced rearrangements involving 3q26 include t(3;21)(q26;q22), t(3;12)(q26;p13), and t(2;3)(p15;22;q26).[440]

AML with t(3;5)(q25.1;q35) has been reported in approximately one fourth of patients with erythroleukemia (M6), and the marrow often has trilineage dysplasia and abnormal megakaryocytes. Unlike patients with inv(3), patients with t(3;5) do not have thrombocytosis.[441] The genes involved are *NPM* on chromosome 5 and myelodysplasia/myeloid leukemia factor 1 (*MLF1*) on chromosome 3.[442]

PROGNOSIS

Prognosis Is Multifactorial

A number of clinical and biologic features, detailed below, predict prognosis in AML, and prognosis is actually determined by interactions between these factors (Table 75.8). As an example,

TABLE 75.8

PROGNOSTIC FACTORS IN ACUTE MYELOID LEUKEMIA

Factor	Favorable	Unfavorable
Clinical		
Age	<45 y	<2 y, >60 y
ECOG performance status	0–1	>1
Leukemia	De novo	Antecedent hematologic disorder; myelodysplastic syndrome, myeloproliferative disorder
Infection	Absent	Present
Prior chemotherapy	No	Yes
WBC count	$<25{,}000/mm^3$	$>100{,}000/mm^2$
Serum LDH	Normal	Elevated
Extramedullary disease	Absent	Present
CNS disease	Absent	Present
Cytoreduction	Rapid	Delayed
Morphology		
Auer rods	Present	Absent
Eosinophils	Present	Absent
Megaloblastic erythroids	Absent	Present
Dysplastic megakaryocytes	Absent	Present
FAB type	M2, M3, M4	M0, M6, M7
Surface/Enzyme Markers		
Myeloid	$CD34^-$, $CD14^-$, $CD13^-$	$CD34^+$
HLA-DR	Absent	Present
TdT	Absent	Present
Lymphoid	$CD2^+$	$CD7^+$, $CD56^+$ Biphenotypic (two or more lymphoid markers)
MDR-1	Absent	Present
Cytogenetics		
(see Tables 75.4 and 75.6)	t(15;17), t(8;21), inv(16)	–7, del(7q), –5, del(5q), 3q21 and 3q26 abnormalities, complex karyotype
Molecular Markers		
FLT3 mutation	Absent	Present
EVI1 overexpression	Absent	Present
MLL partial tandem duplication	Absent	Present
NPM1 mutation	Present	Absent
CEBP-α mutation	Present	Absent
BAALC overexpression	Absent	Present
VEGF overexpression	Absent	Present

ECOG, Eastern Cooperative Oncology Group; FAB, French-American-British; HLA, human lymphocyte antigen; LDH, lactate dehydrogenase; MDR, multidrug resistance gene.

structural cytogenetic abnormalities involving the genes encoding the core binding factor transcription factor subunits, including t(8;21), inv(16), and t(16;16), define the favorable cytogenetic subgroup of AML, but treatment outcome is significantly worse in older patients with these cytogenetic abnormalities,[443] and in patients whose AML cells have mutations of the growth factor receptor KIT.[364,365,366] As another example, in a Southwest Oncology Group study of older AML patients, secondary AML, unfavorable karyotype and expression of the MDR protein MDR1 (Pgp) were each independently significant associated with lower CR rates, but CR rates ranged from a high of 81% to a low of only 12% depending on how many of these three adverse prognostic factors were present.[444]

Clinical Factors

Age is a powerful prognostic factor, with older adult patients having worse outcomes than younger adults.[443] The clinical state of the patient, as reflected in performance status and co-morbid conditions, also affects outcome.[445] Patients with secondary AML, defined by a preceding bone marrow disorder, including MDS or MPN, or with t-AML, have an inferior response and survival compared to those with de novo AML.[446,447] Hyperleukocytosis correlates with shorter overall survival[448] due to both increased induction deaths[449] and an association with *FLT3* mutations.[36] Extramedullary disease is unfavorable.[448] Finally, one report demonstrated lower CR rates and shorter overall survival in African American males, in relation to whites and African American females.[450]

Morphology

Favorable morphologic features include presence of Auer rods (M1–M4) and of eosinophils (M2 and M4Eo), the latter because of the association with the favorable cytogenetic abnormalities t(8;21) in M2 and inv(16) in M4Eo. The eosinophils in M2 show only minor abnormalities such as faint green-blue/yellow granules, whereas in M4Eo they are dysplastic and often have large, irregular deeply purple granules (Figs. 75.6 and 75.9). Morphologic dysplasia is unfavorable,[415] likely by virtue of association with unfavorable karyotypes.[451] In regard to FAB types, patients with M0.[393], M6[452] and M7[423,424] generally have lower survival rates. FAB M5 is associated with extramedullary disease and with *FLT3* mutations[35]

Immunophenotype

The effect of surface markers on prognosis is variable and is interdependent with other factors. Although CD34 has been reported as an adverse factor,[379, 448] in some studies it has had no impact on outcome.[453,454] CD34 expression is a poor prognostic factor when it is associated with the multidrug resistance gene (MDR1).[455] CD34 expression is associated with prognostically adverse karyotypes, including abnormalities of chromosome 5 (–5/5q–) and 7,[454] but it is also expressed in favorable AML subtypes, including AML with t(8;21)[378, 454] and inv(16).[376] The lack of HLA-DR reactivity as observed in APL (M3) has been associated with a good prognosis in some,[456] but not all,[457] series, whereas absence of CD33 expression may be unfavorable.[453] CD7 expression is prognostically unfavorable.[458] CD56 expression correlates with extramedullary disease, which is unfavorable.[448] Both CD19 and CD56 are frequently expressed on AML cells in t(8;21) AML; CD19 does not have prognostic significance, and CD56 is associated with shorter disease-free survival in these patients.[383] Finally, detection of residual or recurrent blasts by multiparameter flow cytometry at diverse time points following therapy predicts adverse outcome.[206,208,459–461]

Multidrug Resistance

Expression of multidrug resistance (*MDR*) genes has been identified as having adverse prognostic significance in AML.[377,462,463] The best described *MDR* gene is *MDR1*, whose gene product, P-glycoprotein (Pgp), is a 170-Kda cell membrane ATP-binding (ABC) protein (ABCB1) that functions as a drug efflux pump for naturally occurring substances, including anthracyclines, epipodophylotoxins, vinca alkaloids, and taxanes,[463,464] as well as the calicheamicin moiety of gemtuzumab ozogamicin.[465] Pgp expression can be detected on the surface of AML cells by flow cytometry using specific antibodies such as MRK16 and can be correlated with functional effux of substrate fluorescent dyes by AML blasts. Expression of MDR-1/Pgp on blasts is more commonly found in older AML patients, often in conjunction with adverse cytogenetic findings, and is associated with a lower CR rate.[377] Moreover, MDR-1/Pgp overexpression and *FLT3*-ITDs occur largely in different AML patient populations.[305]

Other transport proteins that mediate cellular drug efflux and appear to mediate drug resistance in AML include the ABC proteins multidrug resistance-associated protein 1 (MRP-1; ABCC1) and breast cancer resistance protein (BRCP; ABCG2).[377,462,466] MRP-1 has adverse prognostic significance in AML,[467] especially when co-expressed with MDR-1/Pgp,[462,468] and BCRP also has adverse prognostic significance.[469] The major vault protein lung resistance protein (LRP) is not an ABC protein, but rather an intracellular protein that affects cytoplasmic-nuclear drug transport; its expression in AML cells has been associated with adverse treatment outcome in some series.[463,470]

Cytogenetics

Cytogenetic subgroups identify prognosis better than any other factor in both younger and older adult AML patients,[28,29,31,32,471,472] and stratification of therapy based on cytogenetic prognostic group has become the standard of care in AML.[473] Criteria that subdivide AML patients into favorable, intermediate and unfavorable cytogenetic risk groups vary only minimally among cancer cooperative group studies (Table 75.9). Studies of cytogenetics in AML are important not only in terms of defining prognostic subgroups, but also in terms of defining the features and optimal management of AML with uncommon individual karyotypes.[278,474] A representative survival curve according to cytogenetic findings is illustratrated in Figure 75.11.[475]

APL [t(15;17)] and AML with either of two core binding factor (CBF) abnormalities, t(8;21) and inv(16) or t(16;16), are regarded as favorable types of AML. AML with either of the two CBF abnormalities has both a high CR rate and a high rate of disease-free survival, particularly when treated with high-dose cytarabine-based post-remission regimens.[399,476] Nevertheless, favorable cytogenetic prognosis may be modified by other factors. For example, when t(8;21) is present in older patients[443] or when t(8;21) AML cells express the neural cell adhesion molecule CD56[383] or have mutations of the growth factor receptor KIT,[364,365–366] prognosis is worse. The standard of care for AML with favorable karyotypes is post-remission chemotherapy with high-dose cytarabine, rather than transplantation in remission.[473]

Unfavorable cytogenetic groups are consistently defined by del(5q)/–5, –7/del(7q) and/or complex karyotypes (defined by either ≥3 or ≥5 unrelated abnormalities), or inv(3)/t(3;3), t(6;9) or t(9;22). There is some variability in additional karyotypes included in unfavorable cytogenetic groups among different cooperative groups[28,29] and within cooperative groups, when considering induction outcome, cumulative incidence of relapse or overall survival.[29] Additional karyotypes predicting adverse outcomes in different series include abnormalities of 9q, 11q, 12p, 17p, 20q, and 21q, +8, and +21. 11q23 abnormalities have adverse significance with regard to survival, except for t(9;11).[278] The standard of care for AML with unfavorable karyotypes is

[a]Patients with t(15;17) or t(9;22) were not included in this analysis. Trisomy 8 with core-binding factor or t(9;11) was not adverse; del (5q) was intermediate if sole abnormality (Byrd JC, Mrózek RK, Dodge AJ, et al. Pretreatment cytogenetic abnormalities are predictive of induction success, cumulative incidence of relapse, and overall survival in adult patients with de novo acute myeloid leukemia: results from Cancer and Leukemia Group B (CALGB 8461). Blood 2002;100:4325–4336).

allogeneic hematopoietic stem cell transplantation when this option is available, or clinical trials.[473]

The intermediate-risk cytogenetic group is defined as AML with a normal karyotype or with cytogenetic abnormalities not defined as favorable or unfavorable, although the Southwest Oncology Group classification also includes an "other" group for uncommon abnormalities not specifically listed as favorable.[28] Patients with normal karyotypes represent a heterogeneous group that is increasingly able to be further categorized by molecular abnormalities.

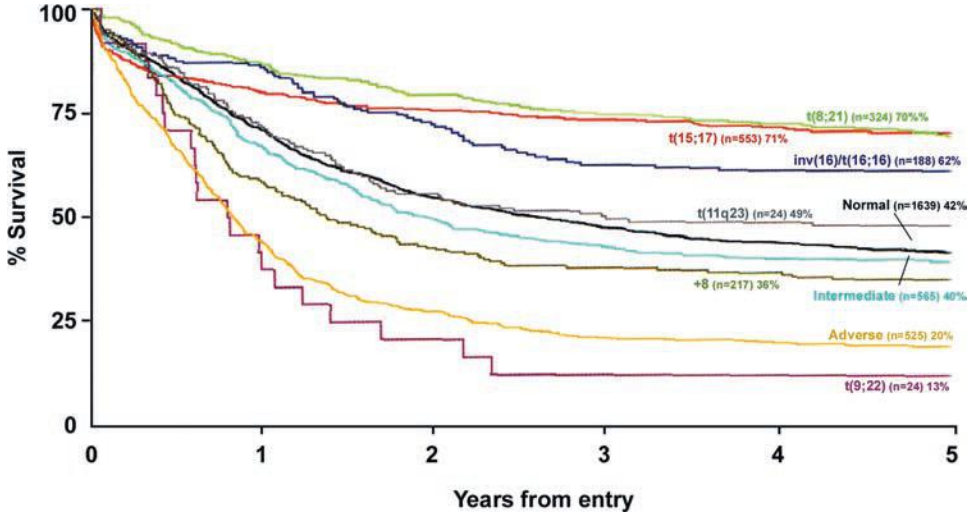

FIGURE 75.11. Overall survival of patients up to 60 years treated in UK Medical Research Council AML 10 and AML 12 trials according to cytogenetics. (With permission from Grimwade D. Impact of cytogenetics on clinical outcome in AML. In: Karp J, ed. Acute myelogenous leukemia. Totawa, NJ: Humana Press, 2007:181.)

Cytogenetic analysis at the time of assessment of response to remission induction therapy is prognostically significant because the relapse rate is higher and both disease-free and overall survival is shorter in patients with persistence of abnormal metaphases following induction chemotherapy.[477] Cytogenetic risk groups remain prognostically significant following alloSCT for primary refractory AML,[478] but not for AML in CR.[479,480]

Molecular

Molecular studies are particularly helpful in subdividing the group of AML patients with a normal karyotype, and in guiding their management.[49,292] Individual molecular abnormalities and their prognostic significance are detailed above. Prognosis is best determined by combinations of cytogenetic and molecular findings, and this approach was recently formalized by the European LeukemiaNet.[51] The European LeukemiaNet classification is shown in Table 75.10.

Biologic Parameters

Diverse parameters reflecting leukemia biology have been found to have prognostic significance in AML. Increased expression of antiapoptotic proteins such as BCL-2 and/or decreased expression of proapoptotic proteins in AML cells is associated with resistance to chemotherapy and adverse prognosis.[481–484] Overexpression of vascular endothelial growth factor (VEGF) and other proteins associated with angiogenesis correlates with increased angiogenesis and has been associated with a worse prognosis in AML.[485–488] Expression of the chemokine receptor CXCR-4 on AML cells has also been found to be prognostically unfavorable.[489,490] Finally, activation of signal transduction pathways in AML cells is associated with a poor prognosis,[265] although much remains to be elucidated in this area.

Gene Polymorphisms

Polymorphisms in genes encoding proteins involved in drug detoxification, such as glutathione S-transferases,[155,491] drug resistance, such as *MDR1*,[492] and DNA repair, such as *XPA*,[493] *XPD*, *ERCC1*, and *XRCC3*,[159] have been variably associated with treatment toxicities and treatment outcome. The ultimate goal of these studies is stratification of chemotherapy based on genotypes.

THERAPY

Overview of Treatment

Treatment for AML is divided into two phases, remission induction therapy and post-remission therapy (Fig. 75.12). The goal of induction therapy is attainment of a complete remission, which, except in APL, usually requires a period of marrow aplasia, or a "morphologic leukemia-free state," following induction chemotherapy. Serial changes in peripheral blood counts during induction therapy include clearance of blasts from the blood, followed by pancytopenia requiring red blood cell and platelet transfusion support and management of complications of neutropenia, followed by increases in neutrophil and platelet counts and then resolution of anemia in patients with favorable responses to treatment. Table 75.11 outlines the management of AML at diagnosis and during induction therapy.

Post-remission therapy is therapy administered after patients achieve complete remission. Its goal is to prolong complete remission by delaying or preventing recurrence of AML, called relapse, and to maximize the chance of cure. Post-remission therapy may consist of intensification, consolidation, and maintenance therapies. Intensification may include allogeneic or autologous hematopoietic stem cell transplantation, whereas consolidation involves either regimens similar to those used in induction or the use of drugs at higher dosages than in induction; maintenance therapy is less intensive and less myelosuppressive than induction.[494]. Maintenance therapy is standard for ALL and for APL, but not for AML, although new approaches are being tested.[495]

Endpoints of Acute Myeloid Leukemia Treatment

Early assessment of the efficacy of remission induction chemotherapy is by sampling of the bone marrow approximately 14 days following initiation of chemotherapy, during pancytopenia. The morphologic leukemia-free state[4] desired at this time-point is defined by the presence of less than 5% blasts in an aspirate sample with marrow spicules and with a count of at least 200 nucleated cells and absence of blasts with Auer rods. A bone

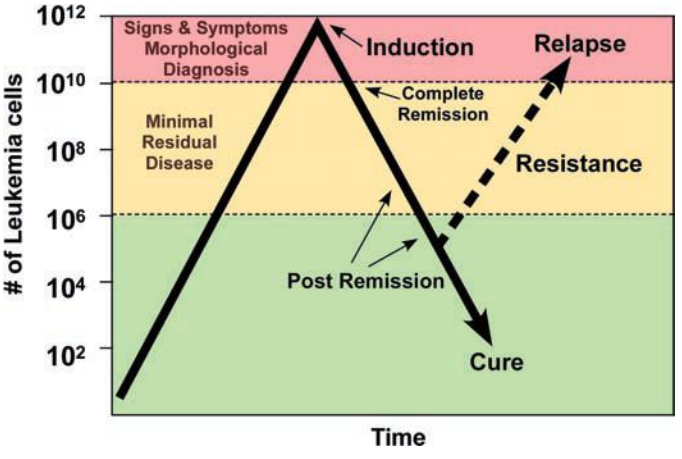

FIGURE 75.12. Phases of therapy. The diagnosis of acute myeloid leukemia can be made when the leukemia cell number is $>10^{10}$. Induction therapy achieves a clinical complete remission and is followed by post-remission therapy with a goal of cure. If cells develop mechanisms of resistance, relapse occurs.

marrow biopsy performed at the same time allows more bone marrow tissue to be examined and allows identification of clusters of blasts. Patients with clear residual AML at the time of early assessment are unlikely to go on to achieve remission, and additional or alternative therapy should be considered. Persistent detection of cells with the phenotype of the patient's pre-treatment leukemia cells by flow cytometry in marrow that is morphologically leukemia-free is viewed as persistence of leukemia, although therapeutic decisions about re-induction therapy in clinical trials have generally not been based on flow cytometry findings. If presence of residual leukemia is questionable, a bone marrow aspirate and biopsy should be repeated a week later. A morpohologic leukemia-free state also requires absence of extramedullary disease.

Patients are then assessed for response to induction therapy at the time of blood count recovery. The definition of complete remission has evolved.[4] The term complete remission generally refers to morphologic complete remission, defined by red blood cell transfusion independence, an absolute neutrophil count of more than 1,000/μl and a platelet count of 100,000/μl or greater and the presence of less than 5% blasts in a bone marrow aspirate sample with marrow spicules and with a count of at least 200 nucleated cells, absence of blasts with Auer rods, and absence of extramedullary leukemia. The currently recommended International Working Group (IWG) criteria do not include requirements with regard to bone marrow biopsy cellularity or duration of response, but persistent detection of AML cells with the phenotype of the patient's pre-treatment leukemia cells by flow cytometry in marrow that is morphologically leukemia-free is considered persistence of leukemia.[4]

Cytogenetic complete remission (CRc) has been proposed as a separate category of CR, indicating reversion to a normal marrow karyotype at CR in patients with an abnormal karyotype at presentation of AML.[4] Persistence of abnormal metaphases in morphologically normal marrows of patients following recovery from induction chemotherapy is associated with shorter survival in AML patients.[477] It is important to specify how many metaphases were examined.

Molecular complete remission (CRm) is also relevant in some subtypes of AML.[4] Quantitative reverse transcriptase polymerase chain reaction (RT-PCR) may detect residual disease in AML cases with fusion genes resulting from chromosomal translocations [e.g., *PML-RARα* in t(15;17), *AML1/ETO* fusion in t(8;21), *CBFβ*-MYH11 fusion in inv(16), and others]. The prognostic significance of CRm achievement is clearly established for APL[496,497] and CRm is recognized as a therapeutic objective in APL, whereas the significance of CRm in the other subsets of AML is still controversial, particularly in AML with t(8;21), a prognostically favorable subtype of AML in which AML1/ETO transcripts may continue to be detected in patients in long-term morphologic complete remission.[498] It is important to establish and specify the sensitivities of assays used in assessing CRm.

Another category of response to induction chemotherapy is morphologic complete remission with incomplete blood count recovery (CRi), defined by fulfillment of all of the criteria for CR except for residual neutropenia (<1,000/μl) or thrombocytopenia (< 100,000/μl).[4] This category of response was particularly evident in clinical trials of gemtuzumab ozogamicin,[499] in which patients commonly met all criteria for complete remission except for platelet count recovery. The term CRp was used to indicate complete remission with incomplete platelet recovery following gemtuzumab ozogamicin treatment,[499] but CRi is a broader term also incorporating incomplete neutrophil recovery, but not both. Survival of patients with CRp appears to be better than for those with treatment failure due to resistant disease, but not as good as those with morphologic CR. In a retrospective study of more than 6,000 patients with AML treated on ECOG, SWOG, and MD Anderson Cancer Center clinical trials, patients who achieved CR had longer relapse-free survival than patients who achieved CRp, after adjustment for covariates, whereas achieving CRp had a positive impact on survival, compared with resistant disease.[500] Moreover, favorable pre-treatment prognostic factors predicted a higher likelihood of achieving a CR rather than CRp.[500]

Partial remission is defined by attainment of the blood count criteria for complete remission, and a decrease of at least 50% in the percentage of blasts in the bone marrow aspirate, to 5% to 25%, or less than 5% blasts in the marrow with presence of Auer rods.[4]

Remission induction treatment failure can be divided into at least three categories[4] (Table 75.12). Patients who survive at least 7 days after completion of treatment and have persistent AML in marrow and/or blood are said to have treatment failure due to resistant disease. Patients who survive at least 7 days after completion of treatment and die while cytopenic and with a post-treatment bone marrow within 7 days of death demonstrating aplasia or hypoplasia are said to have treatment failure due to

TABLE 75.11

MANAGEMENT OF ACUTE MYELOID LEUKEMIA AT DIAGNOSIS

Patient History

Review preceding myelodysplasia, prior diagnosis of cancer, previous chemotherapy, occupational exposure, family history, number of full siblings.

Physical Examination

Assess performance status.

Screen for infection: dental, nasopharyngeal, lung, perirectal.

Search for extramedullary disease: skin, neurologic, adenopathy, organomegaly, testicular.

Baseline Laboratory

Complete blood count with differential; type and screen.

Bone marrow examination: include cytogenetic analysis and save sample for molecular diagnostics if applicable.

Screen electrolytes, liver and renal function, tumor lysis parameters.

Screen for DIC.

Viral serologies, particularly HSV, CMV, hepatitis, and HIV.

HLA-A, -B, -DR type.

Chest radiograph: rule out pneumonia, leukostasis, mediastinal mass.

Cardiac status: ejection fraction by echocardiogram or MUGA.

Supportive Care

Transfusions: platelets, packed red blood cells (unless hyperleukocytosis), cryoprecipitate with or without fresh-frozen plasma in DIC.

Central line placement.

Hydration.

Allopurinol. Rasburicase (after checking G6PD).

Treat ongoing infections.

Infection prophylaxis: acyclovir (if HSV-positive), antifungal agents (fluconazole or voriconazole), antibacterial agents (usually to cover Gram-negative and Gram-positive organisms).

If hyperleukocytosis, hydroxyurea, and leukapheresis, uncertain role of CNS radiation.

Therapy

Induction chemotherapy cytarabine and anthracycline; possible role of etoposide or mitoxantrone; possible role for high-dose cytarabine.

Monitor for DIC and tumor lysis, infection, drug toxicities.

APL, acute promyelocytic leukemia; CMV, cytomegalovirus; CNS, central nervous system; DIC, disseminated intravascular coagulation; HIV, human immunodeficiency virus; HLA, human lymphocyte antigen; HSV, herpes simplex virus; MUGA, multiple uptake gated acquisition scan.

TABLE 75.12

TYPES OF FAILURE IN THERAPY OF ACUTE MYELOID LEUKEMIA

Drug Resistance
No response based on persistence of blasts and absence of hypocellularity (usually day 14)
Hypocellular or partial marrow with subsequent regrowth of leukemia
Complications of Aplasia
Hypoplastic death (within 4 wk)
Regeneration failure: marrow remains hypocellular for >4 wk
Indeterminate Cause
Death within 2–3 wk of initiating therapy (marrow either negative or not tested)
Hematologic Remission but Persistent Disease
Myelodysplasia, extramedullary disease; cytogenetic, flow cytometric, or molecular disease

complications of aplasia. Finally, patients with treatment failure of indeterminate cause include those who die less than 7 days after completion of treatment, those who die 7 or more days after completion of treatment whose blood did not show persistent leukemia and whose marrow was not examined post-treatment, and those who die without completing treatment.

Remission Induction Therapy

Table 75.13 outlines active agents in AML and includes their cell cycle specificity, major toxicities, response rates, and clinical uses. Cytarabine and anthracyclines have been the subject of most intense study. Cytarabine is incorporated into DNA during DNA synthesis and is only effective in cells in the S-phase of the cell cycle. Anthracyclines are not cell cycle-specific and appear to be the most active single agents. Synergy exists between agents with different mechanisms of action, and combination chemotherapy produces better results in AML. Particular considerations with regard to choice of treatment in older AML patients are discussed below, as is AML diagnosed during pregnancy.

Conventional Induction Therapy

The most common induction chemotherapy regimens in AML involve the use of cytarabine (ara-C) and an anthracycline. Cytarabine is usually administered as a continuous infusion of 100 to 200 mg/m^2/day for 7 days, with an anthracycline given by intravenous push daily on the first 3 days of ara-C therapy, a combination called "7 + 3." Studies performed by CALGB in the 1980s established the efficacy of this regimen for newly diagnosed AML and since then has been the most commonly used induction regimen for treatment of adult patients with AML.[501–504]

Continuous infusion of ara-C at a dosage of 100 mg/m^2 has been shown to be superior to pulse doses of 100 mg/m^2 every 12 hours.[501] "7 + 3" has been shown to be superior to the same drugs given over 5 days and 2 days (5 + 2), respectively,[501] and appears equivalent to "10 + 3."[503] Increasing the ara-C dose in "7 + 3" from 100 mg/m^2/day to 200 mg/m^2/day or prolonging the infusion to 10 days, in combination with daunorubicin, increased the toxicity with no to minimal improvement in efficacy.[503–505]

The addition of oral thioguanine 100 mg/m^2 twice on days 1 to 7 (7+ 3 + 7) did not improve the results. The anthracycline most commonly used in 7 + 3 is daunorubicin, and its dose has ranged between 30 and 90 mg/m^2 in different studies. In early studies, daunorubicin 45 mg/m^2 daily was compared to 30 mg/m^2 daily in the 7 + 3 regimen, and resulted in higher CR rates in patients younger than age 60 years.[502] A single course of 7 + 3 ara-C and daunorubicin (45 mg/m^2) therapy produces a CR rate in the range of 40% to 50%. When a second course of ara-C and daunorubicin (either 5 + 2 or 7 + 3) is administered to patients with morphologic evidence of persistent leukemia in the bone marrow on day 14, the overall CR rate increases to 50% to 85%. Higher response rates (70% to 85%) are seen in patients under 60 years of age with de novo AML.

Two recent phase 3 randomized clinical trials from the United States and South Korea have confirmed the clinical benefit of daunorubicin dose intensification (90 mg/m^2 vs. 45 mg/m^2) in the context of the 7 + 3 regimen in patients younger than 60 years of age with previously untreated AML.[506,507] In the US study, 90 mg/m^2 daunorubicin, as compared with 45 mg/m^2 of the drug, resulted in a significantly higher CR rate (70.6% vs. 57.3%) and, most important, better overall survival (median, 23.7 vs. 15.7 months). The rates of serious adverse events including heart failure and other cardiac toxicities were similar between the two groups.[506] In the study conducted in South Korea,[507] the CR rates were also significantly higher (82.5% vs. 72.0%) in the group who received 90 mg/m^2 daunorubicin compared to the group receiving 45 mg/m^2 group. With approximately 4.5 years of median follow-up, both overall survival (46.8% vs. 34.6%) and event-free survival (40.8% vs. 28.4%,) were significantly better in the 90 mg/m^2 arm, compared to the 45 mg/m^2 arm. The advantage of higher-dose daunorubicin was observed in patients with an intermediate-risk cytogenetics but not in those with an unfavorable karyotype or a high-risk molecular profile. The toxicities were similar in the two groups.

Another clinical trial tested the potential benefit of high-dose daunorubicin in older patients receiving intensive chemotherapy.[508] Newly diagnosed AML patients 60 years of age and older received the 7 + 3 regimen, consisting of cytarabine 200 mg/m^2 and daunorubicin either 45 mg/m^2 or 90 mg/m^2, followed by a second cycle of 1,000 mg/m^2 cytarabine every 12 hours for 6 days. Complete remission rates (64% vs. 54%) and rates of complete remission after the first cycle of induction treatment (52% vs. 35%) were significantly higher in the group who received 90 mg/m^2 daunorubicin, compared to the 45 mg/m^2 group. There was no significant difference between the two groups in 30-day mortality rates, hematologic toxicities or moderate, severe, or life-threatening adverse events. The OS rates were similar between the two groups. Patients 60 to 65 years of age had higher rates of CR (73% vs. 51%), EFS (29% vs. 14%), and OS (38% vs. 23%) in the 90 mg/m^2 group as compared with the patients in the same age group who received 45 mg/m^2 daunorubicin, however, a difference was not seen in those over 65 years, with the exception of the favorable cytogenetic group, who benefited from daunorubicin dose intensification regardless of age.

Modifications of Standard Induction Therapy

The anthracycline idarubicin and the anthracenedione mitoxantrone have been used instead of daunorubicin in 7 + 3. In three randomized trials, idarubicin, given as 12 mg/m^2 daily for 3 days with ara-C, tended to produce a higher CR rate than daunorubicin and ara-C, more often required only one cycle to induce remission, and was associated with a better survival in some trials.[509–511] The long-term follow-up of the aforementioned three randomized studies suggested better OS for idarubicin compared with daunorubicin in only one study.[512] However, superiority of idarubicin (10 to 12 mg/m^2) over daunorubicin (45 to 60 mg/m^2) in the achievement of CR when used in the 7 + 3 regimen was confirmed in a meta-analysis.[513] In a randomized trial in AML patients between 50 to 70 years, idarubicin produced a higher CR rate than high-dose daunorubicin (80 mg/m^2/day for 3 days).[514]

TABLE 75.13

STANDARD SINGLE AGENTS IN ACUTE MYELOID LEUKEMIA

	Class of Agent	Route of Delivery	Cell-Cycle Specificity	Mechanism of Action	Plasma Half-Life (h)	Main Route of Excretion	Response Rate (%)	Major Toxicities Other Than Myelosuppression	Comments
Cytarabine	Pyrimidine analog	IV, SC	S	Active form ara-CTP inhibits DNA polymerase and is incorporated in DNA (S phase).	1–2	Renal	15–35	Cerebellar, gastrointestinal, hepatic, skin	Antileukemic effect is dose-and schedule-dependent. Cerebellar toxicity occurs in patients >50 y receiving high doses (3 g/m^2).
Daunorubicin, doxorubicin, idarubicin, epirubicin	Anthracycline antibiotics	IV	NS	Inhibits DNA replication by intercalation of base pairs; inhibits topoisomerase II.	15–30	Hepatic	40–50	Cardiac, gastrointestinal	Cumulative, dose-dependent cardiomyopathy in patients receiving >500 mg/m^2 for daunorubicin. (cardiomyopathy uncommon <290 mg/m^2). Increased gastrointestinal toxicity with doxorubicin (idarubicin has longer half-life and probably better efficacy).
6-Thioguanine	Purine analog	PO, IV	S	Ribonucleotide form is incorporated into DNA, leading to strand breaks.	6–12	Renal, hepatic	10	Hepatic, gastrointestinal	Synergistic with cytarabine; unlikely to add to combination of cytarabine and anthracycline.
Mitoxantrone	Anthracenedione	IV	NS	Intercalates into DNA; induces topoisomerase II–mediated damage.	25–50	Hepatic > renal	25–50	Cardiac, gastrointestinal	Probably less cardiotoxic than anthracycline antibiotics.
VP-16 (etoposide)	Epipodophyllotoxin	IV, PO	S	Forms complex with DNA and topoisomerase II, leading to strand breaks (G2 phase).	6–12	Renal > hepatic	10–30	Gastrointestinal, hepatic, stomatitis	Effects are dose- and schedule-dependent. Oral dose usually twice IV dose. Efficacious in acute monocytic leukemia of infancy. Etoposide phosphate is a water-soluble prodrug of etoposide.
Amsacrine (m-AMSA)	Acridine derivative	IV	S	Intercalates into DNA, produces strand breaks (G2 phase).	7–8	Hepatic > renal	30–50	Cardiac, including QT prolongation; gastrointestinal	Most effective when combined with high-dose cytarabine.
5-Azacytidine, decitabine	Pyrimidine analogs	IV, SC	S	Phosphorylated form incorporates into RNA and DNA.	3–6	Renal	10–20	Gastrointestinal, hepatic, skin, neurologic	No cross-resistance with cytarabine; limited by neurologic toxicities. Approved agents for MDS.
Carboplatinum	Platinum analog	IV	NS	Covalent binding to DNA.	0.2–40	Renal	20–28	Gastrointestinal	Less nephrotoxicity, ototoxicity, and emesis than cisplatinum, but more myelosuppression.
Fludarabine, cladribine, pentostatin clofarabine	Purine analogs	IV	NS	Inhibit DNA polymerase, incorporated into DNA and RNA, nicotinamide adenine dinucleotide depletion.	Biphasic: α, <30 min; β, 6–20 h	Hepatic, renal	5–25	Neurotoxicity, pulmonary (fludarabine); immunosuppression (T-cell depletion)	Synergism with cytarabine, can potentiate the accumulation of ara-CTP if given before cytarabine. SC and PO under development.

IV, intravenous; MDS, myelodysplasia; NS, nonspecific; PO, orally; S, specific; SC, subcutaneous.

Substitution of idarubicin with either fludarabine or topotecan in combination with ara-C for treatment of newly diagnosed AML, refractory anemia with excess blasts in transformation (RAEB-t), or RAEB resulted in lower CR rates and shorter EFS and OS.[515]

Historically, mitoxantrone has been used more often to treat relapsed AML, and it may have less cardiotoxicity than the anthracyclines.[516] A randomized trial of daunorubicin, idarubicin, and mitoxantrone with standard-dose ara-C as induction therapy in older AML patients showed no differences in clinical outcome.[517]

Daunorubicin (50 mg/m^2) on days 1 to 3 plus ara-C (25 mg/m^2 bolus followed by 160 mg/m^2 as a continuous infusion daily for 5 days) and 6-thioguanine (100 mg/m^2 orally every 12 h daily for 5 days) (DAT) was compared with amsacrine (190 mg/m^2, IV on days 1 to 3) plus ara-C and 6-thioguanine at the similar doses (AAT) in a trial involving approximately 100 adult patients with de novo AML. Patients who achieved CR received two courses of the same chemotherapy regimen as consolidation therapy. Stratified by age, CR rate and OS were better in the AAT group compared to the DAT group.

Other studies have tested the addition of a third agent to the 7 + 3 regimen. The addition of etoposide to 7 + 3 at 75 mg/m^2/day for 7 days (7 + 3 + 7) did not improve CR rates and was associated with more mucositis, but it did improve median remission duration (12 months for 7 + 3 vs. 18 months for 7 + 3 + 7). Overall survival was similar between the two groups.[518] A three-drug induction regimen known as ADE, consisting of ara-C 100 mg/m^2/day for 7 days and both daunorubicin 90 mg/m^2 and etoposide 100 mg/m^2 daily for 3 days, was tested by CALGB in previously untreated de novo AML patients less than 60 years, without excess cardiotoxicity, and with a complete remission rate of 75% and a median disease-free survival of 1.34 years and median overall survival of 1.86 years.[519] Moreover, ADE consisting of ara-C 100 mg/m^2/day for 7 days and both daunorubicin 60 mg/m^2 and etoposide 100 mg/m^2 daily for 3 days was used in previously untreated older AML patients, with rates of CR, nonresponse, and death of 46%, 34%, and 20% with median disease-free survival of 7 months; these results were not superior to historical results.[520]

Because Pgp overexpression and function in AML cells are strongly associated with adverse treatment outcome, clinical trials of Pgp modulators, or noncytotoxic competitive inhibitors of drug transport by Pgp, were undertaken in AML. Addition of PSC-833, a cyclosporin derivative which is a potent Pgp inhibitor, to induction regimens containing the Pgp substrates daunorubicin or mitoxantrone and etoposide did not show clinical benefit,[521,522] nor did addition of zosuquidar, another potent Pgp inihibitor.[523] In contrast, addition of cyclosporin A to chemotherapy was beneficial in some trials.[524,525] Cyclosporin A blocks drug transport by multiple MDR proteins known to be expressed in AML.[526]

High-dose Cytarabine

The antileukemic effect of cytarabine depends on dosage and schedule. Cytarabine is effective at both high and standard dosages. Although at plasma concentrations greater than 10 μM, which are achieved with high-dose ara-C (2 to 3 g/m^2 daily), the drug diffuses freely into cells,[527] at concentrations less than 1 μM, which are achieved with 100 to 200 mg/m^2 daily, ara-C influx into cells is strongly correlated with the number of nucleoside transporters per leukemic blast.[528] High-dose cytarabine (HiDAC) (1 to 3 g/m^2 every 12 to 24 hours, for 4 to 12 doses), with or without either an anthracycline, mitoxantrone, or etoposide, is particularly effective as intensification therapy or as therapy for relapsed disease.[529–531] HiDAC crosses the blood–brain barrier and can help prevent CNS leukemia, but cerebellar toxicity may develop, particularly in patients 50 years of age or older.[532] Lengthening the duration of administration from 1 hour to 3 hours or decreasing the dose from 3 g/m^2 to 1.5 g/m^2 may lessen the risk of cerebellar toxicity and is common practice in patients over 50 years of age. Patients receiving HiDAC must be tested for cerebellar toxicity before each dose, and subsequent doses of HiDAC must be withheld if cerebellar toxicity is documented or suspected; the ara-C dose must then be decreased, and HiDAC also cannot be administered as part of any subsequent therapy. Conjunctivitis and a painful, blistering erythematous rash involving the palms and soles are common side effects following HiDAC. Administration of corticosteroid eyedrops may prevent conjunctivitis, which is caused by secretion of cytarabine administered at high doses into tears.

Although HiDAC has most often been given as consolidation therapy or for relapsed disease, high CR rates (up to 90%) were observed when HiDAC was given during induction in some studies in the early 1990s.[533] In a randomized trial by the Australian Leukemia Study Group in newly diagnosed AML patients less than 60 years old,[534] the CR rate was similar with HiDAC (6 g/m^2 per day) and standard-dose (100 to 200 mg/m^2 daily administered as a 7-day continuous infusion) ara-C-based remission induction and post-remission therapy, but HiDAC was associated with a significantly longer estimated median remission duration (45 vs. 12 months) and higher percentage of 5-year relapse-free survival (48% vs. 25%), but also with greater hematologic and nonhematologic toxicities. Another randomized trial of high-dose (4 g/m^2 per day) versus standard-dose ara-C in newly diagnosed AML patients less than 65 years old by the Southwest Oncology Group[535] demonstrated slightly better relapse-free survival (33% vs. 21% at 4 years for patients less than age 50 and 21% vs. 9% for ages 50 to 64 years), but a significantly higher risk of fatal toxicity with high-dose ara-C. The efficacy of HiDAC, as part of a double induction strategy, was tested against standard-dose ara-C in a large randomized trial.[536] Two courses of standard-dose cytarabine, daunorubicin, and 6-thioguanine (TAD) were compared with one course of TAD followed by high-dose cytarabine (3 g/m^2 every 12 hours for 6 doses) with mitoxantrone (HAM) starting on day 21 regardless of the presence or absence of leukemic blasts in the bone marrow. CR rates (65% vs. 71%) and survival were similar between the two groups. Recently, another randomized clinical trial in more than 800 AML patients younger than 60 years tested the efficacy and toxicity of different doses of cytarabine in the setting of a double-induction chemotherapy regimen.[537] Patients were randomly assigned to receive either intermediate doses of cytarabine (200 mg/m^2 for cycle 1 followed by 1 g/m^2 twice daily for cycle 2) or HiDAC (1 g/m^2 twice daily for cycle 1 followed by 2 g/m^2 twice daily for cycle 2), with idarubicin in cycle 1 and amsacrine in cycle 2 in all patients. If patients achieved a CR, they received consolidation therapy that did not contain cytarabine. This trial showed no efficacy advantage for HiDAC when compared to intermediate-dose cytarabine. The rates of CR (80% vs. 82%), CR after the first cycle 1 (60% vs. 66%), 30-day mortality (10% in both groups), event-free survival (34% vs. 35%), and overall survival (40% vs. 42%) at 5 years were similar for intermediate dose and HiDAC, respectively.[537] Patients in the HiDAC group experienced higher rates of grade 3 and grade 4 toxicities (51% vs. 61%) in cycle 1, and prolonged hospitalization, and delayed neutrophil and platelet recovery in cycle 2. On the basis of these data, the use of HiDAC for induction chemotherapy for newly diagnosed AML is not generally recommended, unless in special circumstances.

Other Nucleoside Analogues

Nucleoside analogues including cladribine (2-CdA), fludarabine, clofarabine, gemcitabine, pentostatin, troxacitabine, and sapacitabine have also been tested in AML.[538–541,542,543]

Fludarabine has been extensively studied in AML because of pre-clinical[544] and clinical data demonstrating that its administration prior to ara-C sensitizes leukemic blasts to ara-C by enhancing ara-CTP formation.[545] The observation that administration of

G-CSF with fludarabine further enhanced this effect[546] led to the design of a regimen consisting of fludarabine with high-dose cytarabine and G-CSF (FLAG).[547–549] Derivative regimens incorporating idarubicin with (FLAG-IDA)[550,551] or without G-CSF (FLAI)[552] are also active in AML.

Clofarabine is a second-generation nucleoside analog that has activity in AML by itself or when administered prior to ara-C.[553,554] In a phase II trial in hematologic malignancies, an overall response rate of 48% was reported; AML patients with a short first CR (≤1 year) had a response rate of 18%, compared to 87% in those with a longer first CR.[553] Clofarabine combined with ara-C produced a response rate of 60% and a CR rate of 52% in untreated AML, and a response rate of 38% and a CR rate of 22% in relapsed AML.[554,555] In two single-arm studies, single-agent intravenous clofarabine (30 mg/m^2 daily for 5 days) demonstrated a CR + CRi rate of approximately 46% to 48%, with CR rates of 32% to 38% in high-risk older patients, including those with an unfavorable karyotype.[556,557]

Recently, a 652-patient Polish Adult Leukemia Group (PALG) randomized multicenter trial in patients age 60 years or younger with AML demonstrated that cladribine, but not fludarabine, added to 7 + 3 induction chemotherapy prolonged survival.[542] Patients received 7 + 3 alone (AraC 200 mg/m^2 on days 1 to 7 as a continuous infusion plus daunorubicin 60 mg/m^2 daily infusion on days 1 to 3) or 7 + 3 plus a 3-h infusion of cladribine (5 mg/m^2 daily on days 1 to 5), or 7 + 3 plus a 30-min infusion of fludarabine (25 mg/m^2 daily on days 1 to 5). Consolidation chemotherapy included high-dose cytarabine and stem cell transplantation or 2 years maintenance chemotherapy, based on relapse risk. Both the CR rates (68% vs. 56% vs. 59%) and 3-year overall survival rates (45% vs. 33% vs. 35%) were significantly improved by addition of cladribine to the 7 + 3 regimen, compared to 7 + 3 alone and 7 + 3 + fludarabine, respectively. Toxicity was not significantly different in the three arms. Patients with an unfavorable karyotype also benefited from 7 + 3 + cladribine.

Hematopoietic Growth Factors

A variety of purified cytokines has been investigated as modifiers of cytopenias and of leukemia growth in vitro and in vivo. The best studied are the myeloid hematopoietic growth factors GM-CSF and G-CSF. Due to in vitro data demonstrating proliferative effects on AML blasts and based on clinical trial data outlined below, routine use of the myeloid growth factors in AML is not recommended.

Despite concerns about proliferative effects of myeloid CSFs on AML cell growth, studies were initiated in the 1990s to determine their clinical efficacy in AML. Two studies evaluated *Escherichia coli*-derived G-CSF in patients with relapsed or refractory leukemia and yeast-derived GM-CSF in older patients with de novo AML. Both reports indicated that the CSFs could be administered safely, with a statistically significant reduction in the duration of neutropenia and in early deaths, and trends toward an improvement in the CR rate, but not in survival.[558,559]

Subsequently, a number of phase III trials of GM-CSF and G-CSF consistently showed more rapid neutrophil recovery, which usually results in fewer infections and shorter hospitalizations, but no improvement in CR rates, relapse rates, or overall survival.[560–567] Two randomized trials evaluating the role of G-CSF after consolidation therapy showed decreases in the duration of severe neutropenia and a decreased rate of infection, but no effect on CR duration or OS.[566,568]

There were also attempts to exploit the proliferative effect of myeloid growth factors on leukemia cells to recruit AML cells into S-phase in order to increase chemosensitivity to ara-C, an S-phase-specific agent. In these clinical trials, G-CSF or GM-CSF was administered prior to and/or during chemotherapy, so-called "growth factor priming." These clinical trials have generally not demonstrated clinical benefit,[517,563,569–571] with some exceptions.[572,573] One possible reason is that, although G-CSF administered to untreated AML patients prior to chemotherapy did increase the percentage of blasts in S-phase, this percentage remained low.[574] Hematopoietic growth factor priming is not recommended, outside of clinical trials.[575]

Post-remission Therapy

In the absence of post-remission therapy, the probability of cure is approximately zero[576] with all patients relapsing within a median of 6 months, so post-remission therapy is essential, with the goals of decreasing and attempting to eliminate residual disease, delaying relapse and increasing the likelihood of cure.

Although additional therapy clearly is required beyond induction therapy, utilizing drugs at similar doses to those used in induction therapy, with or without maintenance therapy, has not had a major impact on survival in AML. With a CR rate of 60% to 75%, 15% to 25% of adults could be expected to have prolonged survival after consolidation or maintenance therapy administered through 1980.

Studies involving the use of HiDAC at different dosages and schedules as post-remission therapy suggested that survival in AML could be improved by dose escalation (Table 75.14).[577–580] Wolff et al. reported the efficacy of HiDAC/daunomycin intensification in AML, with a projected 49% survival that was age-dependent (83%, 50%, and 23% for age groups 25 or less, 26 to 45, and more than 45 years, respectively).[579]

Randomized trials were performed to confirm the value of HiDAC consolidation.[581,582,583] In an ECOG trial of 143 patients in first CR after daunorubicin, cytarabine, and 6-thioguanine, patients were randomly assigned to 24 months of low-dose maintenance therapy or one course of HiDAC (3 g/m^2 every 12 hours for 6 days) plus amsacrine.[582] Although HiDAC caused more toxic deaths, the 4-year DFS in patients less than 60 years of age was 28%, compared to 15% for those receiving maintenance therapy. In contrast the Leukemia Group for the Swiss Society for Cancer randomly assigned 137 patients in first CR after ara-C, daunorubicin, etoposide, and AMSA to standard-dose ara-C at 100 mg/m^2/day for 7 days or HiDAC at 3 g/m^2 every 12 hours for 6 days and found no difference in DFS.[584]

In a landmark clinical trial, the CALGB randomly assigned 596 patients in first CR after 7 + 3 to one of three different ara-C dose schedules: HiDAC at 3 g/m^2 over 3 hours every 12 hours on days 1, 3, and 5 (6 doses); intermediate-dose ara-C at 400 mg/m^2/day for 5 days by continuous infusion; or lower-dose ara-C at 100 mg/m^2 for 5 days by continuous infusion.[583] The estimated probabilities of remaining in CR at 4 years for patients less than 61 years of age were 44%, 29%, and 24% for the three treatments, respectively (Fig. 75.13, $P = 0.002$), but there were no differences among the arms in patients over the age of 60, with a probability of 16% or less of remaining in CR. These results clearly show that consolidation with HiDAC improves DFS in younger patients in first CR. Multiple cycles may be required to obtain the maximum benefit of HiDAC consolidation.[535,583]

The efficacy of HiDAC consolidation therapy also varies by cytogenetic group. In an analysis of cytogenetic correlates in the CALGB three-arm consolidation study referred to above,[583] Bloomfield et al. found that the impact of HiDAC consolidation was greatest in the favorable cytogenetic group, with 78% of patients remaining in remission at 5 years, compared to 40% of those with a normal karyotype, and 21% of those with other abnormalities.[585] The favorable impact of repetitive cycles of HiDAC in AML with the favorable karyotypes t(8;21) and inv(16) was confirmed in series focusing on patients with those abnormalities.[476] In addition, patients less than 60 years old with a normal karyotype had 5-year disease-free survival rates of 41% and 45% following four cycles of HiDAC or ara-C 400 mg/m^2 consolidation or one cycle of

HiDAC/etoposide followed by autologous hematopoietic stem cell transplantation.[586] Of note, these studies antedated the availability of molecular data.

A recent, large ($n = 781$) prospective randomized trial from Japan compared four courses of conventional multiagent chemotherapy to three courses of HiDAC (2 g/m^2 twice daily for 5 days) alone as post-remission therapy for AML in adult patients younger than 65 years in first complete remission.[587] Five-year DFS (43% vs. 39%) and 5-year OS (58% vs. 56%) were similar for the HiDAC group and the multiagent chemotherapy, respectively. In patients with favorable cytogenetic risk, 5-year DFS (57% vs. 39%) and 5-year OS (75% vs. 66%) were significantly better in the HiDAC group compared with the multiagent chemotherapy group. The frequency of infections was higher in the HiDAC group. Another recent clinical trial ($n = 237$) from France compared HiDAC with timed-sequential chemotherapy in patients 15 to 50 years of age with AML in first remission.[588] No significant difference was reported between the two arms with respect to 5-year EFS, cumulative incidence of relapse, or treatment-related mortality. Finally, a clinical trial ($n = 933$) from Germany compared two HiDAC regimens (36 g/m^2 vs. 12 g/m^2) as a first consolidation in untreated AML patients age 15 to 60 years.[589] In the intention-to-treat analysis, there were no significant differences in the 5-year OS (30% vs. 33%) or DFS (37% vs. 38%).

Data with regard to administration of hematopoietic growth factors after post-remission therapy are similar to those on administration after induction. Two randomized trials evaluating the role of G-CSF after consolidation therapy both showed decreases in the duration of severe neutropenia and a decreased rate of infection, but no effect on complete response duration or overall survival.[566,568]

In summary, for younger adults with favorable cytogenetic and molecular findings. HiDAC intensification alone (four cycles using CALGB doses and schedule) is often considered the best treatment choice. For younger adults with intermediate-prognosis cytogenetic and molecular findings, reasonable choices include HiDAC consolidation alone (four cycles using CALGB doses and schedule), or allogeneic transplantation. For older patients with good performance status and who have an available donor and meet age and health criteria, allogeneic transplantation should be considered, and a modified HiDAC regimen can be used for those without transplant options or opting not to pursue transplant. Because there is no post-remission chemotherapy regimen established as superior to others in older patients, participation in a clinical trial is recommended. For all patients who have adverse prognostic features including, in particular, prognostically unfavorable karyotypes or molecular findings (see section "Prognosis") and who have an available donor and meet age and health criteria, allogeneic hematopoietic SCT is the treatment of choice in first remission (see "Stem Cell Transplant" section).

In contrast to the approach in ALL, maintenance chemotherapy does not play an important role in AML. Randomized trials showed that maintenance therapy may prolong initial remissions,[200,590] but has no benefit in improving the cure rate of AML.[591,592] Moreover, maintenance chemotherapy appears unwarranted in AML if post-remission therapy is of adequate intensity.[591,592] Novel approaches to maintenance therapy are being explored,[495] but their ultimate benefit is unknown.

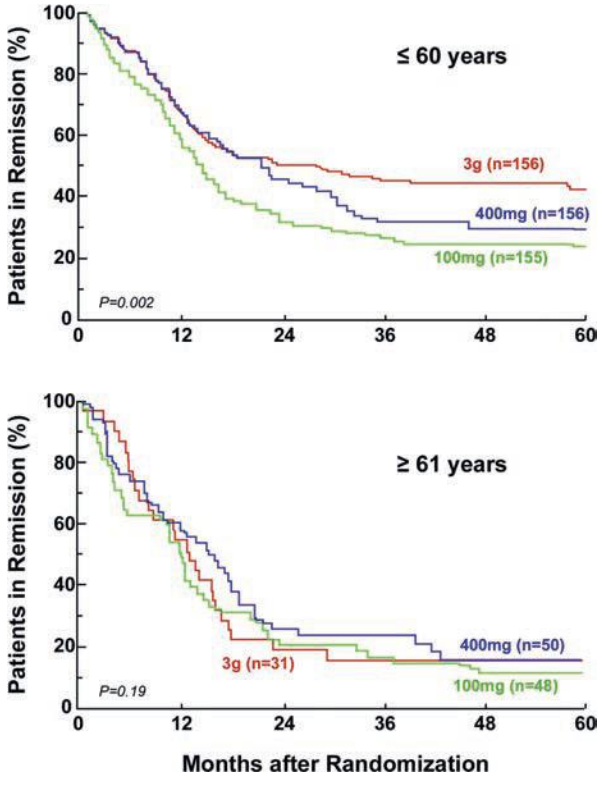

FIGURE 75.13. Effect of different doses of cytarabine on disease-free survival, patients 60 years of age or younger (A), and patients >60 years of age (B). Only patients who underwent randomization are included. The *p* values are for the differences among the three treatment groups. Median follow-up was 52 months. Novel Agents

New agents with novel mechanisms of actions are being investigated for the treatment of AML. Table 75.15 shows some of these agents with their chemical structures. Also see the section on "Other Nucleoside Analogs."

Several pre-clinical and early-phase clinical trials have been conducted to test the potential antileukemic activity of novel agents that target molecular mutations, epigenetic gene silencing, and aberrant signal transduction. Targets include, but are not limited to, the *FLT3*-ITD mutation, the epigenome (DNA methylation and histone acetylation), kinases (Pim, aurora, RAS/RAF/MAP), metabolic pathways (PI3K/AKT/mTOR), cellular reduction-oxidation (redox) states, mitochondria and reactive oxygen species, the WNT/β-catenin signaling pathway, Hedgehog signaling, *TP53*, angiogenesis, ubiquitin–proteasome pathways, cell surface farnesylation, and anti- and proapoptotic proteins such as MCL-1, BCL-2, and BAX.

DNA methylation may contribute to leukemogenesis by silencing tumor suppressor genes, and the DNA methyltransferase inhibitors azacitidine and decitabine inhibit DNA methylation and have had activity in phase I–II trials in patients with AML as well as MDS, as do histone deacetylase inhibitors such as phenylbutyrate, valproic acid, depsipeptide, suberoylanilide hydroxamic acid (SAHA), and MS-275.[593–598] DNA methyltransferase inhibitors are being evaluated as initial therapy for AML in older adults.[599,600–603]

FLT3 Inhibitors

Because of the importance of *FLT3*-ITD resulting in constitutive FLT3 signaling as an adverse prognostic factor in AML, as outlined above, inhibitors of FLT3 signaling have been developed and are being tested in clinical trials in AML (Fig. 75.14). *FLT3* inhibitors that have been tested include midostaurin,[604] lestaurtinib,[605] sorafenib,[606] sunitinib,[607] tandutinib,[608] and AC220.[609] CEP-701 (lestaurtinib) is an orally administered indolocarbazole derivative that is cytotoxic to AML blasts with FLT3-ITD in vitro[610] and in vivo[611] and has clinical activity in AML.[612,613] It was tested in combination with chemotherapy, with the design of the combination regimen based on pre-clinical data,[614] but unfortunately no clinical benefit was seen.[605] Clinical trials of other agents are recently completed or in progress. Resistance to FLT3 inhibitors may occur by activation of other signaling pathways[615] or by progressive up-regulation of FLT3 ligand.[309] FLT3 inhibitors also have in vitro activity in AML without *FLT3* mutations.[613]

Gemtuzumab Ozogamicin

In early studies in AML, unconjugated monoclonal antibodies targeting CD14, CD15, and CD33 produced low response rates (<10%).[616,617] Consequently, investigators turned to conjugated antibody therapy, with CD33 being the best studied target, as it is present on AML cells in 90% of cases[209] and is expressed on normal hematopoietic cells but not on normal hematopoietic stem cells. The best studied anti-CD33 antibody conjugate is gemtuzumab ozogamicin (Mylotarg), which uses a recombinant humanized anti-CD33 monoclonal antibody to deliver calicheamicin, an antibiotic that binds to the minor grooves of DNA, causing double-strand breaks and apoptosis.[618] Calicheamicin is a substrate for Pgp-mediated efflux.[619]

When two 9 mg/m^2 gemtuzumab ozogamicin doses were given over 4 h 14 days apart to patients with CD33$^+$ AML in untreated first relapse in phase II trials, the overall response rate was 26%, including 13% CR, and 13% CRp.[620,621] Response rates did not differ based on age or length of first remission. The median overall survival was 4.9 months for all patients and 12.6 months for responders. Severe myelosuppression was uniformly present, reflecting expression of CD33 on mature myeloid cells, but sepsis (17%) and pneumonia (8%) were relatively uncommon.[621]

Gemtuzumab ozogamicin was subsequently also tested as frontline therapy. A 33%/5% CR/CRp rate was seen in AML patients 61 to 75 years of age who were not candidates for standard chemotherapy, but toxicity was excessive in patients older than 75 years.[622] In a randomized trial, the addition of gemtuzumab ozogamicin to different induction and consolidation chemotherapy regimens resulted in no difference in CR rate or survival,[623] but survival benefit was demonstrated for patients with favorable-risk cytogenetic findings.

Gemtuzumab ozogamicin was approved by the United States Food and Drug Administration in May, 2000 under the accelerated approval regulations for the treatment of patients 60 years of age or older with CD33-positive AML in first relapse. Post-marketing reports of fatal anaphylaxis, tumor lysis, adult respiratory distress syndrome (ARDS), and hepatic veno-occlusive disease (VOD) required labeling revisions and the initiation of a surveillance program.[620] Tumor lysis and ARDS were primarily observed in patients with leukocyte counts above 30,000/ml. VOD was also observed.[620,624]

Under accelerated approval, additional clinical trials after approval are required to confirm the drug's benefit. If those trials fail to confirm clinical benefit to patients, the FDA can withdraw the drug from the market. For gemtuzumab ozogamicin, a confirmatory clinical trial was designed and begun in 2004 to determine whether adding gemtuzumab ozogamicin to standard chemotherapy would improve survival of patients with AML. The trial was stopped early when no clinical benefit was observed, and after a greater number of deaths occurred in patients who received gemtuzumab ozogamicin compared with those who received chemotherapy alone. Gemtuzumab ozogamicin was withdrawn from the

TABLE 75.15

NEW AGENTS IN DEVELOPEMENT FOR TREATMENT OF ACUTE MYELOID LEUKEMIA

Compound	Chemical Structure	Mechanism of Action
AC-220		Flt3 kinase inhibitor
Aflibercept	Fusion Protein	Angiogenesis inhibitor, VEGF antagonist
ARRY-520		Kinesin spindle protein inhibitor, cell cycle inhibitor, mitotic inhibitor
AT-9283		Aurora kinase inhibitor, Janus kinase 2 inhibitor, cell cycle inhibitor, mitotic inhibitor
Azacitidine		DNA methyltransferase inhibitor
AZD-1152		Aurora kinase inhibitor
Belinostat		Histone deacetylase inhibitor
Bortezomib		Proteasome inhibitor, transcription factor NF-κB inhibitor
CP-4055 (Elacyt)		Antimetabolite, DNA/RNA synthesis inhibitor ara-C-5′-elaidic acid ester
CSL-360	Monoclonal antibody	Monoclonal antibody against leukemia stem cells
Decitabine		DNA methyltransferase inhibitor
17-DMAG		Hsp90 inhibitor
Entinostat		Histone deacetylase inhibitor
Everolimus		mTOR inhibitor, angiogenesis inhibitor

Compound	Chemical Structure	Mechanism of Action
Flavopiridol		Cyclin-dependent kinase (Cdk) inhibitor
Lenalidomide		Immunomodulation, angiogenesis inhibition, tumor necrosis factor α antagonist
Lintuzumab	Monoclonal antibody	Monoclonal antibody against CD33
Midostaurin		Protein kinase C inhibitor, Flt-3 kinase inhibitor, cell cycle inhibitor
Mocetinostat		Histone deacetylase inhibitor
Obatoclax mesylate		Mcl-1 antagonist, Bcl2 antagonist
Sapacitabine		Antimetabolite, DNA synthesis inhibitor
Sirolimus		mTOR inhibitor, angiogenesis inhibitor
Sorafenib		Flt-3 kinase inhibitor, RET tyrosine kinase inhibitor, B-raf kinase inhibitor, EGF receptor kinase, inhibitor, PDGF receptor kinase inhibitor, angiogenesis inhibitor
Sunitinib		Flt-3 kinase inhibitor, c-kit inhibitor, EGF receptor kinase inhibitor, PDGF receptor kinase inhibitor
Temsirolimus		mTOR kinase inhibitor
Tandutinib		Flt-3 kinase inhibitor, c-kit inhibitor, PDGF receptor kinase inhibitor
Tipifarnib		Farnesyltransferase inhibitor
Voreloxin		DNA Topoisomerase II inhibitor, DNA-dependent protein kinase inhibitor
Vorinostat (SAHA)		Histone deacetylase inhibitor

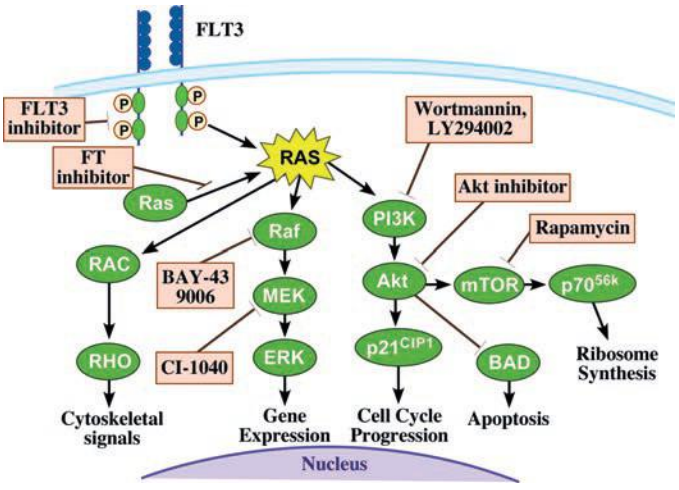

FIGURE 75.14. Signal transduction pathways downstream to FLT 3 and other tyrosine kinase receptors include Ras/Raf/MEK and PI3K/Akt. FT, farnesyl transferase. (See text for description of targets and inhibitors.) (Drawing by Tim Gilfilen, Medical Art Group, Vanderbilt University.)

market in June, 2010. Nevertheless other subsequently published studies have shown benefit.[625]

Other Novel Agents in Acute Myeloid Leukemia

Lenalidomide has antiangiogenic effects and other effects on the marrow microenvironment, has been approved for MDS with 5q–, and is under investigation in AML.[626,627] Angiogenesis is targeted by several other novel agents: SU5416 (Semaxinib) in an example of a small molecule receptor tyrosine kinase inhibitor directed at the vascular endothelial growth factor pathway; early trials with SU5416 indicate activity in AML.[628] The anti-VEGF monoclonal antibody bevacizumab also has activity in AML.[629] Bortezomib (Velcade) is a small molecule proteasome inhibitor that has activity in vitro in AML and is in clinical trials.[630] Tipifarnib (Zarnestra) is an orally administered nonpeptidomimetic enzyme-specific inhibitor of farnesyl protein transferase, an enzyme that promotes RAS processing and transduction of proliferative signals.[626,631] Inhibitors of mammalian target of rapamycin (mTOR) signaling have activity in AML.[632,633] Heat shock protein 90 (Hsp 90) is a molecular chaperone involved in signaling pathways for cellular proliferation and survival, and a small molecule inhibitor of Hsp 90, the benzoquinone antibiotic 17-allylamino-17-demethoxygeldanamycin (17-AAG), suppresses the chaperone function of Hsp 90.[634]

Immunotherapy

Immunotherapeutic interventions are being explored in the setting of minimal residual disease following post-remission therapy in AML. Post-consolidation immunotherapy with interleukin-2 and histamine dihydrochloride, both administered subcutaneously, significantly improved 3-year leukemia-free survival.[635] In addition, diverse novel vaccines and vaccine strategies are being developed and are beginning to be tested clinically in AML.[636,637] The ideal vaccine strategy is to identify leukemia-associated antigens that are absent in hematopoietic stem cells or normal tissues and can elicit a cytotoxic T-cell response.[637] The ability of AML blasts to differentiate into dendritic cells that can present target antigens is a method of vaccination under investigation.[636] Peptide vaccination trials in AML have targeted different epitopes of the Wilms' tumor gene 1, the proteinase 3-derived epitope peptide, and the receptor for hyaluronic acid mediated motility (RHAMM/CD 168)-derived epitope R3. Other AMl targets include preferentially expressed antigen of melanoma (PRAME), G250/CA9, BCL2, laminin receptor 1 (LamR1), and telomerase reverse transcriptase (hTERT).[637] WT1 has been the target in recent promising clinical trials.[638,639]

Therapy of Acute Myeloid Leukemia in Older Patients

Older patients with AML, usually defined as those 60 years of age and greater, have a worse outcome than younger patients.[443] Reasons include differences in performance status and co-morbidities, but also in biology, including cytogenetics and other parameters associated with drug resistance.[640] The biology of AML may differ in older patients, with the malignant cell originating in an earlier stem cell than in younger patients.[217] Prior MDS and t-AML are more common. Unfavorable cytogenetic findings are more common in the elderly, whereas the favorable abnormalities are less common. Increased expression of the MDR1 protein on AML blasts is more common in older patients.[377,463] In addition, older patients are more likely to have defects in the MSH2 protein which is involved in DNA repair and is associated with microsatellite instability and *TP53* mutations.[595]

Although the overall prognosis of AML patients over 60 years of age is poor, CR rates approaching those of younger patients can be observed, so chemotherapy should not be withheld on the basis of age alone. Patients with favorable and intermediate karyotypes and with good performance status may respond well to chemotherapy,[443] and CR rates with chemotherapy in older patients are usually in the 35% to 60% range. Unfortunately, however, median remission duration is less than one year in older patients regardless of post-remission chemotherapy regimen. Therefore, for older patients who achieve complete remission, reduced-intensity allogeneic hematopoietic stem cell transplantation should be strongly considered. In general, because of poor long-term DFS with chemotherapy (5% to 15%), it is important to discuss the poor prognosis with patients and families, to enroll patients on clinical trials, and to implement low-intensity therapies for patients unlikely to benefit from intensive chemotherapy.

For older patients unlikely to benefit from chemotherapy because of disease- and/or patient-related factors, a number of novel agents and approaches are being pursued in clinical trials and as standard therapies. These currently include the DNA methyltransferase inhibitors decitabine and azacitidine, the nucleoside analogs clofarabine and sapacitabine, the immunomodulatory agent lenalidomide, and the farnesyl transferase inhibitor tipifarnib. Some of these agents, such as the DNA methyltransferase inhibitors, may be administered in the outpatient setting.

In summary, for older AML patients, the critical decision is whether to administer intensive induction chemotherapy. This decision should not be solely based on age, but also on performance status, co-morbidities, and AML risk profile including primarily cytogenetics.[307,443] It has been shown to be feasible to wait for and use cytogenetic results in choosing initial treatment for older AML patients.[641] In older patients who achieve complete remission, the option of reduced-intensity allogeneic hematopoietic stem cell transplantation should be considered.[642] Older patients with poor performance status, advanced age, and unfavorable-risk AML should optimally be treated on clinical trials of novel therapies.

Acute Myeloid Leukemia in Pregnancy

Although development of AML during pregnancy is rare, occurring in less than 1 in 10,000 pregnancies, it represents a major quandary in patient management.[643–645] Transmission of leukemia from mother to fetus is extremely unusual.[646,647] Diagnosis of AML is less common in the first trimester than in the second or third trimesters, occurring in 14% in a series of 59 patients.[648] Teratogenic effects of chemotherapy are more common in the

first trimester and appear to be minimal in the second or third trimester.[645,649,650] Options in the first trimester include therapeutic abortion and supportive therapy until the second trimester. Chemotherapy with intensive supportive care can result in a successful outcome for the fetus and the mother with leukemia in the second or third trimester[644,645,650,651] usually without a need to terminate pregnancy. Fetuses exposed to antileukemia therapy in utero may have slight fetal growth retardation as well as transient myelosuppression if treatment is given near delivery, but generally have normal growth and development in childhood.[652,653] The choice of induction chemotherapy is similar to that in nonpregnant patients. In addition to close monitoring of the mother and the fetus, delivery should optimally occur during a noncytopenic period.[654]

Relapsed and Refractory Acute Myeloid Leukemia

Approximately half of younger patients and a large majority (>85%) of older patients will either not achieve a complete remission or will relapse. The percentage of patients who have refractory AML (i.e., never obtain a complete remission) is at least 20%, but varies depending upon age, cytogenetics, and other prognostic factors. The definition of refractory AML includes patients who do not achieve complete remission with induction chemotherapy, those with a short (less than 6 to 12 months) first complete remission and patients who have relapsed twice or more.[655] Prognostically relevant variables at first relapse include length of relapse-free interval after first complete remission, cytogenetics at diagnosis, age at relapse, and whether stem cell transplantation was performed previously.[656] All patients with relapsed or refractory AML are candidates for clinical trials with novel therapies (see "Therapy" section).

AlloSCT is superior to chemotherapy for patients with relapsed or refractory disease, but many patients do not have a donor, or are too old or too ill for alloSCT (see "Stem Cell Transplantation" section). Although patients with a matched related donor can be offered an alloSCT in early relapse, there is an advantage and sometimes a necessity to receive additional chemotherapy to lessen the leukemia burden before a transplant, particularly if there is a delay in obtaining an alternative (i.e., unrelated) donor or if a nonmyeloablative approach is utilized (see "Stem Cell Transplantation" section). Autologous SCT is also an alternative for patients in second remission, but it is probably inferior to alloSCT and is not universally recommended.

Second remissions can be obtained in 30% to 80% of patients who had an initial first remission, are generally shorter in duration than first remissions, and are achieved more readily in patients with initial remissions longer than one year or with favorable cytogenetics.[657–659] Second CR was achieved in 55% to 60% of patients with initial CR > 1 year, compared to 33% to 46% with CR < 1 year.[655, 658] Second CR was obtained in 80% to 88% of patients with favorable cytogenetics, 18% to 49% with intermediate, and 0% to 30% with poor risk.[657,660]

To date, there is no standard regimen for induction of a second CR. Dose escalation and use of noncross-resistant regimens have been helpful in inducing second remissions. Cytarabine has been used in doses ranging from 500 mg/m^2 to 3 g/m^2 every 12 to 24 h for 3 to 6 days, alone or in combination with other agents, including anthracyclines, etoposide, clofarabine, fludarabine, gemtuzumab ozogamicin, irinotecan, L-asparaginase, mitoxantrone, and topotecan.[661–671] HiDAC alone resulted in a CR rate of 40%, compared to 56% in patients receiving HiDAC with an anthracycline,[661] but two large randomized trials have not shown a benefit to adding a second agent to cytarabine.[531,672]

A liposomal formulation of ara-C and daunorubicin with specific molar ratio (CPX-351) has shown promising activity in in vitro and in vivo studies.[673,674] Preliminary results from a randomized trial (n = 126) showed no significant differences in CR/CRi rates for CPX-351 compared to other salvage chemotherapy (51% vs. 41%), but there were 2 months overall survival advantage for AML patients with unfavorable prognostic risk disease who received CPX-351 compared to other therapies (6.6 months vs. 4.2 months).

Reversal of drug resistance may be accomplished through the use of drugs that compete with chemotherapy agents for binding sites on p-glycoprotein. A randomized trial comparing cyclosporine A with chemotherapy versus chemotherapy alone in poor-risk AML favored the cyclosporine A arm;[524] however, trials evaluating the cyclosporine D derivative PSC-833 (valspodar) and zosuquidar, a third-generation MDR modifier with less effect on pharmacokinetics of chemotherapy drugs, in initial therapy have been disappointing, as discussed above.[521,522]

The DNA methyltransferase inhibitors azacitidine and decitabine have been used for the treatment of relapsed or refractory AML with generation of anecdotal evidence to support their use in this setting.[675,676,677]

Single-agent clofarabine resulted in 30% CR rate in a phase 2 single-arm clinical trial in patients with relapsed or refractory leukemias.[553] A combination of clofarabine with ara-C generated a response rate of 38% in another single arm study.[554] A phase 3 prospective randomized trial (n = 320) in patients older than 55 years of age with relapsed/refractory AML compared the combination of clofarabine plus ara-C (clofarabine at 40 mg/m^2/day × 5 days, ara-C 1 g/m^2/day × 5 days) versus ara-C alone.[678] Overall survival as the primary endpoint was not different between the two arms (6.6 months for the combination vs. 6.4 months in the ara-C arm), but CR rate (41% for the combination vs. 16% for ara-C alone, P = 0.001) was higher with the combination regimen.

Novel molecules as single agents are warranted and have been commonly used in the context of phase I and II clinical trials in relapsed patients who have short first remissions or have failed an initial salvage regimen (see "Therapy" section).

STEM CELL TRANSPLANTATION

AML has replaced CML as the most common disease to be treated with alloSCT due to the success of tyrosine kinase inhibitors in treating CML. AlloSCT is thought to have excellent efficacy in treatment of AML due to both the effect of high-dose chemotherapy with or without whole body irradiation utilized in the conditioning regimen and the immunologic graft-versus-leukemia (GVL) effect.[679] AlloSCT is associated with the lowest relapse rates and can be effective in chemotherapy-refractory acute leukemia. Patient age, disease status, cytogenetics, prior therapy, co-morbidities, performance status, timing, and type of transplant determine its oucome.

AlloSCT is recommended for AML in second remission, but its benefit needs to be assessed against its risk for patients in first remission. Randomized trials in the 1990s comparing alloSCT to autoSCT and chemotherapy produced mixed results; there tended to be better disease-free survival with allogeneic SCT, but no improvement in overall survival[680,681] (Figs. 75.15 and 75.16). Primary problems with alloSCT have been lack of suitable donors and a high early mortality caused by organ toxicity, infections, and graft-versus-host disease (GVHD).

The landscape of SCT is constantly changing (Chapters 104 and 105), and overall survival after allografts is gradually improving.[682–684] Major improvements in alloSCT have included: (1) high-resolution DNA typing for HLA matching; (2) improved prevention and treatment of GVHD; (3) improved supportive care, including molecular monitoring of CMV and use of pre-emptive antiviral therapy and improved antifungal therapy; (4) the development of reduced-intensity (nonmyeloablative) conditioning regimens;

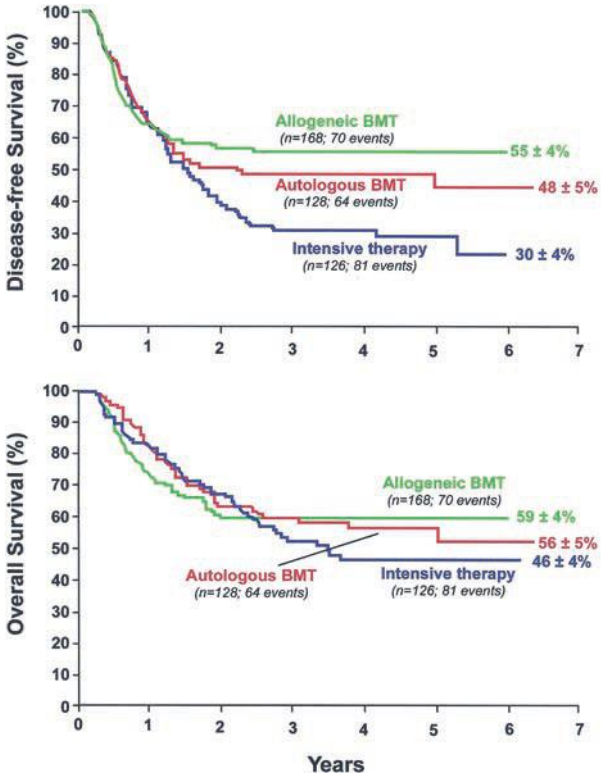

FIGURE 75.15. Impact of different post-remission therapies on survival. A: Disease-free survival (DFS). Allogeneic bone marrow transplantation (BMT) has the best DFS, versus randomization between autologous BMT and (p = 0.05). **B:** Overall survival (OS): There were no differences in OS among the three. (With permission from Zittoun RA, Mandelli F, Willemze R, et al. Autologous or allogeneic bone marrow transplantation compared with intensive chemotherapy in acute myelogenous leukemia. N Engl J Med 1995;332:217–223.)

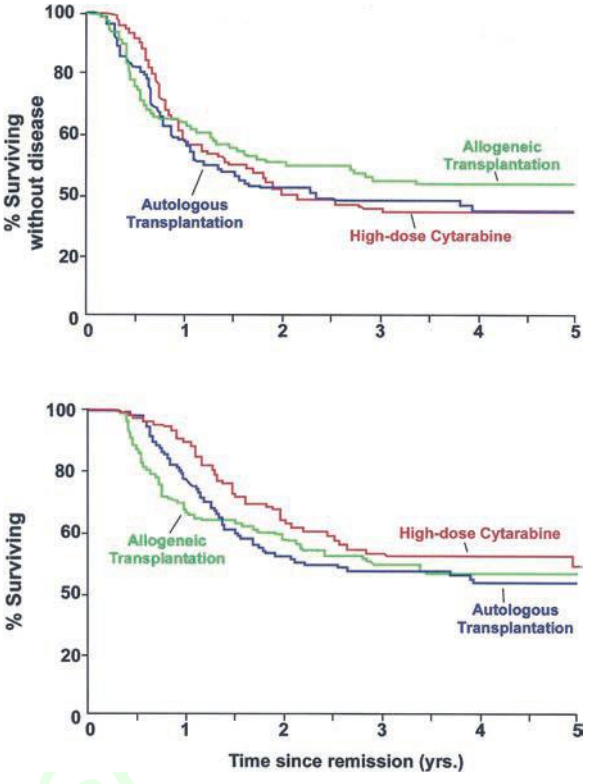

FIGURE 75.16. A: Disease-free survival according to post-remission therapy was not statistically significant at 4 years: autologous bone marrow transplantation (autoBMT), 35 6 9%; allogeneic bone marrow transplantation (alloBMT), 43 6 10%; high-dose cytarabine, 35 6 9%. B: Overall survival at 4 years was better for high-dose cytarabine, 52 ± 9%, than for either alloBMT, 46 ± 10% (p = 0.04) or auto BMT, 43 ± 9% (p = 0.05). (With permission from Cassileth PA, Harrington DP, Appelbaum FR, et al. Chemotherapy compared with autologous or allogeneic bone marrow transplantation in the management of acute myeloid leukemia in first remission. N Engl J Med 1998;339:1649–1656.)

and (5) the use of co-morbidity indices to predict prognosis and to select patients and type of transplant.[685–687] The donor pool is expanding with the increased availability of unrelated donors and umbilical cord transplants in adults and with innovative immunosuppression to allow HLA-mismatched donors.[688–691] The HLA-haploidentical 2 or 3-loci mismatched related donor is an important and viable alternative stem cell source for patients who do not have matched donors, and it has been used in many transplant centers with outcomes that appear not to be inferior to transplantation from matched unrelated donors.[692]

Age is no longer an absolute contraindication to alloSCT with the use of nonmyeloablative conditioning regimens (Fig. 75.17),[685] which allow older patients and those with co-morbid illnesses to undergo alloSCT with low early mortality, albeit with a higher relapse rate. Because nonmyeloablative SCT has less antileukemic effect, it relies on the graft-versus-leukemia (GVL) effect. Transplant-related mortality with nonmyeloablative conditioning regimens is reduced to the 10% to 20% range, but the relapse rates of 30% to 65% are higher than for myeloablative SCT. Overall survival appears to be equivalent following reduced-intensity and myeloablative conditioning regimens in patients in remission or with low tumor burden.[693,694] The 3-year DFS for AML utilizing reduced intensity conditioning has been 30% to 66%.[695]

AutoSCT is associated with lower transplant-related mortality than alloSCT, but with higher relapse rates. In vitro purging with cyclophosphamide derivatives or by positive stem cell selection has been associated with a lower relapse rate, but the role of purging remains controversial because it can delay engraftment and it has not been validated in a large randomized trial.[696]

A randomized trial comparing alloSCT to autoSCT in first CR, the EORTC-GIMEMA AML-10 trial, favored the allo (donor) arm over the auto (no donor) arm, but only in patients with poor-risk cytogenetics.[697] Other reports have favored autoSCT over alloSCT.[698,699] In a retrospective comparison of autoSCT and matched unrelated donor (MUD) SCT, the 3-year survival probabilities were: 57% ± 4 versus 44% ± 7 (P = 0.002) in CR1 and 46% ± 7 versus 33% ± 5 in CR2 (P = 0.006).[699] However, cytogenetic data were unavailable for most patients and it is likely that alloSCT would have had better outcomes than autoSCT in patients with poor-risk cytogenetics. Due to a leukemia-free stem cell source and a lower relapse rate, alloSCT from a matched related donor (MRD) tends to be preferred over autoSCT.

Transplant in first CR is generally not recommended for patients with favorable-risk cytogenetics, including t(8;21) and inv(16), but gene mutations may identify patients with good-risk cytogenetics who are unlikely to be cured by chemotherapy and should be considered for early transplantation. *KIT* mutations are associated with an inferior survival for favorable-risk core-binding factor AML.[364,365,366]

FLT3 mutations, particularly of the internal tandem duplication (ITD) type, are the most important adverse prognostic factor in cytogenetically normal AML. A retrospective, single-institution study suggested that performing alloSCT in early first complete remission could improve long-term outcomes for *FLT3*/ITD AML,[700] with 4 years overall survival for the 31 *FLT3*/ITD patients comparable to the 102 patients with WT *FLT3*. Patients with normal karyotype and *FLT3* mutations also appear to benefit from autoSCT.[701] In addition, patients with a normal karyotype who had *NPM-1* mutations and did not have *FLT3*-ITD did not

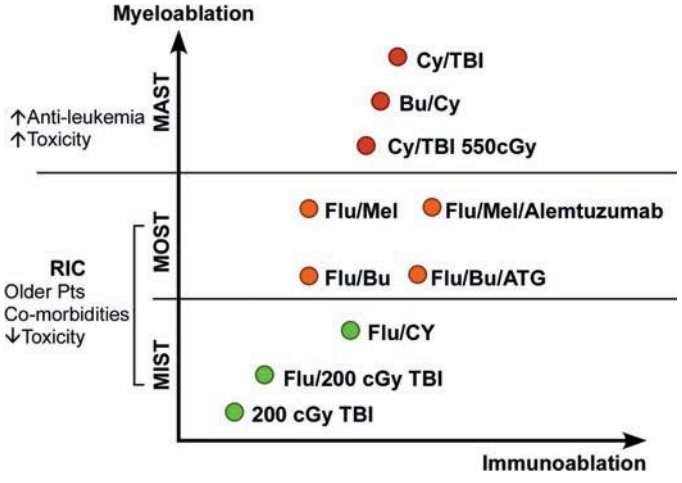

FIGURE 75.17. Diagram showing intensity of different regimens. The horizontal axis indicates the degree of immunoablation, and the vertical axis that of myeloablation. ATG, antithymocyte globulin; Bu, busulfan; CY, cyclophosphamide; Flu, fludarabine; MAST, myeloablative SCT; Mel, melphalan; MIST, minimal-intensity SCT; MOST, moderate-intensity SCT; RIC, reduced-intensity stem cell transplantation (SCT); TBI, total-body irradiation. Bone Marrow Transplant 2005;36:565–574.)

benefit from alloSCT, whereas those with other combinations of the mutations did benefit in a retrospective evaluation.[45]

The role of SCT in the treatment of AML has been investigated in several prospective clinical trials.[680,681,697,702–704] In four major prospective trials, involving approximately 2,700 AML patients in first CR, only 71% of eligible patients received alloSCT, and only 47% of the remainder were randomized.[702] Intent-to-treat analyses comparing survival between donor versus no-donor are recommended to assess the impact of alloSCT in prospective trials. In three large prospective trials, EORTC-GIMEMA favored the donor arm for poor-risk cytogenetics, the MRC 10 favored the donor arm for intermediate-risk cytogenetics, and the HOVON-SAKK favored the donor arm for both risk groups.[697,702,704] A systematic review and meta-analysis of clinical trials involving more than 3,500 patients with AML in first complete remission including prospective biologic assignment reported a significant survival advantage of alloSCT compared to non-alloSCT in the treatment of AML patients with intermediate and unfavorable cytogenetics, but not with favorable cytogenetics (Fig. 75.18).[705]

Although there is general agreement that alloSCT offers the best option for preventing relapse in patients with AML with intermediate- or poor-risk cytogenetics, its overall impact on survival and the optimal timing and method of SCT (related vs. unrelated; myeloablative vs. reduced intensity) remain unresolved issues. In most trials utilizing alloSCT in first CR for patients

without favorable cytogenetics, 5-year DFS is 45% to 75% using an MRD.[706,707] There has been a significant decline in transplant-related mortality to less than 10% for patients in first CR in some reports due to a decrease in deaths from GVHD, infections, and organ toxicity; this decline in transplant-related mortality has led to improved survival in first remission patients but not in patients in relapse or second remission[708] (Fig. 75.19).

Despite improvements in HLA matching and supportive care, results of transplants from unrelated donors are usually inferior to those from matched siblings in first CR.[709] In contrast, recent reports have indicated equivalent survival for sibling and unrelated transplants for AML, particularly for patients in early relapse or second CR, for whom DFS is in the 20% to 40% range (Fig. 75.20).[710] Fortunately approximately one third of patients who fail induction therapy but achieve remission with subsequent therapy and proceed to alloSCT can have prolonged DFS.[711] For patients with refractory or advanced AML, the salvage rate is 5% to 30%.[478,712]

Patients with acute GVHD (grades II–IV) or chronic GVHD and patients transplanted from unrelated donors have had lower relapse rates than patients without GVHD or transplanted from matched related donors, respectively.[713] However, GVHD and the therapy of GVHD can be debilitating or fatal, especially for the older patient. There are ongoing trials with different nonmyeloablative regimens and different immunosuppressive agents to control GVHD without losing GVL.[714,715]

FUTURE DIRECTIONS

Further studies will identify and characterize additional gene mutations, epigenetic changes, patterns of microRNA expression, and aberrant signal transduction that will serve to further refine prognostic subsets and provide new therapeutic targets. Refined approaches to transplantation will increase its safety and efficacy, and its applicability in older patients, who are in great need of more effective therapies to prolong disease-free and overall survival. Novel immunotherapeutic approaches may also favorably affect outcomes in the future. The detection of residual disease is an ongoing area of study that should come into increasing use in the management of AML, and measurable minimal residual disease may serve as a target for innovative therapies.

CHAPTER 76

ACUTE LYMPHOBLASTIC LEUKEMIA IN CHILDREN

Elizabeth A. Raetz, Mignon Lee-Chuen Loh, Maureen M. O'Brien, James A. Whitlock

Acute lymphoblastic leukemia (ALL) is the most common childhood malignancy, accounting for approximately 20% of all cancers and 75% of all leukemias among patients younger than 20 years of age.[1] Approximately 2,500 to 3,500 new cases of ALL are diagnosed in children each year in the United States with an incidence of 31.9 cases per one million person-years. Although most patients are younger than 5 years old, ALL occurs in an age-, gender-, ethnically, and socioeconomically diverse population.

Both in the clinic and in the laboratory, the vast heterogeneity of ALL is apparent. Patients may present with greater disease burden with symptoms of leukemic proliferation demonstrated, for example, by bone pain, lymphadenopathy, respiratory distress from a mediastinal mass, or abdominal discomfort secondary to organomegaly, or with no evident disease burden after a more insidious onset of symptoms related to marrow failure, such as, fatigue from anemia, fever from neutropenia, and bruising or bleeding from thrombocytopenia. Although most cases may be classified as B-precursor or T-cell ALL, great diversity is seen in the various combinations of B-, T-, and myeloid-associated membrane markers expressed by leukemia cells. Great diversity is also seen in the broad array of known cytogenetic and molecular abnormalities.[2,3]

ALL remained a fatal childhood disease until effective presymptomatic central nervous system (CNS) therapy was developed in the 1960s. Although combination chemotherapy provided frequent remissions (disappearance of microscopically detectable leukemia in the bone marrow with recovery of adequate marrow function), the subsequent appearance of leukemia cells in the CNS was common, and marrow relapse followed despite further treatment.

Over the following decades, better postinduction intensification has improved the 5-year event-free survival (EFS) from 50% to nearly 90% for children younger than 15 years of age (Fig. 76.1) and allowed replacement of craniospinal radiation for most patients with intrathecal therapy.[4,5] Unlike other childhood cancers for which curative therapy is available, outcomes are best with prolonged treatment extending 2 to 3 years or more. Treatment is tailored to risk of relapse; patients at higher risk of relapse, as defined by specific clinical and biologic features, receive more aggressive treatment, whereas patients at lower risk of relapse obtain excellent outcomes with less morbid treatment. Initial response to induction therapy, assessed by multiparameter flow cytometry or PCR-based technology, now supplements presenting clinical features and cytogenetics for treatment allocation. Despite continued improvements in prognostication, treatment remains the most important prognostic factor.

Because the incidence of ALL is higher than other childhood cancers, the incidence of relapsed ALL is similar to the incidence of newly diagnosed pediatric cancers such as acute myeloid leukemia (AML) and Hodgkin lymphoma despite excellent initial cure rates. Outcomes after relapse, particularly marrow relapse, remain poor despite substantial success in inducing remission and the increasing application of allogeneic hematopoietic stem cell transplantation (HSCT). The majority of patients who relapse will ultimately die of their leukemia.

The diagnosis and characterization of ALL are discussed in Chapter 73. Cytogenetics are discussed in Chapter 3 and molecular genetics are discussed in Chapter 72. This chapter is concerned with the clinical characteristics, treatment, and late sequelae of childhood ALL. Therapy of Burkitt leukemia is addressed in Chapter 89.

PRESENTING CLINICAL FEATURES

Although it affects all age groups, the highest incidence of B-precursor ALL in children is between the ages of 1 and 5 years, with a peak incidence between 3 and 4 years (Fig. 76.2) where favorable cytogenetic patterns such as trisomies (trisomy 4 and 10)

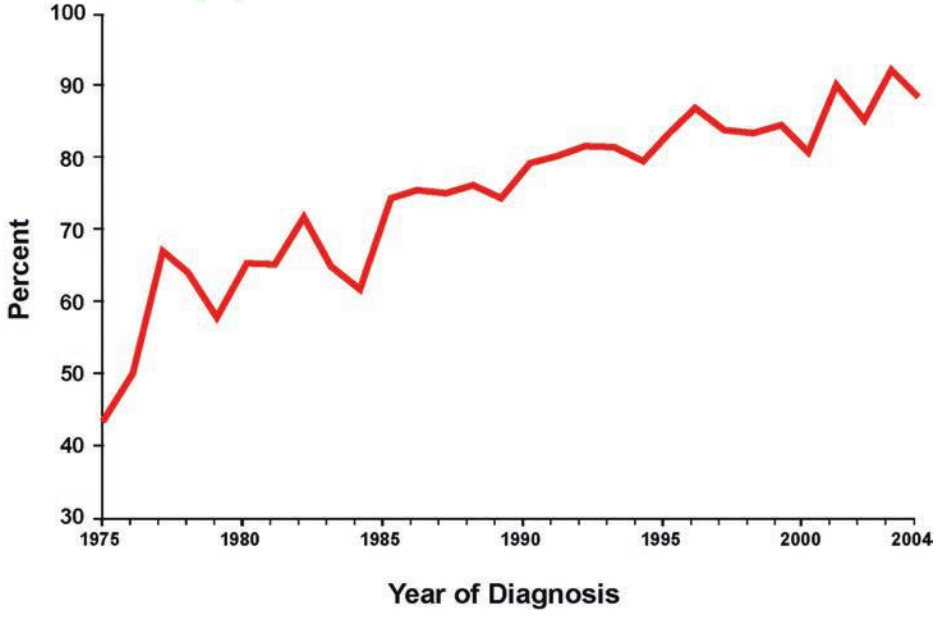

FIGURE 76.1. Five-year relative survival rates by year of diagnosis for acute lymphoblastic leukemia (ALL) (all races, both sexes, age <20 years, 1975 to 2004, SEER Cancer Statistics).

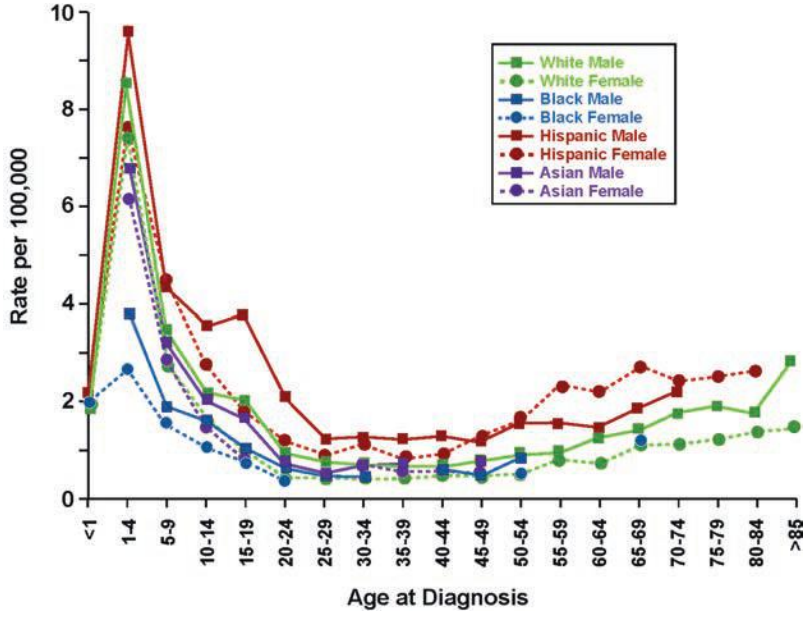

FIGURE 76.2. Age-specific incidence rates of ALL according to race and gender (SEER Cancer Statistics, 2000 to 2009).

and translocation t(12;21) are most common.[6] This early peak is not seen in African Americans, and as a result, ALL is more common in children of Caucasian descent.[7] Children of Hispanic ethnicity have the highest incidence of ALL, and emerging data suggest that genetic polymorphisms may contribute to both the increased risk of ALL for Hispanic children as well as inferior outcomes.[8] Overall, ALL is slightly more common in males compared to females (1.3:1 ratio). Patients with T-cell ALL tend to be older (median age 9 years) and more commonly are male (75%).[9]

Symptoms and signs are a consequence of bone marrow failure or the infiltration of medullary or extramedullary sites by leukemia (Table 76.1). The onset of symptoms may be insidious and slowly progressive over weeks to months, or acute and explosive. In general, the more indolent the onset of symptoms, the better the outcome.[10] Fatigue, lethargy, persistent fever, bruising or bleeding, and bone pain are the most common presenting complaints. Fatigue and lethargy correlate with the severity of anemia. No infectious basis for fever is found in many cases, especially if the neutrophil count exceeds 0.2×10^9/L, but infection

TABLE 76.1

FREQUENCY OF CLINICAL AND LABORATORY FINDINGS AT DIAGNOSIS IN 178 CHILDREN AND ADULTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA

Clinical Features	Percentage	Laboratory Features	Percentage
Symptoms	—	White blood cells ($\times 10^9$/L)	—
Fatigue	92	<10	40
Bone or joint pain	79	10–49	34
Fever without infection	71	50–99	15
Weight loss	66	≥100	11
Abnormal masses	62	Neutrophils ($\times 10^9$/L)	—
Purpura	51	<1	73
Other hemorrhage	27	1–2	9
Infection	17	>2	18
Physical findings	—	Packed cell volume (L/L)	—
Splenomegaly	86	<30	65
Lymphadenopathy	76	>30	35
Hepatomegaly	74	Platelets ($\times 10^9$/L)	—
Sternal tenderness	69	<50	62
Purpura	50	50–150	30
Fundic hemorrhage	14	>150	8

From Boggs DR, Wintrobe MM, Cartwright GE. The acute leukemias. *Medicine* 1962;41:163.

must be presumed and treated with broad-spectrum parenteral antibiotics.[11] Fever usually resolves promptly after the institution of antibiotics and chemotherapy.[12] Thrombocytopenia may cause bruising and bleeding. Approximately 2% of children present with marrow findings consistent with aplastic anemia, followed by overt leukemia within weeks to months.[13]

Bone pain is a frequent complaint and may result from marrow expansion, bone erosion, or leukemic involvement of the periosteum. Young children, in particular, may present with gait disturbances or a refusal to walk. Vertebral compression fractures may complicate generalized osteoporosis, leading to back pain. Prominent skeletal symptoms occur primarily in children with no lymphadenopathy, organomegaly, or leukocytosis, and as a result, the diagnosis of leukemia often is delayed.[14–16] Less commonly, bone pain is caused by recurring episodes of bone marrow necrosis.[17–19] Marrow necrosis is also typically associated with a small leukemic burden and an aleukemic blood picture. In approximately 5% of patients with ALL, bone or joint pain may be the only presenting symptoms and patients may be referred for rheumatology evaluation for concern of juvenile rheumatoid arthritis (JRA). Diagnosis in these patients may be delayed, and differentiation of ALL from JRA is critical to avoid pretreatment with corticosteroids which might have a negative impact on subsequent diagnosis and risk stratification.[20]

Physical findings may include pallor, petechiae or purpura, mucous membrane bleeding, and fever. Extramedullary leukemic spread may be manifest by lymphadenopathy which is present in approximately 50% of patients, as well as splenomegaly and hepatomegaly which are frequently noted on imaging or examination but rarely cause symptoms.[21] Skin involvement is rare; when it occurs, it presents as cutaneous nodules and is associated with a pre-B–cell phenotype.[22]

Approximately 60% of patients with acute T lymphoblastic leukemia (T-ALL) have enlarged anterior mediastinal lymphadenopathy at the time of diagnosis, which is rarely seen in children with B-precursor ALL. The presence of mediastinal mass at diagnosis does not have prognostic significance.[23] The mediastinal mass may be asymptomatic and detected only on chest x-ray, or may cause cough and dyspnea, particularly on lying flat, or with facial swelling and plethora due to vascular compression with superior vena cava syndrome. Identification of clinically significant mediastinal adenopathy is critical prior to sedation for diagnostic procedures such as bone marrow aspiration.

Microscopic leukemic infiltration of the testes in males is common at presentation and requires no specific treatment. Testicular biopsy is discouraged at presentation as a routine part of staging, as it is likely to be positive, even in patients with a normal testicular examination. Overt testicular involvement with leukemia (2% to 3% of patients) presents as painlessly enlarged or irregular testes, and carries no adverse prognosis in the modern treatment era when treated with appropriately intense therapy.[24,25]

CNS involvement by leukemia occurs in approximately 2% to 3% of patients at diagnosis and is more common in patients with T-ALL. Most patients with CNS involvement are asymptomatic and only diagnosed by lumbar puncture. Rarely, symptoms include headaches, vomiting, or cranial nerve palsies.[26]

PRESENTING LABORATORY AND RADIOGRAPHIC FEATURES

The white blood cell (WBC) count is elevated in 60% of patients (see Table 76.1). Neutropenia is frequent. Although leukemic blasts are obvious in smears of patients with high WBC counts, they may be absent or found only after thorough review of blood smears from patients with decreased leukocyte counts. A WBC count in excess of 50×10^9/L is frequently associated with prominent lymphadenopathy, hepatosplenomegaly, and T-cell immunophenotype. A WBC count in excess of 200×10^9/L is termed hyperleukocytosis. Unlike the situation in AML, hyperleukocytosis rarely is complicated by intracerebral hemorrhages or pulmonary insufficiency.[27] Although thrombocytopenia is common, patients with ALL do not present with isolated thrombocytopenia without other abnormal laboratory tests and/or physical findings.[28]

A large leukemic cell burden with a high rate of cell turnover may produce tumor lysis syndrome, that is, multiple metabolic disturbances, the most prominent of which is elevation of the serum uric acid level, which in turn may lead to urate nephropathy. Acute renal failure resulting from urate nephropathy may rarely be a presenting feature, but more commonly follows initiation of antileukemic treatment.[29] Kidney function may be further diminished by leukemic infiltration of the kidney or extrarenal obstruction by enlarged lymph nodes. Increased cell destruction causes hyperphosphatemia and secondary hypocalcemia, which may lead to the precipitation of calcium phosphate in renal tubules and consequent acute renal failure, and hyperkalemia, leading in turn to cardiac arrhythmias or asystole.[30,31] The availability of recombinant uricase, which breaks down uric acid, has improved the treatment of tumor lysis syndrome. The management of these metabolic complications is discussed in Chapter 69. Serum levels of lactic dehydrogenase (LDH) are increased because of an increased turnover of leukemic cells, but have no physiologic consequences and need not be repetitively monitored.

Although occurring less frequently than in AML, coagulopathies may lead to either hemorrhagic or thrombotic complications.[32] Most often coagulopathy follows asparaginase administration and thrombosis is believed mediated by acquired antithrombin III deficiency leading to increased thrombin generation.[33,34] The data for attempts to prevent thromboses with administration of antithrombin III concentrates remain less than compelling.

Radiographic examination of the chest demonstrates an anterior mediastinal mass in 5% to 10% of newly diagnosed patients with ALL, most commonly in patients with T-cell disease. The thymic mass may be associated with pleural effusions, which are frequently malignant and yield diagnostic cells upon thoracentesis. A large mediastinal mass represents a medical emergency, requiring careful monitoring and prompt initiation of chemotherapy, and complicating routine sedation or anesthesia. Skeletal lesions can be radiographically demonstrated in more than 50% of patients.[35] The most common abnormalities include transverse metaphysical radiolucent lines adjacent to the zone of provisional calcification at the end of long bones, generalized rarefaction of bones, cortical and trabecular osteolytic lesions, and periosteal new bone formation.

Bone marrow aspiration is the standard method of establishing a diagnosis, and provides cells for morphologic, histochemical, immunophenotypic, cytogenetic, and molecular analysis. In bone marrow aspiration, careful attention is provided toward minimizing pain and fear for the patient and family, with the routine utilization of conscious sedation or general anesthesia. In ALL, the marrow is typically hypercellular with replacement of fat spaces and normal marrow elements by leukemic cells. In contrast to AML, residual myeloid and erythroid precursors appear morphologically normal. Megakaryocytes are decreased or absent. Bone marrow lymphoblasts are more homogeneous with respect to both morphologic and biologic characteristics than those in the blood. When marrow aspiration is unsuccessful due to increased cell density, a biopsy should be performed. As other diagnostic modalities such as flow cytometry can replace marrow morphology, examination of peripheral blasts, when present in sufficient quantity, may replace marrow aspiration or biopsy when aspiration is unsuccessful or clinically risky.

Lumbar puncture provides evidence of overt CNS involvement in approximately 3% of children with ALL at diagnosis.

Cytocentrifugation (cytospin) of cerebrospinal fluid (CSF) enhances diagnostic sensitivity by concentrating low numbers of cells. Involvement is classified as CNS 1 (no blasts on cytospin), CNS 2 (blasts on cytospin but CSF WBC < 5 cells/μl), and CNS 3 (blasts on cytospin with WBC ≥ 5 cells/μl).[36,37] Recent reports suggest adverse significance for CNS 2 status or a traumatic initial lumbar puncture with blasts in some series.[37,38] As a result, it is recommended that the platelet count be elevated to $>100 \times 10^9$/L by transfusion prior to the diagnostic lumbar puncture to minimize risk of a traumatic tap, and that the procedure be performed by the most highly skilled practitioner with the patient under general anesthesia. Cranial nerve findings in the absence of CSF blasts are highly suggestive of CNS leukemia.

RISK STRATIFICATION

As therapy remains the single most important factor to influence outcome, the relative prognostic significance of characteristics at diagnosis (Table 76.2) varies for the different treatment strategies delivered by national and international investigators. Consequently, evolving combinations of clinical, laboratory, and response variables have been used to guide therapeutic intensity over the years by those who conduct clinical trials for childhood ALL, overall with increasingly successful results. Indeed, the Children's Oncology Group (COG) recently reported that sequential outcomes of over 21,000 patients (age 0 to 22 years) enrolled on COG trials between 1990 and 2005 culminated in survival rates of 90.4% for those children treated between 2000 and 2005 (Fig. 76.3).[5] Concomitantly, studies conducted on long-term survivors of childhood cancer reveal that up to 62% of patients suffer from at least one chronic condition and 27% suffer from a grade 3 or 4 condition.[39] The goal of modern risk stratification, then, is to cure patients while minimizing acute and late toxicity, otherwise known as maximizing the therapeutic benefit.

Differences among the risk classification criteria used to deliver varied intensities of therapy by disparate groups have made accurate comparisons of outcomes difficult, if not impossible. To overcome this obstacle, an international workshop held in Rome in 1985[36] and a subsequent consensus workshop, sponsored by the United States National Cancer Institute in 1993, led to the development of common risk-based criteria.[40] In 1993, the NCI-Rome risk criteria were agreed upon by leaders among the major clinical consortia in an attempt to analyze different datasets using two of the most powerful predictors of outcome across all studies for B-lineage ALL: age and presenting WBC count at diagnosis. The standard-risk group (NCI-SR) includes those patients with B-precursor ALL ages 1 to 9 years with a WBC count less than 50×10^9/L. In 1995, NCI-SR patients were estimated to have EFS rates of approximately 80% and the remaining high-risk (NCI-HR) patients were estimated to have EFS of approximately 65%.

In the current era, approximately 85% of children with ALL will present with B-lineage disease and the remainder will present with T-lineage ALL. Two thirds of patients with B-lineage ALL present with NCI-SR features. Notably, the constellation of age and WBC count cannot reliably be used to predict outcome for patients with T-cell ALL, likely reflecting the different genomic and subsequent biochemical landscape of these malignancies. However, the unique biologic features of T-cell disease, the failure of prognostic factors effective in precursor B-cell ALL to predict outcome in T-cell ALL,[41] the differing patterns of MRD between B- and T-lineage disease,[42] and the advent of T-cell-specific therapies[43,44] all argue for the separate stratification of T-cell ALL in classification and treatment, an approach that has been adopted by many cooperative childhood leukemia groups.

In addition, genomic factors appear to be increasingly relevant for older adolescents and young adults with B-lineage ALL, and recent discoveries may affect not only prognosis but therapy. Finally, for patients less than 1 year of age with B-lineage ALL, the most important adverse prognostic factor remains the presence or absence of a rearrangement (not deletion) in the mixed lineage leukemia (*MLL*) gene, which is most commonly seen in infants less than 3 months of age.

TABLE 76.2

PROGNOSTIC FACTORS IN ACUTE LYMPHOBLASTIC LEUKEMIA

Determinants	Favorable	Unfavorable
White blood cell counts	$<10 \times 10^9$/L	$>200 \times 10^9$/L
Age	1–10 y	<1, >10 y
Gender	Female	Male
Node, liver, spleen enlargement	Absent	Massive
Testicular enlargement	Absent	Present
Central nervous system leukemia	Absent	Overt (blasts + pleocytosis)
FAB morphologic features	L1	L2
Immunophenotype	Pre-B or T	Early T-cell precursor
Ploidy	Hyperdiploidy>50	Hypodiploidy <44
Genetic markers (examples)		
B lineage	Trisomies 4 and 10 t(12;21) (p13;q22) (*ETV6-RUNX1*)	iAMP 21 *IKZF1* deletions/mutations t(4;11) (q21;q23) (*MLL-AFF1*)
T lineage	t(1;14) (p32;q11) (*TAL1-TRD@*) t(10;14) (q24;q11) (*TLX1-TRA@/TRD@*) t(11;14) (p15;q11) (*LMO2-TRA@/TRD@*) t(11;19) (q23;p13) (*MLL-ENL*)	t(10;11) (p13;q14) (*PICALM-MLLT10*) t(5;14) (q35;q32) (*TLX3-BCL11B*) t(7;7) or inv7 (p15q34) (*HOXA-TRB@*)
Time to remission	<8 d	>28 d
Minimal residual disease (day 28–56)	$<10^{-4}$	$>10^{-4}$

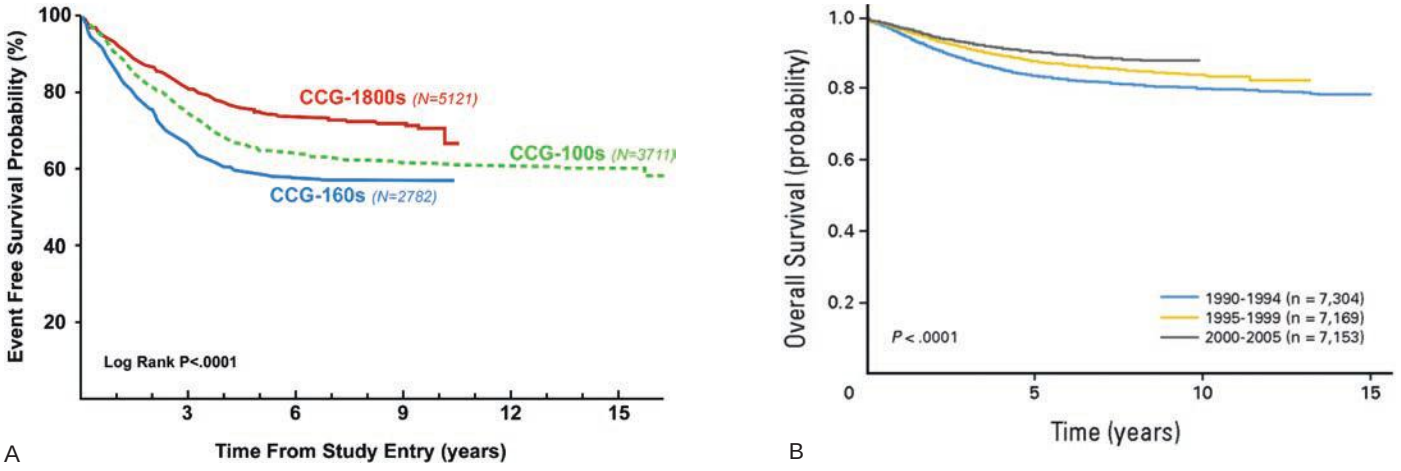

FIGURE 76.3. Survival by treatment era for patients enrolled in Children's Oncology Group trials. A: Earlier trials of Children's Cancer Group: CCG-160s, 1978 to 1983; CCG-100s, 1983 to 1988; CCG-1800s, 1989 to 1985. **B:** Overall survival probability by treatment era for patients enrolled onto Children's Oncology Group trials in 1990–1994, 1995–1999, and 2000–2005. (With permission from Hunger SP, Lu X, Devidas M, et al. Improved Survival for Children and Adolescents With Acute Lymphoblastic Leukemia Between 1990 and 2005: A Report From the Children's Oncology Group. J Clin Oncol 2012; 30:1663–1669.)

The successful intensification of therapy for high-risk ALL has weakened the power of many historically used adverse predictive factors (Fig. 76.4). Although the NCI-Rome criteria represented a major advance in risk classification of childhood ALL, these criteria did not adequately take into account more current biologic features, such as molecular genetic alterations, that likely contribute to the age and presenting WBC count. In addition other powerful predictors of outcome include early response to therapy, as measured by either flow cytometric or polymerase chain reaction methodologies to detect minimal residual disease (MRD). In particular, the strongest predictor of outcome for B-lineage disease across all studies in multivariable analyses is the presence or absence of MRD at the end of the first or second phase of therapy. Indeed, many of the large international consortia have devised complex algorithms to direct therapy, the separate components of which will be presented and then reintegrated into current risk stratification schemes used by the major consortia groups.

Molecular Genetic Alterations Contributing to Modern Risk Stratification

The prognostic significance of various genetic features of leukemic blasts has long been known (Fig. 76.5). In particular, very high risk features for relapse include the presence of the *BCR/ABL*, or Philadelphia chromosome (3% of B-lineage patients), extreme hypodiploidy (less than 44 chromosomes or a DNA index of less than 0.81; 3% of B-lineage patients), and intrachromosomal amplification of 21 (iAMP21; 1% to 3% of B-lineage patients).[45,46,47,48,49,50] Recent analyses of 610 patients with Ph-positive ALL who did not receive tyrosine kinase inhibitor (TKI) therapy and who were treated between 1995 and 2005 revealed improved 7-year overall survival in contrast to those who were treated between 1986 and 1996 (OS 44.9 ± 2.2% vs. 36.0 ± 2.0%, $P = 0.017$).[46] Therapeutic benefit was seen with the use of maximally intensive, myeloablative HSCT. However, the addition of continuous imatinib, a TKI to the backbone of dose-intensive chemotherapy in COG AALL0031 demonstrated for the first time that adding a targeted agent could provide a survival benefit for a disease that was otherwise only optimally treated using HSCT.[45,51] (See Philadelphia chromosome-positive ALL in "Unique Patient Subgroups.")

Similar improvements in outcome have not been established for patients diagnosed with hypodiploid ALL. Identified through either characteristic karyotype findings or DNA indices, rare cases of near-haploid ALL may escape detection due to the presence of a double hypodiploid clone, leading to "masked" near haploidy or hypodiploidy. However, in these cases, one clue may be the retention of two or four copies of chromosome 21, as this chromosome is never lost in a true hypodiploid genome. Experienced cytogenetic review can aid in the identification of these cases. Recent discoveries in the molecular genetics of hypodiploid ALL reveal a high frequency of genes regulating the RAS pathway (*NF1, NRAS, KRAS, PTPN11, FLT3*, and *PAG1*), *IKZF3* (encoding the lymphoid transcription factor), and a histone gene cluster at 6p22 in near haploid ALL (<32 chromosomes), and a similarly high proportion of *TP53*, *RB*, and *IKZF2* mutations in low hypodiploid ALL (32 to 39 chromosomes).[52] Currently, although no specific targeted agents are known directly to inhibit the various perturbed pathways listed above, additional work is being performed in preclinical models in order to further identify optimal therapeutic strategies.

Intrachromosomal amplification of a region on chromosome 21 has also been associated with poor prognosis by several groups, with EFS rates below 60%.[48,49,50] The detection of iAMP21 is relatively easy to distinguish using fluorescence-in-situ hybridization assays which are frequently performed to detect the *ETV6/RUNX1* fusion gene. In these cases, not only is the favorable *ETV6/RUNX1* fusion absent, but ≥5 *RUNX1* (4 or more on a derivative chromosome) signals are present, signifying this amplification.

Although the poor outcomes of infants harboring *MLL* translocations have long been established,[53] the outcomes for older patients have been controversial. Recent data from the COG on the outcomes of 155 patients older than 1 year (2.2% of the entire population studied) reveal that the majority of these patients present with NCI-HR features (4.3% of NCI-HR vs. 1.1% of NCI-SR patients). More than half of the *MLL* rearrangements were t(4;11), and the majority of the remainder were t(11;17) (16%), t:3;11) or t(11;19)(13% each). Although *MLL*-rearranged patients did poorly overall compared with non-*MLL*–rearranged patients, the presence of an *MLL* rearrangement was not statistically significant in a multivariable model. Instead, among *MLL*-rearranged patients who had a rapid response to induction therapy, EFS rates approached 81.1%, considerably better than anticipated. It should be noted, however, that in these clinical trials (AALL0331 and AALL0232), patients with *MLL* rearrangements were treated with maximally intensive augmented BFM therapy, thus illustrating the concept of "treating" away adverse prognostic factors.

Likewise, several leukemic blast genetic factors have been shown to be strong predictors of favorable outcomes among many consortia, including the *ETV6/RUNX1* (formerly *TEL/AML1*) translocation and the presence of trisomy 4 and 10. Fortunately, these are some of the most common genetic features that occur in childhood ALL, with *ETV6/RUNX1* occurring in approximately

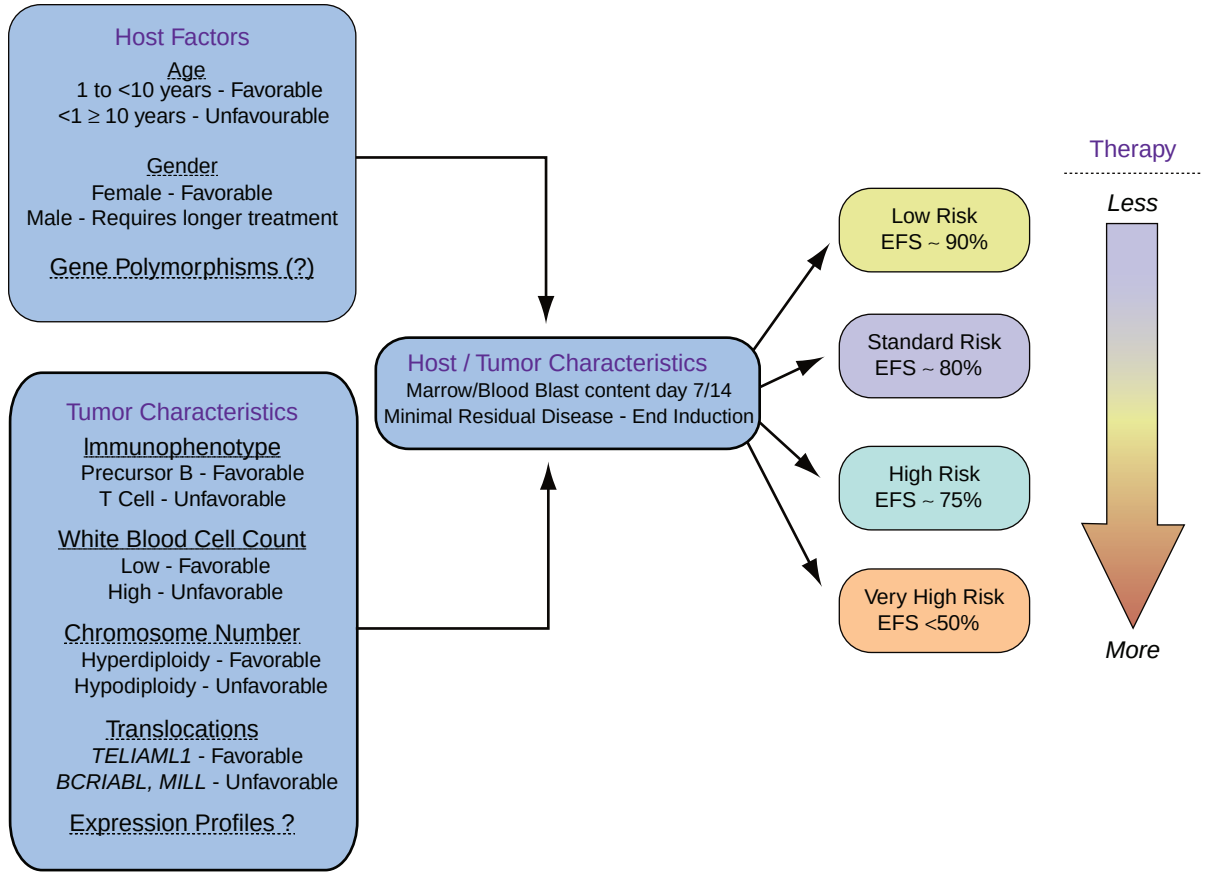

FIGURE 76.4. Risk-group stratification in childhood ALL in 2005. A combination of clinical and biological features along with treatment response was used to select therapy. Children in lower-risk groups received less intensive therapy than those in higher-risk groups. (With permission from Carroll WL, Raetz EA. Building better therapy for children with acute lymphoblastic leukemia. *Cancer Cell* 2005;7:289–291.)

25% and trisomy 4 and 10 occurring in approximately 18% of any risk childhood ALL. Some groups do risk stratify based on the presence of either or both of these factors; however, a multivariate analysis performed on >2,000 COG 9900 patients revealed that double trisomy of 4 and 10 retained independent significance whereas *ETV6/RUNX1* did not. However, among patients with these genetic features and a rapid response to induction therapy within the first week, more than 98% were long-term survivors, leading COG investigators to incorporate response with leukemia-specific genetic factors in their current approaches to risk stratification.

Additional genetic factors that may affect risk stratification and therapy in the future, and are thus beyond the scope of this chapter include those patients who have been recently identified to display a Ph-like gene expression profile (GEP) without harboring *BCR/ABL* (15% of NCI HR patients). These patients frequently harbor genomic rearrangements in *CRLF2* with subsequent overexpression of the TSLP receptor, JAK family mutations, or novel kinase fusion genes. It is important to note that the Ph-like GEP is an independently poor prognostic factor in multivariable analyses when analyzed among NCI HR patients treated on AALL0232, and thus supports identifying alternative approaches, similar to the TKI+ chemotherapy approach used for Ph+ ALL, to maximize outcomes for these patients.[53a]

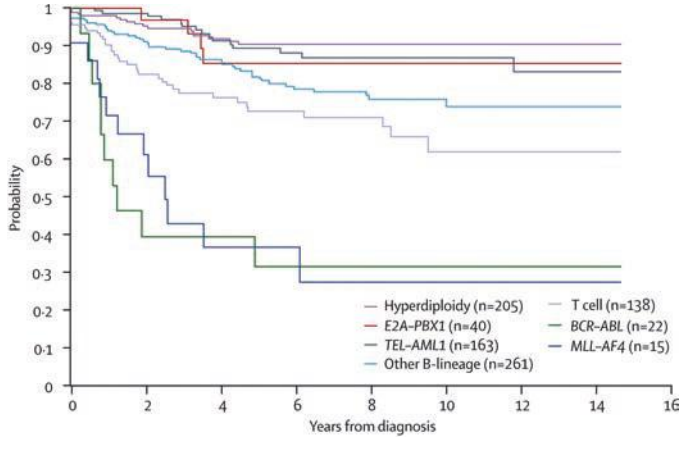

FIGURE 76.5. Kaplan-Meier event-free survival according to biologic subtypes. (With permission from Pui CH, Robison L, Look TA. Acute lymphoblastic leukemia. *Lancet* 2008;371:1030–1043.)

Response to Induction and Minimal Residual Disease

Response to induction has long been valued as a predictor of outcome. In 1983, investigators in the Berlin-Frankfurt-Münster (BFM) group evaluated the use of a 7-day prophase of prednisone and a single dose of intrathecal methotrexate to determine which patients should receive more intensive therapy. Prednisone poor responders (PPR), or those who had more than 1,000 circulating blasts day 8 of therapy, comprised 10% of their population and had an outcome that was 50% as good as the prednisone good responders (PGR). In subsequent protocols beginning in 1986, therapeutic questions were asked of the PPR versus PGR group, and this continues currently. In parallel efforts, the legacy

Children's Cancer Group (CCG) also determined that delivering augmented therapy to those NCI HR patients with a poor bone marrow morphology response (day 7 M2 (5% to 25% blasts by morphology) or M3 (>25% blasts by morphology) improved their outcome.[54]

The technological ability of measuring response to induction using residual blasts grew out of these initial observations. The ability to detect small numbers of leukemic cells in peripheral blood or bone marrow samples from patients in clinical remission by highly sensitive methods such as the polymerase chain reaction[55–59] or multiparametric flow cytometry[60,61,62] has enabled the monitoring of MRD, with the possibility of intensifying therapy for patients at higher risk of relapse. A number of studies have demonstrated the ability to identify impending relapse in subsets of patients, based on correlation of detection of MRD during or following completion of therapy.[55–58,63] Although variations in the sensitivity and specificity of the methods used to detect and to quantify MRD, as well as questions raised by the unexpected finding of persistent genetic abnormalities related to the leukemic clone in patients in apparent sustained remissions[58,64,65] initially delayed the implementation of MRD assessment in patient management, recent studies using improved methodologies have shown that detection of MRD by either multiparametric flow cytometry analysis of leukemia-associated antigens[66,67,68] or polymerase chain reaction detection of leukemia-specific immunoglobulin and T-cell receptor rearrangements[61,69–71,72] definitively correlates with outcome. Indeed, the presence of MRD early in the treatment of ALL patients is highly prognostic of outcome and currently is a key variable to determine the intensity of postinduction therapy for many groups. In the COG 9900 series of clinical trials, end induction bone marrow MRD and day 8 peripheral blood MRD were the most powerful predictors of outcome in a multivariable analysis.[68] It should be noted, however, that MRD is not the sole predictor of outcome in this model; NCI risk group and genetic factors also remain prognostic, thus justifying the current approach that the COG is using in determining risk stratification. Other groups, including the St. Jude Children's Research Group (SJRCH) and the Dana-Farber Cancer Institute (DFCI) incorporate measurements of MRD at the end of induction to intensify patients for additional therapy. Despite MRD being the most powerful predictor of outcome, up to 50% of children who relapse do not have evidence of disease using these sensitive methodologies, implying that additional features, such as critical genetic lesions, affect outcome.

The clinical use of MRD at the end of the first phase of therapy (traditionally deemed "induction") or the second phase of therapy ("consolidation") remains somewhat consortium dependent. In T-cell ALL, the prognostic significance of MRD appears in at least one report to be more powerful at the end of the second phase of therapy than at the end of the first phase.[73]

Finally, outcomes for the small number (<3%) of pediatric patients who fail to attain remission following induction therapy, although predictably poorer than other patients, are not as dismal as might be expected.[74] An intergroup study of 1,041 patients who failed induction reported a 10-year survival of 32±1%. Age ≥10 years, T-cell leukemia, the presence of 11q23 rearrangement, and ≥25% blasts at end of induction had a poor outcome. However, children <6 years of age with precursor B-ALL and without adverse genetics had a 10-year survival at 72±5% when treated with chemotherapy only. Patients with T-cell leukemia had improved survival with allogeneic HSCT.

Current Approaches to Staging/Stratification

Based on the collective information above, the COG has developed a risk-stratification system that incorporates key clinical features including National Cancer Institute (NCI) risk group[75] [Standard Risk (SR): age 1 to 9.99 years and initial WBC count $<50 \times 10^9$/L; High Risk (HR): age 10+ years and/or initial WBC $\geq 50 \times 10^9$/L], immunophenotype, presence/absence of central nervous system or testicular leukemia, presence/absence of specific sentinel genetic lesions [good risk: *ETV6-RUNX1* fusion or hyperdiploidy with trisomies of chromosomes 4 and 10; poor risk: *MLL*-rearrangements (*MLL*-R), hypodiploidy, intrachromosomal amplification of chromosome 21 (iAMP21), Philadelphia chromosome positive (Ph^+) ALL], and early minimal residual disease response for risk stratification and treatment allocation.[51,68,76] The current risk stratification system (AALL08B1) builds on that developed for the first generation COG ALL trials (AALL03B1) with key differences being changing the MRD threshold used to define poor response from ≥0.1% (AALL03B1) to ≥0.01% (AALL08B1), and incorporating day 8 peripheral blood [and day 29 bone marrow (BM)] MRD measurements while eliminating day 8/15 BM morphology[77] (Table 76.3).

TABLE 76.3

OVERVIEW OF THE AALL08B1 CLASSIFICATION SYSTEM FOR B-PRECURSOR ALL

Risk Group (% pts)	Low (15%)	Average[a] (36%)		High[b] (25%)			Very High (25%)			
Projected 5-year EFS	>95%	90–95%		88–90%			<80%			
NCI risk group	SR	SR	SR	SR	SR	HR (<13 years)	SR	HR	HR (≥13 years)	SR or HR
Favorable genetics[c]	Yes	Yes	No	Yes	No	Any	No	Any	Any	Any
Unfavorable Characteristics[d]	No	No	No	No	No	No	No	No	No	Yes
Day 8 PB MRD	<0.01%	≥0.01%	<1%	Any	≥1%	Any	Any	Any	Any	Any
Day 29 BM MRD	<0.01%	<0.01%	<0.01%	≥0.01%	<0.01%	<0.01%	≥0.01%	≥0.01%	<0.01%	Any

BM bone marrow; HR, high risk; MRD, minimal residual disease; PB, peripheral blood; SR, standard risk.
[a]NCI SR patients who are CNS2 may be included in an average risk, but will not be eligible for the low risk arm.
[b]All patients with testicular leukemia will be assigned as HR at start Induction, but may change to VHR if Day 29 MRD ≥0.01% or unfavorable characteristics are present.
[c]"Yes" is defined as the presence of double trisomy 4 and 10 or *ETV6-RUNX1* fusion.
[d]Consists of patients with CNS3, hypodiploidy (<44 chromosomes and/or DNA index <0.81), iAMP21, Induction failure (m3 marrow Day 29), or *MLL* rearrangement (not *MLL* deletion). *BCR-ABL1* positive patients are eligible for a separate Ph^+ ALL study.

TREATMENT

Over successive decades dating back to the 1950s, there has been continued progress in treating children, adolescents, and young adults with newly diagnosed ALL and overall 5-year survival rates now reach 90%.[5] Table 76.4 outlines outcomes from recent trials conducted internationally.[78,79,80,81] The mainstay of treatment is a 2- to 3-year schedule of multiagent chemotherapy generally divided into induction, intensification, and maintenance phases of treatment. An essential component of treatment is presymptomatic CNS therapy and this is accomplished with intrathecal and systemic chemotherapy with the growing trend of limiting the use of cranial irradiation. In recent years improvements in ALL therapy have resulted from further refinements in risk allocation with the successful application of MRD testing and improvements in supportive care. Outcomes have continued to improve as treatment with standard agents is optimized and new targeted therapies are introduced, such as TKIs for the treatment of Ph+ ALL. Ongoing studies by several groups are seeking to further refine elements of ALL therapy including corticosteroid formulation and dosing during induction, frequency of vincristine/steroid pulses in maintenance, the optimal use of asparaginase and methotrexate (MTX) during the intensification phase of treatment, and further reductions in the use of cranial irradiation. The definition of additional high-risk features from emerging genomic discoveries also offers promise for continued improvements in risk stratification in the future. Challenges still remain, however, for several high-risk subgroups, which include the age spectrum of infant and adolescent and young adult (AYA) ALL as well as children with unfavorable blast cytogenetics, induction failures, Down syndrome, T-ALL, and relapsed ALL. As the number of childhood ALL survivors is increasing, several initiatives are also underway to better understand, prevent, and treat sequelae from ALL therapy.

ALL therapy is generally divided into phases, namely, induction, intensification, and maintenance. The goal of induction is hematologic remission, the eradication of all microscopically detectable leukemia with recovery of peripheral neutrophils and platelets. Remission induction in ALL is aided by the availability of three very active drugs with minimal myelotoxicity: vincristine, a glucocorticoid (usually prednisone or dexamethasone), and l-asparaginase [native or "PEGylated" (modified with polyethylene glycol)]. The goal of intensification, or consolidation, is presymptomatic CNS treatment and improvement in the quality of marrow remission. Postinduction intensification has been a productive strategy for enhancing cure rates over the past 30 years. Persistence of detectable MRD after several weeks of intensification is a poor prognostic sign.[71,73,84] The goal of maintenance is the preservation of remission. Childhood ALL is unique in its requirement for prolonged (2 to 3 years) therapy of only modest intensity.

Outcome is usually described in terms of overall survival (OS), EFS, or disease-free survival (DFS). Overall survival is simply the cumulative percentage of living patients, with or without intervening leukemic relapse or second malignant neoplasm. EFS is the cumulative fraction or percentage of patients surviving from time of diagnosis with no intervening adverse event such as failure to achieve remission, death, relapse, or second malignant neoplasm. DFS includes only patients who achieve remission, excluding remission deaths and remission failures, and describes the cumulative fraction or percentage of patients surviving with no intervening adverse event such as remission death, relapse, or second malignant neoplasm. As cure rates have increased, attention has broadened to include late sequelae of therapy that may have a lasting impact on quality of life, such as neurotoxicity, osteonecrosis, anthracycline cardiotoxicity, and secondary malignant neoplasms.[85]

Primary Treatment

Remission Induction

The goal of induction therapy is to rapidly eliminate all leukemia cells using agents with different mechanisms of action. Although the majority of children with ALL will achieve remission with vincristine and a corticosteroid alone, the addition of asparaginase and/or an anthracycline raises the remission induction rate to 98% to 99%.[86] Current practice utilizes 3 to 5 systemic agents in induction over 4 to 6 weeks. The COG and other groups treat children with NCI standard risk ALL with a 3-drug (vincristine, dexamethasone, PEG-asparaginase) induction and reserve the addition of an anthracycline for NCI high risk and T-ALL patients, however, other groups use 4 to 5 drug induction regimens for all patients.[4,79,83,87–89] A 3-drug induction for SR ALL has proven very effective, provided children receive later intensification of therapy.[90] With contemporary supportive care measures, induction death rates from toxicity are typically 1% to 2%.

Corticosteroids are the mainstay of induction regimens and prednisone (PRED) or dexamethasone (DEX) are most commonly

TABLE 76.4

TREATMENT RESULTS FROM SELECTED TRIALS IN CHILDREN WITH ALL

					5-Year Outcome	
Study Group	Years of Study	Patient Numbers	Age Range in Years	% T-ALL	EFS (% ± SE)	OS (% ± SE)

used. Advantages of DEX include better CNS penetration and greater in vitro activity against ALL blasts, and DEX has been used with increasing frequency in recent trials.[91] Compared to historical controls who received PRED, the Dutch ALL VI trial showed 80% versus 66% 3-year EFS advantage for DEX for standard-risk patients.[92] The CCG-1922 study examined the same question in a randomized trial for children with NCI standard risk features and DEX reduced the CNS relapse rate and also was associated with superior EFS at 4 years (88% vs. 81%).[93] A similar advantage for DEX was observed in the MRC ALL-97-99 trial.[94] Based on these results, presently within the COG, DEX is used as the induction steroid as part of a 3-drug induction containing vincristine and PEG-asparaginase for children with standard risk precursor B-cell ALL.

Corticosteroid formulation and dosing have also been studied in NCI high-risk precursor B-cell ALL. The recently completed COG AALL0232 trial compared PRED 60 mg/m^2/day for 28 days to DEX 10 mg/m^2/day for 14 days during induction in patients ages 1 to 30 years and high-dose methotrexate (HD MTX) versus escalating methotrexate plus asparaginase without leucovorin rescue (MTX-ASNase) during interim maintenance. Due to higher than expected rates of osteonecrosis (ON) among 10+ year olds on the DEX arm, the study was amended to restrict the steroid randomization to children <10 years of age. For the patients <10 years, DEX during induction had superior EFS compared to PRED, when combined with high-dose methotrexate during interim maintenance.[95] No benefit of DEX over PRED during induction, however, was observed among patients 10+ years of age and DEX was associated with a much higher risk of ON in the older age group. Based on these results, presently within the COG, DEX is used as the induction steroid for children <10 years of age and high-risk B-cell precursor (BCP) ALL and PRED is used for children and adolescents 10+ years of age within the context of a 4-drug induction also containing daunomycin. Benefits of DEX during induction have also been observed in T-ALL with good initial prednisone responses, where when compared to PRED, DEX during induction was associated with threefold reduction in the incidence of relapse in the AIEOP-BFM 2000 trial.[96]

Some studies, however, have not shown a benefit of DEX compared to PRED.[92,97] A possible explanation for these differences could be related to the DEX to PRED ratio. Studies using a ratio of 1:5 to 1:7 have shown a benefit for DEX whereas those using a DEX to PRED ratio exceeding 1:7 have shown similar outcomes with both formulations.[91] Important concerns have been raised about higher toxicity rates associated with DEX,[98] especially when it is combined with an anthracycline[99,100] however, in the recently completed UKALL 2003 study, DEX at a dose of 6 mg/m^2/day × 28 days was well tolerated within the context of a 4-drug induction.[101]

L-asparaginase is another common element of most induction regimens for ALL that has been used to treat children with ALL since the 1970s. When native L-asparaginase was combined with vincristine and prednisone in early studies, remission induction rates exceeded 90%.[102] Although not considered an essential amino acid, exogenous asparagine is required by lymphoblasts in vivo. Asparaginase, which deaminates asparagine to form aspartate, is unique among anticancer drugs in that it requires neither activation nor intracellular uptake.

Three different formulations of asparaginase have mainly been used to date: native *Escherichia coli* L-asparaginase, polyethylene glycol conjugated *Escherichia coli* L-asparaginase (PEG-asparaginase), and *Erwinia chrysanthemi* L-asparaginase[103] and newer formulations are in clinical development. PEG-asparaginase is now used most often in children with ALL and advantages of this formulation include its long half-life, which allows less frequent dosing and reduced immunogenicity.[104,105] PEG-asparaginase during induction was also associated with more rapid early blast clearance on days 7 and 14 when compared to native *Escherichia coli* L-asparaginase.[104] For individuals who develop hypersensitivity to PEG-asparaginase, *Erwinia chrysanthemi* L-asparaginase is recommended as an alternative, although its half-life is much shorter than that of PEG-asparaginase (0.65 ± 0.13 vs. 5.73 ± 3.24 days),[103] so more frequent administration is required.[106]

Although some patients can be re-treated successfully with PEG-asparaginase with premedication after mild allergic reactions, this is generally not recommended because it can mask the presence of neutralizing antibodies, which reduce asparaginase activity.[107] Historically, asparaginase preparations were all administered intramuscularly due to concerns about the risk for anaphylaxis; however, PEG-asparaginase is now routinely administered intravenously and this has been well tolerated and not associated with greater toxicities.[108]

Response and Outcome

The rapidity of response to chemotherapy during induction, whether measured by routine morphologic assessment or by flow-cytometry–based or molecular MRD techniques, is a robust predictor of outcome as it takes into account all aspects of the treatment as well as the unique biologic features of the host and the disease. In any clinical or cytogenetic patient subset, slower initial response to treatment, whether it be the persistence of peripheral blood blasts following intrathecal MTX and a week of prednisone, or marrow blasts >5% by light microscopy after 1 or 2 weeks of multiagent induction therapy, or persistence of marrow blasts by multiparameter flow cytometry or PCR on completion of 4 weeks of induction therapy, predicts an inferior outcome compared to more rapid initial responses[61,68,84,109–113] End-induction bone marrow MRD was shown to be the most important prognostic variable in multivariate analysis for precursor B-cell ALL in recently completed COG protocols,[68] and peripheral blood MRD 1 week after initiation of therapy is now replacing bone marrow aspirates for early response determination in the newest COG ALL protocols.

Since the benefit of intensifying postinduction therapy for slow early morphologic responses or persistent MRD has been demonstrated,[4,54] response-based treatment allocation is a common feature of most contemporary ALL protocols. Within the COG, all children with precursor B-cell who have end induction (day 29) MRD >0.01% using flow-cytometry–based assays are designated very high risk and receive intensified augmented BFM-based therapy postinduction and similar strategies are used by other groups. Failure to achieve marrow remission, that is, marrow blasts <5% by microscopy, portends a poor outcome. About two thirds of patients with induction failure eventually achieve remission, and of these, about one third are cured.[74] Somewhat better outcomes may be obtained for some patient subsets with induction failures, such as patients with T-ALL, with HSCT in first remission, whereas as others with low-risk features fare just as well with chemotherapy alone.[74,114,115]

Presymptomatic Central Nervous System Therapy

Presymptomatic treatment of the CNS has been established as an essential component of effective ALL therapy for decades. Between 1967 and 1968, in Study Total V, Pinkel et al. at St. Jude Children's Research Hospital treated 31 children with no evidence of CNS leukemia at diagnosis with 24 Gy cranial irradiation and intrathecal methotrexate. Only three patients had a subsequent CNS relapse, and more than half of patients were long-term disease-free survivors. Between 1968 and 1971, in Study Total VI, Pinkel et al. compared 24 Gy cranial–spinal irradiation with no CNS-directed intrathecal methotrexate and confirmed the results of Total V. In Study Total VII, similar benefit was shown for 24 Gy cranial–spinal irradiation and 24 Gy cranial irradiation

with intrathecal methotrexate. In striking contrast to all previous experience, one half of patients remained long-term disease-free survivors.[116,117]

Since this time, efforts have been underway worldwide to define optimal CNS preventative therapy. Current CNS treatment modalities include cranial or craniospinal irradiation, systemic chemotherapy (e.g., dexamethasone, methotrexate and asparaginase), and intrathecal chemotherapy with any combination of 1 to 3 agents. As concerns about the long-term sequelae from radiation therapy have increased, there has been a growing trend to reduce both the dose and the number of children who receive this treatment modality, such that cranial radiation therapy (CRT) is often reserved for just those at highest risk for CNS relapse, for example, children with T-ALL and high-risk features, those with slow initial responses, or CNS leukemia (CNS3) at diagnosis. Some groups have eliminated CRT altogether for all children with ALL without any decline in outcomes, using regimens with triple intrathecal chemotherapy, dexamethasone, and intermediate- or high-dose methotrexate.[4,82]

Historically within the COG, the CCG 161 trial showed that intrathecal therapy extended through the 2- to 3-year duration of systemic therapy could replace cranial irradiation and limited intrathecal therapy for lower-risk patients, age 2 to 10 years with WBC $<10 \times 10^9$/L.[118] The CCG 105 trial extended this observation to intermediate-risk children between the ages of 1 and 9 with WBC between 10 and 50×10^9/L, but only when patients received intensified systemic therapy.[119] With only less intensive, "standard" systemic therapy, cranial irradiation and limited intrathecal therapy were superior to extended intrathecal methotrexate with no irradiation. In CCG 1882, higher-risk patients, either >10 years of age or with WBC $>50 \times 10^9$/L, with a rapid initial response to induction therapy, received either 18 Gy cranial irradiation and extended intrathecal methotrexate or additional intrathecal methotrexate with no whole-brain irradiation. All received intensive systemic therapy. The cumulative incidence of isolated CNS relapse was 3.6% for patients not receiving cranial irradiation and 2.3% for patients receiving cranial irradiation.[54] However, patients receiving additional intrathecal methotrexate had numerically fewer bone marrow relapses, and DFS was similar. Thus, in the presence of effective systemic therapy, cranial irradiation could also be replaced with aggressive intrathecal methotrexate for this largely precursor B-cell ALL population.[54] When this approach was extended to T-cell ALL patients in CCG 1961, isolated CNS relapse comprised two thirds of initial relapses in the superior "stronger" intensification arms.[120] An ongoing COG trial has modified the dose of prophylactic radiation in T-ALL according to risk groups: none for low-risk, 12 Gy for intermediate-risk, and 18 Gy for high-risk disease and future reductions in radiation therapy in T-ALL are planned within the COG with optimization of systemic chemotherapy and IT therapy, so that is envisioned that cranial irradiation will be used only for the 10% to 15% or fewer children with T-ALL and high-risk features or CNS disease in the future.

Triple intrathecal therapy with cytarabine, methotrexate, and hydrocortisone (ITT) has also been compared to single-agent IT MTX for prevention of CNS leukemia. Matloub et al. reported a randomized comparison of ITT and single-agent methotrexate therapy with more than 2,000 randomized patients.[121] Although ITT halved the CNS relapse rate, EFS was similar at 5 years, and survival was actually significantly worse because of inferior salvage after bone marrow relapse, which occurred disproportionately in the ITT arm.

In a recent meta-analysis of patients treated on 47 trials with different comparisons of presymptomatic CNS therapy, effective systemic and protracted intrathecal chemotherapy was shown to yield comparable outcomes to that of CRT.[122] The addition of IV methotrexate was shown to provide additional benefit, reducing rates of both CNS and non-CNS relapse. Although historically CRT provided a benefit with less intensive systemic regimens and few doses of IT therapy, the benefit has not been observed with more contemporary regimens. Furthermore, several comparisons of different doses of cranial radiation showed no benefit from higher doses of CRT.

Traumatic lumbar punctures (>10 RBCs/μl) with blasts (TLP+) have been associated with inferior outcomes.[123,124] Therefore it is important that all possible measures be taken to reduce the risk of bleeding with the initial diagnostic lumbar puncture. The presence of blasts in the CSF but fewer than 5 WBC/μl (CNS2) has been linked to a higher risk of CNS relapse by some, but not all, groups.[37] Some groups have intensified CNS-directed therapy for CNS2 status and/or traumatic lumbar punctures; however, the COG historically has not and this will allow the prognostic significance of CNS status to be examined within the context of improved systemic chemotherapy on current protocols.

Postinduction Intensification

Postinduction intensification is essential for all patients with ALL; however, there is not a consensus on an optimal regimen or duration of therapy.[86] Intensification with methotrexate has been a strategy that has been commonly employed and the optimal dose, formulation, and schedule of methotrexate have been studied by several groups internationally over the past decades.[125–138] The recently completed COG study, CCG-1991, showed a benefit for escalating IV methotrexate without leucovorin rescue compared to oral methotrexate during interim maintenance in standard risk precursor B-cell ALL. The COG recently completed a phase III trial for newly diagnosed NCI high-risk precursor B-cell ALL, which demonstrated the benefit of high-dose MTX (HD-MTX), compared to escalating MTX and asparaginase without leucovorin rescue in this group.[139] This HD-MTX schedule has been used widely in frontline ALL for many years by groups worldwide.[140,141] HD-MTX has also been commonly used in children with T-ALL[142] and comparison of HD-MTX versus escalating MTX and asparaginase during interim maintenance is also presently underway within the COG in pediatric patients with newly diagnosed T-ALL. Individualized MTX dosing has been pursued by investigators at SJCRH in an effort to achieve optimal steady-state plasma concentrations and minimize toxicity.[86] Acute neurologic toxicity has been acceptable and studies are underway to examine late neuropsychological outcomes in patients who receive more intensive systemic MTX therapy.

Asparaginase is another essential element of most ALL intensification regimens and there is extensive clinical experience supporting its use in B- and T-lineage ALL. Since the 1970s, the Dana-Farber Cancer Institute and ALL Consortium has included 20 to 30 consecutive weeks of asparaginase during postinduction consolidation therapy and has demonstrated that this treatment significantly improves long-term EFS.[143]

The DFCI 91-01 showed superior outcomes for patients receiving at least 26 weeks of continuous asparaginase therapy compared to those who received less with 5-year EFS 90% versus 73%, $P = 0.01$, respectively.[144] A similar advantage in disease-free survival was observed in the International BFM Study Group when children with standard-risk ALL were randomized to receive 20 weekly doses of asparaginase.[145] DFCI studies have also compared different asparaginase formulations and the 95-01 trial showed an outcome benefit for weekly native *E. Coli* asparaginase when compared to weekly *Erwinia* asparaginase, postinduction, perhaps secondary to the shorter half-life of the latter drug.[146] A trial comparing IV PEG-asparaginase with native *E. Coli* asparaginase was recently completed with analyses of the toxicity profiles and outcomes underway.[89] Children with low-risk B-lineage ALL (*ETV6-RUNX1* translocations or triple trisomies present with rapid early responses) were randomized to receive 4 additional doses of PEG-asparaginase postinduction in the COG

AALL0331 trial based on in vitro data showing blasts with these features are more sensitive to asparaginase. Analyses of the outcomes of these patients are underway.

Current lines of investigation in optimizing asparaginase therapy include developing measures to detect the presence of neutralizing antibodies that reduce drug activity ("silent inactivation"), further studies to determine the most effective dose and schedule, and measures to reduce the incidence of dose limiting toxicities, the most common of which are hypersensitivity reactions.[147,148]

Most contemporary ALL protocols also include a delayed intensification phase based on BFM therapy and this has been shown to be beneficial for all patient subgroups. In 1970, investigators from the BFM group introduced a 3-month intensive induction/early intensification phase called Protocol I, which followed a VPLD induction with a segment including cyclophosphamide, cytosine arabinoside, and 6-MP.[149] In 1976, a second intensification phase, Protocol II, was added that included a reinduction segment of vincristine, dexamethasone, l-asparaginase, and doxorubicin followed by a segment including cyclophosphamide, cytosine arabinoside, and 6-thioguanine. Outcomes improved compared to historical controls, and advantages were most striking for higher-risk patients. EFS was similar whether Protocol II followed immediately after Protocol I or after 2 months' delay. Morbidity was less when intensification was delayed.[150] In the United States, Protocol II was termed "delayed intensification," and a series of studies conducted in the 1980s and early 1990s established the benefit of delayed intensification therapy for both SR and HR subgroups of patients (Fig. 76.6).[90,149,151–154]

A further CCG modification of this therapy, the "augmented regimen," posited that more resistant cells responsible for relapse might need a stronger and more prolonged postinduction intensification. The augmented regimen provided two applications of delayed intensification and four 2-week courses of nonmyelosuppressive vincristine and l-asparaginase during the periods of myelosuppression that invariably follow the cyclophosphamide, cytosine arabinoside, and thiopurine pulses in consolidation (Protocol Ib) and reconsolidation (Protocol IIb). Two courses of five Capizzi I pulses[155,156] of vincristine, parenteral methotrexate, and l-asparaginase replace the two 2-month courses of oral 6-MP and MTX between consolidation and delayed intensification #1 and between delayed intensification #1 and delayed intensification #2. High-risk patients treated on the CCG-1882 trial with a poor initial response to therapy (i.e., >25% marrow blasts on day 7) were randomized to receive standard or augmented BFM therapy. At 5 years, DFS was 75% for the augmented regimen and 55% for standard intensive therapy (Fig. 76.7).[54]

In order to assess individual components of intensification approaches, CCG-1961 utilized a 2 × 2 factorial design to compare standard versus augmented BFM-based postinduction therapy as well as standard (1 IM and 1 DI phase) versus increased duration (2 IM and 2 DI phases) in patients with rapid initial responses. Augmented therapy improved 5-year EFS (81% vs. 72%, $P < 0.001$; Fig. 76.8) and survival (89% vs. 83%, $P = 0.003$).[120] However, longer intensification with a second IM and DI produced no benefit over standard duration with a single IM and DI in rapid responders. The authors suggested there is a window of opportunity to eradicate resistant clones with intensification, but additional intensification was not successful because of drug-resistant disease. A second DI phase also provided no benefit to SR patients who were rapid responders on the CCG 1991 trial[88] and the recently completed COG AALL0331 trial for standard-risk precursor B-cell ALL is testing whether augmented BFM-based consolidation is beneficial in this population. Replacing oral MTX, 6-MP, vincristine, and DEX during interim maintenance with vincristine and escalating intravenous MTX improved EFS in CCG 1991.[88] (Fig. 76.9)

Maintenance Therapy

Daily oral 6-MP and weekly oral or parenteral MTX, with or without pulses of steroid and vincristine, with an extended periodic intrathecal therapy comprise the most common maintenance or continuation regimens. Oral 6-thioguanine (TG) is a more potent thiopurine than mercaptopurine,[157,158] which has provided the rationale for prior randomized trials comparing the efficacy of MP and TG. The MRC ALL97 trial concluded that TG caused excess toxicity without overall benefit.[159] Children were randomly assigned to either TG or MP during interim maintenance and maintenance therapy and after a median follow-up of 6 years, no differences in EFS or OS were observed. TG conferred a lower risk of isolated CNS disease, however, this was offset by hepatic toxicity. The CCG-1952 trial showed an improvement if EFS in children with standard risk ALL who received TG, however, there was no increase in overall survival and TG-induced veno-occlusive disease of the liver precluded prolonged administration of TG during maintenance.[160] A recent meta-analysis of randomized

trials comparing thiopurines also showed that TG did not improve overall EFS, although it may be beneficial in some subsets of patients.[161] Given these data, and hepatic toxicity that has been observed with TG, it is now standard practice to use daily oral MP in maintenance.

Interpatient variations in MP absorption are well known.[162] An association between levels of erythrocyte TG nucleotides and freedom from relapse has been shown.[163] This observation encouraged attempts to improve outcome by enhancing intracellular TG nucleotide accumulation. Strategies include replacement of oral MP by parenteral MP[93,164] or by oral or parenteral TG.[157,158] Tailoring doses of 6-MP and methotrexate has been associated with improved outcomes and ascertaining the genetic polymorphism status of thiopurine methyltransferase helps in that regard.[86] A number of randomized outcome comparisons have

been undertaken. Thus far, intravenous 6-MP has provided no clinical advantage over oral MP in any study.[93,164]

Most maintenance therapy is continued until children receive a minimum of 2 years of therapy from the time remission is achieved. Although in some groups, such as the COG, treatment for boys is 1 year longer than girls, in most other groups, the duration of maintenance therapy is the same among both genders. Inferior outcomes have been noted when the treatment duration has been shortened to 18 months; however, no benefit to extending maintenance therapy beyond 3 years has been observed. Despite effective postinduction intensification, the BFM Group found that 18 months of treatment was inferior to 24 months (83% vs. 77%).[149] The Childhood ALL Collaborative Group compiled 16 randomized trials that compared shorter and longer therapy in a meta-analysis that included 3,861 patients.[165] Longer therapy provided a small but statistically significant 3.3 percentage-point improvement in EFS and a statistically not significant 0.8 percentage-point improvement in survival. An advantage for longer therapy was found in the 24- versus 18-month and 36- versus 24-month comparisons, but not in the 60- versus 36-month comparisons. Longer therapy provided statistically significant reductions in bone marrow relapse (26%) and testicular relapse (36%), but patients on longer therapy were more likely to die in remission (2.7% vs. 1.2%). Contrary to popular memory, boys and girls derived a similar small benefit from longer therapy. Of course, this type of analysis cannot determine the value of duration of continuation therapy in regimens not studied, but cross-study consistency lends weight to its conclusions. The debate continues as to whether more effective postinduction intensification will allow briefer maintenance therapy or, conversely, will add value to longer therapy as more patients are brought to 24 months in remission. Optimal duration of therapy may differ among subsets, being more important in standard-risk patients and less important in older or T-cell patients.

Vincristine and corticosteroid pulses are a component of maintenance therapy in many ALL protocols; however, the benefit of these pulses is controversial within the context of contemporary, more intensive therapy. Furthermore, there has been growing concern about the potential toxicities of pulse therapy including ON, mood disturbances adversely affecting quality of life, obesity, and peripheral neuropathy. Although studies from earlier treatment eras have shown a benefit for vincristine/corticosteroid pulses in maintenance,[118] a more recent review involving more than 5,000 children with ALL has called the benefit of pulse therapy into question with current regimens where early therapy has been intensified.[166] In a recent multicenter randomized trial in children treated with a BFM-based regimen for intermediate risk ALL, no benefit for the addition of 6 pulses of vincristine and dexamethasone during maintenance therapy was observed.[167] Among younger children, when pulses are used in maintenance therapy, DEX is preferred over PRED due to the outcome benefits that have been reported.[93,94] PRED is used during maintenance among older patients in some groups due to the concerns for a heightened risk of ON with DEX.[168] The COG is currently investigating the use of less frequent vincristine/corticosteroid pulses (every 12 weeks vs. every 4 weeks) during maintenance in children with standard risk ALL on the AALL0932 protocol.

Variations in the common continuation therapy program are found in the DFCI studies,[169–171] the NY I and NY II protocols,[172,173] and Brazilian[174] and Japanese studies.[134] The Japanese Children's Cancer and Leukemia Study Group compared MP 175 mg/m^2/day days 0 to 4 and intravenous methotrexate 225 mg/m^2 day 14 with daily oral MP 50 mg/m^2 and weekly oral methotrexate 20 mg/m^2. All patients received vincristine and prednisone pulses every 4 weeks and intrathecal methotrexate every 12 weeks. The 5-year EFS was 73% for the intermittent alternating regimen and 50% for the conventional regimen. The conventional regimen had more infections and late marrow, CNS,

and testicular relapses.[134] The Brazilian Childhood Cooperative Group protocol ALL-99 compared standard daily versus intermittent dosing of methotrexate and MP in children with low-risk ALL and found less toxicity with the intermittent schedule and significant improvement in EFS among boys with the intermittent regimen (85.7% ± 4.3% vs. 74.9% ± 4.6%; $P = 0.027$).[174]

Unique Patient Subgroups

Philadelphia Chromosome Positive (Ph+) ALL

Prior to the advent of TKI therapy, outcomes for children, adolescents, and young adults with Ph+ ALL were poor with fewer than half of patients surviving[46,175] despite intensive treatment strategies that often included allogeneic stem cell transplant (SCT) in CR1. The COG AALL0031 study introduced imatinib in combination with an intensive chemotherapy platform and the regimen was well tolerated and patients treated with continuous imatinib (340 mg/m^2/day) therapy had a 3-year EFS of 80% versus 35% ($P < 0.0001$) for historical controls treated in the pre-TKI era.[45] The COG successor trial, AALL0622, replaced imatinib with the more potent TKI, dasatinib (60 mg/m^2/day), and further established the safety of combing a TKI with an intensive chemotherapy platform.[176] In efforts to facilitate the study of small ALL subsets, a transatlantic collaboration is now underway with the European EsPhALL group investigating dasatinib in combination with chemotherapy (COG AALL1122). The results of these more recent trials with dasatinib remain to be determined; however, if the promising results achieved with imatinib are observed, SCT may have a more limited role for patients with Ph+ ALL in the future and TKI therapy in combination chemotherapy may be applicable to other high-risk subsets with altered kinase signaling.

T-ALL

T-cell lymphoid malignancies have distinct biochemical, immunologic, and clinical features that distinguish them from B lymphoid malignancies. Historically, the diagnosis of T-ALL portended a worse prognosis than precursor B-cell ALL; however, over the past three decades, the introduction of intensive, high-dose, multiagent pulse chemotherapy has improved the EFS for patients with T-ALL such that outcomes are now comparable to those of children with high-risk B-lineage ALL.[146,177] Intensive therapy is important for all patients with T-ALL as children with NCI standard risk T-ALL have had inferior outcomes when they were treated with standard risk therapy on the CCG 1952 study.[178] Based on these findings, it is now standard practice for children with both NCI SR and HR T-ALL to receive more intensified treatment with a 4-drug induction and augmented postinduction therapy.

The role of high-dose methotrexate (HD-MTX) has been evaluated in T-ALL and in the recently completed POG9404 study patients were randomized to receive HD-MTX (5 g/m^2 at weeks 4, 7, 10, and 13) within the context of a regimen containing intensive asparaginase, doxorubicin, and cranial irradiation. Patients who received HD-MTX had 5-year and 10-year EFS that was significantly better than those who did not receive HD-MTX (5 years: 79.5% ± 3.4%, 10 years: 77.3% ± 5.3%) versus no HD-MTX (5 years: 67.5% ± 3.9%, 10 years: 66.0% ±6.6%; $P = 0.047$).[142]

Another agent, which has been studied in children with T-ALL, is nelarabine, a prodrug of Ara-G, which is uniquely cytotoxic to T-lymphoblasts. Based on its differential effect in T-ALL blasts and promising results in early phase trials for refractory/relapsed disease, nelarabine was added to traditional chemotherapy in children with T-ALL and high-risk features. Combination therapy was acceptably tolerated[44] and this therapy is now being tested in the randomized phase III COG trial AALL0434 in pediatric patients with newly diagnosed intermediate- and high-risk T-ALL.

The overall outcomes for pediatric patients with T-ALL have improved; however, there are subsets of patients who have not fared well, such as those with the persistence of MRD at day 78 (time point 2) of therapy.[73] A recently described immunophenotype in T-ALL is the "early thymocyte precursor (ETP)," where T-cells retain stem cell-like features. The ETP phenotype has been associated with inferior responses to induction therapy and outcomes; children with this T-ALL phenotype might be candidates for novel therapy in the future.[179]

Adolescents and Young Adults with Acute Lymphoblastic Leukemia

Although improvements in outcome for adolescents and young adults, 16+ years of age, with ALL have been observed, they still lag behind those in younger in children. AYAs had a fourfold higher relative risk of death from their disease compared to younger children in recent generations of COG ALL protocols.[5] Treatment approaches for this group of patients have varied as they seek care at both adult and pediatric centers. Several clinical trials have demonstrated that treatment with pediatric protocols, which utilize high cumulative doses of vincristine, corticosteroids, and asparaginase, particularly during periods of myelosuppression, significantly improves outcomes in this population.[5,180,181–183]

In examining AYA outcomes on recently completed pediatric trials, where enrollment commonly spans into young adulthood, the 5-year EFS of AYA patients (ages 16 to 21 years) who achieved rapid initial responses to therapy was 81.8% (SE 5.4%) on augmented arms of the recently completed COG study, CCG-1961 for National Cancer Institute (NCI) high-risk (HR) ALL.[182] Similarly, SJCRH evaluated the outcomes of older adolescents (ages 15–18) on four recent ALL studies (XIIIA, XIIIB, XIV, and XV), and the 5-year EFS for AYA patients on study XV was 86.4% ± 5.2% compared to 87.4% ± 1.7% in younger patients ($P = 0.61$).[183]

In addition to examining the outcomes for AYA patients on pediatric treatment protocols, several retrospective comparisons of AYA outcomes on pediatric versus adult protocols have been undertaken and the vast majority have found a significant advantage for a pediatric approach.[184–186,187] The largest of these studies was a retrospective comparison of 124 patients ages 16 to 20 years enrolled on Cancer and Acute Leukemia Group B (CALGB) ALL trials from 1988 to 2001, to 197 patients ages 16 to 20 years enrolled on COG ALL studies from 1989 to 1995.[187] Both cooperative groups utilized BFM-based chemotherapy regimens. The rates of CR were similar; however, 7-year EFS was significantly better for the patients treated on COG studies (63%, CI 55% to 72%) compared to those treated on CALGB trials (34%, CI 24% to 44%; $P < 0.001$). Several adult centers have utilized pediatric regimens, including a collaborative cooperative group clinical trial involving CALGB, the Eastern Cooperative Oncology Group and Southwest Oncology Group (C-10403; NCT00558519), which was recently completed. Patients with newly diagnosed ALL, ages 16 to 39 years are treated according to the standard arm of the recently completed COG study AALL0232 in the study and this will provide additional insight into outcomes for this unique subset of patients. Current COG frontline ALL trials also accrue AYAs up to 30 years of age.

Infants with Acute Lymphoblastic Leukemia

Infants 12 months of age or younger may present with a constellation of features that portend an unfavorable outcome and this group of patients routinely receives separate treatment regimens that are tailored to their unique features. They are more likely to have hyperleukocytosis, massive hepatosplenomegaly, CNS involvement, chromosomal rearrangements involving *MLL*, and a slow response to induction therapy.[56] Historically, infants with

ALL have inferior outcomes with 4-year EFS rates of 47% on the largest recent trial.[188] Infants with ALL are susceptible to toxicity, especially those <90 days of age at diagnosis. To address these challenges, many groups have recommended that infants with ALL now receive an induction regimen tailored for age with enhanced and aggressive supportive care measures. The FLT3 tyrosine kinase has been shown to be highly expressed in *MLL*-rearranged infant ALL[189] and the addition of the FLT3 inhibitor lestaurtinib, is also being studied in combination with chemotherapy in an ongoing COG trial.[190] The role of allo-HSCT has been debated for infants with ALL as larger analyses have not shown an overall benefit for this strategy but recent data indicate that it may prove beneficial for a subgroup of patients.[188,191,192]

Children with Down Syndrome and Acute Lymphoblastic Leukemia

Down syndrome is the most common genetic risk factor for childhood ALL.[193] Children in whom ALL is associated with Down syndrome have a significantly lower rate of remission, a higher mortality rate during the induction phase, and a poorer long-term survival rate in many studies[194–198,199] in contrast to children with AML and Down syndrome.[200] The adverse influence of Down syndrome may be explained in part by a greater incidence of toxicity related to intensive treatment,[195,197,201] in part by the absence of favorable biologic features such as the *ETV6-RUNX1* fusion and hyperdiploidly, as well as a particularly high incidence of Janus kinase (*JAK2*) mutations and increased expression of the cytokine receptor *CRLF2*.[193,202,203,204,205] Intensification of therapy abrogates the adverse affect of Down syndrome in some studies, but it is attended by greater serious toxicity.[201,206] Given the unique toxicity profile in children with Down syndrome in ALL, the COG has modified therapy and implemented aggressive supportive care for this unique subset of patients.[207]

Treatment after Relapse

Despite the advances made with intensive and risk-stratified treatment regimens for childhood ALL, approximately 20% of patients will relapse. Most relapses occur during treatment or within the first 2 years off therapy, although late relapses have been reported many years after diagnosis. Because of the high incidence of ALL among pediatric malignancies, the number of children with relapsed acute leukemia equals or exceeds the incidence of most other pediatric tumors.[208] In contrast to the success of frontline ALL therapy, outcomes for children with relapsed disease remain suboptimal. Although many patients achieve subsequent remission, long-term survival rates for patients with first marrow relapse of ALL range from 20% to 40%, even with the use of intensive chemotherapy and allogeneic stem cell transplantation.[209,210,211] Analysis of outcomes for patients who relapsed after treatment on frontline CCG studies did not show any differences in survival after relapse for patients treated on CCG trials between 1983 and 1989 and those treated from 1988 to 2002.[212] As a result, despite the fact that 80% of children with ALL will be cured with frontline therapy, more children die from ALL than are diagnosed with non-Hodgkin lymphoma, Wilms tumor, Hodgkin lymphoma, CNS primitive neuroectodermal tumor, AML, and rhabdomyosarcoma.[213]

Population-based data from the Nordic consortium capturing 100% of children age 1 to 15 years diagnosed with ALL from 1981 to 2001 found that 854 of 3,356 children (25%) had a first relapse.[214] 776 patients (90.8%) achieved second remission of whom 29% underwent allogeneic HSCT with overall survival 46% at 10 years, and 71% received ongoing chemotherapy with OS 39% at 10 years. The toxic death rate in CR2 was 19% and 50% of patients experienced a second relapse, demonstrating that lack of disease control is the major cause of failure despite achievement of second remission. Of 274 patients with a second relapse of ALL, 72% achieved a third remission although long-term survival was dismal (12% at 20 years). A retrospective review of 313 children with relapsed ALL treated at institutions in the TACL (Therapeutic Advances in Childhood Leukemia) consortium from 1995 to 2004 found that patients with a second marrow relapse had a complete remission rate of only 44% with 15% 5-year disease-free survival.[215]

Multiple childhood cancer cooperative groups have evaluated cohorts of patients with relapsed ALL to identify prognostic factors for outcome after relapse. On CCG trials from 1983 to 1989, the strongest predictor of prolonged survival after relapse was an initial time to first relapse ≥36 months.[216] More recently, Nguyen and colleagues reported the outcomes of 9,585 patients with newly diagnosed ALL treated on CCG protocols from 1988 to 2002, of whom 1,961 relapsed (20.5%).[212] The most common sites of relapse were isolated bone marrow (57%), isolated CNS (20.9%), concurrent marrow and extramedullary (13.5%), isolated testicular (5.3), and other extramedullary (3.1%). Rare extramedullary sites include isolated leukemic infiltration of the lymph nodes, eyes, and bone.[216–218] Clinical features at the time of initial ALL diagnosis that correlated with increased risk of relapse included age <1 year or ≥10 years, male gender, initial WBC $>100 \times 10^9$/L, African American or Hispanic ethnicity and slow early response to induction therapy. Features associated with survival after relapse include site of relapse, with 5-year OS 59% for those with isolated CNS relapse compared to 24% for isolated marrow relapse and 39% for concurrent marrow and extramedullary relapse. Time to relapse, or duration of first remission, is also a critical feature, with patients with early (<18 months from initial diagnosis) or intermediate (18 to 36 months) relapses faring more poorly than those with late relapse >36 months from initial diagnosis. Among patients with marrow relapse within 36 months from initial diagnosis, long-term survival is rare (below 10%) despite intensive chemotherapy and use of HSCT.[208] Indeed, among patients treated on CCG protocols, 5-year survival for isolated early marrow relapse was 11.5% compared to 18.4% for intermediate, and 43.5% for patients with late marrow relapse. Notably, patients with late isolated extramedullary relapse fared the best, with 5-year survival 78% (isolated CNS), 60% (isolated testicular), and 85% (isolated other extramedullary ± CNS).[212] Other factors that were significant predictors of survival postrelapse included T-cell immunophenotypes, age <1 year or >10 years at the time of initial diagnosis, history of CNS disease, NCI high-risk features at the time of initial diagnosis, and male gender.

Other groups have confirmed the importance of time to relapse and site of relapse[211,219] as well as T-cell immunophenotype. (220) As a result, cooperative group trials for first relapse of ALL risk stratify patients based on these features, allocating patients with favorable features (e.g., late isolated CNS relapse of pre-B ALL) to chemotherapy and CNS radiation, whereas those with unfavorable features are planned to undergo allogeneic HSCT in second remission. The evaluation of minimal residual disease (MRD) following reinduction chemotherapy for relapse has been found to influence prognosis, with those patients with negative (<0.01%) or low-level MRD (<0.1%) having improved outcomes. On the COG AALL01P2 trial of a combination chemotherapy regimen for first marrow relapse, 96% of the pre-B patients with late relapses achieved CR2 after the first block of treatment, although 51% of those had MRD > 0.01%. For those with early marrow relapse of pre-B ALL, the CR2 rate was 68% with 75% of those achieving remission having MRD > 0.01%. The presence of MRD > 0.01% at the end of reinduction block 1 was predictive of 12-month EFS for both early and late relapses. Outcome for the small subgroup of patients with relapsed T-ALL was dismal with 5 of 7 failing to achieve CR2 and no survivors beyond 10 months from relapse.[221] Other investigators have demonstrated the prognostic significance

of MRD prior to HSCT,[222] and it is currently being incorporated into risk classification schemes in clinical trials for relapsed disease.[223,224,225]

Most risk stratification strategies for relapsed ALL do not incorporate cytogenetic features that do not represent currently druggable targets (e.g., hypodiploidy, *MLL* rearrangement, *ETV6-RUNX1* fusion). Some patients with *ETV6-RUNX1* translocations with late bone marrow relapses have been found to have novel deletions of the nontranslocated *ETV6* gene at the time of relapse compared to original diagnosis, suggesting that some of these "relapses" are actually second de novo leukemias that might be treated with conventional frontline chemotherapy.[226,227] In addition, novel molecular predictors of inferior outcome after relapse are emerging, including *IKZF1* deletion and alteration of *TP53*, which in the future may further refine risk stratification.[228]

Treatment of Marrow Relapse

Treatment of relapse begins with an attempt to obtain a second remission. This is usually successful with agents similar to those used at initial presentation, more so in late than in early relapse. In pediatric series, remission induction rates range from 71% to 97%.[209,221,224,229–232] Retreatment of the CNS appears critical even in isolated bone marrow relapse.[233] Postinduction therapy is generally pursued, ranging from conventional chemotherapy intensification and maintenance to marrow ablative therapy and stem cell rescue (see below). Outcomes improve with an increasing duration of first remission,[216,217] with protocol as opposed to ad hoc therapy,[219] and less certainly with increasing intensity of otherwise somewhat effective therapy.[229,234] A substantial number of patients with an initial relapse after 3 years achieve long-term DFS with chemotherapy without bone marrow transplant.[211,229,235]

Treatment of Isolated Extramedullary Relapse

Isolated extramedullary relapses are rarely truly isolated to the apparent site of involvement. PCR-based assays may show the presence of marrow cells sharing the clonotypic immunoglobulin or T-receptor rearrangement found in the leukemic blasts at presentation.[236–238] The principal clinical challenge of isolated extramedullary relapse is prevention of subsequent marrow relapse. Local control of CNS or testicular sites can usually be obtained and maintained with chemotherapy and radiation therapy. Thus, isolated extramedullary relapse usually represents a failure of systemic therapy, not only local therapy.

Isolated CNS Relapse

CNS disease may present with signs of increased intracranial pressure, such as headache or vomiting (especially morning vomiting). Because all patients receive maintenance intrathecal therapy, most CNS relapses occurring during treatment are discovered incidentally. CNS relapses tend to occur between 1 and 3 years after diagnosis.

CNS blasts may be cleared with weekly or twice-weekly intrathecal therapy. Three-agent methotrexate, hydrocortisone, and cytosine arabinoside therapy was no more effective than two-agent methotrexate and hydrocortisone therapy in one trial.[239] Cranial irradiation and intrathecal maintenance therapy were less effective in maintaining CNS remission than craniospinal irradiation.[240] Patients undergo systemic reinduction therapy and cranial or craniospinal irradiation is administered 1 month[241] to 6 months[229,242,243] from relapse. Radiation may be delayed in order to preserve marrow reserve for aggressive systemic therapy.[244] The dose of cranial irradiation is generally 18 to 24 Gy. The spinal dose is 6 to 15 Gy.[229,242,243] Overall, at least 50% of patients may achieve long-term DFS after CNS relapse; time to relapse is prognostic.[244] The bone marrow is the principal site of treatment failure.[245]

In the past, most children received cranial irradiation as part of their initial presymptomatic CNS therapy and treatment after CNS relapse represented a second radiation exposure and higher cumulative dose. Mulhern et al. found an average of more than 10 points decline in full-scale IQ compared to population norms in 40 children 6 years after CNS relapse. Eight children were labeled mentally retarded and were receiving special education assistance. Younger children and those with seizures or structural brain abnormalities had the poorest cognitive outcomes.[246] Winick et al. studied 120 patients with isolated CNS relapse of whom 14 had received prior cranial irradiation. Of these, 17% had signs or symptoms of leukoencephalopathy, presenting with seizure in 85% and ataxia, memory loss, and motor and cranial nerve deficits in others. Of children with prior cranial irradiation, 27% had significant neurotoxicity compared to 15% of children who did not ($P = 0.33$). Twelve patients had progressive neurologic deterioration despite the cessation of intrathecal therapy. Eight had mild stable symptoms and of these, four had learning disabilities.[241] Prevention of subsequent relapse and preservation of neurocognitive function remain dual challenges for patients with CNS relapse.

Isolated Testicular Relapse

Testicular leukemia presents with unilateral or bilateral painless testicular enlargement. At least half of cases occur more than 3 years from diagnosis. Outcomes appear better for patients with overt disease after completion of therapy than for patients with overt disease while still on therapy.[247] In two trials, about 10% of boys had occult testicular relapse on elective biopsy at 3 years from diagnosis. However, no advantage could be shown for early diagnosis and 25 of 839 boys with negative initial biopsies had subsequent testicular relapse.[248,249]

CCG reported a series of patients with overt isolated testicular relapse (ITR) on or shortly after initial therapy. Patients received salvage chemotherapy as per the NY I[173] or CCG BFM-based[151] regimens and bilateral testicular irradiation. Among 57 boys, the 5-year EFS was 43%.[251] This result is similar to that obtained in a POG series with somewhat different chemotherapy.[252] For patients with an earlier or later overt testicular relapse, POG investigators obtained 4-year EFS of 53% or 84%.[253] In adults, testicular irradiation doses greater than 4 to 6 Gy may result in persistent azoospermia. Even scatter from spinal irradiation may cause elevation of FSH or decreased testicular volume in some patients. Leydig cell function is generally spared. However, testicular irradiation doses greater than 20 Gy may compromise Leydig cell function in children, resulting in elevated LH, decreased testosterone, and delayed puberty.[254] Doses greater than 20 Gy are generally used in the treatment of testicular relapse. The use of intensified systemic chemotherapy to allow elimination of radiation therapy in selected low-risk ITR patients is under investigation by COG.

Bone Marrow Transplantation

The potential benefit of allogeneic bone marrow transplantation (BMT) likely derives less from the opportunity for marrow ablative therapy, that is, high-dose chemotherapy with or without total body irradiation, and more from the immunologic benefits of graft-versus-leukemia effect. As the majority of children with relapsed ALL who need a donor for allogeneic transplant will not have a matched sibling donor (MSD), other stem cell sources such as matched unrelated marrow (MUD)[255–257] or peripheral blood or cord blood stem cells,[258,259] and related but partially mismatched marrow, peripheral blood, or cord blood stem cells[260] are increasingly utilized. With continued improvements in tissue typing, management of acute graft-versus-host disease and other supportive care measures, the outcomes of such alternative donor transplants now approximate those from matched related donors.[261]

Definition of the role of BMT in childhood ALL has been an ongoing challenge. Interpretation of reported BMT outcomes is complicated by the preponderance of small series, selection bias, waiting-time bias, and lack of adequate controls. Even in aggregate, small series may not be representative of the total experience. Small numbers quickly erode statistical power and obscure possibly important differences. Selection biases complicate comparisons; in "treatment-received" reports, patients who relapse before a BMT is performed are excluded from the treatment-received experience, but are included in the control group receiving chemotherapy. Patients deemed clinically unfit for BMT because of organ dysfunction or deep-seated infection are excluded from the BMT arm, but may be included in the chemotherapy control. Various statistical techniques can adjust for waiting-time bias but selection bias proves more challenging; therefore, an intent-to-treat analysis is the least biased. Interpretation of BMT results is also complicated by differences in therapy before BMT, in marrow ablative therapy, in graft-versus-host disease prophylaxis, and in supportive care. The superiority of a particular transplant regimen over a particular chemotherapy regimen does not imply that the same or a second transplant regimen will necessarily be superior to a second chemotherapy regimen.

For children in second marrow remission, a case-control analysis of International Bone Marrow Transplant Registry data suggested that matched BMT is superior to chemotherapy for both early and late marrow relapse. The 5-year DFS was estimated at 40% for BMT patients and 17% for matched chemotherapy patients, excluding patients who failed to achieve or maintained remission long enough to have received a transplant had they had a donor (Fig. 76.10). Comparisons of BMT and chemotherapy outcomes for initial remissions before 18 months, at 18 to 36 months, and at 36 months or later were 29% versus 14%, 41% versus 7%, and 53% versus 32%, respectively.[262] A matched-pairs analysis of patients treated with chemotherapy or unrelated donor transplantation was undertaken by the BFM group. Patients treated with HSCT had an EFS of 42% compared to an EFS of only 17% for those treated with chemotherapy; the poorer outcome in the chemotherapy group was primarily attributable to the dismal outcome of those with high-risk features such as early relapse.[220]

In a rare prospective trial, Wheeler and coworkers in the British MRC designated 473 of 3,676 children diagnosed between 1985 and 1997 as "very high (VH) risk" on the basis of presenting clinical and cytogenetic features. Of 288 patients with tissue typing, 99 had a MSD and 76 underwent BMT is first remission. Of 189 patients with no MSD, 25 underwent BMT from a MUD, contrary to protocol. At 10 years, the adjusted EFS was 45% for 101 children receiving first remission BMT versus 39% for 351 children receiving chemotherapy. In contrast, the 10-year EFS was 50% for children without MSD compared to 40% for children with MSD.[263] They concluded that first remission BMT has not improved EFS for VH-risk ALL.

Gaynon et al. undertook a prospective randomized trial (CCG 1941) for children with ALL and early marrow relapse.[209] Of 215 patients enrolled, 165 achieved remission (77%). Forty-two refused postinduction allocation. Fifty-one patients had matched related donors, of which 40 underwent BMT in second remission; 8 died from TRM (20%) and 19 relapsed. Seventy-two patients had no matched related donor and were allocated to alternative donor BMT or chemotherapy. Of 37 patients allocated to alternative donor BMT, 20 underwent BMT in second remission; 8 died from TRM (40%) and 6 relapsed. Of 35 patients allocated to chemotherapy, 10 patients underwent alternative donor BMT; 4 died from TRM and 3 relapsed. Twenty-five patients received only chemotherapy; 2 died from TRM and 16 relapsed. The 2-year EFS for MSD BMT and alternative BMT was 40% and 23%. By intent-to-treat from the end of induction, the 3-year DFS were not significant: 29%, 18%, and 28% for matched related BMT, alternative BMT, and chemotherapy, respectively. Censoring the chemotherapy patients who underwent BMT, the DFS is 36%.

The British MRC has undertaken three prospective trials in patients after relapse. Wheeler et al. studied 489 children who relapsed from the UKALL X trial. Harrison et al. studied 256 relapsed children enrolled on the UKALL R1 trial.[264] In adjusted comparisons, BMT improved 5-year EFS from 26% to 41% in UKALL X ($P = 0.05$). The 5-year EFS was only 3% for patients with marrow relapse prior to 2 years, whatever therapy was pursued. The 5-year EFS was 66% for late extramedullary relapse. On the UKALL R1 study, 67 children had MSD BMT and 139 had no MSD. Sixty-three of 67 patients with MSDs underwent BMT. Contrary to protocol, 41/139 patients with no MSD underwent MUD BMT, of which 6 patients died from TRM (15%). Within the

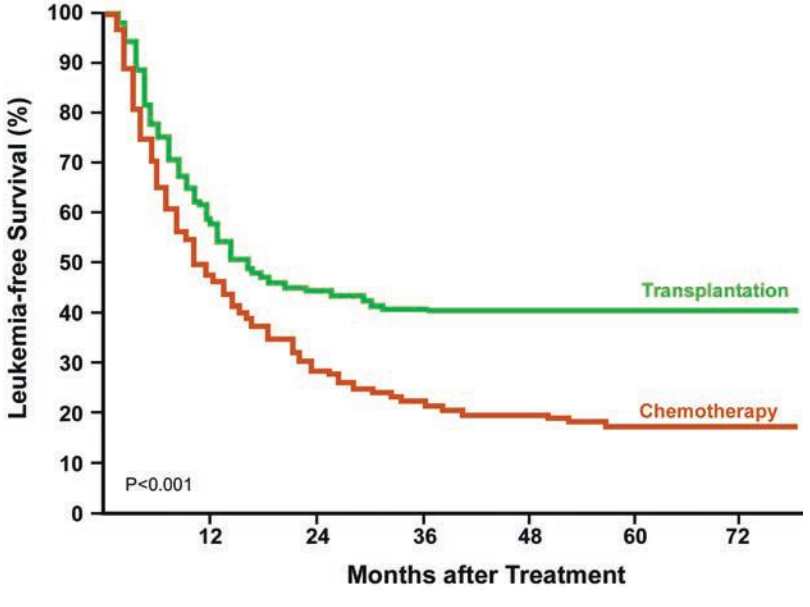

FIGURE 76.10. Probability of leukemia-free survival in matched cohorts ($n = 255$ in each) of children receiving chemotherapy or undergoing sibling donor transplantation for relapsed ALL. (With permission from Barret AJ, Horowitz MM, Pollock BH, et al. Bone marrow transplants from HLA-identical siblings as compared with chemotherapy for children with acute lymphoblastic leukemia in second remission. *N Eng J Med* 1994;331:1253–1258.)

power of the comparison, no statistically significant difference was apparent in intent-to-treat comparisons of patients with MSD versus patients with no MSD or in adjusted treatment-received comparisons of patients undergoing BMT versus patients receiving chemotherapy. The UK ALL-R3 randomized 219 children with first relapse of ALL to receive either idarubicin or mitoxantrone during reinduction therapy; all high-risk patients, and those standard-risk patients with MRD levels ($\geq 10^{-4}$ cells) after 3 courses of reinduction therapy, underwent allogeneic SCT, whereas standard-risk patients with less end-induction MRD received continuation chemotherapy. Estimated 3-year progression-free survival was significantly better in the mitoxantrone group (64.6% ; 95% CI 54.2–73.2) than in the idarubicin group (35.9%; CI 25.9–45.9), despite no obvious difference in end-induction MRD results between the two groups.[224]

Further refinements in improving BMT outcomes may come from reducing pretransplant levels of disease with either standard or novel agents, better conditioning, less TRM, and enhancement of the graft-versus-leukemia effect. Although data clearly link end-induction or pretransplant levels of MRD to outcome,[221,222] no data have been published demonstrating that further therapy in those patients with detectable disease prior to HSCT will improve outcomes; an alternative explanation is that detectable MRD prior to HSCT may reflect adverse biologic features resistant to currently available therapies. Clinical trials are underway or planned that will address this important issue.

The optimal choice of conditioning regimen is also unclear; although the use of regimens utilizing total-body irradiation (TBI) may be superior to busulfan-based regimens in ALL.[265,266] Concerns about the long-term complications of TBI in children have led to plans for an international trial randomizing TBI-based and non-TBI–based regimens in relapsed childhood ALL. The identification of those elements comprising an optimal TBI-based regimen (cytosine arabinoside, cyclophosphamide, or etoposide) are similarly unclear.[267,268] Reduced graft-versus-host disease prophylaxis[269] or rapid withdrawal of GVHD prophylaxis following HSCT in the setting of increasing mixed chimerism[270,271] may enhance graft-versus-leukemia effect and improve outcomes.

Future progress in further improving the outcome of children with newly diagnosed high-risk or relapsed ALL will come from the incorporation of promising new therapies into treatment regimens, either through empiric testing or through the identification of critical signaling pathways that are amenable to therapeutic targeting (Table 76.5).[51] Newer cytotoxic chemotherapy agents that have shown promising results in relapse and are being evaluated or planned for evaluation in high-risk subsets of ALL include clofarabine,[272,273] nelarabine,[43] and bortezomib.[274,275] Among the many other therapies in early development for lymphoid malignancies, the most promising appear to be the immunoconjugates moxetumomab,[276] inotuzumab,[277] and blinatumomab. The latter agent, the first of a novel class of agents known as bispecific T-cell engagers (BiTEs), is a single-chain bispecific antibody construct with specificity for CD19 and CD3 which has shown impressive activity in adults with CD19+ non-Hodgkin lymphomas and ALL.[278,279] Similar activity has been seen in a small number of children,[280] and prospective pediatric trials of this agent are underway.

OUTCOMES

Quality of Life

With steady improvements in survival over successive decades, growing attention and focus have been devoted to the short- and long-term effects of ALL therapy and their impact on quality of life. In a recent analysis of 10-year event-free survivors of childhood ALL, 95% were long-term survivors 30 years from achievement of first complete remission, a rate very similar to the general US population.[85] Although ALL survivors are 3.7 times more likely to report a significant chronic medical condition compared to their siblings and they have poorer self-reported health status, remarkably, 92% of survivors who did not develop a relapse or receive irradiation did not report any severe chronic medication condition after therapy.[281] In an analysis of more than 800 patients who received treatment on SJCRH protocols and attained at least 10-year EFS, quality of life among nonirradiated survivors was very good with rates of health insurance coverage, marriage, and employment that were similar to the age- and sex-adjusted national averages.[85] Many therapeutic trials for childhood ALL now include prospective assessments of common toxicities as well as underlying host factors that contribute to the risk of experiencing side effects from ALL therapy and this is envisioned to facilitate prevention of late effects from treatment more effectively in the future.

Neuropsychological Sequelae

Cognitive outcomes of children who receive ALL therapy have been an area of active investigation as the side effects of CNS-directed therapy have become increasingly recognized.[282] Risk factors for the impairment in neurocognitive functioning have included younger age (<5 years), female gender, more intensive treatment, and cranial irradiation.[283–291] Historically, cranial irradiation, especially when administered to children <3 years of age and at the higher doses used in earlier generation treatment protocols, has been linked to later cognitive impairment as well as a decline in neuropsychological functioning, such as visual–motor integration, processing speed, attention, short-term memory, and executive functioning (organization and planning).[285,287,292–294,295] In recent years, there has been a growing trend to reduce the number of children who receive cranial irradiation and this has prompted assessments of the cognitive and neuropsychological outcomes in children treated with systemic and intrathecal chemotherapy alone. The impact of parenteral methotrexate and intrathecal chemotherapy and other agents such as corticosteroids has been somewhat challenging to define. Factors such as the assessment tools used, heterogeneity in populations tested and the treatment regimens delivered, differences in time points during treatment when testing was undertaken, also contribute to the complexity in defining the risk, and furthermore, the clinical impact of numerical differences in test scores can be difficult to define.

There have been relatively few large prospective studies of children with ALL who have received common treatment and undergone uniform neurocognitive assessments. Comparisons of neurocognitive outcomes in children treated with regimens containing cranial irradiation versus chemotherapy alone have generally suggested better outcomes when radiation is omitted[289,294,295,296] but not all studies have shown a significant difference.[292,297,298] Most studies of outcomes following treatment with chemotherapy without cranial irradiation have reported favorable cognitive and intellectual outcomes; however, some meaningful deficits in neurocognitive function with difficulties in attention, working memory, processing speed, mathematics, and visual–motor integration have been reported.[283,286,299,300,301]

A recently completed study assessing cognitive outcomes 2½ years following remission induction in 243 children who were enrolled on the St. Jude Total Therapy Study XV, which omitted cranial irradiation for all patients, showed that children who received ALL therapy in comparison to a normative group, had a higher likelihood of below-average performance on sustained attention in approximately 40% of patients.[302] Those treated on this protocol, however, did well on global measure of cognitive ability without evidence of impairment on measures of intellectual functioning, academic abilities, learning, or memory. More intensive therapy and younger age portended a higher risk for impairment; however, gender was not a significant risk factor in

TABLE 76.5

NOVEL AGENTS FOR THERAPY OF ACUTE LYMPHOBLASTIC LEUKEMIA

Agent	Comment
Monoclonal Antibodies	
Blinatumomab	Bispecific antibodies (BiTE) that direct $CD3^+$ T-cell against $CD19^+$ B-ALL
Rituximab	Utilized in adult B-cell lymphoma and Burkitt lymphoma/leukemia; under investigation in CD 20^+ precursor B-ALL
Epratuzumab	Under investigation for relapsed $CD22^+$ precursor B-ALL; probable synergy with other antibodies
Inotuzumab ozogamicin	Humanized anti-CD22 antibody conjugated to calicheamicin
Alemtuzumab	Anecdotal responses in $CD52^+$ ALL; under investigation to eradicate minimal residual disease and in patients who have multiple relapses
Antimetabolites	
Clofarabine	Nucleoside analogue; inhibits ribonucleotide reductase and DNA polymerase. Approved for relapsed childhood ALL; CR of 20–24% and overall response of 30–47%
Nelarabine	Pro-drug of ara-G; inhibits purine nucleoside phosphorylase. Approved for third-line treatment for T-ALL; CR rate of 27–35% with a higher rate (46%) in first relapse and lower rate (21%) with CNS disease
Forodesine	Inhibits purine nucleoside phosphorylase. Preliminary data indicate similar activity to nelarabine in T-cell malignancies and with less neurotoxicity
Tyrosine Kinase Inhibitors (TKI)	
Imatinib	Utilized with chemotherapy for Ph+ ALL
Nilotinib	
Dasatinib	
Bosutinib	
Ponatinib	
MK-0457	
Fms-like Tyrosine Kinase Inhibitors (FLT-3) Inhibitors	
Lestaurtinib	Small molecule inhibitors; *FLT3* mutations occur in MLL+ acute leukemias, KIT (CD117) + T-ALL, and hyperdiploid ALL. Lestaurtinib is in phase I trial as inhibitor of JAK2 in ALL
Midostaurin	
Tandutinib	
Sunitinib	
Farnesyltransferase Inhibitors	
Tipifarnib	Inhibition of farnesylation of multiple proteins, including the RAS/RAF pathway, which affects cell survival. Preliminary data indicate activity in T-ALL
Lonafarnib	
Proteasome Inhibitors	
Bortezomib	Inhibits ubiquitin proteasome pathway and blocks nuclear factor κB. Leukemia cells become more sensitive to chemotherapy by inducing phosphorylation of BCL 2 and BCLX and inhibiting MAPK signaling
Carfilzomib	
γ Secretase Inhibitors	
MK-0752	Mutations of *NOTCH 1* occur in ~50% of T-ALL; loss of PTEN (phosphatase and tensin homologue) gene may lead to resistance to NOTCH 1 inhibition and require inhibition of PI3K/AKT pathway
Histone Deacetylase Inhibitors	
Depsipeptide	Synergistic with DNA methyl transferase inhibitors; can induce differentiation and apoptosis by upregulating cyclin-dependent kinase inhibitor A (P21) and down-regulating cyclin D1 and D2
Vorinostat	
AN-9	
Folate acid antagonist	
Pemetrexed	Folic acid. Modest activity in phase I trials; likely synergistic with other agents
Talotrexin	
Mammalian Target of Rapamycin (mTOR) Inhibitors	
Sirolimus	Signal transduction inhibitors; induce cell-cycle arrest so that cells may be less susceptible to cell-cycle specific agents
Temsirolimus	
Everolimus	
Deforolimus (AP-23573)	

this study. Prospective longitudinal studies of large numbers of children who receive contemporary chemotherapy regimens will be helpful in further defining risk factors for adverse neurologic sequelae and the natural history of deficits over time. Monitoring and intervention for neuropsychological effects of therapy is an essential element of ALL survivorship care.

Secondary Malignant Neoplasms

Cancer survivors treated with radiation therapy and/or chemotherapy are at some increased risk for developing a second malignant neoplasm (SMN), although this risk is low in ALL survivors and estimated to be 1.18% at 10 years with contemporary risk-based therapy in a cohort of 8,831 children treated on COG protocols from 1983 to 1995.[303] Similarly, in an analysis of 5,006 children treated on BFM ALL protocols from 1979 to 1995, the cumulative risk of SMNs at 15 years was 1.2% in nonirradiated children versus 3.5% among those who had received prior irradiation.[304] Investigators at SJCRH followed a cohort of ALL survivors for a more extended period of time (median follow-up of 18.7 years) and found that the incidence of SMNs continues to increase over 30 years.[305] Although the majority of late-occurring

SMNs are low-grade tumors such as basal cell carcinoma and meningioma, aggressive tumors occur as well and exceed the incidence in the general population, highlighting the need for lifelong follow-up of childhood ALL survivors. Reported risk factors for SMNs are female gender, prior cranial irradiation, primary disease recurrence, and treatment at a younger age.[303,304]

The majority of the SMNs that occur in survivors of childhood ALL are secondary high- and low-grade brain tumors among children who received prior cranial irradiation.[281] This risk approaches 0.5% at 10 years, which is a tenfold increased risk compared to the general population, and the latency period can exceed 10 years.[303] A higher than anticipated incidence of secondary brain tumors was observed on SJCRH studies where intensive antimetabolite therapy was given before and during radiation and this was linked to mutations in the thiopurine methyltransferase gene, which resulted in defective thiopurine catabolism.[306] This suggests that other components of therapy, as well as underlying genetic characteristics of patients may also be associated with the risk for SMNs.

There is also a risk of chemotherapy-related myelodsyplasia (t-MDS) and AML, linked to exposures to epipodophyllotoxin therapy. The cumulative incidence of secondary AML/MDS among children treated on COG protocols was 0.2%.[303] A higher incidence of 3.8% at 6 years has been reported after treatment on protocols with greater epipodophyllotoxin exposure.[307] These SMNs are characterized by latency periods of <10 years.

Osteonecrosis

Osteonecrosis (ON, avascular necrosis of bone) has been recognized with increasing frequency in the greater number of surviving older children and adults with ALL after chemotherapy or after BMT (Fig. 76.11). Osteonecrosis and decreased bone mineral density are well-known side effects of glucocorticoids and ON has emerged as one of the greatest causes of treatment-related morbidity in survivors of ALL therapy, particularly the adolescents.[168,308,309] Symptomatic ON has been reported to occur in up to 20% of children and adolescents with ALL and its pathogenesis is thought to involve ischemia due to intravascular thrombi and extravascular lipid deposition as well as compromised intramedullary blood flow due to increased intraosseous lipocyte size. Adolescent age (10 to 20 years) and exposure to dexamethasone have been shown to be some of the greatest risk factors for this complication. New evidence is also emerging to suggest that ON may be associated with inherited genomic variation.[310] Pain is the common initial symptom of ON and the hips and knees are the most commonly affected joints. In severe cases, ON results in joint collapse and may require total joint replacement. In a recent report of results from the COG-1961 study for treatment of newly diagnosed NCI high-risk ALL, the use of alternate-week dexamethasone during delayed intensification significantly reduced the incidence of ON compared to continuous dosing schedules with incidence rates of 8.7% versus 17%, $P = 0.0005$, respectively.[308]

Cardiac Toxicity

Anthracyclines are commonly used in the treatment of ALL in adults and children and there is a risk of cardiotoxicity associated with their use, especially in doses that exceed 300 mg/m^2.[311] Cumulative doses of anthracycline have been shown to be the most important predictor of abnormal cardiac function[312,313] and females have also been reported to be at higher risk[313] as well as children with a younger age at exposure.[314] Reported frequencies of anthracycline-induced clinical heart failure have varied from 0% to 16%.[315] Because most ALL protocols have far less cumulative exposure, overt congestive heart failure is now infrequent, although abnormalities in cardiac indices have been reported even with lower anthracycline exposures and the natural history of these findings is being tracked.[316] Lipschultz et al. reported that 17% of patients who had received only 45 mg/m^2 of doxorubicin had slightly elevated age-adjusted left ventricular load, as measured by end-systolic wall stress.[312]

Measures to prevent cardiotoxicity have been investigated and some groups have used the cardioprotectant dexrazoxane.[314] In a randomized study, children with ALL who received dexrazoxane with doxorubicin were less likely to have cardiac injury, as reflected by elevations in troponin T and N-terminal pro-brain natriuretic peptide (NT-proBNP; cardiomyopathy biomarker).[317,318] The potential impact of dexrazoxane on the antitumor effect of anthracyclines and the risk of SMN as well as the association between cardiac biomarkers and long-term cardiac outcomes are areas of ongoing investigation.

Endocrinologic Late Effects

Survivors of ALL are also at risk for a spectrum of endocrinologic late effects. These include impairment in growth, thyroid function, gonadal function, bone health, and adrenal function.[319] There is growing recognition that survivors are at risk for obesity and metabolic syndrome possibly related to steroid exposure and insulin resistance.[320,321,322–324] Screening for endocrinologic sequelae is

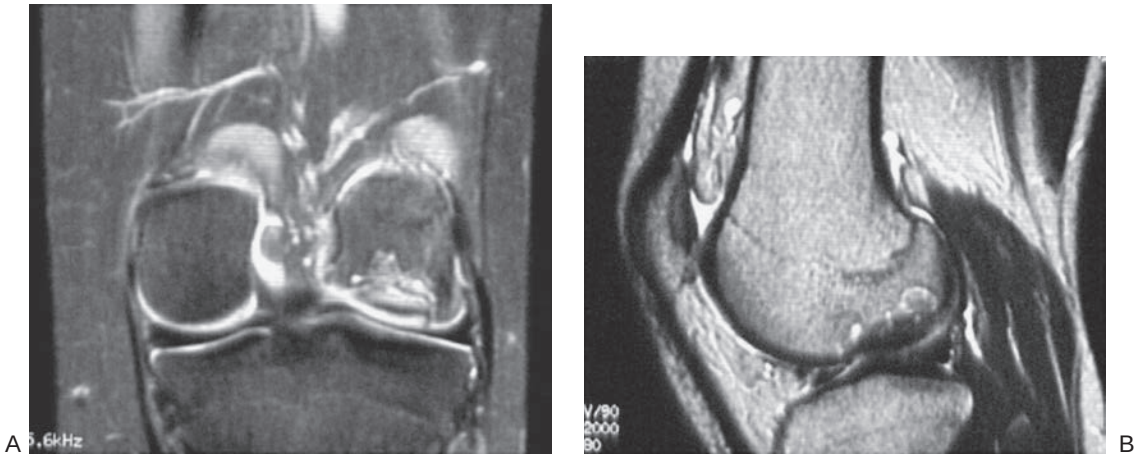

FIGURE 76.11. Coronal (A) and sagittal (B) T2 images from a magnetic resonance imaging scan demonstrating corticosteroid-inducted avascular necrosis of the right medial femoral condyle in a 15-year-old white girl. essential both during and following therapy as many treatment-related side effects can be improved by medical, environmental, and dietary interventions.

SUMMARY

The steady progress in pediatric ALL has served as a model of incremental improvements in therapy through clinical trials. Prognostic risk stratification is shifting from clinical factors to a combination of clinical, immunophenotype, and molecular genetic data. Early identification of minimal residual disease is also now incorporated into therapeutic strategies. Pharmacogenomics may lead to individualization of therapy. Novel agents that are directed at molecular targets are under investigation to improve outcomes. The goal of therapy in ALL is to continue to maximize and maintain remission while minimizing long-term complications.

CHAPTER 77

ACUTE MYELOGENOUS LEUKEMIA IN CHILDREN

Robert J. Arceci

HISTORICAL BACKGROUND

Acute myelogenous leukemia (AML) represents a heterogeneous group of hematologic malignancies arising from the transformation and expansion of an early myeloid stem or progenitor cell. The term *leukemia* originated with Virchow, who, in 1845, recognized a clinical entity characterized by too many white blood cells (WBCs), leading him to name the condition *white blood,* or *leukemia*.[1] Of some historical interest is that Dr. John Hughes Bennett's report of a case of leukemia preceded Virchow's description by ~6 weeks.[1] However, Bennett had concluded that the condition was secondary to an infection and referred to it as *pyemia*. The term *myelogenous*, or *myeloid*, derives from the terms *myelos,* meaning marrow and *genesis,* meaning birth.

The original cases of Virchow and Bennett probably represented what we now know to be either chronic lymphocytic or myelogenous leukemia. The first likely case of acute leukemia was reported by Friedreich and was believed to be lymphocytic.[2] It would take the identification of the myeloblast as a precursor cell for granulocytes by Naegeli in 1900 to set the stage for the description of the first cases of AML or what was originally termed *acute nonlymphocytic leukemia*.[3] Even during the first half of the 20th century, reports describing different types of myeloid leukemia made it clear that this was not one but a variety of distinct disorders, all deriving from a bone marrow precursor myeloblast. Initially, cases of monocytic leukemia were described, followed by myelomonocytic leukemia.[3,4] Cases of erythroleukemia, megakaryoblastic leukemia, and acute promyelocytic leukemia (APL) were subsequently described in 1917, 1931, and 1957, respectively.[5–7] During the mid-1970s, the French/American/British (FAB) classification system was developed and defined the major categories of AML as M1 through M7.[8] More recently, the World Health Organization (WHO) provided a new classification system that utilizes genetic, immunophenotypic, biologic, and clinical features in addition to morphology.[9]

The description and classification of AML moved more rapidly than the development of effective treatments. During the mid-1800s, Virchow used diet therapies, ferric iodide, and application of abdominal and foot baths.[1] In 1865, Lissauer used arsenic (Fowler solution) to treat patients with leukemia, but with little success.[1] Radiation therapy was used in the late 1800s, mostly as a form of palliation for chronic leukemias.[1] In 1938, Forkner stated, "Although leukemia is a fatal disease much can be done to add to the comfort, and promote the general health of sufferers from the chronic forms of the disease. Unfortunately acute leukemia does not respond satisfactorily to any form of treatment."[1] In 1948, Farber demonstrated that the use of the antimetabolite aminopterin could produce transient remissions in children with acute lymphocytic leukemia (ALL).[10] The pioneering work resulted in the National Cancer Institute developing screening programs for other possible antitumor therapies during the 1950s. During the 1960s, several chemotherapeutic agents, particularly cytarabine and anthracyclines, were developed and used in the treatment of AML. During the 1970s, clinical trials demonstrated that combining these two agents would result in long-term remissions for 10% to 15% of patients with AML. The subsequent introduction of more intensive remission induction regimens and post-remission therapy increased the need for more rigorous supportive care measures, and the development of bone marrow transplantation led to current cure rates of about 50%.[11,12]

EPIDEMIOLOGY

Approximately 6,500 children <20 years of age develop acute leukemia annually in the United States, and AML represents approximately 15%, resulting in approximately 600 new cases/year.[13] The remaining cases of acute leukemia in children and adolescents are lymphoblastic leukemia. Essentially the opposite ratios exist for adults, with AML accounting for about 80% of acute leukemia and lymphoblastic the remaining 20%. With the exception of a peak in incidence of AML in infants, the incidence of AML is relatively constant until early adolescence following which it continues to rise slowly through young adulthood and beyond 50 years of age the incidence rises dramatically.[14]

Some variation in the incidence of AML in children has been reported among different racial and ethnic groups. For example, black children have an incidence of 5.8 cases/million, compared to 4.8 cases/million in white children.[15,16] Children and young adults of Hispanic background have the highest annual incidence at 9 cases per million with the major subtype being APL.[17–20] The annual incidence of AML in children from Japan, Australia, and Zimbabwe has been reported as 8, 8, and 11 per million.[21] The increasing incidence of secondary leukemia, resulting from chemotherapy and treatment for other malignancies, is a problem of increasing significance in pediatrics.[22–28]

CELLULAR AND MOLECULAR ORIGINS OF ACUTE MYELOGENOUS LEUKEMIA: HEMATOPOIETIC HIERARCHIES

The determination of the AML stem cell is not solely of biologic interest but has profound significance for understanding the causes of leukemia and potentially the development of curative therapies. This section discusses the cellular and molecular determinants of AML.

Normal hematopoiesis occurs through a series of complex changes that facilitate multipotential hematopoietic stem cells to both expand and differentiate into various mature blood cell types. Because AML is derived from an abnormal immature hematopoietic precursor cell, these leukemias also have the capacity to expand and to show characteristics of limited differentiation. Thus, myeloid leukemias retain many of the molecular and cellular phenotypic characteristics of their normal hematopoietic origins, providing the means to distinguish subtypes of the disease and define potential leukemic stem cell compartments. For example, although most myeloid leukemia cells often express growth, survival, and differentiation receptors for specific cytokines such as KIT, FLT3, and granulocyte-macrophage colony-stimulating factor receptor, some subtypes also express more lineage-specific surface receptors, such as those for granulocyte colony-stimulating factor (G-CSF) and erythropoietin. The same is true for the expression of differentiation markers that characterize various myeloid lineages such as megakaryoblastic, erythroid, or monocytic. These diverse phenotypic characteristics of different subtypes suggest significant heterogeneity of both the genetic changes and the cell of origin in AML.

Some of the earliest biologic tools used to define the cellular compartment in which leukemic stem cells arise included the use of X-linked glucose 6-phosphate dehydrogenase isoenzyme analysis in female patients with chronic myelogenous leukemia

(CML) and then AML.[29,30] Subsequently, karyotypic abnormalities were examined in the maturing colony-forming units to evaluate which lineage (colony-forming unit stem, colony-forming unit granulocyte-macrophage, colony-forming unit megakaryocyte, colony-forming unit granulocyte, colony-forming unit eosinophil, etc.) contained the aberrant chromosomal marker.[31] These studies revealed that although CML arises in a very early pluripotential hematopoietic cell, there are cases of AML that arise in more mature pluri- and unipotential progenitor cells.[31]

By depleting samples of AML with antibodies directed against lineage-specific surface antigens, a very small percentage of lineage-negative (Lin^-) cells were isolated that had the capacity to generate AML at a higher percentage than more mature leukemic cells when transferred to immunodeficient mice. These leukemogenic $CD34^+$, $CD38^-$, Lin^- cells (termed *self-renewing leukemia-initiating cells*) were in most cases rare, having a frequency of as few as 0.2 to $200/10^6$ mononuclear cells.[32,33,34,35] Of further significance was that the frequency of the self-renewing leukemia-initiating cell did not correlate with age, sex, or FAB classification, with the exception of some cases of APL.[33] In the case of APL, a significant percentage of cases appeared to be derived from a more committed progenitor cell.[33,36] Subsequent investigations identified both $CD34^+$ and $CD34^-$ lineage–negative self-renewing leukemia-initiating cell populations that were present at extremely low frequency, demonstrating that the AML stem cell is in many cases derived from a very immature hematopoietic precursor cell.[37]

When these results are placed into the context of the hematopoietic differentiation schema, the conclusion can be made that there must be primary genetic changes that occur in a very primitive self-renewing stem cell and that the nature of those genetic changes in part determines the subtype of AML. For example, a t(8;21) abnormality may lead to M1 AML with minimal differentiation, whereas an inv(16) abnormality may result in an M4Eo subtype. The initiating events may primarily affect the ability of the leukemic stem cell to differentiate but retain the ability to self-replicate.[38,39] Subsequent genetic changes, such as mutation pathways regulating apoptosis, cell survival, and proliferation, may further change the phenotype of the leukemia as well as provide the proliferative potential for the leukemia. These might be considered "driver" and "modifier" mutations, respectively. Mutations that do not affect the phenotype may be considered "passenger" mutations. This latter type of genetic change involves mostly secondary mutations that affect the function of growth and survival factor receptors, such as FLT3 or KIT. By themselves, most single mutations are insufficient to cause leukemia. However, when present together in the same cell, they can cooperate and lead to the development of AML. A slightly different alternative way of understanding the etiology of AML in the context of gene mutations is to consider genetic changes such as *AML-ETO* translocation as a Type I mutation and *FLT3-ITD* or *KIT* point mutations as Type II mutations that in combination result in the proliferation of progenitors with limited and aberrant differentiation.[40]

Genome-wide sequencing has confirmed the above models but also revealed many additional subkaryotypic abnormalities including gene mutations encoding classes of proteins involved in epigenetic patterning[41,42,43] and RNA splicing.[44,45] Such studies have also helped to define the heterogeneity of AML and its clonal evolution during treatment.[46,47] Of interest, although many of the same mutations observed in older adults with AML have been found in children with AML, there is a growing body of evidence that shows significant differences also exist.[48–50]

These results have important implications not only for understanding the etiology and pathogenesis of AML but also for the development of more effective treatments (Fig. 77.1). The causes of generating genetic mutations contributing to AML involve both inherited and environmental factors. In pediatrics, the former class of factors is particularly important.

PREDISPOSING FACTORS AND PATHOPHYSIOLOGY

Inherited Predisposition Syndromes

Abnormal Chromosomal Number

Trisomy 21, or Down syndrome (DS), represents the most common inherited condition that predisposes to the development of leukemia. The overall risk of developing leukemia has been estimated to be about 14-fold above that of the general population.[51,52] Although older children with DS have a similar frequency of ALL and AML, within the first 3 years of life, AML, and particularly acute megakaryoblastic leukemia (AMKL), predominates.[52]

Patients with DS also have an increased predisposition to develop a condition known as *preleukemia* or *transient myeloproliferative disorder* (TMD). Approximately 10% of newborns with DS develop TMD. Although clinically indistinguishable from congenital leukemia (Fig. 77.2), TMD, as the name suggests, is usually self-resolving. It is importantly to note that even children who are mosaic for trisomy 21 but phenotypically normal share the increased risk of developing TMD and subsequent leukemia. Approximately 20% to 30% of children whose TMD resolves still develop AMKL.

The close association of trisomy 21 with TMD and AMKL suggests that predisposing genetic events exist. *RUNX1 (AML1)*,

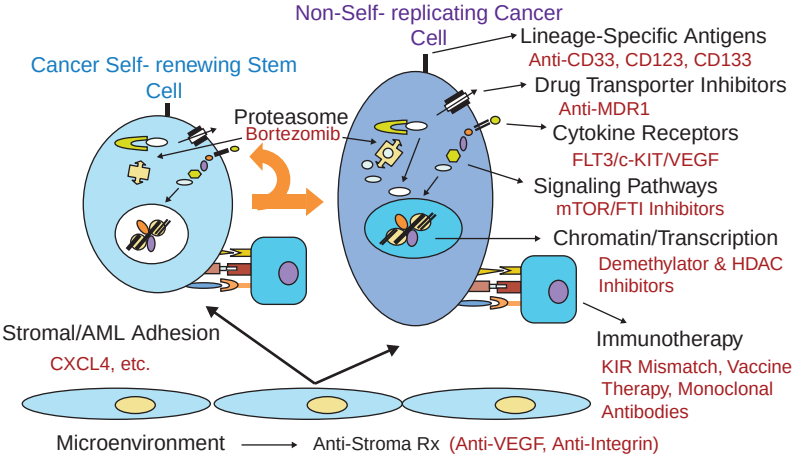

FIGURE 77.1. Therapeutic targets being tested in acute myelogenous leukemia (AML). The schema shows different pathways and/or approaches that have been or are being tested in clinical trials, including those that may affect the leukemia-initiating cell.

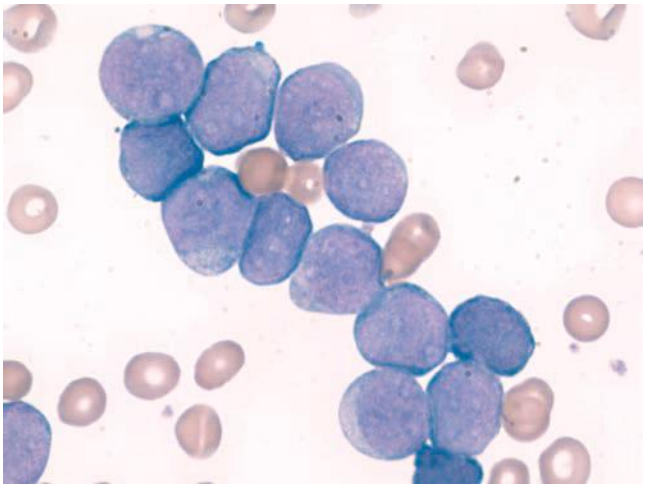

FIGURE 77.2. Photomicrograph of a peripheral blood smear from a patient with Down syndrome and transient myeloproliferative disease.

which is located on chromosome 21 and known to be involved in some subtypes of AML, has been implicated etiologically, but no definitive evidence has yet demonstrated a specific mutation or gene dosage effect leading to AML. However, other investigations have demonstrated the interesting finding that TMD and AMKL are both characterized by mutations of the *GATA1* gene that result in the introduction of a premature stop codon, truncating *GATA1* before the amino-terminal activation domain and reducing its transcriptional activation ability.[53,54] The same *GATA1* mutation has been observed in the blasts from TMD as well as in AMKL.[53–56] These results argue strongly that mutations in the GATA1 hematopoietic transcription factor are an early event in the development of TMD and AMKL in children with DS. It remains unclear why a majority of children with DS and TMD show regression of their disease.

An increased risk of developing AML in patients with Klinefelter syndrome (XXY) and Turner syndrome (XO) has also been reported, but the numbers of such cases are quite low.[57,58]

Inherited Marrow Failure and Chromosome Instability Syndromes

There are several inherited syndromes characterized by progressive marrow failure and cytopenias with a high frequency of AML. Fanconi anemia (FA) is an autosomal recessive inherited disorder with common congenital abnormalities including skeletal abnormalities, short stature, microcephaly, cardiac abnormalities, genitourinary tract abnormalities, café-au-lait spots, and mental retardation. Patients with FA have an estimated 15,000 times greater risk than the general population for developing AML and an actuarial risk of myelodysplastic syndrome (MDS) or AML of approximately 52% by 40 years of age.[59,60] There are multiple gene defects that give rise to FA and affect distinct but functionally related proteins that regulate DNA repair; the mutations result in a hypersensitivity to genotoxic agents such as mitomycin C or diepoxybutane and chromosomal instability.[61] Somatic mutations in several of the FA genes have also been observed in AML outside the setting of FA, thus further strengthening the link of these genes with predisposition for AML.[62,63]

Severe congenital neutropenia (Kostmann syndrome) represents an important inherited cytopenia of the granulocytic lineage with an increased risk of MDS/AML that increases with age.[64] Introduction of G-CSF for the treatment of patients with Kostmann syndrome has been linked to the development of AML. However, it is possible that patients on G-CSF may survive for longer periods, raising the possibility that the development of AML is secondary to an intrinsically increased risk of leukemia in patients with Kostmann syndrome or a combination of this predisposition and G-CSF stimulation. Mutations in the elastase gene have been associated with both cyclic neutropenias and Kostmann syndrome.[65,66] The detection of somatic activating mutations of the G-CSF receptor has been observed before the development of overt AML in patients with Kostmann syndrome.[67,68] Thus, when a rising WBC count is observed in a patient with Kostmann syndrome who was previously stable on G-CSF, one should consider that autoactivating mutations of G-CSF have occurred and that the patient has developed AML.

Shwachman-Diamond syndrome, inherited in an autosomal recessive fashion, is characterized by pancreatic insufficiency, skeletal abnormalities, neutropenia, and an increased incidence of MDS and AML.[63,69,70] Diamond-Blackfan anemia (DBA) is another inherited syndrome characterized by congenital anemia, skeletal and urogenital abnormalities, and an increased risk of developing MDS and AML.[60] An association of mutations and/or deletions in both small and large ribosomal subunit protein-encoding genes has established DBA as a ribosomopathy. In addition to showing an increased frequency of AML, patients with DBA also appear to have a predisposition to other cancers, making DBA a true cancer-predisposition syndrome.

Neurofibromatosis Type I (NF1) is caused by mutations in the neurofibromin gene, encoding a RAS-inactivating GTPase, and closely associated with an increased incidence of juvenile myelomonocytic leukemia (JMML) and AML.[71,72] Noonan syndrome, caused by mutations in the *PTPN11* gene, which encodes a SHP-2 tyrosine phosphatase, also has an increased predisposition to JMML.[73,74] Mutations in *CBL*, encoding an E3 ubiquitin ligase, have been reported to be associated with a dominant inheritance and predisposition to JMML.[75–77] Patients with Li-Fraumeni syndrome and Bloom syndrome, involved defects in *TP53* and the *BLM* helicase gene, respectively, have also been reported to have a propensity to develop leukemia, including AML.[60,78–81]

Additional inherited AML predisposition syndromes include congenital amegakaryocytic thrombocytopenia (defects in the *CFFA2* gene and thrombopoietin receptor gene, *c-mpl*), autosomal dominant macrothrombocytopenia (Fechtner syndrome, *MYH9* gene), familial platelet disorder with propensity to myeloid malignancy (FPD/AML, and germline mutations in the *RUNX1/CEPB-alpha* gene).[60,69,82–87] Other DNA repair/chromosome instability syndromes that can lead to leukemia, although more commonly ALL, include Bloom syndrome, secondary to an inherited defect in the *blm* helicase gene, ataxia telangiectasia, due to defects in the *ATM* gene, and Li-Fraumeni syndrome, due to inherited mutations in *TP53*.[60,78,79,80,81]

Twins and Familial Cases

The increased frequency of both AML and ALL in siblings of patients with leukemia has been recognized since the early 1920s. The risk for identical twins is high when leukemia first develops during infancy; in most cases, transmission has been shown to be the result of transplacental transfer. Transmission rates have been reported to be 20% to 30%, although other investigators have concluded transmission rates may approach 100%.[88,89–90] There is also a high concordance of timing of the onset of leukemia. Molecular studies have demonstrated that identical molecular defects characterized the leukemia in both twins.[88,91–93]

Clinical follow-up is therefore essential in identical twins when one of them is diagnosed with acute leukemia. These normal twins should be followed approximately every 1 to 2 months until approximately 2 years of age with physical examinations and peripheral blood cell counts. Bone marrow examinations should only be done when clinically indicated. The risk of developing acute leukemia for nonidentical twins has been estimated

to be a two- to fourfold increase until about 6 years of age, after which the risk becomes similar to that of the general population. Nontwin familial cases of AML are rare and often associated with constitutional translocations, such as t(7;20) and t(3;6) or monosomy 7.[94–96]

Acquired Predisposition

A variety of acquired AML predisposition disorders exist. For example, patients with severe aplastic anemia (SAA) treated with immunosuppressive agents, such as cyclosporin A and antithymocyte globulin (ATG) or cyclophosphamide, as well as with recombinant human G-CSF have been reported to have up to a 20% risk of developing MDS or AML.[97–99] Paroxysmal nocturnal hemoglobinuria is also associated with an increased risk of developing MDS and AML although less frequently than SAA.[100] Although AML arising in patients with MDS is a relatively common event in adults, MDS is rare in children and may differ in biologic and clinical characteristics from that observed in adults.[101] Acquired monosomy 7 may predispose individuals to developing MDS and AML.[102] The acquisition of predisposing conditions or chromosomal abnormalities is often linked to environmental exposures.

Environmental Factors

A wide variety of genotoxic environmental exposures can predispose individuals to AML. For example, in the period after the dropping of atomic bombs on Nagasaki and Hiroshima during World War II, an approximately 20-fold increase in myeloid leukemia was documented, with a peak incidence between 6 and 8 years.[103–106] The absence of a documented increase in leukemia in children exposed prenatally to the radiation of the atomic bombs has been reported[107] and may be consistent with the absence of definitive evidence that prenatal exposure to x-rays increases leukemia risk.[108] There remains no convincing evidence that ultrasound or the effects of living near high-voltage power lines predisposes individuals to leukemia, although reports differ in their conclusions.[109–111]

Prenatal exposure to chemical genotoxic agents has been reported to increase postnatal incidence of myeloid leukemia. For example, maternal alcohol consumption has been associated with an increased risk of AML in offspring.[112] A significant association of dose–response of prenatal alcohol consumption and the development of AML in offspring was documented.[113] However, not all reports have concluded such strong associations.[112,114] There has been an association of maternal ingestion of topoisomerase II inhibitors and the development of AML with malignant lymphoblastic lymphoma rearrangements in offspring.[115–118] Parental smoking of tobacco or marijuana has also been associated with an increased incidence of AML in offspring although there are reports with dissenting conclusions.[119–121] Some reports have linked cigarette smoking in adults to an increased incidence of AML, making antismoking preventive counseling important, particularly during teenage years.[122]

Exposure of individuals to environmentally derived genotoxic agents is quite substantial, and several specific examples of such exposures have been shown to be etiologically related to the development of AML. Such exposures include petroleum products, benzene, pesticides, and herbicides,[123–127] although these studies have not focused on children. Interestingly, in some instances, such as with organophosphate pesticides, children may be at greater risk for accumulating higher levels of the chemicals.[128]

An increasingly worrisome group of patients are those who develop AML as a result of chemotherapeutic exposures for treatment of their primary cancer or even nonmalignant conditions. For example, exposure to alkylating agents, commonly used to treat patients with brain tumors, lymphomas, and other solid tumors, results in an increased incidence of secondary AML, with a peak incidence at 4 to 5 years but with an at-risk period extending 12 years.[129–131] Exposure to topoisomerase I inhibitors, including anthracyclines, and topoisomerase II inhibitors, including epipodophyllotoxins such as etoposide, is also etiologically linked to the development of AML.[132–135] Whereas cumulative dose and schedule of drug delivery may play important roles in the development of AML[136] nearly any exposures to such genotoxic agents can result in secondary AML, as demonstrated in a child initially treated for neuroblastoma.[137,138] The development of secondary AML in patients treated first for primary cancers may be one of the most compelling reasons to develop alternative and less genotoxic approaches to therapy.

PRESENTATION

The clinical presentation of AML varies greatly with systemic symptoms and severity of illness usually being a result of leukemia cells' replacement of normal hematopoietic progenitors in the bone marrow as well as their infiltration into various organs. Approximately 10^{12} leukemia cells have been estimated to be present at the time of diagnosis. The leukemic blasts can invade extramedullary sites, such as soft tissues, skin (leukemia cutis), gingiva, orbit, and brain. Patients typically present with signs and symptoms of neutropenia, anemia, and thrombocytopenia. On occasion, other systems may be involved at presentation, as in the case of coagulopathy seen most commonly in APL, spinal cord compression from chloromas, or end-organ damage due to hyperleukocytosis.

The total WBC count may be low, normal, or high depending upon the number of circulating leukemic cells. The absolute neutrophil count is often less than 0.5×10^9/L and is associated with an increased risk of infections, often life threatening. Blood cultures and broad-spectrum intravenous antibiotic coverage are indicated in any newly diagnosed patient with leukemia and fever. Anemia results in fatigue, lethargy, decreased exercise tolerance, headache, and pallor. Although uncommon at the time of presentation, congestive heart failure (CHF) may occur, particularly with severe anemia, which is usually normocytic and normochromic although evidence of red cell fragmentation may be seen in cases presenting with disseminated intravascular coagulation (DIC); the transfusion of packed red blood cells should usually be done slowly to prevent precipitating or worsening CHF. Thrombocytopenia often leads to bruising and petechiae, and occasionally overt hemorrhage into the gastrointestinal track, lungs, or central nervous system (CNS). Approximately 50% of patients have hepatosplenomegaly and lymphadenopathy. Gingival hyperplasia and leukemia cutis are less frequent but particularly characteristic of myeloid leukemia with monocytic differentiation.

Patients may also present with anemia, which gives rise to fatigue, pallor, and, in extreme cases, hemodynamic instability. The anemia is typically normocytic and normochromic, although evidence of red cell fragmentation may be seen in severe cases of DIC. The median hemoglobin is ~70 g/L, with a range of 25 to 140 g/L.

Nearly 75% of patients present with a platelet count $<100 \times 10^9$/L.[179] Thrombocytopenia may cause petechiae, purpura, mucosal bleeding, and, rarely, CNS and pulmonary hemorrhage. Thrombocytopenia is exacerbated by coagulopathy, especially in the M3 and M5 AML subtypes. Although the mechanism for DIC is not known in M5 AML, there is convincing evidence that expression of annexin II, a receptor for fibrinolytic proteins, facilitates plasminogen activation by associating plasminogen and its activator, tissue plasminogen activator, at the APL (M3) leukemic blast cell surface.[180]

Patients with peripheral blast counts $>200 \times 10^9$/L are at risk for CNS stroke due to hyperviscosity, and benefit from leukopheresis to drop the blast count rapidly.[181] Similarly, pulmonary insufficiency may occur in patients with very high leukemia blast

counts. Approximately 5% of patients with AML have CNS disease at diagnosis, and a smaller percentage presents with CNS chloromas.[182] These patients may have headaches, cranial nerve palsies, focal neurologic deficits, and, rarely, seizures.

DIFFERENTIAL DIAGNOSIS

Whereas the diagnosis of AML is generally straightforward, the differential diagnosis is broad, including both malignant and nonmalignant conditions. Juvenile rheumatoid arthritis, infectious mononucleosis, aplastic anemia, congenital and acquired cytopenias, and the transient myeloproliferative syndrome of DS infants may all mimic AML. AML may be mistaken for MDS or chronic leukemias, including CML, chronic myelomonocytic leukemia, and JMML. Undifferentiated leukemia or FAB L2 ALL may be morphologically difficult to distinguish from megakaryoblastic AML. Metastatic rhabdomyosarcoma or neuroblastoma in the bone marrow may appear as megakaryoblastic or monoblastic AML, especially in the neonate.

The diagnosis of AML is typically made on bone marrow aspirate examination, with special stains, flow cytometry, and cytogenetics providing additional data. On occasion, definitive diagnosis is difficult either because of technical difficulties in obtaining an adequate specimen or because of conflicting data. Repeat marrow aspirate and biopsy may provide a specimen adequate for diagnosis. Touch preparations of the bone marrow biopsy may be used in cases in which bone marrow aspiration is difficult. Increasingly, a diagnosis can be made from peripheral blood using multiparameter flow cytometry, although in some instances significant differences in antigen expression may exist on leukemic blasts in the bone marrow compared to the peripheral blood.

ACUTE MYELOGENOUS LEUKEMIA SUBTYPES

Both FAB and WHO classification systems are used by clinicians treating pediatric AML patients. Generally, both classification systems apply equally well to pediatric and adult patients. However, some important differences exist. FAB subtypes M0, M1, and M2 correspond to AML that is minimally differentiated, without maturation, and with maturation, respectively, are more common in older rather than younger children, with frequencies in children 10 to 15 years of age very similar to reported adult frequencies.[139,140] On the other hand, FAB subtypes M5 (acute monocytic leukemia) and M7 (AMKL) are significantly more common in younger children.[139,141] Likewise, the increased frequency of M7 AML in young patients is mostly due to the high rate of the M7 subtype in patients with DS.[142] Younger children are less likely to have t(8;21) and t(15;17) but more frequently have chromosome abnormalities involving 11q23. M0 AML is defined as AML without morphologic signs of differentiation and by expression of CD13, CD33, and CD117 (c-KIT) and myeloperoxidase by flow cytometry or electron microscopy (Table 77.1).

TABLE 77.1

COMPARISON OF KEY CHARACTERISTICS OF ACUTE MYELOGENOUS LEUKEMIA (AML) IN PEDIATRIC VERSUS ADULT PATIENTS

Characteristic	Pediatric ≤ 21 y	Adults >21 and <55–60 y
Cytogenetics	Higher frequency favorable risk cytogenetics	Greater percent of unfavorable cytogenetics and drug resistant markers
Antecedent AML predisposing disorders	Rare (some inherited predisposition)	Common (MDS, MPN, and therapy-related)
Subtype	More M4/M5, DS, TMD	Less M4/M5, no DS or TMD
Extramedullary disease	More CNS disease/leukemia cutis	Uncommon except in monocytic lineage
Induction	ADE	"7&3" standard
Remission rates (after 2 courses)	85–90%	60–80%
CNS Prophylaxis	Yes	Not routine
HSCT	Only for high-risk patients	For some intermediate- and most high-risk patients
APL Treatment	ATRA at 25 mg/m^2	ATRA at 45 mg/m^2
Gene mutations		
FLT3-ITD	10–20%	20–50%
KIT	25% in t(8;21)	17% in CBF
N-RAS	20%	10%
PTPN11	5–21% (infants)	Rare
WT1	13% (CN-AML)	10% (Normal karyotype)
NPM1	5–10% (14–22% in CN-AML)	35% (53% in CN-AML)
CEBPA	5% (14% in CN-AML)	10% in CN-AML
IDH1 or 2	16%	2–3%
TET2	Rare	16%
DNMT3A	Rare	20%
Overall survival	Approximately 60–65%	Approximately 40%
Late complications	Growth, endocrine, cardiac, neurocognitive, secondary malignancies	Secondary malignancies

ADE, ARAC, daunomycin and etoposide; CN-AML, cytogenetically normal AML; CNS, central nervous system; DS, down syndrome; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; TMD, transient myeloproliferative disorder.
Adapted from[214,422] and[149].

THERAPY FOR PATIENTS WITH NEWLY DIAGNOSED ACUTE MYELOGENOUS LEUKEMIA

Background

Pediatric AML protocols begin with a remission-induction regimen, followed by a course of consolidation therapy, and, subsequently, intensification courses that may include hematopoietic stem cell transplantation (HSCT). This relatively brief but intensive approach has yielded an approximately 60% to 70% chance of overall survival across different cooperative group protocols.[143–149] Although there is general agreement that pediatric AML therapy should be based on the use of anthracyclines and cytarabine, pediatric cooperative groups differ in their induction regimens and the use of HSCT transplant in the post-remission period. The major pediatric cooperative groups are also presently evaluating various risk-stratification methods as well as the use of novel agents.

Induction Therapy

The primary goal is to achieve a remission of disease, which is currently defined in the United States as peripheral blood count recovery with a normal or slightly hypocellular marrow with fewer than 5% leukemic blasts and no evidence of extramedullary disease. An increasingly important additional marker is the eradication of detectable minimal residual disease (MRD).

The first significant successful remission-induction regimen for patients with AML included 7 days of continuous infusion Ara-C at 100 mg/m^2/day and 3 initial days of an anthracycline, such as daunorubicin, at 45 mg/m^2 to 60 mg/m^2 per day. This regimen resulted in remission rates of between 60% to 70% in children and young adults.[150,151] However, several approaches have been utilized to improve on these remission rates, including altering the schedule and doses of Ara-C and anthracyclines, as well as the introduction of additional agents. Furthermore, supportive care measures, such as the pre-emptive use of broad-spectrum antibiotics and/or blood product transfusions, have proven to reduce significantly remission induction mortality and thus have improved remission rates.

Despite the different approaches taken by the cooperative groups, several important conclusions can be made. First, remission quality, now defined as negative MRD at the end of induction, modifies relapse risk, and more intensive induction regimens may provide deeper (i.e., nondetectable MRD) remissions with lower relapse rates and improved OS. The issue of induction intensification was nicely demonstrated in the Children's Cancer Group (CCG)–2,891 study, in which the intensively timed DCTER (dexamethasone, cytarabine, thioguanine, etoposide, and rubidomycin) arm had a similar morphologic induction success rate compared to the standard timing regimen, but the relapse rate for the intensively timed arm was lower regardless of post-induction therapy.[146] However, more intensive induction regimens also carry greater treatment-related morbidity and mortality that can diminish the net benefit of such intensive therapy. In general, each trial using a very intensive induction regimen has noted an initial toxic death rate of approximately 15%, which decreases to usually less than 5% with acquired treatment experience.[152,153]

This high induction mortality rate has been reduced in several studies by mandated supportive care guidelines (see the section "Supportive Care"). Although escalating the economic cost of AML therapy, these supportive care guidelines are critical for improved outcomes. In the CCG, these guidelines mandated early initiation of broad-spectrum antibiotics, including vancomycin at the first febrile episode, early initiation of treatment doses of antifungal agents after 3 days of persistent fevers, hospitalization until granulocyte recovery, strict hand washing, and use of high-efficiency particulate-air–filtered rooms whenever possible. Institution of these guidelines lowered toxic mortality to ~5% across cooperative group trials.[193]

Various trials have also tried to answer additional remission induction questions, including (1) determining the optimal dose and schedule of cytarabine, 2) determining the optimal anthracycline and dose, and (3) determining what agents can be added to the cytarabine and anthracycline backbone to improve outcomes. Although dose intensification of cytarabine has not been demonstrated to improve remission induction rates, higher doses appear to confer lower rates of leukemia relapse in adults in patients with core-binding factor AML.[151,154] Becton et al. reported the POG 9421 trial that randomized patients to standard versus high-dose cytarabine in induction therapy. No statistically significant differences in remission induction rate or EFS were observed; patients randomized to high-dose cytarabine had an increased risk of bacteremia/sepsis that approached, but did not reach, statistical significance (28% vs. 22%, $P = 0.1$).[155] A second pediatric study has also demonstrated no benefit for high-dose cytarabine over standard-dose cytarabine when used during induction therapy.[148]

Debate continues over the optimal anthracycline choice in induction. The Berlin-Frankfurt-Munster (BFM) group showed evidence that idarubicin was superior to daunomycin in induction,[156,157] and a meta-analysis by the Medical Research Council (MRC)/Institute for Cancer Research of randomized idarubicin/daunomycin comparisons suggested that idarubicin is superior.[158] The CCG-2941 and COG-2961 trials showed that idarubicin was too toxic to be used in sequential courses of intensively timed IdaDCTER therapy.[153,159,160]

The MRC AML-12 trial randomized daunorubicin, ARAC, and thioguanine (ADE) versus mitoxantrone, ARAC, etoposide (MAE) in combination with cytarabine and etoposide. Although the MAE regimen showed a decrease in the relapse rate compared to the ADE-treated group, the increased risk of treatment-related mortality led to no overall benefit in DFS or OS. These results were similar in children and adults.[161,162]

Whereas the addition of other agents to the "7 and 3" backbone has helped increase induction rates from 70% to 85%, no randomized trial has demonstrated the superiority of a particular agent, or combination of agents, over any other combination. Specifically, the MRC-10 trial tested 6-thioguanine versus etoposide with daunomycin and cytarabine and found no statistically significant difference between the two induction regimens.[145] In an attempt to introduce a novel, noncross-resistant agent into induction therapy, the COG AAML03P1 trial demonstrated that gemtuzumab ozogamicin (GO) can be safely added to a backbone of cytarabine, daunorubicin, and etoposide, resulting in a remission rate of 83.5% after 1 cycle of therapy.[147,163] Results of the randomized trial using GO have not been reported at the time of this writing. However, the randomized study from the MRC has demonstrated no change in remission rates with the addition of GO, but an OS advantage particularly for patients with core-binding factor AML.[164] No advantage was observed in a Nordic Society of Pediatric Hematology and Oncology (NOPHO) trial randomizing GO in the post-remission setting.[165]

In summary, current pediatric AML induction regimens successfully induce remission in approximately 85% of patients using a variety of induction strategies. The improvements in induction remission rates have come primarily from intensification of therapy, either by adding additional agents to the "7 and 3" backbone or from dose intensification. Although successful, it appears unlikely that further dose escalation or intensification will significantly improve remission rates. Thus, a central remission induction question now centers on the selection and safe integration of other novel agents aside from GO, in order to increase antileukemic activ ity with less toxicity than conventional chemotherapy.

Post-remission Therapy

Once a complete remission has been achieved, including negative MRD status, additional therapy is required to avoid disease relapse. Various combinations and numbers of courses of therapy have been tested.

Dose and Duration

Although agreement exists on the role of cytarabine-based intensification therapy, especially for core-binding factor myeloid leukemias in which additional courses of cytarabine appear to decrease relapse risk significantly, the optimal number of cycles of intensification chemotherapy is not known.[146,166,167] The published pediatric AML trials have used either 2 or 3 courses of consolidation therapy, for a total of 4 or 5 courses of therapy.[168–170] The MRC AML-10 trial randomized patients to either auto-HSCT transplant or no further therapy and demonstrated a decreased relapse risk in patients receiving auto-HSCT. However, the addition of auto-HSCT was associated with significant morbidity and mortality, thus abrogating any OS advantage.[169] The CCG-2961 trial gave patients a total of 3 courses of chemotherapy with a resulting overall survival of 57% following changes in supportive care recommendations.[171] The MRC AML-12 trial randomized patients to a total of 4 versus 5 courses of chemotherapy with an OS of 81% versus 78%, respectively, at 5 years ($P = 0.5$). However, the survival for patients with very high risk AML was significantly less than for patients with intermediate and favorable risk AML; thus, any attempts to test 4 versus 3 courses of therapy should likely be done in the latter groups.[162]

With the exception of patients with APL, the use of maintenance therapy with relatively low dose chemotherapy has been currently abandoned with the exception of BFM studies, which in part base this choice on the results of BFM-87, in which a maintenance phase was beneficial to a low-risk group of patients who did not receive HSCT. However, when only randomized patients were analyzed, no significant difference in outcome was observed, and no significant difference was observed.[172] Other cooperative groups, however, have shown that maintenance therapy is associated with a decrease in both EFS and OS when compared to shorter, more intensive regimens, with relapsed disease being more resistant to subsequent therapies.[173,174,175]

Hematopoietic Stem Cell Transplantation

Sustained improvements in chemotherapeutic regimens and supportive care have continued to reduce the need for patients to receive allogeneic HSCT. Furthermore, several studies have shown equivalent overall survival when compared to chemotherapy; most co-operative groups have thus omitted autologous HSCT from consideration in order potentially to avoid greater short- and long-term toxicities.[145,168,176,177] However, with equivalency of overall outcome between autologous HSCT and chemotherapy, one might also conclude that either approach would be a reasonable, evidenced-based recommendation.[178] In addition, alternative approaches to transplantation, such as the use of nonablative or intensity-reduced allogeneic or haplo-identical HSCT, remain experimental and need prospective testing in comparison to more conventional approaches.

Pediatric cooperative groups generally agree that intensive cytarabine-based post-remission induction therapy is required to minimize relapse risk. The role of allogeneic HSCT has continued to evolve. This has in large part been due to the advances in chemotherapy-based treatments for patients who might have previously been considered candidates for allogeneic HSCT. Key questions are whether allogeneic HSCT provides an overall improvement in survival and quality of life compared to chemotherapy-only treatment approaches. In order to answer these questions, it has been necessary to define risk groups more carefully in terms of outcome and potential for benefit from HSCT. In addition, whereas most trials have analyzed outcomes on whether patients did or did not have an HLA-matched donor, the improving success being obtained using matched unrelated donor HSCT has led to outcome analysis based on availability of the best HLA-matched donor.[162]

Many trials have shown that allogeneic HSCT results in an improved disease-free survival compared to chemotherapy or autologous HSCT.[162,168,177,179,180,181] However, HSCT has not usually resulted in an improved event-free or overall survival, reflecting the associated increased treatment-related mortality. Such results suggest that HSCT may benefit some groups more than others. Several studies have attempted to define such subgroups more precisely.

The availability of an HLA-matched donor was used to analyze outcome in the MRC AML 10 trial.[182] There was no statistically significant difference in overall survival between those children with (68%) or without (59%) a donor at 10 years, even those there was a significant difference in relapse rate (30% with donors vs. 45% without donors). Based on the MRC cytogenetic and response-based risk stratification, overall survival at 5 years from the time of relapse was 57%, 14%, and 8% for good, standard, and poor risk groups, respectively; this led to the conclusion that allogeneic HSCT should be done in good risk AML in CR2. Although outcomes from MRC AML 10 also suggested that allo-HSCT in first remission as improved for patients with intermediate- and high-risk AML, combined data from the MRC AML 10 and 12 trials showed no statistically significant benefit for these groups of patients compared to chemotherapy alone.[182] BFM trials and POG 8,821 and 9,421 studies showed comparable results although in the POG trials did not do a detailed subgroup stratification.[155,183,184]

In contrast, analysis of post-remission treatment of 1,464 children less than age 21 years on 5 consecutive CCG trials from 1979 to 1996 has shown an advantage to those patients assigned a HSCT in terms of overall survival ($P = 0.026$), disease-free survival ($P = 0.005$), and relapse rate ($P < 0.001$).[185] Subgroup analysis demonstrated that HSCT was associated with improved survival for patients with WBC greater than 50,000/μL and for those with normal karyotype, but was not beneficial for patients with AML characterized by good -risk cryogenics, such as inv(16) or t(8;21). In support of such data, a report from the CCG 2961 trial showed no statistically significant advantage of having a HSCT donor in terms of OS or DFS in the subgroup of patients with inv(16) or t(8;21) chromosomal translocations.[171] A detailed analysis of the effect of donor availability on patients with standard and poor risk features was not reported although no advantage of having a HSCT matched family member donor was observed compared to chemotherapy for the entire study population. Overall, these results appear to be consistent with those reported from pediatric MRC AML trials.

A more detailed analysis of the MRC AML 12 outcomes has reported no advantage of HSCT for patients in the good and intermediate groups, but a statistically significant advantage for relapse-free survival and overall survival for a subset of patients with high-risk AML; for example, in the 12% of patients defined as having poor-risk AML, HSCT was associated with an overall survival of 41% compared to 10% for those who received only chemotherapy ($P = 0.001$).[162]

Whether patients with other subtypes of AML might also benefit from receiving an allogeneic HSCT remains controversial. A high FLT3-ITD mutant to normal allele frequency has been uniformly associated with a poor prognosis when patients are treated with standard chemotherapeutic regimens alone.[186,187,188] A significant question is whether more allogeneic HSCT is able to improve outcomes in patients with a high allelic ratio FLT3-ITD AML.

Some studies have strongly suggested an advantage of HSCT for patients with a high mutant allele frequency of *FLT3*-ITD

mutations.[188–191] Data from the CCG 2941 and 2961 trials showed a borderline significant difference in relapse for patients with FLT3-ITD positive AML who received a allogeneic matched sibling donor HSCT (27% ± 27%) compared to those treated with only chemotherapy (65% ± 15%, $p = 0.05$). However, overall survival at 4 years from the end of the second course of treatment was not significantly different (64% ± 29% for those with FLT3-ITD AML who received an allogeneic HSCT and 48% ± 17% for those treated with chemotherapy [$p = 0.4$]).[188,192] The MRC AML 10 and 12 trials concluded that there was no strong evidence that FLT3 status should be considered as to whether to perform a HSCT based on their analysis of 1,135 young adult patients.[193] Because OS was not significantly improved by having a donor in patients with FLT3-ITD positive or negative AML, it was concluded that allogeneic HSCT is not able to overcome the intrinsic chemoresistance or radiation resistance of FLT3-ITD positive AML. Thus, whether allogeneic HSCT can improve outcomes for patients with FLT3-ITD remains an open question. Nevertheless, most ongoing clinical trials for children and young adults assign allogeneic HSCT for patients with AML characterized by a high mutant FLT3-ITD to normal allelic ratio, often in the context of additional targeted therapy directed toward inhibition of the mutant receptor.

Current strategies for determining which patients should receive matched or single mismatched family donor or alternative donor HSCT are thus based on risk assessment and stratification. Patients with AML characterized by alternations in core binding or transcription factors (e.g., t(8;21), inv(16), biallelic *CEBPA* mutations) have an approximately 80% overall survival with chemotherapy alone and, thus, HSCT is recommended only in CR2. Similarly, children and young adults with APL have an overall survival of 75% to 90%, depending on risk group, with chemotherapy plus all-*trans*-retinoic acid (ATRA) and, more recently, arsenic.[194,195] Thus, HSCT is not usually recommended in CR1 for these patients, but instead following CR2, in which case allogeneic, and in some instances autologous, HSCT result in an approximately 70% overall survival.[195–197]

MLL-rearranged AML represents an extremely heterogeneous group of leukemias associated with variable outcomes. For example, an international trial has reported that survival is 100%, 63%, 27%, and 22% for patients with the t(1;11), the t(9;11), the t(4;11), and the t(6;11), respectively.[198] Because of the wide variability of outcomes along with small numbers of patients with MLL subtypes as well as no prospective definitive data that demonstrate HSCG improves outcome in this group of patients, most cooperative group clinical trials have not used allogeneic HSCT in CR1.[178] An intention-to-treat analysis of the AML-BFM 98 study has suggested an improved OS with allogeneic MSD HSCT for patients with 11q23 (MLL) rearrangements.[199]

AML characterized by a normal karyotype represents a large percentage of cases, however, it is also proving to be a molecularly heterogeneous group. For example, nucleophosmin member 1 (*NPM1*) mutations are associated with an improved outcome, although not necessarily in the presence of high mutant FLT3-ITD to normal allelic ratio is somewhat controversial.[200,201] AML with *CEBPA* mutations is usually associated with normal karyotype AML and improved overall survival, thus making HSCT undesirable in CR1.[50] Point mutations involving *KIT, RAS*, or *WT1* (Wilms tumor 1) have not yet been definitively shown to improve outcome although some data exist linking them to a poorer prognosis.[202,203] Furthermore, patients with AML having high-risk cytogenetics, such as monosomy 7 or del(5q)– and –5, are recommended to have HSCT in CR1 (Table 77.2).

The Children's Oncology Group (COG) frontline AML clinical trial AAML1031 uses allogeneic HSCT in first remission only for patients with predicted high risk of treatment failure based on unfavorable cytogenetic, molecular characteristics and elevated end-of-induction MRD levels.[204] In contrast, the AML-BFM 2004 clinical trial restricted allogeneic HSCT to patients in second CR and to refractory AML, based on results from their AML-BFM 98 study showing no improvement in DFS or OS for high-risk patients receiving allogeneic HSCT.[205] Although the optimal timing for allogeneic HSCT has not been determined, most cooperative groups recommend doing HSCT following the second or third course of chemotherapy, based in part due to the time involved in obtaining HLA typing. The use of matched unrelated donors (MUD), haploidentical donors, single- or double-cord blood donor, or nonablative approaches for HSCT in CR1 are not as clearly established as MSD HSCT, but are increasingly used to provide potential curative treatment for patients with recurrent AML (Table 77.3).[206,207]

TABLE 77.3

CHILDREN'S ONCOLOGY GROUP (COG) RISK CLASSIFICATION FOR AAML1031 TRIAL

Low Risk (~70–75% of Patients with Predicted OS of 70–75%)
Presence of favorable cytogenetics involving inv(16) or t(8;21), mutations of *CEBPA, NPM1,* and with any MRD status at the end of first induction course
OR
Standard risk cytogenetics and negative MRD at end of first induction course
High Risk (~25–30% of Patients with OS < 35%)
Presence of poor prognosis cytogenetic changes such as monosomy 7, del(5q), with any MRD status at end of first induction course
OR
High *FLT3*-ITD to *wild-type* allelic ratio with any MRD status at end of first induction course
OR
Standard risk cytogenetics and positive MRD at end of first induction course

Note: In this schema, patients without minimal residual disease (MRD) or noninformative cytogenetic/molecular studies are classified as having low-risk disease

Summary of Therapy for Patients with Newly Diagnosed Acute Myelogenous Leukemia

Despite some differences in their approaches, most pediatric cooperative groups share a common treatment strategy based on anthracyclines and cytarabine and risk stratified use of HSCT.[173,174,183,184,208–211,212,213,214] Overall survival at 5 years for children with AML is in the 55% to 65% range, with some patients doing significantly better and others worse. As more children and adolescents are long-term survivors, increased attention is also now being paid to survivorship issues.

THERAPY FOR PATIENTS WITH RELAPSED/REFRACTORY DISEASE

Despite AML treatment intensification, recurrent and/or refractory disease remain the major causes of treatment failure. Re-induction regimens typically use high-dose cytarabine, even if prior therapy has included substantial cytarabine exposure. With the addition of agents such as mitoxantrone, etoposide, fludarabine, cladribine, or clofarabine to cytarabine, approximately 50% to 70% of patients with relapsed or refractory patients achieve CR, depending on the time of their relapse relative to their therapy.[215–218,219,220] There is evidence that the combination of fludarabine, idarubicin, and cytarabine (FLAG-Ida) has a high remission-induction rate, which may be of longer duration. However, the toxicity associated with this regimen is also substantial.[218,220,221] The combination of mitoxantrone and high-dose cytarabine used in the CCG-2951 study achieved a 76% overall remission rate.[222] Several adult trials have demonstrated that GO may be safely combined with several chemotherapy regimens for AML re-induction therapy. The COG AAML00P2 trial demonstrated that GO could be safely combined with either cytarabine/mitoxantrone or with cytarabine/L-asparaginase. However, exposure to GO, particularly at single-agent doses, <3 months prior to HSCT increases the risk of severe veno-occlusive disease during HSCT.[223–225]

Patients with refractory or relapsed AML will usually require an allogeneic HSCT from either a related or an unrelated donor to achieve a long-term cure.[206,226] Conditioning regimens are quite variable and randomized, and prospective trials rare. Because many investigators are reluctant to give conditioning regimens that include total-body irradiation to young children, the balance between risks and benefits of total-body irradiation–containing regimens for relapsed AML is largely based on retrospective comparative reports. Donor sources have included MUD, HLA-matched and -mismatched cord blood (single or double) donors, haploidentical donors as well as KIR-mismatched unrelated or haploidentical donors.[227]

Although the use of cord blood units and haploidentical grafts makes alternative donors available for almost every patient, both of these stem cell sources have disadvantages over fully MUD. Cord blood grafts may have less of a graft-versus-leukemia effect, and the small number of stem cells can delay engraftment or increase graft failure. Haploidentical grafts may be associated with higher rates of graft-versus-host disease, as well as higher rates of viral infections and post-transplant lymphoproliferative disease as a result of the intensive immunosuppressive transplant regimens used.[228]

Despite the increased risks of toxicity, infectious complications, and graft-versus-host disease associated with the allogeneic transplant typically used for relapsed or refractory AML, between 20% and 50% of patients may achieve long-term survival.[229,230] Cure is significantly affected by the duration of first CR, with shorter CR-1 (e.g., <6 months off therapy or while on therapy) being associated with lower overall survival.[231] Leukemia karyotype may also modify the probability of achieving CR with relapsed and/or refractory AML.[232] Overall, patients with AML characterized by such high-risk features have a 3-year survival of <20%, whereas patients with initial CR lasting >1 year may have a 30% to 40% 3-year survival. However, the rate of cure for patients with typical core binding factor AML, such as t(8;21), have an excellent survival rate following relapse following CR2 and allogeneic HSCT.

SUPPORTIVE CARE

Current AML treatments are among the most intensive used in children with cancer, and cause a wide variety of severe complications. AML treatment-related morbidity and mortality significantly affect OS of patients, both through treatment delays and deaths due to toxicity. Thus, patients with AML should be cared for by physicians and nurses experienced in AML therapy in institutions with appropriate laboratory, radiology, blood banking, and surgical services.

Standardization of supportive care, as shown by Riley et al., may reduce treatment-related mortality by 50%.[152] AML supportive care guidelines typically focus on infection prophylaxis and treatment, although hematologic support is also critical. Fever and neutropenia in patients with AML constitute a medical emergency. After obtaining blood cultures, broad-spectrum antibiotic therapy should be instituted rapidly. Coverage for penicillin-resistant *Streptococcus viridans* and Gram-negative organisms should be given, and anaerobic coverage should be added if clinically indicated. Local microbial resistance patterns should dictate selection of initial antibiotics, although broad-spectrum antibiotics are typically included in the initial antibiotic selection. Patients should remain on broad-spectrum coverage until their neutropenia shows signs of resolution. Vancomycin use may be limited to 24 to 48 hours until a resistant *S. viridans* infection has been excluded. Although patients with AML are at risk for a wide range of bacterial infections, Gram-negative organisms occur frequently at diagnosis, and α-hemolytic streptococcus is often seen after intensive consolidation regimens.[233]

Empiric antifungal therapy should begin if fever persists for >3 to 5 days after initiation of antibiotic therapy or with recurrent fever. Amphotericin B has been the first-line choice for antifungal coverage, although recently voriconazole and caspofungin have been shown to be effective agents associated with fewer toxicities.[234] Selection of the appropriate antifungal agent is guided by culture results, which may require biopsy, radiographic findings of lesions difficult to biopsy, and the side-effect profiles of the various antifungal agents. Note that strict hand-washing guidelines, mandated hospitalization until neutrophil recovery, and use of high-efficiency particulate-air–filtered rooms whenever possible all significantly decrease the incidence, morbidity, and mortality of infections in pediatric AML patients.

Multiple studies, including the recently reported BFM 98 trial, have demonstrated that G-CSF may decrease the length of neutropenia and the length of hospital stay, but it does not appear to alter severe toxicity or infection rates.[235–237] Unlike studies in adults, G-CSF treatment in patients with hypercellular day 7 bone marrows on CCG-2891 had a statistically significantly improved remission rate and OS, although the introduction of G-CSF in this study was not randomized.[238]

Prophylaxis against opportunistic infections is also an important supportive care issue. Although *Pneumocystis jiroveci* is rare in pediatric patients with AML, prophylaxis with trimethoprim–sulfamethoxazole is often given. *S. viridans* sepsis may be prevented by penicillin prophylaxis in centers where *S. viridans* remains penicillin-sensitive. Penicillin resistance, however, is becoming more frequently detected. High-efficiency particulate-air–filtration has been shown to diminish *Aspergillus* infection in marrow transplant patients and likely benefits AML patients who

experience prolonged periods of neutropenia and immunosuppression.[239] In addition to management of infectious complications, the pre-emptive use of blood products has also been shown to play a critical role in the successful treatment of patients with AML.[240,241]

LATE EFFECTS OF THERAPY

Although intensive AML protocols cure a substantial fraction of children with AML, the late effects of these therapies can be significant. Several investigators have reported on AML late effects, but population-based follow-up studies of recent intensive therapies are lacking and remain a critically needed area of research.[242–244] Leung et al., reporting on 77 patients surviving more than 10 years from diagnosis, observed that increasing radiation dose as well as younger age at diagnosis and timing of radiation therapy were risk factors for growth delay, infertility, academic difficulties, cataracts, and hypothyroidism. Patients receiving total-body irradiation had lower cumulative anthracycline doses (204 mg/m^2 vs. 335 mg/m^2) but did not have a lower rate of cardiomyopathy, suggesting an interaction of radiation and anthracyclines.[244] An analysis of a cohort of infants with leukemia treated by chemotherapy and then HSCT indicated that 59% had growth hormone deficiency, 35% had hypothyroidism, 24% had osteochondromas, 24% had decreased bone mineral density, and 59% had dyslipidemias.[245] Temming et al. reported on results from the United Kingdom that there was a 13.7% and 17.4% prevalence of early and late cardiotoxicity in children survivors of AML treated with chemotherapy.[246] Patients who survive AML therapy also have a significantly increased rate of secondary malignancies.[247] However, primary disease relapse and therapy-related morbidity decrease EFS significantly more than secondary AML.

A population-based study involving children treated on NOPHO clinical trials demonstrated overall equivalent usage of health care services compared to their siblings, although there was a significant increase in use of prescription medications, especially for asthma in the leukemia survivors.[248] A Childhood Cancer Survivor Study (CCSS) analysis of 272 5-year survivors of AML showed excellent resiliency and health in this group with significant concerns relating to secondary malignant neoplasms (the majority of which were in the setting of radiation exposure) as well as lower socioeconomic achievement compared to siblings. In addition, half of the survivors reported at least one chronic medical problem and were considered at increased risk for a severe or life-threatening condition compared to their siblings.[249]

MANAGEMENT OF PATIENTS WITH DOWN SYNDROME

The majority of leukemias in children with DS are lymphoid, although DS children comprise 10% of pediatric AML patients and thus represent the most frequently associated genetic disorder associated with the development of AML.[250] Furthermore, there is an up to twentyfold risk of developing leukemia in children with DS or mosaicism for Trisomy 21. Approximately 5% of newborns with DS experience transient myeloproliferative disease (TMD).[250] Although TMD will usually spontaneously resolve over the course of several weeks to months, about 10% to 20% of these infants will go on to develop AML, mostly of the megakaryoblastic subtype (AMKL). The leukemic blasts in TMD and DS AMKL express exon 2 mutations of *GATA-1* and originate from fetal liver hematopoietic precursors.[251] These disorders may be associated with hydrops fetalis as well as liver cirrhosis.

Because of the spontaneous remissions observed in DS patients with TMD, close observation is usually the first approach to management. However, when life-threatening signs and symptoms occur, often a result of hyperleukocytosis and organomegaly, treatment approaches can include exchange transfusion and/or low-dose cytarabine arabinoside at 1 to 1.5 mg/kg IV for 5 to 7 days.[250,252]

The favorable outcome for young children with DS and AML treated with less intensive chemotherapy regimens has been observed since the 1990s.[253–258,259] However, age at the time of diagnosis is an important prognostic factor in children with DS and AML with children greater than 4 years of age having a significantly worse 4-year EFS of 28% compared to the greater than 85% for younger patients.[250,259,260,261] Older patients with DS and AML are often now treated on conventional AML protocols, albeit with mixed results. Significant improvements in therapy are needed for this group of patients. However, because of the excellent prognosis of younger patients with DS and AML, the goal of trials continues to be directed toward reducing the intensity of therapy, and, particularly, anthracycline exposure.[262]

MANAGEMENT OF PATIENTS WITH NON-DOWN SYNDROME INHERITED SYNDROMES

Patients with inherited syndromes, such as those characterized by DNA repair defects, usually are not able to tolerate the effects of chemotherapy or radiation treatment as well as other children with AML. For example, patients with FA require substantial dose reductions in chemotherapeutic drugs as well as bone marrow transplantation regimens, but such patients can sometimes be cured of their AML. However, chemotherapy to cytoreduce leukemia burden followed by reduced-intensity regimens are therefore recommended for such patients.[263–269] Patients with other familial cancer predisposition syndromes, such as those with germline *CEBPA* mutations, or Kostmann syndrome, who develop AML, can also be effectively treated with allogeneic HSCT.[270–272]

MANAGEMENT OF INFANTS WITH ACUTE MYELOGENOUS LEUKEMIA

Congenital leukemia is defined as that which occurs in the first month of life. Approximately two thirds of patients present with leukemia cutis, giving a "blueberry muffin" baby appearance that may also be seen in metastatic neuroblastoma or rhabdomyosarcoma and histiocytosis (Fig. 77.3). Hepatosplenomegaly is also typically present, but lymphadenopathy less so; CNS involvement is present in 50% of cases that included performance of a lumbar puncture. The WBC count is typically elevated, and the majority of reported congenital myeloid leukemias have been of the M5 subtype. A majority of congenital AML cases have abnormal cytogenetic findings, with approximately one fourth of cases having 11q23 abnormalities.[273,274] AML in infants (usually considered as being less than 12 months of age) is also characterized by a high predominance of *MLL* rearrangements.[275]

Although spontaneous remissions have been reported in neonates with AML,[276] OS tends to be poor, with an OS of 24% at 2 years in the most comprehensive review.[273,274] For these neonates and infants, conventional approaches to therapy using AML regimens used in older children are typically used, but with dose adjustments.[275] This is in part due to the immaturity of organs as well as the immune system, resulting in significant treatment-related toxicities, including death.[275,277] For instance, the AML-BFM studies have suggested the dose reduction of cytarabine arabinoside because of the reduced clearance in children under the age of 2 years.[278] With such intensive, although in part modified, AML-directed regimens, the survival for infants can be similar to that reported in older children, i.e., in the 65% to 75%

FIGURE 77.3. Leukemia cutis in an infant with congenital leukemia. (From Arceci R, Weinstein H. Neoplasia in the neonate and young infant. In Avery GB, ed. Neonatology: pathophysiology and management of the newborn. Philadelphia, PA: JB Lippincott, 2005, with permission.)

range for 5-year overall survival.[153,162,275] The role of transplantation in infants remains unclear.

MANAGEMENT OF ACUTE PROMYELOCYTIC LEUKEMIA

Before the introduction of differentiation targeted therapy, APL had a significantly poor outcome (Chapter 74). The use of ATRA, directed against the fusion proteins characteristically involving the retinoic acid receptor alpha (RARA) formed as a result of the usual t(15;17) chromosomal translocation, reversed this scenario.[279,280] Overall survival at 5 years is now in the 75% to 90% range depending upon the presence of different risk factors when patients are treated with combination regimens that include ATRA and chemotherapy.[195,281,282,283,284,285,286,287] Other RARA fusion proteins occur less frequently and display varying sensitivity to ATRA.

The therapy for APL is essentially identical for pediatric and adult patients. Thus, pediatric patients have usually been enrolled in various adult APL cooperative group trials. This has resulted in pediatric patients being exposed to significant amounts of anthracyclines as well as higher doses of ATRA. For instance, a conventional dose ATRA at 45 mg/m^2 is usually employed in adult trials, and results in a 90% or greater CR rate when used alone or in combination with chemotherapy. This type of treatment in children has been associated with increased toxicities, such as pseudotumor cerebri and "APL differentiation syndrome," which can occur in up to 25% of patients and is characterized by fever, respiratory distress, pulmonary infiltrates, pleural/pericardial effusions, fluid overload, hypotension, and acute renal failure. A dose of 25 mg/m^2 of ATRA appears to be equally effective and is thus recommended in most pediatric trials.[194,195,288–292] The recognition of this syndrome and early treatment with corticosteroids and temporary cessation of ATRA is critical. The effective use of prophylactic corticosteroids has been reported for patients with presenting WBC counts of $> 5{,}000/\mu l$.[293]

In addition, the high doses (usually in the 400 to 750 mg/m^2) of anthracyclines commonly used to treat patients with APL can have particularly significant adverse consequences to cardiac function in children.[195] Thus, an ongoing goal for pediatric trials (and some adult trials) has been to reduce overall anthracycline exposure. The introduction of arsenic trioxide (ATO) as a single agent in APL that has results in CR rates of up to 85% in patients with relapsed disease, has provided a potential alternative to anthracycline.[294–297] In addition, several studies have shown excellent to superior results when testing ATO in combination with chemotherapy along with ATRA.[298,299,300,301] The use of ATRA for induction therapy followed by 6 months of maintenance with arsenic has been reported to achieve a 3-year overall survival of 86%.[302] The combined use of ATRA, arsenic, and immunotargeted therapy with anti-CD33-calicheamicin monoclonal antibody (gemtuzumab ozogamicin or GO) has also been reported.[303,304]

The recently completed COG trial replaced a course of anthracycline-containing chemotherapy with arsenic, thereby reducing anthracycline exposure to 355 mg/m^2 of daunorubicin equivalents for standard-risk patients with negative MRD at the end of induction and to 455 mg/m^2 for high-risk patients and standard-risk patients who have MRD after the third treatment course. Of note, this trial also used high-dose AraC during consolidation based on positive results from a randomized trial in adults.[305]

Unlike other subtypes of AML, maintenance therapy with ATRA plus antimetabolites has also proven to provide improved outcomes for patients with APL, although subsequent data in a randomized trial in adults has suggested that such maintenance therapy may not be required for a subset of patients with good-risk APL.[306] Reducing or omitting maintenance therapy in subsets of pediatric patients with APL has not been reported.

The use of intrathecal (IT) chemotherapy as prophylaxis in patients with APL remains unclear. Some studies have suggested that the incidence of CNS relapse is higher in patients treated with ATRA or with high risk APL, however, definitive data demonstrating that IT prophylaxis reduces extramedullary relapse have not been reported.[307,308] Overall, the incidence of extramedullary relapse in patients with APL is about 3% to 5%.[309] Most pediatric trials continue to include some IT prophylaxis. An important issue, however, is that lumbar puncture may not be safe at the time of presentation because of underlying coagulopathy, thus further complicating the timing of CSF sampling and IT prophylaxis.

Another important consideration in treating patients with APL is to evaluate their initial risk status. Patients who present with APL and a WBC $>10^9$/L are considered in most studies to have high-risk disease and are usually treated with more intense regimens. The presence of FLT3-ITD mutation might predict early death in pediatric patients with APL[310] and a low FLT3-ITD to normal FLT3 allele ration has been reported to be associated with an improved prognosis in APL.[311] Nevertheless, patients with high-risk APL make up a large percentage of the approximately 15% to 20% of patients with APL who experience relapse of their leukemia. The detection of early (molecular) relapse in adults has also proven to be advantageous.[312,313,314] Treatment goals in this situation are to obtain a second CR,

which can usually be achieved with single-agent ATO or in combination with chemotherapy and ATRA. Post-remission therapy is required to improve overall outcome. For example, in one report, 50% of patients who received an additional course of therapy with ATO were alive at 2 years compared to 78% who underwent either allogeneic or autologous HSCT.[315] Thus, some type of HSCT as consolidation therapy for patients with relapsed APL is usually recommended. A study from the European APL Group reported that the 7-year OS for adults was significantly better for those who received autologous HSCT compared to those receiving an allogeneic HSCT (60% vs. 52%, respectively; $p = 0.04$); this difference was in large part due to the increased treatment-related toxicity with allogeneic HSCT.[196] Another important consideration, however, is whether there is any bone marrow, molecular evidence of the APL at the time of stem cell harvest for autologous HSCT. Meloni et al. reported that all patients whose autologous graft was positive by RT-PCR for RARA fusion transcript relapsed within 9 months of autologous HSCT.[316] Thus, autologous HSCT may be beneficial for patients who achieve a molecular remission before graft harvest. For instance, Thirugnanam et al. have reported a 5-year EFS of about 83% for patients who received an autologous HSCT compared to 35% for those who received only maintenance therapy after achieving a second CR.[197] For patients where residual disease persists, allogeneic HSCT may be a more advantageous treatment strategy.[195,317]

A significant and unresolved challenge in both children and adults with APL is the prevention of early death due to hemorrhagic complications, which can occur in about 3% of patients.[318,319] The pathogenesis of the underlying coagulopathy in APL is complex, involving the release of activators of both coagulation and fibrinolysis by the leukemic cells.[320,321] Early detection and initiation of antileukemic treatment along with aggressive supportive care measures to control the coagulopathy are essential.[322,323]

GRANULOCYTIC SARCOMA

Granulocytic sarcoma, myeloid sarcoma, extramedullary AML, and chloroma all refer to AML presenting as a solid tumor from the localized proliferation of malignant myeloblasts. These may occur anywhere in the body, but are most commonly seen in skin, bones, or paraspinal/epidural sites. Chloromas may be present in up to about 5% of cases and are most frequently associated with AML characterized by the t(8;21) chromosomal translocation, but also can be seen in other subtypes, especially in infants with myelomonocytic or monocytic AML.[324] Patients may also present, albeit it rarely, with a chloroma and no detectable bone marrow or other systemic involvement.[324,325] Biopsy of a chloroma with special immunohistochemical staining for myeloid markers, FISH, and cytogenetics for AML-related alterations as well as flow immunophenotyping should be done as such lesions can be confused with lymphomas or bone and soft tissue sarcomas.

The management of patients presenting with chloromas should be similar to that of patients with AML as defined by conventional risk groups. A CCG study reported that EFS and local recurrence rates were similar for patients treated with chemotherapy alone compared to chemotherapy plus radiation to the chloroma(s).[326] Radiation therapy may thus be reserved in cases where a chloroma does not respond to intensive AML-directed chemotherapy.[324,326]

BIPHENOTYPIC LEUKEMIA

Biphenotypic, bilineage, bilineal, or mixed phenotype acute leukemia refer to leukemias which co-express proteins that are characteristically restricted during differentiation to either the lymphoid or myeloid lineage. The WHO classification has referred to these leukemias as having ambiguous lineage, with biphenotypic referring to one population of leukemic blasts that co-express myeloid and lymphoid antigens and bilineage referring to two distinct populations of leukemic blasts of different lineages. Usually more than one lineage marker from the opposite lineage is considered to be necessary to call the leukemia biphenotypic, as the aberrant expression of lymphoid-associated or myeloid-associated antigens may be present on 10% to 20% of AML and 20% to 40% of AML, respectively, and generally have not been shown to have prognostic significance.[327]

The optimal treatment of children with mixed lineage leukemia has not been determined. A recommendation that has resulted in reasonable outcomes is to direct treatment toward the dominant phenotype present. Thus, if a leukemia primarily demonstrates a lymphoid phenotype, then ALL directed therapy can be used to start induction therapy.[328,329,330] Although these leukemias are often considered to arise from earlier progenitors and thus difficult to cure with chemotherapy alone, HSCT may not be required in a significant number of cases.[331]

SECONDARY OR THERAPY-RELATED ACUTE MYELOGENOUS LEUKEMIA

Therapy-related AML (TR-AML) is most commonly related to exposure to specific chemotherapeutic agents, such as alkylating agents or topoisomerase inhibitors, as well as radiation.[22,332] The goal of treatment should be to achieve a CR and then proceed to allogeneic HSCT with the best available donor, including haploidentical donors. In addition to genotoxic exposures, there may also be predisposing genetic or susceptibilities, such as polymorphisms in drug detoxification and DNA repair enzymes.[333,334,335–337] Depending on the level of exposures and predisposing factors, estimates of between 0.4% and 2% risk for developing TR-AML exists for patients undergoing treatment for solid tumors.[247,338,339]

Complete remission rates and overall survival are usually lower for patients with TR-AML compared those with de novo AML.[332,340,341] A high nonrelapse mortality has also been reported for this group of patients undergoing HSCT.[334] Adverse or high-risk cytogenetic abnormalities and molecular alterations are more frequently observed in TR-AML.[22,332] Re-induction regimens should ideally include chemotherapeutic agents which patients have not been exposed to previously to reduce the risk of cross-resistance of the leukemia, although this is not always possible. However, novel agents and regimens available through clinical trials should be strongly considered if available. The relatively poor outcome for such patients increases the importance of determining more effective and less toxic treatments for patients with first malignancies.

PROGNOSTIC FACTORS

One of the greatest challenges in the treatment of patients with AML has been the identification of risk factors that could be used to more precisely direct treatment. Such risk or prognostic factors include those of the host and the disease as well as the treatment that is used (Fig. 77.4). Our limited ability to identify and act on such factors has relegated AML treatment to a population-based approach. However, there has been a continuous effort to improve this through a variety of methodologies and observations, leading to the hope that future therapeutic approaches can be more individualized.

Host Factors

Of the host factors, patient age, race, and specific constitutional abnormalities are most strongly correlated with outcome. In general, patient age is inversely related to treatment outcome. This

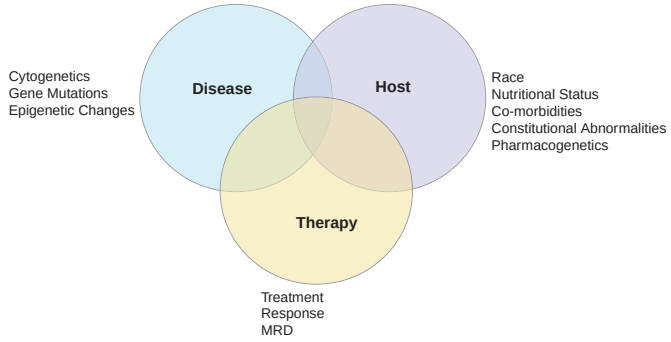

FIGURE 77.4. Relationship of prognostic factors in pediatric acute myelogenous leukemia. See text for details. FAB, French/American/British classification; MRD, minimal residual disease; PCR, polymerase chain reaction; WBC, white blood cell.

relationship was clearly demonstrated in the MRC AML-10 trial and was confirmed in MRC AML-12, in which infants, despite worse toxicity, had higher survival rates than older children.[226,342] The CCG-2891 trial has also demonstrated a benefit of young age[146] although age has not been found to be an independent risk factor in AML-BFM trials.[275,343] These differences may in part be due to treatment effects (Table 77.4).

Although patient gender is not usually included in risk models, females generally have marginally better outcomes than males. In CCG studies, race has consistently been a predictor of outcome, specifically with blacks having a poorer outcome than whites,[344] although this has not been observed in other studies.[345,346] The importance of body weight has also been underscored by a report from the CCG-2961 study, in which there was a twofold greater risk of treatment-related toxic deaths associated with patients who were ≤10th percentile or >95% percentile.[347]

Whereas the pharmacogenetic basis of treatment response is poorly understood, homozygous deletions of the *GST* theta gene, a detoxifying phase II enzyme, have been reported to be associated with decreased survival (52% vs. 40%; $P = 0.05$).[348] This difference in survival is due to an excess of toxicity in patients who are *GST* theta null (24% vs. 12%; $P = 0.05$).

Patients with constitutional abnormalities also have altered risk of treatment response. Most notably, patients with trisomy 21 who are less than 4 years of age may experience more therapy-related toxicity with conventional, dose-intensive AML regimens, but have higher survival rates than patients with a

Results are reported for only those trials that had 150 patients and information provided for each of the column headings. All numbers and percentages were rounded to the lowest value if less than 0.5 and to the next upper integer if ≥0.5.

[a]Ages include patients from 0 up to and including age 15 years: BFM-98 included patients from 0 to less than 17 years of age; number of patients excludes patients with Down syndrome; CCG-2961 included patients from 0 to 21 years of age.

[b]SJCRH AML02 and the COG AAML03P1 have EFS and OS at 3-year follow-up; COG AAML03P1 enrolled patients ≥1 month and ≤21 years of age.

[c]This reported results for two groups of patients who received identical induction therapy but randomized to receive or not receive post-remission gemtuzumab ozogamicin. Numbers in tables represent average of the reported values for each group.

normal constitutional karyotype when less intensive regimens are used.[250,260] Patients with other constitutional abnormalities, particularly FA, have increased toxicity with standard AML therapy. The underlying ineffective hematopoiesis leading to cytopenias limits their ability to recover normal hematopoiesis after AML therapy. As a result, these patients are generally excluded from standard AML protocols.

Disease-associated Factors—Clinical

Several characteristics of leukemia are also associated with outcome, including initial WBC count, FAB morphology, and cytogenetics. Like age, initial WBC blast count is inversely related to outcome. An initial WBC count $<20 \times 10^9$/L is associated with a favorable prognosis, whereas an initial WBC count $>100 \times 10^9$/L has been associated with an unfavorable prognosis in both the MRC and BFM trials. In the CCG-2891 study, patients with a WBC count $>330 \times 10^9$/L had an unfavorable prognosis, with an EFS of 7%, due to early death, induction failure, and relapse.[146] However, in the BFM trials, very high leukemia blast counts at diagnosis were not associated with a worse DFS, but with increased risk of early death and decreased induction remission.[349] High leukemia blast counts are now known to be associated with biologic factors, such as *FLT3*-ITD mutations.

CNS involvement, which occurs in about 5% to 10% of children with AML, has not been shown to result in decreased remission rates or survival, although there may be an increase of isolated CNS relapse.[350,351] Of note, of patients with chloromatous disease, those with orbital involvement have been reported to have an improved outcome.[352]

Morphologic classification schemes, such as the FAB classification, were once used to assign risk to subtypes of AML, however, this has been replaced by a more current WHO classification based on underlying biology.

Whereas the FAB group has been associated with treatment outcome, different studies have found different associations. The BFM group reported that patients with FAB M1–M4 had improved survival over patients with either M0 or M5–7.[309] However, in both MRC-10 and CCG-2891, the M5 FAB subtype was associated with favorable prognosis. FAB M7 in non-trisomy 21 patients has been associated with poor survival in CCG studies.

The cytogenetics karyotype of the leukemia blasts is a robust predictor of outcome. Patients with t(15;17), t(8;21), and inv(16) fare better than patients with other cytogenetic findings. Patients with monosomy 7 or 5 do poorly, as do patients with complex karyotypes, although the concomitant presence of monosomy 7 or 5 with complex karyotypes has made it difficult to discriminate between the contributions of other chromosomal changes. For example, FAB subtypes M1/M2 have been historically associated with a favorable prognosis but have a higher representation of favorable-risk cytogenetic changes. One exception may be with APL, where the early morphologic recognition and initiation of treatment can have important clinical consequences.

Disease-associated Characteristics—Cytogenetics/Molecular

The detection of recurrent chromosomal rearrangements in AML has been used to decide on probable risk of treatment failure since the 1990s. Chromosomal translocations involving core-binding transcription factors have been associated with a favorable prognosis, such as the t(8;21)(q22;q22) and inv(16)(p13.1q22), account for about 14% and 8% of pediatric AML, respectively. Although these core-binding factor leukemias are often considered together as a single group, there are important differences. For instance, the AML-BFM group has reported that reduction of intensity of treatment by omitting a high-dose ARA-C and mitoxantrone course during induction led to a decreased EFS and OS for patients with AML with t(8;21) but not inv(16).[353] AML characterized by t(8;21) is also associated in about 20% of cases with the occurrence of chloromas and expression of CD19 and CD56 antigens.[354,355] The inv(16) translocation is associated with the FAB o morphologic subtype.

The t(15;17)((q22;q21) translocation resulting in the *PML-RARA* gene fusion, occurs in about 5% to 10% of pediatric AML, and, as discussed above, is associated with greater than 75% overall survival using APL-directed therapies. APL with t(11;17), which involves the *PLZF* instead of the *PML* gene, has been associated with decreased sensitivity to ATRA.[356]

Rearrangements of the *MLL* gene at chromosome band 11q23 occur in 15% to 20% of pediatric AML, making them the most commonly observed cytogenetic abnormality.[357,358] The specific types of fusion gene generated from *MLL* rearrangements appear to have different impacts on outcomes. For example, patients with AML having a t(1;11)(q21;q23) have an extremely favorable prognosis whereas those with t(4;11), t(10;11), and t(6;11) have poor outcomes.[359] Patients with t(9;11) AML have been reported to have a favorable prognosis[360] however, subsequent studies have established this translocation to be associated with an intermediate prognostic category.[359] When combined with the core-binding factor leukemias, including APL, *MLL* rearranged AML represents approximately 50% of pediatric AML, which is significantly different from the cytogenetic distribution observed in adults with AML.[361]

Several large studies have defined other chromosomal abnormalities as being associated with unfavorable outcomes. Monosomy 7 or abnormalities of 7q, when recurrent genetic changes are excluded,[362] represents about 3% of pediatric AML. Of note, AML with del(7q) has been reported to have a better prognosis (5-year OS of 51%) compared to monosomy 7 (5-year OS of 30%).[357,358,363] Studies from the MRC and BFM AML groups have reported that abnormalities of chromosome 12p, often associated with 12p13 rearrangements that involve the *ETV6* gene, are associated with an unfavorable prognosis.[357,358] Other poor prognostic cytogenetic changes include t(6;11), t(10;11), t(7;12) t(6;9), 5(5;11), and –17/abn(17p).[364] The t(1;22)(p13;q13) translocation, often associated with megakaryoblastic leukemia in infants less than 12 months of age, was historically considered a poor prognostic feature, but intensive chemotherapy regimens have led to improved outcomes for these patients.[365,366] Rearrangements involving the 3q26 locus that includes the *EVI1* gene, including t(3;3)(q21;26), have been reported to be a poor prognostic factor in adults but are extremely rare in children.[367] However, increased expression of *EVI1* in children with *MLL*-rearranged leukemia, monosomy 7 or megakaryoblastic morphology, has been reported to predict an intermediate or unfavorable prognosis.[368–370] Chromosomal 5q– portends a poor prognosis in adults but is exceedingly rare in childhood AML. Complex karyotypes, usually defined as the presence of three or more chromosome abnormalities in the absence of one of the WHO-noted recurring chromosomal translocations or inversions, are generally associated with unfavorable outcomes regardless of whether good prognosis changes are observed.[357,358]

As cytogenetic abnormalities in AML tend to correlate with patient age, with, for example, *MLL*-rearrangements being common in infants and core-binding factor leukemias more common in older patients,[343] a similar correlation holds for molecularly defined prognostic factors. In addition, approximately 20% of children with AML have essentially normal cytogenetics and thus cannot be stratified into risk groups based on such criteria. Molecular studies have helped to determine patients further with more or less favorable AML in this group.

Internal tandem duplications in the juxtamembrane region of the FLT3 tyrosine kinase receptor, called *FLT3*-ITD mutations, occur in approximately 15% of children, about 25% or

greater in adults, and infrequently in very young children.[371] High mutant to normal allelic ratios have been shown to predict a poor prognosis across several large studies in children and adults.[187,371,372,373,374] Mutations may also occur in the kinase domain of FLT3, but these have not been shown to portend an adverse prognosis.[187,371,372,375] *FLT3* mutations have also been reported to be present in up to 40% of children and adults with APL, and appear to be associated with the microgranular variant, hyperleukocytosis, and early death in children.[310,376–378] Mutations in the KIT tyrosine kinase receptor occur in up to 25% of patients with core-binding factor AML and have been reported in some studies to define a higher risk subgroup,[379,380] but this was not observed in a subsequent COG report.[381]

Mutations in the *NPM1*, a component of nuclear to cytoplasmic transport complexes, tend to increase chemosensitivity and are associated with improved outcomes with 5-year EFS of about 70%.[200,201] Notably, when *NPM1* mutations occur in the presence of *FLT3*-ITD mutations, they do not appear to ameliorate an unfavorable prognosis.[374]

CEBPA mutations occur in approximately 6% of pediatric AML and are usually associated with normal karyotype AML and favorable prognosis.[50,374,382,383,384] Biallelic mutations of *CEBPA* define a distinct subtype of AML with a favorable prognosis.[383,385]

Mutations in the *WT1* gene occur in about 10% of pediatric AML and are usually associated with normal karyotypes, but can be associated with *FLT3*-ITD in approximately 40% of cases.[202,203,386,387] *WT1* mutations are independently associated, however, with poor 5-year OS of about 20%,[203,374] although this poor outcome was not observed in a COG trial.[203] Interestingly, *WT1* single-nucleotide polymorphism (SNP) of rs16754 in exon 7 has been reported to be present on a major allele in 28% of patients and to be associated with an improved 5-year OS of 62% compared to 44% for AML not containing the SNP; in addition, high *WT1* expression was associated with poor outcome in patients without the rs16754 SNP but not in those with the SNP.[387] However, this has not been seen in all studies.[386]

NRAS and *KRAS* mutations have been reported in 10% to 15% and 3% of pediatric AML, and up to 20% in adult AML.[374,388,389,390] *NRAS* mutations have been strongly associated with *NPM1* mutations in patients with excellent prognosis, although an independent impact of *NRAS* on remission rates or OS was not observed.[390]

Regulators of epigenetic patterning have been observed more commonly in adult compared to pediatric AML. For instance, whereas mutations of *TET2* on chromosome 4q24 have been reported in about 12% of adult AML (about 23% in normal cytogenetic AML) and to portend a poor prognosis,[391–393] these mutations occur in only about 6% of pediatric AML and may be, however, similarly associated with poorer prognosis.[48,394,395,396] Mutations of the *IDH1* (isocitrate dehydrogenase) gene interestingly produce a gain-of-function activity that in turn results in increased levels of 2-hydroxyglutarate and aberrantly hypermethylated promoter CpG sites.[397–399] Although *IDH1* mutations have been reported in about 8% of young adults with AML, and often associated with the presence of *NPM1* mutations, they appear to occur in up to 10% of pediatric AML.[49,400,401] Poor outcome has been associated with *IDH1* mutations in adults, but this has not been demonstrated in multivariate analyses from pediatric trials.[49,400,401] A minor SNP at rs11554137 associated with *IDH1*, found in about 10% of pediatric patients with AML, could also not be correlated with outcome.[402] Although mutations of the DNA methyltransferase encoding gene, *DNMT3A*, may occur in up to 20% of adult AML and have been associated with poor prognosis,[41,403–406] such mutations are exceedingly rare in pediatric AML.[48,407,408]

The robust prognostic cytogenetic and molecular characteristics that have been and continue to be identified have resulted in most clinical features, such as age, WBC at diagnosis, and morphologic classification, not to be significant in multivariate analyses. Figure 77.5 summarizes cytogenetic abnormalities and gene mutations in pediatric AML. However, despite the acknowledgment of the increasing heterogeneity of AML based on genetic, RNA expression, and epigenetic patterns, a complete understanding of what predicts response or resistance to therapy is lacking. To this end, increasingly sensitive assays to measure in vivo response to treatment have been developed to help predict outcomes in combination with the cytogenetic and molecular features.

Conventional morphologic assessment of early response to therapy is predictive of outcome, however, the application of flow-cytometric immunophenotyping or molecular methods have demonstrated substantially better sensitivity and predictability.[409,410,411] Although several reports have shown that increasing levels of t(8;21) or inv(16) transcripts portend relapse,[412–414] polymerase chain-reaction–based approaches to detect MRD have also been employed but are limited by the heterogeneous nature of chromosomal changes.[415,416] Detection of the t(15;17) fusion gene on consecutive testing during remission is associated with a high risk of relapse, although this assay is not very informative at the end of induction therapy as the majority of patients will still have detectable fusion transcripts at that time.[417–419]

MRC AML studies have demonstrated that 94% of children with AML have informative immunophenotypes that could identify AML blasts from normal hematopoietic progenitors. The 3-year RFS for those patients with MRK less than 0.1% at the end of induction was 64% compared to 14% for those with MRD values of greater than 0.5%. Note that MRD assessment retained its significance in a multivariate analysis that included such factors as age, WBC, cytogenetics, and *FLT3*-ITD status.[420] A study from SJCRH demonstrated MRD by flow cytometry that MRD values at the end of induction of 1% or higher was the most significant adverse prognostic factor for EFS and OS.[148] Using four-color multiparameter flow cytometry, COG reported from the AAML0531 study that an MRD value at the end of induction greater than 0.1% predicted a DFS at 3 years of 34% compared to 60% for patients without detectable MRD. It is important to note that a significant impact of MRD was absent in patients with favorable cytogenetics and in those with high-risk characteristics.[204] Although these results would suggest limited utility of MRD detection except in intermediate risk AML, they have been used to devise a risk stratification strategy for the ongoing COG AAML1031 trial for newly diagnosed patients with AML. Thus, by combining cytogenetic, molecular, and MRD assessments, two risk stratification groups are being used to direct treatment. Low-risk AML, representing 73% of patients with a predicted OS of about 73%, includes mutations involving CBF, CEBPA, and NPM and no MRD at the end of induction. High-risk AML, representing 27% of patients and with a predicted survival of less than 35%, includes adverse cytogenetic changes such as monosomy 7, del(5q), –5, high *FLT3*-ITD to wild-type allelic ratio, or positive MRD at the end of induction. Patients with low-risk disease will not be recommended for HSCT in first remission, whereas those in the high-risk group will be recommended for transplant in CR1 with the best available donor. Those patients with AML having *FLT3*-ITD receive both pre- and post-HSCT inhibitor (sorafenib). Other cooperative groups continue to evolve risk stratification schema by refining favorable, intermediate, and high-risk AML groups. In pediatric AML, usually only those with high-risk disease are recommended for allogeneic HSCT.

FUTURE THERAPEUTIC CHALLENGES

Although chemotherapy dose intensification with or without bone marrow transplantation has significantly improved the outcome of patients with AML, the associated morbidity and mortality

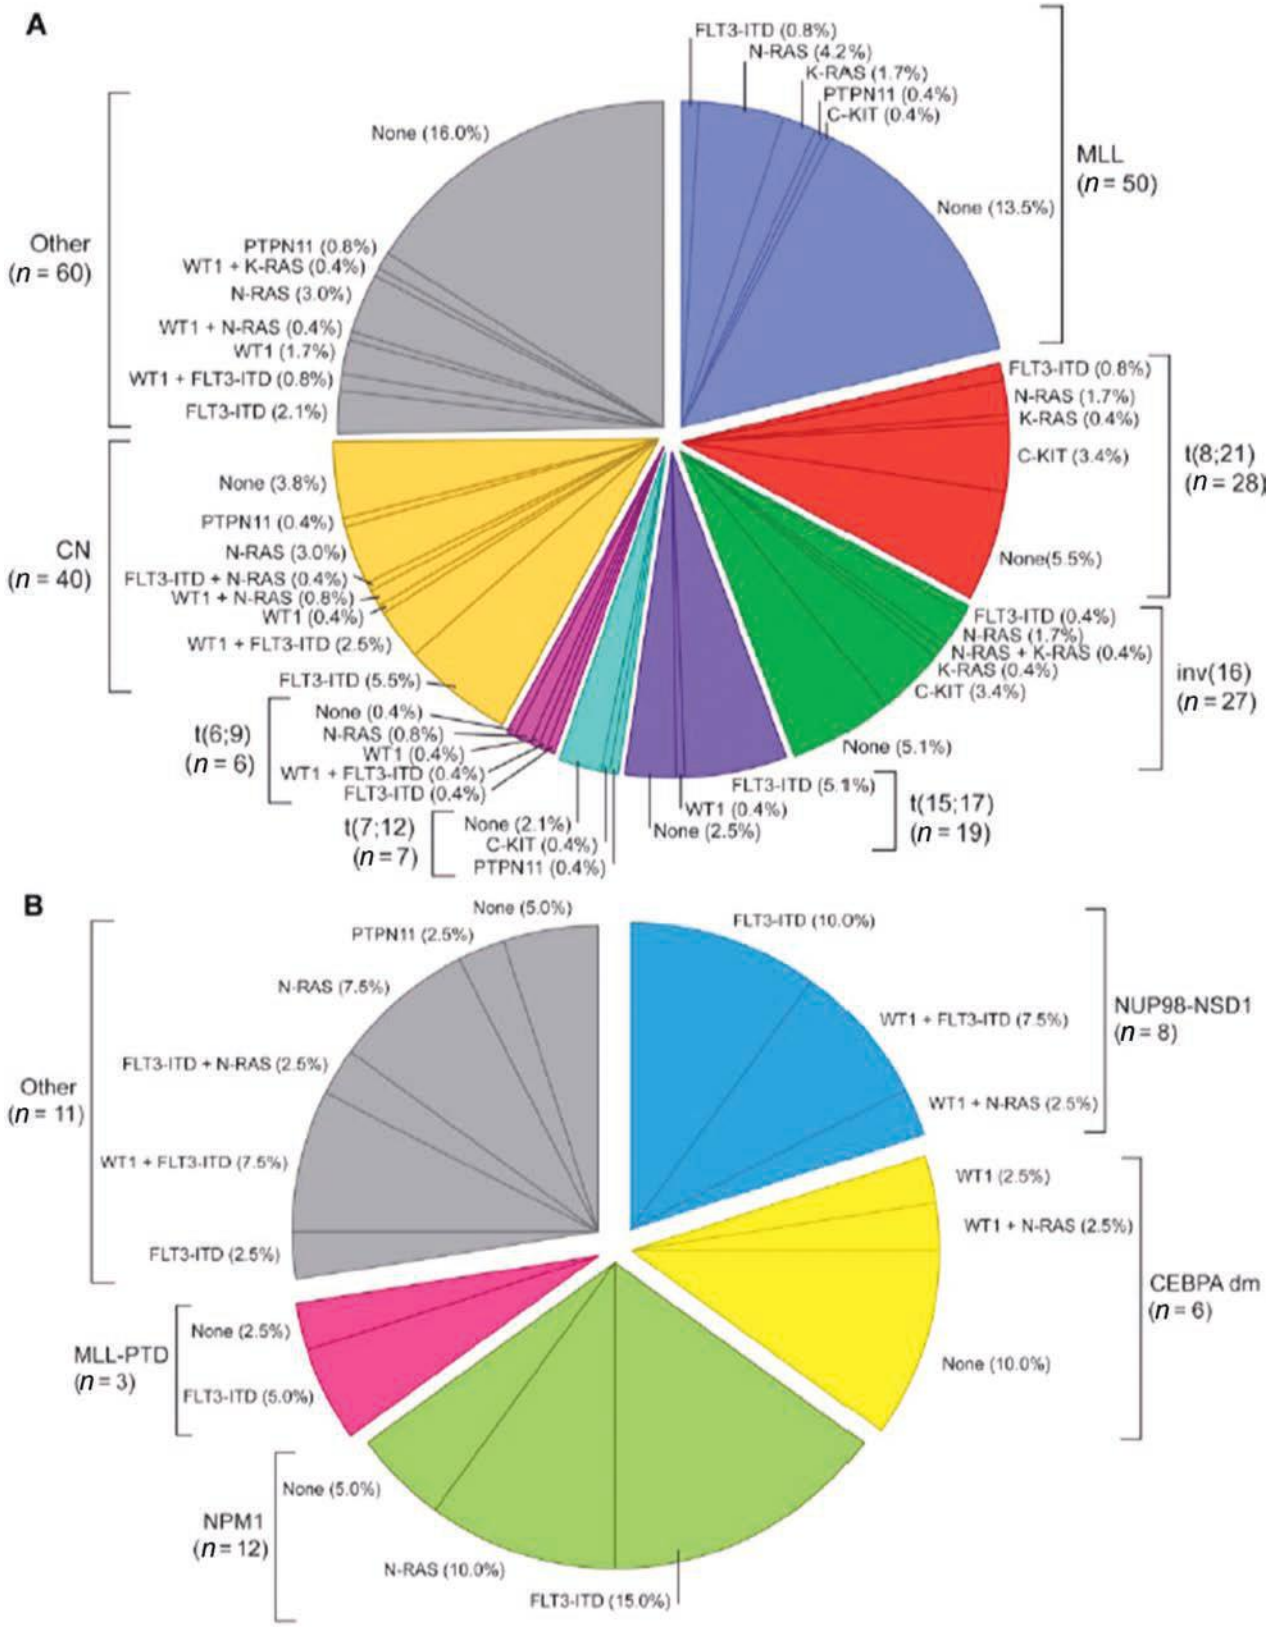

FIGURE 77.5. Pie chart representations of cytogenetic abnormalities and gene mutations alone and in combination in pediatric acute myelogenous leukemia (AML). A: Data shown for all subtypes. **B:** Detailed data apply to only cytogenetically normal (CN) AML. The data are based on 237 pediatric patients with de novo AML. The different pie slices indicate the percentage of patients whose AML had one or more mutations as noted. With permission from Creutzig et al.,[149] Hollink et al.,[421] and Balgobind et al.[374]

preclude similar approaches from being pursued in the future. Instead, future therapeutic advances need to deliver greater leukemic cell killing but without additional collateral toxicity to normal tissues. These advances have been focused on developing targeted therapies directed toward specific molecular pathways that lead to increased leukemic cell survival, proliferation, and drug resistance. Some of these targets may be prognostic factors, but this is certainly not a requirement, as some key pathways that drive leukemia may not necessarily be predictive of outcome in the context of conventional chemotherapeutic approaches.

In part because of the tremendous advances in understanding the genetic defects and their molecular consequences in AML, there are many potential therapeutic targets that are being explored. However, the continuously increasing plethora of molecular data make it particularly challenging to distinguish mutations and pathways that drive leukemic development and behavior which in turn will become increasingly important in the future development of targeted therapies.

Ideally, molecularly targeted therapies should be leukemia-specific. Examples of this approach include strategies targeting the unique fusion proteins that result from distinctive chromosomal translocations or the use of agents that would specifically exploit a mutation in a cytokine receptor such as FLT3-ITD or KIT. Other therapies directed at chromatin remodeling and reprogramming gene expression involve inhibitors of DNA methyltransferases as well as histone modifying enzymes.

Additional approaches would be to target pathways or molecular targets that were shared by tumor cells and some normal cells but on which leukemic cells are more dependent in terms of their survival and proliferation. Such strategies might include the antisense inhibition of antiapoptotic pathways dependent on BCL2 expression, the inhibition of activated RAS and its downstream pathways, and immunotargeted therapy using immunoconjugates or chimeric antibody receptors.

Both specific and selective targeted therapies are currently being tested in both adult and pediatric patients with AML. However, recent data have demonstrated that even molecularly targeted therapies are not often as specific as initial results would suggest and that leukemia resistance commonly develops or is already present at the initiation of treatment, which leads in turn to the selection of resistant leukemic clones, including leukemia-initiating cells (also referred to as leukemia stem cells).

Although targeted therapies hold significant hope for improved antileukemic activity and for potentially sparing normal tissues from damage, there are clearly significant hurdles to overcome, including how to define first the key leukemia-driving molecular pathways, as well as understanding how to optimize the use of such agents in combinations that will address cellular responses and feedback mechanisms of resistance.

CHAPTER 78

ACUTE PROMYELOCYTIC LEUKEMIA

Jeffrey E. Lancet, Peter Maslak, Steven L. Soignet

Acute myelogenous leukemia (AML) is a malignant disorder of the bone marrow where a maturational arrest in blood cell progenitors results in failure of normal hematopoiesis. Acute promyelocytic leukemia (APL) is a subtype of AML with a defined clinical course and a biology that is distinct from the other forms of AML. Morphologically, the most common form of APL can have a characteristic appearance as the bone marrow is effaced by heavily granulated cells with folded, twisted nuclei. Biologically, the cytogenetic changes define the syndrome and the molecular consequences of the chromosomal changes found in APL play a critical role in leukemogenesis. Clinically, patients typically display symptoms associated with cytopenias. The hemorrhagic complications are, however, often out of proportion to the degree of thrombocytopenia reflecting the underlying biologic properties of the transformed promyelocyte. Historically, recognition of this form of AML as a separate entity was important for the clinician, not because the chemotherapy used as treatment differed substantially from the other subtypes of AML, but because the relative common occurrence of life-threatening coagulopathy mandated special supportive maneuvers including the use of low-dose heparin and aggressive blood product support. Yet, despite prompt diagnosis and attention to potential complications associated with the institution of therapy, peri-induction mortality was often significantly higher than in other forms of AML. Some older series reported a treatment-related death rate approaching 50%.[1–3] Hence, APL became a primary example of the most feared features associated with an acute leukemia: a fulminant disorder that struck primarily young people, had devastating effects on an individual's life, and resulted in death for a large number of patients during the early phases of therapy.

The last two decades have seen a fundamental shift from this paradigm, with APL now recognized as one of the most curable forms of acute leukemia. In part, this change has been accomplished because specific supportive care practices have been developed and refined. The most dramatic events, however, have been the introduction of targeted therapy with all-*trans* retinoic acid (ATRA) and, subsequently, arsenic trioxide (ATO). Laboratory investigations into the mechanism of the differentiating/apoptotic effects of these agents have led to an understanding of the basic biology of APL, making the disease a model for the development of new therapies with possible applications across the entire field of cancer medicine.

EPIDEMIOLOGY

AML is, in itself, a rare disease. In 2012, approximately 13,780 new cases of AML in the United States will be diagnosed.[4] There is a moderately higher incidence in males than in females, and the median age is 66 years. APL comprises approximately 7% to 8% of adult AML cases, with a median age of 47 years.[5] An increased incidence has been reported in Hispanic populations, although some recent reports have disputed this finding.[6] One group has reported an association with obesity.[7] Although relatively uncommon in children, clustering of cases in pediatric populations has been described, raising the issue of possible environmental exposure.[8] APL generally is not preceded by a myelodysplastic syndrome. The disease may, however, result as a consequence of prior therapy (particularly with topoisomerase-II inhibitors) for an unrelated malignancy, with a median interval from primary disorder to APL of approximately 25 months.[9,10] In such cases, the clinical characteristics are determined by the karyotype, and these patients do as well as individuals who present with de novo disease. This is in marked contrast to other secondary myeloid leukemias that result from exposure to radiation, topoisomerase therapy, or alkylating agents, in which the prognosis is significantly worse.

CLINICAL PRESENTATION

As with any acute leukemia, the symptoms associated with APL may be relatively nonspecific. Most patients complain of fatigue with a significant decrease in their previous level of activity. The manifestations of hemorrhage are often the most dramatic findings in the physical examination. There may be prominent petechiae or extensive ecchymotic involvement of the skin. Visual changes may result from retinal hemorrhages and subconjunctival hemorrhage may follow episodes of coughing or vomiting. Overt hemorrhage from the gums, nose, mouth, or other bodily orifices can occur.

Frank infiltration of extramedullary sites (i.e., skin, central nervous system [CNS], gums) is rare in the newly diagnosed patients, although such findings have been described in patients who relapse following therapy.[11,12]

LABORATORY ANALYSIS

The clinical laboratory plays an important role in the diagnosis of APL and serves to focus nonspecific complaints and signs toward a hematologic origin. A complete blood count is among the first laboratory tests obtained and is almost always abnormal. Cytopenias, of all three lineages, are the most common findings. The white blood cell count may be elevated in 10% to 30% of patients and has been associated with a morphologic variant of APL (see below).[3,13,14,15,16,17] Early recognition of this entity is important as such patients have historically had a higher incidence of peri-induction morbidity/mortality, which may be attenuated with more aggressive management, based upon more recent studies.[18]

Quantitative abnormalities mandate that the peripheral smear be reviewed by an experienced morphologist. The peripheral blood often contains heavily granulated cells that are characteristic of the disease, but these are more likely to be found in the bone marrow. Direct examination of the blood smear also serves to verify any abnormalities and avoids spurious values such as thrombocytopenia secondary to platelet clumping. In addition, many of the standard "Coulter counter" instruments that rely solely on changes in electric impedance to generate blood cell differentials are unable to differentiate the heavily granulated promyelocytes from granulocytes, causing a false reading on the machine-generated differential. Some of the newer blood analyzers rely on a combination of light scatter and flow cytochemistry (detecting myeloperoxidase [MPO] content) to differentiate between peripheral blood cell types. The high MPO content of the abnormal promyelocytes produces a characteristic scatter plot (Fig. 78.1), which can aid in the confirmation of the diagnosis.[19,20] This finding is particularly useful in identifying patients with the microgranular variant because the cytochemical properties of the cell are unchanged and detected by flow cytometry, whereas the morphology may be problematic.

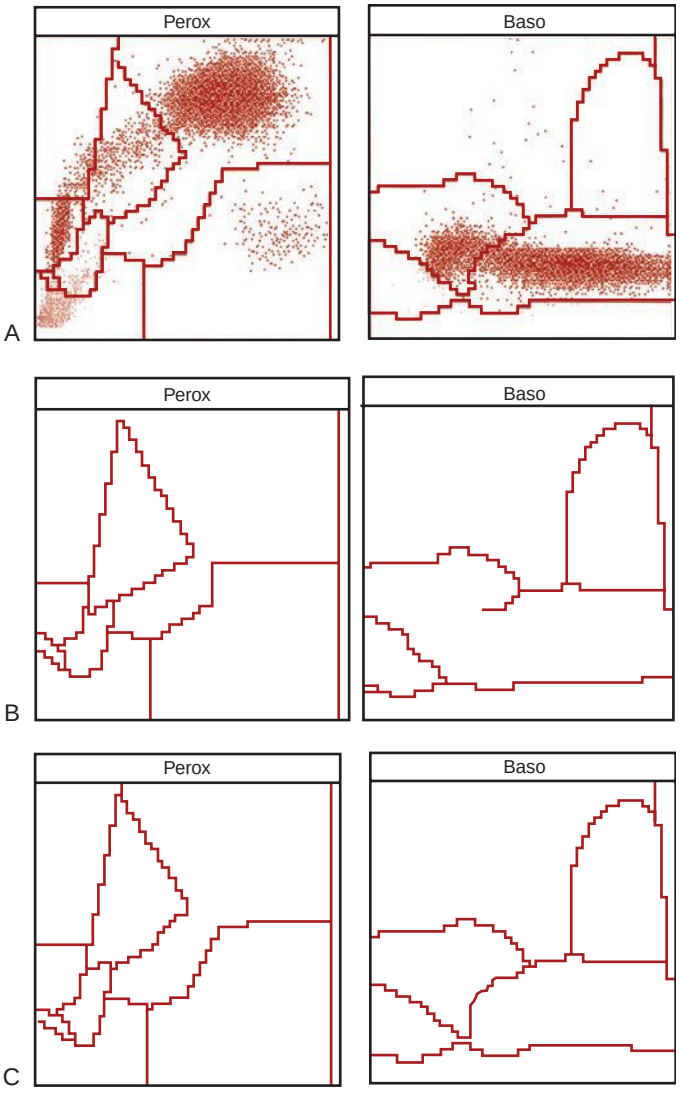

FIGURE 78.1. Representative cytograms from an automated blood analyzer that plots cell volume (*y*-axis) versus peroxidase (Perox) activity (*x*-axis) to generate a blood cell differential. A: Normal cytogram shows a cluster of cells in the upper right of the peroxidase channel (*left panel*) typical for granulocytes. **B:** Untreated acute promyelocytic leukemia. The granulocyte cluster is now shifted to the extreme right, reflecting the high myeloperoxidase content of the abnormal promyelocytes. This pattern is characteristic of acute promyelocytic leukemia and is preserved in the microgranular variant. **C:** Treated acute promyelocytic leukemia. The same patient shown in B approximately 35 days after receiving all-*trans* retinoic acid, idarubicin, and cytarabine. The normal pattern has been restored. Baso, basophile channel; perox, peroxidase channel.

The other blood tests obtained at the time of diagnosis generally serve to screen for complications that can be associated with the leukemia. Serum electrolyte abnormalities need to be corrected, particularly prior to the institution of cytotoxic chemotherapy.[21] Adequate renal function is extremely important as aggressive blood product replacement can be anticipated in this disorder and the management of extreme fluid overload may complicate care.

Coagulation Studies

Because the recognition and management of coagulopathy is of the utmost importance in treating patients with APL, the initial laboratory evaluation may include a platelet count, prothrombin time (PT), activated partial thromboplastin time (PTT), D-dimer or fibrin split products, and fibrinogen.[22] This disease-related coagulopathy, typically bleeding diathesis, represents a major source of morbidity, and despite the effective antileukemia therapy presently available, it remains the leading cause of peri-induction mortality,[23–25] with early hemorrhagic death rates generally ranging from 5% to 11%.[23,25–27] Although less common than hemorrhage, thrombotic complications have been reported in up to 10% of patients at the time of diagnosis.[28] The mechanism underlying the coagulopathy is complex and has been the subject of intensive investigation. Historically, the coagulopathy had been ascribed to disseminated intravascular coagulation (DIC), which resulted as the abnormal promyelocytes lysed and liberated the procoagulant contents of their granules.[29] Evidence for DIC as the underlying mechanism has been provided by finding that APL cells release increased levels of tissue factor.[30,31] Tissue factor may serve to promote interaction between factor VII and other circulating procoagulants resulting in a widespread generation of thrombin. The coagulopathy can occur in the absence of chemotherapy as the neoplastic cells undergo autolysis, and it is found in approximately 80% of APL patients at the time of diagnosis. The coagulopathy may be exacerbated by the institution of chemotherapy, which results in the massive lysis of abnormal promyelocytes amplifying the already existing activation of the coagulation pathway. Both the PT and PTT are abnormally elevated, and the fibrinogen is low, reflecting an ongoing consumption. In addition, a number of other coagulation parameters such as the thrombin time and the level of fibrin split products are elevated, reflecting widespread disruption of the normal coagulation cascade. It is important to note that a fibrinogen in the low range of normal is still cause for concern given that it is an acute-phase reactant and ordinarily would be elevated in an ill patient. Serial measurements (approximately 6 to 12 hours apart) often reveal the developing hypofibrinogenemia indicative of consumption and help guide replacement therapy with blood products.

More recently, other explanations for the bleeding diathesis have attributed important roles for hyperfibrinolysis as well as nonspecific proteolysis.[32] An ongoing unchecked fibrinolytic process will also result in a low fibrinogen producing a clinical picture where hemorrhage is the primary sequela. Evidence for this hypothesis has been provided by the finding that low plasma levels of plasminogen, α_2-plasmin inhibitor, and plasminogen-activator inhibitor 1 are found in fibrinolytic states and are also found in APL. In addition, annexin II, a cell-surface receptor for plasminogen and tissue plasminogen activator, is expressed at abnormally high levels on APL cells but not on blasts from other forms of acute leukemia.[33,34] The increased expression of annexin II may lead to overproduction of plasmin, which results in dysregulated fibrinolysis. The potential for hemorrhage is further amplified by the depletion of the main inhibitor of plasmin, α_2-plasmin inhibitor, which is consumed in an effort to counter the increased production of plasmin. The clinical manifestations of the coagulopathy are controlled and some of the coagulation parameters progressively improve within days following the institution of therapy with either ATRA or ATO.[24,33]

Morphology, Cytochemistry, and Immunophenotype

Examination of the bone marrow aspirate and biopsy are the standard tests by which the diagnosis of acute leukemia is made. The morphologic features of the cells in the blood and the bone marrow may be different, underscoring the importance of sampling the bone marrow. The various morphologic subtypes of APL and their defining features are summarized in Table 78.1.[14,16,17,35,36] Characteristic examples of the morphology are provided in Figure 78.2. In the classic hypergranular variety of APL, the bone marrow aspirate is generally hypercellular and the abnormal promyelocytes constitute the predominant population. Blasts may be increased, but their number alone may not meet the minimal criteria by which classification systems

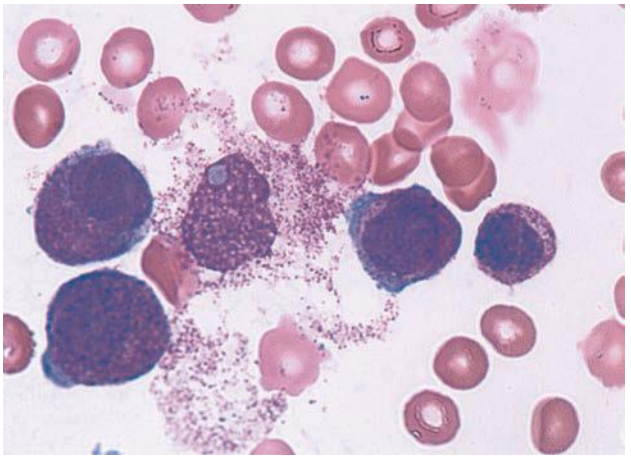
TABLE 78.1

MORPHOLOGIC SUBTYPES OF ACUTE PROMYELOCYTIC LEUKEMIA

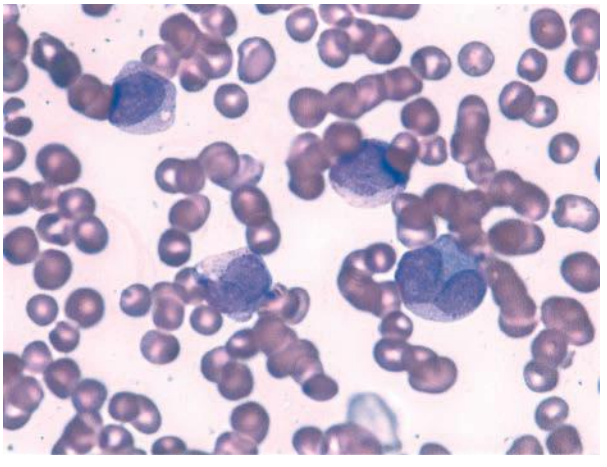
	Hypergranular (Classic M_3)	Microgranular (M_3V)	Promyelocytic Leukemia Hyperbasophilic	Zinc Finger/Retinoic Acid Receptor-α (M_3r)
Nucleus	Folded, lobulated; granules obscure borders	Irregular, folded	High nucleocytoplasmic ratio	Regular round/ovoid: condensed chromatin pattern; Pelger-like cells
Cytoplasm	Prominent azurophilic granules	Fine small granules; "dusky" appearance	Granules sparse; strongly basophilic; cytoplasmic "budding" noted	Granularity intermediate between M_3 and M_2
Auer rods	Frequent; faggot cells	Rare	Not seen	Rare; faggot cells absent

such as the French–American–British (FAB) and World Health Organization define AML. The malignant promyelocytes need to be considered as part of the total blast count to establish a diagnosis of AML. Malignant promyelocytes may be slightly larger than their normal counterpart. Such cells are heavily granulated: the granules often obscure the nucleus, making the nucleocytoplasmic border somewhat indistinct. In addition, the nucleus may be folded or bilobed. The cytoplasm often contains vacuoles, and distinctive Auer rods are frequently visible. Auer rods are coalesced primary granules and may be abundant. Multiple Auer rods clustered together within a single cell resemble a bundle of sticks or twigs, and such cells have been labeled *faggot cells* (after the French term for *bundle of sticks*). Globular cytoplasmic inclusions (pseudo-Chédiak-Higashi inclusions) have also been described. The term *flaming promyelocyte* has been coined to describe cells that appear to be "breaking apart," taking on a vibrant reddish-purple hue with the apparent liberation of granules into the surrounding cellular matrix.

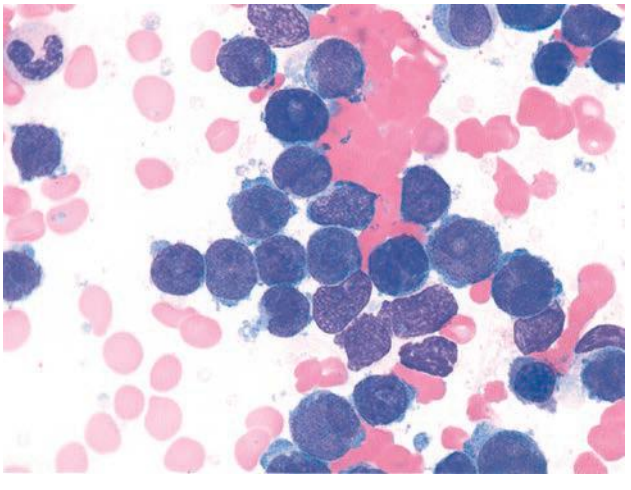
Identification of the microgranular variant (M_3V) according to the FAB classification system) may be more problematic.[14,16] This entity generally constitutes about 20% to 30% of APL cases. It was first recognized because it shared some clinical features as well as the typical t(15;17) with the hypergranular form of APL. The granules in the microgranular variant are less prominent, are somewhat dispersed, and may be difficult to visualize using light microscopy. Instead, the granulation may be fine and the cells may appear "dusky" or "hazy." The shape of the nucleus, which has a characteristic bilobed, folded appearance, is often the key in identifying this disorder. Auer rods may be present but are generally less plentiful than the hypergranular variety. Another clue to



A



B



C

FIGURE 78.2. Morphologic subtypes of acute promyelocytic leukemia. A: "Classic" M_3 is characterized by heavily granulated promyelocytes with abundant Auer rods. **B:** Microgranular variant (M_3v) has fine granulation with bilobed folded nucleus. **C:** Hyperbasophilic variant has few granules, intense basophilia, and small cytoplasmic projections or "buds" reminiscent of micromegakaryocytes (100×, MacNeal Tetrachrome).

diagnosis is the finding of a few of the more typical hypergranulated forms in the bone marrow. Although diminished in number, their presence helps distinguish this disorder from leukemias of monocytic origin. The peripheral white blood cell count may be higher than the classic variety, and any hypergranulated promyelocytes are less likely to be found in the peripheral blood. The characteristic cytogram found via flow cytochemistry (Fig. 78.1B) will be preserved in the microgranular variant, providing useful rapid confirmation of the diagnosis before the cytogenetic or molecular results are available.[17]

A third morphologic form of APL, the hyperbasophilic variant, has been described.[17] This is a relatively uncommon form of APL that some experts group within the M_3V category. However, the morphologic features are distinct enough to warrant separate consideration. The cells in this disorder have few, if any, granules. Instead, the cytoplasm is deeply basophilic and may be noted to have small blebs, buds, or projections, making the appearance reminiscent of micromegakaryocytes. The nucleus tends to occupy most of the cell and has an irregular lobulated appearance. Both the microgranular and hyperbasophilic variants can be mistaken for an acute monocytic leukemia. A variant form of AML associated with CD56 expression and natural killer (NK) cell lineage has been confused with M_3V but lacks the defining t(15,17) cytogenetic abnormality.[37] More recently, a European consensus group has described distinctive morphologic features of APL variants associated with the promyelocytic leukemia zinc finger gene (*PLZF*)/retinoic acid receptor-α (*RAR*α) fusion products (see below) and have proposed a new morphologic category, M_3r. These leukemias exhibit cells that lack a folded or bilobed nucleus but instead have a regular round or oval appearance. An increased number of Pelger-like cells reminiscent of those found in a myelodysplastic syndrome can also be seen. Auer rods are generally rare and the cytoplasmic granularity is intermediate between M_3 and M_2 varieties of AML.[36]

Although not diagnostic for APL, cytochemistry and immunophenotyping may help characterize APL. The cytochemical properties of the abnormal promyelocytes are consistent with a diagnosis of AML.[14,16,17,35,38] The hypergranular variety stains intensely with Sudan black, MPO, or chloroacetate esterase. The microgranular variant retains this staining pattern, although the degree of positivity may be less intense. As discussed above, the high MPO content of abnormal promyelocytes may be detected in the peripheral blood using modern blood analyzers. Less useful is the observation that nonspecific esterase activity has been noted in some abnormal promyelocytes, further confusing the differentiation between acute monocytic leukemia and some forms of APL.[39] These reactions are weaker than those found in monocytes, and some forms of the isoenzymes found in monocytes are absent in the abnormal promyelocytes. Metachromatic staining with toluidine blue has been reported in cases of APL with basophilic differentiation.

Immunophenotyping is also useful in confirming the diagnosis of APL.[38,40] Promyelocytes are partially differentiated cells that are reflected in the immunophenotype. The cells express the early myeloid marker CD33 but lack human leukocyte antigen (HLA)-DR, a marker often associated with some earlier progenitor cells. It is important to emphasize that this immunophenotypic profile is characteristic but not diagnostic of APL. Up to 20% of other types of AML may express CD33 but not HLA-DR. The marker CD9 is expressed in APL but not in other AML subtypes.[41] Unfortunately, this finding is not clinically useful as few screening panels used for diagnosis contain CD9 as part of the initial workup. The stem cell marker C34 is generally not expressed, whereas the myeloid lineage marker CD13 is occasionally observed and possibly associated with the development of retinoic acid syndrome (RAS).[42] The T-cell marker CD7 is negative, as are the myelomonocytic markers CD11b and CD14. CD11b is also an indicator of myeloid maturation and, along with CD16, a surface marker found on granulocytes, can be induced with differentiation therapy. The aberrant expression of the T-cell marker CD2 has been correlated with the microgranular variant, as well as a shorter duration of remission.[43] Reports of a correlation with the short form of the promyelocytic leukemia (*PML*)/*RAR*α fusion transcripts have been mixed.[44,45,46,47] Expression of the P-glycoprotein associated with the MDR phenotype is generally not found in APL. The NK marker CD56 has been reported in true APL (as opposed to NK-AML) and has been associated with a poor prognosis.[48,49]

Differential Diagnosis

As discussed above, the morphologic appearance of APL can be quite striking, given the characteristic appearance of the most common variety, the hypergranular form. The differential diagnosis of APL includes reactive disorders of the bone marrow as well as other subtypes of acute leukemia. Recovery from an insult producing relative aplasia can result in increased myeloid activity with a left shift in the myeloid series. Therapy with the myeloid growth factors, granulocyte colony-stimulating factor or granulocyte–macrophage colony-stimulating factor, can result in a hypercellular bone marrow with prominent toxic granulations. Maturation, however, is preserved, and Auer rods are not found. Other marrow elements such as erythroid and megakaryocytic precursors are present, although the relative number appears somewhat diminished. Chronic myelogenous leukemia may appear with a hypercellular marrow containing a predominant myeloid component that appears heavily granulated. In this disorder, all stages of maturation are present and accompanied by increased eosinophils and/or basophils. Acute myeloid leukemia with maturation (FAB M_2) may contain blasts as well as cells that contain too many granules to be considered blasts but are not mature enough to be classified as promyelocytes. Auer rods are also found in this AML subtype, but these usually occur as single structures and not as clusters. Faggot cells are generally not found. Abnormal promyelocytes can be seen, but these cells do not constitute the predominant population in the bone marrow. A monocytic component may be present in $<20\%$ of the nonerythroid elements. The microgranular and hyperbasophilic variants may be mistaken for monocytic leukemia because of the deeply staining cytoplasm, lack of granules, and folded convoluted nuclei. Other rare forms of leukemia such as mast cell leukemia or basophilic leukemia may, at first, be confused with APL, but lack characteristic features such as Auer rods and the nuclear folding pattern and present with granules that can be readily distinguished from those of the promyelocyte using conventional histochemical stains.

Cytogenetics and Molecular Biology

Despite the minor variations in phenotype discussed above, APL as a clinical syndrome is defined by its cytogenetics. The balanced translocation between chromosomes 15 and 17 characterizes over 95% of cases of APL.[50,51] The breakpoints for the translocation usually occur at q22 loci on chromosome 15 and q21 on chromosome 17. The t(15;17) is generally detected by conventional cytogenetic techniques and provides definitive evidence of the diagnosis of APL. The molecular consequence of this translocation results in a fusion of a portion of the gene for the *RAR*α on chromosome 17 to part of the *PML* gene on chromosome 15.[50,52–54] Although the break within the *RAR* gene is invariable within the second intron of the gene, the point of rearrangement within the *PML* gene can occur at two major breakpoints, resulting in three isoforms of the transcript. Breakpoints within *PML* intron 3 (bcr3) generally yield a shorter messenger RNA transcript, whereas breakpoints within intron 6 (bcr1) result in the long form of the transcript.[46] Breakpoints within intron 6 of *PML* can also occur at a second site (bcr2) and result in a transcript

of variable length. The site of the breakpoint has been reported to have prognostic implications as newly diagnosed patients with the short isoform appear to have a shorter disease-free survival (DFS) and overall survival (OS) compared with the long isoform in some series.[42,46,55] Other authors have correlated the isoform with various other prognostic factors but discount an independent effect on outcome.[56] In all cases, the chimeric gene products that result from this translocation have fundamental implications for the cell and are thought to be causative in producing the malignant phenotype. Variations of this translocation exist, and in some instances have profound clinical implications.

Although the t(15;17) is the defining cytogenetic abnormality in APL, other additional chromosomal abnormalities can be found in 30% to 40% of patients with APL.[57,58] The most common among these are trisomy 8 and isochromosome 17. Additional chromosomal abnormalities do not have a negative impact on the overall prognosis.[58,59] Complex translocations involving other chromosomes in addition to 15 and 17 can occur. Masked translocations, where pieces of chromosome 15 and 17 are transposed but escape detection by conventional techniques, have been reported.[60,61] In most of these cases, the molecular abnormality, either the *PML-RARα* or the reciprocal *RARα*-PML transcript, can be detected. Expression of the fusion gene product ultimately results in the clinical syndrome identified with APL despite the lack of gross chromosomal changes.

Variant translocations also exist and are rare as clinical entities but are instructive in helping define the biology of APL. The most common variants involve translocations between chromosome 17 and either chromosome 5 or 11.[62,63,64,65] These variant translocations retain the same break within the *RARα* intron but differ in the molecular partner gene (X gene), which may account for some of the differences regarding their functional effects on the cell. The individual variants are summarized in Table 78.2. The structural changes within these genes may affect the normal function of the wildtype product, resulting in the phenotypic abnormality, which is expressed as the leukemia. Most notable among the variants is the t(11;17) (q23q21) because this entity is resistant to the differentiation effects of ATRA. This chromosomal translocation results in a fusion of the *RAR* gene with *PLZF*. *PLZF* is similar to *PML* in that it has profound implications for the cell with regard to regulation of transcription of target genes resulting in differentiation. However, *PLZF* is distinctly different from *PML* in that properties of this gene product interact differently with retinoic acid, rendering it ineffective.[66] This form of APL also has a poor response to standard chemotherapy, underscoring the multiple differences in biology between these two entities.

In addition to variant chromosome translocations in APL, it has been discovered that APL commonly harbors co-existing mutations that may have biologic and clinical impact. To date, internal tandem duplication (ITD) mutations of the fms-like tyrosine kinase 3 (*FLT3)* gene are the most frequent concurrent mutational events in APL, occurring at a frequency of 21% to 32%.[67,68,69,70] Constitutive activation of the FLT3 receptor via this mutation is known to confer a proliferative and survival advantage to AML blasts.[71,72] In non-M_3 AML, this mutation occurs at a similar frequency and is generally associated with worse DFS and OS than occurs in *FLT3*-ITD wildtype AML.[74,75] The adverse effect of this mutation in APL is less clear, with most series suggesting that the mere presence of an *FLT3*-ITD mutation does not independently affect survival, although it does associate with other known adverse factors, such as elevated WBC. However, quantitatively higher expression levels of *FLT3*-ITD and longer transcript length may have a negative impact on DFS.[68,70] Given the recent influx of clinically available pharmacologic inhibitors of FLT3, such inhibitors may eventually become incorporated into standard therapy for selected patients with APL whose disease harbors a *FLT3* mutation.

Based on experimental data generated in cell lines, transgenic mice, and correlations with clinical treatment data, a model for leukemogenesis in APL has been developed (Fig. 78.3).[73,74,75,76,77] On the most basic level, this hypothesis states that APL results from transcriptional dysregulation of differentiation produced by the *PML-RARα* gene product. In the normal cell, *RARα* plays an important role in modulating myeloid differentiation by virtue of its ability to recruit various nuclear co-repressors such as SMRT/N-CoR and mSin3. These transcription co-repressors, in turn, bind various histone deacetylases, affecting chromatin conformation and resulting in repression of transcription of target genes fundamental to the differentiation process. Under physiologic conditions, binding of retinoic acid causes dissociation of the co-repressor complex, recruits transcriptional activators, and "opens" the chromatin, facilitating the transcription of the various target genes and allowing normal maturation. The PML-RARα fusion protein has an increased affinity for the N-CoR co-repressor complex such that physiologic doses of RA $<(10^{-8}$ M) fail to produce a dissociation of the complex, resulting in continued transcriptional repression and a maturational block. Instead, supraphysiologic doses achieved by the administration of ATRA are required to recapitulate the behavior of the wildtype receptor. In the PLZF-RARα variant, there is a second binding site for the co-repressor proteins within the PLZF portion of the fusion protein

TABLE 78.2

ACUTE PROMYELOCYTIC LEUKEMIA: CHROMOSOMAL TRANSLOCATIONS AND FUSION PRODUCTS

Translocation	Frequency (%)	Molecular Fusion Product (X-*RARα*)	Function "X" Gene	Retinoid Sensitive	Chemotherapy Sensitive

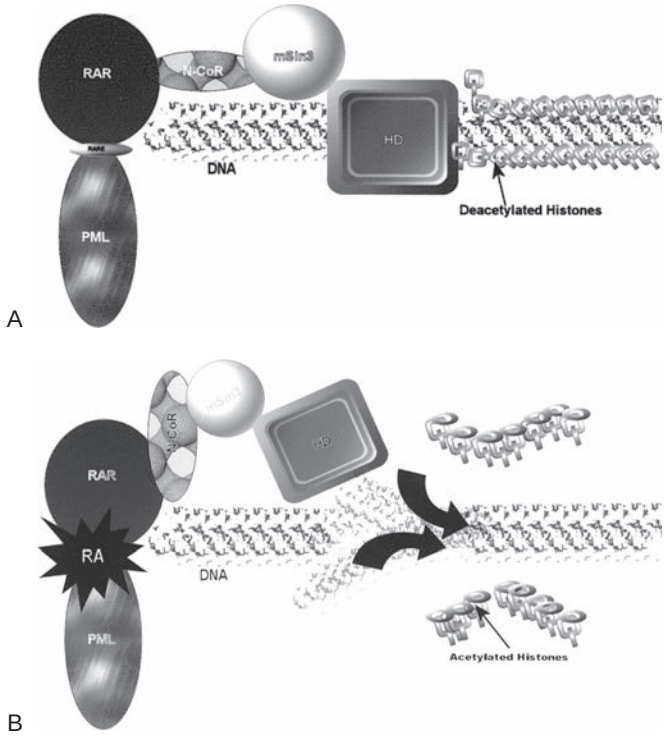

FIGURE 78.3. Model of transcriptional dysregulation in acute promyelocytic leukemia. **A:** Aberrant retinoic acid receptor-α (RARα)/promyelocytic leukemia (PML) fusion product recruits histone deacetylase complex (N-CoR/mSin3/HD), resulting in widespread histone deacetylation, which, in turn, effectively blocks the transcription of downstream genes critical for myeloid maturation. **B:** Binding of pharmacologic doses of retinoic acid (RA) causes a dissociation of the co-repressor complex, resulting in histone acetylation and providing an "open" conformation to the chromatin, which facilitates transcription of downstream target genes, resulting in myeloid maturation. HD, histone deacetylase(s).

that is not sensitive to retinoic acid. Hence, even supraphysiologic doses are unable to free the co-repressor complex and permit the conformational changes in the histones necessary for permitting differentiation to occur. This may be an explanation for the clinical resistance of t(11;17) to ATRA and has led investigators to explore compounds such as histone deacetylase inhibitors that bypass co-repressor binding as defined by the activity of RARs and directly effect transcriptional activation.

Although the model of transcriptional repression through chromatin remodeling may rest on the interaction of the aberrant RARα fusion protein with key regulatory genetic elements, the primary partners in the molecular fusion proteins, namely PML and PLZF, are important in leukemogenesis and may also serve to amplify dysregulation of transcription.[66,73] PML does not directly bind DNA but has been found to regulate transcription through interaction with a number of transcription factors and repressors.[78,79,80] In the normal cell, PML is localized in discreet subnuclear structures called PML oncogenic domains or PML nuclear bodies (PNBs). These PNBs may functionally regulate transcription by either binding various transcription activators/repressors or sequestering them from circulating in the nucleoplasm, thereby preventing any interaction with other regulatory elements, or by providing an environment where the various regulatory factors can interact or be modified. This function, in turn, may affect fundamental cellular processes such as growth, senescence, and apoptosis. PML-RAR disrupts the organization and function of the PNBs and displaces PML, forming a microspeckled pattern in the nucleus. Treatment with RA causes the PNBs to reorganize and presumably restores not only the structure, but also the functional activity.

Less is known regarding the function of PLZF. It also modulates transcriptional repression through multiple interactions with SMRT/N-CoR/mSin3/HDAC complexes and may localize in structures similar to the PNBs. Some of the mediators with which PLZF interacts are insensitive to modulation by RA, and these properties are retained in the PLZF-RAR fusion product, resulting in clinical ATRA resistance.

In addition to providing an understanding of the underlying biology of leukemia with possible application to cancer as a whole, the molecular genetics of APL also provide a useful tool for the clinician in confirming the diagnosis and planning therapy. As discussed above, the vast majority of APL is characterized by the t(15;17), resulting in a PML-RAR fusion product. These genetic changes are specific for APL and, using the modern molecular technique, reverse transcriptase-polymerase chain reaction (RT-PCR), are easily detectable.[81,82,83] RT-PCR has become a standard tool in the management of APL. It is now readily available in commercial laboratories, and there is usually a rapid turnaround time. RT-PCR is useful in confirming the diagnosis of APL, particularly in cases where morphology is problematic. In addition, this unique molecular "signature" can be used to monitor response and test for minimal residual disease (MRD).[55,81,82,83,84,85,86] This ability to have an effective method for detecting MRD is in sharp contrast to the other forms of AML, where response is assessed primarily through morphologic examination of the bone marrow and blood. Therefore, in APL, the concept of remission can be redefined to include a molecular response. Molecular relapse can be detected before it is clinically apparent, and this information can be used to guide therapy. An effective treatment regimen will render the RT-PCR assay for *PML-RAR* negative. The conversion from a negative result to positive that is reproducible on two sequential assays is predictive of clinical relapse. Some groups have reported highly successful results treating the disease in molecular relapse prior to the occurrence of the full-blown clinical syndrome[87] This has led to the standard recommendation that patients with APL be serially monitored via RT-PCR for *PML-RAR* every 3 months during the first 2 years after remission is achieved, when the risk of relapse is the greatest.[55] It is important to note, however, that there are different forms of PCR analysis with different sensitivities, and the clinical results have only been validated with RT-PCR assays having relatively low sensitivities. More recently, the low relapse rate following modern treatment regimens has caused some investigators to question the need for a monitoring strategy, instead reserving such strict monitoring to those defined as having poor-risk disease. The role of real-time quantitative PCR (RQ-PCR) as part of any monitoring strategy has yet to be defined and is currently under investigation.

THERAPY OF ACUTE PROMYELOCYTIC LEUKEMIA

General Principles of Management

Although therapy for APL is highly successful, early death remains an important problem, accounting for at least 50% of the total 3-year mortality rates in this disease, a figure that has not changed substantively over the past 15 to 20 years.[88] As mentioned earlier, the primary early life-threatening complication of APL is hemorrhage.[23–25] Hence, successful management of the patient with APL includes first recognizing the disorder (Table 78.3), and then anticipating the known complications and instituting therapy early enough to limit toxicity, the main challenge being effective support of the patient through the 3 to 5 weeks necessary to achieve remission.

Stabilizing the patient requires interpretation of the history, clinical presentation, and initial laboratory data to correctly diagnose the underlying condition as APL. Many patients present to medical attention with fever, and inasmuch as infection in the setting of neutropenia can be rapidly fatal, empiric antibiotics

TABLE 78.3

KEY STEPS IN DIAGNOSING ACUTE PROMYELOCYTIC LEUKEMIA

Test	Turnover Time
Examine the peripheral blood smear • WBC count often low • Thrombocytopenia often present • High peroxidase channel on automated flow cytochemistry (i.e., ADVIA) • *Pitfall:* Few white cells in the peripheral smear; characteristic cells may not be present	Minutes to hours
Determine morphologic appearance of the bone marrow • Hypercellular aspirate • Most common form: Hypergranulated promyelocytes • Auer rods present and abundant • *Pitfalls:* Morphologic variants can be confused with monocytic leukemia; hypergranulated forms confused with AML with maturation (FAB M_2)	Hours to days
Demonstrate characteristic karyotype/molecular abnormality	
• FISH for *PML/RARα*	Day
• RT-PCR for *PML/RARα*	Days
• Karyotype for t(15;17)	Days to weeks
• *Pitfalls:* Only karyotype may detect cytogenetic variants

are promptly started following an initial attempt at identifying a source of infection.[89] This empiric antibiotic coverage can be altered based on the sensitivities of any organism isolated from the various cultures. Continued fever despite broad-spectrum antibiotics may require empiric therapy with an antifungal such as an azole, amphotericin preparation, or an echinocandin.

Approximately 80% of patients with APL present with coagulopathy in addition to thrombocytopenia. As discussed above, laboratory tests useful as indicators of coagulopathy include the platelet count, PT, PTT, and fibrinogen levels. Other coagulation parameters such as thrombin time, the ethanol gelation test, and the protamine sulfate test may also be obtained, but add little to the clinical decision making in addition to confirming the presence of a coagulopathy. An increased risk of hemorrhage has been associated with elevated WBC, hypofibrinogenemia, and elevated serum creatinine, but not platelet count.[22,90,91]

Although definitive management of this coagulopathy requires treating the underlying leukemia, the initial therapy for the coagulopathy, prior to the onset of the stabilizing effect seen with the retinoid, is primarily supportive and based on aggressive platelet and blood product support. Frequent monitoring is the cornerstone of this management strategy. Intervention may be based on a worsening trend in a laboratory value such as the fibrinogen level. Platelets may be transfused multiple times a day to maintain a platelet count above 50×10^9/L and cryoprecipitate or fresh frozen plasma (FFP) should be administered to maintain fibrinogen levels above 100 mg/dl.[22] Failure to achieve thresholds of platelets above 30×10^9/L and fibrinogen above 150 mg/dl may increase the risk of hemorrhagic events.[91]

The use of low-dose heparin as management of coagulopathy in APL is controversial, never having been addressed in a prospective randomized trial. Although the rationale for such a strategy was, at best, unclear, some early studies reported a decreased rate of morbidity/mortality when heparin was used prophylactically when compared with historical controls with no heparin.[92] However, in a retrospective analysis of the larger GIMEMA series, no differences in early hemorrhagic death were observed between patients receiving low-dose heparin, antifibrinolytic therapy, or supportive care.[90] In addition, the introduction of retinoic acid has changed the clinical scenario because this therapy does not cause an immediate, massive cell lysis and does not worsen the coagulopathy. Instead, the clinical coagulopathy typically abates after about 5 to 8 days of therapy, perhaps rendering further study and discussion of prophylactic low-dose anticoagulation irrelevant.

Despite aggressive blood product support and the early administration of either ATRA or arsenic, patients can and do experience catastrophic hemorrhage or thrombosis. In these instances, it may be appropriate after discussion with the patient's health care proxy to institute life support measures in an effort to stabilize the patient while continuing to administer the leukemia therapy. Hemorrhage in the lung may require mechanical ventilation to support the airways, whereas a limited CNS hemorrhage may require measures to reduce intracranial pressure. The use of the antifibrinolytic ε-aminocaproic acid has been advocated by some for use with CNS bleeding to inhibit fibrinolysis and help stabilize any clot formation.[93] Underlying such heroic measures is the recognition that APL is ultimately a curable disease in the modern era. Primary resistance to either ATRA or ATO is rare, and most of the patients who fail these therapies do so because they are unable to be supported through the acute phases of the illness.

Assessment of Response

The traditional therapy for AML has relied on the strategy of using cytotoxic chemotherapy to induce bone marrow aplasia and clear the bone marrow of the malignant clone, allowing subsequent regrowth of normal progenitor cells with the restoration of normal hematopoiesis. A standard method for assessing whether aplasia has been achieved is to perform a bone marrow examination on approximately day 14 of therapy. The finding of persistent blasts on this day 14 bone marrow may prompt re-treatment with a second course of induction therapy.

This paradigm does not apply to APL. The day 14 bone marrow following the initial course of induction chemotherapy may reveal persistent abnormal promyelocytes, yet the patients are able to achieve remission at week 4 or 5 without further chemotherapy.[94] Therefore, the finding of these abnormal promyelocytes should not automatically trigger a second course of chemotherapy. The pattern of response of APL to standard induction therapy is atypical and once again underscores that this disease is biologically distinct from other forms of AML. Some have interpreted these findings to mean that standard chemotherapy has a differentiating effect on the abnormal promyelocytes, whereas still others have cited a differential effect of cytotoxic therapy on the replicating abnormal progenitors with relative sparing of the quiescent, partially differentiated promyelocytes.

The introduction of ATRA and ATO as agents that accomplish remission by inducing differentiation/apoptosis have further modified the ways in which response is determined. The standard definitions of complete remission (CR) established by National Cancer Institute consensus criteria still remain useful.[95] With the widespread availability of RT-PCR, the definition of CR has been further refined to include molecular remission. Often, the first sign that a patient is responding to therapy is the resolution of the coagulopathy with progressive improvement in the various coagulation parameters.[96] The transfusion requirements for platelets may decrease and FFP may no longer be needed to maintain the fibrinogen level. Leukocytosis, which can occur with either ATRA or ATO, may represent evidence of a biologic response of the abnormal clone to therapy. Peripheral blood leukocytes undergo progressive morphologic changes, which include

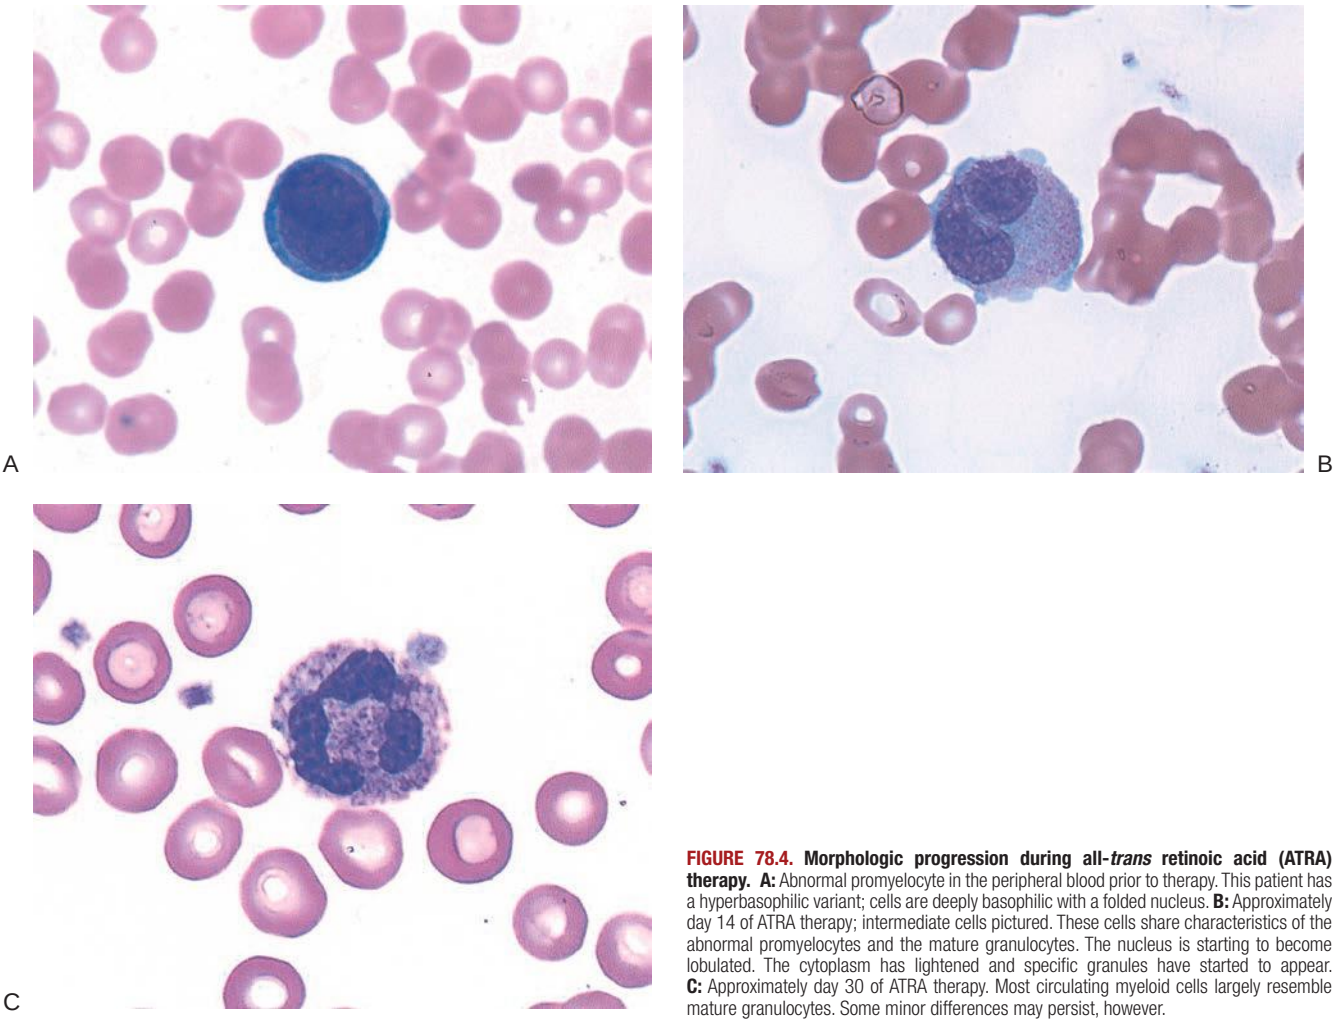

FIGURE 78.4. Morphologic progression during all-*trans* retinoic acid (ATRA) therapy. A: Abnormal promyelocyte in the peripheral blood prior to therapy. This patient has a hyperbasophilic variant; cells are deeply basophilic with a folded nucleus. **B:** Approximately day 14 of ATRA therapy; intermediate cells pictured. These cells share characteristics of the abnormal promyelocytes and the mature granulocytes. The nucleus is starting to become lobulated. The cytoplasm has lightened and specific granules have started to appear. **C:** Approximately day 30 of ATRA therapy. Most circulating myeloid cells largely resemble mature granulocytes. Some minor differences may persist, however.

nuclear condensation and lobulation accompanied by cytoplasmic vacuolization (Fig. 78.4).[96] Granulocytic forms with persistent azurophilic granules may appear and have been labeled "intermediate" cells as they retain features of promyelocytes but display some morphologic characteristics of neutrophils.[97] These cells may also display an intermediate immunophenotype with the co-expression of CD33, a marker associated with immature myeloid cells, and CD16 or CD11b cell-surface markers, which are found on granulocytes and maturing myeloid elements.[84] Various sources have also described the occurrence of polymorphonuclear leukocytes with Auer rods, another anomalous finding resulting from differentiation of the abnormal clone. Techniques such as fluorescence in situ hybridization and premature chromosomal condensation have been used to verify that morphologically maturing cells are derived from the original malignant clone.[98]

Although there may be a variety of clinical and morphologic changes that occur with therapy, the process of achieving CR is gradual. After about 4 to 6 weeks of treatment, the standard definition of CR should apply: adequate cellularity as determined by bone marrow biopsy and normal maturation of all cell lines with <5% blasts. No cells with Auer rods should be visualized. Restoration of normal hematopoiesis should be evidenced by a peripheral blood neutrophil count $\geq 1.5 \times 10^9$/L, and the platelet count should be $>100 \times 10^9$/L. In order to meet criteria for CR, these findings should be present for at least 4 weeks.[95]

Despite fulfilling the morphologic criteria for CR, approximately 85% to 90% of patients treated with ATRA alone and 15% to 25% of relapsed patients treated with ATO alone still have molecular evidence of disease as detected by RT-PCR.[55,99,100,101] The addition of chemotherapy to ATRA increases the proportion of patients who become negative for molecular evidence of the disease.[102,103] Repeated cycles of ATO may be needed to achieve this molecular remission.[101] Given the relative importance of the RT-PCR assay results, some experts have recommended that the bone marrow be sampled and examined for both morphologic and molecular evidence of remission at least every 3 months for the first 2 years post-remission.[55] More recently, RT-PCR of the peripheral blood has been substituted for the bone-marrow–based assay, but such a practice has yet to be clinically validated. Patients whose RT-PCR result converts from a negative to positive should have the bone marrow examination repeated within 1 month to verify this result. Patients tend to relapse within 6 months of completing therapy, so it may be important to continue monitoring during this critical time. Despite relatively intensive molecular monitoring, some patients relapse with overt clinical disease, raising questions regarding the predictive nature of the test as well as the sensitivity and the standardization of the assay.[104,105]

Current Therapy

Although APL was recognized as a distinct subtype of AML in 1957,[106] until the early 1990s this disease was managed with standard therapy used for all subtypes of AML, consisting of a combination of an anthracycline and cytosine arabinoside. Using this approach, investigators reported CR rates in the 50% to 60% range, but with improvement in the management of infections and the APL-related coagulopathy, CR rates increased to as high

as 80%.[90,107,108] The likely reasons for failure of this treatment included mortality related to sepsis, catastrophic hemorrhage, or, less frequently, primary drug resistance.[109,110] However, despite this high CR rate, long-term DFS in patients with APL was approximately 30% to 40%.[3,111,112] Subsequently, the incorporation of ATRA as part of induction therapy in newly diagnosed APL and the use of ATO in relapsed disease have markedly improved the outcome of patients with this disease. See Table 78.4 for representative therapies for APL. A randomized trial has shown that ATO consolidation therapy improves survival in newly diagnosed patients with APL.[113]

Chemotherapy

Anthracyclines are one of the most important cytotoxic agents used in treating all subtypes of AML. Several studies have specifically demonstrated the sensitivity of APL to this class of agents.[3,112] However, whether there is a clinical advantage of one anthracycline compared to another remains controversial. Prospective randomized trials have not convincingly or consistently shown an advantage of either daunorubicin or idarubicin in the treatment of AML,[114,115] and specifically, no prospective randomized trial has compared these agents in the treatment of APL. Currently, both daunorubicin and idarubicin are used in clinical practice for treatment of APL.

Although cytosine arabinoside is the backbone of treatment for AML in general, the importance of this drug in the treatment of APL specifically remains indistinct. In APL patients, monotherapy using either daunorubicin or idarubicin achieves a CR rate in the 55% to 88% range.[112,116,117] A retrospective analysis of 62 patients with APL treated with either single-agent daunorubicin or in combination with cytosine arabinoside for induction therapy showed no difference in CR rates.[117] Similarly, in a randomized Italian Cooperative Group (GIMEMA) prospective study in untreated APL patients comparing idarubicin to the combination of idarubicin plus cytosine arabinoside, no difference in CR rate or event-free survival (EFS) was observed.[116] Longer term follow-up of this GIMEMA study revealed that EFS at 7 years was superior in the idarubicin-only arm.[118] Considering the exquisite sensitivity of APL to anthracyclines, dose-intense single-agent anthracycline, particularly idarubicin, may be more beneficial than and a less toxic alternative to standard combination therapy as suggested by a study[119] conducted by the Spanish Programa para el Tratamiento de Hemopatias Malignas (PETHEMA) group.

All-Trans Retinoic–Based Strategies

The introduction of ATRA into the treatment strategy of APL fundamentally changed the management and outcome of this disease. The first series of patients treated with ATRA was reported

by Huang et al. in 1987.[120] By the mid-1990s more than 3,000 APL patients worldwide had been treated with ATRA, with published data showing a median CR response >85%.[96,98,120,121,122] Although doses of ATRA up to 100 mg/m^2 have been used in various studies, no particular dose–effect correlation has emerged. Most clinical experience has been obtained with a dose of 45 mg/m^2/day administered as a single daily dose or in two equally divided doses and given approximately 12 hours apart. In a multicenter study conducted in APL patients by Castaigne et al.[123] a dose of 25 mg/m^2/day of ATRA revealed similar results in terms of CR rates and pharmacokinetic parameters compared to ATRA at 45 mg/m^2/day. The incidence of hyperleukocytosis and RAS, however, was also the same. In contrast, a small study conducted at the Shanghai Institute of Hematology reported achieving a clinical CR in 24 of 26 (92%) newly diagnosed APL patients with daily oral ATRA of 15 to 20 mg/m^2/day with no reported events of RAS.[124] However, no prospective randomized trials have been conducted to establish the long-term therapeutic effects of a lower dose of ATRA, and therefore doses <45 mg/m^2/day should not be used routinely as standard of care.

The clinical response to ATRA is correlated with the presence of the 15;17 chromosomal translocation assessed by conventional cytogenetics or by RT-PCR.[81,82,85] This translocation involves the molecular rearrangement of *RARα*, which appears to be the link to the clinical responsiveness to ATRA. Some patients with equivocal cellular morphology and normal karyotypes have shown typical rearrangements of *RARα* by molecular testing, and these patients are clinically responsive to ATRA.[81,83] However, patients who are negative by RT-PCR for *PML/RARα* and/or do not exhibit the karyotypic t(15;17) do not respond to ATRA.[63,81] Therefore, it is critical to note that patients with acute leukemia with cytogenetic or molecular findings other than the common t(15;17) or *PML/RARα* that is distinctly found in APL, respectively, do not respond to ATRA and should be immediately treated with standard antileukemic therapy.

In the initial phase II studies with ATRA in APL, two important clinical observations became evident. The first was that up to one half of the patients developed what is now known as RAS, which in the preliminary experience often proved to be fatal. Gradually, a number of treatment strategies emerged that improved the associated morbidity/mortality of this syndrome. Currently, as the result of vigilant monitoring and the initiation of high-dose dexamethasone with the first presenting sign or symptom (discussed below), few patients die as a result of RAS. The second observation was that remissions induced and maintained solely by ATRA are brief in duration, with few patients remaining in remission >1 year.[125,126,127] Subsequently, both randomized[27,121] and nonrandomized[127,128] studies revealed that by combining standard induction therapy (anthracycline based) with ATRA, followed by consolidation treatments, remissions were not only durable, but also superior to those achieved by chemotherapy alone.

In the initial trials incorporating ATRA in the treatment of APL, the drug was given as a single agent until CR was achieved; then patients were consolidated with chemotherapy. However, the optimal schedule and duration of ATRA therapy needed to be determined for best clinical outcome. In the U.S. Intergroup Study,[27] 346 newly diagnosed APL patients were randomized to receive either ATRA or daunorubicin plus cytosine arabinoside for remission induction. Patients who obtained a CR received two cycles of consolidation chemotherapy. Patients who remained in remission after completing consolidation therapy were randomized to either observation only or maintenance treatment with ATRA. Therefore, the majority of patients on this trial received ATRA, either as induction therapy, maintenance, or both. There was no significant difference in the CR rate between the ATRA (72%) and chemotherapy (69%) induction groups, however, the 3-year DFS was statistically improved in the ATRA-treated patients compared to those treated with standard antileukemic therapy (72% vs. 32%, $P < 0.001$). This trial clearly showed the benefit of ATRA in the management of APL, particularly when ATRA was incorporated in the induction therapy. The group of patients who received no ATRA had a 3-year DFS of only 18%, which was consistent with the historical survival rate of APL patients.

The European APL group addressed the issue of scheduling of the ATRA/chemotherapy by prospectively randomizing 413 untreated APL patients between concurrent ATRA plus chemotherapy (daunorubicin and cytosine arabinoside) and sequential ATRA followed by the same chemotherapy. Following one to two courses of consolidation, patients were then randomized to receive either 2 years of maintenance chemotherapy consisting of ATRA alone, methotrexate plus 6-mercaptopurine (6-MP), ATRA plus methotrexate and 6-MP, or no maintenance chemotherapy (observation only).[129] The proportion of patients achieving a CR in these two induction groups was no different, with an overall CR rate of 92%. However, the EFS at 2 years was estimated at 84% in the concurrent ATRA plus chemotherapy group versus 77% in the ATRA followed by chemotherapy group ($P = 0.1$). Longer term follow-up from this trial confirmed statistically significant superior EFS and cumulative incidence of relapse (CIR) at 10 years in the patients assigned to concurrent ATRA plus chemotherapy.[130] One possible advantage from the concurrent ATRA plus chemotherapy treatment approach appears to be a significant (approximately 50%) reduction in the incidence of the potentially fatal RAS.[131,132]

Other groups have advocated for anthracycline dose intensity during ATRA-based induction therapy. Both the GIMEMA group and the Spanish Cooperative Group (PETHEMA) have completed trials in APL utilizing induction therapy with daily ATRA plus idarubicin on days 2, 4, 6, and 8[119,133] Although these trials differed in their consolidation (with respect to use of cytarabine) and maintenance regimens, both demonstrated impressively high CR rates (>90%) and long-term DFS rates of >70% beyond 5 years. Using this same regimen, the GIMEMA group also reported a CR rate of 96% ($n = 107$) in children (younger than 18 years old) with untreated APL, resulting in an OS and EFS of 89% and 76%, respectively, with more than 10 years of follow-up.[134] Hence, dose-intensive anthracycline chemotherapy (without cytarabine) in combination with ATRA during induction results in highly successful outcomes that are comparable with regimens that incorporate cytarabine into induction.

The French–Belgian–Swiss APL 2000 study in non–high-risk APL compared outcomes between patients assigned to induction therapy consisting of daunorubicin plus ATRA versus daunorubicin plus cytarabine plus ATRA, followed by consolidation that included high-dose cytarabine in the patients assigned to the cytarabine arm during induction.[102] In this trial, both DFS and OS were superior in the cytarabine-treated patients. A lower cumulative dose of anthracycline in this trial than in the GIMEMA and PETHEMA trials was postulated as an explanation for the superiority in the cytarabine arm. In addition, it was not clear whether the use of high-dose cytarabine during consolidation in the patients randomized to cytarabine induction could have been responsible for better outcomes. In an attempt to address these questions, a joint analysis of the LPA 99 (PETHEMA) and APL 2000 (French–Belgian–Swiss) trials was performed.[135] This analysis revealed that the DFS and OS benefits of cytarabine during induction were limited to patients with high-risk disease (WBC $\geq 10 \times 10^9$/L) at diagnosis. Based upon the available data to date, then, inclusion of cytarabine within induction and consolidation regimens for patients with high-risk APL appears justified, recognizing the limitations of direct comparisons between trials.

Duration of All-Trans Retinoic Acid

Currently, ATRA is recommended as part of the induction regimen and as maintenance therapy, which is initiated after

the completion of consolidation chemotherapy. There is no benefit to continuous treatment with oral ATRA once patients have achieved a CR. Generally, patients who relapse while taking ATRA, or shortly after discontinuing ATRA, fail to respond to further treatment with standard-dose or high-dose ATRA therapy.[120,127] It would be particularly unusual for patients with a molecular diagnosis of APL who are retinoid-naive to be resistant to ATRA. Given the limited duration of remission with ATRA as a single oral agent, acquired resistance to ATRA could theoretically result from genetic or epigenetic events.[136] Acquired resistance in HL-60, a retinoid-sensitive leukemic cell line, has been associated with point mutations in the *RARα* fusion gene.[137,138] Initial analysis from clinical specimens collected from patients prior to treatment with ATRA and at the time of relapse did not reveal additional mutations in *PML/RAR-α*.[139] More recently, mutations in the high-affinity ATRA binding site of clinical specimens have been identified,[140] with an incidence of up to 40% in the relapsed setting following ATRA-based therapy.[141,142] Interestingly, proximate ATRA selection pressure is not thought to be the sole or main determinant for the emergence of dominant *PML-RARα* mutant subclones, and these subclones are predisposed to further mutations that result in a survival advantage.[142]

It appears that multiple mechanisms are likely involved in the development of resistance. Continuous daily treatment with ATRA is associated with a marked decrease in plasma drug concentrations occurring as early as 1 to 2 weeks of initiation of therapy.[143] The mechanisms by which this occurs include induction of cytochrome P450 catabolic enzymes, increased expression of oxidative co-factors, and/or up-regulation of cellular retinoic acid binding proteins.[143,144] These biologic mechanisms function cooperatively to modulate intracellular retinoid concentrations. Therefore, it is conceivable that prolonged administration of ATRA could result in the development of clinical resistance due to an inability to sustain effective concentrations in vivo that would be required to achieve cytodifferentiation.

Post-remission Consolidation Therapy

As reviewed above, treatment of APL with ATRA alone or in combination with chemotherapy yields a complete clinical remission rate as high as 85% to 95%. However, MRD detected by a positive RT-PCR for the *PML/RARα* transcript is present in 80% to 90% and 50% of patients following induction therapy with ATRA alone[55] and ATRA plus chemotherapy,[26,119] respectively. Invariably, patients with positive cytogenetics for t(15;17) or MRD determined by RT-PCR will clinically relapse.[81,82,83,84,85,86] The percentage of patients with MRD is significantly reduced by the administration of post-remission chemotherapy, which correlates with a higher proportion of patients cured of this disease.[81,86,119] The Memorial Sloan-Kettering group performed serial PCR analysis on the bone marrows of patients with untreated APL who received ATRA induction followed by consolidation treatment with chemotherapy, RA, and biologic agents;[55] 85% had MRD detectable by RT-PCR after ATRA induction, and only (10%) had detectable MRD after completing three cycles of consolidation therapy. Consistent with these results, other groups have reported molecular remission rates ≥90% after two to three cycles of anthracycline-based consolidation therapy.[26,102,133,145,146,147] More recently, a prospective trial assessing MRD kinetics during the entire treatment course using RQ-PCR in 70 patients newly diagnosed with APL was conducted.[148] At a median follow-up of 44 months, of those who achieved a CR, nine patients had clinical relapse. The greatest predictor of relapse (85.7% vs. 7.3%, $P < 0.001$) and DFS (14.3% vs. 91.2%, $P < 0.001$) was an MRD level of $>10^{-3}$ after the first consolidation treatment. Thus, the use of prospective MRD monitoring using quantitative PCR could become a critical component in risk-adaptive and long-term treatment strategies to obtain the best clinical outcome.

Although several groups have incorporated high-dose cytosine arabinoside as part of the consolidation strategy,[27,102,135,149,150] the overall benefit of dose-intense cytosine arabinoside in either induction or consolidation remains unclear. Schlenk et al.[151] evaluated high-dose cytarabine in combination with mitoxantrone as consolidation therapy. In this study 82 newly diagnosed APL patients received induction therapy according to the AIDA protocol (ATRA, idarubicin) followed by one cycle of idarubicin, cytarabine, etoposide and two cycles of HAM (cytarabine 3 g/m^2 every 12 hours days 1 to 3; mitoxantrone 10 mg/m^2 on days 2 and 3). Ten patients died from early/hypoplastic death; 72 (88%) achieved a CR; and 71 of these patients received at least one cycle of HAM. After 46 months, relapse-free survival (RFS) and OS were 83% and 82%, respectively. As discussed, recent data from a French–Belgian–Swiss trial, where patients with high-risk APL (WBC ≥ 10×10^9/L) received standard-dose cytarabine during induction and dose-intensive cytarabine during consolidation, demonstrated an excellent 2-year EFS of 89% along with superior outcomes compared to high-risk patients treated with non-cytarabine–containing regimens.[102,135] More recently, the PETHEMA group launched a trial (LPA2005) that incorporated high-dose cytarabine into consolidation therapy for high-risk patients, demonstrating a decreased CIR and marginally improved DFS compared with their previous trial (LPA99) in which cytarabine was not utilized during consolidation.[146] Similarly, the GIMEMA group also introduced a risk-adapted approach for high-risk patients in the AIDA2000 study, utilizing high-dose cytarabine during the first course of consolidation.[145] Once again, CIR and DFS were improved in high-risk patients treated with high-dose cytarabine compared with patients in the previous study (AIDA0493) that did not utilize high-dose cytarabine during consolidation. Taken together, these findings suggest a role for high-dose cytarabine during consolidation for patients with high-risk APL, but the overall topic remains somewhat confounded by a lack of randomized trials to address this issue.

Historically, most groups have used a combination of ATRA and chemotherapy (anthracycline-based) for remission induction, followed by two to three cycles of consolidation chemotherapy that lacks ATRA inclusion, with the goal of eliminating MRD. As previously noted, results of this approach have been extremely effective, with a high likelihood of cure. In an attempt to further improve outcomes, the PETHEMA groups LPA99 trial used a risk-adaptive approach, adding ATRA to consolidation in the patients with intermediate and high-risk disease, along with increased doses of anthracyclines, and evaluated relapse rates in comparison to patients treated on the previous LPA96 trial, where risk-adapted addition of ATRA and anthracyclines did not occur (Table 78.5). Compared to patients treated with the LPA96 regimen, the risk-adapted approach utilized during consolidation in the LPA99 trial demonstrated an overall reduction in the relapse rate from 20.1% to 8.7% ($P = 0.004$), most notably in the intermediate-risk group, where the reduction was from 14.0%

TABLE 78.5

PREDICTIVE MODEL FOR RELAPSE-FREE SURVIVAL

Risk	WBC Count	Platelet Count
Low	≤10×10^9/L	>40×10^9/L
Intermediate	≤10×10^9/L	≤40×10^9/L
High	>10×10^9/L

Sanz MA, Lo Coco F, Martín G, et al. Definition of relapse risk and role of non-anthracycline drugs for consolidation in patients with acute promyelocytic leukemia: a joint study of the PETHEMA and GIMEMA cooperative groups. Blood 2000;96:1247–1253.

to 2.5% ($P = 0.006$). This approach also translated into apparent improved DFS and OS.[26] Long-term follow-up of this trial confirmed continued DFS benefits with such risk-adapted therapy at 5 years and beyond.[147]

Maintenance Therapy

Traditionally, maintenance therapy has not been a standard component of the state of the art management of AML. However, in APL, there are several small studies that have suggested a possible benefit of maintenance chemotherapy. In an early trial conducted at MD Anderson, 39 of 70 patients with APL who received 6-MP and methotrexate as maintenance therapy had a nearly twofold (56% vs. 30%; $P < 0.01$) higher sustained 3-year remission rate compared to those patients who did not receive maintenance.[152] Subsequently, results of two randomized trials[27,129] and one nonrandomized[119] trial have shown a reduction in the risk of relapse in patients treated with either ATRA and/or chemotherapy as maintenance. In the European APL 93 trial,[129] the largest of these three studies, 289 patients, after completing their consolidation therapy, were randomized to no maintenance or to maintenance with either ATRA (45 mg/m^2/day for 15 days every 3 months), continuous low-dose chemotherapy with 6-MP (90 mg/m^2/day) plus methotrexate (50 mg/m^2 given weekly), or both ATRA and continuous low-dose chemotherapy after completion of their consolidation therapy. The 2-year relapse incidence was 13% compared to 25% in patients who received versus those who did not receive ATRA, respectively ($P = 0.02$), and 11% compared to 27% in patients who received versus those who did not receive chemotherapy as maintenance, respectively ($P = 0.0002$). However, the relapse rate (6 out of 74 patients, 8%) was lowest in the subgroup that was randomized to both ATRA and low-dose chemotherapy. In addition, there was an improvement in OS ($P = 0.01$) in those patients who received chemotherapy maintenance, and a similar trend in those patients who received ATRA maintenance ($P = 0.22$). Interestingly, high-risk patients (presenting with WBC counts >5,000 and older than 60 years) who received both ATRA and low-dose chemotherapy seemed to benefit the most from such therapy. In contrast to these results, the GIMEMA Cooperative Group (AIDA 0493), which randomized patients in molecular CR to the same maintenance therapy used in the European APL 93 study, failed to demonstrate a long-term benefit of any maintenance regimen.[133] Similarly, the Japan Adult Leukemia Study Group APL97 study failed to demonstrate a benefit to maintenance chemotherapy, although ATRA was not included in the maintenance chemotherapy regimen in this trial.[153] Finally, in a recent update to the CALGB9710 US Intergroup Trial, there was no difference in DFS or OS in patients randomized to maintenance therapy with ATRA monotherapy versus those randomized to maintenance with ATRA plus low-dose oral chemotherapy.[154] Although the exact role of maintenance therapy remains to be defined, particularly with respect to its optimal schedule, most current protocols include this maintenance approach in their overall therapeutic strategy.

Most important in the management of APL is that patients in remission should be monitored routinely for evidence of MRD by RT-PCR. The experience to date shows that patients who remain positive after the completion of consolidation therapy, or those who convert from negative to positive (molecular relapse), will inevitably relapse.[69,70,71] Such patients should receive additional therapy; in particular, allogeneic bone marrow or stem cell transplantation should be considered.

Adverse Effects of Retinoic Acid

The toxicity profile of ATRA is comparable to other retinoids. APL patients, however, are uniquely prone to the development of a hyperleukocytosis and a reaction known as RAS.[155,156] RAS is characterized by fever, respiratory distress, radiographic pulmonary infiltrates, pleural or pericardial effusions, weight gain due to fluid overload, episodic hypotension, and acute renal failure. In the setting of ATRA monotherapy, RAS has an incidence of 20% to 30%.[123,126,156] The clinical diagnosis can be challenging because this patient population is at risk to develop pneumonia, sepsis, and congestive heart failure because of the disease and due to complications of cytotoxic chemotherapy. The first sign or symptom of RAS has been reported to occur anytime within the first few days to weeks of initiating ATRA therapy.[139] It is interesting that there have been reports of this adverse event occurring in patients who were maintained on ATRA and whose marrow was recovering post-myelosuppressive doses of chemotherapy.[155] Although hyperleukocytosis is frequently observed preceding RAS, the reaction may occur with a normal leukocyte count in up to one third of cases.[42,26,156] In addition, there are conflicting reports as to whether an elevated pre-treatment leukocyte count is associated with an increased risk for subsequent development of RAS.[155,157] Overall, there have been no clearly established independent prognostic factors for the development of RAS. Fatality from RAS has been correlated with the pre-treatment factors of hypoalbuminemia and ECOG performance status.[23]

Clinically, RAS gives the impression of a "capillary leak syndrome." Postmortem examination performed on patients who have died with progressive hypoxemia and multiorgan failure revealed extensive infiltration of maturing myeloid cells into lung, skin, kidney, liver, and lymph nodes.[156] The cause of RAS is unknown, although several mechanisms have been proposed, including the release of vasoactive cytokines, increased expression of adhesion molecules on myeloid cell surfaces, and attainment of migratory capabilities by the malignant promyelocytes as they undergo differentiation.[42,156] ATRA increases the expression of the surface integrin intracellular adhesion molecule-1 in certain cell lines. Of clinical importance, this effect can be blocked by treatment with dexamethasone[158] Development of this reaction is also correlated with expression of CD13 (aminopeptidase N),[42] which has been associated with a poor outcome in patients with acute myeloid leukemia. These observations suggest a link to the clinical experience of extravascular adhesion and migration of differentiating cells in this reaction.

The progression of RAS can be terminated by early intervention with a short course of high-dose dexamethasone (10 mg twice a day for 3 days), and as a result the mortality from this adverse event has decreased significantly.[132] The importance, however, of the immediate recognition and appropriate interventions cannot be overemphasized. The development of any unexplained signs or symptoms, particularly fluid retention, sporadic fevers, and pulmonary infiltrates, should prompt immediate dexamethasone treatment. Once fully established, the management of RAS has proved especially difficult and often results in significant morbidity and, frequently, death. Therefore, the benefits of empiric steroid therapy far outweigh the risk of complications associated with inappropriate use in leukemic patients with infections. In a nonrandomized prospective study, the Australian Study Group treated patients with prophylaxis corticosteroids (prednisone 75 mg/day) and reported a lower incidence of pulmonary toxicity and RAS.[159] Most groups have not adopted this as a standard approach given the risks/benefits of corticosteroids but instead administer dexamethasone at the earliest appearance of any of the signs or symptoms suggestive of RAS.

Although APL has generally been associated with leukopenia at the time of presentation, leukocytosis ($\geq 10 \times 10^9$/L) frequently occurs in APL patients treated with ATRA alone. In general, it was recognized that patients who developed leukocytosis while receiving ATRA fared as well as patients who developed RAS. In addition, it has been suggested that the development of leukocytosis and RAS is associated with a higher risk of extramedullary relapse (EMR).[160] The prevention and/or management of leukocytosis involves using full-dose chemotherapy along with ATRA. The

concurrent administration of these agents also appears to result in a lower incidence of RAS. With ATRA alone, the incidence of RAS is approximately 25%; when given concurrently with chemotherapy, the GIMEMA Trial, the Japanese Adult Leukemia Study Group, and the European APL study reported an incidence of 10%, 6%, and 15%, respectively.[27,119,129]

Management of Relapsed Acute Promyelocytic Leukemia

Despite the significant improvement in CR and survival rates observed since the incorporation of ATRA in the treatment of APL,[27,98,161] 15% to 20% of these patients relapse and are often resistant to further treatment with ATRA.[98,121] Some patients, however, who have relapsed >6 months after completing their last ATRA therapy have achieved a second CR when retreated with ATRA.[109] This relative "reversal of resistance" may in part be related to the metabolism of ATRA. The plasma levels of ATRA have been shown to decline over time in pharmacokinetics studies where ATRA was given continuously, in part, as a result of autoinduction as discussed earlier. Clinically, this could result in a subtherapeutic plasma level and thereby give the appearance of drug resistance. The up-regulation of the respective metabolic enzymes reverses after a defined period from discontinuation of therapy.[162,163] Therefore, when re-instituting therapy with standard doses of ATRA, the therapeutic levels needed clinically to induce myeloid differentiation are once again obtained.

Patients who achieve a second CR irrespective of agent(s) used will need additional curative therapy. Salvage therapy often entails high doses of cytotoxic chemotherapy followed by either autologous or allogeneic transplantation. Such an approach carries a risk of significant morbidity and mortality and may not be appropriate for some patients, an important consideration in treating very young or elderly patients. Also, an allograft is contingent on finding an HLA-identical donor for these patients, which occurs only for a subset of the patients.

Since the inclusion of ATRA as part of standard first-line therapy, there have been limited clinical data available reviewing the role of dose-intense chemotherapy followed by transplantation in relapsed patients. In the European APL 91 trial[129] and the Italian GIMEMA Group study,[164] 4 of 5 patients and 6 of 15 patients in second CR, respectively, who underwent allografts obtained a prolonged CR. Thomas et al.[165] reported treating 50 patients with APL in first relapse with single-agent ATRA until CR followed by sequential EMA chemotherapy (etoposide 200 mg/m^2/day for 3 days, mitoxantrone 12 mg/m^2/day for 3 days, and cytosine arabinoside 500 mg/m^2/day for two sequences of 3 days). Forty-five (90%) patients achieved a second CR; 37 of these 45 patients had ATRA as part of their first remission regimen when newly diagnosed. While in second CR, 11 patients underwent HLA-identical allogeneic transplant and had a median DFS of 8.2 months; 22 patients underwent autologous transplants and had a 3-year DFS rate of 77%. These results suggest that autologous transplantation effectively cures a large proportion of these patients in first relapse at the risk of significant but acceptable toxicity. For patients undergoing an autologous transplantation in second CR, an important consideration is the RT-PCR status for *PML/RARα*, which is indicative of MRD. In a small series, Meloni et al.[166] reported that all 7 patients whose graft was positive for *PML/RARα* relapsed within 9 months post transplant, and six of eight patients with PCR-negative disease remained in molecular remission at a median of 28 months. Relapse rates are lower with allogeneic transplant, but the treatment-related mortality tends to offset any advantage.[167]

Arsenic Trioxide

Based on initial reports from China,[168,169] a pilot trial using daily infusions of ATO in 12 patients with relapsed APL was conducted in 1997 at Memorial Sloan-Kettering Cancer Center that demonstrated a 92% (11 out of 12 patients) CR rate.[170] Subsequently, in a confirmatory US multicenter study,[101] 40 patients received a daily 1-hour infusion of 0.15 mg/kg of ATO until the elimination of visible leukemic cells in the bone marrow. The CR rate was 85% and median times to bone marrow leukemic blast clearance and CR were 35 days and 59 days, respectively. In addition, 78% of these patients achieved *PML-RARα* transcript negativity by RT-PCR by the completion of their consolidation therapy. Eighteen patients subsequently received one to four cycles of ATO maintenance on a different protocol, and 12 patients ultimately underwent allogeneic (n = 9) or autologous (n = 3) transplant while in CR. When the data from the 12 patients treated in the original single institution study[149] of ATO are combined with results from these 40 patients, combined analysis of the 52 patients in the Memorial Sloan-Kettering and the US multicenter studies revealed a Kaplan-Meier 18-month estimate of OS and RFS of 66% and 50%, respectively.[101] Subsequently, other groups have treated relapse/refractory APL with ATO using a dose and schedule similar to the US Multicenter Study and have reported comparable outcomes in terms of hematologic and molecular remission rates.[99,100] As a result of the high efficacy and safety profile observed, ATO is used as standard therapy in patients with two or more relapses and is now more frequently used in patients after a first relapse, particularly in those patients whose first CR lasted <12 months, and including molecular relapse. The best subsequent treatment strategy (i.e., maintenance ATO vs. autologous transplant vs. allogeneic transplant), remains to be determined.

Since receiving Food and Drug Administration approval in September 2000, ATO has also been shown to be effective when used as a single agent or in combination with ATRA in newly diagnosed APL.[171,172,173,174,175] Representative studies are shown in Table 78.6. Shen[174] et al. randomized 61 newly diagnosed APL patients into three treatment groups: ATRA, ATO, or the combination of the two. CR was achieved in ≥90% in all groups, and median time to CR was the shortest (25.5 days) in the combination arm. Other clinical benefits in the combination arm included faster recovery of platelet count and normalization of coagulation and fibrinolysis parameters, as well as faster decrement in *PML/RARα* transcripts, as measured by RQ-PCR. It is important to note that relapse occurred in 7 of the 37 (19%) patients treated with monotherapy at a median of 18 months, compared with relapsed none of the 20 patients in the combination group ($P < 0.05$). These favorable clinical benefits with the combination of ATRA and ATO were also reported by other investigators.[175] As a single agent for untreated APL, ATO appears to produce a durable long-term benefit, with actuarial 5-year EFS and OS rates of 69% and 74%, respectively.[176]

Considering the efficacy and safety of ATRA and ATO as single agents in APL, the group at MD Anderson evaluated the combination of these two agents as an alternative to ATRA plus chemotherapy in untreated APL.[171,177] Using a treatment strategy based upon risk categorization at diagnosis, 56 low-risk (presenting WBC count $< 10 \times 10^9$/L) and 26 high-risk patients (WBC $> 10 \times 10^9$/L) received ATRA (45 mg/m^2 daily) and ATO (0.15 mg/kg daily, beginning day 10 of ATRA, and later modified to begin on day 1) for induction therapy. In addition to the ATO and ATRA, high-risk patients received chemotherapy (gemtuzumab ozogamicin) on day 1 of induction. Patients achieving a CR then received only ATO plus ATRA as consolidation therapy unless they were molecularly positive for *PML-RARα* 3 months from the CR date or had molecular relapse, and then chemotherapy (gemtuzumab ozogamicin) was given in combination with ATO and ATRA during consolidation. The overall CR rate was 92% (95% in low risk, 81% in high risk). At a median follow-up of 99 weeks, the estimated EFS and OS were >80%. Both EFS and OS were superior in the low-risk group compared with the high-risk group. It was concluded that the combination of ATRA and ATO could be used as an alternative to

chemotherapy in low-risk untreated APL. Further study of ATRA plus ATO plus gemtuzumab ozogamicin in high-risk groups is the subject of an ongoing US Southwest Oncology Group trial.

The CALGB group has also evaluated the role of ATO during consolidation therapy in APL.[113] In this trial, patients with newly diagnosed APL were randomized, following ATRA-based induction, to 2 cycles of ATO versus no ATO consolidation (followed thereafter by 2 cycles of ATRA plus daunorubicin late consolidation in each arm). This study demonstrated significant improvement in EFS in the ATO-treated patients compared with controls, along with a trend toward improved OS in this group, indicating a role for ATO earlier in therapy, prior to relapse. It should be pointed out, however, that differences exist between the US and non-ATO European induction regimens (especially with respect to anthracycline dose intensity), such that the precise overall role of ATO in untreated APL remains undefined.

Finally, and most recently, the Italian-German Cooperative Groups tested ATRA + ATO versus ATRA + idarubicin in newly diagnosed APL, revealing a non-inferior 2 year event-free survival amongst ATRA + ATO treated patients. These data demonstrated, for the first time, that an "all biologic" regimen provides similar or superior outcomes compared to a regimen inclusive of traditional cytotoxic chemotherapy, an observation that may ultimately change the standard of care in APL.[177a]

The most common adverse events observed with ATO in the US multicenter study included leukocytosis (>10 × 10^9/L)

during induction therapy, mild hyperglycemia, and fatigue. Also, 10 patients developed signs and/or symptoms suggestive of RAS and were effectively treated with dexamethasone. A potentially life-threatening side effect was QT prolongation on electrocardiogram, which was observed in 63% of patients. Although all of these patients were asymptomatic, including one patient who developed a brief episode of torsades de pointes, other investigators have reported sudden cardiac death[178,179] associated with ATO therapy in APL patients. Therefore, close monitoring including aggressive management of electrolytes, particularly potassium and magnesium, is undertaken in conjunction with ATO therapy. Both intravenous and oral supplements are liberally provided to maintain the serum potassium > 4 mEq/L and the magnesium level > 1.8 mg/dl. In addition, every effort should be made to limit the concomitant use of other agents known to prolong QT intervals or induce ventricular arrhythmias. Following these management guidelines, in a post-marketing safety update on over 2,200 patients treated with ATO, including 437 patients with APL, no torsade de pointes nor deaths due to ATO (Trisenox)-associated arrhythmia have been reported.[180]

Liposomal All-*Trans* Retinoic Acid and Gemtuzumab Ozogamicin

Other agents that have shown benefit in patients with relapsed APL include *liposomal ATRA* and *gemtuzumab ozogamicin* (Mylotarg). Douer et al.[181] conducted a trial using a liposomal formulation of ATRA and administered it intravenously in 69 patients with newly diagnosed (32 patients) or relapsed (35 patients) APL, and in 2 patients who failed oral ATRA. A CR was achieved in 62% of previously untreated patients and in 70% of those patients in first relapse who were ATRA naive or off oral ATRA for ≥1 year. In those patients who were in first relapse and off oral ATRA for <1 year or in their second or greater relapse, 20% achieved a CR. In a study reported by Tsimberidou et al.,[182] single-agent Lipo-ATRA (liposomal ATRA) was used in untreated APL for induction and for consolidation in those patients who achieved a CR. Molecular disease was monitored by RT-PCR for *PML-RARα* every 3 months from the time of CR, with idarubicin added to those patients who were positive for molecular disease. A CR was obtained in 79% of patients. Of 26 responders 10 who never received chemotherapy remained in first CR at a median of 6.4 years. However, the proportion of patients responding in these studies may be no different than expected in the same population treated with oral ATRA. However, the durability of remissions achieved with single-agent Lipo-ATRA have not been reported with oral ATRA. This agent warrants further exploration in the treatment of APL and clearly is important in a patient population in which oral ATRA is not ideal, such as patients who are not able to tolerate or absorb the oral formulation.

Gemtuzumab ozogamicin is an engineered human anti-CD33 antibody linked with the potent antitumor antibiotic calicheamicin. This agent binds to the CD33 antigen that is found on the surface of leukemic cells in more than 80% of patients with AML, and virtually in 100% with APL. The binding of CD33 by gemtuzumab results in the internalization and hydrolytic release of calicheamicin, which belongs to the anthracycline class of drug. Pre-clinical studies have shown this agent to be effective against ATRA- and ATO-resistant APL cells.[183] Clinical remissions have been observed with gemtuzumab, including a clinical and molecular remission in a patient with multiple relapsed APL.[184] In a study of patients with molecular (not hematologic relapse,[185] 16 patients received gemtuzumab at 6 mg/m^2. There were 14 patients (87%) who achieved a molecular remission after receiving one to three doses, which was sustained for a median of 15 months (range, 7 to 31 months) in 3 patients. This drug was withdrawn from the US market in 2010, and is not commercially available for any indication, although its primary role in APL remains to be determined.

Special Issues

Management of the Elderly Patient

As APL typically manifests in younger patients, the therapeutic experience in older adults (age > 60) is more limited. In large cooperative group studies, older patients comprise between 5% and 20% of the overall study population.[113,133,135,146] In general, older patients with AML demonstrate poorer tolerance for cytotoxic induction therapy,[186,187,188] so the same concerns logically exist for the elderly APL patient, in whom cytotoxic therapy is planned.

Both the PETHEMA and the GIMEMA cooperative groups have comprehensively analyzed their experience with older adults in APL[103,189] in their therapeutic trials (LPA96/99 and 0493, respectively). In both groups, early mortality was more frequently encountered in patients older than 70, initial CR rates were >80%, and 3-year DFS rates were >70%. In the GIMEMA trials, OS at 6 years was 56%.[189] The GIMEMA group recently published the results of its modified APL treatment regimen for patients older than 60, utilizing induction with ATRA + idarubicin, followed by a single course of consolidation with idarubicin + cytarabine, followed thereafter with ATRA maintenance.[190] This regimen produced 5-year OS and DFS rates of 76% and 65%, respectively. The use of ATRA + ATO during induction, based upon the MD Anderson experience, resulted in similar rates of OS among older and younger individuals, suggesting that a regimen free of cytotoxic chemotherapy could be better suited for older patients.[177] Hence, although APL occurs infrequently in older individuals, outcomes are favorable, indicating the importance of pursuing aggressive therapy, with evolution toward reduction or omission of cytotoxic chemotherapeutic agents.

Extramedullary Disease and Relapse

Extramedullary disease (EMD) occurs in approximately 5% to 10% of adult patients with AML, most commonly in the myelomonocytic and monocytic subtypes.[191] Historically, the incidence of EMD in patients with APL has been considered rare.[192,193] However, since the early 1990s there have been numerous reported cases in patients with APL at the time of relapse, mostly involving the skin and CNS.[160,192,194,195,196] In the Italian GIMEMA group study, 13 of 97 patients with relapsed APL had EMD, and in the European APL 93 trial 3 of 75 relapsed patients had documented EMD. Using a competing-risk method to analyze the incidence, presenting features, and risk factors of EMR in 740 patients with APL treated with ATRA and chemotherapy, it was concluded that EMR occurs more frequently in patients with increased WBC counts (>10,000/mm^3) and carries a poor prognosis.[194] It appears that CNS involvement is more common than either skin or organ infiltration. In a series of 21 reported cases of EMR, 14 cases involved the CNS.[11] The same group also analyzed the incidence of EMD involvement in their series of APL patients who were treated with either chemotherapy alone or with AIDA regimen and subsequently relapsed.[11] Accounting for all relapses, there were no conclusive data to support a higher incidence of EMD in patients treated with ATRA. However, the proportion of patients with EMD who had CNS involvement was significantly higher in the group that received ATRA as part of their induction therapy compared to those who received only chemotherapy. One explanation for this observation is that ATRA therapy induces the expression of adhesion molecules such as CD11c, CD13, and CD56 in the malignant promyelocytes and that may facilitate CNS infiltration.[48,197,198] There was no comparative difference in the incidence of other sites of EMD. Of note, 14 of the 16 patients in the AIDA trial with EMD found at relapse also had hematologic or molecular evidence of disease. Treatment for CNS relapse requires systemic re-induction along with four to six cycles of intrathecal methotrexate or

cytosine arabinoside. Some patients may benefit from additional cranial–spinal radiation. It is reasonable to consider CNS prophylaxis, particularly in those patients who present with high WBC counts. However, CNS prophylaxis with either intrathecal chemotherapy alone or combined with cranial irradiation has not been shown to improve DFS in adults with AML in general. This is likely because the majority of the patients have systemic relapse in addition to CNS or EMD.

SUMMARY

APL is a highly curable disease and represents a model for modern cancer therapy. It is unique in that the identification of the specific genotype that is used for diagnosis, monitoring MRD, and detection of early relapse has also resulted in a greater understanding of the fundamental biology of this disease, which serves as a template for the development of targeted therapies. APL is the first known disease that is clinically sensitive to differentiation therapy, and as a result, the paradigm for the treatment of leukemia has been irrevocably altered. As medicine moves through the era of genomics, proteomics, and rationale drug design, the models of pathogenesis based on interactions between both genetic and epigenetic factors may be instrumental in the understanding and treatment of other forms of malignancy.

CHAPTER 79

THE MYELODYSPLASTIC SYNDROMES

Guillermo Garcia-Manero

ABSTRACT

The myelodysplastic syndromes (MDS) are a very complex group of myeloid disorders characterized by peripheral blood cytopenias and morphologic evidence of dysplasia in bone marrow hematopoietic cellular elements. Over the last decade, significant progress has been made in the understanding of MDS. This includes the discovery of multiple molecular alterations, resulting in better classifications, the development of new prognostic scores, and newer forms of therapy. Despite these advances, most patients with MDS will succumb either to complications of the disease itself, such as infections or bleeding, or from transformation to acute myelogenous leukemia. In this chapter, I will provide a summary of current knowledge of MDS, including basic epidemiologic and molecular data, prognostic scores, and therapy, including stem cell transplantation.

INTRODUCTION

The myelodysplastic syndromes (MDS) are a very heterogeneous group of myeloid malignancies that result in bone marrow failure and peripheral blood cytopenias.[1] MDS is diagnosed based on the presence of dysplastic features in the bone marrow. Diagnosis is often supported by the presence of cytogenetic alterations and, more recently, genetic mutations. The natural history of patients with MDS is also very heterogeneous, with a small subgroup of patients surviving for long periods of time with minimal intervention and other patients with very poor prognosis that succumb early to the disease either from complications of infections or bleeding or from transformation to acute myelogenous leukemia (AML).[2,3] Over the last 15 years, the field of MDS has transformed from a rarely studied condition, often considered to be a preleukemia, to the focus of the work of multiple investigators around the world. These efforts have resulted in significant improvements in our understanding of MDS as well as in our ability to treat patients with this group of disorders. Here I will summarize this progress and provide concepts for future work in this area.

Clinical Presentation and Complications of Myelodysplastic Syndrome

The clinical presentation of most patients with MDS is not specific. At the present time, most patients with MDS are diagnosed after a routine examination of peripheral blood. MDS is suspected based on the presence of one or more peripheral blood cytopenias. Although there is no formal data to prove this point, it is my experience that is uncommon to diagnose patients with MDS because of critically symptomatic anemia, bleeding, or neutropenic fever.[4] That said, symptoms of anemia, thrombocytopenia, fever, other constitutional symptoms, or unexplained infectious processes can lead to a diagnosis of MDS. The presence of more than one cytopenia should prompt a diagnostic bone marrow evaluation, as will be discussed below. Because the initial clinical differential diagnosis of MDS is broad and includes potentially clinically significant conditions, it is important to perform a thorough evaluation to rule out other conditions that may exclude a diagnosis of MDS or may contribute to the severity of the disease. Common examples include iron deficiency anemia from gastrointestinal sources, hemolysis, and immune-mediated cytopenias. Inflammatory clinical syndromes, that can be seen, for instance, in the context of connective tissue disorders,[5] are also important to be investigated in patients with suggestive clinical manifestations. Drug-induced cytopenias are not uncommon and need to be excluded.[6] It is also important to realize that all these conditions can overlap. Patients with MDS can have gastrointestinal blood losses that may present with normal to mildly increased red cell volumes. A fraction of patients with MDS may also have evidence of a concomitant hemolytic process. Finally, the diagnosis of MDS should be confirmed after performing a diagnostic test that always includes evaluation of the morphology of a bone marrow specimen.

The natural history of patients with MDS has not been studied in detail. In the earlier phases of the disease it is likely that most of the complications are derived from persistent anemia, thrombocytopenia, and neutropenia. Also, a fraction of patients will progress to either higher-risk MDS or AML. The natural history of patients with higher-risk MDS is probably not different from that of patients with AML. We performed an analysis of the cause of death of patients with lower-risk MDS.[3] In this study, we retrospectively analyzed the cause of death in a cohort of 273 deceased patients with lower-risk MDS that presented to MDACC from 1980 to 2004. Patients had received supportive care only. The cause of death was MDS-related in 230 of 273 patients (84%) with the most common events being infection (38%), transformation to AML (15%), and hemorrhage (13%)[3] (Fig. 79.1).

Diagnostic Evaluation

A diagnosis of MDS is based on evidence of the presence of dysplastic features on examination of a bone marrow aspirate. At the present time, most investigators use criteria proposed by the World Health Organization (WHO).[7] This classification has by and large replaced the prior French-American-British system (FAB) that was commonly used before.[8] By FAB criteria, patients with up to 30% blasts were considered to have MDS. This percentage was decreased to 20% by the WHO classification. It should be noted that WHO should not strictly be used to make treatment decisions, as several of the drugs used in MDS, including decitabine[9] and azacitidine,[10] were approved based on FAB criteria. WHO classification includes the percentage of blasts in both the bone marrow and peripheral blood, the number of dysplastic lineages, and the presence of ring sideroblasts. It is recommended that 500 nucleated bone marrow cells and 200 from peripheral blood be evaluated. Dysplasia should be present in more than 10% of cells evaluated for each specific lineage. Erythroid dysplasia can affect both the nucleus and the cytoplasm, including the presence of sideroblasts, cellular vacuolization, and PAS positivity. Dysgranulopoiesis can be represented by alterations in size, nuclear hypolobation, or irregular hypersegmentation. Dysmegakaryopoiesis is often represented by the presence of micromegakaryocytes, hypolobation, or multinucleation. Examination of a bone marrow biopsy specimen, in conjunction with bone marrow aspirate, helps in evaluating bone marrow cellularity and the presence of significant fibrosis, and in making a diagnosis of hypoplastic MDS versus aplastic anemia.[11]

Based on morphologic criteria, MDS is subclassified into 10 categories (Table 79.1). Bone marrow and peripheral blood findings are also summarized in Table 79.1. A photomicrograph of a representative case of MDS is shown in Figure 79.2. Although morphology is fundamental for diagnosis, and morphologic subsets have different natural histories, morphology by itself is insufficient to make prognostic predictions or to select therapy. Because the diagnosis of MDS can be subjective, several investigators have noted a significant degree of discrepancy in the diagnosis of

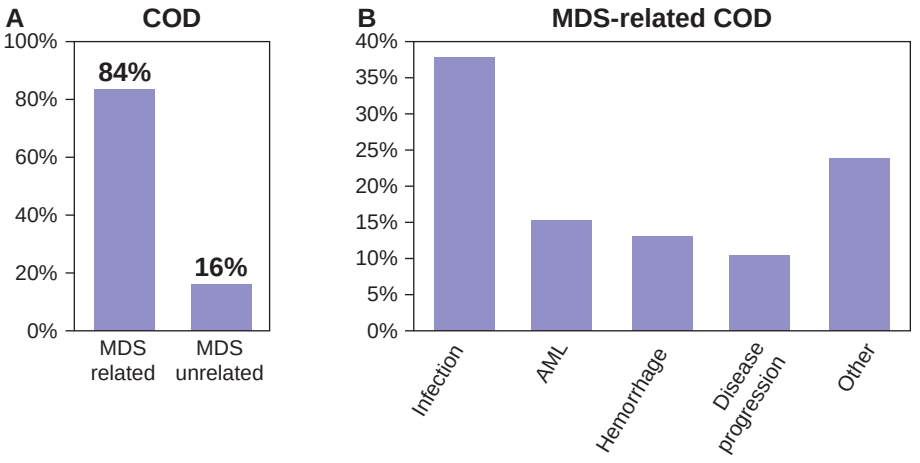

FIGURE 79.1. Cause of death in patients with myelodysplastic syndromes (MDS). A retrospective analysis was performed to determine the cause of death in patients with MDS. As shown in *panel* ***A***, most patients succumb to causes intrinsic to the disease. ***B***, The most common causes of death are infectious complications, transformation to AML, and bleeding. Adapted from Dayyani F, Conley AP, Strom SS, et al. Cause of death in patients with lower-risk myelodysplastic syndrome. Cancer 2010;116:2174–2179.

patients with MDS.[12] In a series of 915 patients with MDS referred to a tertiary care center, discordance in diagnosis using very strict criteria was documented in 12% of patients. A majority of patients were reclassified as having higher-risk disease by the International Prognostic Scoring System (IPSS).[2] This has obvious implications, as most patients with higher-risk disease will be candidates for some form of therapy. Therefore, it is fundamental for the clinician to have proper documentation of the final morphologic diagnosis both for proper prediction of survival and for therapy selection.

A number of diagnostic tools can help the hematopathologist confirm the diagnosis of MDS and classify the disease. The most important assay, which is mandatory in the evaluation of a patient with MDS, is cytogenetic analysis. There is no specific cytogenetic pattern diagnostic of MDS. Typically, 20 metaphases are required for optimal analysis. That said, it is not uncommon to obtain fewer cells in patients with MDS. The presence of cytogenetic alterations can have both a diagnostic and a prognostic value. For instance, in patients with profound marrow hypocellularity, the presence of

TABLE 79.1

WORLD HEALTH ORGANIZATION (WHO) CLASSIFICATION OF MYELODYSPLASTIC SYNDROME (MDS)

Disease	Blood Findings	Bone Marrow Findings
Refractory cytopenias with unilineage dysplasia (RCUD)	Unicytopenia or bicytopenia	Unilineage dysplasia: ≥10% of the cells in one myeloid lineage
Refractory anemia (RA); Refractory neutropenia (RN)	No or rate blasts (<1%)	<5% blasts
Refractory thrombocytopenia (RT)		<15% of erythroid precursors are ring sideroblasts
Refractory anemia with ring sideroblasts (RARS)	Anemia	≥15% of erythroid precursors are ring sideroblasts
	No blasts	Erythroid dysplasia only <5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenia(s)	Dysplasia in ≥ 10% of the cells in ≥ two myeloid lineages (neutrophil and/or erythroid precursors and/or megakaryocytes)
	No or rare blasts (<1%)	<5% blasts in marrow
	No Auer rods	No Auer rods
	$<1 \times 10^9$/L monocytes	±15% ring sideroblasts
Refractory anemia with excess blasts-1 (RAEB-1)	Cytopenia(s)	Unilineage or multilineage dysplasia
	<5% blasts	5%–9% blasts
	No Auer rods	No Auer rods
	$<1 \times 10^9$/L monocytes	
Refractory anemia with excess blasts-2 (RAEB-2)	Cytopenia(s)	Unilineage or multilineage dysplasia
	5%–19% blasts	10%–19% blasts
	Auer rods ±[3]	Auer rods ±[3]
	$<1 \times 10^9$/L monocytes	
Myelodysplastic syndrome—unclassified (MDS-U)	Cytopenias	Unequivocal dysplasia in less than 10% of cells in one or more myeloid cell lines when accompanied by a cytogenetic abnormality considered as presumptive evidence for a diagnosis of MDS (see Table 5.04)
	≤1% blasts	<5% blasts
MDS associated with isolated del(5q)	Anemia	Normal to increased megakaryocytes with hypolobated nuclei <5% blasts
	Usually normal or increased platelet count	Isolated del(5q) cytogenetic abnormality
	No or rate blasts (<1%)	No Auer rods

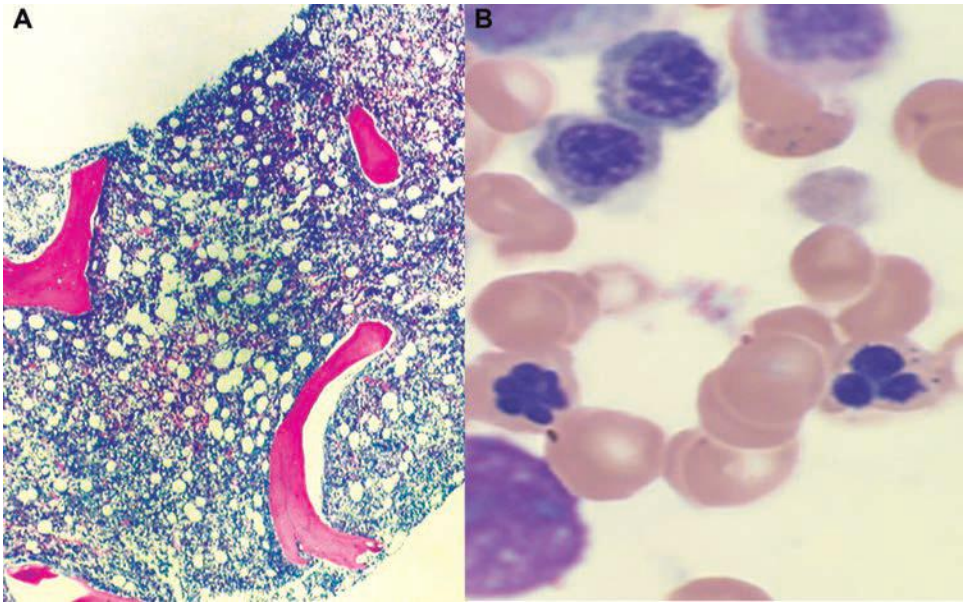

FIGURE 79.2. Representative example of morphologic alteration in MDS. *Panel* ***A*** shows a view of a bone marrow biopsy with almost complete replacement of marrow space with cellular element. *Panel* ***B*** shows a higher magnification of bone marrow aspirate, demonstrating nucleated red cell and micromegakaryocytes characteristic of this disease.

a cytogenetic alteration will allow the differentiation of hypoplastic MDS from aplastic anemia.[11] Finally, and more significantly, specific cytogenetic alterations have different prognostic values. A number of cytogenetic classifications have been proposed in patients with MDS. The most recent one is a 5-subgroup classification that forms the basis of the Revised International Prognostic Scoring System (IPSS-R).[13,14] This cytogenetic scoring system is summarized in Figure 79.3. It is of interest as it further delineates rare cytogenetic alterations with favorable prognostic impact, such as alterations of chromosome 11, and also further defines the weight of alterations of chromosome 7 or complex karyotypes such as those with 3 or more abnormalities. Finally, the presence of specific cytogenetic alterations may help in the selection of specific forms of therapy. A classic example is the presence of deletions of chromosome 5 in patients with the so-called 5q-syndrome.[15] Other alterations, such as chromosome 7 alterations or complex karyotypes may aid the clinician in selecting different forms of therapy with different intensities, such as hypomethylating agents.[10] This is discussed later. A number of groups have proposed the use of fluorescence in situ hybridization (FISH) techniques to aid in the clinical work-up of patients with MDS.[16] At the M.D. Anderson Cancer Center (MDACC), we do not routinely use FISH in MDS because it evaluates only a limited number of chromosomes, and the sensitivity and specificity of the different probes used is not fully understood or standardized. The frequency of cytogenetic alterations depends on risk. For instance, patients in the lower-risk categories by IPSS are diploid in over 50% of cases.[17] This figure increases in patients with more advanced forms of the disease,[18] and over 70% of patients with therapy-related MDS will have a cytogenetic alteration.[19]

Flow cytometry can help in the confirmation of a diagnosis of MDS, and specific phenotypes may have prognostic value.[20] At the present time, there is no flow cytometry panel that is diagnostic of MDS, and flow cytometry cannot replace morphologic examination.[21] It is not uncommon that clinicians may try to quantitate the percentage of blasts by annotating the number of $CD34^+$ cells. Although the number of $CD34^+$ cells has been proposed to have prognostic value,[20,22] it is not an appropriate tool to estimate percentage of blasts and it should be considered only complementary.

Newer genomic technologies are currently being developed that allow the analysis of multiple genetic events in MDS and other

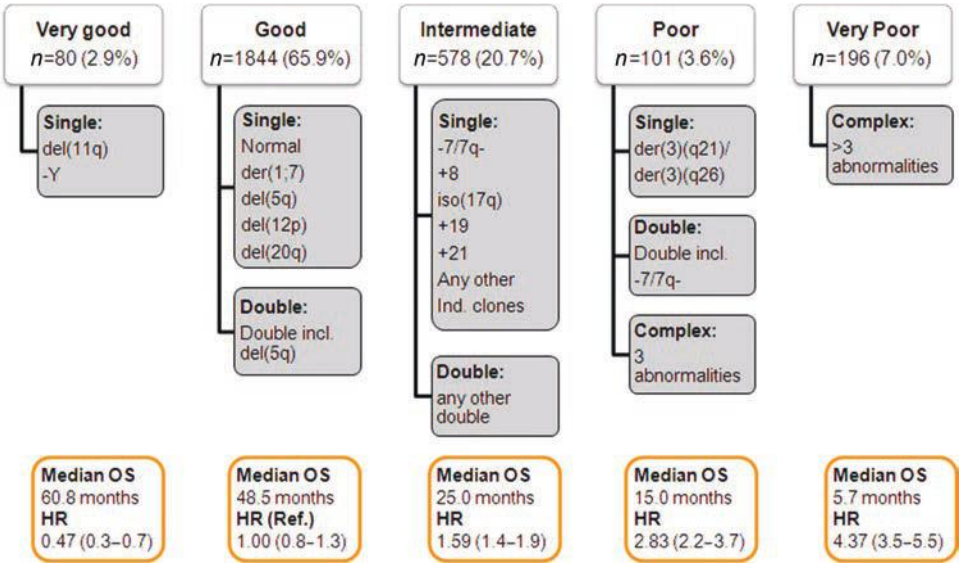

FIGURE 79.3. New 5-subgroup cytogenetic classification of myelodysplastic syndromes (MDS). This new cytogenetic classification divides patients into 5 categories based on their characteristics. Impact on survival is shown for each subset at the *bottom* of each subgroup. Adapted from Schanz J, et al.[14] J Clin Oncol 2012;30:820–829.

cancers. These include next-generation gene sequencing[23] and analysis of single nucleotide polymorphisms.[24] Although these assays are of great interest, they are not currently integrated into clinical practice.

Specific Diagnostic Subgroups of Myelodysplastic Syndrome–Related Syndromes: Chronic Myelomonocytic Leukemia and Overlap Myelodysplastic Myeloproliferative Syndromes

Chronic myelomonocytic leukemia (CMML) is considered a distinct clinical entity by the WHO classification and is grouped in the subset of patients with myelodysplastic myeloproliferative neoplasms. This group also includes BCR/ABL negative chronic myelogenous leukemia (CML), MDS/MPN unclassified, juvenile myelomonocytic leukemia, and potentially refractory anemia with ring sideroblasts and thrombocytosis (RARS-T). Traditionally, CMML has been considered 1 subtype of MDS. IPSS[2] included patients with CMML if the white cell count was less than 12×10^3/L. From a practical and therapeutic perspective, most clinicians still consider CMML as a subtype of MDS. The natural history of patients with CMML is distinct from that of patients with classic MDS. Patients tend to have higher frequency of B symptoms and extramedullary manifestations of the disease. Tissue infiltration causing hepatic or renal dysfunction is not uncommon. Diagnosis is established by the presence of persistent monocytosis ($>1 \times 10^9$/L) in the peripheral blood without evidence of BCR/ABL fusion genes or PDGFR alterations. Blasts, that include promonocytes, should be less than 20% and dysplasia is routine, although often less pronounced that in other MDS categories. CMML is further divided into CMML-1 and CMML-2 based on the percentage of bone marrow and peripheral blood blasts (CMML-1 is less than 10% bone marrow blasts or less than 5% in peripheral blood; whereas CMML-2 will include cases with more blasts). Cells usually express markers of myelomonocytic differentiation that include CD33 and CD13. Cytogenetic alterations occur as in other cases of MDS, and the presence of RAS mutations can be observed in up to 40% of patients.[25] Another group of disorders are the MDS/MPN unclassified (MDS/MPN-U) disorders. These are of particular interest at this time because of the advent of agents that inhibit JAK2,[26] a common molecular alteration in MPN that may explain the proliferative feature of the disease. Although the natural history of patients with MDS/MPN-U is not fully understood, it appears that specific subsets of patients such as those with RARS-T may have a more benign prognosis.[27]

EPIDEMIOLOGY AND ETIOLOGY

Because of the heterogeneity of MDS and a prior concept that MDS was a preleukemic condition of unclear significance affecting older individuals, there are no robust mature registries of MDS, at least in the US. A number of studies have tried to delineate the incidence and prevalence of MDS. Data from the North American Association of Central Cancer Registries (NAACCR) and the Surveillance, Epidemiology and End Results (SEER) program indicate that the average annual age-adjusted incidence rate of MDS for 2001 through 2003 was 3.3 per 100,000. This translates to approximately 9,700 patients with MDS in the US per year. Of interest, incidence rates increased per year in that analysis. Of importance, only a minority of patients were reported to registries by physicians' offices.[28] After this initial study, several other groups have reported higher incidence rates in MDS. For instance, investigators using a claims-based algorithm have reported the incidence of MDS being close to 75 individuals per 100,000 in people over 60 years of age.[29,30] More recently, Cogle et al. constructed 4 claims-based algorithms to assess MDS incidence and applied them to the 2000 to 2008 SEER-Medicare database.[30] Using this approach, the annual incidence of MDS in the US was projected to be 75 per 100,000 persons 65 years or older, much higher than previously estimated. MDS is a disease of aging. The incidence of the disease sharply increases in patients older than 60 years of age, and the median age is 70 years.[28] As the age of the population increases, it is expected that MDS may become a major medical problem, at least in developed countries.

The cause of MDS is not known, but there is strong data that suggest that MDS can also be the result of toxic exposure of bone marrow stem cells. A prototypical example is cases secondary to exposure to prior chemotherapy or radiation therapy, i.e., therapy-related (t)-MDS.[19,31] Therapy-related MDS often is characterized by complex karyotypes and can occur in younger patients. Depending on the type of chemotherapy exposure, different patterns of disease evolution and cytogenetic abnormalities can be documented.[31] The prognosis of patients with t-MDS is very poor, but it is unclear if this is the result of characteristics intrinsic to the disease or because a large majority of these patients have very complex karyotypes that are associated with poor prognosis. For instance, in therapy-related AML (t-AML), it has been shown that common functional p53-pathway variants such as the *MDM2* SNP309 and the *TP53* codon 72 polymorphism may be associated with an increased risk of developing t-AML.[32] This data is of significance as it suggests that predisposing molecular features are involved in the development of therapy-related myeloid malignancies.[33] At MDACC, we evaluated the characteristics of patients with t-MDS. We studied 281 patients with MDS that had received prior chemotherapy and/or radiotherapy for prior malignancy. Multivariate Cox regression analysis identified 7 factors that independently predicted short survival in t-MDS: age ≥ 65 years (HR = 1.63), ECOG performance status 2 to 4 (HR = 1.86), poor cytogenetics (-7 and/or complex; HR = 2.47), WHO MDS subtype (RARS or RAEB-1/2; HR = 1.92), hemoglobin (<11 g/dl; HR = 2.24), platelets ($<50 \times 10^9$/dl; HR = 2.01), and transfusion dependency (HR = 1.59). These risk factors were used to create a prognostic model that segregated patients into three groups with distinct median overall survival: good (0 to 2 risk factors; 34 months), intermediate (3 to 4 risk factors; 12 months), and poor (5 to 7 risk factors; 5 months) ($p < 0.001$); and 1-year leukemia-free survival (96%, 84%, and 72%, respectively, $p = 0.003$). This model also identified distinct survival groups according to t-MDS therapy.

A number of epidemiologic studies have suggested that environmental factors play a role in the development of MDS. Recently, a pooled analysis studied the effects of benzene exposure in oil workers. Exposure to benzene was associated with MDS. High benzene exposure (>3 ppm) was associated with a risk of MDS (OR = 6.32, 95% CI = 1.32 to 30.2). Of interest, no association was observed with AML.[34] In a hospital-based case-control study of 354 adult de novo MDS cases and 452 controls, a family history of hematopoietic cancer (odds ratio [OR] = 1.92), smoking (OR = 1.65), and exposure to agricultural chemicals (OR = 4.55) or solvents (OR = 2.05) were associated with MDS risk. For patients with lower-risk disease (RA/RARS) only smoking (OR = 2.23) and agricultural chemical exposure (OR = 5.68) were identified. For patients with higher-risk disease (RAEB/RAEBT), a family history of hematopoietic cancer (OR = 2.10), smoking (OR = 1.52), and exposure to agricultural chemicals (OR = 3.79) or solvents (OR = 2.71) were independent risk factors. Drinking wine reduced risk for all FAB types by almost 50% (OR = 0.54). A joint effect between smoking and chemical exposure was observed, with the highest risk among smokers exposed to solvents/agricultural chemicals (OR = 3.22).[35]

Finally, a number of genetic syndromes associated with bone marrow failure were recently associated with the development

of MDS.[36] Of importance, several of these disorders are ribosomopathies characterized by altered ribosome biogenesis and function.[37] Syndromes in this category include Diamond-Blackfan anemia, Schwachman-Diamond syndrome, dyskeratosis congenita, cartilage hair hypoplasia, and Treacher Collins syndrome.[37] Haploinsufficiency in ribosomal genes, such as *RPS14*, are also implicated in the pathogenesis of the 5q-syndrome, thus providing further linkage between these conditions.[38] Patients with Fanconi anemia are also at increased risk of developing MDS.[39] Mutations in *Runx1* have been described in MDS of patients with Fanconi anemia.[40]

A number of rare familial syndromes have been reported. For instance, germline mutations in *Runx1* have been shown to occur in families characterized by thrombocytopenia and increased risk of developing MDS and AML.[41] Mutations are more common in the DNA binding domain or N-terminus of the gene. The median incidence of MDS/AML among carriers of *RUNX1* mutation was 35%.[42] It should be noted that not all family members with the mutation had low platelet counts.[42] It should also be noted that allogeneic stem cell transplantation (SCT) was associated with a high rate of complications.[42] Therefore SCT cannot be recommended in all patients at risk. Because mutational analysis of *Runx1* is not commonly performed in clinical practice, it is possible that there are more individuals and families affected by this type of familial syndrome. Younger patients with thrombocytopenia or MDS should be screened for *Runx1* mutations. Germline mutations in *GATA-2* have also been involved in a familial syndrome of MDS/AML, MonoMAC, and lymphedema.[43] MonoMAC is an autosomal dominant syndrome associated with monocytopenia; B and NK cell lymphopenia; and mycobacterial, fungal, and viral infections. This syndrome is also associated with pulmonary alveolar proteinosis.[44]

Molecular Pathogenesis

The cause of MDS is not known but remains strongly linked to senescence. Over the last 5 years we have gained significant knowledge in both genetic and epigenetic alterations that characterize MDS. This information is of great significance and is going to aid not only in understanding the molecular bases of MDS but also in developing molecularly based classifications of MDS, as well as in developing new targeted interventions for patients with MDS.

The molecular analysis of MDS has been revolutionized by the advent of powerful new sequencing techniques. Using these technologies, several groups have reported a large number of genetic mutations in patients with MDS.[23,45] A list is shown in Table 79.2. The most frequent events are genes involved in control of gene splicing[46–48] and epigenetic regulators[49] such as *TET2*[45,50] or *ASXL1*[45,51] or *EZH2*.[45,52] At the present time, it is not known why splicing mutations are so prevalent in MDS and what the downstream effects of these mutations are. The mutations on epigenetic regulators are of special interest. *TET2* mutations were first identified in myeloid leukemia but their functional relevance or clinical impact was unknown.[50,53] The presence of mutations in the *TET* family was rapidly confirmed by several groups.[53] *TET2* is located on chromosome 4q24 and has been shown to have a role in the control of DNA hydroxymethylation.[54,55] Therefore it is likely that patients with mutations in *TET2* will have abnormal DNA methylation patterns that could broadly impact gene expression patterns in MDS. It has been shown that *TET2* has a role in the homeostasis of hematopoietic stem cells.[56,57] Although the prognostic impact of *TET2* is not clear at this time, data from several groups has suggested that the presence of *TET2* mutations may be associated with response to azacitidine.[58] *EZH2* is located on chromosome 7 and is a member of the Polycomb group family. It is a histone 3 k27 methylase and therefore is also involved in the control of epigenetic gene repression. In contrast with *EZH2* mutations described in lymphoma[59] that are activating, *EZH2* mutations in MDS inactivate the gene. Mutations in *EZH2* are associated with a poor prognosis, particularly in patients with lower-risk MDS.[60] Although the analysis of current genetic data in MDS is in flux, it is becoming apparent that specific molecular pathways may separate different subsets of patients. For instance, in the analysis of Bejar et al.,[45] patients could be separated into 2 major subgroups: those with p53 mutations and complex cytogenetics, and those without p53 mutations[45] (Fig. 79.4). These results should be considered as preliminary, as it is likely that ongoing studies using whole genome sequencing technologies will uncover additional mutations that will provide a deeper insight into the biology of MDS.

Together with genetic alterations, epigenetic lesions, in particular aberrant DNA methylation of promoter CpG islands, have been reported in MDS. Aberrant DNA methylation is common both in AML[61] and MDS.[62] This observation has promoted significant interest in the use of hypomethylating agents in MDS, which is discussed below. Although aberrant DNA methylation is common in MDS, whether specific methylation patterns are associated with response to these agents or with overall outcome is not fully understood. In a study by Shen et al.[62] patients with higher methylation scores had worse survival. Further studies correlating methylation and hydroxymethylation patterns with genetic alterations are needed in MDS and other leukemias to clarify these important concepts.

TABLE 79.2

REPORTED FREQUENCY OF GENETIC LESIONS IN MDS

Gene	%	Location	Function
SF3B1	28	2q33	Splicing factor
TET2	21	4q24	Control of cytosine hydroxymethylation
ASXL1	14	20q11	Epigenetic regulator
SRSF2	12	17q25	Splicing factor
RUNX1	9	21q22	Transcription factor
TP53	8	17p13	Transcription factor
U2AF1	7	21q22	Splicing factor
EZH2	6	7q36	Polycomb group protein
NRAS	4	1p13	Signal transduction
JAK2	3	9p24	Tyrosine kinase
ETV6	3	12p13	Transcription factor
CBL	2	11q23	Signal transduction
IDH2	2	15q26	Cell metabolism, epigenetic regulation
NPM1	2	5q35	Phosphoprotein
IDH1	1	2q33	As IDH1
KRAS	<1	12p12	Signal transduction
GNAS	<1	20q13	G protein
PTPN11	<1	12q24	Protein phosphatase
BRAF	<1	7q34	Raf kinase
PTEN	<1	10q23	Phosphatase
CDKN2A	<1	9q121	Cell cycle control

Prognostic Classifications

A number of clinical and variable characteristics are associated with prognosis in MDS. These include percentage of marrow blasts captured by the FAB classification, cytogenetics (discussed above), age, molecular alterations, presence of bone

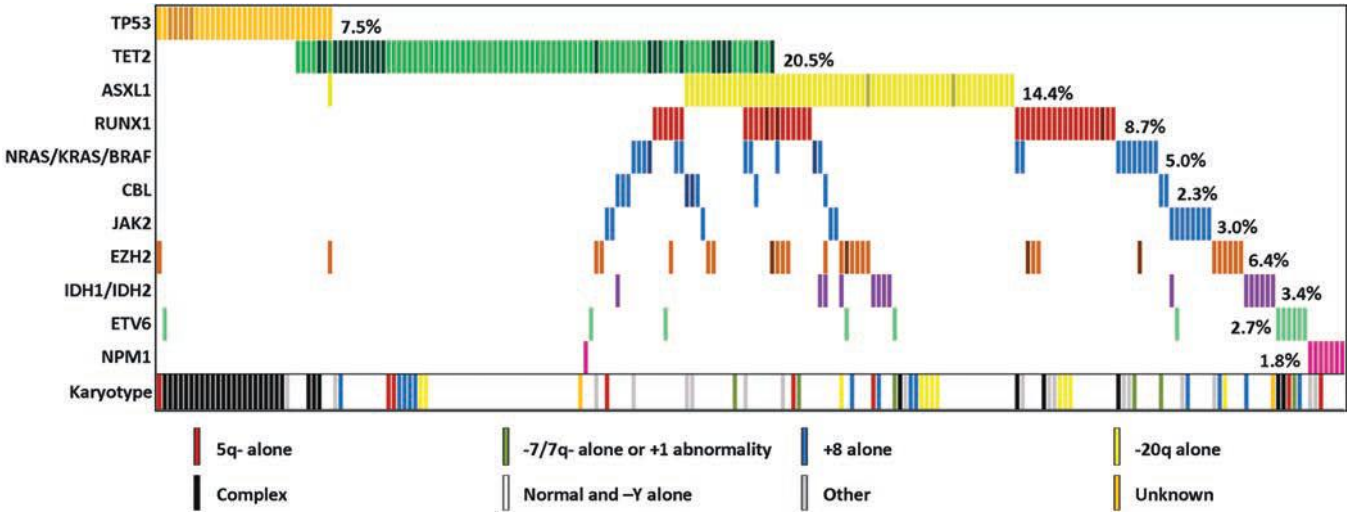

FIGURE 79.4. Distribution of mutations in myelodysplastic syndromes (MDS). Bejar et al. performed an analysis of mutation status in a cohort of 439 patients with MDS. Each row represents a gene, and at the bottom, the cytogenetic characteristics for each patient. Each column represents a patient. Adapted from Bejar R, Stevenson K, Abdel-Wahab O, et al. Clinical effect of point mutations in myelodysplastic syndromes. N Engl J Med 2011;364:2496–2506.

fibrosis, number of marrow $CD34^+$ cells, LDH, ferritin, and beta 2 microglobulin, to name a few. Prognostic stratification has an important role in MDS. One can consider this as a static concept helping the clinician predict survival and risk of transformation at the time of initial presentation without including the impact of any therapy. Other systems may allow prognostic calculation in a dynamic fashion by permitting sequential application during the life of the patient. And finally prognostic models may incorporate calculations of the impact of responses and or survival and response durations for a specific form of therapy. A number of classifications exist that fulfill one or more of these criteria. Until 2012, the standard prognostic classification system for patients with MDS was the IPSS.[2] This model was developed in 1997 by Greenberg et al. and included a cohort of 880 patients that had not received prior therapy. This model has been the basis of most clinical research performed in the field over the last 20 years and therefore is of significant importance. Because IPSS is based on FAB morphologic criteria, in particular the percentage of marrow blasts up to 30%, and most currently approved drugs use either IPSS or FAB for their approval, IPSS still is of significant practical importance. IPSS is summarized in Table 79.3. IPSS has several limitations, the most important being that it underestimates the importance of the severity of cytopenias and it places too much weight on the percentage of blasts at the expense of cytogenetic alterations. Because of these limitations, a number of newer classifications have been developed by several groups. Examples include the WHO-based prognostic scoring system (WPSS) system[63] and the Global MD Anderson Cancer (MDACC) model.[18] That said, neither of these latter two models have been formally accepted

TABLE 79.3

THE INTERNATIONAL PROGNOSTIC SCORING SYSTEM

A: IPSS score is the sum of the three listed prognostic factors

Score	0	0.5	1	1.5	2
BM blasts (%)	<5	5–10	—	11–20	21–30
Karyotype*	Good	Intermediate	Poor		
Cytopenias	0/1	2/3			

*Good: normal, -Y, del(5q), del(20q); Poor: complex (≥3 abnormalities) or chromosome 7 anomalies; Intermediate: other abnormalities
Cytopenias defined as hemoglobin concentration < 10 g/dl, neutrophils < 1.5×10^9/L, and platelets < 100×10^9/L

B: Prognosis determined by IPSS score

Risk group	*IPSS score*	*Median survival (years)*			
Age		≤60 y	>60 y	≤70 y	>70 y
Low	0	11.8	4.8	9	3.9
Intermediate-1	0.5–1.0	5.2	2.7	4.4	2.4
Intermediate-2	1.5–2.0	1.8	1.1	1.3	1.2
High	≥ 2.5	0.3	0.5	0.4	0.4

Adapted from Greenberg P, Cox C, LeBeau MM, et al. International scoring system for evaluating prognosis in myelodysplastic syndromes. Blood 1997;89:2079–2088.

by all groups. Because of this, a very large international effort was initiated approximately 4 years ago to develop a new international MDS scoring system. This system is known as IPSS-R,[13] or revised IPSS, and was recently published.[13] IPSS-R is summarized in Table 79.4. The major differences between IPSS and IPSS-R is that the latter includes the new 5-subgroup cytogenetic classification discussed above and different cut-offs of cytopenias and percentages of marrow blasts, paralleled by 5 prognostic categories. IPSS-R has not been formally evaluated in a prospective fashion and has not yet been tested in patients receiving active therapy. Also, IPSS-R does not include molecular data and therefore is likely to be revised in the near future once large-scale mutational analyses are incorporated into routine clinical practice.

Identification of Patients with "Lower-risk Disease" and Poor Prognosis

Until recently, most investigators have recommended two types of approaches to patients with MDS. Patients in the higher-risk categories, characterized by excess blasts, were recommended therapies similar to those used in AML in an attempt to induce remissions and prolong survival. In contrast, patients with lower-risk disease, low percentage of blasts or cytopenias, have been proposed to undergo interventions to minimize transfusion needs and improve quality of life. Over the last few years, work from several groups has indicated that the prognosis of this group of patients can be very heterogeneous. For instance, the Düsseldorf group reported that the presence of specific cytogenetic alterations, such as those involving chromosomes 5 and 7, were associated with independent poor prognosis with equal or more weight than, for instance, excess blasts.[64,65] Based on this and clinical experience suggesting that prognosis of patients with low or int-1 disease by IPSS was very heterogeneous, a prognostic model was developed for this group of patients.[17] For this study, 856 patients with low and intermediate-1–risk MDS were analyzed. Patients were grouped with diploid and 5q as favorable cytogenetics and all others as unfavorable. The final model included age, unfavorable cytogenetics, platelet count, hemoglobin, and percent of marrow blasts. The survival outcome for each score point is listed in Table 79.5. Based on this, patients could be divided into 3 subgroups. Patients with category 1 (n = 182, 21%) (score 0 to 2 points) had a median survival of 80.3 months (95% CI 68-NA), and a 4-year survival rate of 65% (95% CI 55 to 76). Patients in category 2 (score 3 or 4 points) (n = 408, 48%) had a median survival of 26.6 months (95% CI 22 to 32), and a 4-year survival rate of 33% (95% CI 27 to 40). Patients in category 3 (score 5 to 7 points) (n = 265, 31%) had a median survival of 14.2 months (95% CI 13 to 18), and a 4-year survival rate of 7% (95% CI 3 to 14). The proposed model was able to further stratify patients in either IPSS low or intermediate-1 into 3 risk groups ($p < 0.0001$ for both low-risk and intermediate-1). The IPSS scoring did not segregate patients with low or intermediate-1 risk within each of the 3 risk categories identified by this analysis. Two other factors were studied but not included in the multivariate analysis, ferritin and β2-microglobulin, because data was available only in a fraction of the patients. Only 10% of patients eventually transformed to AML. By univariate analysis, IPSS intermediate-1 versus low-risk (p = 0.005), increased percentage of marrow blasts ($p < 0.001$), infection at presentation (p = 0.001), and chromosome 7 abnormalities (p = 0.01) were associated with a significant higher-risk of AML progression. Only a higher percentage of marrow blasts, chromosome 7 anomalies, and infection at referral remained in the final multivariate model and were associated with an increased risk of AML transformation (p = 0.01 for all three of them). When the results of the lower-risk MDS model were presented, they had not been validated by any group nor was there a hypothesis of why different patients with low-risk features would have different prognoses. Recently, Bejar et al. performed a retrospective analysis of 288 patients with lower-risk MDs and confirmed the lower-risk model.[60] More importantly, these investigators analyzed the mutational status of 22 genes in these patients. Mutations were identified in 71% of cases. Mutations of *EZH2, RUNX1, TP53*, and *ASXL1* were associated with shorter overall survival, independent of the prognostic score. The conclusion of the study was that

combining the lower-risk MDACC model with *EZH2* mutation analysis resulted in the identification of close to a third of patients with a worse-than-expected prognosis. The distribution of mutations and risk category is shown in Figure 79.5. This study has important future implications because it opens the door for molecular stratification of patients with earlier stages of the disease.

Impact of Comorbidities

Patients with MDS tend to be older and to be affected by comorbidities expected due to age or known history of exposures. Therefore it is important to incorporate information regarding how comorbidities affect the natural history of MDS and how they affect therapeutic decisions in MDS. A number of studies have addressed this issue using different systems. Wang et al. conducted a population-based study of older persons with MDS that suggested lower survival in those with comorbid ailments, particularly those with congestive heart failure (CHF) and chronic obstructive pulmonary disease.[66] Moreover, previous studies have shown CHF, pulmonary and liver failure, infections, hemorrhage, and solid tumors as main causes of non-leukemic death in MDS.[3,67,68] At MDACC, we used the ACE-27 comorbidity score to address this issue.[69]

The ACE-27 was developed by Piccirillo et al. and was derived from adult cancer patients.[70] In our analysis, 600 patients with MDS were included. Approximately half of the patients had a baseline IPSS classification of low or intermediate-1. The distribution of comorbidities is shown in Figure 79.6. Baseline ACE-27 comorbidity scores were as follows: none, 137 patients (22.8%); mild, 254 (42.3%); moderate, 127 (21.2%); and severe, 82 (13.7%). Approximately 55% of the patients were diagnosed with disorder of the cardiovascular system, with hypertension being the most common comorbidity (37.0%), followed by coronary artery bypass graft (14.3%). History of prior malignancy was reported in 168 (28.0%) patients. Ninety-seven (16.2%) patients had diabetes mellitus. Median survival according to the ACE-27 scores was: 31.8 months for no comorbidity, 16.8 months for mild comorbidity, 15.2 months for moderate comorbidity, and 9.7 months for severe comorbidity ($p < 0.0001$). A prior history of malignancy and cardiovascular disease were associated with worst survival. Older age, advanced IPSS, and leukemic transformation were associated with a greater risk of death, while having undergone SCT was associated with longer survival. Comorbidity did not have a significant effect on survival for patients in the low-risk category,

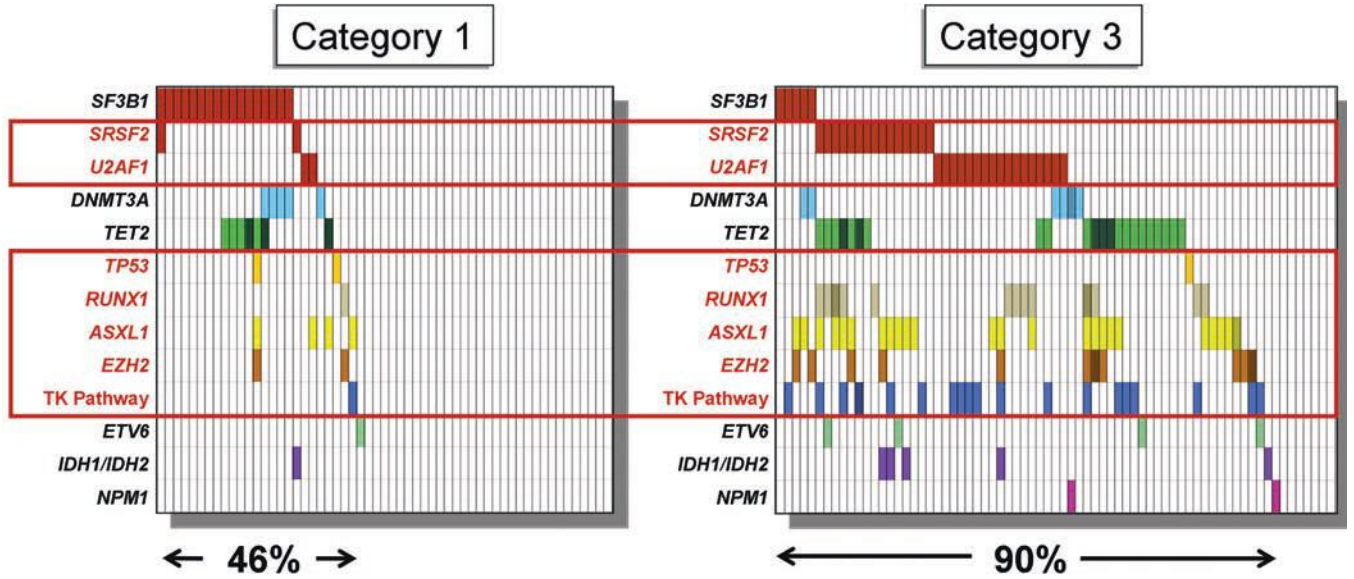

FIGURE 79.5. Distribution of mutational events in lower-risk myelodysplastic syndromes (MDS). Patients were divided based on the MDACC lower-risk score into different categories.[17] Then analysis of distribution of mutations was retrospectively performed using data from Bejar et al.[60]. J Clin Oncol 2012;30:3376–3382. As shown in the figure, patients in the lower-risk category 1 had fewer molecular events than those in the poorer risk subset of category 3.

Comorbidities by ACE-27	*NI*(%)
None (0)	137 (23)
Mild (1)	254 (42)
Moderate (2)	127 (21)
Severe (3)	82 (14)

whereas patients in the intermediate-1 and -2 groups ($p = 0.001$) and high-risk category ($p = 0.04$) had significantly worse survival with increasing ACE-27 scores. Comorbidities significantly decreased survival in those younger than 65 years ($p < 0.0001$), but had no significant effect in those older than 65. We conducted a multivariate analysis using the Cox Proportional Hazards model. Included in the final model are: age, IPSS, and ACE-27 comorbidity scores. The final prognostic model for the overall survival was thus developed as low (score 0 to 1), intermediate (score 2 to 4), and high (score 5 to 8). The model predicted survival on the entire patient group. Patients in the low-risk category had a median survival of 43.0 months versus 23.0 months and 9.0 months for those in the intermediate-risk and high-risk groups, respectively ($p < 0.001$).[69]

THERAPEUTIC APPROACHES FOR PATIENTS WITH MYELODYSPLASTIC SYNDROME

In practical terms, therapy for patients with MDS is divided into approaches for patients with lower-risk disease and those with higher-risk disease. Although investigators may use different criteria, it is accepted that lower-risk disease includes patients with low and int-1 disease and those with higher-risk disease, int-2 or high, by IPSS.[2] The role of IPSS-R in therapy has not been confirmed at this time.[13] In the US, clinicians use guidelines set by NCCN for decision making when selecting therapy.[71] A summary of therapies for patients with MDS is shown in Figure 79.7.

Therapy for Patients with Lower-risk Myelodysplastic Syndrome

Most clinicians believe that the role of therapy in lower-risk MDS should focus on improving symptoms and minimizing transfusion needs, whereas the potential impact on survival remains unproven. We believe in the need to develop curative approaches for patients with lower-risk MDS in the context of clinical trials.

Supportive Care for Patients with Lower-risk Myelodysplastic Syndrome

Supportive care is an integral part of the care for patients with both lower- and higher-risk MDS. In general, we refer to supportive care measures as those that mitigate complications of cytopenias, such as severe anemia, thrombocytopenia, and risk of infections. Indeed, an analysis of cause of death in patients with lower-risk MDS has indicated that the most frequent events associated with death were infectious and bleeding complications.[3] Based on this, three major approaches are considered as supportive care measures in MDS. These include transfusions of red cells and/or platelets, the use of prophylactic antibiotics, and the use of growth factors. Because there is some controversy as to whether this last approach may have a primary effect on the natural history of patients with MDS, we will discuss that below. Finally and more recently, a debate has evolved around the topic of iron chelation in red cell transfusion–dependent patients. This is also discussed in a separate section below.

There are different practices for both red cell and platelet transfusions. In most centers in the US, patients receive red cell transfusions if hemoglobin is less than 8 g/dl or if the patient has symptomatic anemia. Platelets are transfused if the platelet count is less than 10 k/μl or if the patient has active bleeding. These parameters can change based on geographical distribution and practice patterns. Over the years, there has also been a question about the need for irradiated blood products, in particular for patients that could be potential candidates for stem cell transplantation. This is not the standard practice at MDACC. Finally, some centers also provide support with white cell transfusions as an early intervention for patients with neutropenic fever or resistant infections. These are considered experimental at this point.

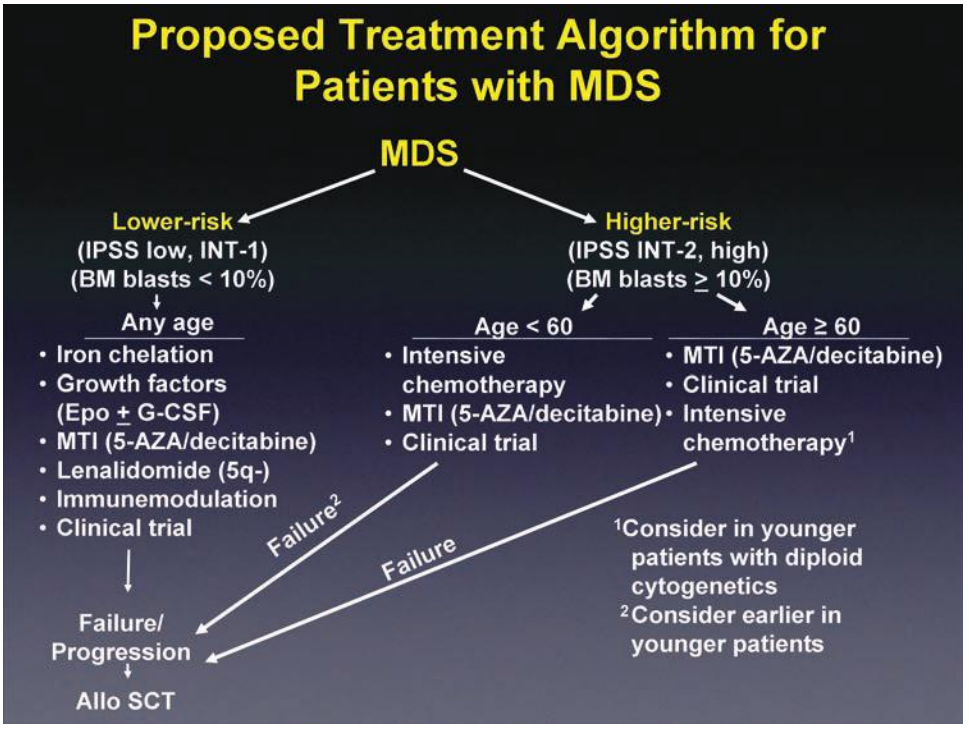

FIGURE 79.7. A treatment algorithm for patients with myelodysplastic syndromes (MDS). GM-CSF, granulocyte-macrophage colony-stimulating factor; IPSS, International Prognostic Scoring System.

The role of prophylactic antibiotics is also questionable. Many centers, including MDACC, use a triple combination of antibacterial, antiviral, and antifungal agents in patients with MDS and significant neutropenia or who are receiving active therapy with a cytotoxic agent. There is no systematic data on the use of this approach, and criticism may stem from the potential development of multidrug resistance.

The Role of Growth Factor Support in Myelodysplastic Syndrome

In 2012, growth factor stimulation may include all 3 hematopoietic lineages, including neutrophils, erythrocytes, and megakaryocytes. Although growth factor support is commonly used in MDS, there is no prospective study that has proven that their use is associated with improvements in the survival of patients with MDS. Patients with isolated neutropenia are uncommon in MDS, and although there are no large series focusing on this subset of patients, it is my impression that their natural history is benign. That said, recent series have associated outcomes in MDS with degrees of neutropenia.[72] In general, the use of prophylactic myeloid growth factors, such as granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF), is not recommended in these patients. It should be noted that the use of these agents is important in patients that are experiencing complications from neutropenia exacerbated by agents used for primary therapy such as lenalidomide or hypomethylating agents that are associated with such an effect. When used in this context, growth factors are commonly used for a short period of time until complications resolve.

Recently, 2 new growth factors for platelet generation have been developed and approved for patients with immune-mediated thrombocytopenia. These agents, romiplostim[73] and eltrombopag,[74] are thrombomimetic agents that stimulate TPO receptors. Results in MDS are controversial.[75] Interim analysis of a large study with romiplostim in patients with low or intermediate-1 MDS with significant thrombocytopenia suggests that patients treated with this agent had a higher risk of developing AML and marrow fibrosis. Whether this was the result of the natural history of the disease or a true leukemogenic effect of the drug is unknown at this time. There is less experience with eltrombopag in MDS.[74] With the current information that we have, we cannot routinely recommend the use of these compounds for patients with MDS. Current investigations with these agents have focused on their use as an adjunct to other therapies in MDS, such as of the azanucleosides, decitabine or azacitidine.[76,77] Recently, in the United States, strict FDA guidelines have limited the use of these agents to patients with significant immune thrombocytopenia and preclude use of them in patients with MDS.

Erythroid stimulating agents (ESA) are commonly used in patients with anemia and lower-risk MDS. These guidelines were developed after reports of a potential association between ESA administration and the development of secondary solid malignancies.[75] That said, it is important to realize that there is no prospective data indicating that ESA use has any significant survival benefit in patients with MDS. The Nordic group pioneered the use of these agents in MDS.[75] Although it is clear that its use is associated with erythroid responses in close to a third of patients, the effect of ESA on survival remains unclear. Of interest, in the latest analysis by this group, a cohort of patients that was treated with epoetin alpha and G-CSF in consecutive clinical trials was compared to a historical group in an Italian database that was not. Only the subset of patients that were minimally transfusion-dependent experienced erythroid responses that translated into a survival advantage and reduced risk of AML compared to the control cohort, matched for prognostic features.[78] Although ESAs remain the most widely utilized agent for management of anemia in MDS, the potential impact on its natural history is limited.

The Role of Iron Chelation in Myelodysplastic Syndrome

Because anemia is a common feature of patients with MDS that results in the need for red cell transfusions, it is not uncommon that patients with MDS may develop significant evidence of iron

overload. A number of groups have suggested that excess iron deposition in the hepatic parenchyma and myocardium are associated with significant morbidity and mortality in patients with MDS.[79] Other groups have challenged that assertion.[17] It is clear that patients who require systematic red cell transfusions are at increased risk of dying from complications of MDS, whether these are derived from end-organ damage to tissues or because this represents a subset of patients with more aggressive natural histories. Based on these concepts, a number of iron chelating agents have been developed not only for MDS, but for other hematologic conditions. For instance, at the present time, an oral chelating agent known as deferasirox is currently approved in Europe and the USA for patients with evidence of iron overload and lower-risk MDS. This was an accelerated approval that awaits validation in a large ongoing phase III trial. In general, iron chelating agents have been shown to decrease ferritin levels in transfusion-dependent patients and to have a manageable toxicity profile.[80] Some studies have also suggested a potential impact on survival.[81] Finally, it should be mentioned that these agents may have other potential effects on MDS that include modifying the risk of both bacterial and fungal infections, stimulation of effective hematopoesis,[82] and delaying transformation to AML. These have not been systematically studied, but could be of significant clinical benefit. Finally, a number of groups have reported that the use of iron chelating agents are associated with significant clinical improvements in patients undergoing stem cell transplantation.[83]

Lenalidomide

Lenalidomide is a derivative of thalidomide with immune modulatory activity that has been shown to have significant activity in patients with lower-risk MDS and anemia. Initial studies with thalidomide indicated that this agent had modest but measurable activity in patients with MDS and resulted in the development of several more potent derivatives.[84] Lenalidomide is an oral immunomodulatory agent. In the initial study, List et al. documented that this agent was safe up to doses of 25 mg daily and that a particular subset of patients with an interstitial deletion of chromosome 5q experienced a high frequency of red blood cell transfusion independence and cytogenetic response with the use of this compound.[15,85] This was confirmed in a subsequent multicenter study that focused on patients with lower-risk MDS, transfusion-dependent anemia, and an alteration of chromosome 5.[86] Characteristics associated with response were a history of less than 4 units of red cell transfusions and platelet counts over 100 k/μl. These responses were durable with a median duration exceeding 2 years. Because this compound has a very acceptable toxicity profile, the drug was approved in the US for the treatment of lower-risk, del(5q) MDS patients with transfusion-dependent anemia. Furthermore, nearly 50% of the patients achieved a complete cytogenetic response after 6 months of treatment. A subsequent dose-comparative study in Europe randomized transfusion-dependent patients with lower-risk del(5q) MDS to either lenalidomide 5 mg daily(n = 69), 10 mg daily for 21 days every 28 days (n = 69), and placebo (n = 67). Crossover to lenalidomide or a higher dose was allowed after 16 weeks for nonresponders. RBC-transfusion independence for more than 26 weeks was achieved in 56% of patients treated with 10 mg of lenalidomide, compared to 41% and 6% of patients receiving 5mg of lenalidomide or placebo, respectively. Median duration of RBC-TI was not reached (median follow-up, 1.55 years), with 60% to 67% of responses ongoing in patients. Of importance, cytogenetic response rates were 41.5% (10 mg) versus 17.4% (5 mg; p = 0.066). For the lenalidomide groups combined, 3-year overall survival and AML risk were 56% and 25%, respectively, indicating that the 10 mg dose is the preferred dose of lenalidomide, that yields higher rates of both RBC-transfusion independence and cytogenetic response.

Lenalidomide has also been studied in patients with lower-risk MDS, but without a chromosome 5 alteration.[87] A phase 2 multicenter trial of lenalidomide was performed in transfusion-dependent patients with low- or int-1–risk MDS without deletion 5q. Eligible patients had 50,000/mm^3 or more platelets and required 2 units or more RBCs within the previous 8 weeks. In summary, 214 patients received 10 mg of oral lenalidomide daily or 10 mg on days 1 to 21 of a 28-day cycle. The drug was well tolerated. Using an intention-to-treat analysis, 56 patients (26%) achieved transfusion independence (TI) after a median of 4.8 weeks of treatment with a median duration of TI of 41.0 weeks. A 50% or greater reduction in transfusion requirement occurred in 37 additional patients, yielding a 43% overall rate of hematologic improvement. Although less active than in patients with del(5q) MDS, a large randomized study is evaluating the clinical activity of lenalidomide in patients without chromosome 5 alterations.

Recent investigations have provided further insight into the karyotype-specific mechanism of action of lenalidomide in patients with del(5q) MDS. Haploinsufficiency for 2 dual-specificity phosphatases encoded within the proximal CDR on chromosome 5q accounts for the differential sensitivity of del(5q) progenitors. Lenalidomide directly inhibits cell division cycle 25 C (Cdc25C) and is an indirect inhibitor of the catalytic subunit alpha isoform of the protein phosphatase 2A (PP2Acα), both coregulators of the G2-M checkpoint.[88] Moreover, lenalidomide also acts to stabilize MDM2, thereby accelerating p53 degradation and permitting cycling of del(5q) before arrest at the G2/M juncture.[89] Ebert et al. reported data that a gene expression signature could be used to predict response to this agent in non-del(5q) MDS.[90] Recently, a group has shown the activity of this compound at the stem cell level.[91]

Antithymocyte Globulin

A fraction of patients with MDS have a significant inflammatory component, and it is possible that they have underlying autoimmune alterations. Patients with so-called hypoplastic MDS, whose pathogenesis may overlap with aplastic anemia, are an example of this.[11] Hypoplastic MDS is defined as bone marrow cellularity of less than 30% to 20%, depending on the age of the patient, with evidence of dysplastic features or a clonal cytogenetic alteration.[11] A group at the NIH has pioneered the use of ATG in patients with MDS.[92] Whether combining this agent with other immunosuppressive agents, such as cyclosporine and/or steroids, is beneficial, is unclear at this time. A recent randomized study in patients with aplastic anemia has suggested that a horse-derived ATG is superior to the one generated from rabbits.[93] The group at the NIH has also developed criteria that allow for a prediction of the response to ATG-based therapy.[94] These include age, an HLA-DR15 class II phenotype, and duration of red blood cell transfusion dependence. Both Kings College in London and MDACC have reported that the most important predictors for response to ATG-based therapy are age and presence of bone marrow hypocellularity.[95] Data from all the studies has indicated that younger patients with hypoplastic MDS benefit from stem cell transplantation and that the prognosis of older patients with hypoplastic MDS is very poor, despite the use of these agents. Also, it has been reported that the ratio of $CD4^+$ to $CD8^+$ cells can be used to predict response to ATG.[96] Until recently there was no salvage therapy for patients that had failed ATG therapy and were not candidates for a stem cell transplant. Recently, the group at NIH has also shown data that the use of eltrombopag may be associated with trilineage response in aplastic anemia patients that failed ATG.[97] This data is of significant importance and needs to be studied in the MDS population. Finally, several groups have also studied the potential role of alemtuzumab as therapy for aplastic anemia and hypoplastic MDS.[98] The actual activity and safety of this compound is not clear at this point.

The Use of Hypomethylating Agents in Lower-risk Myelodysplastic Syndrome

The hypomethylating agents are the standard of care for patients with high-risk MDS. Initial clinical studies in the US performed well before the development of WHO criteria for MDS included patients with all FAB categories. Therefore the approval of these agents in the US, in particular for azacitidine, is for all subsets of patients with MDS.[99] There is relatively little systematic analysis of what is the most effective and safest schedule of this class of compounds in lower-risk MDS. In a randomized phase II study by a group of community oncologists, it was observed that shorter versus longer schedules of azacitidine (5 versus 7 days) were less myelosuppressive and were potentially associated with an increased rate of hematologic responses in a largely lower-risk patient population.[100] A multicenter Phase II randomized trial investigated the activity of two very low dose schedules of decitabine in patients with low and intermediate-1 MDS. In this study, known as DACO-26, decitabine administered at a dose of 15 mg/m^2 subcutaneous daily for 3 days on a 28-day schedule was compared to decitabine given at the same dose and route weekly $\times$ 3, also on a 28-day schedule. Although the final analysis of this study did not show the superiority of one arm versus the other, treatment of patients with lower-risk MDS with this very low dose schedule of decitabine was associated with trilineage responses of over 60% in this group of patients.[101] These lower dose schedules were associated with manageable myelosuppression and no mortality. Based on this concept, a number of investigators have developed oral derivatives of the hypomethylating agents. In principle, nucleoside analogs are difficult to absorb because they are catabolized by cytidine deaminase. That said, both an oral formulation of decitabine and one of azacytidine are in development. Oral azacytidine was first investigated in a Phase 0 trial that demonstrated that the drug could be absorbed by patients with leukemia.[102] These positive results led to the design and completion of a Phase I study of oral azacitidine for patients with MDS.[103] In this study, 41 individuals were treated with doses of oral azacitidine up to 600 mg on a 7-day schedule. An expansion of this study also evaluated more extended schedules for 14 to 21 days with the drug administered once or twice a day at doses of 200 to 300 mg. The results of this study were of interest because it was shown that oral azacitidine was associated with an overall response rate of 35% in previously treated patients and 73% in previously untreated patients. Responses were durable and the drug was very well tolerated. Furthermore, using large-scale DNA methylation analysis platforms, it was shown that oral azacitidine could induce significant induction of promoter DNA hypomethylation. What was interesting from this study was the observation that the pharmacokinetic profile of oral azacitidine was significantly lower than that of the parenteral route of administration. Mean relative oral bioavailability ranged from 6.3% to 20%. These results are interesting in view of a recent report by the Baylin group that studied the effect in animal systems of very low exposure to hypomethylating agents.[104] Planned studies with oral azacitidine include a Phase III trial for patients with lower-risk disease and significant thrombocytopenia starting in 2013.

The Role of Allogeneic Stem Cell Transplantation in Lower-risk Myelodysplastic Syndrome

SCT is curative in a fraction of patients with MDS.[105,106] The questions remain as to who is the best candidate for transplant and when to perform it. Patients with lower-risk MDS are in general characterized by a low percentage of blasts in their bone marrows. In principle this makes them perfect candidates for upfront transplantation, as they do not require debulking preparative chemotherapy prior to stem cell transplantation (SCT). Unfortunately, SCT is associated with significant early mortality that depends on the age of the patient and donor, as well as the degree of matching. Mortality in the first 100 days can range from 10% to 40% depending on the series and the center's expertise. Because most patients with lower-risk MDS are expected to live more than 100 days, initial results evaluating the role of SCT in lower-risk MDS have suggested that early transplantation is not indicated.[107] In a recent collaborative study using datasets from IBMTR and several cohorts of older patients with lower-risk MDS that had received either supportive care, hypomethylating agents, or reduced intensity transplantation, it was shown using a Markov model that transplantation was associated with lower survival. These results are in line with the initial report of Cutler et al.[107] and indicate that transplantation should be delayed as much as possible in this group of patients.

Therapy for Patients with Higher-risk Myelodysplastic Syndrome

Over the last decade we have experienced significant advances in the therapy of patients with higher-risk MDS. Prior to that, the only treatment modalities were induction therapy or salvage stem cell transplantation. The results of these approaches were disappointing, particularly in older patients and in those with complex cytogenetics.[108]

Hypomethylating Agents in High-risk Myelodysplastic Syndrome

Hypomethylating agents are the standard of care in a large majority of patients with higher-risk MDS.[108] They have also transformed our capacity to treat patients with MDS and have increased interest in this disease. The initial significant study with azacitidine is known as CALGB-9221.[99] This study, which I consider seminal in the field, was led by Dr. Lewis Silverman and randomized patients with MDS by FAB classification (including up to 30% blasts) to either supportive care or a 7-day schedule of azacitidine at the dose of 75 mg/m^2 via subcutaneous route. The study had a crossover design in which patients that had not benefited in 1 arm could then be treated in the other arm. The drug was very well tolerated, with virtually no induction mortality. Treatment with azacitidine was associated with significant clinical activity, including a complete remission rate of 7% and an overall response rate of 60%. Of interest, patients that crossed from the supportive care arm to the azacitidine arm had similar rates of response, confirming the activity of the drug. Crossover designs do not allow one to evaluate the impact on survival, and therefore this study was not powered to show the drug's effect on survival. That said, survival in the azacitidine group was close to 20 months. The investigators performed a landmark analysis at 6 months in patients, with or without crossover, that suggested a survival advantage with azacitidine therapy. CALGB-9221 also included a quality of life analysis.[109] The report of this study suggested that patients treated with azacitidine had a better quality of life. All this data served as the basis for approval of this compound in the US. Subsequent analysis of this cohort of patients has also provided significant information regarding the clinical use of azacitidine in MDS. It is now known that responses may require multiple cycles of therapy administration and that in the initial cycles of therapy it is not uncommon to observe significant myelosuppression. Proper supportive care and continuation of therapy, despite cytopenias, are associated with improved outcomes. Because of the lack of survival data with CALGB-9221, European regulators recommended a noncrossover design as an approval strategy for azacitidine in Europe. This study, known as AZA-001, was a randomized trial of azacitidine using the

same schedule as in CALGB-9221 versus treatment with either low-dose cytarabine, AML induction therapy, or supportive care based on physician preference.[10] Patients were stratified by FAB and IPSS. The primary endpoint was overall survival. Efficacy analyses were by intention-to-treat for all patients assigned to receive treatment. In total, 358 patients were randomly assigned to receive azacitidine (n = 179) or conventional care regimens (n = 179). Four patients in the azacitidine and 14 in the conventional care groups received no study drugs but were included in the intention-to-treat efficacy analysis. After a median follow-up of 21.1 months, median overall survival was 24.5 months (9.9 not reached) for the azacitidine group versus 15.0 months (5.6 to 24.1) for the conventional care group (hazard ratio 0.58; 95% CI 0.43 to 0.77; stratified log-rank p = 0.0001). At 2 years, on the basis of Kaplan-Meier estimates, 50.8% (95% CI 42.1 to 58.8) of patients in the azacitidine group were alive compared with 26.2% (18.7 to 34.3) in the conventional care group ($p < 0.0001$). Of interest, response rates were also different among different treatment modalities. Although response rates were higher with intensive chemotherapy, used mainly in younger patients, these did not translate into a clear survival benefit. As with CALGB-9221, the toxicity profile of azacitidine was acceptable with minimal induction mortality. Additional analysis of AZA-001 have also provided significant clues for the clinical management of patients with MDS. First, the median number of cycles with azacitidine in this group of patients was 9. It is believed that the duration of therapy is crucial for the survival advantage documented with this drug. Second, in a post hoc analysis, investigators studied the impact of age and AML blasts by WHO category (20% to 30% blasts) in patients treated with AZA-001. The results indicated that older individuals benefited significantly from therapy and that excess blasts was not a negative predictor of response.[110] Finally, by multivariate analysis, it was shown in AZA-001 that presence of adverse cytogenetic features, such as deletion of chromosome 7, were positively associated with azacitidine therapy when compared to other therapy. That said, it is important to emphasize that outcomes were better in diploid patients. The NCCN guidelines recommend azacitidine as frontline therapy in most patients with higher-risk MDS.[111]

In parallel with azacitidine, decitabine (5-aza-2'-deoxycitidine) is another hypomethylating agent that has been extensively studied in MDS. In an initial randomized non-crossover study, decitabine administration was found to be safe in this group of patients and to have significant clinical activity with an overall response rate of 17%.[9] In this initial study, the drug was administered over 4 hours 3 times a day on a 3-day schedule every 6 weeks. In parallel, a daily schedule for 5 to 10 days was investigated at MDACC.[112] This study suggested that a 5-day schedule at a dose of 20 mg/m^2 was potentially an optimal way to administer decitabine. This was further studied in a 3-arm randomized Bayesian study comparing different doses and schedules of decitabine.[113] The results with the 5-day schedule indicated a complete remission rate of over 30% and overall response rate of 73%.[114] These results were further confirmed with the ADOPT trial, a multicenter single-arm study that served as the basis for the approval of the 5-day schedule of decitabine in the US.[115] As with AZA-001, a survival study with decitabine was performed in Europe.[116] Unfortunately, this study failed to show a survival advantage with decitabine. The reason for this effect is likely due to the design of the study, in which the drug was administered using the initial 3-day schedule every 6 weeks and treatment was capped at 8 months, a fact that resulted in a median number of 4 cycles of decitabine administration. These factors likely negatively influenced the results of this trial. It should be noted that recently decitabine was approved in Europe for the treatment of older patients with AML because of its toxicity profile and modest survival effect in this population.[117]

There are no comparative studies of azacitidine versus decitabine, and therefore it is not possible to make a recommendation in terms of frontline therapy, although most treating physicians nowadays use azacitidine in frontline therapy of patients with higher-risk MDS because of its reported survival benefit.

Biomarkers of Response to Hypomethylating-based Therapy in Myelodysplastic Syndrome

It is obvious from the data above that only a fraction of patients have significant benefit from the use of either decitabine or azacitidine. Because patients require several months of therapy to determine any potential clinical benefit, it would be very important to have access to a potential biomarker of response to this class of agents. Because hypomethylating agents dynamically modify in a transient fashion both global and gene-specific methylation patterns, a number of groups have analyzed the relationship between specific methylation patterns and changes in methylation patterns with response to hypomethylating agents. At the present time, there is no evidence that the specific methylation patterns are associated with a distinct response to these agents.[62,118] A number of groups have reported on specific molecular biomarkers of response to these compounds. For instance, levels of micro-RNA29b, which targets DNMT1, have been reported to be associated with response to decitabine.[119] These results, although functionally relevant, have not been reproduced by other groups.[120] A number of mutational events, such as mutations in TET2, have been associated with response, but not survival, to azacitidine.[121] This observation is of great importance because TET2 is involved in the control of hydroxy DNA methylation. Prospective studies are still needed to prove this association.

Finally, the French group has developed a very simple model to predict outcomes with azacitidine.[122] These investigators analyzed 282 patients treated in France with azacitidine outside clinical trials and identified the following characteristics associated with outcome: previous low-dose cytosine arabinoside treatment, bone marrow blasts >15% (p = 0.004), and abnormal karyotypes (p = 0.03) were independent predictors of lower response rates. Complex karyotypes predicted shorter responses (p = 0.0003). Performance status, intermediate- and poor-risk cytogenetics, presence of circulating blasts, and red blood cell transfusion dependency also independently predicted poorer overall survival (OS). A prognostic score based on those factors was developed (Table 79.6).

Improving Results with Hypomethylating Agents

Although the hypomethylating agents have resulted in very significant improvements for our patients with MDS, it is obvious that most patients will lose response (discussed below) and that new alternatives are needed. One approach is to develop combination strategies with azacitidine or decitabine and a second agent. Over the last decade, a number of groups reported on the activity of the combination of a hypomethylating agent with a histone deacetylase inhibitor (HDACi).[123] These were based on initial observations by Baylin et al. that clearly demonstrated that these agents are highly synergistic in vitro.[124] This resulted in studies combining either azacitidine or decitabine with agents such as valproic acid,[125,126] vorinostat,[127] MGCD0103,[128] and panabinostat.[129] Pilot data from these studies in general indicated that response rates were higher than expected with the combination and that the responses were faster. Unfortunately, no randomized study has proven this observation. An initial randomized trial performed at MDACC with valproic acid and decitabine failed to show an improvement. More recently, ECOG reported results of a combination of azacitidine with a carbamate derivative HDACi known as SD275 that also failed to show an advantage to the combination.

TABLE 79.6

PROGNOSTIC FACTORS OF OVERALL SURVIVAL

Characteristics	Multivariate analysis	
	HR (95% CI)	P
ECOG PS		<0.0001
0–1	1	
≥2	2.0 [1.4–2.9]	
Cytogenic risk		<0.0001
Favorable	1	
Intermediate	1.4 [0.8–2.3]	0.23
Unfavorable	3.0 [2.0–4.3]	<0.0001
Transfusion dependence		<0.0001
≥ 4 RBC units/8 wk	1.9 [1.4–2.6]	
0–3 RBC units/8 wk	1	
PB blasts		<0.0001
Present	2.0 [1.5–2.7]	
Absent	1	

Prognostic score for overall survival. The score was computed (for each patient) based on the presence of PS ≥ 2 (1 point), presence of circulating blasts (1 point), RBC TD ≥ 4 RBC units/8 weeks (1 point), and intermediate- and high-risk cytogenetics (1 and 2 points, respectively). Low score = 0 points, intermediate score = 1-), and high score = 4 to 5 points. Adapted from Itzykson R, et al.[122] Blood 2011;117:403–411.

In parallel with this effort, Sekkeres et al. developed pilot studies of the combination of azacitidine with lenalidomide.[130] Although the rationale and mechanism of action of this combination is unknown at this time, it is clear from the data reported that this combination has significant clinical activity. The optimal dose of lenalidomide in combination is not known at this time and studies have used doses ranging from 10 mg/day to 75 mg/day. Currently, a US intergroup trial is comparing azacitidine versus the combinations with either lenalidomide or vorinostat.

Finally, other ways to optimize the use of these agents is by selecting a specific group of patients according to their patient characteristics, as per the French model, or based on specific genotypic characteristics.

Failure of Hypomethylating Agent

It is now recognized that most patients treated with hypomethylating agents that benefit from drug administration will eventually lose response to these agents. The outcome of this group of patients is extremely poor, with survivals that range from 4 to 6 months after failure (Fig. 79.8).[131,132] The mechanisms of failure at the present time are unknown and are likely due to a combination of factors, ranging from pharmacologic resistance to genetic evolution. This is an important area of research at this point. Because the mechanisms of resistance are not understood it has been difficult to target this problem. A number of chemotherapy agents are being investigated for patients with both higher- and lower-risk hypomethylating failure. These include kinase inhibitors, such as ON1910; more traditional cytotoxic agents, such as clofarabine and sapacitabine; and the p38MAPK inhibitor ARRY614, particularly in patients with lower-risk disease.[133]

The Role of Stem Cell Transplantation in Higher-risk Myelodysplastic Syndrome

SCT is curative in a significant fraction of patients with higher-risk MDS. Data from the Fred Hutchinson Cancer Center has reported long term survival rates of over 30% in selected patients.[134] Confirming this data, an analysis by IBMTR using Markov decision analysis indicated also that survival is improved with transplant in patients with higher-risk MDS. That said, transplant was associated with early risk of mortality in this patient population. Furthermore, most centers recommend against proceeding with transplant in patients with active disease. Therefore, it has become evident that initial bridge therapies are needed to take the patient successfully through transplantation. One common approach is the use of AML induction therapies that have more recently been replaced by the incorporation of hypomethylating agents prior to transplant. A number of groups have shown both in vivo and in vitro that hypomethylating agents have effects on specific subsets of T cell regulatory compartments that may result in increased graft-versus-leukemia effect and control of GVHD.[135] A number of trials are testing this concept.

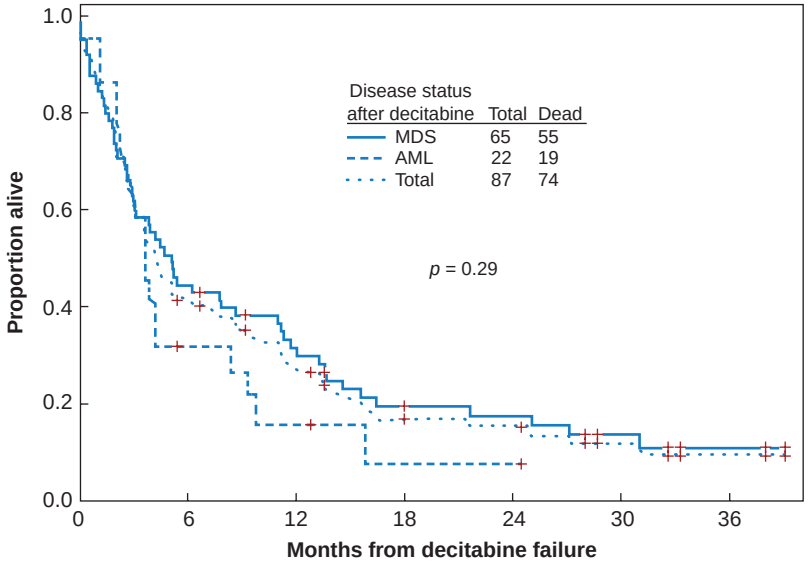

FIGURE 79.8. Survival of patients with myelodysplastic syndromes (MDS) that have failed a hypomethylating agent. Adapted from Jabbour E, et al.[131] Cancer 2010;116:3830–3834.

It is also now clear that early successful transplantation does not eradicate the possibility of relapse posttransplant. With the advent of less toxic reduced intensity transplant treatment modalities, death post-SCT is more commonly associated with relapsed disease than with acute or chronic GVHD. It is of interest that a number of groups have reported now that poor prognostic cytogenetic features are also associated with dismal outcomes posttransplant. Deeg et al. have also reported on the impact of the new five-subset cytogenetic classification on outcomes on patients with MDS receiving SCT.[136] Because of the problem of relapse posttransplant, a number of groups have investigated the role of "maintenance" approaches posttransplant. DeLima et al. pioneered the use of low-dose azacitidine in patients with myeloid leukemias at very high risk of relapse posttransplant.[137] These initial studies are now being further tested in randomized clinical trials, including a planned trial of oral azacitidine post-SCT. Also recently, German investigators have reported on the potential activity of lenalidomide in the posttransplant setting.

CONCLUSION

Over the last decade, we have witnessed significant improvements in our abilities to diagnose, classify, and understand MDS. At the present time, a significant effort is being developed by multiple investigators to better understand specific molecular subsets of patients. These data will also help develop rationale targeted interventions that will result in the improvement of outcomes with current available agents and stem cell transplantation. Finally, we also expect that detailed genomic analysis of MDS will result in the identification of new prognostic and therapeutic targets.

CHAPTER 80

PATHOLOGY OF THE MYELOPROLIFERATIVE NEOPLASMS

Luke R. Shier, Tracy I. George

The myeloproliferative neoplasms include both chronic myeloproliferative disorders and overlap myelodysplastic/myeloproliferative syndromes. This chapter reviews the pathology of the myeloproliferative diseases, including pertinent clinical, laboratory, histologic, cytogenetic, and molecular genetic findings necessary for the classification of these disorders. Both myeloproliferative neoplasms (MPNs) and overlap myelodysplastic/myeloproliferative neoplasms (MDS/MPNs) are clonal neoplasms with typical increased marrow cellularity, maturation of cell lineages, and organomegaly. The MPNs also share effective hematopoiesis and varying amounts of marrow fibrosis, but generally differ by which myeloid cell lineage dominates hematopoiesis. The MDS/MPNs overlap myeloproliferative and myelodysplastic disorders, with varying degrees of effective hematopoiesis and myelodysplasia. A common theme of aberrant activation of tyrosine kinase signaling pathways has emerged among the myeloproliferative diseases[1–3,4,5]. Not only has this helped further our understanding of these complex disorders, but also identification of aberrant kinase signaling cascades has led to targeted small molecule tyrosine kinase inhibitors (TKIs), such as imatinib, being used successfully in the treatment of certain diseases. Thus, the diagnosis and classification of the MPNs and overlap disorders requires correlation of morphology with clinical, hematologic, and molecular genetic findings[6]. An abbreviated overview of select myeloid neoplasms including the myeloproliferative diseases (Table 80.1) correlates each disease with its corresponding identified aberrant tyrosine kinase or related gene involved in the pathogenesis of the disorder and corresponding molecular genetic findings. In categorizing these disorders, separation of the MPNs from the overlap MDS/MPNs is recognized by the presence of myelodysplasia in the latter syndromes. Of the MPNs, there are the four common disorders, recognized as chronic myelogenous leukemia (CML), with its characteristic 9;22 translocation and BCR-ABL1 fusion protein, and three non-CML MPNs: polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF). These common non-CML MPNs (PV, ET, PMF) share a high incidence of the acquired point mutation (V617F) in the *JAK2* kinase[7–10], a cytoplasmic tyrosine kinase important in hematopoietic proliferation. This mutation is associated with constitutive Jak-STAT activation in cell lines and MPN-like disorders in mouse models[3,11], and occurs in stem cells in humans with polycythemia vera predisposing toward erythroid hyperplasia[12,13]. Other *JAK2* mutations have also been described in patients with PV[14]. Given the importance of *JAK2* V617F, the 2008 revision of the World Health Organization (WHO) classification system now includes this mutation in the diagnostic criteria for the common non-CML MPNs[15,16,17].

The MPNs also include a number of uncommon or atypical disorders. These uncommon MPNs include chronic eosinophilic leukemia not otherwise specified (CEL), systemic mastocytosis (SM), and chronic neutrophilic leukemia (CNL). Several atypical MPNs and MDS-MPNs with eosinophilia are now also recognized as sharing tyrosine kinase abnormalities, such as *FIP1L1-PDGFRA* in disorders previously considered to be CEL and SM with eosinophilia, *ETV6-PDGFRB* in cases with features of chronic myelomonocytic leukemia (CMML) with eosinophilia or atypical chronic myeloid leukemia (aCML), and *FGFR1* rearrangements seen in a number of hematologic neoplasms (formerly classified as the 8p11 myeloproliferative syndrome). These disorders are now classified as myeloid neoplasms with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*[18] rather than as subtypes of other MPNs. The presence of these genetic abnormalities is not merely academic, as patients with *PDGFRA* or *PDGFRB* rearrangements have shown responsiveness to TKIs. For example, MPNs with eosinophilia and *FIP1L1-PDGFRA* can contain proliferations of CD25 positive mast cells that are sensitive to imatinib, whereas SM with *KIT* D816V mutations (and dense proliferations of CD25 positive mast cells) is resistant to the same drug[19,20]. The latter patients may respond to second-generation TKIs initially developed for imatinib-resistant CML patients or FLT3 inhibitors developed for patients with acute myeloid leukemia, as these drugs have activity against multiple tyrosine kinases[21,22]. The development of new tyrosine kinase pathway-targeted small molecule inhibitors is likely to accelerate further the molecular classification of myeloproliferative neoplasms.

The overlap MDS/MPNs, according to the WHO classification, have traditionally included chronic myelomonocytic leukemia (CMML), juvenile myelomonocytic leukemia (JMML), and atypical CML (aCML). A provisional entity, refractory anemia with ringed sideroblasts and thrombocytosis (RARS-T), also fits within this overlap group, sharing features of dysplasia and MPN. These overlap syndromes also share tyrosine kinase pathways, including *JAK2* and *MPL* W515K/L mutations in RARS-T. As with all classification schemes, not every patient's findings are amenable to these guidelines, and it is preferred to term these "unclassifiable" until further information clarifies the disorder.

MYELOPROLIFERATIVE NEOPLASMS

The traditional classification of the common MPNs is based on which cell line is most proliferative (i.e., granulocytic, erythroid, and megakaryocytic) and the amount of marrow fibrosis, combined with clinical, laboratory, and cytogenetic/molecular genetic features (Table 80.2). As a consequence of excess cell proliferation with effective maturation, there is resulting leukocytosis, erythrocytosis, and/or thrombocytosis. Subsequent hepatosplenomegaly follows due to sequestration of excess cells, extramedullary hematopoiesis, or infiltration by neoplastic cells. Although this initial dysregulated proliferation may manifest as an indolent disorder, these clonal stem cell disorders all have the potential for evolution. This manifests as either a stepwise increase in fibrosis to an end-stage myelofibrosis or as an increase in blasts, transforming

through an accelerated phase (10% to 19% blasts) to overt acute leukemia (20% or more blasts). The MPNs differ in the incidence of this evolution and transformation.

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia, BCR-ABL1 positive (CML)[23,24,25], is the most common of the MPNs and can occur at any age, although it is uncommon in children. The average age at diagnosis is 50 to 60 years old with a slightly increased male-to-female ratio.

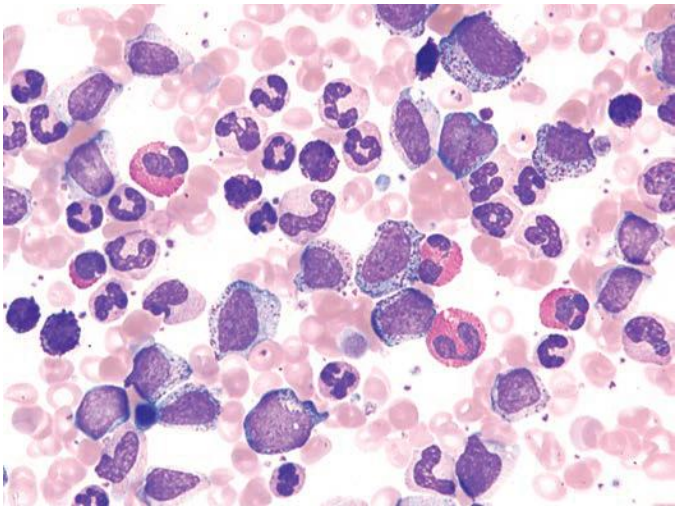

FIGURE 80.1. Chronic myelogenous leukemia. The peripheral blood demonstrates neutrophilia with prominent left shift, eosinophilia, and basophilia. Typically numerous myelocytes and segmented neutrophils predominate. Wright–Giemsa, 500×.

CML is defined by the presence of the Philadelphia chromosome or molecular genetic evidence of the *BCR-ABL1* fusion. In contrast to the t(9;22) of acute leukemias, which usually demonstrate the p190 BCR-ABL1 fusion protein, CML almost always demonstrates the p210 fusion protein of this translocation. The rare p230 fusion protein is typical of the rare neutrophilic form of CML, which is discussed later. CML is primarily a proliferation of granulocytic cells, although multiple cell lines demonstrate the Philadelphia chromosome. This expansion of myeloid cells typically involves the blood, bone marrow, spleen, and liver. Extramedullary involvement may be seen during the blast phase of the disease. The typical clinical course of CML is an indolent chronic phase followed by either blast crisis or progression to an accelerated phase with subsequent blast crisis.

The peripheral blood findings are those of a leukocytosis with granulocytes at all stages of maturation (Fig. 80.1). Segmented neutrophils may show abnormal nuclear segmentation. Myelocytes

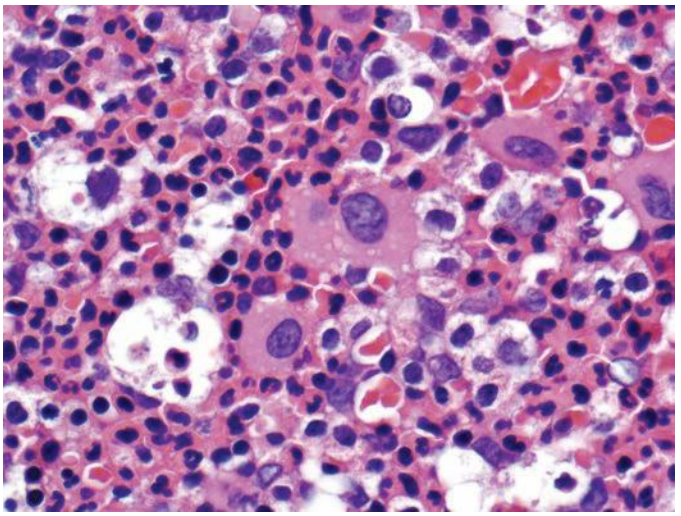

FIGURE 80.2. Chronic myelogenous leukemia (CML). The bone marrow biopsy is hypercellular with myeloid and megakaryocytic hyperplasia. Note the clusters of small hypolobated megakaryocytes typical of CML. Hematoxylin and eosin, 500×.

and metamyelocytes are present in high numbers in the peripheral blood with concomitant basophilia and often eosinophilia. Abnormal basophils with "washed-out" granules may be identified. Platelets are usually elevated. An absolute monocytosis may also be present. The bone marrow is markedly hypercellular with cellularity approaching 100% in most untreated cases (Fig. 80.2). The myeloid-to-erythroid ratio of the bone marrow is increased, often >10:1. An atypical megakaryocytic hyperplasia is present, with clustering of megakaryocytes, which are small and contain hypolobated nuclei. Some degree of reticulin fibrosis is usually demonstrated in these cases, and marked increases in reticulin and collagen marrow fibrosis are associated with accelerated phase and decreased survival[26]. Pseudo-Gaucher histiocytes are common in CML, reportedly present in 37% to 70% of cases[27]. These histiocytes have abundant fibrillar birefringent cytoplasm, and their presence has been associated with an improved survival[26]. Leukemoid reactions, in patients with infectious or other reactive conditions, may demonstrate similar features to CML. These reactive proliferations, however, do not usually show the basophilia, degree of marrow cellularity, or megakaryocyte clustering characteristic of CML. However, cytogenetic or molecular genetic studies are indicated if the differential diagnosis includes CML.

Chronic myelogenous leukemia usually presents in *chronic phase*, which is essentially defined by the lack of features of accelerated phase or blast crisis. Marrow blasts are usually <5%, but may range up to 9%. The natural course of the disease is progression from chronic phase to a more aggressive phase of the disease within 3 to 5 years. Any one of a variety of parameters defines the *accelerated phase* of CML, but the criteria are inconsistent in the literature[28,29]. WHO criteria (Table 80.3) require the presence of either 10% to 19% blasts in the peripheral blood or bone marrow, the acquisition of additional chromosomal abnormalities, elevations of basophils to 20% or more of blood cells, persistent thrombocytopenia (<100 × 10^9/L), or either of the following that do not respond to conventional therapies: platelet elevations of >1,000 × 10^9/L or increasing splenomegaly associated with an increasing white blood cell (WBC) count[30]. In addition, megakaryocytic proliferation in sheets and clusters associated with marked fibrosis and/or marked granulocytic dysplasia has also been described as suggestive of an accelerated phase[31]. *Blast phase*, or blast crisis, of CML is defined by the presence of 20% or more blasts in the peripheral blood or bone marrow (Fig. 80.3)[30]. Large clusters of blasts on the bone marrow biopsy are also sufficient for a diagnosis of blast phase[31]. The development of extramedullary myeloid tumors (myeloid or granulocytic sarcomas, chloromas) is also sufficient for blast phase using the WHO criteria. Cytogenetic clonal evolution, which may be present at the time of transformation to either the accelerated phase or blast phase, typically includes an extra Philadelphia chromosome, trisomy 8, or i(17q)[25,32,33].

TABLE 80.3

WHO CRITERIA FOR ACCELERATED PHASE OF CHRONIC MYELOGENOUS LEUKEMIA[a]

Blasts 10–19% in blood or marrow
Peripheral blood basophilia ≥ 20%
Cytogenetic clonal evolution
Persistent thrombocytopenia (<100 × 10^9/L)
Persistent thrombocytosis (>1,000 × 10^9/L) unresponsive to therapy
Increasing splenomegaly and/or increasing WBC count unresponsive to therapy

WBC, white blood cell; WHO, World Health Organization.
[a]The diagnosis requires one or more of the listed criteria.

Detection of the t(9;22)(q34;q11) by karyotype analysis, fluorescent in situ hybridization (FISH), or reverse transcriptase-polymerase chain reaction (RT-PCR) is essential for the diagnosis of CML. Detection of this abnormality confirms the clonal or neoplastic nature of the proliferation and excludes reactive conditions and other MPNs that may mimic CML. Immunophenotyping studies add little in the chronic phase of CML, but are helpful in defining the blast cell population of accelerated and blast phases of this disease[34,35]. The majority of blast crisis cases will express myeloid-associated antigens without lymphoid markers and are easily classified as *myeloid blast crisis* by immunophenotyping studies; however, some myeloid blast crisis cases may be myeloperoxidase negative by cytochemistry. Although most blast transformations of CML are proliferations of myeloblasts, approximately one third of cases are *lymphoid blast crises* (Fig. 80.4). The vast majority of lymphoid blast crisis cases are of precursor B-cell lineage, but rare T-cell blast crisis cases occur. Lymphoid blast crisis is reported to have a better prognosis than myeloid blast crisis, and lymphoid blast crisis has traditionally been defined as a blast cell proliferation that is terminal deoxynucleotidyl transferase (TdT) positive. More detailed immunophenotyping of these cases

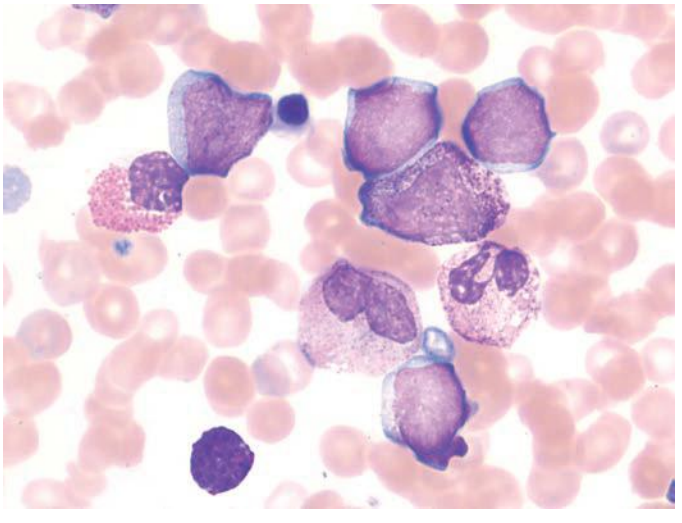

FIGURE 80.3. Myeloid blast crisis of chronic myelogenous leukemia (CML). Peripheral blood smear showing numerous agranular blasts on a background of neutrophils, immature granulocytes, eosinophils, and basophils. When blasts are the dominant cell present, the background changes of CML may be subtle or obscured. Wright–Giemsa, 1,000×.

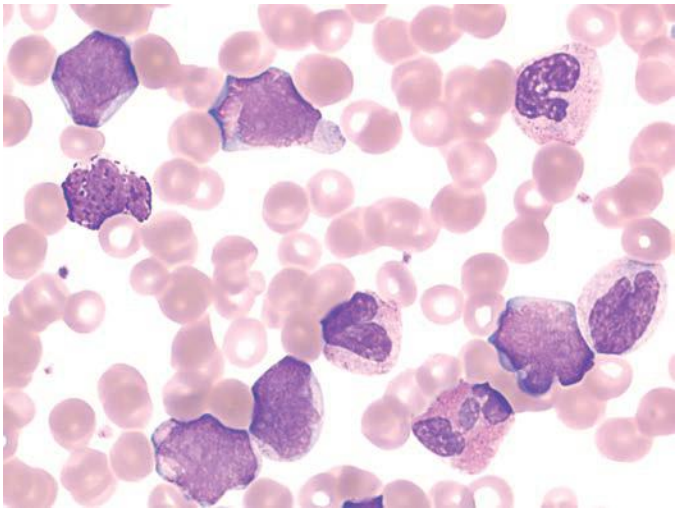

FIGURE 80.4. Lymphoid blast crisis of chronic myelogenous leukemia (CML). Peripheral blood smear shows intermediate-sized blasts with high nuclear-to-cytoplasmic ratios, a very small amount of basophilic cytoplasm, irregular and clefted nuclear contours, and immature chromatin. The background shows features of CML. Flow cytometry demonstrated a B-lymphoblastic immunophenotype. Wright–Giemsa, 1,000×.

usually demonstrates expression of other precursor B-cell markers, such as CD19 and CD10, but expression of myeloid-associated antigens, such as CD13 and CD33, is also common. Cases with a lymphoid immunophenotype lacking myeloperoxidase, irrespective of the expression of other myeloid antigens, have an improved survival[35] and are probably best classified as lymphoid blast crises. A small proportion of CML blast crises are mixed phenotype, which must be distinguished from de novo mixed phenotype acute leukemia (MPAL), a subset of which also has the *BCR-ABL1* gene rearrangement.

Typically, patients with all phases of CML are treated with a TKI, imatinib, which directly blocks the effects of the BCR-ABL1 fusion protein[36]. Imatinib results in a clinical, morphologic, and at least partial cytogenetic remission in most patients, with reduction in marrow cellularity, normalization of the myeloid-to-erythroid ratio, and normalization of megakaryocyte number and morphology[37,38,39,40,41]. The peripheral blood is the first to respond to imatinib therapy with a normalization of the white blood cell and platelet counts, a decrease in basophils, and normal-appearing platelets occurring after about 2 months of therapy. During therapy, the hemoglobin level tends to decrease slightly, and a subset of patients may develop neutropenia or thrombocytopenia. Bone marrow hypercellularity gradually decreases and by 8 to 11 months the marrow is normocellular or hypocellular with a normal or decreased myeloid-to-erythroid ratio in most patients. Even in chronic phase, bone marrow blasts and megakaryocytes decrease, and the number of hypolobated megakaryocytes and the presence of megakaryocyte clustering become less common as the marrow cellularity decreases. This therapy has also been reported to gradually eliminate the marrow fibrosis that is prominent in some cases of CML[37,38,42]. Patients with accelerated or blast phases of CML show similar changes with rapid decreases in peripheral blood and bone marrow blast cell counts[37]. Two thirds of patients treated in chronic phase tolerate imatinib therapy well and experience an excellent and sustained remission[40,41]. More recently, the development of second-generation TKIs (dasatinib, nilotinib) have proven effective in many patients who fail or are not tolerant of imatinib, and these may become effective alternatives for front line therapy[43–45]. Whereas TKIs are now well established as front line therapy, stem cell transplantation (SCT) remains an effective curative option although the risks are not insignificant. SCT is therefore now employed as salvage therapy[46].

Neutrophilic-chronic myelogenous leukemia appears to be a less aggressive variant of CML in which the t(9;22) codes for a 230-kD BCR-ABL1 fusion protein[47]. This disease is associated with a proliferation of more mature granulocytes, usually at the segmented neutrophil stage of development. These patients have less severe clinical symptoms and are slower to progress to a blastic stage. This CML variant has been shown in one study to have low levels of p230 *BCR-ABL1* messenger RNA and undetectable protein product, which may explain the milder phenotype in these patients[48].

Philadelphia chromosome-negative CML is not recognized in the 2008 WHO classification and such a diagnosis should be made with caution. Cryptic *BCR-ABL1* translocations may occur that cannot be identified by routine karyotype analysis. When this is suspected, molecular genetic studies, such as FISH or RT-PCR analysis, are indicated. When these studies are negative, other diagnostic considerations must be entertained. Review of cytogenetic and molecular genetic Philadelphia chromosome-negative CML cases has resulted in most being reclassified as chronic myelomonocytic leukemia or atypical CML (described below)[49].

Polycythemia Vera

Polycythemia vera is a clonal proliferation, usually occurring in elderly patients with a male predominance, that presents as an expansion of the red blood cell mass[50,51,52]. This expansion is secondary to increased red cell production from dysregulated erythropoiesis. An acquired *JAK2* V617F mutation in exon 14 is detected in 95% to 97% of patients with PV[53,54], with exon 12 mutations accounting for most *JAK2* V617F negative cases[14,55]. The WHO 2008 criteria for PV now include *JAK2* or functionally similar mutations as a major criterion for diagnosis (Table 80.4)[15,17]. These mutations produce a PV-like disease in mice[14,55] and involve a stem cell in humans predisposing toward erythroid differentiation[8]. Typically, the spleen is enlarged and erythropoietin levels are decreased in this disease[56]. The presence of a *JAK2* mutation allows for the exclusion of a reactive erythrocytosis, but is not diagnostic for PV, as *JAK2* mutations occur in approximately one half of patients with ET and PMF, as well as involving atypical MPNs and overlap MDS/MPNs at lower levels[53,57,58].

TABLE 80.4

WHO CRITERIA FOR THE DIAGNOSIS OF POLYCYTHEMIA VERA[a]

Major Criteria

- Hemoglobin >18.5 g/dl in men, >16.5 g/dl in women **or** evidence of increased red cell volume[b]
- Presence of *JAK2* mutation

Minor Criteria

- Hypercellular bone marrow biopsy with panmyelosis with prominent erythroid, granulocytic, and megakaryocytic hyperplasia
- Low serum erythropoietin level
- Endogenous erythroid colony formation in vitro

WHO, World Health Organization.
[a]Diagnosis requires the presence of both major criteria and one minor criterion **or** the presence of the first major criterion and two minor criteria. The *JAK2* mutation refers to the *JAK2*V617F or other functionally similar *JAK2* mutation.
[b]Hemoglobin or hematocrit >99% of method-specific range for age, sex, and altitude of residence **or** hemoglobin >17 g/dl in men, >15 g/dl in women if associated with a sustained increase of at least 2 g/dl from an individual's baseline value that cannot be attributed to correction of iron deficiency.
From Swerdlow SH, Campo E, Harris NL, et al. World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues. IARC, Lyon, 2008.

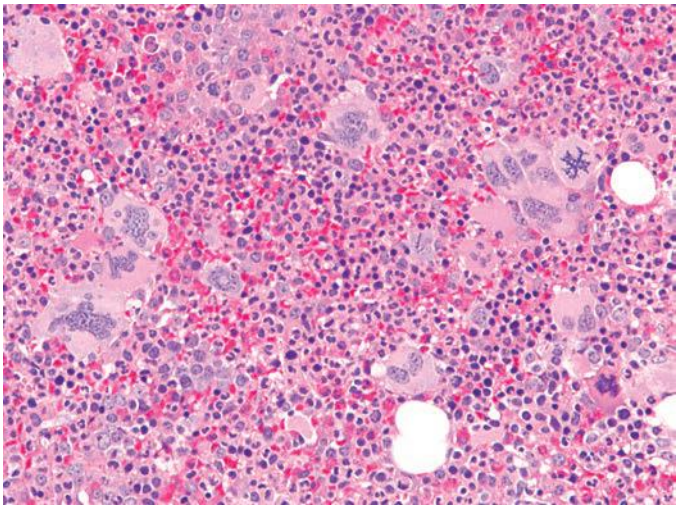

FIGURE 80.5. Polycythemia vera. The bone marrow biopsy from a patient with polycythemia vera is hypercellular, with panmyelosis, an increased number of erythroid precursors, and large atypical megakaryocytes in loose clusters. Hematoxylin and eosin, 200×.

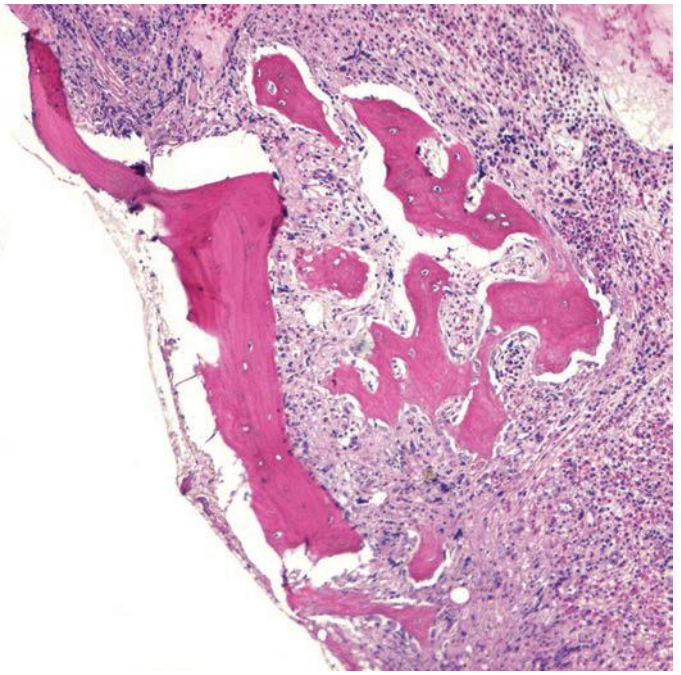

FIGURE 80.6. Post-polycythemic phase of polycythemia vera. Bone marrow biopsy showing increased fibrosis and osteosclerosis. Hematoxylin and eosin, 400×.

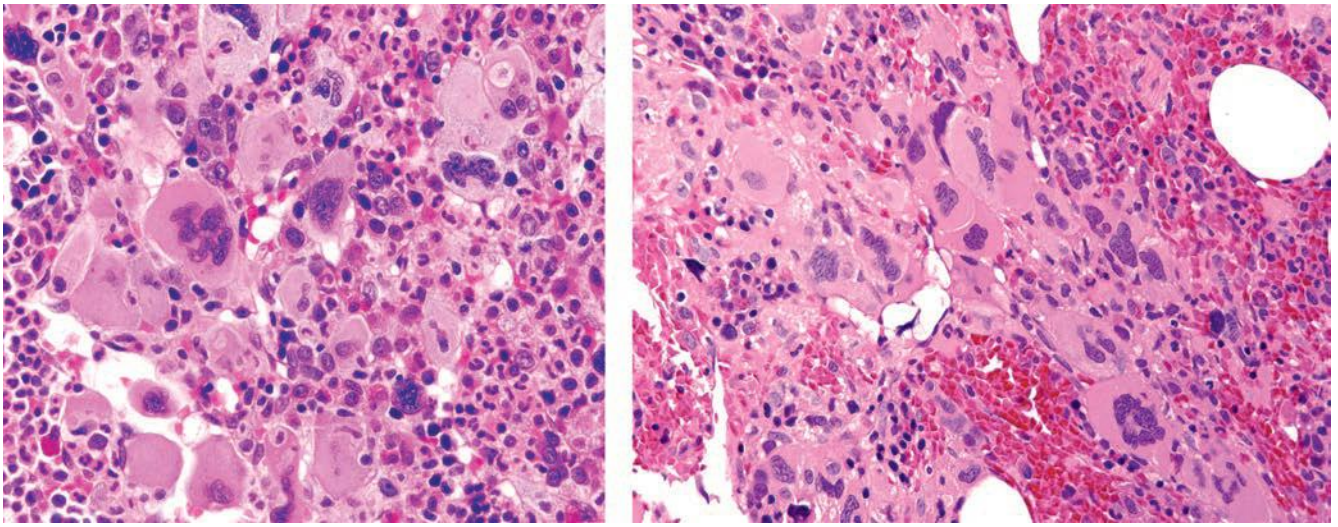
Two morphologic phases of PV are well described[59]. The *proliferative* or *erythrocytotic phase* typically shows elevations of red blood cells, white blood cells, and platelets. Slight elevations in the peripheral blood basophil count may be present, but are not as elevated as is usually seen in CML. A neutrophilia with left-shifted granulocytes is commonly seen. Platelet counts can exceed 600×10^9/L, which may cause confusion with essential thrombocythemia. It is not uncommon for patients to have associated iron deficiency with microcytic red blood cells; absent stainable iron on marrow examination is typical[59]. The bone marrow is usually moderately hypercellular with trilineage proliferation (Fig. 80.5). In contrast to the other MPNs, however, the erythroid series is relatively increased. Loose clusters of pleomorphic megakaryocytes are prominent, with very small and giant megakaryocytes adjacent to each other. Marrow fibrosis may be minimal in this stage of the disease[60,61]. Reactive lymphoid aggregates are also common[62]. The *spent phase* or *post-polycythemic phase* of PV is associated with marked marrow fibrosis and shows peripheral blood and bone marrow changes that are similar or identical to those seen in primary myelofibrosis with leukoerythroblastic peripheral blood changes, splenomegaly, and marrow fibrosis (Fig. 80.6). Differentiation between these two diseases may not be possible without a history of the earlier phase of PV (Fig. 80.7). Approximately 10% of PV patients will transform to acute myeloid leukemia within 15 years and up to half will develop acute leukemia over 20 years (Fig. 80.8)[63]. Rare cases of myelodysplastic transformation are also reported in the literature, which appear to be treatment related[64].

Evaluation of red cell mass (RCM), which previously was recommended for the diagnosis of PV, has now largely been supplanted by *JAK2* testing, bone marrow histology, and serum erythropoietin levels[65]. However, given the overlap in features between PV and other MPNs, some cases may only be resolved by RCM studies, although these studies have their own challenges[65]. An absolute erythrocytosis is the feature that separates



A B

FIGURE 80.7. The post-polycythemic phase of polycythemia vera shows bone marrow changes (A) indistinguishable from those of the fibrotic stage of primary myelofibrosis (B). Both bone marrow biopsies are hypercellular with atypical megakaryocyte clustering, including hyperchromatic enlarged megakaryocytes amidst a fibrotic background. Hematoxylin and eosin, 400×.

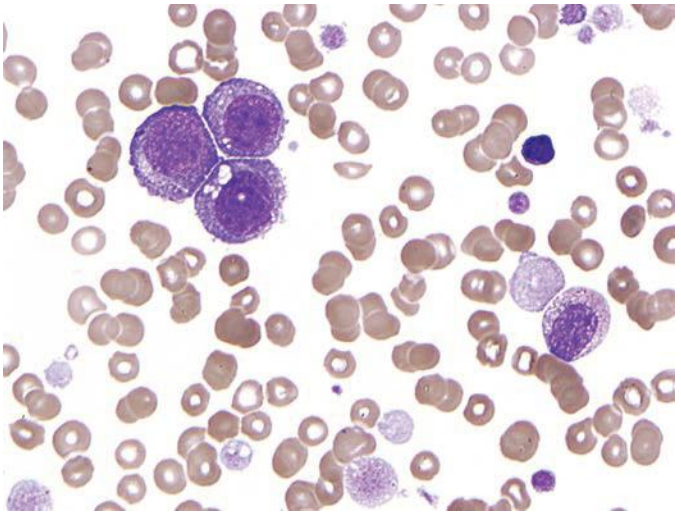


FIGURE 80.8. Transformation of polycythemia vera. Peripheral blood smear shows numerous giant platelets, including hypogranular forms, a myelocyte, a lymphocyte, and a cluster of three blasts. Wright–Giemsa, 600×.

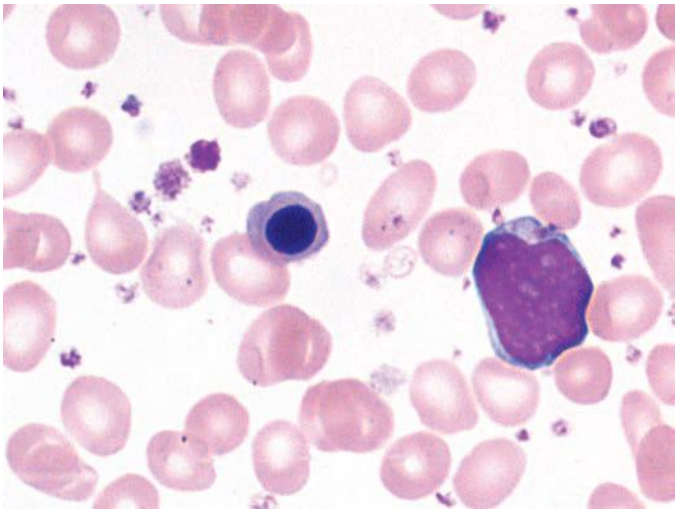

FIGURE 80.9. Primary myelofibrosis. The peripheral blood changes of myelofibrosis show the characteristic findings of leukoerythroblastosis with rare blasts, nucleated red blood cells, large platelets, and teardrop-shaped red cells (dacrocytes). Wright–Giemsa, 1,000×.

PV from other MPNs, and RCM may be decreased in PV patients with concurrent iron deficiency; thus, studies may have to be repeated after iron therapy. Reactive or secondary polycythemias must also be excluded and these may be related to smoking, lung and renal disease, erythropoietin-producing tumors, congenital conditions causing erythropoietin overproduction, and exogenous administration of erythropoietin. Although many of these secondary polycythemias will lack *JAK2* mutations, not all idiopathic erythrocytoses that meet neither criterion for PV or secondary polycythemia are well understood[66]. Some of these idiopathic erythrocytoses represent recently described exon 12 or 14 *JAK2* mutations, whereas others are still being investigated[14,55]. Studies have emphasized the value of bone marrow histology in distinguishing between early-stage PV and reactive polycythemias. The atypical megakaryocytic hyperplasia of PV is not seen in secondary polycythemias. These reactive conditions tend to show only a borderline increase in cellularity, with an altered interstitial compartment containing increased deposition of cellular debris within histiocytic cells, hemosiderin-laden macrophages, and perivascular plasmacytosis[60,61].

Other karyotypic abnormalities may be detected in up to half of cases of PV, with chromosome 20q deletions being the most common[67,68]. These abnormalities, however, are not specific for PV[69]. Various point mutations occur in association with polycythemias, particularly in the congenital or familial forms[70]. Clonogenic stem cell assays are a minor diagnostic criterion used in the diagnosis of PV. Progenitor cells from patients with PV are hypersensitive to several growth factors, and in vitro detection of endogenous erythroid colonies occurs in PV. Although the predictive value of clonogenic stem cell assays in certain defined settings may be high (97%)[71], their availability is limited and these assays are difficult to standardize. Thus, these assays are now infrequently used in the routine diagnosis of PV[72].

Primary Myelofibrosis

Primary myelofibrosis, also known as chronic idiopathic myelofibrosis, myelofibrosis with myeloid metaplasia, and agnogenic myeloid metaplasia, occurs in elderly patients and usually presents with a leukoerythroblastic peripheral blood smear, massive splenomegaly, and marrow fibrosis[73,74]. The peripheral blood changes include the presence of large teardrop-shaped red blood cells (dacrocytes), a granulocyte left-shift that often includes rare myeloblasts, and thrombocytosis with giant platelets that are larger than a red blood cell (Fig. 80.9). Basophilia may be present and bare megakaryocyte nuclei are often seen in the blood and bone marrow. Although spleen enlargement occurs with many myeloproliferative neoplasms, the splenomegaly of PMF is striking, and may cause severe discomfort and wasting syndromes. The bone marrow may be hypercellular, particularly early in the disease when marrow fibrosis is less prominent, in the *prefibrotic phase* of PMF. The myeloid-to-erythroid ratio is slightly increased and megakaryocytes are increased. Atypical megakaryocyte clustering is prominent, with clusters of medium-sized to giant megakaryocytes often adjacent to sinuses and bony trabeculae. The megakaryocytes are atypical with hyperchromatic megakaryocytic nuclei and coarse lobulations[75–78]. The differential diagnosis between the prefibrotic stage of PMF and ET can be quite difficult, but abnormal megakaryopoiesis is most helpful in establishing the diagnosis of PMF, although other features including bone marrow cellularity (increased markedly in the cellular phase of PMF) and left-shifted myeloid hyperplasia (usual in PMF) are also useful[79–82,83,84]. Most patients are diagnosed in the *fibrotic stage* and show marked marrow fibrosis (Fig. 80.10), which may include collagen fibrosis. Interestingly, this accompanying fibrosis is reactive, whereas clonal studies have shown that the trilineage hematopoietic proliferation is monoclonal[85]. Clusters of atypical megakaryocytes remain prominent in association with the fibrosis, and megakaryocyte clusters in sinusoids may be evident. The sinuses are often dilated with intrasinusoidal hematopoiesis. Sclerosis of bone trabeculae also occurs in many patients with broad irregular trabeculae, which can occupy much of the marrow biopsy (Fig. 80.10D). Lymphoid aggregates, of predominantly T-cells, occur commonly in association with PMF.

Ancillary studies are required to exclude the Philadelphia chromosome of CML, and approximately one half of PMF patients will have an acquired *JAK2* mutation[53]. An *MPL* mutation, *MPL* W515L, has also been described in a subset of patients with PMF; some of these patients lacked the *JAK2* mutation whereas others occurred concurrently[86,87]. Studies report that 35% to 61% of patients will demonstrate a cytogenetic abnormality, with deletions of chromosomal arms 20q and 13q most common, as well as der(6)t(1;6) (q21–23;p21.3)[74,88–91]. Other ancillary studies are of limited utility with the exception of immunophenotyping of blasts in cases that undergo blastic transformation.

The Italian criteria for myelofibrosis focused on the fibrotic phase of the disease, requiring diffuse fibrosis of the marrow, among other features[92]. The 2008 WHO criteria for PMF require three major and two of four minor criteria[15]. The first major criterion addresses bone marrow histology and allows diagnosis in either the fibrotic or prefibrotic phase by focusing on

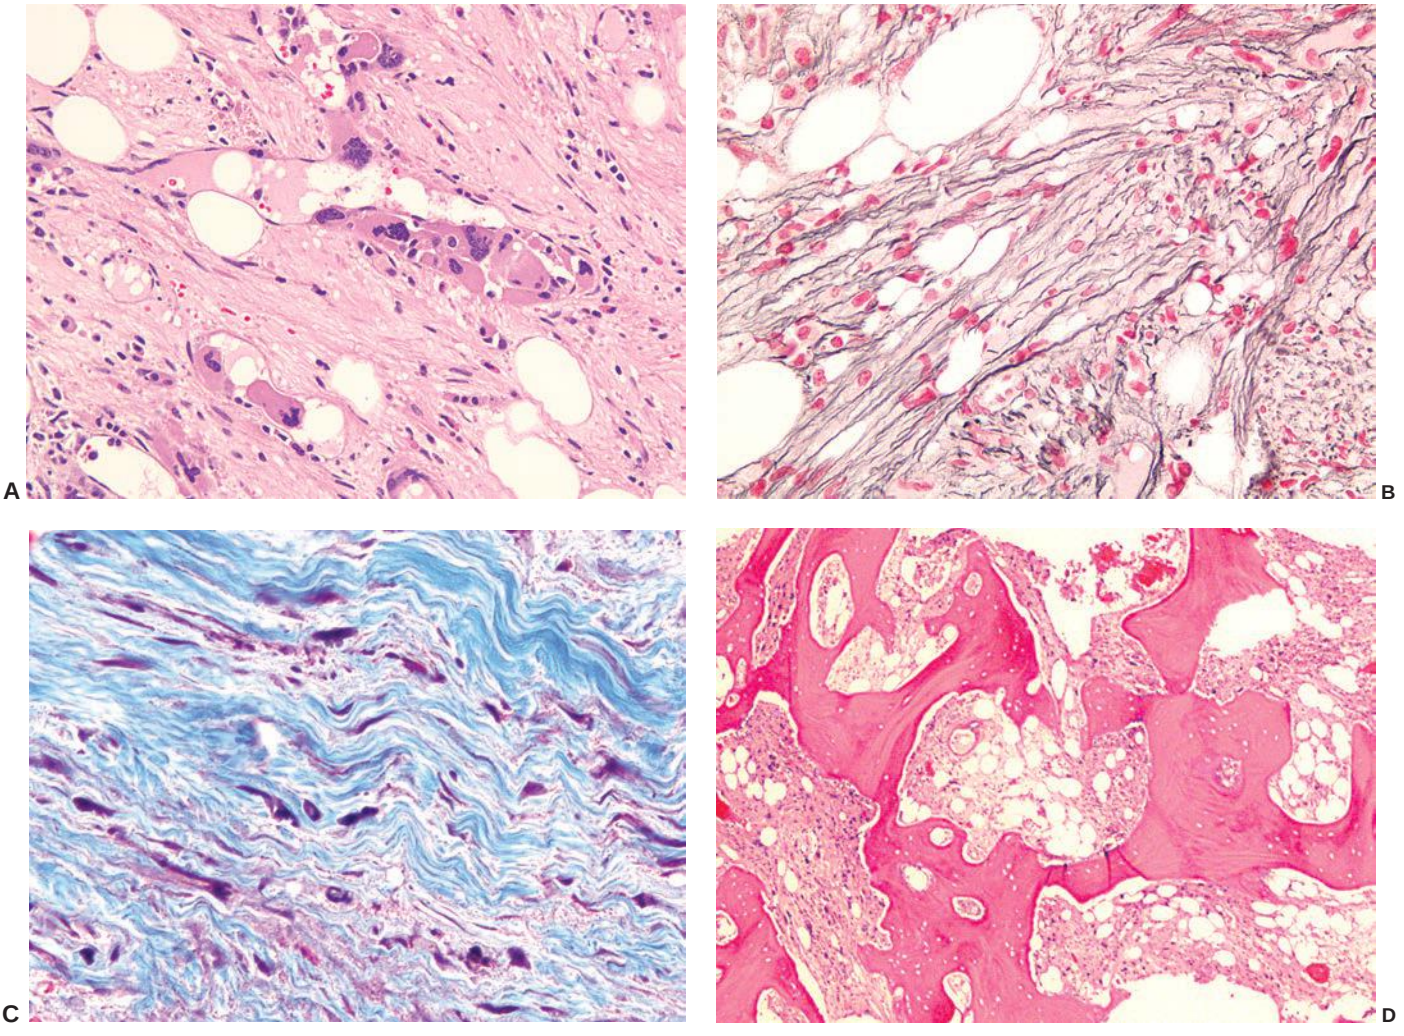

FIGURE 80.10. Bone marrow changes of fibrotic phase primary myelofibrosis. Fibrosis and intrasinusoidal clusters of atypical megakaryocytes are evident in **(A)**. Hematoxylin and eosin, 200×. Diffusely increased coarse reticulin fibrosis is shown in **(B)**. Reticulin stain, 500×. Coarse collagen fibrils are demonstrated in **(C)**. Masson trichrome, 500×. Late-stage osteosclerotic changes are noted in **(D)**, Hematoxylin and eosin, 50×.

characteristic megakaryocytic proliferation and atypia accompanied either by significant fibrosis or a hypercellular marrow with granulocytic proliferation. The two additional required major criteria are the demonstration of the *JAK2* V617F mutation or a similar clonal marker (such as *MPL* W515K/L), and the exclusion of other MPNs, MDS, and *BCR-ABL1*–positive CML (Table 80.5). Two of four minor criteria must also be met, including (a) leukoerythroblastosis, (b) elevated serum lactate dehydrogenase levels, (c) anemia, or (d) splenomegaly. As described above, the megakaryocytic atypia is quite marked with loose to tight clusters of megakaryocytes, including a wide variation in size with hyperchromatic, irregularly folded or bulbous nuclei, as well as abnormal nuclear-to-cytoplasmic ratios[78,93].

Median survival for patients with PMF varies from 17.5 to 1.8 years for low- to high-risk subgroups[94], using the Dynamic International Prognostic Scoring System (DIPSS)-plus with the following eight risk factors: age > 65 years, constitutional symptoms, RBC transfusion need, hemoglobin <10 g/dL, leukocyte count >25 × 10^9/L, circulating blasts ≥1%, platelet count <100 × 10^9/L, and an unfavorable karyotype[95]. The most frequent causes of death are complications of marrow failure (22%), including anemia, infection, and hemorrhage; transformation to AML (15%); and complications related to massive splenomegaly (11%)[88]. At present, there are few therapeutic options for PMF[96]. Allogeneic SCT provides a chance for cure, but the morbidity and mortality in PMF can be significant[97].

Essential Thrombocythemia

Essential thrombocythemia is a bone marrow proliferation characterized primarily by an elevation in peripheral blood platelets, usually over 1,000 × 10^9/L. The 2008 WHO classification specifies four criteria for diagnosis: a sustained platelet count ≥450 × 10^9/L; bone marrow biopsy showing megakaryocyte proliferation with enlarged mature megakaryocytes and with no significant increase or left shift of granulopoiesis or erythropoiesis; the exclusion of PV, PMF, CML, MDS, or another myeloid neoplasm; and either the presence of *JAK2* V617F or another clonal marker or the exclusion of reactive thrombocytosis (Table 80.6)[98]. Causes of reactive thrombocytosis include iron deficiency, splenectomy, surgery, infection, inflammation, connective tissue disease, metastatic cancer, and lymphoproliferative diseases. *JAK2* mutations are found in ~50% of patients with ET, and the *MPL* W515K/L in 3%, with both mutations found in a few patients[58,99].

ET probably represents two different diseases, one clonal and one reactive, even using the listed criteria[100]. Patients with the nonclonal form of the disease may include those with abnormalities of the thrombopoietin gene, and appear to be at a decreased

TABLE 80.5

WHO CRITERIA FOR PRIMARY MYELOFIBROSIS[a]

Major Criteria

- Atypical megakaryocytic hyperplasia, often accompanied by reticulin and/or collagen fibrosis **or** in the absence of fibrosis, megakaryocytic atypia and marrow hypercellularity with granulocytic hyperplasia and erythroid hypoplasia
- Exclusion of WHO criteria for PV, CML, MDS, or other MPNs
- *JAK2* V617F mutation or other clonal marker **or** if no clonal marker, exclusion of marrow fibrosis secondary to inflammatory or other neoplastic disorders

Minor Criteria

- Leukoerythroblastic peripheral blood smear
- Elevated serum lactate dehydrogenase level
- Anemia
- Splenomegaly

CML, chronic myelogenous leukemia; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; PV, polycythemia vera; WHO, World Health Organization.
[a]Diagnosis requires all major criteria and two minor criteria.

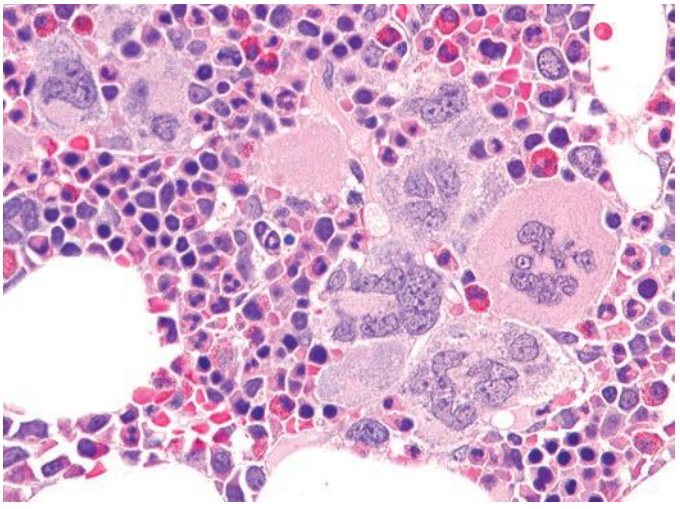

FIGURE 80.11. Essential thrombocythemia. Bone marrow biopsy is mildly hypercellular with atypical megakaryocyte clustering. The megakaryocytes are enlarged with abundant cytoplasm and distinct nuclear lobations. Hematoxylin and eosin, 500×.

risk of developing thrombosis[100,101]. Both types show similar peripheral blood and bone marrow features.

The thrombocytosis in ET is usually accompanied by abnormal large platelets. If leukocytosis is present, it is usually mild without the prominent left-shift or associated increase in basophils seen in CML. The marrow is normocellular to moderately hypercellular with increased numbers of megakaryocytes occurring in loose clusters or distributed throughout the marrow (Fig. 80.11). The megakaryocytes tend to be large with abundant cytoplasm and multilobated nuclei[102], and they are larger than those seen in reactive conditions and CML[80]. The myeloid-to-erythroid ratio is near normal and marrow fibrosis is absent or minimal.

The most frequent significant complications of ET are thrombosis and hemorrhage[103]. In high-risk patients, these complications are significantly reduced with low-dose aspirin and hydroxyurea therapy[104,105]. Transformation to acute leukemia or progression to overt myelofibrosis are uncommon[106,107], provided the diagnosis is made with careful adherence to 2008 WHO criteria in order to differentiate ET from early PMF[83]. Therapy-related AML and MDS, commonly associated with 17p deletions, may occur in ET patients treated with hydroxyurea and/or other chemotherapy[106], but the risk is greater in patients previously treated with radiophosphorus or alkylating agents. When compared with anagrelide, a medication with no known mutagenic potential, hydroxyurea showed no increased risk of leukemogenesis[104]. To date there are no convincing data demonstrating that the rate of leukemic transformation in ET is attributable to hydroxyurea.

There is considerable overlap between ET and PMF[73,80,108]. In one retrospective study of 120 patients[108], of a group of 43 "true" ET, only 1 developed an increase in reticulin fibrosis on subsequent serial bone marrow biopsies; this group also showed an 80% probability to lack splenomegaly. Serial bone marrow biopsies on the other patients identified prefibrotic PMF, with 65 of 77 patients in this group evolving into overt myelofibrosis/osteosclerosis. Survival analysis confirmed the better prognosis of the ET group compared to the PMF group. Thus, in the gray area of ET and the early or cellular phase of PMF, bone marrow morphology plays an important role in discriminating between these two entities, and sequential biopsies may allow for definitive classification in difficult cases. Reactive causes of megakaryocyte hyperplasia and thrombocytosis also must be excluded. RCM studies may be necessary to exclude cases of PV with associated thrombocytosis that might mimic ET. Whereas the presence of the *JAK2* V617F mutation will not distinguish among the non-CML MPNs presenting with thrombocytosis, the presence of this mutation will exclude reactive thrombocytosis[109].

The value of other ancillary studies in ET is similar to CML. The detection of clonal cytogenetic abnormalities is useful in determining that the morphologic changes represent a neoplastic rather than a reactive process. Although the vast majority of cases do not demonstrate cytogenetic abnormalities, abnormalities such as del(20q), trisomy 8, and many others have been reported in ET[110]. Rare Philadelphia chromosome-positive or Philadelphia-negative *BCR-ABL1*–positive ET cases are described in the literature. These appear to have a higher frequency of blast transformation than other types of ET, and most authors consider such cases to be unusual variants of CML[111]. However, both the development of a new *BCR-ABL1* clone in patients with a pre-existing *JAK2* positive MPN, and the development of a *JAK2* V617F clone in patients with CML have also been reported[112].

Rarely, there are patients who present with features of ET with ringed sideroblasts, now considered a provisional entity in the WHO classification, best considered under overlap MDS/MPN, unclassifiable[113–115].

TABLE 80.6

WHO CRITERIA FOR ESSENTIAL THROMBOCYTHEMIA[a]

- Sustained platelet count ≥450 × 10^9/L
- Bone marrow biopsy showing proliferation of enlarged mature megakaryocytes, without significant increase or left-shift of granulopoiesis or erythropoiesis
- Exclusion of WHO criteria for PV, CIMF, CML, MDS, or other myeloid neoplasm
- *JAK2* mutation or other clonal marker, **or** if no clonal marker, then exclusion of reactive thrombocytosis

CML, chronic myelogenous leukemia; MDS, myelodysplastic syndrome; PV, polycythemia vera; PMF, primary myelofibrosis; WHO, World Health Organization.
[a]All criteria must be met for diagnosis.
From Swerdlow SH, Campo E, Harris NL, et al. World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues. IARC, Lyon, 2008.

Chronic Eosinophilic Leukemia

Chronic eosinophilic leukemia, not otherwise specified is a clonal myeloproliferative neoplasm in which the predominant finding is an eosinophilic proliferation in the blood and marrow (Fig. 80.12).

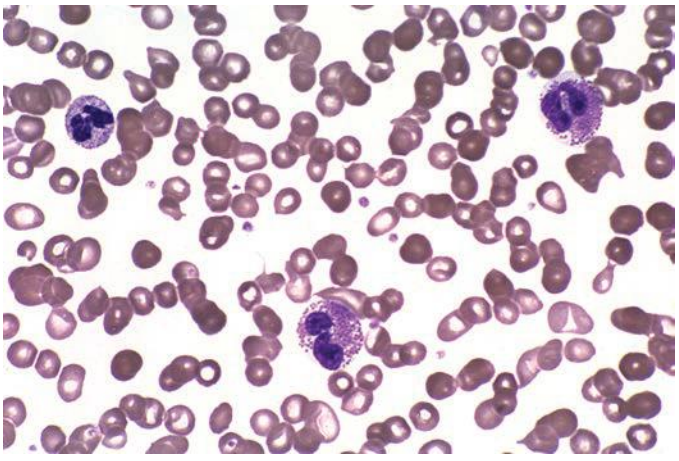

FIGURE 80.12. Chronic eosinophilic leukemia, NOS. Peripheral blood smear showing increased numbers of normal-appearing eosinophils. Wright–Giemsa, 600×.

The peripheral blood shows a sustained proliferation of eosinophils ≥1.5 × 10^9/L and the bone marrow is hypercellular with proliferation of eosinophil precursors. Other myeloid neoplasms with eosinophilia [CML, AML with inv(16)/t(16;16), and neoplasms involving *PDGFRA/B* or *FGFR1*] are excluded. Causes of reactive physiologic eosinophilia, including allergic disease, collagen vascular disease, medication hypersensitivity, pulmonary eosinophilic disease, adrenal insufficiency, parasite infections, other nonmyeloid malignancies, or an aberrant or clonal T-cell population should also be excluded. The latter refers to lymphocyte-variant hypereosinophilia, in which a clonal T-cell population produces cytokines resulting in a reactive eosinophilia[116,117]. The 2008 WHO diagnostic criteria now also require either a clonal cytogenetic or molecular abnormality, or an elevation in blasts >2% in the blood or >5% in the marrow (but less than 20%)[118]. It should be noted that some cases without clonal cytogenetic abnormalities have demonstrated clonality by analysis of X-chromosome inactivation patterns[119].

The diagnosis of idiopathic hypereosinophilic syndrome (HES) is recommended for those cases without any evidence of either a primary myeloproliferative or secondary eosinophilia. Idiopathic HES is defined as eosinophilia ≥1.5 × 10^9/L for 6 or more months without an identifiable cause, with evidence of organ damage. This definition was originally based on criteria of Chusid et al.[120]. The requirement for eosinophilia to persist for a minimum of 6 months need not be strictly adhered to if there is concern for end organ damage. Patients with idiopathic HES may subsequently develop a myeloid malignancy or acquire a clonal abnormality. Eosinophilic tissue damage may affect any organ system, including skin, pulmonary, gastrointestinal, and cardiac[121], presumably related to release of eosinophil granule contents. In the absence of organ damage, the term idiopathic hypereosinophilia is more appropriate.

A variety of clonal cytogenetic abnormalities is reported in CEL, including *PDGFRA/B* rearrangements[19,122,123,124]. The presence of a *PDGFRA/B* rearrangement should be noted in the diagnosis, as these are now classified as neoplasms with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*. Patients with a *PDGFRA/B* rearrangement have a high likelihood of responding to imatinib, but a subset of *FIP1L1–PDGFRA*-negative CEL patients will also respond[19], which argues for a trial of TKI therapy in these patients as well[121].

The diagnostic algorithm for hypereosinophilia should include a bone marrow examination with cytogenetic studies and screening for the *FIP1L1-PDGFRA* fusion gene for those patients whose workup is negative for secondary causes of eosinophilia[121]. As standard cytogenetics will not detect this fusion gene, this must be accomplished by either FISH or RT-PCR[125].

TABLE 80.7

WHO CLASSIFICATION OF MASTOCYTOSIS

Cutaneous mastocytosis
Urticaria pigmentosa/maculopapular cutaneous mastocytosis
Diffuse cutaneous mastocytosis
Solitary mastocytoma of skin
Indolent systemic mastocytosis
Systemic mastocytosis with associated clonal, hematologic non–mast-cell lineage disease
Aggressive systemic mastocytosis
Mast cell leukemia
Mast cell sarcoma
Extracutaneous mastocytoma

WHO, World Health Organization.
From Swerdlow SH, Campo E, Harris NL, et al. World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues. IARC, Lyon, 2008.

Systemic Mastocytosis

Mastocytosis includes a variety of disorders that are characterized by the presence of mast cell aggregates in tissue sections, ranging from isolated indolent proliferations to aggressive systemic disorders[126,127]. The WHO classification of mastocytosis (Table 80.7) separates cutaneous from systemic forms for the disease[128]. Subclassification of systemic mastocytosis subtypes requires correlation with clinical, laboratory, and molecular features (Table 80.8). In tissue or bone marrow biopsy sections, mast cells can range from aggregates of round cells with fine granular pink abundant cytoplasm to more spindled cells with associated fibrosis. Mast cells are often accompanied by eosinophils and small lymphocytes, even plasma cells, and may be overlooked due to these cellular components. On bone marrow aspirate smears, mast cells are most easily identified in the central portion of marrow particles as round or spindled cells with fine basophilic granules that obscure the nucleus. Nuclei may be round to oval in shape, with irregular nuclear contours yielding "dumbbell-shaped" forms. Spindled and more atypical mast cell features tend to correlate with the more aggressive clinical syndromes, but morphology alone is not adequate for classification.

A diagnosis of systemic mastocytosis requires detection of multiple dense mast cell aggregates in tissue sections (major criterion) and one minor criterion or, in the absence of tissue section aggregates, identification of three minor criteria (Table 80.8). Further

TABLE 80.8

WHO CRITERIA FOR SYSTEMIC MASTOCYTOSIS[a]

Major Criterion

Multifocal, dense mast cell infiltrates (≥15 cells) in tissue sections confirmed by tryptase or other special stains

Minor Criteria

- >25% spindled, immature, or atypical mast cells in tissue sections or bone marrow aspirate smears
- Detection of *KIT* D816V mutation
- Expression of CD117 with CD25 and/or CD2
- Serum total tryptase persistently >20 ng/ml (unless associated with a clonal myeloid disorder)

WHO, World Health Organization.

[a]Diagnosis requires major and one minor **or** three minor criteria.

TABLE 80.9

WHO B AND C FINDINGS IN SYSTEMIC MASTOCYTOSIS

B Findings

- >30% of bone marrow mast cells in focal dense aggregates and/or serum total tryptase level >200 ng/ml
- Signs of dysplasia or myeloproliferation in non–mast-cell lineage, but insufficient criteria for a definitive diagnosis of a hematopoietic neoplasm by WHO, with normal or only slightly abnormal blood counts
- Hepatomegaly without liver function impairment, and/or palpable splenomegaly without hypersplenism, and/or palpable or visceral lymphadenopathy

C Findings

- Bone marrow dysfunction manifested by 1+ cytopenias (ANC $<1.0 \times 10^9$/L, Hgb <10 g/dl, or PLT $<100 \times 10^9$/L) without non–mast-cell hematopoietic malignancy
- Palpable hepatomegaly with impairment of liver function, ascites, and/or portal hypertension
- Skeletal involvement with large-sized osteolysis and/or pathologic fractures
- Palpable splenomegaly with hypersplenism
- Malabsorption with weight loss due to gastrointestinal mast cell infiltrates

ANC, absolute neutrophil count; Hgb, hemoglobin; PLT, platelet count; WHO, World Health Organization.
From Swerdlow SH, Campo E, Harris NL, et al. World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues. IARC, Lyon, 2008.

subclassification of systemic mastocytosis requires correlation with clinical, morphologic, and laboratory findings designated as "B" or "C" findings (Table 80.9)[128]. *Indolent systemic mastocytosis*, the most common form of systemic mast cell disease, meets criteria for systemic mastocytosis without B or C findings and no evidence of another hematologic malignancy. Skin lesions are usually present. *Systemic mastocytosis with associated clonal, hematologic nonmast cell lineage disease* is defined just as the name states and occurs in approximately one third of systemic mast cell disease patients. Typically the associated clonal, hematologic disease is a myeloid malignancy. MDS, MPNs, MDS/MPN, AML, and CEL have all been described as associated myeloid malignancies. Associated lymphoid malignancies may also occur, including multiple myeloma, chronic lymphocytic leukemia, acute lymphoblastic leukemia, and hairy cell leukemia. It is the associated hematologic malignancy that determines the prognosis of these patients. In rare cases, mast cell disease is not identified at initial diagnosis but becomes apparent later in the disease. *Aggressive systemic mastocytosis* includes criteria for systemic mastocytosis and includes one or more of the C findings (Table 80.9), which indicates organ dysfunction secondary to mast cell infiltration. These patients have a very short survival of weeks to months. A variant termed *lymphadenopathic mastocytosis with eosinophilia* will present with lymphadenopathy and eosinophilia, but those cases with a *PDGFRA* rearrangement are excluded. Finally, *mast cell leukemia* is a type of systemic mastocytosis with diffuse marrow infiltration with 20% or more mast cells in the bone marrow aspirate smear[129]. This is an aggressive disease with similar prognosis as found in aggressive systemic mastocytosis.

Special stains, including toluidine blue and chloracetate esterase, will mark normal mast cells, but more specific immunophenotypic markers now exist. Mast cells express CD33, CD43, CD68, CD117, and tryptase, with tryptase being the most lineage-specific of these markers[130]. Neoplastic mast cells express CD25 and/or CD2, detectable either by immunohistochemistry or flow cytometry[131]. A typical immunohistochemical panel of CD25, CD117, and tryptase is recommended for most cases to confirm cell lineage and aberrant immunophenotype. In the bone marrow, immunohistochemistry can be performed on the core biopsy and will show paratrabecular aggregates of mast cells with associated fibrosis in systemic mastocytosis (Fig. 80.13). Because bone marrow aspirates may yield hemodilute samples due to the fibrosis with fewer mast cells for analysis, flow cytometry immunophenotyping may require a higher number of events for adequate immunophenotypic characterization of mast cells present[132].

The most common genetic abnormality in mastocytosis is a point mutation of the tyrosine kinase receptor gene *KIT* resulting in a substitution of valine for aspartate at codon 816 of exon 17, Asp816Val, or D816V[128,133,134,135]. D816V is found in over 90% of patients with systemic mastocytosis[128,134,135]. Other mutations include tyrosine or phenylalanine substitutions for aspartate at codon 816 and lysine for glutamic acid at codon 839[136]. *KIT* mutations, including D816V, are not specific for mastocytosis and have been reported in other diseases[137,138].

A proliferation of mast cells with eosinophilia that is associated with the *FIP1L1-PDGFRA* fusion gene[139,140], is now classified with *myeloid and lymphoid neoplasms with eosinophilia and abnormalities of PDGFRA, PDGFRB, or FGFR1*, discussed below.

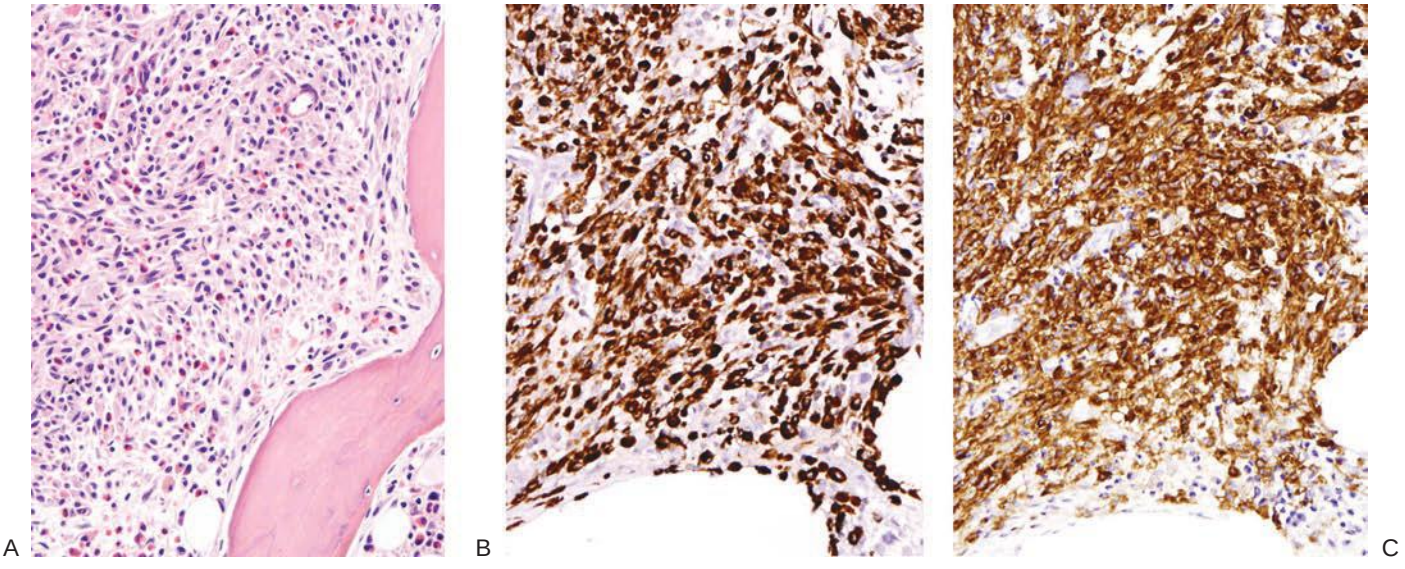

FIGURE 80.13. Aggressive systemic mastocytosis. Bone marrow biopsy shows a paratrabecular nodule of spindled mast cells admixed with scattered eosinophils **(A).** Mast cells are highlighted by tryptase **(B)** and CD25 **(C)**. Hematoxylin and eosin, 200×.

Chronic Neutrophilic Leukemia

Chronic neutrophilic leukemia is a rare myeloproliferative disorder that requires the exclusion of reactive leukocytoses and other MPNs[141–143,144,145,146]. WHO 2008 diagnostic criteria are: peripheral blood leukocytosis ≥25 × 10^9/L with neutrophils and band forms comprising >80%, immature granulocytes <10%, and myeloblasts <1% of white blood cells; bone marrow myeloid hyperplasia with normal maturation, no increase in blasts, and normal or left shifted megakaryocytes; hepatosplenomegaly; no Philadelphia chromosome or *BCR-ABL1*; no rearrangement of *PDGFRA*, *PDGFRB*, or *FGFR1*; no evidence of another myeloproliferative neoplasm (PV, PMF, ET); no evidence of MDS or an MDS/MPN; and either the exclusion of a physiologic neutrophilia (infection, inflammation, underlying malignancy) or molecular or cytogenetic evidence of clonality within myeloid cells[146]. Peripheral blood neutrophils may appear toxic but without dysplasia, and there is no monocytosis, eosinophilia, or basophilia. The platelet count may be normal, but thrombocytopenia develops with progressive splenomegaly. The marrow shows no evidence of dysplasia or significant reticulin fibrosis.

Patients usually are asymptomatic at diagnosis, but do have splenomegaly. Some authors have questioned whether CNL is a distinct clinical entity[147]. The etiology of CNL is unknown, but up to 20% to 30% of cases have been reported as associated with an underlying neoplasm, most typically plasma cell dyscrasias, although it is unclear whether all of these cases are truly clonal proliferations[148–152]. Cytogenetics are abnormal in ~20% of patients and have included trisomy 9, deletion of 11q, deletion of 20q, and trisomy 21[153]. Prognosis is variable and reports of transformation to acute leukemia are documented[142,154,155].

MYELOID AND LYMPHOID NEOPLASMS WITH EOSINOPHILIA AND ABNORMALITIES OF *PDGFRA*, *PDGFRB*, OR *FGFR1*

This new category is comprised of rare myeloproliferative as well as lymphoid neoplasms that share eosinophilia and recently recognized acquired genetic mutations within a specific group of genes resulting in an aberrant tyrosine kinase within a pluripotent hematopoietic stem cell[18,117]. The genes involved are the platelet-derived growth factor receptor alpha (*PDGFRA*) on chromosome 4q12, platelet-derived growth factor receptor beta (*PDGFRB*) at 5q31~33, and fibroblast growth factor receptor 1 (*FGFR1*) at 8p11~13. The associated diseases may present with features of an MPN (CEL or SM), MDS/MPN (CMML), AML, T-lymphoblastic leukemia/lymphoma, or more rarely B-lymphoblastic leukemia/lymphoma. The clinical significance in recognizing these rare but distinct entities is that diseases with rearrangements of *PDGFRA/B* are responsive to TKIs. It is hoped that similar targeted therapy for rearrangements of *FGFR1* will be developed.

Myeloid and Lymphoid Neoplasms with *PDGFRA* Rearrangement

The most common *PDGFRA* rearrangement is *FIP1L1-PDGFRA*, formed by a cryptic deletion at 4q12. This fusion gene has been identified in a subset of patients with CEL and also in patients with features similar to systemic mastocytosis with eosinophilia, but has also been described in AML and T-lymphoblastic lymphoma.

Patients are young men with eosinophilia and a subset may present with elevated serum tryptase levels[139]. A prevalence of 14% of the *FIP1L1-PDGFRA* fusion gene has been reported in patients with primarily eosinophilia[156]. Morphologic findings are those of a hypercellular marrow with a myeloid hyperplasia and marked eosinophilia; fibrosis is typically present (Fig. 80.14). Although in some cases there is no abnormal mast cell infiltrate[156], in other cases tryptase or CD117 immunostaining typically identifies loose, ill-defined mast cell aggregates that are difficult to appreciate on hematoxylin and eosin sections (Fig. 80.14)[139], which does not technically meet WHO criteria for mastocytosis. Mast cells show a similar aberrant immunophenotype with CD25 coexpression and demonstrate the *CHIC2* deletion, a marker for the *FIP1L1-PDGFRA* fusion gene[140], but do not have the *KIT* D816V mutation. Recognition and awareness of this *FIP1L1-PDGFRA* myeloid neoplasm involving eosinophilia and mast cell proliferations but lacking *KIT* mutations should avoid misclassification as CEL or SM[117,121]. The importance of the *FIP1L1-PDGFRA* translocation is underscored by its

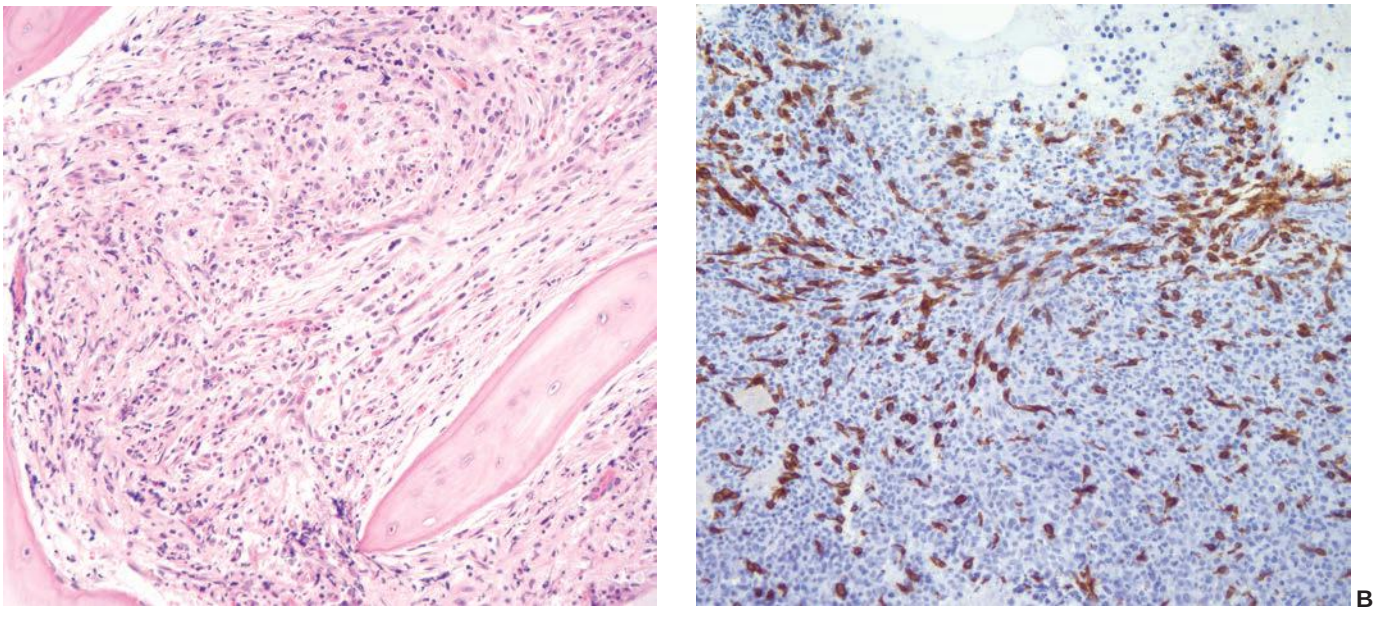

FIGURE 80.14. Chronic eosinophilic leukemia with *PDGFRA*. The bone marrow biopsy is striking for marked fibrosis that accompanies a hypercellular marrow with eosinophilia **(A)**. Hematoxylin and eosin, 200×. A loose infiltrate of mast cells is seen using immunohistochemistry directed against CD117, which was not readily visible on hematoxylin and eosin stained sections of the bone marrow biopsy **(B)**. CD117, 200×.

responsiveness to imatinib with rapid and complete hematologic remissions[19,157–159,160,161].

Myeloid Neoplasms with *PDGFRB* Rearrangement

The most common *PDFGRB* rearrangement is t(5;12)(q33;p13) with production of the fusion oncogene, *ETV6-PDGFRB*, resulting in constitutive activation of the kinase domain of *PDGFRB*[122,123,124]. Translocations involving other fusion partners for *PDGFRB* have also been described[162]. The disease associated with *ETV6-PDGFRB* presents with features suggestive of CMML with eosinophilia (Fig. 80.15). The variant translocations have been associated with features of CMML, CEL, and chronic basophilic leukemia, as well as a Ph-negative MPN resembling CML or aCML. Not all cases have an associated eosinophilia. Isolated cases with features of juvenile myelomonocytic leukemia (JMML) or transformed AML have been reported. The chronic myeloid neoplasms with *PDGFRB* rearrangements appear to be aggressive, with a high risk of acute transformation. Similar to rearrangements of *PDGFRA*, diseases with rearrangements of *PDGFRB* are sensitive to TKI therapy.

Myeloid and Lymphoid Neoplasms with *FGFR1* Abnormalities

Hematologic neoplasms associated with rearrangements of the fibroblast growth factor receptor-1 (*FGFR1*) gene of chromosome band 8q11 are heterogeneous and may manifest as T-lymphoblastic lymphoma, myeloid, lymphoblastic, or mixed lineage acute leukemia, or less commonly B-lymphoblastic lymphoma or CEL[163–166]. Those cases presenting with features of CEL have an increased risk of transformation to acute myeloid leukemia or myeloid sarcoma. Regardless of the presenting neoplasm, patients usually have eosinophilia in the blood, marrow, or both. The *FGFR1* gene most commonly fuses with the *ZMYM2* gene of 13q12 for a t(8;13)(q11;q12), but other translocations may occur[167,168]. Unlike the neoplasms involving *PDGFRA/B*, neoplasms with *FGFR1* rearrangements are not responsive to currently available TKIs.

MYELODYSPLASTIC/ MYELOPROLIFERATIVE NEOPLASMS

Some proliferations have features of both an MPN and MDS[145,169]. These disorders may present with cytopenias and dysplastic changes of any cell line, similar to the myelodysplastic syndromes, as well as leukocytosis, hypercellular marrow with fibrosis, and organomegaly, features more commonly associated with myeloproliferative disorders. The presence of fibrosis alone in a case that is otherwise typical of myelodysplasia is not sufficient to use this category. In addition, patients with a long history of MPN who subsequently develop dysplasia are not classified in this group. The three best delineated overlap MDS/MPNs are chronic myelomonocytic leukemia (CMML), atypical chronic myeloid leukemia (aCML), and juvenile myelomonocytic leukemia (JMML). Features that are helpful in differentiating the chronic phase of CML from atypical CML and chronic myelomonocytic leukemia in adults are listed in Table 80.10.

Chronic Myelomonocytic Leukemia

Chronic myelomonocytic leukemia was originally defined as a myelodysplastic syndrome in the French–American–British (FAB) classification, but is now best classified as a mixed MDS/MPN using the WHO classification[16,170]. Patients often have both dysplastic changes and elevated white blood cell counts with splenomegaly. The disease was originally divided into *myelodysplastic* and *myeloproliferative subtypes* based on a white blood cell count level of 13×10^9/L (i.e., $<13 \times 10^9$/L myelodysplastic type, $\geq 13 \times 10^9$/L myeloproliferative type) using recommendations by the FAB group[171], but clinical studies that stratified patients according to the WBC count failed to show prognostic or biologic differences using this scheme[172,173,174,175].

The diagnosis of CMML requires the presence of $>1 \times 10^9$/L of monocytes in the peripheral blood (Table 80.11). The monocytes may be abnormal in appearance[176]. Promonocytes, with more immature nuclear chromatin, may be present in the blood, but monoblasts are usually rare to absent. Much controversy surrounds the definition of a promonocyte, and distinguishing

TABLE 80.10

THE DIFFERENTIAL DIAGNOSIS OF CHRONIC-PHASE CML, ATYPICAL CML, AND CMML IN ADULTS

Feature	CML	Atypical CML	CMML
BCR/ABL1	+	−	−
WBC	+++	++	+
Basophils[a]	≥2%	<2%	<2%
Monocytes[a]	<3%	3-10%	Usually >10%
Immature granulocytes[a]	>20%	10–20%	<10%
Granulocyte dysplasia	−	++	+
Marrow erythroid hyperplasia	−	−	+

CML, chronic myelogenous leukemia, chronic phase, CMML, chronic myelomonocytic leukemia; WBC, white blood cell count. Only CML is distinguished by the presence of the Philadelphia chromosome or *BCR/ABL1*. CML typically has a higher WBC count than either CMML or atypical CML, with occasional WBC counts of $>200 \times 10^9$/L. A prominent basophilia is also more characteristic of CML, although a mild basophilia may occur in either atypical CML or CMML. A marked monocytosis is more typical of CMML than either CML or atypical CML. CML also shows a marked left-shift in granulocytes on the peripheral blood smear compared to atypical CML or CMML; however, increased circulating blasts may occur in atypical CML compared with CML or CMML. Atypical CML also shows the most prominent granulocytic dysplasia. Finally, a bone marrow erythroid hyperplasia occurs more often in CMML than in *de novo* CML or atypical CML.
[a]Refers to peripheral blood.

a promonocyte from a monoblast or a mature monocyte can be difficult, even in the most experienced of laboratories. A recent consensus guideline defines morphologic criteria to help standardize the differentiation of monoblasts and promonocytes from immature and mature monocytes[177]. The peripheral blood in CMML (Fig. 80.16) may demonstrate cytopenias and dysplastic changes more typical of the myelodysplastic syndromes, or dysplastic changes may be minimal. A subset of patients presents with eosinophilia of $>1.5 \times 10^9$/L and is associated with t(5;12)(q31;p12)[122,124,178,179]. This CMML-like disorder with eosinophilia variant is now classified with the myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*. Although an elevated peripheral blood monocyte count is necessary for the diagnosis of CMML, such a diagnosis should never be made without examination of the bone marrow. Some acute myeloid leukemias with monocytic blasts may show peripheral blood changes similar to CMML due to maturation of the blast cell population in the peripheral blood.

TABLE 80.11

WHO CRITERIA FOR CHRONIC MYELOMONOCYTIC LEUKEMIA

Persistent peripheral blood monocytes $>1.0 \times 10^9$/L
Blasts + promonocytes <20% in blood and marrow
Absence of Philadelphia chromosome or *BCR-ABL1* fusion gene
No rearrangement of *PDGFRA* or *PDGFRB*
Dysplasia in one or more myeloid lineages[a]

WHO, World Health Organization.
[a]If minimal to absent myelodysplasia, the diagnosis also requires either of the following criteria: acquired, clonal cytogenetic abnormality; or persistent monocytosis at least 3 mo and exclusion of all other causes of monocytosis.
From Swerdlow SH, Campo E, Harris NL, et al. World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues. IARC, Lyon, 2008.

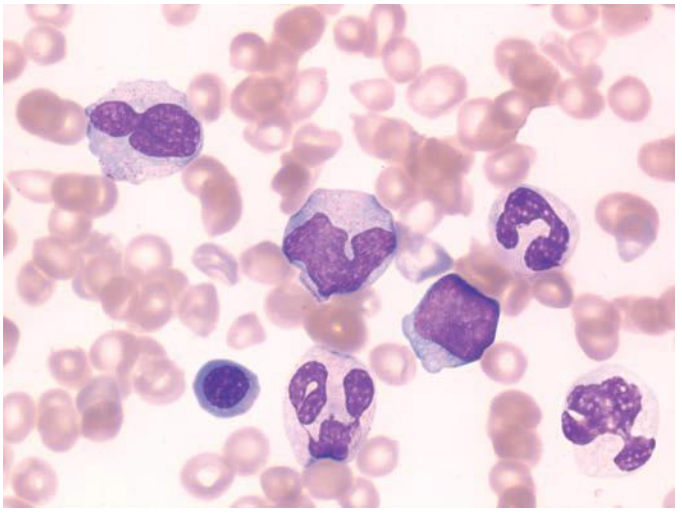

FIGURE 80.16. Chronic myelomonocytic leukemia. Peripheral blood smear with monocytes demonstrating abundant pale cytoplasm containing fine granulation, and folded nuclei with delicate chromatin and small nucleoli. Dysplastic hypogranular neutrophils, a single blast, and a nucleated red cell are also present. Wright–Giemsa, 1000×.

The bone marrow of CMML is usually hypercellular and may demonstrate monocytic or granulocytic hyperplasia (Fig. 80.17). When granulocytic hyperplasia is prominent, it may be difficult to distinguish the abnormal monocyte population from myelocytes. Erythroid precursors and megakaryocytes may demonstrate prominent dysplastic changes, but often these cell types are normal in appearance. Ringed sideroblasts are present in increased numbers in some cases. Blasts and promonocytes may be elevated up to 19%. When bone marrow blasts and promonocytes are ≥20%, such cases are now diagnosed as acute myeloid leukemias. Cases where blasts are <5% in the blood and <10% in the marrow are designated CMML-1, whereas cases with 5% to 19% blasts in the blood or 10% to 19% in the marrow are diagnosed as CMML-2. Multiple studies have shown that increased blasts correlate with poor prognosis[174,180–183]. Variable marrow fibrosis may also be seen in nearly 30% of cases[184].

Ancillary studies are helpful in the differential diagnosis of CMML. Cytochemistry for nonspecific esterase on the peripheral blood and bone marrow confirms the presence of an increase in monocytes and can help differentiate abnormal monocytes of CMML from myelocytes in CML and aCML. Flow cytometry may

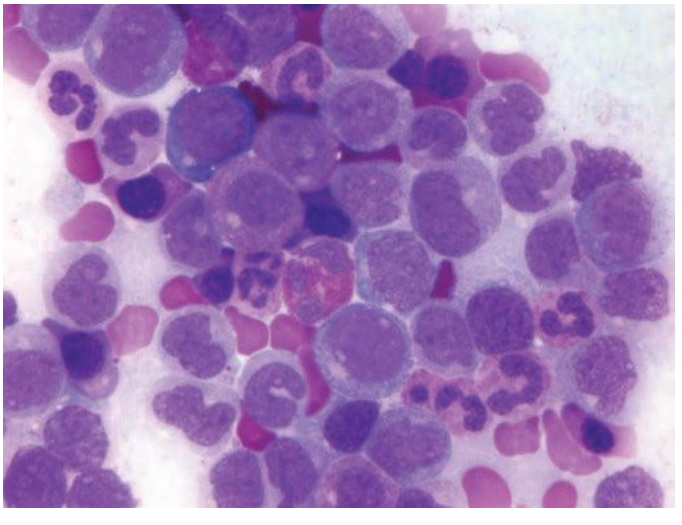

FIGURE 80.17. Chronic myelomonocytic leukemia. Bone marrow aspirate shows a monocytic and left-shifted myeloid hyperplasia. Wright–Giemsa, 1,000×.

be helpful in excluding acute myeloid leukemia, but enumeration of blasts (including monoblasts and promonocytes) must be based on morphology rather than flow cytometry. Cytogenetic and molecular genetic studies, particularly the absence of the Philadelphia chromosome or *BCR-ABL1*, are required to exclude CML. Approximately 20% to 40% of CMML will have detectable clonal abnormalities[185–187]. The most frequent recurring cytogenetic abnormalities include trisomy 8, monosomy7/deletion (7q), structural abnormalities of 12p, and i(17q). Isochromosome 17q has been identified as a possible distinct subtype of mixed MDS/MPN, which is addressed below[188]. *JAK2* mutations have been detected in ~3% of patients[57].

Mutations of *RAS* are detected in approximately one third of CMML cases[189]. Although detection of *RAS* mutations is not typically used for the diagnosis of CMML, abnormalities involving the *RAS* pathway are thought to be involved in the pathogenesis of this disorder and other MPNs, including CML[190].

The differential diagnosis between *BCR-ABL1* negative atypical chronic myeloid leukemia (aCML) and CMML may be difficult, but is critical given the worse prognosis of patients with aCML when compared to CMML. CMML may be distinguished from aCML by peripheral blood features[171], but some overlap with aCML may occur (Table 80.12). Monocytes are slightly elevated in aCML, but do not usually exceed 10%, whereas monocytes in CMML are usually >10%. Also, the degree of granulocyte dysplasia in CMML is not as pronounced as is usually seen in aCML. Atypical CML demonstrates an increase in immature granulocytes, including blasts, promyelocytes, and myelocytes, of up to 20% in the peripheral blood; these cell types are almost always below 10% in the blood of patients with CMML.

Atypical Chronic Myeloid Leukemia, *BCR-ABL1* Negative

Atypical chronic myeloid leukemia is a misnomer with no relation to CML[171,191]. Whenever this diagnosis is considered, CML should be excluded by standard cytogenetics karyotype and PCR or FISH for *BCR-ABL1,* as should rearrangements of *PDGFRA/B*. This rare MDS/MPN affects elderly patients with an apparent male predominance. Patients have some features of usual CML with splenomegaly, an elevated white blood cell count of predominantly granulocytic cells, anemia, and normal or decreased platelets. However, aCML patients are usually older and may have an initial presentation more typical of myelodysplasia with leukopenia and evolution into aCML[192]. The white blood cells are left-shifted with immature granulocytes, including blasts, promyelocytes, and myelocytes, representing 10% to 20% of cells (Fig. 80.18). Monocytes are usually <10% of peripheral blood cells. The bone marrow is hypercellular, with an elevated myeloid-to-erythroid ratio, and marrow fibrosis may be prominent. In contrast to usual CML, basophilia is not prominent, usually <2% of peripheral white blood cells. The myeloid-to-erythroid ratio is usually <10:1 and there is no evidence of the Philadelphia chromosome by either routine karyotype or molecular genetic studies for the *BCR-ABL1* fusion product. Whereas some abnormalities of granulocyte nuclear lobation may be seen in CML, aCML usually has more typical dysplastic changes that may involve all cell lines. Granulocytes may show pseudo-Pelger–Huet changes and cytoplasmic hypogranularity. Dyserythropoiesis and megakaryocyte dysplasia are common and megakaryocytes may be reduced in number with associated thrombocytopenia. Atypical CML appears to be a more aggressive disease than usual CML, with progression occurring within 2 years[192–196]. Patients may develop acute leukemia or bone marrow failure secondary to marked fibrosis. Cytogenetic and molecular genetic studies are essential in the diagnosis of aCML, to exclude t(9;22) or *BCR-ABL1* of usual-type CML. There is no defining cytogenetic abnormality known at this time for aCML, although +8, +13, del(12p), del(20)(q11), and i(17q) have been reported[193–195,197]. In addition, rare cases with features of aCML containing t(5;10)(q33;q22) have been described in which the fusion gene *PDGFRB-CCDC6* is expressed[198–200], but would now be considered cases of myeloid neoplasms with *PDGFRB* rearrangement. In addition, three cases have been shown to have t(4;22)(q12;q11)[201]. *RAS* mutations have also been described[190]. Other ancillary studies, particularly immunophenotyping studies, are usually not helpful unless an elevation in blasts is present.

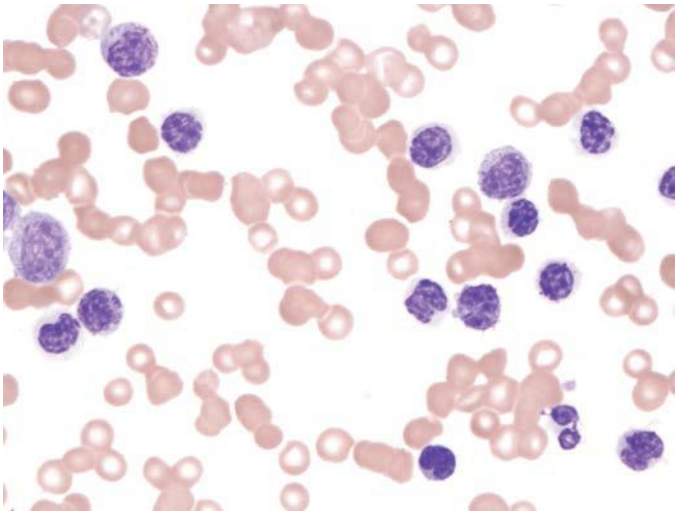

FIGURE 80.18. Atypical chronic myeloid leukemia. The peripheral blood smear shows leukocytosis and marked thrombocytopenia. Granulocytes are left-shifted and dysplastic with hypolobated nuclei and hypogranular cytoplasm. Wright–Giemsa, 600×.

TABLE 80.12

WHO CRITERIA FOR JUVENILE MYELOMONOCYTIC LEUKEMIA

Required Criteria
Peripheral blood monocytes >1.0 × 10^9/L
Blasts + promonocytes <20% in blood and marrow
Absence of Philadelphia chromosome or *BCR/ABL1* fusion gene
Optional Criteria[a]
Increased hemoglobin F for age
Immature granulocytes in peripheral blood
WBC count >10 × 10^9/L
Clonal chromosomal abnormality (i.e., includes monosomy 7)
GM-CSF hypersensitivity of myeloid progenitors in vitro

GM-CSF, granulocyte-macrophage colony-stimulating factor; WBC, white blood cell.
[a]Diagnosis requires all major criteria plus two or more of the optional criteria.
Diagnostic criteria originally from Neimeyer CM, Fenu S, Hasle H, et al. Response to: Differentiating Juvenile Myelomonocytic Leukemia from Infectious Disease. Blood 1998;91:365–367. Reprinted with permission.

Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia[202] is a childhood mixed MDS/MPN that includes childhood leukemias previously classified as CMML, juvenile CML, and infantile monosomy 7 syndrome. JMML, although rare[203–205], is the most common MDS/MPN of children[206,207,208,209,210]. Children with JMML are more often boys and develop the disease by age 4 years in the vast majority of cases. The children usually have elevations of fetal hemoglobin. Skin lesions often precede the diagnosis, and these children present with an elevated white blood cell count, composed of granulocytes and monocytes, which may be identical to CMML of adults (Fig. 80.19).

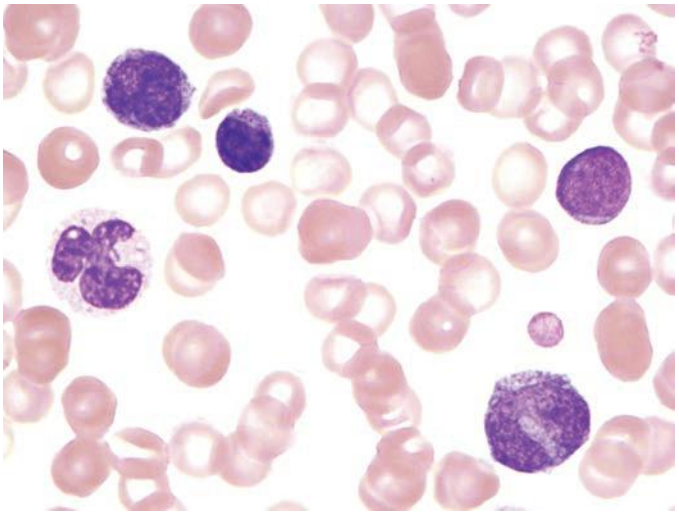

FIGURE 80.19. Juvenile myelomonocytic leukemia. Peripheral blood smear shows left-shifted leukocytosis and dysplastic monocytosis. A small blast is above a sparsely granulated lone platelet adjacent to a monocyte. Two dysplastic monocytes on the upper left contrast with a lymphocyte. Wright–Giemsa, 1,000×. (Reprinted with permission from Tkachuk DC, Hirschmann JV, eds. Wintrobe's atlas of clinical hematology. Philadelphia, PA: Lippincott Williams & Wilkins, 2007. Fig. 4.52.)

Thrombocytopenia is also often present and organomegaly is common. Dysplastic changes and marrow hypercellularity are typical (Fig. 80.20), similar to adult CMML. Overlap with features of adult aCML also occurs and the criteria for aCML and CMML are probably not appropriate in children[211]. JMML must also be differentiated from infection, which can present with similar clinical and morphologic findings[212]. Criteria (Table 80.12) for the diagnosis of JMML describe typical clinical findings of hepatosplenomegaly, lymphadenopathy, pallor, fever, and skin rash[202,213]. Laboratory criteria include the absence of t(9;22), monocytosis of $>1 \times 10^9$/L, and <20% bone marrow blast cells. Exclusion of rearrangements of *PDGFRA/B* is not within current 2008 WHO criteria, but it should be noted that an isolated case of JMML with *PDGFRB* has been reported[214]. *Infantile monosomy 7 syndrome* is clinically similar to JMML and probably represents a subgroup of JMML patients[215]; one notable laboratory difference is that patients with monosomy 7 have normal or modestly elevated hemoglobin F[210]. Cytogenetic abnormalities other than monosomy 7, which may occur with any of the myelodysplastic syndromes, are not specific for JMML. Similar to adult CMML, *RAS* mutations occur in approximately 20% of cases of JMML[216]. There is also an association between JMML and neurofibromatosis type 1, as well as with Noonan syndrome, leading to a markedly increased risk of developing JMML[208,217]. Abnormalities of the *NF1* gene lead to loss of neurofibromin, a guanosine triphosphatase (GTPase)-activating protein for *RAS*, resulting in deregulation of the normal *RAS* signaling pathways, with subsequent selective hypersensitivity of myeloid progenitor cells to granulocyte-macrophage colony-stimulating factor (GM-CSF)[218,219]. The increased prevalence of JMML in Noonan syndrome is linked to abnormalities in the *PTPN11* gene, a gene that encodes SHP-2, required for *RAS*-dependent functions; these mutations also induce hypersensitivity of myeloid progenitors to GM-CSF[220]. Given the aggressive clinical course of JMML with current treatment regimens[206,207,210,221], work has focused on targeting the *RAS* pathway, which may result in new therapies[222,223].

Myelodysplastic/Myeloproliferative Neoplasm, Unclassifiable

Some cases with features of both MDS and MPN do not fit well into any of the previously mentioned categories. Many of these cases have typical features of myelodysplasia, as well as an atypical finding more suggestive of a myeloproliferative disorder, such as marked marrow fibrosis and hypercellularity or organomegaly. Such cases may be termed *myelodysplastic/myeloproliferative disease, unclassifiable,* with a comment describing the atypical findings. One such syndrome is *refractory anemia with ring sideroblasts (RARS) associated with marked thrombocytosis*[113–115,169,224]. These cases have no sex predilection or specific cytogenetic abnormality and must be differentiated from the 5q syndrome. The bone marrow contains >15% ringed sideroblasts with an accompanying atypical megakaryocytic proliferation; megakaryocytes often resemble those seen in essential thrombocythemia (Fig. 80.21). The platelet counts are $>600 \times 10^9$/L. An analysis of 38 such patients showed a heterogeneous spectrum of diseases based on bone marrow findings and cytologic features, including ET, PMF, and MDS[225]. *JAK2* mutations are found in a majority of cases of RARS-T[226]. Also recently described is a mixed MDS/MPN associated with *isochromosome 17q* that occurs in adults with a male predominance associated with severe hyposegmentation of neutrophil nuclei, monocytosis, and a high rate of transformation to acute myeloid leukemia[188]. Abnormalities

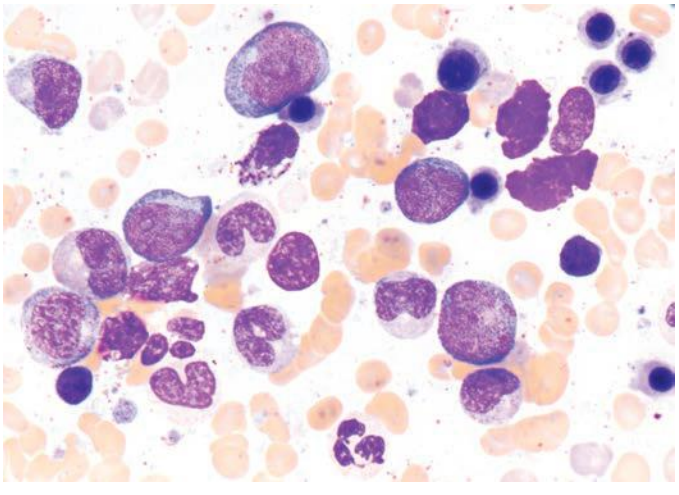

FIGURE 80.20. Juvenile myelomonocytic leukemia. Bone marrow aspirate shows numerous erythroid precursors and left-shifted immature myeloid cells with dysplasia. Wright–Giemsa, 600×.

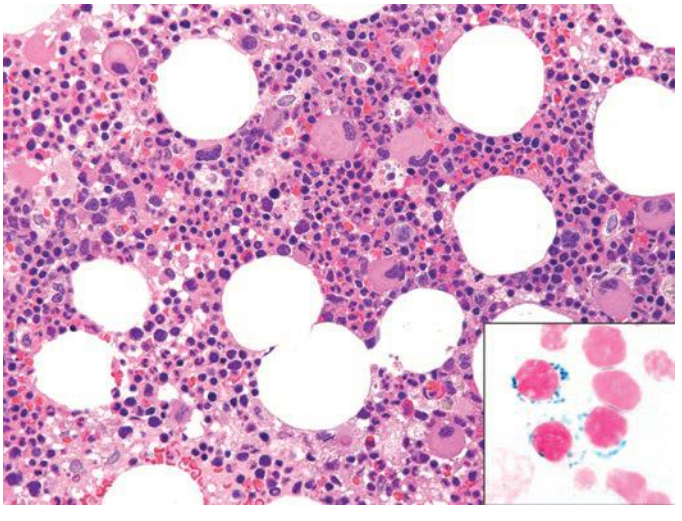

FIGURE 80.21. Refractory anemia with ring sideroblasts and thrombocytosis. The bone marrow biopsy shows dysplastic megakaryocytes, small hypolobated forms, and micromegakaryocytes, in a hypercellular marrow, with inset demonstrating numerous ringed sideroblasts. Hematoxylin and eosin, 400×. Prussian blue stain, 1,000×.

of chromosome 3q21q26 are also associated with MDS or AML patients, accompanied by thrombocytosis with micromegakaryocytes on bone marrow histology[227–232]. These cases usually have a poor prognosis, and should not be placed in the unclassifiable mixed MDS/MPN category. Rather, they should be classified into the appropriate MDS or AML category.

CONCLUSION

The classification of myeloid neoplasms now includes MPN; neoplasms with eosinophilia and abnormalities of *PDGFRA/B* or *FGFR1*, MDS/MPN, MDS; and acute myeloid leukemias. MPN and MDS/MPN, both clonal stem cell diseases, share myeloproliferative features including typically hypercellular marrows, cell lineage maturation, and organomegaly. The MPNs generally differ by which myeloid cell lineage dominates hematopoiesis, and the main players include CML, PV, ET, and PMF. The new category of myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA/B* or *FGFR1* represents another significant step forward in the molecular classification of neoplastic diseases. This category is also highly clinically relevant, due to the responsiveness of the *PDGFRA/B* associated neoplasms to TKI therapy. The overlap MDS/MPNs also show dysplastic features and variable amounts of effective hematopoiesis; these disorders include CMML, JMML, and aCML. Given the mix of morphology among these diseases, correlation with clinical, hematologic, and cytogenetic/molecular genetic findings is imperative for precise classification.

CHAPTER 81

CHRONIC MYELOID LEUKEMIA

Michael W.N. Deininger

HISTORICAL PERSPECTIVE

Chronic myeloid leukemia (CML), although a rare disease, has disproportionately influenced hematology/oncology and modern medicine. Reports of what was probably CML date back to the middle of the 19th century. In 1845, John Hughes Bennett, an Edinburgh pathologist, described a "Case of Hypertrophy of the Spleen and Liver in which Death Took Place from Suppuration of the Blood."[1] It was only a few weeks later when Rudolf Virchow of Berlin reported on a very similar case in an article titled, "Weisses Blut" (white blood).[2] It is likely that both patients involved indeed suffered from CML and presented with its most typical clinical features: leukocytosis and splenomegaly. Whereas Bennett believed that the new disease represented an infection, Virchow recognized the neoplastic nature of the process and coined the term "leukemia," from the Greek words "λευκον αιμα," which mean "white blood." The ensuing academic dispute was eventually settled cordially: Virchow acknowledged Bennett's priority of discovery and Bennett that leukemia is a neoplastic rather than infectious process. Ironically, both were actually preceded by Alfred Donné of Paris, Bennett's previous mentor, whose description of leukemia in his 1844 *Cours de Microscopie* had lacked sufficient detail and visibility to attract attention.[3] The next leap forward came in 1872, when Ernst Neumann established the bone marrow as the origin of leukemia and of blood cells in general.[4] The following 100 years saw progress in understanding leukemia, with perhaps the most notable advance being the recognition of myeloid versus lymphoid disease. In 1951, William Dameshek posited that CML belongs to a larger group of related disorders characterized by increased numbers of differentiated blood cells as the result of enhanced proliferation of the bone marrow, which he accordingly named myeloproliferative disorders.[5]

A fundamental experimental breakthrough by Philadelphia cytogeneticists Peter Nowell and David Hungerford followed in 1960. They observed an abnormally small G-group chromosome in metaphase spreads from several patients with CML.[6] This first consistent karyotypic abnormality associated with cancer settled the debate as to whether DNA or proteins transmitted the neoplastic phenotype to the next generation of cells. The discovery team anticipated that this minute chromosome in CML might represent the first in a long list of cancer chromosomes, and thus referred to it as the Ph[1] chromosome (now more commonly known as Ph). The presence of Ph in all CML cells was indicative of their clonal origin from a single parental cell. Formal proof for this notion was lacking until Fred Fialkow demonstrated X-chromosome inactivation in CML neutrophils by uniform glucose-6-phosphate dehydrogenase (G6PD) isoenzyme expression.[7]

In 1973, Janet Rowley recognized that Ph was not just a shortened chromosome 22, but was in fact the product of a reciprocal translocation between chromosomes 9 and 22.[8] Over the following 25 years, the molecular anatomy and consequences of t(9;22) were revealed with increasing resolution. Work from several laboratories identified the genes juxtaposed by t(9;22) to form a fusion gene on Ph.[9,10] The chromosome 9 partner was found to be *ABL1* (formerly *ABL*), the human homolog of v-abl oncogene of the Abelson murine leukemia virus (A-MuLV).[11] On the derivative chromosome 22, *ABL1* sequences consistently translocated to the same genetic region, which became known as the "breakpoint cluster region" (*BCR*), a name that was subsequently used to describe the new gene fused upstream of *ABL1*. The next critical set of discoveries was that BCR-ABL1, similar to murine v-Abl, is a constitutively active tyrosine kinase and that kinase activity is required for cellular transformation.[12] Lastly, retroviral expression of BCR-ABL1 in murine bone marrow cells was found to induce a CML-like disease in mice, another milestone in the history of cancer research.[13]

Therapy developed slowly. Arsenicals, in use for cancer treatment since ancient times, were the only CML therapy available in the 19th century, usually in the form of Fowler's solution, which contained potassium arsenite. The German physician Heinrich Lissauer is credited with the first publication on the remarkable efficacy of Fowler's solution in a patient with leukemia.[14] In an 1882 *Lancet* paper, Conan Doyle, the author of the Sherlock Holmes detective stories, published on a patient with the clinical presentation of CML who achieved a partial response to arsenic.[15] In the 1920s, splenic irradiation was used for symptomatic relief and remained the mainstay of therapy for the first half of the 20th century. In 1959, busulfan was introduced as the first drug that reliably controlled white blood cell counts in CML and, 10 years later, hydroxyurea premiered as the first intervention that significantly prolonged survival.[16,17] Despite these advances, a cure remained elusive until the late 1970s, when the disappearance of the Ph^+ clone in CML patients treated with allogeneic stem cell transplantation was reported.[18] In the early 1980s, interferon-α (IFN) became the standard drug therapy. This agent induced complete cytogenetic responses (CCyRs) and long-term survival in 10% to 20% of patients.[19]

In 1992, Alexander Levitzki proposed inhibiting ABL1 with small molecules called tyrphostins as a potentially useful approach to treat leukemias driven by *ABL1* oncogenes.[20] At about the same time, Alois Matter, Jürg Zimmermann, and Nick Lydon at Ciba-Geigy had synthesized a compound called GCP57148B,[21] now known as imatinib, that inhibited ABL1 and a restricted set of other tyrosine kinases at submicromolar concentrations. Clinical trials led by Brian Druker from Oregon Health & Science University, very much in the face of skepticism by the manufacturer, rapidly established imatinib's unprecedented activity in patients with CML and revolutionized CML therapy.[22,23,24] Dasatinib and nilotinib, tyrosine kinase inhibitors (TKIs) with increased activity against BCR-ABL1, were initially developed to overcome imatinib resistance, but have since gained approval for frontline therapy.[25,26] However, once CML has progressed beyond the chronic phase, allogeneic stem cell transplant is still the recommendation for all eligible patients. There is compelling evidence that CML stem cells are not dependent on BCR-ABL1 kinase activity, implying that treatment must continue indefinitely in order to prevent recurrence of active leukemia. Current research efforts focus on improving the poor prognosis of advanced CML, controlling TKI resistance, and developing strategies to eradicate CML stem cells.

PATHOPHYSIOLOGY

It is thought that CML originates from a single hematopoietic cell that has acquired Ph. In contrast to an acute myeloid leukemia (AML)–associated fusion gene such as *MOZ-TIF2*, *BCR-ABL1* does not confer self-renewal capacity, implying that the initial translocation event must occur in a multipotent hematopoietic stem cell already endowed with this critical property.[27] *BCR-ABL1* is detected in cells of all hematopoietic lineages.[28] For unknown reasons, the *BCR-ABL1*–induced cellular expansion predominantly

targets the myeloid progenitor cell compartment, giving rise to the clinical phenotype, whereas many newly diagnosed patients have mostly Ph$^-$ stem cells.[29,30] As a consequence, the hierarchical organization of hematopoiesis is maintained during the chronic phase, and a substantial number of Ph$^-$ stem cells are available to reconstitute the system when CML hematopoiesis is therapeutically suppressed. Both factors are important for the response to TKIs. The salient biologic features of CML cells are as follows: increased proliferation, resistance to apoptosis, perturbed interaction with bone marrow stromal cells, and genetic instability.[31]

BCR-ABL1 Translocation and Fusion Gene

Ph is the result of a reciprocal translocation between the long arms of chromosomes 9 and 22 [t(9;22)(q34;q11)].[8] As a result of this translocation, genetic sequences from the *ABL1* gene on 9q34 are fused downstream of the *BCR* gene on 22q11 (Fig. 81.1A,B). With rare exceptions, breaks in chromosome 22 localize to one of three *BCRs* and determine the portions of *BCR* retained in the *BCR-ABL1* fusion mRNA and protein. In contrast, the chromosome 9 breaks can occur over a large genetic region, 5′ of *ABL1* exon Ib, 3′ of *ABL1* exon Ia, or most commonly between the two alternative first *ABL1* exons. Rare exceptions aside, splicing consistently leads to fusion mRNAs that encompass *ABL1* exons 2 to 11 (Fig. 81.2C).[32] Breakpoints in the minor *BCR* (m-*BCR*) give rise to an e1a2 fusion mRNA and p190$^{BCR-ABL}$, which is found in 2/3 of Ph$^+$ acute lymphoblastic leukemia (ALL) cases. The very rare p190$^{BCR-ABL}$ positive CML is associated with monocytosis and exhibits a more aggressive clinical course.[33,34] In an overwhelming majority of CML patients, the break occurs in the major *BCR* (M-*BCR*), generating e13a2 or e14a2 fusion mRNAs (formerly referred to as b2a2 and b3a2) and a p210$^{BCR-ABL}$ fusion protein. p230$^{BCR-ABL}$, the largest of the fusion proteins, corresponds to a break in the micro-*BCR* (*μ-BCR*), an e19a2 fusion mRNA, and is associated with neutrophilic predominance and possibly less aggressive disease.[35] In addition to the major types of *BCR-ABL1* fusion mRNAs, there are a number of rare variants whose main clinical significance is that they can give rise to misleading reverse transcription polymerase chain reaction (RT-PCR) results.[36–38] Approximately two-thirds of CML cases also express the reciprocal *ABL1-BCR* mRNA, but there is no evidence that this influences disease biology or prognosis.[39,40]

BCR and ABL1 Proteins and Their Contribution to Cellular Transformation

BCR is an ubiquitously expressed 160 kD cytoplasmic protein with several functional domains (Fig. 81.2A). The N-terminus contains a coiled-coil motif that allows for dimerization, which is critical for activation of ABL1 kinase in the BCR-ABL1 fusion protein.[41] Further 3′ there are: a serine/threonine kinase motif whose only recognized substrate is Bap-1, a member of the 14-3-3 family of proteins,[42] and *dbl*-like and pleckstrin-homology (PH) domains that stimulate the exchange of GTP for GDP on Rho guanidine exchange factors.[43] The C-terminus contains a putative site for calcium-dependent lipid binding (CaLB) and a GTPase activating function (RAC-GAP). The latter regulates activity of RAC, a small GTPase of the RAS superfamily that regulates actin polymerization and an NADPH oxidase in phagocytic cells.[44,45] Despite these diverse functions, *Bcr* null mice are viable and fertile and the only recognizable defect is an increased oxidative burst in neutrophils, suggesting redundancy of signaling pathways.[46] BCR can be phosphorylated on several tyrosine residues, most importantly tyrosine 177, which binds GRB2, an adapter molecule involved in activation of the RAS pathway in CML cells.[47,48,49] The Rho-GEF and RAC-GAP functions of BCR that are retained in p210$^{BCR-ABL}$ but missing from p190$^{BCR-ABL}$ are thought to attenuate the disease and cause a phenotypic shift from lymphoid to myeloid

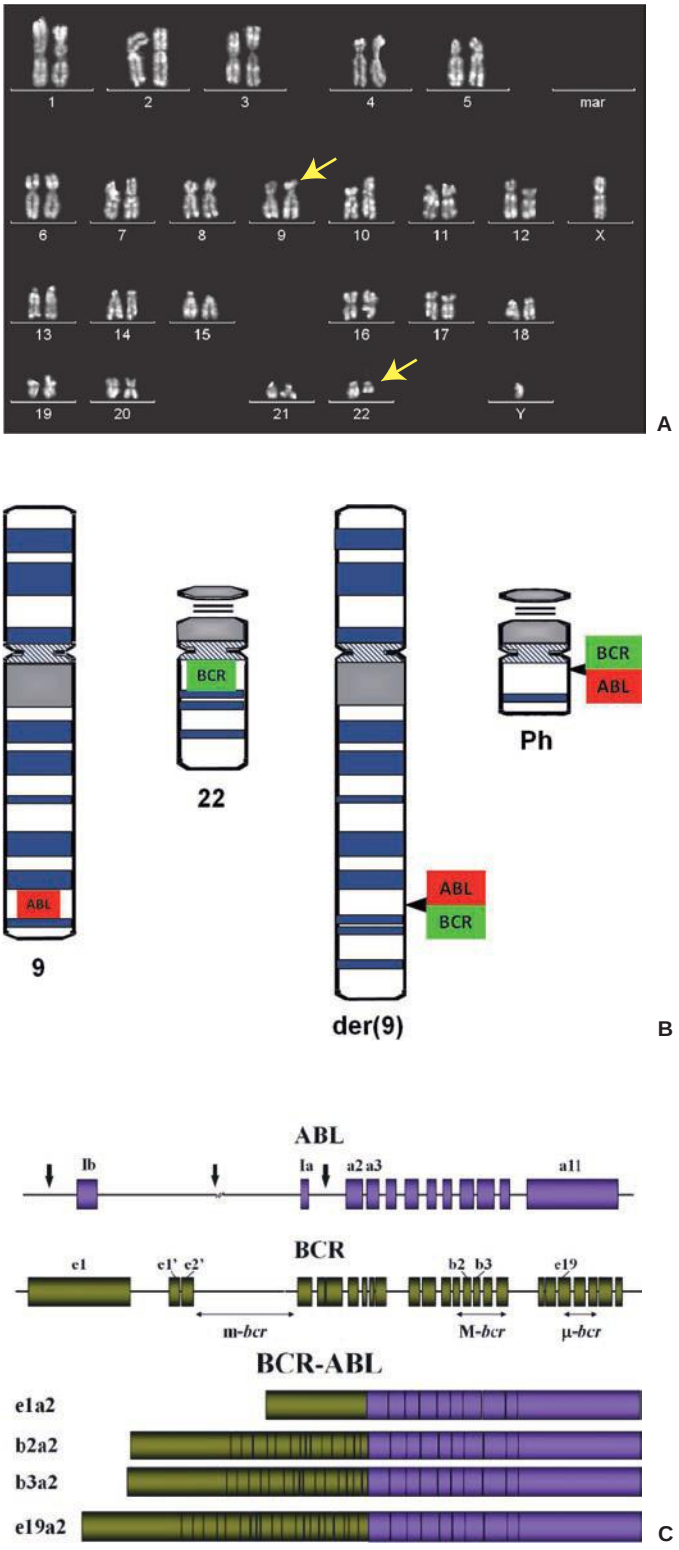

FIGURE 81.1. A: Metaphase karyogram of a newly diagnosed man with CML. The yellow arrows indicate the derivative chromosome 9 and the Philadelphia chromosome (Ph). **B:** Schematic of chromosomes 9, 22 and the derivatives resulting from t(9;22)(q34;q11). **C:** Molecular anatomy of the *BCR-ABL1* fusion gene. The upper panel shows the *ABL1* gene, which contains 11 exons, including two alternative first exons. Arrows indicate the breakpoints at the genomic level. The middle panel depicts the *BCR* gene with the three breakpoint cluster regions (*BCRs*). Breaks in the minor *BCR* (m-*BCR*) give rise to p190$^{BCR-ABL}$, which is typical of Ph$^+$ ALL, whereas breaks in the major *BCR* (M-*BCR*) generate p210$^{BCR-ABL}$, typical of CML and also found in 1/3 of Ph$^+$ ALL patients. Lastly, breaks in the micro-*BCR* (*μ-BCR*) lead to p230$^{BCR-ABL}$, which is associated with neutrophilia. The lower panel shows the structure of the corresponding mRNAs. Note that *BCR* exons b2 and b3 are now commonly referred to as exons e13 and e14, respectively.

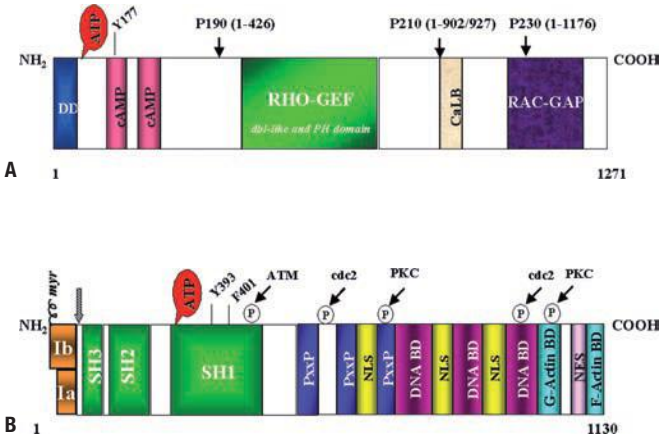

FIGURE 81.2. A: Structure of the BCR protein. Note the dimerization domain (DD) and the two cAMP kinase homologous domains at the N-terminus. Y177 is the autophosphorylation site crucial for binding to GRB2. The center of the molecule contains a region homologous to Rho guanidine nucleotide exchange factors (Rho-GEF) as well as dbl-like and pleckstrin-homology (PH) domains. Toward the C-terminus, a putative site for calcium-dependent lipid binding (CaLB) and a domain with activating function for RAC-GTPase (RAC-GAP) are found. Arrowheads indicate the position of the breakpoints in the BCR-ABL1 fusion proteins. **B:** Structure of the ABL1 protein. The type Ia isoform is slightly shorter than type Ib, which contains a myristoylation (myr) site for attachment to the plasma membrane. Note the three SRC-homology (SH) domains situated toward the NH_2 terminus. Y393 is the major site of autophosphorylation within the kinase domain, and phenylalanine 401 (F401) is highly conserved in PTKs containing SH3 domains. The middle of the protein is dominated by proline-rich regions (PxxP) capable of binding to SH3 domains and also harbors one of three nuclear localization signals (NLS). The C-terminus contains DNA binding as well as G- and F-actin binding domains. Phosphorylation sites by ATM, cdc2, and PKC are shown. The arrowhead indicates the position of the breakpoint in the BCR-ABL1 fusion protein.

leukemia.[43,50,51] It is possible that this reflects the fact that hematopoietic stem cells are susceptible to transformation by $p210^{BCR\text{-}ABL}$, and $p190^{BCR\text{-}ABL}$ targets pre–B–cells.[52] It has been suggested that BCR may negatively regulate BCR-ABL1–induced leukemogenesis.[53] However, the fact that incidence and biology of $p190^{BCR\text{-}ABL}$-induced leukemia are identical in $Bcr^{-/-}$ mice compared to wildtype mice indicates that BCR is not essential for Ph^+ leukemia.[54]

ABL1, the human homolog of the v-*abl* oncogene of the A-MuLV,[55] encodes a nonreceptor tyrosine kinase.[56] The 145-kDa ABL1 protein is ubiquitously expressed and exhibits two isoforms arising from alternative splicing of the first exon.[57] The N-terminal region contains three SRC-homology domains (SH1 to SH3). SH1 carries the tyrosine kinase function, whereas the SH2 and SH3 domains engage in protein–protein interactions (Fig. 81.2B).[58] In addition, proline-rich sequences in the center of ABL1 interact with SH3 domains of other proteins such as Crk.[59,60] The C-terminus contains nuclear localization, DNA binding,[61] and actin-binding motifs.[62] Diverse functions have been attributed to ABL1, which include negative regulation of cell cycle and proliferation,[63,64] response to genotoxic stress,[65,66,67,68,69] and integrin signaling.[70] The emerging picture is complex and perhaps ABL1 could best be characterized as a cellular module that integrates signals from various extra- and intracellular sources to influence decisions in regard to cell cycle and apoptosis. It must be stressed, however, that many results are based primarily on in vitro studies in fibroblasts, not hematopoietic cells. Unfortunately, the generation of *Abl1* null mice failed to shed light on the physiologic function of ABL1. These mice have a severe phenotype, including high perinatal mortality, runting, and skeletal and immune system defects.[71,72] Mice null for *Abl1* and the *Abl*-related gene (formerly *Arg*, now *Abl2*) are embryonically lethal due to absence of neurulation.[73] The latter observation raised considerable concerns about the potential side effects of ABL inhibitors that were fortunately not confirmed clinically.

Constitutive Kinase Activation in the BCR-ABL1 Fusion Protein

In contrast to ABL1, a tightly regulated nuclear kinase, BCR-ABL1 is constitutively active and localized in the cytoplasm. The mechanism by which the replacement of the ABL1 N-terminus with BCR sequences leads to kinase activation has been probed by mutagenesis and X-ray crystallography.[74] A critical feature is the coiled-coil domain of BCR that promotes dimerization, which allows for an initial transphosphorylation event, followed by autophosphorylation of additional tyrosine residues to activate the kinase fully.[75] Moreover, the N-terminal "cap" region of ABL1, when myristoylated, binds a hydrophobic pocket at the base of the kinase domain, thereby forming a latch that maintains ABL1 in an inactive state.[76–78] Replacement of the cap by BCR sequences abolishes this negative regulation. Unexpectedly, recent studies have shown that certain residues within the SH2 domain participate in the regulation of kinase activity, an indication of the complexity of kinase regulation.[79] Lastly, trans-acting binding partners such as the ABL1 interacting proteins have been implicated as physiologic inhibitors whose down-regulation upon disease progression may contribute to BCR-ABL1 activation.[80,81]

Signaling Pathways in BCR-ABL1 Transformed Cells

Two decades of intense research have identified multiple BCR-ABL1 substrates, binding partners, and downstream signaling molecules involved in the process of cellular transformation (Fig. 81.3). Much effort has been directed at linking these pathways to the specific pathologic features that characterize CML cells, such as increased proliferation or genetic instability leading to disease progression. A comprehensive review of the multiple pathways implicated in BCR-ABL1 transformation is beyond the scope of this chapter. Studies of mice with homozygous deletions of signaling proteins have identified very few pathway components with a truly essential function, speaking to the extensive redundancy of the transformation network.

Phosphatidylinositol-3 Kinase

In BCR-ABL1–expressing cells, phosphatidylinositol-3 kinase (PI3K) is activated by at least two different mechanisms. The first requires autophosphorylation of BCR-ABL1 tyrosine 177 (Y177), which generates a docking site for the GRB2 adapter protein, which in turn recruits GAB2, another adapter, into a complex that activates PI3K.[82,83] Consistent with a critical role for the Y177/GRB2/GAB2 axis, mutation of tyrosine 177 to phenylalanine or lack of GAB2 abrogates myeloid leukemia in murine models.[83] Alternatively, PI3K can be activated by complex formation between the p85 regulatory subunit of PI3K, CBL, and CRKL, which bind to the SH2 and proline-rich domains of BCR-ABL1.[84] The main downstream outlet of PI3K is the serine–threonine kinase AKT, a major conduit for oncogenic signals in different cancer types. In CML cells, AKT enhances survival by suppressing activity of the forkhead O transcription factors (FOXO), as well as phosphorylation and inactivation of proapoptotic proteins such as BAD.[85,86,87] Additionally, PI3K promotes proteasomal degradation of p27, a cyclin-dependent kinase inhibitor, through up-regulation of SKP2, the F-Box recognition protein of SCF^{SKP2} E3 ubiquitin ligase. Accordingly, absence of SKP2 from leukemia cells prolongs survival in a murine CML model.[88] Furthermore, AKT activates mTOR, which phosphorylates ribosomal proteins p70S6 kinase (S6K) and 4E-BP1. S6K activation promotes cell growth and proliferation by yet undefined mechanisms. However, phosphorylation by mTOR has been shown to inactivate 4EBP-1, thereby activating the translation initiation factor eIF4E to enhance protein synthesis.[89,90]

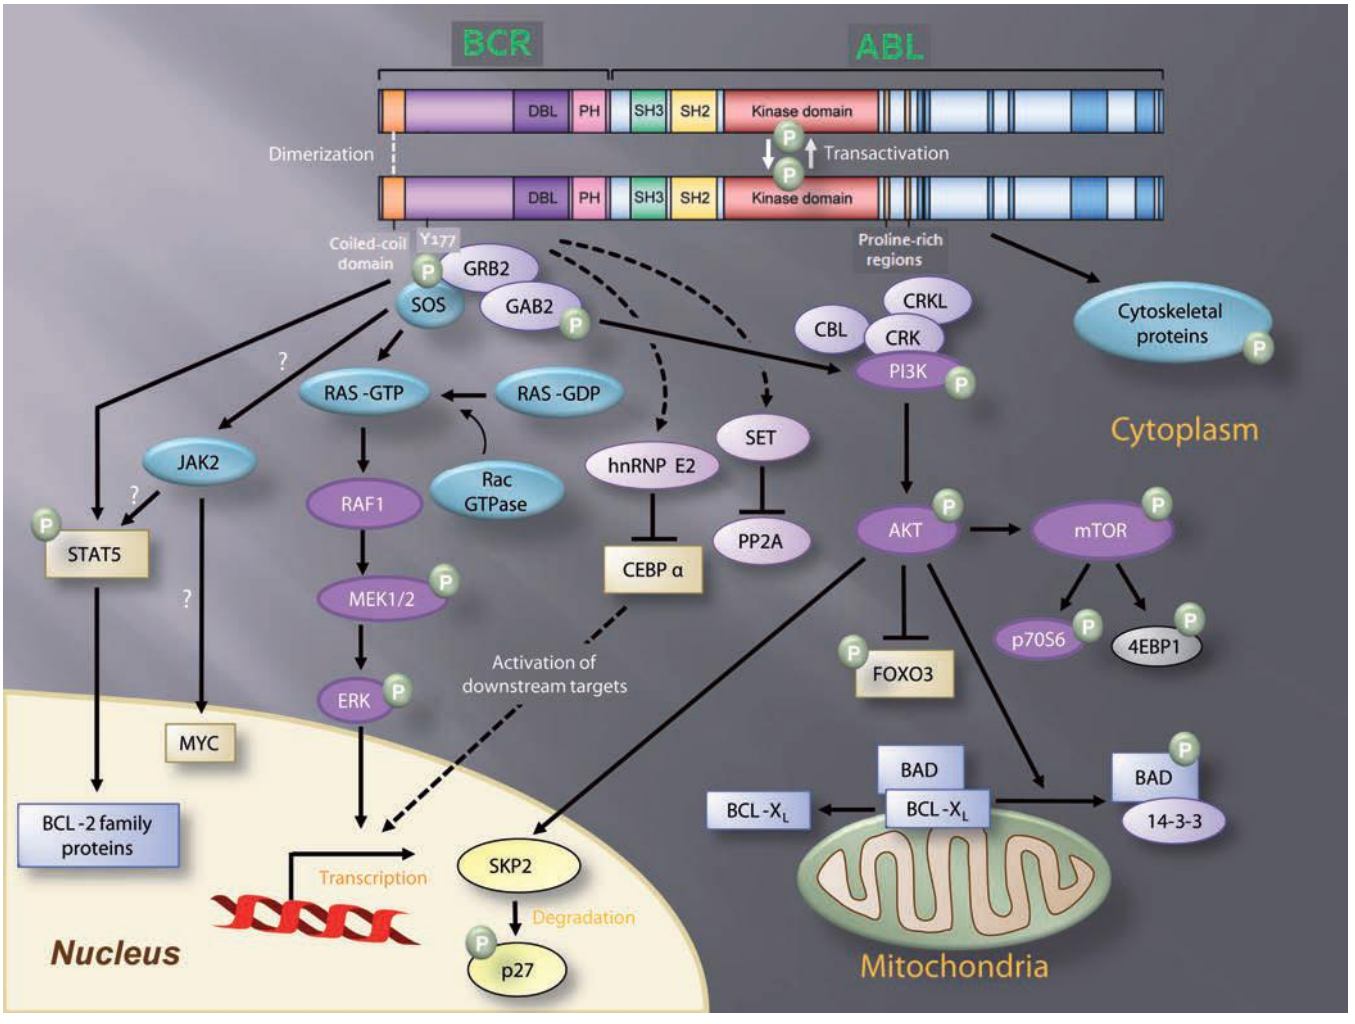

FIGURE 81.3. Simplified representation of molecular signaling pathways activated in chronic myeloid leukemia (CML) cells. Autophosphorylation generates docking sites on BCR-ABL1 that facilitate interaction with intermediary proteins such as GRB2. CRKL and CBL are also direct substrates of BCR-ABL1 that are part of a multimeric complex. Additionally, BCR-ABL–dependent signaling complexes activate multiple pathways, which modulate the function of critical proteins (blue) that inhibit apoptosis, enhance proliferation, perturb adhesion and migration, and impart genomic instability. For details see text.

RAS/Mitogen-activated Protein Kinase Pathways

Phosphorylation of tyrosine 177 with recruitment of GRB2 and SOS promotes exchange of GTP for GDP on RAS.[82,91] In its GTP-bound form, RAS activates the serine–threonine kinase RAF-1,[92,93] which subsequently activates mitogen-activated protein kinase (MAPK). Other small GTPases such as RAC1/2 have also been implicated in BCR-ABL1 signaling.[94] Lack of RAC1/2 has been shown to delay *BCR-ABL1* leukemia in a murine model.[95]

Janus Kinase/Signal Transducer and Activator of Transcription Pathway

The transcription factor signal transducer and activator of transcription 5 (STAT5) is constitutively tyrosine-phosphorylated in CML cells. Initial experiments in mice failed to demonstrate a critical role for STAT5.[96] However, it was subsequently established that the mice used in this study were not null for *Stat5*, but expressed an N-terminally deleted protein with partially retained function. Although STAT5 is not required for the initiation of CML, there is convincing evidence that it plays a rate-limiting role in leukemogenesis.[97,98] In fact, absence of only STAT5A or overexpression of a dominant-negative STAT5 mutant in the bone marrow attenuates CML.[99] The principal consequence of STAT5 activation is inhibition of apoptosis by enhancing transcription of antiapoptotic proteins such as MCL-1 and BCL-X_L.[100] BCR-ABL1 may activate STAT5 through direct phosphorylation or indirectly by promoting phosphorylation by HCK or Janus kinase 2 (JAK2).[101,102] There is controversy about the role of JAK2 in *BCR-ABL1*–induced leukemia. Previous studies had suggested that JAK2 plays an important if not essential role,[103] but a recent report using conditional knockout technology showed that murine CML does not require JAK2.[104]

Cytoskeletal Proteins

BCR-ABL1 phosphorylates several proteins involved in adhesion and migration, including focal adhesion kinase (FAK), CRKL, paxillin, p130CAS, and HEF1.[105–110] Although details remain to be elucidated, it is thought that this may explain why integrin-mediated adhesion of CML progenitors to bone marrow stroma and extracellular matrix is defective. Alternatively, integrin functions may be compromised through activation of RAS or BCR-ABL1 binding to F-actin.[82,111] Given that adhesion to integrins inhibits proliferation of hematopoietic progenitors, the defect in integrin function may contribute to the premature circulation as well as the abnormal proliferation of Ph^+ progenitor cells.[112]

DNA Damage Surveillance and Repair Pathways

The fact that untreated CML-CP invariably progresses to blast phase CML (CML-BP) is testimony to the profound dysregulation of DNA repair in CML. A central finding is the two- to sixfold increase in reactive oxygen species (ROS) in CML $CD34^+$ cells compared with normal controls, which is particularly pronounced in CML-BP cells.[113,114,115] ROS generate oxidized bases and double-strand breaks (DSB). It was estimated that CML cells may contain up to eight times more oxidized bases and DSBs than normal cells.[116] Although PI3K activation is primarily responsible for ROS production,[117] an additional mechanism operational in lymphoid blast phase cells is activation of activation-induced cytidine deaminase (AID), which promotes point mutations.[118] The consequences of increased DNA damage are greatly aggravated by the impairment of DNA damage surveillance and repair. Multiple mechanisms have been implicated, and many but not all of these mechanisms are BCR-ABL1-dependent. For example, BCR-ABL1 has been shown to impair the intra-S-phase cell cycle checkpoint through suppression of checkpoint kinase 1 (CHK1), either by inhibition of the nuclear protein kinase ATR[119] or down-regulation of BRCA1, a substrate of ataxia telangiectasia mutated (ATM).[120] Nonhomologous end-joining (NHEJ) and homologous recombination (HR), critical DSB repair pathways, are also deregulated in CML. For example, the catalytic subunit of DNA-dependent protein kinase (DNA-PKcs) is down-regulated in $CD34^+$ CML progenitors, leading to error-prone NHEJ.[121] Furthermore, BCR-ABL1 up-regulates RAD51.[122] As a result, DSB repair upon challenge with cytotoxic agents and induced ROS is shifted toward a rapid but low fidelity pathway, thus promoting chronic oxidative DNA damage. Lastly, telomere length is correlated with time to disease progression.[123] Whether TKIs themselves may cause DNA damage is controversial. Imatinib was reported to induce centrosome abnormalities in vitro.[124] Given that the overall risk of cancer is not increased in patients on long-term imatinib,[125] the significance of these findings is not clear. Furthermore, the fact that clonal cytogenetic abnormalities in Ph-negative cells (CCA/Ph^-) appear in some CML patients with a cytogenetic response to TKI therapy is consistent in principle with genomic instability prior to acquisition of Ph.[126] Indeed, some patients with CCA/Ph^- have progressed to MDS or AML, especially those with monosomy 7.[127] However, the overall prognosis of patients with CCA/Ph^- is identical to that of other CML patients with a comparable cytogenetic response, which argues against genomic instability predating Ph.[128] The mechanistic underpinning of genomic instability in CML is of considerable complexity.[115,116]

A wealth of data on BCR-ABL1 signaling has been amassed, yet a complete picture is still elusive. As conventional approaches have typically focused on single pathways, efforts are now underway to establish a more comprehensive picture of BCR-ABL1 signaling complexes by quantitative genomics.[129] These data suggest that cellular processes in CML rely on integrated networks rather than single pathways, which co-operate to realize the leukemogenic potential of BCR-ABL1 fully.

Transformation to Accelerated and Blastic Phase

It could be argued that the key objective in CML therapy is the prevention of transformation to blastic phase (BP), an acute leukemia with either myeloid (M-BP) or pre–B–cell phenotype (L-BP). A host of genetic alterations has been associated with transformation to accelerated phase (AP)/BP. CCA/Ph^+ is present in 70% to 80% of cases and includes a number of nonrandom abnormalities, the most common of which are +8 (34% of cases with CCA/Ph^+), +Ph (30%), i(17q) (20%), +19 (13%), –Y (8% of males), +21 (7%), +17 (5%), and monosomy 7 (5%). These frequent chromosomal changes are sometimes referred to as major route abnormalities,[130] although this is not a universally accepted definition. Many other cytogenetic abnormalities have been described in smaller subsets of patients and multiple different mutations have been detected at the molecular level. For example, in M-BP, inactivating mutations of *p53* and *RUNX1* occur in 20% to 30% and 38% of cases, respectively, whereas L-BP is characterized by inactivating mutations in *CDKN2A/B* (50%) or *IKZF1* (55%) (reviewed in Ref. 116).

BCR-ABL1 expression and activity increase with progression to BP. In some patients, rising *BCR-ABL1* mRNA levels are associated with duplication of Ph, but in the majority of cases this seems to result from enhanced transcription due to as yet unknown mechanisms.[131] Increased BCR-ABL1 promotes expression of SET, which in turn inhibits PP2A, a tumor suppressor phosphatase that dephosphorylates BCR-ABL1 and other important substrates by activating SHP-1.[132] Thus, reduced PP2A activity will increase BCR-ABL1 activity and further enhance the signal in a positive feedback loop. Consistent with the importance of this pathway, reduced SHP-1activity has been associated with resistance to TKIs.[133] In addition to SET-mediated inhibition of PP2A, cancerous inhibitor of PP2A (CIP2A) was also shown to inhibit this phosphatase, and high CIP2A activity predicts a high risk of transformation to BP.[134]

The central feature of blastic transformation is the loss of terminal differentiation capacity. Based on the paradigm that AML requires at least two types of mutations, one driving proliferation and one blocking differentiation, it follows that the BP in CML should be associated with inactivating mutations in myeloid differentiation genes.[135] Consistent with this, some patients acquire AML-type translocations such as *CBFβ*-MYH11 at the time of transformation, but these are rare.[136] In the majority of patients, myeloid differentiation is impaired due to suppression of CAAT enhancer binding protein α (C/EBPα), which occurs as a result of increased BCR-ABL1 expression and activity.[137] Mechanistically, this is due to enhanced expression of the RNA-binding protein heterogeneous nuclear ribonucleoprotein E2 (hnRNP-E2), which inhibits C/EBPα translation.[137] Down-regulation of miR-328 is also required for this to occur, as miR-328 would otherwise bind hnRNP-E2, thereby blocking its activity.[138] Repression of other myeloid transcription factors such as C/EBPβ and overexpression of EVI-1 have also been implicated in blastic transformation.[139,140,141] In addition to the loss of differentiation capacity, the organization of leukemic hematopoiesis seems to change upon transformation, as granulocyte–macrophage progenitor cells acquire self-renewal capacity, possibly by activation of nuclear β-catenin, undermining the hierarchical structure of CML-CP hematopoiesis.[142] Various mechanisms have been implicated in β-catenin activation, including stabilization by BCR-ABL1 tyrosine phosphorylation and inactivation of glycogen synthase kinase 3β by missplicing.[143,144] Unsurprisingly, CML-BP responses to therapy are usually short-lived.

CLINICAL FEATURES

Epidemiology

With an annual incidence of 1.3 to $1.6/10^5$ population, CML accounts for 15% to 20% of cases of leukemia in adults. Males are more commonly affected, but there is no geographic, ethnic, or familial predisposition. The only well-established risk factor is exposure to ionizing radiation, evident by the increased CML incidence in survivors of the atomic bomb explosions in Japan; patients who were treated with radiotherapy or exposed to thorotrast, an α-emitting contrast medium used in the 1930s,[145–147] have an increased CML risk as well. From 2004 to 2009, the median age at diagnosis in the United States was 64 years.[148] The prevalence of CML is increasing due to reduced mortality.[149] For the United States, estimates

are 70,000 in 2010, 144,000 in 2030, and 181,000 in 2050, when prevalence will approach a plateau.[150]

Clinical Presentation

Signs and Symptoms

CML may present with fatigue, weight loss, fever, night sweats, bone pain, abdominal pain, and fullness.[151] Rare patients with excessively high white blood cell counts have symptoms related to leukostasis, such as priapism and neurologic deficits. Physical exam may reveal splenomegaly and sometimes hepatomegaly, although involvement of other extramedullary sites is uncommon. None of these signs or symptoms is typical or even pathognomonic for CML, and the clinical presentation has changed considerably due to earlier diagnosis. In the United States and other developed countries, the majority of patients are diagnosed incidentally, when an abnormal complete blood count obtained for an unrelated reason leads to a diagnostic work-up.

Disease Phases

CML evolves in stages termed chronic phase (CML-CP), accelerated phase (CML-AP), and blastic phase (CML-BP). In the Western world, most patients present in CML-CP, whereas more advanced disease at diagnosis is common in developing countries. CML-CP is characterized by left-shifted granulocytosis with maintained terminal differentiation, frequently accompanied by basophilia and sometimes eosinophilia. Thrombocytosis and mild anemia are also common. Dysplasia is not a feature of CML and raises the question of alternative diagnoses, such as atypical CML.[152] Bone marrow aspirate and histology are hypercellular for age, but demonstrate complete cellular maturation (Fig. 81.4A). A fairly typical finding is micromegakaryocytes, which are small monolobated megakaryocytes. Mild reticulin fibrosis may be present, but severe reticulin fibrosis is uncommon and may be associated with poorer outcomes.[153] Without effective therapy, CML-CP inexorably progresses to CML-BP, which can exhibit a pre–B–lymphoid (25%), myeloid (70%), or indeterminate (5%) phenotype (Fig. 81.4B).[154] CML-BP can develop rapidly or over a period of time through the intermediary stage of CML-AP. A variety of clinical and laboratory features has been used to define CML-AP, making comparison of results between different studies difficult. Today, the criteria used in the clinical trials leading to approval of imatinib are widely accepted (Table 81.1).[155] The exception is clonal cytogenetic evolution, i.e., the presence of additional cytogenetic abnormalities in the Ph^+ cell clone (CCA/Ph^+). Although there is agreement that CCA/Ph^+ on treatment is diagnostic of CML-AP and therapy failure,[156] this is not universally accepted for newly diagnosed patients. Recent studies showed that these patients have inferior outcomes even in the absence of any other features of CML-AP, raising the question of whether the criteria should be changed.[157] A blast count of ≥30% in the blood or bone marrow or extramedullary blastic leukemic infiltrates (chloroma) in tissues other than liver or spleen define CML-BP. Gene expression profiling has revealed that CML-AP and CML-BP are closely related to each other, suggesting that CML is a two-phase rather than a three-phase disease.[158] In the future, molecular markers and response to treatment may replace conventional diagnostic criteria used to define the phases of CML.[159]

Risk Scores

Several prognostication systems have been developed to subclassify CML-CP. The oldest, developed by Joseph Sokal, uses a formula based on age, blast count in the blood, platelet count, and spleen size (in cm below the left costal margin). Scores of <0.8, 0.8 to 1.2, and >1.2 define low, intermediate, and high risk.[160] Although the Sokal score was derived from a cohort of patients treated with busulfan-based chemotherapy, it has been applied successfully to risk-stratify patients treated with IFN or TKIs.[161,162] Subsequently, Hasford developed a score optimized for patients on IFN.[163] Recently, a third prognostication system (EUTOS score) optimized for patients on imatinib was reported.[164]

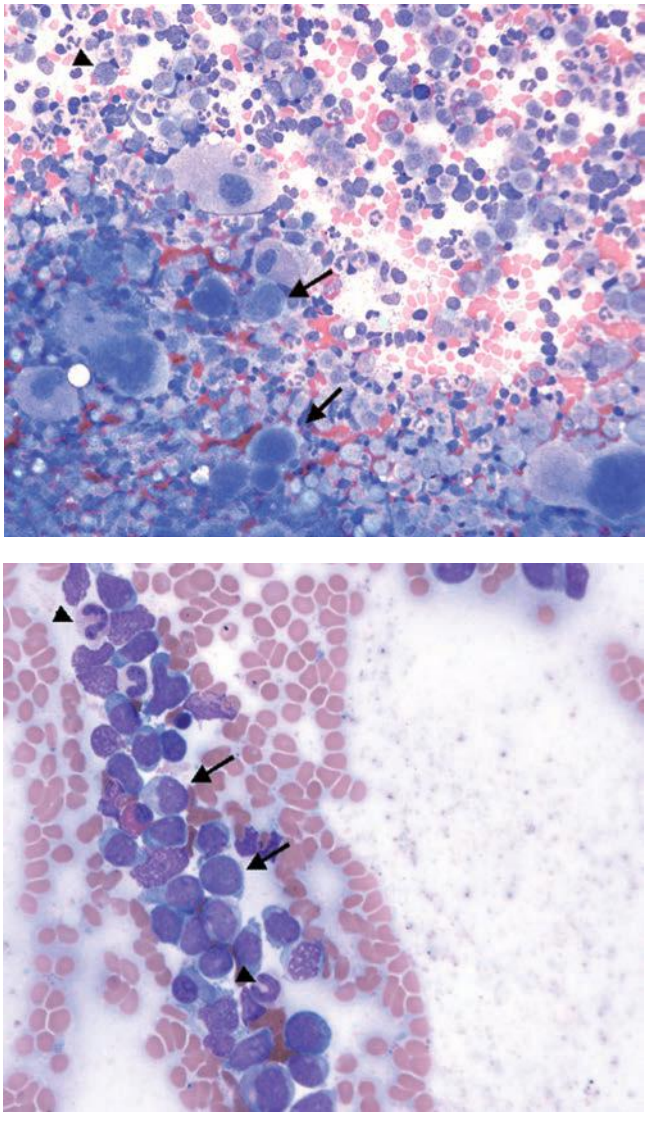

FIGURE 81.4. A: Bone marrow aspirate in chronic phase chronic myeloid leukemia (CML) (magnification ×20). Note the hypercellularity and the predominance of granulopoiesis. Maturation is preserved, with only occasional blasts (*arrowhead*). Numerous megakaryocytes, many of them small with hypolobulated nuclei (micromegakaryocytes), form sheets and clusters (*arrows*). **B**: Bone marrow aspirate in a patient with blastic phase. Most of the cells are immature blasts (*arrows*), with only occasional cells still exhibiting differentiation (*arrowheads*). Courtesy of Dr. Marc Loriaux, Department of Pathology, Oregon Health & Science University, USA.

TABLE 81.1

DEFINITION OF ACCELERATED PHASE[a]
Blast count at least 15% to less than 30% in blood or marrow
Blasts plus promyelocytes of 15–30% in blood or marrow
Basophil count at least 20% in the blood
Platelet count less than 100 × 10^9/L, unrelated to therapy

[a]At least one criterion must be satisfied.

The EUTOS score is simple, relying on basophils and spleen size only, but has not been universally confirmed in independent studies.[165] As with the definitions of disease phases, it is likely that molecular markers will eventually replace clinical risk scores.[159]

DIAGNOSIS AND INITIAL WORK-UP

Clinical Evaluation

A complete history and physical exam are mandatory. Constitutional symptoms raise concerns about more aggressive disease. Spleen size (in cm below the left costal margin in the mid-clavicular line) must be documented. Despite its inaccuracy, this simple clinical test has remained a significant component of all CML risk scores.[160,163,164] Imaging studies such as abdominal ultrasound or computed tomography are not indicated unless there is suspicion of additional abdominal pathology. In the absence of an algorithm to convert imaging-based measurements of spleen size into clinical measurements, these data cannot be used to calculate risk scores. Extramedullary disease other than hepatosplenomegaly is uncommon at presentation, and if suspected must be verified histologically. An immature cellular infiltrate (chloroma) indicates blastic transformation, but if there is differentiation it can be difficult to distinguish between true extramedullary disease and an inflammatory process that recruits CML cells.

Laboratory Tests

Complete Blood Count

A complete blood count (CBC) with manual white blood cell differential count is usually the first diagnostic step or the first abnormal finding in an otherwise asymptomatic patient. The diagnosis of CML is suspected based on the morphology of a Wright- or Giemsa-stained blood smear. Typical features of CML include left-shifted granulopoiesis that may encompass the full spectrum of granulocytic precursors including blasts and promyelocytes, basophilia, and sometimes eosinophilia and thrombocytosis. Some automated cell counters do not provide the percentage of promyelocytes, which is required to determine the phase of disease, and in such cases a manual count is necessary. All risk scores to stratify CML-CP are based on pre-therapeutic values; therefore, it is important to document the counts before any therapy is initiated. Flow cytometry is indicated only if AP/BP is suspected. Problems can arise in cases of discrepancies between morphologic and immunophenotypic blast counts, which are usually based on CD34 expression. In our practice, morphologic blast counts take precedence over flow cytometry, but there is currently no universally accepted rule.

Bone Marrow Aspirate and Biopsy

Bone marrow morphology studies at diagnosis are essential to establish disease phase. Unfortunately, more and more patients do not have a bone marrow biopsy at diagnosis, and in some of these, AP/BP will be overlooked and result in undertreatment. Whether all patients should have a biopsy is debatable, and practice varies considerably from country to country. We routinely perform a biopsy at diagnosis to identify the occasional patient with nests of blasts undetected by cytology. This is particularly important in patients with an aggressive presentation and those with inadequate aspirates or dry taps. As for peripheral blood, flow cytometry is not typically indicated.

Bone Marrow Karyotyping

Metaphase karyotyping of bone marrow cells using G- or R-banding must be performed at diagnosis. In 95% of CML patients, the *BCR-ABL1* fusion gene will be evident as Ph, sometimes as part of complex translocations involving additional chromosomes. These complex translocations do not seem to affect the outcome of patients on TKI therapy, and they must not be confused with clonal cytogenetic abnormalities in Ph^+ cells (CCA/Ph^+, also referred to as clonal cytogenetic evolution).[157] As a rule, a minimum of 20 metaphase spreads is analyzed. Rare patients have a silent Ph that is not identified by karyotyping; in these patients, molecular testing is required to establish the diagnosis of CML. Another important piece of information from karyotyping is CCA/Ph^+, because these patients have inferior progression-free and overall survival on TKI therapy, even in the absence of other features suggestive of AP.[157]

Fluorescence In Situ Hybridization

Fluorescence in situ hybridization (FISH) uses fluorescent DNA probes to label *BCR* and *ABL*1 genetic regions adjacent to the translocation breakpoints, typically red fluorescence to label *ABL1* and green fluorescence to label *BCR* (Fig. 81.5). Most FISH systems identify both *BCR-ABL1* (on Ph) and *ABL1-BCR* fusion signals (on the derivative chromosome 9), and have low false-positive and -negative rates.[166] FISH is usually performed on interphase nuclei. Advantages of FISH compared to conventional karyotyping include higher sensitivity (200 to 500 nuclei are routinely analyzed) and the fact that no metaphases are needed, which is important in view of the 5% to 20% failure rate of metaphase karyotyping. In cases of silent Ph, FISH is an excellent tool to establish the diagnosis of CML. On the other hand, FISH does not detect CCA/Ph^+. Modern FISH probes identify deletions in *ABL1* adjacent to the translocation breakpoint. These deletions (and similar deletions in *BCR*) confer an adverse prognosis to patients treated with IFN and second-line imatinib, but their negative impact is overcome by frontline TKI therapy.[167–169] All in all, FISH at diagnosis does not add actionable information for patients with Ph by standard karyotyping and its routine use in addition to conventional karyotyping is not justified.

Reverse Transcription Polymerase Chain Reaction

The main use of *qualitative* PCR is to identify a *BCR-ABL1* fusion mRNA in patients with suspected CML who are Ph^- by metaphase karyotyping. As such, this technique provides the same information as FISH. If qualitative RT-PCR is used to ascertain the presence of a *BCR-ABL1* translocation, it is important to make sure that the assay detects all types of BCR-ABL1 transcripts, including rare atypical transcripts.[170] *Quantitative* PCR (qPCR) assays will detect most types of *BCR-ABL1* mRNA transcripts, but depending on test design will miss e1a2 and atypical transcripts. Thus, qPCR is not indicated to establish the diagnosis of CML, although it is used routinely to monitor patients on therapy. A detailed

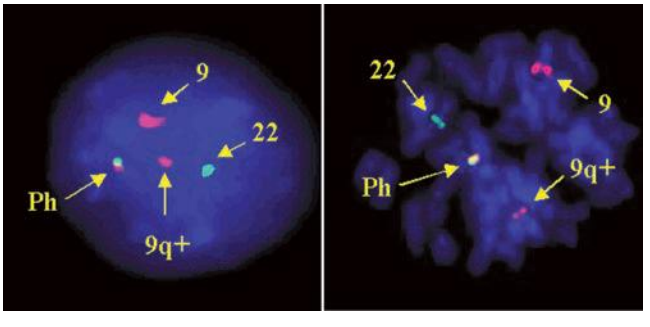

FIGURE 81.5. Fluorescence in situ hybridization (FISH). The left panel shows an interphase nucleus, the right panel a metaphase. FISH was done with the LSI BCR/ABL ES probe (Vysis, Downer's Grove, IL, US) that detects the BCR-ABL1 fusion (yellow) as well as signal on the derivative chromosomes 9 (red) and 22 (green). Courtesy of Christel Mueller, Department of Hematology, University of Leipzig, Germany.

discussion of qPCR for *BCR-ABL1* is provided in the section "Monitoring Response."

Differential Diagnosis

MPNs such as atypical CML, chronic myelomonocytic leukemia (CMML), chronic neutrophilic leukemia, MPN associated with rearrangements within the platelet-derived growth factor receptors (*PDGFRs*) or fibroblast growth factor receptor 3 (*FGFR3*) can be indistinguishable from CML on morphologic and clinical grounds alone. Conversely, some CML patients present with a disease that resembles essential thrombocythemia (ET) or primary myelofibrosis.[152] Given the profound therapeutic implications, it is mandatory to ascertain the presence or absence of *BCR-ABL1* in every patient with MPN. Once Ph or *BCR-ABL1* has been demonstrated, the diagnosis is CML, irrespective of the particular MPN morphology. Tests such as the leukocyte alkaline phosphatase (LAP) score (low in CML, high in leukemoid reactions) or vitamin B12 levels (high in CML) have been superseded by molecular tests and are of historical interest only. CML may present in lymphoid or myeloid BP and these cases can be extremely difficult to distinguish from de novo Ph^+ ALL or Ph^+ AML, a rare and sometimes disputed entity. Residual left-shifted but maturing granulocytic precursors, basophilia, and splenomegaly point to a prior CML-CP. A *BCR* breakpoint in the m-*BCR* with e1a2 *BCR-ABL1* transcript establishes a diagnosis of Ph^+ ALL for all practical purposes.

MONITORING RESPONSE TO THERAPY

Once treatment is initiated, response is measured by clinical, hematologic, cytogenetic, and eventually molecular parameters. These different levels of response reflect the decrease of leukemia burden (Fig. 81.6).

Complete Hematologic Response

Complete hematologic response (CHR) requires the normalization of white blood cell and platelet counts as well as the white blood cell differential. Normalization of hemoglobin is not part of the CHR definition. Additionally, all CML-related clinical symptoms must have resolved and the spleen should not be palpable. The latter requirement is stringent and precise; however, bulky splenomegaly is often slow to resolve and the significance of persistent minimal splenomegaly in patients who meet all other CHR criteria is unknown. The term "major hematologic response" is sometimes used to describe response in patients with AP/BP who clear blasts from the blood and have less than 5% of blasts in the bone marrow without reconstitution of peripheral blood counts.

Cytogenetic Response

At least 20 metaphases must be karyotyped to assess cytogenetic response. A partial cytogenetic response (PCyR) is present if 35% or less of these metaphases are Ph^+, and a CCyR if all are Ph^-. The 35% definition of PCyR reflects the lower bound of the 95% confidence interval around 50% Ph^+ metaphases based on analysis of 20 metaphases. CCyR and PCyR combined are referred to as major cytogenetic response (MCyR). Some studies also report minor (36% to 65% Ph^+) and minimal (66% to 95% Ph^+) cytogenetic response, but these response levels have limited clinical significance. Given the efficacy of TKI therapy and the availability of quantitative RT-PCR (qPCR), CCyR may become the only cytogenetic response level used in the future.

Molecular Response

qPCR is widely used for monitoring of patients on TKI therapy or after allogeneic stem cell transplantation. The use of numerous technologies has created a confusing landscape, which has led to efforts aimed at establishing minimal requirements for test performance. Unfortunately, harmonization of *BCR-ABL1* testing in the United States is lagging behind other developed countries.[171] An exhaustive discussion of qPCR monitoring is beyond the scope of this chapter and the reader is referred to comprehensive reviews of the subject,[172] but a few critical points deserve to be mentioned here. (i) Compared with metaphase karyotyping and FISH, qPCR has a vastly greater dynamic range, which may span up to 5 logs. However, this sensitivity is reached only if the sample is of optimal quality. Thus, reliable laboratories report the sensitivity reached for a given sample to enable correct interpretation of results. (ii) Not all housekeeping genes are equally suitable as control genes for normalization of RNA input; acceptable choices include *ABL1*, *BCR*, *GUS*, and *G6PD*.[172] β-aActin is not suitable due to high-level expression that may conceal degradation of the sample. (iii) In clinical practice it is often necessary to decide whether a rise of *BCR-ABL1* mRNA is significant and should trigger a more extensive work-up. The most important factor is the quality of the test, which determines the extent of intertest variation and, as such, the optimal compromise between sensitivity

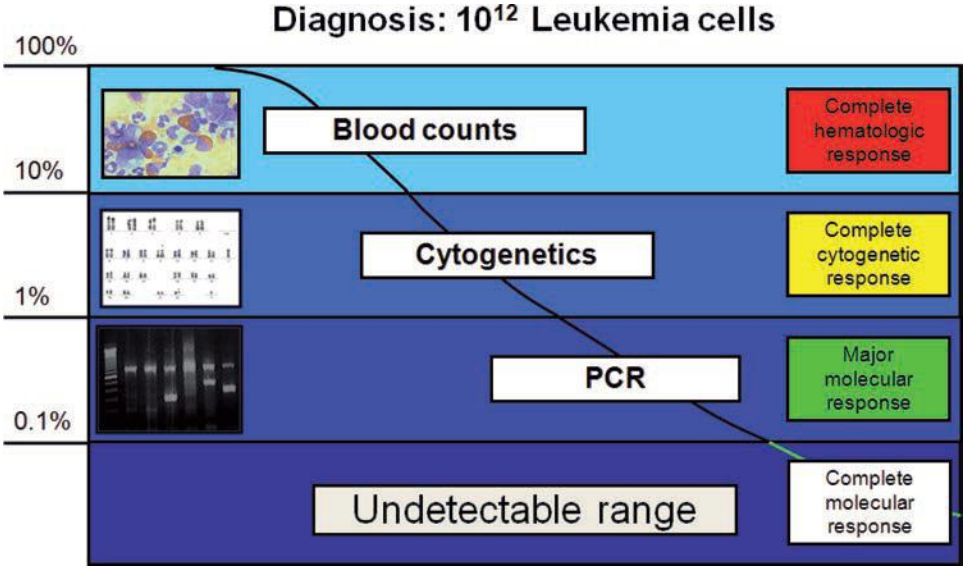

FIGURE 81.6. Reduction of leukemia burden with increasing depth of response. Estimates are that at least 10^{12} chronic myeloid leukemia (CML) cells may be present at diagnosis. Complete hematologic response (CHR) is the first therapeutic objective. A complete cytogenetic response (CCyR) is equivalent to approximately 2-log reduction of disease burden and a major molecular response (MMR) to 3-log reduction, compared with a standardized baseline (not to the individual patient's initial disease burden). Further decreases can lead to a state where even the most sensitive tests fail to detect residual leukemia, which is commonly referred to as a complete molecular response (CMR). PCR, polymerase chain reaction

and specificity.[173] Current recommendation is that a fivefold rise in transcript level be regarded as significant.[172] In excellent laboratories this may decrease to twofold,[174] whereas in poor laboratories even tenfold rises may not be dependable. For the clinician, it is important to know the performance of the laboratory to ascertain correct interpretation of test results. (iv) qPCR is more reproducible at high levels of *BCR-ABL1* than at low levels. Thus, it is good clinical practice to repeat the test in the case of rising *BCR-ABL1* mRNA levels before rushing to far-reaching conclusions, particularly if the changes occur at a low level. (v) A major breakthrough was the introduction of the international scale (IS), which allows for the expression of values from different laboratories and different assays on a uniform scale. To express their individual values on the IS, laboratories obtain a series of standards to calculate a lab-specific conversion factor.[175–177] Key anchoring points of the IS are: (1) 100%, which is equivalent to the average *BCR-ABL1* mRNA expression of a cohort of patients treated on the International Randomized Study of Interferon and STI571 (IRIS) study[178] and (2) a level of 0.1% IS, corresponding to a 3-log reduction compared with this baseline and referred to as a major molecular response (MMR). Achievement of MMR on TKI therapy is an important milestone that portends a good prognosis. Further reductions of *BCR-ABL1* mRNA by 4 or 4.5 logs are referred to as MR^4 or $MR^{4.5}$, respectively. It is extremely important to be aware that the fold reductions of *BCR-ABL1* expressed on IS refer to a standardized baseline, not to the patient's individual baseline, thus representing an absolute measurement of leukemia burden. Residual leukemia levels will be underestimated if the patient-specific baseline is used in patients with high levels of *BCR-ABL1* mRNA at diagnosis. Inasmuch as this correlates with more advanced disease, this is exactly the group of patients where overestimating response may have dire consequences.[131] Equally important, IS values are directly comparable between different laboratories, enabling continuity. (vi) A complete molecular response (CMR) is present if *BCR-ABL1* mRNA is undetectable by qPCR. However, in contrast to MMR, which is an absolute value due to its anchoring to a standardized baseline, a universal definition of CMR is impossible, as it depends on the sensitivity of the assay, which may increase with advances of technology.

Regrettably, major commercial laboratories in the United States have been slow to adopt the IS. Results from these laboratories are not interpretable with respect to the key clinical trials that define current practice standards. In fact, results expressed on some obscure percentage scale can be mistaken for IS results, potentially giving the patient false reassurance about her or his response to TKIs.

BCR-ABL1 Mutation Testing

BCR-ABL1 mutations are an important mechanism of TKI resistance. The current recommendation is to test for mutations in patients with evidence of resistance. The National Comprehensive Cancer Network (NCCN) guidelines and European Leukemia Net (ELN) recommendations advocate for mutation analysis at baseline in patients with AP/BP, but in the absence of prospective studies that modified therapy based on these results, it seems hard to justify this practice.[179] Similarly, the benefit of mutation surveillance in high-risk patients remains to be determined prospectively. Direct sequencing of *BCR-ABL1* amplicons identifies mutant alleles with a sensitivity of 20% to 30% and is currently recommended as the technology of choice.[172] In contrast, detection of BCR-ABL1 kinase domain mutations by very sensitive assays such as allele-specific PCR does not predict failure and is not useful clinically.[180] The optimum may be in the middle: techniques such as high performance liquid chromatography and Sequenom MassARRAY® may have the right sensitivity to avoid too many false-positive results.[181,182] However, it will still be necessary to evaluate these approaches in prospective interventional studies.

THERAPY

Cytotoxic Agents and Interferon-α

Busulfan, an alkylating agent with considerable hematopoietic stem cell toxicity, was the first drug that effectively controlled white blood cell and platelet counts, but is rarely used today except as part of conditioning regimens in allogeneic stem cell transplantation.[16] Chronic busulfan exposure is associated with pulmonary fibrosis, and proper dosing can be challenging due to prolonged cytopenias. Hydroxyurea, a ribonucleotide reductase inhibitor, is indicated as an effective method for lowering white blood cell counts until the diagnosis of CML is confirmed. Because, at conventional doses, hydroxyurea acts predominantly on the more mature progenitor cells, cytopenias are usually short-lived and therapy is easily adjusted based on CBCs. IFN was the first drug therapy that induced durable cytogenetic responses, albeit only in a small minority of patients and for reasons that remain incompletely understood. Combinations with cytarabine, which has single agent activity in CML, were the standard of care in the 1990s.[183,184]

Tyrosine Kinase Inhibitors

TKIs are the standard of care for newly diagnosed CML patients in all disease phases. The three approved TKIs—imatinib, dasatinib, and nilotinib—are made distinct by their potency, activity against *BCR-ABL1* mutants (discussed in detail below), spectrum of activity against kinases other than *BCR-ABL1*, and side effect profiles (Table 81.2). Today's treatment algorithms are based on the results of a series of clinical trials, starting with a phase 1 imatinib study initiated in 1998 (Table 81.3).

Imatinib

A phase 1 trial of imatinib in CML patients who had failed conventional therapy demonstrated activity in all disease phases. It is important to note that cytogenetic responses were seen, particularly in CML-CP.[23,24] No maximum tolerated dose was identified. Based on the cytogenetic responses, an initial dose of 400 mg daily was selected for phase 2 studies in CP, AP, and BP. These trials confirmed or exceeded the phase 1 results and led to approval of imatinib for patients who had failed prior IFN due to resistance or intolerance.[185,186–188] CML-CP responses were mostly durable, but there was a high failure rate in advanced CML, which led to an increase of the starting dose to 600 mg imatinib daily. Approval for frontline use in newly diagnosed patients followed in 2003 based on the results of the IRIS study, which compared imatinib 400 mg daily versus a combination of IFN and cytarabine. This trial showed imatinib to be vastly superior in all major endpoints, but most importantly in progression-free survival.[189] Crossover was permitted for resistance or intolerance and occurred almost exclusively in patients failing IFN. The fact that many of these patients were effectively salvaged by imatinib may explain why no difference in overall survival between the two experimental arms was observed.[190] Subsequent phase 3 studies of imatinib in newly diagnosed CML-CP patients mainly addressed the question of the optimal dose and the role of combinations with IFN and cytarabine. Single-arm studies in comparison with historical controls had suggested higher rates of CCyR and MMR for 800 mg imatinib daily, commonly referred to as high-dose imatinib.[191,192] However, this was not confirmed in two prospective randomized studies. The Tyrosine Kinase Inhibitor Optimization and Selectivity Study (TOPS) trial compared 400 versus 800 mg imatinib daily in newly diagnosed patients irrespective of Sokal risk, and an Italian study compared the identical doses in high Sokal risk patients. Both studies failed in their primary endpoint, improved MMR or CCyR at 12 months at the higher dose.[193,194] Recently, the German CML IV study reported superior rates of MMR at 12 months for

800 mg imatinib daily (59% vs. 44%, $P < 0.001$).[195] Interestingly, in this study, imatinib dosing was more flexible and was maximized based on the individual patient's tolerability, resulting in a median dose of 627 mg imatinib daily. Similarly, the French SPIRIT study reported higher MMR rates at 12 months (49% vs. 38%) for patients treated with 600 versus 400 mg imatinib daily.[196] Thus, the optimal dose of imatinib may be approximately 600 mg daily, equal to the recommended dose for AP/BC.

Dasatinib

An initial phase I study on CML patients in all disease phases who had failed imatinib due to resistance or intolerance revealed considerable activity upon treatment with dasatinib.[197] This study was followed by a series of phase 2 trials that tested dasatinib in larger cohorts of patients in the different disease phases, and two dose optimization studies that tested 100 versus 140 mg daily administered as a single dose or in two separate doses.[198–200,201,202] From these studies, 100 mg dasatinib once daily for CML-CP, and 140 mg once daily for AP and BP, emerged as the recommended doses. Dasatinib was subsequently compared with imatinib 400 mg in a phase 3 study (DASatinib versus Imatinib Study In treatment-Naive CML patients, DASISION) in newly diagnosed CML-CP patients and proved superior in the primary endpoint, CCyR at 12 months, as well as several secondary endpoints, including MMR at 12 months.[202] Progression events were reduced, but the difference did not reach statistical significance, and no difference in overall survival was observed. Based

on the DASISION trial, dasatinib was approved for use in newly diagnosed CML patients.

Nilotinib

An initial phase 1 study tested nilotinib in a cohort of CML and Ph^+ ALL patients who had failed imatinib due to resistance or intolerance. Considerable activity was seen in CP and AP, although results in BP were less impressive.[203] Subsequent phase 2 studies led to approval of nilotinib 400 mg twice daily for patients with CML-CP and CML-AP who had failed prior imatinib therapy.[204,205] The recently published results of CML-BP are comparable to those of dasatinib, but nilotinib is not currently approved for this indication.[206] Nilotinib (300 or 400 mg twice daily) was then compared to imatinib in the Evaluating Nilotinib Efficacy and Safety in Clinical Trials–Newly Diagnosed (ENESTnd) study, with MMR at 12 months as the major endpoint.[207] This study showed both experimental arms superior to the standard arm. Note that progression-free survival was improved with nilotinib. The results of the ENESTnd study led to approval of nilotinib (300 mg twice daily) for frontline therapy in newly diagnosed patients with CML-CP.

Drug Combinations

Imatinib has been tested in combination with multiple cytotoxic agents and signal transduction inhibitors, mostly in the setting of resistance. In the frontline setting, data are limited to combinations with cytarabine and IFN. In the SPIRIT study, 400 mg imatinib daily was compared with 600 mg daily as well as 400 mg daily combined with pegylated IFN or cytarabine, with MMR at 12 months as the major endpoint.[196] Patients in the IFN/imatinib arm had significantly higher rates of MMR than all other arms of the study (57% vs. 38% at 12 months for the comparison with imatinib 400 mg daily). These data were confirmed by a smaller Scandinavian study.[208] Thus far, no differences in overall and progression-free survival were seen, and IFN/imatinib combinations should be considered experimental.

APPROACH TO THE NEWLY DIAGNOSED CHRONIC-PHASE PATIENT

Selection of Frontline Tyrosine Kinase Inhibitor

Once staging and risk assessment are complete, the question is how to choose among the three approved TKIs. Selection is influenced by several considerations, not all of which are strictly medical. As of 2012, there is no significant difference in overall survival between patients treated with imatinib versus dasatinib or nilotinib. However, key molecular endpoints such as MMR and CMR are achieved faster with the two newer TKIs. It seems likely that with more follow-up a relatively small but significant advantage in overall survival will become apparent. This gain must be balanced against the long and very impressive safety record of imatinib.[125] The risk/benefit assessment would change dramatically in favor of the dasatinib or nilotinib if there were a substantial increase in the numbers of patients who can discontinue therapy altogether, an outcome as much desirable as uncertain. An important factor to consider is the risk score. Although molecular responses with dasatinib or nilotinib are superior across all risk categories, progression to AP/BP is very rare in low-risk patients treated with imatinib. Conversely, high-risk patients may benefit disproportionately from dasatinib or nilotinib. Lastly, the patient's past medical history is critical for TKI selection. Diabetes, pancreatitis, and QT prolongation are contraindications for nilotinib,[203] and a history of pleural effusions, heart failure, or gastrointestinal bleeding argues against dasatinib.[197] Peripheral edema is frequently aggravated by imatinib.[209] However, in many cases, there are no firm contraindications against any one of the three TKIs, and it can be a matter of trial and error to identify the drug with the optimal tolerability in a given patient. In some patients, compatibility with lifestyle may favor once-daily dosing to optimize regimen adherence. Lastly, medication cost will play an increasing role. Dasatinib and nilotinib are more expensive than imatinib, and this difference will probably increase dramatically when generic imatinib preparations become available (expected in 2015).

Optimizing drug therapy for newly diagnosed patients in a general way will require a CML management strategy rather than a single drug approach. Important questions will have to be answered in well-designed prospective studies. For example, can second-generation TKIs be used as an induction therapy, followed in good responders by low-cost maintenance imatinib? Or could patients be started on imatinib and switch to a second-generation TKI if an early response assessment reveals an unsatisfactory response?

Monitoring Patients on Therapy

Regardless of the TKI selected for initial therapy, weekly CBCs are indicated until blood counts are stable, at which point intervals are extended. Cytopenias are common during the initial phase of treatment and may require dose interruption and/or reduction. In most cases cytopenias are transient, reflecting therapeutic effects on leukemic hematopoiesis, when residual normal hematopoiesis is still suppressed. Algorithms have been proposed to optimize dose intensity, while avoiding prolonged myelosuppression.[210] In addition, complete metabolic profiles (including lipase in the case of nilotinib) must be done periodically to monitor for liver and pancreatic toxicity as well as electrolyte imbalances. Repeat bone marrow biopsies are indicated until CCyR is achieved, typically at 3, 6, and 12 months. qPCR is the monitoring strategy of choice for patients who attained CCyR. The current recommendation is to perform qPCR every three months. Once stable MMR or even CMR has been achieved, these intervals can be extended to 6 months.[156] Although no exact data are available, it is likely that many rises of *BCR-ABL1* levels in patients with well-controlled CML reflect non-adherence. FISH for *BCR-ABL1* on peripheral blood interphases should be used only if there is no access to reliable qPCR. An expert panel convened by the ELN has recommended milestones of response on TKI therapy, which have been widely accepted internationally, although minor differences remain compared to the NCCN guidelines.[186] The ELN milestones are defined time-points in which responses are classified as optimal, suboptimal, and failure (Table 81.4). In addition, there are so-called warning signs that may trigger clinical actions such as an increased density of surveillance. In their latest version, the ELN recommendations for newly diagnosed CML-CP patients were still based on imatinib as frontline therapy; with the approval of dasatinib and nilotinib, and the maturation of the ENESTnd and DASISION studies, they will need to be adjusted.

APPROACH TO THE PATIENT PRESENTING IN ACCELERATED PHASE/BLASTIC PHASE

As presentation of CML in AP or BP is uncommon in the developed world, there are limited data for this group of patients. However, second-generation TKIs are preferred over imatinib. In the salvage setting, dasatinib has shown slightly higher response rates and more durable responses in CML-AP and is currently the only second-generation TKI approved for CML-BP. In the case of blastic transformation, dasatinib is usually combined with AML- or ALL-type multiagent chemotherapy, although this is not typically the case for AP.[154] All patients with AP/BP should be considered for an allogeneic stem cell transplant, with TKI therapy used to restore a second chronic phase and bridge the time to transplant. Therefore, HLA typing and a transplant consultation are essential parts of the initial work-up for patients who present in AP/BP. Whether to proceed to allografting in an AP/BP patient who attained a very good response to TKI can pose an extremely challenging clinical decision and it is wise to discuss this eventuality prior to starting TKI therapy. Transplant risk, co-morbidities, and the patient's personal preferences are critical factors.

RESISTANCE TO TYROSINE KINASE INHIBITORS

TKI resistance is grouped into primary and secondary (acquired) resistance. At a mechanistic level, resistance can be classified as *BCR-ABL1*–dependent or *BCR-ABL1*–independent. In

TABLE 81.4

EVALUATION OF OVERALL RESPONSE TO IMATINIB FRONTLINE IN EARLY CHRONIC PHASE

	Response			
Evaluation Time, Months	**Optimal**	**Suboptimal**	**Failure**	**Warnings**
Baseline	NA	NA	NA	High risk; CCA/Ph$^+$[a]
3	CHR and at least minor CgR (Ph$^+$ ≤ 65%)	No CgR (Ph$^+$ > 95%)	Less than CHR	NA
6	At least PCgR (Ph$^+$ ≤ 35%)	Less than PCgR (Ph$^+$ > 35%)	No CgR (Ph$^+$ > 95%)	NA
12	CCgR	PCgR (Ph$^+$ 1–35%)	Less than PCgR (Ph$^+$ > 35%)	Less than MMR[b]
18	MMR[b]	Less than MMR[b]	Less than CCgR	NA
Any time during treatment	Stable or improving MMR[b]	Loss of MMR[b]; mutations[c]	Loss of CHR; loss of CCgR; mutations[d]; CCA/Ph$^+$	Increase in *BCR-ABL1* transcript levels[e]; CCA/Ph$^+$

CCA, clonal chromosome abnormalities; CCgR, complete cytogenetic response; CgR, cytogenetic response; CHR, complete hematologic response; MMR, major molecular response; NA, not applicable; PCgR, partial cytogenetic response; Ph$^+$, Philadelphia chromosome positive; Ph$^-$, Philadelphia chromosome negative.

[a]CCA/Ph$^+$ is a warning factor at diagnosis, although its occurrence during treatment (i.e., clonal progression) is a marker of treatment failure. Two consecutive cytogenetic tests are required and must show the same CCA in at least two Ph$^+$ cells.

[b]MMR indicates a ratio of *BCR-ABL1* to *ABL1* or other housekeeping genes of ≤ 0.1% on the international scale.

[c]BCR-ABL1 kinase domain mutations still sensitive to imatinib.

[d]BCR-ABL1 kinase domain mutations poorly sensitive to imatinib.

[e]The significance of the increase may vary by a factor of 2 to 10, depending on the laboratories.

Adapted from Baccarani M, Cortes J, Pane F, et al. Chronic myeloid leukemia: an update of concepts and management recommendations of European LeukemiaNet. J Clin Oncol 2009;27:6041–6051.

BCR-ABL1–dependent resistance, there is reactivation of *BCR-ABL1* kinase, which implies that responses may be recaptured if BCR-ABL1 inhibition is restored. In *BCR-ABL1*–independent resistance, alternative growth and survival pathways substitute for BCR-ABL1 kinase activity.[211]

BCR-ABL1 Kinase Domain Mutations

The best characterized mechanism of TKI resistance is point mutations in the *BCR-ABL1* kinase domain that impair drug binding.[212] Solving the crystal structure of ABL1 in complex with an imatinib analog was instrumental to understanding how kinase domain mutations cause resistance.[213] In contrast to expectations, imatinib was found to bind an inactive conformation of ABL1, with the activation loop of the kinase in a closed position. Additionally, there was extensive downward displacement of the ATP binding loop. Mutations in the kinase domain can cause resistance by steric hindrance or elimination of hydrogen bonds, most impressive in the T315I mutation at the gatekeeper position. A different type of mutation affects the ATP binding loop, preventing the rearrangements required for optimal drug binding. Examples include Q252H, Y253(H/F), and E255(K/V). Lastly, mutations in the activation loop such as H396P stabilize an open conformation, to which imatinib cannot bind.[214] Although imatinib is vulnerable to a broad range of mutations, the spectrum is much more limited for nilotinib and dasatinib, reflecting their greater potency and, in the case of dasatinib, less stringent binding requirements.[215] Clinical resistance mutations are precisely predicted by in vitro assays, which enable the development of pre-emptive strategies to overcome this type of resistance.[216,217,218] Biochemical and cell proliferation data have been used to rank kinase domain mutations according to the degree of TKI resistance they confer (Table 81.5).[219] Although these data are based on in vitro studies, they tend to correlate with clinical responses.[220,221] However, correlations are not as tight as one might suspect, suggesting that additional mechanisms govern clinical resistance. The exception to this rule is the T315I mutation that confers complete resistance to all approved TKIs, both in vitro and in vivo. For several other mutants, the difference in sensitivity is sufficient to support the use of dasatinib over nilotinib or vice versa (Table 81.5). An in-depth discussion of the many reported mutations and their sensitivity profiles is beyond the scope of this chapter and the reader is referred to detailed reviews of this subject.[219,222]

Activation of Alternative Signaling Pathways

In contrast to kinase domain mutations, BCR-ABL1 kinase-independent resistance is less well understood and seems to involve multiple different mechanisms. For example, activation of SRC family kinases, MAP kinase, STAT5, SYK, and PI3K have all been associated with TKI resistance despite sustained inhibition of BCR-ABL1.[223,224,225–227] Extrinsic factors such as cytokines may also play a role.[228,229] Targeting these diverse pathways is therapeutically challenging.

APPROACH TO THE PATIENT WITH TYROSINE KINASE INHIBITOR RESISTANCE

Failure to achieve therapeutic milestones or a loss of response from a given level suggests TKI resistance, and should trigger a careful evaluation. The first call of order is to assess medication adherence through a thorough history. Drug level testing, widely available only for imatinib, is not useful, as patients have been found to make up for skipped doses during the last few days prior to the office visit.[230] Moreover, drug interactions should be considered, especially in patients on multiple co-medications. It is particularly important to include herbal preparations and other over-the-counter remedies, for example, St. John's Wort, which can drastically lower imatinib plasma concentrations.[231] A realistic view, however, is that drug interactions are almost impossible to predict in patients on polypharmacotherapy, and the situation is even more complicated in cases of impaired renal or hepatic function. If nonadherence or drug interactions seem unlikely, a complete resistance work-up that includes a physical exam, CBC, bone marrow aspirate and biopsy, bone marrow metaphase karyotyping, and *BCR-ABL1* mutation analysis is indicated. TKI resistance defines a high-risk situation and should be approached as a diagnosis with significant clinical implications. Key pieces of information derived from this work-up are disease phase, *BCR-ABL1* mutation status, and karyotype, including CCA/Ph$^+$.

Patients with resistance to imatinib can be managed with a second-line TKI alone as long as they are in chronic phase and do not have the T315I mutation. The selection of dasatinib versus

nilotinib is based on past medical history to avoid specific side effects and the type of *BCR-ABL1* mutation (if present). It is good clinical practice to have the patient evaluated or re-evaluated by a transplant center. Analogous to newly diagnosed patients, patients on second-line TKIs must be assessed at regular intervals to determine whether their response meets expectations. One study showed that only 7% of patients who failed to achieve a minor cytogenetic response (≤65% Ph^+ metaphases) at 3 months were in MCyR at 12 months, whereas MCyR at 12 months predicted progression-free and overall survival.[232] Patients who fail frontline or second-line dasatinib or nilotinib are at very high risk, even if still in CP, and have limited drug treatment options. Switching from nilotinib to dasatinib or vice versa is effective only in some patients, and responses are not generally durable.[233] Thus, experimental agents and/or allogeneic stem cell transplant must be considered.

It is likely that this therapeutic space will soon become more nuanced with the advent of third-line TKIs, particularly ponatinib, a highly potent BCR-ABL1 TKI with activity against all reported single mutants, including T315I.[234] Ponatinib showed considerable activity in a phase 1 study of patients with failure to respond to dasatinib and/or nilotinib or the T315I mutation, and a large phase 2 study (PACE trial) confirmed the results.[235,236] Ponatinib is currently under consideration for regulatory approval and may replace dasatinib and nilotinib for second-line therapy. Patients who progress to AP/BP on imatinib are managed with the appropriate second-line TKI, and in the case of BP typically combined with chemotherapy. All eligible patients in this category should be offered an allogeneic stem cell transplant, with the second-line TKI used as a bridge.

DISCONTINUATION OF TYROSINE KINASE INHIBITOR THERAPY

Several studies have reported on patients who discontinued imatinib, typically after achieving CMR and maintaining it for 1 to 2 years.[237,238] The recurrence rate of molecularly detectable leukemia in these patients was approximately 60%, and 40% maintained responses without TKI treatment, sometimes with intermittent low-level positivity by qPCR. It is interesting that almost all recurrences occurred within 6 months, consistent with two distinct patient populations. High Sokal risk at diagnosis and a shorter duration of therapy were associated with recurrence. Patients with recurrence universally responded to re-treatment, suggesting this approach is safe as long as patients are monitored closely. These results have raised hopes that imatinib may be curative in a subset of patients.[239] Larger studies are underway, including patients with CMR on dasatinib or nilotinib. Although these data are clearly very encouraging, they do not at this point support a change of clinical practice. This is particularly important in the United States, where high-quality molecular monitoring is not widely offered. Individual decisions to discontinue therapy may be made in the case of unacceptable side effects and after careful consideration of all alternatives. Otherwise, discontinuation should be regarded as experimental and should only be considered within a clinical study.

ALLOGENEIC STEM CELL TRANSPLANTATION

Allogeneic hematopoietic stem cell transplantation was the first treatment modality that restored Ph^- hematopoiesis and induced durable responses.[18] CML is more susceptible to immunotherapy in an allogeneic setting than most other hematologic cancers. Donor leukocyte infusions (DLIs) were first used in CML patients and demonstrated not only the effectiveness of this approach, but also substantiated the existence of a graft-versus-leukemia effect.[240] Prior to the introduction of imatinib, allografting was recommended to all eligible patients, and even today it is still regarded as the only therapy with curative potential. Only one study prospectively compared allotransplant versus drug therapy. Newly diagnosed patients with CML-CP were biologically randomized to a matched sibling transplant versus IFN-based drug therapy, the best nontransplant treatment available when the trial was initiated.[241] Patients managed with drug therapy had superior survival, with the biggest difference observed in low-risk patients. After approximately 8 years the survival curves crossed, suggesting that transplant would be superior in the long run if IFN were the alternative. However, given the efficacy of TKIs in the frontline setting, and that early transplant-related mortality is clearly higher than the risk of early disease progression, allotransplant is no longer justifiable in newly diagnosed patients with CML-CP, except in unusual circumstances.[156]

Risk scores for allografting in CML were developed by the European Group for Blood and Marrow Transplantation (EBMT) in the pre-imatinib era and identified disease duration of >12 months, more advanced disease, higher age, unrelated donor type, and the combination of a male recipient with a female donor as adverse prognostic factors (Table 81.6).[242] Disease phase had the greatest impact on outcome. Although somewhat historical, the EBMT score is still useful for prognostication. There is consensus that allotransplant should be offered to all patients with progression to AP/BP. Good transplant risk patients who fail imatinib and all patients who fail dasatinib or nilotinib in chronic phase should also be considered, provided they are medically fit to undergo the procedure. Fortunately there is no evidence that imatinib or other TKIs prior to allografting negatively affect the outcome. On the contrary, for unknown reasons, imatinib prior to allotransplant seems to reduce the risk of chronic graft-versus-host disease and possibly relapse risk.[243–245] Recent results from the German CML study group re-assert the importance of transplanting patients while they are still in chronic phase: 3-year overall survival was 91% for patients transplanted in CP after failing imatinib versus 59% for patients transplanted in AP/BP.[246] There is an emerging consensus that bone marrow is preferred over peripheral blood stem cells (PBSCs) in patients with CML-CP, where graft-versus-host disease is a greater concern than disease control.[247] This assessment is different for patients with transformation to AP/BP, even if they have achieved a second chronic phase. High relapse risk patients should receive a TKI post-transplant; *BCR-ABL1* mutation analysis at the time of resistance will help match the optimal

TABLE 81.6

ALLO-HEMATOPOIETIC STEM CELL TRANSPLANTATION RISK FACTORS AND EUROPEAN GROUP FOR BLOOD AND MARROW TRANSPLANTATION RISK SCORE

Risk Factor	Score and Description
Disease phase	0 if CP; 1 if AP; 2 if BP
Age	0 if <20 y; 1 if 20–40 y; 2 if >40 y
Interval from diagnosis	0 if ≤ 1 y; 1 if >1 y
Donor type	0 if HLA-identical sibling; 1 in any other instance
Donor-recipient sex match	1 if female donor and male recipient; 0 for any other match

Note: The EBMT risk score was based on 3,142 patients treated with alloHSCT between 1989 and 1997, prior to the introduction of tyrosine kinase inhibitors. For low-risk patients (i.e., risk score of 0 to 2), the transplantation-related mortality was 31% in the original cohort; however, in a more recent cohort of patients who underwent transplantation between 2000 and 2003, transplantation-related mortality was reduced to 17%. For the patients with a risk score of 3 to 4, transplantation-related mortality was approximately 50%, and it was approximately 70% for the patients with a risk score of 5 to 6.93.
AP, accelerated phase; BP, blast phase; CP, chronic phase.
Adapted from Gratwohl A, Hermans J, Goldman JM, et al. Risk assessment for patients with chronic myeloid leukaemia before allogeneic blood or marrow transplantation. Chronic Leukemia Working Party of the European Group for Blood and Marrow Transplantation. Lancet 1998;352:1087–1092.

TKI to individual patients. Given the high median age at the time of diagnosis, many patients will be eligible only for reduced intensity conditioning regimens. An in-depth discussion of the various conditioning regimens, selection of bone marrow versus PBSCs, and post-transplant immunosuppression is presented elsewhere.

FUTURE PERSPECTIVES

Transformation to BP is rare in the age of TKIs, but the prognosis for patients crossing this threshold remains dismal. Understanding the mechanisms of resistance to advanced TKIs such as ponatinib will be critical for developing effective therapeutic strategies. Although ponatinib blocks all single BCR-ABL1 mutants, responses in BP are rarely maintained regardless of BCR-ABL1 mutational status. In vitro studies have shown that compound mutations, i.e., the presence of two point mutations in the same BCR-ABL1 molecule, can confer high-level ponatinib resistance and the same may occur in vivo.[234] Patients without detectable kinase domain mutations apparently develop truly BCR-ABL1 kinase-independent leukemia. As with refractory AML, it seems that we are approaching a ceiling on what can be achieved by concentrating on the leukemia cells, and future research must take into account the protective effects of the microenvironment.

At the other end of the disease spectrum, the majority of patients responding to TKIs continue to harbor residual leukemia cells, evident either as low-level qPCR positivity or as recurrence in the case of TKI discontinuation, a state often referred to as disease persistence. Ex vivo studies on cells from patients in CMR have identified Ph^+ cells both in progenitor and primitive long-term culture-initiating cells, and the frequency of leukemia stem cells in the $CD34^+CD38^-$ fraction was estimated at 0.59% ± 0.1% based on xenograft studies in immunodeficient mice.[248,249] There is convincing evidence that persistent CML cells are not (or are not solely) dependent on BCR-ABL1 kinase activity for their survival.[250,251] Several pathways have been implicated in mediating survival despite inhibition of BCR-ABL1 activity, including Wnt/β-catenin, PML, Hedgehog, Alox5, BCL6, and PP2A, among others.[252,253,254,255,256,257,258,259] The microenvironment may play a key role in activating these pathways, providing a sanctuary to residual CML cells. Significant efforts are being directed toward identifying therapeutic targets to eradicate residual leukemia. The biggest challenge is that many potential targets have important roles in normal hematopoiesis or development in general, limiting the therapeutic windows of targeted therapies. On the other hand, some patients treated with imatinib maintain CMR or MMR in the absence of continued therapy, and it will be important to understand the biology of these responses. One potential mechanism is that the CML clone, once reduced to very low levels by TKI treatment, is controlled by the immune system; alternatively, clonal extinction may be possible in some patients with biologically low-risk disease.[239] Whether this equals a cure may be a question of defining "cure" in the context of CML. Given that elimination of all leukemia cells cannot be proven, we may define "cure" as a risk of active CML that is not different from that in the general population. Long follow-up is needed to ascertain this point, and late relapses after allogeneic transplantation speak to the resilience of the Ph^+ cell clone.[260] More work is needed to truly turn CML into a problem of the past.

Acknowledgments

This work was supported by HL082978-01, CA04963920A2, Leukemia and Lymphoma Society grant 7036-01, and a Scholarship in Clinical Research of the Leukemia and Lymphoma Society. I am grateful to Kimberly Snow, University of Utah, for excellent editorial assistance and to Drs. Thomas O'Hare and Anna M. Eiring, University of Utah Huntsman Cancer Institute, for their critical feedback and encouragement.

CHAPTER 82

POLYCYTHEMIA VERA

Robert T. Means, Jr.

DEFINITION AND HISTORY

Polycythemia vera (PV), also called *polycythemia rubra vera*, is a chronic clonal myeloproliferative disorder characterized by a striking absolute increase in the number of red blood cells and in the total blood volume, and usually by leukocytosis, thrombocytosis, and splenomegaly. The bone marrow is typically hypercellular and exhibits hyperplasia of myeloid, erythroid, and megakaryocyte lineages.

In 1892, Vaquez described persistent polycythemia, as distinguished from relative and transient forms, in a man whom he believed to have a congenital cardiac lesion even though no auscultatory signs were noted. At autopsy, a year after the patient was first examined, his heart was found to be normal.[1] In 1903 and 1908, Osler recognized that various reports of polycythemia in the literature represented a single disorder and further clarified the clinical picture of the disease,[2–4] and Türk, in 1904, called attention to the occurrence of leukocytosis as well as to immature forms of cells of the red and white series, suggesting a hyperplastic disorder of blood formation involving the marrow as a tissue and not merely erythrocytes.[5] Thus, the general clinical picture of the disease was established in the earliest publications.[6]

Synonyms for PV used in the older literature include erythremia, splenomegalic polycythemia, Vaquez disease, Osler disease, polycythemia with chronic cyanosis, myelopathic polycythemia, erythrocytosis megalosplenica, and cryptogenic polycythemia.

EPIDEMIOLOGY

The age- and sex-adjusted incidence rate of PV was 1.9 per 100,000 person-years in Olmstead County, Minnesota, during the years 1935 to 1989,[7] and 2.6 per 100,000 person-years in Malmo, Sweden, during 1980 to 1984.[8] PV appears to be somewhat more common in men than in women, with reported male-to-female ratios ranging from 1.2 to 2.2 in various studies.[7,9–11] PV in younger patients reportedly shows less marked male predominance.[10] Some[8] but not all[7] studies have suggested that the incidence of PV is increasing over time. The frequency of PV according to age and sex is shown in Figure 82.1.

PV tends to be a disease of older individuals, with peak incidence observed at 60 to 80 years of age,[10,11] with maximum incidence exceeding 20 per 100,000 person-years.[7] The mean age at diagnosis has increased steadily since the 1920s.[11–15] Cases of PV have also been reported in patients younger than the age of 40 years.[16,17]

Racial and ethnic factors influence the incidence of PV. PV is significantly less common in African Americans than Americans of European ancestry.[9,13,18] A number of investigators (beginning with Türk) have reported that the incidence of PV is higher in individuals of Jewish origin.[9,13,19,20] Ashkenazi Jews in Northern Israel exhibit a higher incidence of PV than do their neighbors of Arab or Sephardic Jewish origins.[19]

Familial occurrence of PV has been reported by 6% of patients enrolled in the protocols of the Polycythemia Vera Study Group (PVSG) and in intermittent sporadic cases.[21–25,26,27]

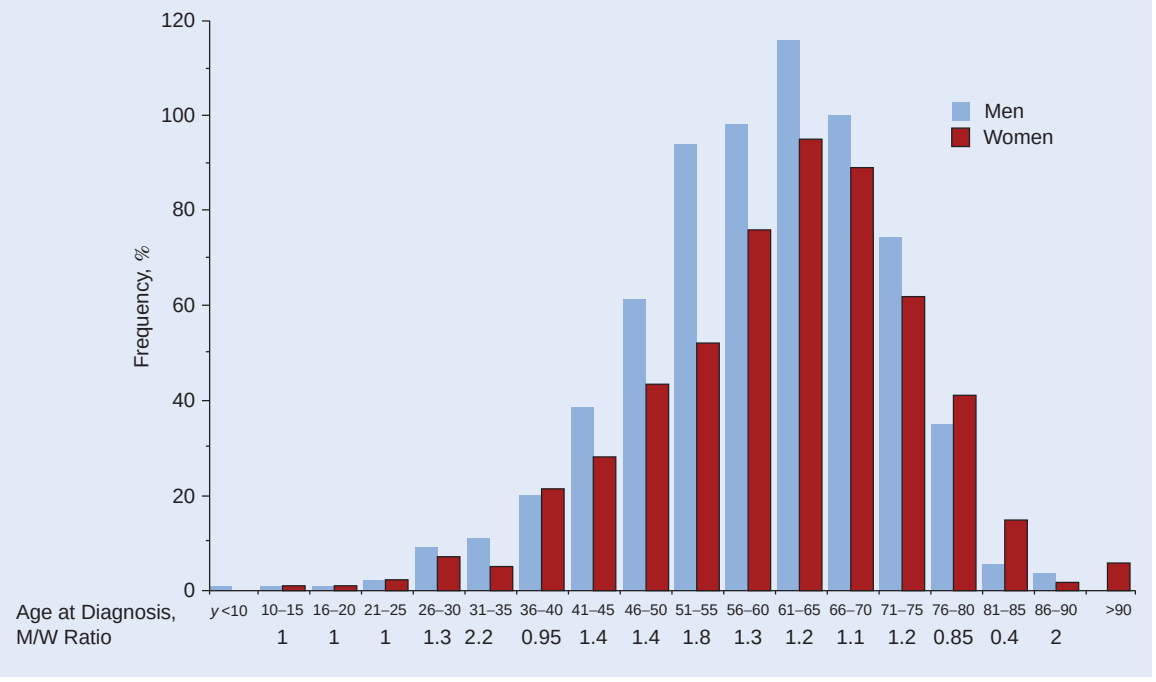

FIGURE 82.1 Frequency of diagnosis of polycythemia vera according to age and sex. Age at diagnosis of polycythemia vera for 671 men (55%) and 542 women (45%). M/W, ratio of men to women for diagnosis of polycythemia vera in each 5-year group. (From Gruppo Italiano Studio Policitemia. Polycythemia vera: the natural history of 1213 patients followed for 20 years. Ann Intern Med 1995;123:656–664, with permission.)

It was previously claimed that PV affected primarily those of slender body habitus, but there is little evidence to support this statement.[13]

CLINICAL FEATURES

The symptoms and signs of PV can be attributed in large part to the expanded total blood volume and to the slowing of the blood flow as a result of increased blood viscosity, as discussed in Chapter 44. At the time of diagnosis, it becomes apparent that the disorder has been present for a long time in most cases. Patients may complain of headache, dizziness, tinnitus, visual disturbances, dyspnea, lassitude, or weakness. Although the color of the skin often is acknowledged to have been abnormal for a long time, this complaint alone rarely brings the patient to the physician. Skin and mucous membrane hemorrhages are not uncommon; these, or a sense of weight or swelling in the abdomen owing to enlargement of the spleen, may be the initial symptoms. The lack of specificity of symptoms may in fact contribute to the delay in diagnosis. On the other hand, some patients have no complaints whatsoever, and polycythemia is discovered incidentally. Table 82.1 lists the frequency of common symptoms and physical findings in patients with PV.

Skin and Mucous Membranes

The color of the face is not cyanotic but is rather "ruddy," as might be produced by severe sunburn or a profound blush. The face also often appears swollen. This "rubor" may be so intense that it produces a startling appearance. The face, particularly the lips, cheeks, tip of the nose, ears, and neck, show this color (Fig. 82.2), but the skin of the trunk usually is not particularly affected. The distal portions of the extremities exhibit these changes more than the proximal portions and may be more truly cyanotic. The skin capillaries

FIGURE 82.2 Photograph of a drawing (original in color) of one of Osler's original patients.

are distended, and the capillary loops are enlarged. The degree of red or blue coloration depends on the state of dilation of the peripheral vascular network and on the speed of circulation through these areas, because these factors determine the quantity of reduced hemoglobin present.[28] This is responsible for the frequent description in earlier reports that PV produced "cyanosis." These findings are not unique to PV, but are also observed in patients with an elevated hematocrit from secondary erythrocytosis.

Ecchymoses and purpura of various sizes are common as the disease progresses. Red or dark-violet spots or brownish pigmentation of the skin may be found, and a great variety of skin lesions[29] have been observed, including dry skin, eczema, acneiform or urticarial changes, acne rosacea, acne urticata,[30] urticaria pigmentosa,[31–34] and neutrophilic dermatosis (Sweet syndrome).[35–38] The eyes may appear bloodshot. The mucous membranes may be a deep raspberry-red, and epistaxis and/or gingival bleeding may occur.

A common complaint is aquagenic pruritus, intense itching after exposure to water (most typically in a bath or shower). This may be the initial presentation of PV and is reported in up to 60% of PV patients younger than the age of 40 years.[17,39,40] The itching may be so troublesome that bathing with hot or even warm water is avoided. The reaction is less frequent after the use of cold water. This complaint tends to disappear as the polycythemia is treated, but may require specific intervention. Reddening, swelling, and pain in the digits (erythromelalgia) may occur and are typically associated with extreme platelet elevations.[41,42]

Cardiovascular System

Cardiac symptoms are not particularly prominent, and cardiac hypertrophy is typically absent. The circulatory minute volume is reduced, and the velocity of blood flow is greatly lowered,[43] but the cardiac output and work are normal.[44,45] Electrocardiograms may show prolonged QT duration.[46] When echocardiographic abnormalities are observed, they are typically associated with previous thromboembolic events and consequent pulmonary hypertension.[47,48] PV occurs in the population generally considered to be at highest risk for myocardial infarction, so whether PV increases this risk, and if it does, to what degree, is unclear.[49] Increased blood viscosity related to polycythemia, however, may contribute to symptoms in patients with atherosclerotic

cardiovascular disease.[50,51] Thrombotic events, in both the arterial and venous circulations, are common in patients with PV. Nineteen percent of the 1,213 patients followed by the Gruppo Italiano Studio Policitemia (GISP) experienced a thrombotic event. Of these, 50.5% of nonfatal thrombotic events were documented as having occurred in the arterial circulation and 38.5% in the venous circulation. More than 80% of fatal thromboses were arterial.[10] Other abnormalities of the venous system include varicosities and phlebitis.[52] Venous thrombosis is more common in women.[53] Moderate or significant thickening of the peripheral arteries is found in patients with PV, and coronary thrombosis, claudication without occlusion, arterial occlusion with gangrene, acroparesthesia, Raynaud phenomenon, and thromboangiitis obliterans have been described.[54,55]

As noted in Table 82.1 and in other studies,[56] hypertension is relatively common in patients with PV. It is unclear whether this reflects the increased incidence of hypertension in the middle-aged and elderly or is a consequence of increased blood viscosity. Certainly, improvement of blood viscosity by reduction of the red cell volume aids in the control of blood pressure.

Gastrointestinal System

In addition to nonspecific gastrointestinal symptoms experienced by everyone at some time, such as feelings of fullness, thirst, gas pains, and constipation, patients with PV have an increased frequency of peptic ulcer, gastrointestinal bleeding, or thrombosis of mesenteric vessels. When compared with dyspeptic controls, PV patients had a three- to fourfold greater frequency of upper gastrointestinal erosions or ulcers.[57,58] The relationship of blood basophil concentration, histamine content, gastric acid secretion, and dyspepsia on peptic ulceration has also been examined in a small group of patients with PV.[59] No convincing correlations were demonstrated. The frequency of *Helicobacter pylori* infection is increased in PV patients.[58]

Massive hemorrhage from varices in the esophagus, stomach, or bowel may be observed.[60–62] Thrombosis in the mesenteric veins and arteries may be mistaken for peritonitis or the perforation of an ulcer. Hepatomegaly is common (Table 82.1), and cirrhosis has also been reported.[63] *Mosse syndrome* is a term applied by some to the co-existence of cirrhosis and PV.[64] Budd–Chiari syndrome also occurs,[65,66,67] particularly in patients with a concurrent hypercoagulable state.[68–71]

Splenomegaly

Palpable splenomegaly occurs in more than two thirds of PV patients (Table 82.1).[12,72] The size of the spleen varies greatly between individual patients and occasionally may extend to the pelvic brim.[73] It is usually hard and smooth. Patients may experience pain in the splenic region, and after infarction a friction rub can be heard in this area. The general assumption is that polycythemia antedates the enlargement of the spleen and that engorgement of this organ with blood and extramedullary hematopoiesis are the major contributors to splenomegaly. Splenomegaly appreciated only by radiographic techniques was considered a minor diagnostic criterion in most pre-2007 diagnostic schemes for PV.[74,75] Experience suggests that most practitioners regard it as the equivalent of splenomegaly observed on physical examination.

Respiratory System

Dyspnea on severe exertion is common, and hoarseness is not unusual. Chest radiographs often reveal prominent vascular markings. Before the establishment of the PVSG diagnostic criteria, which require a reasonably normal arterial oxygen saturation for the diagnosis of PV, it was noted that the vast majority of patients with PV had normal arterial oxygen saturation, even when the hemoglobin levels were high, indicating that the high viscosity of the blood does not prevent normal blood oxygenation; oxygen dissociation studies were also normal.[76–79] High diffusing capacities, which were reduced after phlebotomy, were also noted in a number of patients with PV.[80] In another study, hypoxia, as evidenced by a low arterial oxygen tension and saturation, was observed in the absence of demonstrable co-existent cardiorespiratory disease.[81] In these individuals, ventilation–perfusion ratios were altered, and the diffusing capacity was low. The authors postulated that these findings might be the result of an alteration of the pulmonary vasculature caused by unrecognized thromboembolism. Pulmonary hypertension is reported in patients with PV and other myeloproliferative disorders.[48,82]

Genitourinary System

Vesical, vaginal, and uterine bleeding have been reported, as has nontraumatic perirenal hematoma.[83–86] When hypertension is noted, albuminuria and signs of renal disease may be found.

Neuromuscular System

Headache is the most common neurologic symptom[87] but lassitude, vertigo and giddiness, transitory syncope, insomnia, weakness, and a sensation of fullness in the head and numbness and tingling in the fingers (less often in the feet) are also common.

Visual disturbances are common and include transitory dimness of vision, or even temporary blindness, scotomas, specks and bright points in front of the field of vision, diplopia, and temporary paralysis of one of the eye muscles. On examination of the eye grounds, the vessels may be engorged, tortuous, and irregular in diameter; the veins may be dark purple, and the retina deeply colored. Papilledema and embolism of the central retinal artery have been reported.[88]

The cerebrospinal fluid pressure may be increased.[89] Ringing and roaring in the ears are exceedingly common when the hematocrit is significantly elevated. Ménière syndrome and chorea[90] have also been reported.

Vascular lesions of the brain constitute the most serious complication of PV.[91–94] A variety of neurologic syndromes, ranging from hemiparesis to seizures to alteration of cerebral function, have been reported in patients with PV. All such symptoms and signs presumably are secondary to increased blood volume and/or decreased blood flow. Investigators have shown clearly that cerebral blood flow is greatly diminished at hematocrit levels between 0.53 and 0.62,[95] and that elevated hematocrit is a risk factor for cerebrovascular accidents.[96,97] Central nervous system vascular events represented 30% of the nonfatal thrombotic events and 10.3% of deaths observed in the GISP study.[10]

Pain in the limbs may be troublesome and severe. It has been attributed to pressure on the bone by swollen, hyperplastic bone marrow. Unusual paresthesias may be encountered, but anatomic evidence of spinal cord changes has not typically been found at autopsy.

BLOOD AND LABORATORY FINDINGS

Hematologic Findings

Erythrocytes

Hemoglobin concentration typically is in the range of 18 to 24 g/dl. Red cell counts of 7 to 10×10^{12}/L are common when patients with this disease are first evaluated, and values as high as 12 and even 15×10^{12}/L have been recorded.[98] The individual erythrocytes usually appear normal. Slight anisocytosis may be evident, but poikilocytosis is unusual. Polychromatophilia and,

occasionally, basophilic stippling may be found. An occasional normoblast may be observed in the blood smear, and, in the presence of a relatively normal or definitely increased red cell count, should arouse suspicion of PV. The reticulocyte percentage is not significantly increased. After hemorrhage, however, the reticulocytes may be increased, and a number of other immature forms of the red cell series may be encountered. If bleeding occurs repeatedly, iron-deficient erythropoiesis may develop. This raises an interesting semantic point: these patients are iron deficient in that iron stores are absent, but the total body iron content, including the iron present as hemoglobin in red cells, may be normal. Increased resistance to osmotic lysis has been reported for PV erythrocytes.[99]

Leukocytes

Leukocyte counts of 25.0×10^9/L are not uncommon and values in the 50.0×10^9/L range are occasionally seen.[100] The myeloid leukocytes are both relatively and absolutely increased, metamyelocytes are increased in number, and 1% or 2% of myelocytes, sometimes more, are found. Myeloblasts usually are not observed. Basophil, eosinophil, or monocyte concentrations may be increased and provide a marker of an underlying myeloproliferative disorder. Leukocytes from patients with PV exhibit increased metabolic activity.[101] A total leukocyte count greater than 12.5 to 15.0×10^9/L is a risk factor for thrombosis.[102]

Neither Vaquez nor Osler appreciated the significance of the leukocytosis with a "shift to the left" in the myeloid series of leukocytes that often is present in this disease initially described by them. Türk, in 1904, called attention to this significant finding, which suggested that the whole bone marrow, rather than the erythropoietic tissue alone, was hyperactive. The leukocyte counts were $>10.0 \times 10^9$/L in 50% of Osler's patients. In larger series, leukocytosis is seen in more than 80% of patients, and counts greater than 12.0×10^9/L in approximately 40%.[12,100]

Platelets

The platelet count frequently is increased, usually in the 500 to $1{,}000 \times 10^9$/L range, but counts as high as 3,000 and even $6{,}000 \times 10^9$/L have been reported.[103] Bleeding time and conventional coagulation parameters usually are normal, but the clot may retract poorly. An artifactual elevation of protime and activated partial thromboplastin time may be observed in patients with erythrocytosis. The standard citrated tube used for coagulation studies contains a fixed quantity of anticoagulant for a fixed volume of blood. In polycythemia, there is a relative reduction of plasma, meaning that there will be excess anticoagulant for the volume of plasma. Functional assays of coagulation factors will thus be prolonged. This prolongation has no clinical significance other than provoking panic on the part of the individual reviewing the laboratory results. The leukocyte and platelet counts are not always increased above normal in patients with otherwise typical disease. Normal values were found in 20% of the patients in one series.[15]

Morphologic and qualitative functional platelet abnormalities often are detectable. Platelets may appear to be abnormally large, and even bizarre-shaped, and megakaryocyte fragments sometimes are seen in the blood smear. The hemorrhagic complications of this disease suggest that a hemostatic defect may be present, although physical distention of the vascular bed undoubtedly contributes to bleeding when it occurs. Platelet function defects reported in PV include shortened platelet survival in patients with erythromelalgia,[104] altered von Willebrand factor multimers[105] and acquired von Willebrand syndrome,[106] deficient platelet-aggregating factor-induced aggregation,[107] increased platelet thromboxane production,[108] and platelet factor 3 deficiency.[109] Plasminogen activator inhibitor-1 levels have been reported to be both elevated[109] and decreased[110] in patients with PV. Platelet glycoprotein IIIa expression has also been reported to be decreased in PV patients.[111]

Total Blood Volume

The total blood volume characteristically is increased. The enormous increase in blood volume, which distends even the smaller vessels of the whole body, no doubt accounts for many of the symptoms of this disease. In a group of 30 patients in whom the hematocrit was 0.55 or greater, the total red cell volume, measured by the radioactive phosphorus (^{32}P)-labeled red cell method, was 38.8 to 91.9 ml/kg body weight as compared with the normal average of 29.9 ml/kg.[112] In two thirds of this patient group, the plasma volumes were below the lower limits of normal, and in none was the plasma volume above normal. Similar observations have been made using the chromium isotope method.[11] Because of variations in plasma volume, the packed cell volume (or hematocrit) gives only a rough indication of the size of the red cell mass.

In the early phases of PV, the red cell volume may not be elevated into this range. It has been proposed that a red cell volume > 125% of predicted is an appropriate criterion for polycythemia.[113] In other circumstances, blood loss may result in "autophlebotomy"; that is, the patient becomes iron deficient, and the hemoglobin, hematocrit, and red cell volume fall into the normal range.

Erythrocyte Kinetics

Erythrokinetic studies have shown active hemoglobin production, but otherwise, findings have been diverse. Erythrocyte survival may be normal[114] or shortened,[115] and splenic sequestration may or may not be present. As measured by the ^{15}N-glycine method, the rate of hemoglobin production was approximately two times the normal rate. The plasma iron turnover rate was also increased.[115] This value was not reduced to normal by oxygen administration, as occurs when polycythemia is caused by anoxia.

Increased serum bilirubin[99] and increased urine and stool urobilinogen[116] levels have been demonstrated in some patients with PV, but when adjusted for the increase in the total amount of hemoglobin that must be degraded, fecal urobilinogen values rarely are increased above expected values and may be somewhat reduced.

Neutrophil Kinetics

Studies of neutrophil kinetics in patients with PV in whom neutrophil counts ranged from normal to 23.9×10^9/L showed a blood neutrophil pool that ranged from normal to 12 times normal, with increased margination and a normal or slightly prolonged half disappearance time. The blood neutrophil turnover rate (effective neutrophil production) usually was increased and varied from normal to five times normal mean values.[117] Increased polymorphonuclear leukocyte activation is also observed in PV patients, and is associated with evidence of endothelial damage.[118]

Platelet Kinetics

Studies of platelet kinetics in five patients with PV in whom the platelet concentration was increased revealed effective production rates that ranged from 2 to 13 times normal. The marrow megakaryocyte mass was increased in all five patients studied.[119]

Fibrinogen Turnover

Results of studies involving three patients with erythremia indicated that fibrinogen was consumed in the course of chronic disseminated intravascular coagulation[120]; similar findings were

observed in several patients with erythrocytosis secondary to pulmonary insufficiency. No correlations between fibrinolytic parameters and thrombotic complications of PV have been reported.[121]

Other Laboratory Findings

The viscosity of the blood may be five to eight times greater than normal.[98,122] The specific gravity is 1.075 to 1.080, compared with the normal range of 1.055 to 1.065. The degree of abnormality varies with the relative quantity of red corpuscles. The viscosity and specific gravity of the serum were actually less than normal. The erythrocyte sedimentation rate of polycythemic blood is low.[123] The urine may be normal, but albuminuria is found occasionally, and, less often, casts are present.[100] The increased urobilinogenuria noted in some of the patients has been mentioned. Studies of renal hemodynamics suggested that glomerular filtration, despite the decreased fraction of plasma in the blood, is kept at almost normal values by an increase in renal blood flow and in the proportion of plasma filtered.[124] The amount of uric acid in the serum may be normal or increased. Hyperuricemia was present in 70% of 127 patients in one series[125] and in 55% of 325 patients[11] in another series. Values ranged from 2.8 to 11.7 mg/dl (average, 6.6 mg).[11] Secondary gout occurs in 5% or more of these patients,[13,17,125–127] and symptoms often are atypical.[98] The occurrence of hyperuricemia in association with PV is attributable to overproduction of uric acid.[126,128] A vitamin B_{12}–binding protein, which may be an altered form of transcobalamin I (Chapter 36), has been found in the plasma of patients with PV and in a variety of conditions involving leukocytosis.[129,130] The presence of this protein may explain the observation that, whereas serum B_{12} content may be within the normal range or only moderately elevated, the capacity of the serum to bind additional vitamin B_{12} added in vitro (unsaturated B_{12}–binding capacity, $UB_{12}BC$) is increased. Plasma homocysteine levels in polycythemic patients are higher than nonpolycythemic subjects but still in the normal range.[131] The leukocyte alkaline phosphatase score is normal or elevated in 80% to 100% of PV patients.[113,125]

Serum erythropoietin concentration is typically low in PV and may be elevated in secondary polycythemia. An elevated erythropoietin level in a polycythemic patient with reduced arterial oxygen saturation would be evidence against PV. Birgegard and Wide have proposed that PV can be distinguished from secondary polycythemia by the erythropoietin response to phlebotomy: the erythropoietin concentration rises after phlebotomy in secondary erythrocytosis but remains unchanged in PV.[132] A decreased serum erythropoietin concentration is a minor criterion for the diagnosis of PV in the WHO criteria, and a clinical criterion in the European Clinical and Pathological (ECP) criteria.[74,113,133]

Spurious hyperkalemia has been noted when platelets are greatly increased in number.[134] Hyperhistaminemia and hyperhistaminuria were reported in patients with PV compared with normal controls and secondary polycythemia subjects, but did not correlate with the pruritus often present.[135] The basal metabolic rate may be increased moderately.[136] Gastric acidity ranges from absent to increased.

Patients with PV and thrombosis exhibit a greater frequency of procoagulant abnormalities in antithrombin III, protein C, protein S, and resistance to activated protein C than do PV patients without thrombosis.[137] Studies of prothrombin and factor V gene polymorphisms with a thrombotic diathesis showed no increased incidence of these abnormalities in PV patients.[138] However, polymorphisms of the Pl^{A2} allele of platelet glycoprotein IIIa were associated with increased arterial thrombosis in PV and essential thrombocythemia patients.[138]

Bone Marrow

For most of the last 40 or 50 years, bone marrow examination was not one of the criteria included in the PVSG standard for the diagnosis of PV.[11] The value of bone marrow examination in the differentiation of PV from other myeloproliferative disorders, from secondary polycythemia, from spurious polycythemia, or from the normal state was debated. Some investigators believed it to be an invaluable aid for making this differentiation;[139,140] others regard it as an important diagnostic tool but not one that is capable of definitively establishing the diagnosis.[12] However, both currently accepted diagnostic requirements for PV, the World Health Organization (WHO) criteria and the ECP criteria, formally include bone marrow examination.[133,141]

The marrow typically is hypercellular[142,143] (Fig. 82.3), but normal cellularity is noted at the time of diagnosis in approximately 13% of cases.[144] Hyperplasia involves all of the marrow elements and displaces marrow fat. Cellularity can be estimated with considerable accuracy by low-power examination of clot sections and needle or trephine biopsies. In several series, the mean cellularity of the marrow was 80% to 90% compared to approximately 30% in normal subjects and 40% in patients with secondary erythrocytosis.[139,140,145] As mentioned, a few patients with untreated PV may have normal marrow cellularity.[144,145] Thus, the lack of hypercellularity does not exclude the diagnosis but should make it suspect.

An increase in megakaryocyte number and size is well documented in association with PV and was reported in 95% of 175 cases. When the number of megakaryocytes was expressed in terms of fat-free marrow, however, the megakaryocyte hyperplasia was proportional to overall marrow cellularity.[144] The ratio of the different cell types in the marrow is not strikingly different from normal. Clumps of pronormoblasts and basophilic erythroblasts are seen,[143] and the percentage of nucleated red cells may be moderately elevated.[146] Myelocyte and myeloblast numbers may be greater than normal, and an increase in eosinophils[147] and basophils may be found.[146]

Iron pigment is absent from the marrow in more than 90% of patients, even when phlebotomy has not been performed.[147,148] Increased marrow iron stores have been suggested as a morphologic hallmark favoring a secondary form of erythrocytosis over PV.[145,146] An increase in marrow reticulin levels and/or fibrosis has often been reported, but an increase was observed in only 11% to 15% of patients studied early in the course of

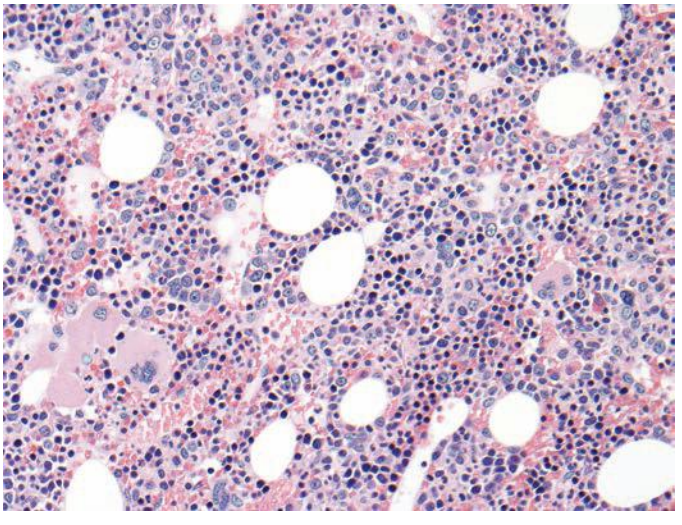

FIGURE 82.3 Bone marrow biopsy from a patient with polycythemia vera, showing hypercellularity and hyperplasia of myeloid, erythroid, and megakaryocyte series (1,000×).

their disease.[144,145] The increase in reticulin correlates with the degree of marrow cellularity.[145] It is slowly progressive but no increase occurs in association with a particular form of treatment or with the duration of the disease.[144] Marrow vascularity may be increased in PV and other myeloproliferative disorders.[146]

Cytogenetics

In early studies of cytogenetic abnormalities associated with PV, aneuploidy was noted in some patients; however, many subjects had been treated previously and modern banding techniques were not used.[149] In more modern studies, cytogenetic abnormalities were observed in 20% to 43% of patients.[150–152] The frequency of chromosomal abnormalities varied with the clinical picture. Results from two series are presented in Table 82.2.[151,152] Fewer than 20% of patients studied at diagnosis had a cytogenetic abnormality. Patients evaluated during a clinical course not associated with progression had cytogenetic abnormalities in 25% to 35% of cases. However, patients who progressed to either myeloid metaplasia, myelofibrosis, or acute leukemia/myelodysplastic syndrome had abnormal cytogenetics in 75% to 100% of evaluations. The greater frequency of cytogenetic abnormalities in patients progressing to myelofibrosis in one of these series may reflect the greater utilization of ^{32}P therapy and alkylating agents among those patients.[152] The cytogenetic abnormalities most commonly observed were trisomy 8, trisomy 9, and deletions of Y, 5q, 6q, 7q, 11q, 13q, and 20q.[151] Although cytogenetics do not predict outcome, they appear to be correlated with disease stage and duration. Specific evaluation for trisomy 8, trisomy 9, and 20q- by fluorescent in situ hybridization may be a useful adjunct to conventional cytogenetics.[153]

PATHOGENESIS

The cause of PV is unknown. The early suggestion that this disease was the compensatory result of anoxemia of the bone marrow was based on the presence of capillary thickening and subintimal and adventitial fibrosis of small vessels in the bone marrow.[154] Direct measurements of bone marrow oxygen saturation, however, gave normal values,[155] and the lack of elevated serum or urinary erythropoietin levels[156,157] is also contrary to this hypothesis.

Clonality

In view of the increased production and turnover of erythrocytes, neutrophils, and platelets as well as the hypercellular marrow, hematopoiesis in PV is abnormal at a multipotent progenitor or stem cell level. Evidence supporting this hypothesis was provided by a study of two black female patients with PV who were heterozygous for X-linked glucose-6-phosphate dehydrogenase deficiency.[158] In these patients, tissues not affected by PV (skin fibroblasts and lymphocytes) possessed both A- and B-type glucose-6-phosphate dehydrogenase isozymes, as expected. Red blood cells, granulocytes, and platelets contained only one isozyme (type A), however, thus demonstrating a probable clonal origin of this disorder at a pluripotent hematopoietic progenitor level. In one other patient, most B lymphocytes were also from the disease clone,[159] indicating involvement of an earlier hematopoietic progenitor that had differentiation potential for the lymphoid as well as the myeloid, erythroid, and megakaryocytic series.

Hematopoietic Progenitor Studies

The number of erythroid progenitors (burst-forming units-erythroid [BFUs-E] and colony-forming units-erythroid [CFUs-E]) detected in PV patients has been variously reported as either similar to that observed in normal persons or increased.[160,161] It has also been suggested that there is an increase in cycling of primitive BFUs-E, and that CFUs-E (typically observed only in marrow) are to be found in the peripheral blood of patients with PV.[162,163]

A hallmark of PV (and other myeloproliferative disorders as well) is erythroid progenitor colony formation in vitro without the addition of exogenous erythropoietin, the phenomenon called *endogenous erythroid colonies* (EECs) or sometimes *erythropoietin-independent colony formation.*[164,165] This phenomenon has been observed with progenitors cultured from the marrow or the blood[162,163,166–169] of PV patients. This can be a consequence of true erythropoietin independence or of exquisite sensitivity to erythropoietin, which would permit a response to the extremely small quantities of erythropoietin present in the serum used in culture media. A variety of investigators, using either serum-free medium or neutralizing antibodies to erythropoietin in serum-containing medium, have provided data suggesting that EECs are a consequence of enhanced sensitivity to erythropoietin.[168,170,171,172] Another group subsequently reported studies suggesting that EECs are a consequence of an altered response pattern induced by hypersensitivity to interleukin-3.[173] Studies using antibodies capable of blocking the erythropoietin receptor suggest that BFUs-E fall into two categories: those that exhibit a normal response to erythropoietin and those that are truly erythropoietin independent.[174]

In addition to interleukin-3 and erythropoietin, erythroid progenitors from PV patients have been reported to exhibit hypersensitivity to granulocyte-macrophage colony-stimulating factor, interleukin-1, stem cell factor, and insulinlike growth factor-1.[175–180]

Hematopoietic Growth Factor Signal Transduction

The reported hypersensitivity of erythroid progenitors to erythropoietin in PV prompted evaluation of the erythropoietin receptor in this disease. The normal human erythropoietin receptor, although the product of a single gene, is detected on CFU-E as a high- and low-affinity receptor.[181,182] In CFU-E

TABLE 82.2

FREQUENCY OF ABNORMAL CYTOGENETICS BY POLYCYTHEMIA VERA DISEASE STAGE IN TWO SERIES

Reference	Patient Number	Frequency (Expressed as Percentage of Patients)				
		At Diagnosis	Polycythemia Vera	Myelofibrosis	Myeloid Metaplasia	Acute Leukemia/ Myelodysplasia
146	64	17	32	85	75	75
145	37	14	25	40	78	100

generated from PV patients, only the low-affinity receptor is present.[183] This differs from the finding in normal individuals, patients with hemolysis, or patients with secondary erythrocytosis. Studies of the erythropoietin receptor gene in PV have typically shown no mutations,[184,185] suggesting that the detection of only the low-affinity receptor class is the result of an alteration in post-translational processing. Normal erythroid progenitors have been reported to express both a full-length erythropoietin receptor and a nonfunctional truncated version, which is believed to act as a dominant negative regulator of erythropoietin signal transduction. Expression of the truncated variant is reportedly decreased in PV patients, suggesting a mechanism for erythropoietin hypersensitivity.[186]

The thrombopoietin receptor (Mpl) has been reported to be markedly decreased or absent on the platelets of PV patients and also of some individuals with myelofibrosis.[187] These individuals exhibit decreased thrombopoietin-induced tyrosine phosphorylation.[187] This decrease in phosphorylation appears to result from aberrant signaling through an abnormal Mpl characterized by decreased glycosylation.[188,189] It has been suggested that this abnormality in Mpl expression and function is both a marker for PV and, through suppression of apoptosis, a potential pathophysiologic contributor.[188] Other investigators have questioned the usefulness of Mpl as a diagnostic marker of PV, as marked heterogeneity in its expression was observed in their laboratory, resulting in overlap with normal individuals.[190]

The characteristic behavior of hematopoietic progenitors in PV may also reflect constitutive or deregulated activation of antiapoptotic mechanisms. Various investigators studying PV have reported constitutive activation of STAT3[191]; deregulation of the antiapoptotic protein Bcl-x[192,193]; decreased expression of SHP-1 phosphatase, a negative regulator of hematopoietic growth factor–induced mitogenesis[194]; increased protein tyrosine phosphatase activity[195]; decreased sensitivity of protein kinase C to the effects of inhibitors[196]; decreased expression of the tumor suppressor gene *H19*[197]; and increased expression of $FLIP_{short}$, a cellular inhibitor of death-receptor–induced apoptosis.[198] Activation of STAT5 and/or Bcl-xL in erythroid progenitors leads to erythropoietin-independent colony formation.[199]

CD177 (PRV-1) is a gene of the urokinase plasminogen activator receptor superfamily, which is highly expressed in granulocytes from PV patients but not from patients with other chronic myeloproliferative disorders or from normal individuals.[200] Polymerase chain-reaction–based techniques for detecting *PRV-1* have been developed, and appear to be highly sensitive and specific for PV.[201] *PRV-1* expression is highly correlated with expression of the *JAK2* V617F mutation (discussed below).[202]

JAK2

The observation that patients with myeloproliferative disorders frequently have a gain-of-function mutation on the short arm of chromosome 9, in which the valine at position 617 of the Janus kinase 2 gene is replaced by phenylalanine (*JAK2* V617F),[203] has had significant impact on the approach to the diagnosis of PV and on investigation into its pathogenesis. This mutation results in constitutive activation of tyrosine kinase signaling through the *JAK/STAT* pathways. *JAK2* V617F has been reported to be present in up to 96% of PV patients at diagnosis,[204] and correlates strongly with the PVSG and 2001 WHO criteria for the diagnosis of PV.[205] However, it is not pathognomonic for PV, inasmuch as a significant proportion of patients with essential thrombocytosis and myelofibrosis also have the *JAK2* V617F mutation.[204] PV patients who lack the *JAK2* V617F mutation often have mutations in exon 12 of the *JAK2* gene.[206,207,208,209]

Although mice expressing *JAK2* V617F have a clinical phenotype resembling a myeloproliferative disorder,[210] *JAK2* mutations do not appear to be the initiating event in the molecular cascade leading to PV, but rather appear to be a relatively late event.[211,212] The specific phenotype seen with *JAK2* V617F mutations is effected by concurrent expression of other genes (*TET2*,[213] *PRV1*,[214] and *IDH1* or *IDH2*[215]) and by the *JAK2* haplotype.[216] *JAK2* V617F expression correlates with the expression of erythrocyte adhesion molecules such as laminin α_5 and Lu/BCAM.[217,218]

DIAGNOSIS

In order to standardize the diagnostic basis of PV so that all patients included in their protocols had clear-cut and inarguable PV, the PVSG developed a set of criteria that were useful clinically and conceptually (Table 82.3).[11] The diagnosis of PV required the presence of all three major criteria (M) or the first two major criteria and two minor criteria (m). The first major criterion provided confirmation that the patient has actual polycythemia, as indicated by an elevated red cell mass. The second major criterion ruled out the most common etiology of secondary polycythemia, severe arterial hypoxemia, by demonstrating a normal or only moderately reduced arterial oxygen saturation. The third requirement, evidence of a myeloproliferative syndrome, was met either by the third major criterion, splenomegaly appreciable on physical examination, or by two of the four minor criteria. Over the years, a number of alternate major and minor criteria developed[113,219] (Table 82.3).

PVSG's goal was to establish exclusive criteria. Although most PV patients meet the PVSG criteria, some do not. The current (2007) WHO criteria and the ECP diagnostic criteria for the diagnosis of PV were developed to address the perceived deficiencies of the PVSG criteria (Table 82.4). The ECP criteria are strongly oriented toward morphologic and molecular diagnostic criteria, and separate PV into overt PV (having a high red cell mass) and early PV.[74,133] For purposes of research or publication, the 2007 WHO and/or ECP criteria have largely replaced the PVSG criteria, although not without some controversy.[220] The WHO and ECP criteria may be less applicable to childhood PV.[221]

The diagnostic approach to erythrocytosis is outlined in Chapter 44 and Tables 44.3 and 44.4. In essence, a patient with polycythemia should undergo testing for *JAK2* V617F. If positive, the patient presumably has PV, although a low erythropoietin concentration or a characteristic bone marrow examination is required for confirmation. If *JAK2* V617F is not present, then one must decide if features are suggestive of PV (essentially, the criteria listed in Table 82.3), or if one should proceed to identify an etiology of secondary polycythemia. Some clinical situations, such as distinguishing *JAK2* V617F-postive essential thrombocytosis with concurrent secondary polycythemia from PV, may be challenging to sort out.

In *JAK2* V617F-negative patients, testing for alternate *JAK2* mutations can be considered. It has been suggested that *JAK2* exon 12 mutations identify a specific subset of PV characterized by "pure" erythrocytosis, with few or no abnormalities in the white blood cell or platelet lineages.[206,222]

NATURAL HISTORY

The clinical picture of PV is characterized by the complications of polycythemia-induced hyperviscosity, expanded blood volume, and thrombosis. The occurrence of these complications is significantly affected by therapy and is discussed under specific therapeutic modalities.

Two other significant complications that may be observed late in the course of PV are the development of myeloid metaplasia with myelofibrosis and acute leukemia. In perhaps 25% of patients with PV, a progressive reduction in erythrocyte survival, decreased erythropoiesis, and myelofibrosis develop.[223]

TABLE 82.3

POLYCYTHEMIA VERA STUDY GROUP DIAGNOSTIC CRITERIA: SIGNIFICANCE AND PROPOSED ALTERNATIVES/ADDITIONS

Significance	Original Criteria	Alternative/Additional Criteria
M1. Identifies actual polycythemia vs. spurious polycythemia	M1. Increased RCM Male >36 ml/mg Female >32 ml/kg	M1. RCM > 125% of predicted
M2. Rules out most common etiology of secondary polycythemia	M2. Arterial O_2 saturation > 92%	M2. Serum erythropoietin concentration not elevated
M3. Evidence of a myeloproliferative state	M3. Clinical splenomegaly or two of the following:	M3. (Additional minor criteria)
	m1. Thrombocytosis > 400,000/μl	Splenomegaly apparent only on scans
	m2. Leukocytosis > 12,000/μl	Hypercellular marrow with trilineage hyperplasia
	m3. Leukocyte alkaline phosphatase activity > 100 (no fever or infection)	Characteristic hematopoietic colony response to growth factors
	m4. Serum B_{12} (>900 pg/ml) or unsaturated B_{12} binding capacity (>2,200 pg/ml)	Evidence of clonal marrow cell population PRV-1 gene expression in granulocytes Decreased Mpl expression on platelets

RCM, red cell mass.

Extramedullary hematopoiesis takes place in the spleen and liver. A rising leukocyte count with increased immature myeloid forms accompanies these changes. In addition, the teardrop and nucleated red cells characteristic of myelofibrosis and myeloid metaplasia appear in the blood. The spleen may enlarge dramatically. A picture simulating that of acute myeloblastic leukemia develops in approximately one third of these patients.[223] Others develop progressive anemia and thrombocytopenia and die of a variety of intercurrent complications in the "spent" or "burnt-out" phase of myeloid metaplasia.[224] It has been suggested that post-polycythemia myeloid metaplasia syndrome was related to the use of ^{32}P therapy,[224] although it clearly occurs in patients who have never received this therapy. In still other patients,[10,223] an acute leukemia-like picture develops without preceding evidence of myeloid metaplasia or myelofibrosis. It has been suggested that the small number of patients who have cytogenetic abnormalities at diagnosis are those who will eventually develop leukemia, but this is not observed in all series.[151,152,223] The effect of therapy on the development of leukemia is discussed in the "Chemotherapy" section that follows.

A number of other diseases have been reported in association with PV. It is unclear whether these represent coincidence or an actual pathophysiologic relationship. These include hyperthyroidism,[225] neurofibromatosis (von Recklinghausen disease),[226] chronic lymphocytic leukemia,[227] lymphoma, multiple myeloma,[228] as well as development of a marrow picture resembling aplastic anemia[229] or pernicious anemia.[230,231]

The median survival of untreated PV patients is reported to be 18 months[232]; in a more contemporaneous series of treated patients, median survival is greater than 15 years.[10] Overall survival of PV patients appears decreased compared to age- and sex-matched controls.[233] Table 82.5 gives the causes of death from three large series of PV patients.[10,234,235] Thrombotic and cardiovascular events are the leading cause of death, followed by acute leukemia and other malignancies, hemorrhage, and myelofibrosis/myeloid metaplasia, which represented 2% to 4% of patients. The most important predictors of cardiovascular events are age older than 65 and a history of thrombosis.[235] The *JAK2* V617F allele burden appears to identify patients at higher risk for major vascular events and evolution to myelofibrosis, inasmuch as it also indentifies patients more likely to have marked leukocytosis,[236] which may be the basis for the increased risk.[237,238]

TREATMENT

The object of therapy in PV is to produce a reduction in the red cell mass by methods that (a) permit the longest survival; (b) are associated with fewest significant complications, allowing the patient maximum quality of life; and (c) are least expensive and inconvenient for the patient.

Phlebotomy

Phlebotomy offers prompt and effective reduction of the red cell mass and blood volume to normal values. Many patients can be maintained in an essentially normal state by phlebotomy together with a few simple adjuvants, when necessary, to control hyperuricemia or pruritus. The advantages of phlebotomy are that it is inexpensive, requires extremely limited technical support, and allows rapid control of symptoms. Criticisms of phlebotomy are the potential problem of venous access in elderly patients, that it does not address leukocytosis or thrombocytosis, and that erythropoiesis is stimulated by the blood loss.[156] This last point is only a transient concern; the goal of phlebotomy is to induce a state of iron deficiency that will itself suppress erythropoiesis.

The PVSG took patients who had been phlebotomized to maintain a normal hematocrit (≤0.45) and then randomized patients to phlebotomy to maintain the hematocrit in this range, to therapy with ^{32}P, or to therapy with chlorambucil.[239] Median survival from study entry until death was 9.1 years for patients in the chlorambucil arm, 10.9 years for ^{32}P-treated patients, and 12.6 years for phlebotomized patients ($P = 0.008$). The survival differences did not become apparent until after 7 years into the study, indicating that the development of late events (principally leukemia) was responsible for these differences.[239] Acute leukemia developed in 1.5% of phlebotomy patients, 14.2% of chlorambucil patients, and 9.6% of ^{32}P patients. This complication was more frequent in patients with the "spent phase" of PV. Myelofibrosis was observed in 8.6%, 7.1%, and 7.7% of the phlebotomy, chlorambucil, and ^{32}P patients, respectively.[239]

The apparent advantage of phlebotomy was undercut by an increased risk of thrombosis. Thrombosis-free cumulative survival was significantly worse in the phlebotomy arm ($P = 0.015$). This increased risk was predominantly limited to the first 3 years of therapy.[239] Advanced age and history of previous thrombosis contributed to the relative risk of thrombosis in this and other studies.[10,234]

TABLE 82.4

2007 WORLD HEALTH ORGANIZATION AND EUROPEAN CLINICAL AND PATHOLOGICAL CRITERIA FOR DIAGNOSIS OF POLYCYTHEMIA VERA[74,133]

Who	Ecp
Major Criteria	Pathologic Criteria
A1. Hb > 18.5 g/dl male/16.5 g/dl female; or other evidence of increased RCM	P1. Marrow morphology P2. Bone marrow EEC formation P3. *JAK2* V617F mutation
A2. Presence of *JAK2* V617F or other functionally similar mutation	
Minor Criteria	**Clinical Criteria**
B1. Marrow morphology	C1. Increased RCM (same as WHO A1)
B2. Serum erythropoietin below reference range for normal	C2. Hematocrit 0.45–0.51 male 0.43–0.46 female
B3. EEC colony formation in vitro	C3. Low serum erythropoietin
	C4. Persistent thrombocytosis
Marrow morphology: hypercellular marrow with trilineage hyperplasia; clustering of pleomorphic megakaryocytes; absent stainable iron; no major inflammatory features	Grade I: 400,000–1,500,000/μl; Grade II: >1,500,000/μl
	C5. Palpable splenomegaly or radiologic splenomegaly > 12 cm
	C6. Granulocytosis > 10,000/μl; or leukocytosis > 12,000/μl; or increased LAP score; or increased PRV-1 expression, in absence of fever or infection
	C7. Platelet-mediated microvascular disease or thrombosis
	C8. Typical PV signs/symptoms of hypervolemia
	C9. Pruritus, fatigue, upper abdominal discomfort
	C10. Absence of secondary erythrocytosis
Diagnosis	Diagnosis
A1 + A2 + any one from B	P1 + P2 + P3 = PV
A1 + any two from B	P1 + P2 + P3 + C1 = overt PV
	P1 + P2 + P3 + C2 + any (C3–C10) = early PV

ECP, European Clinical and Pathological; EEC, endogenous erythroid colony formation; Hb, hemoglobin; LAP, leukocyte alkaline phosphatase; PV, polycythemia vera; RCM, red cell mass; WHO, World Health Organization.

ECLAP, European Collaborative on Low-Dose Aspirin in Polycythemia Vera[235]; GISP, Gruppo Italiano Studio Policitemia[10]; PVSG, Polycythemia Vera Study Group.[234]

Phlebotomy and Antiplatelet Agents

In an effort to reduce the thrombotic risk that impairs the otherwise excellent response to phlebotomy, the PVSG randomized patients to phlebotomy with aspirin, 300 mg three times daily, and dipyridamole, 75 mg three times daily, versus ^{32}P. The study was stopped early because of excessive thrombosis, hemorrhage, and death in the phlebotomy/aspirin/dipyridamole arm.[239] A subsequent study, however, found that total aspirin doses of 325 mg/day or less and phlebotomy resulted in no hemorrhagic or thrombotic complications in 69 patient-years of follow-up.[240] However, this latter study contained a preponderance of patients with known disease duration longer than 3 years; as discussed above, the thrombotic risk occurs predominantly in the first 3 years after diagnosis. A small placebo-controlled study performed by the GISP using an aspirin dose of 40 mg/day (112 patients followed for 1 year) reported similar results.[241] The European Collaborative for Low Dose Aspirin in Polycythemia Vera study randomized 518 patients to aspirin 100 mg/day or placebo, and followed them for at least a year. Median duration since the diagnosis of PV was <5 years. Patients in the aspirin group had no increased bleeding incidence and had a decrease of combined endpoint including nonfatal stroke, nonfatal myocardial infarction, pulmonary embolism, and major venous thrombosis. However, there was no impact on cardiovascular mortality or overall mortality.[242] This study supports the safety of administering low-dose aspirin; its efficacy may have been underestimated, because optimum control of the hematocrit appears not to have been obtained in most patients (median hematocrit 0.48).[242] In a large retrospective study, patients treated with antithrombotic agents such as aspirin, phlebotomy to keep the hematocrit < 0.48, and who did not receive alkylating agents, had survival that did not differ from that of healthy age-matched controls.[243]

The goal of phlebotomy should be to maintain the hematocrit in the normal range (0.42 to 0.44 for men, 0.39 to 0.42 for women). This reflects a slight reduction in the previous upper limit target for men: the Cytoreductive Therapy in Polycythemia Vera (CYTO-PV) Collaborative Group has recently reported that patients treated with a hematocrit goal of less than 0.45 had significantly lower cardiovascular mortality and fewer major thrombotic events than patients in the 0.45 to 0.50 hematocrit ranged. Patients with hematocrits < 0.45 obtained their target with phlebotomy with or without cytoreductive drugs as needed.[244] In elderly patients, patients with known cardiovascular disease, or hospitalized patients with severe symptoms, phlebotomy should be initiated cautiously, either using frequent small-volume phlebotomy (100 to 150 ml every day or on alternate days) or in larger (500 ml) volumes using fluid replacement so that the patient remains isovolemic.[245] The hazards of excessively aggressive initial phlebotomy have been well described.[246] After the hematocrit falls to <0.55, or more than 750 to 1,000 ml of blood have been removed, phlebotomy of 250 to 500 ml can generally be carried out safely at weekly or less frequent intervals, as clinically indicated. Some advocate the administration of iron during phlebotomy to prevent the "symptoms" of iron deficiency. In many ways, this defeats the long-term purpose of phlebotomy, which is to establish a state of iron deficiency that will restrict red cell production. It has also been demonstrated that iron-deficient PV patients have no significant symptoms compared with other PV patients.[247]

Chemotherapy

Alkylating Agents

Many chemotherapeutic agents have been used for the treatment of PV. Many agents fell into disuse through a poor toxicity-to-efficacy ratio and are noted here for historical interest: these include nitrogen mustard,[248] melphalan,[249] triethylene melamine,[250] pyrimethamine,[251] and Vercyte (a neutral piperazine compound).[252] Busulfan,[253] pipobroman,[254] and chlorambucil[255] are alkylating agents that were widely used in PV in the modern era, but the increased frequency of leukemia observed with alkylating agents led to a discontinuation of their first-line use.[234,256,257] They may have some utility in selected high-risk cases resistant to other modalities.

Hydroxyurea

The nonalkylating myelosuppressive agent hydroxyurea is the chemotherapeutic agent most widely used in PV at present.[258,259] Its efficacy in controlling erythrocyte, leukocyte, and platelet counts in PV has been clearly demonstrated.[260,261] Thrombotic complications are less common than are observed in patients treated with phlebotomy only.[239] Hydroxyurea permits rapid reduction of leukocyte and platelet counts; supplemental phlebotomy may occasionally be necessary to reduce the red cell mass.[239] As a rule, neutropenia or thrombocytopenia corrects rapidly after cessation or reduction of hydroxyurea dose; for the same reason, however, missing a few days of therapy may be associated with recurrence of leukocytosis or thrombocytosis.

The incidence of leukemia in patients treated long term with hydroxyurea appears to be low and similar to that observed in patients treated with phlebotomy alone.[239,256,262,263] However, a study in which older PV patients initially treated with ^{32}P were randomized to maintenance with hydroxyurea or observation with phlebotomy showed a higher incidence of leukemia in the hydroxyurea arm. This suggests that there may be at least some leukemogenic potential with this agent.[264] A higher *JAK2* V617F allele burden has been reported to predict sensitivity to hydroxyurea.[265] Response to hydroxyurea has been associated with a decline in *JAK2* V617F expression by some[266,267] but not all[268] investigators. The usual starting dose of hydroxyurea is 500 mg either once or twice daily and is adjusted according to clinical requirements. The development of leg ulcers, particularly over the malleoli of the ankles, is an idiosyncratic adverse effect requiring immediate drug cessation.[269–271]

Interferon

Recombinant human interferon-α is an agent that has also demonstrated efficacy in PV.[272–274] In at least one study, interferon was more efficacious than phlebotomy.[274] Another group found that only a subset of patients was responsive to interferon.[273] In general, interferon appears to control leukocytosis and thrombocytosis and to reduce or eliminate the need for phlebotomy in a significant proportion of patients.[275,276,277] It also appears to improve pruritus.[275,276,278] Reversal of marrow fibrosis has been reported in some, although not all, studies.[275,279] Pegylated interferon-α may decrease the expression of *JAK2* V617F, suggesting that it induces responses at a molecular level, rather than simply controlling abnormal blood counts.[280] The precise role of interferon in PV, whether as therapy of first or later choice, remains to be firmly established, as does its optimum dose schedule.[259] Many hematologists use interferon as first-line therapy in younger patients, particularly women of childbearing years.

Anagrelide

Anagrelide is a platelet-aggregating agent that is useful in the control of thrombocytosis refractory to hydroxyurea or interferon in myeloproliferative disorders such as PV.[281] A large study of anagrelide and low-dose aspirin compared to hydroxyurea and low-dose aspirin in essential thrombocytosis patients at high risk for vascular events found that control of platelet counts was equivalent, but patients in the anagrelide arm had a higher rate of arterial thrombosis, serious hemorrhage, and transformation to myelofibrosis, but a lower rate of venous thrombosis.[282] These findings, although not directly referring to PV, suggest that anagrelide should stay a second-line agent for thrombocytosis.

Imatinib Mesylate

Imatinib mesylate has been reported to decrease blood counts, splenomegaly, and need for phlebotomy in small series of PV patients.[283–285] This presumably reflects effects mediated through *c-kit*. Other studies of imatinib in PV have been less encouraging.[286] Imatinib may be most useful in younger PV patients with normal or near-normal platelet counts.[287]

Anti-JAK2 Agents

Given the significant role of *JAK2* V617F in the pathogenesis and diagnosis of PV, agents directed against *JAK2* would appear to be promising additions to the therapeutic armamentarium. At present, such agents appear to be beneficial in symptoms of post-PV myelofibrosis or for splenomegaly, but not for molecular improvement.[288] Therapy targeted against *JAK2* may benefit refractory pruritus in PV patients.[40]

Radioactive Phosphorus

Whole-body or regional external beam irradiation is not especially useful in PV.[289] However, administration of ^{32}P was first- or second-line therapy for many years. It fell into disfavor because of the increased incidence of acute leukemia (10% to 15%), developing 7 or more years after treatment.[225,239,290] However, it may be useful in carefully selected high-risk elderly patients with limited life expectancy. In such patients, ^{32}P is effective and easily tolerated therapy that can induce satisfactory clinical and hematologic remissions that may last years.[291,292] Survival after treatment is reported to be 10 to 14.5 years.[100,290,293]

^{32}P is provided as a dibasic sodium salt and administered intravenously.[292,294] It passes to tissues like bone that have a high phosphorus content and metabolize phosphorus rapidly. Its uptake by rapidly dividing cells is greater than that by normal cells. Because the physical half-life of this isotope is 14.3 days, steady irradiation of tissue takes place for several weeks.[294] The fall in the red cell count usually does not begin until 30 to 60 days from the time ^{32}P is given.

A usual dose is 3 to 5 mCi of ^{32}P intravenously, or 2.3 mCi/m.[221,295] No additional ^{32}P is given for 3 months to avoid cumulative effects. If the hematocrit rises above 0.44 in the interval, phlebotomy should be performed. If, after 3 months, the need for phlebotomy persists and leukopenia and thrombocytopenia are not present, a second injection of 1 to 4 mCi may be given. Examinations are repeated at 3-month intervals. Some patients do not require a second injection or further phlebotomies for 6 to 18 months or longer. A small minority, reportedly 10% of patients, need a third injection. After this third injection, no further injections are given for at least 12 to 18 months.[296]

An analysis of 300 courses administered to 139 patients showed that an average of 6.7 mCi had been given during the first 6 months of treatment.[100] Most of these patients were re-treated

within intervals of 6 to 10 months. In another series of 241 patients,[297] the average dose required to produce remissions was 5.7 mCi in patients without leukocytosis or myeloid immaturity and as much as 8.3 mCi in others. The range of dose required was 3 to 21 mCi.

As outlined above, the benefits of ^{32}P may exceed the potential risks in a very small number of carefully selected elderly symptomatic patients who are resistant to, or intolerant of, other modalities. Obviously a full explanation of the associated risks and benefit is required prior to treatment.

Other Modalities

Splenectomy is useful only as a palliative measure in the late stages of the disease, when the spleen becomes massive and causes early satiety and weight loss, severe anemia, or thrombocytopenia.[222] Hematopoietic stem cell transplantation has been reported in 10 PV patients who had progressed to myelofibrosis or myelodysplastic syndrome/acute leukemia.[298] Five of these patients had a complete response. There is also one report of a successful bone marrow transplant in an adolescent with PV.[299]

Special Topics

Pruritus

It has been reported that pruritus, upper gastrointestinal distress, and the urticarial manifestations of PV correlate with increased levels of whole blood histamine, which in turn is roughly related to the basophil leukocyte count[300] (although other studies have questioned this model[301]). These clinical manifestations were controlled by the administration of a potent antihistaminic agent, cyproheptadine (4 mg three or four times per day), in 12 of 18 patients so treated.[300] Cimetidine,[302] serotonin release inhibitors,[40] and hydroxyurea[40] have been useful in approximately 40% of patients with pruritus. Interferon has been used in intractable cases.[277] Anecdotal experience suggests that aspirin (80 to 325 mg/day) also relieves pruritus in certain patients. Experimental agents showing efficacy against pruritus include *JAK2* inhibitors and mammalian target of rapamycin (mTOR) inhibitors.[40] As noted earlier, the most effective management of pruritus is establishing good hematologic control of PV.

Hyperuricemia

Because of the excessive urinary load of uric acid excreted by patients with myeloproliferative disorders,[303] urate may be precipitated in the kidneys, leading to stone formation or nephropathy. An effective means of reducing uric acid production in patients with PV, other than by myelosuppression, is by the use of allopurinol, 300 mg/day.[278] This agent is most useful during the short periods at the initiation of cytoreductive therapy when cell turnover is likely to be high and the avoidance of uric acid deposition is a major concern.

Surgery

Patients with poorly controlled PV are at increased risk for complications of elective surgery. In a series of 54 PV patients, a complication rate of 83% (46% morbidity, 37% mortality) was observed in poorly controlled patients, compared to a complication rate of 21% (16% morbidity, 5% mortality) in well-controlled patients.[304] Fewer and less serious complications were observed in patients who had had stable, well-controlled counts for more than 4 months.[304] It is recommended that PV patients undergoing elective surgery be in good hematologic control for at least 4 months. In more urgent surgery, control should be obtained as quickly as possible using phlebotomy with volume replacement, hydroxyurea, and cytapheresis if necessary, and should be maintained as long as possible pre- and post operatively.

Summary and Recommendations for Treatment

Although treatment with any of a variety of approaches is effective and prolongs survival, no modality is clearly the best for everyone. The following recommendations represent a reasonable approach. More detailed recommendations have been published elsewhere.[259,305,306,307]

Most newly diagnosed patients should undergo phlebotomy to obtain symptomatic control of polycythemia. The rate and volume of phlebotomy are dictated by the patient's clinical status, as outlined in the section on phlebotomy above. The hematocrit should be reduced to the upper normal range (<0.45 for men, 0.39 to 0.42 for women).

The long-term therapy chosen to control PV varies according to the patient's clinical status. Young patients (younger than 50 years) with no history of thrombosis and without severe thrombocytosis ($>1{,}000 \times 10^9$/L) can probably be managed best with phlebotomy alone, with a target hematocrit as above. The addition of aspirin, 325 mg/day or less, may be beneficial. Patients with a history of thrombosis who are older than 65 to 70 years should be treated with myelosuppressive agents.[258] Patients with severe thrombocytosis are considered by many hematologists to be in this category, as well. Patients between the ages of 50 and 65 to 70 years with no history of thrombosis or severe thrombocytosis can be managed with myelosuppressive agents or phlebotomy, although the latter modality may increase their risk for thrombotic events.

The current myelosuppressive agent of first choice is hydroxyurea. Although the additional risk of leukemia with long-term hydroxyurea therapy appears to be small, it is probably not zero.[234,308] Interferon is clearly an effective agent in PV and should be considered a possible alternative to hydroxyurea. It may be particularly useful in younger patients and women of childbearing years. Imatinib may be useful in young patients with normal platelet counts. ^{32}P may be beneficial in a small number of very carefully selected symptomatic elderly patients refractory to or intolerant of other approaches, in whom the potential leukemic risks are outweighed by limitations imposed by other clinical conditions.

CHAPTER 83

MYELOFIBROSIS

Rami Komrokji, Eric Padron, Srdan Verstovsek

DEFINITION

Myelofibrosis (MF) is a rare, serious myeloid malignancy classified as one of the Philadelphia chromosome negative [Ph(–)] myeloproliferative neoplasms (MPNs).[1]

MF is subdivided into primary MF (PMF) and secondary MF.[2] Secondary MF may arise from polycythemia vera (PV) or essential thrombocythemia (ET).[3]

Terms frequently used synonymously with PMF include chronic idiopathic myelofibrosis ([CIMF; World Health Organization [(WHO]), agnogenic myeloid metaplasia, MF with myeloid metaplasia, and idiopathic MF.[4,5]

The International Working Group for Myelofibrosis Research and Treatment (IWG-MRT) has defined MF as either PMF (de novo presenting disease), or post-PV or ET MF (MF transformation from prior PV or ET). Furthermore, patients with transformation to acute leukemia are referred to as PMF in blast phase (PMF-BP) or post-PV/ET MF in blast phase.[5]

The hallmark of MF neoplasm is an increase in mature blood cells, which arise from clonal expansion driven by genetic mutations in pluripotent cells of the bone marrow compartment. The response to this malignant myeloproliferative process is the secretion of multiple profibrogenic, -angiogenic, and -inflammatory cytokines that eventually results in polyclonal bone marrow fibrosis. MF is typically associated with progressive splenomegaly and in many cases with hepatomegaly, which can lead to other complications such as portal hypertension or splenic infarcts, cytopenias, and an increased likelihood of transforming to a blast phase.[6,7]

HISTORICAL PERSPECTIVE

1879 First report of PMF was by Heuck.[8]

1935 Secondary myelofibrosis (post-PV MF) was described by Hirsch.[9]

1951 Dameshek coined the classification of PMF as a myeloproliferative disorder (MPD).[10]

1960 The Philadelphia chromosome abnormality t(9;22)(q32;q13) was described in chronic myeloid leukemia (CML) by Nowell and Hungerford.[11]

1978 PMF was characterized as a stem-cell–derived clonal myeloproliferative disorder associated with reactive MF by Fialkow's group.[12]

1992 The JAK-STAT pathway was described.[13]

2005 Several groups described a novel gain-of-function mutation in the gene encoding Janus kinase (JAK) 2. The mutation is a single nucleotide change, which results in a valine to phenylalanine substitution at codon 617 (*JAK2* V617F) in over 90% of patients with PV and ~50% of those with either PMF or ET.[14–17]

2006 A mutation in the myeloproliferative leukemia virus gene (*MPL*) for the thrombopoietin receptor was described in ~5% of patients with PMF.[18] The mutation was a substitution of tryptophan to leucine at position 515 in the *MPL* gene sequence, *MPL* W515L. The "W" and "L" are the shorthand way to indicate which change occurred and resulted in the gene becoming abnormally active.[19]

2008 The WHO classification changed the term from MPD to MPN.[3]

2009 Other novel mutations were described for PMF in other genes, including ten-eleven–transloaction 2 (*TET2*), additional sex-combslike 1 (*ASXL1*), Casitas B-lineage lymphoma (*CBL*), isocitrate dehydrogenase (*IDH*) 1 and 2, and IKAROS family zinc finger-1 (*IKZF1*). These mutations occur in 0% to 17% of MPNs and are more common in chronic (*TET2*, *ASXL1*, *CBL*) or juvenile (*CBL*) myelomonocytic leukemia, myelodysplastic syndromes (MDS) (*TET2*, *ASXL1*), and secondary acute myeloid leukemia, including the blast phase of MPN.[20]

2011 The FDA approved the first JAK2 inhibitor, ruxolitinib, for treatment of intermediate- or high-risk PMF or secondary MF.

EPIDEMIOLOGY

PMF is a rare disease. The annual incidence of MF has been estimated to be 0.41 to 1.46 cases per 100,000 individuals.[21,22] The prevalence of MF in the United States has been estimated as 16,000 to 18,500 patients. MF is slightly more common in males and more common in older patients.[21] The median age of patients at the time of diagnosis is 67 years.[21] Among the Philadelphia chromosome negative MPNs (e.g., MF, PV, ET), MF is the most symptomatic and carries the worst prognosis.

A higher incidence of PMF and related MPN has been suggested for persons of Jewish Ashkenazi ancestry.[23] Benzene, industrial solvents, and radiation exposure have been reported to be associated with increased risk of PMF.[24–26]

PATHOGENESIS

Current understanding suggests that PMF occurs secondary to acquired mutations that target the hematopoietic stem cell.[1,12,27] As a result, ineffective hematopoeisis and proliferation of dysfunctional megakaryocytes are commonly seen in MF. The hallmark of the disease pathologically is bone marrow reticulin and collagen fibrosis, ineffective extramedullary hematopoiesis (EMH), and deregulated cytokine production.

The disease-initiating mutations remain unknown. Cytogenetic abnormalities originating on the progenitor cell level are well described in MF. In general, approximately half of patients with PMF display cytogenetic abnormalities that include del(20)(q11;q13), del(13)(q12;q22), trisomy 8, trisomy 9, del(12)(p11;p13), monosomy or deletions chromosome 7, and partial trisomy 1q. None of these abnormalities is specific to PMF, although the presence of either del(13)(q12;q22) or der(6)t(1;6)(q21–23;p21–23) is strongly suggestive of PMF diagnosis. Molecular cytogenetics using FISH did not reveal additional karyotypically occult cytogenetic lesions, but comparative genomic hybridization (CGH) studies have disclosed gains of chromosome 9p as the most frequent abnormality occurring in 50% of patients.[28,29–31]

Deregulation of the Janus kinase-signal transducer and activator of transcription (JAK-STAT) pathway is the key contributor to the clinical phenotype of the disease regardless of the presence or absence of the *JAK2* V617F mutation. The mutation described is not a disease initiating abnormality. The JAK-STAT pathway plays a pivotal role in the differentiation and development of hematopoietic cells and the functioning of the immune system.[32] The JAK family comprises JAK1, JAK2, JAK3, and TYK2.[33] Cytokines and growth factors activate the extracellular portion of their cognate receptors,[33,34] which promote the recruitment of JAK proteins to associate closely with the intracellular portion of these receptors and the activation of

the JAK proteins via phosphorylation (Fig. 83.1). Phosphorylation of JAK proteins, in turn, leads to the phosphorylation and activation of several intracellular downstream signaling proteins, such as STAT proteins.[35] Phosphorylated STATs translocate to the nucleus and act as inducible nuclear transcription factors, which lead to transcriptional modulation and eventual expression of cellular, molecular, and (patho) physiologic actions that were promoted by the initial signal (ligand).

The dysregulation of the JAK-STAT signaling pathway in hematopoietic progenitor cells has been implicated in the pathogenesis of MF. JAK-STAT signaling in the pathogenesis of MF also relates to its role in mediating signaling from proinflammatory cytokines. These cytokines are elevated in environments of myeloproliferative disease and contribute to the debilitating symptoms of MPNs.[36] Somatic mutations that contribute to this dysregulated JAK-STAT activity include gain-of-function mutations directly in *JAK2*, or upstream signaling mutations such as the mutation of the thrombopoietin receptor (*MPL* W515L),[18] and loss of JAK regulation by mutations in the gene for the lymphocyte-specific adaptor protein (*LNK* exon 2 mutations).[37] Mutations in *JAK2* that lead to the constitutive activation of the JAK-STAT pathway, namely the *JAK2* V617F[14–16] and *JAK2* exon 12 mutations, have been identified, although this latter mutation was primarily identified in patients with PV.[38] *JAK2* V617F is the most common mutation occurring in a large proportion (50% to 60%) of patients with PMF.[14,15] With JAK2 activating mutations, the pathway becomes cytokine- and growth-factor–independent; therefore, even in the absence of these ligands, the intracellular signaling proteins are constitutively active. Clonal expansion leads to an increased *JAK2* V617F allele burden and homozygosity influencing disease phenotype and differentiation of PV and ET.

Megakaryocyte-derived transforming growth factor-β_1 (TGF-β_1) has been identified as the primary cytokine that mediates many of the bone marrow stromal changes (i.e., collagen fibrosis, osteosclerosis, angiogenesis) in PMF.[39,40] In mice, the PMF phenotype has been induced either by systemic overexpression of thrombopoietin (TPO^{high} mice) or by megakaryocyte lineage-restricted underexpression of the transcription factor GATA-1 (GATA-1^{low} mice). In both instances, the megakaryocytes display abnormal distribution of P-selectin that is believed to promote a pathologic interaction between megakaryocytes and neutrophils, resulting in the release of both fibrogenic and angiogenic cytokines including TGF-β, platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), tissue inhibitors of matrix metalloproteinases, and neutrophil-derived elastase and other proteases.[41,42]

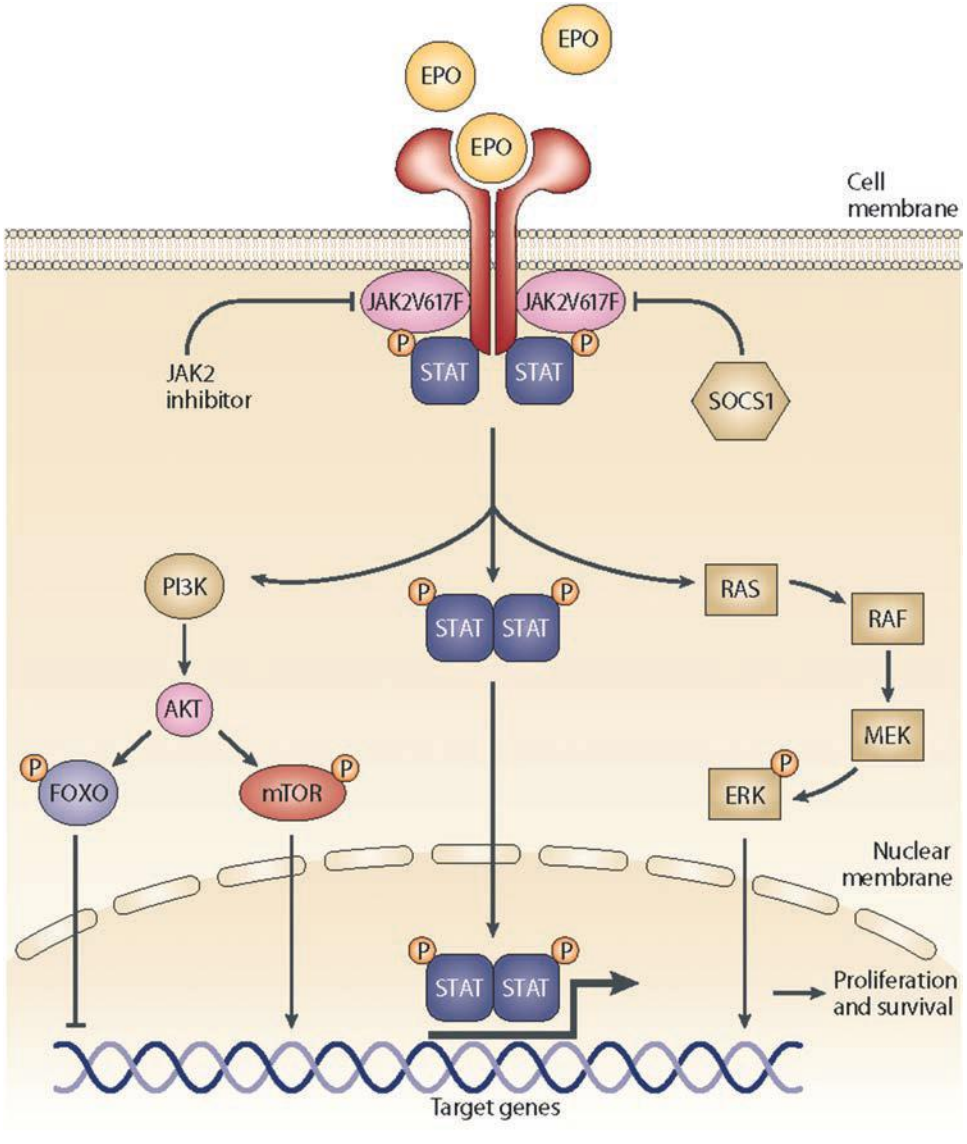

FIGURE 83.1. The JAK-STAT signaling pathway. Cytokines and growth factors bind to the extracellular receptor and induce a series of intracellular changes: (1) JAK proteins associate with the intracellular portion of the receptor and are phosphorylated; (2) phosphorylated-JAK proteins in turn phosphorylate STAT proteins, which then phosphorylate other downstream proteins; and (3) phosphorylated-STAT translocates into the nucleus and promotes the transcription of genes. Other proteins also regulate this signaling pathway, such as SOCS1, which prevents activation of this pathway. (With permission from Quintas-Cardama A, Kantarjian H, Cortes J, et al. Janus kinase inhibitors for the treatment of myeloproliferative neoplasias and beyond. Nat Rev Drug Discov 2011;10:127–140.)

Another characteristic feature in PMF that accompanies the aberrant bone marrow stromal reaction involves peripheral blood expansion of both CD34-positive myeloid progenitors and endothelial cells.[43,44] Current consensus implicates both circulating progenitor cell trapping and abnormal cytokine stimulation of embryonic hematopoietic sites as mechanisms of hepatosplenic EMH in PMF.[45,46] Such a contention is supported by the high concordance between bone marrow and splenic tissue cytogenetic findings in PMF.[47]

Disease progression to blast phase (acute myeloid leukemia [AML]) is probably driven by additional clonal evolution and acquired mutations (see section "Disease Course").

CLINICAL FEATURES

Splenomegaly is a well-established clinical feature of MF with 85% or more of MF patients presenting with palpable splenomegaly at the time of diagnosis. One third of patients will have marked splenomegaly (Fig. 83.2) and 50% of patients will also have hepatomegaly.[48,49] Spleen-related symptoms include abdominal discomfort, early satiety, and pain under the left ribs. Portal hypertension and variceal bleeding can be morbid complications of splenomegaly. Some patients may experience severe pain secondary to splenic infarcts.[50]

Constitutional symptoms are common and often debilitating. Disease burden due to those symptoms often interfere with daily quality of life. These symptoms include fatigue, pruritus, night sweats, fever and bone/muscle pain, and cachexia. Presence of those symptoms is associated with worse outcome.

Cytopenias can dominate the course of the disease especially at the advanced stages. Two thirds of patients may have anemia at diagnosis and 20% are transfusion-dependent.[51,52] Thrombocytopenia may be present in 21% to 37% and leukopenia in 7% to 22%.[53]

Some patients present with leukocytosis (41% to 49% incidence), and/or thrombocytosis (13% to 31%). Furthermore, >10% of patients may present with extreme thrombocytosis (platelet count $>1{,}000 \times 10^9$/L), whereas >20% present with marked leukocytosis (leukocyte count $>20 \times 10^9$/L).[53] Patients with MF are also at risk for developing thrombo-hemorrhagic complications secondary to leukocytosis and/or thrombocytosis.[54]

Other potential symptoms and complications include ascites, portal hypertension, lymphadenopathy, pleural effusions, and nerve or cord compression secondary to EMH.[55]

Characteristic laboratory findings in MF may include peripheral blood leukoerythroblastosis, dacryocytosis, teardrop-shaped red blood cells (see Fig. 80.9), circulating immature myeloid cells, increased serum lactate dehydrogenase, increased vitamin B12 levels, and hyperuricemia. The characteristic bone marrow aspirate and biopsy findings may be limited by the inability to collect an adequate bone marrow aspirate (so-called dry tap). The clustering of atypical megakaryocytes, which may often be mistaken as dysplasia by an inexperienced pathologist, is a pathologic hallmark of myeloproliferative syndromes.[56] Reticulin staining demonstrates an increased deposition of reticulin fibers. Collagen fibrosis can be appreciated and may be more disease-specific compared to reticulin staining. In some early cases of MF, the bone marrow could only be hypercellular with no evidence of fibrosis.[7] Figure 83.3 illustrates typical bone marrow findings in MF.

Circulating levels of $CD34^+$, hematopoietic stem cells and progenitors are high in patients with MF compared with healthy patients as well as patients with other Philadelphia chromosome negative MPNs.[42]

DIAGNOSIS

The differential diagnosis of MF should include bone marrow fibrosis associated with nonneoplastic and neoplastic conditions (Table 83.1) including but not limited to chronic myeloid leukemia (CML), MDS, chronic myelomonocytic leukemia (CMML), lymphoma, or AML. Presence of *JAK2* or *MPL* mutation is a reliable screen to rule out reactive bone marrow fibrosis or a nonmyeloid malignancy. The diagnosis of PMF is facilitated using the WHO criteria, whereas post-PV or post-EF MF diagnosis is based on the IWG-MRT criteria (Table 83.2).[3,57]

PMF is typically characterized by the presence of morphologically bizarre megakaryocytes in clusters. However, it is important to note that the presence of apparent reticulin fibrosis is not essential for the diagnosis of PMF. Accordingly, there are two histologic variants of PMF: fibrotic and cellular (prefibrotic) phases.[58] Reticulin fibrosis is either absent or minimal in cellular-phase PMF, and it is thus possible to confuse cellular-phase PMF with ET. However, bone marrow is markedly hypercellular, with both granulocytic and megakaryocytic proliferation in PMF, as opposed to often normocellular bone marrow with only megakaryocytic hyperplasia in ET. Further distinction is facilitated by the appreciation of subtle differences in megakaryocyte

FIGURE 83.2. Splenomegaly due to extramedullary hematopoiesis in a patient with myelofibrosis. A: Massive splenomegaly. **B:** Chronic idiopathic myelofibrosis in the spleen. The red pulp shows extensive involvement by maturing myeloid and erythroid cells, as well as atypical megakaryocytes. Some of this abnormal extramedullary hematopoiesis is in a sinus at the lower right side of the figure.

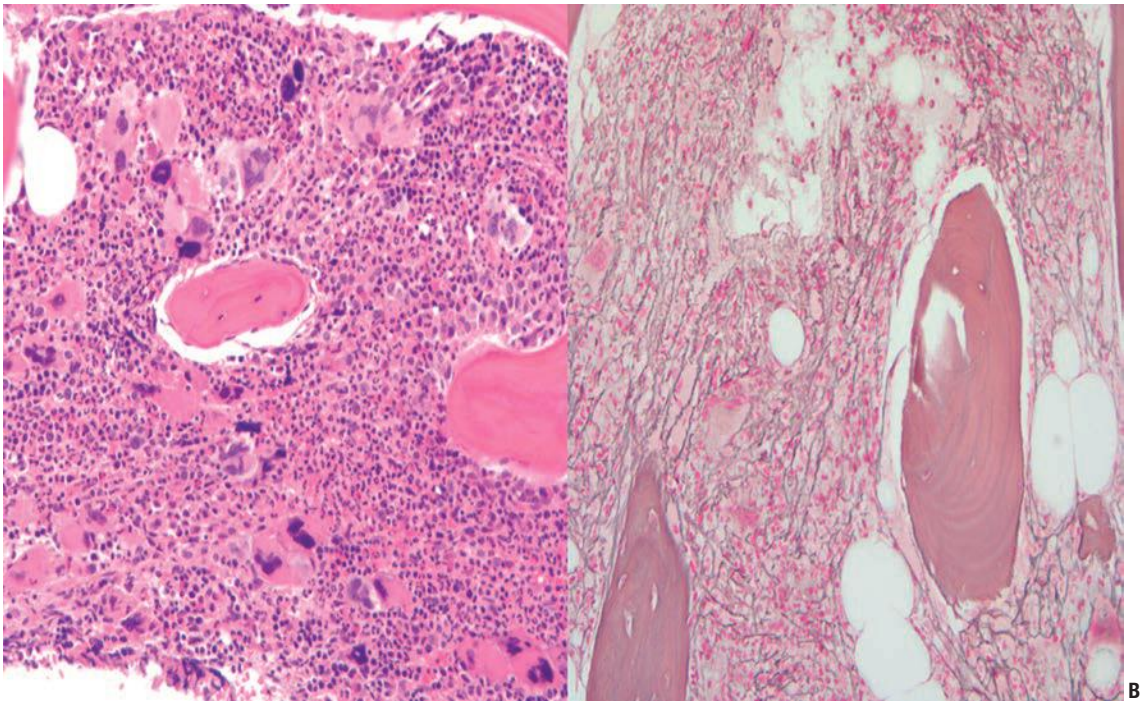

FIGURE 83.3. Bone marrow in myelofibrosis. **A:** Hypercellular bone marrow biopsy with megakaryocytic atypia. **B:** Reticulin stain demonstrating presence of myelofibrosis.

morphology; PMF megakaryocytes display defective maturation with prominent "cloudlike" hyperchromatic nuclei, whereas ET megakaryocytes appear mature although large in size, with well-lobulated (i.e., staghornlike) nuclei.[59] Other distinguishing features between cellular-phase PMF and ET include the presence of myelophthisis and/or increased LDH in the former but not the latter. One distinct WHO category of AML (i.e., acute MF) can sometimes be confused with PMF. Patients with fibrotic AML, either AML M7 or other AML subtype, usually present with severe constitutional symptoms, pancytopenia, mild or no splenomegaly, and feature an increase in blood and bone marrow blasts that might not necessarily fulfill the required threshold for AML diagnosis.

TABLE 83.1

DIFFERENTIAL DIAGNOSIS FOR BONE MARROW FIBROSIS

Hematologic Disorders		Non-hematologic Disorders
Myeloid Disorders	**Lymphoid Disorders**	
Primary myelofibrosis	Hairy cell leukemia	Metastatic cancer
Chronic myeloid leukemia	Hodgkin lymphoma	Autoimmune myelofibrosis
Myelodysplastic syndrome	Non-Hodgkin lymphoma	Systemic lupus erythematosus
Chronic myelomonocytic leukemia	Multiple myeloma	Kala-Azar (leishmaniasis)
Chronic eosinophilic leukemia		Tuberculosis
Systemic mastocytosis		Paget disease
Acute megakaryocytic leukemia		HIV infection
Other acute myeloid leukemias		Vitamin D-deficient rickets
Acute lymphocytic leukemia		Renal osteodystrophy
Acute myelofibrosis		Hyperparathyroidism
Malignant histiocytosis		Gray platelet syndrome
		Familial infantile myelofibrosis
		Idiopathic pulmonary hypertension

TABLE 83.2

WHO CRITERIA FOR DIAGNOSIS OF PRIMARY AND POST-ET/PV MYELOFIBROSIS

WHO Criteria: Primary MF	IWG Criteria: Post-ET MF and Post-PV MF
Major Criteria (All Required) • Megakaryocyte proliferation and atypia • Reticulin or collagen fibrosis • Does not meet criteria for other myeloid disorders (e.g., PV, CML, MDS) • Clonal marker (e.g., *MPL*W515K/L, *JAK2*V617F) or no evidence for secondary marrow fibrosis Minor Criteria (Must Meet 2) • Increase in serum LDH • Palpable splenomegaly • Leukoerythroblastosis • Anemia	Major Criteria (All Required) • Previous diagnosis of ET or PV • Grade 2–3 bone marrow fibrosis (on 0–3 scale) or Grade 3–4 bone marrow fibrosis (on 0–4 scale) Minor Criteria (Must Meet 2) • ≥5 cm increase in palpable splenomegaly or new splenomegaly • Leukoerythroblastosis • One or more constitutional symptoms • Increase in serum LDH (Post-ET MF only) • Anemia with Hgb ≥2 mg/ml decrease from baseline (post-ET MF only) • Anemia or sustained loss of requirement for either cytoreductive treatment or phlebotomy (post-PV MF only)

IWG, International Working Group; Post-ET MF, post-essential thrombocythemia myelofibrosis; Post-PV MF, post polycythemia vera myelofibrosis; WHO, World Health Organization.

DISEASE COURSE

MF is a progressive disease. Patients develop progressive splenomegaly and its related complications, and suffer from debilitating disease burden symptoms such as cachexia, bone pain, and/or profound fatigue. Cytopenias can worsen during the course of the disease with more patients becoming red blood cell transfusion dependent and developing thrombocytopenia and neutropenia. The rate of secondary AML transformation (or better termed blast phase-PMF) is 10% to 15%. Blast phase-PMF is very difficult to manage, and response to intensive chemotherapy is poor.[60] The major causes of death in PMF include infections (26% to 29%), bleeding (11% to 22%), heart failure (7% to 15%), liver failure (3% to 8%), and portal hypertension (6%).[61,62]

RISK STRATIFICATION AND PROGNOSIS

MF is a progressive hematologic disease and its prognosis is dependent on several factors. The International Prognostic Scoring System (IPSS) estimates survival from the time of diagnosis using the following risk factors: (1) age 65 years or older; (2) anemia (hemoglobin <10 g/dl); (3) presence of constitutional symptoms; (4) leukocytosis (white blood cell count >25 × 10^9/L); and (5) circulating blasts of at least 1%.[63] Patients presenting with more than two of the aforementioned prognostic factors of MF have a median survival of less than 3 years, whereas patients without any of the factors have a median survival of more than 10 years. The presence of 0, 1, 2, and ≥3 factors using IPSS define low, intermediate-1, intermediate 2, and high-risk disease, respectively.

Patient karyotype abnormality is also prognostic of survival. In a retrospective review of 200 MF patients, in comparison with trisomy 8 or a complex karyotype, patients with sole 13q deletion, 20q deletion, or trisomy 9 had an improved survival and no leukemia transformation.[64] In a study of 433 patients with PMF, a high-risk cytogenetic profile was when patients had a complex karyotype or sole or two abnormalities that included +8, –7/7q, i(17q), –5/5q–, 12p–, or 11q23 rearrangement, and a low-risk profile was when patients had normal karyotype, or sole abnormalities not present in the high-risk group, including +9, 13q–, 20q–, or chromosome 1 translocations/ duplications.[65] The 5-year survival rates were 8% and 51%, respectively (Fig. 83.4). In a study of 793 patients, 62 (8%) displayed an unfavorable karyotype by way of complex cytogenetics (n = 41) or sole trisomy 8 (n = 21).[66] The presence of monosomal karyotype in 41% of the patients with complex cytogenetics had an extremely poor prognosis with a 2-year leukemia transformation rate of 29.4% and a median survival of only 6 months.

In an update to the IPSS, the Dynamic IPSS (DIPSS) was modified using the same prognostic factors from IPSS.[67] Unlike the IPSS, the DIPSS may be used at any time-point in disease to estimate survival; opposed to IPSS, in DIPSS the development of disease-related anemia carries two points. Most recently, the DIPSS was updated to the DIPSS-plus, which incorporates three more prognostic factors including red blood cell transfusion need, platelet count <100 × 10^9/L, and unfavorable karyotype (Fig. 83.5).[68] Table 83.3 summarizes risk stratification models in MF.

In addition to the prognostic factors in IPSS and DIPSS-plus, increased interleukin-8 (IL-8), IL-10, IL-15, or IL-2 receptor have also been associated with reduced overall survival and leukemia-free survival.[69]

The ability to prognosticate and stratify severity of disease is critical in effectively counseling patients regarding expected outcome and to define the most appropriate treatment strategies. Risk stratification allows the clinician to identify high-risk patients who may benefit from intensive therapy such as allogeneic stem cell transplant where benefit outweighs the risk. Lower risk MF patients or MF patients who are not transplant candidates are managed based on the presence of constitutional symptoms, symptomatic splenomegaly, or severe cytopenias.

Response Criteria and Assessment Tools

The International Working Group for Myelofibrosis Research and Treatment (IWG-MRT) developed criteria for response to therapy in MF, modeled after other criteria, such as the IWG criteria for MDS.[70] Treatment responses are categorized as complete remission (CR), partial remission (PR), or clinical improvement. Recently

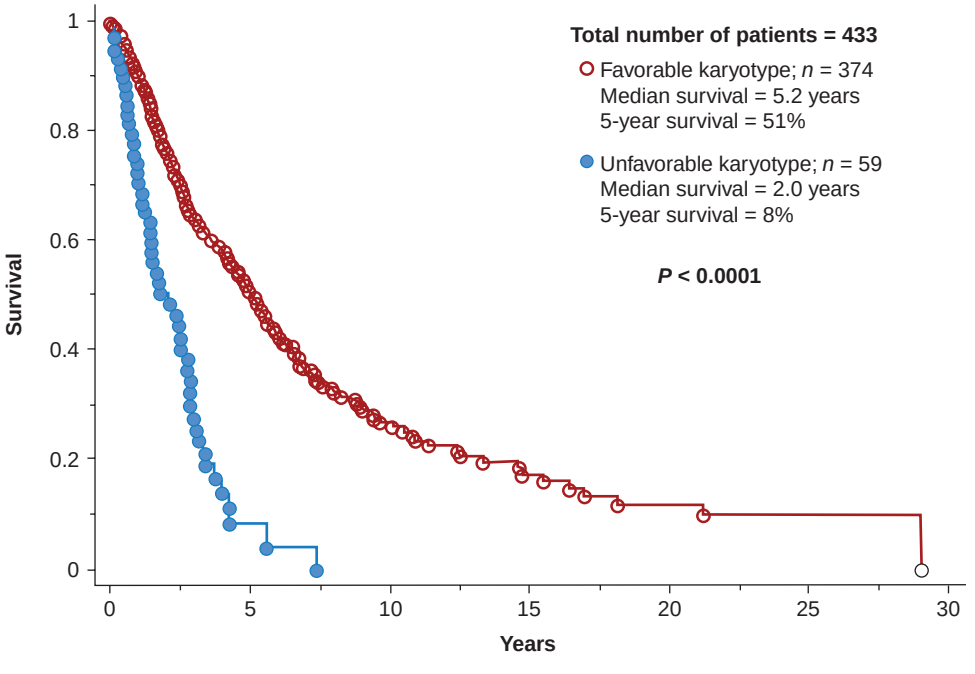

FIGURE 83.4. Survival data of patients with primary myelofibrosis stratified by two-tiered cytogenetic-risk categorization: unfavorable (complex karyotype or sole or two abnormalities that include +8, –7/7q–, i(17q), inv(3), –5/5q—, 12p–, or 11q23 rearrangement) and favorable (all others including normal karyotype). (With permission from Caramazza D, Begna KH, Gangat N, et al. Refined cytogenetic-risk categorization for overall and leukemia-free survival in primary myelofibrosis: a single center study of 433 patients. Leukemia 2011;25:82–88.)

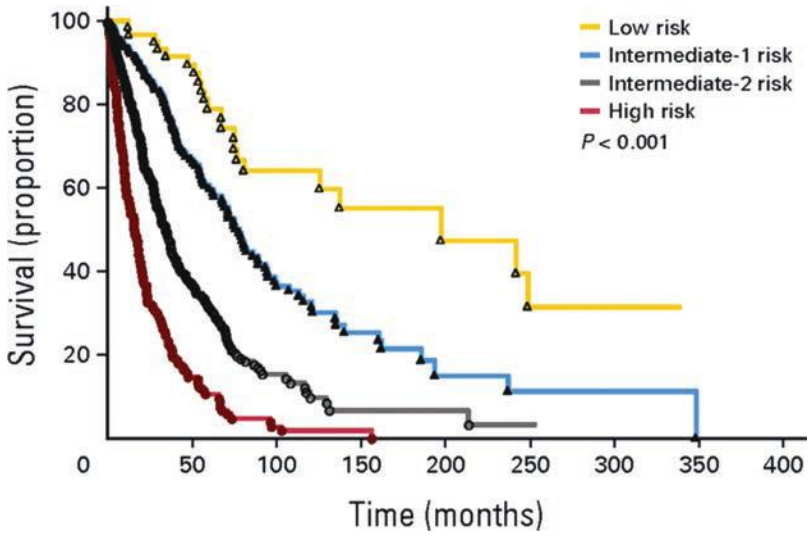

FIGURE 83.5. Survival data of 793 patients with primary myelofibrosis evaluated at time of their first Mayo Clinic referral and stratified by their Dynamic International Prognostic Scoring System (DIPSS) + karyotype + platelet count + transfusion status prognostic scores. Low risk, zero adverse points; $n = 66$; median survival, 185 months. Intermediate-1 risk, one adverse point; $n = 174$; median survival, 78 months. Intermediate-2 risk, two or three adverse points, $n = 360$; median survival, 35 months. High risk, four to six adverse points; $n = 193$; median survival, 16 months. (With permission from Gangat N, Caramazza, D, Vaidya R, et al. DIPSS plus: a refined Dynamic International Prognostic Scoring System for primary myelofibrosis that incorporates prognostic information from karyotype, platelet count, and transfusion status. J Clin Oncol 2011;29:392–397.)

revised response criteria by the IWG and European Leukemia Net (ELN) have been proposed (Table 83.4).[70,71] The criteria for "clinical improvement" incorporate reduction in spleen size and improvements in anemia, platelet count, and neutrophil count. The CR and PR as surrogate markers of survival have not been validated, and it would be difficult to achieve CR or PR with currently available therapy apart from allogeneic hematopoietic cell transplantation (alloHCT).

Some clinical trials define spleen response as a ≥50% reduction in splenic size (length) as assessed by palpation (consistent with IWG-MRT criteria) or ≥35% reduction when assessed by imaging (corresponding to an approximate ≥50% reduction in palpable spleen length, as shown in the Phase I/II trial of ruxolitinib).[36] Evaluating changes in spleen size by palpation, however, may not be as objective as evaluating changes in spleen size by MRI. In a Phase II study evaluating the JAK inhibitor pacritinib (formerly known as SB1518), a 50% reduction in spleen size as assessed by palpation correlated with a 25% reduction in spleen size as assessed by MRI.[72] Thus, use of objective measurements such as MRI or CT to evaluate changes in spleen size may be more useful in evaluating response to therapy, especially in clinical trials. In practice, physical examination or ultrasound remain the most common tools utilized for spleen size assessment.

TABLE 83.3

RISK STRATIFICATION MODELS IN MYELOFIBROSIS

Risk Factor	IPSS	DIPSS	DIPSS plus
Age >65	X	X	X
Constitutional symptoms	X	X	X
Anemia (Hgb <10 g/dl)	X	X	X
WBC >25 × 10^9 /L	X	X	X
Circulating myeloblasts ≥1%	X	X	X
RBC transfusion dependence			X
Unfavorable karyotype, complex karyotype, or sole or 2 abnormalities that include +8, –7/7q–, i(17q), inv(3), –5/5q–, 12p–, or 11q23 rearrangement			X
Platelets <100 × 10^9 /L			X
Points	1 each	1 each except anemia = 2	1 each
Risk Groups (sum points)	0 = Low 1 = Intermediate-1 2 = Intermediate-2 ≥3 = High risk	0 = Low 1–2 =Intermediate-1 3–4= Intermediate-2 5–6= High risk	0 = Low 1= Intermediate-1 2–3 = Intermediate-2 ≥4 = High risk
Median Overall Survival	Low:11.3 y Int-1: 7.9 y Int-2: 4 y High 2.3 y	Low: NR Int-1 14.2 y Int-2: 4 y High 1.5 y	Low: 15.4 Int-1 6.5 y Int-2: 2.9 y High 1.3 y

TABLE 83.4

REVISED INTERNATIONAL WORKING GROUP FOR MYELOPROLIFERATIVE NEOPLASMS RESEARCH AND TREATMENT (IWG-MRT) AND EUROPEAN LEUKEMIA NET (ELN) RESPONSE CRITERIA FOR MYELOFIBROSIS

Response Categories	Required Criteria (For All Response Categories, Benefit Must Last for ≥12 Weeks in Order to Qualify as a Response)
Complete Remission (CR)	*Bone marrow:*[a] Age-adjusted normocellularity; <5% blasts; ≤Grade 1 myelofibrosis[b], and *Peripheral blood:* Hemoglobin ≥100 g/L and <UNL; neutrophil count ≥1 × 10^9/L and <UNL. Platelet count ≥100 × 10^9/L and <UNL; <2% immature myeloid cells[c], and *Clinical:* Resolution of disease symptoms; spleen and liver not palpable; no evidence of EMH.
Partial Remission (PR)	*Peripheral blood:* Hemoglobin ≥100 g/L and <UNL; Neutrophil count ≥1 × 10^9/L and <UNL. Platelet count ≥100 × 10^9/L and <UNL; <2% immature myeloid cells[c], and *Clinical:* Resolution of disease symptoms; spleen and liver not palpable; No evidence of EMH, or *Bone marrow:*[a] Age-adjusted normocellularity; <5% blasts; ≤Grade 1 myelofibrosis[b], and *Peripheral blood:* Hemoglobin ≥85 but <100 g/L and <UNL; neutrophil count ≥1 × 10^9/L and <UNL; Platelet count ≥50 but <100 × 10^9/L and <UNL; <2% immature myeloid cells[c], and *Clinical:* Resolution of disease symptoms; spleen and liver not palpable; no evidence of EMH.
Clinical Improvement (CI)	The achievement of anemia, spleen, or symptoms response without progressive disease or deterioration in anemia[d].
Anemia Response	*Transfusion-independent patients:* a ≥20 g/L increase in hemoglobin level[e]. *Transfusion-dependent patients:* becoming transfusion-independent[f].
Spleen Response[g]	A baseline splenomegaly that is palpable at 5–10 cm, below the LCM, becomes not palpable[h], or A baseline splenomegaly that is palpable at >10 cm, below the LCM, decreases by ≥50%[h] *A baseline splenomegaly that is palpable at <5 cm, below the LCM, is not eligible for spleen response.* *A spleen response requires confirmation by MRI or CT showing ≥35% spleen volume reduction.*
Symptoms Response	A ≥50% reduction in the Myeloproliferative Neoplasm Symptom Assessment Form total symptom score (MPN-SAF TSS)[i].
Progressive Disease[j]	Appearance of a new splenomegaly that is palpable at least 5 cm below the LCM, or A ≥100% increase in palpable distance, below LCM, for baseline splenomegaly of 5 to 10 cm, or A 50% increase in palpable distance, below LCM, for baseline splenomegaly of >10 cm, or Leukemic transformation confirmed by a bone marrow blast count of ≥20%, or A peripheral blood blast count of ≥20% that lasts for at least 2 wk.
Stable Disease	Belonging to none of the above-listed response categories.
Relapse	No longer meeting criteria for at least CI after achieving CR, PR, or CI, or Loss of anemia response persisting for at least 1 mo, or Loss of spleen response persisting for at least 1 mo
	Guidelines for Assessing Treatment-induced Cytogenetic and Molecular Changes
Cytogenetic Remission	At least 10 metaphases must be analyzed for cytogenetic response evaluation, and requires confirmation by repeat testing within 6 mo window. *Complete response*: eradication of a pre-existing abnormality. *Partial response*: ≥50% reduction in abnormal metaphases. (partial response applies only to patients with at least 10 abnormal metaphases at baseline).
Molecular Remission	Molecular response evaluation must be analyzed in peripheral blood granulocytes, and requires confirmation by repeat testing within 6 mo window. *Complete response*: eradication of a pre-existing abnormality. *Partial response*: ≥50% decrease in allele burden. (partial response applies only to patients with at least 20% mutant allele burden at baseline).
Cytogenetic/Molecular Relapse	Re-emergence of a pre-existing cytogenetic or molecular abnormality that is confirmed by repeat testing.

CT, computed tomography; EMH, extramedullary hematopoiesis (no evidence of EMH implies the absence of pathology, or imaging study-proven nonhepatosplenic EMH); LCM, left costal margin; MRI, magnetic resonance imaging; UNL, upper normal limit.

[a]Baseline and post-treatment bone marrow slides are to be stained at the same time and interpreted at one sitting by a central review process. Cytogenetic and molecular responses are not required for CR assignment.

[b]Grading of myelofibrosis is according to the European classification (Thiele K, vasnicka HM, Facchetti F, Franco V, van der Walt J, Orazi A. European consensus on grading bone marrow fibrosis and assessment of cellularity. Haematologica 2005;90:1128).

[c]Immature myeloid cells constitute blasts + promyelocytes + myelocytes + metamyelocytes + nucleated red blood cells. In splenectomized patients, <5% immature myeloid cells is allowed.

[d]See Table 83.1 for definitions of anemia response, spleen response, and progressive disease. Deterioration in anemia constitutes the occurrence of new transfusion dependency or a ≥20 g/L decrease in hemoglobin level from pre-treatment baseline that lasts for at least 12 weeks.

[e]Applicable only to patients with baseline hemoglobin of <100 g/L. In patients not meeting the strict criteria for transfusion-dependency at the time of study enrollment (see below), but have received transfusions within the previous month, the pre-transfusion hemoglobin level should be used as the baseline.

[f]Transfusion dependency before study enrollment is defined as transfusions of at least 6 units of packed red blood cells (PRBC), in the 12 weeks prior to study enrollment, for a hemoglobin level of <85 g/L, in the absence of bleeding or treatment-induced anemia. In addition, the most recent transfusion episode must have occurred in the 28 days prior to study enrollment. Response in transfusion-dependent patients requires absence of any PRBC transfusions during any consecutive "rolling" 12-week interval during the treatment phase, capped by a hemoglobin level of ≥85 g/L.

[g]In splenectomized patients, palpable hepatomegaly is substituted with the same measurement strategy.

[h]Spleen or liver responses must be confirmed by imaging studies where a ≥35% reduction in spleen volume, as assessed by magnetic resonance imaging (MRI) or computed tomography (CT), is required. Furthermore, a ≥35% volume reduction in the spleen or liver, by MRI or CT, constitutes a response regardless of what is reported with physical examination.

[i]Symptoms are evaluated by the Myeloproliferative Neoplasm Symptom Assessment Form total symptom score (MPN-SAF TSS).[9] The MPN-SAF TSS is assessed by the patients themselves and includes fatigue, concentration, early satiety, inactivity, night sweats, itching, bone pain, abdominal discomfort, weight loss, and fevers. Scoring is from 0 (absent/as good as it can be) to 10 (worst imaginable/as bad as it can be) for each item. The MPN-SAF TSS is the summation of all the individual scores (0-to-100 scale). Symptoms response requires ≥50% reduction in the MPN-SAF TSS.

[j]Progressive disease assignment for splenomegaly requires confirmation by MRI or CT showing a ≥25% increase in spleen volume from baseline. Baseline values for both physical examination and imaging studies refer to pre-treatment baseline and not to post-treatment measurements.

Modified from Tefferi A, Cervantes F, Mesa R, et al. Revised response criteria for myelofibrosis: International Working Group-Myeloproliferative Neoplasms Research and Treatment (IWG-MRT) & European LeukemiaNet (ELN) consensus report. Blood 2013; doi: 10.1182/blood-2013-03-488098 [Epub ahead of print].

The Myelofibrosis Symptom Assessment Form (MFSAF) is a tool specifically developed to evaluate the presence and severity of MF-associated symptoms.[73] In a recent version of the MFSAF (v2.0), patients rated the presence and severity of splenomegaly-related symptoms (abdominal discomfort, pain under the ribs on left side, early satiety), systemic symptoms (night sweats, pruritus, bone/muscle pain), and inactivity using a scale of 0 (symptom not present) to 10 (symptom present and worst imaginable).[74]

Fatigue is a problematic symptom and is pervasive, persistently severe, and almost universally present in MF patients.[75] Moreover, it interferes with activities of daily living and quality of life (QoL). Tools to evaluate fatigue include the Functional Assessment of Cancer Therapy Fatigue scale (FACT-F), the Brief Fatigue Inventory (BFI), the Cancer Linear Analogue Scale (CLAS), and the Patient Reported Outcomes Measurement Information System (PROMIS) Fatigue scale.[76,77] The FACT-Lym, which was developed for assessment of symptoms in lymphoma patients, includes an evaluation of constitutional (or "B") symptoms, such as pruritus, bone/muscle pain, and fatigue.[78]

MANAGEMENT

The first step in disease management is risk stratification. For patients with intermediate-2 or high-risk disease allogeneic stem cell transplant should be considered. If patients are non-transplant candidates or have lower risk disease, treatment is only for symptomatic patients (with constitutional and/or spleen-related symptoms) and those with severe cytopenias. The selection of treatment is based on the particular patient's characteristics. Figure 83.6 summarizes a suggested algorithm for management of PMF.

Treatment of Anemia

Treatment of anemia and resultant RBC transfusion dependency remain an unmet challenge in management of PMF. Options for treatment include erythroid stimulating agents (ESA), steroids, androgens, or immunomodulatory drugs (IMids) which include thalidomide and lenalidomide. Transfusion independency had been reported with some of the new JAK-2 inhibitors. Many patients will remain RBC transfusion dependent.

Subcutaneous erythropoietin (Epo) injections (40,000 U weekly) are safe and most suitable for patients with an endogenous serum Epo level <125 U/L. Response rate in such patients is estimated at 50% and might be even higher in transfusion-independent patients.[79] The median duration of response is only 1 year, and some patients experience further enlargement of their spleen during treatment with ESA.

Corticosteroid therapy (variable doses of prednisone, between 0.5 and 1.0 mg/kg/day) has been used in the past, with response rates that were higher in female patients (52%) compared to male patients (29%).[80] Similar response rates (i.e., 30% to 40%) have also been observed with several androgen preparations, including testosterone enanthate (400 to 600 mg intramuscularly, weekly) and oral fluoxymesterone (10 mg/three times a day).[80] The addition of corticosteroids appears to increase the response rate observed with androgens, whereas the presence of cytogenetic abnormality predicts a lesser response rate.[81] Danazol produces a transient (average 5 months) response rate in PMF that is similar to that seen with other androgen preparations (i.e., ~30% to 40% at a dose of 600 mg/day).[82]

Thalidomide and lenalidomide were recently added to the therapeutic armamentarium for PMF-associated anemia after each drug was shown to effect an ~20% response rate.[83,84]

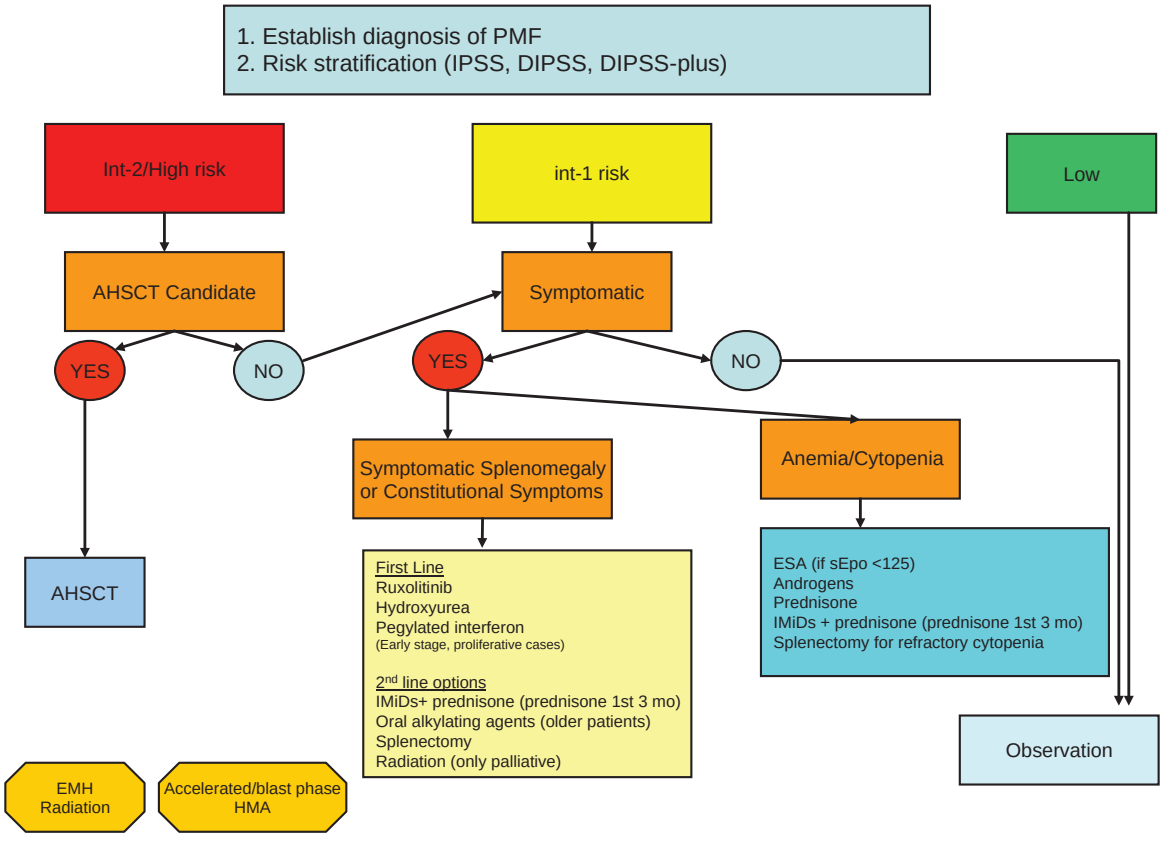

FIGURE 83.6. Suggested algorithm for management of primary myelofibrosis (PMF). AHSCT, allogeneic hematopoietic stem cell transplantation; EMH, extramedullary hematopoeisis; ESA, erythroid stimulating agents; HMA, hypomethylating agents; int, intermediate; ImiDs, immunomodulatory drugs (lenalidomide or thalidomide); sEpo, endogenous serum erythropoietin level.

Thalidomide is used at low doses (50 mg/day) and in combination with corticosteroids (prednisone, 15 to 30 mg/day for 3 months only) [85] and lenalidomide is clearly active in the presence of del(5)(q31).[84,86] A phase II clinical study using lenalidomide 10 mg po daily for 21 days every 28 days (dose adjusted based on platelet count) combined with prednisone for 3 months (30 mg daily first month, 15 mg daily second month, and 15 mg every other day third month) reported a 30% hemoglobin response but not if patients had baseline thrombocytopenia or neutropenia.[87] Pomalidomide was also reported to be active in anemia treatment in PMF where its use remains currently investigational.[88] Phase I/II studies 0.5 mg was the recommended dose and durable hemoglobin responses were reported in 25% of patients. A recent phase III placebo controlled study finished accrual results of which are pending. Outside the context of a clinical trial, we use lenalidomide in patients without baseline of thrombocytopenia/neutropenia and thalidomide if those are present.

Treatment of Splenomegaly and/or Constitutional Symptoms

Splenomegaly and its related symptoms, as well as constitutional symptoms, remain the most common indication for treatment. Options for treatment include hydroxurea, alkylating agents, purine analogues, interferon, IMiDs, JAK-2 inhibitors, splenectomy, and splenic radiation.

Conventional Drug Therapy

Historically, hydroxyurea was considered the first-line therapy for decreasing splenomegaly and the estimated patient response rate is less than 50%.[48] Limitations with hydroxyurea include lack of sustained improvements, rarity in inducing complete regression of the enlarged spleen, the requirement for high doses to induce a response, and the potential for cytopenias.[48] Other agents that may alleviate splenomegaly, but have their own risks, include oral alkylating agents such as melphalan (2.5 mg three times a week),[89] and busulfan (2 to 6 mg/day with close monitoring of blood counts);[90] or intravenous cladribine (5 mg/m^2/day in a 2-hour infusion for 5 consecutive days, repeated for 4 to 6 monthly cycles).[91]

Splenomegaly reduction was reported in 33% of patients with low-dose thalidomide combined with a prednisone taper.[85] Lenalidomide produced similar results in a separate study and was better tolerated in patients with adequate baseline neutrophils and platelets.[87]

Interferon

For treatment of PMF, α has been evaluated; however, its toxicity prohibits its use in many cases with more than half of the patients discontinuing treatment due to toxicity (e.g., worsening cytopenias).[92] It had been suggested that interferon may alter the natural history of the disease and reverse fibrosis in vitro.[93] Although many clinical studies in PMF have been disappointing,[94–96] results of a recent prospective study of 17 low- and intermediate-1 risk patients treated with interferon-α reported that >80% of patients had either response or stable disease (2 patients with complete remission and 7 with partial remission).[97] Interferon-α may be considered in young lower-risk patients and is the treatment of choice in women of childbearing age contemplating pregnancy. Pegylated interferon may be an appealing choice for further study inasmuch as it is given less frequently (usually once a week) and has a better toxicity profile than standard interferon.[98,99]

JAK 2 Inhibitors

There are numerous JAK2 inhibitors undergoing evaluation in clinical trials for the management of MF (Table 83.5).[72,74,100,101,102–104] In November 2011, ruxolitinib was approved by the FDA for treatment of patients with intermediate- (both intermediate-1 and -2) or high-risk MF, including PMF, post-PV MF and post-ET MF marking the first MF disease-specific drug approval and the first in its class.

Ruxolitinib treatment demonstrated efficacy in two large phase III studies in patients with PMF, post-PV MF, and post-ET MF and intermediate-2 or high-risk disease. The COntrolled MyeloFibrosis study with ORal JAK inhibitor Treatment (COMFORT)-I was a double-blind, placebo-controlled phase III clinical study (n = 309) in which patients were randomized (1:1) to ruxolitinib or placebo. Patients randomized to placebo and experiencing worsening symptoms and splenomegaly were allowed to receive ruxolitinib ("crossover"). Significantly more patients in the ruxolitinib arm achieved at least a 35% reduction in spleen volume, as assessed by MRI or CT, versus placebo at week 24 (41.9% vs. 0.7%, $P < 0.001$). Indeed, a great majority

TABLE 83.5

CLINICAL TRIALS WITH JAK INHIBITORS

JAK Inhibitor	Study Phase	Targets	Efficacy	Major Adverse Events
Ruxolitinib	Approved Phase III	JAK-2/JAK-1	Spleen response 42% >50% reduction in symptoms in 46%	Anemia Thrombocytopenia
SAR302503 (TG101348)	Phase III	JAK-2/FLT-3	Spleen Response 45% + improvement of disease related symptoms + control of leukocytosis and thrombocytosis	Anemia Thrombocytopenia Diarrhea Hyperlipasemia
Pacritinib (SB1518)	Phase II	JAK-2/FLT-3	Spleen Response 32% by MRI, 44% by physical exam + improvement of disease-related symptoms	GI-related Symptoms
CYT387	Phase II	JAK-1/JAK-2	+ Spleen response (37%) + RBC transfusion independence (68%)	Thrombocytopenia Hyperlipasemia Peripheral neuropathy
LY2784544	Phase I	*JAK-2* V617F (mutation)-selective	+ spleen response + symptom improvement + reversal of fibrosis	Tumor lysis

of patients in the ruxolitinib arm had some reduction in spleen volume.[74] Improvements in MF-associated symptoms were also achieved with ruxolitinib therapy. Symptom burden was assessed with the modified MFSAF v2.0 where 45.9% of patients in the ruxolitinib arm achieved a 50% or greater improvement in total symptom score by week 24 versus 5.3% in the placebo group ($P < 0.001$). Moreover, patients also experienced improvements in fatigue and QoL. Most patients participating in this trial and receiving ruxolitinib are still on the therapy after 2 years of follow-up. Note that, despite a crossover study design (about three quarters of placebo-treated patients received ruxolitinib upon disease worsening) in the intent-to-treat analysis, those patients randomized to ruxolitinib had improved survival over those initially randomized to placebo.[105]

In a separate open-label, randomized phase III study (COMFORT-II; $n = 219$), patients were randomized (2:1) to ruxolitinib or best available therapy (BAT). This study also allowed a crossover of patients from BAT to ruxolitinib for disease worsening.[100] Significantly more patients in the ruxolitinib arm (28%) achieved at least a 35% reduction in spleen volume versus BAT (0%) ($P < 0.001$) at week 48. Although most patients in the ruxolitinib arm had a reduction in spleen size, the majority of patients in the BAT arm had worsening splenomegaly. Patients in the ruxolitinib arm experienced improvements in global health status (GHS) and role functioning, as well as individual MF-related symptoms captured by the QLQ-C30 instrument, whereas those in the BAT arm experienced worsening by most of these measures. FACT-Lym scores also improved with ruxolitinib treatment. Similarly to the COMFORT-1 study, most patients on ruxolitinib are still on the therapy after 2 years of follow-up. A survival advantage of therapy with ruxolitinib versus therapy with BAT (despite a crossover to ruxolitinib) has recently been reported, similar to the results of COMFORT-1.[106]

The most common adverse drug effects in COMFORT I and II included thrombocytopenia and anemia. The rate of grade 3 or 4 anemia and thrombocytopenia was greater in ruxolitinib-treated patients versus placebo (45.2% and 12.9% vs. 19.2% and 1.3%, respectively) in COMFORT I. Similarly, in COMFORT II patients treated with ruxolitinib versus best available therapy experienced more grade 3 or 4 anemia and thrombocytopenia (42% and 8% vs. 31% and 7%, respectively). In COMFORT I, the mean hemoglobin level reached a nadir of 95 g/L after approximately 8 to 12 weeks of therapy with an increase by week 24 to a new steady state of 101 g/dl. Nonhematologic adverse drug effects included ecchymosis, dizziness, and headache. Note that MF-related symptoms typically returned after 1 week of ruxolitinib discontinuation, strongly suggesting that close monitoring of patients on the therapy during the first 1 to 2 months (when most of the side effects happen) and proactive dose-modification is very important, in order to deliver therapy in the best possible way and avoid unnecessary interruptions.

The starting dose of ruxolitinib is dependent on the baseline platelet count. For patients with a platelet count greater than 200×10^9/L, a dose of 20 mg twice daily is indicated and 15 mg twice daily is indicated in patients with a platelet count between 100×10^9/L and 200×10^9/L. There are no contraindications to the use of ruxolitinib, however, experience with its use in patients with platelet count lower than 100×10^9/L is limited and subject to investigational trials. It is prudent to use ruxolitinib in such patients at the reduced dose, for example, 5 mg twice a day as the starting dose. A baseline complete blood cell count and at 2 to 4 weeks (more often at the start of the therapy) depending on patient response will help guide therapy. If thrombocytopenia develops, the dosage should be reduced. The dosage may be increased to a maximum of 25 mg twice daily depending on patient response. If no reductions in splenomegaly or symptoms are observed after 6 months, therapy should be discontinued. Ruxolitinib is nonspecific for *JAK2* V617F mutation; therefore, it may be useful in all patients with MF.

Splenectomy is associated with significant morbidity and mortality. The perioperative mortality of splenectomy in PMF is between 5% and 10%, and post-splenectomy complications occur in ~50% of patients: surgical-site bleeding, thrombosis, accelerated hepatomegaly, extreme thrombocytosis, and leukocytosis with excess blasts.[107] The indications for splenectomy include symptomatic portal hypertension (e.g., variceal bleeding, ascites), drug-refractory marked splenomegaly that is either painful or is associated with severe cachexia, and frequent red blood cell transfusions or refractory cytopenia.

Radiation provides transient (median response duration of 3 to 6 months) symptomatic relief of mechanical discomfort from hepatosplenomegaly. When it is employed, splenic irradiation is given in a total dose of 0.1 to 0.5 Gy in 5 to 10 fractions and is associated with a >10% mortality rate from consequences of cytopenias.[108] In our practice we restrict use of splenic radiation as a last resort for pure palliation for drug-refractory patients. Radiation therapy is most useful in patients with nonhepatosplenic EMH presenting with mass effect.[109] The thoracic vertebral column is the most frequent site of nonhepatosplenic EMH in PMF; other sites include lymph nodes, the lung, pleura, small bowel, peritoneum, urogenital tract, and heart. When patients are symptomatic, such occurrences are effectively treated with low-dose radiation therapy (0.1 to 1 Gy in 5 to 10 fractions).[109]

Primary Myeofibrosis and Risk of Thrombosis

In a cohort of 707 patients, the cumulative rate of fatal and nonfatal cerebrovascular (CV) events was 7.2%, accounting for 1.75 events per 100 patient-years. (2.23 events per 100 patient-years adjusted).[110] For nonfatal CV events the cumulative rate was 6.6%; the incidences of myocardial infarction and peripheral arterial thrombosis were lower than those of stroke. There was a remarkably high rate of fatal (9 cases) and nonfatal (22 cases) venous thrombosis. In patients presenting with thrombosis at diagnosis or with a thrombotic history, the incidence of recurrences was 9%. In multivariable analysis, age and *JAK*2 mutation were the only two risk factors to independently predict risk of thrombosis; and patients who were *JAK*2 V617F mutated and presented with leukocytosis had the highest incidence of thrombosis (3.9% pt-yr).

Management of Blast-Phase Primary Myelofibrosis

Treatment of the blast phase is typically met with limited success. In a retrospective analysis of 91 cases of blast-phase PMF seen at the Mayo Clinic, 98% of the patients died at a median of 2.6 months (range 0 to 24.2 months) from time of transformation into blast-phase PMF. Aggressive chemotherapy was no better than supportive care, and AML-like induction chemotherapy did not produce complete remission in any patient.[60] Allogeneic stem cell transplant may offer better long-term outcome in a small subset of patients.[111] Outside the context of a clinical trial, we use azanucleosides (azacitidine or decitabine) as an alternative to intensive chemotherapy for patients with accelerated-phase or blast-phase PMF.[112]

Allogeneic Hematopoietic Stem Cell Transplantation

AlloHCT remains the only curative option for patients with PMF. The decision and timing to proceed with HCT is a complex issue weighing potential benefits and substantial morbidity and mortality (see Chapter 104 for more details of HCT for

MF).[113,114,115,116,117,118] The current recommendation is to consider alloHCT worth the risk in patients with PMF whose median survival is expected to be less than 5 years.[119] The consensus is to evaluate alloHCT for patients with a good performance status and no major comorbidities who are intermediate-2 or high-risk disease by risk stratification models. However, an argument can be made to allograft selected low and intermediate-1 DIPSS risk patients who have had 5-year survivals following alloHCT over 80% and 60%, respectively, compared to median survivals of 7 and 2.5 years for intermediate-2 and high-risk patients, respectively.[120]

The use of reduced intensity conditioning (RIC) has expanded the availability of alloHCT in diseases such as PMF where the median age is old and comorbidities are frequently present. The nonrelapse mortality is less and the relapse rate is higher but the disease-free survival of patients undergoing RIC tends to be similar to that of patients who receive myeloablative conditioning.[116] Alternative donors, particularly matched unrelated, are also allowing more patients to undergo alloHCT and the results were initially inferior but are approaching those seen with matched sibling donors.[121] Umbilical cord and haptoidentical transplants are under investigation for patients with MF.[122]

The role of splenectomy for PMF prior to alloHCT is controversial. Splenectomized patients may engraft more quickly, but there is the problem of perioperative morbidity and mortality and there are conflicting results about its effect on graft versus host disease (GVHD) and survival. Massive splenomegaly can resolve following alloHCT, including RIC-alloHCT.[123] Although splenectomy may be considered for an individual patient, pre-emptive splenectomy is not routinely recommended for patients with PMF undergoing HCT.

The role of JAK2 inhibitors prior to alloHCT in PMF is uncertain, but they could reduce spleen size and improve engraftment and could decrease the levels of inflammatory cytokines which might affect GVHD and prognosis post-allo–HCT.[116] Clearing of *JAK2* V617F in the peripheral blood after alloHCT had a significantly reduced risk of relapse than patients who did not clear the mutation.[124] Clinical trials are warranted to determine the efficacy of JAK2 inhibition as a bridge to alloHCT, a strategy to delay HCT, or a therapy after HCT.

SUMMARY

PMF is a progressive MPN associated with significant disease burden, including splenomegaly, cytopenias, and constitutional symptoms that have an impact on patient survival and quality of life. Over the past several years, we uncovered important biologic aspects of the disease such as discovery of the JAK-STAT pathway dysregulation and multiple different mutations leading to abnormal genetic and epigenetic regulation in MF. After establishing the diagnosis, risk stratification is the most important next step. Allogeneic stem cell transplant remains the only curative option and should be offered for higher risk patients. Goals of medical therapy are mostly centered around improving splenomegaly, anemia, and very poor quality of life. Treatment options remain limited but the development of JAK inhibitors results in better control of the signs and symptoms of the disease and, therefore, improves patients' outlook. The inhibitors may serve as a building block for combination therapies that would significantly alter the biology of the disease.

Acknowledgment

The authors recognize Ayalew Tefferi for his many contributions to the understanding and therapy of myelofibrosis.

CHAPTER 84

EOSINOPHILIC NEOPLASMS AND HYPEREOSINOPHILIC SYNDROME

Huong (Marie) Nguyen, Jason Gotlib

HISTORICAL BACKGROUND

Paul Ehrlich's use of aniline dyes facilitated identification of the eosinophil as a unique leukocyte in 1879.[1] Reactive eosinophilias and eosinophilia-associated leukemias were recognized in the early to mid-twentieth century. However, a nomenclature for unexplained eosinophilias was not formulated until 1968 when Hardy and Anderson originated the term hypereosinophilic syndrome (HES).[2] In 1975, Chusid and colleagues generated diagnostic criteria for (idiopathic) hypereosinophilic syndrome based on a small case series of patients: (1) persistent eosinophilia of 1.5×10^9/L for more than 6 months; (2) lack of evidence for parasitic, allergic, or other known causes of eosinophilia; and (3) signs and symptoms of organ involvement.[3] In the last 20 years, the evaluation of eosinophilic disorders has advanced from its descriptive roots to a more comprehensive approach which relies on a combination of histopathology, cytogenetics, molecular genetics, and immunophenotyping. Table 84.1 lists recent modern nosologic and clinicopathologic landmarks which reflect this evolution in the diagnosis and classification of eosinophilic disorders.

DEFINITION OF EOSINOPHILIA

Although minor differences may exist between laboratories, the upper limit of normal for the percent peripheral blood eosinophils is 5%, with a corresponding absolute eosinophil count (AEC) of approximately 0.5×10^9/L (500/mm^3).[4,5] The severity of hypereosinophilia (HE) has been stratified into mild, moderate, or severe (with AECs between the upper range of normal to 1.5×10^9/L (1,500/mm^3), 1.5 to 5.0×10^9/L (1,500 to 5,000/mm^3), or $>5.0 \times 10^9$/L ($>$5,000/mm^3), respectively). Alternatively, the singular term hypereosinophilia has been used to denote an AEC of $>1.5 \times 10^9$/L ($>$1,500/mm^3).

TABLE 84.1

MODERN CLASSIFICATION AND CLINICOPATHOLOGIC LANDMARKS IN EOSINOPHILIC DISORDERS

Year	Event
1968	Term "hypereosinophilic syndrome" coined by Hardy and Anderson
1975	Diagnostic criteria for HES established by Chusid and colleagues
1994	Characterization of the first *PDGFRB* rearrangement (*ETV6-PDGFRB*), t(5;12)(q31-33;p13)
1994	First description of lymphocyte-variant hypereosinophilia
1998	Identification of rearrangement of the *FGFR1* gene as the basis for the 8p11 syndrome
2001	WHO diagnostic criteria for HES and CEL
2001–2002	Successful empiric treatment of HES patients with imatinib
2002	Characterization of the first *PDGFRA* rearrangement (*BCR-PDGFRA*), t(4;22)(q12q11)
2003	Identification of the FIP1L1–PDGFRα fusion as the therapeutic target of imatinib
2003	Identification of *FIP1L1–PDGFRA* using the surrogate test "FISH for the *CHIC2* deletion"
2008	Revised WHO criteria include the category of "Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA, PDGFRB, or FGFR1*"

CEL, chronic eosinophilic leukemia; *FGFR1*, fibroblast growth factor receptor 1; FISH, fluorescent *in situ* hybridization; HES, idiopathic hypereosinophilic syndrome; *PDGFRA*; platelet-derived growth factor receptor alpha; *PDGFRB*, platelet-derived growth factor receptor beta; WHO, World Health Organization.

EPIDEMIOLOGY

HES and chronic eosinophilic leukemia (CEL) are very uncommon disorders. Data obtained from the Surveillance, Epidemiology, and End Results (SEER) program during the years 2001 to 2005 revealed an age-adjusted incidence rate of 0.036 per 100,000.[6] Eosinophilias with recurrent genetic abnormalities (*PDGFRA/B*, *FGFR1*) are yet even more rare, representing approximately 10% cases of initially unexplained eosinophilias in developed countries.[7] SEER identified a peak age range at diagnosis of 65 to 74 years, with cases uncommonly diagnosed in infants and children. The male to female ratio of HES/CEL is approximately 1.5:1, but *FIP1L1–PDGFRA*-positive disease is almost exclusively diagnosed in men, a phenomenon whose biologic basis remains unknown.[6,7]

EOSINOPHIL PHYSIOLOGY

Eosinophil-committed hematopoietic progenitors are identified within the CD34$^+$ progenitor population as interleukin-5 receptor (IL5R)$^+$/CCR3$^+$ cells.[8,9] Their production is tightly regulated by a network of eosinophilopoietic cytokines. IL-5, interleukin-3 (IL-3), and granulocyte–macrophage colony-stimulating factor are the most relevant to eosinophil physiology, and are primarily responsible for the commitment, proliferation, and differentiation of hematopoietic progenitors into the eosinophil lineage.[4,10] These factors are elaborated by several cell types including T-lymphocytes, mast cells, and stromal cells, and bind to their respective receptors on eosinophils.[11] Migration of eosinophils from the circulation to tissues is mediated via interactions between endothelial cell adhesion molecules such as ICAM-1 and VCAM1 and eosinophil surface integrins (e.g., the α1 and β2 integrins VLA-4 and CD18, respectively).[12] Eosinophil migration is influenced by several potent eosinophil chemoattractants including leukotriene β4, complement fragment 5a, platelet activating factor, RANTES, and eotaxins, which are ligands for the eosinophil receptor CCR3.[13–15] Although eosinophils serve as an essential component of the immune system's normal homeostatic function, including defense against infection and recruitment in response to allergy and inflammation, the potential for collateral tissue injury exists due to mediators released from eosinophils undergoing marked or persistent activation. These biologically active molecules are released from intracellular granule compartments and include preformed substances such as major basic protein, eosinophil peroxidase, eosinophil cationic protein, and eosinophil-derived neurotoxin.[4] Eosinophils also contain hydrolytic enzymes such as acid phosphatase, catalase, arylsulfatase, and newly synthesized mediators such as hydrogen peroxide that can contribute to organ damage.[4]

MODERN CLASSIFICATION

The most recent iteration of the World Health Organization (WHO) classification of hematolymphoid neoplasms incorporates eosinophilic disorders among the umbrella of myeloid neoplasms (Table 84.2). The WHO classification recognized the unique molecular basis of a subset of certain eosinophilic disorders by establishing the major category entitled, "Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of platelet-derived growth factor receptor alpha (*PDGFRA)*, platelet-derived growth factor receptor beta (*PDGFRB*), or fibroblast growth factor receptor 1 (*FGFR1*)" (Table 84.3).[16] The diagnostic entity "chronic eosinophilic leukemia not otherwise specified (CEL-NOS)" is one of eight diseases included within another major WHO category, "Myeloproliferative Neoplasms (MPNs)" (Table 84.3).[17] CEL-NOS is defined by the absence of the Philadelphia chromosome or a rearrangement involving *PDGFRA/B* or *FGFR1*, and the exclusion of other WHO-defined acute or chronic primary marrow neoplasms associated with eosinophilia, e.g., acute myeloid leukemia (AML), myelodysplastic syndrome (MDS), MPNs such as chronic

TABLE 84.2

2008 WORLD HEALTH ORGANIZATION CLASSIFICATION OF MYELOID MALIGNANCIES

1. Acute myeloid leukemia and related disorders
2. MPNs
   a. Chronic myelogenous leukemia, *BCR-ABL1* positive
   b. Chronic neutrophilic leukemia
   c. Polycythemia vera
   d. Primary myelofibrosis
   e. Essential thrombocythemia
   f. ***Chronic eosinophilic leukemia, not otherwise specified***
   g. Mastocytosis
   h. Myeloproliferative neoplasm, unclassifiable
3. MDS
   a. Refractory cytopenia with unilineage dysplasia
   b. Refractory anemia
   c. Refractory neutropenia
   d. Refractory thrombocytopenia
   e. Refractory anemia with ring sideroblasts
   f. Refractory cytopenia with multi-lineage dysplasia
   g. Refractory anemia with excess blasts I
   h. Refractory anemia with excess blasts II
   i. MDS with isolated del(5q)
   j. MDS, unclassifiable
4. MDS/MPN
   a. Chronic myelomonocytic leukemia 1
   b. Chronic myelomonocytic leukemia 2
   c. Atypical chronic myeloid leukemia, *BCR-ABL* negative
   d. Juvenile myelomonocytic leukemia
   e. MDS/MPN, unclassifiable
   f. Refractory anemia with ring sideroblasts and thrombocytosis
5. **Myeloid and lymphoid neoplasms associated with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1***
   a. Myeloid and lymphoid neoplasms associated with *PDGFRA* rearrangement
   b. Myeloid neoplasms associated with *PDGFRB* rearrangement
   c. Myeloid and lymphoid neoplasms associated with *FGFR1* abnormalities

MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasms.

TABLE 84.3

2008 WORLD HEALTH ORGANIZATION CLASSIFICATION OF EOSINOPHILIC DISORDERS

1. Myeloid and lymphoid neoplasms associated with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*

1. **Diagnostic criteria of an MPN[a] with eosinophilia associated with *FIP1L1–PDGFRA***
   1. An MPN with prominent eosinophilia **and**
   2. Presence of an *FIP1L1–PDGFRA* fusion gene[b]
2. **Diagnostic criteria of MPN associated with *ETV-6-PDGFRB* fusion gene or other rearrangement of *PDGFRB***
   1. An MPN, often with prominent eosinophilia and sometimes with neutrophilia and monocytosis and
   2. Presence of t(5;12)(q31∼q33;p13), or a variant translocation[c], or demonstration of an *ETV6-PDGFRB* fusion gene or rearrangement of PDGFRB
3. **Diagnostic criteria of MPN or acute leukemia associated with *FGFR1* gene rearrangement**
   1. An MPN with prominent eosinophilia and sometimes with neutrophilia or monocytosis **or** AML or precursor T-cell or precursor B-cell lymphoblastic leukemia/lymphoma (usually associated with peripheral blood or bone marrow eosinophilia) **and**
   2. Presence of t(8;13)(p11;q12) or a variant translocation leading to *FGFR1* rearrangement demonstrated in myeloid cells, lymphoblasts, or both

2. Chronic Eosinophilic Leukemia-NOS

a. Eosinophilia (eosinophil count $> 1.5 \times 10^9$/L)
b. No Ph chromosome or *BCR-ABL* fusion gene or other MPNs (PV, ET, PMF, systemic mastocytosis) or MDS/MPN (CMML or atypical CML)
c. No t(5;12)(q31∼q35;p13) or other rearrangement of *PDGFRB*
d. No *FIP1L1–PDGFRA* fusion gene or other rearrangement of *PDGFRA*
e. No rearrangement of *FGFR1*
f. Blast cell count in the peripheral blood and bone marrow is less than 20% and there is no inv(16)(p13q22) or t(16;16)(p13q22) or other feature diagnostic of AML
g. There is a clonal cytogenetic or molecular genetic abnormality, or blast cells are more than 2% in the peripheral blood or more than 5% in the bone marrow

3. Idiopathic Hypereosinophilic Syndrome

EXCLUSION of the following:

a. Reactive eosinophilia
b. Lymphocyte-variant hypereosinophilia (cytokine-producing immunophenotypically aberrant T-cell population)
c. Chronic eosinophilic leukemia, NOS
d. WHO-defined myeloid malignancies associated with eosinophilia (e.g., MDS, MPNs, MDS/MPNs, or AML)
e. Eosinophilia-associated MPNs or AML/ALL with rearrangements of *PDGFRA*, *PDGFRB*, or *FGFR1*
f. Absolute eosinophil count of $>1{,}500/mm^3$ must persist for at least 6 mo and tissue damage must be present. If there is no tissue damage, idiopathic hypereosinophilia is the preferred diagnosis

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; ET, essential thrombocythemia; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasms; NOS, not otherwise specified; PMF, primary myelofibrosis; PV, polycythemia vera.

[a]Patients presenting with AML or lymphoblastic leukemia/lymphoma with eosinophilia and an *FIP1L1–PDGFRA* fusion gene are also assigned to this category.

[b]If appropriate molecular analysis is not available, this diagnosis should be suspected if there is a Ph-negative MPN with the hematologic features of chronic eosinophilic leukemia associated with splenomegaly, a marked elevation of serum vitamin B_{12}, elevation of serum tryptase, and increased bone marrow mast cells.

[c]Because t(5;12)(q31∼q33;p12) does not always lead to an *ETV6-PDGFRB* fusion gene, molecular confirmation is highly desirable. If molecular analysis is not available, this diagnosis should be suspected if there is a Ph-negative MPN associated with eosinophilia and with a translocation with a 5q31-33 breakpoint.

myelogenous leukemia (CML) or systemic mastocytosis (SM), and overlap MDS/MPNs. It is also defined by an increase in blood or marrow blasts (<20%), and/or nonspecific cytogenetic abnormalities. The diagnostic criteria of HES formulated by Chusid and colleagues is recapitulated by the WHO, but the original requirement that eosinophilia persist for more than 6 months is no longer consistently embraced. This relates to the faster-paced and more sophisticated evaluation of eosinophilia that is now feasible, and the recognition that early treatment can be critical to mitigating eosinophilia-mediated organ damage. The nosological distinction between "idiopathic hypereosinophilia" and "idiopathic HES" reflects the requirement that organ damage be present in the latter. "Lymphocyte-variant hypereosinophilia" is a provisional diagnosis that is referred to in the WHO classification and should be considered before settling on the diagnosis of idiopathic hypereosinophilia or HES, which are diagnoses of exclusion.[17]

In 2011, members from the Working Conference on Eosinophil Disorders and Syndromes proposed a new terminology for eosinophilic syndromes.[18] The panel recommended the higher level term "Hypereosinophilia (HE)" for persistent and marked eosinophilia (AEC $> 1.5 \times 10^9$/L). In turn, HE subtypes were divided into a hereditary (familial) variant (HE_{FA}), HE of undetermined significance (HE_{US}), primary (clonal/neoplastic) HE produced by clonal/neoplastic eosinophils (HE_N), and secondary (reactive) HE (HE_R). HE_{US} was introduced as a novel term in lieu of "idiopathic hypereosinophilia." Any HE (not just idiopathic) associated with organ damage is referred to as "HES" with specific variants designated by subscripts (e.g., HES_{US}, HES_N, and HES_R). Additional recommendations advanced by the consensus panel are summarized in their report.[18]

DIAGNOSTIC EVALUATION FOR HYPEREOSINOPHILIA

In addition to a hematology consultation, a multidisciplinary evaluation including allergy/immunology, dermatology, and infectious diseases/tropical medicine may be required to identify the etiology of HE. The workup of HE (Fig. 84.1) should commence with a thorough evaluation of reactive causes, with particular attention to comorbid health conditions, medications, and travel

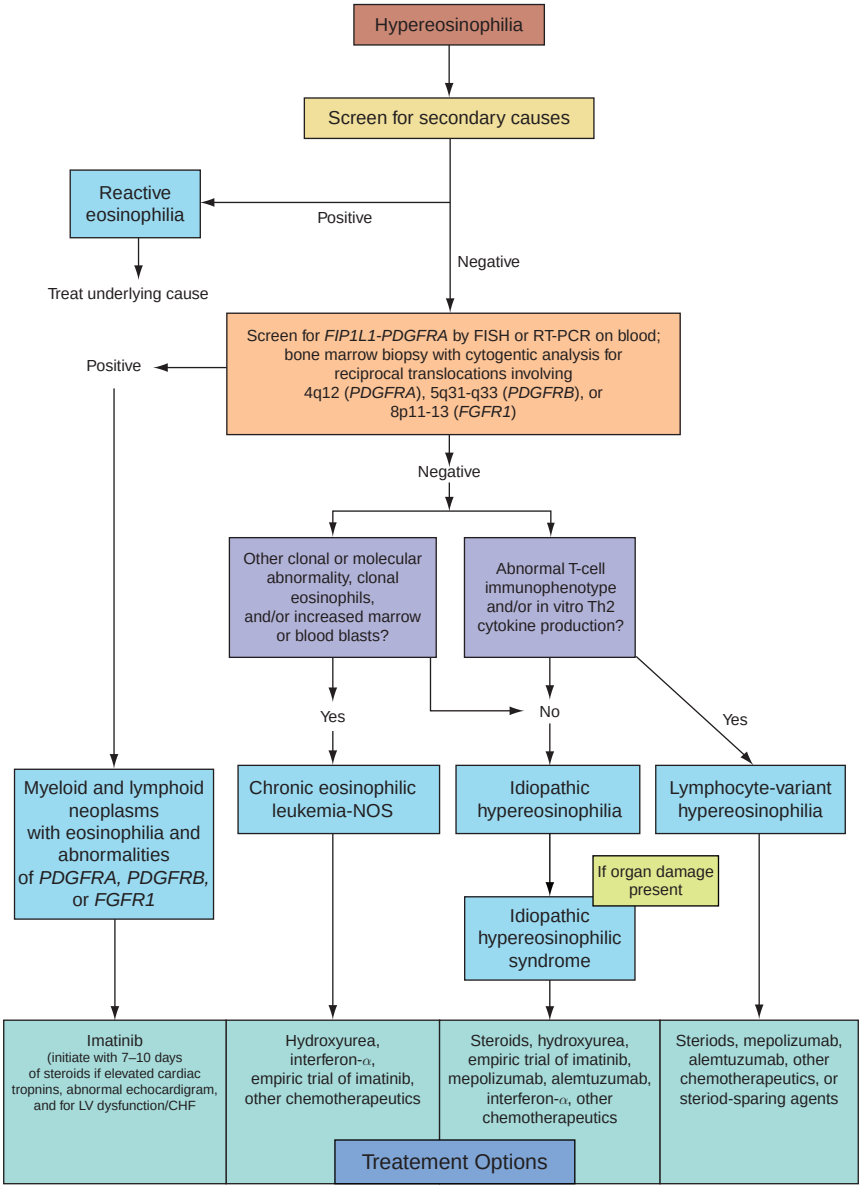

FIGURE 84.1 Algorithm for the diagnosis and treatment of eosinophilic disorders.

history/environmental exposures. Helminth infections are the most common cause of HE in developing countries, and hypersensitivity/atopy is the most frequent etiology in industrialized nations. In addition to infection and hypersensitivity conditions, other secondary causes of HE include connective tissue disorders (Churg-Strauss syndrome), granulomatosis with polyangiitis (Wegener's, systemic lupus erythematosus), solid or hematologic malignancies, metabolic disorders (e.g., adrenal insufficiency), eosinophilic pulmonary diseases, and rare entities such as familial eosinophilia,[19] hyper-immunoglobulin (Ig)E syndrome, Omenn syndrome, episodic angioedema and eosinophilia (Gleich's syndrome), and eosinophilia-myalgia syndrome (possibly related to tryptophan ingestion and the historical epidemic of toxic-oil syndrome).[20,21]

In addition to a complete blood count with a white blood cell count (WBC) differential to measure the severity of eosinophilia, the initial laboratory workup for reactive causes of HE typically includes stool culture and serial ova and parasite testing, and sometimes serologic testing for specific parasites (e.g., strongyloides antibody). Testing for specific bacteria, fungi, or viruses may also be warranted in selected cases. The use of chest x-ray, electrocardiogram and/or echocardiography, and computed tomography scan of the chest or abdomen/pelvis are similarly guided by the patient's symptoms and physical exam findings. Imaging studies may help discern the basis for eosinophilia, establish the presence or severity of organ damage, and guide the need for tissue biopsy. For eosinophilic lung diseases, pulmonary function testing, bronchoscopy, and serologic tests (e.g., aspergillus IgE to evaluate for allergic bronchopulmonary aspergillosis) may be obtained to further characterize lung involvement.

If secondary causes of eosinophilia are excluded, the workup should proceed to the evaluation of a primary bone marrow disorder. Bone marrow aspirate and trephine biopsy with cytogenetics and immunophenotyping (with relevant iron and reticulin/trichrome stains) are useful to elucidate WHO-defined clonal myeloid neoplasms associated with eosinophilia such as acute myeloid leukemia, specifically AML with inv(16)(p13q22) or t(16;16)(p13;q22), CML or other MPNs (e.g., SM), and overlap MDS/MPN disorders such as chronic myelomonocytic leukemia (CMML).[17]

Myeloid malignancies primarily defined by eosinophilia include the aforementioned CEL-NOS and the category of *PDGFRA/B* or *FGFR1*-rearranged neoplasms. Diagnostic assessment of primary eosinophilia should begin with screening of the peripheral blood for the *FIP1L1–PDGFRA* gene fusion by interphase or metaphase fluorescence in situ hybridization (FISH).[22] Less commonly, reverse-transcriptase polymerase chain reaction (PCR) is used to detect the fusion. FISH probes that hybridize between the *FIP1L1* and *PDGFRA* loci detect the 800-kb interstitial deletion on chromosome 4q12 that results in gene fusion. Because the *CHIC2* gene is located in this deleted genetic segment, the test has been referred to as "FISH for the *CHIC2* deletion."[23] If *FIP1L1–PDGFRA* screening is not available, serum tryptase has been used as a surrogate marker for *FIP1L1–PDGFRA*-positive disease, since increased levels have been associated with the fusion or myeloproliferative forms of HE.[24] In contrast to *FIP1L1–PDGFRA*, which is not detectable by standard karyotyping, rearrangements involving *PDGFRB* and *FGFR1* can be inferred by cytogenetic analysis, represented by the breakpoints 5q31-33 (*PDGFRB*) and 8p11-12 (*FGFR1*), respectively.[16] Reciprocal chromosomal translocations involving the breakpoints 9p24 or 13q12 may relate to *JAK2* (e.g., *PCM1-JAK2*) or *FLT3* (e.g., *ETV6-FLT3*) fusions, respectively, and have been associated with eosinophilia.[25,26] Knowledge of these breakpoints is critical because targeted therapy may have clinical efficacy against these constitutively activated tyrosine kinases. Bone marrow biopsy studies as highlighted above should be performed to complement peripheral blood analyses.

If both secondary and primary causes of eosinophilias are excluded, lymphocyte-variant HE should be considered next in the diagnostic algorithm.[27] Patients with lymphocyte-variant HE often have cutaneous signs and symptoms as the primary disease manifestation. Although patients' skin disease can be symptomatic, the natural history of this condition is typically indolent, with rare patients progressing to T-cell lymphoma or Sézary syndrome. Progression has been associated with acquisition of cytogenetic abnormalities (e.g., partial 6q and 10p deletions, trisomy 7) in T cells and with proliferation of lymphocytes with the $CD3^{-}CD4^{+}$ phenotype.[28,29,30,31,31] This syndrome represents a mixture of clonal and reactive processes resulting in the expansion of a clone of T-lymphocytes that produce cytokines that drive eosinophilia.[27,32,33] Although these laboratory findings constitute basic elements of this syndrome, neither the WHO nor other consensus panels have established specific diagnostic criteria for this condition.[16–18] The finding of isolated T-cell clonality by PCR without T-cell immunophenotypic abnormalities or demonstration of Th2 cytokine production is not adequate to make a diagnosis of this variant.[32] In an analysis of patients diagnosed with HES, 18/42 (43%) subjects exhibited a clonal T-cell receptor gene rearrangement by PCR.[34] However, the biologic relevance of such clonal T-cell populations to eosinophilia was not established.[34] Therefore, whether such patients should still be referred to as HES, or as lymphocyte-variant HE, remains a matter of debate. Laboratory features that suggest this disorder are shown in Table 84.4.

BIOLOGY OF FIP1L1–PDGFRA

FIP1L1–PDGFRA can promote the proliferation and survival of eosinophils through the activation of several signaling pathways such as phosphoinositol 3-kinase (PI3 kinase), ERK1/2, and STAT5.[22,35] The exact mechanism by which FIP1L1–PDGFRα preferentially affects eosinophils remains unclear. Recently, it was found that in vitro inhibition of JAK2 in the *FIP1L1–PDGFRA*-positive EOL-1 cell line, primary *FIP1L1–PDGFRA*-positive cells, and T674I *FIP1L1–PDGFRA*-imatinib-resistant cells, by either JAK2-specific short interfering RNA or the tryphostin derivative AG490 (a JAK inhibitor), significantly reduced cellular proliferation and induced cellular apoptosis.[36] JAK2 inhibition also reduced PI3 kinase, AKT, and nuclear factor kappa B activity in a dose-dependent manner, and suppressed expression levels of

TABLE 84.4

LABORATORY FINDINGS IN LYMPHOCYTE-VARIANT HYPEREOSINOPHILIA

1. Cytokine-producing abnormal T-lymphocyte population with aberrant immunophenotype
   a. Double-negative, immature T cells (e.g., $CD3^{+}CD4^{-}CD8^{-}$), or
   b. Absence of CD3 (e.g., $CD3^{-}CD4^{+}$), a normal component of the T-cell receptor, or
   c. Elevated CD5 expression on $CD3^{-}CD4^{+}$ cells, or
   d. Loss of surface CD7 and/or expression of CD27
2. Reactive eosinophilia in response to T-lymphocyte secretion of eosinophilopoietic cytokines
3. Elevated serum IgE levels
4. Lymphocyte production of cytokines (e.g., IL-5, IL-4, IL-13) suggesting Th2 cytokine profile
5. Elevated production of TARC, a chemokine in Th2-mediated diseases

IL, interleukin; TARC, thymus and activation-regulated chemokine; Th2, T cells with helper type 2.

c-myc and survivin.[36] The results suggest that JAK2 is activated by FIP1L1–PDGFRα and is required for cellular proliferation, possibly through induction of c-myc and survivin.

In one murine model, expression of the *FIP1L1–PDGFRA* fusion in bone marrow cells was not sufficient to cause eosinophilia, but only a general myeloproliferative disease.[37] However, in another murine model, expression of *FIP1L1–PDGFRA* together with overexpression of IL-5, the most potent eosinophilopoietic cytokine, mimicked more typical features of HES, such as tissue infiltration of eosinophils.[38] Polymorphic variation at the IL-5 receptor-a (*IL5RA*) gene revealed an association between a single nucleotide polymorphism in the 5′ untranslated region of *IL5RA* and the eosinophil count/presence of tissue infiltration in *FIP1L1–PDGFRA*-positive patients.[39] These data suggest that *FIP1L1–PDGFRA* alone is not sufficient to explain the development of HES/CEL, and that additional factors such as IL-5 signaling may also be implicated in the disease phenotype.

The structure of the FIP1L1–PDGFRa fusion protein is similar to the structure of the ETV6–PDGFRα, ZNF198–FGFR1, and BCR–ABL1 proteins, for which homotypic oligomerization mediated by domains within ETV6, ZNF198, or BCR has been reported.[40–42] Oligomerization of the corresponding fusion proteins leads to activation of the tyrosine kinase domains, which in turn activate downstream signaling pathways regulating cell proliferation and survival. In contrast, interruption of the juxtamembrane of PDGFRα, either due to mutations or duplications, causes constitutive activation of kinase activity.[43,44] This mechanism occurs with internal tandem duplications in *FLT3* and mutations of *KIT* in AML or gastrointestinal stromal tumors.[45,46] Fusion of FIP1L1 to the PDGFRa protein yields a constitutively active tyrosine kinase only if the juxtamembrane domain of PDGFRα is partially or completely removed.[47] The different breakpoints within the *PDGFRA* gene are tightly clustered, resulting in the removal of part of the juxtamembrane domain and activation of the kinase domain.[48] In contrast, with many PDGFRB fusions, the juxtamembrane is completely intact, and activation of PDGFRB kinase activity is obtained through oligomerization mediated by the fusion partner.

In addition to dysregulation of *PDGFRA* by fusion to *FIP1L1* or other partner genes, activating point mutations have been identified in *PDGFRA* in patients with HE.[49] Although there was variability in their transforming ability, injection of cells harboring these mutants into mice induced a leukemia-like disease. Imatinib treatment significantly decreased leukemic growth and prolonged survival.[49]

CLINICAL PRESENTATION AND PROGNOSIS

Clinicopathologic Features

Patients with *FIP1L1–PDGFRA*–associated eosinophilia present with features of an MPN: splenomegaly, hypercellular bone marrows, and clinicopathologic characteristics which overlap with systemic mast cell disease, including increased numbers of abnormal-appearing bone marrow mast cells, marrow fibrosis, and elevated serum tryptase levels (see Fig. 84.2).[24,48] Soon after the discovery of the fusion, a debate arose regarding whether *FIP1L1–PDGFRA*-positive disease represents a subtype of SM rather than a primary eosinophilic neoplasm, because atypical mast cells can be found in the marrows of these patients. In a Mayo Clinic series, the bone marrow biopsies of *FIP1L1–PDGFRA*-positive patients were described as showing a loose, interstitial pattern of mast cells by tryptase immunostaining compared to the multifocal dense aggregates characteristic of D816V *KIT*-positive SM.[50] In some cases, the mast cells exhibited spindle-shaped morphology and aberrant

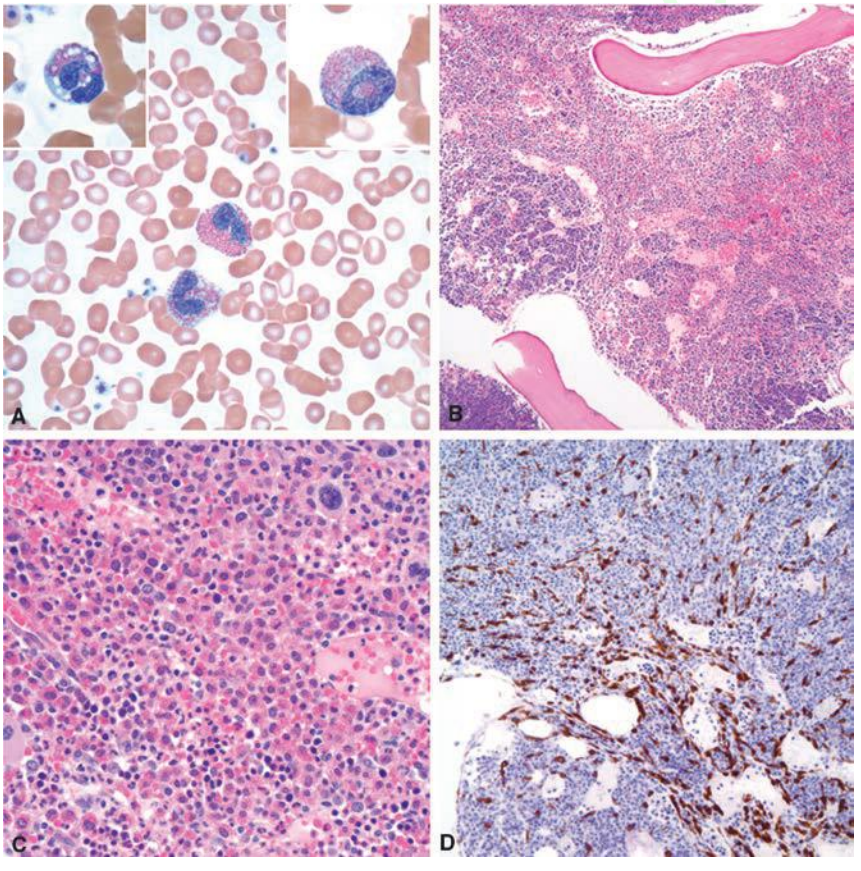

FIGURE 84.2 Histopathology of a *FIP1L1—PDGFRA*-positive myeloid neoplasm associated with eosinophilia. A peripheral eosinophilia is present with an absolute eosinophil count of 2.48 × 10^9/L. Eosinophils include atypical forms with ring nuclei (inset, right), vacuolated cytoplasm (inset, left), as well as irregularly granulated eosinophils **(A)**. Wright-Giemsa, 1,000×. The bone marrow biopsy is hypercellular for age with dilated marrow sinuses, a feature associated with marrow fibrosis **(B)**. Hematoxylin and eosin, 100×. The bone marrow biopsy shows a myeloid hyperplasia with a marked eosinophilia **(C)**. Hematoxylin and eosin, 400×. surface expression of CD25, both WHO minor criteria for SM. However, in the revised 2008 WHO classification, this entity was not considered a subtype of SM, but instead was included in the new category "Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*."[16] Reliable distinction between *KIT* D816V-positive SM with eosinophilia and *FIP1L1–PDGFRA*-positive eosinophilia was demonstrated based on several clinical and laboratory features.[51] In the *KIT* D816V-positive SM cohort, gastrointestinal symptoms, urticaria pigmentosa, thrombocytosis, median serum tryptase value, and the presence of dense marrow mast cell aggregates were significantly elevated or more frequently represented compared to patients with *FIP1L1–PDGFRA*-positive disease. Conversely, male sex, cardiac and pulmonary symptoms, median peak AEC, the eosinophil to tryptase ratio, and serum B12 levels were significantly elevated or more frequently represented in the *FIP1L1–PDGFRA*-positive group. A scoring system that incorporated these findings was devised that could reliably predict these two diagnostic entities.

Although *FIP1L1–PDGFRA*–positivity is almost always associated with the phenotype of a chronic MPN, the fusion may be rarely found in AMLs or T-cell leukemias/lymphomas associated with eosinophilia.[52] In addition to the *FIP1L1–PDGFRA* fusion gene, >5 *PDGFRA* fusion genes, as well as >20 different *PDGFRB* genes, have been described in MPNs with eosinophilia (Fig. 84.3). Among 56,709 cytogenetically defined cases at the Mayo Clinic, only 25 (0.04%) exhibited the t(5;12) breakpoint.[53] The classic variant t(5;12)(q33;p13), likely representing the *ETV6-PDGFRB* gene fusion, was present in only 4 of these cases.[53] Despite the rare frequency (<<1%) of *PDGFRB*-rearrangements in cytogenetically defined cases with features of CMML and other myeloid neoplasms (e.g., atypical CML, juvenile myelomonocytic leukemia, chronic basophilic leukemia, MDS/MPN-unclassifiable),[53] their recognition is critical given their responsiveness to imatinib. However, not all 5q31-33 breakpoints represent the *PDGFRB* gene. For example, IL-3 (on chromosome 5q31) is fused to the Ig heavy chain gene (chromosome 14q32) in a subset of eosinophilia-associated B-cell acute lymphoblastic leukemias (ALLs).[54] In addition, in cases of MDS/AML with associated eosinophilia and a t(5;12)(q31;p13) translocation, an *ETV6-ACS2* gene fusion was identified.[55] Finally, more than 10 fusion partners of *FGFR1* have been described in the context of stem cell leukemia/lymphoma (Fig. 84.3).

Clinical Presentation

In two retrospective series of HES, eosinophilia was an incidental finding in 6% to 12% of patients with HE.[54,55] In a study of 188 patients, the mean peak eosinophil count was 6.6 × 10^9/L (range of 1.5 to 400 × 10^9/L).[55] Primary marrow eosinophilias, also referred to as "myeloproliferative variants of eosinophilia," may be characterized by blood or bone marrow neutrophilia, basophilia, and myeloid immaturity. Eosinophil morphology can be normal or abnormal in marrow-derived eosinophilias and cannot be used as a distinguishing feature between reactive and primary eosinophilias. Marrow findings of Charcot-Leyden crystals, increased blasts, and fibrosis are found in a spectrum of eosinophilic myeloid neoplasms and are not unique to CEL-NOS or myeloid neoplasms with eosinophilia and rearrangements of *PDGRA/B* or *FGFR1*.[16,17]

Common non-hematologic signs and symptoms of HES include (in descending frequency) weakness and fatigue (26%), cough (24%), dyspnea (16%), myalgias or angioedema (14%), rash or fever (12%), and rhinitis (10%).[56] In follow-up of patients with sustained eosinophilia, skin involvement was the most frequent clinical manifestation (69% of patients), followed by pulmonary (44%) and gastrointestinal (38%) findings.[57] Cardiac sequelae (unrelated to hypertension, atherosclerosis, or rheumatic disease) was eventually identified in 20% of patients at follow-up (only 6% at the time of initial presentation).[57] Table 84.5 shows the frequency and type of organ system involvement from 3 historical studies.[56,58,60]

Prognosis

Older case series identify cardiac disease as the primary etiology of premature death. A review of 57 HES cases published through 1973 reported a median survival of 9 months, and the 3-year survival was only 12%.[3] Patients usually presented with advanced disease, with congestive heart failure accounting for 65% of deaths at autopsy. In addition to cardiac involvement, peripheral blood blasts or a WBC count greater than 100 × 10^9/L were poor prognostic factors.[3] A later report of 40 HES patients cited a 5-year survival rate of 80%, decreasing to 42% at 15 years.[58] Factors predictive of a worse outcome included the presence of an MPN, corticosteroid-refractory HE, cardiac disease, male sex, and the height of eosinophilia.[58]

The historical, shortened life expectancy related to heart damage provides a useful example of the consequences of eosinophil-mediated tissue injury. It is typically a step-wise process resulting from local infiltration and release of toxic mediators.[56,60] Damage to the endocardium can lead to local deposition of platelet thrombi, and subsequently to larger mural thrombi and increased risk of thromboembolic disease. With time, fibrous thickening of the endocardial lining and leaflets of the mitral and tricuspid valves can result in a restrictive cardiomyopathy and valvular insufficiency.[61,62] Advances in cardiac surgery have reduced morbidity and mortality related to eosinophil-mediated heart damage.

In WHO-defined myeloid malignancies, the prognostic importance of associated eosinophilia has only been studied in a few diseases. In a series of 123 patients with SM, eosinophilia was prevalent in 34% of cases, but was prognostically neutral and not affected by exclusion of *FIP1L1–PDGFRA*-positive cases.[63] In a study of 1,008 patients with de novo MDS, eosinophilia (and basophilia) predicted a significantly reduced survival without having a significant impact on leukemia-free survival.[64] A retrospective analysis of 288 individuals with newly diagnosed MDS revealed that significantly higher numbers of patients with eosinophilia or basophilia (compared to patients with neither) had chromosomal abnormalities carrying an intermediate or poor prognosis.[65] In addition, the overall survival rate was significantly lower and a higher rate of evolution to AML was observed.[65]

TREATMENT

FIP1L1–PDGFRA-Positive Neoplasms

At the turn of the 21st century, no unique and recurrent clonal marker had been linked to eosinophilic neoplasms despite an ever-growing list of nonspecific chromosomal abnormalities (e.g., trisomy 8) having been catalogued.[66] In 2001, Schaller and Burkland described a male patient with HES who was resistant or intolerant to prior therapies including corticosteroids, hydroxyurea, and interferon-alpha (IFN-α).[67] The patient was treated with imatinib at least partly based on the rationale that the myeloproliferative features of HES could share a similar pathobiology to CML. After several days of imatinib therapy of 100 mg daily, the patient achieved a rapid and complete hematologic remission with resolution of peripheral blood eosinophilia just after 1 month of treatment. Shortly thereafter, a few case series established that imatinib at doses ranging from 100 to 400 mg daily could elicit rapid and complete hematologic responses in patients with heavily pretreated refractory/relapsed HES or CEL.[67,68] In the landmark report published in 2003, the fusion tyrosine kinase FIP1L1–PDGFRα was ultimately identified as the therapeutic target of imatinib in responsive patients.[22] At the same time, the

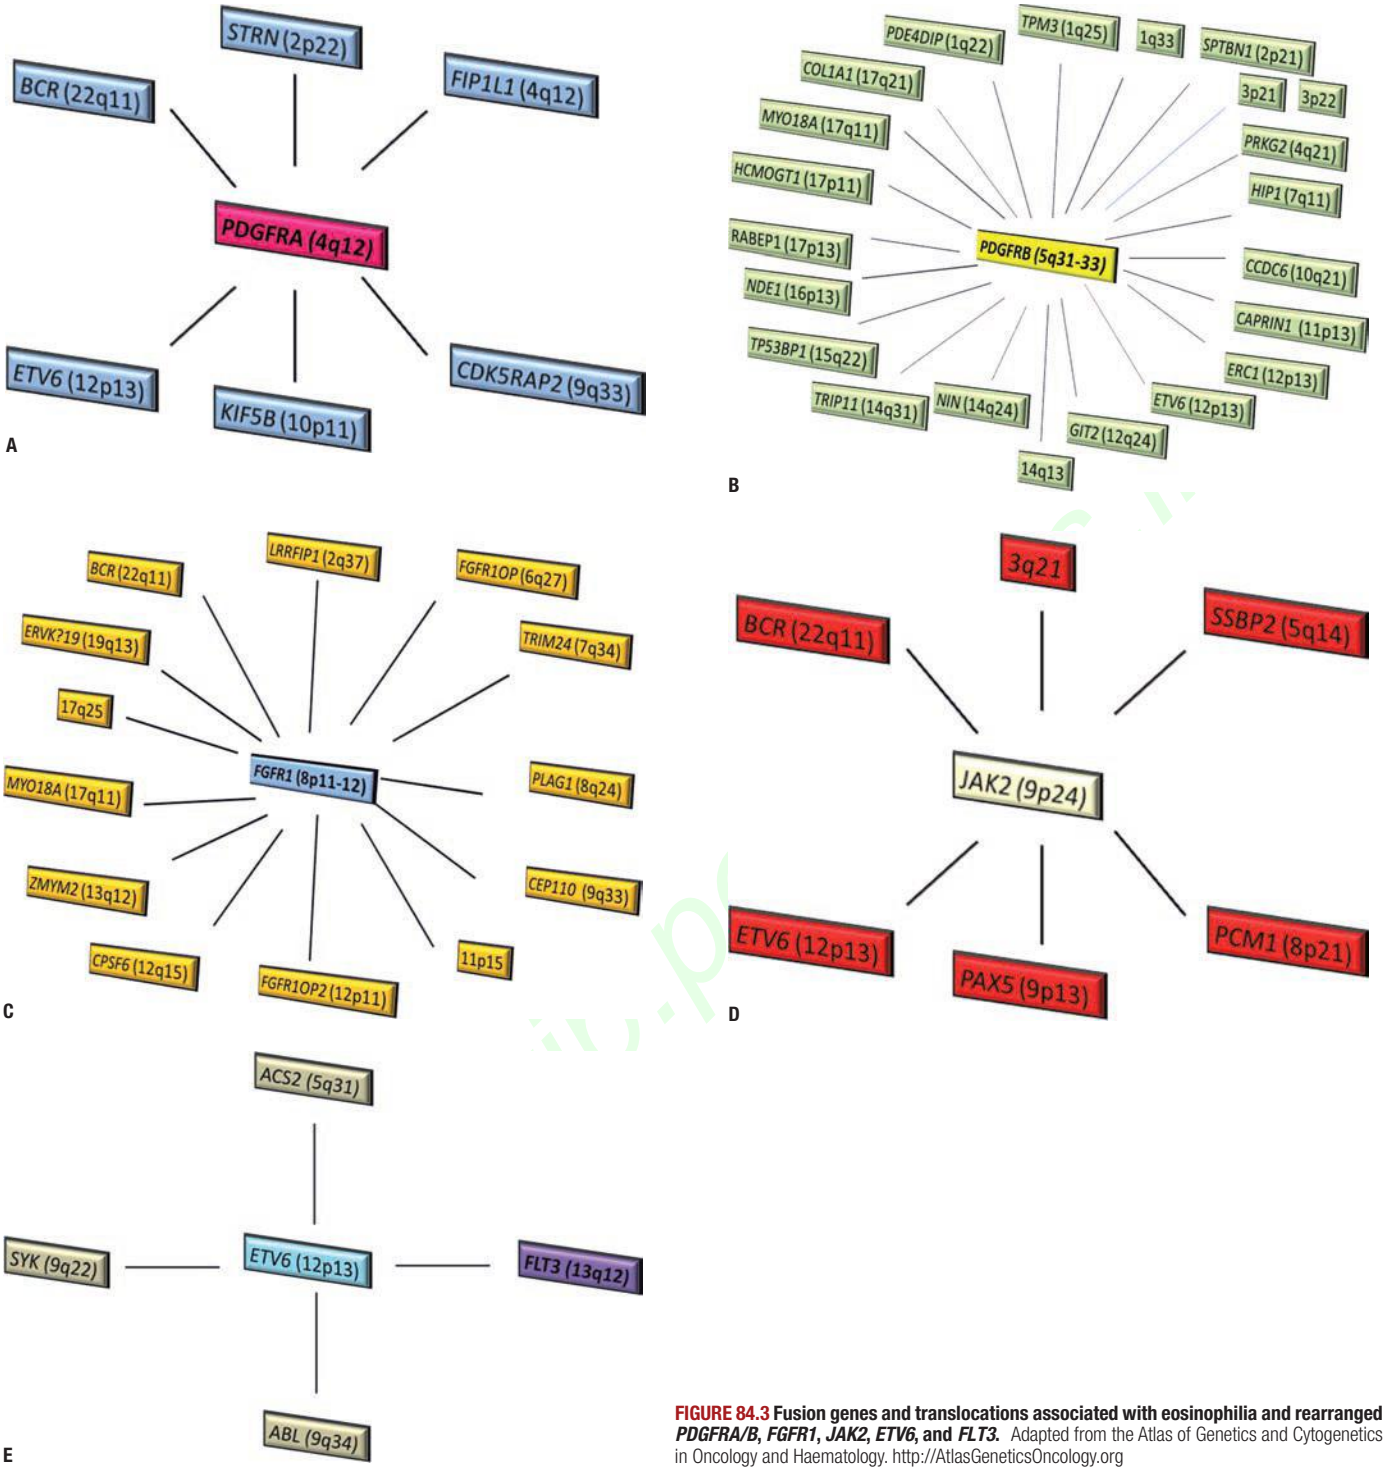

FIGURE 84.3 Fusion genes and translocations associated with eosinophilia and rearranged *PDGFRA/B*, *FGFR1*, *JAK2*, *ETV6*, and *FLT3*. Adapted from the Atlas of Genetics and Cytogenetics in Oncology and Haematology. http://AtlasGeneticsOncology.org

FIP1L1–PDGFRα fusion was discovered in the imatinib-sensitive EOL-1 cell line by another group of investigators.[69]

Similar to the experience with CML, imatinib has transformed the prognosis of patients with the *FIP1L1–PDGFRA* abnormality. In addition to rapid hematologic remissions, molecular remissions can be achieved in the majority of patients with doses in the range of 100 to 300–400 mg daily.[22,67,68] Although maintenance doses of 100 to 200 mg weekly may preserve ongoing molecular remissions in some patients, the optimal dose for maintaining response has not been defined.[70] Because of its good tolerability and safety profile, ongoing therapy with a starting dose of 100 to 400 mg is commonly utilized.

The long-term experience with imatinib-treated *FIP1L1–PDGFRA*-positive myeloid neoplasms is very favorable. In an Italian prospective study of 27 patients followed for a median period of 25 months (range 15 to 60 months), patients were initially dosed at 100 mg daily and increased to 400 mg daily.[71] Complete hematologic remission was achieved in all patients within 1 month, and all patients became PCR-negative for *FIP1L1–PDGFRA* after a median of 3 months (range 1 to

TABLE 84.5

ORGAN MANIFESTATIONS OF EOSINOPHILIC NEOPLASMS/HYPEREOSINOPHILIC SYNDROMES

Organ System	Cumulative Frequency from Three Studies (%)[a]	Examples of Organ-Specific Manifestations
Hematologic	100	Leukocytosis with eosinophilia; neutrophilia, basophilia, myeloid immaturity, immature and/or dysplastic eosinophils; anemia, thrombocytopenia or thrombocytosis, increased marrow blasts, myelofibrosis.
Cardiovascular	58	Cardiomyopathy, congestive heart failure, constrictive pericarditis, myocarditis, mural thrombi, valvular dysfunction, endomyocardial fibrosis, myocardial infarction, pericardial effusion, deep venous thrombosis, superficial thrombophlebitis
Dermatologic	56	Angioedema, urticaria, papules/nodules, dermatitis, plaques, (aquagenic) pruritus, erythroderma, mucosal ulcers, vesicobullous lesions, microthrombi, vasculitis, Wells syndrome
Neurologic	54	Thromboembolic stroke, peripheral neuropathy, encephalopathy, dementia, epilepsy, cerebellar disease, eosinophilic meningitis, vertigo, paresthesia, change in mentation, aphasia, visual disturbances
Pulmonary	49	Pulmonary infiltrates, effusions, fibrosis, emboli, nodules/focal ground glass attenuation, acute respiratory distress syndrome, asthma, sinusitis, rhinitis, cough, dyspnea, recurrent upper respiratory tract infection
Spleen	43	Splenomegaly, hypersplenism, infarct
Liver/gallbladder	30	Hepatomegaly, focal or diffuse hepatic lesions on imaging, chronic active hepatitis, hepatic necrosis, Budd-Chiari syndrome, sclerosing cholangitis, cholecystitis, cholestasis
Ocular	23	Microthrombi, choroidal infarcts, retinal arteritis, episcleritis, keratoconjunctivitis sicca, Adie syndrome (pupillotonia)

10 months). Patients continuing imatinib remained PCR-negative during a median follow-up period of 19 months (range 6 to 56+ months). Another European study prospectively assessed the natural history of molecular responses to imatinib doses of 100 to 400 mg daily.[72] Among 11 patients with high pretreatment transcript levels, all achieved a 3-log reduction in transcript levels by 1 year of therapy, and 9 of 11 patients achieved a molecular remission.

Despite in-depth and durable molecular remissions, discontinuation of imatinib usually leads to disease relapse. In a dose de-escalation trial of imatinib in five patients who had achieved a stable hematologic and molecular remission at 300 to 400 mg daily for at least 1 year, molecular relapse was observed in all patients after 2 to 5 months of either imatinib dose reduction or discontinuation.[73] Molecular remissions were reestablished with reinitiation of imatinib in all patients at a dose range of 100 to 400 mg daily. In a cohort of patients evaluated by the Mayo Clinic, hematologic relapse occurred only several weeks after discontinuation of imatinib in four patients.[74] These data indicate that imatinib does not cure *FIP1L1–PDGFRA*-positive disease and argue for ongoing imatinib therapy to suppress the abnormal clone.

As with CML, *FIP1L1–PDGFRA*-positive patients can develop resistance to imatinib, mostly involving the T674I mutation within the ATP-binding domain of PDGFRA.[22,75,76,77] T674I *PDGFRA* is analogous to the T315I *ABL1* mutation in CML, which confers panresistance to the tyrosine kinase inhibitors imatinib, dasatinib, and nilotinib. However, unlike CML, this secondary resistance is much less common (less than 10 cases in the literature) and is almost exclusively observed during advanced phases of the disease. In one study, it was found that the PDGFRα kinase domain contains a limited number of residues where exchanges critically interfere with the binding of—and inhibition by—available PDGFR kinase inhibitors.[78] This may be one explanation for the low frequency of imatinib resistance in these patients.

Options for second-line treatment for T6741I imatinib resistance are limited. One patient with the *FIP1L1–PDGFRA* T674I mutation in blast crisis responded briefly to sorafenib, but this was followed by rapid emergence of a panresistant *FIP1L1–PDGFRA* D842V mutant.[77] Other reports have demonstrated either in vitro or in vivo activity of sorafenib, midostaurin (PKC412), or nilotinib against the T674I mutant.[37,79,80,81] The ability of alternative tyrosine kinase inhibitors to elicit durable clinical remissions (despite in vitro data demonstrating inhibitory activity against mutated fusions) has been disappointing.[82] To date, the only report of primary resistance to imatinib in chronic phase *FIP1L1–PDGFRA*-positive disease has been attributed to the identification of two novel mutations, *PDGFRA* S601P and L629P.[83]

In patients with rearrangements of *PDGFRB* or *PDGFRA* variants other than *FIP1L1–PDGFRA*, case reports and series indicate that imatinib, usually at doses of 400 mg daily, can elicit durable hematologic and cytogenetic remissions.[84] FISH and conventional karyotyping can gauge cytogenetic responses to imatinib in *PDGFRB*-rearranged cases.

Though well-tolerated, with a safety profile similar to imatinib used in CML, several cases have been reported in which *FIP1L1–PDGFRA*-positive patients treated with imatinib experienced cardiogenic shock.[85,86] It is therefore recommended that for patients with known cardiac disease or elevated troponin levels (possibly related to eosinophil-mediated damage of cardiac tissue), prophylactic steroids should be given for 7 to 10 days at the time of imatinib initiation.

The poor-prognosis *FGFR1*-rearranged neoplasms remain a therapeutic challenge. Patients with these stem cell neoplasms

exhibit an aggressive course usually terminating in AML in 1 to 2 years.[16] Intensive chemotherapy with AML-type inductions or ALL-based regimens such as hyper-cyclophosphamide, vincristine, doxorubicin, and dexamethasone, followed by early allogeneic stem cell transplantation is recommended for patients with *FGFR-1*–rearranged disease. The data for small molecule inhibitors targeting constitutively activated FGFR1 is thus far limited, but several agents are in development. In one report, midostaurin (PKC412) inhibited the dysregulated *ZNF198-FGFR1* fusion in vitro, and elicited a hematologic and cytogenetic response in a patient with this molecular abnormality.[87] For patients with *JAK2* or *FLT3* rearrangements, there may be a role for small molecule inhibitors of FLT3[88] and JAK2, but their use remains investigational.

Treatment of Patients with Hypereosinophilic Syndrome and Chronic Eosinophilic Leukemia, Not Otherwise Specified

Corticosteroids (e.g., prednisone 1 mg/kg) are recommended as first-line treatment for HES. Steroids have potent antieosinophil activity and can produce rapid reductions in eosinophil count. In a retrospective analysis of 188 patients,[57] 141 HES patients on corticosteroids as first-line monotherapy achieved a complete remission (CR) or partial remission (PR) after 1 month, with duration of therapy ranging from 2 to 20 years and a median maintenance dose of 10 mg/day.[57] As symptoms improve and eosinophil counts normalize, a steroid taper can be instituted, particularly given the long-term treatment side effects of steroids.

Hydroxyurea at 500 to 1,000 mg daily is also an effective first-line option for HES, with the understanding that, like corticosteroids, hydroxyurea is palliative and does not change the natural course of the disease. Hydroxyurea can be used as monotherapy or in combination with corticosteroids. In the same retrospective study, 64 HES patients (34%) received hydroxyurea monotherapy, with 13 (72%) achieving CR or PR.[57] One should note that for CEL-NOS and steroid-refractory idiopathic HES, hydroxyurea has been used as a first-line treatment.

IFN-α has been used effectively to induce hematologic and cytogenetic remissions in patients with HES and CEL-NOS who are either refractory to steroids or hydroxyurea, or administered in addition to corticosteroids as a steroid-sparing agent.[89,90,91–94,95] Of the 188 patients in a retrospective study, 46 were treated with IFN-α in combination with steroids, with response rates ranging from 50% to 75%, respectively.[57] IFN-α remissions have been associated with improvement in clinical symptoms as well as occasional improvement or reversion of end-organ injury, including hepatosplenomegaly and cardiac and thromboembolic complications.[89,90,91–94,95] The optimal starting or maintenance dose of IFN-α has not been well defined, but the initial dose required to control eosinophil counts often exceeds the doses required to sustain a remission. Initiation of therapy at 1 million units by subcutaneous injection three times weekly (tiw) and gradual escalation of the dose to 3 to 4 million units tiw or higher may be required to control the eosinophil count. Treatment of four HES patients with PEG-IFN-α-2b among a larger cohort of *BCR-ABL1*-negative MPN patients resulted in one complete and one partial response, but side effects required that the initial study dose be reduced from 3 to 2 μg/kg/week.[96] A lower starting dose of 90 μg/kg weekly (e.g., 1 to 1.5 μg/kg weekly) is better tolerated based on the experience of PEG-IFN-α-2a (Pegasys) in the MPNs polycythemia vera and essential thrombocythemia.[97,98] Side effects of short- and longer-acting formulations of IFN-α are usually dose-dependent and can include fatigue and flu-like symptoms, transaminitis, cytopenias, depression, hypothyroidism, and peripheral neuropathy. IFN-α is considered safe for use in pregnancy.

Second- and third-line agents for the treatment of HES have included vincristine, cyclophosphamide, etoposide, 2-chlorodeoxyadenosine alone or in combination with cytarabine, and cyclosporin-A.[99,100,101,102,103,104,105,106–108] Imatinib has been used empirically in *PDGFRA/B*-rearrangement-negative patients (e.g., with HES or CEL-NOS). At doses of 400 mg or higher,[109] partial hematologic responses are sometimes observed, but are more often transient and may reflect drug-related myelosuppression.

Similar to HES, patients with lymphocyte-variant HE are initially treated with corticosteroids. Refractory or relapsed disease may be considered for treatment with IFN-α or steroid-sparing immunosuppressive agents. Hydroxyurea and imatinib are less likely to demonstrate efficacy in this form of HE. Elevated serum IgE and thymus and activation-regulated chemokine levels have been associated with responsiveness to steroids.[57]

Antibody Approaches

Other treatment options for HES have included the anti-CD52 monoclonal antibody, alemtuzumab, based on the expression of the CD52 antigen on eosinophils. In patients with HES who were refractory to other therapies, infusion of alemtuzumab one to three times weekly produced a hematologic remission in 10 of 11 patients (91%), but responses were not sustained when alemtuzumab was discontinued.[110] Other antibody treatment approaches to HES include the use of mepolizumab, an anti-IL-5, humanized monoclonal antibody that inhibits binding of IL-5 to the alpha chain of the IL5R found on eosinophils.[111] Mepolizumab has been evaluated in a large, randomized, double-blinded, placebo-controlled trial of 85 HES patients (e.g., *FIP1L1–PDGFRA*-negative patients).[112] Patients were randomized to intravenous mepolizumab 750 mg or placebo every 4 weeks for 36 weeks. No adverse events were significantly more frequent with mepolizumab compared to placebo. A significantly higher proportion of mepolizumab-treated HES patients versus placebo were able to achieve the primary efficacy endpoint of a daily prednisone dose of $<$10 mg daily for at least 8 consecutive weeks. Therefore, mepolizumab has a potential role as a steroid-sparing agent for these patients. Mepolizumab has not yet been approved by the FDA, but is currently available on a compassionate use basis (ClinicalTrials.gov Identifier NCT00244686) for individuals with life-threatening HES who have failed prior therapies.

Allogeneic stem cell transplant has been attempted for patients with aggressive disease with anecdotal benefit. Disease-free survival ranging from 8 months to 5 years has been reported,[113,114,115,116,117] with one patient relapsing at 40 months.[118] Allogeneic transplantation using nonmyeloablative conditioning regimens have been reported in three patients, with remission duration of 3 to 12 months at the time of reported follow-up.[119,120] In one patient who underwent an allogeneic stem cell transplantation from an HLA-matched sibling, the patient was disease free at 3 years and there was no evidence of the *FIP1L1–PDGFRA* fusion which was present at diagnosis.[121] Despite success in selected cases, the role of transplantation in HES is not well established.

Although less commonly used today, cardiac surgery has extended the life of patients with late-stage cardiac disease manifested by endomyocardial fibrosis, mural thrombosis, and valvular insufficiency.[56,60] Mitral and/or tricuspid valve repair or replacement[61,122,123,124,125] and endomyocardectomy for late-stage fibrotic heart disease[61,126] can improve cardiac function. Bioprosthetic devices are preferred over their mechanical counterparts because of the reduced frequency of valve thrombosis. Anticoagulants and antiplatelet agents have shown variable success in preventing recurrent thromboembolism.[127,128,129]

SUMMARY

Recognition of molecularly defined eosinophilias, whose pathobiology is linked to dysregulated tyrosine kinases, has transformed the classification and treatment of these diseases. The sensitivity

of *PDGFRA/B*-rearranged eosinophilic neoplasms to imatinib has reversed the course of these historically poor-prognosis diseases. In addition to small molecule inhibitors, antibody approaches (e.g., mepolizumab, alemtuzumab) and pegylated IFN offer therapeutic options beyond corticosteroids and cytotoxic chemotherapy. Despite these advances, the pathogenesis of HES, CEL-NOS, and lymphocyte-variant HE remains obscure. Translational research approaches which incorporate next generation sequencing technologies and functional assays to interrogate eosinophil biology (e.g., phospho-specific flow cytometry) should help facilitate the identification of therapeutic targets in these conditions.

CHAPTER 85

SYSTEMIC MASTOCYTOSIS

Dean D. Metcalfe

HISTORICAL BACKGROUND

Mastocytosis is a heterogeneous disease characterized by the abnormal growth and accumulation of mast cells in one or more organs. The first case of mastocytosis was reported in 1869 by Nettleship and Tay under the heading of "rare forms of urticaria." Cutaneous lesions were described as "brown cutaneous lesions that wheal after scratching"[1] and were termed *urticaria pigmentosa* (UP) 1 year after this initial description.[2] The association between mast cells and mastocytosis was made in 1887, when Unna found that UP lesions were characterized by an increased number of mast cells in the dermis.[3]

Subsequent appreciation of the full clinical spectrum of these disorders has identified variants of mastocytosis that involve mast cell infiltration of visceral organs, and these forms of disease have collectively been termed *systemic mastocytosis* (SM).[4] It is now accepted that SM may present with or without skin lesions and may show an indolent or aggressive clinical course, in some cases complicated by concomitant emergence of a clonal non–mast cell lineage disorder, such as one of the myeloproliferative disorders or myelodysplastic syndromes. This has led to further classification of mastocytosis based on hematologic findings, molecular markers, and serum levels of biomarkers like tryptase and the cluster designation (CD) markers such as CD25, thereby grouping patients into better-defined clinical categories, which have been adopted by the World Health Organization (WHO).[5]

PATHOPHYSIOLOGY

The current understanding of the etiology of mastocytosis has evolved from concentrated research efforts in the 1990s that linked two key factors controlling mast cell growth and activity—stem cell factor (SCF) and the SCF receptor, KIT, and disruption of the normal function of KIT through activating mutations.[6]

Mastocytosis is thus recognized in the majority of cases to represent a clonal disorder of a pluripotent hematopoietic progenitor cell with the most common mutation consisting of an activating mutation at codon 816 in *KIT*.[6–9] This precursor is believed to be more primitive than precursors committed to either the neutrophil/macrophage or erythroid cell lineages, with the affected clone showing variable expansion in these lineages in the peripheral blood of patients with SM.[10] Thus, mastocytosis in such cases represents a somatic cell disorder that is confined to hematopoietic lineages. Although T and B cells of such mastocytosis patients carry a codon 816 mutation (such as D816V), unlike mast cells, these cells do not express surface KIT when mature, and thus may be less susceptible to the biologic effects of constitutively activated KIT.

Early research efforts in the area of mast cell biology concentrated on identifying the key biochemical pathways and mediators that accounted for the clinical sequelae seen in physiologic processes due to mast cell activation, including anaphylaxis and allergic diseases. Subsequent work by Kitamura et al.[11,12] focused on murine models of mast cell deficiency via studies on mice that exhibited abnormal *Kit* (W/W^v mice)[11] and laid the foundation for suggesting the pathophysiologic basis of human mastocytosis as compromising dysfunction at the c-kit-SCF axis.[12] Two predominant hypotheses thus emerged regarding the etiology of mastocytosis: (a) mastocytosis as a result of local overproduction of soluble SCF and (b) mastocytosis as a result of mutations in *KIT* and downstream signaling molecules that lead to cell proliferation. Over time, with the lack of evidence of overproduction of SCF in tissues[13] and with the identification of the D816V mutation in *KIT* in patients with mastocytosis,[6] the second hypothesis rose to prominence.

Human mast cells normally reside in tissues associated with epithelial surfaces, blood vessels, nerves, and glands, and are derived from $CD34^+$ pluripotential progenitor cells.[14,15] Except for a population of mast cells that reside in the bone marrow, mast cells complete maturation in peripheral tissues. During this maturation, mast cells downregulate CD34, but continue to express cell-surface CD117.[14,15,16] Under normal physiologic conditions, mast cells and mast cell progenitors do not or only minimally express CD2, CD25, or CD35 on their cell surface. This expression pattern, however, is altered in most patients with mastocytosis.[17]

The *KIT* mutation D816V or another similar activating mutation in *KIT* is found in the majority of adults with SM. However, this single mutation cannot alone explain the multiple variants of mastocytosis. In one hypothesis, c-kit D816V would play an important and possibly causative role in indolent mastocytosis, where the pathologic hallmark is mast cell differentiation and clustering without signs of substantial proliferation. More advanced cases of mastocytosis would then require additional genetic defects not specific to mastocytosis; for example, a mutation in *TET2* or *NRAS*[18] that would contribute to the excessive proliferation of mast cell progenitors.

Human mast cells are heterogeneous in terms of morphologic, biochemical, and functional characteristics. These differences correlate with differences in their anatomic locations and, when perturbed in function, associate with specific clinical signs and symptoms. Clinical sequelae of mastocytosis are thus not only the result of organ infiltration, but also the result of mast cell mediator release from spontaneous or induced mechanisms.

Mast cells are deemed to be long-lived cells, though it appears that at least some mast cells may proliferate locally in tissues in response to inflammatory or repair processes. In tissue sections, mast cells typically appear as either round or elongated cells, usually with a nonsegmented nucleus with moderate condensation of nuclear chromatin, and contain prominent cytoplasmic granules and lipid bodies. The cytoplasmic granules of mast cells contain heparin and chondroitin sulfate proteoglycans covalently linked to a protein core. Under appropriate conditions, the proteoglycan complexes stain metachromatically with basic dyes.

Human mast cells are characterized primarily as either mucosal or connective tissue mast cells, the former being located at mucosal locations, such as the lamina propria of the gastrointestinal (GI) tract, and containing a specific tryptase (thus a "T-type" mast cell). The latter are more commonly found near the epithelial surface of the skin and respiratory, GI, and genitourinary tracts and containing both tryptase and a chymotryptase (CT mast cells).[19] Human mast cell granules also contain such biologically active molecules as tumor necrosis factor-α, histamine, acid hydrolases, cathepsin G, and carboxypeptidase.[20] They are activated by a number of stimuli that are both FcεRI dependent and FcεRI independent. After activation, mast cells immediately release granule-associated mediators and generate lipid-derived substances that induce immediate allergic responses. Together, these mediators are deemed responsible for many of the clinical sequelae of the immediate hypersensitivity reaction, including pruritus, flushing, palpitations, and lightheadedness, also commonly reported in patients with mastocytosis.

Major lipid mediators produced on appropriate activation via immunoglobulin E (IgE) or non-IgE stimuli include prostaglandin D_2 and leukotriene C_4.[31] Mast cell activation is followed hours later by the synthesis and release of additional chemokines and cytokines, which then contribute to chronic inflammation. Growth factors and cytokines reported to be synthesized and released from mast cells include basic fibroblast growth factor, nerve growth factor, tumor necrosis factor, granulocyte–macrophage colony-stimulating factor, vascular endothelial growth factor, interleukin-1 (IL-1), IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-9, IL-10, IL-13, and IL-16.[19,21]

Studies performed in rodents, nonhuman primates, and humans have shown that many aspects of mast cell development are critically regulated by SCF, produced by such cells as endothelial cells, fibroblasts, and mast cells.[19,21,22] SCF has been shown to work in concert with other growth factors, such as IL-3, IL-4, IL-5, IL-6, IL-9, and nerve growth factor, to induce optimal mast cell precursor proliferation and survival.[14,15,20] SCF has also been reported to be present in the lesional skin of patients with UP[23] but was not identified in blister fluids[13] and has been reported within neoplastic mast cells.[24] SCF augments mast cell mediator release in response to stimulation by IgE and antigen.[22] Cells bearing mutated KIT on their surface have been shown to have an increased chemotactic response toward SCF.[25] SCF may influence the aggregation of mast cells leading to mast cell lesions as found in SM within marrow.

The binding of SCF to KIT induces dimerization, with activation of intrinsic tyrosine kinase activity and phosphorylation of the receptor. This in turn leads to exposure of specific recognition motifs for intracellular binding proteins containing Src homology (SH2) domains such as phospholipase Cγ-1, phosphatidylinositol-3′ kinase, mitogen-activated kinase, and Ras protein.[20,26] Activating or gain-of-function mutations in *KIT* are associated with constitutive tyrosine kinase activation and ligand-independent autophosphorylation of KIT, thereby giving affected mast cells a survival advantage over wild-type cells.[20,27,28,29]

The D816V mutation was first reported in patients with mastocytosis in the peripheral blood mononuclear cells (PBMCs) of adult patients with mastocytosis with an associated hematologic disorder and in patients with persistent mastocytosis and extensive disease,[6,7,29] but codon 816 mutations (D816Y and D816H) have been shown to be present in UP lesions of adults and in a subset of pediatric patients with more severe mastocytosis.[6,7,30] An E839K mutation has been reported in skin lesions of some pediatric patients with mastocytosis.[31] Exceedingly rare *KIT* mutations, which are reported to be present in less than 1% of patients with mastocytosis, include R815K, D820G, V533D, V559A, del419, K509I, and A533D.[32,33] KIT-dependent downstream signaling events including the JAK-STAT pathway may magnify the consequences of mutations in KIT.[32] In addition to D817V, the V560G mutation within the juxtamembrane domain of KIT was detected in the human mast cell leukemia (MCL) cell line HMC-1,[34] the E839K-dominant inactivating mutation in several reported cases of pediatric mastocytosis, and the rare germline mutation F522C.[27,35] Thus far, somewhat different mutation patterns appear to be emerging for adult- versus pediatric-onset mastocytosis, which may explain the differences in presentation and clinical course for these two different patient populations.

Irrespective of effects on KIT, inhibition of mast cell apoptosis through other biologic pathways may also contribute to the pathogenesis of mastocytosis. A subset of SM patients with associated eosinophilia and increased serum tryptase levels has been described; these patients carry the Fip1-like-1–platelet-derived growth factor receptor-α (*FIP1L1-PDGFRA*) fusion oncogene in pluripotent hematopoietic progenitor cells, which results from an approximately 800-kb interstitial deletion of chromosome 4q12.[36] Similarly, a rare case of SM and chronic basophilic leukemia was found secondary to a *PRKG2-PDGFRB* fusion.[37] A polymorphism in the gene for the IL-4 receptor α-chain has been shown to be associated with less extensive mast cell involvement, with disease usually localized to the skin.[38] In addition, the bone marrow cells of patients with mastocytosis have been found to constitutively express the antiapoptotic proteins Bcl-XL and Bcl-2,[39] which may explain the long survival of these cells and perhaps their resistance to chemotherapy-induced apoptosis.

Additional studies using gene expression analysis of bone marrow mononuclear cells derived from patients with indolent SM revealed that, compared with healthy controls, patients with mastocytosis displayed a highly consistent profile with 168 genes that were significantly up- or downregulated in patient samples.[40] Further analysis using such microarray technology will be useful to identify candidate genes distinguishing patient groups showing divergent clinical behavior.

Consistent with the progressive genetic instability that is often described in other human tumors, increased chromosomal abnormalities unrelated to the *KIT* locus have been detected in patients with more malignant forms of mastocytosis, and new abnormalities may appear in a subset of such patients on disease progression.[41] No recurrent patterns of chromosomal changes have been consistently reported in patients with SM. The implications of these findings are that, at least in some patients with mastocytosis, the etiology of their disease may encompass a broader chromosomal problem of genetic instability. For instance, tumor mast cell lines express persistently high telomerase activity throughout the cell cycle which does not appear to be dependent on intracellular signals or cell replication, in contrast to normal human progenitor mast cells that experience transient induction of telomerase activity that is dependent on growth factor-mediated signals such as SCF-, IL-3-, and IL-6–mediated p38 mitogen-activated kinase and phosphatidylinositol-3' kinase.[42]

CLINICAL FEATURES

The clinical manifestations of mastocytosis are diverse and may be divided into those that are systemic or localized.[20,31,33] Systemic effects of this disorder result from the release of significant amounts of mast cell mediators into the circulation. Clinical signs and symptoms that comprise systemic mediator release are those reported with anaphylaxis and include flushing, pruritus, hypotension, syncope, palpitations, and tachycardia. GI symptoms are commonly associated with mastocytosis and include nausea, vomiting, abdominal cramping, bloating, and/or diarrhea. Peptic ulcer disease, which appears to reflect at least partially increased gastric acid secretion due to hyperhistaminemia, may occur in up to 50% of patients with systemic disease.[43] Malabsorption, though less common, tends to be mild and may occur in those with progressive disease. Local sequelae of mastocytosis are largely due to the effects of mast cell collections at specific organ sites and may result in severe end-organ dysfunction due to infiltration of normal tissue with mast cells and subsequent fibrosis (e.g., end-stage liver disease due to fibrosis and bone marrow failure).

For some patients, in particular those with advanced disease or with an associated hematologic disorder, the most bothersome complaints include severe and nonspecific constitutional symptoms of fatigue, weakness, anorexia, weight loss, low-grade fevers, night sweats, musculoskeletal pain, headaches, depression, altered attention span, irritability, and even subtle cognitive deficits such as mild memory loss. Some of these symptoms are attributable to ongoing chronic disease, whereas others may in part be a result of the central nervous system effects of mast cell mediators.

Attacks in some individuals are precipitated by stimuli such as heat, cold, pressure, alcohol, medications (e.g., opiates, nonsteroidal antiinflammatory agents, and estrogens), radiocontrast agents, and venoms. Reactions may be more severe in such patients (e.g., anaphylaxis after hymenoptera stings) because of an expanded mast cell population.[21,44] Patients with aggressive disease also often present with lymphadenopathy, splenomegaly,

or hepatomegaly that may or may not be symptomatic. One of the most difficult clinical scenarios of mastocytosis from a management perspective is the treatment of severe musculoskeletal pain and/or pathologic fractures due to the osteoporosis that results from release of mast cell mediators and/or an expanding marrow compartment with active proliferation of mast cells. Besides local disruption of normal bone architecture, mast cell infiltration of bone may cause bone loss due to the secretion of heparin, IL-6, proteases, and mediators, and from their paracrine effects on osteoclast function.

The most frequently involved organs in SM are the skin, bone marrow, lymph nodes, spleen, liver, and GI tract. The lungs are usually spared in mastocytosis. Atopy (e.g., eczema, allergic rhinitis) and airway hyperreactivity (e.g., asthma) are not generally features of this disease.

Mastocytosis is one of eight subcategories of myeloproliferative neoplasms in the 2008 WHO classification of tumors of hematopoietic and lymphoid tissues.[5] The criteria for the diagnosis of cutaneous and SM adopted by the WHO are provided in Table 85.1. The diagnosis of SM requires that one major and one minor criterion or three minor criteria be present. WHO Criteria for variants of SM are provided in Table 85.2.

The prognosis of patients with adult mastocytosis is dependent on the extent of disease and presence of an associated hematologic disorder. Patients with ISM tend to remain within this category of disease, although a subset will progress to more aggressive forms of disease such as SM-AHNMD (associated non–mast cell lineage clonal hematologic disorder with systemic mastocytosis). For children with isolated UP, at least 50% of cases are reported to resolve by adulthood.[45] Patients with SM-AHNMD have a course

TABLE 85.1

WORLD HEALTH ORGANIZATION DIAGNOSTIC CRITERIA FOR CUTANEOUS AND SYSTEMIC MASTOCYTOSIS

Cutaneous mastocytosis (CM)

Typical clinical findings of urticaria pigmentosa (UP)/maculopapular cutaneous mastocytosis (MPCM), diffuse cutaneous mastocytosis (DCM), or solitary mastocytoma, and typical infiltrates of mast cells in a multifocal or diffuse pattern on skin biopsy.

Systemic mastocytosis (SM)

The diagnosis of SM is made if one major and one minor criterion are present, or if three minor criteria are met.

Major criterion

Multifocal, dense infiltrates of mast cells (15 or more in aggregates) detected in sections of bone marrow and/or another extracutaneous organ, and confirmed by tryptase immunohistochemistry or other special stains.

Minor criteria

a. In biopsy sections of bone marrow or other extracutaneous organs, more than 25% of the mast cells in the infiltrate are spindle-shaped or have atypical morphology, or, of all mast cells in bone marrow aspirate smears, more than 25% are immature or atypical mast cells.

b. Detection of an activating point mutation at codon 816 of *KIT* in bone marrow, blood, or another extracutaneous organ.

c. Mast cells in bone marrow, blood, or another extracutaneous organ express CD117 with CD2 and/or CD25.

d. Serum total tryptase persistently greater than 20 ng/ml in the absence of an associated clonal myeloid disorder.

WHO, World Health Organization.

TABLE 85.2

WORLD HEALTH ORGANIZATION CRITERIA FOR VARIANTS OF SYSTEMIC MASTOCYTOSIS

Indolent systemic mastocytosis (ISM)

Meets criteria for SM (see Table 88.1). No "C" findings (see below). No evidence of an associated non–mast cell lineage clonal hematologic disorder (AHNMD). In this variant, the mast cell burden is low and skin lesions are usually present.

- Bone marrow mastocytosis

As above for ISM with bone marrow involvement, but no skin lesions.

- Smoldering systemic mastocytosis

As above for ISM, but with two or more "B" findings and no "C" findings.

Systemic mastocytosis with associated clonal, hematologic non–mast cell lineage disease (SM-AHNMD)

Meets criteria for SM and criteria for an associated, clonal hematologic non–mast cell lineage disorder, AHNMD (MDS, MPN, AML, lymphoma, or other hematologic neoplasm that meets the criteria for a distinct entity in the WHO classification).

Aggressive systemic mastocytosis (ASM)

Meets criteria for SM with one or more "C" findings. No evidence of mast cell leukemia. Usually without skin lesions.

- Lymphadenopathic mastocytosis with eosinophilia

Progressive lymphadenopathy with peripheral blood eosinophilia, often with extensive bone involvement, and hepatosplenomegaly, but usually without skin lesions. Cases with rearrangement of PDGFRA are excluded.

Mast cell leukemia (MCL)

Meets criteria for SM. Bone marrow biopsy shows a diffuse infiltration by atypical, immature mast cells. Bone marrow aspirate smears show 20% or more mast cells. Mast cells account for 10% or more of peripheral white blood cells. Variant: leukemic mast cell leukemia as above, but less than 10% of white blood cells are mast cells. Usually without skin lesions.

Mast cell sarcoma (MCS)

Unifocal mast cell tumor. No evidence of SM. Destructive growth pattern. High-grade cytology.

Extracutaneous mastocytoma

Unifocal mast cell tumor. No evidence of SM. No skin lesions. Non-destructive growth pattern. Low-grade cytology

"B" findings

1. Bone marrow biopsy showing greater than 30% infiltration by mast cells (focal, dense aggregates) and/or serum total tryptase level greater than 200 ng/ml.
2. Signs of dysplasia or myeloproliferation in non–mast cell lineages, but insufficient criteria for definitive diagnosis of a hematopoietic neoplasm with normal or slightly abnormal blood counts.
3. Hepatomegaly without impairment of liver function, and/or palpable splenomegaly without hypersplenism, and/or lymphadenopathy.

"C" findings

1. Bone marrow dysfunction manifested by one or more cytopenia (ANC $<1.0 \times 10^9$/L, Hb <10 g/dl, or platelets $<100 \times 10^9$/L), but no obvious non–mast cell hematopoietic malignancy.
2. Palpable hepatomegaly with impairment of liver function, ascites, and/or portal hypertension.
3. Skeletal involvement with large osteolytic lesions and/or pathologic fractures.
4. Palpable splenomegaly with hypersplenism.
5. Malabsorption with weight loss due to GI mast cell infiltrates.

[a]WHO, World Health Organization.

that depends largely on the prognosis of the specific hematologic disorder and response to aggressive therapy.[20] The mean survival time for patients with MCL is usually less than 12 months, although the prognosis is improving with the use of newer tyrosine kinase inhibitors. The survival time with aggressive systemic mastocytosis (ASM) is 2 to 4 years with aggressive management. Variables strongly associated with poor survival in adult patients include advanced age, weight loss, anemia, thrombocytopenia, hypoalbuminemia, and excess bone marrow blasts.[46]

Cutaneous Mastocytosis

Cutaneous mastocytosis is composed of three distinct clinical variants: UP/maculopapular cutaneous mastocytosis, solitary mastocytoma, and diffuse-erythrodermic disease, also known as diffuse cutaneous mastocytosis (DCM) (Table 85.1). UP is further subcategorized into four subvariants: Typical UP, a plaque form, a nodular form, and telangiectasia macularis eruptiva perstans (TMEP).[5]

The classic lesions of cutaneous mast cell disease are UP, which consist of reddish-brown macules, papules, or plaques that urticate (i.e., form a wheal and erythema with a distinct border when stroked [a positive Darier sign]). However, in a number of patients, cutaneous lesions are lacking, and other organs, particularly the bone marrow, when biopsied, support the diagnosis of SM.

UP lesions tend to occur in a generalized distribution, most commonly occurring over the trunk and generally sparing the face, scalp, palms, and soles. When abundant, they may form a cobblestone appearance. There appears to be no sex predilection or familial pattern of cutaneous disease, though mastocytosis of one form or another has been described in families, including several sets of twins.[45]

Histologically, UP lesions are composed of a collection of mast cells within the papillary dermis with variable extension throughout the reticular dermis and into the subcutaneous fat. An increase in dermal mast cells ≥ 10 times that of normal skin, in the absence of other pathology, is highly suggestive of UP.[45,47] Petechiae, ecchymoses, and telangiectasias may be present in or adjacent to UP lesions. Blister formation and hemorrhage may occur, particularly in infants and young children. This complication is presumed to occur due to high local levels of mediators released from mast cells, but why this younger age group is more adversely affected is unknown. After age 10 years, vesicles do not generally occur, and UP lesions tend to be smaller and more numerous. Onset of UP lesions tends to follow a biphasic curve, with one peak at 2.5 months of age and another at 26.5 years.[47] Of pediatric patients in whom UP occurs, approximately half lose these lesions by adolescence. The remaining patients generally have lighter macular lesions at previously involved sites. Pruritus is the most common symptom that accompanies UP. Approximately 15% to 30% of pediatric patients whose skin lesions persist into adulthood progress to develop SM.[48]

Although UP in adults may persist indefinitely, a subset of patients, estimated from 7% to 19% in published series, experience fading or resolution of cutaneous lesions over time.[49] Regression of UP in patients with indolent SM (ISM) appears to parallel a decrease in disease severity in terms of constitutional symptoms, although bone marrow findings of ISM remain. In contrast, disappearance of lesions in patients with an associated hematologic disorder may herald progression of disease, with more severe bone marrow pathology noted on follow-up biopsies. The absence or presence of the Asp816Val mutation in PBMCs did not predict the course of UP. Disease progression in patients with SM-AHNMD is therefore better monitored with serum tryptase levels and bone marrow biopsy findings than with changes in the number, distribution, or intensity of skin lesions.

DCM is a less frequent cutaneous manifestation and generally presents before the age of 3 years. It is characterized by a diffuse mast cell infiltration of the dermis and thus the entire skin is generally involved. DCM presents as a yellow-red-brown discoloration with a peau d'orange appearance, or as a generalized erythroderma in which severe edema gives the skin a doughy appearance. Additionally, yellow-cream–colored papules have been described that resemble xanthomas and pseudoxanthoma elasticum.[47] Only rarely does skin appear superficially normal in DCM. Dermatographism and formation of hemorrhagic blisters may occur. GI manifestations, such as diarrhea, flushing, and hypotension, may be associated, and such patients have an increased risk for more serious clinical sequelae such as shock, significant GI bleeding, and death. DCM may resolve spontaneously by age 5 to 15 months, but when persistent, the skin may remain thickened and doughy and recalcitrant to treatment.

Solitary mastocytomas are considered a variant of cutaneous mastocytosis that may present at birth or more commonly within the first 3 months of age, with spontaneous involution during childhood.[45,47] They are only rarely described in adults. They present as macules, plaques, or nodules and are formed by dermal collections of mast cells without cellular atypia. They are most commonly seen on the extremities and may involve the palms or soles. When systemic symptoms are present, they most commonly involve flushing.

TMEP is a rare form of cutaneous mastocytosis (<1% of cases) that is thought to usually be limited to the skin and only reported in adults. Select cases with concomitant splenomegaly, increased mast cells in the bone marrow, and abnormal skeletal radiographs suggest that this form of cutaneous disease may have systemic features.[47,50] The characteristic skin lesion in TMEP is a telangiectatic, red macule on a tan-brown background. Individual lesions are 2 to 6 mm in diameter and are without sharply defined borders. Pruritus, purpura, and blister formation are not generally associated with TMEP, though lesions may become edematous when rubbed. Occasionally, these lesions are found to coexist with UP.

Indolent Systemic Mastocytosis

ISM is characterized by mast cell involvement at various organ sites, although significant organ dysfunction (C findings) is usually absent, and prognosis in these patients is generally good. In most cases, clonal mast cells express CD2 and/or CD25 surface markers and contain the D816V mutation. The bone marrow is the most common site of extracutaneous mastocytosis, with the vast majority of adult patients with indolent disease demonstrating bone marrow mast cell infiltration.[51,52,53,54] The criteria for diagnosis of ISM are provided in Table 85.2.[5]

Characteristic bone marrow lesions of SM consist of focal dense, mixed, diffuse dense, or diffuse interstitial aggregates of mast cells, with differing histopathologic patterns of mast cell infiltration of the bone marrow related to differing prognoses and subtype of mastocytosis.[6] Focal infiltrates are frequently observed in paratrabecular and perivascular areas and may be associated with adjacent lymphoid or eosinophil aggregates, or both.[55] Mast cells in these patients show characteristic cytologic abnormalities, including cytoplasmic surface projections, eccentric oval nuclei, and a hypogranulated cytoplasm (atypical mast cell type I).[5] A representative bone marrow aspirate from a patient with ISM with characteristic morphologic features compared with a control bone marrow aspirate is shown in Figure 85.1. Clonal mast cells generally express CD2 or CD25, or both, on their cell surface, and the D816V mutation.[5,17,52] The bone marrow lesions of SM may contain a mixed population of B and T cells, in addition to mast cells identified by antitryptase staining. The histopathology of these lymphoid aggregates is similar to benign lymphoid aggregates associated with reactive bone marrow and not lymphoproliferative disease, the latter being uncommon in patients with adult-onset ISM. In bone marrow extensively involved by mast cell infiltration, the bony trabeculae may be moderately to markedly thickened.

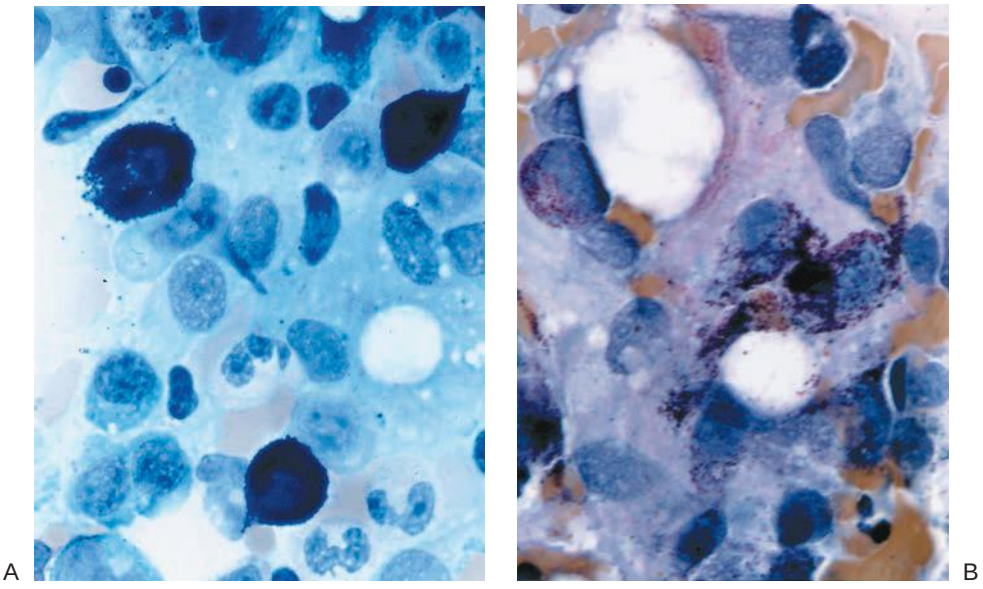

FIGURE 85.1. Morphologic features of mast cells from normal versus mastocytosis bone marrow aspirate. Panel **A** shows staining of a control bone marrow aspirate from an individual with aplastic anemia using toluidine blue stain (magnification, 40×). Panel **B** shows a hematoxylin and eosin stain of a bone marrow aspirate acquired from a patient with indolent systemic mastocytosis and illustrates representative spindle-shaped mast cells with an eccentric nucleus (magnification, 40×).

A number of hematologic abnormalities have been reported in patients with SM, including cytopenias (e.g., anemia, thrombocytopenia, leukopenia, and lymphopenia) and increased blood cell counts (e.g., leukocytosis, eosinophilia, basophilia, monocytosis, lymphocytosis, and thrombocytosis).[53] Hematologic abnormalities in children with mastocytosis are unusual, with a normochromic normocytic anemia being the most common finding.[31] Prolonged bleeding times have been reported in infants with mastocytosis due to abnormal thrombin clotting times. In published reports of rare pediatric mastocytosis patients who have developed an associated hematologic malignancy, these were most frequently acute myeloid leukemias and acute lymphoblastic leukemias.[31]

Isolated bone marrow mastocytosis is a rare subvariant of ISM that is distinctive in lacking cutaneous and multiorgan involvement.[5] The tryptase level in this group of patients is usually >20 ng/ml. These patients generally require no specific therapy, but ISM must be differentiated from ASM or MCL, in which skin lesions are also absent.

Smoldering mastocytosis is another subvariant of ISM.[54] Unlike typical ISM, these patients manifest two or more B findings (but no C findings) and have a higher mast cell burden (e.g., bone marrow infiltration grade >30% [dense infiltrates] and serum tryptase >200 ng/ml) with extension of a clonal disease process to several myeloid lineages. Although these patients have no overt myeloproliferative or myelodysplastic disease, they are at higher risk for progression to more aggressive forms of mastocytosis and carry a worse prognosis than those with indolent disease. Bone marrow lesions typically contain dense focal and diffuse mast cell infiltrates, and mast cells detected in such lesions may be immature. Markers of a poorer prognosis seen in this subvariant include a hypercellular bone marrow, hepatosplenomegaly or lymphadenopathy, and presence of a *KIT* mutation in PBMCs.

In contrast to adults with SM, definitive marrow involvement in children is much less common. In a study of 17 children with cutaneous or disseminated mastocytosis, only ten patients had small focal mast cell lesions on bone marrow biopsy, and only five demonstrated increased mast cells on bone marrow aspirate.[55] A follow-up of 15 of these patients 20 years later revealed that 10 patients had complete clinical regression of disease, while 5 patients had major or partial disease regression.[56] Those experiencing complete disease progression had no evidence of systemic disease on initial bone marrow examination.

Lymphadenopathy is present in a subset of patients with mastocytosis and is more commonly seen in those with an associated hematologic disorder. Peripheral adenopathy has been reported to be present in 26% of patients and central lymphadenopathy in 19% of patients at the time of diagnosis of SM.[57] Hyperplasia of lymph nodes is the result of infiltration with mast cells, and in approximately one-half of cases is associated with aggregates of eosinophils. Infiltrates are more commonly observed in the paracortex, follicles, medullary cords, and sinuses. Other histopathologic findings may include extramedullary hematopoiesis, small blood vessel proliferation in paracortical areas, and collagen fibrosis.[58]

The presence of lymphadenopathy by itself does not signal aggressive disease. However, patients who present with progressive lymphadenopathy, with or without hepatosplenomegaly, and especially if accompanied by peripheral blood abnormalities, should be closely monitored for evolution into a more aggressive systemic disorder. This latter patient population may be more likely to harbor mutations in *KIT*.

Splenomegaly due to splenic infiltration with mast cells is likewise a frequent finding in systemic disease and has also been reported to occur in the absence of demonstrable mast cell infiltration on biopsy.[59] A review of pathologic features of 16 spleens from patients with mastocytosis showed a paratrabecular distribution of mast cell infiltrates in 15 of 16 spleens. In addition, parafollicular, follicular, and diffuse infiltrates were noted in ten (64%), two (4%), and one (7%) patients, respectively.[57] Varying degrees of trabecular and capsular fibrosis and eosinophilic hematopoiesis and plasmacytosis were seen, and 71% of all biopsies revealed extramedullary hematopoiesis. The prognostic significance of splenomegaly is seen with markedly increased splenic weights (>700 g) that have been reported to correlate with SM-AHNMD or ASM[59] and may be a contributing factor to the hematologic abnormalities seen in such patients.

Mast cell infiltration of the liver is a common finding in SM, although severe liver disease and hepatomegaly are relatively uncommon except, again, in patients with more aggressive forms of disease. In a study of 41 patients with mastocytosis, liver disease was reported in 61%.[60] Approximately one-half of the patients with liver disease in this series exhibited elevated liver function tests, either an elevated alkaline phosphatase, 5′ nucleotidase, or γ-glutamyl transpeptidase. Mast cell infiltration has been described to show two distinct patterns: diffuse infiltration

involving the cords and sinuses in the red pulp and focal infiltration in the white pulp of the liver. Hepatomegaly, infiltration of the liver by mast cells on liver biopsy, and hepatic fibrosis correlate with elevated levels of serum alkaline phosphatase. These findings are more commonly seen in patients with aggressive disease, ascites, or portal hypertension. As confirmed on liver biopsy, portal fibrosis and venopathy with subsequent veno-occlusive disease appear to be a result of vascular obstruction by mast cell infiltrates.[60] Fibrosis, including that which affects the liver, often accompanies mast cell proliferation and may be due to mast cell release of such proinflammatory mediators as transforming growth factor-β.

GI symptoms reported in SM include abdominal pain, cramping, nausea, vomiting, diarrhea, and peptic ulcer disease. Malabsorption syndrome due to mucosal mast cell infiltration is less commonly observed.[43,61] One prospective study revealed that 6 of 16 patients with SM had a significantly elevated basal acid secretion, with concomitantly low gastrin levels.[43] These data were found to be consistent with the hypothesis that histamine secreted by mast cells contributes to gastric hypersecretion. Subsequent studies have shown that biopsy of gastric tissues in mastocytosis patients with acid hypersecretion symptoms did not always demonstrate increased mast cell infiltrates, thereby suggesting that the hyperhistaminemia observed in such patients may be due to oversecretion by all mast cells and not to an increased mast cell burden in the gastric tissues. GI disease is much less common in children, although GI bleeding is a potential complication with severe disease,[45] and abdominal cramping and diarrhea have also been reported.

Musculoskeletal pain in patients with SM has been well documented, although of uncertain etiology unless associated with osteopenia or osteoporosis, with more aggravated cases of osteoporosis leading to pathologic fractures.[62,63,64] In some cases, osteoporosis or pathologic fractures, or both, may be the initial manifestation of mastocytosis.

In the evaluation of skeletal disease in mastocytosis, bone scans may show focal or diffuse abnormalities, and the latter have been associated with more aggressive disease and a worse prognosis. The most commonly reported abnormalities are diffuse, poorly demarcated, sclerotic, and lucent areas involving the axial skeleton.[63] In addition to bone loss, patients with mastocytosis may also exhibit concomitant abnormal bone formation, resulting in osteosclerosis.

Occasionally, patients in whom bone involvement by mastocytosis is not seen on routine diagnostic evaluation and symptoms are not found to be attributable to any known cause may nonetheless report myalgias and arthralgias, often in concert with constitutional symptoms of fatigue, general weakness, and depression. Management of this patient subset may be particularly challenging and may require behavior modification practices as well as therapeutic intervention utilizing both non-narcotic and narcotic analgesics for adequate pain relief.

Systemic Mastocytosis with an Associated Hematologic Clonal Non–mast Cell Lineage Disorder

A subset of patients with SM either present with, or develop over time, a defined hematologic disease in association with mastocytosis. These patients are categorized as SM-AHNMD.[5,53,64,65] Among 138 consecutive reported cases with SM-AHNMD, 89% had an associated myeloid neoplasm: myeloproliferative neoplasm (45%), chronic myelomonocytic leukemia (29%), myelodysplastic syndrome (23%), and acute leukemia (3%).[66] Also rarely observed are myeloma or lymphoma.[5,53,64,65] In all such patients, WHO criteria to diagnose an AHNMD as well as ISM criteria may be applied with specific reference to the associated diagnostic entity.[6,66] Management of these patients involves targeting the underlying non–mast cell hematologic disorder either via close observation for stable disease, chemotherapy for progressive disease, or bone marrow (stem cell) transplantation in suitable candidates. The prognosis for such patients is dictated by the course of the associated non–mast cell lineage disorder.

Bone marrow findings that are more common with SM-AHNMD and have been associated with the D816V *KIT* mutation include a hypercellular bone marrow, dysplasia of myeloid or erythroid cell lineages, and an increased megakaryocyte number or megakaryocyte atypia. Fibrosis may be seen and is more frequent in patients with an associated hematologic disorder. Mast cells with bilobed nuclei, if seen on biopsy, portend a poor prognosis.

An imatinib-sensitive, *FIP1L1-PDGFRA* fusion oncogene–positive subset of SM patients with associated eosinophilia and increased serum tryptase levels has been described. Such patients display clinical and histologic features of a myeloproliferative disorder but lack the pathognomonic clusters of atypical mast cells in the bone marrow on routine hematoxylin and eosin staining.[36,67] This syndrome has been variably classified as a unique subtype of SM, as a "myeloproliferative variant" of hypereosinophilic syndrome, as a chronic eosinophilic leukemia, or as a myelomastocytic overlap syndrome. However, the WHO classification[5] now places these cases, with PDGFRA/PDGRFB-rearranged myeloproliferative neoplasm with an increase in mast cells in the bone marrow, under myeloid of lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB* of *FGFR1*. It is thus recommended that all suspected mastocytosis cases with hypereosinophilia undergo screening for the *FIP1L1-PDGFRA* fusion by either fluorescence *in situ* hybridization or reverse transcriptase-polymerase chain reaction. Similarly, an imatinib-sensitive *PRKG2-PDGFRB* fusion has been identified in a patient presenting with increased numbers of mast cells and peripheral basophilia.[37] Such cases would now be considered within the category of myeloid neoplasms with *PDGFRB* rearrangements.

Aggressive Systemic Mastocytosis

ASM is a unique variant of mastocytosis characterized by abnormal myelopoiesis with mixed focal and diffuse mast cell infiltration of the bone marrow. These cells may be atypical and may be associated with other peripheral blood abnormalities (initially often presenting with eosinophilia), hepatosplenomegaly, osteopenia and pathologic fractures, and life-threatening organ impairment.[5,68] A subset of cases appears to be associated with a prior history of malignant germ cell tumors.[69] This disease has been described in many respects as resembling a "lymphoma-like" illness with progressive infiltration of organs with mast cell infiltrates. Cutaneous involvement is usually absent.

In some patients, bone marrow aspirates may reveal significant numbers of mast cells with bi- or multilobed nuclei (high-grade morphology). Metachromatic blasts may also be detected. The peripheral blood smear may show cytopenias, leukocytosis, eosinophilia, or monocytosis.[70] Laboratory test abnormalities are frequently observed in such patients, with elevations in liver function, serum calcium, and alkaline phosphatase tests and prolonged prothrombin and partial thromboplastin time. As a result of impaired hepatic function and a propensity for spontaneous mast cell degranulation, ASM patients with more advanced disease may be at high risk for spontaneous hemorrhage during periods of mast cell activation. Serum tryptase levels may be high and demonstrate wide fluctuations due to spontaneous mast cell degranulation.

Mast Cell Leukemia

MCL is a rare variant of mastocytosis, with a grave prognosis and poorly understood pathophysiology.[5,66,71] MCL is defined by the presence of mast cells as ≥10% of circulating peripheral white

blood cells. The bone marrow typically shows a dense and diffuse infiltration (≥20%) with mast cells that display an immature, blastlike morphology with bi- or multilobed nuclei. Many of these mast cells express CD2 or CD25, or both.[5,72] The *KIT* mutation D816V may be detected. Other peripheral blood abnormalities may be observed and include leukocytosis, anemia, and/or thrombocytopenia.[72] In general, such patients manifest bone marrow and peripheral blood abnormalities that are insufficient to fulfill WHO criteria for SM-AHNMD.[5] In the aleukemic variant of MCL, mast cells account for <10% of peripheral white blood cells, and patients develop pancytopenia.[5] Similar to aggressive mastocytosis, MCL patients are prone to bleeding diatheses, with or without signs of consumption or hyperfibrinolysis.

Mast Cell Sarcoma

Mast cell sarcoma (MCS) is a rare and ill-defined malignant mast cell neoplasm composed of immature cells with a high nucleus-to-cytoplasm ratio, nucleoli, and a hypogranulated cytoplasm. It carries a highly unfavorable prognosis. The cellular atypia described in MCS is comparable to the high-grade cytologic abnormalities found in MCL. It is characterized by local, destructive, sarcoma-like growth, with transformation to generalized involvement of multiple organ sites in its terminal phase. Cases described in the literature have included MCS of the larynx, the ascending colon, and an intracranial site.[73,74,75] This disorder may terminate as MCL, with no known effective life-prolonging or curative treatments.

Extracutaneous Mastocytoma

Extracutaneous mastocytoma is another rare variant of mast cell disease, with most cases reported in the literature occurring in the lungs.[76] They are generally considered benign because of their low-grade histology consisting of mature mast cells, and lack of progression to aggressive disease or MCL. Because they may present similarly to MCS, they must be differentiated from the latter.

Monoclonal Mast Cell Activation Syndrome

Monoclonal mast cell activation syndrome (MMAS) is a term adopted by a consensus conference to be applied to patients who are found to have one or two minor diagnostic criteria for mastocytosis but lack the full diagnostic criteria for systemic disease.[33] Patients with such findings have been identified within groups of patients diagnosed with idiopathic anaphylaxis and patients with anaphylaxis to stinging insects.[44,77,78] Most of these patients have a tryptase level below 20 ng/ml. The suggestion has been made that these studies may be identifying patients with an advancing clonal mast cell disorder that may one day meet the diagnostic criteria for SM.

For now such patients are treated under guidelines for the treatment of anaphylaxis. Follow-up at yearly intervals is recommended. The follow-up examination should include a physical exam to rule out evolving organomegaly or lymphadenopathy, a serum tryptase level to determine if there is indirect evidence of an expanding mast cell compartment, and a CBC with differential and platelet count to help rule out an evolving hematologic disorder.

Mast Cell Activation Syndrome

The term mast cell activation syndrome (MCAS) is now applied as a diagnosis for individuals who present with episodic allergic-like signs and symptoms such as flushing, urticaria, diarrhea, and wheezing involving two or more organ systems; and where an extensive medical evaluation has failed to identify an etiology. The assumption is that individuals to whom this diagnosis is applied are having episodes due to the release of mediators associated with hyperreactivity of mast cells that then activate spontaneously.

Diagnostic criteria have been proposed to separate this possibility from other causes of such clinical findings. These additional criteria include response to anti-mediator therapy and an elevation in a validated urinary or serum marker of mast cell activation such as serum tryptase with an episode.[79,80] Primary (clonal) and other clinical disorders associated with mast cell activation, as well as other conditions associated with vasoactive mediator release must be eliminated as possible causes of the clinical findings. Clonal disorders to be considered include mastocytosis and MMAS. Other disorders associated with mast cell activation including allergic diseases, mast cell activation associated with chronic inflammatory or neoplastic disorders, and chronic autoimmune urticaria must be eliminated as diagnostic possibilities. Conditions such as carcinoid syndrome must also be sought and rejected. Once the diagnostic criteria are met, therapy is symptomatic. Care must be maintained lest one of the diagnoses eliminated during the initial evaluation reaches the level of diagnosis.

LABORATORY FINDINGS

The diagnosis of mastocytosis is based on the finding of confluent clusters of mast cells in affected organ sites or diffuse infiltration with replacement of normal tissue by mast cells, coupled with clinical signs and symptoms and laboratory tests that are consistent with mast cell disease.[5] Bone marrow biopsy in pediatric-onset cutaneous disease is generally not recommended unless there is evidence of systemic disease, such as unexplained peripheral blood abnormalities, hepatosplenomegaly, or lymphadenopathy.[55] In patients with elevated serum total tryptase,[5] a bone marrow biopsy and aspiration should be considered, particularly in adults. The consideration to obtain tissue biopsy specimens from the liver, spleen, GI tract, or lymph nodes should be based on a high suspicion of disease involvement and likelihood of yielding clinically useful information. Slight increases in mast cell numbers in target tissues (up to fourfold) are not diagnostic, as they may reflect normal variation or inflammatory or reactive processes.

Examination of the bone marrow in patients with suspected mastocytosis includes both an inspection of the bone marrow biopsy and the aspirate. Immunohistochemical staining of the bone marrow biopsy with antibody directed to mast cell tryptase is the method of choice to visualize mast cells,[5,81,82] as shown in Figure 85.2. In most patients with SM, tryptase-positive infiltrates are composed of spindle-shaped mast cells. In these patients, SM can be diagnosed without additional tests, provided that major and minor SM criteria are met. In the case of patients with tryptase-positive round cell infiltrates (designated TROCI-bm) where the infiltrates comprise >95% round cells and <5% spindle-shaped cells, application of additional immunohistochemistry markers to confirm the diagnosis of SM should be applied if possible (e.g., 2D7 or BB1), since basophils and sometimes blast cells also express tryptase.[33] The coexpression of CD2 and/or CD25 in CD117 (KIT)-positive mast cells by flow cytometry of bone marrow aspirates or by immunohistochemical analysis of bone marrow biopsies is generally accepted to be the most sensitive and specific method to support the diagnosis of SM in bone marrow.[21,33,52] The cellular composition of lymphoid collections is evaluated by using lineage-specific antibodies against CD3 and CD20, respectively,[24] as seen in Figure 85.3. Other approaches commonly used include reticulin staining to detect fibrosis and Masson trichrome staining to evaluate the extent of collagen deposition.

The finding of clusters of confluent mast cells on bone marrow aspirate is consistent with SM; however, not all patients demonstrate this finding. Therefore, underestimation of the degree of mast cell infiltration through examination of an aspirate may be more common than appreciated, with aspirates compromised because of underlying marrow fibrosis and a resultant inability to obtain adequate marrow aspirate or spicules at fibrotic marrow

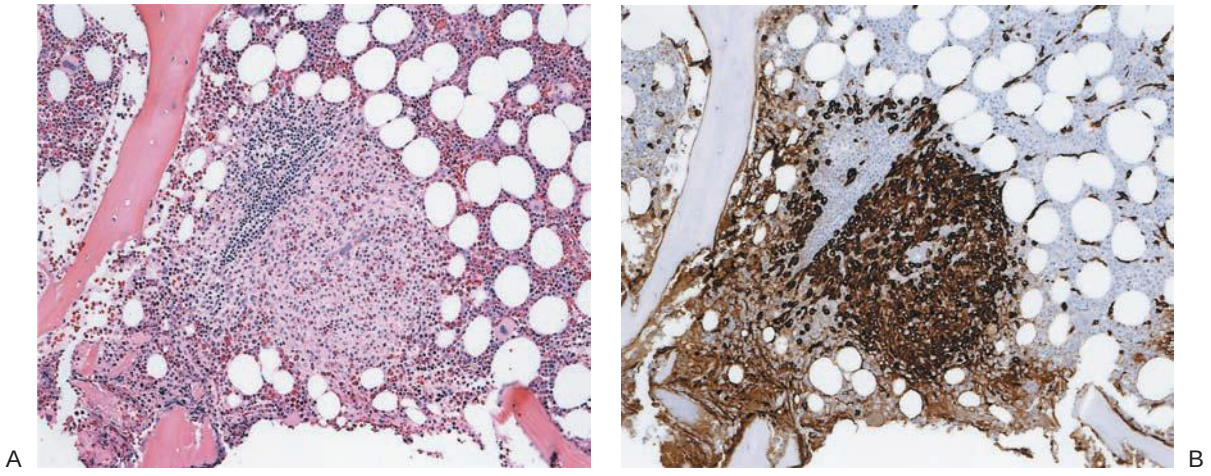

FIGURE 85.2. Bone marrow histopathology showing focal mast cell infiltrates in a bone marrow biopsy taken from a patient with indolent systemic mastocytosis. Panel **A** shows staining of a representative mast cell lesion with hematoxylin and eosin stain (magnification, 10×) and panel **B** shows staining of the same section with antitryptase antibody (magnification, 10×).

sites. Surrogate disease markers in mastocytosis include serum or plasma tryptase levels, serum histamine, urinary histamine metabolites, soluble CD117, soluble CD25, and CD2.[83]

Serum mast cell tryptase is the most commonly used surrogate marker for SM and is quantified using a commercial enzyme-linked immunosorbent assay. It has both high sensitivity and high specificity.[83,84] A total tryptase >20 ng/ml is suggestive of mastocytosis and has been included as a minor criterion in the diagnosis of SM.[5,33] Normal baseline levels in healthy individuals are generally ≤ 12 ng/ml. Tryptase levels ≤ 20 ng/ml have been

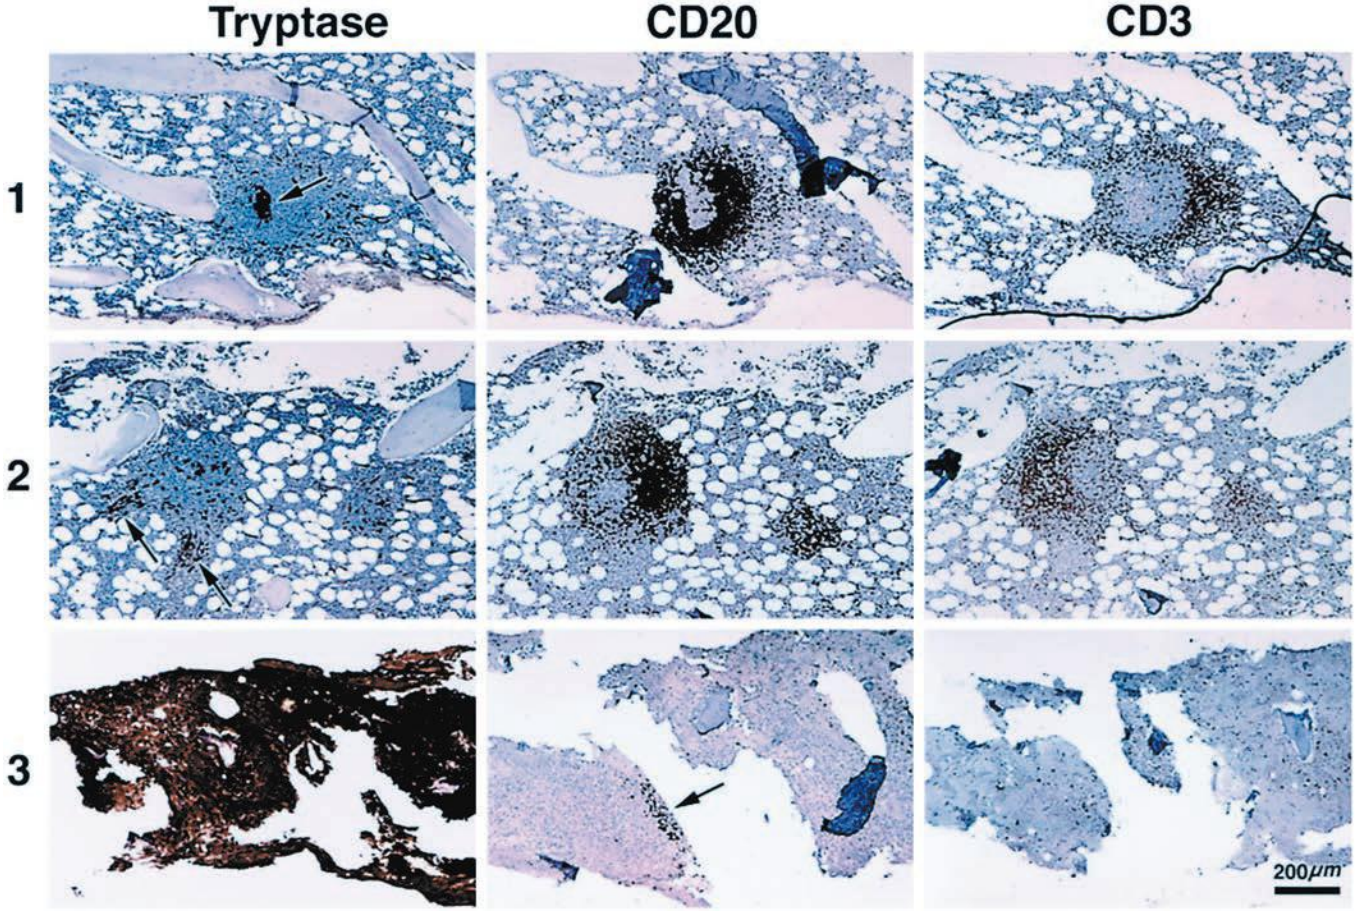

FIGURE 85.3. Immunohistochemical staining of lymphoid aggregates in two patients with a focal (1 and 2) and one patient with a diffuse (3) increase in mast cells. Antibodies are shown on top of each column. Nodular lesions shown in 1 and 2 contain a central core of mast cells (*arrows*) surrounded by B cells (CD20) and a peripheral rim of T cells (CD3). Diffuse mast cell infiltrates (3) are seen in association with a small B cell collection (*arrow*) and scattered single T cells. The bar represents 200 μm. (From Akin C, Jaffe ES, Raffeld M, et al. An immunohistochemical study of the bone marrow lesions of systemic mastocytosis. Am J Clin Pathol 2002;118:242–247, by permission of Dr. Cem Akin and the *American Journal of Clinical Pathology*.)

detected in patients with cutaneous mastocytosis and in those with limited systemic disease.[81] In general, higher tryptase values increase the likelihood of multiorgan involvement. Thus, the tryptase level is an important parameter in evaluating patients with suspected mastocytosis and is useful in assessing disease severity and monitoring disease activity.

Other mast cell mediators that are surrogate disease markers for mastocytosis include serum histamine and 24-hour urine sampling for the urinary histamine metabolites, *N*-methylhistamine, and methylimidazole acetic acid. These tests are less commonly used with the availability of a commercial tryptase assay. A comparison of serum tryptase to urine N-methylhistamine in patients with suspected mastocytosis indicated that serum tryptase (using the UniCAP fluorenzyme immunoassay) was able to better identify patients with an increased number of mast cell aggregates.[85] Other disadvantages of using blood and urinary histamine levels for diagnosis and prognostication of patients with mastocytosis are the variability of histamine levels among healthy individuals and patients, difficulty in assay standardization, and the problem of false-positive results due to presumed synthesis of histamine by bacteria in the urinary tract. Other variables that can alter results of histamine assays are prior ingestion of foods rich in histamine and improper storage of the urine sample. Because basophils also contain histamine, hematologic disorders presenting with basophilia or allergic events that lead to basophil and mast cell activation result in elevated histamine levels.

Various metabolites of arachidonic acid are also elevated in patients with mastocytosis. These include urinary PGD-M or 9α, 11β-dihydroxy-15-oxo-2,2,18,19-tetranorprost-5-ene-1,20-dioxic acid, as well as plasma thromboxane B_2 and its metabolites. Because the source of prostaglandins and thromboxanes in mastocytosis is not exclusively limited to mast cells, reliance on assays that measure these metabolites is unlikely to be sufficiently specific for diagnostic purposes. However, if measured, elevations in one or more mast cell mediators raise the suspicion of mastocytosis and warrant further diagnostic evaluation.

Identification of genetic markers of mastocytosis, such as point mutations in *KIT*, helps support the diagnosis of mastocytosis. The identification of the D816V mutation fulfills a minor diagnostic criterion in the diagnosis of mastocytosis. Such mutations are more easily identified in patients with more severe disease due to the relative clonal expansion of cells derived from the neoplastic progenitor. Such mutations may be helpful in following disease progression by assessing the relative intensity of the reverse transcriptase-polymerase chain reaction complementary DNA bands over the patient's course. Analysis for *KIT* mutations are best performed on bone marrow and, specifically, on sorted malignant mast cells so as to increase sensitivity. Inability to identify the presence of a point mutation at codon 816 in *KIT* does not eliminate the possibility that cells bearing this mutation are present, as the malignant clone may have not expanded to sufficient cell numbers to allow for detection of the mutation in *KIT*.[21] In patients with coexisting eosinophilia, peripheral blood should be examined for the presence of the *FIP1L1/PDGFR*α fusion gene. Several techniques to detect *KIT* mutations have been reported, but current recommendations for the most sensitive assays include RT-PCR-positive restriction fragment length polymorphism testing, peptide nucleic acid-mediated PCR, or allele-specific PCR.[33] When employing *KIT* mutations as a diagnostic criterion for SM, it is important to be aware that such mutations are also detectable in some patients with germ cell tumors or other non–mast cell tumors with or without coexisting SM.[33] Plasma IL-6 levels may correlate with disease severity, in particular the extent of bone marrow pathology and presence of a non–mast cell hematologic disorder, but are not currently recommended for diagnosis or routine monitoring of patients.[13,86]

Additional surrogate markers that may also be useful in assessing more severe forms of mastocytosis, such as SM-AHNMD, and in following disease severity are the soluble receptors CD117 (KIT) and CD25 (the α-chain of the IL-2 receptor).[87] These receptors are expressed in both membrane-bound and soluble forms, with the latter being a result of proteolytic cleavage. Soluble forms of these receptors are more readily detectable in the circulation in patients with an increased mast cell burden and correlate with disease severity and bone marrow pathology. Soluble CD117 levels are also found to be elevated in some patients with acute myeloid leukemias and advanced myelodysplastic syndromes. Elevated CD25 levels may be seen in patients with hairy cell leukemia, solid tumors, and a number of infectious and autoimmune diseases. A comparison of the plasma CD117 and tryptase levels for various categories of mastocytosis revealed that tryptase levels were more sensitive indicators of early disease, whereas elevated plasma CD117 levels demonstrated a stronger correlation with advanced disease.[87]

A dual-energy X-ray absorptiometry scan should be employed to monitor osteoporosis in those with mastocytosis. Sites commonly measured include the lumbar spine and hip. The diagnosis is established according to WHO criteria defining osteopenia.[33] A physical examination, serum tryptase determination, and complete blood count should be recommended at yearly intervals in patients with stable ISM.[21,33]

DIFFERENTIAL DIAGNOSIS

The differential diagnostic list of disorders for mastocytosis consists of those diseases that have a similar clinical presentation. These include hereditary or acquired angioedema, idiopathic flushing or anaphylaxis, carcinoid tumor, pheochromocytoma, and idiopathic capillary leak syndrome. Pheochromocytoma should be considered when episodic hypertension is a predominant clinical manifestation. Unexplained gastroduodenal disease should include evaluation for Zollinger-Ellison gastrinoma. *Helicobacter pylori* infection should be considered in all patients with gastric ulcers, even in those patients diagnosed with mastocytosis.

DCM should be included in the differential diagnosis of neonatal blister disorders such as pemphigoid. Extensive bullae with crusting may be the first presentation in an infant who later develops DCM.

A number of non–mast cell hematologic disorders, such as the myeloproliferative disorders (e.g., chronic myelogenous leukemia) or lymphoma of the bone marrow, may present with an increased number of mast cells and, in some cases, immature mast cells on bone marrow biopsy, though circumscribed lesions are generally lacking in these disorders and WHO criteria for diagnosis of primary mast cell disease are not met.[88,89] Diseases with bone marrow lesions on biopsy that appear similar to SM on gross analysis include primary myelofibrosis, angioimmunoblastic lymphadenopathy, eosinophilic fibrohistiocytoma, and "myelomastocytic leukemia."[88,90] Close evaluation of histopathologic specimens differentiates these disorders from mastocytosis in part on the basis of a general absence of mast cell infiltrates. Myelofibrosis can resemble mastocytosis when fibrosis is extensive and the marrow is diffusely infiltrated with an increased number of mast cells. The distinguishing feature between these two disorders is the greater absolute number of mast cells on bone marrow biopsy in mastocytosis. Although differentiation of mastocytosis from angioimmunoblastic lymphadenopathy may be made on the basis of the presence of plasma cells and immunoblasts in the latter and absence of neovascularity in mastocytosis, differentiation of mastocytosis from fibrohistiocytoma is more difficult. Large histiocytic cells noted in eosinophilic fibrohistiocytic lesions have a similar appearance to the large mast cells seen in many mast cell lesions.[91]

Conditions with secondary changes in mast cell numbers have been observed at sites of pathology in a number of autoimmune

disorders, including systemic lupus erythematosus, rheumatoid arthritis, psoriatic arthritis, and scleroderma; with chronic liver or renal disease; and with a variety of infectious diseases, although in such cases, these increases are nominal.[20] On resolution of the infection, mast cell numbers generally return to normal. At sites of allergic inflammation, increases of mast cells up to fourfold over normal have been described.

MANAGEMENT

Treatment of all categories of mastocytosis involves control of symptoms by blocking the action of mast cell mediators, though several new therapeutic strategies may hold promise for more severe forms of the disease by targeting mast cell growth and development.[92,93,94] Because of the heterogeneous nature of disease manifestations in this group of disorders, therapy should be individualized to each patient's clinical presentation and prognosis. Aggressive forms of therapy are not indicated in patients with indolent mastocytosis, as this disease category has a favorable prognosis. A summary of treatment approaches for mastocytosis is provided in Table 85.3.

The treatment for most categories of mastocytosis includes H_1 and H_2 antihistamine blockade for prophylaxis of hypotensive episodes, for control of cutaneous manifestations such as pruritus and flushing, and for gastric hypersecretion. Corticosteroids are used for control of malabsorption and ascites and for prevention or amelioration of anaphylaxis.[20,92,95,96] Nonsedating antihistamines have utility when patient sedation is a key concern and are now considered the agents of choice for pruritus and urticaria. Alternative approaches include administration of a nonsedating antihistamine during the day, with supplementation of one of the potent sedating antihistamines at bedtime for added symptom relief.

Addition of an H_2 antihistamine may be beneficial in cases in which insufficient symptom control is afforded by use of an H_1 antihistamine alone.[92,96] Aspirin has been used in some patients to treat flushing, tachycardia, and syncope. However, aspirin must be used with caution, as it may cause vascular collapse in some patients with mastocytosis and may also exacerbate peptic ulcer disease. Neither chemotherapy nor splenectomy appears to have any role in the treatment of cutaneous or indolent forms of mastocytosis.

For cutaneous manifestations of mastocytosis, other therapies may be beneficial in addition to antihistamines.[92] UP and DCM have been shown to be responsive to corticosteroids[97,98] and oral methoxypsoralen therapy with long-wave ultraviolet radiation; psoralen and ultraviolet A light has been used for both UP and DCM.[99,100,101] Indeed, some patients report a decrease in the number or intensity of cutaneous lesions after repeated exposure to natural sunlight.[102] Photochemotherapy, however, should only be used in instances of extensive cutaneous disease unresponsive to other therapy. TMEP, a rare variant of cutaneous disease, is somewhat more complicated in that lesions are chronic and tend to be unresponsive to currently available therapies. Neither corticosteroids nor psoralen and ultraviolet A light have been shown to afford significant improvement in TMEP, and improvement is transient in UP and DCM.[102] A limited body of literature indicates that laser therapy may have some utility in the treatment of TMEP.[92] In children with mastocytomas with associated severe systemic symptoms due to mast cell mediator release, surgical excision of the mastocytoma may be considered.[45] An alternative approach used involves injection of the mastocytoma with corticosteroids to induce involution.[103] There are also now considerations of alternative approaches to the treatment of cutaneous mastocytosis not yet validated, including the use of topical pimecrolimus, an immunomodulating agent used in the treatment of eczema.[104]

TABLE 85.3

SUGGESTED THERAPY FOR MASTOCYTOSIS

FOR ALL VARIANTS: Hypotensive/anaphylaxis

Epinephrine (intramuscular [e.g., Epi-Pen])

More severe, frequent episodes: consider prophylaxis with H_1 and H_2 antihistamines ± corticosteroids

Cutaneous disease

Antihistamines: H_1 ± H_2

Corticosteroids

Psoralen and ultraviolet A light: consider for recalcitrant disease

Laser therapy: consider for telangiectasia macularis eruptiva perstans

Gastrointestinal disease

Peptic ulcer disease/gastroesophageal reflux: H_2 antihistamines, omeprazole

Abdominal cramping: cromolyn sodium

Diarrhea: anticholinergics, cromolyn sodium, omeprazole

Malabsorption: corticosteroids

Ascites: corticosteroids, consider a portacaval shunt

Bone disease

Calcium supplementation ± vitamin D

Bisphosphonates

Consider estrogen therapy for postmenopausal women, testosterone replacement in men with low testosterone levels

Consider interferon-α2b in patients with severe bone disease and severe musculoskeletal pain

Radiotherapy: palliative therapy for severe, localized bone pain

INDOLENT SYSTEMIC MASTOCYTOSIS

No cytoreductive treatment

SMOLDERING SYSTEMIC MASTOCYTOSIS

In severe selected cases with disease progression consider interferon-α, cladribine, and tyrosine kinase inhibitors

SYSTEMIC MASTOCYTOSIS WITH AN ASSOCIATED NON–MAST CELL LINEAGE DISEASE

If indicated, treatment of the associated non–mast cell hematologic disorder

Interferon-α
Cladribine

Consider a tyrosine kinase inhibitor

AGGRESSIVE SYSTEMIC MASTOCYTOSIS

Interferon-α

Cladribine
Consider a tyrosine kinase inhibitor and/or combination therapy

Consider bone marrow transplantation

Consider splenectomy if patient has an enlarged spleen and/or cytopenias and if chemotherapy is to be considered

MAST CELL LEUKEMIA

Consider interferon-α or cladribine or a tyrosine kinase inhibitor
Combined chemotherapy

Consider phase 1 or phase 2 investigational research studies, including bone marrow transplantation

Management of GI symptoms should address the type and severity of symptoms. H_2 antihistamines are specifically used to treat gastric hypersecretion and peptic ulcer disease associated with mastocytosis. Proton pump inhibitors (e.g., omeprazole) may be effective in decreasing diarrhea in addition to controlling gastric acid hypersecretion.[102] Antileukotrienes are effective in some patients in helping control symptoms of flushing, diarrhea, and abdominal cramping. Anticholinergics and orally administered cromolyn sodium may also be useful for control of diarrhea.[105] Intestinal absorption of cromolyn is limited (≤1%), and a number

of weeks of therapy may be needed before clinical benefits are seen. The recommended adult dosage is 200 mg four times daily, and doses ranging from 60 mg daily to 100 mg four times daily have been used in children.[45,92] In addition to its efficacy in treating GI symptoms, cromolyn has been reported to decrease musculoskeletal pain and headaches and improve cognitive abilities.[92] Its purported mechanism of action is in decreasing mast cell degranulation. As such, its use would not be expected to alter the natural course of the disease.

Malabsorption is generally managed with corticosteroids.[92] In adults, oral prednisone (40 to 60 mg/day) usually results in a decrease in malabsorption over 10 to 20 days, after which steroids can usually be tapered to as low as 15 to 20 mg every other day. A more difficult treatment dilemma, ascites, has been shown to improve with systemic corticosteroids.[92] Again, in adults, treatment with prednisone, 40 to 60 mg/day, with tapering to an every-other-day dose, usually results in a decrease in ascites. A subgroup of patients with mastocytosis who develop ascites may also develop portal hypertension, which may be exceedingly difficult to manage and indicates a poor prognosis.[106] At least one patient with portal hypertension was reported to have been successfully managed with a portacaval shunt.[107]

Epinephrine is used to treat acute episodes of hypotension.[92] Treatment of refractory hypotension and shock requires fluid resuscitative measures along with additional pharmacologic intervention.

Osteoporosis in those with mastocytosis may be underdetected and, hence, undertreated. Recommended approaches to treatment include calcium supplementation, vitamin D, and use of bisphosphonates.[33,92] Narcotic analgesics should be used with care, as these, particularly at high doses or in susceptible patients, have been suspected of potentiating mast cell degranulation. Radiotherapy may have a palliative role in decreasing bone pain in isolated areas.[108] In severe cases or patients with drug intolerance, an intravenous bisphosphonate or low-dose interferon-α2b may be appropriate, as the literature indicates that interferon-α2b may have some efficacy in decreasing musculoskeletal pain and improving bone mineralization in patients with extensive bony involvement.[92] Patients with osteolysis and pathologic fractures are candidates for cytoreductive drugs (plus a bisphosphonate). The decision to initiate treatment with interferon-α2b therapy should take into consideration side effects such as fever, malaise, nausea, and hypothyroidism, along with the small but well-described risk for anaphylaxis. Patients with mastocytosis who ultimately require joint replacement due to extensive bone loss generally tolerate these procedures well; however, such procedures do not obviate further decline in bone mass.[109]

Neither chemotherapy, cytoreductive therapy such as cladribine (see below), nor splenectomy have any role in the treatment of indolent mastocytosis. Smoldering SM patients with rapid progression of B findings or new C findings may be an exception to this general rule.[102] Therapeutic options for patients with SM-AHNMD, ASM, and MCL are at the present time based on treating associated medical conditions and, when associated, the underlying hematologic disorder.[20,110,111,112,113,114,115]

Interferon-α with or without steroids is often employed as first-line cytoreductive therapy in more aggressive forms of SM.[110,115] The optimal dose and duration of therapy are unclear and results are mixed. In general, interferon-α treatment appears to diminish skin findings and symptoms, decrease mast cell infiltration of the marrow, lessen osteoporosis, and ameliorate cytopenias.[111] The time to response may approach a year, and relapse after discontinuing interferon-α is common.[115] Furthermore, its use is complicated by flu-like symptoms, fever, hypothyroidism, and cytopenias.[92] One group commonly starts with 1 to 3 million units subcutaneously three times per week, followed by gradual escalation to 3 to 5 million units 3 to 5 times per week.[115] Prednisone is commonly used from the start and tapered as possible. Duration of therapy is determined by the response and absence of significant side effects.

Cladribine (2-chlorodeoxyadenosine, 2CdA), a purine nucleoside analog, has been reported to reduce neoplastic mast cell burden and induce clinical remissions in patients with more aggressive forms of mastocytosis.[112,115] Cladribine is a reasonable therapeutic approach in treating those with aggressive forms of mastocytosis who need a rapid reduction in mast cell burden, or have interferon-α–resistant advanced disease or interferon intolerance. Potential toxicities include myelosuppression, lymphopenia, and opportunistic infections. Prophylactic glucocorticoids, antihistamines, and antibiotics are recommended.

Peripheral stem cell or bone marrow transplantation has the potential of allowing long-term engraftment of healthy bone marrow progenitors along with provision for a graft-versus-leukemia effect. Allogeneic nonmyeloablative bone marrow transplantation from human leukocyte antigen-identical sibling donors has been shown to cause less transplant-related mortality when compared to myeloablative transplantation.[116] Here, too, limited published data are available, but overall results to date have been disappointing even when a graft versus mast cell state was induced.[113,116,117,118,119] The current thinking with regard to transplantation is that effective prior cytoreductive therapy may be necessary to achieve long-term disease control and cure.

In SM-AHNMD patients with significant cytopenias and splenomegaly, splenectomy may result in some amelioration of the cytopenias and thereby reduce a patient's transfusion requirement or risk of bleeding or infection.[120] Such patients might also be better able to tolerate chemotherapy, as suggested by a study in which patients with more aggressive forms of mastocytosis who underwent splenectomy had a mean survival time of 34 months compared to 26 months in those who did not undergo splenectomy.[120]

Tyrosine kinase inhibitors are under investigation as a therapeutic class that could be used to interfere with mast cell proliferation and survival. Imatinib mesylate *in vitro* inhibits the phosphorylation of wild-type KIT, and F522C and V560G mutants. It is ineffective at inhibiting KIT bearing the common D816V mutation.[121,122,123] Major toxicities include diarrhea and peripheral edema. Interstitial pneumonitis appears to be a rare side effect. These data underscore the importance of performing a mutational analysis of *KIT* prior to initiating therapy with imatinib.

Future directions for treatment of mastocytosis involve the second generation tyrosine kinase inhibitors including midostaurin (PKC412), dasatinib, and nilotinib. Midostaurin has activity against the D816Y and D816 *KIT* mutants.[124,125,126] In a phase-2 study, midostaurin was orally administered to patients with mastocytosis variants including SM-CMML, SM-MDS, SM-MDS/MPN-U, and MCL.[127] There was a major response rate of 38%, which included improvement of hemoglobin and platelet counts, improvement of liver function abnormalities, and improvement of ascites. Side effects included nausea, vomiting, diarrhea, and fatigue. Treatment had to be discontinued in 69% of the patients. Additional studies are needed to clarify the advantage of midostaurin vs. 2-CdA or interferon-α. Dasatinib also has activity against *KIT* mutants including D816V.[126] In one study, dasatinib was given to patients with ISM, ASM, and SM-AHMD.[128] Twenty-seven percent experienced symptomatic improvement, but significant toxicities were observed in 58%. It is not clear which patient group will obtain the most benefit. Nilotinib has a target profile similar to imatinib. A phase II trial evaluated nilotinib in 60 patients with SM. An overall response was observed in 12 patients.[94,129] The clinical trials evaluating tyrosine kinase inhibitors have been relatively disappointing as judged by achieving complete remission, in part due to multiple off-target effects and the fact that neoplastic mast cells acquire additional *KIT*-independent mutations that contribute to mast cell proliferation.[94] This has led to an ongoing search for more specific inhibitors of *KIT*[130] and raises the possibility that combination therapy directed at multiple targets may be required.

Irrespective of the intricacies of treating this diverse group of disorders, an important component of management of all categories of mastocytosis is patient avoidance of triggering factors such as alcohol and nonsteroidal antiinflammatory agents in sensitive patients; pressure, friction, or extremes of temperature; and agents to which the patient is specifically allergic.[77,78,92] As with other syndromes in which patients may be at risk for severe type I hypersensitivity reactions, patients with mastocytosis should carry epinephrine-filled syringes and be skilled in self-administration. In situations where surgery under general anesthesia is necessary, patients with mastocytosis should undergo appropriate prophylaxis with H_1 and H_2 antihistamines, as medications used in general anesthesia are known to variably induce mast cell degranulation. Pharmacologic agents that should be avoided if possible include β-adrenergic agents and α-adrenergic and cholinergic receptor antagonists. Serum tryptase levels should be obtained and blood coagulation parameters monitored perioperatively and during anesthesia if a suspected mast cell degranulation event occurs.[131]

DEVELOPMENT OF CLINICAL RESPONSE CRITERIA TO ASSESS EFFICACY TO THERAPY

Despite the emergence of novel pharmaceutical agents for the treatment of mastocytosis, assessment of response to therapy using uniform criteria that are objective, reproducible, and mastocytosis variant–specific remains the subject of discussion. Response criteria developed by consensus have been published.[33] These criteria or modified versions have been used in clinical trials. Clinical evidence of organ damage forms the basis of judging the level of response and determining where additional criteria, including changes in mast cell burden and serum tryptase levels, are employed to subcategorize levels of major response. More recently, attempts have been made to make response criteria more clinically relevant using disease-related symptoms, organomegaly, organopathy, and bone marrow findings.[132,134] It is hoped that further consensus and the resulting algorithms and recommendations that arise will greatly facilitate the management of patients in clinical practice, provide better guidelines for selection of appropriate categories of mastocytosis for evaluation in clinical trials, and ultimately allow for individualized and molecularly tailored therapy of patients with mastocytosis, based on their genotype and phenotype.

CHAPTER 86

DIAGNOSIS AND CLASSIFICATION OF LYMPHOMAS

William R. Macon, Paul J. Kurtin, Ahmet Dogan

SPECIMEN EVALUATION

Tissue Sampling and Processing

Precise assessment of hematopathologic specimens depends, in large part, on adequate sampling and proper handling of tissues, both of which may be influenced significantly by clinicians. Therefore, effective communication between the clinician and the pathologist is imperative for obtaining pertinent patient history and the proper specimen. The largest lymph node or mass lesion generally provides the most useful material for accurate diagnosis and should undergo surgical biopsy. Fresh tissue, moistened in a balanced solution, such as normal saline, should be sent intact to the surgical pathology laboratory without delay to maximize the immunophenotypic, genotypic, and karyotypic studies that are available and to minimize irreversible tissue artifacts. Frozen sections should be discouraged on small specimens, as lymphoid hyperplasias may appear indistinguishable from lymphomas, and freezing permanently distorts the tissue. Touch imprints are generally satisfactory for initial evaluation and for directing specimen workup.

Needle biopsy and aspiration cytology is playing an expanded role in the primary diagnosis and monitoring of patients with malignant lymphomas. The major advantages of these techniques include: (a) their relatively noninvasive nature and (b) the rapidity with which the cytology can be reviewed (minutes) and the aspirated cells immunophenotyped (2 to 3 hours by flow cytometry). With computed tomography guidance, lesions in the mediastinum and retroperitoneum or in any highly vascular organ or tissue can be sampled with minimal morbidity. Technical advances in flow cytometry and molecular biology continue to reduce the amount of tissue required to provide immunophenotypic and genetic data.

Just as with lymph node and bone marrow biopsies, however, optimal information can be obtained only by close coordination between the clinician, the person performing the aspirate (radiologist or pathologist), and the hematopathologist providing ancillary diagnostic services. If the material is put into fixative, it cannot be used for flow cytometric phenotypic analysis or standard karyotypic studies.

The limitations of fine-needle aspiration (FNA) include: (a) the possibility of missing focal lesions, (b) the difficulty in making a primary diagnosis of malignant lymphoma in which the tumor cells are a minor population (e.g., Hodgkin lymphoma [HL] and T cell/histiocyte–rich large B-cell lymphoma [THRLBCL]), and (c) the difficulty in precisely classifying many reactive processes in which architectural features are of prominent diagnostic importance. For example, in patients with mediastinal masses, it may be impossible to distinguish between normal thymus, thymoma, and T lymphoblastic lymphoma by the cytology of the lymphoid population. Furthermore, immunophenotypic studies may identify a common thymocyte phenotype that can be dominant in all three. Despite these limitations, FNA coupled with flow cytometry and fluorescence in situ hybridization (FISH) will play a major role in the diagnosis of many non-Hodgkin lymphomas (NHLs) in the future.

Morphologic Examination

Morphologic examination starts at low magnification to evaluate tissue architecture and patterns of infiltration. Lymphomas may cause partial or complete destruction of the normal architectural features of the lymph node. Growth patterns are generally described as nodular or diffuse. Lymphomas are often distributed within specific anatomic compartments of the lymph node, such as follicle (germinal) centers, follicle mantles, or the paracortical and medullary areas. The low magnification pattern of neoplastic cell distribution within the lymph node suggests the type of lymphoma present (Fig. 86.1). High magnification is then used to examine cytologic features, such as the neoplastic cell types (e.g., small cleaved cells [centrocytes], large transformed cells [centroblasts or immunoblasts], and plasmacytoid lymphocytes or plasma cells), because this information helps establish the classification and grade of the tumor. In some lymphomas, the composition of the reactive cell constituents also may be of prognostic significance.

Immunophenotypic and Genotypic Analysis

Immunophenotypic analysis uses antibodies of variable specificity to detect cellular antigens (surface, cytoplasmic, or nuclear) in cell suspensions (flow cytometry) or in frozen or paraffin-embedded tissue sections (Table 86.1). These studies are often invaluable, because they help in distinguishing subtle lymphomatous infiltrates from reactive hyperplasias, can demonstrate the lineage of the neoplastic cell (e.g., B cell, T cell, and natural killer [NK] cell), can provide data necessary for precise classification of some

TABLE 86.1

IMMUNOPHENOTYPIC MARKERS USED IN DIAGNOSIS OF MALIGNANT LYMPHOMAS

Antibody Designation	Reactivity	Examples of Lymphoid Neoplasms
CD1a	Thymocytes, dendritic cells, and epidermal Langerhans cells	T lymphoblastic leukemia/lymphoma and Langerhans cell histiocytosis
CD2	T cells and natural killer cells	T-cell and natural killer cell lymphomas
CD3	T cells	T-cell lymphomas
CD4	Helper and inducer T cells, monocytes, and macrophages	T-cell lymphomas and diffuse large B-cell lymphoma with ALK expression (rare)
CD5	T-cells and B-cell subset	T-cell lymphomas, chronic lymphocytic leukemia/small lymphocytic lymphoma, and mantle cell lymphoma
CD7	T cells and natural killer cells	T-cell and natural killer cell lymphomas
CD8	Cytotoxic and suppressor cells T cells and natural killer cells	Cytotoxic T-cell lymphomas and natural killer cell lymphomas
CD10	Precursor B cells, B-cell subset (follicle center cells), and follicle center T-helper cells	B and some T lymphoblastic leukemias/lymphomas, follicular lymphoma, some diffuse large B-cell lymphomas, Burkitt lymphoma, and angioimmunoblastic T-cell lymphoma
CD15	Granulocytes, monocytes, Reed-Sternberg cells, activated lymphocytes, and some epithelial cells	Classical Hodgkin lymphomas
CD19	B cells	B-cell lymphomas
CD20	B cells	B-cell lymphomas and nodular lymphocyte predominant Hodgkin lymphoma
CD21	B-cell subset and follicular dendritic cells	Follicular dendritic cell sarcoma and follicular dendritic cell meshworks in angioimmunoblastic T-cell lymphoma
CD22	B-cell subset	Some B-cell lymphomas and hairy cell leukemia
CD23	Activated B cells, mantle B cells, and follicular dendritic cells	Chronic lymphocytic leukemia/small lymphocytic lymphoma and follicular dendritic cell meshworks in angioimmunoblastic T-cell lymphoma
CD25	Activated T- and B cells and activated macrophages	Adult T-cell leukemia/lymphoma, anaplastic large cell lymphoma, and hairy cell leukemia
CD30	Activated T- and B cells and Reed-Sternberg cells	Classical Hodgkin lymphomas, anaplastic large cell lymphoma, some peripheral T-cell lymphomas, NOS, and some large B-cell lymphomas
CD38	Plasma cells, thymocytes, and activated T cells	Plasma cell neoplasms, B-cell lymphomas with plasmacytic differentiation, and some chronic lymphocytic leukemias/small lymphocytic lymphomas
CD43	T cells, B cell subset, granulocytes, and monocytes and macrophages	T-cell lymphomas, chronic lymphocytic leukemia/small lymphocytic lymphoma, mantle cell lymphoma, some marginal zone B-cell lymphomas, and Burkitt lymphoma
CD45	Leukocytes	Non-Hodgkin lymphomas and nodular lymphocyte predominant Hodgkin lymphoma
CD45RA	B cells, T-cell subset, granulocytes, and monocytes	B-cell lymphomas and some T-cell lymphomas
CD45RB	B cells, T-cell subset, granulocytes, and monocytes and macrophages	B-cell lymphomas and some T-cell lymphomas
CD45RO	T cells, B-cell subset, granulocytes, and monocytes and macrophages	Most T-cell lymphomas and some diffuse large B-cell lymphomas
CD56	Natural killer cells and T-cell subset	Natural killer cell lymphomas, some cytotoxic T-cell lymphomas, and plasma cell neoplasms
CD57	Natural killer cells and T-cell subset	Natural killer cell lymphomas, some cytotoxic T-cell lymphomas, and diffuse large B-cell lymphoma with ALK expression (rare)
CD68	Monocytes and macrophages	Histiocytic sarcomas and reactive histiocytes in many lymphomas
CD79a	B cells	Most B-cell lymphomas and plasma cell neoplasms
CD103	Intestinal intraepithelial T cells	Enteropathy-associated T-cell lymphoma and hairy cell leukemia
CD138	Plasma cells	Plasma cell neoplasms and some B-cell lymphomas with plasmacytic differentiation
CD246 (ALK)	Neoplastic cells in anaplastic large cell lymphoma	Most anaplastic large cell lymphomas and diffuse large B-cell lymphoma with ALK expression (rare)
Bcl-2	B-cell subset and T cells	Follicular lymphoma and most other B-cell and T-cell lymphomas
Bcl-6	Follicle center B cells	Follicular lymphoma and some diffuse large B-cell lymphomas
Clusterin	Follicular dendritic cells	Follicular dendritic cell sarcoma, anaplastic large cell lymphoma, and follicular dendritic cell meshworks in angioimmunoblastic T-cell lymphoma
CXCL13	Follicle center T-helper cells	Angioimmunoblastic T-cell lymphoma and nodular lymphocyte predominant Hodgkin lymphoma
Cyclin D1	Neoplastic mantle cells	Mantle cell lymphoma, hairy cell leukemia, and some plasma cell neoplasms
Epithelial membrane antigen	Epithelial cells and plasma cells	Anaplastic large cell lymphoma, nodular lymphocyte predominant Hodgkin lymphoma, plasmablastic lymphoma, and plasma cell neoplasms

Fascin	Follicular dendritic cells, histiocytes, Reed-Sternberg cells, and Epstein-Barr virus–infected immunoblasts	Classical Hodgkin lymphoma, Epstein -Barr virus-positive B-cell and T-cell lymphomas, follicular dendritic cell sarcoma
FoxP3	$CD4^+/CD25^+$ regulatory T cells	Adult T-cell leukemia/lymphoma
Granzyme A, B, and M	Natural killer cells and activated cytotoxic T cells	Natural killer cell and activated cytotoxic T-cell lymphomas
IgA, IgD, IgE, IgG, and IgM	Immunoglobulin heavy chains	B-cell lymphomas and plasma cell neoplasms
Kappa and Lambda	Immunoglobulin light chains	B-cell lymphomas and plasma cell neoplasms
Ki-67/mib-1	Nuclear proliferation antigens	
MUM-1	B cells in terminal phase of differentiation, plasma cells, activated T cells, and Reed-Sternberg cells	Lymphoplasmacytic lymphoma, some diffuse large B-cell lymphomas, plasma cell neoplasms, some T-cell lymphomas, and Hodgkin lymphomas
PAX-5	B cells and Reed-Sternberg cells	B-cell lymphomas and Hodgkin lymphomas
T-cell receptor α/β	α/β T cells	Most T-cell lymphomas
T-cell receptor γ/δ	γ/σ T cells	Few T-cell lymphomas
TdT	Lymphoblasts and some myeloblasts	B and T lymphoblastic leukemias/lymphomas
TIA-1	Natural killer cells and cytotoxic T cells	Natural killer cell and cytotoxic T-cell lymphomas

lymphomas (e.g., mantle cell lymphoma vs. small lymphocytic lymphoma [SLL]) (Table 86.2), can identify important nonlineage-related markers (e.g., CD15, CD30, and CD56), and can determine the proliferative rate of lymphomas. Immunoglobulin (Ig) light chain restriction is evidence of B-cell clonality, whereas aberrant B-cell or T-cell phenotypes infer clonality.[1,2] As small monotypic (light chain–restricted) B-cell or genotypically clonal B-cell or T-cell populations may be seen in reactive processes, correlation of these studies with the morphologic features is essential to prevent misdiagnosis and clinical confusion.[3–5]

TABLE 86.2

PATHOLOGIC FEATURES IN THE DIFFERENTIAL DIAGNOSIS OF SMALL B-CELL LYMPHOMAS

			Immunophenotype				
Lymphoma Type	**Growth Pattern**	**Cytology**	**CD5**	**CD10**	**CD23**	**Surface Ig**	**Genetics**
Follicular lymphoma	Nodular (follicular)	Lymphocytes with irregular cleaved nuclei (centrocytes) and admixed large cells (centroblasts)	−	+	−	Bright	t(14;18)(q32; q21) in >85%
Chronic lymphocytic leukemia/small lymphocytic lymphoma	Diffuse with proliferation centers	Small lymphocytes with round nuclei and scant cytoplasm	+	−	+	Weak IgM and IgD > IgG > IgA	Trisomy 12 20% to 30%
Lymphoplasmacytic lymphoma	Diffuse or interfollicular	Small lymphocytes, plasma cells, and plasmacytoid lymphocytes	−	−	−	Moderate IgM	MYD88 L265P mutation
Mantle cell lymphoma	Diffuse or vaguely nodular	Small lymphocytes with irregular nuclei, scant cytoplasm, and few admixed large cells	+	−	−	Moderate IgM and IgD; Lambda > kappa	t(11;14)(q13; q32)
Nodal marginal zone B-cell lymphoma	Interfollicular and perisinusoidal	Small lymphocytes with round, folded nuclei and abundant cytoplasm ± plasma cells	−	−	−	Moderate IgM	None
Splenic marginal zone B-cell lymphoma	Nodular	Biphasic: inner core of small lymphocytes with irregular nuclei and scant cytoplasm; outer core of medium-size lymphocytes with round nuclei and abundant clear cytoplasm +/− plasma cells	−	−	−	IgM +/− IgD	Del 7q
Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue	Diffuse	Small lymphocytes with round, folded nuclei and abundant cytoplasm ± plasma cells	−	−	−	IgM	Trisomy 3 or t(11;18)(q21; q21)

Ig, immunoglobulin; +, positive; −, negative.

Each of the major immunologic techniques has its strengths and liabilities. Flow cytometry permits rapid analysis of large numbers of cells for virtually any surface or cytoplasmic antigen. Flow cytometry is the primary tool used for phenotyping most NHLs and leukemias and is a very sensitive and specific technique for detecting residual disease.[6,7,8,9] Studies for coexpression of more than one marker are easily accomplished (e.g., CD5 on CD19+ B cells). Flow cytometry also allows correlation of phenotypic characteristics with cell cycle kinetics and other biologic features of cells. Data storage in list mode permits retrospective off-line multiparameter analysis of lymphocyte subpopulations. However, for most analyses, flow cytometry requires viable cell populations. The quality of the information produced by flow cytometry is directly related to the quality of the communication between the flow cytometrist and the pathologist. The basic question is, "Is the cell population of interest to the pathologist the same cell population analyzed by flow cytometry?"

Immunohistochemical studies on paraffin-embedded tissue permit direct visualization of antigens on the cell of interest. Leukocyte common antigen (CD45) is a reliable marker for identifying most hematopoietic or lymphoid neoplasms but can be negative in acute leukemias, plasma cell neoplasms, anaplastic large cell lymphoma (ALCL), and classical HLs.[10,11] Two markers that work well in paraffin, such as CD20 (pan-B cell) and CD3 (pan-T cell), are adequate to categorize most NHLs as to their B-cell or T-cell lineage.[12,13] Detection of light chain restriction is most easily achieved in B-cell lymphomas that have abundant cytoplasmic Ig (most lymphomas with plasmacytic differentiation and many large B-cell lymphomas). The major liability of paraffin immunohistochemistry is the loss of some lymphocyte antigens during tissue processing. However, the explosion of fixation-sensitive markers for lymphoma-associated antigens (e.g., CD2, CD4, CD5, CD8, CD10, CD23, cyclin D1, and anaplastic lymphoma kinase [ALK]) has allowed precise classification of most lymphomas in paraffin-embedded tissue, obviating the need to rebiopsy to obtain fresh tissue for flow cytometry and cytogenetics.[14]

Genotypic analysis using the Southern blot technique provides a sensitive, but time-consuming and expensive, means of detecting clonal lymphoproliferations and their lineage. Polymerase chain reaction (PCR) is more sensitive than Southern blot for detecting clonality and also can be performed more rapidly. PCR is particularly helpful for establishing B-cell or T-cell clonality in lymphoproliferations present in paraffin-embedded small biopsies, such as those obtained by endoscopy.[15] These methods are most useful when immunophenotypic studies are inconclusive and are the only practical way of proving B-cell or T-cell clonality. Southern blot and PCR also can demonstrate significant chromosomal abnormalities (e.g., *CCND1*, *BCL2*, and *MYC* gene rearrangements) and viral nucleic acids that may be involved in lymphomagenesis (e.g., Epstein-Barr virus [EBV], human T-cell lymphotropic virus type 1 [HTLV-1], and human herpes virus 8). PCR also is proving valuable in the detection of minimal amounts of residual disease in treated patients.

More recently, FISH applied to paraffin-embedded tissue has allowed detection of critical translocations in NHLs with sensitivity that is much greater than classic cytogenetics on fresh tissue or PCR on fresh or fixed tissue.[16,17,18] FISH can be performed on very small specimens (e.g., smears and touch imprints) and may be completed in less than 24 hours. FISH added to flow cytometry is greatly increasing the opportunity for making rapid primary diagnoses of NHLs on FNA material.[19,20]

In the coming 5 years, it is expected that next-generation whole genome/exome/transcriptome sequencing technologies will alter the way lymphomas are diagnosed, classified, risk stratified, and treated. Already a number of detailed genetic analyses have been published for diffuse large B-cell lymphoma (DLBCL), mantle cell lymphoma, Burkitt lymphoma, hairy cell leukemia, chronic lymphocytic leukemia (CLL), splenic marginal zone lymphoma, and ALCL. These studies have highlighted a marked heterogeneity within histologically defined lymphoma subtypes, but also have identified a range of genetic abnormalities shared between different tumor types. Translation of these findings to meaningful diagnostic, prognostic, predictive, and therapeutic tests and strategies will be the main challenge for the near future.

Classification of Non-Hodgkin Lymphomas

For the clinician, pathologist, and basic scientist working in lymphoid neoplasia, the classification of NHLs is a persistent, confusing, and controversial problem. Several competing classification schemes have evolved, all with their supporters and detractors. In the 1950s, Rappaport developed a classification system based on growth pattern (nodular or diffuse) and cytology of lymphocytes (well differentiated, poorly differentiated, undifferentiated, or histiocytic).[21,22] This scheme enjoyed enormous popularity because of its simplicity and reproducibility, but was superseded by classification schemes that reflected advances in cellular immunology.

In the early 1970s, Lukes and Collins,[23] in the United States, and Lennert,[24] in Kiel, Germany, proposed NHL classifications that related morphology to lymphocyte lineage. Both recognized follicular structures as a histologic correlate of B-cell differentiation. Each subdivided follicular lymphomas by the cytologic appearance of the predominant follicle center cell type: small and large cleaved cells in the Lukes-Collins classification (centrocytes in Kiel classification) and small and large noncleaved (transformed) cells in the Lukes-Collins classification (centroblasts in Kiel classification). For NHLs with diffuse growth patterns, immunophenotypic studies facilitated and, in many cases, were essential for precise classification.[25,26]

In 1982, the Working Formulation (WF) was introduced in an attempt to provide a morphologic classification scheme with prognostic relevance.[27] Although the WF was an improvement over the earlier Rappaport classification, it had the same limitations as all purely morphologic classification schemes, separating biologically closely related lymphomas and grouping together biologically unrelated entities. All consideration regarding immunophenotype was excluded, so that the WF did not foster recognition of new entities.

In 1994, the Revised European American Lymphoma (REAL) classification was proposed and listed well-defined, "real disease entities recognized and diagnosed in daily practice".[28] More recently, the World Health Organization (WHO) classification[29] built on the REAL classification and corrected some of its deficiencies. The WHO classification has many strongpoints and is comprehensive, and its most recent edition includes virtually all lymphoid malignancies described at the time of its publication in 2008 (Table 86.3).[30] It defines diseases by four features: morphology, immunophenotype, genetics, and clinical information. Accordingly, the major diagnostic criteria for each of the major groups of NHL and HL are presented in the following discussion.

B-CELL LYMPHOMAS

B-Cell Lymphoblastic Leukemia/Lymphoma

Lymphoblastic lymphoma is a malignant lymphoma of precursor lymphocytes. Approximately 10% of lymphoblastic lymphomas are of B-cell lineage.[30] They are distinguished from extramedullary acute lymphoblastic leukemia (ALL) by (a) the absence of peripheral blood involvement at presentation, (b) absence or only patchy marrow involvement (<25%) by blast cells, and (c) a clinical picture dominated by extramedullary tumor. Although they

TABLE 86.3

WORLD HEALTH ORGANIZATION CLASSIFICATION OF MALIGNANT LYMPHOMAS

B-cell Neoplasms	T-cell and NK-cell Neoplasms
Precursor B-cell neoplasm	Precursor T-cell neoplasm
B lymphoblastic leukemia/lymphoma	T lymphoblastic leukemia/lymphoma
Mature B-cell lymphomas	Mature T cell and NK cell lymphomas
Follicular lymphoma	Peripheral T-cell lymphoma, NOS
Chronic lymphocytic leukemia/small lymphocytic lymphoma	Angioimmunoblastic T-cell lymphoma
Lymphoplasmacytic lymphoma	Anaplastic large cell lymphoma
Mantle cell lymphoma	Adult T-cell leukemia/lymphoma
Nodal marginal zone B-cell lymphoma	Hepatosplenic T-cell lymphoma
Splenic marginal zone B-cell lymphoma	Subcutaneous panniculitis-like T-cell lymphoma
Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue	Enteropathy-associated T-cell lymphoma
Diffuse large B-cell lymphoma, NOS	Mycosis fungoides/Sézary syndrome
T-cell/histiocyte-rich large B-cell lymphoma	Extranodal NK/T-cell lymphoma, nasal type
Primary mediastinal (thymic) large B-cell lymphoma	
Primary diffuse large B-cell lymphoma of the CNS	
Epstein-Barr virus–positive diffuse large B-cell lymphoma of the elderly	
Rare large B-cell lymphoma types: DLBCL associated with chronic inflammation; lymphomatoid granulomatosis; intravascular large B-cell lymphoma; ALK-positive large B-cell lymphoma; plasmablastic lymphoma; large B-cell lymphoma arising in HHV-8-associated multicentric Castleman disease; primary effusion lymphoma	
Burkitt lymphoma	
Hodgkin lymphomas	
Classical Hodgkin lymphoma	
Mixed cellularity Hodgkin lymphoma	
Lymphocyte-rich classical Hodgkin lymphoma	
Nodular sclerosis Hodgkin lymphoma	
Lymphocyte depleted Hodgkin lymphoma	
Nodular lymphocyte predominant Hodgkin lymphoma	

ALK, anaplastic lymphoma kinase; CNS, central nervous system; DLBCL, diffuse large B-cell lymphoma; HHV, human herpes virus; NK, natural killer; NOS, not otherwise specified.

may occur at any age, the majority of these rare lymphomas have been described in children and young adults. These neoplasms present frequently in extranodal sites such as bone and soft tissue or as skin tumors of the scalp and face.[31,32,33,34] They almost never present as mediastinal masses.

Histologically, they exhibit a diffuse growth pattern with frequent mitoses and a "starry sky" appearance. Linear capsular infiltration and interfollicular involvement is characteristic in lymph nodes. Cytologically, the tumor cells are small to intermediate in size with irregular nuclear borders, dispersed chromatin, small nucleoli, and scant cytoplasm.[33]

Most B lymphoblastic lymphomas are CD19, CD79a, CD10, and terminal deoxynucleotidyl transferase (TdT) positive with undetectable cytoplasmic Ig and variable expression of CD45 (weak to absent) and CD20.[33,34] Only a few surface Ig-positive cases have been described.[35] Lymphoblastic lymphomas in tissue sections may be difficult to distinguish from nonhematopoietic small cell undifferentiated tumors, such as Ewing sarcoma, rhabdomyosarcoma, and neuroblastoma, as well as T lymphoblastic lymphoma and blastoid variants of mantle cell lymphoma. Therefore, immunohistochemical studies are essential for diagnosis.[36,37]

Studies of the genetics of B lymphoblastic lymphoma are limited. The blasts show clonal Ig gene rearrangements without somatic mutation consistent with a pregerminal center cell of origin.[38] It appears that hyperdiploidy or the presence of many of the translocations seen in pediatric ALL, such as t(9;22), t(1;19), and t(4;11), are uncommon. Chromosome 21 additions, including trisomy and tetrasomy, have been described.[34]

Follicular Lymphoma

The WHO classification of follicular lymphomas requires at least a partial follicular growth pattern (Fig. 86.2A). It excludes lymphomas, such as extranodal marginal zone B-cell lymphomas of mucosa-associated lymphoid tissue (MALT lymphomas) and mantle cell lymphomas, which also may have a nodular growth pattern. The incidence of follicular lymphomas is second only to DLBCL in the United States and Western Europe. These usually indolent lymphomas commonly present as painless lymphadenopathy in middle-aged or elderly adults. They commonly involve the bone marrow early.[30] Follicular lymphomas in young children and some extranodal follicular lymphomas (e.g., skin and gastrointestinal tract) tend to be more localized at presentation than nodal follicular lymphomas in adults.[39,40,41,42]

Background

The follicle center is the major site of B-lymphocyte differentiation and proliferation.[43,44] It may also serve as the site of lymphomagenesis of most B-cell lymphomas and HLs.[45] B-lymphocytes move into the follicle after they first encounter protein antigen in the paracortex, to begin a series of steps that ultimately produces plasma cells with high-affinity Ig and memory B cells. Morphologically, the follicular center reflects this biologic transformation by frequent mitoses and by its range of cell types, including cleaved cells (or centrocytes) and large noncleaved cells (or centroblasts). Differentiation results in the Ig heavy chain class switching from IgM to IgG, IgA, or IgE, and in enhanced Ig synthesis. Proliferation produces the clonal expansion that is the basis of immunologic memory and an effective humoral immune response.[43,44]

Somatic mutation in the Ig genes occurring during proliferation is followed by selection of B cells with surface Ig of higher affinity for antigen. Successful interaction of B cells with antigen-bearing follicular dendritic cells triggers B-cell expression of BCL2 protein that saves the B cell from apoptotic cell death.[46] Tingible body macrophages mark the passing via apoptosis of B cells not selected for survival. Somatic mutation may serve to identify those neoplasms that have arisen from B cells that have been exposed to antigen in the environment of the follicle, such as follicular lymphomas and multiple myeloma, versus those that have not, such as most mantle cell lymphomas. Most B-cell NHLs and HLs have extensive somatic mutations.[45,47,48] Somatic mutation of non-Ig genes, such as *BCL6*, may participate in lymphomagenesis.[49] The recognition of the contribution of somatic mutation, receptor editing, and class switching in lymphomagenesis supports a major role for the follicle in neoplastic transformation.[45,50,51]

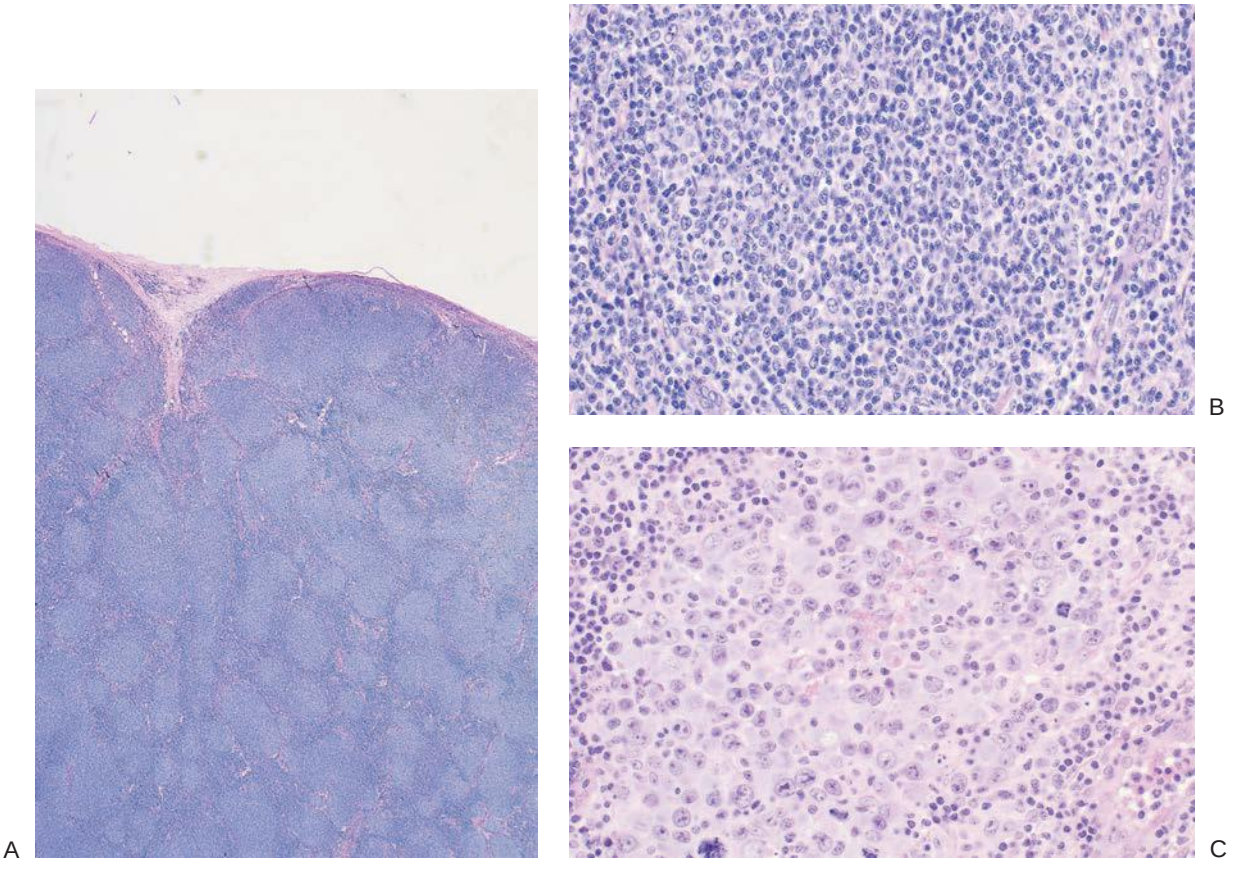

FIGURE 86.2. Lymph node: follicular lymphoma. A: Low magnification demonstrates effacement of architecture by a follicular proliferation producing a nodular pattern. **B:** In a higher magnification, the follicles are composed almost entirely of centrocytes (follicular lymphoma, grade 1), whereas, in **(C)**, from another patient, the follicles are dominated by centroblasts (follicular lymphoma, grade 3).

Grading

A major problem area within follicular lymphoma is grading. Virtually all follicular lymphomas are composed of a mixture of centrocytes and centroblasts. Numerous studies have correlated the number of centroblasts with prognosis. Most studies agree that follicular lymphomas composed predominantly of centrocytes have a more indolent course than those composed predominantly of centroblasts.[52–54] The most popular scheme for subclassification of follicular lymphoma is a modified version of that proposed by Berard, which bases categorization on numbers of centroblasts per standardized high magnification field (HMF) with fewer than six per HMF classified as grade 1 follicular lymphoma, 6 to 15 per HMF as grade 2, and greater than 15 per HMF as grade 3.[55] In all of these schemes of grading, there is substantial subjectivity and often disappointing interinstitutional reproducibility.[56,57]

Morphology

Follicular lymphomas are recognized at low magnification by the effacement of nodal architecture by follicles that crowd one another and fill the cortex and the medulla (Fig. 86.2A). Tingible body macrophages are not seen in contrast to reactive follicles. Mantle zones are usually thin or absent.[58] Occasional patients, usually with limited stage disease, have partial nodal involvement amidst residual reactive lymphoid follicles.[59] A small number of follicular lymphomas show differentiation to marginal zone–like cells with a "halo-like" distribution around neoplastic follicles. These marginal zone cells, although often CD10 and BCL2 protein negative, are genetically identical to the neoplastic cells of the follicles.[60] On high magnification, low-grade (WHO grades 1 and 2) follicular lymphomas are composed of a relatively homogeneous population of centrocytes (smaller than, or the same size as a macrophage nucleus) with twisted nuclei, condensed chromatin, and inapparent nucleoli (Fig. 86.2B). Centrocytes frequently infiltrate the interfollicular areas and capsule. A variable number of centroblasts with oval to round nuclei (greater in size than a macrophage nucleus), dispersed chromatin, and one to three nucleoli that often abut the nuclear membrane also are present. Grade 3 follicular lymphomas, which by definition have an increased number of centroblasts (Fig. 86.2C), have been provisionally subcategorized into 3a and 3b, with the former having a mix of centrocytes and centroblasts, and the latter consisting exclusively of centroblasts.[61] Areas of diffuse growth composed predominately of centrocytes do not appear to affect prognosis.[52] Low-grade follicular lymphomas with a purely diffuse growth pattern are uncommon and may be difficult to separate morphologically from mantle cell lymphoma without immunophenotypic or cytogenetic studies. Recently, an early phase of follicular lymphoma restricted to the B-cell follicles without altering the lymph node architecture has been recognized.[62,63] These are often referred to as "follicular lymphoma in situ," and are identified in lymph nodes removed for other reasons. These lesions appear to have an indolent course with a very low rate of progression to clinically significant follicular lymphoma.

Follicular lymphomas composed mostly of large centrocytes (large cleaved cell lymphoma) are not recognized as a separate entity in the WHO classification. Large centrocytes differ from small centrocytes not only in nuclear size (larger than macrophage nucleus), but also in chromatin pattern, which is more open with occasional small nucleoli. The nuclei are elongated and twisted like small centrocytes. Because of the abundant cytoplasm of tumor cells, the follicles appear pale. A minority of follicular

lymphomas of large centrocytes exhibit a predominantly diffuse growth pattern. Several studies suggest that these lymphomas have a course similar to that of low-grade follicular lymphomas composed predominantly of small centrocytes.[64]

Follicular lymphomas, particularly those arising in the retroperitoneum, have a propensity for extranodal growth and interfollicular sclerosis.[65] Occasionally, follicular lymphomas present with massive nodal necrosis. Immunopositivity for CD20 and clonal Ig gene rearrangements can sometimes be demonstrated in these necrotic lymph nodes without morphologically viable lymphocytes.[66,67] A small number of follicular lymphomas contain plasma cells that may be polytypic or monotypic with the same Ig heavy chain and light chain as the follicle center cells.[68] Rarely, accumulations of intracytoplasmic Ig give cells in follicular lymphomas a signet ring cell–like appearance.[69] A leukemic phase may be present in as much as 10% of patients with low-grade follicular lymphomas. Circulating cells show nuclear irregularity and are immunophenotypically distinct from neoplastic cells of B-cell CLL/SLL or mantle cell lymphoma. Neoplastic transformation to a DLBCL occurs in approximately one-half of cases.[70,71,72,73] Pathology reports should emphasize areas of diffuse growth of large cells, as they are sufficient for regarding the tumor as higher grade regardless of the grade of the tumor in any residual follicles.[74] More recently, a rare form of transformation in which the tumor cells have a blast-like morphology has been recognized. These blastoid variants of follicular lymphoma are aggressive clinically.[75] Another aggressive variant of follicular lymphoma has a low-grade histologic appearance with a high proliferation index on Ki-67 staining.[76] Rare clinicopathological variants of follicular lymphoma include so-called pediatric-type follicular lymphoma[77] and extranodal follicular lymphomas arising in the duodenum, skin, thyroid gland, and genitourinary tract. The pediatric-type follicular lymphoma is characterized by presentation in children and young adults, large cell cytology, lack of *BCL2* gene rearrangement, limited stage disease, and indolent clinical behavior. Similarly, primary extranodal follicular lymphomas tend to have a more indolent behavior irrespective of the large cell component.

Immunophenotype

Follicular lymphomas generally express bright surface Ig fluorescence, but a small number of large cell follicular lymphomas are surface Ig negative.[1] Most follicular lymphomas are $CD10^+$ (WHO grades 1 and 2), as are more than one-half of grade 3 lymphomas.[78] Most follicular lymphomas are BCL6 positive as well. Follicular lymphomas are almost always $CD5^-$, but rare $CD5^+/CD10^+$ cases have been described that often exhibit atypical histopathology such as floral variants or patterns that may be confused with progressive transformation of germinal centers.[79,80] Expression of BCL2 protein may be helpful in differentiating some follicular lymphoid hyperplasia from follicular lymphoma; however, overexpression of BCL2 protein does not help differentiate follicular lymphomas from other NHLs.[81] Overexpression of p53, detected by immunohistochemistry, may identify patients with increased risk for transformation.[82,83] Low-grade follicular lymphomas differ from most other small B-cell lymphomas in having a significant admixture of T cells, and some authors have suggested that large numbers of T cells indicate a favorable prognostic feature.[84] Immunohistochemical and gene expression data have correlated features of the tumor microenvironment such as number of infiltrating macrophages and composition of T-cell subsets with prognosis in follicular lymphomas.[85–88]

Genetics

More than 85% of nodal follicular lymphomas and 25% to 30% of DLBCLs have a t(14;18) (q32;q21) chromosomal abnormality. These numbers are lower in children and in patients with extranodal presentations. Molecular genetic studies and FISH may identify additional cases not recognized by conventional cytogenetics.[89,90,91] Abnormalities of chromosomes 3q27, 5, 7, 12, and 13q are more common in a higher grade (WHO grade 3) or in transformation of follicular lymphoma. Abnormalities of chromosome 8q24 are associated with blastoid variants of follicular lymphoma.[92,93] Recently a subset of follicular lymphomas occurring young adults and children (so-called pediatric follicular lymphoma) has been shown to have translocations involving the *IRF4* gene.[94] The pattern of somatic mutation in follicular lymphomas suggests a role for antigen selection in their clonal evolution.[47,48]

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

B-cell CLL/SLL is a neoplasm of small round B cells that usually have scant surface Ig and a $CD5^+/CD23^+$ phenotype. SLL is the term used to describe the disease when lymph node involvement is the dominant feature. Usually, these lymphomas present in elderly patients with a leukemic phase and generalized lymphadenopathy on routine physical examination. Bone marrow involvement is often extensive. Occasionally, patients present with bacterial infection related to hypogammaglobulinemia or with signs and symptoms secondary to anemia or thrombocytopenia that may have an autoimmune basis. CLL may occur in familial clusters with a decreasing age of onset from generation to generation.[95]

Lymph node architecture is totally effaced with loss of lymphoid follicles and obliteration of sinuses by an infiltrate of monomorphic small round lymphocytes with condensed chromatin and scant cytoplasm. Growth centers or proliferation centers (collections of intermediate-size round lymphocytes with open chromatin and small nucleoli called paraimmunoblasts) are dispersed throughout the lymph node and are thought to represent foci of cell proliferation (Fig. 86.3).[96] Morphologic features that correlate with a worse prognosis include prominent proliferation centers in lymph nodes or increased numbers (>10%) of prolymphocytes (intermediate-size lymphocytes with prominent central nucleoli) in the blood.[97,98] A clinically aggressive paraimmunoblastic variant of SLL has been described in which cells resembling those in growth centers predominate throughout the node.[99]

Richter syndrome, which is the evolution of CLL/SLL to a large cell lymphoma, occurs in less than 5% of patients and may arise as transformation of the neoplastic small B cell or as an unrelated B-cell clone.[100,101,102] Less commonly, B-cell SLL may transform to prolymphocytic leukemia.[103] Rarely, HL complicates B-cell SLL.[104] Of interest is a description of 13 cases of B-cell SLL with Reed-Sternberg (RS)–like cells that contained EBV RNA as detected by in situ hybridization; three of these patients developed disseminated HL.[105] The diagnosis of concurrent HL in a lymph node with CLL/SLL requires both RS cells and a polymorphic reactive cell background.

On immunologic typing studies, neoplastic lymphocytes have weak or scant monotypic surface Ig, which usually is IgM associated with IgD. Neoplastic lymphocytes coexpress the nominal T-cell antigen CD5 with B-cell markers CD19, CD20 (weak); CD21, CD11c (weak); and CD23. The tumor cells are negative for FMC7, CD10, and cyclin D1. Phenotypically, SLL and CLL are identical.[106] Admixed T cells are usually few in number. CD23 expression and FMC7 and cyclin D1 negativity are helpful in the phenotypic separation of CLL/SLL from mantle cell lymphoma, another $CD5^+$ small B-cell neoplasm.[107] With the increased use of flow cytometry, small populations of circulating light chain–restricted B cells with a CLL/SLL phenotype are being detected in asymptomatic patients with no clinical features of neoplasia.[108]

Classic cytogenetic studies demonstrate specific chromosomal abnormalities in more than one-third of patients with CLL/SLL, with FISH detecting abnormalities of chromosomes 11, 12, 13,

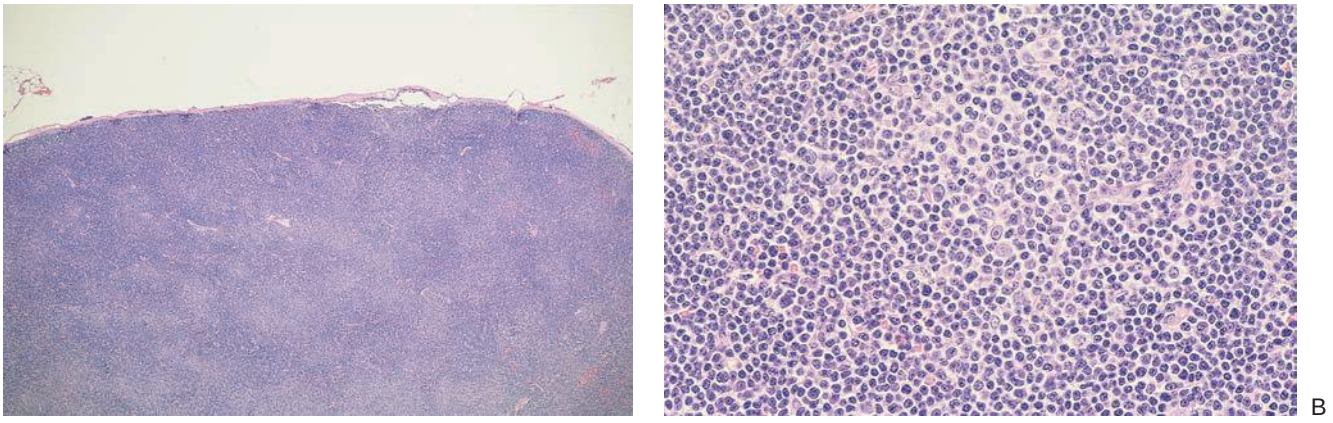

FIGURE 86.3. Lymph node: chronic lymphocytic leukemia/small lymphocytic lymphoma. A: Low magnification shows diffuse alteration of architecture, with pale areas corresponding to proliferation centers. **B:** A higher power of a proliferation center that is composed of intermediate-sized cells with small nucleoli that are surrounded by small round lymphocytes.

and 17 in almost two-thirds of patients. Deletion of 13q is the most frequent abnormality and correlates with a stable clinical course in older patients. Trisomy 12, *ATM* deletions (11q), and *TP53* deletions (17p) are associated with progressive disease.[109,110] Molecular genetic studies divide CLL/SLL into two major groups based on the presence or absence of somatic mutation. The absence of somatic mutation is associated with a more aggressive clinical course and correlates with an increased expression of CD38 and the tyrosine kinase, ZAP-70.[111,112,113,114,115] Risk stratification in CLL/SLL has therefore become an increasingly complex and controversial exercise with no clear consensus as to the relative roles of cytogenetics, molecular genetics for somatic mutation status, and use of surrogate markers such as CD38 and ZAP-70.[116,117]

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphomas (LPLs) are uncommon B cell neoplasms composed of small lymphocytes, plasmacytoid lymphocytes, plasma cells, and variable numbers of large lymphocytes. These lymphomas, like CLL/SLL, often have marrow involvement and a leukemic phase. They are often associated with high levels of an IgM paraprotein (Waldenström macroglobulinemia) or type II cryoglobulinemia.[118,119] Some patients have antecedent systemic or localized abnormal immune reactions, such as Sjögren syndrome.[120] Many patients have hepatitis C infection.[121] LPL must be differentiated from other small B-cell lymphomas that frequently exhibit plasmacytic differentiation, including nodal and extranodal marginal zone B-cell lymphomas.

LPLs are morphologically diverse and may cause diffuse or partial alteration of lymph node architecture. Many have an interfollicular distribution and abundant macrophages that may impart a mottled low magnification appearance, resembling HL. On high magnification, small lymphocytes are admixed with variable numbers of plasma cells, plasmacytoid lymphocytes, and admixed large lymphocytes. Other features indicating plasmacytic differentiation include Dutcher bodies (cytoplasmic Ig inclusions that appear to be intranuclear) and extracellular periodic acid-Schiff–positive material. Mast cells and hemosiderin-laden macrophages are often present. These lymphomas may transform to large cell lymphomas.[122–124] These higher grade lymphomas usually produce the same Ig heavy chains and light chains as the original tumor.

Plasmacytoid lymphocytes and plasma cells contain abundant intracellular Ig, which usually is monotypic IgM without IgD and can be detected using paraffin immunoperoxidase reactions. In cell suspension studies, neoplastic lymphocytes usually express more surface Ig than is usually seen in CLL/SLL.[124] Tumor cells express pan–B-cell markers CD19 and CD20 and are usually $CD5^-$ and $CD10^-$.[125,126] As the tumor cells are actively secreting Ig, many patients have high levels of monoclonal IgM producing hyperviscosity (Waldenström macroglobulinemia). The IgM may have rheumatoid factor activity or function as cryoglobulin, or both.[118] Less commonly, these neoplasms may be associated with production of other Ig heavy chain classes.[127]

LPLs lack translocations involving the Ig heavy chain gene locus but most have a 3p22.2 abnormality resulting in the somatic mutation *MYD88* L265P, particularly in patients with Waldenström macroglobulinemia.[128,129] This variant is present in few cases of other B-cell neoplasms that have features similar to LPL. Somatic mutations of Ig genes are commonly found in Waldenström macroglobulinemia.[130,131]

Mantle Cell Lymphoma

Mantle cell lymphoma is a B-cell lymphoma typically composed of small lymphocytes with irregular nuclear outlines that have a $CD5^+$ and $CD23^-$ phenotype and overexpress cyclin D1. These lymphomas are usually widespread at diagnosis with generalized adenopathy and extensive bone marrow involvement. They may involve extranodal sites, such as the Waldeyer ring, or present as lymphomatous polyposis of the lower gastrointestinal tract.[132,133,134] A few have a leukemic phase mimicking CLL, prolymphocytic leukemia, or acute leukemia (blastoid variants of mantle cell lymphoma).[135] Recognition of mantle cell lymphoma is clinically important, as these lymphomas pursue a more aggressive clinical course than other small B-cell lymphomas.[136,137]

Mantle cell lymphomas are composed of small lymphocytes with irregular nuclear contours. Mitotic activity is often brisk, and large lymphocytes are usually few in number except in the pleomorphic form of the blastoid variant, in which they predominate. Mantle cell lymphomas usually have a diffuse growth pattern (Fig. 86.4A,B) or surround reactive germinal centers in a mantle zone pattern. Extension of the lymphoma into the capsule and perinodal fat is common.[132,133,138] The blastoid variant of mantle cell lymphoma is characterized by nuclei with increased size, dispersed chromatin, small nucleoli, frequent mitoses, and an aggressive clinical course. There is now molecular genetic evidence that at least some blastoid variants of mantle cell lymphoma are morphologic transformations of typical mantle cell lymphoma.[139] The differential diagnosis of blastoid transformation of mantle cell lymphoma includes acute leukemia involving lymph nodes and lymphoblastic lymphoma.[37,140]

The neoplastic cell shares immunophenotypic features with normal mantle zone lymphocytes, including moderate amounts of surface IgM, usually with IgD. Neoplastic cells are generally $CD5^+$ and $CD10^-$, but a subset of mantle cell lymphomas has $CD5^-$ tumor cells.[141] Mantle cell lymphomas usually mark with

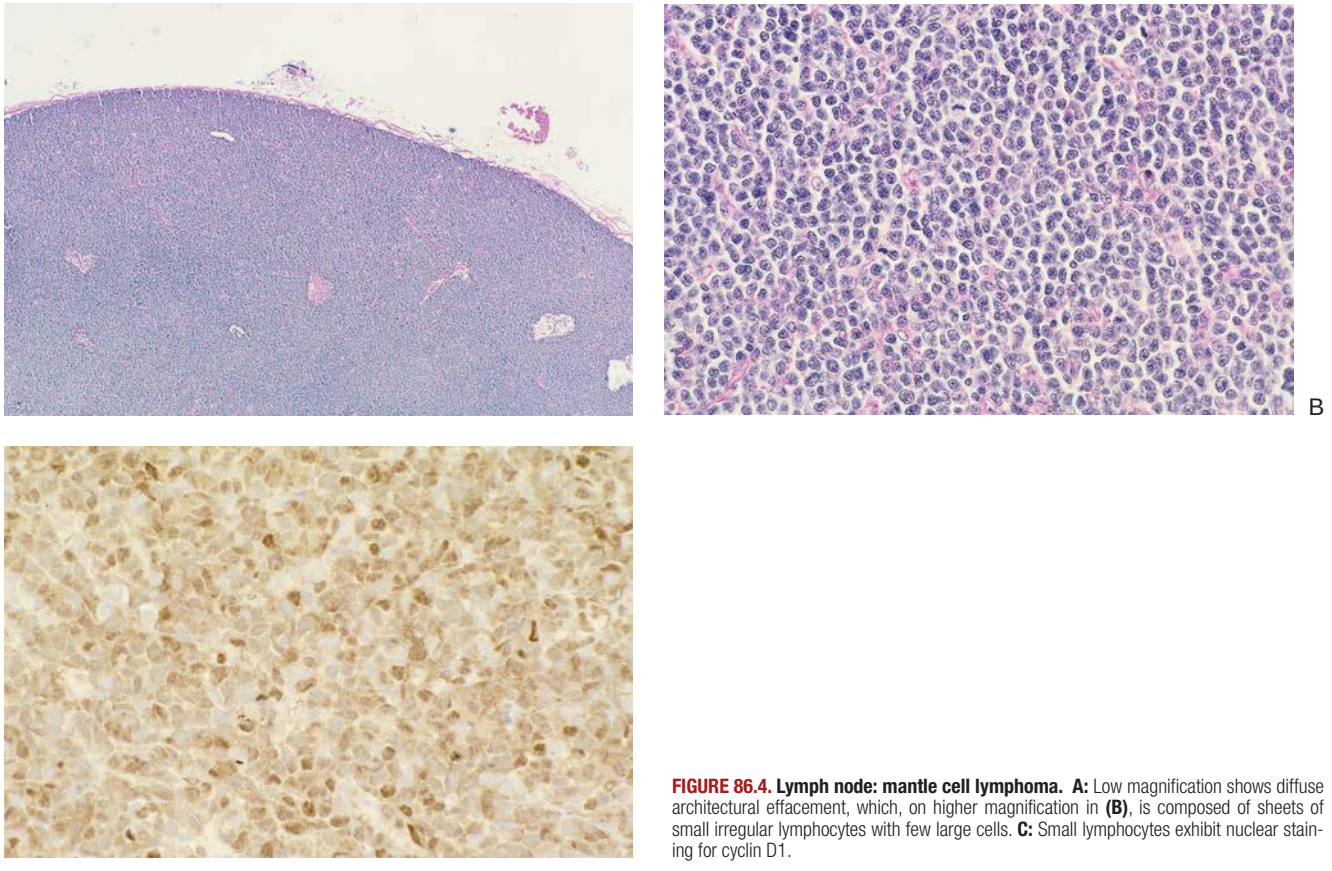

FIGURE 86.4. Lymph node: mantle cell lymphoma. A: Low magnification shows diffuse architectural effacement, which, on higher magnification in **(B)**, is composed of sheets of small irregular lymphocytes with few large cells. **C:** Small lymphocytes exhibit nuclear staining for cyclin D1.

antibodies to pan–B-cell antigens CD19, CD20, and CD22. CD23 is negative or sometimes partially expressed, and FMC7 is positive in contrast to the tumor cells of CLL/SLL.[107,142] Overexpression of cyclin D1 is almost universal in mantle cell lymphoma[143] (Fig. 86.4C), is not seen in follicular lymphoid hyperplasia, and is uncommon in other small B-cell malignancies, with the exception of plasmacytic neoplasms and hairy cell leukemia.[144] Recent gene expression studies have identified *SOX11* expression as another specific marker for mantle cell lymphoma.[145] Rare "in situ" mantle cell lymphomas have been recognized in which cyclin D1–positive cells fill unexpanded mantle zones without distortion of nodal architecture.[146] The clinical significance of these cases is unclear at this time. High Ki-67 expression is associated with a poor prognosis.[147,148]

On classic cytogenetics, most cases of mantle cell lymphoma show evidence of t(11;14) (q13;q32) involving the cyclin D1 gene (*CCND1*).[149,150] FISH analysis of paraffin-embedded tissue extends the sensitivity of t(11;14) detection to greater than 90% and does not require fresh or frozen tissue.[16] Rare cyclin D1-negative mantle cell lymphomas exhibit a gene expression profile similar to cyclin D1-positive tumors including expression of *SOX11*.[151] The former cases show overexpression of cyclin D2 or cyclin D3 without translocations involving these genes. Almost one-third of patients with mantle cell lymphoma have somatic mutation of their Ig heavy chain genes. The presence of somatic mutation is associated with nonnodal disease, lack of *SOX11* expression, and a more indolent clinical course.[152,153,154]

Nodal Marginal Zone B-cell Lymphoma

Nodal marginal zone B-cell lymphomas represent a rare, clinically and biologically heterogeneous entity.[155–157] The diagnosis often rests on exclusion of other possible lymphomas, in particular, nodal involvement by splenic marginal zone B-cell lymphoma (SMZL) and extranodal marginal zone B-cell lymphoma of MALT lymphoma. Clinically, these lymphomas appear more aggressive than other marginal zone lymphomas.[158] They have a tendency to early relapse, and a small minority transform to large cell lymphoma.[157]

Nodal marginal zone lymphomas characteristically involve the interfollicular areas of lymph nodes and are composed predominantly of "monocytoid" small- and medium-sized lymphocytes of uniform size with distinct cell membranes that surround an abundant amount of pale cytoplasm. Nuclei are bland and oval to coffee bean in shape. In some cases, plasma cells are prominent.[159,160] Admixed large lymphocytes are present, and mitotic activity is variable.[155]

Nodal marginal zone B-cell lymphomas express pan–B-cell antigens (CD19, CD20, and CD79a) and monotypic Ig (IgM without IgD) and are typically negative for CD5, CD10, and cyclin D1. A variable number are positive for BCL2 protein and CD43.[155,156]

Genetic studies are limited and have not identified any common cytogenetic abnormalities. Somatic mutation is usually, but not always, present in the Ig genes.[156]

Splenic Marginal Zone B-cell Lymphoma

SMZL is a rare disease accounting for approximately 1% of all lymphomas and approximately 20% of lymphoproliferative disorders in diagnostic splenectomy specimens.[161,162] SMZL is a small B-cell lymphoma of the white pulp of the spleen that often involves the splenic hilar lymph nodes, bone marrow, and peripheral blood.[163] The patients typically present with splenomegaly, B symptoms (fever, weight loss, and night sweats), abdominal pain, and cytopenias.[164,165] A low level of monoclonal paraprotein can be detected in approximately one-half of the patients.[166,167]

The spleen is massively enlarged, weighing well over 1,000 g in most cases. Microscopically, the most striking feature is a nodular infiltrate centered on the preexisting white pulp lymphoid follicles.[168] The tumor has a biphasic pattern with an inner core of small lymphocytes and an outer margin of medium-sized lymphocytes. The inner central zone of small lymphocytes resembles normal mantle zone cells with scant cytoplasm and small irregular nuclei, clumped chromatin, and indistinct nucleoli. The lymphocytes occupying the marginal zone appear similar to normal splenic marginal zone lymphocytes. These have well-defined clear cytoplasm and round/oval nuclei with a more open chromatin pattern and indistinct nucleoli. Variable numbers of large lymphocytes with prominent nucleoli are also present in the marginal zone. Occasionally, plasmacytic differentiation within the marginal zone or in the center of the nodules can be observed. Bone marrow involvement is nodular or interstitial and frequently intrasinusoidal. Tumor cells in peripheral blood often have short villous projections.[163,166] This cytologic appearance is the reason why some cases of SMZL were called splenic lymphoma with villous lymphocytes. Transformation to large B-cell lymphoma is seen in as many as 15% of cases.[169]

Neoplastic cells are CD45, CD20, and BCL2 protein positive with monotypic IgM, with or without IgD. Tumor cells are negative for CD10, CD21, CD43, and cyclin D1, and in most cases, for CD5.[163,164,168] Unlike hairy cell leukemia, they are usually CD11c, CD103, and DBA.44 negative.

Allelic loss of 7q21–32 is seen in slightly less than one-half of patients.[170] Chromosomal translocations that are seen in other small B-cell lymphomas involving *CCND1*, *BCL2*, and *MALT1* are not present. On molecular genetic studies, approximately one-half of cases show somatic mutation, and one-half have unmutated Ig genes.[171] The latter group more frequently has deletions and allelic loss of 7q31–32 and may have a worse prognosis.

Recently, a primary low-grade B-cell splenic lymphoma showing morphologic features distinct from splenic marginal lymphoma has been described. This entity is often referred to as "splenic diffuse red pulp small B-cell lymphoma." It is characterized by diffuse red pulp involvement in the spleen, intrasinusoidal involvement in the bone marrow, more frequent expression of IgG and DBA.44 by immunohistochemistry, bright expression of CD11c and CD22 by flow cytometry, and an indolent clinical behavior.[172,173]

Extranodal Marginal Zone B-cell Lymphoma of Mucosa-associated Lymphoid Tissue

Extranodal marginal zone B-cell lymphoma of MALT lymphoma is the third most common type of NHL, accounting for approximately 6% to 8% of all NHLs in the Western hemisphere.[174] Although MALT lymphomas are clinically indolent, the disease is typically chronic, requiring long-term clinical surveillance and, often, repeated biopsies.[175,176]

Most MALT lymphomas arise in mucosal sites devoid of organized lymphoid structures. Development of MALT lymphoma is often preceded by a chronic inflammatory process that leads to acquisition of lymphoid tissue.[177,178–187] This forms the background for the emergence of the lymphoma. The examples of chronic inflammatory processes that are associated with MALT lymphoma development are listed in Table 86.4.

The infectious process not only creates the microenvironment for development of the tumor but also the microenvironment necessary to sustain the tumor progression. Eradication of the infectious etiology has been shown to lead to remission in gastric, orbital, and cutaneous MALT lymphomas and is recognized as the first line of therapy, particularly for gastric MALT lymphoma.

MALT lymphomas are cytologically low-grade lymphoid neoplasms and are thought to arise from the marginal zone B-cell compartment of the mucosal lymphoid follicles.[188] The cytologic features and the architecture of the tumor often mimic the features of normal mucosal organized lymphoid tissues such as intestinal Peyer's patches. For this reason, many of the cases have been mistakenly diagnosed as pseudo-lymphomas before the application of clonality and genetic studies. MALT lymphomas tend to remain localized at the site of origin for many years. When they disseminate they tend to go to other mucosal sites, a phenomenon thought to be a result of homing programming. Transformation to large cell lymphoma occurs in a minority of cases.[176]

TABLE 86.4

RISK FACTORS FOR EXTRANODAL MARGINAL ZONE B-CELL LYMPHOMAS OF MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT LYMPHOMAS)

Site	Risk Factor	Reference
Stomach	*Helicobacter pylori*	177,178
Intestine	*Campylobacter jejuni*	179,180
Orbit	*Chlamydia psittaci*	181,182
Salivary gland	Hepatitis C virus, autoimmunity (Sjögren syndrome)	183
Thyroid	Autoimmunity (Hashimoto's thyroiditis)	184
Skin	*Borrelia burgdorferi*	185–187

The lymphoma cells assume varied cytologic appearances, often within individual specimens. Characteristic are the centrocyte-like cells, small to medium-sized lymphocytes with irregular nuclei. Alternatively, the neoplastic cells may have a monocytoid appearance with abundant pale cytoplasm and distinct cell borders. The tumor cells also may resemble mature small lymphocytes. Scattered large cells are usually dispersed throughout the lymphoma. Variable numbers of plasma cells are frequently present, often adjacent to epithelium. In approximately one-third of cases the plasma cells are part of the neoplastic clone and may show atypical features such as Dutcher bodies. Regardless of the neoplastic cells' appearance, they produce a diffuse infiltrate that invades epithelial structures, producing lymphoepithelial lesions (Fig. 86.5A,B) and subsequent epithelial disruption.[189] Reactive lymphoid follicles are generally present, and the neoplastic lymphocytes may infiltrate and colonize them.[190]

MALT lymphomas express B-cell antigens (CD19 and CD20) and monotypic surface Ig (usually IgM without IgD). They may be $CD43^+$ but usually lack other antigens expressed by small B-cell lymphomas, such as CD5, CD10, CD23, and cyclin D1. Cytoplasmic Ig is present in cases exhibiting plasmacytic differentiation.[190] These lymphomas demonstrate clonal Ig gene rearrangements and show extensive somatic mutations characteristic of post-germinal center B cells.

The three major chromosomal translocations seen in MALT lymphomas are t(11;18)(q22;q21)/*BIRC3* (*API2*)-*MALT1*, t(14;18)(q32;q21)/*IGH@*-*MALT1*, and t(1;14)(p22;q32)/*IGH*-*BCL10*.[175,176] Remarkably, these appear to promote lymphoma development by a common mechanism. This concordance results from the roles of both the adapter protein BCL10 and the caspase-like protein MALT1 in antigen receptor-mediated activation of nuclear factor kappa B (NFκB), a transcription factor that regulates the expression of genes involved in lymphocyte proliferation and survival.[191,192] Importantly, MALT lymphomas do not carry t(11;14)(q13;q32)/*IGH@*-*CCND1* or t(14;18)(q32;q21)/*IGH@*-*BCL2* chromosomal abnormalities typical of mantle cell lymphoma or follicular lymphoma, respectively.

T(11;18) identifies gastric MALT lymphomas that (a) present with advanced-stage disease, (b) do not respond to *Helicobacter pylori* eradication, and (c) are unlikely to transform to large cell lymphoma.[193,194]

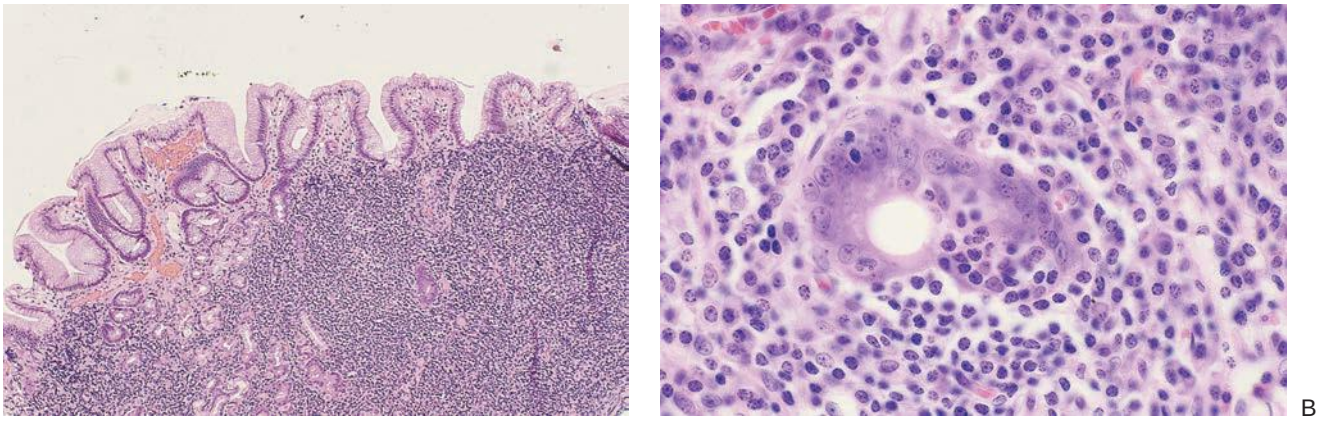

FIGURE 86.5. Stomach: extranodal marginal zone B cell lymphoma of mucosa-associated lymphoid tissue. A: The submucosa contains a diffuse infiltrate of small lymphocytes. **B:** Centrocyte-like cells with moderate amounts of clear cytoplasm invade gastric glands, producing lymphoepithelial lesions.

Diffuse Large B-cell Lymphoma

DLBCLs are a morphologically, phenotypically, and genetically heterogeneous group of mature B-cell malignancies unified by the presence of large (nuclear size greater than the macrophage nuclei) neoplastic B cells. Comprising 30% to 40% of all lymphomas, they are the most common lymphoma type in the United States and Europe.[174,195] A greater appreciation for their complexity has followed from recent clinical, pathologic, and biologic studies, so that the most recent WHO classification recognizes 13 subtypes/DLBCL clinical entities.[30] The more common DLBCL entities are discussed below.

Diffuse Large B-cell Lymphoma, Not Otherwise Specified

DLBCL, not otherwise specified (NOS), occurs in all age groups, with an incidence that increases with age, and with a sight male predominance.[196,197] Though most DLBCL, NOS cases arise de novo, risk factors for DLBCL, NOS include immunosuppression and prior low-grade B cell lymphoma. The most common presentation is as a bulky mass of lymph nodes, but up to 40% of cases arise in extranodal sites, including spleen or bone marrow. Staging bone marrows are involved in approximately 10% to 25% of cases. The pattern of bone marrow involvement may be concordant or discordant—constituted by a lower grade lymphoma. The former is associated with an adverse outcome; the latter with response to initial therapy similar to the cases without bone marrow involvement, but with increased risk for late recurrence.[198]

Morphology

Regardless of the anatomic site involved by DLBCL, NOS, the basic pathologic features are similar. The large neoplastic lymphoid cells grow in a purely diffuse pattern and efface the underlying tissue architecture (Fig. 86.6). Tingible body macrophages, apoptotic bodies, mitotic figures, and zones of necrosis and/or fibrosis variably accompany the neoplastic cells. Three cytologic variants are recognized by the WHO: centroblastic, immunoblastic (Fig. 86.7), and anaplastic.[197] Rounded nuclei, dispersed chromatin, multiple small nucleoli, and modestly abundant basophilic cytoplasm characterize centroblastic DLBCL. These cells resemble the centroblasts of normal germinal centers. Round nuclei, with dispersed or marginated chromatin, prominent single centrally located nucleoli, and abundant cytoplasm usually eccentrically distributed relative to the nucleus are the cytologic features of immunoblastic DLBCL. Patients whose DLBCL contains 90% of cells with immunoblastic cytology may have an adverse outcome.[196,199] A pleomorphic cell population that includes multinucleated tumor giant cells constitutes anaplastic DLBCL. The designation "anaplastic" for a DLBCL is a cytologic descriptive term that should not be confused with anaplastic large cell lymphoma, now considered a separate lymphoma entity comprised of neoplastic T cells. Occasional DLBCL have further cytologic diversity that includes signet ring cells, cells with multilobate nuclei, or spindle-shaped cells.

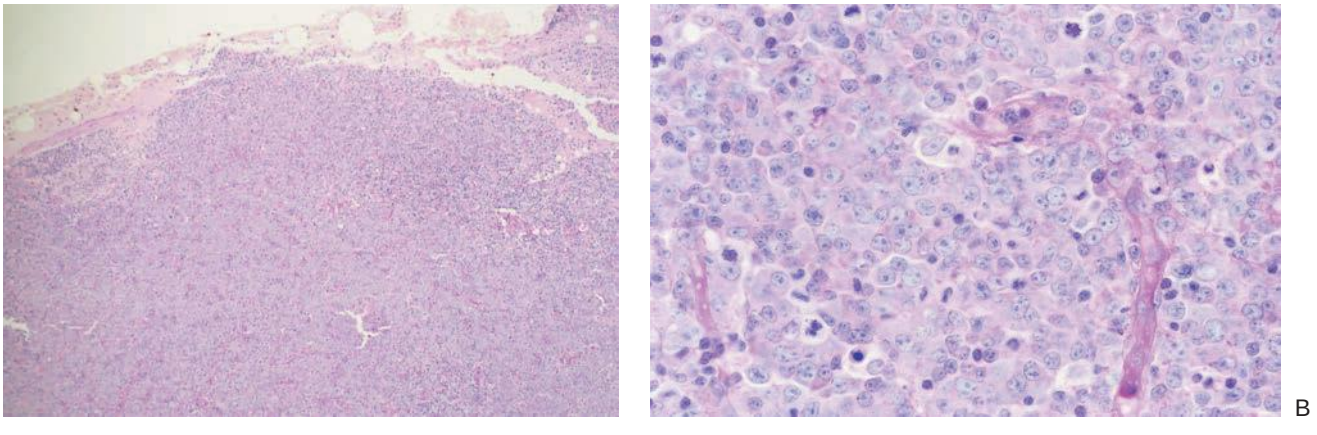

FIGURE 86.6. Lymph node: diffuse large B cell lymphoma. A: On low magnification, a neoplastic large lymphocyte population diffusely effaces lymph node architecture. **B:** On high magnification, round nuclei, partially clumped chromatin, small nucleoli and modest amounts of pale cytoplasm characterize the tumor cells. Note the apoptotic bodies and mitotic figures.

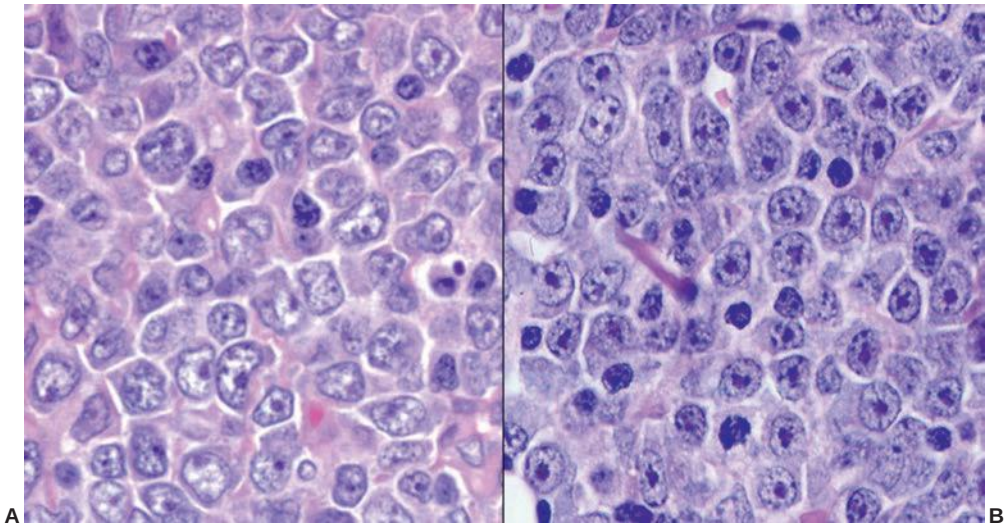

FIGURE 86.7. Lymph node: cytologic variability in diffuse large B cell lymphoma. **A:** Centroblastic. **B:** Immunoblastic.

Immunophenotype

DLBCL cells express CD45 and a variety of pan–B-cell antigens, including CD19, CD20, CD22, CD79a, and PAX-5 in almost every case.[200] Ninety percent express light chain restricted surface Ig. Following rituximab (R) therapy, CD20 may be lost from the tumor cells,[201] in which case B-cell lineage is defined by expression of one or more of the other B-cell antigens. Variable subsets of DLBCL express CD10, BCL6, GCET1, LMO2,[202] BCL2, IRF4 (MUM1), and FoxP1.[203] The pattern of expression of these latter markers by immunohistochemistry variably correlates with germinal center (CD10, BCL6, GCET1, LMO2) or nongerminal center (IRF4 and FoxP1) B-cell derivation of the DLBCL as defined by gene expression profiling (Fig. 86.8). Germinal center B cell (GCB)–derived DLBCL are thought to have a better prognosis than non-GCB DLBCL, and so

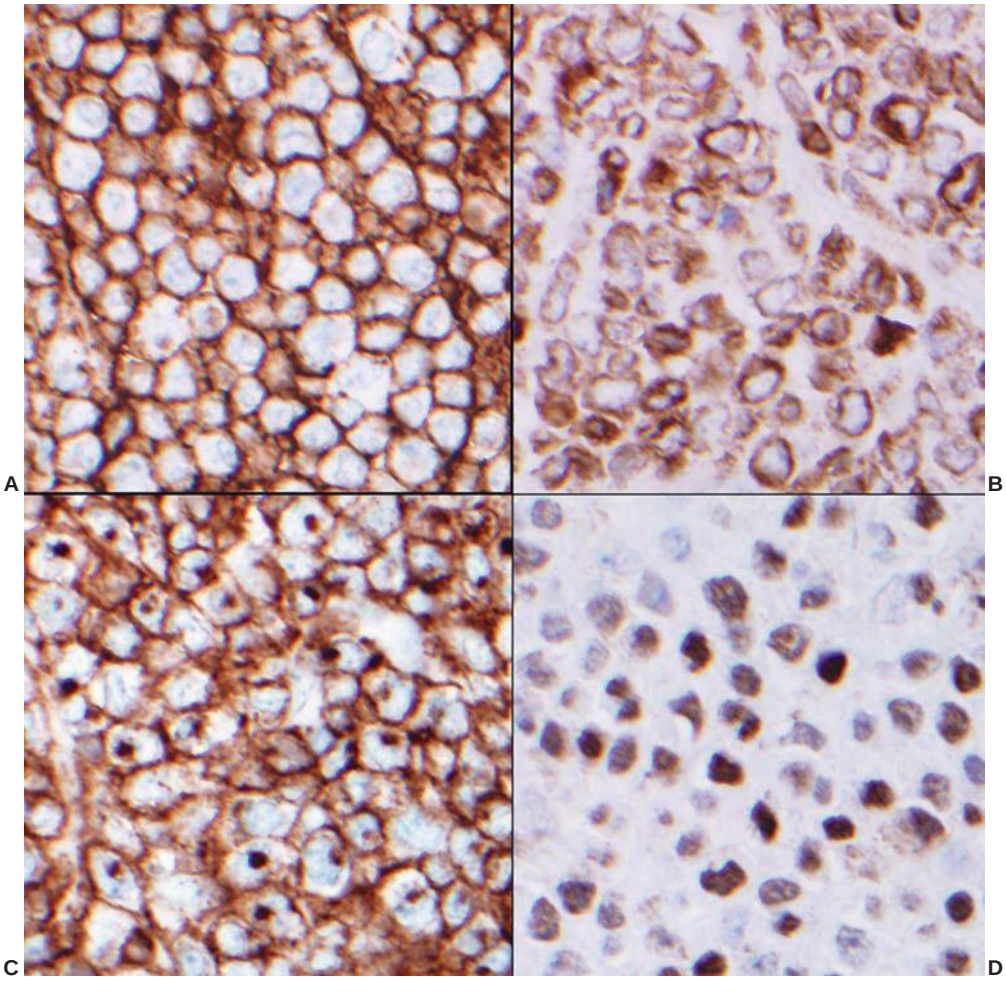

FIGURE 86.8. Lymph node: germinal center B cell lymphoma phenotype. By the criteria of the Hans algorithm this DLBCL has a germinal center phenotype. Using immunohistochemistry on paraffin sections the neoplastic cells express: **A:** CD20, **B:** bcl-2, **C:** CD10, and **D:** bcl-6.

for practical purposes, several immunohistochemistry algorithms, Choi,[204] Hans,[205] Muris,[206] Nyman,[207] and Talley,[208] have been proposed by which GCB and non-GCB are assigned. All have been shown to predict prognosis of R-CHOP–treated DLBCL patients in some, but not all studies. Therefore, phenotyping to assign a DLBCL to the GCB vs. non-GCB subtype for the purpose of selecting optimal therapy has been inconsistently applied to routine practice. Approximately 5% of DLBCL cases express CD5.[200,209] These cases are distinguished from the blastoid variant of mantle cell lymphoma because they are cyclin D1$^-$. They tend to occur in older patients, are more frequent in women than in men, and tend to be disseminated at the time of diagnosis.[209] They are biologically distinct by genetic and gene expression profiling studies,[210,211] but are not recognized as a separate entity in the WHO classification. One other marker of interest in DLBCL is Ki-67, a marker of cells in cycle. The fraction of Ki-67$^+$ cells in a tumor is a general indicator of its proliferative rate. Ki-67 positivity ranges from 30% to nearly 100% in DLBCL cases, and it too, if expressed in greater than 90% of the cells, has been suggested as an adverse prognostic indicator in DLBCL.[212]

Genetics

There is no single genetic abnormality that typifies DLBCL. Rather, a complex karyotype with genetic imbalances occurs in two-thirds of cases.[213] In decreasing frequency, subsets of DLBCL cases have recurrent translocations involving *BCL6* (3q27), *BCL2* (18q21), and *MYC* (8q24) usually, but not always, to Ig heavy or light chain gene loci. *BCL6* and *BCL2* translocations do not predict prognosis in DLBCL patients but *MYC* translocations do.[214] *FAS* and *BCL6*[215] hypermutation are relatively common in DLBCL cases as are amplifications of *REL*[216] and *BCL2*. Finally, particularly in DLBCL that arises from a lower grade lymphoma, p53 deletion or point mutations are also observed.[217] Together these mutations are pathogenetic by promoting entry of the neoplastic cells into the cell cycle, inhibition of apoptosis, promoting genetic instability, and/or producing maturation arrest in the neoplastic cells. Finally, there is a subset of cases of morphologically typical DLBCL that usually express CD10 and BCL2 that contain translocations involving both *MYC* and *BCL2*.[218] Colloquially termed "double-hit" lymphomas, these tumors have a particularly aggressive clinical course and are resistant to most chemotherapy regimens.[219,220,221,222] By convention, they are typically categorized among "*B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma*".[223]

T-cell/Histiocyte-rich Large B-cell Lymphoma

The typical patient with THRLBCL presents with systemic symptoms and widespread disease involving lymph nodes and bone marrow with or without hepatosplenic involvement. THRLBCL occurs at a younger median age than DLBCL, NOS and has a decided male predominance.[224,225–228]

Morphology

In lymph nodes a heterogeneous cell population diffusely effaces the architecture. Small lymphocytes and histiocytes in varying proportions dominate the histologic picture. In contrast, the neoplastic cells are in the minority and are singly distributed without clustering together or forming sheets. Centroblast-like, immunoblast-like, or pleomorphic cytologic features typify the neoplastic cells in most cases (Fig. 86.9). Because the reactive elements

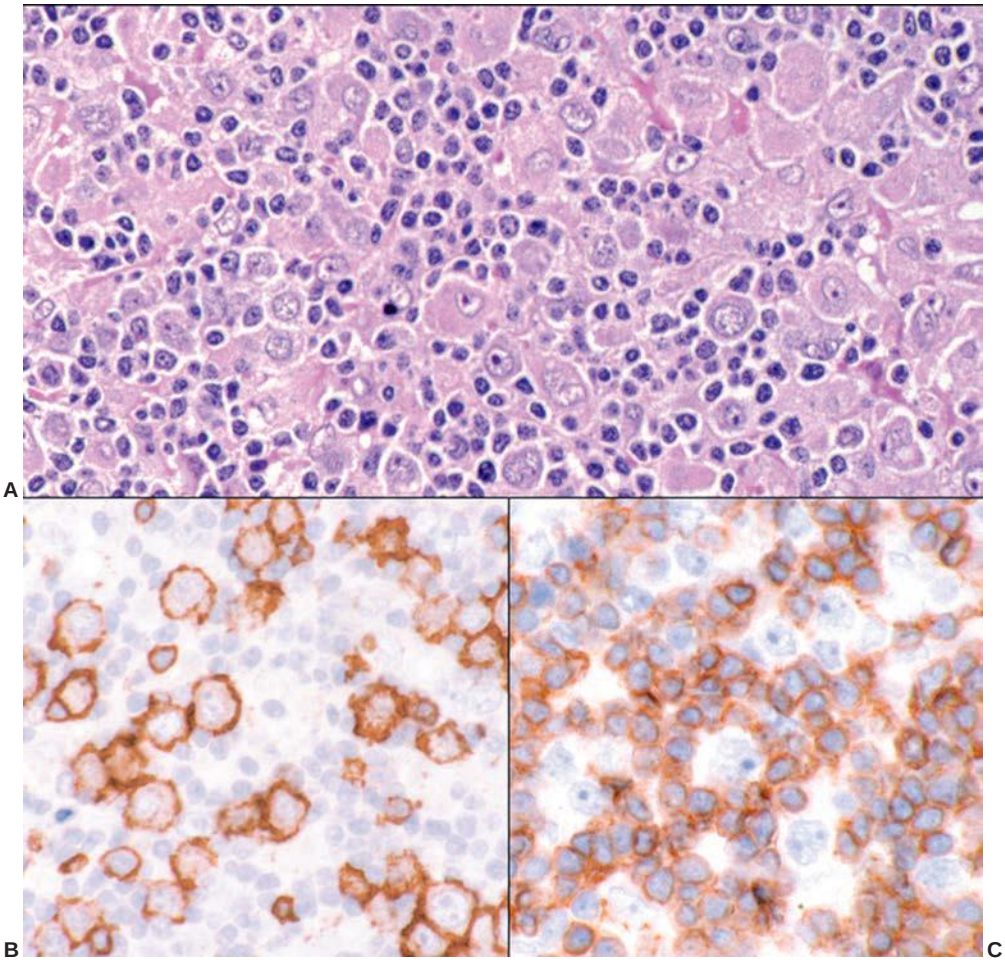

FIGURE 86.9. Lymph node: T-cell/histiocyte-rich large B-cell lymphoma. A: A mixture of small lymphocytes and histiocytes dominates the morphology. Occasional large neoplastic cells with rounded to lobulated nuclei, delicate chromatin, small nucleoli, and pale cytoplasm are present. Immunoperoxidase stains for **(B)** CD20 highlight the neoplastic cells and for **(C)** CD3 demonstrate staining in the nonneoplastic T-cells.

dominate the histologic picture, the challenge in these cases is to recognize THRLBCL as lymphoma rather than a reactive process. In some cases the neoplastic cells have characteristics similar to LP cells of nodular lymphocyte predominant Hodgkin lymphoma (NLPHL); in others they resemble diagnostic RS cells of classical Hodgkin lymphoma (CHL). In these cases the diagnostic challenge is to distinguish THRLBCL from HL. The phenotype of both the neoplastic cells and the reacting cell populations usually resolves the differential diagnostic problems.

Immunophenotype

The large neoplastic cells express CD45 and pan–B cell antigens (CD19, CD20, CD22, and PAX-5), are usually positive for BCL6, and variably express BCL2. They typically lack expression of classical Hodgkin cell–associated markers such as CD15 and CD30. The small background lymphocytes are $CD3^+$ T cells and the histiocytes express CD68 and CD163. Virtually no small nonneoplastic $CD20^+$ or IgD^+ lymphocytes accompany the large cells and the lesions are devoid of both CD57/CD279 (PD-1) rosettes surrounding the neoplastic B cells and $CD21^+$ follicular dendritic cell meshworks. These latter are immunoarchitectural features that help to distinguish THRLBCL from NLPHL.[229]

Genetics

Genetics are nondistinctive. But, as expected, these tumors have a gene expression profile enriched for a T cell/histiocytic host response.[230]

Primary Mediastinal (Thymic) Large B-cell Lymphoma

Primary mediastinal large B-cell lymphoma (PMBCL) is a biologically, clinically, and pathologically distinct lymphoma type[231] thought to arise from a peculiar subset of intrathymic B cells.[232,233] The tumor originates in the thymus, and grows into a mediastinal mass that produces symptoms as it enlarges and infiltrates and compresses local structures such as lung, pericardium, and superior vena cava. Women are affected more commonly than men and PMBCL typically occurs at a younger age (median, 35 years) than DLBCL, NOS.[234,235]

Morphology

A diffusely growing population of medium to large lymphoid cells effaces the architecture of the underlying thymus and infiltrates into adjacent anatomic sites. The tumor cells are variably accompanied by a richly vascular fibrous stroma that frequently circumscribes clusters of neoplastic cells. This can be a cause of diagnostic difficulty, because fibrosis itself and/or compression artifact introduced when biopsying a firm mass, can obscure the tumor cells. PMBCL is cytologically characterized by case-to-case variability. Some examples are composed of cells resembling centroblasts; others contain a prominent population of immunoblast-like neoplastic cells. Cells with multilobulated nuclei and varying amounts of clear cytoplasm or with features of RS or Hodgkin cells can constitute the neoplasm in some cases. This cytologic diversity is not of prognostic significance, but pathologists must appreciate it as part of the possible spectrum observed in PMBCL. A nonneoplastic population of T cells and histiocytes often accompanies, and together with fibrosis can also potentially obscure, the neoplastic cells. Finally, residual thymic Hassall's corpuscles can be found in some cases.

Immunophenotype

The tumor cells express CD45, CD19, CD20, PAX5, and the transcription factors OCT2 and BOB1.[231] They are frequently positive for CD23,[236] BCL6, and IRF4 (MUM1), and either lack or show only variable immunoreactivity for CD30. They are typically negative for surface and cytoplasmic Ig and for CD15. Stains for keratin highlight the residual thymic epithelial elements.

Genetics

Gains in chromosomes 9p24 (75% of cases)[237] and the *REL*[238] locus on 2p (50% of cases) typify PMBCL, which unlike other DLBCL cases only rarely harbors *BCL2* or *BCL6* translocations.

Other Considerations

In gene expression profiling studies, PMLBCL cases are more similar to cases of nodular sclerosis Hodgkin lymphoma (NSHL) than to DLBCL, NOS.[239,240,241,242] Both tumor types contain similar genetic abnormalities and have activation of the NFκB pathway, altered JAK/STAT signaling, and aberrant activation of the PI3K/AKT pathway. Thus it is no surprise that morphologic and clinical overlap between PMBCL and NSHL occurs. In most cases sufficient sampling, careful microscopic observations, and application of immunohistochemical stains can readily distinguish these two from one another. However, in rare instances, PMBCL cannot be distinguished from NSHL. Recognition of this phenomenon has led the WHO to acknowledge a lymphoma category termed "*B cell lymphoma, unclassifiable, with features intermediate between DLBCL and CHL,*"[243] or, colloquially, "gray zone lymphoma."[244] The actual diagnostic criteria for use of this term are incompletely defined. It should be applied rarely and only for those cases where an abundant tissue sample has been comprehensively evaluated by morphology and phenotype and the distinction between PMBCL and CHL is still impossible.

Primary Diffuse Large B-cell Lymphoma of the Central Nervous System

This tumor is defined as a neoplasm of large B cells exclusively involving the brain parenchyma or the eye (retina, vitreous, but not the soft tissues of the orbit).[245] Secondary brain involvement by systemic lymphoma, exclusive meningeal involvement, or a history of immunodeficiency/immunosuppression excludes the diagnosis of primary central nervous system lymphoma (PCNSL). The lymphomas may be unifocal (75%) or multifocal (25%) in the brain. Of patients who present with intraocular involvement, intraparenchymal brain involvement eventually develops in the majority, and about 20% of patients who present with intracerebral disease will develop intraocular involvement. Most patients with PCNSL are elderly. There is a slight male predominance.[246–248]

Morphology

PCNSLs preferentially involve perivascular spaces with varying degrees of infiltration into the brain parenchyma. The neoplastic cells usually have cytologic features of centroblasts or immunoblasts or a combination of both. Reactive astrocytes, activated microglial cells, and histiocytes complete the histologic picture. Preoperative corticosteroid therapy to reduce intracerebral edema prior to biopsy can cause intralesional necrosis or regression of the neoplasm. Sometimes tumor cell ghosts can be recognized within the necrotic areas suggesting the diagnosis, but in some cases steroid therapy leaves behind only a mixture of small T-lymphocytes and histiocytes or sheets of foamy macrophages. Necrosis in a large B cell lymphoma involving the central nervous system (CNS) is also relatively common in cases that are associated with EBV or with immunosuppression. Thus necrotic areas in a large cell lymphoma involving the CNS should raise the question of prior corticosteroid therapy, underlying immunosuppression, or an association of the lesion with EBV, and the diagnosis/classification of the tumor adjusted accordingly.[245]

Immunophenotype

PCNSL cells are $CD19^+$ and $CD20^+$. They almost always express IRF4 and are positive for BCL6 in a substantial subset of the cases. Because they typically lack immunoreactivity for CD10 and are positive for IRF4, only a small subset of PCNSL have a GCB

phenotype using the GCB versus non-GCB immunohistochemistry-based classifier algorithms.[249]

Genetics

Complex karyotypes are common in PCNSL cases. *BCL6* translocations occur in 15% to 45% of cases with both *IGH@* and non-Ig gene partners. Translocations involving *MYC* and *BCL2* are rare in this lymphoma type.[247,250]

Epstein-Barr Virus–Positive Diffuse Large B-cell Lymphoma of the Elderly

EBV-positive DLBCL of the elderly has only recently been formally recognized as a distinct entity.[251] By definition, it occurs in adults greater than 50 years of age who have no identifiable underlying cause for immunosuppression/immunodeficiency. It is presumed that age-related immune senescence allows latently infected EBV^+ B cells to escape from immune surveillance and proliferate to form these tumors. In this regard they are pathogenetically analogous to EBV-related posttransplant lymphoproliferative disorders in which iatrogenic immunosuppression allows for EBV^+ B cell proliferation to occur. EBV-positive DLBCL of the elderly increases in frequency with age, has a male predominance, and typically involves extranodal sites.[252,253]

Morphology

A diffusely growing cell population that not infrequently is associated with necrosis effaces the architecture of the underlying tissue.[254] Many cases are composed of a relatively monomorphic population of large lymphoid cells ("large cell lymphoma subtype") resembling centroblasts and immunoblasts with varying proportions of RS-like cells. The most abnormal-appearing neoplastic cells frequently surround the areas of necrosis (Fig. 86.10A). Other cases, termed "polymorphous subtype" contain a tumor cell population of large immunoblasts, plasma cells, and cells with transition features between plasma cells and immunoblasts. They are often variably mixed with small lymphocytes and histiocytes. While it is no longer thought that "large cell lymphoma" and "polymorphous" subtypes of EBV-positive DLBCL of the elderly carry prognostic significance, pathologists must recognize them as part of the morphologic spectrum of this tumor and therefore it is useful to maintain this distinction.[255]

Immunophenotype

The neoplastic cells in the *large cell lymphoma* subtype of EBV-positive DLBCL of the elderly usually express CD45, CD19, CD20, PAX5, and IRF4 (Fig. 86.10B). They are usually negative for CD10. The greater the number of neoplastic plasmacytoid and plasma cells contained in the tumor, the less frequently CD20 is expressed

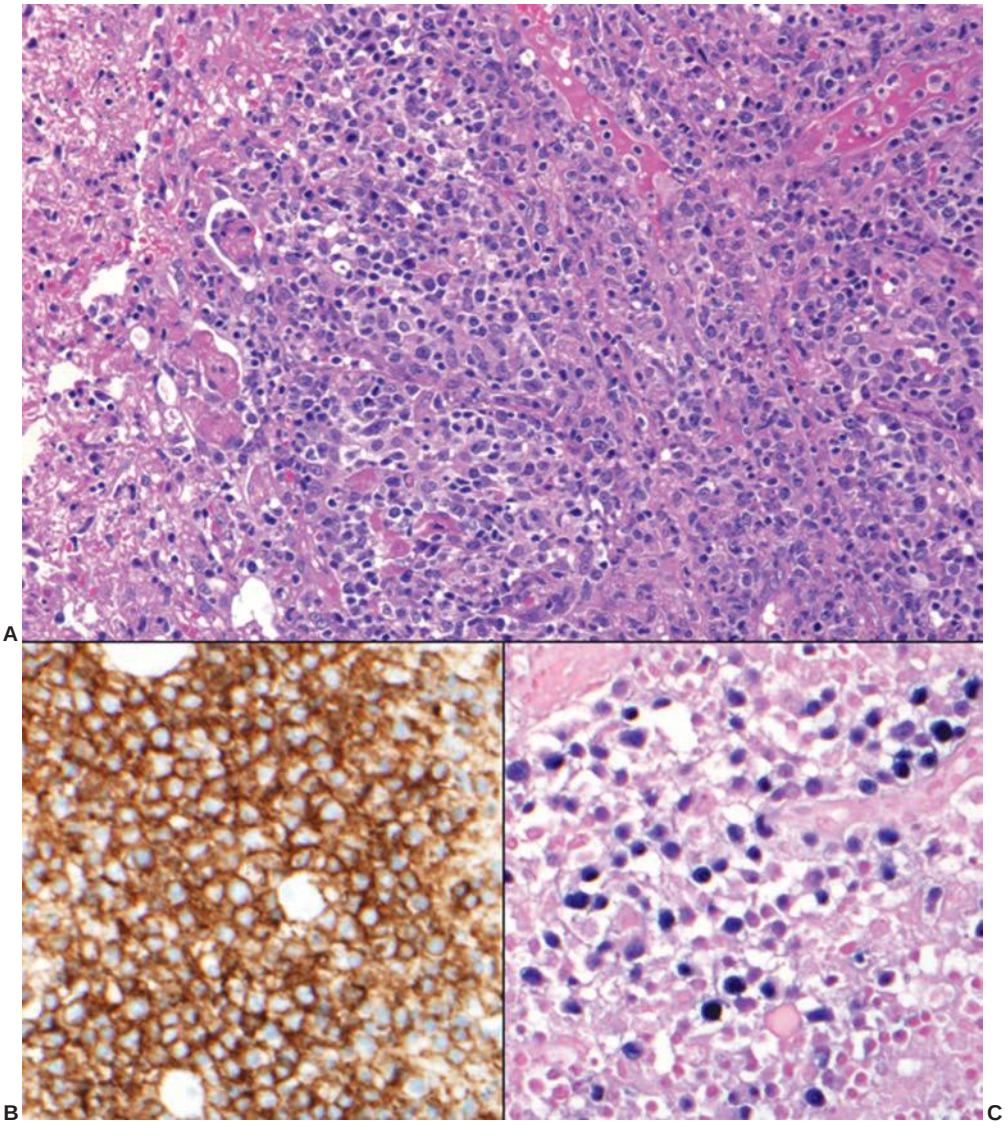

FIGURE 86.10. Soft tissue: EBV-positive DLBCL of the elderly. A: The tumor diffusely effaces tissue architecture and is associated with necrosis (*left*). The neoplastic cells are medium size and large with hyperchromatic, irregular nuclei. They are positive for **(B)** CD20 by immunohistochemistry and for **(C)** EBER by in situ hybridization.

by the tumor and the more frequently IRF4$^+$ and CD138$^+$ cells constitute the tumor cell population. The ease with which light chain–restricted cytoplasmic Ig expression can be demonstrated also increases with increasing plasma cell differentiation in these tumors. By definition, the tumor cells are positive for EBV, most sensitively detected by in situ hybridization with probes that recognize EBV-encoded RNA (EBER) (Fig. 86.10C). By immunohistochemistry, the neoplasms express EBV latent membrane protein (LMP)-1 in 94% of cases and Epstein-Barr nuclear antigen 2 in 28% of cases.[252]

Genetics

Insufficient numbers of cases have been studied to comment on recurring genetic abnormalities in these tumors.

Other Considerations

EBV-positive DLBCL of the elderly has most recently been recognized as the most malignant end of a spectrum of EBV-related lymphoproliferative disorders occurring in adults. While it is outside the scope of this chapter to comment on the more benign entities, EBV reactivation with reactive lymphoid hyperplasia, EBV-associated polymorphous extranodal lymphoproliferations including mucocutaneous ulcer,[256] and polymorphous nodal EBV-associated lymphoproliferations all are within the differential diagnosis of EBV-positive DLBCL of the elderly.[257] The differential diagnosis of EBV-related lesions in adults also includes posttransplant lymphoproliferative disorders and EBV-related lymphoproliferations that occur following immunomodulatory therapy for autoimmune diseases. They are morphologically and phenotypically similar to EBV-positive DLBCL of the elderly. Except in the situation of pathologically and clinically overt DLBCL, consideration of the patient's history and following the clinical evolution of the lesion are important so that aggressive therapy is not prematurely instituted in EBV-associated lymphoproliferative disorders in adults.

Rare Large B-cell Lymphoma Types

Some rare large B-cell lymphoma types have been described in the WHO classification[30] and are shown in Table 86.5 and illustrated in Figure 86.11.

Burkitt Lymphoma

Burkitt lymphoma is a high-grade B-cell lymphoma composed of medium-sized, rapidly dividing lymphocytes. These lymphomas usually affect children and young adults and often present at extranodal sites. Less commonly, they have a leukemic phase. Three clinical forms are recognized: (a) endemic, which classically presents as jaw or facial masses in young boys

TABLE 86.5

RARE LARGE B-CELL LYMPHOMA TYPES

Rare Large B-cell Lymphoma Type	Clinical Features	Morphology	Phenotype	Genetics
DLBCL associated with chronic inflammation[258–261]	• Elderly patients • M:F = 12:1 • Arises in sites associated with longstanding (>10 y) chronic inflammation (e.g., lung/pleura in tuberculosis patients or near prosthetic/chronically inflamed joints)	• Similar to DLBCL, NOS	• Most: CD19$^+$, CD20$^+$, PAX-5+ • Some: CD20$^-$, IRF-4$^+$, CD138$^+$ • Rare: B cells aberrant T cell antigen expression • EBER+ almost all	• Complex clonal karyotype
Lymphomatoid granulomatosis[262,263,264]	• Predominantly adults • M:F = 2:1 • May be immunodeficiency related • Typically extranodal: lung (90%)—prototypic site, kidney, brain, liver, skin, others	• Angiocentric, angiodestructive lympho-histiocytic infiltrates associated with necrotic zones ("granulomatosis") • Varying proportion of large abnormal lymphocytes resembling centroblasts and immunoblasts and small lymphocytes	• Large lymphoid cells: CD19$^+$, CD20$^\pm$, EBER+ • Small lymphocytes: CD3$^+$ T cells enriched in Tia-1 positive cytolytic lymphocytes	• Non-distinctive
Intravascular large B-cell lymphoma[265,266,267]	• Predominantly adults • M:F = 1:1 • Protean clinical manifestations • Anatomic sites: disseminated, bone marrow, brain, lung, skin, kidney, others, but only rarely detectable in peripheral blood • Hemophagocytic syndrome (more common in Asian cases)	• Large neoplastic lymphoid cells resembling centroblasts or immunoblasts • Neoplastic cells confined to blood vessel lumens • Minimal or no extravascular infiltrates	• CD19$^+$, CD20$^+$ • CD5$^+$ in 38%, CD10$^+$ in 13%, remainder are IRF-4+	• Insufficient studied cases
ALK-positive large B-cell lymphoma[268,269,270,271]	• Very rare • Predominantly adults, but described in children • M:F = 3:1 • Anatomic sites: lymph nodes most common, isolated cases reported in extranodal locations	• Preferentially involves lymph node sinuses • Cytologic features similar to immunoblasts/plasmablasts	• CD138$^+$, IRF-4+ • CD20$^-$ (most cases) • ALK+ (entity defining phenotype) • Cytoplasmic Ig light chain restriction and expression of IgH, usually IgA	• t(2:17)(p23;q23); involves *ALK* and *CLTC* genes (most cases) • t(2:5)(p23; q35) involves *ALK* and *NPM* genes • Other rare translocations/insertions involving *ALK*

Plasmablastic lymphoma[272,273,274]	• Predominantly adults • Male predominance • Underlying immunodeficiency in almost all (HIV, immunomodulatory therapy for autoimmune diseases, organ transplant, immune senescence in elderly) • MUST exclude multiple myeloma in EBV negative cases • Anatomic sites: extranodal (oral cavity, nasopharynx, orbit, skin, gastrointestinal, others)	• Diffuse sheets of cells with plasmablastic cytology (round nuclei, marginated chromatin, distinct central nucleoli, eccentrically distributed cytoplasm with a perinuclear hof) variably mixed with more "mature" plasma cells	• $CD138^+$, $CD38^+$, $IRF\text{-}4^+$ • CD20 and PAX-5– to minimally positive • Cytoplasmic Ig light chain restriction and expression of IgH, usually IgG • EBER+ (almost all, if negative, consider myeloma)	• Complex karyotype • *MYC@* translocation usually with *IGH@*, i.e., t(8:14)(q24;q32) in 50%
Large B-cell lymphoma arising in HHV8-associated multicentric Castleman disease[275]	• HIV+ adults • Baseline clinical features of HHV-8-associated multicentric Castleman disease • Severe immunodeficiency associated with asymmetric lymph node enlargement and /or splenomegaly • Also associated with concurrent Kaposi sarcoma	• Background of Castleman disease (regressively transformed germinal centers and interfollicular plasma cell sheets • Progression from isolated immunoblast/plasmablast-like cells in follicular mantles (polyclonal) to aggregates of these cells (emergence of monoclonal proliferation) to sheets of overtly neoplastic large lymphoid cells that diffusely efface tissue architecture	• CD20±, $CD138^-$, IRF-4+ • Cytoplasmic Ig light chain restriction (almost always λ) and expression of IgH, almost always IgM • HHV-8+ (entity defining phenotype) • EBER−	• Insufficient studied cases
PEL[276,277,278]	• Epidemiology linked to cause for immunosuppression (found in almost all cases): young gay HIV+ males, solid organ transplant recipients, elderly patients with immune related immunosenescence, often from Mediterranean countries with high HHV-8 prevalence • Pleural, pericardial and abdominal cavities, minimal organ infiltration, rare lymph node or extranodal cases ("solid PEL")	• Immunoblastic/plasmablastic cytology, often with pleomorphic tumor giant cells and abundant apoptotic bodies in cytocentrifuge preparations or cell blocks made from involved fluids • Preferentially involve sinuses in rare cases involving lymph nodes	• CD45+, $CD19^-$, $CD20^-$, $CD79a^-$ • Surface and cytoplasmic immunoglobulin negative • Variable expression of CD38, CD138, and IRF-4 • HHV-8+ and EBER+ (disease defining phenotype, present in almost all cases)	• Complex clonal karyotype

ALK, anaplastic lymphoma kinase; DLBCL, diffuse large B-cell lymphoma; EBER, Epstein-Barr virus–encoded RNA; HHV, human herpes virus; NK, natural killer; NOS, not otherwise specified; PEL, primary effusion lymphoma.

in equatorial Africa; (b) sporadic, which may present at any age with frequent abdominal involvement; and (c) epidemic (immunodeficiency-associated), such as in patients who are human immunodeficiency virus (HIV)-positive. All subtypes are characterized by chromosomal rearrangements involving the *MYC* oncogene that lead to its inappropriate expression in B cells. The three forms have variable association with EBV infection, 100% in endemic Burkitt lymphomas and 20% to 40% in sporadic and immunodeficiency-associated Burkitt lymphomas.[30,279–281]

Burkitt lymphomas typically have a diffuse growth pattern that is dominated on low magnification by the "starry sky" produced by tingible body macrophages (Fig. 86.12A). Tumor cells may home into residual follicles and often have a cohesive appearance at the interface of tumor and soft tissue. Nuclear size is equivalent to that of endothelial cells or macrophages. The nuclei are round to oval with small nucleoli and a moderate amount of amphophilic cytoplasm. Mitoses are frequent (Fig. 86.12B). On Wright-stained touch imprints, the neoplastic cells show remarkable nuclear homogeneity and the presence of characteristic vacuolated, basophilic cytoplasm.

Immunophenotypically, these lymphomas express pan-B cell antigens, are $CD10^+$ and $BCL6^+$, and are negative for BCL2.[30] They have monotypic surface Ig (usually IgM) and are TdT^-, indicating a mature B cell phenotype. Ki-67/mib-1 staining shows greater than 95% of tumor cells are positive, which is consistent with a high growth fraction.

These tumors have reciprocal translocations involving the *MYC* oncogene mapped to chromosome 8q24, which is usually juxtaposed to the *IGH@* gene on chromosome 14q32. The translocation less commonly involves the κ–light chain (*IGK@*; chromosome 2p12) or λ–light chain (*IGL@*; chromosome 22q11) genes.[282] In endemic Burkitt lymphoma, the translocation breakpoints are located far upstream 5′ to *MYC* and in the joining region of *IGH@*.[283] In the sporadic form, the breakpoints are immediately 5′ to *MYC* and in the switch region of *IGH@*. In the immunodeficiency-associated cases, the breakpoints involve the first exon or intron of *MYC* and the switch region of *IGH@*. Therefore, different mechanisms may generate the chromosomal breakpoints in the various forms of this lymphoma.[284] All forms show the presence of somatic mutation, which is ongoing in some cases of epidemic Burkitt lymphoma.[285,286]

Pediatric Burkitt lymphomas, whether endemic or sporadic, appear to be a more homogeneous entity than adult Burkitt lymphomas in terms of morphology, immunophenotype, and cytogenetics.[219,286,287] Furthermore, there may be considerable overlap in the pathologic features of some adult Burkitt lymphomas and DLBCLs, which makes accurate distinction problematic, resulting in the previously discussed WHO classification category "*B cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma.*"[223] Gene expression profiling may provide a more precise biologic definition of Burkitt lymphoma,[288,289] but this technique is not currently useful for daily clinical practice.

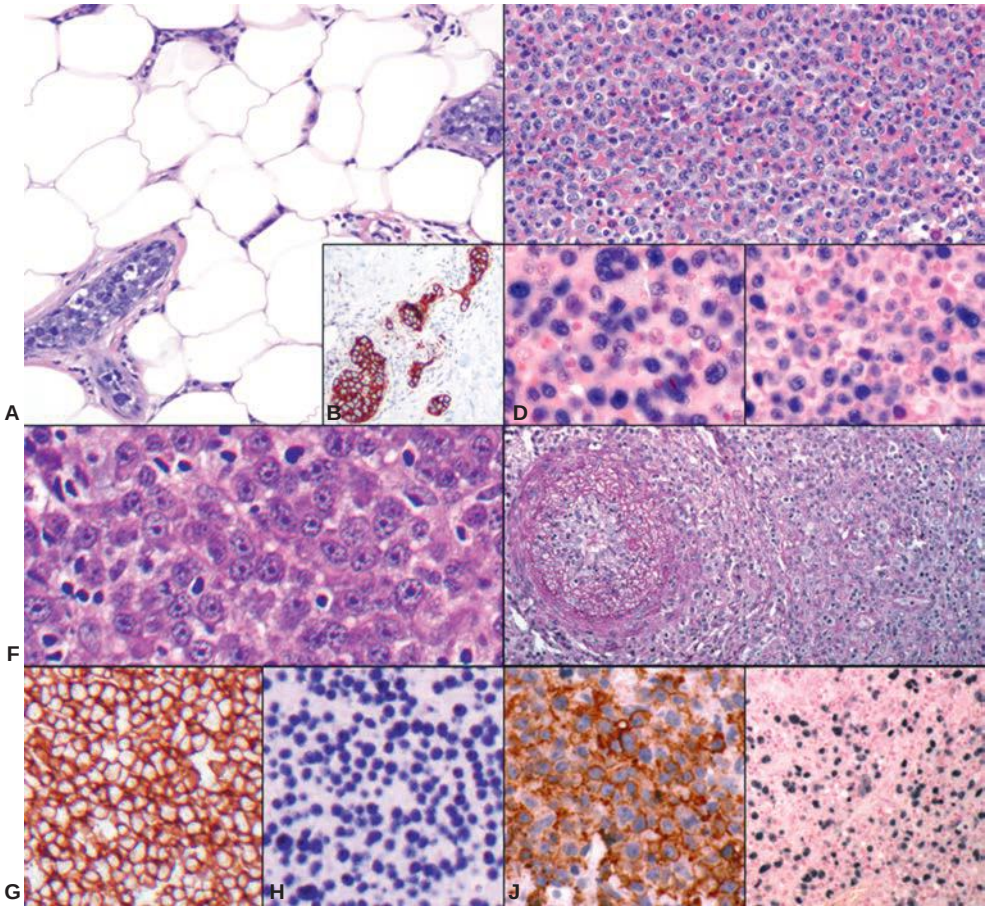

FIGURE 86.11. Various tissue sites: uncommon types of DLBCL. The tumor cells express **(J)** CD20 and are **(K)** EBER positive.

T-CELL AND NATURAL KILLER-CELL LYMPHOMAS

T-cell and NK-cell lymphomas may be grouped together, because their normal counterparts apparently arise from a common progenitor cell that expresses CD3ε and is unable to develop into B cells.[290] Furthermore, some lymphomas from these two lymphoid lineages have considerable morphologic, immunologic, and clinical overlap. Overall, T and NK cell lymphomas are less common than B-cell malignancies, as they comprise approximately 10% of NHLs in the United States and Western Europe.[30]

The WHO classification divides T-cell and NK-cell neoplasms into precursor and mature categories.[30] The mature (peripheral) T-cell and NK-cell neoplasms are subdivided into those that are leukemic, cutaneous and extranodal, and nodal in origin. Most peripheral T-cell lymphomas (PTCLs) are postthymic malignancies that express TCR α/β chains and are apparently derived from the adaptive (antigen-specific receptor-based) immune system (e.g., PTCL, NOS, angioimmunoblastic T-cell lymphoma

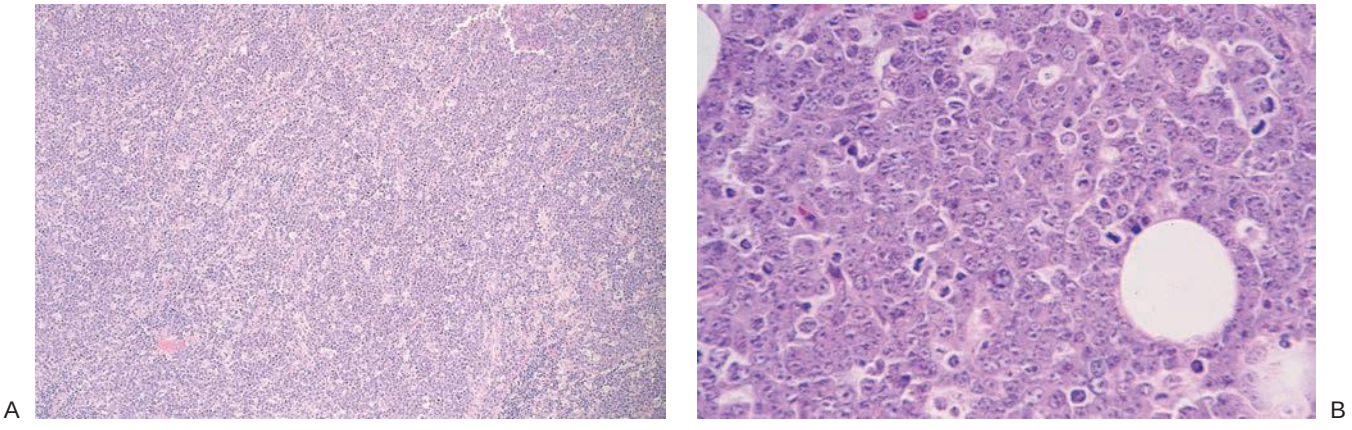

FIGURE 86.12. Lymph node: Burkitt lymphoma. A: The architecture is effaced by a diffuse infiltrate with a "starry sky" appearance. **B:** High magnification shows a monotonous population of small noncleaved lymphocytes with round to oval nuclei and variable cytoplasm. Mitotic figures are frequent. Numerous tingible body macrophages are present.

[AITL], and systemic ALCL).[291] They generally arise in peripheral lymphoid organs from naïve, effector (regulatory [$CD4^+$] and cytotoxic [$CD8^+$]) or memory T cells.[292] NK cell lymphomas and a small number of PTCLs that may be extrathymically-derived are related to the innate (non-MHC–restricted) immune system.[291] The PTCLs in this group (e.g., hepatosplenic T-cell lymphoma [HSTCL], subcutaneous panniculitis-like T-cell lymphoma, and enteropathy-associated T-cell lymphoma [EATL]) tend to arise in mucosal or cutaneous sites, and often express TCR γ/δ chains, NK-cell-associated antigens, and cytotoxic granule-associated proteins, including granzyme M.[293,294,295]

Precursor and peripheral T- and NK-cell lymphomas are discussed in the following sections. T lymphoblastic leukemia (T-ALL) (Chapters 73, 74, and 76), T-cell prolymphocytic leukemia and T-cell large granular lymphocytic leukemia (Chapters 88 and 90) and mycosis fungoides (Chapter 92) are discussed elsewhere in this text.

T Lymphoblastic Leukemia/Lymphoma

T lymphoblastic leukemia/lymphoma is a highly aggressive malignancy of immature (precursor) T cells that generally presents in children and young adults. The lymphomatous form of the disease typically presents as an anterior mediastinal mass, often accompanied by supradiaphragmatic lymphadenopathy. These lymphomas efface the thymic and nodal architecture in a diffuse pattern, and infiltrate the capsule and adjacent soft tissue. Numerous tingible body macrophages impart a "starry sky" appearance similar to Burkitt lymphoma (Fig. 86.13A). Monomorphic neoplastic lymphocytes are small to intermediate in size, contain scant cytoplasm, and have round to convoluted nuclei (Fig. 86.13B). The chromatin is dispersed and blast-like, and nucleoli are usually indistinct. Mitotic figures are abundant. These morphologic features are indistinguishable from disseminated T-ALL[296] and the infrequent B-cell lymphoblastic lymphomas that were discussed previously.

T lymphoblastic lymphomas express diverse T-cell antigens, but most are $CD3^+$ and $CD7^+$. Some lesions correspond to early ($CD1^-$, cytoplasmic $CD3^+$, $CD4^-$, and $CD8^-$), common ($CD1^+$, cytoplasmic $CD3^+$, $CD4^+$, and $CD8^+$), or late ($CD1^-$, surface $CD3^+$, $CD4^+$, or $CD8^+$) thymocytes.[297] Cytoplasmic CD3 expression is the most specific early marker of a T-cell phenotype and is also present in T-ALL.[298,299] TdT is present in T lymphoblastic lymphomas, and 25% of these lymphomas are $CD10^+$. HLA-DR expression is absent in almost all cases unlike B-ALL and most non-lymphoid leukemias. CD34 expression is also uncommon in T lymphoblastic lymphomas. Occasional T lymphoblastic lymphomas express NK-cell–associated antigens (e.g., CD16, CD56, or CD57).[300]

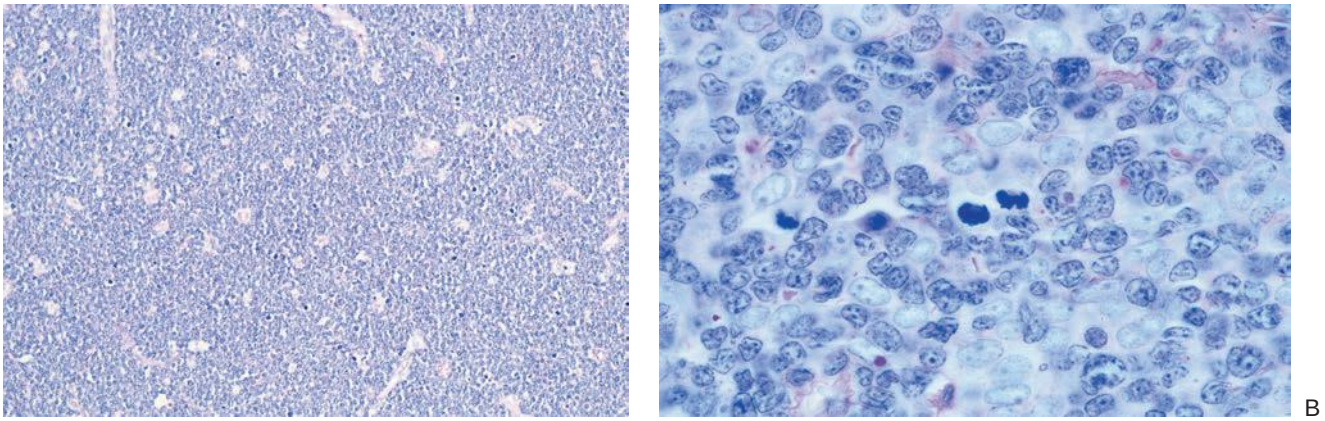
Because T lymphoblastic lymphoma and T-ALL have considerable overlap of morphologic, immunologic, and clinical features, it may be impossible to distinguish between the two for individual precursor T-cell neoplasms. Extensive mediastinal and peripheral lymph node involvement with limited bone marrow and peripheral blood disease favors a diagnosis of T lymphoblastic lymphoma, whereas the presence of greater than 25% T-cell lymphoblasts in the marrow is considered T-ALL.[30]

Peripheral T-cell Lymphoma, Not Otherwise Specified

Several specific types of PTCLs are recognized by the WHO classification, as discussed separately in the following sections. However, nearly one-third of PTCLs do not fit a distinctive type and are regarded as PTCL, NOS. These lymphomas are heterogeneous, but usually present in adults who have disseminated disease accompanied by B symptoms and poor performance status. There is generally a diffuse growth pattern, but rare cases may appear nodular.[301,302] A variety of the following morphologic features may also be seen: neoplastic lymphocytes of varying size that often have clear cytoplasm; large tumor cells that may have hyperlobated nuclei, may be multinucleate, or may resemble RS cells; frequent reactive epithelioid histiocytes; delicate connective tissue bands that segregate cells into clusters; and hypervascularity.[301] These lesions have diverse and often aberrant T cell phenotypes.[303] Most express α/β TCRs and demonstrate TCR gene rearrangements.[304,305] Tumors with a cytotoxic lymphocyte phenotype or that are EBV^+ appear to have a worse prognosis than other lymphomas in this category.[306,307] A recurrent t(5;9)(q31-q32;q22) chromosomal abnormality that fuses *ITK* to *SYK* has been identified in a very small number of PTCL, NOS that tend to have follicular involvement.[308] Rare cases of cytotoxic PTCL, NOS, with skin and bone marrow involvement, have a t(6;14)(p25;q11.2) that fuses *IRF4* to the TCR–alpha (*TRA@*) locus.[309] Otherwise, recurrent chromosomal translocations in PTCL, NOS have not been described. Gene expression profiling may determine different molecular subgroups or therapeutic targets among PTCL, NOS, but the impact of the nonneoplastic cell constituents on the results of such studies must be considered.[310,311]

T-zone Lymphoma

T-zone lymphoma is recognized as a morphologic variant among the PTCL, NOS in the WHO classification.[30] The characteristic histopathologic feature is an interfollicular growth of primarily



A B

FIGURE 86.13. Lymph node: T lymphoblastic lymphoma. A: The nodal architecture is completely effaced by a diffuse lymphoid infiltrate. The interspersed macrophages help impart a "starry sky" appearance. **B:** The neoplastic cells are intermediate in size and have delicate chromatin characteristic of blasts, indistinct nucleoli, and scant cytoplasm. Frequent mitoses are present *(center)*.

small neoplastic T cells with clear cytoplasm that are associated with prominent high endothelial venules and spared secondary lymphoid follicles.

Lymphoepithelioid Cell Lymphoma

Lymphoepithelioid cell (Lennert) lymphoma[312–314] is also considered a morphologic variant among PTCL, NOS in the WHO classification.[30] The most striking histologic feature is the numerous clusters of epithelioid histiocytes that are relatively evenly dispersed throughout tissues obliterated by a lymphomatous infiltrate composed primarily of small neoplastic T cells. This moderately aggressive lymphoma must be distinguished from some cases of HL, B-cell lymphomas, and other PTCLs that are also accompanied by a high content of epithelioid histiocytes.[123,315–317] Misinterpretation as a reactive process may occur when attention is focused on the histiocytes rather than on the lymphoid infiltrate that destroys tissue architecture. When localized, Lennert lymphoma tends to involve the head and neck region, particularly cervical lymph nodes and sometimes the Waldeyer ring.

Follicular T-cell Lymphoma

Follicular T-cell lymphoma is another variant of PTCL, NOS that is recognized in the WHO classification.[30] It is characterized by intrafollicular aggregates of T cells with clear cytoplasm that have a follicular T-follicular helper (T_{FH}) cell phenotype.[318] The resulting expansion of the lymphoid follicles may mimic follicular lymphoma or, sometimes, NLPHL. A t(5;9)(q31-q32;q22) is present in some cases.[308]

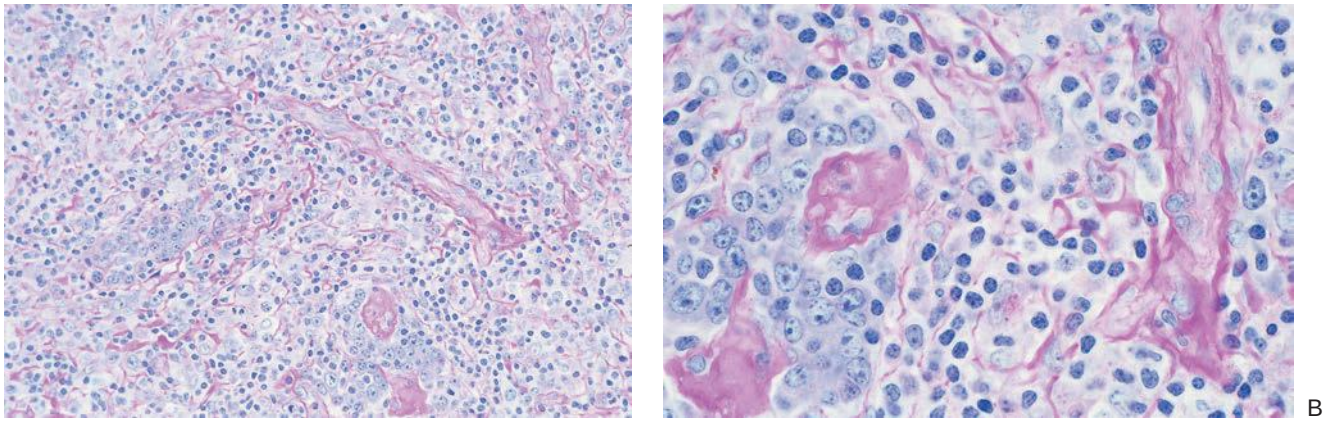
Angioimmunoblastic T-cell Lymphoma

AITL was first described in the 1970s as a clinical syndrome characterized by generalized lymphadenopathy, hepatosplenomegaly, anemia, and hypergammaglobulinemia.[319,320] The lymph node histology showed a number of distinctive features, including partial effacement of the architecture by a polymorphic inflammatory cell infiltrate, including large lymphocytes (immunoblasts), and marked vascular proliferation. Based on these histologic appearances, the disease was called a variety of terms, including immunoblastic lymphadenopathy, lymphogranulomatosis X, and angioimmunoblastic lymphadenopathy with dysproteinemia (AILD). The latter term for this clinical syndrome was accepted by most investigators.[319]

AILD was initially thought to be an atypical lymphoid hyperplasia, a premalignant lesion with a tendency to develop into a lymphoma, rather than as a frank neoplasm from the onset. With the advent of immunophenotyping and molecular techniques, it became apparent that most cases of AILD contained monoclonal T-cell populations as well as clonal cytogenetic abnormalities, strongly suggesting that most of the cases were neoplastic from the onset.[320] It was included in the updated Kiel classification of lymphomas as T-cell lymphoma of AILD-type. Since then, the WHO classification has dropped the term AILD-like TCL and opted for the term AITL to stress the neoplastic nature of this disease.

Morphology

AITL is characterized by partial effacement of the lymph node architecture by a polymorphic inflammatory cell infiltrate predominantly within the paracortical areas (Fig. 86.14A). In the original descriptions of AITL, absence of hyperplastic B-cell follicles was considered to be a characteristic feature. It is now recognized that the architectural changes in AITL fall into three overlapping patterns.[321,322] In pattern I (15% of the cases), there is partial preservation of the lymph node architecture. Hyperplastic B-cell follicles with poorly developed mantle zones and ill-defined borders are easily identifiable in the cortex of the lymph node. These merge into the expanded paracortex, containing a polymorphic infiltrate of small lymphocytes, immunoblasts, plasma cells, macrophages, and eosinophils within a prominent vascular network. Pattern II (25% of the cases) is characterized by loss of normal architecture except for the presence of occasional depleted follicles with concentrically arranged follicular dendritic cells. In some cases, follicular dendritic cell proliferation extending beyond the follicles can be identified. The rest of the lymph node shows a polymorphic inflammatory cell infiltrate with increased numbers of immunoblasts and vascular proliferation similar to that described for pattern I. In pattern III (60% of the cases), the normal architecture is completely effaced and no B-cell follicles can be identified. Prominent irregular proliferation of follicular dendritic cells can be seen in hematoxylin and eosin (H&E)–stained sections in some cases, and this is accompanied by extensive vascular proliferation and a polymorphic inflammatory cell infiltrate similar to that seen in patterns I and II. Approximately one-half of the cases contain perivascular collections of atypical medium-large lymphoid cells with clear or pale cytoplasm (Fig. 86.14B), whereas in other cases cytologic features of malignancy may not be apparent. In a few cases where consecutive biopsies from the same patient have been reviewed, there appears to be a transition from pattern 1 to pattern 3 as the tumor progresses. This suggests that pattern 3 cases represent advanced disease.[322]



A B

FIGURE 86.14. Lymph node: angioimmunoblastic T-cell lymphoma. A: There is a diffuse lymphoproliferation that is associated with prominent periodic acid-Schiff–staining blood vessels. **B:** Perivascular clusters of "clear cell" immunoblasts *(left)* are admixed with small lymphocytes and periodic acid-Schiff–staining blood vessels.

Although generalized lymphadenopathy is the main presenting sign, many of the patients have evidence of extranodal involvement at the time of diagnosis. The most frequently involved extranodal sites include the bone marrow, spleen, skin, and lungs. The histologic appearances in these sites are usually nonspecific but mimic some of the features described in the lymph node including increased vascularity and a polymorphic inflammatory cell infiltrate.[323–325] Cytologic features of malignancy can rarely be identified and tumor involvement can be shown only by immunohistochemistry and molecular clonality analysis. Therefore, the initial diagnosis of AITL rests on histologic examination of the lymph node.

Immunophenotype

Immunohistochemistry shows the expansion of the interfollicular areas by a diffuse infiltrate of $CD3^+$ T cells. In most cases $CD4^+$ T cells dominate, but there is usually an intermixed population of $CD8^+$ cells. B-cell markers CD20 and CD79a highlight the residual follicle center and mantle zone B cells as well as many of the immunoblasts in the interfollicular areas. In some instances these can be numerous, mimicking a large B-cell lymphoma or classical HL, though they are typically polytypic for Ig light chain expression. One of the most important immunophenotypic features in AITL is the expansion of the follicular dendritic cell meshwork that typically surrounds the paracortical small vessels. Although this is sometimes visible on H&E–stained sections, it is best demonstrated by staining for follicular dendritic cell markers such as CD21.[326,327,328]

Until recently, the assessment of immunophenotype of the AITL cells was difficult, since the neoplastic cells in many cases were not readily identifiable and no specific markers were available to highlight the tumor cells. However, recent phenotyping and gene expression profiling studies have shown that the neoplastic cells of AITL express a number of T_{FH} cell markers, including CD10, CXCL13, and CD279 (PD-1), which suggests AITL may be derived from intrafollicular T cells.[318,322,329] T_{FH} cell markers are not expressed by normal peripheral T cells except for a minority of follicle center T cells. The expression of CD10, CXCL13, and CD279 on neoplastic T cells appears highly specific for AITL, as most other PTCLs are negative for these antigens. Although it is not yet known whether CD10 is expressed by all tumor cells or only by a subset of the tumor cells, the availability of specific markers for AITL has helped understand the biology of this disease. Initially, the tumor cells account for only a small fraction of the whole infiltrate (pattern 1). The cells are intimately related to the residual reactive B-cell follicles and the expanded follicular dendritic cell meshwork, some being located within the follicle centers and others surrounding the follicles. As the tumor progresses (patterns 2 and 3) the neoplastic cells spill into the interfollicular area but retain the intimate association with the follicular dendritic cell meshwork. This suggests that the follicular dendritic cell microenvironment may be important in tumor growth. Interestingly, follicular dendritic cells also express CXCL13, a chemokine critical for B-cell entry into follicle centers. In T-cell lymphomas, CXCL13 shows a very similar expression pattern as CD10 and can be utilized as a diagnostic marker for AITL.[330,331–333] The neoplastic T cells in extranodal dissemination may retain expression of CD10 and this may be helpful for diagnosis.[334]

Virtually all cases of AITL contain increased numbers of EBV-infected cells with immunoblastic or RS cell-like morphology. Double immunolabeling suggests that these are B cells, and convincing evidence for infection of T cells is lacking.

The overwhelming evidence suggests that there is a monoclonal T-cell population in the vast majority of AITLs. Interestingly, the presence of a B-cell clone can also be demonstrated in a subset of cases.[320] These are thought to be expanded EBV-infected B-cell clones possibly secondary to underlying immunodeficiency/immune activation.

Anaplastic Large Cell Lymphoma

ALCL is typically characterized by an infiltrate of highly pleomorphic large lymphocytes that express strong reactivity with antibodies directed against CD30, a T-cell activation-associated antigen.[335,336] The entity initially included all lymphomas composed of large cells and uniformly expressing CD30 (Ki-1). However, the current WHO classification restricts the entity to those cases showing either a T-cell lineage or a null phenotype and excludes $CD30^+$ large B-cell lymphomas.

As defined by the WHO classification primary, ALCL comprises three different clinicopathologic entities sharing similar morphology and immunophenotype but showing distinct clinical features. These are (1) systemic ALCL, ALK-positive[337]; (2) systemic ALCL, ALK-negative[338]; and (3) cutaneous ALCL, which is grouped among cases classified as "*primary cutaneous CD30-positive T-cell lymphoproliferative disorders.*"[339]

Anaplastic Lymphoma Kinase–Positive Anaplastic Large Cell Lymphoma

Primary systemic ALCL, ALK-positive is a moderately aggressive tumor that generally presents in young patients who have peripheral lymphadenopathy and extranodal disease that often includes the skin.[340,341] The lymphoma preferentially infiltrates nodal sinuses (Fig. 86.15A) and extends into the paracortical region, often sparing secondary lymphoid follicles. The neoplastic large cells seem cohesive and usually have great variability in nuclear appearance, including some that are horseshoe- or doughnut-shaped ("hallmark" cells) (Fig. 86.15B) or are multinucleate with a resemblance to RS cells of HL.[342] These features of the tumor cells are characteristic of the common variant of ALCL with pleomorphic cytology. The common variant, comprising approximately 70% of ALCL, also includes cases with monomorphic cytologic features in which the nuclei are round rather than pleomorphic. The chromatin pattern is dispersed (blast-like), and there are often prominent nucleoli. The cytoplasm is abundant, and the mitotic rate is often brisk. The common variant of ALCL may be misdiagnosed as metastatic carcinoma or malignant histiocytosis because of the pleomorphic cytologic features of the tumor cells.[335,336] Small cell and lymphohistiocytic variants have been described, each comprising approximately 10% of ALCL.[343,344] The latter two variants may be misdiagnosed as an inflammatory process.

The tumor cells in ALCL are always $CD30^+$, may express pan–T-cell antigens such as CD2 and CD3 and, frequently, cytotoxic granule-associated proteins.[345,346] Most cases express ALK oncoprotein, most frequently due to a t(2;5) (p23;q35.1) chromosomal abnormality.[347,348] This translocation fuses the *ALK* gene on chromosome 2 and the nucleophosmin (*NPM1*) gene on chromosome 5.[349] The fusion protein can be detected with a cytoplasmic and nuclear ALK staining pattern by immunohistochemistry.[350] Approximately 70% to 80% of ALK-positive ALCL have cytoplasmic and nuclear staining, whereas the remainder have cytoplasmic staining only, indicating variant translocations involving *ALK* and partner genes other than *NPM1*. Variant *ALK* gene translocations include t(1;2)(q21.3;p23), which fuses the tropomyosin 3 (*TPM3*) gene on chromosome 1 and *ALK*; t(2;3)(p23;q12.2), which involves the *TRK*-fused gene (*TFG*) on chromosome 3 and *ALK*; inv(2)(p23q35), which involves the *ATIC* gene (encoding for 5-aminoimidazole-4-carboxamide-ribonucleotide) on chromosome 2 and *ALK*; and t(2;17)(p23;q11-qter), which fuses the clathrin heavy chain (*CLTC*) gene on chromosome 17 and *ALK*.[351–354]

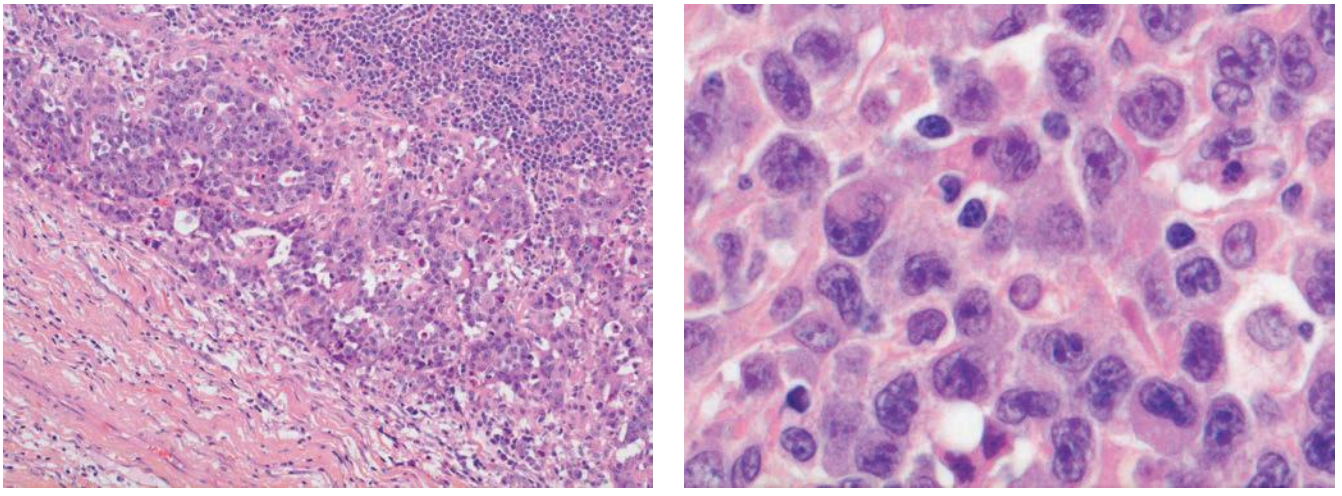


FIGURE 86.15. Lymph node: anaplastic large cell lymphoma. A: Tumor cell infiltrates with a cohesive appearance fill the sinuses, mimicking a metastatic carcinoma. **B:** The lymphoma is composed of pleomorphic large lymphocytes, some of which have the horseshoe- or bean-shaped nuclei that are characteristic of "hallmark" cells of anaplastic large cell lymphoma.

Anaplastic Lymphoma Kinase–Negative Anaplastic Large Cell Lymphoma

Systemic ALCLs lacking ALK expression are morphologically and immunophenotypically very similar to ALK-positive ALCLs but they lack genetic abnormalities involving *ALK* and ALK protein expression. ALK-negative ALCLs also appear genetically distinct from ALK-positive ALCLs by comparative genomic hybridization and microarray gene expression profiling.[355–357] Furthermore, the patients are typically older and, clinically, have a worse prognosis compared to ALK-positive ALCLs.[358,359] Therefore, whether or not ALK-negative ALCLs should be regarded as ALCLs or grouped among PTCLs, unspecified is controversial. However, this debate does not appear to need an answer at this time because ALK-negative ALCL and PTCL, NOS share a similar poor prognosis.[360] The first recurrent translocation, t(6;7)(pter-q22.33;q32.3), among ALK-negative ALCLs, was recently described, which results in fusion of *DUSP22* and *FRA7H*.[361]

Primary Cutaneous Anaplastic Large Cell Lymphoma

Primary cutaneous ALCL typically occurs in adults who have localized disease at the time of diagnosis.[339,340] This form of ALCL is often indolent and may be an extension of lymphomatoid papulosis (LyP) type A. The tumor cells generally resemble those of the common variant of primary systemic ALCL and express T-cell antigens. Primary cutaneous ALCL is usually epithelial membrane antigen negative and lacks t(2;5) and ALK expression, suggesting it has a different pathogenetic mechanism than that of primary systemic ALK-positive ALCL.[339,340,348] A significant subset of primary cutaneous ALCLs have *IRF4* translocations, an abnormality rarely seen in LyP, mycosis fungoides, and systemic ALCL.[362]

Other Considerations

ALCLs have been reported in seroma fluid or in capsules associated with silicone or saline breast implants.[363,364] The absolute risk of developing ALCL adjacent to breast implants is exceedingly low, and the tumors show no propensity for producing solid tumors or systemic disease despite being consistently ALK-negative. This clonal proliferation has an indolent clinical behavior similar to primary cutaneous ALCL.

$CD30^+$ T-cell lymphoproliferations confined to the mucosa in the head and neck may have morphologic and immunophenotypic features resembling ALK-negative ALCL, but the clinical course is indolent like *primary cutaneous CD30-positive T-cell lymphoproliferative disorders*.[365]

Adult T-cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is a peripheral T-cell neoplasm caused by HTLV-1, and it is most prevalent where the retrovirus is endemic (southwestern Japan, central Africa, and the Caribbean basin). However, the incidence of the disease appears to be increasing in nonendemic areas due to spreading by carriers of the virus.[366] There is a long latency period for HTLV-1, and the lifetime risk of developing ATLL is <5% among those infected. ATLL occurs in adults and has four clinical subtypes: acute, chronic, lymphomatous, and smoldering.[367,368,369] Bone marrow infiltrates are interstitial or diffuse and may be less impressive than the degree of peripheral blood involvement. Circulating tumor cells have hyperlobate nuclei, sometimes with a cloverleaf shape. Lymph nodes are generally effaced by a diffuse infiltrate of pleomorphic lymphocytes of variable size, an appearance that may be difficult to distinguish from some PTCL, NOS by morphology alone.[370] Cutaneous infiltrates may be difficult to distinguish from mycosis fungoides, because ATLL can have epidermotropism with formation of Pautrier's microabscesses.[367] The neoplastic cells express T-cell antigens but often lack CD7. Most cases are $CD4^+$, express the activation marker CD25 (interleukin-2 receptor) and are positive for FoxP3, a phenotype characteristic of regulatory T cells.[371] ATLL exhibits TCR gene rearrangements and clonal integration of HTLV-1 genomes.[369] The virally-encoded protein, Tax, activates numerous transcription factors and represses cell cycle–active proteins, resulting in persistent clonal proliferation of virally-infected cells.

Hepatosplenic T-cell Lymphoma

HSTCL, a rare extranodal lymphoma comprising <1% of NHLs, probably arises from the cytotoxic γ/δ and α/β T cells of the splenic red pulp.[372] Despite the few descriptions of HSTCLs,[373,374,375,376] a fairly typical clinicopathologic picture has emerged for these neoplasms. Most cases involve young, adult men who present with B symptoms, massive hepatosplenomegaly, no lymphadenopathy, moderate anemia, and marked thrombocytopenia. Approximately

20% of HSTCLs arise in the setting of prolonged antigenic stimulation or chronic immunosuppression, such as following solid organ transplantation or treatment of inflammatory bowel disease.[375,377] The disease is aggressive, and most patients die within 2 years, even if a remission is achieved initially with therapy.

This lymphoma preferentially infiltrates the cords and sinuses of the splenic red pulp, hepatic sinusoids, and bone marrow sinuses. A leukemic phase may develop as the disease progresses. Tumor cells are generally small to intermediate in size, but some cases may have a predominance of large cells. There are condensed chromatin, indistinct nucleoli, and scant eosinophilic cytoplasm. Circulating tumor cells are generally agranular, but cytoplasmic granules have been detected by electron microscopy in some cases.[378] There may be an associated hemophagocytosis by benign histiocytes.[378] The characteristic phenotype is $CD2^+$, $CD3^+$, $CD4^-$, $CD5^-$, $CD7^+$, and $CD8^-$. Most reported cases express TCR γ/δ chains, but a subset has TCR α/β chains.[376] The TCR γ/δ cases are derived preferentially from the Vδ1 subset of γ/δ T cells.[379] NK-cell–associated antigens, such as CD16 and CD56, are often detected.[336,374,378] The pattern of cytotoxic granule-associated protein expression, TIA-1+, granzyme M+, granzyme B-, and perforin-, is consistent with nonactivated cytotoxic T cells of the innate immune system.[295,374,375,376,378] HSTCLs also express killer cell Ig-like receptors (KIRs) consistent with a derivation from memory T cells, and their exhibiting multiple KIR isoforms (CD158a, CD158b, and CD158e) is unique among cytotoxic T-cell lymphomas.[380] TCR gene rearrangements are observed. Karyotypic studies often show isochromosome 7q that may be accompanied by trisomy 8 and loss of a sex chromosome.[374,375,376,378,381] HSTCL has a distinct molecular signature when compared with gene expression profiling of other T-cell lymphomas.[382]

Subcutaneous Panniculitis-like T-cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma usually presents as multiple erythematous subcutaneous nodules of variable size (0.5 to 12.0 cm) on the extremities or trunk, or both, of adults.[383,384,385,386] This moderately aggressive lymphoma tends to remain localized to the subcutis throughout the clinical course that may be complicated by a severe, and often fatal, hemophagocytic syndrome.

The lymphoma primarily involves the subcutaneous adipose tissue, where there is a lobular panniculitic infiltrate of pleomorphic lymphocytes of variable size. There may be tumor in the deep dermis, but the upper dermis and epidermis are spared. Karyorrhexis and fat necrosis are always present, as are benign histiocytes that often exhibit phagocytosis of nuclear debris or red blood cells. The lymphoma cells express a T-cell phenotype that may be aberrant. Only cases with α/β TCRs are accepted in this disease category.[386] Lymphomas that have a subcutaneous panniculitis-like growth pattern but express γ/δ TCRs are included in the cutaneous γ/δ T-cell lymphoma group among the primary cutaneous PTCL, unspecified category.[386] Subcutaneous panniculitis-like T-cell lymphomas often express CD8, contain cytotoxic granule-associated proteins, and may express NK-cell–associated antigens.[385,386] TCR gene rearrangements have been identified.[385,386]

Enteropathy-associated T-cell Lymphoma

EATL is a tumor of the intraepithelial lymphocytes most frequently arising as a complication of celiac disease, which is often not clinically evident.[387,388] Most patients are middle-aged to elderly; it is unusual for these lymphomas to present before 40 years of age. The most common presenting symptoms are abdominal pain and weight loss. Diarrhea is present less often but is not infrequent. There may be signs of acute obstruction or spontaneous perforation. The disease has an aggressive course, with most patients dying within a few years of diagnosis.

It is now realized that the pathology of the tumor shows a spectrum.[389,390,391] At one end of the spectrum, the lymphoma is limited to the intraepithelial lymphocyte population (intraepithelial EATL). No tumor mass or cytologic features of malignancy are seen, but there is often aberrant loss of CD8 expression and a monoclonal T-cell population by molecular analysis. These patients frequently present with refractory celiac disease and demonstrate serologic findings of celiac disease. Some of these cases are complicated by multiple ulcers in the small intestinal mucosa (ulcerative jejunitis). Tumors cannot be identified by histology in the ulcer bases, which contain a mixed inflammatory cell infiltrate. TCR gene rearrangements can be demonstrated, however.[392] At the other end of the spectrum, the lymphoma presents as single or multiple tumor masses along the small intestine, most frequently in the jejunum. Histologically, the tumor cells are usually intermediate to large in size with oval to pleomorphic nuclei (type I EATL). There is generally abundant clear to eosinophilic cytoplasm, and azurophilic cytoplasmic granules are occasionally observed on touch imprints of the tumor. Mitotic activity is usually brisk. The phenotype is variable but is often $CD2^+$, $CD3^+$, $CD4^-$, $CD5^-$, $CD7^+$, $CD8^{-/+}$, TCRα/β positive, and TCRγ/δ negative. Some cases may be $CD30^+$ and must be distinguished from ALCL. A unique subset of EATL, which often lacks clinical features of celiac disease, is composed of small- to medium-sized lymphoid cells (Type II EATL). These tumors, in addition to pan–T-cell markers, coexpress CD8 and CD56.

Many cases demonstrate TCR β-chain (*TRB@*) gene rearrangements. Comparative genomic hybridization has shown chromosomal imbalances in 87% of EATLs with gains at chromosome 9q being the most frequent by far.[393]

Virtually all cases presenting with a tumor mass contain clonally-linked intraepithelial low-grade lymphoma in the distant small intestinal mucosa, suggesting that the large cell lymphoma has arisen from an underlying intraepithelial lymphoma. This intraepithelial component is a very helpful hint in establishing the nature of a large cell lymphoma in the intestinal tract.

Extranodal Natural Killer/T-cell Lymphoma Nasal Type

Nasal NK/T-cell lymphomas occur in the nasopharyngeal or sinonasal areas and include cases with morphologic features described previously as *polymorphic reticulosis* and *lethal midline granuloma*. These lymphomas are often angiocentric, angioinvasive, and angiodestructive lesions composed of a polymorphic infiltrate of small lymphocytes and immunoblasts with significant cytologic atypia.[394,395] The lymphoid infiltrate often occludes vessels producing areas of ischemic necrosis. The clinical course is typically aggressive and prognosis is poor. These lymphomas are observed most frequently in East Asia and among the native American populations of Mexico, Central America, and South America. They are rare in the United States and Europe. Any age group can be affected.

Recent studies have shown these lymphomas are true NK-cell lymphomas or cytotoxic PTCLs. Most cases express NK-cell–associated antigens, particularly CD56, and some contain azurophilic cytoplasmic granules on Romanowsky-type–stained smears or cytotoxic granule-associated proteins recognized by immunohistochemistry.[394,395–397] The true NK-cell lymphomas lack TCR gene rearrangements, whereas the few well-defined T-cell cases demonstrate TCR gene rearrangements or transcripts.[394,395–398] Most of these lymphomas are EBV-associated.[395,397–399] Extranodal NK/T-cell lymphoma, nasal type has a distinct molecular signature when compared with gene expression profiling of PTCL, NOS.[400]

Nonnasal NK/T-cell lymphomas may be called extranodal NK/T-cell lymphoma, nasal type, because they share many of the

features of the more commonly occurring NK/T-cell lymphomas in the nasal region.[401] Skin, soft tissue, gastrointestinal tract, and testis are the most frequent nonnasal extranodal sites involved by NK/T-cell lymphomas.[402–404] Some cutaneous and subcutaneous NK/T-cell lymphomas may represent secondary spread from nasal NK/T-cell lymphomas. Cutaneous cases are generally true NK-cell lymphomas. Most express CD56, and azurophilic cytoplasmic granules are often present. There is also a high degree of association with EBV, particularly those of apparent, true NK-cell origin.[404,405]

HODGKIN LYMPHOMAS

Although HL has distinct clinical manifestations that help to define the disease, its simplest pathology definition is a neoplasm of RS cells and RS cell variants (collectively termed Hodgkin cells) that are associated with an inflammatory response that often dominates the morphologic picture. This histopathologic definition formulated by Jackson and Parker and further refined by Lukes, Butler, and Hicks, has formed the basis for reproducible diagnosis of this disease for many years. However, based on advances in the understanding of the biology of Hodgkin cells, the WHO modified the defining features of HL to include phenotypic criteria.[406] Thus, HL was subdivided into 2 major categories: lymphocyte predominant HL and classical HL. LPHL is rather homogeneous, both histopathologically and clinically. However, there is heterogeneity in the histopathology and clinical features of CHL and so the WHO classification continues to recognize as subtypes of CHL mixed cellularity (MC), lymphocyte-rich (LR), nodular sclerosis (NS), and lymphocyte-depleted (LD) types. Aside from the modification to include phenotype in the definition of CHL, the subtypes of CHL are recognized using the same basic criteria as those proffered in the Rye modification of the Lukes, Butler, and Hicks HL classification scheme.[407,408] Although the prognostic significance of the histologic type of CHL has not been proven to be independent of clinical stage, the diagnostic importance of this classification scheme is not diminished. To the contrary, it is very useful to pathologists, helping them to recognize the histologic diversity of HL, and to managing clinicians, helping them to predict the likelihood of advanced-stage disease. In general, LPHL and NSHL correlate with low stage disease; LDHL with advanced-stage disease; and MCHL presents an intermediate risk for widespread disease.[409]

Classical Hodgkin Lymphoma

The histopathologic features of CHL include architectural effacement of the involved tissue by a mixed cell infiltrate that includes RS cells, large neoplastic cells with some, but not all of the features of RS cells (termed Hodgkin cells or RS cell variants), and inflammatory cells, including varying numbers of small lymphocytes, macrophages, plasma cells, eosinophils, neutrophils, and fibroblasts.[406,407,410] HL is an unusual neoplasm because the RS cells and Hodgkin cells are in the minority, and the inflammatory host response constitutes most of the cellular infiltrates. RS cells are characteristically described as large cells, 20 to 50 μm in diameter, with bilobed, multilobed, or multiple nuclei (Fig. 86.16). Each nucleus or nuclear lobe has a thick nuclear membrane with vesicular chromatin. Typically, large inclusion-like nucleoli surrounded by a perinucleolar halo are present. The cytoplasm is abundant, eosinophilic to amphophilic and homogeneous throughout. By current WHO lymphoma classification criteria, CHL is not only cytologically defined, it is also phenotypically defined. Immunohistochemistry performed on paraffin sections of the tumor is the preferred modality to phenotype cases of HL. The RS cells and variants in CHL express CD30 and PAX5, they often express CD15 and they are negative for CD45 (Fig. 86.17).

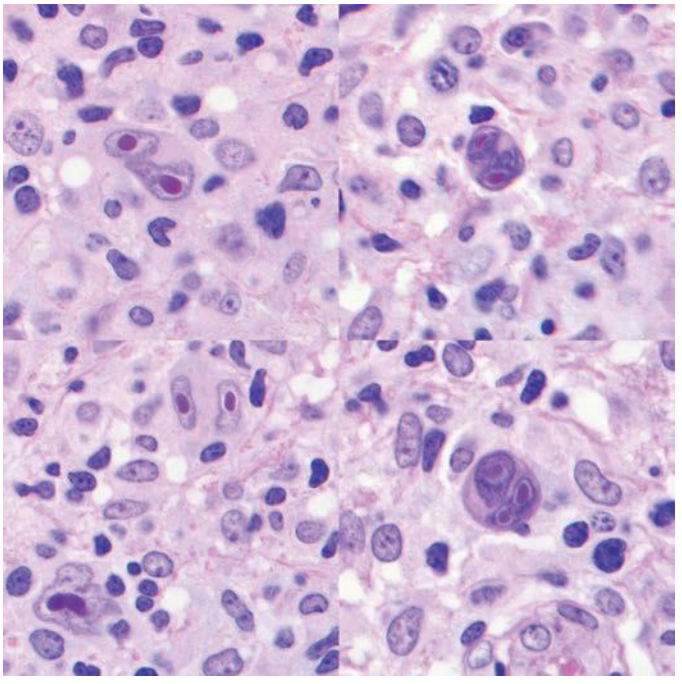

FIGURE 86.16. Lymph node: classical Hodgkin lymphoma. This composite photograph highlights the features of diagnostic Reed-Sternberg cells: multiple or bilobed nuclei, prominent inclusion-like nucleoli, and abundant eosinophilic cytoplasm.

Variable immunoreactivity for CD20 is present in a subset of cases. Hodgkin cells do not express CD3.

Although the presence and phenotype of RS cells constitute defining features of CHL, cells that are cytologically (and phenotypically) identical to RS cells can be seen in reactive conditions, such as infectious mononucleosis[411,412] and in other NHLs. Therefore, tissue architectural effacement and the inflammatory cells that accompany the Hodgkin cells are also critical criteria for the diagnosis of HL. Careful attention to the inflammatory cells, particularly the lymphocytes, helps the pathologist to distinguish HLs from NHLs containing RS-like cells. In the former, there is a dimorphism between the Hodgkin cells and the small bland appearing lymphocytes. NHLs with RS-like cells often contain a population of medium-size lymphocytes with cytologic features, including nuclear irregularities and pleomorphism. The presence of the prominent host response in HL also complicates separation of HL from benign, inflammatory processes. Granulomas containing multinucleated giant cells with or without central necrosis, abundant neutrophils, numerous eosinophils, granulation tissue, collagen deposition, and vascular proliferation are the hallmarks of the host immune response to a variety of infectious agents or can be seen in allergic reactions and autoimmune diseases. Tissues involved by CHL can contain these same features. Once the essential diagnostic features of HL are recognized CHL is subclassified based upon the presence or absence of particular types of RS cell variants and upon the varying proportions of reacting host inflammatory cells and fibrosis.

Mixed Cellularity Hodgkin Lymphoma

Mixed cellularity Hodgkin lymphoma (MCHL) is probably best thought of as the prototype of CHL because it contains all of the essential diagnostic features of this disorder.[413] In the most characteristic cases RS cells, RS cell variants, and an admixture of lymphocytes, plasma cells, eosinophils, and macrophages diffusely efface lymph node architecture (Fig. 86.18). RS cells are typically quite numerous. There may be a delicate collagen fibrosis between the cells, but collagen bands that thicken the lymph

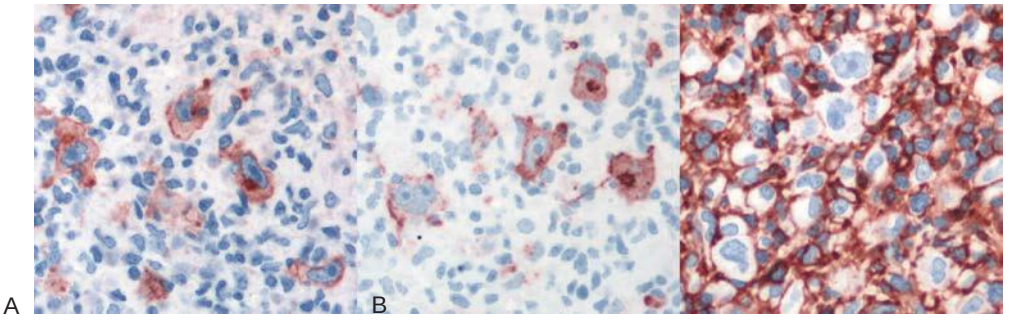

FIGURE 86.17. Lymph node: phenotypic features of Reed-Sternberg cells in classical Hodgkin lymphoma. A: The large Hodgkin cells are positive for CD30 and **B:** CD15, **C:** but are negative for CD45 in immunoperoxidase stains performed on paraffin sections of this involved lymph node.

node capsule and define the borders of nodules are not present. In addition, lacunar cells and LP variants of RS cells are not identified. Within this basic morphologic framework, MCHL can span a considerable histologic spectrum based on the relative numbers of Hodgkin cells and the different types and proportions of reacting cells present in the cellular infiltrates.

In some lymph nodes, the diagnostic infiltrates of HL occur between reactive germinal centers. This pattern was termed "interfollicular Hodgkin's disease".[414] In lymph nodes containing interfollicular HL, the reactive follicles predominate. In most cases, they are constituted by centroblasts, centrocytes, tingible body macrophages, and frequent mitotic figures. However, in a small number of cases, regressive transformation of germinal centers identical to the follicular changes in hyaline vascular type Castleman disease are present. The areas diagnostic of HL occur between the follicles and contain varying numbers of RS cells, small lymphocytes, macrophages, eosinophils, and plasma cells. Interfollicular HL does not constitute a specific subtype of CHL; rather it represents early, partial lymph node involvement by MC or NS type. There are no reported distinctive clinical features of interfollicular HL.

Lymphocyte-rich Classical Hodgkin Lymphoma

Once CHL and LPHL were defined phenotypically, it was recognized that there were HLs containing Hodgkin cells that were phenotypically identical to those in classical types of HL, but whose reaction was composed almost exclusively of small lymphocytes. These cases would have been diagnosed as LPHL prior to the WHO lymphoma classification, but in deference to the phenotype are now termed "lymphocyte-rich classical Hodgkin lymphoma."[415,416,417] Their clinical features more closely resemble MCHL than LPHL. LRHL grows in either a nodular or diffuse pattern. There are relatively sparse RS cells and Hodgkin cells; almost all of the remaining cells in the infiltrates are small lymphocytes (Fig. 86.19). RS cells and variants in LRHL express the same antigens as their counterparts in other types of CHL. Small nonneoplastic T- and B-lymphocytes comprise almost all of the rest of the cells in this disease. The differential diagnosis includes LPHL distinguished by the phenotype of the Hodgkin cells (see below) and T-cell/histiocyte-rich large B-cell lymphomas.[227,418,419–421]

Nodular Sclerosis Hodgkin Lymphoma

NSHL is the most common histologic type of HL encountered in the United States and it is the most reproducibly diagnosed. In addition to meeting the general criteria of HL (phenotypically characteristic RS cells and the appropriate inflammatory cellularity), two additional criteria define this subtype: collagen band formation and lacunar cells (Fig. 86.20).[422] Within this basic definitional framework there is a broad spectrum of possible histologic appearances of NSHL, depending on the relative contributions of RS cells and lacunar cells, the degree of collagen sclerosis, the proportions of the various inflammatory cells and the presence and extent of necrosis.

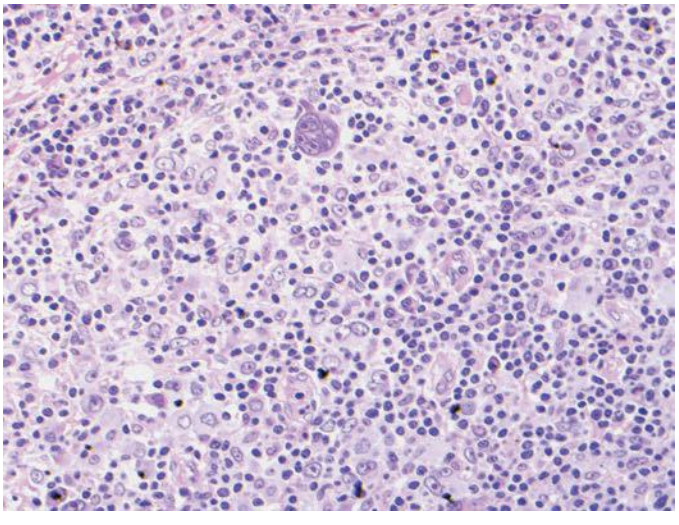

FIGURE 86.18. Lymph node: mixed cellularity Hodgkin lymphoma. There are many large Hodgkin cells, a diagnostic Reed-Sternberg cell *(upper center)*, and a background population of small lymphocytes, histiocytes, plasma cells, and eosinophils.

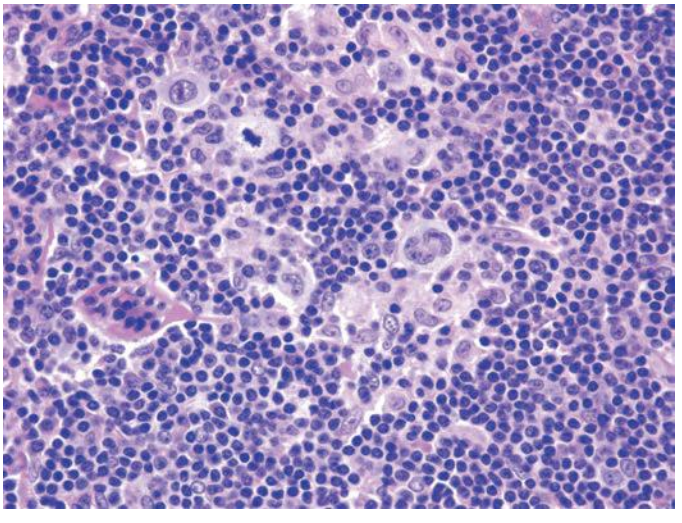

FIGURE 86.19. Lymph node: lymphocyte-rich classical Hodgkin lymphoma. Few Hodgkin and Reed-Sternberg cells are present in a background composed almost exclusively of small lymphocytes and histiocytes.

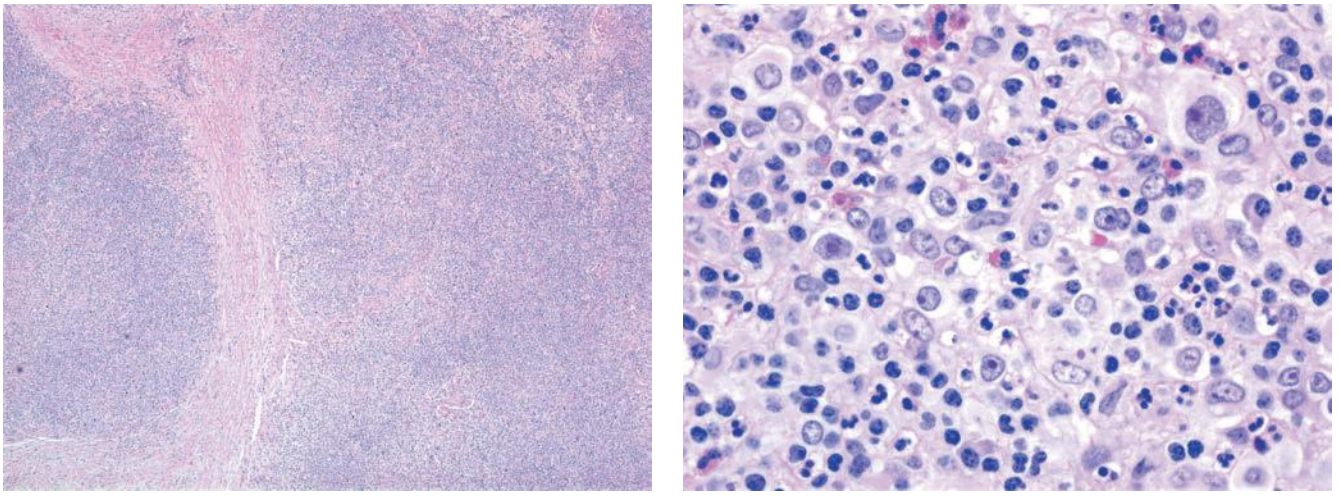

FIGURE 86.20. Lymph node: nodular sclerosis Hodgkin lymphoma. A: Collagen band formation is illustrated, circumscribing the mixed cell infiltrates into nodules. **B:** This photograph demonstrates the cytologic features of lacunar cells *(upper right)*. Note also the background population of small lymphocytes, neutrophils, eosinophils, and plasma cells.

Lacunar cells have distinctive nuclear and cytoplasmic features.[407,410] The nuclei are hyperlobated with delicate chromatin and small nucleoli. The cytoplasm is abundant and pale, staining to clear with sharply demarcated peripheral margins. It is in B5 or Zenker's fixed tissue sections where the distinctive cytologic features of lacunar cells are best appreciated. However, in formalin-fixed tissue sections, lacunar cells stand out because their cytoplasm retracts from the adjacent cells, forming the lacunae from which these cells derive their name. Lacunar cells may be very numerous, forming large aggregates or clusters or they may be individually distributed. The earliest manifestation of NSHL in lymph nodes is the appearance of lacunar cells in the corticomedullary junction without collagen deposition, a phenomenon termed cellular phase of NSHL by some authors.

Collagen band formation, the second diagnostic criteria of NSHL, begins in the lymph node capsule and extends into the cortex. The degree of sclerosis varies from collagen bands that completely circumscribe the cellular nodules to obliterating sclerosis in which the majority of the lymph node is replaced by collagen.

In an attempt to define prognostic subgroups of patients with NSHL, histologic grading schemes have been devised, most notably, those proposed by the British National Lymphoma Investigation (BNLI).[423] By the BNLI criteria, the cellular composition of the nodules determines the histologic grade. Any one of the following indicated higher grade (grade II): replacement of the cellular nodules by bland looking fibroblasts and histiocytes with little pleomorphism and few RS cells and lacunar variants; nodules composed of uniform sheets of lacunar cells (the "syncytial variant" of NSHL); and nodules composed of numerous lacunar cells that include pleomorphic giant cells. NSHL that lack these features are designated grade I. In the studies of the BNLI and others, stage-matched, similarly treated patients with grade II NSHL have a worse survival than their counterparts with grade I NSHL. The WHO does not require grading of NSHL cases because not all studies have replicated survival differences based of BNLI grade.[424–426]

Lymphocyte-depleted Hodgkin Lymphoma

Lymphocyte-depleted Hodgkin lymphoma (LDHL) is the least common type of HL.[427] Although the Rye conference on HL contracted the original histologically defined categories of diffuse fibrosis and reticular types of HL into LDHL, maintaining the separation is most useful to pathologists who must recognize the histologic variability of LDHL.[408] The term lymphocyte-depleted is also somewhat imprecise, because it implies that this type of HL is defined solely by the absence of lymphocytes rather than by the presence of numerous RS cells and variants or by the presence of a peculiar type of collagen fibrosis. Therefore, for the purposes of this discussion the distinction of reticular and diffuse fibrosis variants of LDHL will be maintained.[407,428,429]

The reticular variant of LDHL has two basic morphologic expressions. In each there is diffuse architectural effacement of the lymph node, absence of distinct nodularity, absence of birefringent collagen bands, diminished numbers of lymphocytes, and a cytologic composition dominated by RS cells. In each, granular interstitial material can be present between the cellular elements, and areas of necrosis can be prominent. Numerous typical RS cells with large nucleoli numerically predominate the cellular infiltrates in one manifestation of the reticular variant of LDHL. In the other, the frequent RS cells are extremely pleomorphic, almost sarcomatoid appearing. Because the reticular variant of LDHL has histologic features that overlap considerably with other NHLs and with other pleomorphic malignancies, the definition of reticular variant of LDHL requires that the neoplastic cells exhibit the distinctive phenotype of RS cells. LDHL, reticular variant, can be particularly difficult to distinguish from ALCL.

In the diffuse fibrosis variant of LDHL nonbirefringent collagen admixed with relatively few RS cells and variants accompanied by a rather minimal inflammatory cellularity, particularly poor in lymphocytes effaces the lymph node architecture (Fig. 86.21). In early stages, the lymph node is usually small with a depleted appearance and with fibrosis that appears amorphous and compact and that is deposited in the reticular framework of the lymph node, sparing the lymph node sinuses and capsule. At the opposite end of the diffuse fibrosis spectrum, almost the entire lymph node is replaced by compact, hyalinized, disorderly collagen. In these late stages, RS cells and variants are quite infrequent. Unless this latter feature is appreciated, the diagnosis of LDHL can be missed entirely.

Immunophenotypic Features of Classical Hodgkin Lymphoma

Phenotypic, cytogenetic, molecular genetic, and cell culture experiments indicate that Hodgkin cells are activated post-germinal center B-lymphocytes. They are uniformly positive for CD30[406,430,431] and PAX5.[432] They express CD15 in 75% to 80% of cases[433] and are negative for CD45.[10] They variably express other pan–B-cell

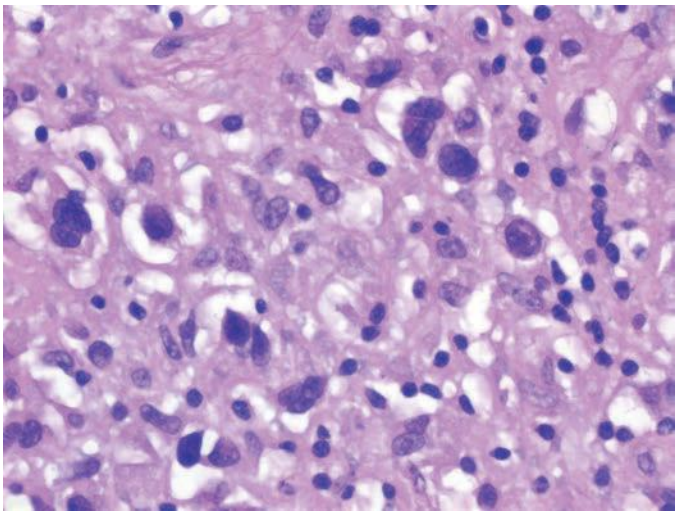

FIGURE 86.21. Lymph node: Lymphocyte-depleted Hodgkin lymphoma, diffuse fibrosis variant. Hodgkin cells and a few small lymphocytes are present amid the disorganized collagen.

antigens, such as CD19, CD20, and CD79a. However, strong uniform positivity for any of these markers by the entire Hodgkin cell population in CHL is not characteristic and should suggest an alternative diagnosis. Hodgkin cells typically lack staining for Ig. The biologic bases for this finding include "crippling" point mutations in the Ig genes or diminished expression of Ig transcription factors (OCT2, BOB1, PU.1).[434,435,436]

Epstein-Barr Virus and Classical Hodgkin Lymphoma

Several lines of evidence suggest that HL is related to EBV.[437] Epidemiologic studies show that there is an increased incidence of HL in people who have had infectious mononucleosis.[438,439] Conversely people with HL have higher antibody titers to EBV than age-matched control patients.[440] In addition, there are great morphologic and phenotypic similarities between RS-like cells in the tissue reaction to EBV and actual RS cells in HLs.[441]

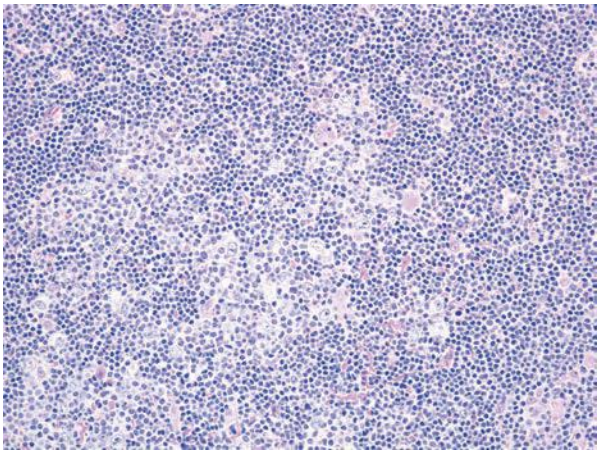
The most useful technique to study HL tissues for the presence of EBV has been in situ hybridization using probes that recognize EBER. The frequency of HLs positive for EBV using this technique varies. In Western countries, RS cells are EBV$^+$ in up to 50% of cases, with the highest frequency detected in MCHL.[442–444,445] The incidence of EBV positivity in RS cells from tissue samples obtained from patients from underdeveloped countries is much higher; in some nations it approaches 100%.[444,446–451] EBV has also been found in Hodgkin cells in most HLs that complicate HIV infections.[452,453] The RS cells in EBV$^+$ HLs express EBV LMP-1 and in many instances LMP-2A, but these cells lack the EBV proteins EBNA-2, glycoprotein 350/250, viral capsid antigen, and early membrane antigen.[454–458] These findings are consistent with a type II latency pattern. When considering only nonimmunosuppressed patients, the data regarding the significance of EBV positivity for HL clinical outcome is somewhat contradictory.[459–461] But in general, Hodgkin cell positivity for EBV suggests a favorable outcome in children and young adults, but predicts for an adverse outcome in older adults (greater than 50 years old).

Nodular Lymphocyte Predominant Hodgkin Lymphoma

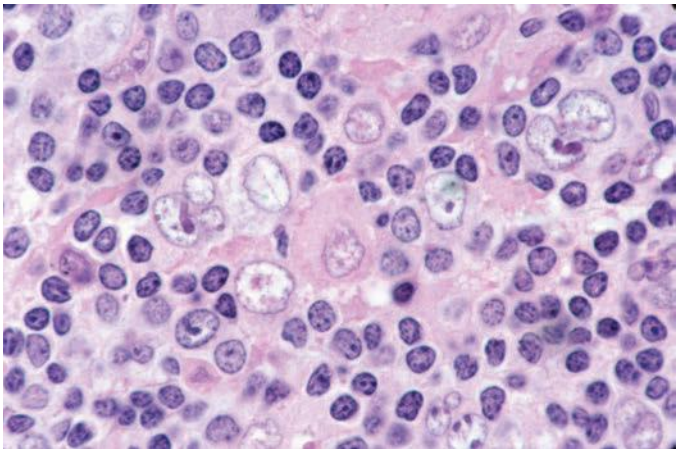
The WHO classification requires both morphologic and phenotypic criteria for the diagnosis of NLPHL.[462] In addition, since the description of diffusely growing large B-cell lymphomas with a background rich in nonneoplastic T cells and/or histiocytes (T-cell/histiocyte–rich large B-cell lymphomas), the boundary between diffuse LPHL and THRLBCL has been blurred. Therefore, in the WHO classification, nodular LPHL is the defined entity with some reservations expressed about the feasibility of separating de novo diffuse LPHL from THRLBCL.[4,462]

The morphologic features of LPHL include the presence of RS cell variants, colloquially termed "LP cells," and a host response rich in lymphocytes and macrophages.[410,463] LP cells are large and have distinctly indented or lobulated nuclei ("popcorn cells"), delicate chromatin, small nucleoli, and moderately abundant wispy pale staining cytoplasm.

In prototypic cases, nodular LPHL variably effaces the lymph node architecture by small lymphocytes, macrophages, and LP cells growing in a macronodular pattern (Fig. 86.22). The nodules are usually larger than reactive lymphoid follicles and vary in number in any given lymph node. In early involvement, only a few nodules are present in the lymph node cortex, accompanied by follicular lymphoid hyperplasia and progressively transformed germinal centers (PTGCs). In the most histologically advanced cases, the nodules coalesce, becoming confluent, such that almost all the tumor grows in a diffuse pattern with only focal nodularity.



A



B

FIGURE 86.22. Lymph node: nodular lymphocyte-predominant Hodgkin lymphoma. A: This photograph was taken from one of the nodules. It shows the few LP Reed-Sternberg cell variants together with abundant small lymphocytes and few histiocytes. **B:** This high-power field shows typical LP cells with their lobulated nuclei, delicate chromatin, small nucleoli, and pale staining cytoplasm.

The latter can be so minimal that wide sampling of the lymph node or application of immunohistochemistry is required to find the nodular areas. The cytologic composition of the nodules varies from case to case. Usually small lymphocytes, similar to mantle zone B cells, comprise the majority of the cellularity of the nodule. Epithelioid macrophages can be present within the nodules, distributed singly or in small clusters, or they can satellite around the nodules in a wreath-like arrangement. LP cells, a diagnostic requirement for this HL type, are present. The numbers of LP cells can vary greatly from one nodule to the next, ranging from one or two per nodule to near-confluent aggregates. Diagnostic RS cells are extremely rare. If there are any more than one or two cells that have the features of RS cells in cases thought to represent nodular LPHL, the diagnosis of CHL should be entertained. In contrast to CHL, plasma cells, eosinophils, and fibrosis are conspicuous by their absence in nodular LPHL. Finally, a careful search usually uncovers the presence of intranodular follicular dendritic cells. Based on morphology and immunohistochemistry the Stanford group reported six patterns of nodular LPHL: "classic" (B-cell–rich) nodular, serpiginous/interconnected nodular, nodular with prominent extra-nodular LP cells, T-cell–rich nodular, diffuse with a T-cell–rich background (T-cell–rich B-cell lymphoma [TCRBCL]–like), and a (diffuse) B-cell–rich pattern.[464] This variability highlights the complexity of the histopathology and immunoarchitecture of this disease.

Progressive transformation of germinal centers[465,466] is an unusual reactive pattern that often accompanies the infiltrates of nodular LPHL. PTGCs are larger than usual germinal centers. They have a "darker" appearance because they are composed of a large proportion of small lymphocytes indistinguishable from mantle zone lymphocytes. Although small lymphocytes predominate, all PTGC contain single and clustered germinal center cells, scattered tingible body macrophages, and expanded follicular dendritic cell meshworks. In contrast to the nodules of nodular LPHL, PTGC do not tend toward confluence, do not efface lymph node architecture, and do not contain LP cells. The germinal center B cells of PTGC exhibit Ig gene somatic hypermutation with intranodular clonal expansion. However, the Ig gene rearrangements found in different nodules of PTGC are dissimilar. This feature distinguishes PTGC from the nodules in LPHL in which the LP cells of different nodules within the same lymph node are clonally-related to one another.[467] PTGC can be present in reactive lymph node specimens from patients prior to the development of LPHL, concurrent with LPHL, or following LPHL, suggesting a relationship between these two conditions.[466,468,469] However, PTGC occur much more frequently as a reactive process accompanying follicular lymphoid hyperplasia. Their presence does not de facto indicate the presence of nodular LPHL, nor do they necessarily predict for subsequent development of LPHL.[470]

Immunophenotypic Features of Lymphocyte Predominant Hodgkin Lymphoma

Unlike Hodgkin cells in other types of HL, LP cells have a distinctive and consistent phenotype, indicating GCB lineage (Fig. 86.23). They are consistently positive for pan–B-cell antigens, such as CD19, CD20, CD22, CD79a, PAX5,[463,471,472,473,474,475] and J chain.[476] The neoplastic cells in LPHL are also positive for Ig light chains when optimized paraffin section immunohistochemistry is used. Kappa light chain expressing cases greatly outnumber lambda light chain expressing cases.[477] While the heavy chain type expressed by LP cells is usually IgG, a subset of cases with unique histologic and clinical attributes contains LP cells positive for IgD.[478] These cases typically occur in young males. BCL6, a zinc-finger protein normally expressed by follicle center B-lymphocytes is also localized to the nuclei of LP cells.[479] LP cells strongly express B-lymphocyte transcription factors OCT2 and BOB1. In contrast to other types of HL, the LP cells are frequently positive for CD45. By definition, they lack staining for CD30 and CD15, and in a subset of cases, they express epithelial membrane antigen.[471]

In most cases of nodular LPHL, the majority of the small lymphocytes accompanying the intranodular LP cells are polytypic IgD and IgM expressing B cells. The small lymphocytes that are immediately adjacent to the LP cells ("rosetting" around the LP cells) also have a distinctive phenotype.[480–482] They are CD2, CD3, CD4, CD57, CXCL13, BCL6, and CD279 (PD-1) positive.[483] This unusual cell population has the phenotype of transiently activated germinal center T cells. Finally, expanded mesh works of CD21$^+$ follicular dendritic cells form the immunoarchitectural background of the nodules of LPHL. In combination, the phenotypic attributes of LP cells coupled with the immunoarchitecture of the reactive cell populations is highly characteristic for LPHL.

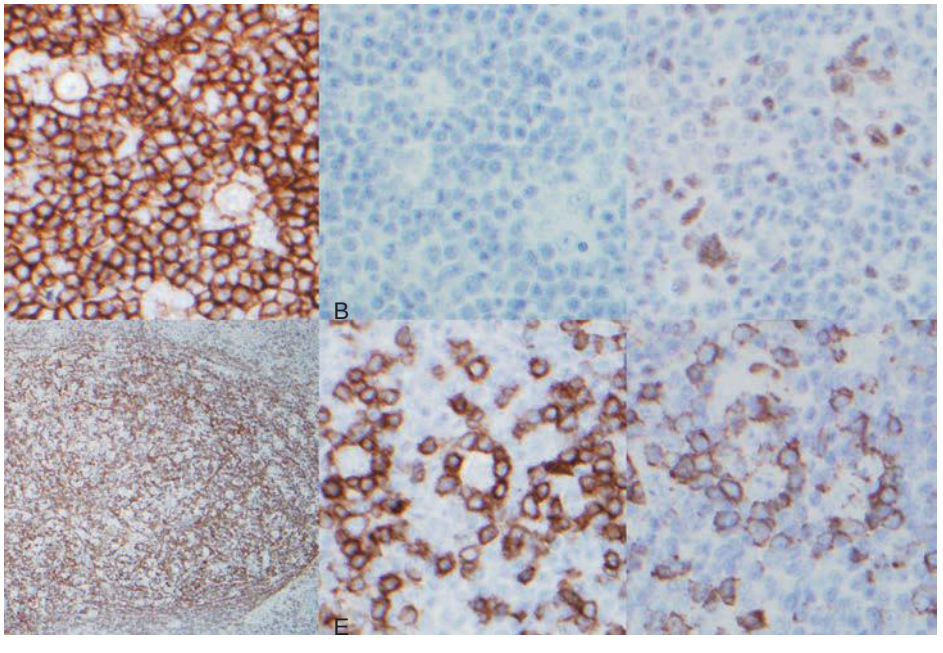


FIGURE 86.23. Lymph node: immunoarchitecture of nodular lymphocyte-predominant Hodgkin lymphoma. A: The LP cells and most of the background small lymphocytes are strongly positive for CD20. **B:** The LP cells and small lymphocytes are CD30-negative. **C:** The LP cells show nuclear bcl-6 positivity. **D:** CD21-positive follicular dendritic cells form a meshwork that defines the nodules in this disorder. **E:** Small lymphocytes in the immediate vicinity of the LP cells, some forming rosettes around tumor cells, are CD3-positive and **F:** CD57-positive T-cells.

Involvement of Extranodal Sites by Hodgkin Lymphoma

Once a diagnosis of HL has been definitively established based on characteristic morphologic and immunophenotypic criteria in the initial biopsy specimen, the criteria for involvement of other sites are relaxed. In any involved anatomic site, Hodgkin cells, including diagnostic RS cells, do not occur as isolated cells but always carry with them the host immune reaction. So, in staging samples, Hodgkin cells together with the appropriate inflammatory background are all that is required to diagnose involvement by HL. Diagnostic RS cells need not be present and phenotyping does not have to be performed, as long as the infiltrates have features within the morphologic spectrum of HL.

Spleen, liver, and bone marrow are the most frequent sites of extranodal involvement by HL. In the spleen, it is very unusual to find HL in random histologic sections. Sectioning at two-millimeter intervals and careful gross examination allow one to identify the small white nodules of potential HL and to sample them for histologic examination. If it is difficult to cut the fresh spleen thin enough, resectioning and reexamining the gross anatomy of the spleen following a brief period of fixation optimizes the probability of identifying HL. Because the number of nodules of splenic involvement by HL is of prognostic significance[484] (greater than five confers a greater risk for recurrence following initial therapy), this should be recorded. In the liver, HL most frequently involves the periportal areas.[485,486] It should be remembered that hepatic involvement by HL is almost never encountered in the absence of splenic involvement. Finally, sarcoid-type granulomas can be encountered in any tissue sample obtained from a patient with HL.[487,488] By themselves, they do not indicate the presence of HL in the tissues in which they are found and should not advance the stage of the disease. However, because sarcoid-type granulomas are potentially part of the inflammatory background of HL, Hodgkin cells must be searched for whenever these granulomas are observed.

Bone marrow involvement by HL in general is quite infrequent, seen in no more than 5% to 10% of cases at diagnosis. However, the frequency of bone marrow involvement varies with the histologic type of HL. In LPHL, encountering a bone marrow positive for HL is very rare.[489,490] Intertrabecular and paratrabecular aggregates of small lymphocytes admixed with macrophages and occasional LP cells typify bone marrow involvement by LPHL. The LP cells can be present on only one or two levels of the biopsy specimen and therefore step sectioning any lymphoid aggregates in the bone marrow from patients with LPHL may be necessary to find the LP cells and confirm bone marrow involvement.

In CHL, the bone marrow is positive in 5%, 10%, and greater than 50% of patients with NSHL, MCHL, and LDHL, respectively.[491,492,493] In all, the histologic pattern of bone marrow involvement is similar, such that the type of CHL cannot be specified from the bone marrow findings alone. There are intertrabecular or paratrabecular aggregates of mixed cell composition including lymphocytes, macrophages, eosinophils, and plasma cells, together with a few RS cells or Hodgkin cells (Fig. 86.24). The areas of involvement can be quite hypocellular appearing, are usually associated with fibrosis, and often have stellate borders. In some cases, histiocytes predominate, simulating granulomatous infiltrates. In others, the fibrosis and eosinophilic infiltrates simulate systemic mastocytosis. In patients with HL who are HIV-infected, or in patients with LDHL[492] who present with fever of undetermined origin and minimal peripheral adenopathy, the bone marrow often becomes the primary site from which a diagnosis of HL is established. In these instances, one must find diagnostic RS cells. Because bone marrow involvement by PTCL and THRLBCL can closely simulate HL, it is also essential to perform phenotypic studies on paraffin section of the bone marrow specimen to confirm that the RS cells and variants are $CD15^+$, $CD30^+$, $PAX5^+$, and $CD45^-$ before rendering a definitive diagnosis of classical HL on the basis of the bone marrow alone. Finally, the noninvolved bone marrow from patients with HL can show trilineage hyperplasia, eosinophil hyperplasia, benign lymphoid aggregates, and noncaseating granulomas, all due to the generalized host response to HL. In the absence of RS cells and/or variants, these features do not indicate bone marrow involvement by HL. Flow cytometry and cytogenetic analysis play no role in assessing the bone marrow for involvement by HL.

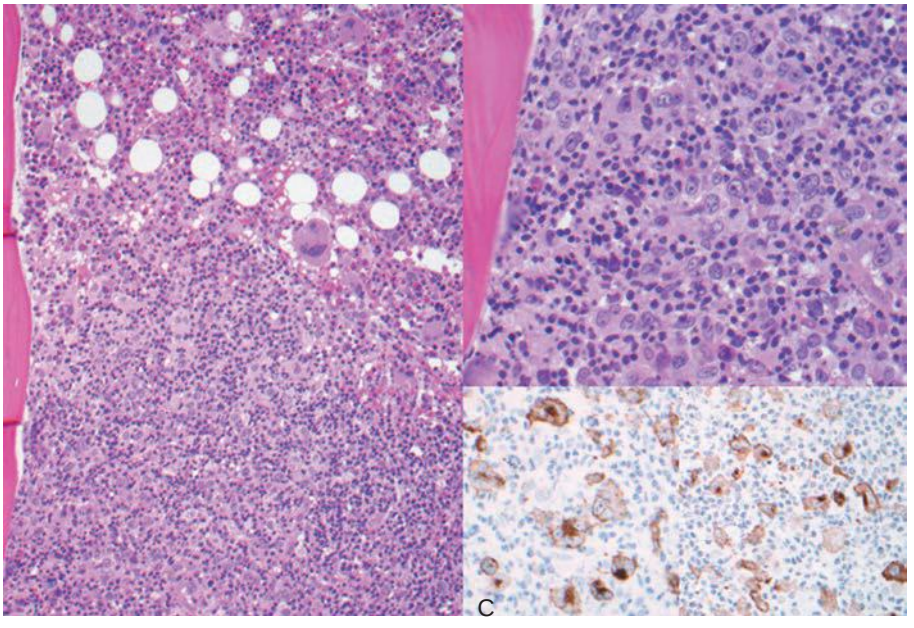

FIGURE 86.24. Bone marrow: classical Hodgkin lymphoma. A: The bone marrow is focally replaced by Hodgkin lymphoma. **B:** Small lymphocytes, macrophages, and Hodgkin cells (but no diagnostic Reed-Sternberg cells) are present in the infiltrates. Using paraffin section immunohistochemistry, the Hodgkin cells expressed **C:** CD30 and **D:** CD15.

CHAPTER 87

MOLECULAR GENETIC ASPECTS OF NON-HODGKIN LYMPHOMAS

Annette S. Kim

INTRODUCTION

The non-Hodgkin lymphomas (NHLs) are a diverse group of mature lymphoid neoplasms with a wide range of cellular morphologies, histologic presentations, clinical presentations, cells of origin, etiologies, and responses to therapy. Due to the protean manifestations, NHLs remain a significant diagnostic challenge for hematopathologists. In fact, using morphology alone, the interpathologist consensus is 41% to 93%, depending on the diagnosis.[1] This lack of consensus is especially true of the T-cell lymphomas which are even more varied in presentation than their B-cell counterparts. Incorporation of clinical history and immunophenotyping can improve the consensus, but pathognomonic diagnostic clues are often missing.

The NHLs represent 4% of all cancers with an overall annual incidence of 19.6/100,000 in the United States (Fig. 87.1), making it the seventh most common cancer in both males and females.[2,3,4] Despite their relatively high frequency in clinical practice, the NHLs have defied numerous attempts to classify them. Early classification schemes relied heavily upon morphology. However, as the classification of acute leukemias moved to emphasize the cell of origin, so too did lymphoma classifications attempt to identify a cell of origin and stage of maturation. Most recently, leukemia classification schemes have advanced beyond morphologic or immunophenotypic criteria to molecular genetic criteria for the subclassification of acute leukemias. Not only are leukemias defined by their genetic translocations, but rapidly molecular mutations, invisible on the metaphase cytogenetic level of resolution, are defining diagnostic and prognostic categories.

In fact, the researchers of the NHLs were pioneers in the discovery of molecular genetic underpinnings of hematolymphoid malignancies. The first reciprocal translocations that caused tumorigenesis were identified in Burkitt lymphoma (BL), translocations involving the *MYC* oncogene.[5] These were followed by the discovery of the t(14;18) in follicular lymphoma (FL).[6] However, after an initial flurry of activity, the NHLs have lagged behind their leukemia counterparts in the identification of the molecular genetic causes of neoplasia. The most recent 2008 World Health Organization classification scheme still largely relies upon cell of origin as the primary discriminator of the B-cell NHLs,[4,7,8] and T-cell lymphomas are even less well understood in general, with many of the classifications defined by the site of the tumor. Molecular changes in NHLs, although often associated with a given type of lymphoma, do not solely characterize that entity.[4,9] For example, 10% to 15% of FLs lack the hallmark t(14;18),[10] whereas t(14;18) can be seen in some types of de novo diffuse large B-cell lymphoma (DLBCL) without a preceding history of FL. Other molecular genetic changes are often more phenomenologic, rather than pathognomonic, of the particular type of lymphoma and only further highlight the molecular heterogeneity of these neoplasms.

However, other molecular aberrations are likely as yet unrecognized and new efforts in next generation sequencing (NGS) and mutational analysis in general are slowly elucidating new markers of disease. It is possible, however, that disease classification in the future of NHL will not be defined by single molecular aberrations, but by pathway dysregulation. Therefore, more global methods of assessing molecular genetic aberrations may become more prominent in the diagnosis and prognosis on NHLs in the years to come.

OVERVIEW OF METHODOLOGIES

Commonly Used Techniques

One of the mainstays of molecular testing in lymphoid malignancies is the use of clonality testing. These methods are based upon the unique rearrangement of either the B-cell receptor (BCR), composed of an immunoglobulin (Ig) heavy chain and one of two light chains, or the T-cell receptor (TCR), heterodimers of either α/β subunits or γ/δ subunits. However, there are other recurrent reciprocal translocations that can also be assessed by polymerase chain reaction (PCR), quantitative real-time polymerase chain reaction (q-PCR), fluorescent in situ hybridization (FISH), or metaphase cytogenetics (MC). The latter two methodologies can also identify other structural or numeric aberrations as well. These other methodologies, often in conjunction with clonality testing, are useful diagnostically as well as potentially for the measurement of minimal residual disease (MRD) during therapy monitoring. Gene naming conventions throughout the chapter follow the nomenclature recommendations set forth by the HUGO Gene Nomenclature Committee.[11]

Clonality Testing

Immunoglobulin Gene Rearrangements

The expression of Ig is one of the defining characteristics of all mature B-cells. At the earliest stages of B-cell ontogeny, recombination of the Ig heavy chain (*IGH@*) can be detected, well before the expression of the complete heterotetrameric product composed of two heavy chains and two light chains on the surface of the B-cell, where the light chain can be either kappa or lambda (Fig. 87.2). Although the individual Ig genes are located at disparate locations in the genome—the *IGH@* locus on chromosome 14q32, the kappa locus (*IGK@*) at 2p11, and the lambda locus (*IGL@*) at 22q11—the genes are all structured in a similar fashion to enable the unique somatic recombination of germline gene segments that create the antigen specificity of the final Ig protein heterotetramer. During this recombination process, individual variable regions (V regions), joining regions (J regions), and constant regions (C regions) are selected which form the body of the final Ig chain and contribute to the antigen specificity. In addition, the *IGH@* locus also contains diversity regions (D regions), for a final VDJC rearrangement (versus VJC for the light chains).[12]

Each gene segment is marked for potential recombination by a recombination signal sequence (RSS) which is acted upon by the recombination-activating genes 1 and 2 to create double-stranded DNA breaks that are recombined through nonhomologous end-joining, with assistance from the DNA-bending proteins, HMG1 and HMG2. The D-J recombination is the first rearrangement of the *IGH@* locus, followed by V-DJ and VDJ-C. At each recombination site, these double-stranded breaks can be further modified by being filled in with palindromic nucleotide insertions (P nucleotides), removal of one to two nucleotides through a random exonuclease activity, or further varied by the addition of N nucleotides that are not present in the germline sequence through terminal deoxynucleotidyl transferase. These actions also contribute to the diversity of the Igs. The cut and modified ends of the coding sequence are then also repaired by nonhomologous end-joining.[12]

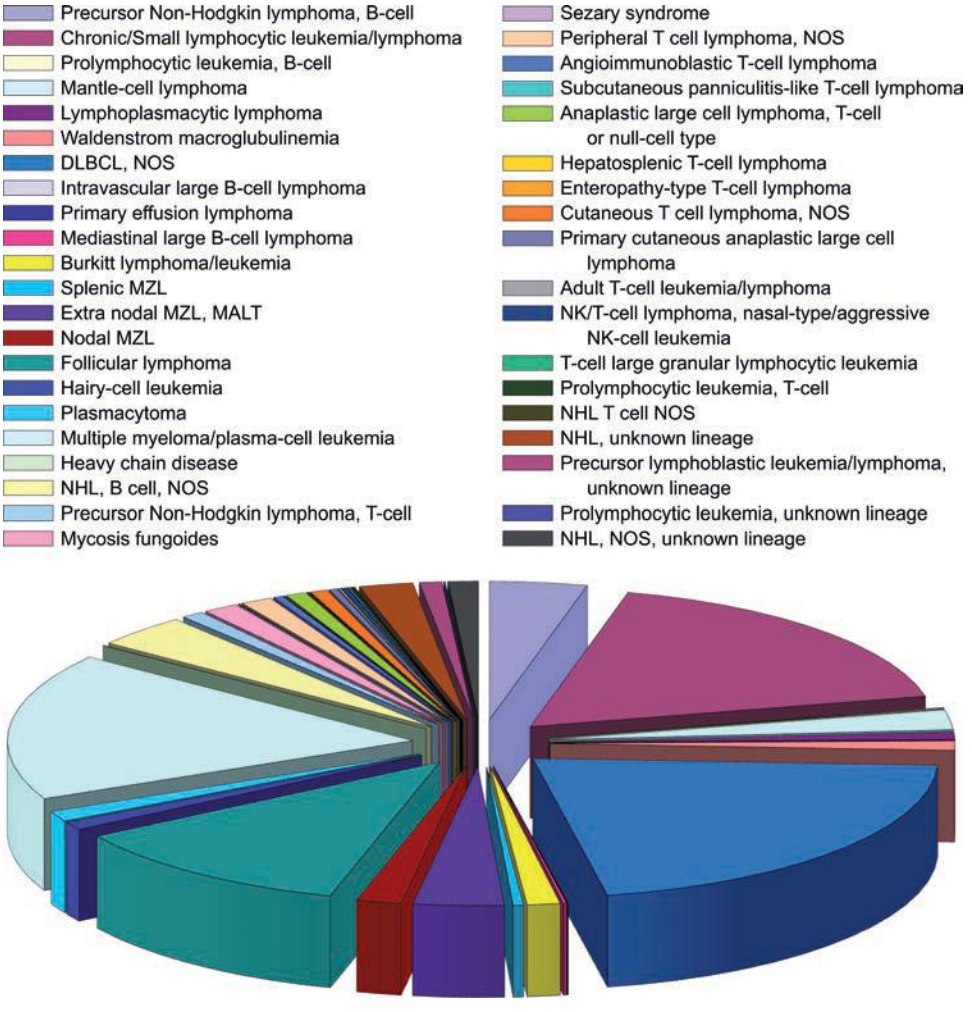

FIGURE 87.1. Surveillance epidemiology and end result (SEER) data for the relative incidence of non-Hodgkin lymphomas. See Reference 3.

The variable regions of all the Ig proteins form a canonical beta-sheet structure which necessarily means that the majority of amino acids are paradoxically highly conserved.[13] These conserved regions are termed the framework regions, FR1-3 (Fig. 87.3). Between these framework regions are the truly variable complementary determining regions (CDRs1-3) which encode sequences of approximately 10 amino acids that project from the tips of the beta-sheet as fingers reaching out to contact antigen. Therefore, although the *IGH@* gene contains up to 200 different V regions (approximately 80 of which are widely used in human biology),[12] consensus primers can be constructed against the V regions that will permit the amplification of the gene across the VDJ recombination sites by PCR. Due to the variability of the encompassed CDRs as well as the diversity created by the random exonuclease activity and N nucleotide addition, physiologic B-cells should each have a distinctively sized PCR product, and

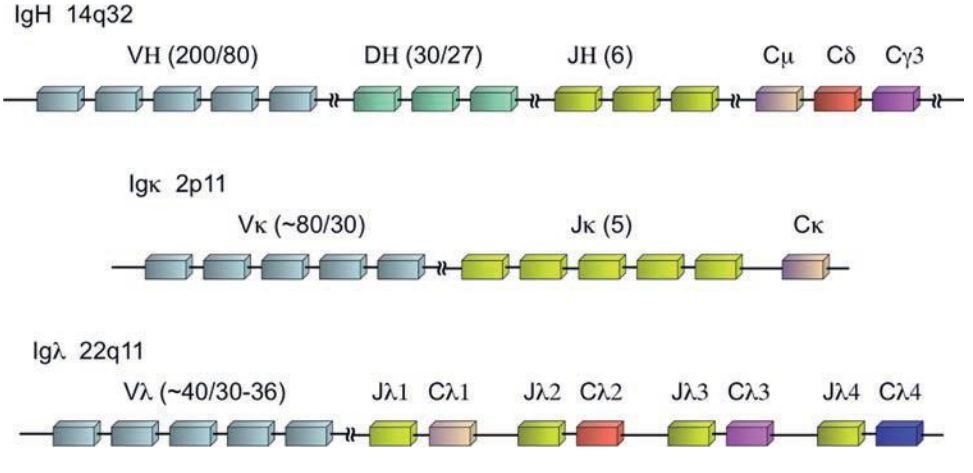

FIGURE 87.2. Immunoglobulin genes and their chromosomal organization. The number of subunits of each type (V, D, or J) is noted in parentheses as follows: total number of subunits/number of subunits in physiologic use.

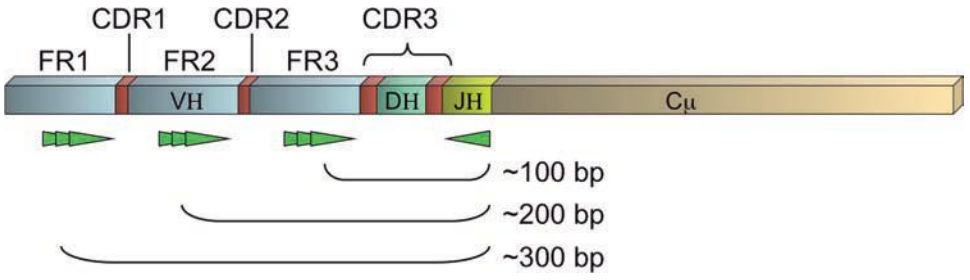

FIGURE 87.3. Schematic of an immunoglobulin gene rearrangement. Shown are the framework regions (FR1–3, light blue), complementary determining regions (CDRs, red; note CDR3 is composed of the DH region and the flanking variable junctions created by random exonuclease activity and N and P nucleotide insertions), and representations of potential locations of primers in the FRs noted (*bright green*). General sizes of polymerase chain reaction (PCR) products are indicated.

clonal populations should have identical PCR products. This forms the basis of the Ig gene rearrangement studies by PCR. Southern blot (SB) methods, which look for the unique rearrangements on unamplified DNA, have been considered the gold standard for gene rearrangement studies, but have fallen into disuse with the ease of PCR-based methods and now next generation sequencing.

PCR primers may be constructed against any of the three framework regions. Although more variability is theoretically captured by using FR1 primers, the PCR products are longer and therefore more difficult to obtain using standard methods (Fig. 87.3). Therefore, many labs use only FR3 primers (coupled with J region primers), or a combination of FR3 and FR2 primers. However, somatic hypermutation (SHM), a process that occurs physiologically in the germinal centers of lymphoid tissues when a B-cell is exposed to antigen, can cause sequence changes in both the CDRs and the FRs.[7,13] This normal physiologic process can prevent the binding of individual primers should a mutation occur in the targeted "consensus" sequence. Thus, SHM limits the clinical sensitivity of limited sets of primers to detect clonal populations of B-cells (e.g., some clones may not be detected by PCR due to failure of the consensus primers to bind to that clone's specific sequence). However, several commercial kits are now available that utilize multiplexed sets of primers against all the FRs, in the hopes that at least one primer will have an intact unmutated sequence to permit amplification of the unique PCR product.[14,15,16,17] In addition, primers against *IGK@* and *IGL@* can also be utilized, although the PCR products do not form a well-dispersed Gaussian distribution as in the case of the *IGH@* assay, complicating their interpretation.[16]

Table 87.1 shows the range of clinical detection rates (clinical sensitivity) of multiplexed *IGH@* PCR assays compiled from several published papers.[14,15,17] These data clearly demonstrate the high clinical detection rates for neoplasms of pre-germinal center B-cells (pre-GCB). However, the gene rearrangement assays have a lower clinical sensitivity for neoplasms of post-GCB-cells and particularly of germinal center lesions, during which active SHM may be ongoing, resulting in very low detection rates.[7,18] *IGK@* or *IGL@* assays can be used if the *IGH@* assay fails to detect a clonal rearrangement for a known neoplastic B-cell process. Therefore, combinations of primers of all three frameworks of *IGH@* and for *IGK@* are required to ensure reasonable clinical sensitivity across all B-cell neoplasms.[14,15,17] On the other hand, the detection of an apparently clonal population does not equate with neoplasia, as pseudoclonality can be seen in reactive conditions with a strong reaction to a particular antigen, or in cases of a limited B-cell repertoire.

Analytical sensitivity of the *IGH@* PCR assay depends upon the number of polytypic background B-cells. In cases of limited background B-cells, the neoplastic clone can be detected at 1 cell in 100 nonneoplastic (and non-B lineage) cells, or approximately 1%. However, in cases of significant numbers of background polytypic B-cells, the detection of a clonal peak rising above the Gaussian distribution of background B-cell rearrangements can be as low at roughly 5% analytical sensitivity (Fig. 87.4). The analytical sensitivity can be increased by the design of allele-specific oligonucleotide primers. However, this technique requires sequencing of the patient's specific clonal Ig rearrangement. With the advent of rapid sequencing methods, this may become more practical in the future. However, recently next generation sequencing itself has been developed as a method to determine clonality and to monitor MRD.[18a]

T-cell Gene Rearrangements

The TCR is a heterodimer of two proteins that form the functional receptor, either $\alpha\beta$ or $\gamma\delta$. During T-cell ontogeny, the γ (*TRG@*) and δ (*TRD@*) genes rearrange first, so that the $\gamma\delta$ receptor is the first to be expressed. Subsequently the α (*TRA@*) and β (*TRB@*) genes rearrange, and ultimately 85% to 98% of mature peripheral T-cells express the $\alpha\beta$ receptor.[19,20] It is interesting that the location of these genes is such that the δ locus is actually embedded within the α gene on chromosome 14q11 (Fig. 87.5). Thus, in the vast majority of the cases, the subsequent rearrangement of the α gene results in excision of the δ gene from the cell's DNA, and any previously rearranged sequences are lost. However, the β and γ loci, although both on chromosome 7, are distinct (7q34 and 7p15, respectively), and the rearrangement of the γ loci is retained, even if the cell ultimately expresses the $\alpha\beta$ T-cell receptor.

Like the immunoglobulin genes, the *TCR* genes are composed of V, D (β and δ genes only), J, and C regions (Fig. 87.5). However, unlike the immunoglobulin genes, there are no specific framework regions, and therefore consensus primers are difficult to design for the various V regions. Therefore, with the exception of homology between a few of the V regions, separate V region primers are required to assess all physiologically

TABLE 87.1

CLINICAL SENSITIVITIES OF THE IMMUNOGLOBULIN GENE REARRANGEMENT STUDIES[14,15,17]

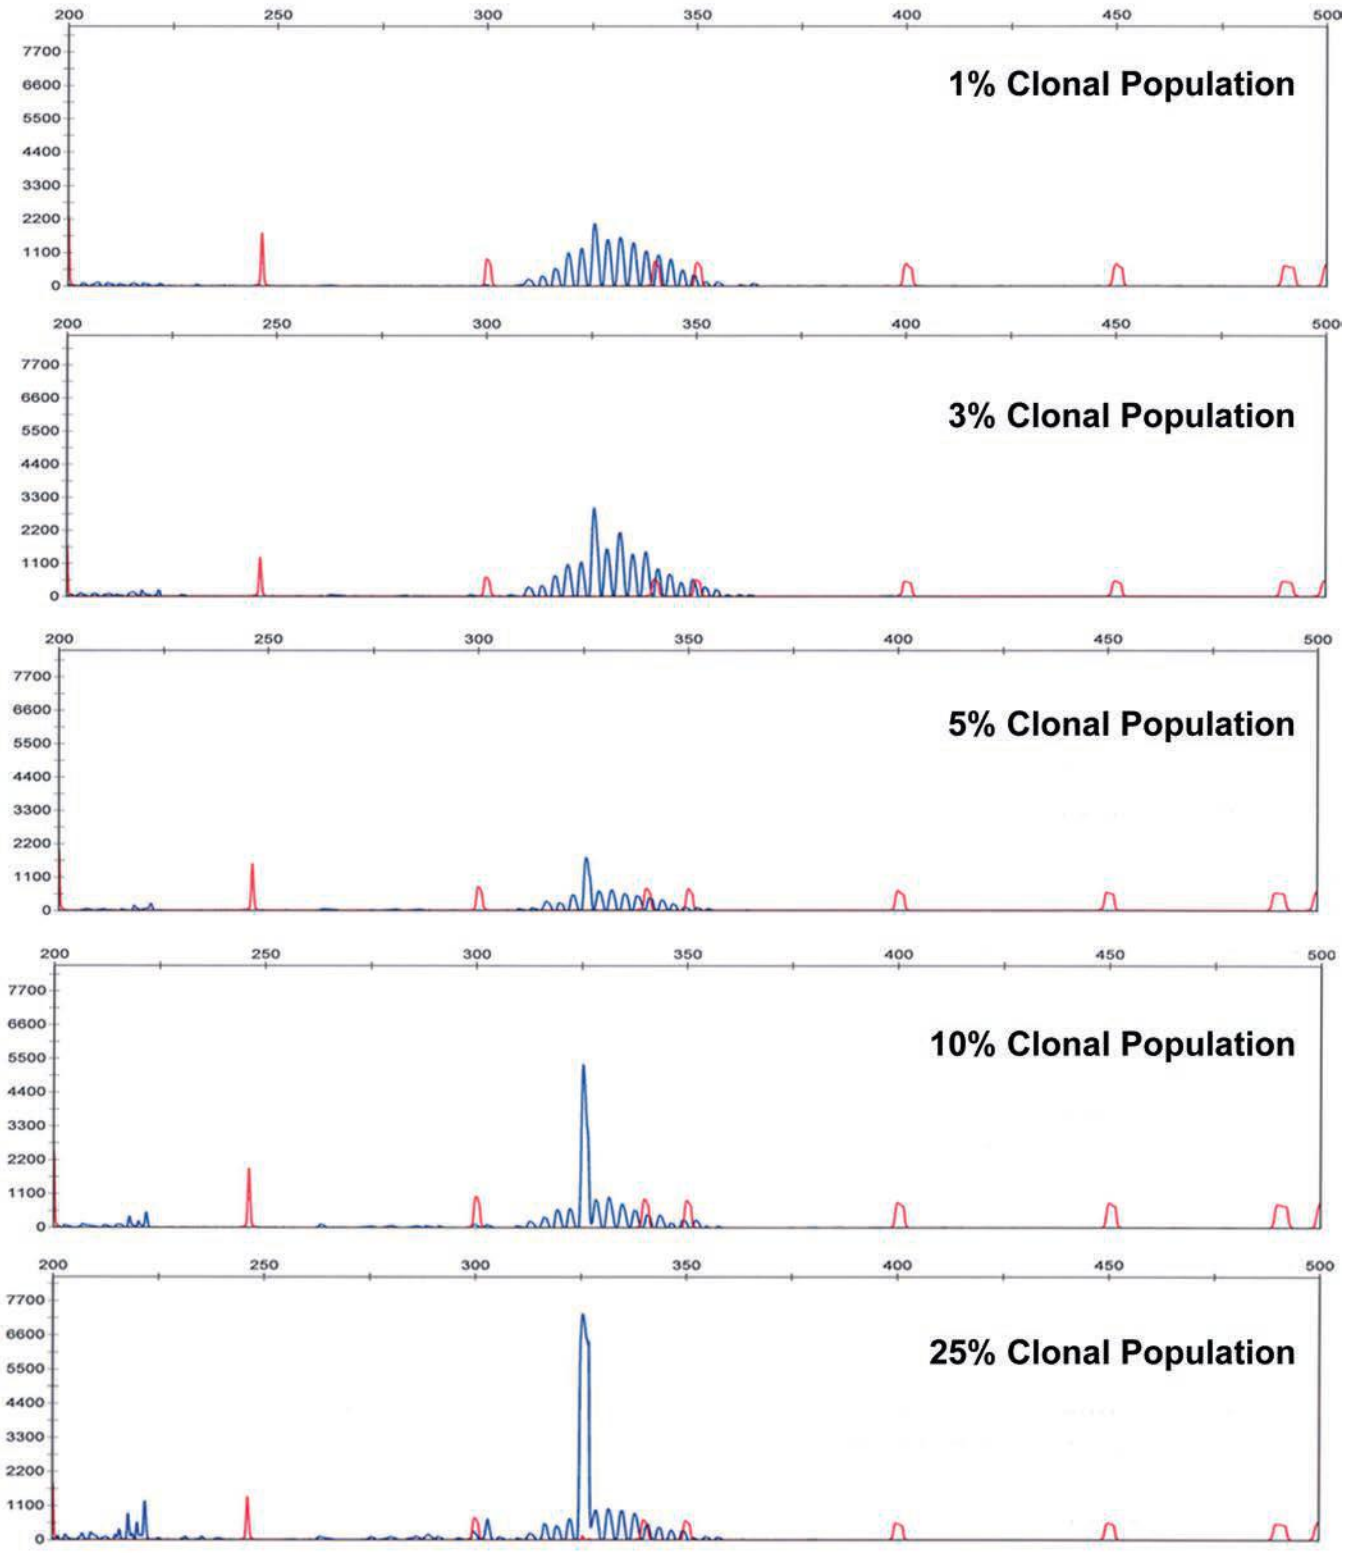

FIGURE 87.4. Analytical sensitivity of immunoglobulin gene rearrangement studies as illustrated by dilutions of a clonal population into a polyclonal background.

relevant *TCR* gene rearrangements. Due to the location of the α gene within the δ gene which limits its utility, the limited number of γ gene V regions (only Vγ1–11 are physiologically relevant of the 15 Vγ segments),[21] and the homology between the Vγ segments 1 to 8 which allows the use of a common primer for those segments, typically *TRG*@ is the common target of most clinical assays, with or without the addition of *TRB*@ assessment as well.

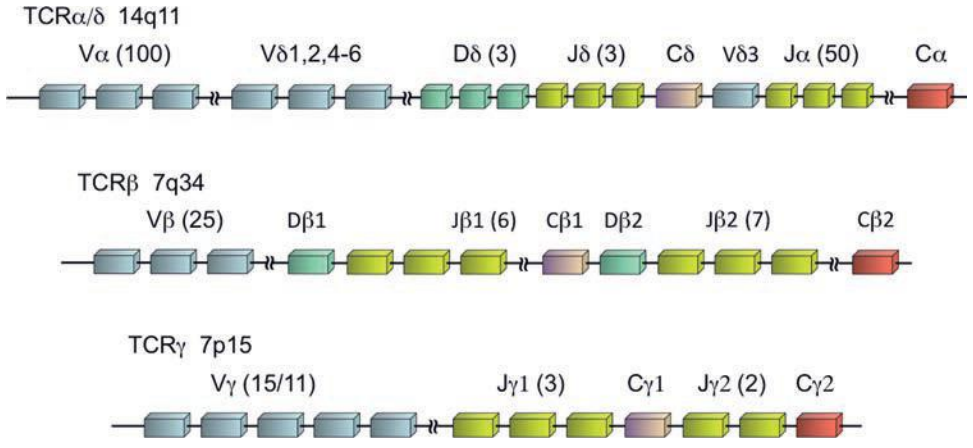

FIGURE 87.5. T-cell receptor genes. The number of subunits of each type (V, D, or J) is noted in parentheses as follows: total number of subunits/number of subunits in physiologic use.

The clinical sensitivity of the *TRG@* assay is higher than for the corresponding Ig assay due to the absence of SHM of the TCR. However, the assay still does not detect 100% of all neoplastic rearrangements due to other acquired mutations, and the true clinical sensitivity is approximately 89% to 94%.[15,17,22] In cases of a known neoplastic T-cell process, *TRB@* assay can also be used to look for a clonal marker of disease. The analytical sensitivity of the TCR clonality assays is similar to that of the immunoglobulin assays, although for biologic reasons limited T-cell repertoires can often lead to pseudoclonality or oligoclonality in certain tissues (such as skin), making it easy to overcall or undercall TCR clonality results. Therefore, the presence of an apparently clonal population does not equate with neoplasia, and the absence of a clonal population does not exclude a neoplastic process. Next generation sequencing methods have also been developed for diagnostic and MRD purposes for the assessment of T cell clonality.[18a]

Southern Blot

As alluded to earlier, SB is the gold standard, albeit outdated, method for all clonality testing and has been used to test for various translocations or other chromosomal aberrations as well. First introduced in 1975, this technique uses unamplified genomic DNA from the sample which is fragmented using restriction enzymes.[23] These cleavage products are separated by size via agarose gel electrophoresis and then transferred or "blotted" to a nitrocellulose membrane. The membrane is then treated with typically radiolabeled probes that are complementary to a particular sequence of interest. The radiolabel provides signal amplification at the final detection stage that affords an analytical sensitivity of approximately 2% to 3% tumor cells of the sample cellularity.

This method is extremely time consuming, labor intensive, and requires numerous precautions for the handling and disposal of radioactivity. For these reasons, SB has been replaced in most clinical laboratories by methods based upon PCR.

Polymerase Chain Reaction

PCR is a commonly used method for template amplification due to its ease, versatility, and analytical sensitivity. The achievable levels of amplification are such that as few as 1 neoplastic cell can be detected out of 10^5 to 10^7 cells (0.001% to 0.00001% analytical sensitivity). Amplification also permits the use of this assay in small sample volumes. In addition, if the size of the amplicon (product of the PCR reaction) is small, even partially sheared DNA, such as that obtained from formalin fixed paraffin-embedded tissue, is adequate for the assay. The high sensitivity of the assay also makes it ideal for the detection of MRD.

In this assay, forward and reverse primers (typically 15 to 25 bp in length) are generated against the target region. These primers may be specific for a mutated versus a wild-type sequence or may flank the area of interest (especially flanking areas of small insertions or deletions, or flanking a translocation site). Using a specific temperature-resistant polymerase (Taq polymerase) that allows repeated cycles of strand melting (separation of double-stranded DNA), primer annealing, and polymerase-mediated extension of the primers based upon the target sequence, the targeted region in DNA can be doubled per cycle. If compatible conditions can be designed for multiple sets of primers, the PCR assay can be multiplexed. The template can consist of genomic DNA, or mRNA that has been reverse transcribed into clonal DNA (cDNA).

PCR products, or amplicons, can be detected in several different ways. *Qualitative detection methods* include agarose gel electrophoresis and capillary electrophoresis, both of which allow the separation of amplicons by size. In the latter method, fluorescently tagged primers are used, which allows separation of the amplicons along the capillary tube and detection using a fluorescent camera as the separated products exit the tube. By using multiple different fluorophores on each primer set, even multiplexed assays can be analyzed by this method.

Quantitative detection methods can also be used, typically involving some version of quantitative real-time PCR (q-PCR). In this technique, fluorescence is directly proportional to the amount of amplicon generated. This fluorescence can be generated after the amplification is completed by the intercalation of a fluorescent dye, such as SYBR green, or can be continuously generated during each cycle of amplification by the release of fluorescence during the extension step (e.g., Taqman probes). Using pre-made dilutions of the desired amplicon to generate a standard curve, direct quantitation of the amount of the target in the sample can be made.

Fluorescent In Situ Hybridization

FISH is another molecular method of interrogating genomic aberrations. FISH utilizes longer probes than PCR (typically 200 to 400 bp in length) which bind in a complementary sequence-specific fashion to the intact chromatin of interphase cells.[24] FISH is commonly used to identify balanced translocations, and can also identify copy number variations (CNVs) of large segments of chromatin. In the former case, by using probes directed against the translocation partners, each labeled with a different fluorophores, the presence of a translocation is marked by fusion of the two signals (Fig. 87.6). FISH can also be used in cases where the translocation partner is unknown by the use of breakapart probes, probes located adjacent to each other on either side of the putative breakpoint in the one known translocation partner,

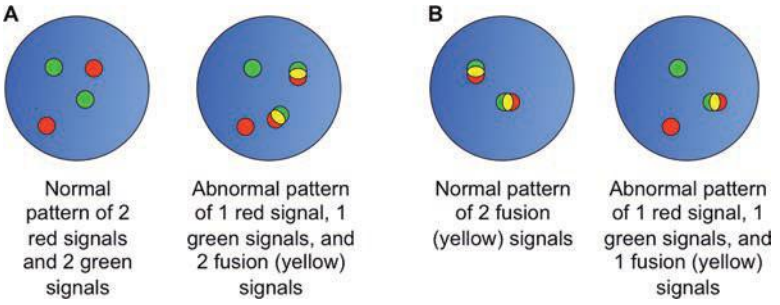

FIGURE 87.6. Examples of FISH patterns. A: Schematic of dual color dual fusion fluorescent in situ hybridization (FISH) probes. **B:** Schematic of breakapart FISH probes.

which appear as a fused signal when the gene is intact, and separate signals when a translocation occurs.

This method, like that of PCR methods, is necessarily targeted and therefore biased by the subjective nature of which probes are selected for study (Table 87.2). Unlike PCR, FISH has low resolution of the sites of aberrancy, in the range of 2 to 5 kb (kilobase pairs).[24] The analytical sensitivity depends upon the nature of the probes utilized in the assay and the number of interphases assessed. However, typical analytical sensitivities range from 1% to 5% for 200 interphase cells evaluated. Nevertheless, FISH remains a mainstay in the identification of genetic aberrances in lymphoid lesions due to the variety of breakpoints and translocation partners in these malignancies which often limit the use of the highly targeted PCR methods.

Metaphase Cytogenetics

Conventional karyotyping, based upon metaphase cytogenetics (MC), is a mainstay in hematopathology due to its unbiased and uniform genomewide coverage (Table 87.2). Due to the requirement to culture the cells in order to obtain metaphase spreads and the time-consuming microscopy to generate the karyotypes, the method takes typically at least 2 days. In addition, terminally differentiated cells, such as mature lymphocytes and plasma cells, do not readily undergo mitosis, and therefore standard methods often fail to identify the neoplastic karyotype of most lymphoid neoplasms.[25,26]

The resolution of MC is low, 5 to 10 Mb (megabase pairs).[27] In addition, due to the need to construct the individual karyotypes manually, even with the aid of computers, typically only 20 metaphases are examined, and the analytical sensitivity is therefore only approximately 10% (for balanced translocations, 2 of 20 metaphases must demonstrate the same abnormality for it to be considered a clonal change, and 3 metaphases must demonstrate the same CNV for it to be considered clonal).[28] Thus, this methodology is of limited utility in MRD testing and often is not helpful for lymphoid neoplasms with routine culture conditions.

Other Techniques

Somatic Hypermutation

SHM testing can be used both to identify clonal rearrangements of the *IGH@* gene and to calculate the percent of nucleotides that have undergone SHM in the V regions of *IGH@*. This assay has been used to understand the biology of many B-cell neoplasms. However, its main clinical utility has been in the determination of the mutational status in chronic lymphocytic leukemia/small

TABLE 87.2

CHARACTERISTICS OF DIFFERENT GENOMEWIDE STUDIES

Method	Resolution	Genome Coverage	Sensitivity	Detection of UPD and CN LOH	Detection of Balanced Translocations	Detection of Unbalanced Translocations	Utility in Screening New Lesions	Distinguish Different Individual Clones	Utilize Interphase DNA	Distinguish Somative Versus Germline Aberrations
aCGH	5–6 kb	Uniform	2–30%	No	No	Yes	Yes	No	Yes	Yes
aSNP	25–50 kb	Not Uniform	2–30%	Yes	No	No	Yes	No	Yes	No
Conventional karyotyping	5–10 Mb	Uniform	10%[a]	No	Yes	Yes	Yes	Yes	No	No/Yes
FISH	2–5 kb	Targeted	1–5%	No	Yes	No	No	Yes	Yes	No/Yes
PCR	Potentially single nucleotide aberrations	Targeted	Variable, potentially as low as 0.00001%	No	Possible	Possible	Yes	No	Yes	Possible
NGS	Potentially single nucleotide aberrations	uniform or targeted	5–10%	Possible	Possible	Possible	Yes	No	Yes	Possible

aCGH, array comparative genomic hybridization; aSNP, array single nucleotide polymorphisms; CN LOH, copy neutral loss of heterozygosity; FISH, fluorescent in situ hybridization; NGS, next generation sequencing; PCR, polymerase chain reaction; UPD, uniparental disomy.
[a]Clonality is typically defined as involving at least 2 of 20 metaphases.[28] For PCR and NGS methods, depending on the design of the assay/experiment, different questions may be answered. For instance, if normal and tumor tissues are examined for a particular mutation, somatic versus germline mutational status can be ascertained by PCR.
Portions adapted from Reference 27.

lymphocytic lymphoma (CLL/SLL). Typically a cutoff of 98% homology to germline is used to determine the mutational status, with greater than 98% homology corresponding to the unmutated designation, which carries a poor prognosis in CLL, and less than or equal to 98% homology describing a somatically hypermutated state, which is associated with a better prognosis in CLL.[29,30]

PCR using typically FR1 primers or leader primers (primers located in the leader region upstream from FR1) are used in conjunction with partner J_H primers. PCR can be performed on either genomic DNA (gDNA) or cDNA. Many laboratories report both results which typically are very similar, although each input type has its distinct advantages. Utilization of gDNA is the easiest to perform inasmuch as it involves the isolation of the more stable DNA from the samples (compared to labile RNA required for the preparation of cDNA) and avoids a requisite reverse transcription step. However, cDNA is better for the identification of function rearrangements as well as double in-frame small insertions and deletions (indels). In addition, it is better at defining the Ig isotype. After PCR, the amplicons can then be directly sequenced using labeled sequencing primers by capillary electrophoresis, or can be cloned into a plasmid and then sequenced following colony expansion and plasmid extraction. The latter method is required if there is significant background amplification (background polyclonal B-cells), but is quite time consuming and labor intensive.

Array Comparative Genomic Hybridization and Array Single Nucleotide Polymorphism

CGH was initially developed as a method to identify CNVs in patient tissues. The methodology is based upon the differential labeling of patient and control DNA, followed by competitively hybridizing those labeled samples to metaphase spreads. Areas of deletions would be seen as regions with a predominance of the control DNA fluorophore, whereas areas of duplications show a predominance of the patient DNA fluorophore. Due to the limitations of metaphase spreads, the array format was developed to contain an array of probes that span the genome (Fig. 87.7). The probes for array comparative genomic hybridization (aCGH) can be obtained from bacterial artificial chromosome (BAC)-derived sequences, cDNA, or from oligonucleotides. Using this method, CNVs and unbalanced translocations can be interrogated uniformly throughout the genome at a resolution as low as 5 to 6 kb (kilobase pairs) in some cases (Table 87.2).[27,31,32] The analytical sensitivity varies from 2% to 30% sensitivity.

By contrast, aSNP (array single nucleotide polymorphisms) is a single-color experiment that hybridizes labeled patient DNA or amplicons to an array composed of probes that are sequence-specific to interrogate individual SNPs. Because these are designed to target specific SNPs at their nonrandom genomic locations, the genome coverage is not uniform and this method is not useful in identifying balanced translocations or in distinguishing germline from somatic changes.[27,32] However, aSNP is especially useful in the identification of copy neutral loss of heterozygosity and uniparental disomy that are not assessed by aCGH. Analytical sensitivities are similar to those for aCGH. To leverage the advantages of both aSNP and aCGH, many commercial platforms are now available that combine the two array methods.

Due to the challenges of obtaining metaphases in lymphoid neoplasms, aCGH was rapidly applied to the study of chronic lymphocytic leukemia (CLL), for which disease aCGH can identify clonal abnormalities in 100% of cases.[26] For comparison with FISH and metaphase cytogenetics, other studies have demonstrated the ability of aCGH to detect abnormalities in 12% of normal karyotype CLL cases[26] and in 21% of cases where no aberration was detected by FISH.[33]

Metaphases are also difficult to obtain in plasma cell neoplasms, leading to the prominent role of FISH in the diagnosis and prognosis of myeloma. However, because FISH is targeted, it cannot provide an unbiased genomewide assessment as can be achieved by aCGH. Gutierrez et al. found CNVs by aCGH in 69% of myeloma patients and that those patients had significantly decreased overall survival.[34] The prognostic significance of other specific loci, which include gains of 1q and 7q, have also been studied using aCGH.[35,36] The latter study also highlighted the utility of this method in paraffin-embedded tissue.

Next Generation Sequencing

Whole genome sequencing (WGS) provides the theoretically optimal combination of uniform unbiased genomewide coverage with nucleotide-level resolution for the discovery of acquired genetic aberrations in oncology (Table 87.2). The caveats, of course, center upon the cost and analysis of the potentially terabytes of data accumulated by a single WGS analysis. Prior to 2005, nearly all DNA sequencing was performed using some variant of Sanger sequencing, a method by which sequencing was achieved by chain termination first described in 1977.[37] These Sanger-based methods typically required large quantities of input DNA since the DNA needed to serve as the template for at least as many polymerase extension reactions as nucleotides to be sequenced. The polymerase products are separated by size to determine the sequence. This traditional sequencing is plagued by poor quality of the initial 15 to 40 bases of the sequence, and read lengths are limited to 500 to 1,000 bases.[38]

All NGS methodologies are based on read-through sequence determination, or sequence by synthesis, rather than chain-termination technology, and the sequencing is conducted in a massively parallel fashion (Fig. 87.8).[38,39] Sheared DNA, the

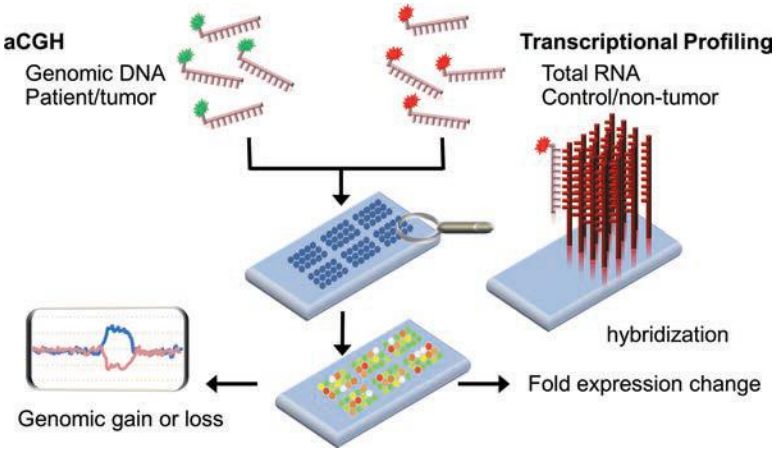

FIGURE 87.7. Schematic of array comparative hybridization (aCGH) and transcriptional profiling using a dual-channel platform. Patient and control genomic DNA (aCGH) or RNA (transcriptional profiling) are differentially labeled with fluorophores, then stoichiometrically mixed and allowed to hybridize to probes fixed to a solid surface. The relative amounts of fluorescence at each feature is measured to gain information about gains or losses in the patient sample compared to control (aCGH) or about over- or underexpression of genes (transcriptional profiling).

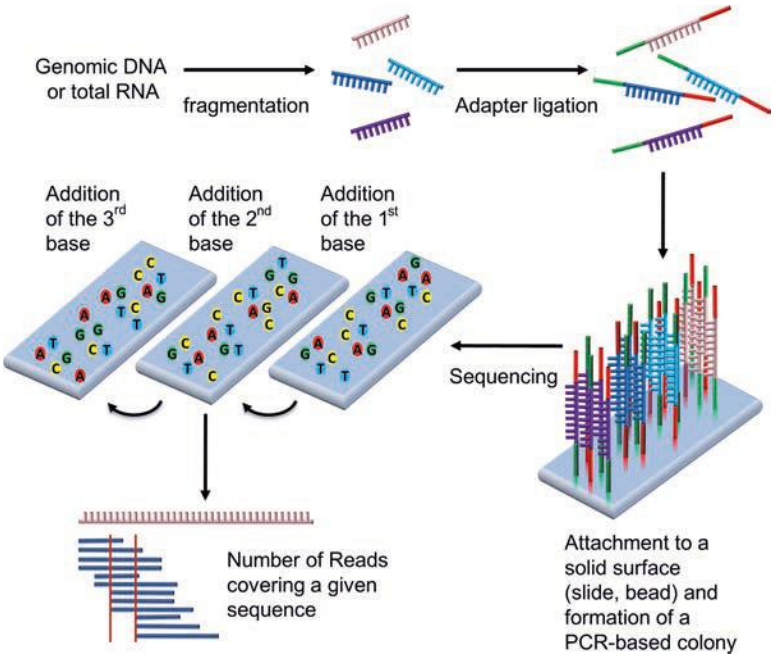

FIGURE 87.8. Schematic of next generation sequencing using dye-labeled nucleotides which act as reversible chain terminators. The DNA is first sheared and modified with adaptors. These adaptors can be used to immobilize the DNA fragments and serve as primers for polymerase chain reaction (PCR) amplification and for sequencing using the reversible chain terminators. The sequence of each fragment is determined, followed by the computational alignment of the fragments to construct the genomic sequence.

template, is immobilized in spatially fixed and arrayed positions by a variety of means and then iteratively interrogated by the repeated addition of each of the 4 nucleotides. Several methods of detection are utilized by the various commercial platforms. Illumina and Helicos BioSciences both use dye-labeled nucleotides which are reversible chain terminators; i.e., after detection of addition of a labeled nucleotide, the chain termination is chemically reversed before the next nucleotide is added (Fig. 87.7). Roche's pyrosequencing-based technology and Ion Torrent's semiconductor-based platform are both based upon the detection of the release of pyrophosphate or H^+ ion, respectively, which are chemically produced each time a nucleotide is added by the polymerase. Applied Biosystem's SOLiD™ platform uses a library of probes which encompasses all combinations of a dinucleotide sequence that are iteratively added through ligation to the growing strand.

Although the first human genome project took approximately 13 years and cost nearly 3 billion dollars to complete through Sanger-based methods, the advent of NGS has dramatically changed the landscape.[40] Today, a full genome can be sequenced at a cost of $1 to $5000 and take less than a day.[38] The read length for NGS is significantly shorter than for Sanger sequencing, often 30 to 400 bp. Therefore, the ability to map these sequences back to the genome requires significant overlap of the reads, from tens to even millions of reads per nucleotide. The higher number of reads are required to detect even small insertions and deletions or translocations. The analytical sensitivity for typical NGS can approach 5% tumor cells in a background of nonneoplastic cells.[41] However, newer deep sequencing methods have been adapted for MRD testing. Using very high read depths, sensitivities of 0.0001% can be achieved.[18a]

WGS can encompass vast amounts of data, however. For example the roughly 3 Gb (gigabase pairs) of the human genome at only 30 reads per nucleotide results in 90 Gb of data. However, by targeting the sequencing to a smaller portion of the genome, the data generated can be significantly decreased. Therefore, methods have been developed to conduct whole exome sequencing (WES), targeted WES, transcriptome sequencing (RNA-seq), sequencing of DNA methylation sites (bisulfite seq), mirnome sequencing (miRNA-seq), sequencing of immunoprecipitated DNA (ChIP-seq), and many others.[38] Targeting 500 kb at 100 reads generates only 50 Mb of data. Many of these targeted platforms can essentially perform expression profiling by sequencing.

Transcriptional Profiling

Initially developed in the 1980s, transcriptional profiling was the first *omic* technology to see widespread utilization. This methodology enables the assessment of the transcriptome, the sum of expressed genes reflected in the mRNA population of the cell(s). Since the 1990s, a number of high-density commercial microarray platforms, in addition to the numerous academic methods, have been available, differing in their amplification methods, types of probes, probe content, probe design, probe adherence technologies, and labeling and hybridization methods.[42] The two main types of DNA microarrays that have dominated the field involved probes made from either cDNA libraries or oligonucleotides, although the majority of the commercial platforms now use oligonucleotide probes. Transcriptional profiling can be performed as either a single-channel or a dual-channel experiment (Fig. 87.7).

This methodology does not capture the protein expression of various genes and any post-translational modifications. In addition, when the mRNA levels are varied between two samples, it is impossible to determine in a single timepoint comparison whether the differences are due to primary changes at the DNA mutational level, primary changes at the transcriptional level, or secondary changes at the transcriptional level resulting from the true disease-causing aberration. Therefore, the results are largely phenomenologic until extensive research is conducted to deconvolute the true disease-causing aberrancy. In addition, the methodology has limited analytical sensitivity for small fold changes, and limited clinical sensitivity if the reference samples are not chosen wisely. This methodology may be falling into disuse with the advent of NGS.

Nonetheless, transcriptional profiling has led to significant discoveries in lymphoid malignancies. One main utility has been in the definition of prognostic subgroups. For example, its use in the study of SHM status in CLL led to the identification of ZAP70 expression as an independent poor prognostic marker.[43] Similarly, in DLBCL, transcriptional profiling has identified three widely used prognostic subgroups: GCB-like with better prognosis, and activated B-cell (ABC) and type 3 DLBCL, which does not

express either set of genes at a high level, the latter two subgroups with poorer prognosis.[44]

Gene expression profiling studies have also been useful in clarifying the biologic relationships between various hematolymphoid neoplasms. Studies have demonstrated, for example, the similarities at the transcriptional level between primary mediastinal large B-cell lymphoma (PMBL) and classical Hodgkin lymphoma (cHL)-derived cell lines,[45] or between anaplastic large cell lymphoma (ALCL) and cHL.[46]

MicroRNAs, Epigenetic Changes

MicroRNAs

Both plants and animals have evolved microRNAs (miRNAs), single-stranded RNAs of ~21 nucleotides, as a mechanism for translational regulation. These miRNAs are encoded in the genome and are transcribed by DNA polymerase II. Following processing in both the nucleus and cytoplasm, the mature miRNA, mediated by the RNA-induced silencing complex, binds in a complementary fashion to the 3′untranslated regions (3′-UTR) of target mRNAs to cause translational repression.

Physiologically, miRNAs play a key role in the development and identity of different cell types.[47,48] The pattern of transcription of miRNAs during ontogeny is tightly regulated.[49,50] Additionally, miRNAs expression patterns are also associated with specific cell types at a given stage of development. For example, differentiation of the hematopoietic lineages involves carefully co-ordinated changes of expressed miRNAs.[51,52] In addition, to their roles in differentiation, whether at the organism or cellular level, miRNAs are important in cell identity.[53] Thus, miRNAs, individually or in profiles, can be markers of tissue type.

Due to their roles in cell identity and differentiation, miRNAs have been investigated in numerous tumor types. Interestingly, the location of all miRNAs in the human genome is nonrandom. It has been demonstrated that miRNAs are concentrated by a factor of nine in genomic fragile sites and others that are commonly altered in cancer.[48] Thus, over one-half of 186 miRNAs evaluated in one study were located at cancer-associated genomic regions, such as regions of loss of heterozygosity, common breakpoints and areas of amplification. These findings suggest that aberrant miRNA expression might be a common pathway in oncogenesis.

For example, the commonly deleted region in CLL (13q14) contains two miRNAs, *miR-15a* and *miR-16-1*.[56,54,55] These are consequently down-regulated in CLL, resulting in overexpression of their target mRNAs, *BCL2* and *MCL1,* and an overall antiapoptotic effect.[56] By contrast, *miR-155* has been identified as up-regulated in a number of B-cell lymphomas. First identified in cases of childhood BL, expression of the pre-miRNA for *miR-155* was found to be up-regulated in BL, DLBCL (associated with the ABC subtype), CLL, and marginal zone lymphoma.[57–59,60,61] The miRNA polycistron *miR-17-92*, located at 13q31, is also implicated in lymphomas such DLBCL, FL, mantle cell lymphoma (MCL), and primary cutaneous B-cell lymphoma, among others.[62]

Using miRNA RT-PCR, microarrays, and NGS methods, miRNA expression patterns have been interrogated and represent an unfolding field of lymphoma research. The future may see these miRNAs as the target of diagnostic, prognostic, or even therapy-monitoring assays.

Epigenetics

Epigenetics involves the heritable alterations in gene expression that are not caused by actual changes in the genomic sequence. Epigenetic changes occur through one of two main pathways. Methylation of the 5-position of cytosines, particularly in CpG rich sites such as CpG islands, shores, and shelves, results in transcriptional repression. CpG islands are defined as regions >500 bp in length with a CG percentage >55% and an observed to expected CpG ratio of >65%.[63,64] Alternatively, post-translational modification of the amino acids of histones via methylation or acetylation can result in heritable changes in histone structure and therefore the accessibility of the DNA to transcription. DNA methylation has been the better-examined epigenetic mechanism of the two, and methylome studies can be conducted via NGS, methylation arrays, and targeted methylation methods.

All methods to interrogate methylation status depend upon one of three main techniques.[65,66,67] Isoschizomer restriction enzyme-based methods rely upon the selective cleavage of either methylated or unmethylated sequences by specific restriction enzymes. A second method uses the chemistry of bisulfite to convert unmethylated cytosine to uracil, thereby causing a sequence change in unmethylated CpG sites but not in methylated sites. These differences can then be identified via sequencing or sequence-specific hybridization methods. Lastly, proteins that selectively bind to methylated CpG sites, whether the naturally occurring methylation binding protein or antibodies generated against CpG sites, can be used to pull down methylated fragments of DNA. All three techniques can be used to prepare samples for sequencing, arrays, or more targeted methods.

RECURRENT MOLECULAR ABERRANCIES IN B-CELL AND T-CELL NEOPLASMS

Tables 87.3 and 87.4 list many of the common reciprocal translocations found in B-cell and T-cell malignancies, respectively. Of note, many of the reciprocal translocations involve one of the immunoglobulin genes in the case of B-cell lymphomas (most commonly *IGH@* on chromosome 14q32). A smaller proportion of T-cell lymphomas involve the TCRα/δ locus on chromosome 14q11. The ensuing text highlights some of the better known translocations, and discusses selected other molecular aberrancies identified in specific lymphoid neoplasms.

Mature Neoplasms of B-cells

Burkitt Lymphoma

BL is a highly aggressive B-cell neoplasm that can have a lymphomatous, leukemic, or combined presentation, although these forms are not biologically distinct. However, there are three subtypes of BL that appear to have different epidemiologic and molecular bases, while related by their common dependence upon *MYC* dysregulation.[4] The endemic variant of BL is prevalent in equatorial Africa, tending to occur in young children between the ages of 4 and 7, with involvement of the mandible, maxilla, other facial bones, and abdomen.[5] There is an association of this form of BL with Epstein-Barr virus (EBV) which is also endemic to that geographic region, and approximately 95% of endemic BL contains clonal EBV DNA. Sporadic BL is found predominantly in adolescents and young adults of Western countries, and is the most common form of childhood lymphoma in the United States. In these cases, the disease is predominately abdominal with less frequent association with EBV in 5% to 30% of cases.[4,9,68] Immunodeficiency-associated BL is the third biologic subtype, where the most common association is with human immunodeficiency virus (HIV), although this form of BL can be seen secondary to other causes of immunodeficiency, both primary and secondary in nature. In approximately 25% to 40% of cases, there is an association with clonal EBV as well.[69,70]

Translocations of the *MYC* gene characterize BL as well as a subset of aggressive DLBCLs, many of which are currently best classified as B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and BL. Thus, although essentially all BLs have some form of a *MYC* translocation, a *MYC* translocation is not specific to BL.

The most common translocation partner of *MYC*, located at 8q24, is the *IGH@* locus on chromosome 14q32. This t(8;14)(q24;q32) can be identified in 80% of all BL and results in the overexpression of *MYC*.[71,72] The remaining cases of BL place *MYC* under the regulation, not of the heavy chain locus, but under one of the light chains, with a kappa light chain partner in a t(2;8)(p11;q24) and with lambda in t(8;22)(q24;q11).[73,74] The *MYC* gene is composed of three exons, the first noncoding, and the remaining two coding. *MYC* encodes for a transcription factor involved in both cell proliferation as well as apoptosis (Fig. 87.9]). Dysregulated function of MYC results in increased cell cycling through its inhibition of p21 and p27 as well its promotion of CDK2 and CDK4.[75] This is manifest pathologically by the numerous mitoses in BL as well as the extremely high proliferation rate, with Ki-67 expression typically >99%. In addition, MYC is proapoptotic, correlating with the numerous apoptotic bodies that create the classic "starry sky" histologic appearance of these tumors.

Although all cases of BL contain a translocation of *MYC*, the different subtypes of BL are molecularly distinct as well.[76,77,78,79] All the translocations with immunoglobulin genes result in the transcription of the full *MYC* coding sequences. However, the breakpoints of *MYC* and immunoglobulin genes vary among the BL subtypes. In endemic BL, the *MYC* breakpoint is located approximately 300 kb upstream from exon 1. This breakpoint translocates the full *MYC* gene to the J_H region of *IGH@*. By contrast, the *MYC* breakpoint in sporadic BL can occur 5′ to exon 1 or within intron 1, still translocating the full *MYC* coding region in either scenario to the one of the C regions of *IGH@* (Cμ, Cγ, and Cα have all been documented). In the translocations involving either *IGK@* or *IGL@*, the *MYC* gene typically remains on chromosome 8, with the breakpoint 3′ to the third and final coding exon to which the *IGK@* or *IGL@* locus is affixed at either a V or J segment. These differing molecular breakpoints may be related to differences in the stages of B-cell development during which the

[b]Indicates adverse prognostic significance in addition to its diagnostic role when extra copies of 7q are identified.

oncogenic change occurs. The sporadic cases may develop during class switching, whereas endemic cases may occur during SHM.[9]

As a result of the wide range of potential breakpoints in both the *MYC* gene and the immunoglobulin genes, PCR-based assays for *MYC* translocations are not practical, although primers have been generated against specific *MYC* breakpoints.[80] Rather, FISH is the optimal means for detection of *MYC* translocations at diagnosis. Specific probes against both *MYC* and *IGH@* can be used to assess for the t(8;14)(q24;q32). However these probes will be less sensitive for the variant light chain rearrangements. Therefore, *MYC* breakapart probes provide greater sensitivity for any *MYC* rearrangement, regardless of the immunoglobulin partner.[81]

In addition to BL, 5% to 16% of DLBCLs may contain a *MYC* translocation[82,226] and *MYC* translocations are seen in 35% to 50% of B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and BL.[4] Therefore, the presence of a *MYC* translocation alone does not define BL in the absence of the appropriate morphologic and immunophenotypic features. In cases where either the morphology or the immunophenotype is not classic for BL, additional FISH studies are recommended to rule out a double- or even triple-hit lymphoma.[83,84] These include FISH assessment for the *BCL2-IGH@* translocation t(14;18)(q32;q21) as well as for rearrangements of *BCL6* on chromosome 3q27. In addition, use of *MYC* breakapart probes are critical in these cases as the translocation partner in some cases may involve nonimmunoglobulin-related genes.[4]

Gene expression profiling studies have clearly supported the distinction of BL from DLBCL and the category formerly known as atypical BL (many of which are currently classified as B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and BL).[85,86] These studies have also highlighted the overexpression of T-cell leukemia 1 (TCL1) in BL which appears to be dependent upon the presence of EBV. Other studies have identified significant overexpression of *miR-155*.[57,59] In fact, the combinatorial decreases of several miRNAs, including *miR-34b*, may help explain the overexpression of MYC in those cases that appear to lack a *MYC* rearrangement (up to 10% of BL in some studies).[86,87,88] Another mechanism to account for these rare cases may be mutations in the *MYC* gene, although most of these are found in addition to a *MYC* translocation and may enhance the tumorigenicity of the *MYC* dysregulation.[89]

Guidelines for Molecular Testing in Burkitt Lymphoma

FISH confirmation of a *MYC* rearrangement is recommended at diagnosis of BL. However, FISH is not a sensitive marker of MRD. Due to the extensive SHM of BL as a neoplasm of GCBs, PCR-based immunoglobulin gene rearrangement studies have very poor clinical sensitivity, and, in the absence of allele-specific primers, PCR for immunoglobulin gene rearrangements is not superior to FISH in terms of analytical sensitivity. PCR directed against the *MYC* rearrangement itself sees little practical use due to the low clinical sensitivity. NGS may provide a good means for MRD testing. Therefore, FISH remains the optimal diagnostic test, and there is a limited role for any testing for MRD other than potentially NGS. As mentioned earlier, in cases that do not have the classic morphologic or immunophenotypic profile of BL, additional FISH studies for *BCL2* and *BCL6* gene rearrangements are also recommended.

Follicular Lymphoma

FL accounts for approximately 20% of all lymphomas, and is the second most common B-cell lymphoma, especially prevalent in Western nations.[4] FL is predominantly a disease of adults and subclassifications are based upon the histologic grade and degree of nodularity. Notable subtypes include primary cutaneous FL, pediatric FL, and FL of specific extranodal sites such as the duodenum or testes.

A *BCL2* translocation can be found in approximately 85% to 90% of cases of FL as well as in 20% to 25% of de novo DLBCLs (not transformed from a known prior FL), occasional cases of CLL, and rarely in other lymphomas.[10,90,91,92] Therefore, although the *BCL2* rearrangement is the canonical cytogenetic abnormality associated with FL, it is not pathognomonic for this entity.

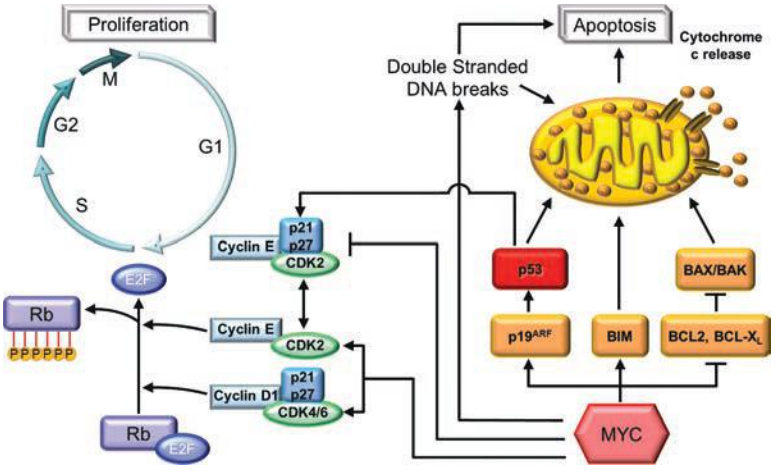

FIGURE 87.9. Apoptosis and proliferation pathways illustrating some of the roles of cyclin D1, MYC, and BCL2. Cyclin D1 associates with the cyclin-dependent kinases, CDK4 and CDK6, to form a complex that hyperphosphorylates the retinoblastoma protein (Rb). When phosphorylated, Rb is unable to sequester and inhibit the function of E2F1 in promoting entry into S phase and promoting cell cycling. MYC inhibits p21 and p27, inhibitors of the cyclin-dependent kinases, and promotes the expression of CDK2 and CDK4. MYC also inhibits several antiapoptotic proteins, such as BCL2. BCL2 forms a heterodimer with BAX, thereby preventing the formation of proapoptotic BAX/BAK homodimers. MYC also promotes the $p19^{ARF}$ activation of p53-mediated apoptosis and cell cycle arrest through p21 and p27.

The t(14;18)(q32,q21) is involved in the pathogenesis of FL, placing the *BCL2* gene on 18q21 under the regulation of the *IGH@* gene locus at 14q32. The translocation, which appears to be directed by the RSS-mediated VDJ rearrangement process, results in the overexpression of BCL2 which can be determined by immunohistochemical staining (IHC) except in cases when a mutation in BCL2, superimposed on the rearrangement, prevents the antibody from binding.[93] BCL2 is a mitochondrial membrane-bound protein that plays a critical role in the prevention of apoptosis (Fig. 87.9). BCL2 forms a heterodimer with BAX, thereby preventing the formation of proapoptotic BAX or BAK homodimers.[94,95] For GCBs, which should undergo apoptosis in the absence of appropriate nonself antigen stimulation, the overexpression of BCL2 results in the failure of the neoplastic cells to apoptose. This pathogenesis explains the rather indolent behavior of this lymphoma in the absence of additional hits that create a more proliferative drive.

Because FL is a neoplasm of GCBs, ongoing SHM limits the utility of immunoglobulin gene rearrangement molecular assays. Indeed, these assays have a notoriously low clinical sensitivity for FL using a single set of *IGH@* FR3 primers, ranging from 13% to 52%.[14,15,17] This corresponds to the extremely high average frequency of mutations in FL, of 11.6% for IgG clones, 9.9% for IgA clones, and 7.8% for IgM clones.[96] V_H contains an overall of 11.0% mutations in essentially 100% of cases of FL, where V_K contains a mean mutation rate of only 0.5% in only 33% of cases.[97] Therefore, the addition of *IGK@* primers greatly enhances the clinical sensitivity of the assay for FLs. The *IGK@* locus tends to harbor fewer mutations, 4.7% according to one study.[98] Therefore, by combining multiple immunoglobulin primers against both *IGH@* and *IGK@*, a clonal rearrangement can be identified.[14,15,17,97] However, without the development of allele-specific primers, any background B-cells can decrease the sensitivity of the detection of the clone to 1% to 5%.

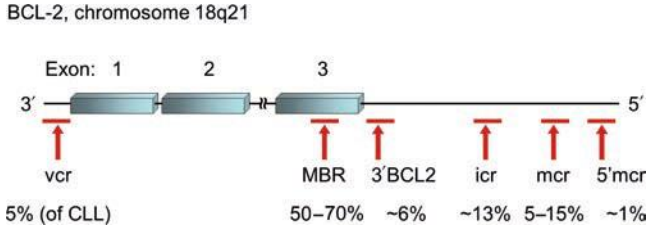

FIGURE 87.10. Location of breakpoint clusters in the *BCL2* gene and their relative frequencies in follicular lymphoma and other B-cell neoplasms. MBR, major breakpoint region; mcr, minor cluster region; icr, intermediate cluster region; vcr, variable cluster region.[99,100]

However, within the *BCL2* locus there are several clusters of breakpoints spread out over the entire length of the coding gene and extending to more than 30 kb downstream from the final exon 3 (Fig. 87.10).[99,100] The majority of the potential breakpoint clusters involve translocation of the full coding sequence of *BCL2* to chromosome 14. The major breakpoint region (MBR) is located within the 3′-UTR of exon 3 and accounts for 50% to 70% of potential breakpoints in *BCL2*. The minor cluster region (mcr) is located 20 to 30 kb farther downstream of exon 3, accounting for 5% to 15% of cases. The most common laboratory practice is to design primers for the MBR and mcr regions separately, using partner primers in the J_H subunit. These two sets of primers are able to detect approximately 70% to 85% of potential rearrangements.[10] However, there are several additional sites within the *BCL2* locus that can also be involved in rearrangements with immunoglobulin.[99,100] The intermediate cluster region (icr) may actually be more prevalent in neoplasms than the mcr, accounting for approximately 13% of translocations. The icr is located between the MBR and the mcr as is the 3′ BCL2 cluster which accounts for 6% of cases. The 5′ mcr is the farthest downstream breakpoint region, but only accounts for approximately 1% of cases. Lastly, the variable cluster region (vcr) is located 5′ to the first exon but is found predominantly in the rare cases of CLL which harbor a t(14;18) as well as rare cases of FL. The vcr is the only one of the breakpoint regions that occasionally can be involved in translocations involving either *IGK@* or *IGL@* instead of *IGH@*. Unlike in BL, there is no definitive evidence that the location of the breakpoint plays a particular role in prognosis or disease biology.[100]

Given the only 70% to 85% clinical sensitivity of most clinical PCR-based assays for t(14;18)(q32;q21), FISH for the rearrangement does play a role in those cases where the diagnosis is not definitive and the molecular testing fails to identify the translocation.[101] The clinical sensitivity of FISH is significantly higher (100% correlation with SB) due to the far longer probes used in this method which are not dependent upon the specific site of the break. However, due to the limited analytical sensitivity of FISH compared to PCR-based methods, FISH is less useful in monitoring patients for MRD. For cases in which there is morphologic concern for a more high-grade process (foci of grade 3B or concomitant DLBCL), FISH for *MYC* and *BCL6* rearrangements may also be helpful to identify transformation to a double- or triple-hit lymphoma.[83,84]

Even with the more clinically sensitive FISH studies, still approximately 10% of FLs will be negative for a t(14;18). Approximately 5% to 15% of FL cases may have translocations

involving *BCL6* instead, often associated with more aggressive lesions with increased large cells.[102,103,104,105] In addition, the FL variants such as primary cutaneous FL and pediatric FL are also typically t(14;18)-negative.[4] Higher grade FL is also associated with a higher incidence of t(14;18)-negativity.[106] These t(14;18)-negative FLs have been associated with down-regulation of miR-16, miR-26a, miR-101, miR-29c, and miR-138, supporting a later germinal center cell of origin.[107]

Studies on the prognostic significance of t(14;18) testing results have demonstrated that the achievement of PCR-negativity after induction chemotherapy did not significantly effect progression-free survival.[108] However, there is a significantly better survival in those patients who were PCR-negative in the bone marrow at diagnosis and for those who achieved PCR-negativity in the bone marrow after maintenance rituximab chemotherapy.[108,109] Thus, there is a role for molecular testing of t(14;18) in prognostication, although the role in MRD testing may be limited to after long-term maintenance therapy.

The use of molecular testing for *BCL2-IGH@* rearrangements for MRD monitoring carries one significant caveat. Using highly sensitive nested PCR methods or RT-PCR, t(14;18) may be found in up to 50% of normal individuals, the incidence increasing with age.[110] At this time, there is no indication that these t(14;18)-positive individuals are at any higher risk of developing FL. This phenomenon may serve as the basis for those individuals who enjoy prolonged complete remission while remaining PCR-positive.[111]

The presence of t(14;18) in normal individuals suggests that overexpression of BCL2 alone is not tumorigenic. Indeed, careful cytogenetic examination of FL by karyotype, aCGH, or aSNP can identify additional aberrations in up to 97% of FLs, including loss of 1p, 6q, 10q, 13q, and 17p as well as gains of 1q, 2p, 7, 8, 12q, 18q, and X.[112,113] Even in those cases without a CNV, copy neutral loss of heterozygosity can occur.[114] Cytogenetic abnormalities tend to accumulate with transformation of FL to DLBCL, and deletions or mutations of *TP53* located on 17p13, deletions of 6q or 9p are particularly associated with poor prognosis.[115,116] Losses or copy number neutral LOH of 1p36, at which site *TP73* and *TNFRSF14* are located, have been associated predominantly with diffuse FL.[117,118] In addition, acquisition of a *MYC* translocation may also be associated with transformation.[4]

Gene expression profiling studies in FL have identified two separate prognostic groups distinguished by their tumor microenvironment. Whereas a prominent T-cell signature is associated with better prognosis, a dominant macrophage signature is associated with poor outcomes.[119] Given the impracticality of diagnostic transcriptional profiling for all patients at this time, immunohistochemical surrogates have been sought including the quantitation of $CD68^+$ macrophages and the histologic localization and number of $FoxP3^+$ Treg cells, but the interpretation of these studies remains somewhat controversial.[117] Other studies have examined markers of microvascular density,[120] other antiapoptotic proteins in the BCL2 family,[121,122] BCL2/BAK ratios,[123] and CCNB1 expression[124] in FL for prognosis and diagnosis.

MiRNA profiling has identified expression profiles that distinguish FL from nonneoplastic cases as well as DLBCL, and can even discriminate between transformed and nontransformed FL.[125] Methylation studies have identified global hypermethylation in FL including the methylation of the promoters of *CDKN2B* (*p15)* and *CDKN2A* (*p16)*.[126] It is interesting that this global hypermethylation occurs with the concomitant overexpression of the methyltransferase EZH2 in FL.[127] However, in those 7% to 22% of cases of FLs with a mutation in *EZH2* identified by NGS there is paradoxically reduced transferase activity.[128,129]

In fact, genes involved in epigenetic regulation are commonly mutated in FL. *MLL2*, a histone methyltransferase, contains somatic mutations in 89% of FL whereas *MEF2B*, a gene that interacts with *CREBBP* and *EP300* to acetylate histones, is mutated in 13.4% of FL.[130] As mentioned earlier, *EZH2* mutations are common in B-cell lymphomas of germinal center origin, with the exception of BL.[129] Many of the genes that are affected by somatic mutation are similar to those found in cases of DLBCL as well, suggesting a common oncogenic pathway revolving around epigenetic dysregulation.

Guidelines for Molecular Testing in Follicular Lymphoma

At diagnosis, PCR or SB for the t(14;18) is recommended to establish the sensitivity of the assay for that patient's specific rearrangement. If positive, this marker can then be used to monitor MRD in this patient for prognostic import after maintenance therapy. Due to the extensive SHM of BL as a neoplasm of GCBs, PCR-based immunoglobulin gene rearrangement studies have very poor clinical sensitivity, and, in the absence of allele-specific primers, PCR for immunoglobulin gene rearrangements is not superior to FISH in terms of analytical sensitivity, and is vastly inferior to PCR for t(14;18) or NGS deep sequencing methods. Therefore, if the molecular assay for the *BCL2-IGH@* translocation fails to detect the patient's clonal rearrangement, then FISH for t(14;18) may be necessary if the diagnosis is cannot be made morphologically. If there is morphologic evidence for a more high-grade process disease, then FISH for *MYC* and *BCL6* may also be appropriate.

Mantle Cell Lymphoma

MCL accounts for 5% to 6% of NHLs, occurring predominantly in males over the age of 55 years (male:female ratio of 4:1).[4,131] MCL is typically thought of as an aggressive disease that is often widespread at diagnosis, although more indolent cases, often with a more leukemic presentation, can have longer survival times (average 79 months rather than 36 to 60 months for typical cases).[132,133] Other morphologic variants, such as the pleomorphic or blastoid variants, tend to have poorer outcomes.[4]

The hallmark cytogenetic aberration in MCL is the *CCND1-IGH@* translocation that can be found in 90% to 99% of all cases of MCL.[134,135] In addition, this rearrangement can also be seen in 20% to 25% of plasma cell myelomas, and some cases of CLL or prolymphocytic leukemia (PLL), and splenic marginal zone lymphomas.[136,137–139,140] This translocation results in the overexpression of cyclin D1 which can be assessed via IHC, with greater than 90% sensitivity for the translocation.[140] However, overexpression of cyclinD1 is also associated with the above lymphoid neoplasms as well as in the proliferation centers of typical CLL and in some cases of hairy cell leukemia (HCL) that do not harbor the translocation.[141,142]

The t(11;14)(q13;q32) in MCL juxtaposes the *CCND1* gene on 11q13 which encodes for cyclin D1 with J_H subunit of the *IGH@* locus on 14q32. As in the cases of *MYC* and *BCL2*, the majority of the translocations place the entire coding region of *CCND1* under regulation of the *IGH@* locus, resulting in overexpression of the full cyclin D1 protein. As in FL, the translocation with the J_H subunit is directed by the RSS. Cyclin D1 associates with the cyclin-dependent kinases, CDK4 and CDK6, to form a complex

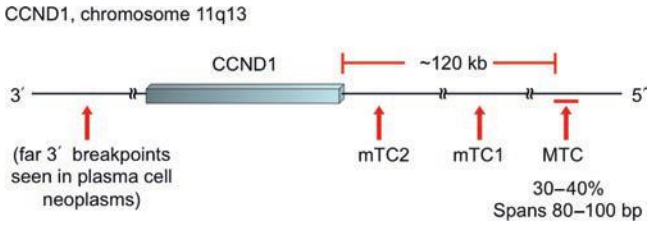

FIGURE 87.11. Location of breakpoint regions in the *CCND1* gene and the frequency of the most common breakpoint in mantle cell lymphoma. MTC: major translocation cluster, mTC: minor translocation clusters 1 and 2.[99,146]

that hyperphosphorylates the retinoblastoma protein (Rb).[143] When phosphorylated, Rb is unable to sequester and inhibit the function of E2F1 in promoting entry into S phase and promoting cell cycling (Fig. 87.9). This increased proliferation is marked by Ki-67 IHC staining, with higher levels of Ki-67 portending a more aggressive disease (cut-offs vary from >40% to >60%).[144,145]

The majority of the *CCND1* breakpoints occur upstream or centromeric to the coding sequence (Fig. 87.11). However, these breakpoint regions are spread out across approximately 120 kb.[99,146] Although there are three main regions of breakpoints, these are not tightly clustered. The major translocation cluster (MTC) spans an 80 to 100 bp region located the farthest upstream from the *CCND1* gene, accounting for 30% to 40% of translocations. This region was formerly known as the B-cell lymphoma/leukemia 1 region (*BCL1*), prior to the recognition that the gene responsible for the biology of MCL was actually the downstream *CCND1* gene. The minor translocation clusters (mTC1 and mTC2) lie closer to the *CCND1* coding sequence. In addition, occasional breakpoints 3′ to the coding sequence can be seen, especially in plasma cell myeloma. In addition to the translocations, deletions or point mutations in the 3′-UTR of *CCND1* mRNA have been identified in 5% to 10% of patients which result in increased stability of the transcript, potentially due to inability of miR-16-1 to target the mRNA. The resultant increased half-life of the transcript is associated with increased proliferative rate and poor survival.[147,148] By contrast, recently discovered 5′-UTR and first exon mutations in *CCND1* appear to be bystander mutations without prognostic significance.[149]

The wide distribution of these breakpoints explains the poor clinical sensitivity of PCR-based molecular assays for the t(11;14). The majority of PCR assays are designed to target just the MTC, resulting in a 30% to 40% clinical sensitivity, and due to variability within the J_H subunit as well, product sizes can span 143 to 934 bp.[146] By contrast, FISH, with its large probes, has nearly 100% sensitivity for the rearrangement.[135,140] However, given the greater than 90% correlation with IHC, in most cases IHC alone is required to make the diagnosis, with the caveat that other benign and neoplastic entities can have some cyclin D1 expression without harboring the t(11;14).

FISH and IHC, however, are not sufficiently sensitive for the detection of MRD. However, a clonal immunoglobulin gene rearrangement can be identified in the majority of cases of MCL (approaching 100% in some studies with a single set of FR3 primers).[14,15,17] The high clinical sensitivity of this test is due to the pre-germinal center naive B-cell origin of this neoplasm. In the majority of cases, the clonal cell population has not undergone any SHM. More detailed analysis, however, reveals that 26% of cases of MCL do indeed exceed the 2% nonhomology with germline used to define SHM, with an average mutation rate of 1.51% for the 32 cases examined.[150]

For the development of a true MRD test, however, the analytical sensitivity must be below the 1% to 5% range achievable by either FISH, IHC, or immunoglobulin gene rearrangements using standard primers. Using allele-specific primers, the utility of RT-PCR for *IGH@* VDJ rearrangement assays (peripheral blood either MRD positive or negative) has been demonstrated in the prediction of progression-free survival.[151] These methods, however, have not yet achieved widespread clinical utilization.

Approximately 1% to 10% of cases of MCL are t(11;14)-negative, involving variant translocations. These are divided among cyclin D1 overexpression by rearrangement with the light chains as well as overexpression of cyclin D2 or D3 with the immunoglobulins: t(2;11)(p11;q13) (*CCND1-IGK@*), t(11;22)(q13;q11) (*CCND1-IGL@*), t(12;14)(p13;q32) (*CCND2-IGH@*), t(2;12)(p11;p13) (*CCND2-IGK@*), t(12;22)(p13;q21) (*CCND2-IGL@*), and t(6;14)(p21;q32) (*CCND3-IGH@*).[135] These cases may be difficult to diagnose using cyclin D1 FISH, although breakapart of the *CCND1* signal may be seen with the light chain variants and breakapart of the *IGH@* locus may be seen with either *CCND2* or *CCND3* recombinations with *IGH@*. Strong expression of SOX11 by IHC has been identified in 90% of MCLs, including the t(11;14)-negative cases.[152,153] Expression of this transcription factor is negative in nearly all other mature B- and T-cell lymphoma, with the exception of some cases of BL, T-prolymphocytic leukemia (T-PLL), and lymphoblastic neoplasms. However, to date this immunohistochemical stain is not widely employed in histology laboratories.

MCL is also commonly associated with other genetic aberrations. The most common secondary abnormality is loss or mutation of the *ATM* gene, with inactivating mutations identified in 40% to 75% of cases and deletions of 11q22-23 in 21% to 59% of cases.[4] Mutations of *TP53* seen in approximately 7% to 20% of cases of MCL and deletions of the 17p13-pter are seen in 21% to 45% of cases.[4,154,155] Decreased function of either ATM or p53 affects the ability of MCL cells to respond appropriately to DNA damage, enabling the accumulation of additional genetic changes. Approximately 20% to 30% of MCL have deletions of the *INK4α*/ARF locus (*CDKN2A*) which encodes for both p14 and p16 in alternate reading frames.[156–158,159] The latter protein is an inhibitor of both CDK4 and CDK6; therefore its deletion facilitates cell cycling in conjunction with cyclin D1 overexpression. The p14ARF protein inhibits MDM2/HDM2 which negatively regulates p53. Thus, deletion of p14 results in decreased p53 function as a tumor suppressor and regulator of DNA damage.

Other common aberrations identified by karyotyping or aCGH include gains of 3q, 7p, 8q (*MYC*), 12q (*CDK4*), 12, 15q, and 18q (*BCL2*) and losses of 1p, 6q, 8p, 9p (*CDKN2A*), 9q, 10p (*BMI1*), 11q, 13q, and 17p (*TP53*) (SB validated candidate genes in parentheses).[135] Many of these changes are aberrations commonly associated with CLL, such as del(11q23), del(17p13), +12, del(13q14), and may suggest some commonality in pathogenic pathways. Blastoid and pleomorphic MCL may harbor tetraploid cytogenetics as well as gains of 3q, 7p, and 12q, and losses of 9p21 (*CDKN2A*) and 17p (*TP53*).[135] By contrast, indolent cases of MCL often have t(11;14) as the sole abnormality.[135]

Gene expression profiling on a large series of MCL patients has identified a characteristic signature of 20 genes which, not surprisingly, are associated with proliferation.[159] When this gene set was pared down to a minimal set of 5 genes (*RAN, MYC, TNFRSF10B, POLE2,* and *SLC29A2*), the profile by RT-PCR was able to predict survival.[160] Methylation profiling has been helpful in distinguishing MCL from CLL, identifying a MCL methylation profile demonstrating hypermethylation of developmental genes, in particular homeobox genes.[161,162] miRNA profiling has also identified several candidate miRNAs which might serve as adverse prognostic markers, such as down-regulation of miR-29 and up-regulation of miR-17-5p/miR-20a.[163,164]

NGS has recently confirmed mutations of *TP53* (7% to 20%), *ATM* (20% to 33%), and *CHEK2* (anecdotal)[135,154,155,165–167] but also discovered a 12% prevalence of *NOTCH1* mutations in MCL associated with decreased overall survival.[149] These mutations are truncation mutations or small frameshift indels in the PEST domain that result in decreased ubiquitination and increased

NOTCH1 activity. These mutations are similar in frequency and location to those seen in CLL, and differ from the more prevalent and widespread *NOTCH1* mutations in precursor T lymphoblastic leukemia.

Guidelines for Molecular Testing in Mantle Cell Lymphoma

At diagnosis, IHC for cyclin D1 overexpression is required. Further testing by FISH is only required for the rare cyclin D1-negative cases. IHC for SOX11 can also be considered in those cases (limited availability at this time). There are no good MRD markers for MCL, in the absence of allele-specific primers for patient-defined immunoglobulin gene rearrangements. Additional prognostic information may be gleaned from loss of the *TP53* locus, and *NOTCH1* mutational testing may be relevant in the future.

Extranodal Marginal Zone Lymphoma (Mucosa-associated Lymphoid Tissue Lymphoma)

Extranodal marginal zone lymphomas comprise 7% to 8% of all B-cell lymphomas and are the most common NHL of extranodal site.[4] This neoplasm is not to be confused with splenic marginal zone lymphoma or nodal marginal zone lymphoma, as these entities lack the characteristic reciprocal translocations found in the lymphomas of the mucosa-associated lymphoid tissue (MALT). It is interesting that these lymphomas are not traditionally found in normal physiologic sites of MALT, but rather in sites exposed to chronic inflammation that acquire a significant lymphoid infiltrate.[9] This chronic inflammation is often associated with specific infectious agents or autoimmune disease, and these instigating etiologies segregate by the sites of the MALT lymphomas (Table 87.5).[168,169]

Four recurrent reciprocal translocations are identified in MALT lymphomas: t(11;18)(q22;q21), t(1;14)(p22;q32), t(14;18)(q32;q21), and t(3;14)(p14.1;q32). The first three of these translocations all involve overexpression or fusion of components within the NF-κB pathway, resulting in overstimulation of the pathway and overexpression of NF-κB-dependent genes involved in antiapoptosis and cellular proliferation (Fig. 87.12).[168] Typically, stimulation of the BCR (Ig complex) induces the interaction of BCL10 and MALT1 which promotes dimerization of MALT1. This complex in turn causes oligomerization of the TNF receptor-associated factor 6 (TRAF6). This activation of TRAF6 results in promotion of IKKγ-mediated phosphorylation of Iκ-B. Phosphorylated Iκ-B is then targeted for degradation, releasing NF-κB, which translocates to the nucleus and promotes transcription of genes involved in lymphocyte survival and proliferation. The various NF-κB pathway-related translocations cause induction of this pathway independent of stimulation through the BCR.

The t(11;18)(q22;q21) creates a fusion product between *BIRC3* (*API2*) on 11q22 and *MALT1* on 18q21 and is the most common recurrent translocation in MALT lymphomas.[170,171] Although BIRC3 contains some independent antiapoptotic activity, more importantly for MALT lymphomas it also contains a dimerization domain. This fusion therefore results in MALT1 units that can dimerize independent of the BCR, thereby creating constitutive, antigen-independent stimulation of the NF-κB pathway. All of the translocation sites in *BIRC3* (at least 4 known) are localized downstream from the BIR domains in the gene, resulting in full BIR domain activity in the fusion protein.[172] These domains mark BIRC3 as a member of the inhibitors of apoptosis (IAP) family of proteins that inhibit the caspases. However, these domains are also capable of homophilic interactions, causing dimerization. Over 90% of the translocation sites in *BIRC3* occur at a single site, just 5′ to its CARD domain, so designing primers against this most common breakpoint region is possible. Unfortunately, the *MALT1* breakpoint regions are spread over 300 bp throughout the middle portion of the gene, leaving the carboxyl terminus of the *MALT1* gene fused to *BIRC3*.[172] Nevertheless, PCR-based assays have been designed for this lesion, which, depending on the primers, have variable but overall moderate clinical sensitivity. FISH probes, which easily span the possible breakpoint sites, provide higher clinical sensitivity for this translocation which has significant therapeutic relevance (vide infra).[173]

The t(1;14)(p22;q32) results in the overexpression of the *BCL10* gene on 1p22 through its relocation under the *IGH@* enhancer. The resultant increased concentration of BCL10 in the cytoplasm results in its forced association with MALT1 and activation of the NF-κB pathway. Interestingly, the interaction of BCL10 with MALT1 appears to help localize BCL10 to the cytoplasm,

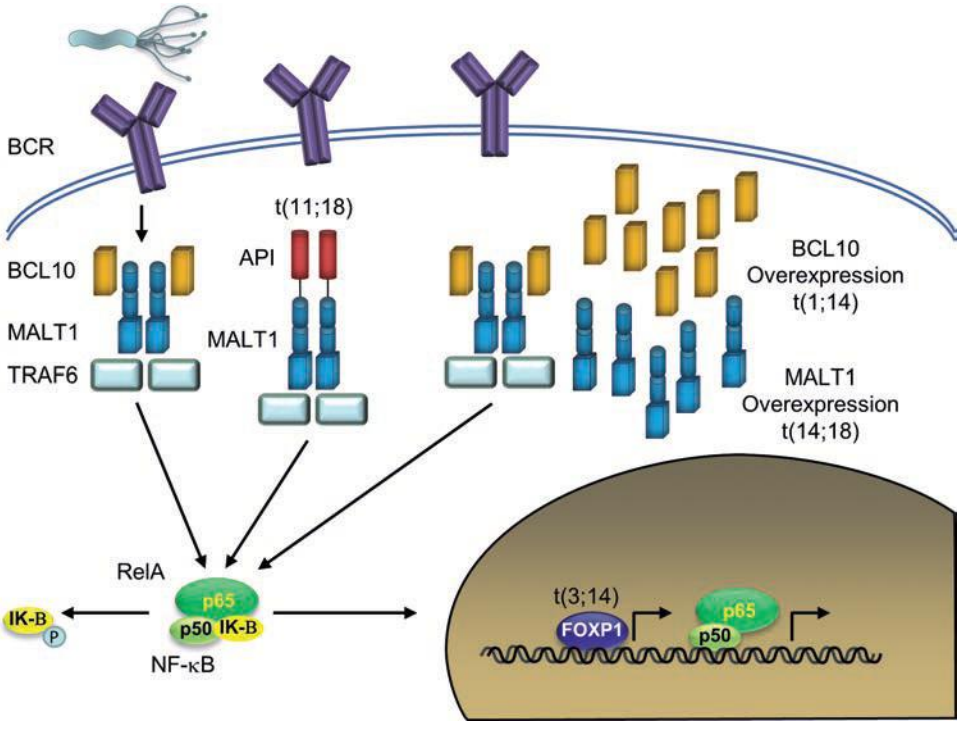

FIGURE 87.12. Biology of translocations common in extranodal marginal zone lymphomas. On the far left: *Helicobacter pylori* stimulation of the B-cell receptor (BCR) induces the interaction of BCL10 and MALT1, promoting dimerization of MALT1 and downstream oligomerization of TRAF6. This activation of TRAF6 results in promotion of IKKγ-mediated phosphorylation of Iκ-B (IKKγ not shown). Phosphorylated Iκ-B is then targeted for degradation, releasing NF-κB, which translocates to the nucleus and transcriptionally activates genes involved in lymphocyte survival and proliferation. The t(11;18) induces BCR-independent dimerization of MALT1 and activation of the pathway. The t(1;14) induces BCL10 overexpression and promotes dimerization of MALT1 as does overexpression of MALT1 itself via a t(14;18). Lastly the t(3;14) induces a FOXP1 transcriptional program that must be related to the NF-κB program.[168]

and overexpression of BCL10 results in excess unbound BCL10 and consequent nuclear expression of BCL10 in cells with this translocation. The formation of BIRC3–MALT1 fusion in cases harboring the t(11;18) likewise frees BCL10 from the cytoplasm and results in nuclear expression of BCL10. This can be seen immunohistochemically, and may prove to be a good surrogate for these translocations.[172,174,175] Currently, there is limited offering of FISH or any molecular assay for this translocation, although *IGH*@-breakapart probes can be used to identify the translocation, albeit not its partner.

The t(14;18)(q32;q21) seen in approximately 10% of MALT lymphomas contains the identical karyotypic breakpoints to those seen in FL.[176] However, with increased resolution, the *BCL2* gene is in reality located 5 Mb telomeric to the *MALT1* gene.[177] As in FL and MCL, this translocation juxtaposes the *IGH*@ partner, in this case *MALT1*, with the *IGH*@ enhancer through a RSS-guided rearrangement to the J_H subunit of *IGH*@.[176] The resultant overexpression of MALT1 protein results in elevated cytoplasmic concentrations of the protein, which stochastically force enough proximity to induce TRAF6 oligomerization and NF-κB activation. The majority of *MALT1* breakpoints appear to occur within an 87 bp region which may permit the development of a PCR-based assay for this translocation. However, due to the relatively low frequency of this translocation in MALT lymphoma, clinical development has not been widespread. Rather, FISH probes for these loci are commonly available.

Finally, the t(3;14)(p14.1;q32) involves the overexpression of the *FOXP1* gene on 3p14 due to its relocation to the *IGH*@ gene locus.[178] *FOXP1* encodes a transcriptional repressor in the Forkhead family which is critical for B-cell development and whose overexpression is implicated in several B-cell lymphomas in addition to MALT lymphomas, including DLBCL, FL, and cutaneous B-cell lymphomas. Although FOXP1 can be interrogated by IHC, this antibody is not commonly used in clinical laboratories, nor are directed FISH probes or PCR-based assays. *IGH*@-breakapart probes can be used to identify the translocation, albeit not its partner.

These translocations are associated with specific sites and etiologies of MALT lymphomas.[168] The t(11;18) and t(1;14) are most common in gastric, intestinal, and lung MALT lymphomas with the t(11;18) being especially prevalent in the gastric and lung neoplasms. By contrast, the t(14;18) and t(3;14) occur in the ocular adnexa and skin, with the t(14;18) also rarely found in the salivary gland lymphomas and the t(3;14) commonly found in the thyroid lesions. Each of these different sites has a distinct source of chronic inflammation that has been associated with MALT lymphomas in these sites, although exactly how the particular instigating agent causes specific reciprocal translocations remains to be understood. However, it is known that although early gastric MALT lymphomas are dependent upon *Helicobacter pylori* stimulation of the B-cell, once the neoplasm acquires a t(11;18), it becomes independent of the bacterium. Thus, whereas antibiotics successfully treat up to 75% of gastric MALT lymphomas, the cases with t(11;18) are refractory to antibiotic therapy.[179]

Inasmuch as MALT lymphomas are derived from post-germinal center marginal zone B-cells, they tend to have significant SHM. Thus, immunoglobulin gene rearrangement studies identify clonal rearrangements in only 62% to 68% of cases using a single set of FR3 primers.[14,15,17] However, when a clonal population can be identified, it can be a valuable test both for diagnostic purposes as well as for monitoring for MRD. Distinguishing reactive lymphoid hyperplasia from MALT lymphoma in sites of chronic inflammation can be histologically challenging; in these cases, Ig gene rearrangement studies, when positive, can be helpful. However, these results must be interpreted with caution, as inflammatory lesions can demonstrate pseudoclonality due a limited repertoire of B-cells responding to a given antigen. Similarly, a negative result may be due to SHM and does not preclude a neoplasm.

MALT lymphomas, as well as other marginal zone lymphomas, can demonstrate ancillary cytogenetic changes, in particular trisomies of 3, 7, 12, and 18.[180] In addition, with transformation to DLBCL, additional aberrations may accumulate in *TP53, CDKN2B (p15),CDKN2A (p16), RB1*, and *MYC*.[168] The accumulation of genetic changes is also reflected in the accumulation of miRNA expression changes from controls, to gastritis, to MALT

Diagnosis	MRD
Consider FISH for various translocations Consider PCR or NGS for Ig gene rearrangement studies	Consider PCR or NGS for Ig gene rearrangement studies

lymphoma, to DLBCL.[181,182] Note that in the transformation to DLBCL, gastric MALT lymphomas appear to acquire a signature of 27 down-regulated miRNAs that are all transcriptionally repressed by MYC, and MYC overexpression was found in 80% of the DLBCLs, but only 20% of the low grade MALT lymphomas. In particular *miR-34a* down-regulation caused overexpression of its target, FOXP1, in DLBCL but not in MALT lymphoma.[183] A similar gradation of accumulated changes is seen in the increase in the CpG island methylator phenotype from 0% in controls, 62% in MALT lymphomas, and 93% of DLBCLs.[184]

Guidelines for Molecular Testing in Extranodal Marginal Zone Lymphoma

No specific molecular testing is required to make the diagnosis of a MALT lymphoma. However, FISH for t(11;18) may have therapeutic implications for the patient at diagnosis. In addition, assessment of whether a clonal population can be detected by Ig gene rearrangement studies at diagnosis may be helpful both in distinguishing a reactive process for neoplasia and in the identification of a molecular marker of disease for therapy monitoring.

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Accounting for only 6.7% of NHLs, CLL/SLL is nonetheless the most common adult chronic leukemia in Western countries.[4,9] The majority of these cases are leukemic (CLL), with the isolated lymphomatous presentation of SLL uncommon. Although considered to be overall an indolent disease, there is wide variability in clinical outcomes, with some patients enjoying survival measured in decades, and others succumbing to disease or disease-associated sequelae within just a few years. A minority of cases can progress to more aggressive disease, including DLBCL (Richter's transformation, 2% to 8%), Hodgkin lymphoma (<1%), and prolymphocytic leukemia (PLL).[4]

Genetic aberrations are found in the vast majority of cases of CLL, although the identification of these changes varies widely upon the methodology. Conventional MC identifies abnormalities in only approximately 40% of cases.[185] However, FISH can detect cytogenetic changes in about 80% of CLL cases.[186] Typical FISH panels interrogate four common chromosomal aberrancies: deletions of 13q14, 11q22-23, and 17p13 as well as trisomy of chromosome 12. Array CGH methods have the potential to identify even more aberrations, and some institutions routinely perform aCGH for CLL, although most of the published studies still use FISH as the gold standard for comparison.[187,188]

Deletions of 13q14 are the most common recurrent abnormality in CLL and account for 50% to 60% of cases.[186] Patients can show either homozygous or heterozygous losses of 13q14, both associated with favorable prognosis. The locus affected by this deletion appears to contain two miRNAs, *miR-15a* and *miR-16-1*, and deletion of these miRNAs are common in familial cases of CLL as well.[54,55] These miRNAs have been demonstrated to target and translationally repress a number of genes involved in apoptosis, including *BCL2*, *MCL1*, and *TP53*, therefore the loss of these miRNAs results in increased expression of the antiapoptotic genes *BCL2* and *MCL1* (Fig. 87.13). Although *TP53* is proapoptotic, its role in CLL may be more complex than previously understood. The protein product of *TP53*, p53, also promotes transcription of two other miRNAs, *miR-34b* and *miR-34c*, both of which target the mRNA of *ZAP70*.[189] Thus in 13q14-deleted CLLs, there is increased p53 expression, increased *miR-34b* and *miR-34c*, and decreased ZAP70 protein. ZAP70 has independently been determined to portend a poor prognosis.[43]

Deletions of 11q22-23 are identified in approximately 17% of cases of CLL.[190] This locus contains a number of important genes in the pathogenesis of CLL. *ATM* is located in this deleted region at 11q22.3. As noted earlier, ATM phosphorylates p53, resulting in its protection from ubiquitination and degradation by MDM2. The active p53 then can induce cell cycle arrest followed by either apoptosis or DNA repair. Therefore, loss of the *ATM* locus is tantamount to decreased function of p53. In addition, miRNAs, *miR-34b* and *miR-34c*, are located at 11q23.1 and are also deleted with *ATM*. The deletion of these miRNAs results in increased ZAP70 protein, the poor prognostic marker.[43,189] Deletions of 11q22-23 are therefore consistent with a poor prognosis. Recent studies have suggested the importance of adding alkylating agents such as cyclophosphamide to regimens used to treat patients with deletion 11q22-23.[191]

Deletions of 17p13 involve the loss of the *TP53* locus, and are found in approximately 8% of cases of CLL, also associated with a poor prognosis.[190] By itself, deletion of the tumor suppressor gene is typically associated across malignancies with negative prognosis. In CLL, it has been demonstrated that loss of p53 can also result in decreased *miR-34b* and *miR-34c* transcription and

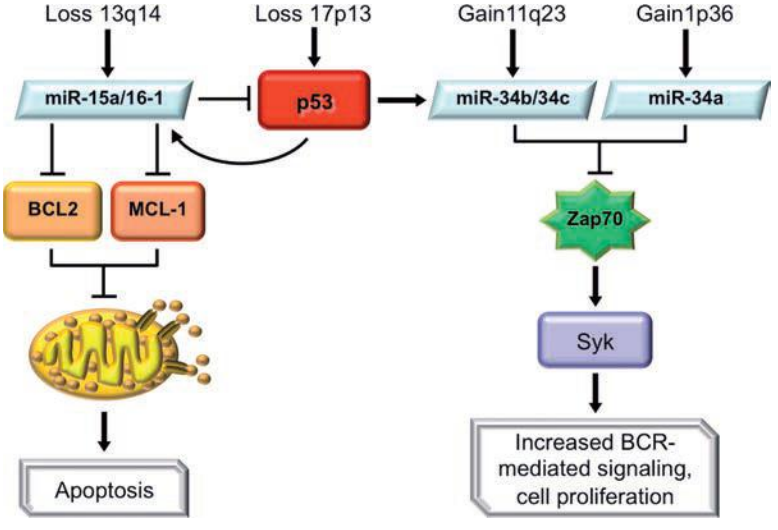

FIGURE 87.13. Chronic lymphocytic leukemia (CLL) biology. Loss of 13q14 causes decreased miR15a/16-1, resulting in decreased apoptosis. Trisomy 11 results in increased miR-34b/34c, with resultant decreased ZAP 70 and decreased B-cell receptor (BCR) signaling. However, loss of 17q13 results in increased ZAP 70 and increased BCR-mediated signaling with decreased apoptosis.

therefore increased ZAP70 expression.[189] The identification of del(17p) is a critical predictor of fludarabine-resistance. Because fludarabine forms the backbone of most chemoimmunotherapy regimens for CLL, FISH for *TP53* provides therapeutically important information, and may prompt the use of alemtuzumab instead of fludarabine.[192]

Trisomy 12 is found in approximately 20% of cases of CLL, and can be associated with more atypical morphologic features such as irregular nuclear contours and less condensed chromatin as well as increased CD11c expression.[4,190,193] Trisomy 12 is considered to be an intermediate risk factor in CLL but can be associated with specific other abnormalities that may modify its prognostic import.

Although it has subsequently been shown to be an independent poor prognostic marker, the importance of ZAP70 expression was originally identified as a surrogate marker for SHM status through gene expression profiling studies.[43,194,195] CLL cases are nearly divided evenly in their mutational status, approximately 40% to 50% SHM-negative and 50% to 60% SHM-positive.[29,30] The discovery of SHM in CLL caused a revolution in the thinking of the biologic origin of CLL. These same gene expression profiling studies also determined that CLL is a neoplasm of memory B-cells, approximately 50% of which pass through the germinal center thereby acquiring SHM in a T-cell dependent fashion, whereas the remaining memory B-cells are part of our innate immune system and become memory B-cells without traversing the germinal center in a T-cell independent manner.[194–196] These latter cases therefore do not acquire SHM. Prognostically, the SHM-positive cases of CLL have longer overall survival (median 293 months for low stage disease), and SHM-negative cases portend a poor prognosis (median survival 95 months for low stage disease).[30,197] Despite the presence of SHM in roughly half the cases of CLL, nonetheless, Ig gene rearrangement studies have a universally high level of detection of clonal rearrangements using standard framework primers.[14,15,17]

The V_H repertoire utilized in CLL is biased, implying a common set of antigens or superantigens in the pathogenesis of CLL that have yet to be identified.[198–199,200,201] In some cases, certain Ig genes appear to be preferentially used in unmutated rearrangements (V_H1-69, V_K1-33, V_L3-21) whereas others are associated with SHM-positive cases (V_H4-34, V_K3-7, V_L3-23, V_L2-30, V_L2-8).[200,201] Within these gene regions even the specific amino acid changes that occur in these regions in those cases exhibiting SHM involve stereotyped changes, providing further evidence of selection for specific pathogenic antigens.[200] Certain of the stereotypes are associated with poor prognosis regardless of mutational status. The most well documented of these is V_H3-21, although V_H3-48 and V_H3-53 have been discussed in this context as well.[197,202,203,204] Other B-cell Ig gene stereotypes have been associated with better prognosis, including V_H4-34 and V_H2-30.[200] Monoclonal B-cell lymphocytosis appears to utilize V_H4-59/61 preferentially, although it has a similar array of cytogenetic changes as CLL.[205]

SLL, although derived from the same cell of origin as CLL, demonstrates slightly different prognostic markers. SLL is associated with a lower rate of SHM than CLL (26% of cases compared to 40% of cases.[206] The prevalence of trisomy 12 and V_H3-21 is also significantly increased in SLL compared to CLL.[207]

Disease progression and transformation in CLL appears to be associated with an accumulation of genetic changes, particularly deletion of 6q21-q24.[186,208] Therefore, at relapse or progressive disease, the number and nature of cytogenetic aberrancies can differ from diagnosis. Acquisition of reciprocal translocations, even those commonly associated with other B-cell lymphomas such as rearrangements of *BCL2, MYC,* and *BCL3*, can be seen at disease progression.[90,92,209–212] Many of these involve the light chain Ig loci in addition to *IGH@*.

The accumulation of mutations during disease progression has been documented by NGS as well. NGS has confirmed mutation rates for *TP53* (15%) and *ATM* (9%).[213] In addition, several new mutations have been identified that may play key roles in CLL pathogenesis. Mutations in *NOTCH1* have been identified in 4% to 12% of CLLs, associated with decreased overall survival.[213,214,215,216] The majority of these cases contain a two-nucleotide deletion in the PEST domain. Similar to those identified in MCL, these deletions are expected to result in decreased ubiquitination and increased NOTCH1 activity. The prevalence of *NOTCH1* mutations increases with Richter transformation (from 8.3% to 31.0%) as well as with chemorefractoriness (20.8%).[215] *NOTCH1* can directly stimulate *MYC* transcription, and mutations of *NOTCH1* appear to be mutually exclusive with *MYC* activation, suggesting that the *MYC* oncogenic pathway can be accessed by either mechanism in CLL. *NOTCH1* mutation or *MYC* activation can coexist with decreased p53 function, perhaps to counteract the role of *MYC* in apoptosis, especially in cases of fludarabine-refractory CLL or Richter's transformation.[215,217,218] *NOTCH1* mutations are associated with trisomy 12 and unmutated Ig status.[214,215,218]

NGS has also identified several other genes that are mutated in CLL.[213,214,215,216] *MYD88* mutations, occurring in 10% of cases, predominantly involve missense mutations occurring at only three sites within a 40 bp region of the gene.[213] These patients tend to be younger with disease presenting at a more advanced clinical state, and are highly associated with SHM and del(13q). *FBXW7* mutations (4% of cases), as well as *NOTCH1* mutations, are associated with trisomy 12. *TP53* mutations (15% of cases) often occur in conjunction with del(17p), to result in biallelic loss of function. Lastly, *SF3B1* was identified as one of the most common mutations in CLL, occurring with a frequency of 15% of all CLL cases.[219] This gene functions in the catalytic core of the SF3b complex of the spliceosome. The majority of the mutations are a single K700E mutation (mutational hotspots also include codons 662 and 666) which is believed to be a gain-of-function mutation causing aberrant splicing in these patients. This mutation is commonly associated with del(11q) or mutations in the *ATM* gene, and found in predominantly unmutated cases of CLL. It is interesting that *SF3B1* mutations and *TP53* aberrations appear to be mutually exclusive in fludarabine-refractory cases, suggesting some overlap in their roles in chemorefractoriness, although perhaps *SF3B1* and *ATM* aberrations are synergistic. *SF3B1* mutations have also been identified in the myeloid neoplasm, myelodysplastic syndrome, suggesting interesting hypotheses about the relationship between myeloid and T-cells developmentally as well as the role of aberrant splicing in general oncogenesis.[220–224]

Guidelines for Molecular Testing in Chronic Lymphocytic Leukemia

Although no molecular testing is required to make a diagnosis of CLL, molecular cytogenetic aberrations may play an important role in prognostication and also in the selection of chemoimmunotherapy regimens. These include FISH or aCGH for the recurrent abnormalities and SHM testing. In addition, assessment of a clonal population at diagnosis may be helpful in the identification of a molecular marker of disease for therapy monitoring. Several of the novel markers identified by NGS, such as *NOTCH1* and *SF3B1* have highly localized mutations for which very sensitive PCR methods can easily be developed in addition to NGS. These may be used prognostically at diagnosis, and possibly for monitoring MRD, although no studies exist exploring this role for molecular studies at this time.

Diffuse Large B-cell Lymphoma

DLBCL, not otherwise specified, is the most common adult lymphoma, comprising approximately 30% to 40% of cases of NHL.[4] This is a heterogeneous category of disease for which there is varied clinical presentation, response to therapy, and molecular

Diagnosis	MRD

Future: novel markers by PCR or NGS	

aberrancies. These features have made the study of DLBCL challenging, and molecular discoveries have lagged behind some of the more homogeneous lymphoma entities. Nevertheless, gene rearrangements can be identified by FISH using breakapart probes in approximately 65% of cases of DLBCL, split among those involving *BCL6* (45% of cases), *BCL2* (21% of cases), *BCL10* (18% of cases), and *MYC* (16% of cases).[225,226]

BCL6 gene rearrangements involve the translocation of the entire coding region of *BCL6* on chromosome 3q27 to its partner chromosome. At least 20 such partners have been described, including both Ig and non-Ig genes, mandating the requirement for breakapart FISH probes against *BCL6*.[227] These translocations place the *BCL6* coding sequencing downstream of the heterologous promoter sequences of the partner chromosome, resulting in overexpression of *BCL6*.[228] The breakpoints in the *BCL6* are predominantly located in the MBR which consists of the 5′ flanking region, the first noncoding exon, and part of the first intron. An alternative breakpoint region (ABR), found in 17% of *BCL6* translocations, is located 240 to 280 kb 5′ to the MBR and requires a separate FISH probe to identify these rearrangements.[229] Most FISH studies only use the single MBR-directed breakapart probes, thereby decreasing their clinical sensitivity,[229,230,231,232] but newer FISH assays cover both breakpoints. *BCL6* translocations are associated primarily with germinal center histogenic origin, and confer an advantageous prognosis, although they can be seen in nongerminal center DLBCLs as well where they appear to be associated with poor outcome.[233]

BCL6 encodes a POZ (Poxvirus zinc finger) domain, that is involved in both homodimerization and heterodimerization with other POZ-containing proteins, as well as a DNA recognition sequence. BCL6 is a germinal center-specific transcriptional repressor, regulating genes such as *PRDM1* (*BLIMP1*) and *CDKN1B*, *TP53*, *ATR*, and *BCL2*.[7,234] *PRDM1* is another transcriptional factor that regulates the transition from the GCB stage to the plasma cell stage of differentiation through inhibition of *MYC* expression, preventing further proliferation. *CDKN1B* encodes for p27, a cell cycle inhibitor. *ATR* and *TP53* are involved in DNA damage repair and cell cycle arrest, whereas *BCL2* inhibits apoptosis. Therefore overexpression of BCL6 blocks plasmacytic differentiation, promotes proliferation, and inhibits apoptosis. BCL6 inhibition has therefore become an active area for the development of new therapeutics.[235–238]

By locking the neoplastic B-cells in the germinal center stage of maturation, *BCL6* translocations permit ongoing SHM. *BCL6* is itself a target of this SHM both physiologically and in DLBCL. The mutations are clustered in the MBR and are seen in approximately 25% to 45% of cases of DLBCL, often multiple or biallelic.[226,239,240] These mutations are found in both rearranged and wild-type alleles and, interestingly, the SHM occurs even when the translocation partner is not one of the Ig genes.[241] These mutations can affect the *BCL6* binding sites in exon 1, preventing the normal negative feedback inhibition of BCL6 and accounting for a second cause of BCL6 overexpression.[241]

The *BCL2* rearrangement found in 20% to 30% of DLBCLs is the identical hallmark t(14;18)(q32;q21) of FL.[4,91] In many cases these are de novo DLBCLs, without transformation from a preceding or concomitant FL. As in FL, this translocation is associated with a germinal center origin of the lymphomas. However, *BCL2* overexpression due to chromosomal gains at this locus can be associated with more ABC –type DLBCLs.[225]

BCL10 overexpression as a result of reciprocal translocations appear to be unrelated to any associated MALT lymphoma in most cases, and are associated with a poor prognosis.[226]

Lastly, *MYC* translocations are found in up to 16% of cases of DLBCL (most studies suggest 5% to 10%).[225,226] *MYC* rearrangements are found in de novo DLBCL, as a secondary acquired genetic change during the process of transformation from a low-grade lymphoma, and in the recently described category B-cell lymphoma unclassifiable, with features intermediate between DLBCL and BL.[9] In all three cases, the *MYC* translocation carries a poor prognosis[242] and may be a component of double- or triple-hit lymphomas, which carry especially dire prognoses.[243,244] Double-hit lymphomas harboring both *MYC* and *BCL2* can be identified by FISH and recent studies suggest that IHC for these two markers may also be prognostically important.[244]

Gene expression profiling studies have distinguished three separate biologic subtypes of DLBCL.[60,245] The germinal center B-cell–like DLBCLs (GCB DLBCLs) were characterized by expression of genes such as *MME* (*CD10*), *BCL6*, and *MYBL1* (*A-MYB*). These cases had a 5-year overall survival of 60%.[60,246] By contrast, the ABC–like subtype of DLBCL expressed genes that are induced by mitogenic stimulation, such as *BCL2*, *IRF4* (which encodes for MUM1), and *CCND2*. The ABC lymphomas had only a 35% 5-year median overall survival.[60,246] In addition, a third category of DLBCL, termed the "type 3" category did not molecularly cluster with either the GCB or ABC groups.[60]

Due to the cost and impracticality of performing gene expression profiling for routine diagnosis, a flurry of research has been devoted to the identification of IHC surrogates for the GCB and ABC categories. From the three marker algorithms involving CD10/BCL6/MUM1[247,248] or BCL2/CD10/MUM1,[249] to the five marker algorithms such as GCET1/CD10/BCL6/MUM1/FOXP1 or GCET1/CD10/MUM1/FOXP1/LMO2,[250,251] all have shown excellent correlation to the gene expression profiles in their own institutions, but show only moderate correlation in the hands of an outside institution.[90,247–251,252,253] In addition, most studies have shown that the addition of rituximab to current chemotherapy regimens so improves the outcomes of the ABC group as to eliminate all prognostic differences between the groups, although this is still a contested area.[252,254,255] Accordingly, the initial excitement for IHC surrogates has somewhat abated, and many no longer attempt to subclassify DLBCL into GCB or ABC, preferring instead to rely upon Ki-67 and *MYC* dysregulation.

Both gene and miRNA expression profiling have identified important markers of response to anthracycline-based chemotherapy. Earlier studies by gene expression profiling detailed the 5-year survival rates of the GCB, ABC, and type 3 subgroups of DLBCL in the pre-rituximab era (60%, 35%, and 39%, respectively).[91,246] However, more recent miRNA studies using standard rituximab-containing therapy identified miRNA signatures that correlate with the cell of origin (GCB versus ABC), as well as a completely distinct set of miRNAs which correlated with outcome.[256] This study cast further doubt upon the prognostic relevance of the ABC and GCB determinations in the rituximab era. It is interesting that two of the miRNAs overexpressed in the GCB DLBCLs, *miR-151* and *miR-28*, are predicted to down-regulate

FOXP1 (a marker expressed in the ABC subtype) whereas *miR-451*, a miRNA in the ABC signature is predicted to down-regulate CD10 (a germinal center marker).[256]

Both genomic deletions and promoter methylation have been found to account for decreased expression of *CDKN2A* which encodes p14 and p16.[257,258] As mentioned previously, these proteins play important roles in promoting cell cycling and in inhibiting p53 function. Other mutations identified by NGS (WES) in DLBCL have included expected deletions of *CDKN2A* and *CDKN2B* as well as mutations in *PRDM1*, *TNFAIP3*, *CARD11*, *CD79B*, and *MYD88*.[259] Many of these genes are important in the NF-κB pathway which has been shown to underlie the ABC subtype of DLBCL. In addition, mutations were found in *CREBBP*, *EZH2* (6% to 14% of samples), and *MLL* (11% to 24% of samples) which are involved in the epigenetic regulation.[129,130,259]

Guidelines for Molecular Testing in Diffuse Large B-cell Lymphoma

There are no molecular tests required for the diagnosis of DLBCL. If the t(14;18) is present, this rearrangement can provide a good marker for MRD. Ig gene rearrangements have only a moderate level of clinical sensitivity for DLBCL, and, in the absence of allele-specific primers, have moderate analytical sensitivity. FISH may be helpful in the identification of double- or triple-hit lymphomas, although currently probes for *BCL10* are uncommon.

Hairy Cell Leukemia

HCL is a rare leukemic mature B-cell neoplasm which affects middle aged to older adults with a strong male:female bias (5:1).[4] Until recently, no consistent or specific cytogenetic abnormalities had been identified in HCL, although gains in chromosome 5 (20%) and losses of the long arm of chromosome 7 (10%) had been identified.[260-262] The cell of origin is believed to be a late post-germinal center memory B-cell, since more than 85% of cases demonstrate significant SHM.[4,263] Unlike many of the other B-cell lymphomas which develop reciprocal translocations during RSS-guided VDJ rearrangement, reciprocal translocations are rare in HCL. This is further supported by the balanced genomic profile of HCL by aSNP.[264] Instead, many cases of HCL appear to have multiple clonally related Ig-isotypes, suggesting that the defect lies in the class switching process.[265] Gene expression profiling has likewise failed to determine a pathogenic pathway in HCL. These studies instead demonstrate a molecular signature that matches the morphologic and clinical characteristics of the disease, with prominent signatures generated by adhesion molecules, homing molecules, and molecules involved in marrow fibrosis.[266]

However, the advent of NGS has permitted the identification of point mutations in HCL. Of those identified, the V600E mutation in *BRAF* has been proven in several studies to be 100% sensitive for HCL, and highly specific as well, with no mutation identified in cases that can be morphologic mimics such as splenic marginal zone lymphoma and unclassifiable splenic B-cell lymphoma/leukemia.[267,268] This mutation is most commonly found as a heterozygous somatic mutation, but in rare cases can be homozygous. This mutation has been found to activate the MAPK pathway, a pathway previously identified as important in HCL. Dysregulation of this pathway results in constitutive transcription of cyclin D1 and down-regulation of p27, both of which conspire to cause increased cellular proliferation, and explain the expression of cyclin D1 by IHC in HCL without any evidence of the t(11;14). Highly sensitive PCR-based *BRAF* assays have already been developed for melanoma, and may be helpful in the diagnosis and almost certainly in the future monitoring of patients with HCL.[269,270]

Guidelines for Molecular Testing in Hairy Cell Leukemia

Molecular testing is generally not needed for the diagnosis of HCL when morphology and immunophenotype are definitive. Therefore the V600E *BRAF* mutation is likely not required at diagnosis, although it may be helpful in distinguishing HCL from some of its morphologic mimics. Sensitive PCR-based methods for the detection of the mutation should be helpful in monitoring MRD status in these patients, although no studies to date have examined *BRAF* mutations in the MRD setting of HCL. Due to the high rates of SHM, Ig gene rearrangement studies are not recommended and are less sensitive than *BRAF* testing for MRD.

Lyon, France: International Agency for Research on Cancer, 2008.

Mature Neoplasms of T-cells

Anaplastic Large Cell Lymphoma, Anaplastic Lymphoma Kinase-positive

Anaplastic Lymphoma Kinase (ALK)-positive ALCLs comprise roughly 3% of all adult NHLS (12% of T-cell NHLs), but as much as 20% of childhood lymphomas.[3,4] Incidence peaks in the second decade of life, and cases in elderly adults are rare. These lymphomas are highly chemosensitive, although aggressive, and the overall 5-year survival approaches 80%, up to 90% in patients with low prognostic indices. By contrast, incidence of ALK-negative ALCLs peaks in the sixth decade of life, and survival is considerably less than in the ALK-positive cases (36% 5-year survival). For these reasons, these two forms of ALCL are classified separately, and, despite their similarity in morphology and CD30 expression that initially grouped them together as ALCLs, they have very different epidemiology and clinical outcomes.

These two entities also differ significantly in what is known of their molecular underpinnings, although both have clonally rearranged T-cell genes: 76% of ALK-positive ALCLs, 89% of ALK-negative ALCLs. Together, 79% of all ALCLs can be detected by a combination of *TRG@* and *TRB@* sets of commercial primers.[22] Although the ALK-negative cases have only rare recurrent cytogenetic aberrations, the ALK-positive cases of ALCL have well-documented driving reciprocal translocations involving the *ALK* locus on chromosome 2p23 and a limited set of partner chromosomes. *ALK* encodes for a transmembrane tyrosine kinase protein which is found in neural cells, but has no appreciable expression in normal hematopoietic cells.[271] The breakpoints in *ALK* are located near this transmembrane domain and result in the full expression of the tyrosine kinase domain in the fusion product in all cases. The most common partner is the *NPM1* gene on chromosome 5q35.1, found in 84% of ALK-positive cases, resulting in a t(2;5)(p23;q35.1) (Fig. 87.14).[4,272] *NPM1* encodes for nucleophosmin, a protein that shuttles ribonucleoproteins from the nucleus to the cytoplasm and is involved in preribosomal assembly.[273] As a result, the fusion protein is also found in both locations, and IHC stains targeting the normally cytoplasmic C-terminus of ALK show both nuclear and cytoplasmic staining.[4] The fusion attaches the N-terminus of NPM containing an oligomerization domain to ALK, resulting in constitutive activation of ALK kinase activity. This kinase activity activates numerous pathways involved in growth and cell survival, including AKT/PI3K/mTOR, Jak/STAT, JUN, and MYC pathways.[274] The dependence of the ALCL cells upon the fusion protein has made the fusion and its downstream collaborators a target for the development of novel therapeutics.[275,276]

In addition to the t(2;5)(p23;q35.1), several other translocations of *ALK* are summarized in Fig. 87.14.[4] In each case, the partner chromosome contains an oligomerization domain and in most cases there is a single breakpoint region involved. The physiologic localization of the partner protein is mimicked in the fusion protein, resulting in characteristic patterns on ALK IHC.

Although the t(2;5)(p23;q35.1) can be identified by a number of molecular techniques, including PCR, reverse transcription PCR, SB, and FISH, the most prevalent method in clinical use is FISH, inasmuch as it has the best clinical sensitivity for the variant rearrangements.[277,278,279] In addition, CGH studies have determined that 58% of ALK-positive ALCLs may carry additional aberrations such as gains of 17p and 17q24-qter and losses of 4q13-q21 and 11q14.[280] These aberrations were not associated with any particular prognostic import. Here too, ALK-negative cases of ALCL demonstrate a different pattern of imbalances (gains of 1q, 6p21, 3p, and losses of 16pter, 6q13q21 a15, and 17p13) in 65% of cases which further supports their biologic separation.[280,281]

Gene expression profiling studies of ALCLs have identified a profile of activated T-cells involving the JAK3/STAT3 pathway (*IL26, IL31RA, IL9*), molecules that characterize Th17-cells (*IL17A*, *IL17F*, *RORC*), as well as overexpression of *ALK*, albeit with down-regulation of a number of other molecules which typically characterize T-cells.[282,283,284] In fact the profiles of both ALK-positive and ALK-negative ALCLs resemble the signature obtained from cHL, with overexpression of members of the NF-κB pathway, and in fact, the cHL cell lines more closely resemble ALK-positive ALCL than other B-cell lymphomas, despite the differences in their cells of origin.[46,282,285] Both ALK-positive and ALK-negative cases also form a common ALCL signature that is distinct from that of other T-cell lymphomas, supporting their continued separation from peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS).[284] However, distinct signatures separate the ALCLs by ALK status as well, with ALK-positive tumors overexpressing the cyclin, *CCND3*, as well other signal transduction molecules (*SYK, LYN, CDC37*) and ALK-negative lymphomas demonstrating decreased expression of p19INK4D, a cell cycle inhibitor, and underexpression of homeobox transcription factors, *HOXC6* and *HOXA4*.[286]

Recently studies on miRNAs in ALK-positive ALCLs have identified both *miR-135b* and *miR-29a* as regulated by the expression of the *NPM1-ALK* fusion. The resultant up-regulation of *miR-135b* blocks IL-17 production by ALCL cells, suppressing a Th2 phenotype and inducing a Th17 phenotype.[287] These results are compatible with the gene expression profiling studies that also find a prominent Th17 signature.[283] *NPM-ALK* mediated down-regulation of *miR-29a* may result in the downstream overexpression of MCL1 and inhibition of apoptosis.[288] In the miR-29a study, the authors propose that the down-regulation of miR-29a is due to methylation of the miRNA promoter. Similarly, the *NPM1-ALK* fusion has also been implicated in the methylation of the *IL2RG* gene promoter directly through STAT3 regulation of DNA methyl transferases and indirectly through repression of *miR-21* expression.[289] Comparisons with ALK-negative ALCLs have been made through miRNA profiling, and identified several miRNAs up-regulated in the ALK-positive cases (*miR-866-3p*, *miR-20b*, *miR-20a*, *miR-17*, and *miR-106a*) and *miR-155* which was highly up-regulated in the ALK-negative cases.[274]

Lastly, a recurrent t(6;7)(p25.3;q32.2) has recently been identified in ALK-negative ALCL via NGS methods.[290] This reciprocal translocation places the *DUSP22* phosphatase gene or the *IRF4* gene (encoding MUM1) on chromosome 6p25.3 adjacent to chromosome 7q32.3, near the *FRA7H* fragile genomic site and *miR-29*, and is the first balanced translocation identified in this diagnostic entity. Using FISH probes against these loci, 20% to 45% of cases of ALK-negative ALCL (both systemic and primary cutaneous) were shown to have this rearrangement, approximately two-thirds with *DUSP22*, whereas only rare PTCLs were positive and with no other cutaneous T-cell lymphomas.[275,290] *DUSP22* and *IRF4* are located within 40 kb of each other. Translocations of *IRF4* do not appear to affect MUM1 expression; however, *DUSP22*-containing rearrangements result in a decrease of DUSP22 expression, which has been shown to have tumor suppressor activity in some other T-cell neoplasms, as well as overexpression of miR-29.[290]

Guidelines for Molecular Testing in Anaplastic Large Cell Lymphoma

Beyond IHC, no particular molecular studies are required for the diagnosis of ALCL. TCR gene rearrangement studies may be helpful for the identification of a molecular marker to monitor response to therapy (MRD testing), although the test only has analytical sensitivity of approximately 1% to 5%. If TCR studies fail to detect a reliable marker of disease, FISH for the t(2;5) may be helpful for ALK-positive cases, although the analytical sensitivity for this assay is not superior to the molecular studies. As the probes for the *DUSP22/IRF4* and *FRA7H* loci become available, this may become a useful discriminator between ALK-negative ALCL and PTCL, NOS, permitting better prognostication.[291]

Peripheral T-cell Lymphoma, Not Otherwise Specified

PTCL, NOS, is a diagnosis of exclusion, accounting for approximately 26% of T-cell NHLs.[292] This category encompasses a wide range of neoplasms of T-cells that fail to fall clearly into the other defined categories of T-cell lymphomas. Many of these lymphomas are defined by site, rather than by the biology of the cell of origin. As a result, there is a wide range of clinical, epidemiologic, and pathologic findings. In addition, there are few cytogenetic changes specifically associated with PTCL, but rather a panoply of nonspecific changes. Essentially all cases of PTCL, NOS, contain clonally rearranged TCR genes that can be detected by a combination of *TRG*@ and *TRB*@ commercial primers.[22]

Discrimination between ALK-positive ALCL, ALK-negative ALCL, and PTCL, NOS, has been the focus of much research in an attempt to define different cells of origin, aspiring to the success seen in the B-cell lymphomas. The diagnostic dilemma is particularly challenging between ALK-negative ALCL and PTCL, NOS, with high expression of CD30. The distinction between these two entities is clinical relevant inasmuch as prognostically the ALK-negative ALCLs fare better than the PTCLs (74% 5-year overall survival for cases with a low prognostic index, IPI 0-1, versus 52% to 56% for similar IPI PTCL groups, respectively).[291,292]

Cytogenetic studies have identified a wide spectrum of changes in these latter two entities (ALK-positive ALCL detailed in the previous section) which point to slightly different patterns of aberrations, albeit with some overlap. Both disease categories share common gains of 1q and 3p and losses of 13q.[281] As mentioned in the previous section, ALK-negative ALCL also demonstrate losses of 16pter, 6q13q21, 15, and 17p13 whereas PTCL, NOS, showed losses of 6q22q24, 9p21-pter, 10p13pter, 10q23-24, and 12q21-q22 as well as additional gains of 7q22q31, 5p, 11q13, and 12p13.[281,293,294] None of the specific aberrations appear to have discrete impacts on overall survival although general cytogenetic complexity does correspond to poorer overall survival.

SNP arrays have identified candidate genes at the site of recurrent losses in PTCL at chromosome 9p21.3, encompassing *CDKN2A* and *CDKN2B*, loci that encode for key proteins in regulating cell cycling and apoptosis, p14/p16 and p15, respectively.[295] In addition, the recurrent gain at 7p22 contains the apoptosis-related gene *CARD11* (*CARMA1*), corresponding to overexpression of the corresponding mRNA. Prognostically, gains at chromosomes 2 and 5 are associated with poor clinical outcomes in PTCL.[295]

Gene expression profiling has been perhaps the most useful in discerning differences in biology of different T-cell lymphomas. However, due to its heterogeneity, PTCL, NOS, not surprisingly has been difficult to associate with a clear defining transcriptional signature, often interspersed among the other subtypes of T-cell lymphomas.[296] The most successful profiling experiments have been able to assign profiles to PTCL, NOS, which most closely resemble activated $CD4^+$ or $CD8^+$ T cells.[297] Transcriptional profiling has identified one discrete subset of PTCL, NOS, which expresses a signature characteristic of cytotoxic T-cells and is associated with a poor prognosis. Although not all these tumors are $CD8^+$ (in fact, 55% were $CD4^+$), they expressed two key transcription factors found in $CD8^+$ T-cells, T-bet (*TBX21*) and eomesodermin, as well as their target genes (*CXCR3, IL2RB, CCL3, IFNG*). These cells also expressed typical cytotoxic molecules and even killer cell immunoglobulin-like receptor family members and other NK-cell markers.[283]

A single recurrent translocation has been found in a particular histologic subtype of PTCL accounting for 18% of PTCL, NOS.[298,299] The t(5;9)(q31-q32;q22) represents one of the few recurrent translocations in PTCL, NOS, and appears to be specific, inasmuch as it is not found in angioimmunoblastic T-cell lymphoma (AITL) or ALK-negative ALCL.[299] This rearrangement fuses the inducible T-cell kinase (*ITK*) with the spleen tyrosine kinase (*SYK*). *ITK* is activated through the TCR. *SYK* is integral in the function of both the BCR and the TCR, playing the predominant role in B-cells whereas ZAP-70 plays an analogous role in T-cells.[300] The fusion results in loss of the *ITK* kinase domain and autoinhibitory SH2 and SH3 domains (with retention of the pleckstrin homology domain and proline-rich region) and their replacement by the kinase domain of *SYK*, which may prove to be a reasonable target for kinase inhibitors such as fostamatinib.[275] These lymphomas demonstrate a characteristic histologic pattern of lymphoid follicles ("follicular pattern" PTCL) which immunophenotypically marks a neoplasm of follicular helper T-cells. This raises the possibility that this neoplasm may be more closely related to AITL than to other cases of PTCL, NOS, although the t(5;9) has yet to be identified in AITL.

Although the *ITK-SYK* translocation is limited to follicular pattern PTCL, approximately 95% of all peripheral T-cell lymphomas demonstrate overexpression of SYK by IHC, whereas nonneoplastic T-cells are negative. The kinase in these lymphomas is phosphorylated and therefore in an activated state, suggesting the possibility of *SYK* inhibition in the treatment of PTCL.[275,301] Similarly, overexpression of *PDGFR*A has been identified in 85% to 90% of PTCLs by gene expression profiling studies and RT-PCR without any genomic imbalances involving the 4q11-q13 locus, providing another potential molecular target for treatment.[275,297,302]

Rare cases of a *IRF4-TRA*@ fusion in PTCL have also been noted, resulting from a t(6;14)(p25;q11.2). These cases appear to be associated with a cytotoxic T-cell phenotype and involve the bone marrow and skin without concomitant lymphadenopathy.[303]

Recently, mutations in *TET2* and *DNMT3A,* commonly associated with acute myeloid leukemias (AML), have also been identified in PTCL.[304,305–308] Both genes involve epigenetic regulation of transcription through CpG methylation. *TET2* is involved in the oxidation of the 5-methyl group of 5-methylcytosine, believed to be the first step in demethylation. *DNMT3A* is a DNA methyltransferase, although the role of *DNMT3A* mutations in global methylation status is unclear. *TET2* mutations have been found in 12% of nodal and extranodal T-cell lymphomas (compared to only 2% of B-cell lymphomas) and are not found in the leukemic or disseminated T-cell neoplasms such as T-PLL, T-cell large granular lymphocytic leukemia, or adult T-cell leukemia/lymphoma.[308] *TET2* mutations are often found in conjunction with mutations in *DNMT3A* as well.[304]

Guidelines for Molecular Testing in Peripheral T-cell Lymphoma

TCR gene rearrangement studies may be helpful for the identification of a molecular marker to monitor response to therapy (MRD testing), although the test only has analytical sensitivity of approximately 1% to 5%. In addition, SYK and PDGFRα overexpression by IHC may become therapeutically relevant in the future as may molecular testing for mutations in *TET2* and *DNMT3A*. Because *TET2* mutations are spread throughout the gene and the common R882 site in *DNMT3A* does not account for all mutations in that gene either, these targets for molecular testing will be less useful as markers of MRD.

Angioimmunoblastic T-cell Lymphoma

AITL is an EBV-associated T-cell lymphoma associated with a wide range of systemic symptomatology.[4,275] It is one of the more common subtypes of peripheral T-cell lymphomas, accounting

for 15% to 20% of cases, although it comprises only 1% to 2% of all NHLs.[4] Patients typically present in their sixth or seventh decade. Systemic symptoms include hepatosplenomegaly, lymphadenopathy, polyclonal hypergammaglobulinemia, rash, pruritus, cold agglutinin disease associated with hemolytic anemia, positive rheumatoid factor, the presence of antismooth muscle antibodies, and immunodeficiency. Interestingly, although this lymphoma is associated with EBV, only the background B-cells in this lymphoma are EBV-positive. The EBV-driven B-cells can undergo a resultant immunoblastic proliferation and often can demonstrate a clonal/pseudoclonal Ig gene rearrangement. The T-cells, by contrast, are EBV-negative. AITL is one of the few T-cell lymphomas for which the cell of origin is well established to be a $CD4^+$ follicular helper T-cell. Clonally rearranged TCR genes are identified in 95% of cases of AITL using commercial primers.[22]

Early attempts at establishing a gene expression profile of AITL were plagued by the numerous contaminating B-cells, dendritic cells, and endothelial cells in this lymphoma.[296,309,310] However, recent studies have confirmed a signature of follicular helper T-cells in AITL, with expression of *CXCL13, CXCR5, BCL6, PDCD1, CD40LG,* and *NFATC1*.[283,311] These studies have defined the characteristic protein profile of the neoplastic cells in AITL through the use of a range of IHC markers and in situ hybridization for EBV RNA. In addition, a signature of immunosuppressive cytokines and their receptors was also notable (TNF-β1, TNF-βR2, IL-10Rα, IL-10-Rβ).[283] A prognostic signature was also obtained for AITL by gene expression profiling. Cases with a poor prognosis (1.05 years median overall survival versus 3.06 years, $P < 0.001$) demonstrate high expression levels of *PDGFR*α and *PDGFR*β, suggesting the potential for tyrosine kinase inhibitors in treating this disorder.[275,283]

Until recently little was known about any recurrent genetic aberrations in AITL. aCGH studies identify gains of 22q, 19 and 11q11-q14 (11q13) and losses of 13q.[293] The gain of 11q13 is shared by both AITL and PTCL, NOS, and may involve either *CCND1* or *GSTP1*, a gene often co-amplified with *CCND1* encoding for a glutathione transferase. aSNP studies show general copy number or LOH findings very similar to those of PTCL, NOS. Specifically in AITL, gains of 13q22.3 may involve *MYCBP2*, a gene that encodes a MYC binding protein with putative ubiquitin ligase activity that may regulate *MYC*-mediated transcription. These gains are associated with poor prognosis in these patients.[295]

Recently, mutations in *TET2*, *DNMT3A*, and *IDH2* have been identified at a high prevalence in AITL. All three genes are involved in the DNA methylation. The roles of *TET2* and *DNMT3A* in the regulation of DNA methylation have been described above. *TET2* mutations have been found in up to 33% of cases of AITL, located throughout the gene on chromosome 10.308 It is common for *TET2* mutations to occur in conjunction with *DNMT3A* mutations, implying some synergism.[304] *IDH2*, located on chromosome 15q21-qter, encodes for a mitochondrial NADP(+)-dependent isocitrate dehydrogenase which physiologically plays a role in the citric acid cycle, converting isocitrate to α-ketoglutarate. The mutant enzyme is believed to catalyze the production of (*R*)-2-hydroxyglutarate which may inhibit the function of TET2 and Jumonji histone demethylases, thereby affecting epigenetic regulation of the cell.[312–315] *IDH2* mutations (predominantly R172, with fewer R140) were identified in approximately 45% of all cases of AITL.[316] Identical mutations are also seen in gliomas and AMLs.[314,317] Unlike in these other disease types, mutations in *IDH1* are not identified and there is no suggestion of any prognostic import of the identification of this mutation at this time. Likewise, *TET2* and *DNMT3A* mutations are also common in AML and other myeloid neoplasms. The coincident finding of similar sets of mutations in myeloid and T-cell neoplasms may be a result of the established relationship of these lineages,[220,224] and may point to possible common pathways on tumorigenesis. These mutations may also provide targets for novel therapeutics in AITL and MRD monitoring, although to date no studies have been conducted to investigate their use in MRD testing. *IDH2* provides the greatest potential for MRD testing inasmuch as a single mutation at R172 accounts for 15/16 cases examined, allowing for high clinical sensitivity and the development of highly sensitive allele-specific PCR assays.

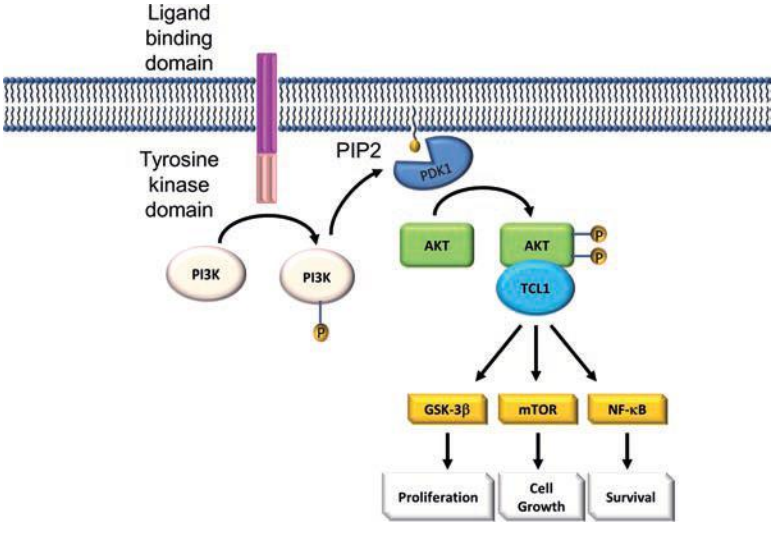

FIGURE 87.15. Biology of TCL-1. Receptor tyrosine kinases activate PI3K through phosphorylation which in turn catalyzes the formation of phosphatidylinositol-3,4-biphosphate (PIP2) and phosphatidylinositol-3,4,5-triphosphate (PIP3). These molecules localize PDK1 to the membrane which then phosphorylates AKT. The interaction of TCL1 with activated AKT further enhances the phosphorylation of downstream AKT target substrates.

Guidelines for Molecular Testing in Angioimmunoblastic Lymphoma

TCR gene rearrangement studies may be helpful for the identification of a molecular marker to monitor response to therapy (MRD testing), although the test only has analytical sensitivity of approximately 1% to 5%. Future testing modalities may also include use of the *IDH2* R172 or R140 mutations in diagnosis and monitoring of MRD for AITL. In addition, assessment of PDGFR expression may be prognostically helpful, although a clinically useful testing modality has not yet been identified.

T-prolymphocytic Leukemia

T-PLL is a rare aggressive T-cell neoplasm found in adults. Involvement is predominantly of the peripheral blood and bone marrow, with frequent infiltration of the lymph nodes and occasionally of the skin (20% of cases).[4] This neoplasm is not known to be virally driven, although it occurs with increased frequency in patient with ataxia-telangiectasia due to mutations in the *ATM* gene.[318] Clonal rearrangements of the TCR genes are detectable in essentially all cases of T-PLL using commercial primers against TCRG and TCRB.[22]

Although the cell of origin is poorly understood, T-PLL is easily distinguished from other T-cell neoplasms by the presence of hallmark translocations and inversions involving the oncogenes *TCL1A*, *TCL1B*, or *MTCP1* with the *TRA@* gene. These rearrangements are found in greater than 90% of cases of T-PLL.[319] *TCL1A* and *TCL1B* are located on chromosome 14q32, resulting in inv(14)(q11;q32.1) or t(14;14)(q11;q32.1). Less frequently, translocations can involve the homologous *MTCP1* locus in chromosome Xq28 in a t(X;14)(q28;q11). Overexpression of the genes fused to the *TRA@* locus at the J/D segment is the result in all these aberrations. This overexpression is independent of the orientation relative to the *TRA@* enhancer, due to the presence of *TCL1A* and *TCL1B* in opposite orientations within a 120 kb region which separates the two breakpoint clusters common at 14q32.1.[318] Less commonly, rearrangements of *TCL1* can involve *TRB@* as well.[320]

TCL1A and *TCL1B* encode for a cytoplasmic protein that is typically expressed in early double-negative T-cell progenitors and most B-cells, but not in mature T-cells. However, its overexpression in T-PLL, a mature T-cell neoplasm, appears to be oncogenic, functioning through activation of the AKT pathway (Fig. 87.15).[318] In addition, recently ATM has been identified as a TCL1-interaction protein, leading to activation of the NF-κB pathway.[321]

Various profiling methods (aCGH, aSNP, and gene expression profiling) have identified other common secondary cytogenetic aberrations in T-PLL, which can lead to quite complex karyotypes.[322,323] These changes include large regions of gains in 6p and 8q, as well as losses of 6q, 8p, 10p, 11q, and 22q. These loci correspond to genes found to be over- or underexpressed by gene expression profiling which involved pathways in lymphomagenesis, cell cycle regulation, apoptosis, and DNA repair.[322] In particular, *SMARCB1*, a gene involved in chromatin remodeling and checkpoint control, may be recurrently lost on 22q11.23.[324]

Guidelines for Molecular Testing in T-prolymphocytic Leukemia

TCR gene rearrangement studies may be helpful for the identification of a molecular marker to monitor response to therapy (MRD testing), although the test only has analytical sensitivity of approximately 1% to 5%. Likewise, FISH for inv(14) or t(14;14) suffers from a similar lack of analytical sensitivity.

Diagnosis	MRD
Consider PCR or NGS for TCR gene rearrangement studies	Consider PCR or NGS for TCR gene rearrangement studies
FISH for inv(14) or t(14;14)	Consider FISH for inv(14) or t(14;14)

CHAPTER 88

NON-HODGKIN LYMPHOMA IN ADULTS

John P. Greer, Nishitha M. Reddy, Michael E. Williams

HISTORICAL PERSPECTIVE

Thomas Hodgkin was the first to recognize that lymphadenopathy could occur as a primary disorder rather than secondary to infection or carcinoma in his 1832 paper entitled, "On Some Morbid Appearances of the Absorbent Glands and Spleen."[1] Since Hodgkin's initial description, there have been four historical phases in the study of non-Hodgkin lymphoma (NHL): (1) clinical features, 1832 to 1900; (2) histopathology, 1900 to 1972; (3) immunopathology, 1972 to the present; and (4) molecular genetics, 1982 to the present. These phases naturally overlap and all contribute to the understanding of NHL.[2]

From 1863 to 1865, Virchow introduced the terms aleukemia and lymphosarcoma to distinguish lymphoproliferative diseases from leukemia[3] and in 1871, Billroth used the term malignant lymphoma for a vague collection of primary lymphoid disorders.[4] In 1893, Kundrat proposed that the term lymphosarcoma was more specific than the term originally used by Virchow and should be reserved for the sarcomatous tumors of lymph nodes.[5]

At the turn of the last century, Sternberg[6] and Reed[7] identified the giant cells characteristic of Hodgkin lymphoma (HL) and introduced histopathology as a method for diagnosis and classification of lymphoma. Brill[8] and Symmers[9] described follicular lymphoma (FL) in the 1920s and indicated it was a malignant, albeit indolent, disorder. Ewing (1914), Oberling (1928), and Roulet (1930) used the term reticulum cell sarcoma which came to be used for large cell lymphoma and was distinct from lymphosarcoma, mainly composed of small lymphocytes.[10] In 1941, Gall and Mallory developed a classification scheme on NHL that had both clinical and histopathologic significance.[11] The histopathologic phase of NHL culminated in the 1956 classic work of Rappaport who developed a morphologic classification which stratified cases according to the pattern of growth with nodular replacing follicular and contrasting with diffuse.[12] There were four categories of lymphoma: well differentiated lymphocytic, poorly differentiated lymphocytic, mixed lymphocytic and histocytic, and histocytic.

In 1967, Good and Finstad discussed the relationship of B and T cells to lymphoid neoplasia, and Dameshek introduced the concepts that lymphomas were aberrations of immunologically competent cells and that transformation of lymphocytes to "blast" forms (immunoblasts) could occur secondary to antigenic stimulation.[4] In 1972, the immunologic origin of lymphoid neoplasia was confirmed by the presence of monotypic immunoglobulin (Ig) on the cell surface (B cell) or by sheep erythrocyte rosette formation with neoplastic cells (T cell).[13,14] Lymphoblastic lymphoma (LBL) was determined to originate from thymocytes by Smith in 1973.[15] Barcos and Lukes described the clinicopathologic features of "convoluted lymphocytic lymphoma" of thymic origin and used the term *LBL*, which was later preferred by Nathwani because of similarities to blasts of T cell acute lymphoblastic leukemia (ALL).[14,16]

In 1974, Lennert in Kiel, Germany, and Lukes and Collins in the United States classified NHL on the basis of the cell of origin within the immune system (Fig. 88.1).[17,18] Subsequently, monoclonal antibodies to lymphocyte differentiation antigens have been able to detect sequential stages in the development of B and T cells and to identify subtypes of NHL. Recurrent cytogenetic translocations involving the IG gene locus on chromosome 14 were identified in Burkitt lymphoma (BL) in 1976 and in FL in 1979.[19,20] In the 1980s, the lymphoid origin of NHL was confirmed at the molecular level with the identification of specific IG gene and T cell receptor (TCR) gene rearrangements in B and T cell lymphomas, respectively.[21,22]

In 1982, a Working Formulation (WF) of NHL separated diseases according to histologic grade and made correlations with survival; however, the WF lumped disparate diseases together by basing the diagnosis on morphology without utilizing immunophenotyping or molecular genetic techniques. The laboratories of Leder and Croce in 1982 identified *MYC* as the gene translocated from chromosome 8 to the IG genes in BL.[20,23,24] Subsequently, the genes defining FL, *BCL2/IGH,* and mantle cell lymphoma, *CCND1/IGH*, were described.[23,24] Recurrent translocations were less commonly seen in T cell lymphomas, but novel genes were translocated with the loci of T cell receptor genes in T-LBL/ALL. In 1989, a proportion of T-anaplastic large cell lymphomas (ALCL) were found to have t(2;5) (p23-, q35);[25] and in 1994, Morris identified the genes, *ALK/NPM*, involved in the translocation.[26]

Issacson and Stein formed an international group of pathologists, International Lymphoma Study Group (ILSG), to develop a consensus about diagnosis and terminology of lymphoid neoplasms.[2] In 1994, a Revised European-American Lymphoma (REAL) classification was proposed to identify specific types of lymphomas of B and T cell origin.[27] The REAL classification dropped the grading schema of lymphomas and developed a diagnosis by identifying clinical features, morphology, immunophenotype, and genetic data when available. An International Lymphoma Classification Project organized by Armitage affirmed the clinical utility and the reproductibility of the REAL classification.[28] The World Health Organization (WHO) has adopted the diagnostic principles of the REAL classification, and the WHO classification is utilized as the schema for diagnosis of all hematopoietic neoplasms.

EPIDEMIOLOGY

There is a worldwide epidemic of NHL that varies according to gender, race, and geography. The rise in NHL has been faster than that of all other malignancies except lung cancer in women, melanoma, and prostate cancer.[29] The age-adjusted incidence of NHL in the United States increased from 11.1 per 100,000 people in 1975 to 19.3 in 2002; there has been a plateau in the incidence with 19.6 in 2009. There were approximately 484,000 people (250,000 men and 232,000 women) alive in 2009 with a history of NHL. More than 70,000 new cases will be diagnosed and nearly 19,000 will die of NHL in the United States (US) in 2012.[30] Worldwide, 356,000 new cases of NHL occurred in 2008 and over 191,000 deaths were due to NHL.[31]

Part of the increase was attributed to the development of NHL in patients with the acquired immunodeficiency syndrome (AIDS); however, there are a large number of other possible contributing factors to the epidemic (Table 88.1). Improvement in disease detection and cancer registration have likely played a role. Even before the AIDS crisis, there was a steady increase of 3% to 4% per year from the 1970s up until the early 1990s, when there was even a drop-off in some subgroups of patients (Fig. 88.2). Part of the drop-off is attributed to the introduction of highly active antiretroviral therapy (HAART) for AIDS patients.[32] The consensus is that the increase in NHL remains unexplained by either the AIDS crisis or improvements in diagnosis.

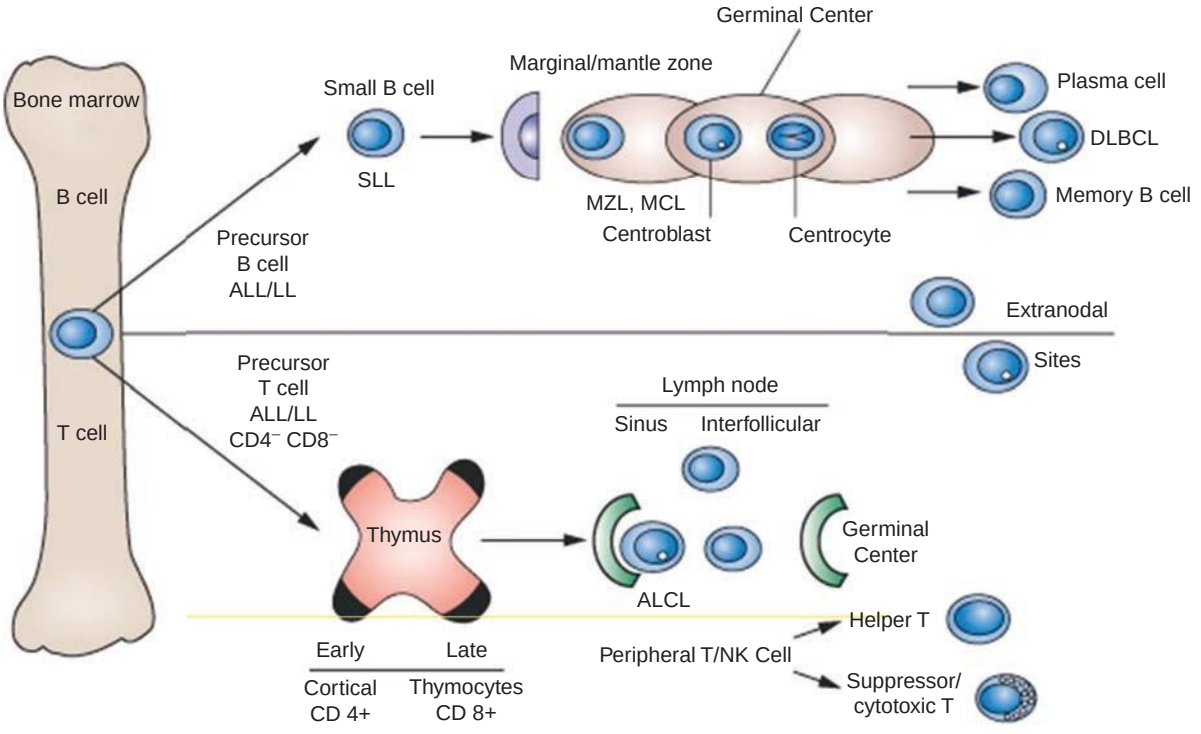

FIGURE 88.1. Cellular origins of non-Hodgkin lymphoma by B and T cell differentiation pathways. B and T cells originate in the marrow, where they are antigen independent. The follicular center is a normal site of antigen-dependent B cells which go through different stages: (a) proliferation of centroblasts (large noncleaved cells), (b) selection of centrocytes (small cleaved cells) or cell death via apoptosis, (c) differentiation into postgerminal center memory B lymphocytes or plasma cells, often in association with increased antigen affinity and an immunoglobulin isotype switch. The T cells depend upon the thymus for early differentiation before becoming peripheral T cells. The most immature T cell precursors are negative for both CD4 and CD8. Thymocytes can become committed to either the gamma-delta or alpha-beta lineage. As thymocytes within the alpha-beta lineage mature they gain CD4 and then CD8 to become double positive thymocytes. Normal thymocytes downregulate the expression of CD4 or CD8 to become mature peripheral T cells, which are subdivided into helper ($CD4^+$) and suppressor/cytotoxic ($CD8^+$) subsets. Corresponding lymphomas are based on stage of cellular differentiation and site(s) of nodal and/or extranodal origin. BCL, precursor B cell lymphoblastic lymphoma; SLL, small lymphocytic lymphoma; MZL, marginal zone lymphoma (MALT types, postgerminal center); MCL, mantle cell lymphoma (pre-germinal center); FL, follicular lymphoma; DLBCL, diffuse large B cell lymphoma; TCL, precursor T cell lymphoblastic lymphoma; ALCL, anaplastic large cell lymphoma (sinus involvement). Peripheral T/NK lymphomas tend to involve the interfollicular zone of lymph nodes or specific extranodal sites.

TABLE 88.1

EPIDEMIOLOGIC FACTORS THAT ARE ASSOCIATED WITH AN INCREASED RISK OF NON-HODGKIN LYMPHOMA

- Immunodeficiency
  - Congenital
  - Acquired
- Infectious agents
- Male gender
- Increasing age
- Family history of non-Hodgkin lymphoma
- Prior cancer history
- Drug Exposure:
  - Immunosuppressive agents
  - Antiepileptic medication
- Occupational History
  - Exposure to: herbicides
    - pesticides
    - wood dust
    - epoxy glue
    - solvents
- Other possible etiologic factors
  - Hair dye use
  - Nutritional factors
  - Blood transfusion

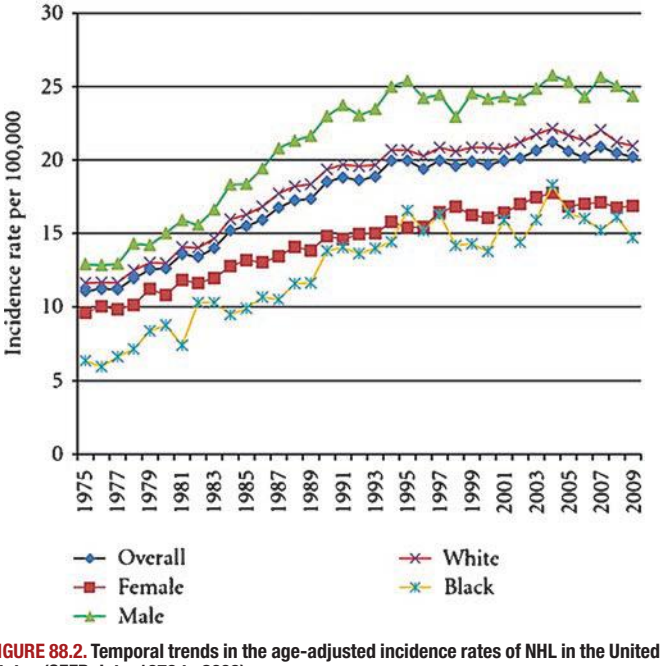

FIGURE 88.2. Temporal trends in the age-adjusted incidence rates of NHL in the United States (SEER data, 1979 to 2009).

Age, Race, and Sex Differences

The frequency of various lymphoid neoplasms is age-dependent, has a variable worldwide distribution, and is more common in males than females. Lymphomas represent approximately 10% of all childhood cancers in developed countries and are third in relative frequency behind acute leukemias and brain tumors. They are more common in adults than in children and have a steady increase in incidence from childhood through age 80 years (Fig. 88.3).[33] They are the fifth most common cancer in the United States and represent 4% of all cancers. The mean age at diagnosis is 45 to 55 years and the median age for 2005 to 2009 was 66 years. The annual incidence rate of NHL in 2005 to 2009 was 40% higher for males (23.8 per 100,000) than females (16.3 per 100,000). The median age of death was 75 years of age. The highest age-adjusted mortality in 2009 was in white males (8.7 per 100,000) and the lowest mortality has been in Asian/Pacific Islander females (3.4 per 100,000).[33] The incidence and mortality rates for NHL vary worldwide, with North America having the highest (Fig. 88.4).

A comparison of NHL in children and adults is outlined in Table 88.2. Lymphomas involving peripheral lymph nodes are usually of B cell origin in North America and Europe and are more common in adults than in children, who often present with gastrointestinal involvement (BL) or mediastinal widening (usually lymphoblastic lymphoma of T cell origin). The histologic appearance of NHL is more variable in adults, who frequently have low grade follicular or diffuse patterns in which the majority of malignant cells are small, dormant lymphocytes; children predominantly have high-grade diffuse patterns in which the malignant cells have a "blastic" or transformed appearance and a high mitotic rate. A possible explanation of the differences between childhood and adult NHL is that most childhood lymphomas arise from early cells that are antigen-independent, whereas many adult lymphomas arise from fully differentiated cells and are antigen-dependent.

Extranodal presentation of NHL occurs in 15% to 25% of adult patients in the United States, is higher in Europe, and is up to 40% to 50% in Asia.[34] Clinicopathologic features of the epidemic of NHL include a faster rise in extranodal than nodal disease, an increase in diffuse pattern over nodular, and in aggressive NHL than in indolent disease.[35] NHL of the brain has risen 4 times as rapidly as other extranodal sites and is partly due to AIDS, but the upward trend began before the AIDS crisis and continues to rise in immunocompetent hosts of all ages and in both genders.[36] The most common extranodal sites are the gastrointestinal tract and nasopharynx; other common sites include brain, skin, bone, thyroid, salivary glands, and testis.

Familial aggregation of NHL plays a small role in the epidemic and accounts for a 1.5- to 4-fold increased risk for NHL in close relatives of patients with lymphoma or other hematopoietic neoplasm.[37] Aggregation has been reported to be stronger for siblings and male relatives.[38,39] Anticipation (earlier age of onset in subsequent generations) has been reported in NHL;[40] however, others have disputed the finding by suggesting that the studies do not account for the increasing incidence of NHL.[41]

There is an increased risk for both NHL and HL in families with an autoimmune lymphoproliferative syndrome (ALPS, also known as the Canale-Smith syndrome), which is characterized by chronic lymphadenopathy, splenomegaly, autoimmune features, and expanded T cells, negative for CD4 and CD8.[42] Both NHL and HL, particularly nodular lymphocyte–predominant, may occur decades after recognition of the syndrome and are associated with germline *FAS* mutations and defective lymphocyte apoptosis. Somatic *FAS* mutations and *CASP10* germline mutations are other subtypes of ALPS.[43]

A prior history of cancer, Jewish ancestry, and small size families have been suggested as risk factors for lymphoma.[44] In families with a diagnosis of NHL, there are reports indicating an increased risk for melanoma and other cancers, including pancreas and stomach.[38] Patients who have both a family history of hematologic cancer and occupational exposures to certain substances (e.g., gasoline or benzene) appear to have an increased risk for NHL.[45]

Infectious Agents

Infectious diseases have contributed to understanding the mechanisms of lymphomagenesis. The role infections play in specific lymphomas vary according to host factors, environment,

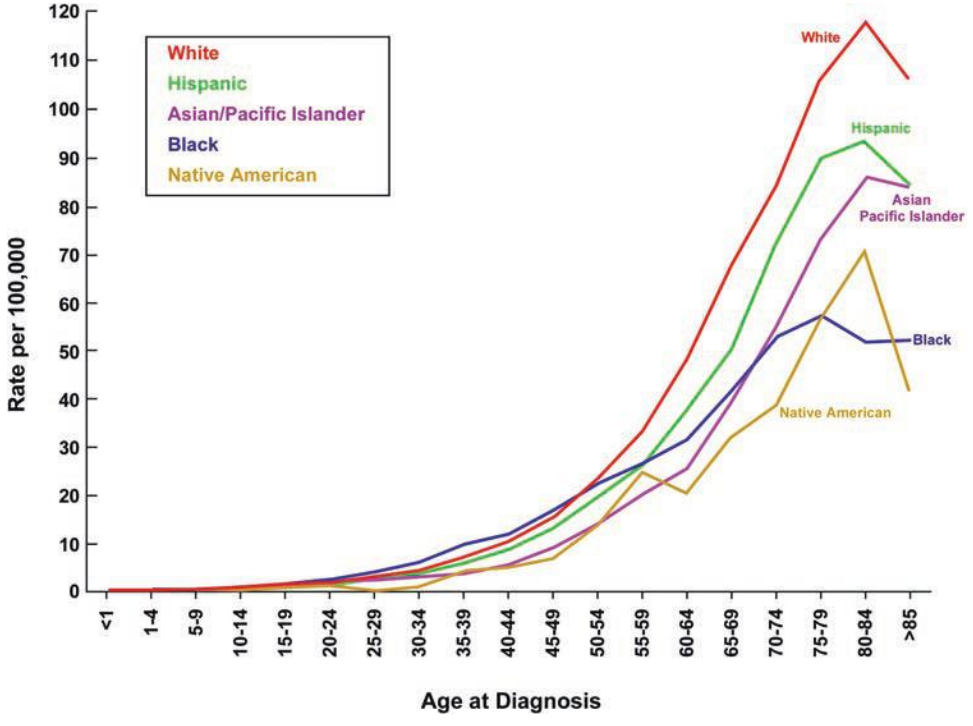

FIGURE 88.3. Age-specific incidence rates of NHL according to race (SEER data, 1979 to 2009).

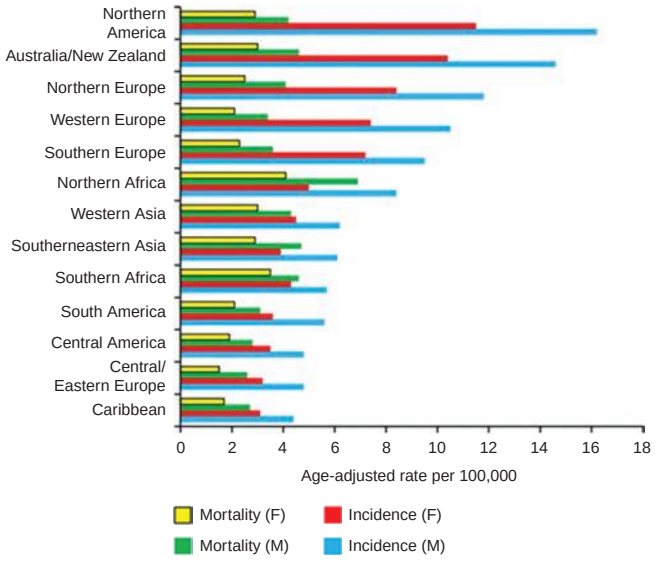

FIGURE 88.4. Age-adjusted incidence and mortality rates of NHL in selected world regions. From International Agency for Research on Cancer GLOBOCAN 2008 data, from Bassig BA, Lan Q, Rothman N, et al. Current understanding of lifestyle and environmental factors and risk of non-Hodgkin lymphoma: an epidemiological update. J Cancer Epidemiol 2012: 978930, with permission.

and geography.[46] There are at least two mechanisms in which infections contribute to lymphomagenesis. The best described is direct lymphocyte transformation by microbial agents. Lymphotropic viruses include Epstein-Barr virus (EBV), human T-leukemia virus-1 (HTLV-1), and human herpes virus 8 (HHV8). An alternative mechanism is an agent, such as *Helicobacter pylori (H. pylori)*, infecting host tissues and eliciting a lymphoproliferation response that remains dependent upon the presence of the agent, or antigen. The former does not usually respond to antimicrobial therapy, while the latter does. There are an expanding number of infections associated with specific types of NHL (Table 88.3).

The complex interplay of environmental and host factors in the pathogenesis of lymphoma was recognized through Dennis Burkitt's description in 1958 of an aggressive tumor of young children that was characterized by frequent jaw and abdominal involvement (Fig. 88.5A). Using careful epidemiologic surveys, Burkitt identified a tumor belt across equatorial Africa that was associated with temperature, rainfall, and elevation (Fig. 88.5B).[47,48] Subsequently, the geographic distribution of this neoplasm was shown to correlate with that of endemic malaria. In 1964, Epstein, Achong, and Barr found viral particles in tumor cell lines derived from Burkitt's patients.[10] A direct causative role for the virus was subsequently questioned by its infrequency in BL occurring outside Africa; however, the EBV was shown to be trophic for B cells, to induce B cell proliferation and differentiation, and to be the etiologic agent for infectious mononucleosis. In 1965, Burkitt was the first to discover that the lymphoma could be cured with chemotherapy.[49]

The identification of a 14q+ cytogenetic abnormality in BL by Manalov and Manalova[50] in 1971 led to the description of the 8;14 chromosomal translocation by Zech[19] in 1976. Subsequent molecular genetic studies showed that this translocation juxtaposed the *MYC* oncogene on chromosome 8 to the *IG* heavy chain gene sequences on chromosome 14.[51] These observations suggest that the 8;14 translocation of endemic Burkitt NHL arises in a state of EBV-induced polyclonal B cell proliferation in the setting of immunodeficiency associated with chronic malaria.[52] Support for this theory has been derived by the role of EBV in lymphoproliferation in other immunodeficient conditions. EBV has also been implicated in posttransplant lymphomas, AIDS-related lymphomas (mostly central nervous system [CNS] and variably with systemic), some T/NK lymphomas, particularly nasal; some HL, and several lymphomas that developed after chronic infectious mononucleosis.[53–55]

Shortly after immunologic classifications for NHL were proposed, adult T cell leukemia/lymphoma (ATL) was described in Japan by Takatsuki and Uchiyama in 1977.[56] The clinical course of ATL was variable, but the majority of patients presented with an acute form, which was characterized by lymphadenopathy, organomegaly, skin lesions, hypercalcemia, and an elevated white count with multilobated lymphocytes, referred to as "cloverleaf" or "flower" cells (see Fig. 88.21D), and a rapidly fatal course. In 1980 to 1982, Poiesz et al. in Gallo's lab in the United States and

TABLE 88.2

CLINICOPATHOLOGIC DIFFERENCES BETWEEN CHILDHOOD AND ADULT NON-HODGKIN LYMPHOMAS

	Children	Adults
Incidence	Rare	Common
Median Age	10–15 years	55–70 years
Presentation	Extranodal > nodal	Nodal > extranodal
Most Common Histologic Diagnoses	B cell: Burkitt Diffuse large cell T cell: Lymphoblastic ALK + anaplastic large cell	B cell: Diffuse large cell (DLBCL) Follicular T cell: Peripheral T cell, not otherwise specified Anaplastic large cell Angioimmunoblastic
Immunophenotype	60–70% B cell	85–90% B cell (United States, Europe); 20–35% T/NK cell (Asia)
Paraprotein	None	Rare (<5%)
Clinical Course	Aggressive	Variable—often indolent
Curability	70–95%	<30%, except 40% to 70% in aggressive subtypes, particularly DLBCL

TABLE 88.3

INFECTIONS AND ASSOCIATIONS WITH LYMPHOMA

Agent	Lymphoma Type(s)
Epstein-Barr virus (EBV)	Burkitt lymphoma (Africa) Posttransplant lymphoproliferative disorders Acquired immunodeficiency syndrome–related lymphoma (central nervous system, others) Natural killer/T cell nasal lymphoma Hodgkin lymphoma Diffuse large B cell lymphoma of the elderly
Human T-lymphotropic virus I (HTLV-1)	Adult T cell leukemia/lymphoma
Human herpes virus 8/Kaposi sarcoma–associated herpes virus	Primary effusion lymphoma Plasmablastic lymphoma
Helicobacter pylori	Gastric MALToma[a]
Hepatitis B virus	Diffuse large B cell lymphoma
Hepatitis C virus	Splenic marginal zone lymphoma; other B cell lymphomas
Campylobacter jejuni	Immunoproliferative small intestinal disease[a]
Borrelia burgdorferi	Primary cutaneous B cell lymphoma[a]
Chlamydia psittaci	Ocular adnexal lymphoma[a]

[a]Extranodal marginal zone lymphoma, MALT-type.

Yoshida et al. in Hinuma's lab in Japan independently discovered an unique retrovirus, HTLV-1, as the etiologic agent of ATL.[57,58] HTLV-1 was shown to be endemic to certain geographic areas: southwestern Japan, in which 6% to 20% of the population is seropositive for HTLV-1; the Caribbean Islands, New Guinea, parts of Central Africa and South America, parts of West Africa, the Middle East and Melanesia (Fig. 88.6).[59,60]

HTLV-1 is an RNA-containing delta retrovirus that infects mature T cells, usually $CD3^+$, $CD4^+$, and $HLA\text{-}DR^+$. The molecular pathogenesis revolves around TAX, a potent HTLV-1 transcription activator protein, and HTLV-1 basic ZIP factor, HBZ (Fig. 88.7).[59] T cell dysregulation may initially involve an autocrine interleukin (IL)-2 loop as well as paracrine effects from other cellular genes and cytokines. The TAX protein is prominent during the initial infection by increasing the expression of viral genes through viral long terminal repeats (LTRs) and by stimulating the transcription of cellular genes through signaling pathways of nuclear factor Kappa B (NFκB), serum response factor (SRF), cyclic AMP response element binding protein (CREB), and activated protein 1 (AP1).[59] The TAX protein induces proliferation and inhibits apoptosis of HTLV-1 cells through induction of IκB-alpha degradation, which activates the NFκB pathway, which in turn promotes expression of cell-cycle regulators (cyclin D2 and CDκ6) and leads to increased activation of PI3-kinase signaling.[61] TAX deregulates the expression of cytokines (IL-2 and IL-15) and antiapoptotic genes, upregulates vascular cell adhesion molecules, activates osteoclasts, and alters interferon signaling, all of which contribute to the pathogenesis of ATL.

HBZ is transcribed from the 3′-LTR and is the only gene which is conserved and unmethylated in all ATL cases, while the *TAX* gene is often inactivated by epigenetic changes or the loss of 5′-LTR.[62] Unlike TAX, which activates both the classical and alternative NFκB pathways and suppresses TGF-β signaling, HBZ suppresses the classical pathway without inhibiting alternative NFκB signaling and promotes TGF-β signaling, which leads to upregulation of forkhead box P3 (FOXP3) protein. By enhancing TGF-β and increasing FOXP3 expression, HBZ allows infected T cells to convert to Tregs, which contribute to viral persistence and leukemogenesis. *HBZ* promotes T cell proliferation in its RNA form by the regulation of E2F transcription factor 1 pathway; the HBZ protein interacts with CREB-2 and suppresses TAX-mediated viral transcription.[62,63] Initially, the T lymphoproliferation is polyclonal and controlled by host defense mechanisms;[64] however, as TAX expression diminishes, an oligoclonal or monoclonal T cell proliferation that is IL-2–independent emerges, resulting in the clinical manifestations of ATL. HTLV-1 contributes to a multistep process of worsening genetic instability characterized by mutation of *TP53*, deletion of tumor suppressor genes *CDKN2B/p15* and *CDKN2A/p16*, and DNA methylation.[59]

HTLV-I can be transmitted by blood transfusions, needle sharing, sexual intercourse, and from mother to child through breast milk or through the placenta. Over 20 million people worldwide are estimated to be infected with HTLV-1, and over 90% will remain asymptomatic carriers.[60] The virus can have a prolonged latency period of decades before clinical syndromes appear[64,65] (see section on "Mature T/NK Leukemias"). Where the virus is endemic, ATL occurs at a rate of 20 to 86 cases per 100,000 population per year, with a lifetime risk of approximately 1% to 6% for those persons seropositive for HTLV-I antibodies.[64] In Japan, males are 3 times more likely to develop ATLL than females, with a peak age around 60 years, while in the Caribbean there is no gender difference and the peak age is 40 years.[66]

HTLV-I infection induces the production of antibodies to various viral core proteins which can be used as serologic markers of infection.[67] The diagnosis is usually suggested by a screening enzyme-linked immunoabsorbent assay and confirmed by Western blot. Because of slow replication, seroconversion may take up to 2 years in HTLV-I infection compared to the 3 to 6 months for HIV. PCR utilizes primers and probes of the Pol (polymerase or reverse transcripter) and TAX (transactivator) regions and is the most sensitive and specific assay for detecting HTLV-I. HTLV-I can lead to other diseases, including myelopathy/tropical spastic paraparesis, uveitis, bronchopneumopathy, and arthropathy.[60,67]

Other viruses have been implicated in lymphoid neoplasia and include HTLV-II, herpes virus (HHV-6), HHV-8, (Kaposi's sarcoma-associated herpes virus [KSHV]), and hepatitis B and C. HTLV-2 was isolated in 1982 by Kalyanaraman et al. from a

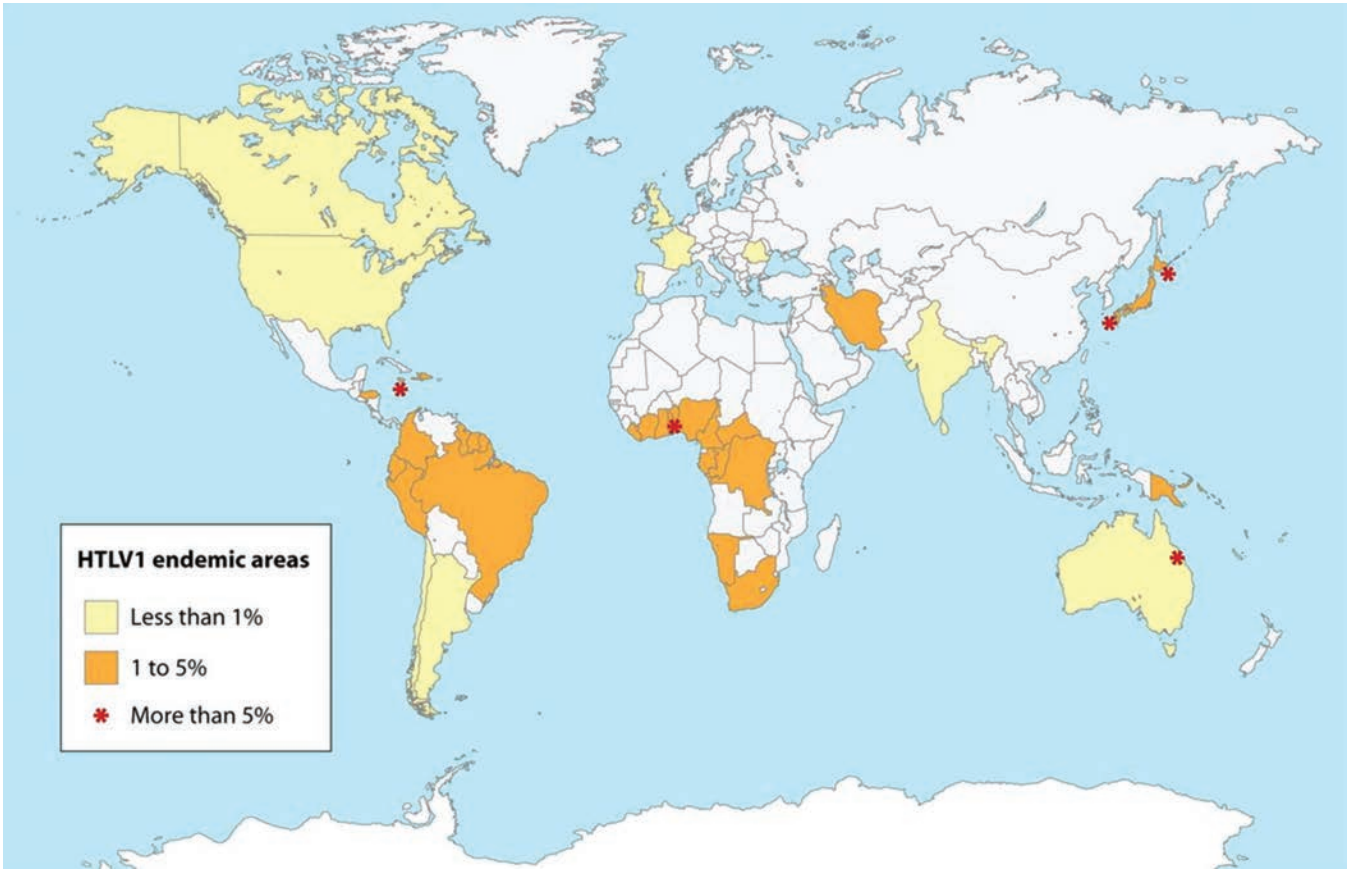

FIGURE 88.6. Geographic distribution of HTLV-1 in countries where the disease is endemic. The stars emphasize high-prevalence areas. The country boundaries shown in the map are not coincidental with the areas of endemicity, reflecting the cluster nature of HTLV infection. From Goncalves DU, Proietti FA, Ribas JG, et al. Epidemiology, treatment, and prevention of human T cell leukemia virus type 1-associated diseases. Clin Microbiol Rev 2010;23:577–589, with permission.

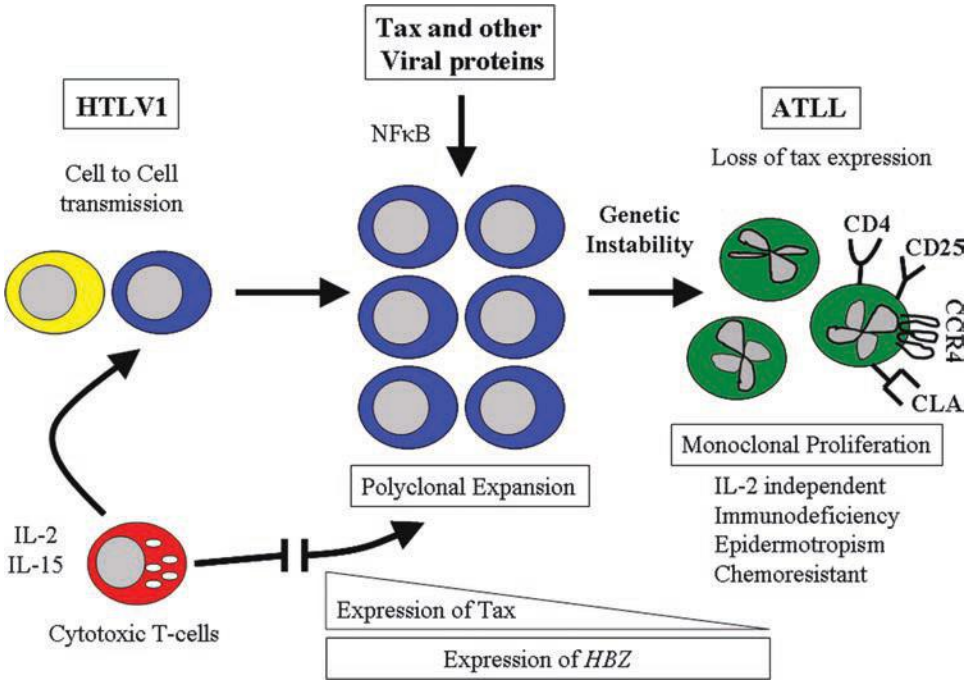

FIGURE 88.7. Course of HTLV-1 infection. After infection of a mature T helper cell, there is a long latency period (decades) which can be controlled by cytotoxic T cells and an autocrine IL-2 loop. Clonal proliferation is promoted by pleiotropic actions of Tax and other viral proteins that inhibit apoptosis and induce IκBα, which activates the NFκB pathway. *HBZ* promotes T cell proliferation and the HBZ protein suppresses *TAX*-mediated viral transcription. As TAX expression is lost, there is the emergence of a monoclonal T cell population that is independent of IL-2.CC chemokine receptor 4 (CCR4) and cutaneous lymphocyte antigen (CLA) on ATL cells interact with endothelial cells in the skin and contribute to epidermotropism. ATL follows a multistep process of worsening genetic instability and is subdivided into clinical syndromes characterized by immunodeficiency and chemoresistance.

patient with an unusual T cell variant of hairy cell leukemia.[68] It has subsequently been isolated only rarely in lymphoid neoplasia and in HTLV-I negative tropical spastic paraparesis, but it is prevalent in intravenous drug abusers.[69] Two other related viruses, HTLV-3 and HTLV-4, were reported in 2005 in Central Africa but have not been linked to human disease.[70] Salahuddin et al. identified HHV-6 in B lymphocytes from 6 patients with various lymphoproliferative disorders;[71] it was identified subsequently as the etiologic agent for exanthem subitum (roseola infantum) and as a cause for pneumonia in immunocompromised hosts.[72] A role for HTLV-2 or HHV6 in lymphoproliferation has not been detected. KSHV, also referred to as HHV-8, has been identified in AIDS-related body-cavity based B cell lymphomas and multicentric Castleman disease and has been associated with EBV genome in the absence of *MYC* rearrangement.[73,74] Theoretically, KSHV acts synergistically with EBV to transform B cells and causes a unique clinical presentation.

There is conflicting data regarding the risk of NHL in patients infected with hepatitis B (HBV) and C (HCV), but the association appears valid, particularly in endemic areas. Meta-analyses have reported a 2- to 3- and a 2- to 4-fold risk of developing NHL in HBV and HCV-infected patients, respectively.[75,76,77,78] The incubation time for lymphoma to occur in patients infected with hepatitis is estimated to be as long as 15 years.[79] DLBCL is the most common subtype associated with HBV.[75] Besides the association of HBV with NHL, cytotoxic therapy with or without rituximab can lead to HBV reactivation, resulting in hepatitis and even liver failure.[78,80] Screening HBV status prior to chemotherapy and prophylaxis with antiviral therapy for positive patients can decrease the rate of reactivation.[81]

The causative fraction of NHL by HCV varies widely according to country, but is estimated to be as high as 10% where HCV is endemic, such as Egypt, Italy, and South Korea.[82] Chronic HCV infection is often (40% to 90%) present in patients with type II mixed cryoglobulinemia (MC); and 5% to 10% of MC patients have or will develop a B cell lymphoma (see Chapter 101).[83–85] Early studies stating that indolent B cell lymphomas, lymphoplasmacytic and marginal zone, were the most common subtypes associated with HCV have not been confirmed, but they were reported mainly in patients with MC who do have an increased risk for indolent lymphomas.[76,86] Spleen involvement is more common in DLBCL with HCV (34% vs. 13%); some of the DLBCL have undergone transformation from an indolent NHL.[87] Rearrangement of either *IGH* or the *BCL2* genes occurs in up to three-fourths of patients with HCV and MC and can regress with antiviral therapy.[88] Complete responses to antiviral therapy, primarily peg-interferon and ribavirin, occur in 60% to 75% of patients with HCV-positive lymphomas.[89,90,91] Adding rituximab to antiviral therapy is well tolerated and improves responses.[92,93] Proposed mechanisms of HCV's role in lymphomagenesis include chronic antigenic stimulation, activation of B cells by an HCV E2 protein, and direct infection of B cells, a combination of which could lead to genetic aberrations.[76,85]

H. pylori is a gram-negative rod which was discovered by Warren and Marshall in 1983 and was shown to be associated with peptic ulcer disease, gastric carcinoma, and NHL.[94,95,96] Gastric lymphoma was found to have a high frequency in certain parts of Europe, such as the Veneto region of Italy, and was usually an indolent B cell lymphoma of mucosa-associated lymphoid tissue (MALToma), a term proposed by Isaacson and Wright.[97,98] Parsonett recognized that *H. pylori* infection preceded the development of lymphoma,[99] and Wotherspoon reported in 1993 that antibiotic treatment for *H. pylori* caused regression of the lymphoma in over two-thirds of patients.[100] Over one-half of *H. pylori* large B cell gastric lymphoma will also respond to antibiotics.[101]

MALToma of the stomach serves as a model for lymphomagenesis secondary to antigenic stimulation (Fig. 88.8).[102] Both B and T cells are recruited to the gastric mucosa following *H. pylori* infection. Proliferation of B cells are dependent upon reactive T cells.[103] There is a continuous spectrum of pathologic lesions during the transition from gastritis to low grade MALToma to the less frequent large B cell.[102] PCR may be helpful in identifying a malignant B cell clone which may persist after histologic regression following antibiotic therapy.[104] Somatic hypermutation is characteristic of the B cell clone of MALToma and, along with the observation of plasmacytic differentiation, indicates a post germinal center origin. Translocation-positive gastric MALTomas lead to activation of the NFκB pathway which causes overexpression

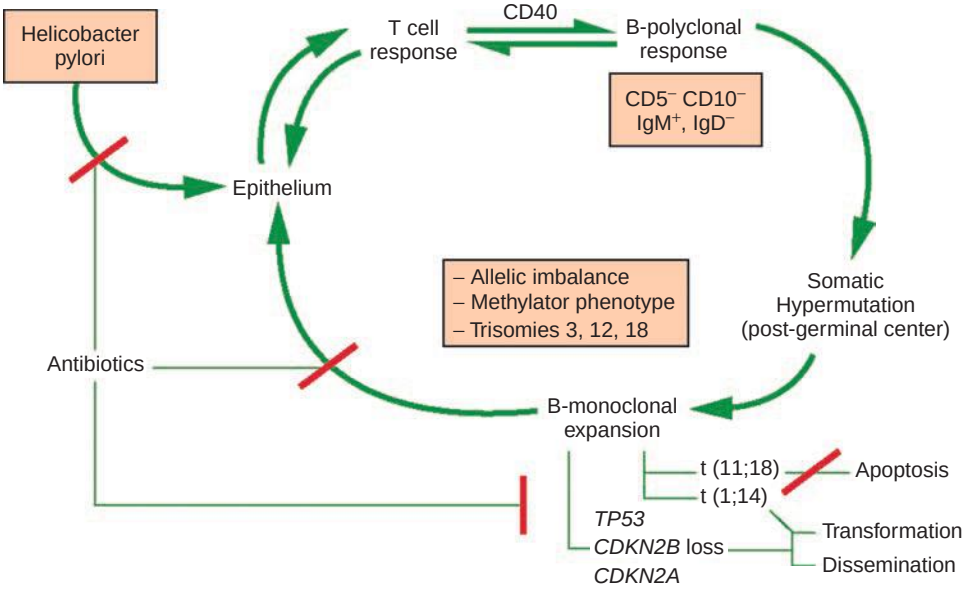

FIGURE 88.8. MALToma of the stomach: model for lymphomagenesis. *Helicobacter pylori* infects the epithelial cells and there is recruitment of both T and B cells. Contact-dependent T cell help is mediated by CD40 and CD40 ligand interaction. B cells undergo a T cell–dependent polyclonal response which can develop into a postgerminal center monoclonal B cell lymphoma. Three-fourths of gastric MALTomas have allelic imbalance, methylator phenotype, and/or trisomies and respond to antibiotics that eradicate *Helicobacter pylori*. Alternatively, there can be clonal evolution that involves a specific translocation (i.e., t[11;18] or t[11;14]) and/or a loss of tumor suppressor genes (i.e., *TP53, CDKN2B/p15, CDKN2A/p16),* which are associated with dissemination of disease. The t(11;18) rarely is associated with transformation while the t(11;14) may progress to a diffuse large B cell lymphoma.

of BCL2, blocks apoptosis of B cells, and leads to antibiotic resistance, while translocation-negative cases involve inflammatory and immune responses, which maintain B and T cell interaction and respond to *H. pylori* eradication.[105] The oncoprotein of the *CAGA* gene has been shown to be directly delivered into B cells by *H. pylori*, and it likely contributes to lymphomagenesis.[106]

The most common genetic abnormality in gastric MALToma is the t(11;18)(q21;q21) which is present in one-quarter to one-third of cases, and up to one-half of *H. pylori* negative cases.[107,108] The genes involved at t(11;18) are an apoptosis inhibitor-2 gene (*API2)* and a novel 18q gene, *MALT,* and are more likely to result in disseminated disease but less likely to undergo histologic transformation than other genetic abnormalities.[109] The t(14:18) in MALToma involves *IGH/MALT2* and may coexist with trisomies 3, 12, or 18; occurs in 5% gastric MALTomas; and is more common in nongastrointestinal sites.[108] The t(1;14)(p22;q32) and t(1;2)(p22;q12) involve the *BCL10* gene[102,110] and are present in 1% to 3% of gastric MALTomas.[102,108,110] *BCL1* and *BCL2* gene rearrangements are usually not present in MALTomas, and *BCL-6* has rarely (1% to 2%) been reported.[102,111] There is controversy whether the B cell clones remain dependent upon antigen stimulation or expand through autonomous (antigen-independent) growth. Loss of tumor suppressor genes and amplification of 3q27 have been associated with histologic progression and dissemination of MALTomas.[109,112]

Other infections associated with specific MALTomas include *Borrelia burgdorferi* with primary cutaneous B cell lymphoma, *Chlamydia psittaci* with ocular adnexal MALTomas, and *Campylobacter jejuni* with immunoproliferative small intestinal disease (also called alpha heavy chain disease or Mediterranean lymphoma).[46,113] Their frequency varies according to endemic geography and have been found more commonly in Europe than in North America or Asia. The ability to diagnose the association depends upon either immunohistochemistry using a monoclonal antibody detecting the agent or, preferably, targeted polymerase chain reaction (PCR) that detects the DNA of the infectious agent. When the infections are present in these MALTomas, the lymphomas will regress in the majority of patients treated with antibiotics.[114,115]

Environmental Factors

Environmental associations implicated in the pathogenesis of NHL include not only infections, but also drug exposure and toxic chemical exposure. Immunosuppressive agents contribute to lymphomagenesis through interaction with EBV, particularly in organ transplants. Phenytoin and carbamazepine have been associated with both pseudolymphoma and malignant lymphoma, with the former condition presenting with fever, rash, and adenopathy that regress after drug withdrawal.[116] Methotrexate and the tumor necrosis factor (TNF) alpha inhibitors (adalimumab, certolizumab, etanercept, golimumab, and infliximab) have been associated with an increased risk of lymphoma in some but not all studies in rheumatoid arthritis, which itself may have an increased risk (see section on "Prelymphomatous Conditions").[117] In a meta-analysis of randomized controlled studies, there was a trend for an increased risk of B-NHL in patients receiving anti-TNF therapy, but it did not reach statistical significance.[118] Hepatosplenic T cell lymphoma has been reported in patients with Crohn disease receiving anti-TNF therapy usually with other immunomodulators.[119] Although epidemiologic studies are flawed by methodologic weaknesses, other drugs possibly associated with NHL include analgesics, antibiotics, steroids, digitalis, estrogen, and tranquilizers.[44,120–122] A Danish study found no increased risk of NHL in women using postmenopausal hormone replacement.[123]

Occupational exposures have been suggested as factors in the epidemic, but studies are often flawed because of small numbers and being retrospective. An increased risk of NHL has been reported among people employed in agriculture, forestry, fishing, construction, motor vehicles, telephone communication, and leather Industries.[124,125] Specific jobs at risk include plant and poultry farmers, butchers, gardeners, painters and plasterers, car repair and gasoline station workers, carpenters, brick and stone masons, plumbers, welders and solderers, roofers, and teachers. The associations tend to increase with longer duration of employment, and studies have correlated specific jobs with histologic types.[125]

Chemicals that have been implicated in the epidemic include organochlorines and phenoxyacetic acids that are commonly found in pesticides and herbicides.[126–129] A number of organochlorine compounds have been banned in the United States, including dichlorodiphenyl-trichloroethane (DDT, used from 1939 to 1972), polychlorinated biphenyls (PCBs, 1929 to 1977), and chlordane (1947 to 1988); however, studies have correlated the presence of these and similar chemicals in carpet dust and in adipose tissue with a higher risk of developing NHL. An excess risk for NHL has also been suggested for exposure to organic solvents, such as benzene, xylene, toluene and trichloroethylene, fertilizers, epoxy glues, and wood dust.[130] Variations in immune genes or DNA repair genes may affect an individual's risk of developing NHL after exposure to solvents,[131,132] which may also directly impair cell-mediated immunity.

Hair dyes, ultraviolet light (UV), and nutritional factors have been implicated in some epidemiologic studies and negated in others.[133–136] Hair dye is more likely to be a factor in women than in men because of greater use in women. There has been an increased risk for NHL in women who used hair dyes before 1980, but not among women after 1980, probably related to removal of carcinogenic compounds.[136,137]

Several studies noted an increase in NHL among patients with melanoma or squamous cell skin cancer and suggested a role for UV suppressing the immune system;[133] however, there was no correlation between NHL mortality and increased UV light exposure in the southern United States or in Scandinavia.[134,138] Additionally, a reduced risk of NHL has been reported with higher sun exposure.[138,139] A hypothesis is that reduced risk in mid-latitudes arises from vitamin D production with UVB light, while an increased risk arises from immunosuppression by more UVA light in higher latitudes.[140] Other studies have found no protective effect of UV radiation and no association between vitamin D and NHL risk.[141,142]

Nutritional factors, including milk, butter, liver, meat, coffee, and cola consumption, have been identified as possible risk factors.[143–147] A high-meat diet and a high intake of fat from animal sources have been associated with an increased risk of NHL; there was a decreased risk with increased ingestion of fruits.[135] Other studies have reported a lower risk for NHL with higher intakes of vegetables, lutein and zeaxanthin, and zinc.[148] Milk consumption has had conflicting reports.[135,147] Obesity and lack of exercise have been suggested as contributing to the epidemic in some studies and refuted in others.[147,149,150]

Blood transfusion has been implicated as contributing to the increased incidence of NHL.[151–153] The use of blood products beginning in the 1950s has coincided with the epidemic. Transmission of infectious agents through blood transfusion could suppress the immune system, and make a patient susceptible to the development of lymphoma. Blood transfusion has been associated with all types of histologies, but a meta-analysis found a higher risk for CLL/SLL.[152,153] While cohort studies have supported the connection between blood transfusion and lymphoma, case-control studies have not consistently confirmed the association.[151,153,154]

A number of other factors have been mentioned as possibly contributing to the epidemic, including ionizing radiation, electromagnetic fields, alcohol, tobacco, and chronic fatigue syndrome, but the data is weak to support an association of any of these factors

with an increased risk of NHL.[155–158] The epidemiology of NHL continues under investigation and requires carefully designed studies with large cohorts and prolonged follow-up to determine the validity of an association between a factor and NHL. InterLymph, an international consortium of NHL studies, is providing large databases to assess the impact of environmental risk factors.[159]

PRELYMPHOMATOUS CONDITIONS

The mechanism of developing lymphomas has been best studied in those occurring in immunodeficiency states. These disorders can be subdivided into congenital, or primary, immunodeficiencies, and acquired, or secondary, immunodeficiencies (Table 88.4). Common components to all these disorders are defects in immunoregulation, particularly in T cell immunity, resulting in decreased cytokines, and uncontrolled B cell growth in lymphoid tissue, often in association with the EBV genome. Since 1973, cases of malignant disease in children with immunodeficiency have been recorded by immunodeficiency cancer registries, and NHL constitutes the majority of the cases.[160,161] The median age of onset is 7 years and there is a predominance of males over females, due in part to the contribution of X-linked disorders.[160] The importance of EBV in the pathogenesis of lymphoproliferation in immunodeficiency was suggested by Purtilo et al. in 1974, when they described an X-linked disorder in which 6 boys in a single family died of infectious mononucleosis, agammaglobulinemia, or malignant lymphoma.[162] The role of EBV in lymphomas developing in patients with immunodeficiencies is addressed in Chapters 62 through 64.

Organ Transplants

In the early 1980s, a range of lymphoproliferative lesions was described that occurred in patients receiving chronic immunosuppressive therapy after solid organ transplantation. The clinical and pathologic spectrum of diseases included primary infectious mononucleosis, polymorphic B cell hyperplasia, and intermediate- to high-grade B cell lymphomas in which necrosis, cytologic atypia, monotypic Ig expression, and cytogenetic abnormalities are harbingers of neoplastic transformation and aggressive behavior.[163] Serologic and molecular studies linked many of these lymphoproliferations to primary or secondary EBV infection.[164] The risk of developing lymphoproliferation after transplantation is dependent upon age, EBV status, type of transplant, and amount of immunosuppression.[165] A lower chance occurs in older as opposed to younger age, sibling over cadaver donor, and single over multiple transplants. Early reports from Stanford University indicated that up to 40% of patients surviving cardiac transplantation developed a malignant lymphoma.[166] With less immunosuppression, the incidence is 1% to 15% after solid organ transplants, which is a 30- to 60-fold increase in lymphomas compared to the general population.[167,168] The diagnosis and management of posttransplant lymphoproliferative disease (PTLD) is described in Chapter 62.

TABLE 88.4

PRELYMPHOMATOUS CONDITIONS

Congenital	Acquired
Ataxia telangiectasia	Immunodeficiency
Wiskott-Aldrich syndrome	Organ transplants
	Acquired immunodeficiency syndrome
Severe combined immunodeficiency	
Common variable immunodeficiency	Autoimmune disorders
	Sjögren syndrome
Hyper IgM syndrome	Hashimoto thyroiditis
Hyper IgE syndrome	Rheumatoid arthritis
	Systemic lupus erythematosus
X-linked hypogammaglobulinemia	Inflammatory bowel disease
X-linked lymphoproliferative syndrome	Castleman disease
	Hodgkin lymphoma
Autoimmune lymphoproliferative syndrome	Lymphomatoid granulomatosis
	Predisposition to T cell lymphoma
	Nontropical sprue
	Angioimmunoblastic lymphadenopathy
	Lymphomatoid papulosis

Acquired Immunodeficiency Syndrome

AIDS was recognized as a disease in 1981 and the first case of lymphoma in an AIDS patient was reported in 1982.[169] This was followed by a series of 90 homosexual patients with NHL reported by Ziegler et al. in 1984.[170] In 1985, the diagnosis of NHL in association with positive serologic evidence for human immunodeficiency virus (HIV) became a criterion for the diagnosis of AIDS.[171] In Ziegler's series, presenting features included generalized adenopathy and opportunistic infections in one-third of patients.[170] Extranodal sites of disease and advanced stage occur in three-fourths of patients with AIDS-related lymphoma (ARL). The most common extranodal sites are the meninges, gastrointestinal tract, bone marrow, liver, and lung/pleura; unusual sites include rectum, oral cavity, heart/pericardium, common bile duct, and skin.[172] NHLs in AIDS patients are usually of B cell origin and include diffuse large B cell (DLBCL: immunoblastic, or large transformed) and BL. Unique presentations of ARL include plasmablastic lymphoma of the oral cavity[173] and primary effusion lymphoma.[73] Differences in the histology of ARL have not impacted survival;[174] however, they are likely to become more important with improved survival in AIDS.

The prevalence of NHL in AIDS is 3% to 6%, and before the era of highly active antiretroviral therapy (HAART) there were projected increased risks over time.[175] The risk of lymphoma is increased 60- to 650-fold among HIV-infected patients compared to the general population and is associated with older age, severe immunodeficiency (defined by CD4 count and HIV viral load), and prolonged HIV infection.[176,177] Since the introduction of HAART in 1996, epidemiologic studies in developed countries are reporting an increase in ARL as the first AIDS-defining illness but decreased overall incidence in ARL, particularly in primary CNS NHL and in DLBCL (immunoblastic) histology.[172,177,178,179] Additionally, survival for ARL has improved.[177,180] Prognostic factors and therapy of ARL are addressed in Chapter 64.

Autoimmune and Other Immunologic Disorders

Chronic inflammation, immune hyperactivity, and/or immunosuppression are elements of autoimmune disorders that predispose patients to lymphoma.[98,181,182] Many of these lymphomas arise in extranodal sites where there is sparse lymphoid tissue; they are usually localized, low grade B cell lymphomas arising from mucosa-associated lymphoid tissue (MALT). Isaacson and Wright initially recognized MALTomas in the gastrointestinal tract and indicated they were a subset of immunoproliferative small intestinal disease, or Mediterranean lymphoma; however, they subsequently identified similar lymphomas occurring in the lung and salivary gland.[183] Multiple other extranodal sites have been involved with MALTomas and include thyroid gland, thymus, breast, conjunctiva, gallbladder, skin, cervix, larynx, and trachea. Although the term MALToma is misleading due to the fact that not all of the lesions arise in mucosal tissue, two common features are chronic inflammation and the presence of glandular epithelium that is destroyed by progressive lymphocytic infiltration.

Lymphomas associated with Sjögren syndrome (SS) and Hashimoto thyroiditis (HT) are of B cell origin and tend to occur in elderly females. The presumed pathogenesis of lymphomas in these patients is associated with chronic antigenic stimulation causing polyclonal B cell growth with eventual development of a monoclonal B cell lymphoma. Bunim and Talal reported the first association of lymphoma and SS in 1963,[184] and Kassan et al. subsequently reported a greater than 40-fold risk for lymphomas in these patients.[185] Approximately 5% of patients with primary SS will develop lymphoma.[186,187]

The histologic lesion of SS is a myoepithelial sialoadenitis (MESA) characterized by lymphoid infiltration of the salivary gland along with acinar atrophy and proliferation of ductal cells to form myoepithelial islands.[188] Although the initial clinical course of SS usually is benign, clonally rearranged IG genes can be detected in the biopsy of MESA.[189] Furthermore, the finding of light chain restriction in minor salivary glands of the lip by in situ hybridization techniques correlates with development of lymphoma.[190] These findings suggest, as in many other prelymphomatous conditions, that the "benign" lesion actually represents either a monoclonal population of unknown significance or malignant lymphoma in situ. B-lymphocyte activator of the TNF-family (BAFF) is overexpressed in SS salivary glands, induces BCL-2 which impairs apoptosis, and likely contributes to lymphomagenesis.[191] Overt lymphoma tends to occur in those lesions with extensive, confluent areas of monotypic B cell proliferation, and the lymphomas most commonly seen are marginal zone, lymphoplasmacytic, or DLBCL types.

Lindsay and Dailey described an association between lymphoma of the thyroid and HT in 1957.[192] Subsequent studies indicate that over 75% of thyroid lymphomas are preceded by HT, made evident by thyroiditis in the nonlymphomatous portion of the pathologic specimens and by antithyroid antibodies in most patients.[193] There is a 60- to 80-fold increase in thyroid lymphoma after thyroiditis, but the lifetime risk is only 1% to 2%.[194] Unlike the lesion of SS, which has IG gene rearrangement, the lesion of HT does not usually have a clonal population of cells identified by DNA analysis;[195] however, similar *IGH* bands have been detected in a minority of HT patients and subsequent thyroid lymphoma, supporting the hypothesis of clonal evolution of NHL from HT.[196] Most thyroid lymphomas express surface IgG rather than the IgM characteristic of follicular center cell (FCC) lymphomas, suggesting that thyroid lymphomas involve B cell progenitors with the ability to differentiate further from IgM to IgG production.[197]

Lymphomas have been reported in patients with other autoimmune disorders, including rheumatoid arthritis (RA), systemic lupus erythematosis (SLE), scleroderma, inflammatory bowel disease, and dermatomyositis; however, the increased incidence in these disorders are complicated by the use of immunosuppressive therapy and by possible methodologic flaws in the epidemiologic studies.[198] The increased risk for lymphoma in RA varies from 2- to 15-fold and is higher in patients with more severe disease or with Felty syndrome.[199] A large study reported an increased NHL risk (2.9[1.7 to 4.9]) in RA patients treated with any biologic agent and a greater risk with anti-TNF agents than methotrexate.[200] A meta-analysis of randomized clinical trials in RA reported no increased risk of malignancy with biologic therapy, but did find an increased risk for NHL of 2.1 (0.55 to 8.4) in patients receiving anti-TNF therapy compared with controls.[201] A wide spectrum of lesions have been described in RA patients, ranging from lesions that resemble posttransplant polymorphous lymphoproliferation to large B cell lymphomas, the most common type, HL, and, rarely, PTCL.[198,202] EBV may be present in tumor cells, and the lymphoproliferations may regress with discontinuation of immunosuppression.[202,203] T-large granular lymphocyte leukemia is often associated with rheumatoid arthritis and neutropenia.[204] The risk of NHL in SLE is increased 3- to 4-fold and DLBCL is the most common type.[205]

Castleman disease (CD) (giant lymph node hyperplasia, angiofollicular lymph node hyperplasia) was first recognized in the 1920s and was further described as a clinicopathologic entity in 1954.[206,207] It has two types of clinical presentations (localized and multicentric) and three types of histologic subtypes (hyaline vascular, plasma cell, and mixed).[208,209] The hyaline vascular type is the most common subtype and presents as localized adenopathy, often in the mediastinum. It can be amenable to surgical resection; and although it was initially reported to be radioresistant, it has been successfully treated with radiation as well.[210] The plasma cell variant is associated with systemic symptoms, anemia of chronic disease, hypergammaglobulinemia, and a variety of unusual syndromes, including myasthenia gravis, nephrotic syndrome, peripheral neuropathy, amyloidosis, and temporal arteritis.[211] A plasmablastic subvariant is associated with HIV infection. Increased expression of the gene coding for IL-6 has been identified in CD, and retroviral transduction of the gene into mice has reproduced histology and symptoms.[212] Moreover, antibodies to IL-6 or its receptor have ameliorated the disease.[213]

The plasma cell variant tends to be either a local form, more commonly occurring in a young adult and amenable to local therapy, or a multicentric form occurring in an older adult or in an HIV-infected patient with diffuse adenopathy and a variable, but often fatal, clinical course in which 20% to 30% of patients develop either Kaposi sarcoma or B cell lymphoma.[211,214,215] Immunophenotyping and IG gene rearrangements of the plasma cell variant in CD indicate that patients usually have polyclonal lesions;[216] however, monoclonal IG gene rearrangements have been identified in patients with the multicentric form and in patients developing B cell lymphoma.[217] KSHV (HHV8) has been identified in HIV-associated multicentric CD cases and levels of KSHV DNA correlate with symptomatic disease.[215,218] KSHV positive plasmablasts have lambda light chain restriction, are localized to the mantle zone of germinal centers, and can coalesce to form microscopic lymphomas.[219] The lymphomas have had a variable histologic pattern but they are usually of B cell origin with mantle cell the most common subtype and have a poor prognosis.[220] Plasmablastic lymphoma and primary effusion lymphoma have also been reported.[74] There is no standard of treatment for multicentric CD, and anecdotal cases have utilized rituximab, interferon, thalidomide, tocilizumab (anti-IL6), antiviral therapy, and chemotherapy with variable success.[207,215,221,222]

NHL may follow HL, with prior therapy and the cell-mediated immune defect characteristic of HL serving as possible contributing factors. Krikorian et al. reported 6 cases from Stanford University of intermediate- to high-grade lymphoma developing after HL.[223] In subsequent series, authors estimated that 1% to 5% of patients with HL will develop NHL;[224] some studies have indicated a greater risk in the nodular variant of lymphocyte predominant HL (LPHL), which has a unique $CD20^+$ B cell immunophenotype.[225,226] The large B cell lymphomas associated with LPHL generally are regarded as a progression of LPHL rather than as secondary neoplasms. Single cell analysis of the lymphocytic and histiocytic cells of LPHL have proven a clonal relation to large B cell lymphoma developing in the same patient.[227] There are rare patients with intermediate clinical and pathological features between DLBCL and classical HL that have been referred to as "mediastinal gray zone lymphoma," or "large B cell lymphoma with Hodgkin-like features."[228] Most NHL that occur after all subtypes of HL are of B cell origin,[225,229] but those of T cell immunophenotype have followed HL as well.[230]The EBV genome has been found in some cases of NHL developing after HL.[231]

T cell lymphomas commonly do not occur in the setting of immunodeficiencies, with the exception of ataxia telangiectasia; however, some disorders appear to predispose to PTCL, and up to one-tenth of lymphomas in organ transplants are of T cell origin. PTLD of T cell origin tend to occur late and have a poor prognosis.[232] Hepatosplenic $\gamma\delta$ T cell lymphoma can occur late

after solid organ transplantation and in patients with Crohn disease, the majority of whom were on anti-TNF therapy.[119,233] PTCL comprise only 3% of all AIDS lymphomas.[234] Patients with gluten-sensitive enteropathy or celiac disease have an increased incidence of intestinal T cell lymphoma.[235] Although Isaacson et al. initially reported that these lymphomas were variants of malignant histiocytosis, subsequent studies with gene rearrangement techniques indicated a T cell origin and they are referred to as enteropathy-associated T cell lymphoma (EATL).[236] Primary anaplastic large cell lymphoma has been reported after breast implant surgery.[237]

Skin disorders may also evolve into a malignant CTCL (Chapter 92). Clonality, as evidenced by TCR gene rearrangements, has been detected in some patients with lymphomatoid papulosis[238] as well as in those with other cutaneous T cell processes of uncertain malignant potential, such as pityriasis lichenoides et varioliformis acuta,[239] granulomatous slack skin disease,[240] and pagetoid reticulosis.[241] The latter two disorders are considered variants of mycosis fungoides.

CLINICAL FEATURES AT PRESENTATION

The majority of patients with NHL present with painless adenopathy, more commonly in the cervical or supraclavicular regions;[242] however, extranodal disease can be detected at presentation in up to 40% of patients and varies depending upon immune status and geographic differences. Systemic symptoms occur in less than 25% of patients in most large series.[242,243] When present, however, they usually are associated with advanced stages of disease and a poor prognosis. Significant cytopenias are rare unless marrow involvement is extensive or there are associated immune mediated cytopenias, hypersplenism, or rarely, hemophagocytosis. Leukemia presentations in NHL are rare and variably impact prognosis.[244,245]

The gastrointestinal tract is the most common extranodal site at presentation and is involved in 5% to 20% of adults with NHL.[246] The stomach is most frequently involved followed by the small intestine, the colon, and the esophagus. Approximately 90% of primary gastrointestinal lymphomas are of B cell origin. Certain subtypes have a site predilection: MALToma in the stomach, Burkitt (non-African) in the terminal ileum; mantle cell in the terminal ileum, jejunum, and colon; T cell (EATL) in the jejunum; follicular in the duodenum.

Gastrointestinal symptoms are often nonspecific with vague abdominal pain the most common presenting symptom. Epigastric pain, dyspepsia, nausea and, less often, early satiety, suggest stomach involvement. Frank bleeding occurs in less than 30% of patients with gastrointestinal lymphomas, and usually is from either a gastric (melanotic stool) or large bowel source.[247] Patients with rectal involvement usually present with hematochezia or a change in bowel habits.[248] Obstruction, specifically intussusception, or perforation are associated with aggressive small bowel lymphomas, particularly BL and EATL. Mantle cell lymphoma presents with gastrointestinal symptoms in 20% to 30% of patients, and multiple polyposis may be found on colonoscopy (Fig. 88.9). Lymphomatous polyposis of the gastrointestinal tract is not restricted to MCL and has also been detected in FL and MALToma.[246,249] Although the mucosa may appear normal, abnormal histology in the gastrointestinal tract is found in over 80% of MCL patients.[250] Dysphagia, airway obstruction, and eustachian tube blockage with or without cervical adenopathy are symptoms suggesting Waldeyer's ring involvement. Epistaxis and nasal obstruction usually with facial edema are common signs of involvement of nasal lymphomas.

Hepatosplenomegaly is a common feature of advanced indolent B cell lymphoma, including small B lymphocytic lymphoma, and splenic marginal zone lymphoma (SZML), and can be the predominant clinical feature of hepatosplenic T cell lymphoma. Subclinical secondary involvement of the liver has been reported in 26% to 40% of NHL, while primary hepatic lymphoma (PHL) is extremely rare, representing 0.05% of extranodal lymphoma.[251,252] Primary splenic lymphoma is similarly rare, and splenectomy may be considered for diagnosis and therapy.[253] Primary NHL of the liver usually is a large B cell type, can be associated with hepatitis C (40% to 60%), and can arise in immunodeficient hosts. Presenting features include right upper quadrant pain, anorexia, nausea, coagulopathy, and elevated liver enzymes without significant jaundice.[251,252,254] Hypercalcemia is present in 40% of patients. Hypodense, nonenhancing (possible rim enhancement) masses on CT imaging are characteristic of primary liver NHL. Solitary masses occur in approximately two-thirds, multiple masses in one-third, and diffuse infiltration is unusual.[251,254] Obstructive jaundice can occur in NHL secondary to periportal lymphadenopathy or to primary lymphoma of the bile duct or pancreas. Rarely, liver involvement with NHL may present with hepatic failure.[255]

The skin is another common extranodal presentation of NHL, and the most common primary cutaneous type is the cerebriform T cell of mycosis fungoides/Sezary syndrome (Chapter 92). While mycosis fungoides tends to be confined to the skin with characteristic stages, B cell lymphomas involving the skin represent only 15% to 25% of primary cutaneous lymphoma and usually present

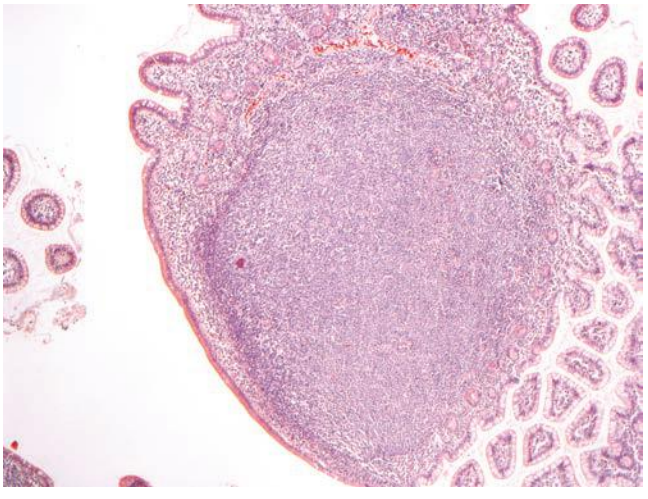

FIGURE 88.9. Mantle cell lymphoma. A: Intestine involved by multiple lymphomatous polyposis. Multiple small nodules extensively involve the bowel mucosa. Image provided by Dr. Lawrence Weiss, City of Hope National Medical Center. **B:** Aggregates of small B cells from multiple nodules just beneath the mucosa express CD5 and cyclin D1. Image provided by Dr. Dan Arber, Stanford University, Palo Alto, CA.

as nodules involving head, neck, or trunk.[256,257] The major types of primary cutaneous B cell lymphomas and their distinguishing immunotypes include marginal zone (MALT-type) ($CD20^+$, $CD5^-$, $CD10^-$), primary cutaneous follicular lymphoma (PCFL) ($CD20^+$, $CD10^+$), and primary cutaneous large B cell lymphoma (PCBCL) ($CD20^+$; usually $CD10^-$). Other T cell lymphomas with unique skin involvement include anaplastic large cell lymphoma (ALCL), which can be a primary cutaneous type or a systemic disease;[258] subcutaneous panniculitis-like PTCL, $\alpha\beta$ subtype; and 3 provisional entities, cutaneous $\gamma\delta$ T cell lymphoma (TCL), aggressive epidermotropic $CD8^+$ cytotoxic TCL, and primary cutaneous $CD4^+$ small/medium-sized pleomorphic TCL.

Neurologic symptoms and signs, including headache, confusion, lethargy, dysphasia, hemiparesis, seizures, and cranial nerve palsies, and rarely, multifocal leucoencephalopathy, may be presenting features of CNS involvement.[259] Cognitive and personality changes are more common in primary CNS lymphoma (PCNSL) due to a predilection for involvement in the frontal lobes, corpus callosum, and periventricular areas. Approximately 90% of PCNSL are DLBCL; the remainder are indolent B cell lymphomas, BLs, and peripheral T cell lymphomas.[259,260]

The detection of a single lesion on MRI favors PCNSL, but multifocal lesions can occur in approximately one-third of normal hosts and formerly more frequently in AIDS patients (Fig. 88.10). The differential in AIDS patients with intracranial mass lesions includes not only CNS lymphoma, but also toxoplasmosis, progressive multi- focal leukoencephalopathy, and other opportunistic infections. CT scanning of CNS lymphoma usually identifies a contrast enhancing lesion or lesions with a mass effect and edema which may have ring enhancement, a common finding in toxoplasmosis. The definitive diagnostic procedure is CT-guided stereotactic biopsy.[261] Positron emission tomography (PET) scanning may distinguish lymphoma and toxoplasmosis and obviate the need for biopsy in some AIDS patients.[262]

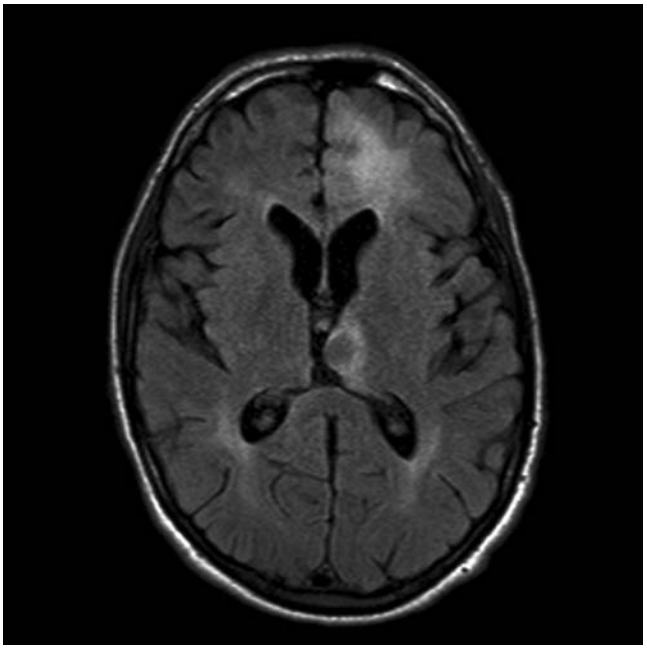

FIGURE 88.10. Primary CNS lymphoma. This FLAIR sequence MRI demonstrates a small periventricular mass lesion in the left thalamus. The lesion displays a signal intensity that is isointense compared with normal gray matter structures. This feature is consistent with a highly cellular lesion, a finding that suggests lymphoma but is not specific for that diagnosis. In addition, there are multiple areas of high signal intensity with ill-defined borders, most pronounced in the left frontal region. This appearance is also nonspecific, reflecting increased water content or decreased myelin in those regions, as may occur with any cause of inflammation. It is consistent with a multifocal, widely infiltrative process, and supportive of the diagnosis of lymphoma. Description provided by Dr. Paul Moots, Vanderbilt University, Nashville, TN.

Lymphomatous meningeal infiltration may be detected in up to 15% of patients with parenchymal PCNSL or may occur as an early or late complication in patients with specific sites of disease, including nasopharynx through local extension, testicular, or extensive marrow involvement.[263] The histologies involving the spinal fluid are usually aggressive and include Burkitt, lymphoblastic, and DLBCL. Primary leptomeningeal lymphoma is when there is no systemic lymphoma or parenchymal disease and occurs in 7% of presentations with CNS disease.[263] Neurolymphomatosis is a rare syndrome characterized by a clinical neuropathy with variable pain and is due to lymphomatous infiltration of peripheral nerve(s), nerve root or plexus, or cranial nerves.[264]Intravascular B cell lymphoma usually has subcutaneous skin lesions, but can present with a wide variety of neurological symptoms, including neuropathies, myopathy, dementia, and stroke.[265]

Because of the risk of leptomeningeal disease in PCNSL, ARL, Burkitt, lymphoblastic, and DLBCL with the specific sites noted above, the CSF should be examined by cytology and flow cytometry, and prophylaxis should be considered in these patients. Elevated LDH and more than one extranodal site have been associated with CNS disease in patients with intermediate to high-grade histologies.[266]

Symptoms of spinal cord compression may include back pain, paresthesias, weakness, and incontinence, and requires emergent recognition and therapy. Compression occurs through extension of a paravertebral mass or direct involvement of a vertebral body. MRI of the entire spine is recommended to exclude multiple sites of involvement. The thoracic spine is the most common area, followed by lumbar and then cervical.[267]

Primary ocular lymphoma is part of the spectrum of CNS lymphoma, usually with DLBCL histology; and is defined by infiltration by lymphoma cells in the visual tract, retina, vitreous, or optic nerve head. Approximately 5% to 15% of PCNSL have ocular involvement at diagnosis while CNS involvement may follow isolated ocular lymphoma in 50% to 80% of patients.[259] Ocular symptoms include blurred vision and loss of visual acuity, or "floaters," but patients can be asymptomatic. Slit lamp examination is recommended for patients with CNS or ocular lymphoma. The external eye usually is normal, and the diagnosis can be confused with uveitis, vitritis, or glaucoma.[268]

Lymphomas of the extraocular space are more common than ocular lymphomas and can arise in the superficial conjunctiva or eyelids or deeper in the lacrimal gland or retrobulbar tissues.[269,270] Blurred vision, ptosis, chemosis, epiphora, and proptosis can occur depending upon the orbital site involved. Most orbital lymphomas are of B cell origin and are low grade, particularly in the conjunctiva or eyelids, but can be a large B cell lymphoma in the lacrimal gland or retrobulbar area. Bilateral involvement occurs in 10% to 15% of patients, mostly in conjunctival forms. CNS involvement rarely occurs, and the risk of distant spread is less with conjunctival lesions.

Other symptoms and signs depend on unusual extranodal presentations. Bone pain is uncommon unless the lymphoma has a leukemic component or the patient has extranodal bone lymphoma, which accounts for 3% to 5% of extranodal NHL.[271] The long bones are most commonly affected and there may be soft tissue swelling.[272] The lesions may be lytic, sclerotic, or mixed with periosteal erosion, and are best evaluated by MRI. Genitourinary presentations include renal mass, ureteral obstruction, testicular mass, ovarian mass, and vaginal bleeding. The most common cause of a testicular mass in an elderly male is NHL. Primary breast lymphoma is rare, accounts for 0.04% to 0.5% of all malignant breast tumors, and has a bimodal presentation. Breast lymphoma in young women is associated with pregnancy and lactation and often has diffuse involvement of both breasts.[273] Older women tend to have discrete masses with unilateral involvement. Large B cell lymphoma is the most common type of the above extranodal NHL.

Lung and heart are rarely involved in NHL, but patients commonly present with cardiopulmonary symptoms. Cough, dyspnea, and chest pain usually of a short duration of a few weeks may be the presenting symptoms of mediastinal nodal involvement. The superior vena caval syndrome can occur with either T-lymphoblastic lymphoma or large B cell lymphoma of the mediastinum. Pleural effusions require cytology and immunophenotyping by flow cytometry to determine if there is lymphomatous involvement. The most common primary lung lymphoma is a MALToma, a small B cell bronchus-associated lymphoid tissue (BALT) lymphoma which more commonly presents as localized opacities.[274,275] Bronchoscopy may reveal bronchial narrowing and biopsy can identify submucosal involvement. Open thoracotomy or video-assisted thoracoscopy is required in the majority of cases because bronchoscopy is diagnostic in approximately one-third of patients.[275] Primary lymphoma of the pleura has been associated with chronic tuberculosis pyothorax or empyema.[276] Primary cardiac lymphoma is extremely rare, usually occurs as a large B cell NHL in an immunocompromised host, and may present with heart failure, pericardial effusion, or arrhythmia, including heart block.[277]

NHL occasionally will present with metabolic and endocrine problems, which tend to be more prominent following introduction of therapy, particularly in the setting of a large tumor volume or aggressive histologies. Hypercalcemia, hyperuricemic renal failure, and severe hypoglycemia are unusual metabolic presentations. Hypercalcemia is present in approximately one-fifth of patients with ATL at diagnosis and occurs in up to 70% during the course of the illness.[59] A few cases of primary adrenal lymphoma have been reported and the initial presentation is usually due to the mass effect.[278] Rarely, adrenal insufficiency may be the initial presentation of NHL and is rapidly fatal if unrecognized.[279]

STAGING

The Ann Arbor staging classification (Table 88.5) developed for HL in 1971 has been the standard scheme for NHL;[280] however, it does not account for tumor burden and does not correlate well with prognosis. Other staging systems have been developed for NHL, particularly in children (Chapter 89), specific pathologies, and extranodal sites of disease, including gastrointestinal (Table 88.5). Prognosis and therapy depend not only on stage, but also on the pathologic features of the lymphoma and by a variety of clinical parameters which reflect tumor bulk and kinetics (e.g., size of mass, LDH level, number of extranodal sites).[281,282]

The International Prognostic Index (IPI) (Table 88.5) was developed to correlate clinical parameters with prognosis and appears more useful than the Ann Arbor staging system in predicting survival.[283] When the REAL classification was under evaluation for clinical utility, an early report indicated that a high IPI did not predict an adverse outcome for ALCL; however, subsequent studies have indicated that the IPI correlates with prognosis for all histologies.[284,285] There are situations where the IPI may be less useful, such as large B cell lymphoma of the mediastinum, for which prognosis depends upon the extent of local disease.

TABLE 88.5

STAGING OF NON-HODGKIN LYMPHOMA

Staging System	Stage	Definition
Ann Arbor	I	Involvement of a single lymph node region or of a single extranodal organ or site (I_E)
	II	Involvement of two or more node regions on the same side of the diaphragm, or localized involvement of an extranodal site or organ (II_E) and one or more lymph node regions on the same side of the diaphragm
	III	Involvement of lymph node regions on both sides of the diaphragm which may also be accompanied by localized involvement of an extranodal organ or site (III_E) or spleen (III_S) or both (III_{SE})
	IV	Diffuse or disseminated involvement of one or more distant extranodal organs with or without associated lymph node involvement
	B symptoms	Fever >38°C, night sweats, and/or weight loss >10% of body weight in the 6 months preceding admission are defined as systemic symptoms
Staging Modification		The E designation is used when extranodal lymphoid malignancies arise in tissues separate from, but near, the major lymphatic aggregates. Stage IV refers to disease that is diffusely spread throughout an extranodal site, such as the liver. If pathologic proof of involvement of one or more extralymphatic sites has been documented, the symbol for the site of involvement, followed by a plus sign (+), is listed. Sites are identified by the following notation: H, Liver, S, spleen; L, Lung; P, pleura; M, bone marrow; O, bone; D, skin. Current practice assigns a clinical stage (CS) based on the findings of the clinical evaluation and a pathologic stage (PS) based on the findings made as a result of invasive procedures beyond the initial biopsy

International Prognostic Index

Adverse Factor	Risk Group	Number of Factors
Performance status ≥ 2*	Low	0, 1
LDH > normal*	Low-intermediate	2
Extranodal sites ≥ 2	High-intermediate	3
Stage III/IV disease*	High	4.5
Age > 60

STAGING OF NON-HODGKIN LYMPHOMA (CONTINUED)

Follicular Lymphoma International Prognostic Index (FLIPI)

Adverse Factor	Risk Group	Number of Factors
Age > 60 years	Low	0,1
Stage III/IV	Intermediate	2
Hemoglobin <120 g/L	High	≥ 3
Number of nodal areas >4		
LDH > normal		
FLIPI2: Adverse Factor		
β-2 Microglobulin elevated		
Age >60 y		
Bone marrow positive for lymphoma		
Anemia, hemoglobin < 120 g/L		
One or more nodes > 6 cm		

Proposed Staging System for Gastrointestinal Non-Hodgkin Lymphoma[a]

Stage	Description
Stage I	Tumor confined to gastrointestinal tract without serosal penetration Single primary site
Stage II	Tumor extending into abdomen from primary site—nodal involvement II_1 Local (gastric/mesenteric) II_2 Distant (para-aortic/para-caval)
Stage II_E	Penetration of serosa to involve adjacent "structures"; enumerate actual site of involvement, such as Stage II_E (large intestine) Perforation/peritonitis
Stage IV	Disseminated extranodal involvement or a gastrointestinal tract lesion with supradiaphragmatic nodal involvement

[a]From Rohatiner A. Report on a workshop convened to discuss the pathological and staging classifications of gastrointestinal tract lymphoma. Ann Oncol 1994;5:397–400.

Modification in clinical prognostic indices have been made for different types of NHL and biologic parameters can further subdivide groups (see section on "Prognostic Factors").

Table 88.6 outlines the clinical evaluation and staging studies to consider when evaluating patients with NHL. Bone marrow evaluation detects disease in 20% to 40% of all patients with NHL and from 50% to 70% of patients with indolent lymphomas.[286] Flow cytometry (FC) can increase the overall percent involvement; but morphology can be positive when FC is negative, as well as vice versa.[287] Immunoperoxidase techniques may identify isolated tumor cells not visualized on routine hematoxylin and eosin stains. Because NHL can have focal involvement, there may be a slight advantage in performing bilateral posterior iliac crest biopsies.[288] MRI is a sensitive technique to identify marrow involvement in patients whose biopsies have been negative.[289] Molecular studies, particularly PCR, are more sensitive than morphology and further increase the percentage of marrow involvement; however, there is an ongoing debate about the impact of molecular markers on prognosis in NHL.[290]

Positron emission tomography (PET) using ^{18}F-fluorodeoxyglucose (^{18}F-FDG) has replaced 67-gallium (^{67}Ga) scintigraphy as a nuclear medicine imaging technique to diagnose disseminated disease and to assess response (see section on "Functional Imaging in Prognostic Factors"). Patients with a tumor that remains ^{18}F-FDG avid during therapy are more likely to develop progressive disease than those patients with lesions that become FDG negative.[291] ^{18}F-FDG uptake varies according to histology and proliferative activity, with less uptake in the indolent lymphomas than in the aggressive lymphomas. Although there is increasing reliance on PET scans, there is no substitute for tissue diagnosis to confirm the presence of disease.

TABLE 88.6

STAGING STUDIES IN NON-HODGKIN LYMPHOMA

- Complete history and physical examination, inquiring about B symptoms, HIV risk, infections, autoimmune diseases, immunosuppressive therapy
- Complete blood count, including leukocyte count with differential, platelet count
- Chemistry profile, particularly lactate dehydrogenase: also alkaline phosphatase, uric acid, creatinine, calcium, and albumin
- Computerized tomography of chest, abdomen, pelvis and neck
- Bone marrow aspiration and biopsy – cytogenetics [+fluorescent *in situ* hybridization (FISH) in specific lymphomas: *BCL2, BCL1, MYC, ALK,* others] and consider molecular tests and gene rearrangement studies in selected patients
- Lumbar puncture with cytology in selected patients: all patients with Burkitt and lymphoblastic lymphomas; patients with non-Hodgkin lymphoma in certain sites: nasopharynx, epidural space, testes, and large cell with marrow involvement; HIV+ patients
- Gastrointestinal endoscopy for patients with Waldeyer ring involvement or abdominal symptoms
- Cytologic assessment of third space fluids (pleura, peritoneum)
- Immunophenotype of pathology specimen (cytogenetics/gene rearrangement data in selected patients)
- Immunophenotype of pathology specimen (cytogenetics/gene rearrangement data in selected patients)
- Selected radiologic procedures as clinically appropriate (e.g. PET scan, MRI, ultrasound, bone scan)
- Other blood evaluations: levels of β_2-microglobulin and cytokines (IL-2 receptor, tumor necrosis factor)

PROGNOSTIC FACTORS

The broad spectrum of NHL is reflected by a highly variable prognosis among and within individual subtypes of the disease. Recent advances in clinical scoring systems, molecular and immunophenotypic markers, and functional imaging techniques such as PET scans have improved the ability to predict therapeutic response and clinical outcome for individual patients. Table 88.7 outlines clinical, laboratory, and biologic features that affect prognosis in NHL. Prognostic biomarkers specific to individual NHL subtypes are also discussed with these entities in this chapter. An important aim of ongoing studies of prognostic markers is to identify approaches for rational and effective risk-adapted therapy that takes into account the marked heterogeneity within individual NHL entities and among patients with otherwise histologically identical diseases.

Histologic Type

The WHO classification separates disorders into B, T, and NK cell neoplasms, with the B and T cell lymphomas further subdivided into precursor versus mature subtypes. The B cell lymphomas represent about 85% of NHL in Western countries, whereas Tcell subtypes are more prevalent in Asia. B cell NHL are clinically stratified as indolent (e.g., follicular, marginal zone, and small lymphocytic) versus aggressive (e.g., DLBCL, mantle cell, and Burkitt) subtypes. Patients with follicular grade 1 to 2 lymphoma typically experience prolonged survival despite a continuous rate of relapse, while FL grade IIIa may have prolonged disease-free survival following anthracycline-based induction therapy.[292,293] Discordant lymphoma is encountered when DLBCL presents with a coexisting indolent lymphoma in the marrow or lymph node; in most cases this represents an aggressive component that has transformed from a preexisting indolent B cell clone. These patients show lower rates of complete response and freedom from progression than de novo DLBCL, although the overall survival (OS) does not differ.[294] Concordant involvement of the marrow has an inferior OS compared to DLBCL with discordant involvement or a negative marrow.[295]

Since the initial recognition of T cell lymphomas in the 1970s, there has been controversy about the effect of recognizing the cell of origin on prognosis. Large, prospective trials have indicated a worse prognosis for PTCL than for DLBCL except for ALCL of Tcell origin, which has a survival equivalent or superior to DLBCL (Fig. 88.11).[296,297] Within B and T cell lymphoma subtypes there are clinical, immunophenotypic, and genetic markers that further predict prognosis. Randomized pediatric trials for the most aggressive lymphomas (Burkitt and T-lymphoblastic) have identified the effects of pathology and different therapies on outcome.[298] The improved response and survival with anti-CD20 monoclonal antibody plus chemotherapy compared to chemotherapy alone in DLBCL is additional evidence supporting the importance of recognizing the cell of origin.[299]

TABLE 88.7

CLINICAL AND PATHOLOGIC FEATURES THAT AFFECT TREATMENT OUTCOME IN NON-HODGKIN LYMPHOMA

Clinical Features
Stage (I/II vs. III/IV)
Age (≤60 vs. >60 years)
Performance status (ECOG 0, 1 vs. ≥2)
B symptoms
Mass size (<10 cm vs. ≥10 cm)
Number of extranodal sites (< 2 vs. ≥ 2)
Bone marrow involvement
Functional imaging (PET)
Treatment courses to CR (≤ 3 vs. > 3)
Laboratory Parameters
Lactate dehydrogenase
β_2- Microglobulin
Biologic Characteristics
Histology
Lineage (B cell vs. T cell)

Genotype

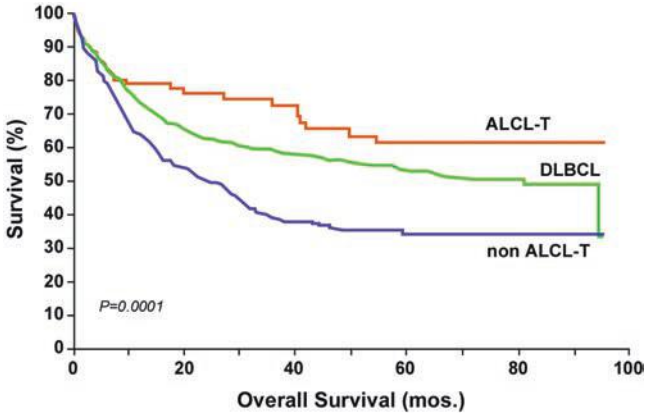

FIGURE 88.11. Overall survival of 228 PTCL (non-ALCL) and 60 T-ALCL compared with 1,595 DLBCL patients. From Gisselbrecht C, Gaulard P, LePage E, et al. Prognostic significance of T cell phenotype in aggressive non-Hodgkin's lymphoma. Blood 1998;92:76–82, with permission.

Clinical Scoring Systems

The International Prognostic Index (IPI) score has utility in predicting survival for DLBCL based on readily available clinical and laboratory parameters (Table 88.5).[300] Revisions to the IPI have been based on the improved outcomes observed for patients treated with the R-CHOP immunochemotherapy regimen incorporating rituximab as opposed to earlier chemotherapy-only regimens.[301] Whereas the original IPI identified 4 prognostic subgroups, the revised IPI found that patients could be stratified into 3 groups, defined as very good (0 risk factors) (10% of patients, 4-year overall survival [OS] 94%), good (1 or 2 factors) (45% of patients, 4-year OS 79%), and poor (≥3 factors) (45% of patients, 4-year OS 55%) (Fig. 88.12).

As a component of the IPI, serum LDH represents a surrogate quantitative measure for tumor burden. Other serologic markers, particularly β_2 microglobulin (β_2m), have been identified as prognostic factors. β_2m is a low-molecular-weight polypeptide noncovalently linked to the heavy chain of Class I histocompatibility antigens that is shed with cell turnover.[302] Combined with serum LDH, β_2m provides a reliable serologic system for predicting freedom from relapse and survival in large cell lymphoma.[303] Patients at low risk for disease recurrence have normal levels of both markers, whereas elevations in levels of both LDH and β-2m (>3.0 mg/L) predict shortened remission and survival.[303] The IPI also is predictive in FL, but its discriminatory value is limited because most patients fall into low- or low-intermediate–risk groups. A scoring system designated the FLIPI stratifies patients into low-, intermediate-, or high-risk groups based on the number of nodal groups involved, age, Ann Arbor stage, hemoglobin level, and LDH (Table 88.5).[304] The FLIPI has been validated as a useful prognostic tool, and provides a means of comparing relative patient risk distribution among clinical trials. The FLIPI2 scoring system (Table 88.5)

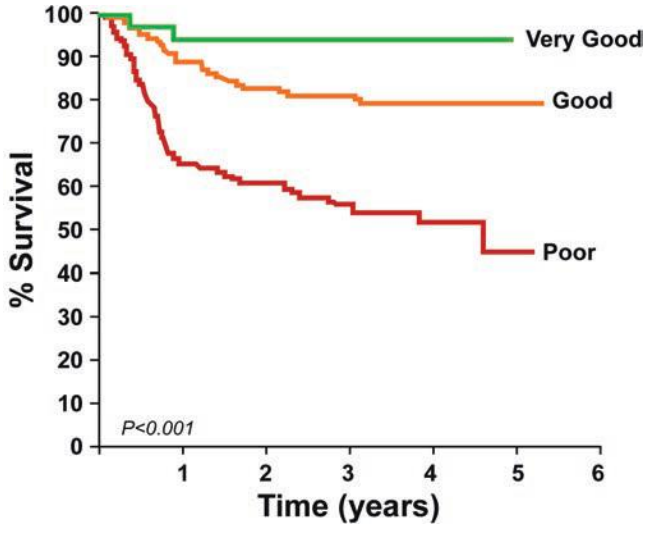

FIGURE 88.12. Progression-free survival according to the revised International Prognostic Index. From Sehn LH, Berry B, Chhanabhai M, et al. The revised International Prognostic Index (R-IPI) is a better predictor of outcome than the standard IPI for patients with diffuse large B cell lymphoma treated with R-CHOP. Blood 2007;109:1857–1861, with permission.

is more relevant to current patients, however, as it is based on initial therapy with rituximab-containing regimens (Fig. 88.13). The acronym "BABA6" can be used for the 5 FLIPI2 markers: **B**eta-2 microglobulin > normal, **A**nemia with hemoglobin <120 g/L, **B**one marrow positive for lymphoma, **A**ge > 60 years, and one or more nodal masses ≥**6** cm in diameter. Five- and ten-year overall survival rates had a strong inverse correlation with low-, intermediate-, and high-risk FLIPI2 scores.[305]

A mantle cell lymphoma IPI (MIPI) score has also been validated that utilizes the clinical parameters of age, LDH, white blood cell count, and performance status, and has been further refined to include the proliferation marker Ki-67.[306] Similarly, a prognostic index for PTCL (PIT) includes 4 variables:bone marrow involvement, age, performance status, and LDH.[307]

Immunophenotypic and Molecular Markers

Advances in the molecular and cellular biology of lymphoma have contributed to better understanding of tumor-specific variables that affect clinical behavior and therapeutic response. Cell kinetics (low-growth vs. high-growth fraction), tumor microenvironment (e.g., monocyte/macrophage vs. T cell predominance), and cell adhesion molecules are biologic parameters that contribute to lymphomagenesis and may correlate with prognosis. In DLBCL and mantle cell lymphoma, a high proliferative fraction as defined by expression of the nuclear proliferation antigen Ki-67 (MIB1; >30% to 60% of malignant cells) has identified patients at risk for early relapse and short survival.[306,308,309]

Correlations between acquired molecular abnormalities and specific lymphoma entities are a central part of the WHO classification and the understanding of lymphomagenesis. Immunophenotyping further identifies protein expression patterns that correlate with specific cytogenetic abnormalities and with prognosis (Table 88.8). Examples include nuclear cyclin D1 expression with the t(11;14)(q13;q32) of mantle cell lymphoma, and anaplastic lymphoma kinase (ALK) expression with

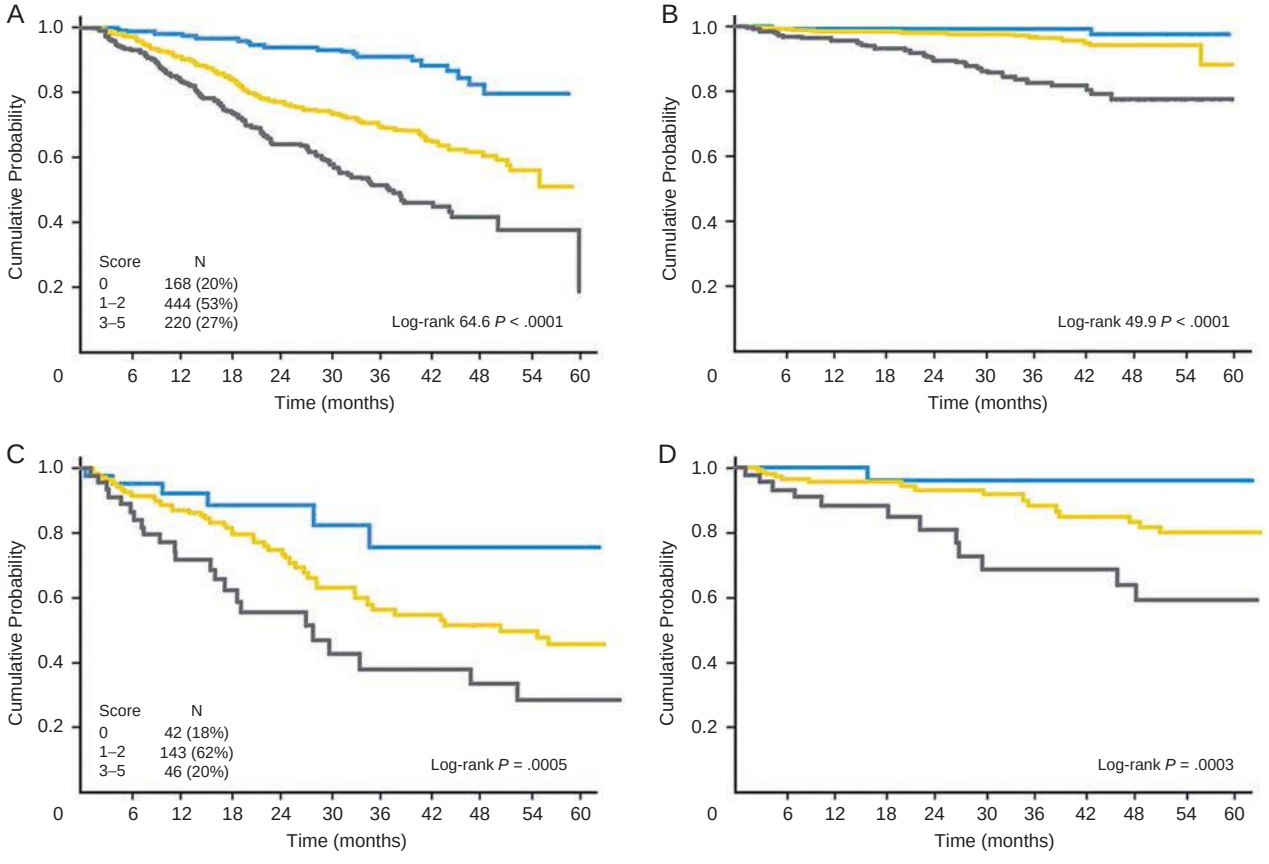

FIGURE 88.13. Progression-free survival are overall survival according to the Follicular Lymphoma International Index 2. A and B are the PFS and OS for the training sample (832 patients) and C and D are for the validation sample (231 patients). FLIPI2: low risk (blue line), score 0; intermediate risk (yellow line), score 1–2; high risk (grey line), score 3–5. From Federico M, Bellei M, Marcheselli L, et al. TABLE 88.8

PROGNOSTIC BIOMARKERS BY IMMUNOHISTOCHEMISTRY IN AGGRESSIVE LYMPHOMA

Biomarker	Pathway/Function	Correlation	Reference
ALK	Proliferation (tyrosine kinase)	Improved survival if positive in T-ALCL	310, 561, 562
BCL-2	Apoptosis	Decreased survival in activated B-cell-like (ABC) expressing BCL-2	506
Ki-67	Proliferation	Expression associated with increased proliferative rate and decreased survival in MCL, PTCL, and DLBCL	306, 309
FOX P1	Transcription factor	Poor survival in cases with strong expression (DLBCL)	317, 521
BCL-6	Transcriptional repressor, marker of germinal center origin	Improved response and survival in BCL-6 positive DLBCL	311
CD10+; or CD10-, BCL-6+, MUM1-	Markers for Germinal center B-like (GCB) subtype	Improved survival vs. non-GCB (DLBCL)	315, 316
CD10-, BCL-6-; or CD10-, BCL-6+, MUM1+	Markers for non-GCB subtypes	Decreased survival vs. GCB (DLBCL)	315, 316
MYC plus BCL-2	Proliferation and apoptosis	Double hit DLBCL, poor prognosis	319, 320
$TP53^{+}$, CDKN1A-	Proliferation and apoptosis	*TP53* mutation, poor prognosis DLBCL and PTCL	517,586

ALCL, anaplastic large cell lymphoma;DLBCL, diffuse large B cell lymphoma; MCL, mantle cell lymphoma;PTCL, peripheral T cell lymphoma.

the t(2;5) and its variants in ALCL.[310] BCL-6 expression has been associated with an improved outcome in DLBCL, but its absence may be less deleterious in the rituximab era.[311]

Gene expression profiling using cDNA microarrays has been a powerful tool for dissecting pathogenetically relevant mutations and therapeutically targetable pathways in lymphomas. For example, DLBCL may be stratified into prognostic subtypes based upon molecular profile.[323,324] These include primary mediastinal Bcell lymphoma (PMBL), germinal center Bcell–like (GCB), activated Bcell–like (ABC), and a fourth type with a microarray signature distinct from the other types. PMBL and GCB have better prognoses than the others in patients treated with CHOP-like chemotherapy (Fig. 88.14).[325] Since molecular profiling is not currently practical for routine clinical use, efforts have been made to use immunophenotypic expression patterns to stratify DLBCL into GCB or non-GCB subtypes. One of these systems, the Hans algorithm, uses immunostains for CD10, BCL-6, and MUM1, with good correlation with gene expression profile analysis.[317,318]

A modification, the Choi algorithm, also uses these markers plus GCET1 and FOXP1 to stratify patients into GCB vs. ABC DLBCL, again with good correlation with patient overall survival.[315] To further enhance this scoring system, the Choi algorithm was integrated with immunohistochemical staining for a marker of the DLBCL tumor microenvironment and stromal-1 signature (SPARC: **s**ecreted **p**rotein, **a**cidic, and **r**ich in **c**ysteine), a good prognostic marker when expressed;and markers of angiogenesis and microvessel density within the tumor stroma, a poor prognostic marker when increased. The resulting "biologic prognostic model" assigned 1 point each for each adverse prognostic marker; those patients with 0 or 1 marker designated "low-risk" and those ≥ 2 as intermediate- or high-risk.[326] All patients had de novo DLBCL treated with R-CHOP or R-CHOP–like regimens in this multicenter study. A highly significant correlation was found for improved event-free and overall survival for those in the low-risk group.

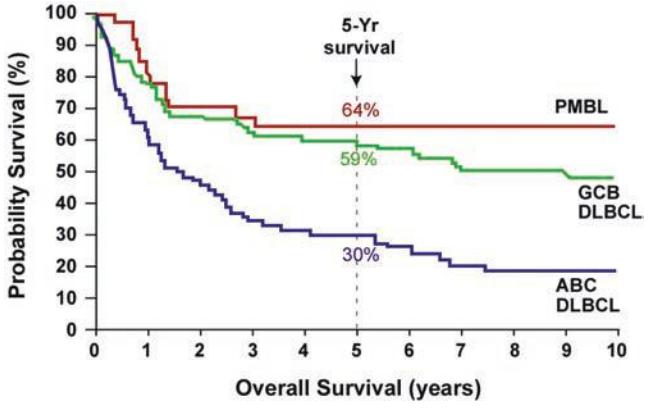

FIGURE 88.14. Gene expression arrays can stratify diffuse large B cell lymphoma (DLBCL) into at least three subtypes, primary mediastinal B cell lymphoma (PMBL), germinal center B cell (GCB), and activated B cell-like (ABC). This Kaplan-Meier curve indicates differing survival among the groups. From Rosenwald A, Wright G, Leroy K, et al. Molecular diagnosis of primary mediastinal B cell lymphoma identifies a clinically favorable subgroup of diffuse large B cell lymphoma related to Hodgkin lymphoma. J Exp Med 2003;198:851–862, with permission.

About 5% to 8% of DLBCL carry translocations in the *MYC* oncogene, often with coexisting *BCL2* and/or *BCL6* translocations ("doublehit" or "triplehit"). MYC protein expression identifies *MYC* deregulation not detected by FISH; and coexpression with BCL-2 is present in 21% to 29% of DLBCL.[319,320] Double hit DLBCL has a poor outcome with standard R-CHOP chemotherapy; as such, testing for these markers using immunohistochemistry or FISH analysis and applying alternative treatment strategies for these patients is now being assessed.[327,328]

Whereas molecular and phenotypic features of the tumor cells themselves have prognostic relevance in DLBCL, gene expression profiling in FLs revealed prognostic subsets correlating with survival based on the type of tumor-infiltrating immune cells.[329] FL patients with a predominant T cell signature had improved outcome versus those patients with an immune response signature reflecting a predominant monocyte/macrophage infiltrate. An immunophenotypic correlate was shown by analysis of lymphoma-associated macrophage (LAM) content, wherein FL patients with >15 LAM per high-power field had inferior survival compared to those with fewer LAM.[330] Similarly, a high number of regulatory T cells in the tumor microenvironment as assessed by FOXP3 expression was associated with improved survival.[331,332]

It should be recognized that prognostic markers for treatment response and patient outcome are defined within the context of specific regimens and thus may become irrelevant when newer therapeutics are applied. As such, it is essential to revalidate these markers with new regimens and targeted therapies.

Treatment-associated Parameters

The ability to deliver a prescribed treatment regimen is a recognized prerequisite to optimal patient outcome in any area of oncology. Treatment delays, dose reductions, or eliminating one or more agents during a patient's therapy—i.e., a reduction in doseintensity or dose-density—may lead to a lower likelihood of achieving durable remission or cure. While tumor-associated features correlate with outcome, as described above, patient-associated variability in pharmacokinetics may have an important impact even with strict adherence to a treatment regimen. The dose-adjusted R-EPOCH regimen (rituximab, continuous-infusion etoposide, doxorubicin, and vincristine plus cyclophosphamide and prednisone) was designed to address potential underdosing by integrating scheduled incremental dose increases based upon interim neutrophil counts between cycles for treatment of DLBCL.[333] Phase II studies have shown improved progression-free survival as compared with historic R-CHOP data; a U.S. Intergroup trial led by CALGB is directly comparing DA-R-EPOCH with R-CHOP. This study is also correlating GCB vs. non-GCB DLBCL subtype with the treatment regimen and patient outcome. Looking forward, it is anticipated that methods for pharmacogenomic assessment and dose-optimized delivery of chemotherapy and targeted agents will become available to improve treatment response and to decrease treatment-associated toxicities.

Functional Imaging

The use of ^{18}F-FDG–PET scans has improved the sensitivity for initial staging and posttreatment restaging of NHL.[334] Assessment of treatment response by anatomic staging with routine CT scans, especially in aggressive lymphomas, reveals that many patients have measurable residual abnormalities. The significance of such findings is often problematic as to whether they represent fibrous tissue only versus residual lymphoma, and biopsy of these residual masses may be inconclusive or falsely negative due to sampling error or necrosis. Properly performed and interpreted PET scans have a high discriminatory value in identifying residual lymphoma in patients with incomplete therapeutic response. Several studies have correlated posttreatment PET positivity with relapse and poor survival, and prospective clinical trials are ongoing to assess the use of PET imaging to stratify patients for early institution of dose-intensive therapy.[335]

The use of interim PET imaging following two to three cycles of chemotherapy has shown a strong correlation with outcome in HL; however, interim PET in DLBCL remains controversial. Interim 18-FDG-PET/CT failed to predict outcome in diffuse large Bcell lymphoma patients treated at diagnosis with rituximab-CHOP.[336,337] Retrospective data in mantle cell lymphoma suggested an improved outcome for negative posttreatment PET/CT but not for interim scans.[338] Pre- and postinduction PET/CT imaging was performed in 122 patients with FL who took part in a prospective clinical trial of rituximab-chemotherapy followed by maintenance rituximab versus observation.[339] Patients remaining PET-positive after induction therapy had significantly inferior progression-free survival and increased risk of death compared to PET-negative individuals. Interestingly, response by traditional posttreatment restaging including CT scans did not correlate with outcome.

Response criteria for NHL now include recommendations for incorporation of functional imaging by PET in patients with DLBCL and HL (Table 88.9).[340] In addition, guidelines for standardization and interpretation of PET scans have been recommended for use in clinical trials and in prospective registries assessing treatment outcomes and prognosis.[341]

THERAPEUTIC PRINCIPLES

Therapy follows assessment of the patient, pathology, and stage of disease. The ability of the patient to tolerate therapy is dependent upon age, performance status, and, if present, immunodeficiency due to a prelymphomatous condition. How advanced age

TABLE 88.9

2007 RESPONSE CRITERIA FOR NON-HODGKIN LYMPHOMA

Response Category	Definition	Nodal Masses	Spleen/Liver	Bone Marrow
Complete response	Disappearance of all evidence of disease	a) FDG-avid or PET positive prior to therapy becomes negative; a post treatment mass of any size is permitted if PET negative b) If variably FDG-avid or PET positive, all lymph nodes should regress to normal size on CT	Not palpable; nodules disappear	Infiltrate cleared on repeat biopsy; if indeterminate by morphology, immunohistochemistry should be negative
Partial Response	Regression of measurable disease and no new sites	a) ≥ 50% decrease in SPD of up to 6 largest masses; no increase in size of other nodes b) One or more persistently FDG-avid or PET positive sites c) Regression on CT if variably FDG-avid or PET negative	≥ 50% decrease in SPD of nodules; no increase in size of liver or spleen	Irrelevant if positive prior to therapy and partial response at other sites
Stable Disease	Failure to attain CR/PR, but does not meet criteria for progressive disease	a) FDG-avid or PET positive at prior sites of disease and no new sites on PET or CT b) Variably FDG-avid or PET negative; no change in size of previous lesions on CT		
Relapsed or Progressive Disease	Any new lesion or increase by ≥50% of previously involved sites from nadir	Appearance of a new lesion(s) > 1.5 cm in any axis, ≥ 50% increase in SPD of more than one node, or ≥50% increase in longest diameter of a previously identified node > 1 cm in short axis. Lesions PET positive if FDG-avid lymphoma or PET positive prior to therapy	>50% increase from nadir in the SPD of any previous lesions	New or recurrent involvement

CT, computed tomography; FDG (^{18}F)fluorodoxyglucose; PET, positron emission tomography; PR, partial remission; SPD, sum of the product of the diameters.

Adapted from Cheson BD, Pfistner B, Juweid ME, et al. Revised response criteria for malignant lymphoma. J Clin Oncol 2007;25:579–586.

adversely affects outcome in therapy is controversial, but comorbid illnesses and biologic differences of lymphomas can contribute to higher mortality in the elderly. Treatment-related toxicities are greater in elderly patients, but deaths from unrelated causes are also increased.[342,343] Biologic differences of NHL between young and old patients are implicated by a greater lymphoma-related mortality in some series of elderly patients compared with younger cohorts[344] (see section on "Therapy in the Elderly").

The type of therapy is based on pathology. One of the clinical disadvantages of the WHO/REAL classifications was deleting the WF grading system. Clinical schemas have been proposed to recognize the biologic behavior along with the cell of origin of the lymphoid neoplasm (Table 88.10).

The intensity of therapy is based on pathology and stage of disease. Advanced stage, tumor bulk as reflected by size (usually greater than 10 cm) and LDH, and number of extranodal sites of involvement were recognized early as independent prognostic determinants in NHL and contribute to the IPI. The IPI has correlated clinical features into prognostic groups for both indolent and aggressive lymphomas.[345,346]

TABLE 88.10

CLINICAL SCHEMA FOR LYMPHOID NEOPLASMS

B Cell Lineage	T/NK Cell Lineage
Indolent Lymphomas/Leukemia	
Chronic lymphocytic leukemia/small lymphocytic lymphoma	Large granular lymphocytic leukemia, T and NK cell types
Lymphoplasmacytic lymphoma/ Waldenström macroglobulinemia	Mycosis fungoides/Sezary syndrome
	Primary cutaneous anaplastic large cell
Follicular lymphoma (grade I/II)	Smoldering and chronic adult T cell leukemia/lymphoma (HTLV1$^+$)
Marginal zone B cell lymphoma Splenic marginal zone lymphoma Extranodal (MALT-B cell lymphoma) Nodal (monocytoid)	
Aggressive Lymphomas	
Mantle cell lymphoma (can be indolent)	Prolymphocytic leukemia (can be indolent)
Follicular (large cell)-grade III	Peripheral T cell lymphoma, not otherwise specified
Diffuse large B cell lymphoma	Anaplastic large cell lymphoma (ALK +/ALK-)
Primary mediastinal large B cell lymphoma	Angioimmunoblastic lymphoma
Large B cell lymphoma with intermediate features between DLBCL and Hodgkin lymphoma	Enteropathy-associated T cell lymphoma Nasal type NK/T cell lymphoma Hepatosplenic $\gamma\delta$ T cell lymphoma Subcutaneous panniculitis-like T cell lymphoma, $\alpha\beta$ (can be indolent)
Highly Aggressive Lymphomas/Acute Leukemias	
Precursor B-lymphoblastic lymphoma/ leukemia	Precursor T-lymphoblastic lymphoma/ leukemia
Burkitt lymphoma/B cell acute leukemia Large B cell lymphoma with intermediate features between DLBCL and Burkitt lymphoma	Adult T cell lymphoma/leukemia (HTLV-1+) (lymphoma and acute leukemia subtypes)
	Natural killer cell leukemia

ALK, anaplastic lymphoma kinase; DLBCL, diffuse large B cell lymphoma ; HTLV-1, human T-leukemia virus-1; NK, natural killer.

After therapy is instituted, response formerly was assessed according to standardized criteria developed in 1999;[347] however, new criteria based on PET scans, immunohistochemistry and flow cytometry are now being used[340] (Table 88.9). Previously, nodal masses should be ≤1.5 cm to be considered normal but should be ≤1.0 cm if initially clinically abnormal in the 1.0 to 1.5 cm range.[347] A common problem particularly in large cell NHL is a residual mass after therapy. A designation of unconfirmed complete response (CRu) was given if there was a greater than 75% reduction in tumor size after therapy; but the criteria utilizing PET scans eliminates the CRu category.[340] Persistently positive PET scans after therapy suggest residual disease, but biopsy should be performed if a therapeutic decision is going to be made. The end points of clinical trials should be well defined, and their importance may vary according to type of lymphoma. For example, PFS is more important in aggressive lymphomas than in indolent lymphomas, for which OS or time to next treatment may be more relevant. The problem with the latter endpoint is that guidelines for initiation of treatment need to be standardized as well.

INDOLENT LYMPHOMAS

Indolent lymphomas are characterized by a long median survival and by a slow but continuous decline in survival. They are usually advanced stage at presentation; respond to therapy, but relapse; over time, may transform to a more aggressive course; and rarely, spontaneously regress. With the availability of new chemotherapy agents and the advent of immunotherapy, the therapeutic options for indolent lymphomas are increasing in number and prognosis is improving (Table 88.11). While the expansion of therapies represents a major advancement, the decisions of when to initiate therapy and what type of therapy to select are often controversial and confusing for the individual patient.

Indolent B cell lymphomas include FL, small lymphocytic lymphoma, lymphoplasmacytoid lymphoma, and marginal zone lymphoma. Indolent T/NK cell lymphomas are less common and are less well recognized, other than mycosis fungoides (Chapter 92).

TABLE 88.11

THERAPEUTIC OPTIONS FOR INDOLENT LYMPHOMA

- Watchful waiting
- Local radiation for limited stage disease
- Chemotherapy
  - Alkylating agent
  - Nucleoside analogue
  - Bendamustine
  - Combination chemotherapy
- Immunotherapy
  - Unconjugated monoclonal antibody
  - Radioimmunotherapy
  - Interferons
  - Cellular
  - Vaccines
- Combined modality
  - Chemotherapy and immunotherapy
  - Chemotherapy and radiation
- Transplantation
  - Autologous ± purging
  - Allogeneic:
    - Myeloablative
    - Nonmyeloablative
- Selected therapies
  - Antibiotics in selected MALTomas
  - Splenectomy

T/NK lymphomas/leukemias which can have an indolent phase include large granular T/NK leukemia, smoldering and chronic HTLV-1+ ATL, T-prolymphocytic leukemia, and, more controversially, some types of PTCL. FLs formerly included follicular small cleaved (FSCL), mixed (FML), and large cell (FLCL), and roughly correlated with cytologic grades 1, 2, and 3, respectively. Cytologic grading of FL is under scrutiny due to poor reproducibility among pathologists.

FL (grades I and II) is the second most common NHL behind DLBCL and is the most common indolent lymphoma in North America and Europe, usually comprising 25% to 35% of lymphomas, compared to 5% to 12% in Asia and developing countries.[348,349,350] Most patients present with asymptomatic lymphadenopathy; B symptoms occur in approximately one-fourth of patients.[292] The disease occurs primarily in the elderly (median age, 55 to 65 years), has a near equal male:female ratio, and usually is disseminated at diagnosis (stage III/IV ≥ 70%).[292,351,352] Marrow involvement occurs in 30% to 60% of FL.[351–353] Evaluating the marrow or blood for the *BCL-2* translocation will often identify occult disease and can upstage patients by molecular criteria.[354,355]

Prior to the recognition of different types of lymphomas by immunophenotyping and the prevalence of *BCL-2* translocation in FL, extensive descriptions were made about pathologic differences among FLs. The degree of nodularity was associated with a better prognosis in grade I FL, but it was not of major significance without near complete absence of follicles, as in diffuse small cleaved cell lymphoma (DSCL).[351] With present--day immunophenotyping, most DSCL are more aggressive diseases than FL and include mantle cell NHL and PTCL. FL immunophenotyping is characterized by the presence of $CD10^+$, $CD20^+$, $BCL2^+$, $CD23^{+/-}$, $CD43^-$, $CD5^-$, $CCND1^-$, and $BCL6^+$.

Cytologic grading further subclassifies FL into grades 1 to 3. Histologic grades 1 and 2 are treated as indolent disease, while grade 3b is usually excluded from clinical trials involving FL due to its similar behavior to that of intermediate-grade lymphoma. Identification of *BCL2* translocations and Ki-67 may add to the prognosis of FL. Approximately 70% of patients have translocations at the major breakpoint region (MBR) located in the untranslated region 3′ of the last exon of the *BCL2* gene, and 10% to 15% of patients have translocations in the minor cluster region (mcr) which is 30 kb downstream of the *BCL2* gene.[348] Lopez-Guillermo correlated survival with *BCL2* rearrangements: the 3-year failure-free survival (FFS) for mcr, MBR, and germline cases were 95%, 76%, and 57%, respectively ($P < 0.001$).[356] The impact of persistence of *BCL2* rearrangement in FL after therapy is controversial, because there is data indicating its presence adversely affects clinical progression after therapy and, alternatively, other series indicate that it has no effect on long-term survival.[355,357] Patients with low grade and a high proliferation index (Ki-67 > 30%) appear to have clinically aggressive behavior.[358,359] Median survivals for FL were static in the range of 8 to 12 years for several decades, but are now improving due, in part, to monoclonal antibody therapy and better supportive care.[351,352,360,361]

The microenvironment and gene expression profiling in FL are likely to add prognostic information and potential therapeutic targets. There has been conflicting data about the presence of tumor-associated $CD68^+$ macrophages (TAM) and T-reg cells, with initial reports indicating a poor prognosis for the former and a favorable prognosis for the latter. Subsequent studies have not confirmed these findings.[330,332,364] Gene profiling identified a favorable "immune response 1" signature encoding T cells (*CD7*, *CD8B1*, *ITK*, *LEF1*, and *STAT4*) and macrophages. *(ACTN1* and *TNFSF3B)* and an unfavorable "immune response 2" signature of genes in macrophages and/or dendritic cells (*TLR5*, *FCGR1A*, *SEPT10*, *CCR1*, *LGMN*, and *C3AR1*). Future studies will incorporate genetic, molecular, and biologic data into prognostic models which will influence the selection of therapy.

Small B lymphocytic lymphoma (SLL) comprises 3% to 10% of all NHL and is part of the spectrum of diffuse small B cell lymphomas which includes lymphoplasmacytoid lymphoma, marginal zone lymphomas, and mantle cell lymphoma (Chapter 86).[365,366] There is extensive clinical overlap with chronic lymphocytic leukemia (CLL) (Chapter 90), although there is more prominent lymphadenopathy and less lymphocytosis in SLL than in CLL.[367–369,370] The WHO considers SLL and CLL different clinical presentations of the same disease. An initial lymphocyte count greater than 5×10^9/L is considered diagnostic of CLL. Over time, 10% to 20% of patients develop a lymphocytosis consistent with CLL. SLL represents 4% to 6% of NHL in the West, is a disease of the elderly (median age, 55 to 65 years), and has a male:female ratio of approximately 2:1.[367,368] Patients usually present with generalized adenopathy, and marrow involvement is found in most patients (70% to 80%). Median survivals have been variable from a low of 4 to 6 years to 10+ years, may depend upon prognostic factors and the criteria utilized to separate SLL from CLL, but are similarly improving in the rituximab era.[371] Deletion at chromosome 6q is the most common cytogenetic abnormality in SLL, but has had no effect on prognosis,[372] whereas del(17p) and del(11q) are associated with poorer prognosis.[373] Both unmutated genes as opposed to hypermutated genes and expression of CD38 or ZAP 70 have been associated with a worse prognosis in CLL.[374] Between 2% and 8% of SLL and CLL evolve into an aggressive large cell process known as *Richter syndrome*, which is characterized by bulky retroperitoneal adenopathy, rising LDH, and survival usually less than 1 year.[375,376] Prognosis is better if transformation occurs in previously untreated patients.[370]

Lymphoplasmacytic lymphoma (LPL) largely overlaps with Waldenström macroglobulinemia (WM) (Chapter 100). LPL represents 1% to 2% of NHL, usually occurs in the elderly (median age 60 to 70 years), and presents with lymphadenopathy (15% to 20%), splenomegaly (10% to 20%), and marrow involvement in most patients.[377,378] A paraprotein is found in 29% to 50% of patients, with IgM the most prevalent type, and can contribute to hyperviscosity (6% to 20%), neuropathy, and glomerular disease.[377] A positive Coombs' test, cold agglutinin disease, cryoglobulinemia, autoimmune diseases, and positive hepatitis C serology can be associated with LPL and WM.[379,380] Mutation of the myeloid differentiation primary response gene[88] (*MYC88*) is nearly universal in WM and can be useful in differentiating it from other disorders.[381] Translocation (9;14) involving the paired box gene *PAX5* can be detected in LPL, but its frequency and significance are a matter of debate.[378] Deletion of 6q is the most common cytogenetic abnormality but it is not specific for LPL/WM.[378] Median survivals have been variable, usually in the 7- to 10-year range, and are worse with advanced age, cytopenias, organomegaly, elevated B_2 M, and hypoalbuminemia.[378,382,383]

Marginal zone B cell lymphomas (MZL) usually account for between 5% and 7% of all NHL and include extranodal MALToma, nodal based disease, and SMZL.[384] Extranodal MALTomas represent the most common MZL (50% to 70%) and are discussed in the section "Management of Extranodal Lymphomas". Nodal MZL occurs in the elderly (median age, 59 to 65 years) and preferentially in women (up to 2:1 female:male ratio), may present with localized lymphadenopathy, and has less marrow involvement (28% to 45%) than other indolent lymphomas.[371,384,385,386] Cytopenias or a paraprotein (10%) are rarely present. The most frequent cytogenetic abnormalities are gains in chromosomes 3 and 18q23.[387] Median survival has been variable due to limited numbers of patients but has been recorded in the 9- to 12-year range.[371]

SMZL occurs in the elderly (median age, 61 to 70 years), has a slight female predominance, and usually presents because of symptoms of splenomegaly.[384,388,389] Cytopenias are common (46% to 60%); peripheral adenopathy is rare (10% to 15%); and marrow involvement is usually detected (73% to 100%).[390,391]

A paraprotein may be present and is usually IgM. Despite disseminated disease, splenectomy can alleviate symptoms and improve cytopenias.[389,390] Median survival has been recorded to be 10.5 years, but is shorter in the presence of a paraprotein, elevated β-2m, or lymphocytosis (>9 × 10^9/L).[391,392] A simple prognostic scoring system is based on 3 factors: hemoglobin <120 g/L, LDH level greater than normal, and albumin <35 g/L. The 5-year cause-specific survival was subdivided into 3 groups: 88% for no adverse factor, 73% (one factor), and 50% (two or more factors).[388] Complete or partial trisomy 3 is the most frequent (~85%) cytogenetic abnormality.[393] The abnormality characteristic of SMZL is a deletion or translocation of chromosome 7q32, present in 40% of patients.[384] Adverse cytogenetics include del(17p), del(8p), and del(7q) with unmutated genes.[394,395]

Special Clinicopathologic Features

Clinicopathologic features unique to indolent lymphomas are histologic transformation (HT) and spontaneous regression. The forerunner and counterpart of HT is the Richter syndrome of CLL/SLL.[375,376,396,397] HT of indolent lymphomas usually is associated clinically with increasing adenopathy and LDH levels. All of the indolent lymphomas can undergo transformation, but the most common lymphoma to do so is grade I FL; the transformation is characterized pathologically by a loss of a follicular pattern and an increase in the number of large noncleaved cells.[397,398–400] Predictive factors for HT of FL have included no prior CR, hypoalbuminemia, an elevated B_2m (>3 mg/L), and a high FLIPI score at diagnosis.[396,401] The median time from initial diagnosis to HT is 4 to 6 years.[398–400] Historically, the incidence of HT is uncertain, but has been estimated to be between 10% and 70% of indolent lymphomas. Discrepancies among studies are related to methodological differences, including the definition of transformation.[397] The risk of HT in FL is estimated at 2% to 4% per year, and it appears to increase over time, but some series have suggested a plateau at 20 years (Fig. 88.15A).[401–403] Autopsy series of nodular lymphomas have identified diffuse morphologic changes, usually with increased large cells, in more than two-thirds of patients.[404] HT may involve the expression of additional cytogenetic abnormalities and oncogenes.[405–407] The disease course usually progresses rapidly after HT, with median survival usually less than 1 year and ranges from 2.5 to 22 months (Fig. 88.15B).[398,401,403] Patients with limited stage disease, low FLIPI, and no prior chemotherapy at the time of histologic transformation are more likely to have prolonged survival.[397,400,403]

Spontaneous regression has occurred in the indolent lymphomas, but its exact incidence is uncertain. Horning and Rosenberg reported regression in 19 (23%) of 83 untreated FL patients, including complete regression in 6 patients.[402] Spontaneous regression occurs in approximately one-fourth of primary cutaneous ALCL (see section on "ALCL"). Spontaneous remission in DLCL has rarely been observed.[408]

Additional clinicopathologic terms that are often misnomers are *discordant histology*, *composite lymphoma*, and *gray zone lymphoma*. Discordant histology refers to identifying different histologic grades of lymphoma in the same patient. The most commonly identified discordant histology is a peripheral node with predominantly large cells and a marrow with small cleaved cells (see section on "Prognostic Factors").[295,409] Composite lymphoma has been used to describe a mixture of histologic grades but probably should be restricted to lymphomas that have two distinct histopathologic types, i.e., two distinct diseases, preferably with both immunophenotypic and molecular genetic differences.[410] Gray zone lymphomas are intermediate between two diseases with DLBCL having overlap features with either Hodgkin or BL.[228,411]

Stages I and II Indolent Lymphoma

Limited stage disease in indolent lymphomas is infrequent and may be as low as 6%, as reported by the National Cancer Institute (NCI) series of pathologically staged patients;[412] most series that involve clinical staging report between 10% and 20% of patients with limited stage disease.[351,413] Immunophenotyping and molecular genetic studies may identify more advanced stage disease as well as predict the clinical course, but their impact on therapeutic decisions is controversial. Radiation therapy has achieved disease-free survival (DFS) in 31% to 85% of limited stage FL patients with follow-up over 10 years, including reports from Stanford University of relapse-free survival (RFS) of 44% and 37% at 10 and 20 years, and from Dana Farber Cancer Institute of freedom from treatment failure (FFTF) of 47% and 43% at 10 and 15 years.[414,415] The median survival in the latter study involving predominantly stage I FL (only grades 1 and 2) was 19 years.[415] While these reports suggest that some limited stage patients may be curable, there is not a clear plateau on the survival curves. Most relapses have occurred outside the radiation field. The best results have been in young patients (less than 50 years), with stage I and nonbulky disease (less than 2.5 cm).[413] Observation alone can be considered in patients with clinically insignificant disease and has no adverse effect on prognosis even

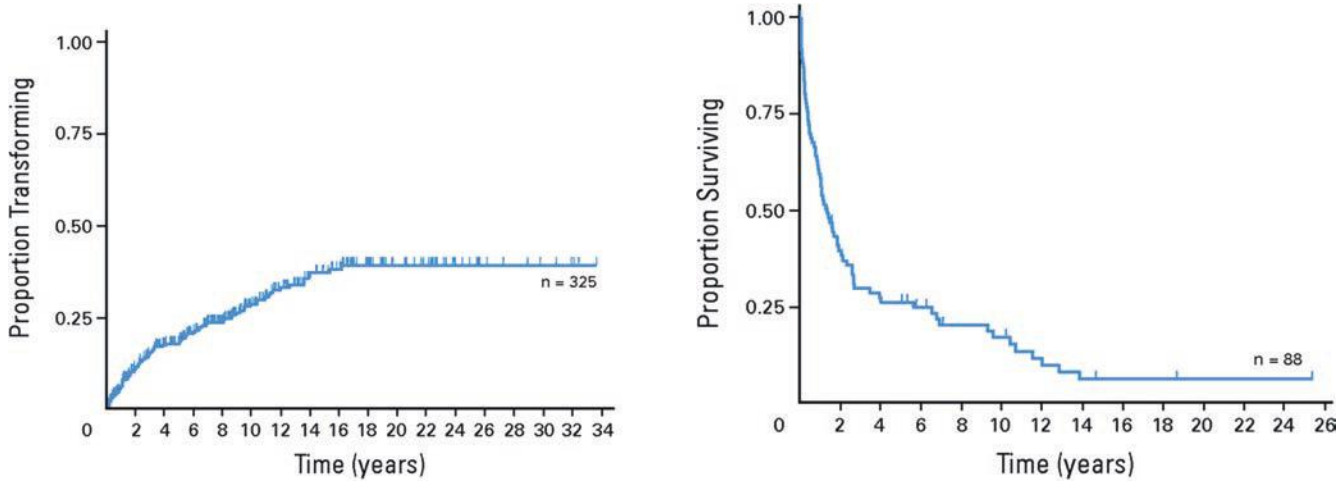

FIGURE 88.15. Histologic transformation of follicular lymphoma. A: Cumulative incidence of transformation. **B:** Survival (median = 1.2 years) in patients after transformation. From Montoto S, Davies AJ, Matthews J, et al. Risk and clinical implications of transformation of follicular lymphoma to diffuse large B cell lymphoma. J Clin Oncol 2007;25:2426–2433, with permission.

in the rituximab era.[416,417] In a study that evaluated the role of reduced field of radiation (involved regional field or involved nodal radiation therapy), the 10-year PFS and OS were 49% and 66%, respectively. By reducing the field of radiation, there was no difference in the recurrence rate.[418]

Rituximab (anti-CD20 monoclonal antibody) (see section on "Immunotherapy") was initially approved for relapsed indolent lymphomas with response rates in the 50% range, but is now being used as front-line single agent therapy with response rates of 47% to 76%.[419,420] The rationale for its use in limited stage patients includes its efficacy with low tumor burden, better PFS with molecular responses, and the fact that most limited stage patients actually have advanced stage disease.[421]

Stages III and IV Indolent Lymphoma

Many investigators advocate initial "watchful waiting" for asymptomatic patients with advanced stage indolent lymphomas, because of a continual risk of relapse; early chemotherapy has not improved overall survival (OS).[422,423] Although stages III and IV usually are considered together, stage III has a tendency toward better survival than stage IV.[351,413] Among the most controversial aspects in the management of indolent lymphomas are the initiation of therapy and the selection of type of therapy (Table 88.11). The choices of therapy are multiple and vary widely from no initial therapy, rituximab alone, to various chemotherapy agents (single or in combination) with or without monoclonal antibody therapy, to radioimmunotherapy, and to transplantation.[422,424]

The number of choices are increasing but there is general agreement that once a decision has been made to start therapy, combination chemotherapy with rituximab offers the best response.[350,425] Clinical features which usually warrant therapy include B symptoms, bulky lymphadenopathy, nodal encroachment on vital organs, massive organomegaly, cytopenias, or transformation.[363,422,426,427] Age of the patient, histologic grade, performance status, comorbid illnesses, patient preference, and physician training and bias influence therapeutic decisions. A number of clinical scoring systems, including the FLIPI and subsequent modifications have been devised not only to predict prognosis, but also to select patients for therapy (see section on "Prognostic Factors"). Because indolent lymphomas usually have long median survivals, prolonged follow-up is required and randomized trials are needed to determine optimal therapy.

Watchful waiting can be psychologically difficult for both patient and physician, but remains a valid approach based on initial observations and randomized trials before the availability of rituximab. There are 3 randomized trials that compared watchful waiting to some form of initial therapy.[423,428,429] The NCI group used an aggressive combined modality regimen ProMACE (prednisone, methotrexate, Adriamycin [doxorubicin], cyclophosphamide, and etoposide) and MOPP (mustard, Oncovin [vincristine], procarbazine, and prednisone) plus total lymphoid irradiation; the French used interferon or prednimustine; and the British used chlorambucil. There was no difference in overall survival between observation and therapy in all these reports. In the latter study, the median follow-up was 16 years; and the median length of time until chemotherapy was started in the observation group was 31 months. The actuarial chance of not requiring chemotherapy at 10 years was 19%.[429] In a phase III trial evaluating the role of immediate treatment with rituximab versus watchful waiting for advanced stage disease, the median PFS was significantly longer in patients receiving rituximab therapy (NR vs.24 months; $P < 0.001$); but there was no difference in OS.[430]

There is no standard of care treatment recommendation for upfront therapy of FL. Rituximab is uniformly incorporated with chemotherapy at the time of treatment initiation. Multiple randomized trials comparing chemotherapy plus rituximab to chemotherapy alone have shown improved response rates and PFS with the rituximab arm.[425] Due to the lack of randomized trials, disparate therapeutic approaches have been adopted worldwide. The most commonly used regimens for advanced indolent lymphoma, particularly FL, were formerly alkylator based and included single agents, chlorambucil or cyclophosphamide, with or without prednisone; and CVP (cyclophosphamide, vincristine, prednisone);[431] however, the addition of doxorubicin in R-CHOP is the most commonly used regimen. Nucleoside analogs, bendamustine, and mitoxantrone are all being used in different upfront regimens as well. In a multicenter longitudinal study by the National LymphoCare in the United States, the initial chemotherapeutic regimen of choice was R-CHOP (55%), followed by R-CVP (23%) and R- fludarabine based (15.5%).[432]

Nucleoside analogs are well tolerated, with few gastrointestinal side effects and no alopecia, but cause prolonged decrease in T cell immunity and contribute to immune mediated cytopenias. Responses with single agent nucleoside analogs are 40% to 50% (10% to 20% CR) in previously treated patients, and 60% to 90% (37% to 50% CR) in untreated patients.[433–435] Adding rituximab to fludarabine yielded a response rate of 90% with 80% CR.[436]

Combination of nucleoside analogs with other agents are being used in indolent lymphomas. In phase I and II trials of fludarabine plus cyclophosphamide in untreated indolent lymphomas and SLL/CLL, the response rates have been 92% to 100%, including CR rates of 47% to 89%.[437,438] The addition of rituximab to this combination has similarly high response rates and can achieve molecular remission.[439] Despite these encouraging results, opportunistic infections are increased with the combination; there may be increased incidence of myelodysplasia; and stem cells may be difficult to collect after its use.

The combination of fludarabine, mitoxantrone (Novantrone) and dexamethasone (FND) has also been established as an effective combination with response rates over 90% (CR 43% to 67%) in both treated and untreated indolent lymphoma.[440,441] In previously untreated patients, the 2-year PFS was 63% and OS was 93%.[442] Steroids may not increase efficacy and have been dropped by some investigators. In a phase III study comparing R-FM vs. R-CVP vs. R-CHOP, the rate of CR was similar in all treatment arms; however, the 3-year time to treatment failure was significantly shorter in the R-CVP arm compared with R-FM or R-CHOP (46%, 61%, and 64%, respectively). The rate of secondary malignancies was notably higher in the R-FM arm (8%).[443]

An area of controversy in indolent lymphomas is the use of anthracyclines with initial therapy. Retrospective studies have been equivocal with some showing no significant differences in response and OS[444,445] while others show superiority to anthracycline-based regimens over less aggressive therapy.[446] R-CHOP was established as an effective regimen in a limited number ($N = 38$) of patients.[447] The response rate was 100% with 87% CR/Cru, with a median time to progression of 82.3 months; 42% remain in continuous remission (6.4 to 8.8 years). Subsequently, R-CHOP was shown to have a higher response rate and prolonged remission when compared to CHOP alone.[425] Both mitoxantrone and doxorubicin contribute to cardiotoxicity, and an argument could be made to restrict their use to FL, with either grade 3 histology, particularly 3b, and/or a high prognostic index score. In a randomized phase III trial by Rummel et al.bendamustine and rituximab (BR) was compared with R-CHOP therapy in patients with low grade lymphomas. The preliminary data favored BR over R-CHOP with a CR rate (40.1% vs. 30.8%, $P = 0.03$) and PFS (69.5 vs. 31.2 months, $P < 0.001$).[448] Other options for therapy in indolent lymphomas include radioimmunotherapy, salvage chemotherapy regimens, novel agents, and transplantation, which are addressed in subsequent sections.

Immunotherapy

Immunotherapy for lymphoma includes a broad and expanding number of approaches. These include nonspecific immunostimulation with interferons (now largely of historic interest in lymphoma therapy), passive humoral therapy with antilymphoid monoclonal antibodies, radioimmunotherapy, drug-antibody conjugates, patient-specific anti-idiotype vaccines, and novel approaches to cellular therapy such as chimeric antigen receptor (CAR)-directed Tcells.

Despite modest evidence of biologic activity, IFN has not been widely adopted in standard lymphoma therapy because of its toxicity and the emergence of more active immunotherapeutics. The most widely used agent among these is rituximab, a chimeric IgG anti-CD20 monoclonal antibody consisting of a murine IgG anti-CD20 antigen binding domain coupled with a human IgG light and heavychain–constant region.[421] CD20 is a highly useful antigenic target in that it is not expressed on mature plasma cells or on hematopoietic stem cells and does not shed or internalize after binding with antibody. Major mechanisms of response include antibody-dependent cellular cytotoxicity (ADCC) via Ig heavychain receptors (FcR) on monocytes, T cells, and natural killer cells, as well as complement activation. Rituximab is an integral component as a single agent or in combination with chemotherapy in the treatment of all subtypes of Bcell lymphomas. In a phase I dose-escalation trial, Maloney et al. determined a dosage of 375 mg/m^2 weekly for 4 doses as the dose for subsequent phase II trials.[449,450] In a multicenter trial involving 166 patients with relapsed indolent NHL, McLaughlin et al. reported a 48% response and a median time to progression of 13 months for responders.[451] This study led to rituximab's approval by the U.S. FDA for relapsed indolent NHL in 1997.

Rituximab has response rates of 47% to 76% (up to 20% to 45% CR) as front-line singleagent therapy, depending upon disease burden and Bcell lymphoma subtype. Randomized trials almost uniformly have favored the rituximab-plus-chemotherapy arms over chemotherapy alone for both indolent and diffuse large Bcell lymphomas. Rituximab maintenance therapy following rituximab or rituximab-chemotherapy induction has improved PFS but, in most studies, not overall survival.

A number of novel next-generation antibodies have been developed to better engage hostresponse mechanisms, many being tested on ongoing clinical trials.[452,453] These include bispecific molecules that bind both tumor and effector Tcells such as blinatumomab (anti-CD19 plus anti-CD3), or the concomitant use of the effector cell agonist anti-CD137 following rituximab.[454] Other Tcell immunomodulators such as anti-CTLA-4 and anti-PD-1 are being pursued in both hematologic malignancies and solid tumors.

Radioimmunotherapy includes two agents consisting of a radioisotope (yttrium-90 [^{90}Y] or iodine-131 [^{131}I]) conjugated to a murine anti-CD20 antibody. In a randomized trial comparing ^{90}Y-ibritumomab tiuxetan to rituximab in relapsed/refractory follicular or CD20$^+$ transformed NHL, Witzig et al. reported that radioimmunotherapy had a higher response rate (80 vs. 56%, $P = 0.002$; 30 vs. 16% for CR, $P = 0.04$). Although there was no difference in median duration of response (14.2 months vs. 12.1 months), durable responses of ≥6 months were statistically more frequent with radioimmunotherapy (64 vs. 47%, $P = 0.030$). Iodine-131 tositumomab similarly showed response rates of 65% in patients with chemorefractory indolent or transformed NHL, compared to 28% response after their last chemotherapy ($P< 0.001$).[455] The median duration of response was 6.5 months for ^{131}I tositumomab, compared to 3.4 months after chemotherapy ($P< 0.001$).[455] When used as initial therapy in patients with FL, the response rate was 97%, including 75% CR, and the median PFS was 6.1 years.[456] Postinduction consolidation therapy with ^{90}Y-ibritumomab tiuxetan significantly improved response durations following complete or partial remission to chemotherapy or rituximab-chemotherapy induction (FIT trial).[457] RIT is also being investigated as a component of induction therapy or conditioning prior to stem cell transplantation in relapsed Bcell NHL.

Vaccination with anti-idiotype vaccines unique to individual patient lymphomas was pioneered by Levy and colleagues at Stanford University.[458] Unfortunately, multicenter Phase II–III clinical trials have been largely disappointing, although one anti-idiotype vaccine that showed an improved disease-free survival in FL patients achieving remission with induction chemotherapy has been FDA approved for this indication.[459]

The ability of monoclonal antibodies to target lymphoma cells has made them an appealing vehicle for delivering a cytotoxic agent, analogous to RIT, with a number of such therapeutics in development. A paradigm for this approach is brentuximab vedotin, an anti-CD30 monoclonal conjugated to the mitotic spindle inhibitor monomethyl auristatin E (MMAE). Once bound to a CD30-positive tumor cell such as anaplastic large cell lymphoma (ALCL) or Hodgkin lymphoma Reed-Sternberg cells, the bound CD30 is internalized and the MMAE is released. Response rates of 80% and higher have been achieved in relapsed or refractory patients, some of whom have then been able to proceed to consolidative and potentially curative stem cell transplantation.[460]

Cellular immunotherapy for lymphomas is an important component of allogeneic stem cell transplantation efficacy, albeit with concomitant risk of graft-versus-host disease. A novel approach instead utilizes autologous patient Tcells genetically modified to express a chimeric antigen receptor (CAR) that combines an anti-Bcell antigen such as CD19 with Tcell activators CD3 and CD137. This strategy showed dramatic efficacy and proof of principle in patients with refractory CLL.[461] Additional studies are ongoing in lymphoma using similar constructs, aimed at further enhancing efficacy and safety while overcoming some of the technical challenges inherent in generating CAR-modified Tcells.

A more detailed discussion of immunotherapy is reviewed in Chapter 70.

MANTLE CELL LYMPHOMA

Mantle cell lymphoma (MCL) was referred to as centrocytic, intermediate lymphocytic, and mantle zone lymphoma in earlier classifications and was given its present name in 1992.[462–464] MCL represents ~ 5% of NHL in Western populations. It occurs predominantly in the elderly (median age, 60 to 68 years) and with a two- to threefold male predominance.[465–467] Most patients present with diffuse lymphadenopathy and splenomegaly.[465–467] B symptoms are present in 25% to 50% of patients, and 15% to 30% have or will develop a unique gastrointestinal presentation with multiple lymphomatous polyposis (Fig. 88.9).[250,465–467] Bone marrow involvement is detected in 60% to 90% of patients, and up to 25% will have an overt leukemic phase, although most patients have a small circulating clone detectable by flow cytometry.[465–467] Central nervous system involvement has been documented in 9% of patients during the course of the illness, usually as a later event.[468,469]

MCL has a characteristic, although not completely unique, phenotype, with most expressing CD5 and negative for CD10 and CD 23, which helps distinguish MCL from follicular and small lymphocytic lymphomas. Virtually all MCL demonstrate the classic cytogenetic marker t(11;14) (q13;q32) by conventional cytogenetic analysis and fluorescence in situ hybridization (FISH).[470,471] Expression of nuclear cyclin D1 protein is found in >90% of cases and is considered the most reliable immunophenotypic marker in the diagnosis of MCL,[472] although variant MCL with cyclin D2 or cyclin D3 expression also occur.[473,474] A minimally deleted segment of 11q22–q23 affecting the *ATM* gene in 50% of MCL suggests that this is an early genetic event along with *the*

BCL-1/CCND1 (cyclin D1) translocation to chromosome 14.[475] Loss of tumor suppressor genes, including *TP53* and *CDKN2/p16*, appears to occur later and has been associated with an aggressive clinical course.[476–479]

Marked clinical and biologic heterogeneity of MCL is now well recognized, with about a quarter of patients having "indolent" disease that may not require immediate therapy. These patients often present with lymphocytosis and splenomegaly, and their symptoms may be confused with CLL if proper flow cytometry and FISH markers are not obtained at diagnosis. Others present with low tumor burden lymphadenopathy and lack systemic symptoms, and watchful waiting for the assessment of the pace of disease has been proposed as initial management in these cases.[480] Biomarkers of clinically indolent cases include mutated immunoglobulin heavy chain variable genes, lack of nuclear SOX11 expression and *TP53* mutation, few if any karyotypic changes aside from the t(11;14), and a characteristic molecular signature.[481]

Clinically aggressive MCL typically has high tumor burden, blastoid morphology, and complex cytogenetics in addition to the t(11;14) and/or high Ki-67 expression. Molecular markers that appear both pathogenically and prognostically relevant include the *NOTCH1* mutation,[482] dysregulation of the Hippo tumor suppressor pathway,[483] and a unique microRNA signature and expression of miR-29.[484,485] The percentage of tumor cells expressing the proliferation marker Ki-67 has been incorporated into the MIPI score to enhance the discrimination of clinical outcomes among low-, intermediate-, and high-risk MCL patients treated with CHOP or R-CHOP regimens (Fig. 88.16).[306,486]

Clinical outcomes and survival have improved in recent years as treatment options have expanded, although MCL remains incurable with standard approaches. Most studies show the absence of a plateau on survival curves. Response rates to initial therapy are typically above 80% with a number of chemoimmunotherapy regimens; CRs are usually <50% and median time to treatment failure is about 18 to 24 months. There is no current standard of care for induction treatment, nor for therapeutically sequencing the various active regimens and targeted agents at relapse. Younger patients often receive an intensive regimen with or without autologous stem cell transplantation in first remission,

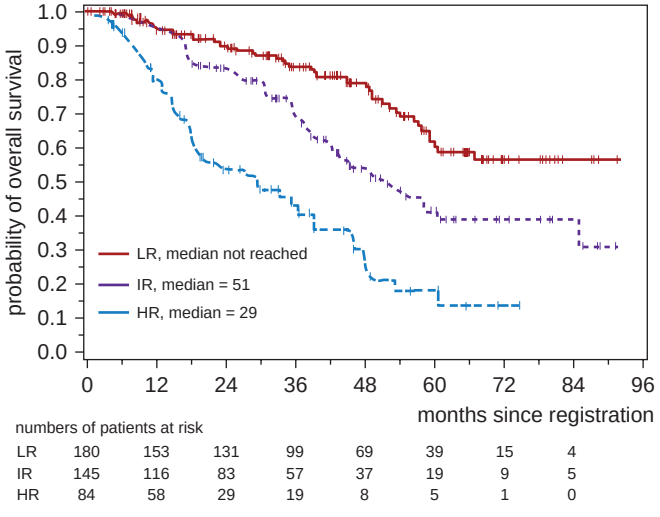

FIGURE 88.16. Overall survival in advanced-stage patients according to the Mantle Cell International Prognostic Index (MIPI) and Ki67. Low risk (LR) score <5.7; intermediate risk (IR) ≥5.7 and <6.2; high risk (HR) =6.2. The combined biologic score is calculated as 0.03535 times age (years) plus 0.6978 (if ECOG > 1) plus 1.367 times $\log_{10}$ (LDH/ULN) plus 0.9393 times $\log_{10}$ (WBC count) plus 0.02142 times Ki-67 (%). From Hoster E, Dreyling M, Klapper W, et al. A new prognostic index (MIPI) for patients with advanced-stage mantle cell lymphoma. Blood 2008;111:558–565, with permission.

while older patients and those with significant comorbid disease are managed with less aggressive approaches. Romaguera et al. utilized rituximab- hyper-CVAD/MTX-Ara-C (fractionated cyclophosphamide plus vincristine, doxorubicin, and dexamethasone alternating with high-dose methotrexate-cytarabine regimen) in a single-institution phase II trial.[487] Among 97 previously untreated patients, 87% achieved complete response. With a median 8-year follow-up, patients <65 years old had a time to treatment failure of 46% and OS 68%, whereas older patients were 16% and 33%, respectively. A multicenter trial in 60 patients 70 years or younger confirmed a high CR rate of 72% and a 5-year OS of 61%, as well as high treatment-associated toxicity—only 37% of patients completed the planned course of therapy.[488] Patients with low- or intermediate-risk MIPI had much improved outcomes as compared to those with high-risk scores. High-dose cytarabine has emerged as an important component of therapy in a large phase III trial by the European MCL Network comparing R-CHOP versus R-CHOP alternating with R-DHAP (dexamethasone, high-dose Ara-C and cisplatinum) followed by autologous stem cell transplantation.[489] Time to treatment failure for the 420 patients was significantly improved with the addition of R-DHAP, although 4-year OS did not differ at about 80% in each arm. This study also showed that achievement of minimal residual disease (MRD)–negativity in the peripheral blood and bone marrow was strongly associated with prolonged disease-free survival.[490]

Bendamustine, a highly active chemotherapeutic in relapsed MCL, was studied as initial therapy in combination with rituximab (BR) and compared with R-CHOP in a phase III trial of nontransplant-eligible patients.[448] PFS was improved in the BR arm although with a similar continuous rate of relapse. The European MCL Network completed a phase III trial in 560 elderly, nontransplant-eligible patients comparing R-CHOP versus R-FC (fludarabine, cyclophosphamide) followed by a second randomization to interferon-alfa versus rituximab maintenance therapy.[491] CR rates were similar with the two induction regimens, although toxicity, treatment failure, and 4-year OS were inferior with R-FC. The 4-year OS was significantly improved for R-CHOP followed by maintenance rituximab given once every 2 months until progression as compared with interferon (87% vs. 63%, respectively, $P = 0.005$). MRD-negativity was a strong predictor of improved outcome.[490] Maintenance rituximab can thus be recommended in this patient population, with confirmatory studies ongoing following BR-based induction and in a U.S. cooperative group trial testing the combination of rituximab plus lenalidomide maintenance.

In younger, fit patients, reinduction followed by related or unrelated allogeneic stem cell transplantation has shown excellent response, with 50% to 60% of patients remaining event-free at 2 years, suggesting a possible graft-versus-lymphoma effect.[492,493] While treatment-associated morbidity and mortality remain high, allogeneic transplant consolidation should be considered for selected patients given its potential for durable remission and cure.

A number of treatment options are available for patients with relapsed MCL. The proteasome inhibitor bortezomib provides responses in 33% of relapsed or refractory MCL patients.[494] As noted, bendamustine is a highly active regimen in the relapse setting, as are several novel targeted agents including the immunomodulatory drug lenalidomide, the mTOR inhibitors temsirolimus and everolimus, and inhibitors of cyclin D1 and cyclin-dependent kinases CDK 4 and -6 (flavopiridol, PD0332991).[495,496–498] Agents targeting the B cell receptor pathway have shown very high response rates in relapsed and refractory MCL. These include the Bruton tyrosine kinase inhibitor ibrutinib and the PI3 kinase inhibitor CAL-101(GS-110)[499,500] (see section on "Novel Agents"). It is anticipated that these agents will become integral components of induction and consolidation or maintenance regimens, and will continue to improve outcomes and survival for this challenging lymphoma.

AGGRESSIVE LYMPHOMAS

Diffuse Large B Cell Lymphomas

DLBCL is the most common type of adult NHL in North America and Europe, making up 30% to 40% of NHL. DLBCL represents a heterogeneous group of diseases and attempts to subdivide it have been based on morphology, cytogenetics, immunohistochemistry, predominant clinical presentations, and genomic profiles (Table 88.12). Morphologic distinctions in DLBCL can be difficult to reproduce and may not be clinically useful. Morphologic variants include centroblastic, intravascular DLBCL associated with chronic inflammation, EBV-positive DLBCL, immunoblastic (IBL), T cell/histiocyte–rich and anaplastic (see Chapter 86). Although IBL was categorized as high grade in the WF Classification, it is regarded as intermediate-grade in that no apparent differences in survival exist between it and other DLBCL.[501] IBL may need to be distinguished from extramedullary involvement by a plasmablastic variant of plasma cell myeloma.

T cell/histocyte–rich B cell lymphoma (T/HRBCL) represents 1% to 3% of DLBCL and is a subtype in which the malignant large B cell is the minority cell.[502–504] T/HRBCL was first described as T cell–rich B cell lymphoma in 1988 by Ramsay and can be confused with HL, both classical and nodular lymphocyte predominant types, PTCL, and indolent lymphomas.[503–505] T/HRBCL occurs at a younger median age than typical DLBCL with most series reporting fourth to fifth decade median ages compared to sixth decade.[503] Patients with T/HRBCL have more B symptoms (26% to 62%), splenomegaly (21% to 60%), and marrow involvement (32% to 53%) than traditional DLBCL. Although some series of T/HRBCL have had inferior CR rates compared to DLBCL, there may have been a disproportionate number of patients with a high IPI; and case-controlled series have shown no differences in OS.[503] T/HRBCL can be further defined by molecular profiling that identifies a unique cluster of genes involved in host response.[506,507]

EBV-positive DLBCL of the elderly is a recent entity which is clinically recognized for its aggressive behavior with frequent extranodal presentation and poor prognosis.[508] This type of lymphoma is thought to be a result of immunosenescence with aging. The median age at presentation is 75 years. Another form of EBV-positive DLBCL is DLBCL associated with chronic inflammation involving joints or body cavities (pyothorax).[508,509]

There is no single cytogenetic abnormality which defines DLBCL, but there are a number commonly found with DLBCL, including t(3;14), t(14;18), and t(8;14) and related variants. These cytogenetic abnormalities are commonly found with other types of lymphomas; and when observed in DLBCL, there can be a clinical problem distinguishing transformation from a de novo presentation. *BCL6* gene on 3q27 is associated with multiple chromosomal partners; and translocations involving 3q27 are found in 30% to 35% of DLBCL.[510] The prognostic implication of *BCL6* abnormalities has been variable, with data indicating a worse survival with nonIG gene *BCL6* rearrangements than with *IGH/BCL6* translocations of t(3;14).[511]

The t(14;18) is present in 20% to 25% of DLBCL and may represent transformation from a FL or a true de novo presentation. While *BCL2* genetic translocation has not been correlated with survival in de novo DLBCL, BCL2 protein expression has been associated with an inferior survival, specifically in the activated B cell type of DLBCL.[314] The t(8;14) is usually found in BL and is rare in DLBCL. Double hit lymphomas harbor dual translocations with *MYC;* t(8;14), and *BCL2* ; t(14;18),[512] are refractory to standard chemotherapy regimens, and have a poor prognosis. The synergistic activity of antiapoptosis driven by *BCL2* and proliferation by *MYC* is responsible for the poor outcome with traditional chemotherapy.[513–515]

Large B cell lymphoma of the leg is seen in the elderly and has a poorer prognosis than other cutaneous B cell lymphomas.[516,517] Intravascular B cell lymphoma was recognized in 1959 and was known as malignant angioendotheliomatosis.[518] It occurs in the elderly (median age 65 to 70 years) and most commonly affects the skin and central nervous system. Symptoms are usually related to ischemia secondary to occlusion of blood vessels, and approximately one-half of cases are first detected at autopsy.[519]

Gray zone lymphoma is an entity applied to tumors that demonstrate morphological and immunophenotypic features between classical HL and DLBCL, especially primary mediastinal large B cell lymphoma (PMLBCL).[520] These lymphomas have a poorer outcome than HL or PMLBCL. Unclassifiable B cell lymphomas with features between DLBCL and BL are also included in the WHO classification. These tumors are generally aggressive and respond poorly to standard chemotherapy, though the optimal treatment regimen is not defined.

DLBCL can rarely involve the anaplastic lymphoma kinase (*ALK*) gene, and most ALK+ DLBCL have a single or complex t(2;17)(p23;q23) involving the *ALK* gene at chromosome band 2p23 and the clathrin gene at chromosome band 17q23.[521] ALK+ DLBCL lacks expression of pan-B cell antigens, CD20 and CD79a, but is positive for CD138 and epithelial membrane antigen (EMA). Although data is limited due to the rarity of the disease, ALK+ DLBCL is usually advanced stage and has a poor prognosis.[521]

Mutations in the *TP53* gene have been detected in 20% of DLBCL and are associated with a poor prognosis. TP53 expression is detectable by immunohistochemistry in 30% to 40% of DLBCL, does not correlate with the presence of mutations, and has not consistently affected prognosis. However, combining TP53 and its downstream target CDKN1A/P21 (acting as a cyclin-dependent kinase inhibitor) has shown that the TP53+/P21-immunophenotype is a surrogate for *TP53* mutations and is associated with poor survival in DLBCL, even with a low-risk IPI.[321]

Expression of individual antigens assessed by immunophenotyping may help define subsets of DLBCL and may have prognostic value (see section on "Prognostic Factors"). CD10, also known as the common acute lymphoblastic leukemia antigen, is a marker for germinal center derivation and is detected in 20% to 30% of DLBCL. CD10 expression has been associated with improved survival or no effect.[522] CD5, an antigen primarily expressed by

Plasmablastic lymphoma
Unclassifiable types
LBCL with intermediate features between DLBCL and Hodgkin lymphoma
LBCL with intermediate features between DLBCL and Burkitt lymphoma

DLBCL, diffuse large B cell lymphoma ; EBV, Epstein-Barr virus.

T cells and a small subset of B cells (B-1 cells), is present on 5% to 10% of DLBCL. $CD5^+$ DLBCL has been associated with a high IPI and poor survival in most, but not all studies.[522]

As noted in the Prognosis Section, DLBCL can be subdivided by gene expression profiling (GEP) using cDNA or oligonucleotide microarrays into 4 subgroups: germinal center B cell (GCB), activated B cells (ABC), primary mediastinal B cell, and unclassified DLBCL.[523] Comparative genomic hybridization (CGH) has shown differences in genetic imbalances between GCB and ABC DLBCL. GCB is characterized by the gain of 1q, 2p, 7q, and 12q; and ABC has gains of 3q, 18q, and 19q and loss of 6q and 9p21, the latter of which is described with the *CDKN2A* locus and an aggressive course.[524]

Tissue microarray (TMA) technology can be performed on formalin-fixed and paraffin-embedded samples and is easier and less expensive than GEP, which requires fresh or optimally cryopreserved samples. TMA can identify protein surrogates for dysregulated genes detected by GEP. Expression of BCL6 and CD10 were associated with a germinal center type and favorable outcome, whereas MUM1, CYCLIN D2, FOX P1, and/or protein kinase C beta (PKC-β) were associated with either the activated B cell or unclassified type and a poor prognosis.[316,525]

GEP and TMA are technically difficult studies to perform. Hans et al. proposed a reliable immunohistochemical staining using BCL-6, CD10, and MUM1 which is 80% concordant with that of the DNA-expression analysis.[317] Choi et al. described a similar approach with additional staining with GCET-1 and FOXP1 that showed a 93% concordance rate.[315] The clinical utility of these studies are being evaluated in prospective studies (see section on Prognostic Factors).

Current therapy of DLBCL is directed at clinical features, pathology, and stage of disease. As DLBCL represents a group of potentially curable neoplasms, prognostic factors are important to recognize and can influence the type, intensity, and duration of therapy. Selecting the intensity of therapy based upon prognostic factors is referred to as risk stratification and has been applied successfully in pediatrics, in which the curability of all types and stages of NHL is over 80%. The IPI is currently the best prognosticator for survival in DLBCL. Immunohistochemistry can delineate different types of DLBCL, but there is no consensus about the best panel of markers to either subclassify or prognosticate DLBCL. In the rituximab era, the prognosis has improved and the impact of IPI and immunohistochemistry was reassessed and classifies patients into very good, good, or poor risk groups with 94%, 75%, and 55% 4-year OS, respectively.[300]

Mediastinal (Thymic) Large B Cell Lymphoma

The WHO classification recognizes a distinct large B cell lymphoma postulated to arise from a thymic B cell and that can be confused with lymphoblastic lymphoma, HL, thymomas, and extragonadal germ cell neoplasms.[526–530] Older literature referred to this entity as primary sclerosing mediastinal large cell lymphoma. PMLBCL constitute 2% to 3% of NHL and occur predominantly in females (female:male ~2:1) and young adults; three-fourths of cases are less than 35 years old.[526] Gains in chromosome *9p24* or *2p15* have been recognized in up to 75% and 50% of patients, respectively.[530,531] *BCL-2* and *BCL-6* gene rearrangements rarely occur; overexpression of the *MAL* gene is common.[532] Interestingly, gene expression analysis has revealed a molecular signature with similarities to classical HL, perhaps reflected in the shared clinical and pathologic features and dysregulation of c-REL/NF-κB pathways.[533,534]

Presenting features are usually of short duration, varying from a few weeks to several months, and include chest pain (73%), cough (60%), dyspnea (46%), and superior vena caval obstruction (30% to 57%).[528,530] Over two-thirds of patients have large masses (≥ 10cm) (Fig. 88.17). Local extension of the mass into the pericardium, chest wall, or lung is common, while distant involvement of peripheral nodes, marrow, or CNS is infrequent.[526,529] The stage of disease is I or II in 80% of patients at diagnosis. Unusual extranodal sites of involvement include kidney, ovaries, and adrenal glands.

Although early reports indicated a poor prognosis despite combination chemotherapy, recent studies have had a good prognosis similar to or better than other DLBCL.[527,528,535] Poor prognostic factors in PMLBCL have been the presence of pleural or pericardial effusion, multiple extranodal sites (≥2) of disease, bulk (≥ 10 cm), high LDH (>3× normal), and a persistently positive gallium or PET scan posttherapy.[526,528,529] The age-adjusted IPI was not found to be predictive in these patients.[535] Some of the best treatment results historically included involved field radiation therapy,[528,529] but some series have had equally good results without radiation, indicating that the role of radiation remains controversial.[527,535] Some centers have favored regimens other than R-CHOP, including R-MACOP-B/VACOP-B regimens and R-EPOCH. The latter was reported to have EFS of 90% in a series of 26 patients, without the use of radiation therapy.[536,537] Others have advocated autologous HCT as consolidative therapy among patients with "high-risk" PMLBCL, but there are sparse phase II trials to commend this approach.[538]

Peripheral T/Natural Killer Cell Lymphomas

The clinical significance and the management of T/natural killer (NK) neoplasms are areas of controversy in part because of the relative infrequency as compared to B cell lymphomas, and the lack of controlled trials evaluating the impact of immunophenotype on prognosis.[296,539,540] PTCL and NK cell neoplasms represent 5% to 15% of all NHL, and there are multiple subtypes so that most represent less than 1% of NHL[541] (Table 88.13). These diseases have a geographic variation with more nodal disease in North America and Europe, including PTCL, unspecified; anaplastic large cell lymphoma (ALCL) and angioimmunoblastic T cell lymphoma (AILT); and more extranodal disease in Asia due to EBV-related nasal NK/T lymphoma and HTLV-1 associated ATL.[542] The prognosis in most peripheral T/NK neoplasms is poor, with 5-year survival less than 30%.[539,540,542,543] PTCLs may be associated with paraneoplastic phenomena, including skin rashes, autoimmune hemolytic anemia, hypergammaglobulinemia, eosinophilia, hypercalcemia, vasculitis, hemophagocytosis, and fever of unknown origin, which may obscure the initial diagnosis.

Attempts have been made to separate postthymic T cell neoplasms; however, the so-called low grade T cell lymphomas may have an aggressive course and can undergo histologic transformation similar to that seen in indolent B cell lymphomas.[544] Cytogenetic differences have been utilized in an attempt to separate PTCL into low- and high-grade categories.[545] PTCL that have been described with an indolent course include AILT, T-zone lymphoma, and lymphoepithelioid (Lennert) lymphoma;[544,546] only AILT is described in the WHO classification as a distinct entity, while the latter two would be referred to as PTCL, unspecified. Lennert lymphoma typically occurs in older patients, often with diffuse adenopathy and involvement of Waldeyer's ring and has a clinical course characterized by recurrent relapses.[546]

Mature T/NK neoplasms do not have the high frequency of translocations involving the T cell receptor genes at 14q11 (alph-adelta), 7q34 (beta), and 7p14 (gamma), that the B cell lymphomas do with IG gene receptors, particularly with the *IGH*. The best described translocation is the t(2;5) (p23;q35) associated with ALCL (vide infra). It produces a fusion gene between the cytoplasmic part of anaplastic lymphoma kinase (*ALK*), a receptor tyrosine kinase of the insulin receptor subfamily on chromosome 2, and the amino-terminal portion of nucleophosmin (*NPM*) on chromosome 5.[26] A novel t(5;9) translocation involving the IL-2-inducible T cell kinase (*ITK*) gene on chromosome 5 and the

spleen tyrosine kinase (*SYK*) on chromosome 9 was identified in 5 (17%) PTCL, NOS cases.[545] Another translocation involving the multiple myeloma gene (*MUM1*)/ IFN-regulatory factor-4 (*IRF4*) gene locus with the *TRA@* gene, t(6;14) (p25;q11.2) was found in two cases of PTCL, NOS and led to the recognition by FISH screening of non-TCR-related *IRF4* translocations in ALK-negative ALCLs. A balanced translocation between *DUSP22* phosphatase gene on 6p25.3 and *FRA7H* on 7q23 was subsequently found in both systemic and cutaneous ALCL.[547]

Although CHOP has been the mainstay of therapy for aggressive lymphomas, its results have been poor for most mature T/NK neoplasms.[548–550] The response rates to CHOP have been inferior compared to B cell lymphomas, and there has been no ubiquitous monoclonal antibody similar to rituximab to improve survival. Adding agents to CHOP may slightly improve responses but is limited by increased toxicity. Adding etoposide to CHOP had modest improvement for only young patients, primarily with ALK-positive ALCL, in the combined analysis of trials by the German High-Grade Non-Hodgkin Lymphoma Study Group.[551] Escalating therapy, such as Mega-CHOEP or HyperCVAD, has not improved responses or survival.[551] Addition of alemtuzumab to CHOP led to increased infections so that its use is likely limited.[552] Using novel non-anthracycline-based regimens suchas PEGS (cisplatin, etoposide, gemcitabine, solumedrol) have not improved survival.[553]

How to incorporate newly approved agents such as pralatrexate, an antifolate, and romidepsin, a histone deacetylase inhibitor, into therapy is under investigation in PTCL. The response rate and toxicities in relapsed PTCL for pralatrexate was 29% (11% CR) with 22% mucositis and 18% to 32% cytopenias, and for romidepsin was 38% (18% CR) with 26% grade 3/4 neutropenia.[554,555] Because of the overall poor results with CHOP, stem cell transplant, both autologous and allogeneic, has been advocated in first remission in many patients with T/NK neoplasms although there is no randomized trial to prove its superiority.[556,557]

The WHO classification separates the mature T/NK neoplasms by site of involvement: nodal, extranodal, leukemic, and cutaneous. In the subsequent section, the focus is primarily on nodal and extranodal diseases followed by a brief description of the leukemias. Cutaneous T cell lymphomas are reviewed in Chapter 92.

Anaplastic Large Cell Lymphoma

Since the original description of Ki-1$^+$ (CD30) ALCL by Stein in 1985, a type of ALCL has become a paradigm for the WHO classification for NHL.[258,558,559] The first clinical description of ALCL was in a series by Kadin et al. in 6 children, all of whom had skin lesions.[560] Subsequent studies recognized a common lymphoma (2% to 8% of NHL) with a wide morphologic spectrum, young median age, peripheral adenopathy with relative sparing of the mediastinum, frequent extranodal disease, and a good prognosis.[258,561,562] In 1989, a proportion of ALCLs were associated with a specific chromosomal translocation;[25] and in 1994, Morris identified the genes involved in the t(2;5).[26]

ALK rearrangements are present in 50% to 70% of CD30$^+$ ALCL, and the t(2;5) occurs in approximately three-fourths of these patients.[258,563] Cytogenetic variants have been described with t(1;2)(q25;p23) as the most common.[563] Immunocytochemical stain for the ALK protein is usually present in both cytoplasm and nuclei of the classic t(2;5)(p23;q35), while only in the cytoplasm of the variants.[258,312] Because the variants are of T or null cell origin and occur in a similar age group as the t(2;5), Falini proposed the term "ALKoma" for all patients expressing the ALK protein.[312]
