Patients with elevated Lp(a) benefit most from aggressive LDL cholesterol lowering. Although hepatic 3-methylglutaryl coenzyme A reductase inhibitors ("statins") may be the ideal agents for LDL lowering and atherosclerotic plaque stabilization, this class of drug does not appreciably lower Lp(a) levels themselves.[310] Nicotinic acid (niacin), usually in high doses, is the first-line pharmacologic therapy to lower Lp(a) levels. Reductions up to 38% have been reported.[311] Because nicotinic acid therapy may be poorly tolerated, a gradual escalation in dose and pretreatment with aspirin are recommended. In women, estrogen replacement therapy can lower Lp(a) levels by as much as 50%.[308]

Tissue Factor Pathway Inhibitor

Tissue factor pathway inhibitor (TFPI) is a major anticoagulant, present in plasma, and associated with vascular endothelium. TFPI binds to and neutralizes the TF/factor VIIa complex to inhibit activation of factor X. Low levels of TFPI are a weak risk factor for a first venous thrombosis, as well as recurrent VTE events.[312,313] Recent studies have also linked TFPI deficiency to arterial thrombosis.[314]

Combined Defects

Compound heterozygosity for two different natural anticoagulant deficiencies is extremely rare, because of the low prevalence of each individual defect. The phenotypic presentation of such compound heterozygotes does not appear to be as severe as it is for the homozygous forms of each deficiency, with the rarely reported patient presenting with VTE of early onset (in the teenage years).[98,214] Because factor V Leiden is the most common inherited thrombophilia, double heterozygosity for factor V Leiden and a natural anticoagulant deficiency has been described in some families.[125,315] In families with both factor V Leiden and protein C deficiency, 73% of compound heterozygotes reported a history of VTE, compared with 31% and 13% of relatives with

protein C deficiency only and factor V Leiden only, respectively.[125] In families with factor V Leiden and AT deficiency, 92% of double-heterozygous carriers had a history of VTE, as opposed to 57% and 20% of individuals with AT deficiency only and factor V Leiden only, respectively.[315]

Combined heterozygosity for both the factor V Leiden and prothrombin G20210A mutations, which is estimated to occur in 1 in 1,000 persons, does appear to be associated with an increased relative risk of both first and recurrent VTE.[190,210,316] In a pooled analysis of eight case-control studies including more than 2,000 patients with VTE, a 2.2% prevalence for the combined mutations was found in patients.[190] Double heterozygosity was associated with a 20-fold increased relative risk of VTE.[190] The risk of recurrent VTE for heterozygous carriers of both factor V Leiden and PT G20210A also appears to be increased (2.6-fold).[210]

The prevalence of factor V Leiden carriership in combination with acquired hypercoagulable states has also been studied. Factor V Leiden appears to increase the risk of VTE in patients with antiphospholipid antibodies but is not a prerequisite for the development of VTE in those patients.[317] The interaction between factor V Leiden and hyperhomocysteinemia has been a matter of interest since the observation, not corroborated by further studies, that factor V Leiden appeared to be a prerequisite for VTE in individuals from families with classic homocystinuria.[318] Nonetheless, two studies on the interaction between mild to moderate hyperhomocysteinemia and factor V Leiden have yielded somewhat different findings. Den Heijer et al. found that the risk of VTE associated with the combination of conditions (2-fold) did not exceed the risk associated with each condition alone (9.5-fold for factor V Leiden, 2.2-fold for hyperhomocysteinemia).[248] However, in the large Physicians' Health Study, the concomitant presence of both conditions did appear to be synergistic.[189]

Inherited Risk Factors in Childhood Venous Thrombosis

Many of the common inherited thrombotic disorders described in adult patients have been linked to pediatric thrombosis. A prospective European study identified a single genetic risk factor in 54% of pediatric thrombosis patients.[319] Common defects identified were factor V Leiden (32%), protein C deficiency (9%), protein S deficiency (6%), prothrombin gene mutation (4%), and AT deficiency (3%).[319] In most patients, thrombosis is precipitated by superimposed nongenetic risk factors that included central venous catheters, cancer, sepsis, immobility, surgery, trauma, or use of oral contraceptives.[320] For neonatal patients with thrombosis, the most significant factor associated with thrombosis is the presence of a central venous catheter.[321] In children with recurrent thrombosis, the factor V Leiden mutation is present in most patients.[322] Homozygous deficiencies of protein C or protein S are causal in neonatal purpura fulminans.[133,160] When pediatric patients are evaluated for protein C, protein S, or AT deficiency, pediatric reference ranges are mandatory, because age-related changes occur in the levels of these proteins.[322a]

A consensus panel of the International Society on Thrombosis and Haemostasis has recommended that pediatric patents with thrombosis be routinely tested for inherited and acquired disorders in a comprehensive fashion.[323] However, many of the suggested tests are not recommended by the College of American Pathologists' consensus panel, and there are no data to indicate that patients with a genetic predisposition to thrombosis—children or adults—should be treated differently[324,325] from those without risk factors (discussed in the following section).

Perspective on Laboratory Testing for Inherited Thrombotic Disorders

Increased availability of hypercoagulable-state test "panels" and enhanced ability to identify an abnormality in tested patients have prompted widespread testing of thrombosis patients. Testing for acquired and inherited hypercoagulable states uncovers an abnormality in >50% of patients presenting with an initial VTE but may have minimal actual impact on management in most of these patients.[24,98,326,327] Such laboratory screening should be reserved for patients for whom the results of individual tests significantly affect the choice of anticoagulant agent, intensity of anticoagulant therapy, therapeutic monitoring, family screening, family planning, prognosis determination, and, most of all, duration of antithrombotic therapy. Testing "just to know" is neither cost-effective nor clinically appropriate. Table 55.4 lists situations in which hypercoagulable-state testing should be considered, but not necessarily performed, unless an a priori use of the test results has been determined. Table 55.5 lists potential elements of an initial battery of tests to detect a defined hypercoagulable state.

Patients should be considered for evaluation of these disorders if they are young (<45 years of age) with recurrent thrombosis, or if they have had a single idiopathic thrombotic event and have a positive family history.[89] This recommendation is based on the fact that, with the exception of hyperhomocysteinemia and qualitative abnormalities of plasminogen, inherited thrombotic disorders, especially the five most common (APC-R, prothrombin G20210A, protein C deficiency, protein S deficiency, and AT deficiency), are autosomal dominant disorders, and most patients with these disorders (but not all[328]) have supportive family histories. Patients without a family history of thrombosis should be evaluated for common acquired etiologies for thrombosis, including malignancy, myeloproliferative disorders, PNH, and antiphospholipid antibodies.[89] Because thrombosis may induce an acute-phase response that may affect functional coagulation assays, testing is ideally done when the patient has fully recovered from the acute event and is not receiving anticoagulants. Functional assays are preferred over immunologic assays, so that both type I and type II disorders can be detected. An important exception to this recommendation is APC-R, which can be screened for using a DNA test that is not affected by acute-phase responses or anticoagulant therapy. Diagnosis of protein C or S deficiency in patients already anticoagulated with warfarin can be facilitated by parental testing, testing symptomatic family members who are not receiving anticoagulation, referral to a reference laboratory that has standardized assays for these natural anticoagulants in anticoagulated patients, or temporary cessation of warfarin therapy (minimum of 3 to 4 weeks).[89] Patients with arterial thrombosis should be considered for testing for hyperhomocysteinemia, Lp(a), and, possibly, protein S deficiency and antiphospholipid antibodies.[3]

TABLE 55.4

CLINICAL CIRCUMSTANCES IN WHICH SELECTED HYPERCOAGULABLE STATE TESTING MAY BE CONSIDERED

Idiopathic VTE
VTE in unusual sites
Heparin resistance
Recurrent VTE (especially if idiopathic)
VTE at young age (<45 y)
VTE in the setting of a strong family history of VTE
Unexplained recurrent (≥3 in first trimester) pregnancy loss
Family members of VTE patients with known inherited hypercoagulable states

VTE, venous thromboembolism.

TABLE 55.5

SCREENING LABORATORY EVALUATION FOR PATIENTS SUSPECTED OF HAVING A HYPERCOAGULABLE STATE

Activated protein C resistance (diluting patient plasma with factor V–deficient plasma)
Prothrombin G20210A mutation testing by polymerase chain reaction
Activity assays for antithrombin, protein C, and protein S[a]
Activated partial thromboplastin time, mixing studies, and dilute Russell viper venom time[a,b]
Fasting total plasma homocysteine level
Anticardiolipin and β_2-glycoprotein 1 antibody testing by enzyme-linked immunosorbent assays
Factor VIII activity[a]

[a]Assays should not be done at the time of acute thrombosis or while the patient is anticoagulated.
[b]aPTT and dRVVT mixing studies that do not correct should be further evaluated for the lupus anticoagulant with phospholipid correction tests.

In addition to a positive family history of thrombosis, other clinical features may suggest inherited thrombosis, including recurrent spontaneous thromboses, thrombosis in unusual sites (mesenteric vein), thrombosis at an early age, heparin resistance (suggestive of AT deficiency), warfarin-induced skin necrosis and neonatal purpura fulminans (suggestive of protein C or protein S deficiency), and thrombosis occurring with estrogen therapy or pregnancy (suggestive of APC-R or prothrombin G20210A). The presence of these clinical events may justify laboratory evaluation of these patients. Even in situations in which the relative risk of thrombosis and recurrent thrombosis is increased, the absolute risk for a particular patient may not warrant the risks of chronic anticoagulation. Thus, one should always assess the pretest use of hypercoagulable-state testing before embarking on an expensive investigation.

A more fundamental question is whether routine laboratory testing for inherited thrombotic disorders will change treatment (intensity or duration of anticoagulation). This is a controversial subject because the available data do not support the contention that patients with an inherited thrombotic disorder should be managed differently from patients without such a disorder.[24,327] Several prospective trials performed to address this question found that positive inherited thrombophilia testing results did not affect the rate of recurrent VTE (reviewed in Reference 24). Another study found that thrombophilia testing at a major urban medical center was overutilized, and that a majority of tests were ordered at suboptimal times.[329]

There are three thrombotic risk factors that may influence treatment strategy: The presence of antiphospholipid antibodies (discussed in Chapter 54), AT deficiency, and (perhaps) hyperhomocysteinemia. Patients with antiphospholipid antibodies may require a longer duration of oral anticoagulation, and some patients with hyperhomocysteinemia may respond to vitamin therapy to resolve this thrombosis risk factor (although clinical trial data have not demonstrated a benefit of lowering homocysteine levels[257–259]). Patients identified as having AT deficiency may benefit from this diagnosis because availability of AT concentrates may optimize their management. Table 55.6 summarizes the clinical laboratory testing recommendations of the College of American Pathologists' Consensus Conference on Thrombophilia.

Laboratory Testing for the Prethrombotic State

Levels of fibrin degradation products, including cross-linked fibrin degradation products (D-dimer), are usually increased in the presence of acute VTE. Absence of an elevated level of D-dimer in patients undergoing an evaluation for acute DVT or PE has an excellent negative predictive value for thrombosis.[330] D-dimer measured 3 months after oral anticoagulation for DVT treatment was discontinued has been shown to have a negative predictive value of 95.6% for VTE recurrence.[331] It has also been shown that baseline elevations of D-dimer are strongly and positively related to the occurrence of future venous thrombosis.[332] Plasma levels of fibrinopeptide A can be increased in venous thrombosis patients, but this assay has the disadvantage of requiring rigorous attention to specimen collection to avoid an activated plasma sample. The activation peptide generated when prothrombin is cleaved to form thrombin, prothrombin fragment 1+2, is a sensitive measure of thrombin formation.[333] Other markers of activation of coagulation include thrombin–AT complex and plasmin–antiplasmin complex.

One active area of investigation is optimizing the combination of a sensitive D-dimer assay with clinical criteria to exclude VTE[334,335] or risk of recurrent VTE.[336,337] Figure 55.2 depicts one strategy algorithm to incorporate D-dimer testing in thrombosis evaluation.

ANTITHROMBOTIC THERAPY

Arterial and venous thrombotic events combined, including acute coronary syndromes, stroke, peripheral arterial thrombosis, DVT, and PE, are likely responsible for more morbidity and mortality than any other condition in the developed world.

Cardiovascular disease was reported to be the underlying cause of death in ~30% of all deaths in the United States in 2010.[1] Every year 750,000 new strokes occur in the United States, of which 85% are ischemic in nature.[338] Because approximately one third of these patients die as a direct or indirect result of their cerebrovascular-thrombosis–related occlusion, stroke is the third leading cause of death in this country. In addition, stroke is the leading cause of serious long-term disability in the United States, with roughly 4.7 million total stroke survivors.[338] Acute limb ischemia secondary to peripheral arterial thrombosis and thromboembolism involving native and prosthetic vessels is a relatively uncommon but ominous form of vascular accident. National databases suggest a rate of 16 events annually per 100,000 population.[339] In a fashion similar to coronary artery thrombosis, acute peripheral arterial thrombosis typically develops at sites of pre-existing peripheral atherosclerotic occlusive disease (PAOD). PAOD has been diagnosed in as many as 17% of men and 20% of women >55 years of age and is highly predictive for the coexistence of coronary and cerebral vascular disease. It has been estimated that PAOD progresses to critical limb ischemia in 15% to 20% of patients.[340,341]

Acute VTE, including DVT and PE, is a common, potentially life-threatening, often preventable vascular condition associated with trauma, major surgery, advanced congestive heart failure, pregnancy, HRT, malignancy, and inherited hypercoagulability. Proximal lower-extremity DVT can result in venous limb gangrene (phlegmasia cerulea dolens), chronic stasis changes related to the postthrombotic syndrome (PTS), and symptomatic PE. PE in its most severe presentation can result in pulmonary hypertension, right-sided heart failure, cardiopulmonary collapse, and death.

A common feature of the management of all thromboembolic vascular diseases is the use of antithrombotic agents. Antithrombotic agents, including antiplatelet drugs, anticoagulants, and thrombolytic agents, are used to prevent thrombotic events, prevent or mitigate the complications of thrombotic events, and restore vascular patency to prevent loss of tissue, organ, and limb function, as well as life. Based on the pathologic basis of thrombosis involving different vascular beds, drugs that inhibit platelet activation and aggregation play a primary role in arterial disease management, whereas drugs that inhibit thrombin and fibrin generation play a primary role in venous disease

TABLE 55.6

SUMMARY OF THE COLLEGE OF AMERICAN PATHOLOGISTS™ RECOMMENDATIONS ON LABORATORY TESTING FOR INHERITED THROMBOSIS

Thrombotic Disorder	Who Should Be Tested?	Test Method(s)	Comments
FVL	First VTE at age <50 y Recurrent VTE First unprovoked VTE First VTE, unusual site First VTE, positive family history First VTE related to pregnancy or hormonal therapy Unexplained second- or third-trimester pregnancy loss	APC-R assay using factor V–deficient plasma *or* DNA-based assay	Patients with relatives who are known to have FVL should be tested directly with DNA-based assays. Patients with positive APC-R assays should have confirmatory DNA tests.
Prothrombin gene mutation	As above	DNA-based assay	Prothrombin activity assays should not be used.
Homocysteinemia	Arterial vascular disease; controversial for VTE	High-performance liquid chromatography or immunoassays	Genotyping for methylenetetrahydrofolate reductase mutations is not recommended. Fasting may not be necessary. Proper sample processing is necessary. Testing in VTE patients may be appropriate to identify and treat affected patients with vitamins.
PC deficiency	Infants with neonatal purpura fulminans; VTE patient from a family with known PC deficiency Asymptomatic female from a known PC-deficient family before hormonal therapy	Chromogenic substrate assays preferred Functional assays are useful Immunologic assays are discouraged	Avoid testing during acute thrombosis or anticoagulant therapy. Exclude causes of acquired PC deficiency. Consider age-dependent reference ranges.
PS deficiency	Patient with VTE from a family with known PS deficiency	Functional assay *or* immunoassay for free PS Total PS antigen assays not recommended	Abnormal functional assay results should be confirmed with an immunoassay for free PS. Exclude acquired causes of PS deficiency. Avoid testing during acute thrombosis, anticoagulant therapy, and pregnancy. Consider age- and gender-dependent reference ranges.
AT deficiency	Patient with VTE from a family with known AT deficiency Asymptomatic female from a known AT-deficient family before hormonal therapy	Chromogenic substrate assays preferred AT antigen assays not recommended	Exclude acquired causes of AT deficiency. Avoid testing during acute thrombosis or anticoagulant therapy.
Elevated factor VIII levels	Controversial	Factor VIII activity assay	Test 6 mo after thrombosis. Avoid anticoagulant therapy.
Dysfibrinogenemia	Not recommended		
Heparin cofactor II	Not recommended		
Factor XIII polymorphisms	Not recommended		
Plasminogen activator inhibitor-1	Not recommended		
Plasminogen deficiency	Test in non-DVT patients with ligneous conjunctivitis		

APC, activated protein C; AT, antithrombin; FVL, factor V Leiden; PC, protein C; PS, protein S; VTE, venous thromboembolism.

management. The following sections describe the pharmacodynamics, pharmacokinetics, and clinical uses of select antithrombotic agents.

Antiplatelet Drugs

Given the important role of platelets in mediating arterial thrombosis and the significant morbidity and mortality of arterial thrombotic disorders, the safety and efficacy of antiplatelet drugs have been evaluated in numerous primary and secondary prevention trials. A 1988 meta-analysis indicated that antiplatelet treatment reduced overall mortality from vascular disease by 15% and that nonfatal vascular events were reduced by 30%.[342] A 2002 update on this subject supports the original observation of the efficacy of antiplatelet therapy.[343] The American College of Chest Physicians' consensus conference has summarized the status of clinical trials with aspirin and other antiplatelet drugs.[344]

Numerous potential targets exist for antiplatelet therapy (Fig. 55.3). Platelet cyclo-oxygenase (COX) is the target of acetylation and irreversible inactivation by aspirin.[345,346] ADP-induced platelet aggregation can be selectively inhibited by the thienopyridines, ticlopidine, clopidogrel, prasugrel, and by ticagrelor, a member of the cyclopentyltriazolopyrimidine class of drugs.[345,346] Dipyridamole alters platelet function, in part, by inhibition of cyclic nucleotide phosphodiesterase to increase platelet cyclic AMP levels.[346] Other potential targets for antiplatelet therapy include the platelet membrane receptor, gpIb, mediator of platelet adhesion, and inhibitors to thrombin, the most potent stimulus to platelet activation.[345,346] Interference with fibrinogen-mediated platelet aggregation by anti-gpIIb–IIIa antibodies and peptides is well established.[344]

A

Clinical Criteria	Score
Active cancer	+1
Paralysis or immobilization	+1
Major surgery in past month	+1
Extremity tenderness	+1
Extremity is swollen	+1
Calf swelling (>3 cm vs. asymptomatic extremity)	+1
Edematous extremity	+1
Presence of collateral superficial veins	+1
Alternative diagnosis to DVT	–2
High probability	≥3
Moderate probability	1 or 2
Low probability	≤0

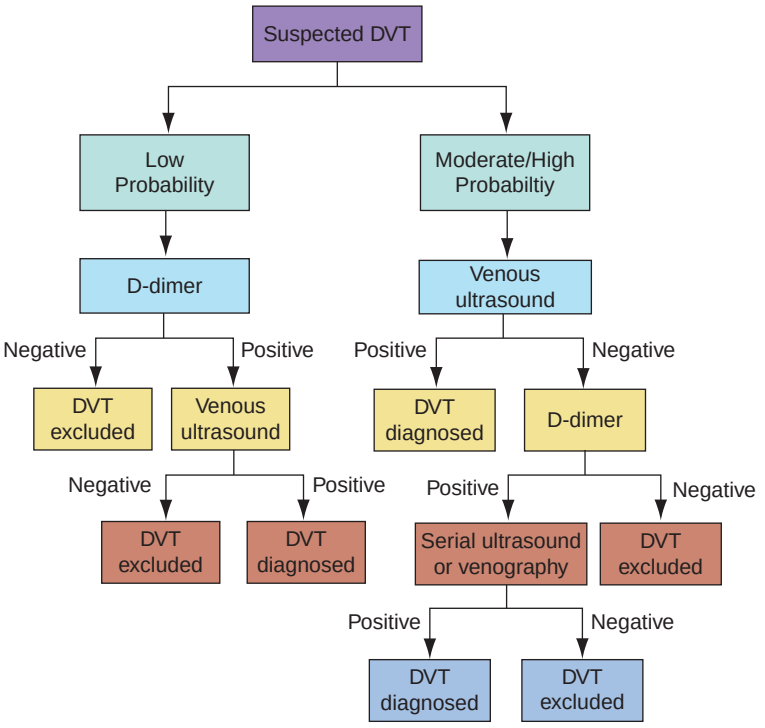

FIGURE 55.2. Algorithm for excluding deep vein thrombosis (DVT) using clinical criteria, D-dimer testing, and venous ultrasound. Clinical criteria are based on those of Wells PS, Anderson DR, Bormanis J, et al. Value of assessment of pretest probability of deep-vein thrombosis in clinical management. Lancet 1997;350:1795–1798. D-dimer methods are similar to those described by Hirsh J, Lee AY. How we diagnose and treat deep vein thrombosis. Blood 2002;99: 3102–3110. **A:** Based on clinical criteria fulfilled by the patient, the cumulative score is tallied. High probability is a score ≥3, moderate probability is 1 or 2, low probability is ≤0. **B:** The probability score is used with D-dimer assay and ultrasound to determine which patients may be excluded from DVT testing.

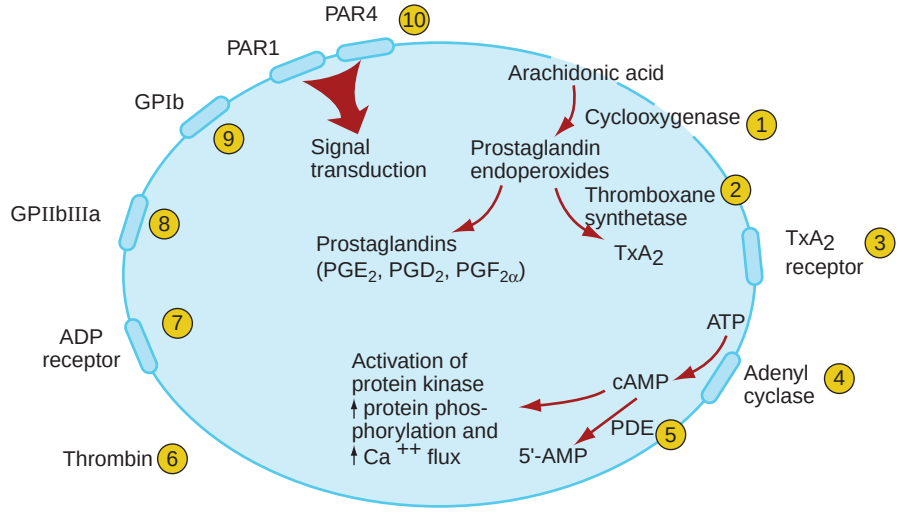

FIGURE 55.3. Targets for antiplatelet agents. This diagram summarizes certain aspects of platelet function relevant to antiplatelet therapy. Platelet metabolic pathways, membrane receptors, and enzymes are depicted with specific therapeutic targets enumerated. Four target categories for antiplatelet drugs are the arachidonic acid pathway, which regulates production of prostaglandins (PGs) and thromboxanes; the cyclic adenosine monophosphate (cAMP) mechanism, which modulates important metabolic events; platelet membrane glycoproteins (GPs), which act as receptors for platelet agonists; and thrombin, a key stimulus to platelet activation. Specific targets for antiplatelet therapies include the following: *(1)* COX is the target of acetylation and irreversible inactivation by aspirin, as well as reversible inactivation by the nonsteroidal anti-inflammatory agents; *(2)* inhibitors to thromboxane synthetase prevent generation of thromboxane A_2 (TxA_2); *(3)* an example of a TxA_2 receptor antagonist is BM 531; *(4)* infusion of PGE_1 or stable analogs of prostacyclin (Iloprost) increases platelet concentrations of cAMP via stimulation of adenylate cyclase; *(5)* dipyridamole increases platelet cAMP concentrations by inhibition of cyclic nucleotide phosphodiesterase (PDE), and cilostazol inhibits PDE3 to increase platelet cGMP concentrations; *(6)* because thrombin is the most potent stimulus to platelet activation, inhibitors of thrombin (heparin, argatroban, and bivalirudin) are important agents in preventing platelet-dependent thrombosis; *(7)* ticlopidine, clopidogrel, prasugrel, and ticagrelor inhibit platelet activation by inhibition of adenosine-diphosphate (ADP)–induced aggregation; *(8)* monoclonal antibodies or peptides directed against the GPIIb–IIIa complex inhibit fibrinogen binding to platelets and subsequent platelet aggregation; *(9)* inhibitors to the von Willebrand factor receptor (GPIb) are being developed to prevent platelet adhesion; and (10) inhibitors to protease-activated receptors 1 and 4 (PAR 1 and 4) such as vorapaxar antagonize thrombin activation of platelets. ATP, adenosine triphosphate. Reproduced and modified from Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524–599.

Aspirin

Aspirin (acetylsalicylic acid) is the prototypical antiplatelet drug, exerting its antithrombotic action by irreversibly inactivating (by acetylation) the COX activity of platelet prostaglandin H synthase-1 (COX-1) and prostaglandin H synthase-2 (COX-2).[347] This COX inhibition leads to the prevention of TxA_2 synthesis and impairment of platelet secretion and aggregation.[348] A variety of nonsteroidal anti-inflammatory drugs can inhibit TxA_2-dependent platelet function via competitive reversible inhibition of COX-1. A lesser degree of COX-1 inhibition may explain why long-term use of nonaspirin nonsteroidal anti-inflammatory drugs is not protective against first MIs in postmenopausal women.[349] Aspirin is the least expensive, most widely studied, and most widely used antiplatelet drug.

Aspirin (when not enteric-coated) is rapidly absorbed from the upper gastrointestinal tract; plasma salicylate concentrations peak within 1 hour of ingestion. The effects of aspirin on platelet function occur within 1 hour and last for the duration of the affected platelets' lifespan (~1 week). The toxicity of aspirin is dose-related, explaining why clinical studies have focused on finding the lowest effective antithrombotic dose of the drug. Toxicities include gastrointestinal discomfort and blood loss, and the risk of systemic bleeding. Clinical trials suggest that aspirin doses as low as 75 mg/day or 30 mg/day are antithrombotic.[343,344]

In addition to reducing aspirin toxicity, lower aspirin doses also inhibit vascular endothelial cell prostacyclin production to a lesser extent, because inhibition of endothelial cell COX is of shorter duration and requires higher aspirin doses than does platelet COX inhibition.[350] The inhibitory effects of chronic low-dose aspirin administration are cumulative.[351] However, even when taken chronically in large doses, aspirin is not believed to be thrombogenic.[352]

The 2012 consensus conference statement on antiplatelet therapy indicates that aspirin has been convincingly demonstrated to be effective in treatment of the following thrombotic disorders: Stable and unstable angina, acute MI, transient ischemic attack and incomplete stroke, stroke after carotid artery surgery, atrial fibrillation (low risk), and prosthetic heart valves (in combination with warfarin).[344] The minimum effective aspirin dose for these indications is 75 to 325 mg/day. Aspirin has also been shown to reduce mortality post-coronary–artery bypass surgery and to be effective for primary prevention of cardiovascular events,[353,354] although more recent meta-analysis data of aspirin use for primary prophylaxis show less-certain benefits.[355]

Data from the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial highlight aspirin's pre-eminent antiplatelet role in cardioprevention.[356] CHARISMA assessed whether adding clopidogrel (75 mg/day) to aspirin therapy (75 to 162 mg/day) provided any benefit over aspirin monotherapy in preventing MI, stroke, or death from cardiovascular disease. The study involved 15,603 patients aged 45 years or older who were at high risk for these events. The study showed that the addition of clopidogrel to aspirin did not result in a significant lowering of risk of the primary composite endpoint. In addition, the rate of severe bleeding was 1.7% and 1.3% for the clopidogrel-plus-aspirin and aspirin-only groups, respectively. Clopidogrel in addition to aspirin did reduce the relative risk of a recurrent MI, stroke, or cardiovascular death by 12.5% in the subgroup of patients with established atherothrombotic disease. The subgroup of patients with multiple risk factors but no clearly established vascular disease did not benefit from the addition of clopidogrel and actually had nonstatistically significant increases in cardiovascular events and bleeding. Clopidogrel plus aspirin remains an approved and standard therapy in conjunction with coronary artery stenting.

Aspirin may modify the natural history of intermittent claudication from lower-extremity arteriosclerosis. Because these patients are at high risk for future cardiovascular and cerebrovascular atherothrombotic events, life-long aspirin therapy is recommended.[357] Similar therapy is advisable after peripheral arterial bypass surgery and carotid endarterectomy.

The Pulmonary Embolism Prevention trial was a large-scale, double-blind, multicenter study of 13,356 patients undergoing surgery for hip fracture and an additional 4,088 patients undergoing elective knee or hip arthroplasty.[358] Patients were assigned to a regimen of 160 mg of aspirin or placebo once daily for 5 weeks, with the first dose given before surgery. Other forms of prophylaxis were allowed, and 40% of patients received unfractionated heparin (UFH) or LMWH in addition to the aspirin. The study demonstrated that aspirin reduced the incidence of fatal PE (58% risk reduction) and symptomatic nonfatal DVT or PE (36% risk reduction) in patients with hip fracture.[358] Although beneficial when compared to placebo, aspirin cannot be recommended as first-line VTE prophylaxis in hip fracture patients, because the benefit of aspirin is less than with anticoagulants.[359] The potential role of aspirin in treating VTE has been resurrected by the results of a VTE treatment trial that demonstrated that aspirin therapy, begun after 6 to 18 months of oral anticoagulant treatment, reduced VTE recurrence by ~40% compared to placebo.[360] Aspirin, used as prophylaxis for VTE recurrence, would have the advantage of being an active drug to also prevent arterial thrombosis.[360a]

The concept of "aspirin resistance" has been popularized. This term refers to persistent platelet activation that occurs in patients treated with aspirin who experience treatment failure. There are numerous reasons for aspirin resistance;[361] current recommendations are to not test routinely for aspirin resistance and to not change therapy based on such test results.[362] One literature review concluded that the most common cause for aspirin resistance was noncompliance.[363] Routine laboratory monitoring for aspirin resistance is not recommended.[364]

Thienopyridines

Ticlopidine and clopidogrel are structurally related compounds that selectively inhibit ADP-induced platelet aggregation and likely ADP-mediated amplification of the platelet response to other agonists.[365] A lack of in vitro platelet aggregation inhibition suggests that in vivo hepatic transformation to an active metabolite is necessary for an antiplatelet effect. Both agents were initially used as aspirin substitutes in aspirin-intolerant patients. Enthusiasm for ticlopidine has been dampened by associated hematologic complications. Ticlopidine has been associated with neutropenia, thrombocytopenia, aplastic anemia, and thrombotic thrombocytopenic purpura.[366–369]

Clopidogrel, an irreversible inhibitor of the $P2Y_{12}$ ADP receptor, is rapidly absorbed and extensively metabolized. The plasma half-life of the main systemic metabolite, SR 26334, is roughly 8 hours.[370] Platelet function returns to normal approximately 7 days after the last dose of clopidogrel. The Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events trial compared clopidogrel to aspirin in patients who had experienced a recent stroke or a recent MI and in those presenting with symptomatic peripheral arterial disease.[371] A modest difference in efficacy was observed. The annual ischemic event rate for aspirin was 5.83% compared to 5.32% for clopidogrel. The majority of the difference in efficacy occurred in the patients who entered the trial because of symptomatic peripheral arterial disease, with a 23.8% relative risk reduction.[371] The Clopidogrel in Unstable Angina to Prevent Recurrent Events trial has demonstrated an advantage of clopidogrel plus aspirin over aspirin alone in patients with acute coronary syndromes.[372] Clopidogrel, like ticlopidine, can rarely precipitate thrombotic thrombocytopenic purpura.[373]

Despite the current standard antiplatelet regimen of aspirin and clopidogrel (with or without glycoprotein IIb/IIIa inhibitors) in percutaneous coronary intervention (PCI) patients, peri-procedural and postprocedural ischemic events continue to occur. Prasugrel, a newer potent thienopyridine $P2Y_{12}$ receptor antagonist, can

achieve more rapid and higher levels of inhibition of ADP-induced platelet aggregation than clopidogrel.[374] However, although a major clinical trial with prasugrel found that it did not reduce overall mortality, it did increase major bleeding (reviewed in Reference 344).

Ticagrelor, a new antiplatelet agent of the cyclopentyltriazolopyrimidine class, reversibly inhibits the $P2Y_{12}$ ADP receptor in platelets.[346] An international trial that compared clopidogrel versus ticagrelor in patients with an acute coronary syndrome found that although the overall trial results demonstrated that ticagrelor was the superior drug, the results for United States' patients showed the opposite, with clopidogrel associated with better outcomes. Major bleeding rates between the two drugs were similar.[346] Perioperative management of patients on antiplatelet therapy has been reviewed.[374a]

Integrin $\alpha_{IIb}\beta_3$ (Glycoprotein IIb/IIIa) Receptor Antagonists

Because of the multitude of pathways that lead to platelet aggregation, it is not surprising that the clinical efficacy of the antiplatelet agents described above is only partial. Even combination therapy with clopidogrel and aspirin, resulting in partial inhibition of TxA_2- and ADP-mediated platelet aggregation, leaves platelets susceptible to agonists such as thrombin and collagen.[341] Because expression of functionally active gpIIb/IIIa on platelet surfaces is the final common pathway of platelet aggregation regardless of initial stimulus, it is logical to target this glycoprotein receptor with antiplatelet agents for maximal platelet inhibition.

gpIIb/IIIa is a member of the integrin family of receptors. These receptors recognize the amino acid sequence arginine–glycine–aspartate (Arg–Gly–Asp [RGD]), which represents the cell attachment regulation sequence present in certain adhesive proteins such as fibrinogen.[375] Inhibitors of fibrinogen binding to gpIIb/IIIa, called the *disintegrins,* include a chimeric monoclonal antibody against the receptor, naturally occurring RGD sequence-containing peptides from snake (pit viper) venoms, synthetic RGD peptides, synthetic Lys–Gly–Asp (KGD) peptides, peptidomimetics, and nonpeptide RGD mimetics.[344,376,377,378]

Three parenteral gpIIb/IIIa inhibitors have been extensively studied, primarily in the settings of PCI, unstable angina, and non-Q–wave MI. These are abciximab, eptifibatide, and tirofiban.[344,346] Abciximab (c7E3 Fab) is a chimeric Fab fragment of human and murine protein that binds to gpIIb/IIIa. Abciximab is unique among the gpIIb/IIIa antagonists because it also blocks the $\alpha_v\beta_3$ receptor.[379] Eptifibatide is a synthetic cyclic heptapeptide with a KGD sequence that is more specific for gpIIb/IIIa than the RGD sequence.[344,376] Tirofiban is a synthetic peptidomimetic based on the RGD sequence.[380] Oral gpIIb/IIIa inhibitors have been generally unsuccessful. Current and emerging antiplatelet therapies have been reviewed.[346]

Anticoagulant Drugs

Anticoagulant drugs are ubiquitous in medical and surgical practice. Anticoagulants are used to prevent and treat thrombosis. Traditionally, short-term anticoagulation is provided in the form of an intravenous infusion or subcutaneous injection whereas more chronic anticoagulation is facilitated by the use of oral agents. However, narrow-spectrum (single-protein–target) oral anticoagulants (e.g., dabigatran, rivaroxaban, and apixaban) are beginning to supplant more broad-spectrum anticoagulants (e.g., heparin and warfarin) and this trend will likely continue. The 2012 version of the American College of Chest Physicians Clinical Practice Guidelines has been published.[381]

Heparin

Heparin is a naturally occurring, highly sulfated glycosaminoglycan that is normally present in human tissues (Fig. 55.4). McLean first isolated heparin from ox liver and identified its anticoagulant properties.[382] Commercial UFH is obtained from either bovine lung or porcine intestinal mucosa and consists of a heterogeneous mixture of polysaccharides (glycosaminoglycans) with molecular weights ranging from 4,000 to 30,000 D, with a mean molecular weight of approximately 15,000 D (approximately 45 saccharide units). UFH molecules possessing anticoagulant activity constitute approximately one third by weight of commercial heparin products.[383] Sodium and calcium salts of heparin are available, and most commercial heparin preparations have specific activities of ~150 U/mg. Heparin structure consists of alternating residues of uronic acid and glucosamine that are variably sulfated.[384] Sulfation of residues in heparin is a major determinant of the anticoagulant activity of a given heparin preparation; the heparin molecules with anticoagulant activity exhibit high-affinity binding to AT.

UFH molecules contain a randomly distributed unique pentasaccharide sequence that binds to AT. Once bound to UFH, the natural anticoagulant effect of AT is potentiated, resulting in the accelerated binding and inactivation of serine proteases in general, and factor Xa and thrombin in particular.[385,386] The inhibition of these factors affects the common pathway of coagulation, resulting in decreased formation of thrombin and fibrin.

Heparin's interaction with AT is thought to occur as follows and is depicted in Figure 55.5. A ternary complex with heparin, thrombin, and AT first occurs; this association permits inactivation of thrombin by the active site inhibitor domain of AT. Lastly, heparin dissociates from the AT–thrombin complex to subsequently catalyze additional AT-mediated reactions.[387] A pentasaccharide series interacts only with the AT-binding sequence and promotes factor Xa inhibition substantially but has minimal effect on thrombin inhibition.[388] In this case, only the conformational change induced by the pentasaccharide is necessary for factor Xa inhibition to occur. Oligosaccharides of greater length (at least 18 residues) are necessary for enhancement of thrombin inhibition by AT. It is likely that in this latter case, a ternary complex of ATIII, thrombin, and heparin forms to mediate protease inhibition.[389] In vitro experiments suggest that UFH exerts its major anticoagulant effect by promoting AT suppression of thrombin-dependent amplification reactions.[390]

In addition to its anticoagulant activity, heparin possesses other, unrelated biologic effects.[391] Heparin hydrolyzes triglycerides

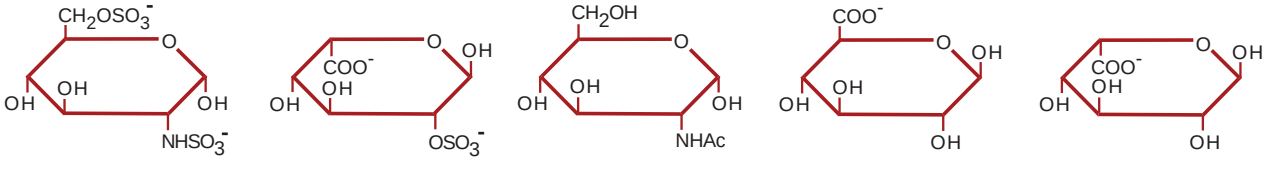

FIGURE 55.4. Structure of the common active saccharide moieties found in commercial unfractionated heparin. These polymeric structures are termed *glycosaminoglycans.* From left to right, the saccharide structures are 2-deoxy-2-sulfamino-α-D-glucose-6-sulfate; α-L-iduronic acid-2-sulfate; 2-acetamido-2-deoxy-α-D-glucose; β-D-glucuronic acid; and α-L-iduronic acid. Reproduced from Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524–599, with permission.

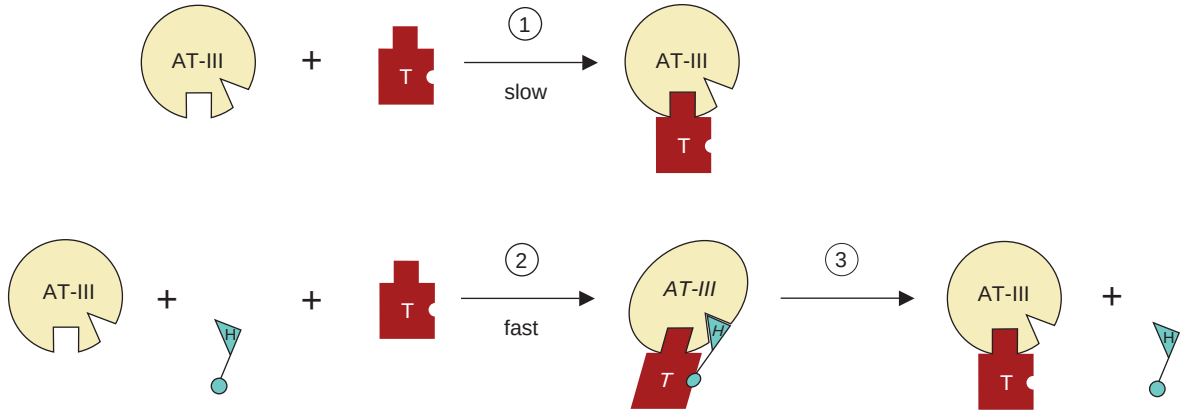

FIGURE 55.5. Inhibition of thrombin activity by the heparin (H)–antithrombin (AT) mechanism. Reaction *1* indicates that in the absence of heparin catalysis, AT can irreversibly inactivate thrombin (T), albeit in an inefficient manner. In the presence of H, a conformation change occurs in the AT molecule, and heparin also acts as a template to bind both AT and T, promoting rapid inactivation of coagulation (reaction *2*). In reaction *3*, heparin is released from the AT–T complex and is available to catalyze subsequent reactions. Inhibition of factor Xa by AT–H does not require binding of heparin to the factor Xa molecule.

from chylomicrons and very-low-density lipoproteins by release of endothelial cell lipoprotein lipase into the blood.[392] Heparin can also activate platelets, suppress cell-mediated immunity, and affect metabolism of aldosterone and thyroxine. Heparin is active when given parenterally, either intravenously or subcutaneously. Because of its highly charged nature and inability to cross biologic membranes alone, oral use of heparin has historically been viewed as impossible. Recently, delivery systems have been developed that make oral heparin a possibility and when sufficient amounts of heparin are administered orally, a prophylactic intensity of anticoagulation can be achieved.[393]

The half-life of heparin varies with the dosage given, with the half-life increasing with increasing dosage.[394] A 100-U/kg intravenous dose is cleared with a half-life of ~1 hour. The clearance of heparin is also affected by the extent of thromboembolism, with extensive thrombosis decreasing heparin half-life.[395] Heparin is cleared by the reticuloendothelial system and metabolized by the liver, and metabolic products are excreted in the urine. The anticoagulant effect of heparin is also altered by its nonspecific binding to plasma proteins and cells.[396] Given these numerous variables affecting the plasma half-life of heparin, therapeutic use of this drug generally requires close laboratory monitoring to ensure attainment of a therapeutic effect and regulation of heparin levels within a targeted range to optimize safety and efficacy. When using intravenous heparin, the use of established nomogram-guided therapy is preferred.[397] Table 55.7 illustrates an example of a weight-based nomogram for using UFH. This assumes that the hospital laboratory has calibrated the aPTT values such that an aPTT range from 1.5 to 2.5 times the mean laboratory control aPTT is equivalent to plasma heparin levels of 0.3 to 0.7 U/ml, as measured by anti–factor Xa activity.[397]

Pharmacologic reversal of UFH anticoagulant activity can be achieved with protamine sulfate. Protamine is a positively charged moiety derived from salmon sperm that can interact with the negatively charged UFH to form a stable complex that lacks anticoagulant activity. One milligram of protamine can inactivate ~100 U of UFH. Protamine, in excess, can promote an anticoagulant state. Because of a clinically meaningful risk of anaphylaxis, protamine should be administered with caution and is normally reserved for use in case of life-threatening bleeding or UFH overdose and reversal of anticoagulation following cardiopulmonary bypass.

An additional challenge to the use of heparin to prevent and treat thrombosis is heparin resistance. "True" heparin resistance manifests as inadequate anticoagulant and antithrombotic responses from what would otherwise be perceived as an adequate, and probably weight-based, dose of heparin. Some have deemed a requirement of >35,000 U of heparin per 24-hour period, regardless of patient weight, to reflect this form of heparin resistance.[398] With true heparin resistance, both a measurement of anticoagulant activity such as the aPTT and a measurement of antithrombotic activity such as the anti–factor Xa activity assay demonstrate inadequate degrees of heparin activity. True heparin resistance most likely results from the nonspecific binding of heparin to mononuclear white cells, vascular endothelial cells, and acute-phase proteins such as histidine-rich glycoprotein, vitronectin, and PF4, resulting in an inadequate quantity of free or AT-bound heparin.[396] Another potential cause of heparin resistance is acquired AT deficiency such as can be seen in cancer patients.

Patients can also manifest an "apparent" heparin resistance characterized by dissociation between the aPTT and heparin assays.[398] In these patients, the aPTT may be normal or near normal, whereas the anti–factor Xa activity assay reveals an appropriate target heparin activity level between 0.3 and 0.7 U/ml. Simply escalating the dose of heparin to achieve the desired aPTT without checking a heparin assay may result in a pronounced bleeding risk. Dissociation between the aPTT and

TABLE 55.7

WEIGHT-BASED NOMOGRAM OF UNFRACTIONATED HEPARIN (UFH) IN TREATMENT OF VENOUS THROMBOEMBOLISM

Initial UFH Bolus	80 U/kg
Initial UFH infusion rate	18 U/kg/h
Check aPTT after 6 h of IV infusion; modify infusion rate as follows:	
If aPTT<1.2 × control, repeat bolus (80 U/kg) and increase infusion rate by	4 U/kg/h
If aPTT is 1.2–1.5 × control, repeat bolus (40 U/kg) and increase infusion rate by	2 U/kg/h
If aPTT is 1.5–2.3 × control, no change	—
If aPTT is 2.3–3.0 × control, decrease infusion rate by	2 U/kg/h
If aPTT >3 × control, hold infusion for 1 h, then decrease infusion by	3 U/kg/h

aPTT, activated partial thromboplastin time.

heparin concentration likely reflects elevated levels of factor VIII that can shorten the in vitro aPTT without affecting the antithrombotic actions of the drug.

Low-molecular-weight Heparins

LMWH is derived from the enzymatic or chemical cleavage of UFH to produce a mixture of low-molecular–weight glycosaminoglycan molecules with a mean molecular weight of ~5,000 D (~15 saccharide units).[396] For example, enoxaparin sodium is produced by benzylation followed by alkaline hydrolysis, dalteparin sodium is produced by controlled nitrous acid depolymerization, and tinzaparin sodium is produced by enzymatic digestion with heparinase. LMWH binds AT via the same pentasaccharide sequence as UFH.[396] However, because of the predominance of molecules <18 saccharide units in length, LMWH has limited anti–thrombin (IIa) activity compared to its anti–factor Xa activity. Whereas UFH has an anti–factor Xa to anti-IIa activity ratio of 1:1, LMWHs have reported ratios of 1.9:1 to 4.1:1.[396] Because of limited thrombin inhibition, LMWH therapy cannot be monitored using the aPTT. Other differences between LMWH preparations include the degree of TF pathway inhibitor release, degree of sulfation, and degree of stimulated vWF release.[399–401] These differences form the basis for many medical organizations' stating that LMWHs are unique drugs and not therapeutically interchangeable.[402–404]

At low doses, subcutaneous LMWH has 90% bioavailability, compared to 30% for UFH. LMWHs have limited nonspecific binding to plasma proteins and platelets, endothelial cells, and macrophages compared to UFH, as well as a predictable clearance and a longer half-life that facilitates once- or twice-daily administration.[396,405] Unlike UFH, the half-life of LMWH is not dose-dependent.[396] These characteristics make LMWH preferred in settings that may normally result in heparin resistance. These advantages of LMWH allow these drugs to be given subcutaneously, once or twice daily and without the need for laboratory monitoring.[396] Similar to UFH, absolute contraindications for LMWH include active bleeding, HIT, or a history of HIT, and known sensitivity to LMWH, UFH, or pork products.

LMWHs have substantial renal clearance; therefore, multiday therapeutic use of LMWH in patients with significant renal insufficiency (creatinine clearance <30 ml/minute) should be avoided.[406] In the setting of less severe renal insufficiency, LMWH should be used with caution and with a reduced dosing frequency. Only ~60% of LMWH anticoagulant activity can be reversed after the administration of protamine sulfate.[407] Table 55.8 summarizes the LMWH products available in the United States and their properties and U.S. Food and Drug Administration (FDA)-approved indications.

Heparinoids

Heparinoids are low-molecular–weight glycosaminoglycans that are not derived from heparin. Heparinoids include dermatan sulfate and danaparoid sodium. Dermatan sulfate and low-molecular–weight dermatan sulfate act as anticoagulants by activating HCII.[408,409] Danaparoid sodium is a glycosaminoglycan mixture derived from porcine intestinal mucosa and composed of heparan sulfate (84%), dermatan sulfate (12%), and chondroitin sulfate (4%).[410] Danaparoid has an anti–factor Xa activity to anti-IIa activity ratio of greater than 22:1 (compared to a 1:1 ratio for heparin), which explains why it is minimally neutralized by protamine sulfate.[410]

The largest collection of clinical experience with danaparoid is in the setting of HIT. Danaparoid may cross-react with 10% to 50% of HIT sera, but in vivo cross-reactivity, although reported, has not been commonly observed.[411,412] Danaparoid has a relatively long half-life of ~24 hours, which may make its use less desirable in patients at high risk for developing bleeding or those likely to need surgery. Significant experience exists with the administration of danaparoid by both intravenous and subcutaneous routes. Danaparoid anticoagulation is monitored using an anti–factor Xa activity chromogenic assay calibrated with danaparoid standards. The drug is approved for deep vein thromboprophylaxis after orthopedic surgery at a dose of 750 U anti-Xa twice daily by subcutaneous injection. A common dose for the treatment of active thrombosis in patients with normal renal function is 1,500 U as an intravenous bolus followed by 1,500 U subcutaneously twice daily. The target therapeutic anti–factor Xa activity is 0.5 to 0.8 U/ml. Danaparoid's potential for cross-reactivity and the longer half-life make it less desirable than a direct thrombin inhibitor (DTI) for the treatment of patients with HIT.[396] The manufacturer of the drug has discontinued availability of danaparoid in the United States.

Pentasaccharides

Because factor Xa is situated at the start of the common pathway of coagulation and upstream of thrombin in the cascade, it is an attractive target for new anticoagulants. By not directly inhibiting thrombin activity, factor Xa inhibitors might allow small amounts of thrombin to be generated, facilitating hemostasis and theoretically leading to a more favorable bleeding-risk profile. Fondaparinux is an FDA-approved synthetic pentasaccharide (molecular weight, 1,728 D) that causes selective indirect (i.e., AT-mediated) inhibition of factor Xa.[413] Fondaparinux is administered subcutaneously, has a half-life of ~17 hours, and does not require therapeutic monitoring. Fondaparinux elimination is prolonged in patients with renal impairment. The reduction in clearance increases as the creatinine clearance decreases. Elimination is also prolonged in patients >75 years of age and in those weighing <50 kg. Fondaparinux has been used with success to treat HIT.[414] Fondaparinux is approved for the prevention and treatment of VTE.

A long-acting, hypermethylated pentasaccharide, idraparinux, and a similar compound with a biotin moiety at the reducing end unit allowing for neutralization with avidin, idrabiotaparinux, have a half-life of up to 130 hours, which may facilitate anticoagulation with once-weekly subcutaneous dosing.[415] However, Phase III trials to date have been disappointing. In the VTE treatment studies, idraparinux was less effective than comparators, and in a large atrial fibrillation trial, idraparinux was equally effective as vitamin K antagonists, but caused more bleeding.[416,417]

Parenteral Direct Thrombin Inhibitors

The parenteral DTIs have been studied for use in patients with acute coronary events, but are most widely utilized in patients with HIT. In these patients, elimination of all heparin exposure is the most essential element in the treatment. This includes discontinuing heparin intravenous catheter flushes, prophylactic subcutaneous heparin or LMWH, and heparin-coated indwelling catheters. Yet, despite heparin discontinuation and platelet count recovery, patients with isolated, serologically confirmed HIT have up to a 50% risk of developing a confirmed thrombotic event during the 30-day period after heparin cessation.[418] The persistent prothrombotic tendency associated with HIT and the patient's original indication for heparin therapy warrant use of an alternative anticoagulant agent such as the DTIs after heparin cessation (Table 55.9).

Hirudins

Hirudin, a polypeptide originally isolated from the salivary glands of the medicinal leech, directly inhibits thrombin. Two recombinant forms of hirudin, lepirudin, and desirudin, are available for clinical use. Lepirudin is a recombinant hirudin analog that received FDA approval in 1998 for anticoagulant treatment in patients with HIT in the setting of thromboembolic disease to

TABLE 55.8

LOW-MOLECULAR-WEIGHT HEPARIN AND POLYSACCHARIDE PRODUCTS AVAILABLE IN THE UNITED STATES

Low-Molecular-Weight Heparin	Approved Indications	FDA-Approved Dosage Regimen
Dalteparin (Fragmin®)	DVT/PE prophylaxis for abdominal surgery	2,500 U SC daily, starting 1–2 h before surgery and continued 5–10 d postoperatively.
		High-risk patients (e.g., malignancy): 5,000 U SC daily, starting the evening before surgery and continued for 5–10 d postoperatively. Or, give 2,500 U SC 1–2 h before surgery, then give 2,500 U SC 12 h later, and 5,000 U SC daily for 5–10 d postoperatively.
	DVT/PE prophylaxis for hip replacement surgery	Preoperative start, evening before surgery: 5,000 U SC daily, starting 10–14 h before surgery. The usual duration is 5–10 d postoperatively, although 14 d has been studied. Allow 24 h between doses.
		Preoperative start, day of surgery: 2,500 U SC within 2 h before surgery, then 2,500 U SC 4–8 h after surgery, then 5,000 U SC daily postoperatively. The usual duration is 5–10 d postoperatively, although 14 d has been studied. Allow at least 6 h between the first postoperative dose and the next postoperative dose.
		Postoperative start: 2,500 U SC 4–8 h after surgery, then 5,000 U SC daily. The usual duration is 5–10 d postoperatively, although 14 d has been studied. Allow at least 6 h between the first postoperative dose and the next postoperative dose.
	DVT/PE prophylaxis in medical patients with severely restricted mobility due to acute illness	5,000 U SC daily for 12–14 d.
	Prophylaxis of ischemic complications of non-Q–wave myocardial infarction in patients on concurrent aspirin therapy	120 U/kg SC every 12 h for 5–8 d, given concurrently with aspirin 75–165 mg/d PO. Do not exceed 10,000 U/dose. Continue until patient is clinically stabilized.
	Prophylaxis of ischemic complications of unstable angina in patients on concurrent aspirin therapy	120 U/kg SC every 12 h for 5–8 d, given concurrently with aspirin 75–165 mg/d PO. Do not exceed 10,000 U/dose. Continue until patient is clinically stabilized.
	Extended treatment of DVT/PE in cancer patients	200 U/kg SC daily (max. 18,000 U) for 1 mo, then 150 U/kg SC daily (max. 18,000 U) for 5 mo
Enoxaparin (Lovenox®)	DVT/PE prophylaxis for abdominal surgery	40 mg SC daily, starting 2 h before surgery. The usual duration is 7–10 d postoperatively, although 12 d has been studied.
	DVT/PE prophylaxis for hip replacement surgery	30 mg SC every 12 h, starting 12–24 h after surgery. The usual duration is 7–10 d postoperatively, although 14 d has been studied.
		An alternative regimen is 40 mg SC daily, starting 9–15 h before surgery and continued for 3 wk.
	DVT/PE prophylaxis for knee replacement surgery	30 mg SC every 12 h, starting 12–24 h after surgery. The usual duration is 7–10 d postoperatively, although 14 d has been studied.
	DVT/PE prophylaxis in medical patients with severely restricted mobility due to acute illness	40 mg SC daily. The usual duration is 6–11 d, although 14 d has been studied.
	Treatment of DVT with or without PE (inpatient therapy) in patients starting on warfarin sodium	1 mg/kg SC every 12 h, or 1.5 mg/kg SC daily (at the same time each day). Start warfarin when appropriate (usually within 72 h of starting enoxaparin). Continue enoxaparin for at least 5 d, until INR is therapeutic; usually an additional 7 d is needed, although up to 17 d may be required.
	Treatment of DVT without PE (outpatient therapy) in patients starting on warfarin sodium	1 mg/kg SC every 12 h. Start warfarin when appropriate (usually within 72 hr of starting enoxaparin). Continue enoxaparin for at least 5 d, until INR is therapeutic; usually an additional 7 d is needed, although up to 17 d may be required.
	Prophylaxis of ischemic complications of non-Q–wave myocardial infarction in patients on concurrent aspirin therapy	1 mg/kg SC every 12 h given concurrently with aspirin 100–325 mg/d PO. The usual duration is 2–8 d, although up to 12.5 d has been studied.
	Prophylaxis of ischemic complications of unstable angina in patients on concurrent aspirin therapy	1 mg/kg SC every 12 h given concurrently with aspirin 100–325 mg/d PO. The usual duration is 2–8 d, although up to 12.5 d has been studied.
Fondaparinux (Arixtra®)	DVT/PE prophylaxis following abdominal surgery	2.5 mg SC daily, starting 6–8 h after surgery. The usual duration is 5–9 d, although up to 10 d has been studied.
	DVT/PE prophylaxis following hip replacement surgery	2.5 mg SC daily, starting 6–8 h after surgery. The usual duration is 5–9 d, although up to 11 d has been studied.
	DVT/PE prophylaxis following hip fracture surgery	2.5 mg SC daily, starting 6–8 h after surgery. The usual duration is 5–9 d, although up to 11 d has been studied.
	DVT/PE prophylaxis following knee replacement surgery	2.5 mg SC daily, starting 6–8 h after surgery. The usual duration is 5–9 d, although up to 11 d has been studied.
	Treatment of DVT and PE in patients starting on warfarin sodium	5 mg SC daily for patients <50 kg, 7.5 mg SC daily for patients 50–100 kg, or 10 mg SC daily for patients >100 kg. Start warfarin when appropriate (usually within 72 h of starting fondaparinux). Continue fondaparinux for at least 5 d, until INR is therapeutic; The usual duration is 5–9 d, although up to 26 d has been studied.

DVT, deep vein thrombosis; INR, international normalized ratio; IV, intravenous; PE, pulmonary embolism; PO, orally; SC, subcutaneously.

TABLE 55.9

COMPARISON OF DIRECT THROMBIN INHIBITORS

Drug Profile	Lepirudin (Refludan)*	Argatroban (Argatroban)	Bivalirudin (Angiomax)
Derivative	Recombinant hirudin	L-Arginine derivative	Synthetic hirudin-based peptide
Action	Direct thrombin inhibitor	Direct thrombin inhibitor	Direct thrombin inhibitor
Clearance	Renal	Hepatic	Renal
Administration	IV (or SC)	IV	IV or SC
Half-life	1.5 hr	40 min	25 min
Monitoring	aPTT	aPTT	aPTT or ACT
Heparin cross-reactivity	None	None	None
Effect on international normalized ratio	Yes	Yes	Yes
Approved for heparin-induced thrombocytopenia	Yes	Yes	Yes
Immunogenic	Yes	No	Unknown

ACT, activated clotting time; aPTT, activated partial thromboplastin time; IV, intravenous; SC, subcutaneous. *No longer available in the U.S.

prevent further thrombosis.[419] Lepirudin differs from native hirudin in that it lacks sulfation on the tyrosine at position 63 and has a leucine at position 1 rather than isoleucine.[420] Lepirudin is a potent DTI that lacks any structural homology with heparin, does not cross-react with heparin, has a short half-life, is able to inactivate clot-bound thrombin, and can be monitored using the ubiquitous aPTT assay or the less readily available ecarin clotting time.[421]

In composite, when compared to historical controls in patients with HIT with associated thrombosis, lepirudin (n = 389 patients, 3 cohorts) demonstrates a relative risk of 0.70 (95% confidence intervals [CIs], 0.27 to 1.8), 0.28 (0.15 to 0.52), and 2.31 (0.94 to 5.71) for limb amputation, new thrombosis, and major bleeding, respectively.[422]

Current lepirudin dosing recommendations are an infusion of 0.15 mg/kg/hour (up to 110 kg) with or without an initial bolus of 0.4mg/kg.[397] The target aPTT is 1.5 to 2.5 times the median value for the normal range. Monitoring during bypass requires performance of the less readily available ecarin clotting time with a target plasma lepirudin concentration of 2.0 μg/ml.[423] The activated clotting time (ACT) and point-of-care aPTT assays do not appear to be suitable for lepirudin therapeutic monitoring.[424] Outpatient subcutaneous lepirudin has been used to treat patients with HIT and thrombosis and patients who are refractory to other anticoagulant therapy.[425]

The major challenges of lepirudin treatment are the lack of an antidote, the extreme care needed when treating patients with even mild renal insufficiency, and immunogenicity. In the event of lepirudin overdose or lepirudin-induced bleeding, infusions of prothrombin complex concentrates or recombinant factor VIIa may help promote hemostasis.[419] High-flux capillary hemodialysis membranes may facilitate the hemofiltration of lepirudin in some cases.[426] Partial-exchange transfusions, plasmapheresis, and immobilized thrombin affinity columns have also been tried to neutralize the effects of lepirudin.[419] Marked bolus and infusion rate reductions are necessary in patients with a creatinine clearance of <60 ml/minute (serum creatinine >1.6 mg/dl). Lepirudin is to be avoided completely or administered with extreme care in the settings of hemodialysis and acute renal failure and in patients undergoing continuous venovenous hemodialysis, even in the setting of a normal serum creatinine. Careful monitoring of both the aPTT and serum creatinine is indicated during lepirudin therapy. Approximately 40% of HIT patients treated with lepirudin develop antihirudin antibodies of the IgG class.[427] The antibodies seem to be capable of decreasing renal elimination of the drug rather than exerting any in vivo neutralizing effect. This paradoxic enhancement of the anticoagulant effect of lepirudin often warrants a significant reduction of infusion rate. Lepirudin is no longer available in the United States.

Desirudin is another recombinant form of hirudin that is approved in the United States for VTE prevention after elective hip replacement surgery. When used for thromboprophylaxis, desirudin is given subcutaneously at a dose of 15 mg twice daily.[397] More recently, a small open-label study comparing desirudin, dosed at 30 mg twice daily, to argatroban in patients with HITT has been reported.[428]

Argatroban

Argatroban is a synthetic, small-molecule, L-arginine derivative that received FDA approval in June 2000 for prophylaxis and treatment of thrombosis in patients with HIT. Argatroban is a rapid and reversible DTI, in contrast to lepirudin, which is an irreversible thrombin inhibitor. Argatroban is capable of inhibiting both free and fibrin-associated thrombin. Argatroban exerts its antithrombotic effects by inhibiting thrombin-mediated reactions including fibrin formation; activation of coagulation factors V, VIII, and XIII; activation of the natural anticoagulant protein C; and platelet activation.[429] Like lepirudin, argatroban does not cross-react with heparin. Argatroban is metabolized by the liver with biliary excretion and has a half-life of only 40 minutes. Renal excretion has also been documented; however, renal impairment has been shown to have little adverse effect on drug clearance and half-life. Unlike lepirudin, argatroban does not require dose adjustment in the setting of renal insufficiency. Dose reduction is required in patients with significant hepatic disease.[429]

In two cohorts (n = 419) of patients with HITT treated with argatroban and compared to historical controls who were followed for 37 days, the relative risk for death due to thrombosis, limb amputation, new thrombosis, and major bleeding was 0.12 (95% CI, 0.05 to 0.34), 1.26 (95% [CI]; 0.53 to 2.99), 0.45 (95% [CI];0.28 to 0.71), and 3.70 (95% [CI]; 0.52 to 26.5), respectively.[422]

Argatroban is dosed based on patient weight. The recommended starting intravenous infusion rate is 2 μg/kg/minute with a target aPTT of 1.5 to 3.0 times the baseline value. Therapy may also be monitored by whole-blood ACT and the ecarin clotting time. Like lepirudin, argatroban prolongs the PT as well as the aPTT. This PT prolongation makes determination of an accurate INR during conversion to oral warfarin therapy a challenge. Holding the infusion of either DTI for several hours before INR determination is prudent. Argatroban has been shown to provide adequate anticoagulation with minimal bleeding risk while enabling procedural success in HIT patients undergoing PCI.[430] Patients were given a 350-μg/kg bolus of argatroban followed by 25 μg/kg/minute infusion titrated to achieve an ACT of 300 to 450 seconds. This dosing regimen may provide satisfactory anticoagulation during cardiopulmonary bypass and allow intraoperative dose adjustments based on the readily available ACT.

Bivalirudin

Bivalirudin is a semisynthetic, bivalent DTI consisting of a dodecapeptide analog of the carboxy-terminus of hirudin.[431] Bivalirudin has four glycine residues that connect the thrombin exosite 1 and thrombin active-site moieties. After binding to bivalirudin, thrombin cleaves a Pro–Arg bond at the amino-terminus of the molecule, making it a reversible thrombin inhibitor. The short half-life of bivalirudin (~25 minutes) may enhance its safety profile. Bivalirudin is used primarily during PCIs, in which it has been

shown to be at least as effective as heparin with gpIIb/IIIa inhibition, but with an improved safety profile.[432,433] Bivalirudin has also been evaluated in patients presenting with acute coronary syndromes as an alternate to heparin.[434] In patients with moderate- or high-risk acute coronary syndromes who were undergoing invasive treatment including gpIIb/IIIa inhibition, bivalirudin was associated with rates of ischemia and bleeding similar to those in heparin-treated subjects. However, bivalirudin alone was associated with similar rates of ischemia and significantly lower rates of bleeding compared to heparin plus gpIIb/IIIa blockade.[434] Bivalirudin has also been evaluated for the management of patients with HIT, especially those requiring cardiac surgery. The currently recommended dose of bivalirudin is a bolus of 0.75 mg/kg followed by an infusion of 1.75 mg/kg/h for the duration of the procedure.[397] Bivalirudin is also recommended for anticoagulation in managing hemodialysis patients with HIT.[422]

Warfarin

In the 1920s, cattle developed a bleeding disorder when they were fed spoiled sweet clover. Campbell and Link later identified the active agent as bishydroxycoumarin (dicoumarol).[435] Drugs that inhibit the biosynthesis of the vitamin-K–dependent coagulation proteins are derived either from 4-hydroxycoumarin or 1,3-indanedione. Although the indanediones are used in Europe, a coumarin derivative, warfarin, is the major formulation used in the United States. Warfarin inhibits γ-carboxylation of select glutamic acid residues in the N-terminus of prothrombin and factors VII, IX, and X, as well as the vitamin-K–dependent natural anticoagulants, protein C and protein S.[436] Warfarin inhibits the two enzymes critical for the generation of reduced vitamin K, namely, vitamin K epoxide reductase and vitamin K reductase.[437,438] Reduced vitamin K is necessary for catalyzing γ-carboxylation of glutamic acid residues. Inhibition of γ-carboxylation by warfarin leads to synthesis of incomplete, hypofunctional coagulation proteins that are unable to bind to cellular surfaces to mediate coagulation reactions. The effect of warfarin on vitamin-K–dependent procoagulant protein production is depicted in Figure 55.6. Details of vitamin K metabolism are presented in Chapter 18.

Commercially available warfarin is a racemic mixture of levorotatory and dextrorotatory forms of the drug. The half-life of warfarin in blood is ~36 hours.[439] Laboratory monitoring of warfarin therapy is best done using functional coagulation tests, such as the PT. Plasma warfarin levels are most useful in evaluating the unusual patient who does not respond to standard warfarin dosages or in whom malabsorption, noncompliance, or inherited drug resistance is an issue.[438,440]

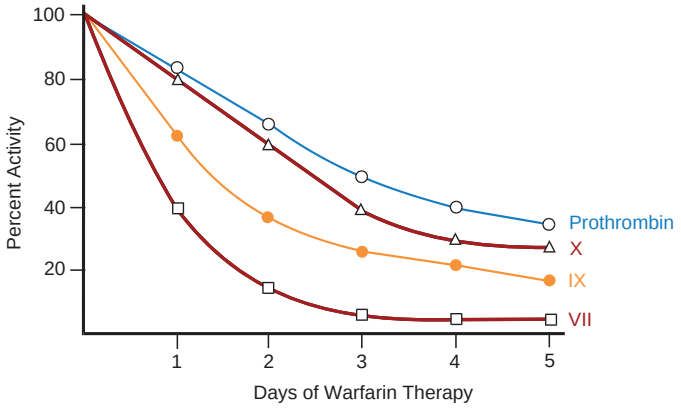

FIGURE 55.6. Effects of standard warfarin therapy on the plasma vitamin-K–dependent procoagulant coagulation proteins. Administration of 5 to 10 mg daily of warfarin results in inhibition of synthesis of functional vitamin-K–dependent proteins. The coagulant activity of these proteins in plasma declines as a function of their half-life. Half-lives of factors VII, IX, and X and prothrombin are 6, 24, and 40 and 60 hours, respectively. Although 1 to 2 days of warfarin prolongs the PT assay (because of the rapid decrease in factor VII concentration), therapeutic anticoagulation requires at least 4 to 5 days. Data from O'Reilly RA. The pharmacodynamics of the oral anticoagulant drugs. Prog Hemost Thromb 1974;2:175–213; reproduced from Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524–599, with permission.

Because factor X and prothrombin have half-lives >2 days, reduction of all vitamin-K–dependent coagulation proteins into the therapeutic range (~20% of normal) requires 4 to 5 days of therapy.[441] This is the basis for the "parenteral anticoagulant overlap" period of 4 to 5 days during which patients receive therapeutic parenteral anticoagulant while waiting to achieve the therapeutic effects of warfarin.[442] An animal study indicated that depression of both factor X and prothrombin levels by warfarin was important in the prevention of hypercoagulability.[441]

Warfarin dosage is influenced by numerous variables, including the patient's age, body mass, dietary stores of vitamin K, liver function, co-existing medical disorders, concurrent medications,[443] and presence or absence of cytochrome P-450 complex (CYP2C9) and vitamin K epoxide reductase complex subunit 1 (VKORC1) single-nucleotide polymorphisms that affect coumarin metabolism or sensitivity.[444–446] Patients with liver disease, malnutrition, or other factors associated with sensitivity to warfarin should receive lower warfarin dosages. The most common adverse interaction of warfarin use occurs in a patient with marginal dietary vitamin K intake (postoperative state) who is given a broad-spectrum antibiotic, reducing enteric bacterial synthesis of vitamin K, resulting in increased sensitivity to warfarin.[438] Starting warfarin therapy early after heparin therapy (day 1 or 2) has many advantages, including earlier hospital discharge on adequate oral anticoagulation and potential reduction in the incidence of HIT.[447] The metabolism of warfarin may be affected by other drugs metabolized by the cytochrome P-450 enzyme complex, drugs that displace albumin-bound warfarin into the circulation, drugs that impair gastrointestinal absorption, and many antibiotics that alter the natural flora of the colon (an endogenous source of vitamin K)[438,443] (Table 55.10).

Certain genotypes for CYP2C9 and VKORC1 have a significant effect on the pharmacokinetic and pharmacodynamic response to warfarin dosing, respectively. Although there is a clear gene–dose relationship, it is uncertain if the routine use of genotype-guided warfarin dosing improves clinical outcomes.[446] Yet, as clinical dosing algorithms are increasingly refined, the prospects for warfarin pharmacogenetics increase.[448] Clinical outcome trials are underway to determine definitively the role of genetic testing in routine warfarin therapy.

Certain patients may require very large doses of warfarin (>50 mg/day) to achieve therapeutic anticoagulation; the term *warfarin resistance* has been applied.[440] Patients who are difficult to anticoagulate with warfarin, either because they exhibit warfarin resistance or because they are very sensitive to the drug and cannot be safely regulated, may be candidates for long-term parenteral anticoagulants, or a novel oral anticoagulant.

Laboratory Monitoring of Warfarin Therapy

The PT assay is useful to monitor warfarin therapy, because this assay measures three vitamin-K–dependent coagulation proteins: Factors VII, X, and prothrombin. The PT is particularly sensitive to factor VII deficiency; with a half-life of 4 to 6 hours, the factor VII level may drop rapidly after only 1 day of warfarin therapy and prolong the PT value. However, because the other vitamin-K–dependent proteins have longer half-lives, therapeutic anticoagulation takes 4 to 5 days. There is no advantage to giving larger loading doses of warfarin (e.g., >10 mg); this regimen only results in a more rapid drop in factor VII levels, delay in attainment of a stable PT, a precipitous fall in protein C levels, and predisposition to warfarin-induced skin necrosis.[439,449,450]

To understand current recommendations for monitoring warfarin therapy, it is important to appreciate the concept of the INR,

Data from the 2003 Physicians' Desk Reference. Montvale, NJ: Thomson Healthcare; Hirsh J, Dalen JE, Anderson DR, et al. Oral anticoagulants: mechanism of action, clinical effectiveness, and optimal therapeutic range. Chest 2001;119(Suppl):108S–121S.

a method that standardizes PT assays.[438,451] An international reference thromboplastin preparation has been adopted by the World Health Organization (WHO). Each new commercial thromboplastin is calibrated against the primary WHO reference preparation. These results are used to calculate the relative sensitivity of the unknown preparation compared with the WHO standard (international sensitivity index [ISI]). The method to determine the ISI for a particular thromboplastin is depicted in Figure 55.7. By adjusting for the ISI of a particular thromboplastin, an INR, defined as the PT ratio that would have been obtained if the WHO standard thromboplastin had been used, can be determined. The INR is calculated using the following formula: $\text{INR} = (\text{PT ratio})^{\text{ISI}}$ (Fig. 55.8).

The American College of Chest Physicians' consensus panel recommends low-intensity warfarin therapy (INR, 2.0 to 3.0) for all indications except prosthetic mechanical heart valves and prophylaxis of recurrent MI, for which higher-intensity warfarin therapy (INR, 2.5 to 3.5) is suggested.[438]

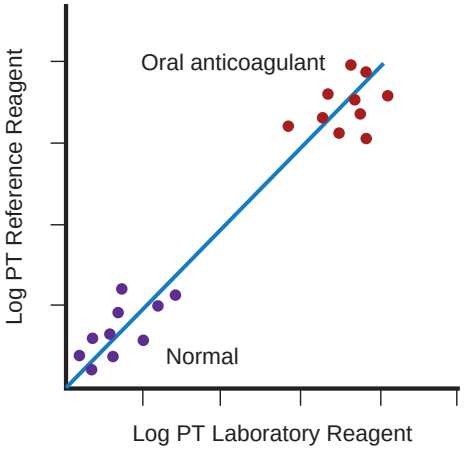

FIGURE 55.7. Method for determination of an international sensitivity index (ISI) value for a laboratory's thromboplastin preparation. Log prothrombin time (PT) values are determined using a reference thromboplastin reagent and the commercial laboratory thromboplastin reagent on patients receiving stable (2 weeks) oral anticoagulant therapy and a group of normal, untreated volunteers. The best-fit line is determined, and the slope of this line multiplied by the ISI of the reference thromboplastin reagent is the ISI value for the commercial thromboplastin reagent. From Rodgers GM. Laboratory monitoring of anticoagulant and fibrinolytic therapy. In: Kjeldsberg C, McKenna R, Perkins S, et al., eds. Practical diagnosis of hematologic disorders, 2nd ed. Chicago, IL: ASCP Press, 1995:745–755, with permission.

Adverse Effects of Warfarin Therapy

Bleeding. A direct relationship exists between the risk of bleeding and the intensity of anticoagulation, with patients receiving higher-intensity (INR > 3.0) therapy having a fivefold greater risk of bleeding.[452] Other major factors contributing to bleeding include co-existing conditions such as structural gastrointestinal lesions, hypertension, renal disease, and cerebrovascular disease.[453,454] Investigation of patients who experience visceral bleeding while on warfarin therapy often results in identification of structural disease.[455] Highest bleeding rates occur early in the course of warfarin therapy and in patients with cerebrovascular disease.[456,453] For patients given low-intensity warfarin therapy for prophylaxis of VTE, the risk of major bleeding is <1%. Antiplatelet medications or other drugs

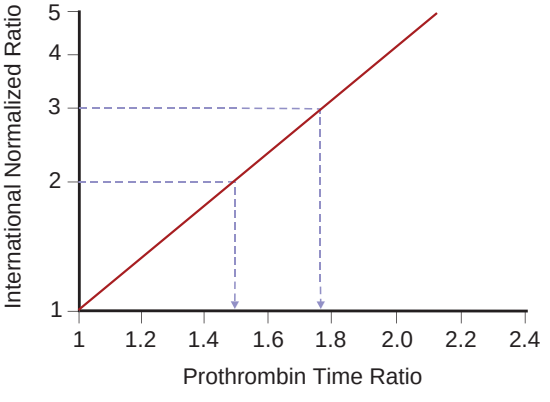

FIGURE 55.8. Relationship between a patient's prothrombin time (PT) ratio on warfarin therapy and the corresponding international normalized ratio (INR) value. The slope of the line represents the international sensitivity index (ISI) value of the particular thromboplastin preparation used in the laboratory's PT assay. In this example, for low-intensity warfarin therapy (INR 2.0 to 3.0), a PT ratio between 1.50 and 1.75 would be required. Thromboplastins with higher ISI values would have slopes greater than that shown and would be less sensitive reagents for the PT assay, whereas thromboplastins with lower ISI values would have slopes less than that shown (more sensitive reagents). From Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524–599, with permission.

that potentiate warfarin activity are important contributors to bleeding (Table 55.10).

Treatment strategy of bleeding in patients receiving warfarin depends on several factors: The duration of expected warfarin therapy, the severity of bleeding, and the extent of INR elevation. Patients with minor bleeding (bruising, microscopic hematuria) and an INR of <6.0 can have warfarin withheld until the INR approaches the desired INR target. Warfarin can then be resumed at a lower maintenance dosage. If patients have visceral bleeding that is not immediately life threatening, their coagulopathy can be reversed with vitamin K, 2.5 to 10 mg, IV or PO. Patients with significant emergent bleeding should be reversed with fresh-frozen plasma (4 to 5 U) or prothrombin complex concentrates in addition to parenterally administered vitamin K. If the INR < 10 and no clinical bleeding exists, several warfarin doses should be held and the INR reassessed; the routine administration of vitamin K in these patients does not lead to improved outcomes and is not recommended.[438,457] For an INR > 10 in patients without bleeding, oral vitamin K can be given (2 to 10 mg) and repeated at 12- to 24-hour intervals, depending on posttreatment lNR values and the patient's clinical condition. Failure of vitamin K to correct the coagulopathy suggests that another process is present, such as liver disease or DIC. The management of warfarin overdosage and reversal has been reviewed.[438]

Patients who ingest rodenticides that contain long-acting vitamin K antagonists ("superwarfarins") may require massive daily doses (≥100 mg) of vitamin K to correct the coagulopathy, for periods of weeks to months (see Chapter 54).

For patients on long-term warfarin therapy who require temporary interruption for procedures or elective surgery, an individualized risk–benefit assessment should be performed to determine the need for bridging therapy with a parenteral anticoagulant during the period of interruption (i.e., when warfarin is discontinued 4 to 5 days before surgery; Table 55.11). Postoperatively, heparin or LMWH can be used to achieve anticoagulation overlap until re-initiation of therapeutic warfarin has been achieved; however, in most cases after a major surgical procedure, the use of therapeutic-dosed parenteral anticoagulants should be avoided in the first 48 to 72 hours postoperatively due to a high risk of bleeding.[458,459,460,461]

Nonhemorrhagic adverse effects of warfarin therapy include alopecia, gastrointestinal discomfort, rash, and liver dysfunction.[453] A warfarin embryopathy can occur when pregnant mothers receive warfarin during the first trimester. A bone matrix protein, osteocalcin, is vitamin-K–dependent, and in the presence of vitamin K deficiency induced by warfarin, osteocalcin is synthesized in a nonfunctional manner, resulting in fetal bone malformations.[462] Additional fetal abnormalities have been noted when warfarin is used during pregnancy. Because of these fetal risks, most practitioners avoid warfarin during pregnancy.[463]

Warfarin-induced Skin Necrosis. Skin necrosis is an unusual but devastating complication of warfarin therapy, occurring within the first week of initiating therapy. Affected patients have usually received large loading doses of warfarin, perhaps in the absence of therapeutic heparin anticoagulation. The basis for this complication is thought to be a warfarin-induced rapid reduction in protein C levels in patients with a pre-existing inherited protein C deficiency that results in a hypercoagulable state and thrombosis. Not all heterozygous protein-C–deficient patients receiving warfarin experience this complication, and not all patients with this complication have protein C deficiency.

Clinically, the skin lesions begin on certain subcutaneous areas of the body (breasts, abdomen, thighs) as erythematous patches.[464] Lesions progress to blebs followed by demarcated skin necrosis. Skin biopsy reveals generalized thrombosis of skin vessels. This complication may require amputation, plastic reconstructive surgery, or both. The use of standard maintenance doses of warfarin (5 to 10 mg/day) beginning after patients are therapeutically anticoagulated with heparin may avoid this complication. Patients who experience warfarin-induced skin necrosis should be heparinized, warfarin should be discontinued, and vitamin K should be administered promptly.Patients experiencing this complication should be screened for protein C deficiency. A few cases of warfarin-induced skin necrosis have been reported in protein-S–deficient patients.[465] A literature review of warfarin-induced skin necrosis found that warfarin therapy could be reinstituted in affected patients; smaller initial doses of warfarin were recommended.[466]

The "purple toe syndrome" is an uncommon disorder that has been described in patients with underlying atherosclerotic vascular disease who are receiving anticoagulants including warfarin therapy.[467,468,469] These patients present with atheroembolic symptoms including ischemic toes (purple toes), livedo reticularis, gangrene, abdominal pain, or symptoms of renal infarction. Involved visceral organs include the kidneys, pancreas, spleen,

TABLE 55.11

GENERAL APPROACH TO PERI-PROCEDURAL ANTICOAGULATION FOR PATIENTS ON LONG-TERM WARFARIN THERAPY

	Indication for Warfarin		
Thromboembolic Risk Group	**Mechanical Valve**	**Atrial Fibrillation**	**Venous Thromboembolism (VTE)**
High Management strategy: Bridge(caution in postoperative dosing)	Mitral Older generation Recent stroke	$CHADS_2$[a] Score = 5–6 Stroke past 3 mo Rheumatic valve disease	VTE past 3 mo Severe thrombophilia
Intermediate Management strategy: Bridge (caution in postoperative dosing)	Bileaflet aortic valve + stroke risk factors	$CHADS_2$ Score = 3–4	VTE past 3–12 mo Thrombophilia Recurrent VTE Active cancer
Low Management strategy: No Bridge	Bileaflet Aortic valve No stroke risk factors	$CHADS_2$ Score = 0–2 (and no prior stroke)	VTE past > 12 mo and no other risk factors

[a]CHADS2 stroke score is calculated by adding one point for each of: congestive heart failure, hypertension, Age > 75 years old, diabetes and 2 points for prior stroke. Adapted from Douketis JD, Spyropoulos AC, Spencer FA, et al. Perioperative management of antithrombotic therapy: antithrombotic therapy and prevention of thrombosis, 9th ed: American college of chest physicians evidence-based clinical practice guidelines. Chest 2012;141(2):e326S–e350S.

and liver. This complication may be difficult to distinguish from warfarin-induced skin necrosis, except that on biopsy, cholesterol emboli are present in the purple toe syndrome, and widespread vascular thromboses are seen in skin necrosis. Treatment involves prompt recognition of the syndrome and discontinuation of warfarin therapy.[470]

Novel Oral Anticoagulants. Warfarin has substantial limitations including inter- and intrapatient dosing variability, drug–drug and drug–diet interactions, and a narrow therapeutic index. These limitations necessitate routine laboratory monitoring and dose adjustment that can be cumbersome for some patients. An oral anticoagulant that is safe and effective, has predictable pharmacology, has few drug–drug and drug–dietary interactions, and does not require laboratory monitoring has the potential to revolutionize the chronic management of patients with atrial fibrillation, prosthetic heart valves, and recurrent venous thrombosis as well as facilitate better compliance with out-of-hospital thromboprophylaxis regimens. Over the past 5 years, there has been a rapid emergence of such novel oral anticoagulants (NOACs) into the clinical landscape. At the forefront are the oral DTI dabigatran etexilate and the oral factor Xa inhibitors (e.g., rivaroxaban, apixaban, and edoxaban). Tables 55.12 and 55.13 summarize the properties of the NOACs that are currently available for clinical use and the comparative results of large-scale studies in patients with atrial fibrillation, respectively.[471] It is important to note that numerous additional agents are also currently under investigation.[471]

Dabigatran Etexilate

Dabigatran etexilate is an oral prodrug that is rapidly converted by serum esterases to dabigatran, a potent univalent DTI. Oral bioavailability is ~6% to 7%, and uptake is reduced by proton pump inhibitors and delayed with food; however, these kinetic alterations are not thought to be clinically significant and do not require dose adjustments. Peak dabigatran serum levels occur ~2 hours after an oral dose; dabigatran is primarily eliminated by renal clearance, and has a half-life of ~14 to 17 hours.[471] Although a reduced dose has been approved for use in the United States by the FDA for patients with a creatinine clearance of less than 30 ml/minute, this recommendation is solely based upon drug kinetic modeling, and the drug is contraindicated in patients with a clearance <15 ml/minute.[472] A reduced dose should also be considered for frail elderly patients with a reduced creatinine clearance; however, no dose reduction is needed at any age for patients with normal renal function. Strong p-glycoprotein inhibitors (e.g., quinidine, ketoconazole) and inducers (e.g., rifampin, St John's Wort) affect serum levels. Because of the predictability in dose-response, laboratory monitoring is unnecessary. If, however, laboratory assessment is required (e.g., need for urgent surgery or management of bleeding) a normal aPTT, thrombin time, or ecarin clotting time suggest little drug activity is present. Conversely, the INR is insensitive to the presence of dabigatran and is not a useful test for drug presence.[473] Table 55.14 suggests a management approach to patients requiring temporary interruption of anticoagulation for an invasive procedure. As with all anticoagulants, the primary adverse effect of dabigatran is an increase in bleeding risk. In addition, dabigatran is associated with an increased risk of dyspepsia, and in some clinical trials has been associated with higher gastrointestinal bleeding rates and myocardial ischemia events as compared to warfarin.[473] In cases of overdose, the rapid administration of charcoal may decrease absorption, and hemodialysis can remove 60% of plasma drug levels.[474] Management of bleeding is problematic as there is no known reversal agent. Patients who have bleeding on dabigatran should be managed with aggressive conservative measures including active control of bleeding site. In cases of life-threatening bleeding, the administration of recombinant factor VIIa or activated prothrombin complex concentrates can be tried, although their utility is unproven.[473]

To date, dabigatran etexilate has undergone extensive clinical investigation in the RE-VOLUTION program, a large clinical trials program assessing the efficacy and safety of dabigatran across a variety of indications. For a recent and thorough survey of clinical trial results, we refer the reader to a recent review.[473] Based upon the results of the RE-LY trial, dabigatran etexilate is currently approved in the United States for the prevention of stroke and systemic embolism in patients with atrial fibrillation.[475] In RE-LY, 18,113 patients with nonvalvular atrial fibrillation and at least one additional stroke risk factor were randomized to receive warfarin or dabigatran dosed either 110 mg or 150 mg twice daily. Dabigatran dosed at 110 mg twice daily was demonstrated to be noninferior to warfarin (RR, 0.91; 95% [CI], 0.74 to 1.11; $p < 0.001$), and dabigatran dosed at 150 mg twice daily was demonstrated to be superior to warfarin (RR, 0.66; 95% [CI], 0.53 to 0.82; $p < 0.001$) in preventing the primary outcome of stroke or systemic embolism. As compared to warfarin, major bleeding, the primary safety outcome, was less common in the 110–mg twice–daily dabigatran group (RR, 0.80; 95% [CI], 0.69 to 0.93; $p = 0.003$), but was similar when compared to the 150–mg twice–daily dose (RR, 0.93; 95% [CI], 0.81 to 1.07; $p = 0.31$), but hemorrhagic stroke was lower for both dabigatran doses.[475] Using a composite of adverse clinical events (stroke, systemic embolism, MI, death, PE, and major bleeding), dabigatran was clearly superior for those patients on warfarin who have a time in TTR of less than 57.1% whereas benefit was less certain in those with a TTR of >72.6% with hazard ratios of 0.67 (95% CI, 0.56 to 0.80) and 1.11 (95% CI, 0.91 to 1.35), respectively.[476]

Pfizer), edoxaban (Daiichi), betrixaban (Portola), and TAK-442 (Takeda).[471] Currently, rivaroxaban and apixaban are the most advanced in their clinical trials programs and are approved for use in the European Union, Canada, or the United States.

Rivaroxaban is a reversible small molecule direct factor Xa inhibitor that binds to and inactivates both fluid-phase factor Xa as well as factor Xa associated with the prothrombinase complex. Rivaroxaban has an oral bioavailability of ~60% to 80%, with peak levels achieved 2 to 3 hours after an oral dose. The drug is metabolized in part by both CYP3A4-dependent and CYP3A4-independent pathways, and has an elimination half-life of ~7 to 11 hours.[471] The kidneys eliminate approximately 35% of active drug as well as inactive metabolites. Potent combined P-gp and CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, lopinavir/ritonavir, ritonavir, indinavir/ritonavir, and conivaptan) and inducers (e.g., carbamezapine, phenytoin, rifampin, St John's Wort) should be avoided in patients on rivaroxaban because they can significantly increase or decrease plasma drug concentrations, respectively.[477]

Rivaroxaban is currently approved for the prevention of VTE in patients undergoing elective joint replacement surgery, the prevention of stroke and systemic embolism in patients with nonvalvular atrial fibrillation, and the treatment of VTE.[477] In the RECORD trials, rivaroxaban (10 mg daily) was compared to enoxaparin for thromboprophylaxis in patients undergoing elective joint replacement surgery. In a pooled analysis, the combined endpoint of symptomatic VTE and mortality occurred less often in patients receiving rivaroxaban (1.3% vs. 0.6%, $p < 0.001$), whereas clinically relevant bleeding was more frequent (2.6% vs. 3.3%, $p = 0.026$).[478] The ROCKET-AF trial was a large (n = 14,000) double-blind, noninferiority, randomized trial comparing rivaroxaban (20 mg daily in patients with normal renal function and 15 mg daily in patients with a creatinine clearance of 30 to 49 ml/min) to adjusted-dose warfarin (target INR 2 to 3) in patients with atrial fibrillation who were at an increased risk of stroke or systemic embolism.[479] Rivaroxaban met the prespecified endpoint of stroke/systemic embolism occurrence with a HR of 0.88 (95% CI 0.74 to 1.03, $p < 0.001$ for noninferiority), had similar rates of major bleeding (HR 1.04, 95% CI 0.9 to 1.2, $p = 0.58$), and less intracranial hemorrhage (HR 0.67, 95% CI 0.47 to 0.93, $p = 0.02$).[479]

Apixaban is a reversible, small molecule, direct factor Xa inhibitor that, as does rivaroxaban, binds to and inactivates both fluid-phase as well as clot-bound factor Xa. Apixaban has an oral bioavailability of >45%, achieves peak levels ~3 hours after an oral dose, has an elimination half-life of ~8 to 14 hours, and

is eliminated via multiple mechanisms. Similar to rivaroxaban, potent inhibitors of CYP3A4 (e.g., ketoconazole, itraconazole, lopinavir/ritonavir, ritonavir, indinavir/ritonavir, and conivaptan) and inducers (e.g., carbamezapine, phenytoin, rifampin, St John's Wort) should be avoided.[471]

Apixaban has also been studied for thromboprophylaxis, stroke prevention in atrial fibrillation, and VTE treatment. Apixaban is currently approved for use in the European Union, Canada, and approved in the United States for the treatment of non-valvular atrial fibrillation. The AVERROES trial was a large (n = 5,599) double-blind, randomized trial comparing apixaban (5 mg twice daily) to aspirin (81 to 324 mg) in patients with atrial fibrillation who were unsuitable candidates for warfarin therapy. Compared to aspirin, apixaban was more effective and equally safe with a HR of 0.45 (95% CI 0.32 to 0.62, $p < 0.001$) for stroke/systemic embolism occurrence, HR 1.13 (95% CI 0.74 to 1.75, $p = 0.57$) for major bleeding, and a HR 0.85 (95% CI 0.38 to 1.9, $p = 0.69$) for intracranial bleeding.[480] The ARISTOTLE trial was a large (n = 18,201) double-blind, double dummy, randomized trial comparing apixaban (5 mg twice daily) to adjusted dose warfarin (INR 2 to 3) in patients with atrial fibrillation. Compared to warfarin, apixaban was more effective and safer with a HR of 0.79 (95% CI 0.66 to 0.95, $p = 0.01$) for stroke/systemic embolism occurrence, HR 0.69 (95% CI 0.6 to 0.8, $p < 0.001$) for major bleeding, and a HR 0.42 (95% CI 0.3 to 0.58, $p < 0.001$) for intracranial bleeding.[481]

Because of the predictability in dose-response, laboratory monitoring of the oral factor-Xa inhibitors is unnecessary. If, however, lab assessment is required (e.g., need for urgent surgery or management of bleeding), a normal aPTT and a normal INR suggest little anticoagulant presence, although clinical judgment is required. [274a,482] Table 55.14 suggests a management approach to patients requiring temporary interruption of anticoagulation for an invasive procedure. Like all anticoagulants, the primary adverse effect of the factor Xa inhibitors is an increase in bleeding risk. Both rivaroxaban and apixaban have significant protein binding and so are not anticipated to be dialyzable. Management of bleeding in patients on these agents is problematic as there is no known reversal agent. Patients who have bleeding on rivaroxaban or apixaban should be managed with aggressive conservative measures including active control of bleeding site.[474] In cases of life-threatening bleeding, the administration of activated prothrombin complex concentrates may be effective in reversing the effect.[483]

Thrombolytic Drugs

The major reaction of the fibrinolytic (plasminogen) system involves the conversion by PAs of the inactive proenzyme, plasminogen, into the active enzyme, plasmin. Plasmin can degrade fibrinogen, fibrin monomers, and cross-linked fibrin (as found in thrombi) into FDPs. These plasmin-mediated reactions generate many species of FDPs including unique species of FDP such as fragment X from fibrinogenolysis and cross-linked FDPs such as (DD)E- and D-dimer from cross-linked fibrin.[484,485] Knowledge of these reactions is necessary to appreciate the mechanisms of action and limitations of commercial PAs.

A common feature of the management of all thromboembolic diseases is the desire to restore vascular patency in a timely fashion to prevent loss of tissue, organ, and limb function, as well as life. Acute arterial thrombosis warrants an attempt at immediate thrombolysis, whereas venous thrombosis only warrants such intervention in extreme cases. Recognition of the importance of the endogenous fibrinolytic system in limiting the size of hemostatic thrombi, clearing hemostatic thrombi after vascular repair, and preventing pathologic thrombosis has resulted in the development of pharmacologic fibrinolytic (thrombolytic) agents to facilitate rapid restoration of vascular patency. Most thrombolytic agents are recombinant forms of physiologic PAs. The commercially available PAs differ with regard to plasma half-life, fibrin selectivity, primary clinical usage, primary infusion strategy, and immunogenicity. Currently available and investigational PAs and their key characteristics are summarized in Table 55.15.

Most thrombolytic agents are fashioned after endogenous t-PA or urokinase. Traditional thrombolytic drugs include bacteria-derived streptokinase (SK), anisoylated plasminogen SK activator complex, urokinase (two-chain u-PA), and recombinant t-PA (rt-PA). Newer molecules have been and are being developed in an attempt to improve on the traditional agents. Major goals of new thrombolytic agent development include increasing fibrin specificity, theoretically to reduce bleeding complications, prolonging initial plasma half-life to facilitate single- or double-bolus administration, reducing sensitivity to inactivation by PAI-1, and improving production efficiency. New thrombolytic agents include mutants of PAs, chimeric PAs, conjugates of PAs with monoclonal antibodies, and novel PAs from animal or bacterial origin. Non-PA thrombolytic agents that can degrade fibrin and/or fibrinogen directly (e.g., microplasmin, alfimeprase, and ancrod) are also under investigation.

TABLE 55.15

PROPERTIES OF CURRENTLY AVAILABLE AND INVESTIGATIONAL THROMBOLYTIC AGENTS

Thrombolytic Agent	Molecular Weight (Daltons)	Plasma Half-life (Minutes)	Key Properties
Streptokinase	47,000	20 (drug); 90 (lytic effect)	Complexes with plasminogen to achieve activity
Anisoylated plasminogen streptokinase activator complex	131,000	40–90	Streptokinase and plasminogen complex
Urokinase	34,000/54,000	15	Direct plasminogen activator derived from fetal kidney cells
Recombinant urokinase	54,000	7	Recombinant high-molecular–weight urokinase
Recombinant prourokinase	49,000	7	Active after conversion to urokinase
Alteplase	65,000	4–8	A recombinant t-PA
Reteplase (recombinant plasminogen activator)	39,000	15	Truncated t-PA with an extended half-life
Tenecteplase	65,000	20 (initial); 90–130 (terminal)	A modified t-PA with an extended half-life, enhanced plasminogen activator inhibitor-1 resistance, and greater fibrin specificity
Desmoteplase (rDSPAα1)	52,000	2.8 h	Highly fibrin specific and lacking in neurotoxic effects of alteplase
Plasmin	85,000	—	Catheter-directed therapy

t-PA, tissue-type plasminogen activator.

Streptokinase

SK is obtained from cultures of β-hemolytic streptococci. By itself, SK has no PA activity, but after combining with plasminogen, a complex is formed that is capable of activating other plasminogen molecules to plasmin.[486] Purified SK has a molecular weight of 47,000 D. SK was the first clinically used thrombolytic agent. It is not fibrin-selective in that its therapeutic use results in systemic fibrin(ogen)olysis and what is termed the *lytic state* from proteolysis of fibrinogen, factors V and VIII, and other plasma proteins.[486] Platelet function may also be perturbed, because plasmin can proteolyze key platelet membrane receptors.[487] Generation of FDPs also contributes to the significant hemostatic defect of thrombolytic therapy. Although the lytic state predisposes patients to bleeding, the benefit of decreased blood viscosity that results from the lytic state may be clinically important. The half-life of SK is ~20 minutes. Because SK is a bacterial protein, it is antigenic, and allergic reactions occur in ~6% of patients. Anaphylaxis during SK use occurs in ~0.1% of patients.[488] Patients previously exposed to SK or those with previous streptococcal infections may acquire antistreptococcal antibody levels sufficient to neutralize the activity of SK. Therefore, all patients receiving SK should be monitored to ensure attainment of the lytic state. This can be done with the thrombin time assay. SK has been used primarily to treat VTE and MI, as well as to treat central venous access-device–associated thrombosis.

Urokinase-type Plasminogen Activator

In the past, u-PA was obtained from human fetal kidney cell cultures. It is currently produced using nonhuman mammalian tissue cultures. Its molecular weight is 34,000 D. u-PA is not fibrin-selective, and this drug also produces a lytic state. The half-life of u-PA is ~15 minutes. u-PA is used to treat VTE, MI, and thrombolysis of clotted catheters.

Tissue-type Plasminogen Activator

Currently, t-PA is produced by recombinant technology as a two-chain species, with a molecular weight of ~65,000 D.[489,490] In vitro, t-PA is fibrin-specific, because of its high affinity for fibrin with which it forms a ternary complex with plasminogen. However, with t-PA dosage regimens currently being used, the lytic state is produced in vivo.[491] Consequently, bleeding complications with t-PA are similar to those with SK or u-PA.[492] The half-life of t-PA is much shorter than that of SK or u-PA, ~5 minutes. t-PA is used to treat VTE and acute MI[492–496] and has also been approved for use in acute ischemic stroke (within 3 hours of stroke onset) and venous catheter withdrawal occlusion.[497] Laboratory monitoring of t-PA therapy is usually not recommended.

Tissue-type Plasminogen Activator Variants

Recombinant PA (r-PA; reteplase) is a nonglycosylated deletion mutant of wild-type human t-PA comprised of only the kringle 2 and the protease domains of the parent molecule. Lack of the finger domain imparts lower fibrin-binding affinity.[498] Lack of glycosylation, a finger domain, and an epidermal growth factor domain impart an extended half-life (15 minutes vs. 5 minutes). The longer half-life allows for double-bolus administration. The longer half-lives of r-PA and TNK–rt-PA compared with t-PA facilitate bolus administration primarily for acute coronary thrombosis.

Other Plasminogen Activators

Recombinant glycosylated prourokinase (single-chain u-PA) has a greater stability than recombinant nonglycosylated prourokinase and has been evaluated for catheter-directed, intra-arterial treatment of stroke.[499] Staphylokinase is produced by *Staphylococcus aureus*. It appears to have substantial thrombolytic activity, but it may also be immunogenic.[500] Vampire bat (*Desmodus rotundus*) salivary PA (rDSPAα1, desmoteplase) possesses >72% primary structure homology to human t-PA but lacks a kringle 2 domain[501] which may impart greater fibrin specificity. Finally, although not a PA, plasmin therapy has been investigated in arterial vascular disease.[471]

Thrombolytic Therapy–Associated Bleeding

Bleeding is the most common complication associated with thrombolytic therapy, regardless of the agent. The bleeding stems from plasmin's inability to distinguish between hemostatic and pathologic thrombi. This complication can range from minor bleeding at an intravenous infusion site to life-threatening hemorrhage.[502] Intracranial hemorrhage is a relatively uncommon but serious complication of thrombolysis in patients being treated for acute MI.

The factors that increase the risk for bleeding during thrombolytic therapy are not fully understood. However, Gurwitz and associates used the National Registry for MI to determine risk factors for this adverse event in individuals treated with t-PA.[503] Their analysis of 673 patients with intracranial hemorrhage indicated that older age, female sex, black ethnicity, systolic blood pressure ≥140 mm Hg, diastolic blood pressure ≥100 mm Hg, history of stroke, t-PA dose ≥1.5 mg/kg, and lower body weight were all significantly associated with an increased risk for intracranial hemorrhage. It is also possible that the properties of the agent used for thrombolysis may contribute to the risk for bleeding complications.

Thrombolytic Fibrin Specificity and Hemorrhagic Risk

Thrombolytic agents can be characterized along a variety of dimensions, but one that is often mentioned is fibrin specificity.[504] The ability of a thrombolytic agent (PA) to distinguish between plasminogen in the general circulation and plasminogen bound to fibrin surfaces dictates its fibrin specificity. Activation of fibrin-bound plasminogen results in the generation of fibrin-bound plasmin that is protected from inactivation by α_2-antiplasmin. Bound plasmin generates soluble fibrin degradation products; circulating plasmin degrades fibrinogen into FDPs. Fibrin specificity differs from fibrin affinity, which is a measure of how avidly a given agent binds to fibrin, but not its specificity for this molecule.[504] At present, there is little evidence to support the view that differences in fibrin affinity among PAs are significantly correlated with either the efficacy or safety of these preparations.[505] High fibrin specificity is thought to be associated with lower risk for hemorrhagic complications in patients undergoing thrombolytic therapy because of the belief that plasmin generated on the fibrin surface of a thrombus restricts its activity only to that surface. This view is not universally supported by available data from large-scale clinical trials.

A relationship between high fibrin specificity and reduced bleeding risk has been demonstrated.[506] The results of the Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT)-2 trial, which included 16,949 patients with acute MI, showed that the use of the highly fibrin-specific thrombolytic agent TNK-tPA, compared with rt-PA, was associated with a significantly lower risk for major noncerebral bleeding.[506] This lower rate of bleeding complications was correlated with a significant reduction in the need for blood transfusions. The ASSENT-2 investigators also reported that TNK-tPA was associated with a significantly lower risk for noncerebral bleeding than the less-specific agent alteplase.[507] Intracranial bleeding rates were comparable with the two agents.

Results from other large-scale studies support the opposing view that high fibrin specificity may actually be associated with increased risk for intracranial bleeding in patients undergoing

thrombolytic therapy for acute MI. For example, the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial showed that the risk of intracranial bleeding was slightly higher in 41,021 patients with MIs who received treatment with rt-PA as compared with SK.[508] These findings are consistent with those from another very large-scale comparison of SK with rt-PA in 20,768 patients with MI (Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico 2 [GISSI-2]), which showed a significantly higher risk of stroke in patients who received the latter, more fibrin-specific agent.[509] Similarly, the Third International Study of Infarct Survival (ISIS-3) showed that treatment of patients with anisoylated plasminogen SK activator complex was associated with increased risk for intracranial bleeding compared with SK in a large cohort of 41,299 patients who received thrombolytic therapy for suspected MI.[510]

There are a number of potential explanations for the association between high fibrin specificity and increased intracranial bleeding observed in the patients treated in the GUSTO, GISSI-2, and ISIS-3 trials. These include the inability of fibrin-specific agents to distinguish between pathologic thrombi and hemostatic thrombi, and the possibility that treatment with fibrin-specific agents resulted in greater degradation of hemostatic fibrinogen and other circulating coagulation factors than SK. Finally, it may be that fibrin-specific therapy resulted in increased production and accumulation of fragment X, and that this enhanced the bleeding risk.[511]

VENOUS THROMBOEMBOLIC DISEASE

VTE, encompassing both DVT and PE is a common disease that carries a substantial risk of morbidity and mortality, is associated with high healthcare costs, and for many patients can be prevented. It has been estimated that between 500,000 and 2 million VTE cases, including calf vein thrombosis, proximal DVT, and PE, occur annually in the United States alone. It is estimated that up to 50% of DVT and PE are asymptomatic or undetected.[512]

The major clinical consequences of extremity DVT include the PTS (chronic swelling, stasis dermatitis, stasis ulceration, and venous claudication: All secondary to venous insufficiency) and PE. The major clinical consequences of PE include acute lung infarction, chronic dyspnea, chronic pulmonary hypertension, and death. DVT restricted to the calf veins uncommonly results in clinically important PE and is rarely associated with a fatal outcome. In contrast, inadequately treated DVT involving the popliteal or more proximal leg veins is associated with a 20% to 50% risk of clinically relevant recurrence and is strongly associated with both symptomatic and fatal PE.[513,514] In untreated patients, death from PE occurs most frequently within 24 to 48 hours of initial presentation. All-cause mortality rates in treated patients with PE is as high as 11% at 2 weeks and 17% at 3 months.[512] Even small PE in patients with emphysema, cardiac disease, or lung involvement with malignancy may result in death. Any VTE in a patient with a contraindication to anticoagulation presents a therapeutic challenge and greater likelihood of adverse outcome.

Management of Venous Thromboembolism

For a majority of patients with VTE, treatment is traditionally straightforward and includes an initial treatment phase (first 5 to 7 days) wherein there is an immediate initiation of a therapeutically dosed parenteral anticoagulant (e.g., heparin or low-molecular–weight heparin) and simultaneous initiation of long-term therapy (e.g., vitamin K antagonist), followed by a long-term treatment phase (from 5 to 7 days to 3 months) where the parenteral anticoagulant is discontinued, and VKA therapy is continued, and then an extended treatment phase (3 months to indefinite) where there is a decision to continue treatment or not.[515,516,517] The emergence of the NOACs will greatly simplify this approach for a majority of patients.

Initial Treatment of Venous Thromboembolism

The mainstay of pharmacologic therapy for VTE is anticoagulation. A delay in achieving therapeutic anticoagulant intensity may have a negative effect on a patient's long-term VTE recurrence rate.[518,519] VKA have a delayed onset of action and the necessity of instituting a rapid-onset parenteral anticoagulant (e.g., heparin) in patients with acute VTE during VKA initiation has been highlighted.[520] As long as warfarin is dosed to a therapeutic level, overlap therapy with heparins can be minimized to 5 days.[517,521,522]

UFH remains the preferred initial parenteral anticoagulant for certain patients with acute VTE such as those with end-stage renal disease. When heparin is used, weight-based dosing (80-U/kg bolus followed by 18 U/kg/hour) with subsequent dose adjustments based on a standardized nomogram (Table 55.7) facilitates achieving a target aPTT.[523] Use of any published nomogram helps facilitate the rapid achievement of target intensity anticoagulation. Adjusted-dose subcutaneous UFH, intermittent intravenous UFH boluses, and fixed dose subcutaneous heparin have also been used effectively in the treatment of VTE.[513,524,525] The therapeutic intensity of UFH is monitored using the aPTT. An aPTT therapeutic range that correlates with an anti-FXa activity level of 0.3 to 0.7 U/ml is preferred.[397] The aPTT should be checked every 4 to 6 hours until the aPTT surpasses the minimum of the therapeutic range.

As compared to heparin, weight-based subcutaneous LMWH is a preferred treatment option for most patients with acute VTE.[517] In 1992 two separate groups of investigators demonstrated that fixed-dose LMWH therapy was at least as safe and effective as adjusted-dose intravenous heparin in patients with proximal vein thrombosis.[526,527] Subsequently, numerous other comparative trials have been performed, and in a meta-analysis of 13 comparative trials Dolovich et al.[528] demonstrated the LMWHs to be comparable to heparin for the initial treatment of VTE with regard to recurrence, major bleeding, and total mortality.[528] Similarly, in a meta-analysis of 2,110 patients who presented with acute symptomatic PE, LMWH were found to be at least as effective (OR for recurrence, 0.68, 95% CI, 0.42 to 1.09) and safe (OR for major bleeding, 0.67, 95% CI, 0.36 to 1.27) as heparin.[529] Enoxaparin sodium is dosed at 1.0 mg/kg body weight every 12 hours or 1.5 mg/kg once daily.[530] Tinzaparin is dosed at 175 U/kg once daily.[517] Dalteparin is dosed at 200 U/kg (up to 18,000 U) once daily. The Matisse trials also support the use of fondaparinux in patients with VTE with efficacy and safety at least as good as LMWH.[517,531]

Efficient initial dosing of VKA therapy in patients with VTE minimizes excessive duration (i.e., beyond 5 to 7 days) of potentially costly parenteral anticoagulants and may allow for shorter hospitalization. The use of standardized warfarin initiation dosing nomograms has been shown to be efficient and safe.[450,532,533] In two separate studies of predominantly inpatients, dosing nomograms using a 5-mg initial dose was compared to 10 mg and shown to be effective in achieving a therapeutic INR within 5 days with less risk of excessive anticoagulation.[450,532] More recently a 10-mg initial VKA dose nomogram in outpatients being treated for VTE had a greater percentage of patients achieving a therapeutic INR by day 5 of therapy with no difference in excessive anticoagulation or adverse events as compared to a lower initial dose.[533] Lower initial doses (e.g., 5 mg or less) may be most appropriate for those patients who are elderly, have low body weight, are on interacting medications, or have poor nutrition, whereas a higher dose (e.g., 10 mg) may be acceptable for others.

The initial treatment of VTE used to be confined to the inpatient setting; however, two clinical trials demonstrated that

outpatient LMWH treatment for carefully selected patients with acute DVT is safe and effective and can lead to substantial cost savings.[534–536] Assuming an appropriate care-delivery system is in place, outpatient DVT treatment has become appropriate for a majority of DVT patients except perhaps, those with massive ileofemoral DVT, a high bleeding risk, or substantial co-morbid illness that otherwise necessitates hospitalization.[537] Appropriate initial site-of-care for patients who present with acute PE is more controversial. Unlike patients with acute DVT, patients with acute PE represent a very heterogeneous risk-group with 3-month mortality rates ranging from 1.4% to 17.4%.[512,538] Standardized clinical assessments, biomarkers, and right ventricular size on imaging can all help to identify patients with a favorable prognosis. For carefully selected, low-risk patients with acute PE, a predominantly outpatient management approach has been shown to be safe and effective.[539]

Anticoagulation Considerations in Special Populations with Venous Thromboembolism

In occasional patients with thrombosis, the aPTT assay may not be reliable in monitoring UFH therapy, for example, patients with the lupus anticoagulant and a prolonged baseline aPTT. For these patients, one option would be to use UFH levels that can be obtained by an automated assay using an anti–factor Xa method. In this instance, the targeted therapeutic range would be 0.35 to 0.7 U/ml. Alternatively, these patients could be given LMWH or fondaparinux, with the dosage determined solely by body weight and no necessity for laboratory monitoring. Patients with marked elevation in factor VIII levels may also be more reliably anticoagulated using LMWH.[400]

Obese patients are underrepresented in VTE treatment trials, and that has led to uncertainty about optimal LMWH dosing in these patients.[540,541] Studies evaluating drug (e.g., dalteparin, enoxaparin, tinzaparin) activity with the use of anti-Xa activity levels, suggest the pharmacodynamics of LMWHs in obese patients (weighing up to 190 kg) are similar to nonobese patients.[542–544] Consequently, weight-based dosing (using total body weight) in obese patients without dose-capping and without anti-Xa monitoring appears appropriate.[397,540] However, due to limited published experience, anti-Xa monitoring with subsequent dose adjustment should be considered in patients at extreme weights, i.e., those patients weighing over 190 kg in whom LMWH are used.[540]

The concomitant presence of renal insufficiency (creatinine clearance [CrCl] <30 ml/minute) is associated with worse outcomes, including fatal bleeding, in patients with VTE.[545] Although inconsistent, the LMWHs have a significant degree of renal clearance with anti-Xa activity levels strongly correlating with CrCl and drug accumulation occurring in those patients with a CrCl less than 30 ml/minute.[397] Clinically, unadjusted LMWH therapy is associated with greater bleeding complications (OR 2.25, 95% CI 1.19 to 4.27) in patients with CrCl <30 ml/min compared to those without renal impairment.[546] Because of potentially worse outcomes with LMWHs in patients with significant renal impairment, weight-based adjusted-dose UFH is recommended over LMWH for VTE treatment.[397,540,541]

Extended Treatment of Venous Thromboembolism

The optimal duration of anticoagulation should be determined for each individual patient. Patients with DVT secondary to a time-limited (transient) risk factor such as recent surgery, immobilization, trauma, or pregnancy may be anticoagulated for a short duration of 3 months, as long as the risk factor has resolved. Patients with recurrent unprovoked VTE (two or more events) or ongoing major risk factors, such as malignancy or antiphospholipid antibody syndrome, require indefinite therapy. Patients with a first unprovoked VTE should be anticoagulated for a minimum of 3 months and consideration should be given to longer duration of therapy.[517] In general, patients with an unprovoked VTE have a risk of recurrence of ~5% to 7%/year after 3 months of therapy if anticoagulation is discontinued.[517] Continuation of anticoagulation beyond 3 months (e.g., 6 or 12 months) reduces this risk as long as the patient remains on anticoagulation, but the heightened long-term recurrence risk remains unchanged once anticoagulation is discontinued. Unfortunately, residual thrombus on repeat imaging and the presence of the most common thrombophilias (e.g., heterozygote factor V Leiden mutation, prothrombin gene mutation, etc.) are only weak predictors of recurrence risk and so their utility in helping to decide whether to continue or stop anticoagulation after the initial 3 months in patients with unprovoked VTE is controversial.[547,548,550] For these reasons, current guidelines suggest extended duration of therapy for patients with unprovoked VTE as long as the predicted long-term bleeding risk is estimated to be low.[517] The use of posttreatment D-dimer to guide the decision to continue or stop anticoagulation after 3 months has potential utility.[551] It is probable that with additional data, D-dimer testing will continue to have an emerging role in helping with duration of therapy decisions in some patients with unprovoked VTE. Guidelines for the duration of anticoagulant therapy are suggested in Table 55.16.

For those patients assigned to extended (e.g., beyond initial 3 months) duration therapy, the intensity of oral anticoagulation has been a subject of controversy. A consensus group concluded that low-intensity oral anticoagulation (INR 1.5 to 2.0) was less effective and no safer than standard-intensity therapy (INR 2.0 to 3.0).[552]

All patients anticoagulated with warfarin should be educated regarding maintaining a stable diet. Patients should be encouraged to consume a constant intake of dietary vitamin K and avoid large variations or fluctuations in their diet. Because of the number of pharmacologic interactions that exist between warfarin and other drugs (Table 55.10), patients should be instructed to inform their physician of the addition or withdrawal of any medication during warfarin therapy. In addition, patients should be encouraged to avoid over-the-counter multivitamin supplements or herbal preparations that contain vitamin K or vitamin K analogs and those known to have an effect on warfarin anticoagulation (e.g., ginkgo biloba). The risk of bleeding during therapy should be explained to all patients. It is strongly recommended that patients avoid high-risk activities, including contact sports. Patients should be instructed to seek medical attention for severe bleeding or bleeding that is not controlled after 10 to 15 minutes of continuous compression. The appropriate use of protective gear, such as bicycle helmets, should be emphasized. Patients should be instructed to carry a wallet card that identifies their use of an anticoagulant. In addition, they should be encouraged to wear a medical identification bracelet or necklace.

TABLE 55.16

DURATION OF ANTICOAGULATION IN VENOUS THROMBOEMBOLIC DISEASE

Disease	Duration
Situational DVT or PE (transient risk factors)	3 mo
Unprovoked DVT or PE	3 mo (minimum)/indefinite
Recurrent unprovoked DVT or PE	Indefinite
DVT with ongoing risk factors[a]	Long-term/indefinite
Massive PE	Long-term/indefinite
Calf vein DVT	3 mo

DVT, deep venous thrombosis; PE, pulmonary embolism.
[a]For example, malignancy, antiphospholipid antibody syndrome, or natural anticoagulant deficiency.

Patient instruction is best provided by anticoagulation clinics that focus specifically on anticoagulation monitoring and education. Studies suggest that anticoagulation services offer better control of anticoagulation (time in therapeutic range, TTR).[553] Point-of-care instruments that can reliably monitor a patient's INR values in the hospital or home setting are being increasingly used.[554] Patient self-testing and self-management of oral anticoagulation therapy have been demonstrated to be effective, but overall impact on clinical outcomes, cost-effectiveness, and patient selection remain incompletely defined.[555–557]

In select cases, LMWH may be used in lieu of oral warfarin for chronic-phase anticoagulation. Because of its teratogenic effects, warfarin therapy is contraindicated in pregnancy, so long-term heparin or LMWH is prudent for pregnant patients; LMWH may be preferred in pregnancy, because osteopenia occurs less often with LMWH than with UFH.[558]

In addition, patients with variable oral intake, episodic vomiting, malabsorption, and difficult to regulate INR values on warfarin may be better served by chronic subcutaneous LMWH administration.

The management, efficacy, and safety of VKA are particularly problematic in cancer patients with VTE.[559] Both recurrent VTE and major bleeding events are significantly more common in patients with cancer compared to those without in the first month of therapy and are not explained by anticoagulant intensity outside the target range.[560] Due to the limitations of VKA in this population, long-term LMWH therapy has been evaluated as an alternative to LMWH followed by VKA in cancer patients with VTE. In the pivotal 2003 CLOT trial, Lee et al. randomized 672 patients with acute proximal DVT, PE, or both to either 6 months of dalteparin (200 IU per kilogram of body weight once daily for 1 month followed by 150 IU per kilogram once daily for 5 months) to 5 to 7 days of dalteparin followed by 6 months of VKA with a target INR of 2.5. During the 6-month study period, recurrent VTE was significantly less common in the long-term LMWH group (hazard ratio 0.48, 95% CI 0.30 to 0.77) without a difference in bleeding events or mortality.[561] In a separate randomized open-label clinical trial comparing usual care to long-term tinzaparin in patients with a proximal DVT in the setting of cancer (n = 200), Hull et al.[562] demonstrated long-term tinzaparin to be associated with fewer recurrent VTE events, 16% versus 7% (absolute risk difference −9%, 95% CI −21.7% to −0.7%).[562] Most recently, a Cochrane meta-analysis of six randomized trials showed that long-term LMWH, compared to usual therapy provided a reduction in VTE (HR 0.47, 95% CI 0.32 to 0.71) with no statistically significant survival benefit (HR 0.96, 95% CI 0.81 to 1.14) or difference in bleeding outcomes (RR 0.91, 95% CI 0.64 to 1.31).[563] From a patient perspective, long-term LMWH therapy is deemed acceptable and is preferable to VKA.[564] Based upon favorable outcomes, long-term LMWH therapy in cancer patients is currently endorsed by numerous practice guidelines as the preferred therapeutic approach in these patients.[517,565,566,567]

Novel Oral Anticoagulants for the Treament of Venous Thromboembolism

Rivaroxaban has recently been approved for VTE treatment, and the continued emergence of the NOACs will likely change the treatment approach for many patients with VTE. Noninferiority trials have compared a single drug treatment approach (e.g., rivaroxaban) or treatment after an initial course of LMWH (e.g., dabigatran etexilate) to standard therapy in patients with acute VTE. Other similar trials evaluating apixaban and edoxaban are near completion. In the EINSTEIN-DVT trial (n = 3449), oral rivaroxaban, 15 mg twice daily for 3 weeks and then 20 mg once daily, was compared to standard therapy in patients with acute DVT.[568] Rivaroxban was demonstrated to have both similar efficacy (hazard ratio for the primary endpoint of symptomatic recurrence was 0.68, 95% CI 0.44 to 1.04) and safety.[568] In a companion study of patients with acute PE, the EINSTEIN-PE trial (n = 4,832), as compared to usual therapy, rivaroxaban was similarly effective and safe, HR 1.12 (95% CI 0.75 to 1.68) and 0.49 (95% CI .031 to 0.79), respectively.[569] In the RE-COVER trial (n = 2,539), patients with acute VTE received either VKA or dabigatran, 150 mg twice daily, after an initial period of parenteral anticoagulantion with LMWH. After 6 months of therapy recurrence, HR 1.10, 95% CI 0.65 to 1.84, and major bleeding, HR 0.82, 95% CI 0.45 to 1.48, were similar.[570]

Calf Deep Venous Thrombosis

Many perceive that calf DVT is of limited clinical significance. This misunderstanding and underappreciation of the potential morbidity and mortality associated with calf DVT have resulted in a lack of clear consensus on the optimal management strategy for this condition. Isolated calf DVT may account for as few as 6.2% of all symptomatic acute DVT and as many as 43.0% of all acute VTE.[571] Studies have also demonstrated that although calf DVT and proximal DVT may be considered separate diseases at their outset, 15% to 25% of calf DVT propagate into the proximal veins within 2 to 3 weeks wherein a risk of embolism ensues.[572–575] Such "proximal conversion" renders what was initially a calf DVT just as dangerous as any proximal DVT.

Whereas the primary goals of proximal DVT treatment include the prevention of DVT recurrence and PE, the most essential goals of calf DVT treatment should be to treat severe symptoms and to prevent early proximal conversion. Current treatment approaches for isolated calf DVT are either to implement the same intensity and duration of anticoagulant therapy as is used for proximal DVT or to implement serial duplex ultrasound surveillance, with therapy begun only in the event of proximal conversion or significant extension. Surveillance consists of serial imaging (e.g., twice weekly) for 2 weeks, the usual period for proximal conversion. The limitations of serial surveillance include cost, compliance, and convenience whereas anticoagulant therapy has limitations of cost, inconvenience, and risk of bleeding. Anticoagulation is preferable for those patients with a low bleeding risk who have severe symptoms or risk factors for extension (thrombus >5 cm, involves multiple calf veins, proximal extent near the calf trifurcation, ongoing underlying risk factors such as immobility or cancer, prior history of VTE, or occurrence without provocation).[517]

Whereas 6 months of anticoagulation has been shown to be superior to 6 weeks' duration of therapy in patients with proximal DVT, the shorter course of therapy has not been shown to be inferior in patients with initial distal thrombosis.[571] In general, calf vein DVT should be treated for 3 months.[517] However, patients with situational calf DVT (DVT with a clear precipitant such as major surgery or hospitalization) can be considered for only 6 weeks of treatment, assuming the precipitating illness or event has resolved. Inferior vena cava (IVC) filter placement is not recommended for calf DVT in most circumstances.

Advanced Therapies for Venous Thromboembolism

Vena Caval Filter

Patients with acute VTE and active bleeding require placement of an IVC filter, as do patients with acute VTE who have failed therapeutic anticoagulation. Relative contraindications to anticoagulation are listed in Table 55.17. It is important to note that active bleeding may be a treatable and transient contraindication to anticoagulation. An IVC filter should not be viewed as an equivalent substitute to anticoagulation in the setting of acute VTE and is certainly not an "insurance policy" against subsequent PE. The use of IVC filters has been associated with an increased

TABLE 55.17

RELATIVE CONTRAINDICATIONS TO ANTICOAGULATION THERAPY

Bacterial endocarditis
Recent organ biopsy or noncompressible arterial intervention site
Recent gastrointestinal or genitourinary bleeding (<10 d)
Thrombocytopenia or marked anemia
History of a bleeding disorder
History of intracranial, spinal, or ocular bleeding
Recent (<2 wk) history of major surgery, stroke, or trauma
Hepatic insufficiency

risk of recurrent DVT, reduced PE, and no difference in overall mortality.[576,577] In patients with filters placed because of bleeding, appropriate anticoagulation should begin as soon as the bleeding source has been properly and completely treated. Because of the significant risk of rebleeding, such a patient should have his or her anticoagulation begun in the hospital. Placement and subsequent removal of a temporary (or retrievable) IVC filter once the contraindication to anticoagulation has passed seems ideal. Placement of an IVC filter because of a "free-floating" DVT may not be necessary in all patients.[578] Guidelines on using IVC filters have been published.[517,579]

Catheter-directed Thrombolysis of Deep Venous Thrombosis

Catheter-directed thrombolytic therapy is usually reserved for patients with extensive DVT involving the IVC or iliac veins and for patients who have signs and symptoms of actual or impending phlegmasia cerulea dolens.[580–585] An initial venogram is performed via a distal vessel, usually a popliteal or foot vein, to delineate fully the extent of the DVT. Access for the vascular access sheath is best accomplished via the popliteal vein, typically using ultrasound guidance to assure nontraumatic, single-puncture catheter placement. A multiple-side–hole catheter is advanced and embedded within the thrombus. Thrombolytic agent is infused through this catheter. At a minimum, low-dose heparin (500 U/hour) should be infused through the sheath to prevent sheath thrombosis. Periodic surveillance with venography should be performed to assess resolution of the DVT. As lysis is achieved, the infusion catheter may require repositioning to maintain infusion within the thrombus.[581]

Lytic therapy for DVT carries the same contraindications as for lysis of PE. Active bleeding is an absolute contraindication to the procedure; relative contraindications include those for any anticoagulant. In addition, a history of contrast allergy or renal insufficiency is a relative contraindication to the procedure. Complications are similar to the complications for PE lysis. The major complication associated with the use of lytic agents is bleeding. Access-site bleeding is the most common complication. Bleeding in the popliteal space may be particularly significant because the popliteal vein is poorly compressible. Additional complications such as intracranial bleeding are also seen with lytic infusion for DVT lysis. PE, potentially fatal, has been reported in patients undergoing DVT lytic therapy.

Only SK has an approved indication for use in lytic treatment of DVT. Urokinase, rt-PA, r-PA, and TNK–t-PA are not approved for DVT lysis. After the completion of thrombolytic therapy, patients should be anticoagulated with an appropriate parenteral agent (UFH, LMWH, or DTI) and converted to warfarin in the usual fashion. Patients who have a contraindication to lysis may be able to derive some benefit from mechanical thrombectomy performed at the time of venography/intervention. However, mechanical thrombectomy should not be attempted in patients with a contraindication to anticoagulation, because any benefit from suction thrombectomy would likely be lost without maintenance of therapeutic anticoagulation.

Benefits of DVT thrombolysis include the ability subsequently to diagnose and treat any underlying venous stenosis, venous compression (as in May-Thurner syndrome), or venous webs that may be discovered after thrombolysis.[582,583] The use of angioplasty, stent placement, or both may improve outcomes in these patients.[584] Most recently, the combined use of localized pharmacomechanical intervention has been demonstrated to reduce subsequent PTS occurrence but increase overall bleeding.[586,587] These more recent findings are important as the primary goal of catheter-based interventions for the management of DVT is to reduce the subsequent occurrence of PTS. PTS develops in up to 50% of patients with symptomatic DVT.[588] Pain, swelling, edema, pigmentation changes, and skin ulcers may occur. PTS results from damage to venous valves by clot, leading to valvular incompetence and venous reflux.[588] Management of PTS involves use of graduated elastic compression stockings[589], and, as discussed, consideration of use of invasive catheter-directed approaches to treat DVT (and prevent PTS); however, consensus opinion currently recommends against the routine use of thrombolytic therapy, and large randomized trials are in progress.[517]

Thrombolysis for Pulmonary Embolism

Most patients with symptomatic PE should be treated solely with anticoagulation. Some patients with PE may derive benefit from thrombolytic therapy to actively degrade the thrombus obstructing the pulmonary vasculature. Clear indications for PE thrombolysis are debatable.[590,591] Thrombolysis has been demonstrated to improve survival in patients with massive PE plus shock and is probably indicated in these patients. When compared to anticoagulation alone, thrombolytic therapy results in more rapid thrombus lysis, an early improvement in pulmonary blood flow, and improvement of right ventricular function.[592] However, these improvements in cardiopulmonary function alone have not resulted in decreased mortality in stable patients without significant hemodynamic compromise. Even in patients with submassive PE, initial thrombolysis with intravenous alteplase did not reduce mortality.[593] It remains unclear whether patients with PE and evidence of right ventricular dysfunction or elevated cardiac troponin levels (or both) benefit from thrombolysis.

Currently approved drug regimens for PE lysis include the following: SK, 250,000-U intravenous bolus over 30 minutes followed by 100,000-U/hour intravenous infusion for 24 hours; rt-PA, 100-mg intravenous infusion over 2 hours; and urokinase, 4,400-U/kg bolus over 10 minutes followed by intravenous infusion of 4,400 U/kg/hour for 12 hours. Reteplase is not FDA-approved for PE management, but when administered as two 10-U boluses separated by 30 minutes, it has been shown to improve pulmonary vascular resistance and blood flow more rapidly than standard-dose rt-PA.[594] Lytic therapy is contraindicated in patients with an increased risk of bleeding. Active bleeding is an absolute contraindication to therapy. In addition, recent organ biopsy or arterial puncture in a noncompressible site and recent cardiopulmonary resuscitation, uncontrolled hypertension, and pregnancy or recent delivery are relative contraindications. For all patients, the potential benefits of lysis must be weighed heavily against the potential risks of bleeding.[595]

Major hemorrhage rates have varied between 4% and 22% in studies at the currently recommended doses. Extrapolation from acute MI thrombolysis trials supports intracranial hemorrhage rates between 1% and 3%, approximately one half of which are

fatal. There is no benefit to lytic infusion via a centrally placed catheter when compared to peripheral infusion in patients with PE. Many believe that heparin should not be administered concomitantly with the lytic agent. An aPTT should be determined at the completion of the lysis; if the aPTT is ≤2.5 times the control, then heparin infusion should be started/resumed. If the aPTT is >2.5 times the control, the aPTT should be repeated every 4 hours; once it decreases into an acceptable range, the heparin infusion may be initiated. If a complication of therapy occurs, the lytic agent and any other anticoagulants should be held. Fresh-frozen plasma and cryoprecipitate may be used to replete fibrinogen and clotting factors. Consideration should be given to the use of antifibrinolytic agents to reverse excessive fibrinolysis.[590,591]

PREVENTION OF VENOUS THROMBOEMBOLIC DISEASE

If physicians focused more on VTE prophylaxis, much less time would be needed to emphasize methods for VTE diagnosis and treatment. Fatal PE is considered to be the most common preventable cause of hospital death.[596] Because the clinical diagnosis of VTE is unreliable and serial surveillance of all high-risk patients is expensive, widespread use of anticoagulants (or other prophylactic measures) has been recommended and is the subject of recent comprehensive practice guidelines by the American College of Chest Physicians.[359,597,598,599]

Optimal delivery of thromboprophylaxis requires an assessment of risk versus benefit, and this is particularly relevant to medically-ill patients wherein the absolute risk of clinically relevant VTE may be less than in patients undergoing major surgical procedures. There is an abundance of literature supporting the benefits of thromboprophylaxis in surgical patients, but the absolute clinical impact in nonsurgical patients is less certain. In a recent meta-analysis by Lederle and colleagues, medically-ill patients who received pharmacologic prophylaxis had reduced incidence of symptomatic PE (number needed to treat 306), but increased bleeding events (number needed to harm 296 for major bleeding), and no reduction in total mortality.[600] Risk assessment, however, is imperfect and can be viewed as group risk (e.g., all orthopedic patients) or individualized risk (e.g., based upon individual patient characteristics). Figure 55.9 illustrates several VTE risk assessment models that have been validated.[601–603] It is important to note that not all patients at risk develop a thrombosis, and not all thromboses result in symptoms, morbidity, or death. The benefit of pharmacologic thromboprophylaxis must always be weighed against the bleeding risk. Patients at high risk for bleeding should still receive prophylaxis in the form of an intermittent pneumatic compression device, thromboembolism-deterrence stockings, or both. Furthermore, prophylaxis strategies must take into account whether a patient has a history of HIT. Figure 55.10 illustrates a general approach to thromboprophylaxis, and Table 55.17 lists relative contraindications to anticoagulant therapy.

Duration of thromboprophylaxis has also received attention. In general, extended prophylaxis (i.e., up to 4 weeks) has been suggested for patients undergoing elective hip arthroplasty, hip fracture repair, and high-risk abdominal-pelvic cancer surgery. Extending prophylaxis in medical patients, however, has not been shown to be effective and is associated with increased bleeding.[604,605]

HEPARIN-INDUCED THROMBOCYTOPENIA

Although bleeding is the most common adverse event associated with heparin and LMWH therapy, HIT, also known as the *white clot syndrome,* is increasingly recognized as a potentially severe, albeit paradoxical, immune-mediated complication of heparin therapy.[606,607] HIT is a "clinical–pathologic" syndrome, meaning that the diagnosis is optimally based on compatible clinical features as well as laboratory assay results positive for heparin-dependent antibodies. Platelet activation occurs in vivo in normal people. This results in release of PF4, a tetrameric platelet α-granule constituent into blood where it may also bind to the external platelet surface. Heparin is a polyanion, i.e., a chain of negatively

FIGURE 55.9. Individualized venous thromboembolism risk assessment models (RAMs). Individualized risk assessment for venous thromboembolism using validated risk assessment models may optimize patient selection and subsequent net benefit of thromboprophylaxis for acutely ill hospitalized patients or those undergoing major surgical intervention. In general, RAMs have a good positive predictive value in identifying high-risk patients, but may be relatively less useful in identifying lower-risk patients. AMI, acute myocardial infarction; BMI, body mass index; CHF, congestive heart failure; CVC, central venous catheter; HIT, heparin-induced thrombocytopenia; IBD, inflammatory bowel disease; ICU/CCU, intensive care unit or critical care unit; LE, lower extremity; OCP/ERT, oral contraceptives/estrogen replacement therapy; SCI, spical cord injury; VTE, venous thromboembolism. FIGURE 55.10. General approach to venous thromboembolism (VTE) prophylaxis in hospitalized patients. Some form of venous thromboembolism risk assessment should be performed in patients admitted to the hospital to identify those patients who are most likely to benefit from thromboprophylaxis. Risk assessment can be either individualized or considering at-risk patient groups (e.g., orthopedic surgery patients). Once risk has been identified, the choice of prophylactic strategy should be based upon the patient's bleeding risk, history of heparin-induced thrombocytopenia, renal function, duration of therapy, and cost. CrCl, creatinine clearance; DTI, direct thrombin inhibitor; HIT, heparin-induced thrombocytopenia; LMWH, low-molecular–weight heparin; ml/min, milliliters per minute; NOACs, novel oral anticoagulants; VKA, vitamin-K–antagonists.

charged oligosaccharides, that can bind to positively charged PF4 tetramers, resulting in heparin-PF4 complex formation that is immunogenic under certain circumstances.[608] Binding of IgG to the heparin-PF4 complex forms an immune complex that triggers cross-linking of the platelet FcγIIa receptor, an event that leads to platelet activation and formation of thrombogenic microparticles.[609] The end result is development of thrombocytopenia in the setting of a profound hypercoagulable state.

HIT typically develops between 5 and 14 days after the commencement of heparin therapy and produces a variable but often moderate degree of thrombocytopenia wherein nadir platelet counts are typically in the range of 60,000/μl and the development of severe thrombocytopenia (<20,000/μl) is unusual.[610–612] A platelet count fall that begins before day 5 of heparin is unlikely to represent HIT except in patients with a recent (within 3 months) heparin exposure.[606] These patients may experience an abrupt onset of thrombocytopenia on re-exposure to heparin as a result of acute platelet activation due to preformed, circulating HIT-associated antibodies. In contrast, delayed-onset HIT represents a clinical challenge as patients may develop thrombocytopenia with or without thrombosis days to weeks after heparin cessation.[613]

Although the exact incidence of HIT has not been well established, HIT has been noted to develop in up to 3% to 5% of patients exposed to unfractionated porcine-intestine–derived heparin.[610] Patients exposed to bovine-lung–derived UFH have been reported to have a greater likelihood of developing HIT than those exposed to porcine-intestine–derived UFH, and UFH induces pathogenic HIT antibodies to a greater extent than LMWH (~5% vs. ~1%, respectively, in orthopedic patients).[614,615] Warkentin et al. evaluated the incidence of HIT in 665 patients randomized to receive subcutaneous UFH or LMWH for venous thromboprophylaxis after elective hip surgery. HIT was diagnosed in 2.7% (9/332) of patients given UFH versus 0% (0/333) of those given LMWH. HIT with thrombosis developed in 88.9% (8/9) of the patients who developed HIT, compared with a thrombosis rate of 17.8% (117/656) in patients without HIT.[606] The clinical setting also influences the frequency of HIT; patients undergoing cardiac surgery who receive UFH have a higher incidence of pathogenic HIT antibodies (2.5%) compared to medical (<1%) or obstetric (<0.1%) patients, and HIT may develop more commonly in women.[614,616]

The most feared complication of HIT is thrombosis. Thirty-six to fifty percent of patients with HIT have been noted to develop life- or limb-threatening thromboses.[610] The thrombotic tendency associated with HIT can last for at least 30 days, and HIT with thrombosis can develop well after the discontinuation of heparin and platelet-count recovery. Venous thrombosis is more common than arterial thrombosis in HIT patients, especially in those who receive UFH for postoperative DVT prevention.[612,617] Extremity DVT is the most frequently encountered venous thrombotic complication in HIT patients, followed in frequency by PE and cerebral sinus thrombosis.[610] Most HIT-associated arterial thromboses involve the extremities, but stroke, MI, and renal artery thrombosis related to heparin infusions have been described. HIT with thrombosis after coronary artery bypass grafting may present as bypass-graft occlusion, left atrial thrombus formation, valvular thrombosis, or PE.[618] Acute graft occlusion secondary to HIT has been described in vascular surgery patients even after platelet-count normalization. It is reasonable to assume that patients with pre-existing vascular lesions, intravascular catheters, sepsis, or postoperative venous stasis are particularly susceptible to the thrombotic complications of HIT.

Other clinical presentations of HIT include heparin-induced skin lesions, heparin "resistance," and adrenal vein thrombosis leading to hemorrhagic infarction.[619,620] Heparin-induced skin lesions have been observed in ~10% to 20% of patients who generate HIT-IgG in response to subcutaneous UFH injections. The skin lesions develop at heparin injection sites and can range from painful red plaques to overt skin necrosis reminiscent of warfarin-induced skin necrosis. Thrombocytopenia may not develop in the majority of patients with heparin-induced skin lesions, but those who develop skin lesions and thrombocytopenia appear to be at extremely high risk for arterial thrombosis. The thrombocytopenia that develops in HIT is not normally associated with hemorrhagic events, and platelet transfusion may exacerbate the HIT-induced prothrombotic tendency.[610]

HIT is primarily a clinical diagnosis. HIT should be strongly suspected in any patient who develops thrombocytopenia while receiving heparin in any dose or by any route of administration. Whereas HIT is usually associated with a platelet count below the lower limits of normal (150,000/μl in most laboratories), the extent of thrombocytopenia is quite variable, and the diagnosis should be strongly considered in any patient in whom the platelet count falls below 50% of the baseline value (even if still within the normal range) after the fifth day of heparin treatment.[610] Similarly, a 30% fall in baseline platelet count combined with any form of thrombosis in a patient receiving heparin should be

considered due to HIT until proven otherwise. Thrombotic events occurring or progressing during therapeutic-intensity heparin therapy, even if the platelet count is normal, may also constitute a HIT variant.[621–623]

Limitations of laboratory assays for HIT (discussed below) have led to development of a clinical scoring system to determine the pretest probability of HIT, in an attempt to identify patients with the likely diagnosis more rapidly. The "4T's" scoring system (Table 55.18) uses easily available clinical information (nadir platelet count, timing of thrombocytopenia, presence or absence of thrombosis, and alternative explanations for thrombocytopenia) to classify patients into high (score of 6 to 8), intermediate (score of 4 to 5), or low (score of ≤3) probability of HIT.[624] Study results indicate that this scoring system has a high negative predictive value. Consequently, a low pretest score may be useful in ruling out an HIT diagnosis.[624] A meta-analysis of clinical trials using the 4T's scoring system found that the negative predictive value of a low probability score was 99.8%.[624a]

The currently available in vitro diagnostic assays for HIT are either immunoassays or functional assays.[625] Immunoassays detect the presence of heparin–PF4 antibodies using ELISA methodology.[626] HIT ELISAs have high sensitivity, but poor specificity for the diagnosis.[627] Most will detect IgG, IgM, and IgA antibodies, but only IgG antibodies are thought to be pathogenic in the disorder. In addition, not all antibodies to the heparin-PF4 complex will induce platelet activation.[627] Recent data indicate that the optimal immunoassay uses ELISA methodology to detect only IgG antibodies.[628] The reliability of an IgG ELISA in diagnosing HIT can be further improved by considering the "positivity" of the result. ELISA optical density results near the upper limit of the normal range (usually ~0.4 O.D. units) are less likely to be associated with clinical HIT than a much higher positive result (≥1.0 O.D. units).[629]

Functional assays detect platelet aggregation or platelet activation after exposure to suspected HIT serum and heparin. Functional assays include the platelet aggregation test, the heparin-induced platelet aggregation test, heparin-induced platelet release of ATP detected by lumi-aggregometry, the ^{14}C-serotonin release assay (^{14}C-SRA), heparin-induced platelet microparticle formation detected by flow cytometry, and enzyme immunoassay detection of platelet serotonin release. Traditionally, the ^{14}C-SRA has been considered the "gold standard" for HIT diagnostic confirmation. However, most studies evaluating the diagnostic use of the available functional assays and immunoassays, including studies of ^{14}C-SRA, used a clinical diagnosis of HIT as the true "gold standard." Also, the SRA is tedious to perform, has a lengthy turnaround time, and is offered by few laboratories. Patients should be assessed clinically (Table 55.18) using the 4T's pretest likelihood scoring system to determine their likelihood of having HIT while awaiting immunoassay results. Those patients with a low pretest likelihood for HIT probably need no further testing or alternative anticoagulation, and an alternate explanation for thrombocytopenia should be pursued. Conversely, patients with a high pretest probability for HIT should receive alternative anticoagulation, and for any positive immunoassay result, no further testing is indicated. Patients with a high pretest probability, but who have negative immunoassay results should be tested with the SRA to confirm or refute a diagnosis of HIT. Patients with an intermediate likelihood of HIT should receive an alternative anticoagulant while awaiting immunoassay results. If the result is strongly positive (e.g., >1 O.D. units), no further testing may be necessary. If the result is negative or only weakly positive, the SRA should be performed to diagnose or exclude HIT definitively. Alternative anticoagulation should be continued while awaiting the SRA results. Figure 55.11 suggests an initial diagnostic and management approach to HIT.

TABLE 55.18

THE 4T'S CLINICAL PREDICTION SCORE FOR THE DIAGNOSIS OF HEPARIN-INDUCED THROMBOCYTOPENIA

4T's	Score = 2 points	Score = 1 point	Score = 0 points
Thrombocytopenia	Platelet count fall >50% and platelet count nadir ≥20,000 and no surgery within preceding 3 d	Platelet count fall 30–50% or platelet count nadir 10–19,000 *or* Platelet count fall >50% but surgery within preceding 3 d	Platelet count fall <30% *or* Platelet count nadir <10,000
Timing of platelet count fall	Onset of fall 5–10 d after heparin start *or* Platelet count fall ≤1 d after heparin start with prior heparin exposure within 30 d	Uncertain as to time course but likely platelet count fall 5–10 d after heparin start *or* Platelet count fall after day 10 of heparin start *or* Platelet count fall within 1 d after heparin start with prior heparin exposure in past 31–100 d	Platelet count fall <4 d after heparin start and no recent heparin exposure
Thrombosis (or other clinical events)	Confirmed new thrombosis *or* Skin necrosis at injection site *or* Acute systemic reaction to IV UFH *or* Adrenal hemorrhage	Recurrent VTE in a patient receiving therapeutic anticoagulation *or* Suspected thrombosis *or* Erythematous skin lesions at heparin injection sites	—
Other cause for thrombocytopenia	None obvious	Possible	Probable/definite (DIC, sepsis, drug-induced, etc.)

Each 4T's parameter is evaluated and scored; patients with scores ≤3 points are at low risk for HIT. Those with scores of 4–5 points are at intermediate risk, and patients with scores of 6–8 points are at high risk of HIT.
DIC, disseminated intravascular coagulation; UFH, unfractionated heparin; VTE, venous thromboembolism.
Data from references 422, 624.

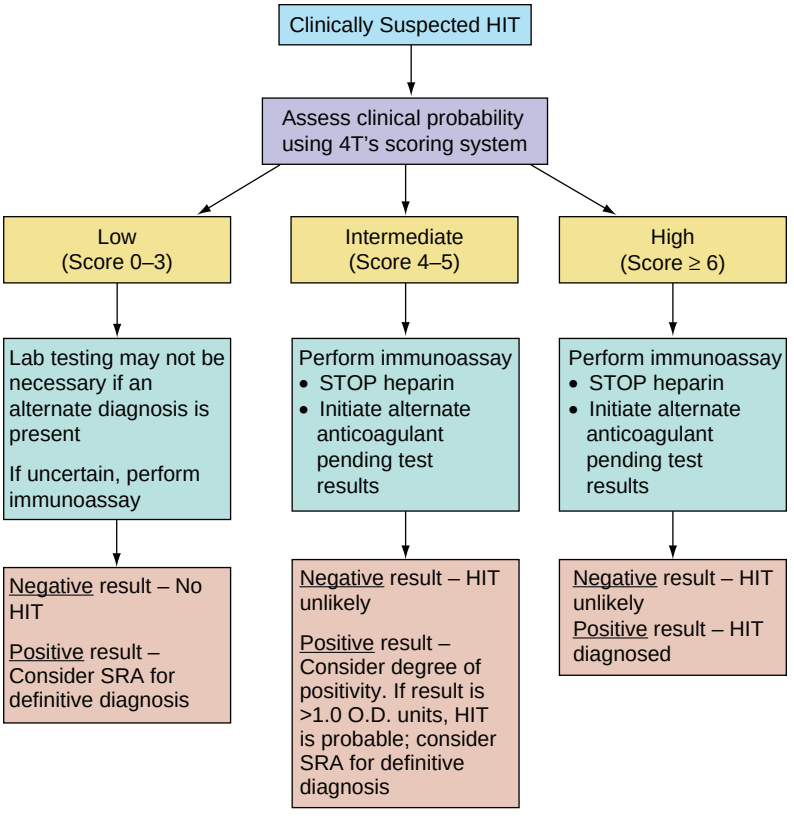

FIGURE 55.11. Initial management of patients with suspected heparin-induced thrombocytopenia (HIT). Patients with suspected HIT should be approached in a rapid and evidence-based fashion, wherein a pretest probability assessment is completed (e.g., using the 4T's scoring system, Table 55.18) and application of an immunoassay test, in particular to those patients at intermediate to high pretest probability. While awaiting immunoassay test results, implementation of an alternative anticoagulant (e.g., direct thrombin inhibitor) is recommended. Patients with discordant clinical probability assessment and immunoassay results or those with intermediate findings should undergo additional testing with a functional platelet activation assay, such as the serotonin release assay (SRA). HIT, heparin-induced thrombocytopenia; O.D., optical density.

The initial treatment of HIT with or without thrombosis is to discontinue all exposure to heparin or LMWHs (including heparin-coated catheters) and immediately begin an alternative anticoagulant, usually a DTI, such as argatroban, lepirudin, or bivalirudin).[422] DTI therapy is continued as monotherapy until normalization of the platelet count, at which time bridging therapy with warfarin is started. Warfarin anticoagulation may be desired for long-term therapy, but should never be used as the sole alternative anticoagulant in patients with HIT. Warfarin treatment is the major factor contributing to limb amputation caused by progression of otherwise unremarkable deep vein thromboses to phlegmasia cerulea dolens in patients with HIT.[630,631] The combination of HIT-associated hypercoagulability and warfarin-induced protein C deficiency most likely produces a profound procoagulant state that causes venous limb gangrene. After both platelet count normalization and subsequent initation of warfarin, both warfarin and DTI are continued for at least 5 days, or until a therapeutic INR (2.0 to 3.0) is achieved on warfarin alone. For isolated HIT without and with thrombosis, respectively, warfarin therapy duration of 4 weeks and 12 weeks is recommended.[422] Fondaparinux has also been used to treat HIT in small case series, but is not approved to treat HIT.[632] Patients should be informed that they should never be exposed to heparin again, although protocols are available in which short-term exposure to heparin can be safely done in patients who require heparin therapy.[633]

Considering the complexity of HIT diagnosis and treatment, HIT prevention must be emphasized. Patients receiving UFH should have platelet-count monitoring at baseline and at least every third day between day 5 and day 14 of heparin exposure. Platelet count monitoring recommendations in patients receiving heparin have been published in the recent ACCP guidelines.[422] Appropriate medical record documentation and patient education should help avert heparin re-exposure in patients with a history of HIT. Re-exposure to heparin in patients with past HIT should be delayed at least 3 months, kept to a minimum duration to provide succinct anamnesis, and avoided whenever possible. LMWH and fondaparinux may be preferable to UFH for both the treatment and prevention of thromboembolic disease because of the greatly reduced likelihood of initiating HIT.[634] For those patients with acute or subacute HIT who require urgent cardiac surgery or PCI, the use of bivalrudin is recommended.[422]

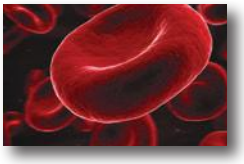
PART VI

Benign Disorders of Leukocytes, the Spleen, and/or Immunoglobins



CHAPTER 56

DIAGNOSTIC APPROACH TO MALIGNANT AND NONMALIGNANT DISORDERS OF THE PHAGOCYTIC AND IMMUNE SYSTEMS

Daniel A. Arber, Thomas L. McCurley, John P. Greer

Cost-effective, efficient evaluation of patients with hematologic diseases is often based on the quality of collaboration between clinicians and pathologists. This has become even more important as the number and complexity of diagnostic tests has exploded. Flow cytometry, cytogenetic, fluorescence in situ hybridization (FISH), and molecular genetic testing present opportunities for improving diagnostic precision but are expensive, and each has its limitations and shortcomings. The goal of this chapter is to guide selection of testing to minimize the cost and time involved in making diagnoses in common clinical problems in hematology.

This chapter introduces an approach to disorders that produce abnormalities of circulating blood cells, constitutional symptoms, or enlargement of lymph nodes or the spleen. The emphasis is on distinguishing benign from malignant disease. The disorders may take the form of (a) immune reactions, particularly infection resulting in changes in blood leukocytes, lymphadenopathy, and/or organomegaly; (b) neoplastic diseases (leukemias, lymphomas, and plasmacytic neoplasms and related diseases); and (c) inherited or acquired diseases that result in immunodeficiency.

APPROACH TO DIAGNOSIS

Patients with disorders of the immune system (innate and adaptive) usually come to medical attention with symptoms and signs suggestive of infection. Many patients with hematopoietic lymphoid neoplasms may also present with fever or other nonlocalizing constitutional signs and symptoms such as fatigue, generalized lymphadenopathy, abnormal bleeding, weight loss, bone pain, arthralgias, and pruritus. Suspicion of an underlying immune disorder, benign or malignant, may be raised during the course of a routine examination or during the evaluation of unrelated disorders by the detection of skin lesions, lymphadenopathy, splenomegaly, or hilar or mediastinal masses. In other instances, routine blood examination may disclose abnormalities in the numbers or morphology of circulating red cells, white cells, or platelets.

A detailed history should be obtained, and a thorough physical examination should be performed. Age of the patient, immunocompetence (focusing on types and number of infections), family history, travel history, animal exposure, history of prior therapy, and drug ingestion are particularly important areas to address. Complete blood cell count (CBC) and blood examination (including morphologic assessment of red cells, white cells, and platelets) may be diagnostic or help determine the next step in diagnosis. Chest x-ray and computed tomography (CT) may assist in identifying possible biopsy sites. Electrophoresis to characterize serum or urine immunoglobulins, marrow examination, lymph node aspiration or biopsy, liver biopsy, and splenectomy with flow cytometry immunophenotyping of blood, marrow, or tissue, may be necessary. In addition, evaluation of delayed type hypersensitivity and tests of neutrophil and/or lymphocyte function may be required. Finally, cytogenetic and molecular genetic testing may be necessary for a complete assessment. Clearly, not all or even most of these tests and surgical procedures are indicated for each patient who has the symptoms or signs described. Rather, a logical sequence is undertaken for each patient, tailored to the particular findings. A diagrammatic summary of a sequential approach is shown in Figure 56.1.

The examination of stained tissues by light microscopy remains the principal means of establishing a diagnosis in most of the benign and malignant conditions considered in Parts VI (Nonmalignant Disorders of Leukocytes, the Spleen, and/or Immunoglobins) and VII (Hematologic Malignancies). Other studies, however, including immunophenotypic studies, cytogenetics, and molecular genetics, are increasingly valuable in making, confirming, and "fine-tuning" diagnoses as well as in defining clinically important subcategories of disease.[1,2]

Flow cytometry has become a primary immunophenotyping method in the diagnosis, classification, and detection of residual disease in patients with hematologic malignancies, and is covered in more detail in Chapter 2. For example, flow cytometry is helpful in the differential diagnosis of reactive and neoplastic lymphoid proliferations, but requires specimens that are submitted fresh or in saline. Figure 56.2 demonstrates the difference between immunoglobulin light chain distribution in a patient with follicular hyperplasia (with polytypic light chain expression) versus a patient with a diffuse large B-cell lymphoma (with monotypic light chain expression). In T-cell neoplasms, the detection of a population of lymphocytes with aberrant phenotypes (e.g., lost or diminished expression of pan T-cell markers) as illustrated in Figure 56.3, is very helpful in detecting abnormal T-cell populations. Flow cytometry is essential for classification of acute leukemia, in part because most diagnostic studies can be completed in less than 2 hours. Additionally, flow cytometry immunophenotyping detects myeloid antigen expression in cases that are myeloperoxidase or Sudan black B negative by cytochemical studies. Finally, flow cytometry can detect aberrant blast cell immunophenotypes, which are useful for the detection of minimal residual disease in post-therapy specimens. The level of detection of minimal residual disease by flow cytometry is well

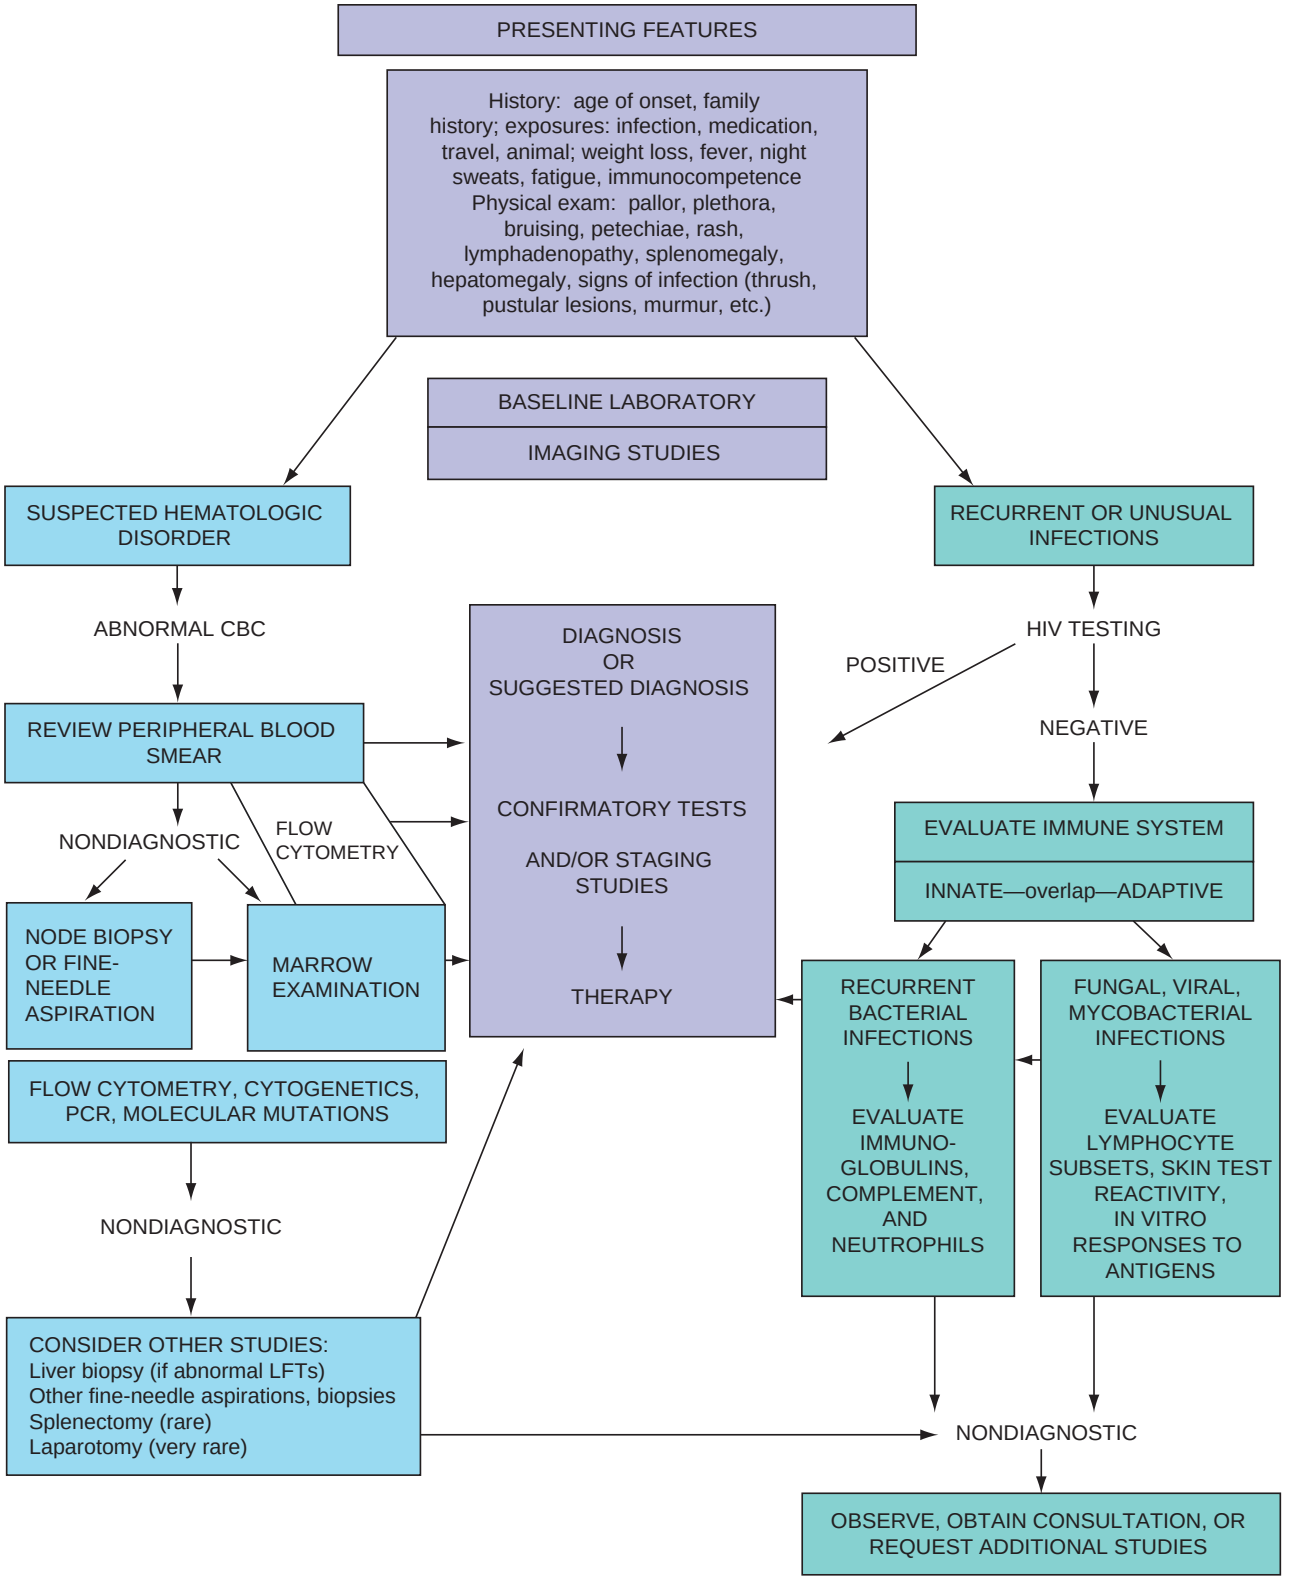


FIGURE 56.1. Diagnostic steps in diseases of the hematopoietic lymphoid system. CBC, complete blood cell count; HIV, human immunodeficiency virus.

below what can be identified by morphologic assessment of aspirate smears. However, flow cytometry does have limitations. It requires fresh or viable tissue and is of less value in the diagnosis of Hodgkin lymphoma (HL), T-cell–rich B-cell lymphomas, and subclassification of reactive processes (see Table 56.1), and may miss some T-cell neoplasms that do not demonstrate aberrant immunophenotypes. Most laboratories do not use methods that are effective in detecting the rare tumor cells of HL, but some studies have used this method effectively and this application of flow cytometry may emerge in the future.[3] Additional applications in morphologically difficult areas such as myelodysplastic syndromes are evolving.

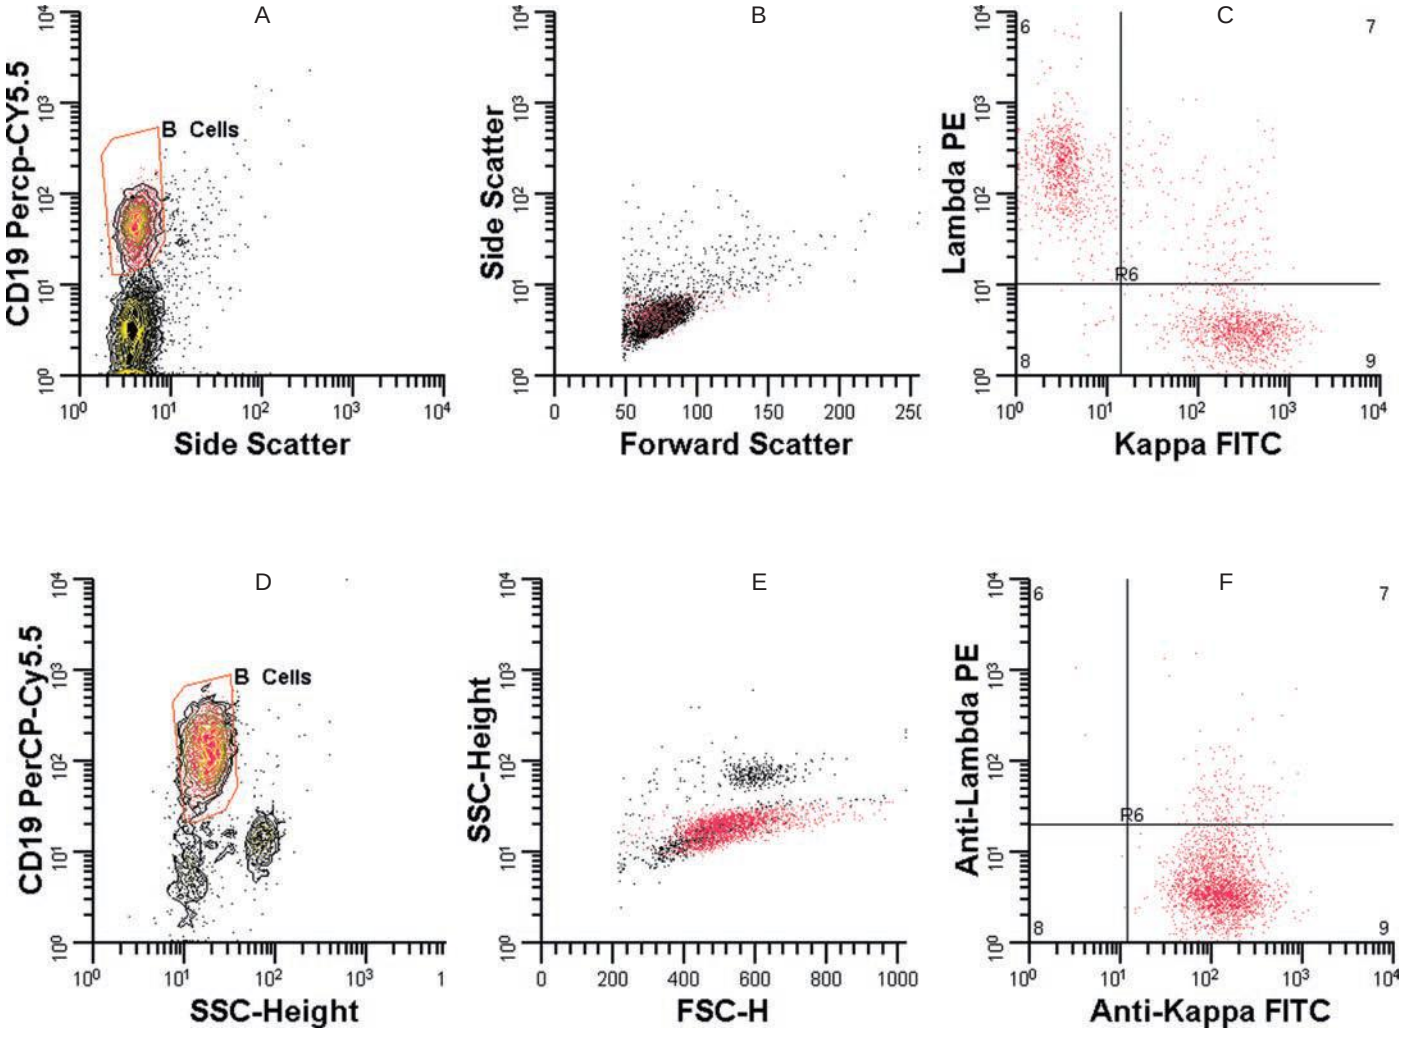

FIGURE 56.2. Flow cytometry of reactive B cells and monotypic B cells. **A:** Histogram (picture) of pan B-cell anti-CD19 antibody expression versus this log side scatter signal (related to cellular complexity), which is used to define and identify the B-cell lymphocytes. **B:** Histogram shows lymphocytes based on forward scatter signal (size) versus log side scatter signal. The red population shows that the $CD19^+$ B cells and predominantly T-cell $CD19^-$ population (*black dots*) are of similar small size. (1) **C:** A two-parameter histogram gating on $CD19^+$ B cells with anti-Kappa fluorescein isothiocyanate (*FITC*) versus anti-lambda phycoerythrin. This pattern, which shows a mix of kappa and lambda, is consistent with a reactive polyclonal B-cell population. **D:** Histogram (picture) of anti-CD19 antibody expression versus log side scatter in a second patient. **E:** Histogram shows lymphocytes based on forward scatter signal versus log side scatter signal. The red population which represents the $CD19^+$ B cells is larger in size than the smaller $CD19^-$ population (*black dots*). **F:** A two-parameter histogram of anti-kappa fluorescein isothiocyanate (*FITC*) versus anti-lambda phycoerythrin. Red dots are the $CD19^+$ B cells from histogram and show a dominant kappa expressing B-cell population consistent with a large B-cell lymphoma. (Diagrams courtesy of Bruce Grieg, MT, Vanderbilt University.)

Cytogenetic studies have made enormous contributions to our understanding of the genetic pathogenesis of hematologic malignancies, and the field has established itself as a primary player in the diagnosis of prognostically important subsets of leukemia and lymphoma (e.g., Burkitt lymphoma, mantle cell lymphoma, and acute promyelocytic leukemia) (see Chapter 3). FISH has an expanding role in diagnosis (Table 56.2), and has several key advantages over routine cytogenetics: (1) it can be performed on interphase nuclei in fixed tissues (including paraffin-embedded), (2) results are available in 24 to 48 hours, and (3) it shows enhanced sensitivity over routine cytogenetics for critical translocations. Figure 56.4 illustrates FISH studies showing a *MYC* break apart probe in a patient with an 8;14 translocation in Burkitt lymphoma.

Molecular genetic studies, primarily polymerase chain reaction (PCR) techniques, are the most sensitive for detecting small critical genetic mutations or translocations in samples which may contain very few (less than one in a million) tumor cells (see Chapter 4). PCR has also replaced Southern blot analysis as the standard for the demonstration of T-cell and B-cell clonality and is ideal for detecting minimal residual disease in patients with lymphoma as well as in patients with chronic myelogenous leukemia (CML) (Table 56.3). Many of these applications work in fixed tissues. These studies are of limited or no value in patients with HL, myelodysplasia (MDS), or translocations that have widely spaced, variable breakpoints, as in mantle cell lymphoma.

Hematologic neoplasms are clonal tumors, and methods that can prove clonality of a cell population are extremely useful when the differential diagnosis is between a benign and neoplastic proliferation. The demonstration that an expanded B-cell population is clonal by immunoglobulin light chain restriction, karyotype analysis, or gene rearrangement studies facilitates the distinction between benign and malignant proliferations. However, clonality does not always indicate malignancy, and small clonal populations and pseudoclones may exist in non-neoplastic conditions.[1,2,4,5] Clinicians have recognized for years that the vast majority of patients with monoclonal gammopathies do not have an underlying B-cell neoplasm. Similarly, sensitive molecular genetic techniques frequently identify oligoclonal and monoclonal T- and B-cell populations in "benign" disorders,

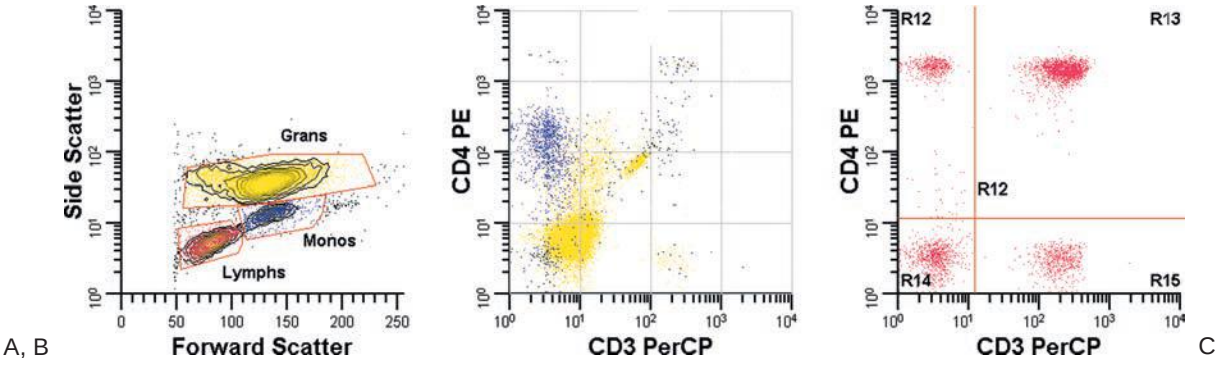

FIGURE 56.3. Histograms demonstrating a phenotypically aberrant T-cell population in a patient with peripheral blood involvement by a T-cell lymphoproliferative disorder. In **A,** a side scatter versus forward histogram, the lymphocytes (low forward scatter, low side scatter) are painted red. The granulocytes with high side scatter and high forward scatter are painted yellow and the monocytes with forward scatter similar to granulocytes but with intermediate side scatter are painted blue. **B** displays the granulocytes and monocytes stained with anti-CD3 and anti-CD4, both of which do not stain with the pan T-cell marker anti-CD3 but the monocytes express intermediate levels of CD4. In **C** which displays CD3 and CD4 expression on the lymphocytes (painted red), normal T helper cells express CD4 and CD3 while the neoplastic T-cell population (upper left) expresses bright CD4 but have lost CD3. (Histograms courtesy Bruce Grieg, MT, Vanderbilt University.)

including lymphomatoid papulosis, autoimmune disorders (e.g., Sjögren syndrome and Hashimoto thyroiditis) in association with viral infections, celiac disease, and other lymphoid hyperplasias (particularly those in extranodal sites)[5,6,7] (Table 56.4). Although these disorders may evolve into frank malignancy, they can remain clinically benign, remit spontaneously, or regress in the setting of antibiotics and removal of an antigen (*Helicobacter pylori* in gastric marginal zone lymphoma). Thus, although new techniques to identify clonality have astonishing sensitivity, the clinical, laboratory, and histopathologic data must be correlated to distinguish benign from malignant disorders. A major pitfall in diagnosis is failure to recognize that very sensitive studies for clonality by flow cytometry, protein electrophoresis, or molecular techniques are accompanied by a corresponding loss of specificity for the diagnosis of frank neoplasia.

In the next sections, the examination of the blood, marrow, nodes, and spleen are reviewed in the context of making a diagnosis, introducing the subsequent chapters, and outlining overviews on the evaluation of fever of unknown origin (FUO) and patients with recurrent infection.

TABLE 56.1

MAJOR CLINICAL APPLICATIONS OF FLOW CYTOMETRY

Established	Evolving	Limited Value or Superceded by Other Techniques
• Acute leukemia (diagnosis and detection of residual disease) • Chronic lymphoid leukemias	Myelodysplastic syndromes	
Suspected non-Hodgkin lymphoma[a]	Multiple myeloma[b]	Hodgkin lymphoma
Paroxysmal nocturnal hemoglobinuria		Myeloproliferative disease (except blast crisis)

Major disadvantage of this technique: Requires viable cells. False negatives occur with necrotic or sclerotic tissues, partial tissue involvement and in tumors where neoplastic cells are in a minority (e.g., T-cell–rich B-cell lymphoma).
Major advantages of this technique: Can be applied to any tissue or body fluid. Rapid turnaround times.
[a]Flow cytometry should be performed on all fine-needle aspirations and tissue biopsies in which a hematopoietic lymphoid process is suggested by clinical history or touch preps/frozen sections.
[b]Flow cytometry using cytoplasmic immunoglobulin light chain markers is effective in establishing clonality of plasma cells in multiple myeloma, but not useful in accurately enumerating plasma cells.

TABLE 56.2

COMMON CLINICAL APPLICATIONS OF CYTOGENETICS INCLUDING FLUORESCENCE IN SITU HYBRIDIZATION

Acute Leukemia with prognostically important translocations
- APL with t(15;17)(q24.1;21.1) (*PML/RARA*) and *RARA* variants
- AML with t(8;21)(q22;q22) (*RUNX1-RUNX1T1*)
- AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22) (*CBFB/MYH11*)
- AML with t(9;11)(p22;q23); *MLLT3-MLL* and other *MLL* translocations
- ALL with t(12;21)(p13;q22) (*ETV6-RUNX1*)
- ALL with t(4;11)(q21.3;q23) (*AFF4-MLL*) and other *MLL* translocations
- ALL with t(9;22)(q34;q11.2) (*BCR-ABL1*)

Non-Hodgkin lymphoma with diagnostically critical translocations
- Burkitt lymphoma: t(8;14)(q24;q32.33) (*MYC-IGH@*) and other *MYC* variants
- Mantle cell lymphoma: t(11;14)(q13;q32.33) (*CCND1-IGH@*)
- Follicular lymphoma: t(14;18)(q32.33;q21.3) (*IGH@-BCL2*)
- Diffuse large B-cell lymphoma: 8q24 (*MYC*), 18q21.2 (*BCL2*) and 3q27 (*BCL6*) translocations
- Anaplastic large cell lymphoma: t(2;5)(p23;5q35.1) (*ALK-NPM1*) and other *ALK* variants

Myelodysplasia
- 5q31 deletion
- Gains and loss of chromosomes 5 and 7

Myeloproliferative neoplasms
- Chronic myelogenous leukemia: t(9;22)(q34;q11.2) (*BCR-ABL1*)
- Myeloid (and lymphoid) neoplasm with *PDGFRA, PDGFRB and FGFR1* abnormalities

Chronic lymphocytic leukemia
- 13q deletion
- 11q deletion
- 17q deletion
- Trisomy 12

Plasma cell myeloma
- 13q deletion
- 17q deletion
- t(11;14)(q13;q32.33) (*CCND1-IGH@*)
- t(14;16)(q32.33;q22-q23)(*IGH@-MAF*)
- t(4;14)(p16.3;q32.33)(*FGFR3-IGH@* or *WHSC1-IGH@*)
- t(6;14)(p21;q32.33)(*CCND3-IGH@*)
- t(14;20)(q32.33;q11.1-q13.1)(*IGH@-MAFB*)

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; APL, acute promyelocytic leukemia.

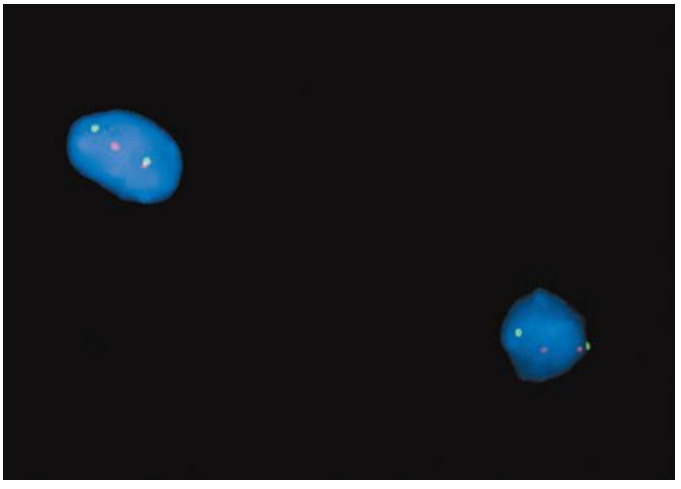

FIGURE 56.4. FISH studies demonstrating a *MYC* translocation in Burkitt lymphoma using a dual color *MYC* break apart probe with the red labeled probe binding the 5 prime end of *MYC* and the green labeled probe binding the 3 prime end of *MYC*. In the chromosomes with unarranged *MYC*, the green and red signals are together but the colors separate when *MYC* is part of a translocation with the *IGH@* gene on chromosome 14.

TABLE 56.4

EXAMPLES OF CLONAL PROCESSES WHICH MAY BE CLINICALLY IRRELEVANT

B-Cell Clonality
Monoclonal gammopathies on protein electrophoresis with immunofixation
Small circulating monotypic B-cell populations in healthy adults by flow cytometry
Transient clonal *IGH@* rearrangements by PCR in(1) salivary glands in Sjögren syndrome, (2) in thyroid tissues in Hashimoto thyroiditis, (3) in bone marrow following solid organ or bone marrow transplantation, (4) small biopsies (i.e., skin, gastric)
Clonal *IGH@-BCL2* rearrangements detected in low quantity in normal children and adults in blood and tonsil by ultrasensitive PCR methods
T-Cell Clonality
Transient clonal T-cell receptor rearrangements by PCR in blood of healthy elderly patient
Clonal T-cell receptor rearrangement by PCR in skin of patients with reactive dermatitis
Clonal T-cell receptor rearrangement by PCR in celiac disease

PCR, polymerase chain reaction.

EXAMINATION OF THE BLOOD

Physicians are too busy to examine peripheral blood smears in all of their patients. They usually do so in one of these circumstances: (a) patients with constitutional symptoms, particularly fever (see section on "Fever of Unknown Origin") or weight loss, without an obvious underlying cause; (b) an abnormality in blood counts, either cytosis or cytopenia; or (c) as a part of the evaluation of a patient with clinical features of immunodeficiency.

The blood counts and peripheral smear are frequently abnormal in patients with constitutional symptoms, immunodeficiency, hematologic neoplasms, or a variety of other syndromes associated with lymphadenopathy or splenomegaly. Anemia, when present, usually is normochromic and normocytic. Many patients with chronic disease, MDS, plasma cell myeloma, and, rarely, acute leukemias have anemia but no other abnormalities. In patients with anemia of unknown origin, the evaluation begins with examination of the blood smear, red cell indices, and reticulocyte count. The evaluation proceeds based on the results of these simple tests as outlined in Chapter 22.

TABLE 56.3

COMMON APPLICATIONS OF NON-FLUORESCENCE IN SITU HYBRIDIZATION MOLECULAR GENETIC TECHNIQUES

Established	Of Little or Limited Value
	Myelodysplastic syndromes[a]
B-cell lymphoma B-cell clonality *IGH@* PCR *IGK@* PCR *IGH@/BCL2* PCR	Hodgkin lymphoma
T-cell lymphoma T-cell clonality *TRG@* PCR *TRB@* PCR	Non-Hodgkin lymphoma with translocations with widely spaced breakpoints (e.g., mantle cell lymphoma)
Acute leukemia • Balanced translocation PCR (similar to those listed in Table 56.2 for FISH) • *NPM1, FLT3, KIT, CEBPA, DNMT3A* mutations	
Myeloproliferative neoplasms *BCR/ABL1* PCR *JAK2* mutations	
Post-transplant engraftment	

[a]Emerging mutations may become prognostically significant in myelodysplastic syndromes.

Abnormal Platelet Counts

Thrombocytopenia

The major differential diagnosis of patients with thrombocytopenia includes (a) thrombocytopenia secondary to autoantibody-mediated platelet destruction (idiopathic thrombocytopenic purpura [ITP], systemic lupus erythematosus [SLE], drug-related thrombocytopenia, and perhaps human immunodeficiency virus [HIV]); (b) primary marrow disease, particularly MDS or acute leukemia; and (c) peripheral consumption secondary to intravascular activation of clotting (e.g., disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, or hemolytic uremic syndrome). Although thrombocytopenia can be secondary to a nutritional deficiency (e.g., folate, vitamin B_{12}), usually the macrocytic anemia is the dominant clinical feature.

In ITP and drug-related thrombocytopenias, the peripheral smear red cell and white cell morphology should be normal and rare giant platelets (megathrombocytes) are present. Thrombocytopenic patients with SLE may also be neutropenic and lymphopenic. Thrombocytopenia is present in up to 50% of patients with antiphospholipid antibody syndrome.[8] Thrombocytopenia is the first sign of HIV infection in 10% of patients who may also be lymphopenic.[9] Thrombocytopenia occurs in up to 45% of patients with hepatitis C viral infection. MDS and leukemia rarely present with isolated thrombocytopenia. Most MDS patients are anemic and have white blood cell (WBC) abnormalities (e.g., blasts or hyposegmented or hypogranulated polymorphonuclear neutrophils [PMNs]) that indicate primary marrow disease. Schistocytes and polychromatophilic red cells in patients with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and hemolytic uremic syndrome are helpful in pointing away from marrow disease or an autoimmune thrombocytopenia. In rare patients, platelets will satellite around PMNs or clump in blood collected in ethylenediaminetetraacetic acid. This artifact, readily apparent on examination of stained blood smears, disappears

when blood is anticoagulated in heparin.[10] Similarly, when blood is collected for platelet counts on heel sticks, clumping (also seen on smears) may produce spurious thrombocytopenia.

Congenital thrombocytopenias are rare, but can be misdiagnosed as ITP, and size of platelets may guide further evaluation.[11] Small platelets in a male suggest X-linked Wiskott Aldrich syndrome (WAS). Large platelets are found in von Willebrand 2B, May-Hegglin anomaly, Bernard-Soulier syndrome, and the gray platelet syndrome. Normal-sized platelets are found in amegakaryocytic thrombocytopenia, thrombocytopenia with absent radii, and familial platelet disorders with a predisposition to acute myeloid leukemia (AML).

Drug-induced thrombocytopenia (DITP) may be misdiagnosed as ITP and overlooked if patients are not asked about over-the-counter medicines, food, beverages, and/or herbal supplements.[11] DITP can be due to immune-mediated or non-immune processes. In a large series of patients initially diagnosed as ITP, 8% were found to have DITP with quinine (including tonic water) as the most common cause.[12] Hematologists are frequently consulted about heparin-induced thrombocytopenia (HIT) which is due to antibodies against platelet factor 4 heparin complexes and leads to an increased risk of thrombosis.[13]

Bone marrow examination with cytogenetic studies is essential only in the cases of thrombocytopenia in patients with suspected MDS or acute leukemia or in those for whom the diagnosis of autoimmune or consumptive thrombocytopenia is in doubt. In most children or young adults with otherwise normal counts and a normal blood smear, a bone marrow is probably not needed.[14] Amegakaryocytic thrombocytopenias secondary to genetic or autoimmune disease are exceedingly rare.

Thrombocytosis

Thrombocytosis with platelet counts of greater than 600 $\times 10^9$/L are commonly seen transiently during a variety of infections, after splenectomy, after acute blood loss, or during recovery from marrow injury or nutritional deficiency. The concern in persistent thrombocytosis is the presence of an underlying myeloproliferative neoplasm or occult malignancy. The presence of a myeloproliferative neoplasm is almost always suggested by the peripheral blood counts and smear (e.g., polycythemia in polycythemia vera [PV], leukoerythroblastic changes in primary myelofibrosis [PMF or agnogenic myeloid metaplasia], and leukocytosis with immature myeloid precursors in CML). The one myeloproliferative neoplasm in which thrombocytosis is often an isolated finding is essential thrombocythemia (ET), a diagnosis that is supported by the demonstration of megakaryocytic dysplasia on bone marrow examination or the demonstration of *JAK2* mutations on molecular genetic studies of peripheral blood.[15,16] The *JAK2* V617F mutation is estimated to occur in 60% of ET and myelofibrosis and 95% of PV.[17] Congenital thrombocytosis is rare and results from mutations in either thrombopoietin (*THPO*) or its receptor (*MPL*).[18]

Morphologic Changes in Leukocytes

Morphologic changes in WBC are often diagnostic of certain rare diseases such as Alder-Reilly or Pelger-Huët anomaly, some of which are associated with infection (Chediak-Higashi syndrome) (Chapter 58).

Changes in the blood of patients with acute leukemia strongly suggest the diagnosis in virtually all patients.[7] In approximately 60% of these individuals, the smear confirms the diagnosis by the presence of a large proportion of immature cells, whether or not the leukocyte count is increased. Blasts are easily demonstrable in blood smears of more than 90% of patients, and, even in patients whose blood smears have few blasts, anemia, thrombocytopenia, neutropenia, or combinations of these changes are suggestive of acute leukemia. For almost all such patients, bone marrow aspiration proves diagnostic and should be supplemented by flow cytometry immunophenotyping and karyotype analysis.

Lymphocytosis of Small Mature Lymphocytes

More than 5.0 $\times 10^9$ small lymphocytes/L of blood in adults over 50 years of age is usually indicative of chronic lymphocytic leukemia (CLL). Many patients are asymptomatic and one-fourth are diagnosed while undergoing blood work for another problem. Flow cytometry demonstrating small B lymphocytes with weak CD20 and weak, monotypic light chain expression and coexpression of CD5 and CD23 is characteristic. Proceeding with other examinations in such patients, such as lymph node biopsy or bone marrow examination, is usually unnecessary, but immunophenotyping is required to exclude other B-cell lymphomas in the blood, such as mantle cell lymphoma, that may mimic CLL. In children, pertussis is associated with lymphocytosis of small CD4 T cells[19] that may be worrisome for a lymphoid leukemia on review of the blood smear. Chronic polyclonal B-cell lymphocytosis is well described in young to middle-aged asymptomatic women who usually smoke.[20] These women typically present with a lymphocyte count that is less than 5×10^9/L, the number required for a diagnosis of CLL, and the B cells are polytypic by immunoglobulin light chain studies and by PCR studies of the immunoglobulin heavy chain. Monotypic B-cell proliferations that present with less than 5×10^9/L B cells are now classified as monoclonal B lymphocytosis rather than as overt CLL.[21]

Lymphocytosis of "Atypical Lymphocytes"

Atypical or abnormal lymphocytes are a classic feature of Epstein-Barr virus (EBV) infectious mononucleosis but also occur in other acute viral infections including cytomegalovirus (CMV), hantavirus, hepatitis, HIV, and less commonly in lymphomas with a leukemic phase (e.g., human T-lymphotropic virus -1, hepatosplenic T-cell lymphoma, etc.). Thrombocytopenia, an elevated hematocrit, neutrophilia, and circulating lymphoblasts in a patient from the desert Southwest strongly suggest hantavirus infection.[22] Usually the clinical features and other routine laboratory tests such as serologic studies for viral infection make the diagnosis straightforward. When distinguishing reactive lymphocytes from leukemic blasts or the leukemic phase of a lymphoma is difficult, flow cytometry can provide invaluable help in defining the phenotype and clonality of circulating cells.

Neutrophilic Leukocytosis

The presence of CML is strongly considered in a patient with neutrophilic leukocytosis, particularly when the WBC count is greater than 50.0×10^9/L and is accompanied by an increase in circulating immature myeloid cells and basophilia. Additional findings suggesting the diagnosis of CML include (a) symptoms of fatigue, bone pain, left upper quadrant pain, or fullness; (b) sternal tenderness and splenomegaly on physical examination; and (c) thrombocytosis. A leukemoid reaction must also be considered and can be caused by either benign, particularly infectious, or malignant conditions. Interphase FISH studies on peripheral blood for the *BCR/ABL1* translocation can establish the diagnosis of CML, obviating the need for bone marrow examination; but many recommend an initial bone marrow to screen for other cytogenetic abnormalities that could affect prognosis.

Chronic idiopathic neutrophilia is defined by leukocytosis of 11.0 to 40.0×10^9/L and is associated with smoking and obesity.[23] Familial neutrophilia (WBC $> 20.0 \times 10^9$/L) is a rare autosomal dominant disorder which is caused by a mutation in the granulocyte colony-stimulating factor (G-CSF) receptor.[24] A transient myeloproliferative disorder is seen in up to 10% of children

with Down syndrome.[25] Neonates with persistent leukocytosis, delayed separation of the umbilical stump, and recurrent infections should be screened for leukocyte adhesion deficiency (LAD) (see section "Recurrent Infections").

Monocytosis

Monocytosis ($> 1.0 \times 10^9$/L) is commonly caused by infections, including granulomatous disease (tuberculosis [TB], fungal disease), brucellosis, infectious mononucleosis, syphilis, protozoal infections (kala-azar, malaria) and rickettsial infections. Monocytosis may be prominent in chronic myelomonocytic leukemia (CMML), juvenile myelomonocytic leukemia, or AMLs with a monocytic component.[26] These neoplastic monocytic proliferations cannot be distinguished on peripheral blood evaluation alone and a bone marrow examination is necessary to separate CMML from AML. Autoimmune disease, inflammatory bowel disease, and sarcoidosis may be associated with monocytosis. Monocytosis has been associated with carcinomas (lung, colorectal, renal) and has been caused by secretion of interleukin (IL)-6 by the neoplastic cells.[27]

Eosinophilia

Unexpected eosinophilia is most commonly seen in patients with atopy or reactions to drugs or environmental allergens.[28] Autochthonous parasitic disease as a cause of eosinophilia is rare in the United States, but visceral larva migrans caused by *Toxocara canis* or *cati* can be seen. In international travelers and immigrants, evaluations for tissue invasive parasites is warranted. In patients who are immunosuppressed (particularly organ transplant recipients and patients on high-dose steroids for autoimmune diseases) strongyloides should be excluded.

Persistently high eosinophilia ($> 1.5 \times 10^9$/L for > 6 months) carries significant risk for end organ damage and requires thorough investigation. A minority of these patients have elevated IL-5 levels with circulating clonal T-cell populations with aberrant phenotypes by flow cytometry.[29] Several neoplastic eosinophil proliferations are now recognized (see Chapter 84), including a group with a cryptic translocation involving *FIP1LI-PDGFRA*.[30,31] The latter patients can respond to imatinib therapy, while other genetic subtypes do not.

Increased Circulating Plasma Cells

Patients with plasma cell (multiple) myeloma usually have a few plasma cells in the blood, although occasionally large numbers are noted (plasma cell leukemia). Such patients almost invariably have other symptoms and signs of myeloma. A few plasma cells may also be observed in blood smears of patients with infectious mononucleosis or other viral infections. Plasma cells also are seen in the blood of persons recovering from bacterial infections or having allergic reactions, especially serum sickness. The first step when the diagnosis of myeloma is considered is to perform studies of serum and urine immunoglobulins. The technique of immunoelectrophoresis has been replaced by electrophoresis with immunofixation. This sensitive and specific technique identifies a monoclonal serum Ig and/or light chain in urine in more than 5% of patients with myeloma. The diagnosis is confirmed on bone marrow examination.

Neutropenia

Neutropenia may be mild (ANC < 1.5 but $> 1.0 \times 10^9$/L), moderate (ANC < 1.0 but $> 0.5 \times 10^9$/L), or severe (ANC $< 0.5 \times 10^9$/L).[32] There can be ethnic variation, as exemplified by a prevalence of neutropenia of 4.5% among African-Americans in the United States compared to 0.79% and 0.38% in whites and Mexican-Americans, respectively.[33] While infections and drugs are the leading causes of neutropenia, nutritional deficiencies (B12, folate, copper) should be ruled out early because of their responsiveness to replacement therapy. Alcohol abuse may present with isolated neutropenia, but is usually accompanied by other features of alcohol or nutritional marrow injury (macrocytosis, ringed sideroblasts). Immune-mediated neutropenia can be primary without an etiology or secondary to drugs, particularly B-lactam antibiotics and antithyroid medications; and autoimmune disease, including SLE, rheumatoid arthritis, and Graves' disease.[34–36] Late-onset neutropenia following rituximab therapy has been reported in 5% to 27% of lymphoma patients.[37]

Chronic idiopathic neutropenia (CIN) is a diagnosis of exclusion, rarely has increased infections, and is due to increased inflammatory changes within the bone marrow microenvironment. CIN is associated with activated T cells and increased levels of interferon γ (IFN-γ), tumor necrosis factor α, Fas-ligand, and transforming growth factor $\beta 1$, which suppresses IL-10, an antiinflammatory cytokine, and promotes apoptosis of neutrophil progenitor cells.[38]

Hematologists should be familiar with congenital neutropenias, particularly cyclic neutropenia and severe congenital neutropenia (Kostmann syndrome), because the former can be mild and not be recognized until adulthood and the latter, which is supported by G-CSF, can evolve into leukemia in one-fifth of patients.[39] Mutations in the neutrophil elastase gene (*ELA2*) account for 60% of cases of severe congenital neutropenia, either in autosomal dominant or sporadic forms, while mutations in the HS-1-associated protein X (*HAX1*) gene are found in 30% of cases and are autosomal recessive.[40]

Bone marrow aspiration and biopsy are usually reserved for neutropenia patients where there is an index of suspicion of malignancy usually due to immature cells in the differential; physical clues, such as adenopathy or splenomegaly; and/or other hematologic and laboratory abnormalities. MDS rarely presents as an isolated neutropenia and usually will have accompanying dysplastic abnormalities in more than one cell line. Patients with two indolent leukemias, hairy cell leukemia and large granular lymphocyte (LGL) leukemia, often present with bacterial infections secondary to neutropenia. Circulating hairy cell cases may be few in number, but a bone marrow examination with flow cytometry is usually diagnostic. LGL leukemia can be either T-cell (85% to 90%) or NK-cell (10% to 15%) in origin, is suspected when there are LGLs in the peripheral blood smear, and can be diagnosed by flow cytometry.[41] Molecular genetic studies of the T-cell receptor gene can be confirmatory of clonality in T-LGL.[42]

Lymphopenia

Lymphopenia is defined as an absolute lymphocyte count $< 1.5 \times 10^9$/L in adults and $< 2.0 \times 10^9$/L in children. Since 70% to 80% of circulating lymphocytes are T cells (most of which are CD4 T cells), severe lymphopenia implies T-cell deficiency and warrants serologic investigation for HIV infection. In infants with infection, the possibility of severe combined immunodeficiency (SCID) or DiGeorge syndrome is suggested. Lymphopenia is common in systemic autoimmune diseases like lupus and sarcoidosis and in serious illness/infections associated with hypercortisolism.

A variety of viral infections including influenza and measles may produce transient lymphopenia in association with loss of skin test reactivity and transient susceptibility to reactivation of TB.[43] One rare but noteworthy population with persistent lymphopenia is HIV-negative patients with CD4 T-cell counts less than 0.3×10^9/L. These patients fall into two categories, those susceptible to infection (who usually have low CD4/CD8 ratios) and those who have no increased susceptibility for infection with normal CD4/CD8 ratios.[44]

Peripheral Blood Findings in Infection

Blood leukocyte changes that are secondary to a variety of diseases usually consist of neutrophilia, eosinophilia, monocytosis, or abnormal-appearing lymphocytes. Changes in the distribution or appearance of circulating WBCs may provide important clues to the presence and type of an underlying infection. Eosinophilia is common in atopic individuals but can be seen in many parasitic infections. Atypical lymphocytosis is a helpful diagnostic clue in viral infections, particularly EBV infection. In many parasitic diseases, such as malaria, acute Chagas disease, and filariasis, the infectious agent may be demonstrated on peripheral blood smears. However, these three parasitic diseases are rarely autochthonous in North America, and the diagnosis is suggested by the nationality as well as the recent travel history of the patient.[45–47]

Although in most infections the causative agents are not demonstrable in peripheral blood, there are certain notable exceptions. In acquired immunodeficiency syndrome (AIDS) patients or in other severely immunocompromised patients, mycobacteria (Fig. 56.5A), fungi, such as histoplasmosis (Fig. 56.5B), or *Candida* may occasionally be identified on the peripheral blood smear. Residents of the central United States (particularly Arkansas and Missouri) and the Southeast may acquire ehrlichiosis through tick vectors. Anaplasmosis, formerly called human granulocytic

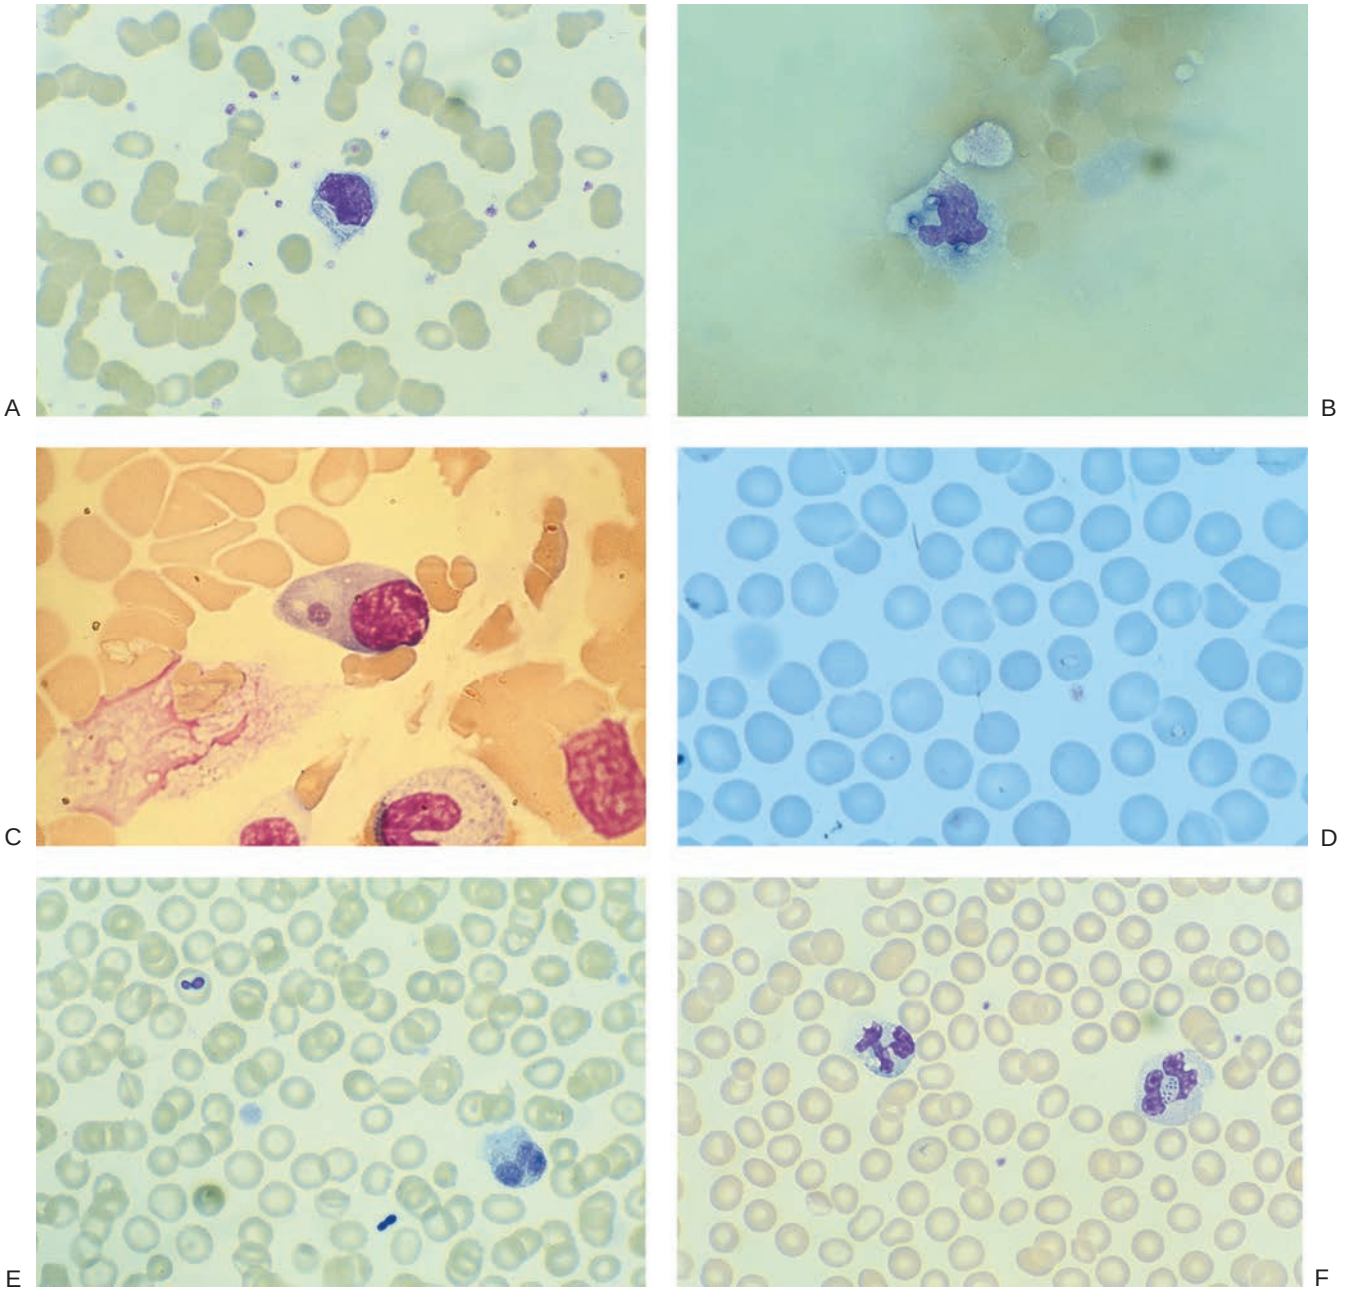

FIGURE 56.5. Wright-stained peripheral blood smears demonstrating (A) *Mycobacteria avium-intracellulare* as negative staining rods in a monocyte from patient with human immunodeficiency virus infection, **(B)** *Histoplasma capsulatum* with three intracellular yeast forms in a monocyte at the feather edge of smear in patient with acquired immunodeficiency syndrome, **(C)** *Ehrlichia chaffeensis* as a single basophilic cytoplasmic inclusion (photomicrograph courtesy of Dr. Charles Coleman, University of Missouri), **(D)** babesia as single intracellular ring forms in two erythrocytes, **(E)** *Malassezia furfur* as extracellular budding yeasts (one of which is overlying an erythrocyte) in an infant on total parenteral alimentation, and **(F)** intracellular bacteria in a neutrophil with an adjacent vacuolated neutrophil in a patient with septicemia.

ehrlichiosis, is a closely related tickborne disease found more often in the Northeast and upper Midwest. The typical inclusions in mononuclear cells (*Ehrlichia chaffeensis*) (Fig. 56.5C) or in neutrophils (*Anaplasma phagocytophilum)* are present in up to one-third of these patients, who often present with unexplained fever with accompanying leukopenia and elevated transaminases. The diagnosis of ehrlichiosis/anaplasmosis may be confirmed either serologically or by PCR methods.[48] Babesiosis, first recognized in the 1890s as the cause of Texas cattle fever, has now been identified in febrile patients in the Northeast (Nantucket, Martha's Vineyard, Connecticut), Wisconsin, and on the West Coast. Infections can be life threatening in splenectomized patients. The diagnosis is suggested by finding single ring forms (1.0 to 3.5 μm in diameter) in red blood cells (Fig. 56.5D) (characteristic tetrads are usually seen only in infected animals).[49] In nonimmunocompromised patients with indwelling venous catheters, *Malassezia furfur* (Fig. 56.5E), *Candida,* and *Torulopsis* (*C. glabrata*) may be identified in the peripheral blood.[50,51] In bacterial sepsis, visible circulating bacteria are rare, but the presence of cytoplasmic neutrophilic vacuoles in a fresh finger stick blood smear is a specific clue to the diagnosis of septicemia[52] (Fig. 56.5F). Toxic granulation (also seen in patients with sepsis) is often quite prominent in uninfected patients receiving granulocyte or granulocyte/macrophage colony-stimulating factor.

EXAMINATION OF THE BONE MARROW

If a diagnosis is not established by examining the blood, bone marrow examination may be helpful (Table 56.5). Needle biopsy is usually performed in addition to aspiration, particularly if lymphoma, carcinoma, granulomatous conditions, or myelofibrosis are under consideration. To adequately triage marrow, the stained aspirate smear is reviewed along with the clinical information and any previous studies shortly after the procedure. This allows rapid decisions about cytogenetics (including FISH), molecular genetics, and flow cytometry to be made when viable cells are still available and also limits inappropriate studies (Table 56.6). In the case of inaspirable marrows, touch preparations should be made for morphologic assessment, and sufficient cells for flow cytometry may be obtained by maintaining negative pressure on withdrawal of the biopsy or aspirate needle and then rinsing the needle in nutrient media or buffered saline. In some cases, a second, fresh core biopsy can be minced and processed for flow cytometry and cytogenetic studies.

In cases of acute leukemia, the first question is whether it is lymphoid or nonlymphoid. Identification of Auer rods on Wright-stained aspirate smears is specific for a myeloid leukemia; however, Auer rods are found only in a minority of cases. Morphology is very important in the early identification of myeloid leukemias with promyelocytic differentiation, which can be sent for confirmatory FISH studies for the 15;17 translocation and can be completed in less than 24 hours. Flow cytometry is now a standard part of the diagnosis of many hematologic diseases, including all acute leukemias (Table 56.1), and for detecting minimal residual disease post therapy.[53,54–56,57] Most cases (> 95%) can be classified as to lineage in less than 2 hours during the normal working hours of the laboratory. Flow cytometry is helpful in suggesting possible promyelocytic differentiation (DR^-, $CD2^+$, bright myeloperoxidase), megakaryoblastic differentiation ($CD61^+$, $CD41^+$, myeloperoxidase$^-$), or the t(8;21)(q22;q22) ($CD19^+$, $CD34^+$, myeloid antigen$^+$), but is not as useful in identifying other subsets in the French-American-British Cooperative Group (FAB) or World Health Organization classification. Cytochemical stains which were essential for FAB classification are now being performed infrequently and are now used most commonly when flow cytometry findings are ambiguous, especially in the case of possible mixed phenotype acute leukemia. Immunohistochemistry on the bone marrow core biopsy is helpful for lesions that may not be present in aspirated material, such as fibrosed areas of lymphoma or metastatic tumors. In some cases, both flow cytometry immunophenotyping and immunohistochemistry are required due to sampling differences between the aspirate and biopsy. Some cytoplasmic markers, such as BCL2 and cyclin D1, are only available by immunohistochemistry in most laboratories.

FISH and cytogenetics are playing an expanded role in the classification of hematologic neoplasia and the identification of prognostically favorable and unfavorable subsets of disease.[54,58–61] Favorable cytogenetics in AML include t(15;17)(q24.1;21.1) (*PML/RARA*) of APL, t(8;21)(q22;q22) (*RUNX1-RUNX1T1*), and inv(16)(p13.1q22) or t(16;16)(p13.1;q22) (*CBFB/MYH11*);these identify patients who are predominantly treated with either all-trans-retinoic acid plus chemotherapy (APL) or chemotherapy alone without early transplantation. Hyperdiploidy (more than 50 chromosomes per leukemia cell) and t(12;21)(p13;q22) (*ETV6-RUNX1*) are found in approximately 50% of childhood acute lymphoblastic leukemia (ALL) and confer a favorable prognosis.[62] Hypodiploidy (less than 45 chromosomes per leukemia cell), t(4;11)(q21.3;q23) (*AFF4-MLL*), and t(9;22)(q34;q11.2) (*BCR-ABL1*) are associated with a poor prognosis in ALL.

In suspected MDS, FISH and cytogenetic studies are helpful when morphologic abnormalities in hematopoietic cells are

TABLE 56.5

INDICATIONS FOR BONE MARROW EXAMINATION

Unexplained cytopenia
Evaluation of leukemia
Confirmation of myeloproliferative neoplasm
Unexplained lymphadenopathy
Splenomegaly without a diagnosis
Diagnosis or staging of lymphoid neoplasms
Constitutional symptoms (fever, weight loss) without a diagnosis
Bone pain with abnormal laboratory work (e.g., complete blood cell count, ↑ protein, ↑ lactate dehydrogenase, and ↑ uric acid)

TABLE 56.6

SUSPECTED DIAGNOSIS ON MARROW SMEAR

Suspected Diagnosis	Flow Cytometry	Cytogenetics/FISH
Acute leukemia	+	+
Suspected myelodysplasia	*a*	+
Myeloproliferative neoplasm (particularly chronic myelogenous leukemia)	*b*	+
Lymphocytosis (predominantly small cells)		
Child	No	No
Adult	+	*c*
Suspected non-Hodgkin lymphoma with large cells	+	+
Plasma cell myeloma	*d*	+

FISH, fluorescence in situ hybridization.
[a]Evolving application but not well established in many centers
[b]Helpful only in blast crisis
[c]If flow cytometry shows an aberrant T-cell or monotypic B-cell population
[d]Flow cytometry underestimates the percentage of plasma cells in bone marrow which is better assessed by immunohistochemistry on tissue sections

relatively subtle.[63,64] Identifying 5q31 deletion in MDS is important because the patients may respond to lenalidomide.[65] Patients with abnormalities of chromosome 7 and/or complex cytogenetics are more likely to evolve to AML and should be considered for early allogeneic transplantation. Flow cytometric evaluation of MDS is an evolving application which holds great promise, although it is not well standardized in this application and thus not available at many institutions.[66] Flow cytometry is of no help in the evaluation of myeloproliferative neoplasms except when the presence of increased blasts on marrow smear point to an evolving acute leukemia/blast transformation.[53]

Molecular genetics can identify clonality in lymphoid neoplasms, confirm diagnoses in CML and subtypes of acute leukemia, and monitor minimal residual disease when a molecular marker is present (Table 56.3). *NPM1* and *CEBPA* mutations, when present alone, are favorable mutations in AML while *FLT3* and *DNMT3* mutations are usually unfavorable. In the core binding factor leukemias (AML with t[8;21][q22;q22][*RUNX1-RUNX1T1*] and AML with inv[16][p13.1q22] or t[16;16][p13.1;q22][*CBFB/MYH11*]), mutations of *KIT* are usually unfavorable. *JAK2* mutations are present in most patients with PV and over one-half of patients with PMF and ET.[15,17] Genomic profiles are being evaluated in hematopoietic neoplasms and can discriminate prognostic subgroups. Restriction fragment length polymorphisms and chimerism studies identifying percentage of donor myeloid and lymphoid cells are employed to monitor engraftments in allogeneic transplantation.

Lymphocytosis on a marrow smear is common in very young children. Phenotypically, the lymphocytes are usually B cells in all stages of differentiation (so-called hematogones). In such cases, the numbers and morphology of the myeloid, megakaryocytic, and erythroid cell lines are usually normal, which is helpful in differentiating these non-neoplastic precursor B cells from the blasts of the pre-B ALL.[67] Lymphocytosis on marrow smear in an older adult should always have phenotypic studies by flow cytometry. Further cytogenetic/FISH studies are helpful in small B-cell lymphomas with ambiguous phenotypes or in confirmation of the diagnosis of mantle cell lymphoma (by FISH).[68] In unusual proliferations, cells from the bone marrow aspiration should be frozen for possible future studies.

Bone marrow examination should also be considered in patients who complain of bone pain whether or not bone lesions have been demonstrated radiographically and particularly if there is an abnormal CBC or abnormal chemistries, such as an elevated lactate dehydrogenase (LDH), total protein, or uric acid. Some processes, including myeloma, lymphoma, carcinoma, neuroblastoma, and granulomatous infections, may be quite focal and missed on marrow examination. Occasionally, radionuclide scans with gallium-67 or indium,[111] CT, magnetic resonance imaging (MRI), and/or positron emission tomography (PET) scans may be helpful in localizing various types of tumors and identifying specific marrow sites for biopsy.[69–73] Again, serum and urine electrophoresis, with immunofixation (which allows detection of monoclonal immunoglobulins hiding in the beta region) should be performed on adults with bone pain. Screening tests for neuroblastoma, including urine catecholamines, should be performed in children with bone pain and a nondiagnostic marrow examination.

EXAMINATION OF LYMPH NODES AND TISSUES

This section is concerned with the evaluation of the patient with palpable or visible enlargement of cervical, supraclavicular, axillary, inguinal, mediastinal, or hilar lymph nodes or tonsils. If the blood and marrow (when indicated, as discussed in the previous sections) fail to provide a diagnosis, the clinician should consider a fine-needle aspiration (FNA) or biopsy of enlarged lymphoid tissue. The presence of a variety of signs and symptoms may modify and shorten the diagnostic evaluation. For example, if the patient is ill with B symptoms or the clinical picture is fairly typical of a lymphoma, lymph node biopsy or aspiration should be performed immediately.

The causes of enlargement of lymph nodes are extremely varied. Table 56.7 outlines the major categories of disease leading to lymphadenopathy. This table is in no sense exhaustive. The approach to lymphadenopathy is similar to that of FUO, with the most common broad diagnoses being infection, cancer, and immune disorders. The first step is determining whether adenopathy is localized or generalized, and this differentiation points to a local disease versus systemic illness.

The most common cause of lymphoid enlargement is lymphocyte proliferation in response to antigenic stimulation.

TABLE 56.7

CONDITIONS LEADING TO LYMPH NODE ENLARGEMENT

Lymphadenopathy Primarily Related to Immune Response from Infections

- Viral infections
  - Local or generalized lymphadenopathy with systemic infections (e.g., infectious mononucleosis (cervical), rubella (occipital), infectious hepatitis, and acquired immunodeficiency syndrome)
- Pyogenic infections
  - Local enlargement of nodes draining areas of local infection (e.g., furuncles caused by staphylococci and oral infection)
  - Local enlargement of nodes draining the portal of entry of infections such as cat scratch fever, cryptococcosis, lymphogranuloma venereum, primary chancre of syphilis, and tularemia
  - Generalized lymphadenopathy from (e.g., *Salmonella* septicemia bacterial endocarditis, secondary syphilis, and toxoplasmosis)
  - Lymphadenopathy primarily from infection of the node by organisms
    - Pyogenic infection: the classic example is the bubo of *Pasteurella pestis;* more commonly, abscess formation by staphylococcal invasion
    - Granuloma formation: the entrance of tubercle bacilli or fungi, such as *Histoplasma capsulatum,* into nodes often results in granuloma formation as well as hypertrophy; identifiable organisms can be present within the granuloma.

Neoplasia

- Primary neoplastic diseases of nodes: non-Hodgkin and Hodgkin lymphomas
- Metastatic neoplastic processes occurring in nodes
- Lymphoid leukemias: acute lymphoblastic leukemia and chronic lymphocytic leukemia
- Myeloid leukemias: acute myeloid leukemia (granulocytic sarcoma) and chronic myelogenous leukemia
- Primary myelofibrosis with extramedullary hematopoiesis, producing lymph node enlargement
- Metastases from carcinoma, producing lymph node enlargement

Autoimmune Diseases (e.g., systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, and Hashimoto thyroiditis)

Reaction to Drugs, such as the Hydantoins

Dermatopathic Related to Skin Diseases

Miscellaneous Diseases

- Granuloma formation as seen with sarcoid or in patients exposed to beryllium
- Reactive hyperplasia, as seen in hyperthyroidism
- Progressive transformation of germinal centers
- Kikuchi-Fujimoto disease (histiocytic necrotizing lymphadenitis)
- Kawasaki disease
- Castleman disease
- Histiocytic disorders
  - Langerhans cell histocytosis
  - Erdheim Chester disease
  - Rosai Dorfman disease

The frequency of trichophyton infection of toes and trauma to feet and legs is reflected in the frequency of palpable inguinal nodes (usually smaller than 1 cm in diameter). If the patient's occupation or hobby leads to frequent trauma of hands and arms, small palpable epitrochlear and axillary nodes are expected. Thus, the assessment of the lymphoid system in a laborer differs somewhat from that of an educator (unless the latter's hobby is gardening or hunting).

Children and adolescents commonly have more palpable nodes than do adults.[74] This difference is presumed to reflect their more frequent exposure to new antigens and a larger total lymphoid mass in relation to body weight as compared to adults. Thus, significant generalized adenopathy has a more liberal definition in the young than in adults. Prominently visible tonsils, protruding into the oropharynx, are expected in preschool children but are uncommon in adults.

Retroperitoneal lymphadenopathy must be extreme before an abdominal mass becomes palpable. CT scan and lymphangiography (LG) provide complementary information concerning the status of retroperitoneal lymph nodes, although LG is no longer used.[75] Abdominal CT scan provides images of nodal areas that usually are not visualized with LG, such as pararectal, omental, and superior retroperitoneal areas, and the hilus of the spleen and liver. Other imaging techniques, such as PET scan, gallium scan, and radiolabeled monoclonal antibody scans, may further delineate worrisome lymph nodes.

Improvements in imaging and clinical dependence upon imaging has led to its increased use and contributed to the rising cost of health care.[76] Additionally, imaging techniques are so sensitive that incidental findings of uncertain clinical significance such as chest, adrenal, or renal masses may require additional evaluation, which further contributes to the expense.[77] In conjunction with CT scans, PET scans are used to assess extent of disease and response to therapy in HL and many types of non-Hodgkin lymphoma (NHL).[78]

Experience with many patients is the best guide in the selection and timing of lymph node biopsies or FNA. If doubt exists as to whether enlargement is significant, the choice between immediate biopsy or periodic observation to discover whether the nodes will enlarge or shrink should be made on the basis of ancillary findings. If other signs and/or symptoms are suggestive of lymphoma, biopsy of small, questionably enlarged nodes may yield a diagnosis. Biopsy should be performed after no more than 1 or 2 months of observation if the physician is still suspicious that the nodes are abnormal. Again, however, the physician's suspicion must be tempered by experience. Persistently enlarged lymph nodes considered abnormal in an adult may be well within the limits of normal in a child or adolescent patient.

There is no absolute size which can be used to determine the presence of pathology. Age of the patient, history, location, and physical evaluation assist in making a decision about biopsy. A size of 1.5 cm was used as a discrimination measurement in a study of 220 lymph node biopsies.[79] Others have suggested that a persistent lymph node of 10 mm or more except in the inguinal region is a reasonable guideline. A multifactorial, retrospective analysis involving 22 clinical findings was made of 123 patients, ages 9 to 25 years, in whom results of lymph node biopsies were known.[80] Only three variables proved to have significant discriminatory function; nodes larger than 2 cm in diameter on physical examination and abnormal findings on chest radiographs favored the diagnosis of a disorder necessitating treatment, whereas a history of recent symptoms related to otolaryngologic disease in the presence of enlarged cervical nodes was strong evidence against the presence of a disease requiring therapy.

Certain physical characteristics of nodes aid in the diagnosis of the cause of lymphadenopathy. Infected nodes usually are tender, and the overlying skin often is inflamed. Such nodes may be matted together. In certain types of infection, such as TB, aspergillosis, or actinomycosis, sinus tract formation is common. Infected nodes may be fluctuant. Nodes undergoing an immune response to infection also may be tender, but other signs of inflammation usually are absent. Tenderness may be related to other conditions, but this is uncommon. Carcinomatous nodes usually are hard and may be bound to one another and to surrounding tissue. Lymphomatous nodes are more often firm, rubbery, discrete, and freely movable; occasionally, anaplastic large cell lymphoma has a significant inflammatory component.

The location of the nodes may be helpful in diagnosis, and, again, the age and immunocompetence of the patient are critical factors in determining the approach. Axillary and inguinal adenopathy are often enlarged because of trauma or infection distally. Cervical lymphadenopathy is often due to localized infection but also can represent metastatic disease from the head and neck. Posterior occipital lymphadenopathy is classically seen in rubella (also toxoplasmosis) usually in conjunction with a maculopapular rash. Supraclavicular lymphadenopathy more often represents distant metastases or contiguous spread from the mediastinum. Isolated mediastinal adenopathy in a young person is usually HL. Large, bilateral hilar nodes without other detectable adenopathy are unusual in lymphomas and are more suggestive of sarcoidosis.

Infections may be either localized or generalized as the cause of lymphadenopathy. The most common forms of localized infections with cervical lymphadenopathy are pharyngitis and tonsillitis due to viral, mycoplasmal, and pyogenic infections (*Streptococcus, Staphylococcus aureus,* and *S. epidermidis*).[81] Although the above usually cause bilateral adenopathy, unilateral adenopathy occurs with tonsillar abscesses, salivary adenitis, and dental abscesses.[82] Systemic infections that may present with localized adenopathy include cat scratch disease, Lyme disease, tularemia, toxoplasmosis, and bubonic plague, but these patients usually have constitutional symptoms and may give a history of animal or tick exposure, or have a characteristic rash (e.g., Lyme disease). TB involving the cervical lymph nodes (scrofula) is one of the more common presentations of extrapulmonary TB.[83] Adenopathy in HIV patients tends to be generalized and painless and can be due to HIV alone or other infections (e.g., atypical mycobacteria, toxoplasmosis, syphilis) or lymphoma.

Immunologic disorders may present with adenopathy as a prominent clinical feature. Kikuchi-Fujimoto disease (histiocytic necrotizing lymphadenitis) is a self-limiting illness characterized by cervical adenopathy and systemic symptoms; excisional biopsy is often performed to rule out neoplasia.[84,85] Kawasaki disease is a multisystem vasculitis of infants and children usually with mucocutaneous lesions and cervical adenopathy; therapy with intravenous gammaglobulin and aspirin can prevent or ameliorate coronary artery abnormalities.[86,87] Patients with SLE and rheumatoid arthritis may develop adenopathy but usually have characteristic clinical features and serology. Early lymph node biopsy should be considered in patients at increased risk for developing lymphoma such as those with an underlying autoimmune disorder (e.g., Sjögren syndrome and rheumatoid arthritis treated with methotrexate) or immunodeficiency (e.g., HIV infection and posttransplant). Drugs, such as phenytoin, allopurinol, and cephalosporins, can be associated with diffuse adenopathy that may regress with discontinuation of the drug.

In the event of a strong presumption of malignancy (particularly metastatic carcinoma or in patients with a previous diagnosis of lymphoma), or in lymphadenopathy in areas difficult to biopsy (retroperitoneum), needle biopsy or aspiration is becoming the primary procedure for diagnosis[88,89] (Table 56.8). The procedure for lymph node aspiration is simple and can produce diagnostic information in the time it takes to stain and examine the smears. In addition the use of cultures, flow cytometry, and cytogenetic studies on aspirated material greatly amplify the quality of diagnostic information and its availability.[90] This approach requires a two-step triage: 1) rapid examination of the smear to determine

TABLE 56.8

APPLICATION OF FINE-NEEDLE ASPIRATION OF LYMPH NODES AND EXTRANODAL MASSES

Established[a]	Limitations
Diagnosis of relapse in lymphoma	Primary diagnosis of lymphoma[a]
Diagnosis of nonhematologic malignancies	Specific diagnoses of reactive processes
Presumptive diagnosis of reactive processes	
Primary diagnosis of many nonhematologic malignancies and metastases	

[a]Most of these require flow cytometry as an adjunct. In processes which are focally neoplastic or tumor cells are in minority (Hodgkin and T-cell–rich B-cell lymphoma), a missed diagnosis is possible.

if flow cytometry is warranted;2) if flow shows evidence for a neoplasm, deciding whether or which cytogenetic/FISH/molecular genetic studies are indicated. However, the frequency of indeterminate or incorrect diagnosis is higher with needle biopsy aspiration than with excisional biopsy, as the histologic diagnosis often depends on changes in the overall architecture of the lymph node in addition to the cytology of individual cells.[91] Excisional biopsy yields more tissue for diagnostic studies, facilitating preparation of multiple histologic sections for routine and special stains as well as providing more adequate material for cultures and immunophenotypic and genetic studies. Therefore, when appropriate, excisional lymph node biopsy is preferred over FNA or core biopsy for complete diagnostic evaluation.

For excisional biopsy or FNA, the largest palpable node available is given preference. More than one node should be removed, if possible, avoiding irradiated areas. When other considerations are equal, biopsy of cervical or supraclavicular nodes is preferable to biopsy of axillary nodes, and biopsy of nodes from any of these regions is preferable to that of inguinal nodes. As previously mentioned, inguinal nodes frequently are enlarged from chronic foot infection, in which case the architecture often is distorted. Axillary nodes, unless enlarged, may be difficult to find during surgical procedures because of the complex and changed anatomy during exposure of this area.

In the "good old days" when most diagnoses of disease involving marrow or lymph nodes were made (or not made) based solely on the morphology of smears and tissue sections, coordination of the efforts of the clinician, surgeon, and pathologist was less important and much less complex. Today, with a bewildering array of morphologic, cytochemical, immunologic, molecular genetic, and cytogenetic techniques available (and essential for many diagnoses), the clinician, surgeon, and pathologist must work closely together to optimize the diagnostic information of any biopsy while, at the same time, limiting expense. The major pitfall in these efforts is improper specimen handling, precluding the use of important techniques available only in fresh tissue (i.e., cultures for pathogens, cytogenetics, and flow cytometry for surface markers).

The process of evaluation begins before the procedure. The studies that are done are guided by clinical information and a review of previous biopsy material. At the time of biopsy or needle aspiration, the studies available within minutes of the procedure (i.e., the Wright-stained marrow aspirate smear of bone marrow or the hematoxylin- and eosin-stained smear of a lymph node biopsy touch prep) are used to decide which diagnostic techniques will be applied to any given case. If the suspicion of infection is high, material for cultures is best obtained in the sterile environment of the operating room before sending it to pathology.

Table 56.9 includes guidelines for the diagnostic evaluation of tissue biopsies and aspirations based on clinical information and the aspirate smear/touch prep appearance. The most important clinical information is the likelihood that a process is (a) NHL, (b) HL, (c) a carcinoma, or (d) a reactive process. The clinical information, including the age of the patient along with the touch prep or smear appearance, often helps in determining whether flow cytometry or cytogenetics is needed (as in many cases of NHL or leukemia).

NHL would be uncommon in a child or young adult with a predominance of small lymphocytes on touch preps (Fig. 56.6A), but would more likely occur in an elderly patient. In a child or teenager, the major differential diagnosis would be between a reactive node or lymphocyte-predominant HL. In neither diagnosis would flow cytometry or cytogenetics be of much benefit. On the other hand, in an older patient in whom a small B-cell NHL is more likely, immunophenotyping is of great help in proving clonality and in identifying immunophenotypic patterns characteristic of subsets of NHL of therapeutic and prognostic significance (e.g., hairy cell leukemia and mantle cell lymphoma). The role of FISH

TABLE 56.9

GUIDELINES FOR EVALUATION OF LYMPH NODE BIOPSIES/FINE-NEEDLE ASPIRATION

	Touch Prep Cytology					
Tests to Consider	Small Lymphocytes		Mixed Small Lymphocytes and Large Lymphocytes (No Atypical Large Cells)		Mixed Small and Large Lymphocytes (A Few Large Atypical Cells)	Frequent Large Lymphocytes or Blasts
Age of patient	Child or young adult	Adult	Child or young adult	Adult	Child or adult	Child or adult
Flow cytometry	No	Yes	*a*	Yes	*b*	Yes
Cytogenetics/ molecular genetics/FISH	No	*c*	*d*	*d*	*d*	Yes

FISH, fluorescence in situ hybridization.
[a]If clinical features are highly suggestive of non-Hodgkin lymphoma or tissue is from a site difficult to sample (e.g., mediastinum or retroperitoneum) a limited panel for B-cell clonality and T-cell distribution may be helpful.
[b]If clinical features and gross appearance are typical for Hodgkin lymphoma, flow cytometry and genetic studies are unlikely to be helpful.
[c]If flow cytometry suggests a neoplastic process.
[d]Usually not helpful except if screening flow cytometric studies demonstrate an abnormal B- or T-cell population.

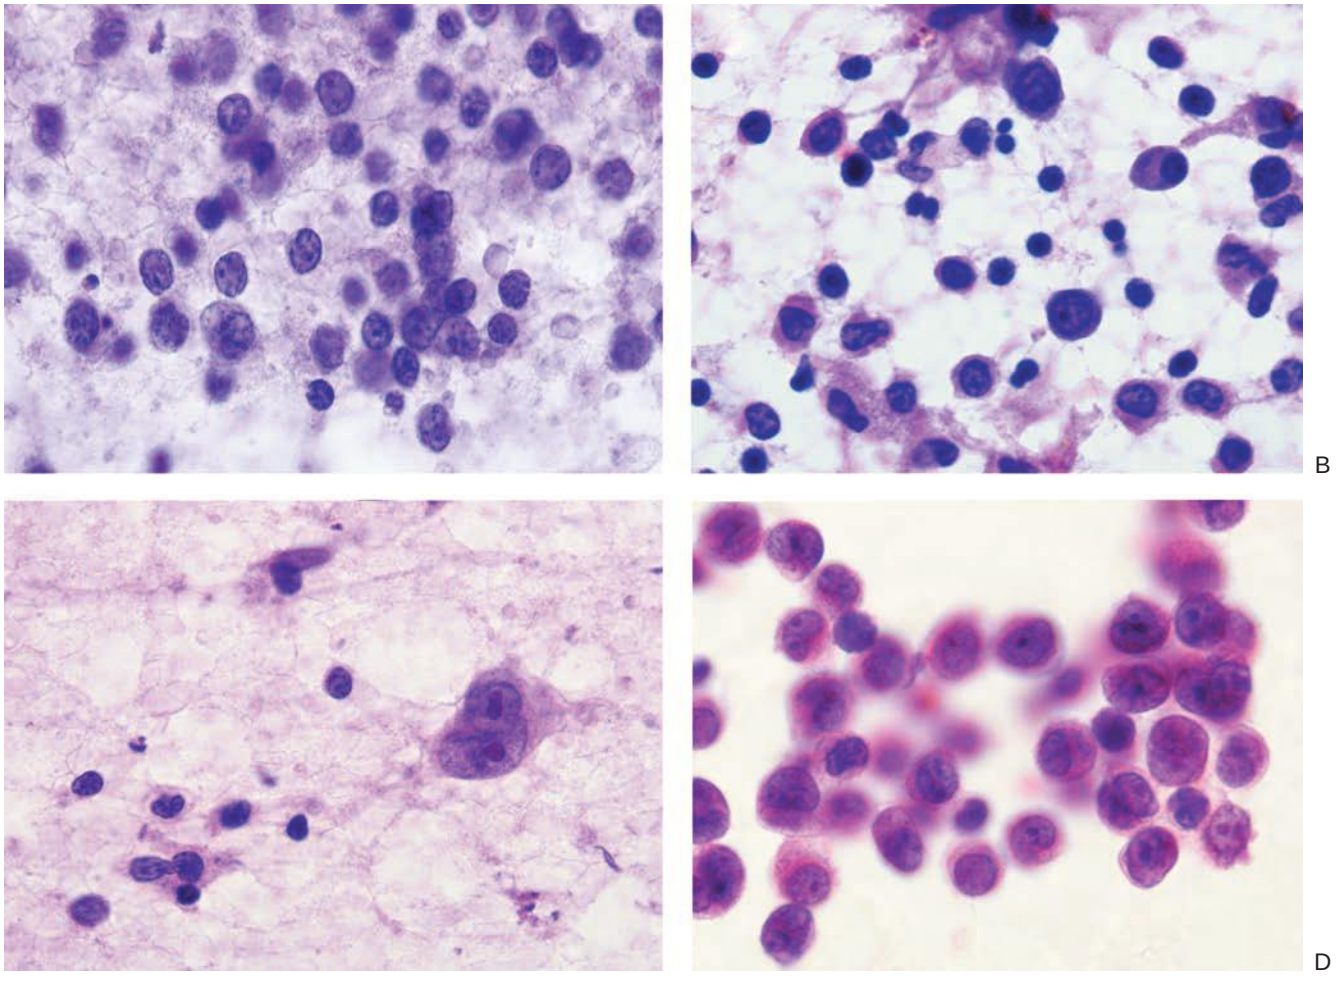

FIGURE 56.6. High power of hematoxylin eosin–stained touch preps of lymph node biopsies demonstrating (A) predominance of small lymphocytes in an adult with small lymphocytic lymphoma/chronic lymphocytic leukemia; **(B)** mixed pattern of small and large lymphocytes, macrophages, plasma cells, and neutrophils in a child with reactive adenitis; **(C)** mixed population of small and large lymphocytes with occasional large atypical cells in a patient with classical Hodgkin lymphoma; and **(D)** predominance of large lymphocytes (many with polylobate nuclei) in a patient with large B-cell lymphoma of the mediastinum.

and cytogenetic studies is assuming increasing importance in the diagnosis of small B-cell lymphomas, particularly follicular (t[14;18]) and mantle cell (t[11;14]) lymphoma, and is prognostically important in subsets of extranodal marginal zone lymphoma (e.g., t[11;18]).[92–95]

In children and young adults with a touch prep showing a polymorphous mix of small and large lymphocytes and inflammatory cells (Fig. 56.6B), flow cytometry is not routinely performed. Most patients with this mixed pattern on touch preps will have a reactive process or HL (Fig. 56.6C); however, a few B-cell NHL and peripheral T-cell lymphomas may show such patterns. If the clinical likelihood of NHL is high, or in those patients with occasional large atypical cells who do not have clinical features of HL, a limited and inexpensive panel for B-cell clonality and T-cell antigen loss can be performed. If these studies demonstrate an abnormality either in the small or large cell population, then more expanded panels can be run. If the case is not typed and on permanent tissue sections appears to be NHL, immunophenotyping can be performed on paraffin sections and information about clonality (T and B) can be retrieved from frozen tissue or the paraffin-embedded tissue as needed.[96,97]

In patients with numerous large cells or blasts on a touch prep (Fig. 56.6D) typing studies (and in many, cytogenetics) are essential in identifying prognostically significant patient subgroups. For example, in patients with blast cells on touch prep, the differential diagnosis would be lymphoblastic lymphoma (both B and T), blastic transformation of mantle cell lymphoma, and extramedullary acute leukemia. Flow cytometry is quite useful in the differential diagnosis and can provide an answer in hours (well in advance of other cytogenetic or immunohistologic techniques) (Figs. 56.2 and 56.3). Tissue should also be placed in glutaraldehyde for electron microscopy in these cases, because poorly differentiated tumors, such as neuroblastoma or rhabdomyosarcoma, may mimic hematopoietic neoplasms on touch prep.

A histologic appearance of reactive hyperplasia or of nonspecific granulomatous changes does not rule out the possibility of HL or NHL at another site. For example, not all enlarged nodes from patients known to have HL show evidence of the disease[98]; it is not surprising that the first biopsy may give negative findings in a patient in whom a second biopsy is diagnostic.[99,100] Similarly, analysis of surface antigens on cells from an initial biopsy that may not contain the tumor may indicate that the B-cell population is polyclonal when later specimens containing the tumor show a monoclonal proliferation.[101] Molecular studies may identify monoclonal lymphoid populations earlier than flow cytometry or routine immunoperoxidase stains in selected cases. In equivocal or difficult cases, particularly those in which there are discrepancies between the histologic diagnosis, the clinical picture, and the results of ancillary studies, consideration should be given to obtaining consultation in hematopathology.[102] If more than one node is removed initially, the likelihood of positive findings is enhanced. In nondiagnostic biopsies, the decision to obtain more

tissue for further study must be individualized. If no other nodes are enlarged and the patient has few or no symptoms, observation may be advisable. Prompt diagnosis and proper therapy are important in bacterial and fungal infections, HL, aggressive NHL, and acute leukemias, but are less important for the eventual outcome of the other conditions listed in Table 56.7.

EXAMINATION OF THE SPLEEN

Many of the conditions that lead to lymphadenopathy also produce a palpably enlarged spleen. Consequently, the preceding discussion regarding evaluation of the patient with lymphadenopathy is equally applicable to the patient with splenomegaly. When splenomegaly is associated with systemic infection (acute splenic tumor), the spleen usually is barely palpable, soft to firm, but not hard, and splenomegaly disappears shortly after recovery from the infection. A palpable spleen usually indicates disease, but a soft spleen tip can be palpated by an experienced physician in approximately 1% to 2% of apparently healthy persons.[103]

Splenic puncture may be helpful in the evaluation of patients with certain conditions (e.g., leishmaniasis and kala-azar), but is rarely used in North America.[104,105] Diagnostic splenectomy is required in some patients, especially those in whom the only palpably enlarged tissue is the spleen. Before this procedure is considered, however, numerous other studies should be considered and may include CT scan, liver/spleen scan, and other imaging studies to outline splenic vein patency, as well as hepatic blood flow and any associated adenopathy. In many cases, results of these studies indicate the diagnosis. For instance, splenic hypertrophy owing to increased red cell destruction, such as occurs in hereditary spherocytosis and thalassemia, should be detected by means of appropriate blood and other examinations. Biopsy of enlarged nodes should always be carried out before splenectomy is undertaken. Examination of the marrow should also be considered. Liver function tests (LFTs) and needle biopsy of the liver also are warranted to exclude, among other considerations, the possibility that the splenomegaly results from hepatic disease, producing increased portal pressure.

Indications for splenectomy are discussed in Chapter 65 and elsewhere in relation to the various diseases associated with splenomegaly. If no explanation is found for splenomegaly, splenectomy should be considered to make or to exclude a diagnosis of lymphoma.

FEVER OF UNKNOWN ORIGIN

The classic definition of FUO proposed by Petersdorf and Beeson in 1961 is a temperature elevation of 38.3°C (101°F) or higher persisting over 3 weeks in duration and without a diagnosis after 1 week of intensive in-hospital investigation.[106] The definition of FUO has been modified due to the changing medical environment which required a shift to an initial outpatient evaluation. Durack and Street proposed the duration of evaluation for FUO be changed to only 3 days of hospitalization or at least 3outpatient visits or 1 week of ambulatory investigation.[107] Because of changing medical practices and different types of patients with prolonged fever, FUO is currently subdivided according to four categories: (a) classic FUO, (b) nosocomial FUO, (c) immune-deficient FUO, and (d) HIV-related FUO. Host factors (e.g., age of the patient and immunocompetence) and environment (e.g., socioeconomic status and geographic location) are factors in the evaluation of FUO. Arnow and Flaherty have proposed a minimum number of tests to be performed prior to labeling a patient with FUO.[108]

The "big three" categories of FUO remain infections, autoimmune or non-infectious inflammatory disease (NIID), and malignancies (Table 56.10), although the incidence of cancer has

TABLE 56.10

DISEASES CAUSING FEVER OF UNKNOWN ORIGIN

Malignancy

Common
- Hodgkin lymphoma
- Non-Hodgkin lymphoma
- Hypernephroma
- Metastatic carcinoma: liver, central nervous system

Uncommon/rare
- Hepatomas
- Pancreatic carcinoma
- Acute leukemia/myelodysplastic syndrome
- Atrial myxoma
- Neuroblastoma
- Central nervous system tumor

Infection

Common
- Tuberculosis: extrapulmonary—renal, meningitis, miliary
- Abscesses
  - Intraabdominal
  - Subdiaphragmatic (periappendiceal, pericolonic, hepatic)
  - Pelvic

Uncommon
- Abscesses: splenic, perinephric, dental, brain
- Subacute bacterial endocarditis (if culture-negative, suspect right-sided endocarditis, intravenous drug abuse)
- Cytomegalovirus
- Toxoplasmosis
- *Salmonella* enteric fevers

Rare
- Localized, culture-negative infections: sinusitis, osteomyelitis, chronic meningitis, cholecystitis, urinary tract infection, mastoiditis
- Viruses: Epstein-Barr, hepatitis (all types), human immunodeficiency virus, parvovirus, other
- Cat scratch disease
- Brucellosis
- Listeriosis
- Spirochetal infections
- Relapsing fever
- Lyme disease
- Leptospirosis
- Rat bite fever

Autoimmune Disease

Common
- Still disease
- Giant cell (temporal) arteritis

Uncommon
- Periarteritis nodosa
- Rheumatoid arthritis
- Wegener granulomatosis

Rare
- Systemic lupus erythematosus
- Vasculitis (Takayasu arteritis, hypersensitivity vasculitis)
- Felty syndrome
- Acute rheumatic fever
- Pseudogout
- Sjögren syndrome
- Behçet disease
- Familial Mediterranean fever
- Polymyositis
- Tumor necrosis factor receptor–associated periodic syndrome

Miscellaneous

Common
- Drug fever
- Cirrhosis
- Alcoholic hepatitis

Uncommon: granulomatous hepatitis

Rare
- Gastrointestinal: regional enteritis, Whipple disease
- Endocrine: hyperthyroidism, hyperparathyroidism, pheochromocytoma, Addison disease, subacute thyroiditis, hypothalamic dysfunction
- Granulomatous disease: sarcoidosis
- Vascular related: pulmonary emboli, subacute dissecting aneurysm, giant hepatic hemangioma, occult hematomas
- Immune-related: hyperimmunoglobulin D syndrome, pseudolymphoma
- Factitious fever
- Habitual hyperthermia
- Cyclic neutropenia
- Other: Fabry disease, Kikuchi-Fujimoto disease, Weber-Christian disease, mesenteric fibromatosis, malakoplakia, Castleman disease, hemophagocytic syndromes

Undiagnosed Conditions

Rare (*continued*)

Rickettsial infections: Rocky Mountain spotted fever, endemic typhus, Q fever, ehrlichiosis, trench fever, bacillary angiomatosis

Parasitic disease: malaria, babesiosis, toxoplasmosis, trypanosomiasis, leishmaniasis, trichinosis, amebic liver abscess

Fungal infections: blastomycosis, histoplasmosis, coccidioidomycosis, cryptococcosis, candidiasis

Yersinia infections

Chlamydial infections: psittacosis, lymphogranuloma venereum

Foreign object–related infections: vascular grafts, indwelling catheters, prosthetic devices

Vascular infections: aortic aneurysm, jugular phlebitis

Adapted from Cunha BA. Fever of unknown origin. In Gorbach SL, Bartlett JB, Blacklow NR, eds. Infectious diseases, 3rd ed. Philadelphia, PA: Lippincott, Williams and Wilkins, 2004: 1569–1578.

declined due to improved diagnostic techniques.[109] Miscellaneous diseases and undiagnosed conditions round out the main five categories of FUO. There are over 200 different causes of FUO, but most patients have common illnesses presenting with unusual manifestations.[106] In a systematic review of the literature for 1995 to 2004 which identified 1,488 cases of FUO, 74% of the patients were accurately diagnosed, with 37% due to infections, 16% due to NIID, 11% due to neoplasms and 10% due to miscellaneous diseases.[110] In developing countries, infections, particularly TB, often represent more than one-half the cases of FUO, whereas developed countries have a higher incidence of NIID and neoplasms.[111] Undiagnosed conditions and infections are more common in younger patients, whereas NIID, including temporal arteritis and polymyalgia rheumatica, and malignancies are more common in the elderly. Despite improved imaging and better culture techniques, the percentage of undiagnosed conditions has increased to the 25% to 50% range in recent series and is higher in children.[112,113]

Nosocomial FUO is a particular problem for the patient in an intensive care unit and is related to the type of instrumentation (indwelling vascular lines, Foley catheters, and endotracheal tubes),[114] the specific spectrum of microorganisms and their antimicrobial sensitivity, and the degree of immunodeficiency. Common conditions causing nosocomial FUO include septic thrombophlebitis, pulmonary embolism, *Clostridium difficile* enterocolitis, and drug fever.[115] More than 60% of FUO in the immunodeficient host is due to infections; the type and severity of infection correlate with the severity and length of neutropenia.[116] Occult fungal infections, including hepatosplenic candidiasis, aspergillosis, and mucormycosis should be considered in the immunodeficient host with prolonged neutropenia.[115]

The initial exposure to HIV may cause FUO, and the HIV may go undetected due to lack of seroconversion.[117,118] FUO in HIV patients is due to an opportunistic infection in over 70% of patients.[119] Atypical and typical mycobacteria are the most common infections in HIV patients; other infections causing FUO in AIDS include CMV, *Pneumocystis jiroveci,* toxoplasmosis, histoplasmosis, leishmaniasis, and cryptococcosis. In Asia, *Penicillium marneffei* is a common cause of FUO in HIV patients; papular skin lesions with central necrosis are seen in 70% of HIV patients.[120] Lymphoma, both aggressive B-cell NHL and HL, multicentric Castleman, and drug reactions may also be a cause of FUO in HIV patients. Long-lasting fever in HIV without a diagnosis is seen in patients with advanced HIV and low $CD4^+$ T lymphocytes.[118] The use of highly active antiretroviral therapy (HAART) in AIDS has led to a decline in FUO.[118,121] After the start of HAART, an immune reconstitution inflammatory syndrome is seen in 25% to 35% of HIV-positive patients and usually occurs within 2 months. The patient can deteriorate due to worsening of an opportunistic infection, particularly *Mycobacterium tuberculosis, M. avium* complex, or *Cryptococcus neoformans.*[122]

The pattern of fever has been extensively evaluated, but rarely is so specific as to be diagnostic of a disease. Possible exceptions include a Pel-Ebstein pattern of recurrent high fever with intermittent afebrile, asymptomatic periods in HL; the tertian and quartan patterns of malaria; the pulse-temperature dissociation of typhoid fever; the reversal of the normal diurnal pattern observed in disseminated TB; and a cyclical pattern (every 3 to 4 weeks) with cyclic neutropenia.[123] A continuous fever is more likely to be diagnosed than a periodic fever.[124,125] The prognosis of a patient with undiagnosed FUO is favorable, with mortality less than 5%.[126]

In the evaluation of a patient with FUO, history and physical examinations often need to be repeated.[119,127,128] Host factors (e.g., HIV, sickle cell disease, prior malignancy, organ transplant, cardiac valve disease, diabetes, and prior surgery) and external factors (e.g., occupation; travel; and exposures to infections, animals, and drugs) may point to the types of studies warranted to diagnose the etiology of FUO. The goal of the history and physical examination is to identify potentially diagnostic clues. The physical examination should pay particular attention to the skin (e.g., rashes, subcutaneous nodules, aphthous ulcers, and nail beds), eyes (e.g., uveitis and Roth spots and infections on funduscopic examination), sinuses, lymph nodes, heart (e.g., rubs and murmurs), lungs, organomegaly, and perirectal area. Bone, joint, and musculoskeletal examinations are important when symptoms of pain, limping, or weakness are associated with FUO.

The laboratory evaluation of FUO involves a minimal set of tests which may further direct the investigation: CBC, sedimentation rate, C-reactive protein; comprehensive metabolic profile, including lactose dehydrogenase; urinalysis, antinuclear antibodies, rheumatoid factor; viral screens, particularly CMV, EBV, and HIV; tuberculin skin test, and chest x-ray and/or CT scans of specific areas as determined by history and/or physical exam. Three sets of routine blood cultures have been added to the initial battery of tests.[108] If a patient has two of the three laboratory abnormalities: elevated C-reactive protein, elevated ferritin but $< 500\ \mu g/L$, or eosinopenia, infection is more likely than non-infection.[129]

Table 56.11 outlines possible etiologies as suggested by the findings on CBC and sedimentation rate or C-reactive protein. Anemia, an abnormal white cell count, elevated LFTs, and elevated LDH were independent predictors of having a serious illness, commonly neoplasia, and a poor prognosis for patients with FUO.[130] Examination of the blood smear for abnormal cells or pathogens may be warranted according to history, such as travel or tick exposure; or physical exam, particularly petechia, adenopathy, or organomegaly. Flow cytometry can be confirmatory in specifying the type of malignant cell. Ehrlichiosis, malaria, leishmaniasis, histoplasmosis, TB, and babesiosis are among the diseases in which organisms may be seen in the peripheral blood.

NIID that have remained a cause of FUO are those that are not readily diagnosed by serologic testing, such as temporal arteritis and Still disease.[131] Giant cell, or temporal, arteritis (GCA) represented 17% of cases of FUO in the elderly and is suggested by jaw or tongue claudication, localized headaches, visual disturbances, and temporal artery abnormalities (e.g., decreased pulse, tenderness, or nodularity). The diagnosis is suggested by an elevated sedimentation rate (> 50 mm/hour) and formerly was confirmed by an abnormal temporal artery biopsy. Color Doppler ultrasonography and high resolution MRI can diagnose GCA in most patients so that biopsy may be reserved for patients with

negative imaging.[132] Adult onset Still disease can present as an FUO in a younger patient with or without a characteristic rash. Four variables associated with Still disease are arthritis, pharyngitis, splenomegaly, and neutrophilia.[133] The highest elevations in serum ferritin are seen in Still disease and hemophagocytic lymphohistiocytosis (HLH).

HLH may be familial, with 70% to 80% occurring in children under the age of 1 year, or sporadic secondary to infections, malignancies, particularly peripheral T/NK lymphomas, or autoimmune diseases. The most common features of HLH are FUO, hepatosplenomegaly, and cytopenias; and a diagnosis can be made by confirmation of an underlying genetic defect (in 80% of familial cases), or by having five of eight clinical criteria, including ferritin $\geq$ 500 μg/L, soluble CD25 (IL-2 receptor) $\geq$ 2,400 U/ml, and decreased natural killer cell activity.[134,135,136] Early diagnosis of HLH is critical because of a high early mortality, varying from 20% to 70%, and the availability of effective therapy.[134,137] After the syndrome is controlled by immunotherapy with a combination of dexamethasone, etoposide, and cyclosporine, familial forms of HLH which have mutations in genes regulating the granule-dependent exocytosis pathway, and genetic immune deficiencies, such as X-linked lymphoproliferative (XLP), Chediak-Higashi, and Hermansky-Pudlak, should undergo allogeneic stem cell transplant.[134,136,138]

Rare, hereditary disorders characterized by recurrent episodes of fever and autoimmune features include familial Mediterranean fever, tumor necrosis factor receptor–associated periodic syndrome, and the hyperimmunoglobulinemia D syndrome.[139] Familial Mediterranean fever is an autosomal recessive disorder and is caused by mutations in the pyrin–marenostrin gene *MEFV,* which provides inhibitory signals to inflammatory cells.[140] Tumor necrosis factor receptor–associated periodic syndrome is an autosomal dominant condition caused by missense mutations in the gene encoding type I tumor necrosis factor receptor (*TNFRSF1A),* which results in an exaggerated response to tumor necrosis factor.[141] Hyperimmunoglobulin D syndrome is due to mutations in the gene mevalonate kinase (*MVK*), but the mechanism producing fever and autoimmune features is unknown.[142]

Two diseases that can be overlooked are factitious fever and Whipple disease.[143] Patients presenting with factitious fever tend to be young adults who are often in the medical field and have a relative bradycardia. Intravenous injections of organisms or a

febrile child with a Munchausen by proxy parent are other indications of factitious fever. Whipple disease should be suspected in patients with FUO, arthritis, mental status changes, and malabsorption. Diagnosis is made by demonstration of PAS-positive macrophages on small bowel biopsy and can be confirmed by detecting *Tropheryma whipplei* by PCR.

Imaging tests (e.g., CT, MRI, PET/CT, transesophageal echocardiography, and radioisotope scans) have altered the distribution but not the type of illnesses causing FUO.[144,145] Endocarditis and abscesses, as well as neoplasia, have decreased with improved imaging and cultures.[146] The ability to diagnose an etiology of FUO has paradoxically decreased and led to a higher incidence of unclassifiable causes in some recent series.[146][18F]-fluorodeoxyglucose (FDG-PET) in conjunction with fusion CT is emerging as an effective modality in the diagnostic work-up of FUO.[147,148] Advantages of PET/CT over gallium scintigraphy include completion of the exam within a short period of time and improved resolution, while disadvantages include a relatively high cost and limited availability in most of the world.[148] A meta-analysis of FUO studies indicated that 32% of FDG-PET scans and 62% of FDG-PET/CT scans contributed to a final diagnosis.[149] Indium 111 granulocyte scintigraphy may be more helpful than PET scans in diagnosing infections.[150]

Invasive tests have a variable yield and depend upon the type of host, the initial evaluation of FUO, physical exam findings, and laboratory abnormalities. Bone marrow aspiration with biopsy was diagnostic in nearly a fifth of patients with FUO and was particularly helpful in the presence of anemia or thrombocytopenia.[151] Bone marrow exam with cultures is more rewarding in immunocompromised than in immunocompetent hosts. Percutaneous liver biopsy is similarly helpful in HIV-infected patients with FUO, organomegaly, and increased LFTs.[152] Lymph node biopsy is useful in diagnosing lymphomas for which an excisional or core needle biopsy is preferable over a FNA for the initial diagnosis. Necrotizing lymphadenopathy may be present in lymphomas or in reactive processes, including infections (toxoplasmosis, lymphogranuloma venereum, *Yersinia pseudotuberculosis,* cat scratch, tularemia), rheumatologic disorders, Kawasaki, and Kikuchi-Fujimoto disease. The latter is usually seen in middle-aged women of Asian descent who present with fever, cervical adenopathy, and leukopenia and have a self-limited course over 1 to 4 months.[153] Granulomas in lymph node biopsies are nonspecific and may be seen in sarcoidosis, infections, both HL and NHL, and carcinoma. Laparotomy is rarely performed unless there is adenopathy that is not easily approached by less invasive procedures, including FNA, mediastinoscopy, thoracoscopy, and laparoscopy. The goal is to identify treatable disease as expediently as possible.

Empirical antibiotic trials are rarely warranted except in the immunocompromised patient with neutropenia and fever.[154,155] Empirical antifungal therapy was established as an effective strategy in the 1980s for acute leukemia patients with prolonged neutropenia following chemotherapy and for patients undergoing stem cell transplantation (SCT).[155,156] Prophylaxis against infections and pre-emptive antiviral strategies are routinely used in SCT.[157] Occasionally, antibiotics are given in culture-negative endocarditis; and antituberculosis therapy is used in the elderly with suspected miliary TB.[158,159] High-dose steroids with or without alkylating agents can be considered in cases of vasculitis which have diagnostic images or proven biopsies.[158] Naprosyn has been advocated as a means to distinguish fever of malignancy from infection but should not prevent the search for infection.[160] Treatment for malignancy should almost never be instituted without a tissue diagnosis.

RECURRENT INFECTIONS

The most common clinical presentation of immunodeficiency (either congenital or acquired) is infection (Table 56.12). More than one infection requiring hospitalization, infection with unusual pathogens, or an inappropriately delayed response to optimal therapy should all be tip-offs to possible underlying immunodeficiency.[161] Chronic sinusitis, recurrent otitis, persistent thrush, chronic diarrhea, or skin rashes may be an early manifestation of immunodeficiency. Delayed umbilical cord stump separation is indicative of neutrophil defects, including LAD and interleukin-1 receptor (ILR-1)–associated complex deficiency.[162,163] Eczema or pustular rash, skin abscesses, and sinopulmonary infections within the first few weeks of life suggest hyper-IgE (HIES or Job) syndrome.[164] Patients may present with sequelae of immunodeficiency (e.g., delayed growth or failure to thrive in children or unexplained chronic obstructive pulmonary disease). Cytopenias, including lymphopenia or thrombocytopenia, or splenomegaly, may be an early finding.[165] In some patients, particularly those with HIV infection, lymphoma or a nonhematologic malignancy may be the presenting manifestation. In congenital immunodeficiency diseases, such as IgA deficiency, or deficiency of classic pathway complement components, features of autoimmunity may dominate the clinical picture.[166]

Age of onset of infection, family history, including parental consanguinity, and clinical findings provide clues to diagnosis, but laboratory tests identifying abnormal component(s) of the immune system are essential. Testing is directed at different parts of the immune system: T cells and cell-mediated immunity, B cells and humoral immunity, phagocytes, and complement. Congenital defects in T-cell–mediated immunity may appear in the neonatal period and usually effect antibody production which is dependent on intact T-cell function, whereas antibody deficiencies appear at the 6 to 9 months stage after the waning of maternal antibodies. Immunoglobulin levels, flow cytometry, and complement levels detect deficiencies of the immune system, but immune function studies, such as lymphocyte response to mitogens, specific antibody response to vaccine antigens, skin testing, and assays of neutrophil function may be more important in diagnosis. Skin testing is of little value in children younger than 1 year because they are unlikely to have previously been exposed to antigen used in testing. In older children and adults, the presence of reactive skin tests to recall antigens virtually excludes a significant defect in cell-mediated immune response. In utero or neonatal screening

TABLE 56.12

CLINICAL APPROACH TO IMMUNODEFICIENCY

Red Flags for Immunodeficiency

- More than one hospitalization for infection
- Infection with organisms not usually pathogenic
  - Recurrent otitis, sinusitis or pneumonia
  - Persistent thrush
  - Deep skin or organ abscesses
- Growth failure in children
- Delayed or absent response of infection on appropriate therapy

Initial Evaluation

History

- Family history of primary immunodeficiency
- Age of onset of infection
- Type of infection

Physical examination

Initial Investigation for:

- Bacterial infection (implies B-cell, phagocyte, or complement deficiency)
- Infection with intracellular organisms (implies deficient T-cell/cellular immunity)
- CBC and differential for neutrophil count and morphology, quantitative immunoglobulins, CH50
- Human immunodeficiency virus serology, CBC and differential for lymphocyte count, T-subset analysis, skin testing in adults

CBC, complete blood count.

for immune deficiencies can be critical in identifying congenital disorders, many of which are optimally treated with early SCT.[167] T-cell receptor excision circles and kappa-deleting recombination circles can detect T- and B-cell lymphopenia and suggest a diagnosis of SCID and X-linked agammaglobulinemia, respectively.[168] Detecting a molecular mutation in a gene and/or protein controlling part of the immune system is the ideal diagnosis.

Primary immunodeficiency disorders (PIDs) refer to a heterogeneous group of diseases characterized by defects in one of more parts of the immune system (Chapter 63). PIDs are usually inherited and are rare, with an estimated prevalence of 1 in 1,200 live births.[169] IgA deficiency is the most common; it occurs in 1 in 300 to 500 births, but only one-third have significant infections.[170] Although PID may present as life-threatening infections in childhood, more than 40% may not be diagnosed until adulthood. Time until diagnosis of any PID has decreased with better awareness and improved diagnostic tests.[168] Antibody deficiency syndromes comprise approximately 50% to 65% of PID, followed by 30% to 40% combined immune deficiencies, 10% to 18% phagocyte dysfunctions, and 1% to 2% complement deficiencies.[167,171]

An early test in any patient of any age with suspected immunodeficiency is HIV serology. In the HIV-negative patient, the age of the patient, geographic location, and type of infection or problem should dictate the tests ordered.[172] Congenital immunodeficiencies predisposing to sepsis can be subdivided into those affecting innate immunity and those affecting the adaptive immune system. The subdivision is somewhat arbitrary and there can be clinical overlap, as some molecular lesions will affect both types of immunity. The former involves the immediate response of the immune system to a pathogen and includes defects in complement proteins and mannose-binding lectin (MBL), nuclear factor kappa B (NF-κB) activation, phagocyte quantity and quality, and the type-1 cytokine axis.[172] *Neisseria* bacteremia and meningitis are seen in complement deficiencies. Neutrophil defects result in periodontal disease, oral ulceration, or cutaneous and visceral abscesses; and they have a narrow spectrum of infections: S*taphylococcus aureus, Burkholderia cepacia, Serratia marcescens* spp., or *Aspergillus* spp.[173]. In the absence of immune suppression, invasive aspergillosis is seen only in chronic granulomatous disease (CGD), and disseminated nontuberculous mycobacterial infection is seen in patients with defects of the IFN-γ/IL-12 axis. An overwhelming EBV infection may be the initial presentation of XLP syndrome. XLP1 results from defects in signaling lymphocytic activation molecule–associated protein, which is required for the activation of NK and cytotoxic lymphocytes. The adaptive immune system requires time after the initial exposure and representative defects include the different types of SCID, ataxia telangiectasia, and WAS.

In a patient with recurrent bacterial infection, the three major screening tests are a CBC with differential and peripheral blood smear, quantitative immunoglobulins, and a CH50.[174] Giant granules in neutrophils in a patient with oculocutaneous albinism indicates Chédiak-Higashi syndrome. Neutropenia in a neonate suggests Kostmann syndrome (congenital agranulocytosis). Thrombocytopenia with small platelets in a patient with eczema and abnormal gamma globulin levels is consistent with WAS. Interpretation of quantitative immunoglobulins depends on an awareness of the variation in the normal ranges with age. IgG, IgA, and IgM are markedly decreased in children with physiologic hypogammaglobulinemia of infancy, common variable immunodeficiency (CVID), and X-linked agammaglobulinemia. In the first two conditions, patients have circulating B cells by flow cytometry, whereas in X-linked agammaglobulinemia B cells are absent.[175–177] Thymoma is another circumstance with decreased immunoglobulins and decreased or absent B cells.[178] In hyper-IgM syndrome, the presence of markedly elevated IgM with depressed IgG and IgA is virtually diagnostic.[179] Patients with WAS who respond poorly to encapsulated bacteria often have an isolated decrease in IgM or may also have increases in IgE and IgA. Marked elevations of IgE (HIES or Job syndrome) are seen in patients with chemotactic defects, recurrent staphylococcal skin disease, cyst-forming pneumonia, and musculoskeletal abnormalities.[164,180] An autosomal dominant form involving a mutation in signal transducer and activator of transcription 3 (*STAT3*) and an autosomal recessive form resulting from mutation of the dedicator of cytokinesis 8 protein (*DOCK8*) have been described.[181] In occasional patients with recurrent bacterial infection, measurement of IgG subclasses or responses to individual antigens (e.g., tetanus and diphtheria) may be helpful in making a diagnosis.[182]

In adults with low IgG, the three major considerations are CVID, CLL, and multiple myeloma. Patients with CVID not only have recurrent infections but also may develop ITP, autoimmune hemolytic anemia, sarcoid-like granulomatous disease, inflammatory bowel disease, hepatitis, and NHL.[183,184] Patients with CLL have hypogammaglobulinemia, lymphocytosis, and immunophenotypic studies demonstrating a monotypic $CD5^+$, $CD23^+$ B-cell population.[111] In myeloma patients with a decreased IgA, IgM, or IgG, electrophoresis of serum identifies a paraprotein in more than 80% of patients, although immunofixation may be required to uncover IgA monoclonal protein hiding in the beta region. Some myeloma patients have a negative serum electrophoresis with immunofixation. Most of these patients have a monoclonal light chain on urine electrophoresis. Serum light chain assays can identify and quantify the kappa and lambda light chains.

The complement system is a part of innate immunity and can be activated by three pathways.[185] The classical pathway (C1, C4, C2) is activated by binding C1q to immunoglobulins on microbes or by direct binding to cells undergoing apoptosis. Patients with deficiency in the early classic complement pathway often have autoimmune disease (e.g., SLE and rheumatoid arthritis), which in part may be related to the physiologic role of the classic pathway in clearing immune complexes from the circulation.[186] The alternative pathway can be directly activated by microbes; and the lectin pathway is activated by carbohydrate moieties present on microbes. Hemolytic assays to assess the classical and alternative pathways have been available for years, but a complement kit can now assess all three pathways.[187]

Congenital complement deficiencies are rare autosomal recessive diseases except for properdin deficiency which is X-linked. All patients with deficiency of C1, C2, C3, C4, C5, C6, C7, or C8 have a zero CH50 (also seen with improperly handled specimens and occasionally in patients with severe immune complex disease).[186] Deficiency of C3, the central component of all three pathways is associated with SLE, glomerulonephritis, and bacterial infections. Deficiencies of properdin and factor D, components of the alternative pathway, and deficiencies of the late components C5, 6, 7, 8, and 9 often present with fulminant infection due to *Neisseria* species. Deficiency of MBL, an initiator of the lectin pathway, is due to point mutations of the *MBL2* gene and is associated with an increased risk to a variety of infections.[186,187]

If quantitative immunoglobulins, CH50, the absolute neutrophil count, and neutrophil morphology are normal in a patient with recurrent bacterial infections, WBC functional studies for CGD or other enzyme deficiencies are indicated (Chapter 58). The nitroblue tetrazolium test is abnormal in many, but not all, of these defects.[173] CGD is due to deficient function of the reduced nicotinamide adenine dinucleotide phosphate oxidase, which is responsible for the respiratory burst in phagocytes.[171] The diagnosis of CGD is now made by assays that rely on superoxide production. There are four genetic subtypes of CGD, with two-thirds X-linked due to mutations of the cytochrome b-245, beta polypeptide (*CYBB)* gene, and one-third autosomal recessive with the most common due to mutation of the neutrophil cytosolic factor 1 (*NCF1)* gene on chromosome 7q11.23.[171]

Flow cytometry for the CD11b/CD18 complex is diagnostic of patients with LAD type I.[188,189] LAD1 is an autosomal recessive

disorder due to mutations in the gene *ITGB2,* which encodes the common beta 2 subunit of the integrin (CD18) on chromosome 21q22.3.[162,188] There is diminished CD18 on leukocytes, which affects the third phase of the adhesion cascade, the firm adhesion of leukocytes to the endothelium. The severe type of LAD1 is caused by less than 1% expression of CD18 and presents early in life often with delayed umbilical stamp separation; while moderate types have 1% to 30% expression, have fewer severe infections, and are diagnosed later in life.[190] LAD2 is due to mutations in the guanosine diphosphate fucose transporter which lead to a lack of sialyl Lewis X (CD153) and a defect in the first phase, the rolling phase. LAD3 is caused by mutations in *FERMT3* (KINDLIN-3), encoding a molecule responsible for integrin activation, the second phase.[162,173]

Defects affecting phagocyte signaling via the Toll-like receptor canonical pathway include mutations of the myeloid differentiation primary response gene 88 (*MYD88*) and ILR-1–associated kinase 4 (*IRAK4*) which lead to invasive bacterial infections, primarily caused by *Streptococcus pneumoniae, Staphylococcus aureus,* and *Pseudomonas aeruginosa.*[163] Mutations in *IKBKG,* encoding the NF-κB essential modulator (NEMO), result in a susceptibility to a wider variety of infections and frequently have ectodermal dysplasia.[163,191] Mutations in the alternative pathway lead primarily to herpes simplex encephalitis.

WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) syndrome is due to heterozygous mutations of the intracellular c-terminus of the chemokine receptor 4 (*CXCR4*).[192] Hyperfunction of CXCR4 delays egress of neutrophils leading to neutropenia, and reduces circulating $CD27^+$ memory B cells resulting in B-cell lymphopenia and hypogammaglobulinemia.

In HIV-negative children with infections suggesting defective cell-mediated immunity (viral, fungal, or mycobacterial), the evaluation begins with the absolute lymphocyte count (Chapter 63). Because 75% of circulating lymphocytes are T cells, moderate lymphopenia implies T-cell lymphopenia. Distinct forms of SCID are characterized by different combinations of T/B/NK counts: $T^-B^-NK^-$, $T^-B^+NK^-$, $T^-B^-NK^+$, $T^-B^+NK^+$. There are over 20 different gene mutations associated with SCID.[193] Most newborns with SCID appear normal at birth, and the median age at diagnosis is 4 to 7 months.[193] X-linked SCID, the most common type, has absent T and NK cells with normal or elevated B cells, which can mask T-cell lymphopenia and is due to mutation of the *IL2RG* gene, localized at Xg13.1 and encoding the γ chain of the ILR-2. In adenosine deaminase deficiency, the second most common type of SCID, purine nucleoside phosphorylase deficiency, and reticular dysgenesis, all lymphocytes are absent ($T^-B^-NK^-$).

$T^-B^-NK^+$ SCID can be due to mutations in recombination activating genes *RAG1* and *RAG2,* which lead to defects of the first step of antigen receptor V(D)J recombination for both T and B lymphocytes.[194] Defects of the second step of recombination affect nonhomologous end-joining proteins and result not only in immunodeficiency, but also in defects in DNA repair, which predispose to neoplasia and toxicity to conditioning regimens.[195] In DiGeorge syndrome (suggested by hypocalcemia and congenital heart disease), T-cell numbers are decreased, whereas B cells are normal or elevated (sometimes masking T-cell lymphopenia).[166,196] In the bare lymphocyte syndrome in which either class I or class II HLA antigens are observed, the CD8 T-cell subset is decreased in defects involving class I HLA, and CD4 T cells are decreased in defects involving class II.[197] T^+SCID can be due to engraftment of transplacentally derived maternal T lymphocytes or to Omenn syndrome, characterized by erythroderma, hepatosplenomegaly, and eosinophilia, and caused by hypomorphic mutations ("leaky SCID") of *RAG 1/2* and other genes whose null mutations cause typical SCID.[193,198]

In HIV-negative adults, acquired defects in cell-mediated immunity with unusual susceptibility to viral, fungal, or mycobacterial infection are most commonly secondary to immunosuppressive therapy, chemotherapy (particularly nucleoside analogs), or malnutrition. Patients with sarcoidosis and neoplasms, such as HL, may be anergic on skin testing but usually do not develop infection before immunosuppressive therapy.[199,200] In 1992, idiopathic CD4 lymphocytopenia (ICL) was defined in HIV-negative patients who had low CD4 T lymphocytes (0.3×10^9/L or < 20% of total T cells) on a minimum of two separate points at least 6 weeks apart. Patients with a profound decrease in CD4 T-cell numbers and low CD4/CD8 ratios present with opportunistic infections similar to those seen in AIDS.[201,202] Hypomorphic gene mutations, which control T-cell receptor recombination or signaling, have been identified in a few patients with ICL.[203,204] Rarely, ICL patients have normal CD4/CD8 ratios and do not have increased susceptibility to infection.[44,202]

SUMMARY

This chapter is a brief overview and introduction to the subsequent chapters in Part VI on nonmalignant disorders of the phagocytic and immune system. A primary objective is to separate benign from malignant disorders. Identifying a specific defect in the immune system begins with a history and physical examination followed by tests to identify the defect. A single gene mutation may account for a congenital immune deficiency, and prenatal diagnosis may be possible by sex determination in utero if X-linked or by fetal blood sampling if the defective gene is known or if characteristic abnormalities in the peripheral blood can be identified. Some of the congenital immune deficiencies, such as SCID and its variants, represent medical emergencies. Acquired immune abnormalities, particularly functional asplenia, severe hypogammaglobulinemia, and iatrogenic neutropenia or T-cell deficiency, can also be life threatening. Knowledge of the site of the defect in a host's immune system—whether in the neutrophils, humoral, cell-mediated, or complement arms or a combination thereof—is critical in predicting types of infections that can occur and instituting appropriate therapy.

CHAPTER 57

NEUTROPENIA

Caron A. Jacobson, Nancy Berliner

INTRODUCTION

The normal range for the peripheral white blood count (WBC) is between 4.5 × 10^9/L and 10.0 × 10^9/L, with a mean of 7.5 × 10^9/L. The total WBC includes neutrophils and lymphocytes, as well as smaller numbers of monocytes, basophils, and eosinophils. Leukopenia, a depressed WBC, may reflect either neutropenia or lymphopenia. Neutrophils constitute about 60% of the peripheral WBC, and therefore, reduction of WBC number most commonly reflects a decreased absolute neutrophil count (ANC). Neutropenia can occur as a secondary manifestation of an underlying disease or exposure or may reflect primary hematologic disease. This chapter focuses on the primary and secondary causes of neutropenia.

NORMAL NEUTROPHIL KINETICS

The circulating neutrophil pool represents only approximately 5% of the body's total neutrophil number. It is therefore a fairly distant reflection of the dynamics of neutrophil maturation within the bone marrow.[1] Neutrophils arise in the bone marrow from a multipotent progenitor cell that also gives rise to all other formed elements of the blood. Maturation of neutrophil precursors occurs over 6 to 10 days. The majority of mature neutrophils constitute a storage pool that remains in the bone marrow poised for release as needed. The proliferating pool and storage pool together make up about 95% of the total granulocyte mass. Of the remaining 5% of neutrophils that enter the peripheral circulation, about 60% are a "marginating pool" that adheres to the vascular endothelium. These marginated neutrophils are easily mobilized into the circulation in response to stress. Circulating neutrophils survive for only 6 to 12 hours; when mobilized to sites of infection or inflammation, they can migrate into tissues where they survive for 1 to 4 days. Neutropenia can occur upon disruption of any of these processes: it may reflect decreased marrow production, increased margination (especially in the setting of splenomegaly and sequestration by the spleen), or peripheral immune destruction of mature cells.

DEFINITION AND CLASSIFICATION OF NEUTROPENIA

Neutropenia is defined by a decreased ANC, calculated by multiplying the total WBC by the percentage of neutrophils and bands noted on the differential cell count. What constitutes a low ANC differs by age, sex, race, and other factors; the normal range for the ANC for a given population, then, is defined as the mean ANC for that population +/– two standard deviations.[2,3] In general, however, an ANC less than 1.5 × 10^9/L is considered neutropenic in most patient populations. Neutropenia can be further classified as mild, moderate, or severe based on the degree of ANC depression: an ANC of 1.0 to 1.5 × 10^9/L is considered mild, 0.5 to 1.0 × 10^9/L is considered moderate, and less than 0.5 × 10^9/L is considered severe. Although this classification is useful in predicting the risk of severe bacterial infection, other features may modify the risk. The risk of infection may be modified by the neutrophil storage pool.[4] Risk may also be modified by the cause of neutropenia. For instance, chemotherapy-induced neutropenia is associated with a much greater risk of serious infection than chronic immune or nonimmune neutropenia. The risk of infection is also a function of both the degree and duration of neutropenia.[5]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of neutropenia includes pseudoneutropenia, primary or congenital neutropenias (Table 57.1), and acquired neutropenias (Table 57.2). Global marrow defects such as aplastic anemia, leukemia, myelodysplasia, or myeloproliferative disorders can also cause neutropenia and are discussed in other chapters. Here we outline and discuss the causes of isolated neutropenia.

Pseudoneutropenia

Neutropenia may be the result of laboratory or clerical error, an artifact due to prolonged processing time of a peripheral blood specimen, the consequence of neutrophil clumping due to the presence of a paraprotein or certain anticoagulants, or as a result of marginalization of the circulating neutrophil pool.[6,7] In each of these situations, the ANC is not actually low and these patients are not at increased risk of infection. Manual examination of the peripheral blood smear and repeated measurements can help to differentiate these causes of pseudoneutropenia from true neutropenia.

Primary Causes of Neutropenia

Ethnic and Benign Familial Neutropenia

A number of racial and ethnic groups have neutrophil counts that fall below the published normal range, which is largely based on Caucasian populations. These include African Americans, Yemenite Jews, Falasha Jews, and African Bedouins.[8–11] The occurrence of ethnic neutropenia has been linked to single nucleotide polymorphisms in the gene encoding the Duffy antigen receptor for chemokine (*DARC*), which is also the receptor for the malarial parasite. Loss of expression of the Duffy blood group is prevalent in the areas where malaria is endemic, which are also areas where ethnic neutropenia has been described.[12] There is also an autosomal dominantly inherited condition called benign familial neutropenia characterized by neutrophil counts in the 800 to 1,400/μl range, for which the responsible gene is not known.

Ethnic and benign familial neutropenias are not associated with an increased risk of infection.[13,14] Bone marrow biopsies have normal cellularity but a reduction in mature granulocytes and neutrophil kinetic studies reveal a reduced myeloid precursor pool in the marrow, reduced mitotic pool size, and reduced concentration of colony-forming unit culture (CFU-C) consistent with the faulty release of mature neutrophils from the bone marrow.[15,16]

Nonfamilial Chronic Benign and Idiopathic Chronic Severe Neutropenia

Nonfamilial chronic benign neutropenia is a condition defined by neutropenia in the absence of a familial pattern and without an increased risk of infection. There is often a compensatory monocytosis and eosinophilia and bone marrow biopsies show hypercellularity and myeloid hyperplasia with maturation arrest at the band stage of myeloid ontogeny. Neutrophil counts do

TABLE 57.1

DIFFERENTIAL DIAGNOSIS AND FEATURES OF CONGENITAL NEUTROPENIA

Syndrome	Inheritance Pattern	Gene (Frequency)	Clinical Features
Ethnic neutropenia	?	*DARC* SNPs (?%)	African American, Yemenite and Falasha Jews, African Bedouins; Mild and clinically insignificant neutropenia
Benign familial neutropenia	AD	?	Mild and clinically insignificant neutropenia
Severe congenital neutropenia	 AR AD X-linked	Unknown (~40%) *HAX1* (~0–2%) *G6PC3* (~4%) *ELANE* (~55%) *WASP* (~2%)	Severe (ANC <500), chronic neutropenia; increased risk of severe infection and MDS/AML; responsive to G-CSF
Cyclic neutropenia	AD	*ELANE* (100%)	Severe (ANC <200) neutropenia for 3–5 d every 21 d; increased risk of infection during nadir; responsive to G-CSF; no increased risk of MDS/AML; sporadic forms a/w diseases such as LGL
Shwachman-Diamond syndrome	AR	*SBDS* (100%)	ANC 200–800 at infancy; progresses to marrow failure; pancreatic dysfunction, skeletal abnormalities, and developmental retardation; increased risk of MDS/AML; responsive to G-CSF and SCT
Fanconi anemia	AR X-linked	*FANCA*[a]-*SLX4*	Marrow failure; short stature with upper limb abnormalities; *café-au-lait* spots; increased risk of malignancies; neutropenia is responsive to G-CSF and RIC SCT
Dyskeratosis congenita	X-linked AD AR	*DKC1* (~80%) *TERC* (0–20%) *TERT* (0–20%) Misc (0–20%)	Marrow failure; nail dystrophy; leukoplakia; skin pigmentation abnormalities; pulmonary and liver fibrosis; osteoporosis; premature graying of the hair; increased risk of MDS/AML and other malignancies
Glycogen storage disease Ib	AR	*SLC37A4* (100%)	Hepatomegaly; metabolic crises; neutropenia
Myelokathexis	AD	*CXCR4* (100%)	Neutropenia due to marrow retention; can be part of the WHIM syndrome; responsive to G-CSF and the CXCR4 antagonist plerixafor
Chediak-Higashi syndrome	AR	*LYST* (100%)	Oculocutaneous albinism; platelet dysfunction; neurologic disease; neutropenia; risk of HLH
Griscelli syndrome II	AR	*RAB27A* (100%)	Oculocutaneous albinism; neutropenia
Hermansky-Pudlak syndrome II	AR	*AP3B1* (100%)	Oculocutaneous albinism; platelet dysfunction; pulmonary fibrosis; neutropenia
Cartilage-hair hypoplasia	AR	*RMRP* (100%)	Moderate–severe neutropenia; short-limb dwarfism; fine hair; defects in cellular immunity

AD, autosomal dominant; ANC, absolute neutrophil count; AR, autosomal recessive; G-CSF, granulocyte colony stimulating factor; HLH, hemophagocytic lymphohistiocytosis; LGL, large granular lymphocytosis; MDS/AML, myelodysplastic syndrome/acute myelogenous leukemia; Misc, miscellaneous; RIC, reduced intensity conditioning; SCT, stem cell transplantation; SNPs, single nucleotide polymorphisms; WHIM syndrome, warts, hypogammaglobulinemia, immunodeficiency, myelokathexis syndrome.

[a]Indicates the most commonly mutated complementation group in Fanconi anemia.

rise, however, under conditions of stress such as infection or exogenous epinephrine or corticosteroid administration, perhaps explaining the absence of risk for infection.[17] Some cases are associated with the presence of autoantibodies pointing toward an immune mechanism in the pathophysiology of this condition.[18,19] Other cases seem to be the result of abnormal phagocytosis of normal marrow neutrophils by macrophages or the result of T-cell and cytokine-mediated suppression of granulopoiesis in the bone marrow.[20,21] Included in this diagnosis is chronic benign granulocytopenia of infancy and childhood which typically resolves spontaneously around age 4 years.[17] Although neutrophil counts do rise in response to G-CSF administration, G-CSF therapy is not recommended given the relatively benign clinical course associated with this condition.[22,23]

Idiopathic chronic severe neutropenia is distinguished from this benign condition in that it typically affects patients in their late childhood or as adults and has a more severe clinical course with increased risk and number of infections.[24] There is evidence of myeloid hypoplasia, maturation arrest, or abnormal myeloid morphology on bone marrow biopsy; the form associated with severe myeloid hypoplasia is called chronic hypoplastic neutropenia.[25,26] To diagnose patients with idiopathic chronic severe neutropenia, other causes of neutropenia must be ruled out, including autoimmune etiologies. The pathogenesis of this form of severe neutropenia is completely unknown. Despite ANCs that may be in the 100 to 250 cells/μl range, these patients have a remarkably benign course, although some have recurrent infections requiring chronic cytokine support with G-CSF.

A large body of literature has focused on chronic neutropenia in Greece. The incidence of neutropenia on the island of Crete is quite high. This should be distinguished from chronic severe neutropenia, in that nearly all these patients have an ANC in the 0.8 to 1.4 $\times$ 10^9/L range, and an ANC of <0.5 $\times$ 10^9/L rarely if ever occurs. There is evidence that these patients may have a cytokine-mediated, inflammatory component to their illness.[21] It is unknown whether these patients have an increased prevalence of the DARC polymorphism associated with neutropenia.

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) is a disorder of severe neutropenia first described in 1956 by Rolf Kostmann. He postulated that this was the first described congenital disorder of neutrophil number, presenting as an autosomal recessive disorder in neonates and infants with neutrophil counts <500 cells/μl associated with recurrent bacterial infections, most commonly due to *Staphylococcus aureus, Escherichia coli,* and *Pseudomonas aeruginosa*.[27,28] His original report described this syndrome in nine families from a remote region in northern Sweden where consanguinity was common, explaining the increased incidence

TABLE 57.2

DIFFERENTIAL DIAGNOSIS AND FEATURES OF ACQUIRED NEUTROPENIAS

Cause	Mechanism	Management
Infection		
Viral	Redistribution; decreased production; immune destruction	Supportive care; treatment of the underlying infection; G-CSF or WBC transfusions reserved for protracted or severe cases; IVIg may be useful for immune or complement mediated neutrophil destruction
Atypical organisms	Redistribution; decreased production; immune and complement mediated destruction; direct marrow suppression	
Sepsis	Consumption of the marrow neutrophil reserve; increased margination	
Drug-induced		
Penicillin, PTU, gold	Immune-mediated destruction via hapten-induced antibody formation and complement fixation or the formation of circulating immune complexes	Supportive care; removal of the offending agent; G-CSF reserved for protracted or severe cases
Valproic acid, Carbamazepine, β-lactams	Dose-dependent inhibition of CFU-GM resulting in marrow suppression	
Immune-mediated		
Systemic/autoimmune disease	Pan-reactive antibodies against neutrophils and neutrophil precursors	Supportive care; treatment of the underlying condition; G-CSF as needed
LGL/Felty's syndrome	Antineutrophil antibodies and immune complex mediated neutrophil destruction; increased neutrophil adhesion to the endothelium; FAS mediated apoptosis of neutrophils; impaired myelopoiesis; splenic destruction	Supportive care; immunosuppression with methotrexate, cyclosporine, cyclophosphamide, and/or rituximab; G-CSF as needed
Neonatal alloimmune neutropenia	Maternal IgG antibodies to paternally inherited neutrophil antigens	Self-limited; supportive care with antibiotics as needed; plasma exchange, IVIg, maternal neutrophils for life-threatening infections
Autoimmune neutropenia of infancy and childhood; Primary autoimmune neutropenia of adults	Antibody mediated neutrophil destruction, usually against a specific neutrophil antigen	Supportive care; G-CSF therapy to prevent recurrent or severe infection
Pure white cell aplasia	Cellular and humoral immune mediated; associated with thymoma	Thymectomy; adjuvant cyclophosphamide, steroids, cyclosporine, IVIg, and/or SCT
Neutrophil margination/ hypersplenism	C5a and complement activation leading to increased adhesion and aggregation within pulmonary vessels; splenic sequestration	
Nutritional deficiency (B12, folate, copper)	Ineffective myelopoiesis and maturation arrest	Vitamin and mineral replacement

Abbreviations: G-CSF – granulocyte colony stimulating factor; WBC – white blood cell; IVIg – intravenous immunoglobulin; PTU – propylthiouracil; CFU-GM – colony forming unit granulocyte macrophages; LGL – large granular lymphocytosis; IgG – immunoglobulin class G; SCT – stem cell transplantation.

of this rare autosomal recessive syndrome.[27] The syndrome was named infantile genetic agranulocytosis, which later was renamed SCN or Kostmann syndrome. Afflicted children suffer from infections that can occur as early as the first months of life and often include omphalitis and perirectal abscesses; otitis media, pneumonia, gingivitis, and urinary tract infections are also common. The diagnosis is usually apparent within the first 3 months of life. Death may occur as a result of septicemia, peritonitis, and enteritis, with fatal infections common in infancy and early childhood. All patients have severe neutropenia with an ANC $<0.5 \times 10^9$/L, but often $<0.2 \times 10^9$/L, and there is often an increase in other myeloid cell lines including monocytes and eosinophils. SCN was previously hypothesized to be a result of a deficiency in G-CSF or its receptor but further studies have demonstrated that G-CSF production is not impaired in patients with SCN, G-CSF receptor number and function are normal in patients with SCN, and the administration of G-CSF results in correction of neutropenia and improved clinical outcomes.[29–31,32,33] Kostmann's early studies suggested that intramedullary apoptosis of myeloid precursors was a prominent feature of SCN, and more recent studies have confirmed that accelerated apoptosis is a central defect of this disorder, suggesting that G-CSF functions to correct the phenotype in part through its activity as an antiapoptotic agent.[34,35,36,37]

Since the initial description in 1956, SCN has come to be recognized as a syndrome resulting from a heterogeneous mix of genetic mutations with different patterns of inheritance. SCN can follow autosomal dominant, autosomal recessive, and X-linked patterns of inheritance and has been shown to be associated with mutations in a variety of genes including those for neutrophil elastase, *HAX-1, WAS* (*WASP*), *GFI1, SBDS*, and *G6PC3*.[38,39–42] Neutrophil elastase (ELANE) is a serine protease that is synthesized predominantly at the promyelocyte stage of neutrophil maturation and stored in primary granules. It has been hypothesized that *ELANE* mutations lead to cytoplasmic accumulation of defective protein, subsequently triggering apoptosis. Evidence supports activation of the unfolded protein response as the driver of apoptosis in ELANE-associated SCN.[43,44] SCN due to *ELANE* mutations is inherited in an autosomal dominant fashion. It was the first SCN gene to be identified and is responsible for the majority of cases of SCN. It is not the mutation found in the original Swedish cohort described by Kostmann, however, which is an autosomal recessive disorder that results from mutations in *HAX-1*.[45] "Kostmann's syndrome" now refers only to SCN with mutant *HAX-1*.[41] HAX-1 is a mitochondrial protein with weak homology to BCL-2 and its absence results in mitochondrial-dependent apoptosis. WASP regulates actin polymerization in hematopoietic cells. Absolute deficiency in this protein resulting from gene-inactivating mutations results in the Wiskott-Aldrich syndrome, characterized by thrombocytopenia, small platelets, sinopulmonary infections, and eczema. *WASP* mutations resulting in hypomorphic alleles, however, may lead to X-linked thrombocytopenia and neutropenia.[40,42] *GFI1* encodes a transcription factor, growth factor independent-1, that regulates the expression of genes involved in granulopoiesis, Shwachman-Bodian-Diamond syndrome gene (*SBDS*) encodes a gene involved in ribosomal RNA regulation and is responsible for Shwachman-Diamond syndrome (SDS) (which is discussed in a later section), and *G6PC3* encodes the catalytic subunit 3 of glucose-6-phosphatase. Mutations in each of these three genes have been associated with SCN.[46,47,48]

The gene(s) responsible for approximately 40% of SCN, however, remains unknown.[40]

Although G-CSF receptor signaling is intact in the vast majority of patients with SCN, rare patients have been described in which SCN arises from a congenital abnormality in the G-CSF receptor. Not surprisingly, these patients are marked by resistance to therapy with G-CSF.[49,50–52] The most important observation to emerge from the studies of the G-CSF receptor in SCN, however, is the finding of frequent somatic mutations in the G-CSF receptor arising in patients with SCN on cytokine therapy. When searching for potential constitutional mutations in the G-CSF receptor that might cause SCN, investigators identified a somatic missense mutation that appeared to be associated with transformation to myelodysplastic syndrome (MDS) and acute myelogenous leukemia (AML).[49] This mutation introduces a stop codon leading to truncation of the distal intracellular domain of the receptor. The distal portion of the receptor is known to be the site of JAK-STAT activation and maturation signaling.[49] Some investigators have postulated that the mutation causes proliferation at the expense of maturation, explaining why patients with this mutation have a higher risk of MDS/AML.[53] It has clearly been demonstrated that the mutation shifts the dose–response curve for G-CSF, rendering the cells hyperproliferative, and permitting clonal dominance of the mutant clone in the setting of G-CSF therapy. Whether the mutation actually blocks differentiation or merely predisposes to further genetic events by virtue of increasing cell proliferation remains controversial. Regardless, these G-CSF receptor mutations have been found to confer resistance to apoptosis and enhance cell survival in patients with SCN.[54]

In general, patients with SCN have an increased risk of developing MDS and AML at a rate of approximately 2% to 8% per year.[55–57] In patients who do develop MDS and/or AML, there appears to be a sequential gain of mutations that were not present in the subpopulation of progenitor cells in the early SCN phase such that over two thirds of patients with SCN that develop MDS or leukemia have a G-CSF receptor mutation (*CSF3R*).[58] Increasing mutations in the G-CSF receptor gene point toward a role for aberrant G-CSF receptor signaling in leukemogenesis.[58,59] The role of G-CSF in causing or promoting these mutations remains unknown and a subject of considerable controversy.

G-CSF has revolutionized the treatment and management of SCN. Prior to the development of G-CSF as a clinical agent, SCN was almost uniformly fatal, with death from infection occurring in infancy or early childhood. Patients were treated with corticosteroids, testosterone, splenectomy, vitamin B6, and lithium, all of which were largely ineffective.[60,61–63] The use of G-CSF for this disease began in the 1980s, and has prevented infection in the vast majority of patients (80% to 90%), although some patients require higher doses.[57,64] The resultant increased life expectancy of these patients has coincided with an increased incidence of MDS and AML. This has led some to posit that G-CSF therapy facilitates the transformation to these malignant diseases, whereas others contend that prolonged survival allows for the emergence of a predisposition to MDS/AML as part of the natural history of this disease. The potential role of G-CSF in the development of MDS/AML in SCN is discussed later in this chapter. Chronic G-CSF therapy in this disease has led to other complications, including osteoporosis, vasculitis, splenomegaly, hepatomegaly, and glomerulonephritis.[57,64]

Cyclic Neutropenia

Cyclic neutropenia (CN) is a periodic disorder characterized by neutropenia (ANC $\leq 0.2 \times 10^9$/L) occurring at approximately 21-day intervals, although one quarter of patients may have cycles as short as 12 days or as long as 36 days.[65–67] Nadirs of the ANC last 3 to 5 days and may be associated with recurrent fevers, aphthous ulcers, and infections of the skin, upper respiratory tract, and ears. The severity of infection reflects the severity and duration of neutropenia.[68] Fatal infections are uncommon, however, owing to the relatively brief period of neutropenia that is the hallmark of this disease, and as a result patients enjoy favorable overall survivals. With time, the cyclic nature of the disorder becomes less prominent, however, and patients can look more like patients with chronic neutropenia.[69] It was first described in 1910 in an infant with recurrent episodes of fever, stomatitis, skin infections, and neutropenia.[70] Diagnosis of CN can be demonstrated by documenting intermittent neutropenia via blood counts every 2 to 3 weeks over a course of 6 weeks, but can now be confirmed by the detection of a pathogenic mutation in the setting of a suggestive pattern of WBC fluctuation. CN is inherited as an autosomal dominant disorder, although it may arise sporadically. CN can also be acquired in association with systemic diseases such as large granular lymphocytosis.[71,72] Virtually 100% of patients with congenital CN also have point mutations in the gene for neutrophil elastase (*ELANE*).[73] These mutations are largely distinct from those that are associated with SCN, although both syndromes have been seen arising from the same mutation within the same pedigree.[74,75]

Serial measurements of other hematopoietic cells in patients with CN reveal a periodicity to the numbers of platelets, reticulocytes, monocytes, and eosinophils as well, and the condition is sometimes referred to as cyclic hematopoiesis.[76] As opposed to the depression seen in the neutrophil count, these other cells are often increased in number on or around periods of neutropenia.[77] Bone marrow biopsies done during times of neutropenia and times of normal neutrophil counts reveal an absence of neutrophils and neutrophil precursors immediately preceding the period of neutropenia, whereas neutrophil precursors increase in number before recovery of peripheral neutrophil counts.[78] The periodicity of the cell counts is thought to be the result of variations in the rate of release of mature cells from the marrow. Although knock-in mice fail to reproduce the phenotype of either SCN or CN, a dog model of CN has provided insight into its pathogenesis.[79] In grey collie dogs, the disease can be transmitted to unaffected animals following bone marrow transplantation from an affected animal and can be cured following transplantation from an unaffected animal.[80] In humans, a patient with acute lymphoblastic leukemia treated with a donor stem cell transplantation from a sibling with this disorder developed the disease.[81] These observations and experiments support the notion that this disease is the result of an intrinsic stem cell regulatory defect, possibly related to accelerated apoptosis.[82] A comparison of bone marrow biopsies from patients with CN and SCN, and normal subjects revealed that there were no differences in the frequency of CD34, KIT, and G-CSFR expression on marrow precursor cells between CN patients and normal subjects.[83] Differences emerged, however, in response to hematopoietic growth factors with impaired granulopoiesis in both $CD34^+/KIT^+/G\text{-}CSFR^+$ and $CD34^+/KIT^+/G\text{-}CSFR^-$ cells in patients with CN; in SCN impaired granulopoiesis was only observed in the former.

Despite the impairment of granulopoiesis observed in response to hematopoietic growth factors, this disease is successfully treated with G-CSF and is not associated with an increased risk of leukemic transformation.[57,69,84] G-CSF therapy does not prevent the cyclical depressions in neutrophil counts but does decrease the duration of neutropenia. GM-CSF therapy, on the other hand, has been noted to prevent the cycles but not to increase the neutrophil numbers to the same extent as seen with G-CSF.[85] G-CSF remains the treatment of choice for this disease when therapy is required. Lower doses of G-CSF are needed for the treatment of CN than SCN, with a median dose of 2.5 μg/kg/day in one cohort.[65] G-CSF is safe and well tolerated, although patients may develop a gradual asymptomatic splenic enlargement.[69] The acquired, adult-onset forms of CN that are associated with systemic diseases are treated differently and are often successfully managed with immunosuppression including daily or alternate-daily corticosteroids or cyclosporine.[86,87] These therapies are not successful in the congenital forms of this disease.[65,68]

Congenital Immune Defects with Associated Neutropenia

Patients with inherited immunodeficiencies of humoral and/or cellular immunity are at risk of developing neutropenia. The infectious consequences in such patients are magnified due to the co-existing immune defects. Diseases involving immunoglobulin production, including X-linked agammaglobulinemia, hyper-IgM syndrome, dysgammaglobulinemia type I, isolated IgA deficiency, and familial forms of hypogammaglobulinemia have all been associated with periodic neutropenia and in some are thought to be related to the production of autoantibodies.[88–92] These patients should be treated with intravenous immunoglobulin, which may correct both immune defects, with growth factors reserved for patients who do not respond to immunoglobulin replacement.[93] Likewise, neutropenia has been associated with defects in cellular immunity; one familial syndrome was described in 1976 in which patients manifested severe neutropenia coincident with decreased antibody production in response to tetanus and poliomyelitis vaccines with resultant infectious complications.[94] Finally, reticular dysgenesis is a rare immunodeficiency marked by severe neutropenia, lymphopenia, agammaglobulinemia and absent cellular immunity believed to be due to an inherent defect in hematopoietic stem cells committed to myeloid and lymphoid development.[95,96] It is not responsive to G-CSF but can be cured with stem cell transplantation.[97–99]

Other Congenital Syndromes with Associated Neutropenia

Neutropenia is an important feature of several other congenital disorders. (see also Chapter 37.) These include SDS, Fanconi anemia (FA), dyskeratosis congenita (DKC), glycogen storage disease Ib, myelokathexis, Chediak-Higashi syndrome (CHS), Griscelli syndrome type II (GS2), Hermansky-Pudlak syndrome II (HPSII), and cartilage-hair hypoplasia.

SDS usually presents with neutropenia in infancy and subsequently progresses to marrow failure. It is also associated with pancreatic dysfunction and skeletal abnormalities.[100] It was initially described in 1964 and is also associated with anemia, thrombocytopenia, developmental and mental retardation, diarrhea, weight loss, failure to thrive, eczema, recurrent otitis media and pneumonia, and neutrophil motility defects.[101–103] SDS is an autosomal recessive disease caused by mutations in the *SBDS* on chromosome *7*q, which is involved in the regulation of ribosomal RNA processing.[47] Neutropenia, in the range of 0.2 to 0.8 $\times$ 10^9/L, appears to be the result of myeloid hypoplasia.[104] The mechanism of neutropenia is unknown, but neutrophils from affected patients appear to have increased ubiquitin-proteasome–rich cytoplasmic structures.[105] SDS patients are predisposed to the development of MDS/AML, with myelodysplasia or clonal cytogenetic abnormalities (usually monosomy 7) present in up to one third of patients. The risk of severe hematologic complications is greatest in patients with cytopenias and symptoms before 3 months of age.[106,107] Before the use of G-CSF for this disease mortality reached 25% and was the result of infection, marrow failure, and/or malignancy.[108] The use of G-CSF, at an average dose of 4.3 μg/kg/day, corrects the neutropenia and decreases the risk and mortality from infection.[109] As seen in SCN, however, the use of G-CSF and improvements in survival have also been associated with increased risk of MDS and AML and it is unclear if this is due to G-CSF or the natural history of the disease; the risk of MDS/AML is similar to that seen in SCN in the International Registry but was slightly lower than this in the French Registry.[110] Stem cell transplantation can be curative but is associated with increased transplant-related morbidity and mortality and thus requires careful consideration and consultation with experienced transplant centers.[111,112,113,114] The successful use of reduced intensity conditioning transplantation for this disease may make transplant a more widely available option for these patients.[115]

FA is the most common cause of congenital aplastic anemia. It can be inherited in an autosomal recessive or X-linked manner and is due to mutations in genes involved in DNA repair. Marrow failure develops somewhat later than in other congenital marrow syndromes (median age 7 years), presumably because marrow failure occurs secondary to acquired mutations in the setting of defective DNA repair.[116,117,118] Multiple genes have been found to be mutated in FA and 15 complementation groups have been identified (*FANCA-SLX4 I* [*FA-P*]), with *FANCA* being the most common.[119] In addition to marrow dysfunction, up to two thirds of patients with FA have a constellation of other abnormalities, including short stature with upper limb anomalies, and hyperpigmented, *café-au-lait* spots. FA patients are at increased risk for malignancies, especially MDS/AML and squamous cell carcinomas.[120] The diagnosis of FA is established by demonstrating chromosomal fragility following exposure to diepoxybutane or mitomycin C; subsequent gene analysis can then identify mutations in one of the genes involved in the DNA repair complex.[121] Stem cell transplantation can treat the hematologic manifestations of the disease but carries a high risk of morbidity and mortality due to the effects of conditioning on these patients with impaired DNA repair; consequently, reduced intensity conditioning regimens are necessary.[122,123,124,125,126] Other therapies for the hematologic manifestations of this disease include androgens, which may be effective in half of FA patients, and growth factors such as G-CSF at doses starting at 5 μg/kg/d.[127,128]

DKC is a rare multiorgan syndrome associated with neutropenia and/or aplastic anemia; patients may also have other abnormalities, including nail dystrophy, leukoplakia, and abnormal skin pigmentation.[129–131] Additional clinical manifestations include premature graying of the hair, idiopathic pulmonary fibrosis, cancer predisposition (including AML and solid tumors including squamous cell carcinomas), osteoporosis, and cirrhosis.[132] The majority of cases involve mutations in the *DKC1* gene on chromosome Xq28 but DKC can also be due to genetic mutations that are inherited in an autosomal dominant or recessive manner such as mutations in *TERT* and *TERC*.[133,134] The *DKC1* gene encodes dyskerin, a protein that is involved in RNA function and telomere maintenance. *TERT* and *TERC* are the genes for the reverse transcriptase portion of telomerase and the telomerase RNA component, respectively, and as is *DKC1*, are crucial for maintenance of telomere length. Clinical manifestations reflect progressive telomere shortening, and are therefore not present at birth; clinical symptoms typically do not present until the second decade of life. The severity and penetrance of some variants of DKC is unpredictable. However, inasmuch as offspring of affected individuals will inherit shortened telomeres, this is a syndrome that can manifest anticipation, with earlier and more severe symptoms occurring in consecutive generations. Telomere length in three different lymphocyte subsets can be measured to screen for this disease; patients with DKC have telomere lengths less than the first percentile for age in all three cell lines.[135] Genetic testing for known mutations can be helpful but does not rule out the disease as a subset of patients lack identifiable mutations. G-CSF or GM-CSF is effective in improving neutrophil counts in patients with DKC, and allogeneic stem cell transplantation, with reduced intensity conditioning given the sensitivity to genotoxic agents, is effective in treating the hematologic manifestations of this disease.[131,136–138] DKC affects other organ systems, however, which will not improve following stem cell transplantation, and pulmonary disease and solid tumors remain a major source of morbidity and mortality following stem cell transplantation.

Glycogen storage disease Ib is an autosomal recessive disorder caused by mutations in the gene for glucose-6-phosphatase translocase. This leads to hepatomegaly and a metabolic disorder related to intracellular accumulation of polysaccharide. It is also

associated with defects in the neutrophil respiratory burst that increase apoptosis of circulating neutrophils and lead to neutropenia.[139,140] Patients typically present at 6 months of age with hepatomegaly, hypoglycemia, and lactic acidosis.[141] Neutropenia presents within the first year of life in the majority of patients and although it is usually intermittent, it has no faithful periodicity or cycle.[142] Diagnosis is made by looking for the most common genetic mutations but if none are identified, liver biopsy to confirm excess glycogen stores and steatosis without prominent fibrosis is recommended. A strict carbohydrate-restricted diet is necessary to control the disease and G-CSF can be used to treat the neutropenia.[143,144] Liver transplantation has been used to correct many complications of this disease but neutropenia persists.[145] Neutropenia has also been reported in other metabolic disorders, including propionic academia, methylmalonic academia, and isovaleric academia.[146–148]

Myelokathexis is a rare syndrome in which mature neutrophils are retained in the bone marrow, leading to a decreased peripheral ANC.[149] Retained neutrophils display an abnormal morphology with cytoplasmic vacuolization, pyknotic nuclei, nuclear hypersegmentation, and thin nuclear strands connecting nuclear lobes.[150] There is also evidence that neutrophils undergo accelerated apoptosis in affected patients, resulting in a shortened peripheral lifespan. Evidence suggests that this is a cell-intrinsic defect, as neutrophil survival is also reduced following injection into unaffected volunteers.[150,151] Accelerated apoptosis may be due to decreased expression of Bcl-x, an inhibitor of apoptosis. The storage pool of mature neutrophils is not reduced, and neutrophil counts rise in response to infection in patients with myelokathexis, making the risk of overwhelming infectious complications low. There is a female predominance in this disease and most patients are diagnosed in infancy.[152] The combination of myelokathexis with hypogammaglobulinemia and warts is termed WHIM syndrome (warts, hypogammaglobulinemia, immunodeficiency, myelokathexis),[153] which is caused by heterozygous mutations in the gene for the chemokine receptor *CXCR4*.[154] These mutations cause hyperreactivity of CXCR4, leading to retention of neutrophils in the marrow. These patients respond to growth factor therapy with G-CSF or GM-CSF, which down-regulate the expression of CXCR4.[155,156] The CXCR4 antagonist, plerixafor, has been given to nine patients with the WHIM syndrome with resultant transient normalization of WBC counts.[157,158]

Congenital disorders of vesicular trafficking are also associated with neutropenia. These include CHS, GS2, and HPSII.[159] These diseases are also associated with disorders of other granulated cells, leading to oculocutaneous albinism (from disrupted melanin granules), bleeding (from abnormal platelet secretory granules), and neurologic disease (from abnormal trafficking and release of neuronal granules). All of these diseases can enter a terminal phase of hemophagocytic syndrome, often in the setting of Epstein-Barr virus (EBV) infection. In all cases, this is postulated to occur because of abnormal secretion of perforin-containing granules into the immunologic synapse, impairing natural killer-cell–mediated killing. CHS is an autosomal recessive disorder caused by mutations in the *LYST* gene (lysosomal trafficking regulatory gene) and is associated with characteristic neutrophils containing giant granules.[159,160,161] Three quarters of patients with CHS develop moderate to severe neutropenia, thought to be the result of increased destruction of peripheral neutrophils and decreased marrow release of neutrophils.[160,162] Infectious risk is increased above that expected for the ANC due to concomitant humoral and cellular immune defects in this disease.[163,164] GS2 is also an autosomal recessive disorder, due to mutations in a small GTPase *RAB27A*, which is part of the protein complex necessary for granule release.[165,166] HPSII is due to defects in *AP3B1* which encodes a part of a protein transport complex that mediates sorting of lysosomal proteins.[167] Defects in *AP3B1* lead to widespread functional impairment of cells carrying secretory granules. As for many of the syndromes and diseases noted above, stem cell transplantation can cure the hematologic manifestations of these diseases and may be necessary to control the hemophagocytosis associated with CHS and GS2, but does not treat the other systemic findings.[168,169] Otherwise, growth factor support and antibiotics provide supportive care and steroids, splenectomy, intravenous immunoglobulin, and chemotherapy have been used to manage the accelerated phase of CHS.[170,171]

Lastly, cartilage-hair hypoplasia is a rare syndrome associated with moderate to severe neutropenia, as well as short-limb dwarfism, fine hair, and defects in cellular immunity.[172] It is inherited in an autosomal recessive manner and has increased prevalence in the Amish and Finnish populations.[173,174] It is caused by mutations in the *RMRP* gene on chromosome 9 which has an unknown function but is a noncoding RNA essential for early murine development.[175,176] As in other syndromes with combined neutropenia and cellular immune defects, infectious risk is additive. G-CSF is effective and stem cell transplantation can cure the hematologic and immunologic manifestations of this disease.[177,178]

Secondary Causes of Neutropenia

Post-infectious Neutropenia

Several viral infections have been shown to cause a transient neutropenia, including varicella, measles, rubella, hepatitis A and B, Epstein-Barr, influenza, parvovirus, and cytomegalovirus. Neutropenia typically corresponds to the period of peak viremia during the first 1 to 2 days of clinical symptoms. Neutropenia usually resolves within 3 to 7 days. Neutropenia results from a combination of decreased production and immune destruction of neutrophils; in addition, some viral infections increase neutrophil adherence to the vasculature, causing increased margination.[179,180] Because neutropenia is short lived, it rarely results in bacterial superinfection regardless of its severity. However, the neutropenia associated with hepatitis B and EBV infections can be more prolonged and thus more dangerous. Human immunodeficiency virus (HIV) infection is commonly associated with neutropenia that arises from a combination of decreased marrow production of neutrophils and peripheral immune destruction.[181] As with EBV and hepatitis B infection, this neutropenia may be protracted as a result of direct viral infection of hematopoietic precursor cells or as a result of antineutrophil antibodies. Moderate neutropenia can also be seen in association with atypical bacterial infections, including those caused by *Mycobacterium tuberculosis*, ehrlichiosis, rickettsia, tularemia, and brucellosis. This may be related to by direct bone marrow suppression of myelopoiesis by toxins released by the pathogenic organisms, decreased neutrophil production as a result of infection-mediated decrease in growth factor production, and complement mediated peripheral neutrophil destruction. Neutropenia is fairly common in the setting of overwhelming sepsis, and reflects consumption of marrow reserves of neutrophils. This is usually seen at the extremes of life, in infants and elderly patients, in which patients typically have decreased marrow reserves.[182] Management of patients with infection-related neutropenia requires good supportive care with treatment of the underlying infection. G-CSF or white blood cell transfusions are reserved for protracted and severe cases.[183,184] Intravenous immunoglobulin may be effective for neutropenia that results from autoimmune or complement-mediated destruction as a result of the underlying infection.[185]

Drug-induced Neutropenia and Neutropenia due to Marrow Injury

Although accurate estimates of the incidence of drug-induced neutropenia are not readily available, a 10-year Swedish experience, a 5-year Dutch experience, a 22-year Spanish experience, and the

International Aplastic Anemia and Agranulocytosis Study demonstrate an annual incidence of severe drug-induced neutropenia of 1.0 to 3.4 cases per million population per year.[186–188] Multiple drugs have been implicated in neutropenia and agranulocytosis, both in predictable and idiosyncratic patterns. Antineoplastic, antiviral, and immunosuppressive agents all cause an expected dose-dependent decrease in neutrophils, often accompanied by general marrow suppression. Common drugs known to cause neutropenia that is more idiosyncratic include clozapine, the thionamides, and sulfasalazine. Most drugs cause direct dose-dependent marrow suppression and others incite immune-mediated destruction; these mechanisms may not be mutually exclusive.[189,190–192] Immune-mediated destruction may occur by one of two mechanisms: the drug may act as a hapten and induce antibody formation and complement fixation, or the drug can cause the formation of circulating immune complexes that bind to neutrophils. The former is the mechanism associated with penicillin, propylthiouracil, and gold and the latter is associated with quinine administration. Marrow suppression, on the other hand, is the result of dose-dependent inhibition of colony-forming unit granulocyte macrophages and can be seen with valproic acid, carbamazepine, and β-lactam antibiotics. Finally, drugs can cause damage to the marrow microenvironment and myeloid precursors; certain patients with specific genetic polymorphisms or other medical problems may be at increased risk for drug-induced neutropenia by this mechanism.[193–195]

Drug-induced neutropenia typically occurs after 1 to 2 weeks of exposure to the drug, although it may occur after a longer period of exposure. Recovery usually begins within days of stopping the drug, but this pattern is highly variable depending on the mechanism of neutropenia. For example, immune-mediated neutropenia may be immediate, occurring within hours of administration of the drug especially if there has been a previous exposure and prior antibody production, whereas drugs that cause direct marrow suppression or toxicity follow the paradigm above.[196] Some patients may present with agranulocytosis, fever, and possible sepsis; in these patients mortality may be significant. Neutrophil recovery is often preceded by the appearance of monocytes and immature neutrophil forms. Although marrow examination is rarely necessary, one can roughly predict the duration of neutropenia from the cellularity of the marrow, as patients with hypercellular marrows or marrows with abundant metamyelocytes and later forms tend to have more rapid reconstitution following discontinuation of the offending medication. Management is similar to that for post-infectious neutropenia with supportive care and removal of the offending agent, although growth factor support is recommended for patients presenting with agranulocytosis.[197]

Radiation can also result in acute or chronic marrow failure. Exposure to radiation is also a risk factor for AML/MDS. These diseases are discussed in greater detail in Chapters 75 and 79, respectively. Likewise, metastatic carcinoma to the bone can also cause marrow failure as the marrow becomes increasingly occupied by the metastatic cells.

Immune Neutropenia

As previously discussed, infection and drugs can cause immune-mediated neutrophil destruction. However, primary immune neutropenia can occur in the absence of other inciting events, or can also arise in association with an underlying systemic autoimmune disease. Antineutrophil antibodies are implicated in mediating neutrophil destruction either by destruction in the spleen or by intravascular complement mediated neutrophil lysis. A number of neutrophil-specific antigens have been identified in patients with a history of autoimmune neutropenia, including human neutrophil antigen (HNA)-1, an isoform of the Fcγ IIIB receptor, and HNA-4 and HNA-5, which are CD11b and CD11a, respectively.[198,199] The clinical presentation is variable, and depends on whether the antineutrophil antibodies react primarily with mature neutrophils or with myeloid progenitor cells, whether the antibodies are primary or secondary to an underlying condition, and whether the antibody is of restricted or nonrestricted clonality.[200,201] Some patients may have an absence of only mature neutrophils, whereas others may be missing all or some myeloid forms. In primary immune neutropenia, antibodies are more likely to be directed against a specific neutrophil-specific antigen whereas secondary conditions are commonly associated with pan-reactive antibodies. Similarly, antibodies that are produced as a result of an exposure to a foreign antigen are more likely to be polyclonal and short lived, whereas those due to the loss of suppression of a clone of cells producing an autoantibody are associated with a more protracted and severe course of neutropenia. Bone marrow biopsy findings will depend on the stage in neutrophil maturation against which the antibodies are directed, but in most cases, the marrow is hyper- or normocellular with a "maturation arrest" that reflects destruction of later stage cells.

Hyperthyroidism, Wegener granulomatosis, rheumatoid arthritis, systemic lupus erythematosus (SLE), chronic hepatitis and other systemic infections, and malignancy are autoimmune and systemic disorders associated with antineutrophil antibodies. In many of these diseases, especially SLE, neutropenia is often mild and reflects the activity of the underlying disease. It rarely requires treatment outside of treatment of the underlying disease.[202]

Felty syndrome and large granular lymphocytic (LGL) leukemia can also cause immune-mediated neutrophil destruction, and may be associated with profound neutropenia and increased infections. LGL is a syndrome of autoimmune neutropenia in association with marrow infiltration by clonal large granular lymphocytes.[203] These lymphocytes are cytotoxic T-cells with the following immunophenotype: $CD3^-$, $CD8^-$, $CD16^-$, and $CD57^+$. LGL can occur sporadically or in association with systemic autoimmune diseases, especially rheumatoid arthritis.[204] LGL is closely related to Felty syndrome, a syndrome associated with splenomegaly and neutropenia in the setting of rheumatoid arthritis.[205] Ninety percent of patients with Felty syndrome and LGL associated with RA are $HLA\text{-}DR4^+$, leading many investigators to postulate that the two syndromes are in a spectrum of the same disease.[206] The pathophysiology of neutropenia is complex, including both antibody-mediated and cell-mediated destruction, immune complexes, and increased FAS mediated apoptosis.[207–209,210,211] The neutropenia is responsive to G-CSF, which is usually utilized until the primary disease can be treated.[212] Treatment options for LGL and Felty syndrome include immunosuppressive therapies including methotrexate, cyclosporine, cyclophosphamide, and, most recently, rituximab for Felty syndrome.[213–217]

Neonatal neutropenia, or neonatal alloimmune neutropenia, is caused by transplacental passage of maternal IgG antibodies against paternal neutrophil antigens, resulting in neutropenia in a similar manner to anemia in Rh hemolytic disease. During gestation, the mother is sensitized to unique fetal neutrophil antigens and produces IgG antibodies against these antigens that can cross the placenta. These antigens will be shared with the father and so will be reactive against the father's neutrophils, thus facilitating the diagnosis. Neutropenia typically resolves within 2 months, and appropriate antibiotics will usually be sufficient to support the patient. In the event of severe or life-threatening infection, plasma exchange, intravenous immunoglobulin, and transfusion of maternal neutrophils have all been used.[218]

Autoimmune neutropenia of infancy and childhood, termed "primary immune neutropenia," occurs in children ages 6 months to 10 years and is the most frequent primary immune neutropenia.[219] Infections tend to be mild and include otitis media, gastroenteritis, and/or cellulitis. Resolution of neutropenia occurs in over 95% of patients by age 2.[220] Primary autoimmune neutropenia in adults is rare, and tends to be more chronic. However, even adults tend to have a mild clinical course.

Lastly, pure white cell aplasia is a rare disease associated with severe pyogenic infections, and associated with a thymoma in over two thirds of cases.[221] It has also occurred following ibuprofen therapy.[222] There is a complete absence of myeloid precursors on bone marrow examination. It is immune-mediated but removal of the thymoma in thymoma-associated cases may not be sufficient for remission. Adjuvant therapy with cytoxan, steroids, cyclosporine, IVIg, and even stem cell transplantation may be needed.[223–225]

Neutropenia Due to Increased Margination and Hypersplenism

Complement activation increases margination of neutrophils and can suppress the peripheral ANC. [226] This has been seen in patients suffering from burns and transfusion reactions as well as a result of exposure to artificial membranes used in dialysis, cardiopulmonary bypass, apheresis, and extracorporeal membrane oxygenation.[227–229] Neutropenia in the setting of transfusion is due to an anamnestic response to foreign antigens on neutrophils in a prior transfused blood product. Complement activation may also lead to direct neutrophil destruction, as in the case of paroxysmal nocturnal hemoglobinuria. Splenomegaly with hypersplenism can also reduce the neutrophil count.[230]

Neutropenia Due to Nutritional Deficiency

Neutropenia is part of the clinical spectrum of megaloblastic anemia arising from deficiency of vitamin B12, folate, and copper.[231,232] These diseases typically cause pancytopenia because of disordered maturation of all cell lines.

CLINICAL PRESENTATION AND DIAGNOSTIC APPROACH TO NEUTROPENIA

One of the first definitions of the syndrome of neutropenia and infection was in 1922 by Werner Schultz who described the findings of sore throat, prostration, and neutropenia in a cohort of middle-aged women and called this entity agranulocytosis.[233] This fulminant form of neutropenia has sometimes been referred to as Schultz disease.[234] The description highlights that the first evidence of neutropenia is often the development of infection, and that severe neutropenia is associated with a risk for spontaneous infection. Although the lower level of the normal ANC is 1,500 cells/μl, patients rarely develop infectious complications of neutropenia until their ANC falls below 500 cells/μl, and in fact, patients with chronic neutropenia rarely develop fever unless their ANC is below 200 cells/μl. Common sites of infection include the oral cavity and mucous membranes including mouth ulcers, pharyngeal inflammation, and periodontitis, the skin with rashes, cellulitis, abscesses, and poor wound healing, the perirectal and anal areas, and the respiratory tract. Endogenous flora are the primary pathogens. It should be remembered that most of the signs and symptoms of infection are generated by neutrophils. Consequently, patients with neutropenia may have minimal signs and symptoms of infection, with minimal inflammatory infiltrates. Fever is the most informative sign in neutropenia patients, and should be evaluated emergently, because in the setting of profound neutropenia, patients may rapidly develop fatal sepsis. A presentation of neutropenia should prompt a careful evaluation for signs and symptoms of infection with cultures and antibiotic administration when indicated.

In children presenting for the first time with neutropenia, growth and development should be documented (Fig. 57.1). Attention should be paid to the skin, bones/appendages, and nails as abnormalities in these may point toward one of the congenital neutropenia syndromes. Family history of recurrent infections and sudden death may be helpful in this regard. If congenital neutropenia is suspected, appropriate genetic testing should be obtained. In adults previously known to have a normal ANC who present with profound neutropenia (agranulocytosis) and an otherwise normal CBC, the diagnosis is almost invariably drug-induced neutropenia. These patients usually present with an acute febrile episode. A thorough history of drug and toxin exposure should be obtained and all potential offending agents discontinued. For patients of all ages, the perineum and perirectal area should be examined, in addition to a complete physical exam. The peripheral blood smear should be examined and tests for vitamin B12 and folate levels obtained. Older tests included hydrocortisone stimulation tests (for marrow myeloid reserve), the epinephrine challenge test (for estimation of the size of the marginated neutrophil pool), and the Rebuck skin window (which evaluates neutrophil margination into tissues) but these are rarely

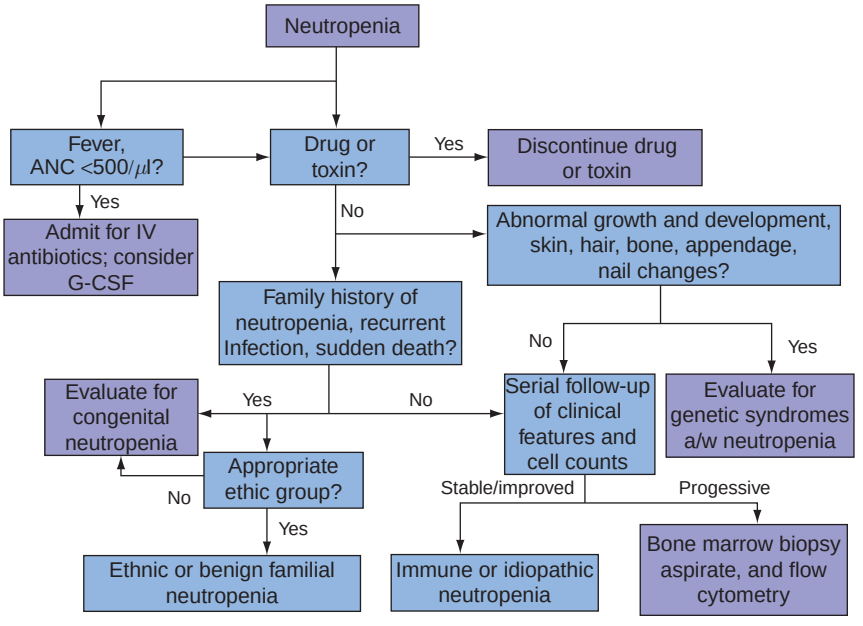

FIGURE 57.1. Diagnostic approach to neutropenia in the infant. ANC, absolute neutrophil count; a/w, associated with; G-CSF, granulocyte colony stimulating factor; IV, intravenous.

used today.[235,236,237] Bone marrow examination is not required unless there are other features to suggest an alternative diagnosis.

In patients presenting with unexplained neutropenia in the absence of a well-documented normal ANC in the past, evaluation depends on the severity of the neutropenia (Fig. 57.2). There is little information to be gained from an extensive evaluation of healthy patients with no history of infections and ANC of 1,200 to 1,500 cells/μl that has been present for many years. In appropriate ethnic groups the diagnosis of constitutional neutropenia obviates the need for further evaluation. Even in patients who do not have clear ethnic or familial neutropenia, studies to rule out marrow pathology in the absence of clinical sequelae or evidence of continued decrease in the blood counts are unlikely to be informative.

In patients with severe neutropenia of indeterminate duration, the pace and extent of diagnosis should be determined by the clinical presentation. In patients in whom cycling is suspected, genetic testing for *ELANE* mutations and peripheral blood flow cytometry and T-cell receptor rearrangement studies to assess for LGL should be obtained. In the cases of a selective severe chronic neutropenia, even in the absence of a history of infection or drug/toxin exposure or an evident B12 or folate deficiency, a single bone marrow examination is recommended to assess for myelodysplasia If marrow morphology is unremarkable and cytogenetics are normal, repeated bone marrow examination is not recommended unless there is a significant change in the peripheral blood counts that suggests a new intervening diagnosis. Bone marrow biopsy should be performed in all patients with bi- or tricytopenias to evaluate the adequacy of hematopoietic marrow pools, the relative maturation of these pools, and the morphology of these pools for clues as to the etiology of the cytopenias.

MANAGEMENT OF NEUTROPENIA

Decisions regarding the treatment of neutropenia depend primarily on the presence or absence of fever. Neutropenia with fever should be treated as a medical emergency, with the goal of evaluating patients and initiating antibiotics within 30 to 60 minutes. The administration of empiric broad-spectrum antibiotics to patients with febrile neutropenia has been demonstrated to improve survival.[238,239] Third- or fourth-generation cephalosporins as single agents have become the standard initial empiric therapy, replacing previous combinations that emphasized double coverage for pseudomonal species.[240] In patients with indwelling lines, the addition of vancomycin may be considered, and patients at increased risk for fungal infection or who remain febrile despite 3 to 5 days of antibiotics should receive antifungal agents.[241]

For patients with mild neutropenia and infections, outpatient antibiotic therapy may be warranted and is based on the clinical judgment of the treating physician. The cause of neutropenia is important in determining further therapies: transient neutropenia due to a drug, infection, or chemotherapy administration may require no further therapy, although G-CSF can be used for high-risk patients with pneumonia, hypotension, and/or fungemia whereas neutropenia due to autoantibodies, an underlying systemic disease, or a congenital syndrome may require preventative approaches including immunologic therapies such as corticosteroids, intravenous immunoglobulin, and/or plasmapheresis, treatment of the underlying disease, G-CSF therapy, or possibly a hematopoietic stem cell transplant. For cases of severe life-threatening infection that is unresponsive to antibiotics, granulocyte transfusion may be warranted.[242]

In patients with neutropenia who have not had a history of infection, treatment is rarely necessary. Patients should be educated to simple approaches to preventing infection, including skin and mouth care, good oral and dental hygiene, avoidance of rectal trauma by rectal thermometers and prevention of constipation with stool softeners, proper cleaning and topical antibiotic application to all skin abrasions. For patients with profound neutropenia not on G-CSF, they should be instructed to notify a physician as soon as they develop a fever. It is advisable that they also be supplied with prophylactic antibiotics such as trimethoprim-sulfamethoxazole or ciprofloxacin to take in the event there is a delay in seeking medical attention; it should be emphasized, however, that use of these agents is for emergencies only and should not be used in place of seeking appropriate medical evaluation and care.

Patients with SCN require lifelong G-CSF therapy. The use of G-CSF has extended the life expectancy for these patients from 2 to 3 years to adulthood.[57] Some patients with CN also require G-CSF, but can often restrict treatment to low daily doses of G-CSF or cyclical administration during the period around the nadir of the ANC. Dose requirements vary depending on G-CSF response.[57,69,84] As previously mentioned, with improved survival of patients with SCN, a significant risk of MDS/AML has emerged.[55–57] The risk of MDS/AML appears to be associated

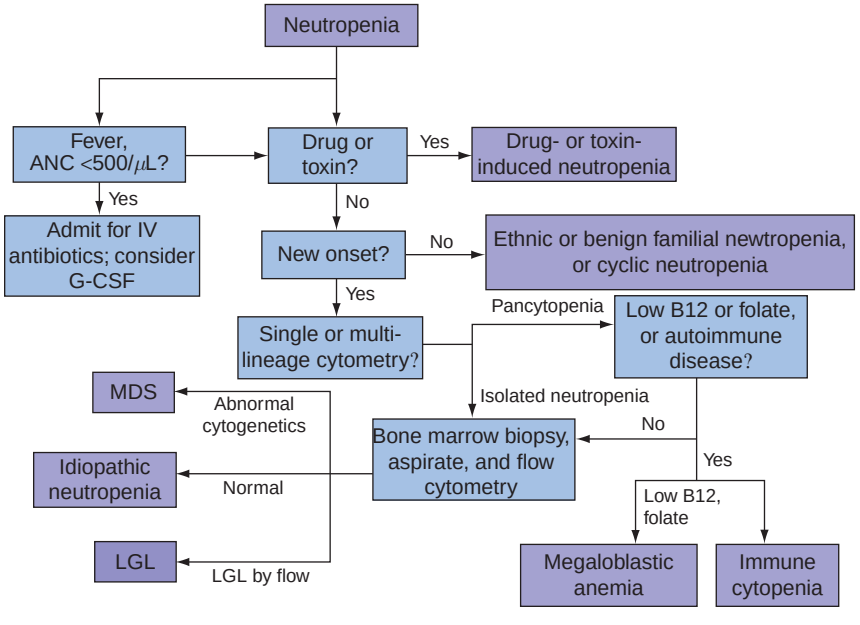

FIGURE 57.2. Diagnostic approach to neutropenia in the adult. ANC, absolute neutrophil count; G-CSF, granulocyte colony stimulating factor; IV, intravenous; LGL, large granular lymphocytosis; MDS, myelodysplastic syndrome.

with higher doses of G-CSF, but whether this is a reflection of the underlying disease phenotype or whether transformation is enhanced or accelerated by G-CSF itself is unknown.[53,54,58,59]

Other congenital syndromes associated with neutropenia, such as SDS, FA, and DKC, respond to doses of G-CSF similar to those used in SCN and these patients are also at increased risk of MDS and/or AML, but again it is not clear if this is due to the G-CSF or the underlying disease.[109,128,131] Patients with idiopathic and CN, as well as neutropenia associated with glycogen storage Ib, and myelokathexis, however, do not develop MDS or AML, despite therapy with G-CSF.[69,84,144,155] One could argue, though, that this may be a dose-dependent phenomenon as patients with SCN, SDS, FA, and DKC require higher doses of G-CSF than do those with idiopathic and CN. Long-term use of G-CSF or GM-CSF has been associated with osteoporosis and organomegaly.

Severe drug-induced neutropenia/agranulocytosis requires the permanent discontinuation of the causative agent. However, agents that cause dose-related marrow suppression and mild neutropenia can be continued if necessary, provided the neutropenia is not progressive or severe. Patients with agranulocytosis frequently present with life-threatening infections. They should be admitted to the hospital for broad-spectrum antibiotics. G-CSF speeds the recovery of the ANC and, given the morbidity and mortality associated with this syndrome, is recommended.

Immune neutropenia related to SLE or other systemic autoimmune disease rarely needs direct treatment, and ANC usually responds to decreased disease activity with therapy directed at the underlying rheumatologic disorder. Patients with LGL respond well to low-dose immunosuppression with cyclophosphamide or methotrexate.

Finally, stem cell transplantation can be useful to reverse the hematologic effects and neutropenia associated with a number of the congenital neutropenia and bone marrow failure syndromes such as SDS, FA, DKC, and cartilage-hair hypoplasia. The risk of transplant in many of these patients is greater than that seen in transplantation for hematologic malignancies due to the nature of the underlying genetic disorder. Furthermore, many of these disorders are associated with disease of other organs, including pulmonary fibrosis, or a risk of solid tumors. Transplantation does nothing to prevent these manifestations of the underlying disease and should be considered before undertaking the procedure.

CHAPTER 58

QUALITATIVE DISORDERS OF LEUKOCYTES

Ashish Kumar, Keith M. Skubitz

DISORDERS OF PHAGOCYTIC LEUKOCYTES CHARACTERIZED BY MORPHOLOGIC CHANGES

For the most part, the disorders considered here are rare, are usually familial, and often reflect a general metabolic defect, the major manifestation of which may be more serious in tissues than in leukocytes. Nevertheless, the leukocytic morphologic abnormalities may come to the attention of the hematologist, and familiarity with them and the associated diseases may facilitate diagnosis.

Pelger-Huët Anomaly

Pelger-Huët anomaly is a benign anomaly of leukocytes and is inherited as a non–sex-linked, dominant trait. It is characterized by distinctive shapes of the nuclei of leukocytes, a reduced number of nuclear segments (best seen in the neutrophils), and coarseness of the chromatin of the nuclei of neutrophils, lymphocytes, and monocytes. The nuclei appear rod-like, dumbbell-shaped, peanut-shaped, and spectacle-like ("pince-nez") with smooth, round, or oval individual lobes, contrasted with the irregular lobes seen in normal neutrophils.[1] The incidence of this disorder in different studies has ranged from as high as 1 in 1,000 persons[2,3] to 1 in 4,000,[4,5] 6,000,[6] or even 10,000.[7] Originally observed mainly in Holland, Germany, and Switzerland, the anomaly has now been described in other parts of the world, including individuals of Asian[8] and African descent and whites. The practical importance of identifying the Pelger-Huët anomaly lies in distinguishing this defect from the shift to the left that occurs in association with infection.

The discovery of this anomaly in rabbits led to breeding experiments and the production of homozygotes.[2,5] These studies demonstrated that in the heterozygote, bilobed, rod-shaped, and spectacle forms predominate, whereas in the homozygote, round nuclei with no evidence of segmentation are predominant. In rabbits, the homozygous form was often lethal, with most animals dying in utero; some survivors suffered skeletal malformations.

Two human homozygotes have been reported.[2,9] In them, the cytoplasm of the neutrophils appeared mature, but the nuclei were round or oval in all the neutrophils, in contrast to the fewer than 40% single-lobed neutrophils present in heterozygotes (Table 58.1).[2,6,9] In the homozygotes, the eosinophils, basophils, and megakaryocytes also were characterized by dense nuclear chromatin and rounded nuclear lobes; these individuals had fewer nuclear lobes than normal subjects.[2] Examination of the bone marrow revealed normal morphologic features in myeloid precursors through the myelocyte stage, and electron microscopy revealed persistence of nucleoli in the otherwise mature neutrophils that contained single oval nuclei.[9] This finding was interpreted as indicating some retardation of nuclear maturation, because no cytochemical defects were noted in the cytoplasm. This syndrome is now known to be due to mutations in the lamin B receptor (*LBR*) gene, a gene important in maintaining nuclear structure.[10,11,12]

Pelger-Huët cells appear to be normal functionally,[9,13,14] are able to phagocytize and kill microorganisms,[5] and survive normally in the circulation in both humans[15] and dogs.[16,17]

The Pelger-Huët heterozygote is recognized by finding (a) 69% to 93% of the neutrophils to be of the bilobed, pince-nez type; (b) few cells with three lobes (usually <10%); and (c) rare or no cells with four lobes (Table 58.1).[4–6] In normal blood smears, no more than 27% of the cells are bilobed, and significant numbers of cells have three or more lobes.[5] The presence of similar abnormalities in the blood smear in other family members also is helpful in establishing the diagnosis. In heterozygotes, mature neutrophils with round or oval nuclei of the type that is characteristic of the homozygous state may increase after stress, such as the injection of colchicine[18,3] A shift toward increased numbers of neutrophil lobes was described in a patient with the anomaly who developed pernicious anemia.[19]

Pseudo– or Acquired Pelger-Huët Anomaly

Cells with morphologic changes, such as those just described, have been observed occasionally in association with myxedema, acute enteritis, agranulocytosis, multiple myeloma, malaria,

TABLE 58.1

DISTRIBUTION OF NUCLEAR LOBES IN NEUTROPHILS OF NORMAL PERSONS AND IN THOSE WITH PELGER-HUËT ANOMALY

	Cases Examined	Number of Lobes[a]				
		1	2	3	4	5
Normals[b]	50	2.8	22.0	54.3	18.1	2.8
		±2.8	±6.3	±5.3	±6.9	±2.1
Pelger-Huët heterozygotes[b]	34	31.3	63.8	4.9	0.3	0
		±9.2	±9.5	±3.7	—	—
Pelger-Huët homozygotes[2,9]	2	100.0	—	—	—	

[a]Mean and variance.

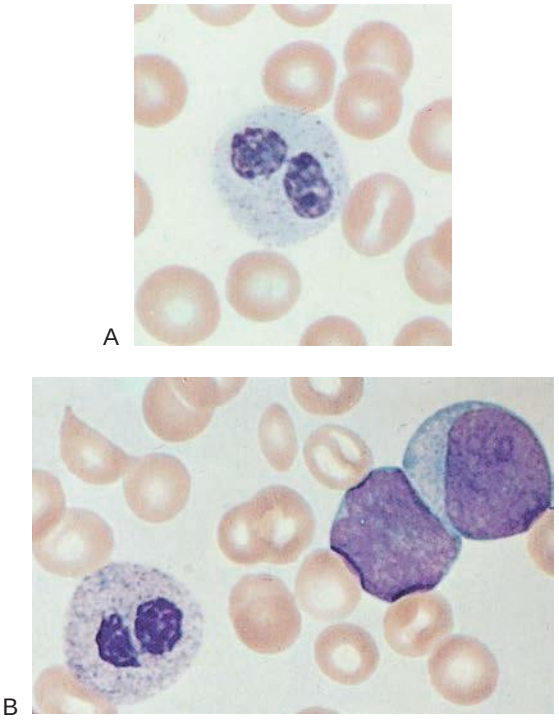

FIGURE 58.1. A: Pseudo–Pelger-Huët cells. B: From a patient with acute myeloblastic leukemia.

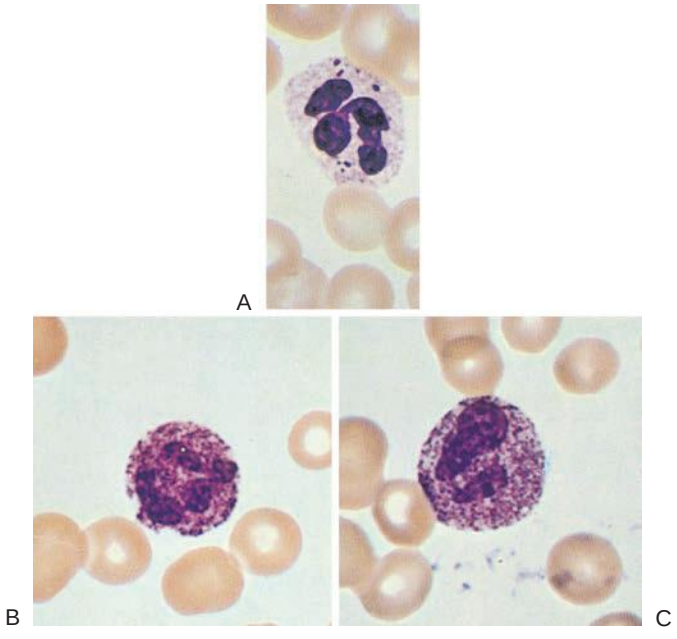

FIGURE 58.2. Neutrophils with Alder-Reilly bodies (A) compared with neutrophils exhibiting toxic granulation (B,C).

leukemoid reactions secondary to metastases to the bone marrow,[20] drug sensitivity,[21] or chronic lymphocytic leukemia.[3] More commonly, pseudo–Pelger-Huët cells (Fig. 58.1)[22] are seen in patients with myeloid leukemia of either the acute or chronic type or in those with myeloid metaplasia.[23,24] In these subjects, the pseudo–Pelger-Huët cells tend to appear late in the disease, often after considerable chemotherapy has been administered. In addition, most of the nuclei are of the single oval type characteristic of the homozygous state.[23]

Alder-Reilly Anomaly

Alder-Reilly anomaly, inherited as a recessive trait,[25] apparently does not interfere with leukocyte function.[26] It is characterized by the presence of larger-than-normal azurophil and basophil granules (Alder-Reilly bodies), which may be easily confused with granulations due to toxic states (Fig. 58.2). These granules stain dark lilac with Wright-Giemsa stains and are seen in patients with various types of bone and cartilage abnormalities.[27,28] They are most common, however, in association with Hurler syndrome, Hunter syndrome, and Maroteaux-Lamy polydystrophic dwarfism.[29]

Similar inclusions may be seen in blood lymphocytes (Gasser cells) and monocytes.[30,31] The lymphocyte inclusions stain dark red or purple with May-Grünwald-Giemsa stain and metachromatically with toluidine blue; normal azurophilic granules do not stain at all.[31,32] Such lymphocyte granules are found in all types of mucopolysaccharidoses except Morquio syndrome, but they are most common in the Hurler, Hunter, Sanfilippo, and Maroteaux-Lamy syndromes.[29,31,32] They tend to occur in clusters rather than diffusely throughout the cytoplasm, are surrounded by vacuoles, and are shaped like a dot or comma. In one series of 19 patients, 8% to 50% of the lymphocytes contained the inclusions, and their presence was thought to be of diagnostic significance.[32]

These inclusions are seen inconsistently in the blood but are more common in the bone marrow. For example, in a series of 18 patients with Hurler form of mucopolysaccharidosis, Alder-Reilly bodies were present in the blood of <10% of them. Careful examination of the bone marrow, however, revealed mucopolysaccharide granules in large mononuclear cells (Buhot cells) in 17 of 18 patients.[33–35]

The type of inclusion seen is not diagnostic of a particular type of mucopolysaccharidosis, and the frequency of the inclusions is not correlated with clinical severity.[36] The basic defect in this group of diseases lies in the incomplete degradation of the protein–carbohydrate complexes known as *mucopolysaccharides*, and the different forms of mucopolysaccharidosis involve different enzymatic deficiencies.[29] The accumulation of partially degraded mucopolysaccharides within lysosomes has been demonstrated by electron microscopy[29]; the degradation of the protein core of the mucopolysaccharide appears to proceed normally, but catabolism of the carbohydrate side chains is impaired.

May-Hegglin Anomaly

The May-Hegglin anomaly is a rare, dominantly inherited disorder characterized by large (2 to 5 μm), well-defined, basophilic, and pyroninophilic inclusions in granulocytes (neutrophils, eosinophils, basophils, monocytes), and accompanied by variable thrombocytopenia and giant platelets containing few granules.[37] For the most part, affected family members have not been ill, but occasionally abnormal bleeding has occurred.[38–41] Clot retraction time is prolonged, and the reaction to the tourniquet test may be positive. Platelet survival was short (half-life = 3 days, as compared with the normal, which is 6.9 ± 1.5 [1 standard deviation] days).[42] Platelet aggregation and retraction were normal, but spreading and serotonin uptake were increased.[43] Enzyme and substrate content per platelet were increased, but this value was decreased as related to platelet volume.[43] The granulocyte inclusions are similar to Döhle bodies in appearance, but they often are larger, are more round and discrete, and may be present in a large percentage of the cells.[40,41,44] It is claimed that these inclusions differ from the Döhle bodies of infection in morphologic appearance in that they are present in granulocytes other than neutrophils.[44] Like Döhle bodies,[40,44] the inclusions were felt to consist mainly of RNA and may exhibit differing ultrastructure.[41,45–47] More recently, mutations in MYH9, the gene encoding NMMHC-A,

have been found in this syndrome.[48,49,50] NMMHC-A is a nonmuscle myosin heavy chain that is part of a family of genes coding for proteins that form part of the actin–myosin force-generating complexes.[51] In the bone marrow, clumping of the megakaryocyte cytoplasm has also been reported.[39]

Mutations in *MYH9* are inherited in an autosomal dominant fashion, but depending on the mutation generate a spectrum of clinical findings manifest as several syndromes due to variable expressivity of the clinical features.[52–58] These clinical syndromes include May-Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, and Epstein syndrome and are characterized by giant platelets, leukocyte inclusions, and variable thrombocytopenia, in addition to problems with hearing, vision, or renal function.[52–57]

Chédiak-Steinbrinck-Higashi Anomaly (Congenital Gigantism of Peroxidase Granules)

Chédiak-Steinbrinck-Higashi anomaly, an autosomal recessive disorder, has been reported in humans,[59,60,61,62] mice,[63] mink,[64] cattle,[64] cats,[65] rats,[66] and a killer whale.[67] It is characterized by partial ocular and cutaneous albinism, increased susceptibility to pyogenic infections, the presence of large lysosome-like organelles in most granule-containing cells, and a bleeding tendency.[68] The abnormal granules are most readily seen in blood and marrow leukocytes, especially granulocytes (Fig. 58.3), and in melanocytes.

In the first families that were reported with this anomaly, the mothers noted that some of their children exhibited pale hair (Fig. 58.4) and photophobia.[59,60] Because these children often had infections and adenopathy and died at an early age, the children born subsequently who were similarly affected were brought to medical attention in the hope of avoiding a fatal outcome.[60] It was then that the large, peroxidase-positive granules were noted in their blood and marrow granulocytes.[59,60,61] Nevertheless, without definitive treatment (bone marrow transplantation, described later) most patients die in infancy or early childhood; only a few survive into early adult life.[69–71]

During the 30 years after the first description of Chédiak-Higashi syndrome (CHS)[72] 59 cases were reported.[69] The similar disorder in animals is of use in investigations of the pathogenic defect and is of significant economic impact in mink, in that affected animals, inbred for their unusual color, seldom survive more than a year and exhibit increased susceptibility to a slow viral infection that produces hepatitis and a myeloma-like illness (Aleutian mink disease).[64]

Etiology and Pathogenesis

The manifestations of this disorder appear to result from abnormal intracellular protein transport, resulting in abnormal granule fusion with larger, fewer-than-normal, and perhaps defective granules being formed in most granule-containing cells throughout the body.[73–77] The resulting abnormalities can be found in the hematopoietic tissues, hair, ocular pigment, skin, adrenal glands, pituitary gland, gastrointestinal organs, peripheral nerves, and elsewhere.[74]

In neutrophils, the anomalously large, peroxidase-positive granules seen by light microscopy[59,60] have been shown by electron microscopy to be abnormal primary (azurophilic) granules, the contents of which remain pleomorphic, the normal granule crystalloid structure not being formed.[73,78] Characterization of the abnormal granules by means of immunofluorescence microscopy demonstrated that they were formed by the progressive aggregation and fusion of azurophilic granules.[79,80]

In a subsequent electron microscopic study, investigators demonstrated the presence of two types of giant, peroxidase-positive granules in CHS neutrophils: large, round, or oval granules with homogeneous internal structure similar to normal azurophilic granules; and irregular granules much larger than those of the first type. Because basophils and eosinophils from CHS patients do not contain type 2 granules, and because type 2 granules are less common in promyelocytes, myelocytes, and young neutrophils in the bone marrow than in blood neutrophils, the authors suggested that normal primary (azurophil) granules are formed, but progressive granule fusion occurs during maturation, especially in the blood. In this process, granules and bits of cytoplasm are trapped within the fused granules.[81] An abnormal calcium uptake pump in CHS lysosomes may be part of the underlying defect.[82,83] Also noted is an increased tendency to autophagic vacuole formation in Chédiak-Higashi neutrophils, perhaps because of increased permeability and leakage of injurious materials from the massive granules.[84] A secretory defect appears to prevent granule release in CHS T cells.[85] Abnormal granules have been observed less often in erythroid cells, whereas in megakaryocytes and platelets, the granules appear normal by light microscopy.[73] By electron microscopy, however, a decrease in dense bodies was seen,[73] and decreased serotonin, adenosine triphosphate, and adenosine diphosphate levels were noted.[68]

Similar large granules containing a glycolipid have been observed in the Schwann cells of peripheral nerves, in neurons in the central nervous system,[84,86] in renal tubular cells,[86] and in the vascular endothelium and fibroblasts.[69,87] In addition, giant pigment granules have been demonstrated in melanosomes[86] and in hair strands.[69,86] In the several different tissues affected, the consistent feature is that the histochemical reactions of the large abnormal granules are those usually seen in normal granules of that cell line[86]; no qualitative alteration in granule enzyme content is noted, but some decrease in granule enzymes and an increase in cytoplasmic enzyme content have been described.[88] The effects of the abnormality in different tissues depend on granule function in that tissue. Thus, the large but fewer melanin granules produce pigment dilution, which explains the peculiar hair color, partial albinism, photophobia, and nystagmus.[86]

The abnormal large granules in neutrophils lead to increased susceptibility to infection. Infection occurs despite an above-normal rate of phagocytosis and a normal postphagocytic metabolic burst (H_2O_2 production).[89] Apparently, the intracellular destruction of some bacteria by Chédiak-Higashi leukocytes is delayed because the postphagocytic delivery of lysosomal enzymes into phagosomes is inefficient and incomplete.[90] A similar defect in granule extrusion has been noted in the renal tubule.[91]

Chédiak-Higashi neutrophils from humans lack cathepsin G and elastase[92] and have reduced C3bi receptor expression.[93] Because measurements of elastase and cathepsin G were normal in the bone marrow of beige mice, the primary lesion is thought not to be a gene defect but rather is likely a disorder of protein processing, protein synthesis, or granule assembly.[92] In addition, a defect in cellular response to chemotactic stimuli both in in vitro and in in vivo skin windows has been demonstrated in humans, mice, and mink,[94,95] and a neutrophil membrane abnormality consisting of spontaneous cap formation has been described.[96] Recent studies show that lysosomes function as calcium-regulated secretory compartments and may play an important role in membrane resealing. Lysosomal exocytosis triggered by membrane wounding is defective in human CHS and beige mouse fibroblasts, and this defect may be central to the CHS phenotype.[82]

Inheritance

In 1972, in families with 127 children, 59 were reported to be affected.[69] This statistic and animal studies[64] indicate that this disorder is inherited as an autosomal recessive trait. Male and female subjects are affected at a ratio of 0.87:1.00. A high proportion of marriages producing affected children have been consanguineous. Some heterozygotes may be identifiable by the presence of granulation in some of their lymphocytes.[97,98]

Clinical Features and Course

The partial albinism (more properly, pigment dilutional defect),[86] silvery hair (Fig. 58.4), and photophobia are usually noted early in infancy. The poor resistance to respiratory and cutaneous infection, especially by *Staphylococcus* and other Gram-positive organisms, soon becomes evident. Four patients studied for more than 1 year experienced 29 episodes of fever and pyogenic infection.[71] Increased bleeding with abnormal platelet function has also been recognized.[99] Many of the afflicted children develop potentially fatal infections during infancy or early childhood. In others, the disease remains quiescent. Eventually, in more than 85% of patients, it changes to an *accelerated* phase that is characterized by lymphadenopathy, hepatosplenomegaly, neuropathy, anemia, neutropenia, and, less often, thrombocytopenia.[100] During this phase, infiltration of the tissues by mononuclear cells is widespread and the accelerated phase is now considered akin to the disorder *hemophagocytic lymphohistiocytosis*.[101] During the accelerated phase, neurologic manifestations (peripheral neuropathy) may become prominent, and hemorrhage may occur.

Laboratory Findings

The characteristic microscopic findings are the large, often multiple, peroxidase-positive lysosomal granules in the granulocytes of the blood and bone marrow, and the large melanosomes in the hair. Less common are granules in the lymphocytes. Abnormal platelet aggregation can be demonstrated regularly.[68] During the early phases of the disease, blood counts yield normal values, but as the disease progresses, anemia, neutropenia, and thrombocytopenia often develop. Immunoglobulin (Ig) and complement levels are normal, as are cellular immune reactions. In the accelerated phase, erythrocyte and granulocyte survival may be shortened.[69]

Gene Defect

The origin of CHS in mice has been found to be a mutation in the *CHS/LYST* gene on chromosome 1 in humans, which codes for a lysosomal trafficking regulatory protein.[102,103] The human homologue *CHS1* has since been cloned, and mutations of this gene have been found in patients with CHS.[76,77,102,104,105–110]

Management

Some believe that the prophylactic administration of antibiotics may be beneficial.[71] The administration of ascorbic acid corrected the defective leukocyte function in vitro and in vivo in several patients,[111,112] and the administration of cholinergic agonists was effective in mice.[96,113] The increased susceptibility to infection has been corrected in mice by the transplantation of normal bone marrow, and the hematopoietic defects can be transmitted to normal mice by transplanting marrow from an animal with CHS.[114] In the accelerated phase, splenectomy has been only temporarily helpful[69]; a few patients have been treated with a combination of vincristine and prednisone. Bone marrow transplantation appears to be a logical treatment, if possible,[115,116,117] but does not alter the neurologic deterioration.[109,117]

Familial Vacuolization of Leukocytes (Jordan Anomaly)

Jordan anomaly is characterized by the presence of vacuoles in the cytoplasm of granulocytes, monocytes, and occasionally lymphocytes and plasma cells. In members of one family, all of the blood neutrophils and more than 70% of the monocytes contained three to ten vacuoles ranging in size from 2 to 5 μm; fewer and smaller vacuoles were seen in eosinophils, basophils, and lymphocytes.[118] By means of histochemical and fluorescence microscopic analysis, the vacuoles were shown to contain lipids. These lipids were seen in promyelocytes, myelocytes, metamyelocytes, and occasionally plasma cells in the bone marrow, but they were not present in myeloblasts, erythroblasts, or megakaryocytes.[118] This type of vacuolization must be distinguished from that characterized by fat-staining vacuoles occurring in people with serious infections, toxic hepatitis, or diabetic ketoacidosis.[119]

The disorder appears to be familial. Two members were affected in each of two unrelated families.[118,119] None of the four patients had acute disease, but in members of one family, progressive muscular dystrophy was present,[118] whereas in members of the other, ichthyosis was associated.[119]

Other Inclusions in Leukocytes

In an infant with congenital bile duct atresia, amorphous, round-to-oval bodies stained green or gray-green with Romanovsky stains in 3% to 13% of the blood neutrophils and in 1% to 5% of the monocytes.[120] Similar inclusions were present in all stages of myeloid cells in the bone marrow but not in lymphocytes or plasma cells. Electron microscopic analysis showed that the inclusions were not enclosed in a phagocytic vesicle.

In the blood monocytes of patients with the Hermansky-Pudlak syndrome,[121] a rare familial disorder characterized by albinism, mild bleeding related to platelet dysfunction, accumulation of ceroidlike pigment in marrow macrophages, and deficiency of the tetraspan protein CD63 in platelets,[122] lipopigment bodies as well as another type of inclusion were demonstrated.

Abnormal Specific (Secondary) Granule Formation

A syndrome of recurrent staphylococcal skin and sinus infections associated with abnormal chemotaxis, impaired staphylococcal killing, and morphologic abnormalities in the neutrophils was described in a 14-year-old boy.[123] No other family members were affected. The patient's polymorphonuclear neutrophils exhibited bilobed nuclei with unevenly distributed chromatin, drumstick-like nuclear projections, and nearly absent cytoplasmic granules that stained with peroxidase but not with alkaline phosphatase. Electron microscopy revealed primary granules, but specific granules were small and reduced in number. These neutrophils were capable of phagocytosis, generated H_2O_2, reduced nitroblue tetrazolium (NBT) dye, and killed *Candida*, but staphylococcal killing was impaired.

Since the original report, at least five cases of specific granule deficiency (SGD) have been identified with both sexes affected, leading to the assumption that the disorder is an autosomal recessive disease.[124,125] SGD neutrophils exhibit decreased chemotaxis and bacterial killing in vitro and decreased migration into skin windows in vivo, and they fail to upregulate CD11/CD18, laminin, or f-met-leu-phe (FMLP) receptors after activation,[124] although oxygen radical generation is apparently normal. Myeloperoxidase (MPO)-positive primary granules are present, but the specific secondary granules appeared to be absent in Wright-stained blood smears and were decreased in number and small when viewed with electron microscopy.[123] These structures do not stain with alkaline phosphatase. The specific granule constituents lactoferrin and B_{12} binding protein are reduced or absent.

Lactoferrin deficiency in patients with SGD is tissue specific (i.e., confined to myeloid cells, whereas lactoferrin is secreted normally in nasal secretions) and is secondary to a deficiency of RNA transcripts.[126] Because morphologic changes have been described in the primary granule[127] and because other granule proteins, such as primary granule defensin[92] and "tertiary" granule gelatinase, are also deficient in SGD neutrophils, it was suggested that the basic defect in SGD is one of regulation of production of these proteins.[126] Thus, this disorder may be one of incomplete granule synthesis rather than a true SGD.[127]

C/EBPE is an important regulator of neutrophil secondary granule genes,[128] and mutations in the *C/EBPE* gene have been found in two patients with SGD.[129–131] Neutrophils from *Cebpe*-deficient mice have functional defects very similar to those of patients with SGD,[129,132] and these mice have defects in eosinophil and macrophage function as well.[133,134] Monocyte/macrophage abnormalities have also been noted in an SGD patient.[135] One case of SGD has been reported with no mutation in the *C/EBPE* gene.[136]

Hereditary Giant Neutrophilia

Neutrophils with a diameter of approximately 17 μm (as compared with a normal diameter of about 13 μm) are rare in blood smears from normal people (1 in 20,000 neutrophils or less). They may be seen with greater frequency in patients who are ill, but even then the number rarely exceeds 0.2% unless a disease involving leukocyte production is present or a reaction to a cytotoxic drug occurs.[137] A family with giant neutrophils in healthy members of three generations has been reported.[137] Over several years, the propositus had an average of 1.6% giant neutrophils in the blood. The large neutrophils appeared to be nearly double the normal cell volume and contained from six to ten nuclear lobes. Therefore, it was suggested that the cells may have been tetraploid. This anomaly appeared to be transmitted as an autosomal dominant trait.

Hereditary Hypersegmentation of Neutrophil Nuclei

Several families have been described whose members had a hereditary (autosomal dominant) increase in the number of neutrophil nuclear segments (Fig. 58.5).[138] The proportion of neutrophils containing five lobes or more exceeded 10% in most heterozygotes and was >14% in several suspected homozygotes, as compared with no more than 10% in normal controls.[138] The bone marrow findings suggested a tendency toward nuclear indentation in early myeloid forms (eosinophils and basophils as well as neutrophils).[138] The normal size of these neutrophils was thought to provide evidence against tetraploidy, but in one study of five female family members, the mean number of nuclear drumsticks appeared to be increased above normal.[139] The chief significance of this anomaly is in its differentiation from other causes of hypersegmentation such as folate or vitamin B_{12} deficiency.

Hypersegmentation of Eosinophils and Negative Staining for Peroxidase and Phospholipids

Hypersegmentation of eosinophils can be inherited as an autosomal recessive trait, and the abnormality is characterized by a lack of sudanophilia and peroxidase activity in all of the eosinophils, whereas these histochemical reactions remain positive in the neutrophils and monocytes.[140,141] In addition, the number of eosinophilic granules per cell appears to be reduced, and some hypersegmentation of the eosinophil nucleus may occur. No disease accompanies the disorder. This has been most commonly reported in people of Jewish (predominantly Yemenite) extraction, although members of other races have not been studied adequately.

FUNCTIONAL DISORDERS OF LEUKOCYTES NOT CHARACTERIZED BY MORPHOLOGIC CHANGES

The topic of neutrophil dysfunction is under active study. Several reviews summarize this topic[142–145]; the reader is also referred to the current literature.

Chronic Granulomatous Disease of Childhood

Chronic granulomatous disease (CGD) is a rare clinical syndrome that results from genetically heterogeneous inherited defects of

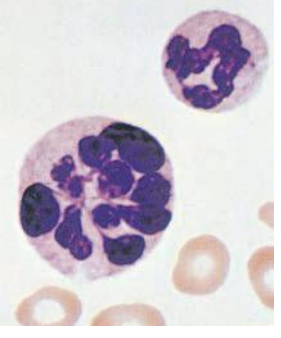

FIGURE 58.5. Hypersegmented neutrophil.

leukocyte function, that result from mutations in one of four genes coding for subunits of the neutrophil NAPDH oxidase.[146–153]

Activation of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase requires protein kinases, lipid-mobilizing enzymes, and factors that activate the Rac GTPase, and thus the CGD phenotype could be due to a variety of other mutations as well. Recent reviews have been published.[145,150,151,154–163]

CGD neutrophils are characterized by a defective respiratory burst during phagocytosis and an inability to generate superoxide. The impaired superoxide production usually occurs transiently in each phagosome with phagocytosis and leads to recurrent bacterial and fungal infections, most commonly at epithelial surfaces. CGD is characterized by recurrent infections with catalase-positive bacteria. CGD neutrophils can use H_2O_2 produced by ingested bacteria to generate hypochlorous acid (HOCl) via MPO and aid in killing the bacteria. Catalase-positive bacteria generate H_2O_2 levels in the phagocytic vacuole that are too low for generation of sufficient HOCl to contribute to significant bacterial killing via this mechanism.[155] This syndrome can be the result of different genetic defects in the superoxide generating system. Variable inheritance patterns have been observed with approximately two-thirds of the pedigrees being X-linked and one-third autosomal recessive. Multiple molecular defects have been identified that result in the CGD phenotype.[144,145,155,157,158,161,164,165] Potential treatments include prophylactic antibiotics, interferon-γ, and bone marrow transplantation. Knowledge in this field is changing rapidly.[151]

CGD neutrophils, eosinophils, monocytes, and macrophages fail to generate superoxide, hydrogen peroxide, and other oxygen radicals after particle phagocytosis (or other stimulation), and thus have decreased microbicidal activity. CGD is associated with no leukocyte morphologic abnormalities and was first noted in male children with a history, beginning in early childhood, of recurrent suppurative infections caused by organisms of low-grade pathogenicity, including fungi, or by staphylococci. The eczematoid, granulomatous, and sometimes purulent skin infections recur repeatedly and clear slowly. Associated adenopathy develops and may persist. Pulmonary and other infections (e.g., osteomyelitis) also are common, and progressive granulomatous disease of the lungs, liver, and other sites develops. Hepatosplenomegaly is common, and biopsy reveals necrotizing granulomas, often with associated purulent inflammation. The disorder often progresses to death in early childhood,[166,167] but some patients survive longer.[152,168] Although rare, CGD has assumed great importance as a prototype of defects in leukocyte bactericidal capacity.

History and Mode of Inheritance

CGD was first described from 1954 to 1957[166,167] as affecting only males. By 1970, more than 90 cases were reported.[148,168] X-linked inheritance was established, and female heterozygotes were identifiable by the presence of defective leukocyte bactericidal capacity intermediate in degree between that of affected patients and that of normal individuals.[169] Measurements of postphagocytic release of $^{14}CO_2$ from glucose-1-^{14}C or reduction of NBT dye were used to detect the defect. By means of the NBT dye test, female carriers were found to have a mixed population of neutrophils, approximately one-half being NBT negative and one-half being NBT positive. The defect is transmitted on an X chromosome, and the degree of deficit in female subjects varies according to random X chromosome inactivation. Consequently, one may expect to find an occasional female carrier with clinical disease as severe as that in male patients.[169,170]

Because of the clinical and pathologic picture of chronic recurrent infection caused by low-grade pathogens and the resultant granuloma formation, it was suggested that a defect in inflammatory response results in lesions comparable to those that normal people develop after infection with tubercle bacilli or brucella.[147] No abnormality in antibody response to diphtheria, tetanus, or poliovirus was demonstrated in these patients, and their delayed hypersensitivity response also was normal.[147] In addition, leukocyte migration and surface phagocytosis were normal.[147] Nevertheless, when leukocytes of CGD patients were incubated with bacteria, such as staphylococci, serratia, or other organisms causing infection in these patients, decreased bacterial killing and prolonged bacterial survival in the phagocytic vacuoles were observed.[171,172] Decreased killing of fungi and incomplete inactivation of vaccinia and herpes virus also was reported,[147,173] but streptococci were killed normally by CGD leukocytes.[172,174]

Although the mechanisms of bacterial killing by normal leukocytes are still incompletely understood, it is clear that phagocytosis is followed by fusion of lysosomes with the phagocytic vacuole, discharge of lysosomal enzymes into the phagosome, and a burst of postphagocytic metabolic activity. These events are usually accompanied by bacterial death and digestion (see Chapters 7 and 10). Early studies of CGD reported that a deficiency of NADPH oxidase or an abnormality in its activation is the underlying cause of this syndrome.[175] The finding that iodination of bacteria in the phagosome appears to be one mode of bacterial killing, and that this process is defective in CGD leukocytes and can be partially repaired by the insertion of an oxidase into the phagosome, either carried on oxidase-coated polystyrene particles[176,177] or as part of the ingested bacteria,[149] provided strong evidence incriminating defective generation of H_2O_2, superoxide,[178] or related ions[179] as the pathogenic defect in this disorder.[176,180] Although most studies have focused on neutrophils, it was recognized in the earliest reports that lipid-laden macrophages were present in the granulomatous lesions,[181] and a defect in the mononuclear phagocytes[182] and in eosinophils[183] also has since been demonstrated. The platelets appear normal.[184]

In the late 1960s and 1970s, an autosomal recessive form of CGD was described.[148,149] It is clinically identical to the X-linked forms, with the exception that the parents of affected children usually have normal neutrophil function, and the clinical course may be milder.[146]

Molecular Pathology

In 1978, a unique cytochrome *b*, termed b_{558} (named for its absorption spectrum) or b_{245} (named for its midpoint potential), present only in phagocytic cells, was described and suggested to be a primary component of the oxidase that normally generates superoxide but, when defective, results in CGD.[185] This cytochrome was absent from X-linked CGD phagocytes (thus termed X^-) but was present in phagocytes from patients with autosomal recessive inheritance patterns (A^+).[185]

In 1985, a family with CGD and an autosomal recessive inheritance pattern but with absence of cytochrome *b* was reported, thus identifying a third type of CGD (A^-).[186] In these studies, a somatic cell hybridization technique was used to demonstrate that fusing monocytes from any two of these three types of CGD (X^-, A^+, or A^-) restored their ability to oxidize NBT, thus defining three distinct molecular defects.[186] Also in 1985, several groups demonstrated that both membrane and cytosolic components are necessary for superoxide generation, and deficiencies in either can result in CGD.[146]

In 1987, cytochrome *b* was purified and shown to be a heterodimer composed of two polypeptides, a heavily glycosylated, 91,000-dalton heavy chain (approximately 50,000 of the molecular weight is peptide) and a 22,000-dalton light chain.[187] Antibodies to these two polypeptides showed them both to be absent from the phagocytes of two types of CGD (X^- and A^-). The defective gene in X-linked, cytochrome-negative CGD has since been cloned and shown to encode for the polypeptide portion of the 91,000-dalton subunit of cytochrome *b* now known as gp91phox.[187,188] Because postphagocytic activation of the

respiratory burst with generation of superoxide and peroxide, as well as bacterial killing, involves complex reactions and multiple enzymes (e.g., phospholipases, protein kinases, NADPH oxidase, glucose-6-phosphate dehydrogenase [G6PD], glutathione peroxidase),[146] one might expect that defects other than those described in NADPH oxidase would result in a disorder phenotypically like that described in the section Variants.

Clinical and Laboratory Features

The clinical picture of CGD includes the development of recurrent infections, especially of the skin and lungs, with septic lymphadenitis, development of hepatosplenomegaly and granulomas, and ultimately death from infection.[147,152,166]

The blood neutrophil count is not reduced, and it increases appropriately with infection or after endotoxin injection; monocytosis is sometimes observed.[147] Because chronic infection is common, the Ig levels often are elevated, and plasma cells may be present in increased numbers in the bone marrow. Ig deficiencies have not been encountered, and antibody titers (both IgM and IgG) increase normally after antigenic stimulation. Reticuloendothelial clearance of colloidal gold also is normal. Peroxidase staining of blood cells demonstrates more intense dye uptake in CGD neutrophils than in normal cells.[183] The classical method for detecting the defect is the postphagocytic, intraphagosomal reduction of almost colorless NBT dye to blue-black formazan.[183,189] When tests are properly standardized with respect to time of incubation of leukocytes with the dye-tagged zymosan particles, affected patients and most carriers are readily recognized. When the reaction to this test is negative in suspected carriers, the reaction to the quantitative dye reduction test usually is positive.[183] Nowadays, the preferred diagnostic test is flow cytometry-based detection of the conversion of the nonfluorescent dye dihydrorhodamine to its oxidized form that emits green fluorescence.[190] The sensitivity and quantitative nature of this method make it more reliable and also allow for detection of residual oxidase activity that can be important in prognosis.[191]

An alteration in the B-cell compartment in patients with CGD has been reported.[192] It appears that CGD is associated with a reduction in the peripheral blood memory B-cell compartment, suggesting a role for NADPH in memory B-cell formation.[192]

Course and Prognosis

There is considerable heterogeneity in the severity of the clinical course of patients with CGD. Without treatment, this disease usually runs a progressive downhill course because of repeated infections and granuloma formation. The average life expectancy was reported to be 5 to 7 years in 1968.[147] One-half of patients are projected to survive into the fourth decade in 2008.[150] Recent studies suggest that the clinical course may be predictable by the specific mutation and those individuals with higher residual ability to produce reactive oxygen intermediates might fare better.[191]

Treatment

Treatment of infections with appropriate antibiotics and surgical procedures remains the cornerstone of management.[149,156,193,194] Prophylactic use of antibiotics, including trimethoprim–sulfamethoxazole and itraconazole with interferon-γ, is generally recommended.[150,151,155,156,158,194,195] Trimethoprim–sulfamethoxazole alone or in combination with dicloxacillin can prolong the infection-free interval in many CGD patients.[193]

In some patients with CGD, the administration of interferon-γ has induced partial correction of cytochrome *b* content and restored phagocyte bactericidal capacity toward normal, and reports have suggested that interferon-γ increases the ability of CGD neutrophils to kill *Aspergillus* and decreases the number of serious infections in patients with CGD.[194–196,197] The exact mechanism by which interferon-γ exerts its beneficial effect in CGD is unclear and may include other effects in addition to augmentation of the respiratory burst. Bone marrow transplantation and gene therapy are potential experimental approaches.[115,193,198,199,200]

Variants

Because the clinical picture of CGD results from delayed killing of catalase-positive bacteria, enzymatic defects in the bactericidal system other than decreased NADPH oxidase may produce an almost identical picture. Results of several studies demonstrate clearly that such biochemical variants exist. For example, in a brother and sister with the clinical picture of CGD, after phagocytosis of latex particles by their neutrophils, all oxidative metabolic reactions were absent. If the latex particles were opsonized with Ig, however, postphagocytic oxidative changes were stimulated dramatically.[186] Another patient was reported in whom no oxidative changes (measured by chemiluminescence) occurred after phagocytosis of a variety of opsonized particles (latex, bacteria, or zymosan), but normal chemiluminescent responses occurred when the neutrophils were stimulated with soluble agents (concanavalin A and phorbol myristate acetate).[201] These patients appear to have a defect in signal transduction and activation of the oxidase system rather than in the oxidase enzyme(s). Another patient with clinically mild, X-linked CGD exhibited normal membrane depolarization (and therefore presumably normal activation), but NADPH oxidase apparently had a low affinity for NADPH and thus produced low but measurable amounts of superoxide.[202]

Neutrophil dysfunction also occurs in a variety of immunodeficiency states. Deficiency in any of the steps of oxidase assembly and activation could result in decreased superoxide production. In the primary immunodeficiency state interleukin-1 receptor–associated kinase 4 deficiency, there was decreased phosphorylation of p47phox, and decreased translocation to the membrane of p47phox, p67phos, and other oxidase components with associated decreased oxidase activity.[203] In NF-kappaB essential modulator (NEMO) deficiency, NEMO-deficient cells had similar but less prominent changes, although p47phox translocation was normal.[203] With Bruton tyrosine kinase (Btk) deficiency (also known as X-linked agammaglobulinemia), the picture is less clear. In patients with X-linked agammaglobulinemia there is both a deficiency of the kinase Btk and neutropenia.[204] Studies suggest that in humans Btk-deficient neutrophils produce excessive NADPH oxidase activity after various stimuli, and that this was associated with increased apoptosis.[204] It appears that the NADPH oxidase complex is partially assembled in resting Btk-deficient human neutrophils, making them ready for activation; that is, human Btk-deficient neutrophils are in a primed state. This is in contrast to studies of BTK-deficient mouse neutrophils where impaired NADPH oxidase activity was found. The model is that in humans BTK functions as a cytosolic component that inhibits translocation of NADPH oxidase components to the membrane and subsequent interactions with other NADPH components.

Lipochrome Histiocytosis

A clinical variant lipochrome histiocytosis was described in three sisters with rheumatoid arthritis, hyperglobulinemia, splenomegaly, pulmonary infiltrates, and increased susceptibility to infection.[205,206] No granulomas were found in tissue biopsies, but lipochrome pigmentation in large macrophages was present throughout the tissues. Studies of blood leukocyte function in two of the sisters revealed impaired postphagocytic respiration, NBT reduction, and hexose monophosphate shunt activity identical to that seen in patients with CGD.

Glucose-6-Phosphate Dehydrogenase Deficiency

NADPH is the major substrate for the respiratory burst oxidase. A bactericidal defect similar to CGD has been described in a patient with a complete deficiency of G6PD, an enzyme important in the generation of NADPH.[207,208] Apparently, almost complete absence of G6PD activity is necessary to interfere with bacterial killing, because no difference from normal could be detected in cells with 25% activity or greater.[209]

Glutathione Peroxidase Deficiency

Two unrelated 9- and 13-year-old girls presented a clinical picture similar to that of CGD and with decreased bactericidal capacity.[210] The findings in these girls differed from those in males with CGD only in that no heterozygotes were detected in their families and their clinical course was somewhat milder. These patients were reported before the nature of the NADPH oxidase was known, and it was suggested that the CGD phenotype was due to glutathione peroxidase deficiency, resulting in inhibition of the oxidase by accumulated peroxides. A subsequent study, however, suggested that glutathione peroxidase activity was normal in these patients and that both had mutations in the NADPH oxidase.[211] Thus, there is no firm evidence that glutathione peroxidase deficiency is a cause of the CGD phenotype.

Glutathione Synthetase or Reductase Deficiency

Reduced glutathione plays an important role in protecting neutrophils (including the NADPH oxidase system) from reactive metabolites, including H_2O_2. Because glutathione levels are generated by both direct synthesis via glutathione synthetase and the reduction of oxidized glutathione by glutathione reductase, deficiencies of these enzymes might be expected to result in defective neutrophil function. The neutrophils of a normally growing infant with a relatively benign history of recurrent otitis and repeated episodes of neutropenia were found to have 5% of normal glutathione synthetase activity and 10% to 20% of normal glutathione content. The cells ingested particles and metabolized 1-^{14}C glucose normally, but after phagocytosis, excess peroxide accumulated and impaired iodination and killing of bacteria were demonstrable. Electron microscopic examination showed damage to the microtubules and membranes of the neutrophils.[212,213] Neutrophil dysfunction resulting from a deficiency of glutathione reductase has also been reported.[214] Patients with glutathione reductase deficiency or glutathione synthetase deficiency generally pursue a fairly benign clinical course. Vitamin E may be useful in patients with severe glutathione synthetase deficiency.[212]

Catalase Deficiency

The neutrophil is protected from products of the NADPH oxidase not only by glutathione but also by superoxide dismutase, which generates H_2O_2 from superoxide, and by catalase, which converts H_2O_2 to H_2O and O_2. A deficiency in neutrophil catalase has been reported in which the surface of the neutrophil was more susceptible to damage by H_2O_2 than normal.[215] These patients do not appear to have severe complications with infections.[215]

Job Syndrome

Job syndrome (also known as hyperimmunoglobulinemia E syndrome) was reported as occurring in two unrelated girls with red hair and fair skin who suffered from repeated staphylococcal cold abscesses, sinusitis, eczema, and pulmonary disease, a syndrome not unlike the affliction of Job.[216] The leukocytes of these patients were capable of normal phagocytosis, bacterial killing, NBT reduction, and iodine fixation,[216,217] unlike those of patients with CGD. Subsequently, hyperimmunoglobulinemia E and defective chemotaxis were demonstrated.[218,219] It is now clear that this disorder is not limited to red-haired women, in that it is seen in both sexes and in patients of varied racial backgrounds and hair colors.[220] The common features are increased susceptibility to infection (usually evident in the first 6 weeks of life), chronic dermatitis, and hyperimmunoglobulinemia E.

Job syndrome is now recognized as a multisystem disease, characterized by not only recurrent infections, elevated IgE, and dermatitis, but also retained primary dentition, unusual facial phenotype, bone fragility, and hyperextensible joints.[221,222] While typically sporadic, autosomal dominant transmission in kindreds has been reported.[220] Most cases of Job syndrome have been associated with mutations of *STAT3*, though others with the syndrome do not have this finding and mutations in other genes have been reported.[223,224,225] Less frequent autosomal recessive transmission is now also recognized, with the gene defect being localized to *DOCK8*.[226]

Job syndrome is rare but with the advent of genetic diagnosis, more patients are being identified and the complete clinical repertoire of the disease is now being realized.[227] Fungal, viral, and bacterial infections are common. Survivors with *DOCK8* mutations have developed T-cell lymphomas and squamous cell carcinoma of the skin in early adulthood.[228] Blood eosinophilia and elevated IgE levels are the most common laboratory findings. Prophylactic treatment with dicloxacillin or trimethoprim–sulfamethoxazole may be helpful in managing afflicted patients. The role of interferon-γ is unclear.[229]

Myeloperoxidase Deficiency

An inherited deficiency of MPO was described in 1969.[230] The 49-year-old male propositus, one of his two sisters, and all four sons exhibited decreased MPO activity; no increased frequency of infections accompanied this defect. In two other families, apparently similarly affected, infection was also not a problem.[230]

Until the late 1970s, this disorder was described in only rare cases (some familial, others apparently sporadic and acquired).[231,232,233] This frequency seemed consistent with the apparently pivotal role of MPO in the oxygen-dependent killing of microorganisms.[230,232] With the development of flow cytometry and automated differential cell-counting techniques, however, MPO deficiency was often detected (approximately 1 in 2,000 subjects) during routine hematologic evaluation of patients admitted to the hospital.[231,233,234] From these studies, MPO deficiency clearly is the most common disorder of neutrophil function.[233] This disorder is now known to be autosomal recessive with mutations localized in the MPO gene on chromosome 17q23.[235]

Most studies of MPO-deficient neutrophils reveal that bacteria and fungi are phagocytized normally, and ingestion is followed by a vigorous respiratory burst. Bactericidal killing, however, is somewhat delayed, reaching normal levels only after 1 to 3 hours.[232] The findings of these studies and the rarity of clinical infections in MPO-deficient individuals support the concept of MPO-independent microbicidal mechanisms.[230,232] In contrast, although ingested normally, several *Candida* species and *Aspergillus* are killed poorly, if at all; and several MPO-deficient patients, including one of the first reported cases, suffered from disseminated fungal infection.[230,232] MPO-deficient mice also have impaired defense against *Candida*,[237,238] and have also been noted to have increased atherogenesis.[236,237]

The respiratory burst in MPO-deficient cells is actually prolonged and supernormal, and evidence exists that MPO normally acts to modulate and terminate the inflammatory response; for example, MPO oxidizes the methionine group in FMLP, thus modulating chemotaxis, and it also modulates NADPH oxidase activity.[232]

Results of studies of the structure of MPO have shown it to be a tetramer (150,000 D) composed of two heavy and two light

chains ($\alpha_2\beta_2$) of 55,000 to 60,000 and 10,000 to 15,000 daltons, respectively.[238,239] MPO is encoded by a single gene generating an 80-kD product that is modified and glycosylated generating a 90-kD enzymatically inactive apopro-MPO that is further modified to the active 90-kD pro-MPO, which is further modified and dimerizes before entering the primary granule.[240,241] In one study, completely MPO-deficient neutrophils lacked all of these subunits but contained the precursor protein, whereas partially MPO-deficient neutrophils contained decreased amounts of the precursor protein and the subunits derived from it. In some cases, specific mutations in the *MPO* gene in MPO deficiency have been described. In spite of these abnormalities, a majority of the patients are asymptomatic and a small percentage suffer from *Candida* infections.[239–241]

MPO deficiency also occurs as an acquired defect in a variety of situations (e.g., pregnancy, lead intoxication, Hodgkin lymphoma, and activated coagulation),[232] but it is encountered most commonly in association with acute myeloblastic leukemia (up to 48% of patients), myeloproliferative states (20% to 60% in chronic myelogenous leukemia, 32% in myelofibrosis), and myelodysplastic syndromes (25%).[232] In many of these conditions, only some of the circulating myeloid cells are deficient, presumably those produced by the abnormal clone.[232]

Other Enzymatic Defects

Two siblings with negative peroxidase, oxidase, and lipid reactions in the neutrophils and monocytes also have been reported.[242]

Cystic Fibrosis

As described above, an important mechanism of bacterial killing by neutrophils involves the production of HOCl from H_2O_2 and chloride. Cystic fibrosis (CF) is caused by mutations in the gene encoding the CF transmembrane conductance regulator (CFTR), a cyclic adenosine monophosphate–regulated chloride channel. CFTR is present in neutrophil secretory vesicles and phagolysosomes.[243] Although CF neutrophils produce extracellular HOCl normally, they have impaired chlorination and killing of phagocytosed bacteria due to defective HOCl production in phagolysosomes.[243]

Leukocyte Adhesion Defects

As described in Chapter 7, cell–cell adhesion plays an important role in neutrophil function. Three types of leukocyte adhesion deficiency (LAD) have been described.[151,244]

Leukocyte Adhesion Deficiency-1 (CD11/CD18 Deficiency)

CD11/CD18 deficiency is a rare, inherited disorder of leukocyte function first reported in 1974. It usually is detected in infancy or early childhood as a result of frequent bacterial (and sometimes viral) infections or delayed umbilical cord separation, and high neutrophil counts.[245] The infections are recurrent, often life threatening or fatal, and usually involve the skin and subcutaneous tissues, middle ear, and oropharynx. Neutrophils are present in the blood in increased numbers (even between infections) and appear normal, but fail to migrate into Rebuck skin windows or sites of infection in normal numbers. When studied in vitro, they exhibit defects in motility, phagocytosis, granule secretion, and particle-stimulated respiratory burst activity. Humoral (immunoglobulins and complement) and cellular immunity (skin tests and lymphocyte stimulation tests) otherwise appeared normal, and no specific enzyme deficiencies were detectable.[246]

The pathogenesis of this disorder was first suggested in 1980 when a patient's neutrophils were found to lack a high-molecular-weight glycoprotein.[247] Subsequent work revealed the absence of CD11/CD18. As described in Chapter 7, the CD11/CD18 family consists of three heterodimeric proteins each composed of a noncovalently associated α (α_L, α_M, or α_X) and β (β_2) chain (Table 58.2). Translocation of α- and β-chains to the cell surface requires assembly of the $\alpha\beta$ heterodimer. Mutations in the β_2-chain (*ITGB2*) prevent normal assembly of the $\alpha\beta$ heterodimer and subsequent translocation to the surface. CD11/CD18-deficient neutrophils roll normally on endothelial cells but do not adhere or migrate with chemotactic stimulation[248] (Table 58.2). Studies involving eight patients revealed two distinct phenotypes: patients with severe deficiency (<0.3%) and patients with moderate deficiency (2.5% to 31.0%) of CD11a/CD18 glycoproteins on the neutrophil surface. The severity of clinical manifestations correlated directly with the degree of glycoprotein deficiency.[249] Results of other studies further expand the heterogeneity of defects causing this disorder in which mutations in *CD18* have been identified.[245,250–263] The disease has also been reported in cattle.[264–266] Hematopoietic cell transplantation is curative for this disease and recommended.[267]

Leukocyte Adhesion Deficiency-2

A second form of LAD has also been described in which the patients have severe mental retardation, short stature, a distinctive facial appearance, the Bombay (hh) blood phenotype, and recurrent bacterial infections, including pneumonia, otitis media, periodontitis, and localized cellulitis without the accumulation of pus, in association with an elevated white count.[248,268,269–272,273] Phagocytosis was normal, but motility and homotypic aggregation were defective. Surface CD18 expression was normal. As described in Chapter 7, cell surface selectins, including CD62E (E-selectin), CD62P (P-selectin), and CD62L (L-selectin), and their ligands (carbohydrates whose structures appear to be related to sialyl-Le^x [CD15s]), play an important role in neutrophil adhesion. The critical structure of CD15s is (NeuAc α2 → 3 Gal β1 → 4, [Fuc α1 → 3] GlcNAc) and the Bombay phenotype is a deficiency of Fuc α1 → 2 Gal linkages, which serve as the core of the A, B, and O blood groups.[274] LAD-2 neutrophils were found to lack CD15s expression and did not bind interleukin-1β–stimulated endothelial cells (which express E-selectin). Because these patients had deficiencies of several fucosylated carbohydrates, the syntheses of which depend on different fucosyltransferase genes, a general defect in fucose metabolism was postulated.[268] This syndrome has since been termed congenital disorder of glycosylation, type IIc, and is a member of a group of disorders characterized by defects in processing protein-bound glycans. In some of these patients mutations in *SLC35C1*, a GDP-fucose transporter, have been described.[272,273] LAD-2 neutrophils do not roll well on endothelial cells and do not adhere under shear stress.[248] However, under

TABLE 58.2

LEUKOCYTE β_2 INTEGRINS

Neutrophil Integrin	Expression	Ligand
$\alpha_L\beta_2$ LFA-1, CD11a/CD18	All leukocytes	ICAM-1 (CD54) ICAM-2 (CD102) ICAM-3 (CD50)
$\alpha_M\beta_2$ HMac-1, CD11b/CD18	Monocytes, neutrophils, some natural killer cells	ICAM-1, iC3b, fibrinogen, factor X
$\alpha_X\beta_2$ p150,95, CD11c/CD18	Monocytes, neutrophils	iC3b, fibrinogen

static conditions, LAD-2 neutrophils can adhere and migrate.[248] Few patients have been described, and these cases may represent different biochemical defects.[275–280] Oral fucose supplementation may be useful in some patients.[276,279] Bone marrow transplantation might be considered in some cases.

Leukocyte Adhesion Deficiency-3

A third form of LAD was described in four patients, which appeared to be due to a defect in integrin activation following stimulation of G-protein–coupled chemokine receptors.[281] LAD-3 follows an autosomal recessive pattern, and is associated with recurrent infections and leukocytosis, with a bleeding tendency like Glanzmann thrombasthenia. LAD-3 has been associated with mutations of *FERMT3*, formerly known as *KIND3*, which codes for a protein that associates with β-integrins.[282,283] These mutations interfere with β-integrin activation.

Rac2 GTPase Mutation

A defect of neutrophil adhesion, oxidase activation, degranulation, and chemotaxis in response to chemoattractants has been reported in one patient who had a double negative mutation in Rac2 GTPase.[284,285] This patient had leukocytosis with a deficiency of pus at sites of infection, exhibiting a similar phenotype as that of *Rac2* knockout mice.[286,287]

FcγRIII Deficiency

Several patients who lack the IgG receptor FcγRIIIB (CD16) have been reported.[288–292] Two homologues of FcγRIII (FcγRIIIA and FcγRIIIB) have been identified. FcγRIIIB is glycosyl-phosphatidyl inositol–linked and expressed on neutrophils. Because FcγRIII bears the NA1 and NA2 polymorphic neutrophil-specific antigens, these cells are NA1 and NA2 negative. The clinical expression of this deficiency ranges from a normal state to one characterized by multiple infections.[288–292]

Actin Dysfunction

A genetic disorder of neutrophil actin function, characterized by recurrent bacterial infections and defects in chemotaxis, adhesion, and phagocytosis, due to neutrophil actin dysfunction (NAD) also has been described.[293–296] These cells appeared to have actin that does not polymerize well and had lower levels of F-actin in both the resting state and after stimulation. Subsequent studies after the death of the index case found that one, but not both, parent was heterozygous for LAD-1. Most patients with LAD-1 do not have abnormal actin polymerization. Patients with this syndrome and overexpression of 47- and 89-kD proteins (NAD 47/89) were also described.[294] A more recent patient was described with overexpression of leufactin—an F-actin–binding protein that regulates microfilaments—and NAD with serious infections.[297,298] Leufactin was shown to be the 47-kD protein overexpressed in NAD 47/89. Overexpression of leufactin, also known as *lymphocyte-specific protein 1*, can create the morphologic and motility abnormalities seen in leufactin-overexpressing neutrophils.[299]

Localized Juvenile Periodontitis

Localized juvenile periodontitis is an adolescent disease characterized by alveolar bone loss, most prominently of the incisors and first molars.[300,301] Interestingly, these patients do not have demonstrable problems with extra-oral infections. Abnormal neutrophil chemotaxis to FMLP and C5a in these patients has been reported,[300,301] and a similar chemotactic defect was also observed in siblings of patients before developing clinical disease. Neutrophils from patients with localized juvenile periodontitis have been reported to express CR2 (the C3d receptor) on the cell surface, in contrast to control cells, which do not.[302] CR2 is present on normal immature neutrophils but is lost during maturation before release from the marrow. The mechanism of this abnormality has not been defined.

Desensitization

After previous exposure to a stimulus, neutrophils react less to subsequent stimulation by the same stimulus.[303–305] This phenomenon has been termed *desensitization*. In some cases, the desensitization appears specific to the original stimulus, but in other cases desensitization to different stimuli is also observed (cross-desensitization).[303–305]

Such desensitization has been observed in patients undergoing hemodialysis, in which exposure of blood to a cuprophane dialyzer membrane results in the generation of C5a, which causes a transient neutropenia due to pulmonary leukostasis, as described in Chapter 7.[306,307] Although C5a generation persists throughout dialysis, the neutropenia is transient.[308] In contrast to neutrophils obtained at the start of dialysis, neutrophils obtained after 2 hours of dialysis (after the leukostasis has resolved) do not aggregate in response to plasma leaving the dialyzer membrane, demonstrating desensitization in vivo.[308] A patient with cytomegalovirus infection and serum-induced granulocyte aggregation (presumably due to C5a) did not experience neutropenia during dialysis; and his neutrophils did not aggregate in response to serum leaving the dialyzer, in contrast to control cells, also demonstrating in vivo desensitization.[308] Similar desensitization was demonstrated in rabbits using the chemotactic peptide FMLP, wherein continuous intravenous infusion of FMLP reproduced a transient neutropenia due to pulmonary sequestration.[309] It is likely that neutrophil desensitization may also occur in other pathologic states, including infection, trauma, and multiorgan failure syndrome, and may contribute to neutrophil dysfunction, although the clinical significance of this phenomenon is unclear.

The phenomenon of desensitization has also been implicated as part of the mechanism by which glucocorticoids inhibit neutrophil function. It appears that the glucocorticoid-regulated protein annexin 1 (lipocortin 1) can bind a formyl-peptide receptor, induce calcium transients, and desensitize neutrophils to subsequent stimulation by other agents.[310] Two formyl-peptide receptors are expressed in neutrophils, the classic FPR and the related receptor FPRL-1/AXL. Annexin 1 appears to bind to FRPL-1/AXL, while some peptides derived from annexin 1 may bind both receptors.[311]

Viral Infection

Neutrophil dysfunction has been reported to occur in response to influenza A exposure. Both influenza A virus and its purified hemagglutinin activate neutrophils, and neutrophil responses to other stimuli are depressed after preexposure to influenza A and parainfluenza.[312,313,314,315–319] Neutrophils from patients with human immunodeficiency virus (HIV) infection also may exhibit abnormal function. In one study, neutrophils from patients with early HIV infection had enhanced superoxide production in response to bacterial products.[320] Another study found evidence for neutrophil activation in patients with HIV infection as manifested by increased CD11b expression, decreased CD62L expression, increased H_2O_2 production, and increased actin polymerization.[321] Interestingly, H_2O_2 production, in response to FMLP after tumor necrosis factor and interleukin-8 priming, was decreased, and CD62L downregulation in response to FMLP was less complete; these abnormalities correlated with the clinical stage of disease. Whether these abnormalities are a direct effect of the HIV virus, a manifestation of desensitization as described in the previous section, or the result of another mechanism is unclear. These observations suggest that neutrophil dysfunction

may occur in response to other viral infections as well, although the clinical significance of such a phenomenon is unclear.

Hyperalimentation Hypophosphatemia

In the past, the use of hyperalimentation without adequate phosphate occasionally resulted in hypophosphatemia that was associated with neutrophil dysfunction, including impaired chemotaxis.[322] The exact mechanism of this defect is unclear, and this syndrome is now rarely encountered, although evidence suggests that the impairment of phagocytosis seen in phosphate depletion may result from an increase in intracellular calcium.[323]

Hyperglycemia

Abnormalities have been observed in several neutrophil functions in patients with poorly controlled diabetes, including phagocytosis, chemotaxis, adhesion, and the oxidative burst.[324,325,326,327,328,329,330] Improvement in glucose control is associated with an improvement in neutrophil function.[330] Improvement in neutrophil function can occur after incubation with insulin for as little as 15 minutes.[330] In patients with non–insulin-dependent diabetes, neutrophil dysfunction is associated with an increased intracellular calcium that returns to normal in association with normalization of phagocytic function when glucose control is improved.[324]

Miscellaneous

Other apparently unique neutrophil disorders have been reported. One patient with leukocytosis, severe bacterial infections, and impaired wound healing had neutrophils that appeared to have a defect in signal transduction.[331] These cells had a severe defect in chemotaxis, activation of the respiratory burst, and azurophil granule release in response to a variety of chemotaxis. In contrast, FMLP induced a normal increase in intracellular free calcium and specific granule release. Actin polymerization was defective in response to FMLP but normal in response to some other stimuli. Phagocytosis of opsonized bacteria was normal. Presumably, these cells have a defect in the intracellular signal transduction pathway.

Neutrophil Dysregulation in the Systemic Inflammatory Response Syndrome

Although this chapter has primarily addressed disorders resulting in decreased neutrophil function, neutrophil activity may also be increased. For example, one study reported increased neutrophil functional activity in patients with severe acute pancreatitis.[332] The clinical significance of this phenomenon is unclear.

FREQUENCY OF IDENTIFIABLE QUALITATIVE NEUTROPHIL DISORDERS

Most patients suspected of having a defect in neutrophil function do not have a well-defined abnormality. In one study of 100 patients referred for evaluation of a suspected neutrophil abnormality, only four were identified as a described syndrome.[333] Some degree of impaired chemotaxis or superoxide production was found in 53 of 100 patients, but no abnormality was found in 41 of 100.

CHAPTER 59

LYSOSOMAL ABNORMALITIES OF THE MONOCYTE–MACROPHAGE SYSTEM: GAUCHER AND NIEMANN-PICK DISEASES

Margaret M. McGovern, Robert J. Desnick

Abnormalities of the monocyte–macrophage system include certain of the inherited lysosomal storage diseases that result from specific defects in lysosomal function. Most of these disorders are caused by the deficiency of a particular hydrolytic enzyme, but others are due to impaired receptors, transporters, or deficiencies of crucial cofactors or protective proteins. Prevalent among these disorders are the sphingolipidoses, which are a unique family of diverse diseases related by their molecular pathology. Here, the clinical, biochemical, and genetic features of two of these disorders are presented: Niemann-Pick types A and B disease, caused by defects in the acid sphingomyelinase (*SMPD1*) gene, and Gaucher disease, caused by defects in the acid α-glucosidase (*GBA*) gene. In each of these autosomal recessive disorders, mutations in the gene that encodes the lysosomal enzyme result in a defective gene product (i.e., a noncatalytic enzyme) that is unable to perform its normal function as a hydrolase. The deficiency of these lysosomal hydrolases results in abnormal metabolism of the enzyme's specific sphingolipid substrate, and the substrate accumulates in the cells of the monocyte–macrophage system, causing the clinical manifestations. For example, in Gaucher disease and Niemann-Pick types A and B diseases, anemia, thrombocytopenia, leukopenia, and/or hepatosplenomegaly can be the presenting symptoms. Thus, these disorders are frequently diagnosed by the hematologist and must be included in the differential diagnosis for patients with monocyte–macrophage involvement.

PATHOPHYSIOLOGY OF THE LYSOSOMAL STORAGE DISEASES

The underlying defect in the inherited lipidoses is the accumulation of metabolites, including glycolipids and sphingomyelin. The glycosphingolipids, which are present in the membranes of many cell types, are formed by the addition of various carbohydrates to a ceramide backbone (Fig. 59.1). The fatty acid portion of ceramide consists primarily of stearic acid (C_{18}) in the brain, whereas in non-neural tissues it is somewhat longer (C_{20} to C_{24}). Each sphingolipid is characterized by the nature of the compound that is esterified to the first carbon of the ceramide molecule. For example, the addition of hexoses and *N*-acetylneuraminic acid to ceramide forms the gangliosides, which are found in brain, whereas the neutral glycolipids are found more ubiquitously in cell membranes. The blood group antigens are also glycosphingolipids. In the lysosomal storage diseases, these lipid compounds vary in amount in different cell types, so their rate and amount of accumulation because of a specific lysosomal enzyme defect will vary, leading to their cell-related manifestations (Fig. 59.2). Tables 59.1 and 59.2 outline the biochemical and phenotypic characteristics and the molecular basis of the lysosomal storage diseases, respectively.

GAUCHER DISEASE

Definition and History

Gaucher disease is a lipid storage disease characterized by the deposition of glucocerebroside in cells of the macrophage-monocyte system. It was first described by Gaucher in 1882, and the storage of glucocerebroside was first recognized by Epstein in 1924. The metabolic defect, which is the deficiency of the lysosomal hydrolase acid β-glucosidase, or β-glucocerebrosidase, was identified by Brady et al.[1] There are three clinical subtypes, which are delineated by the absence or presence and progression of neurologic involvement: type 1 or the non-neuronopathic form; type 2, the infantile-onset, acute neuronopathic form; and type 3, the juvenile-onset neuronopathic form.[2] All three subtypes are inherited as autosomal recessive traits. Type 1 disease is the most common lysosomal

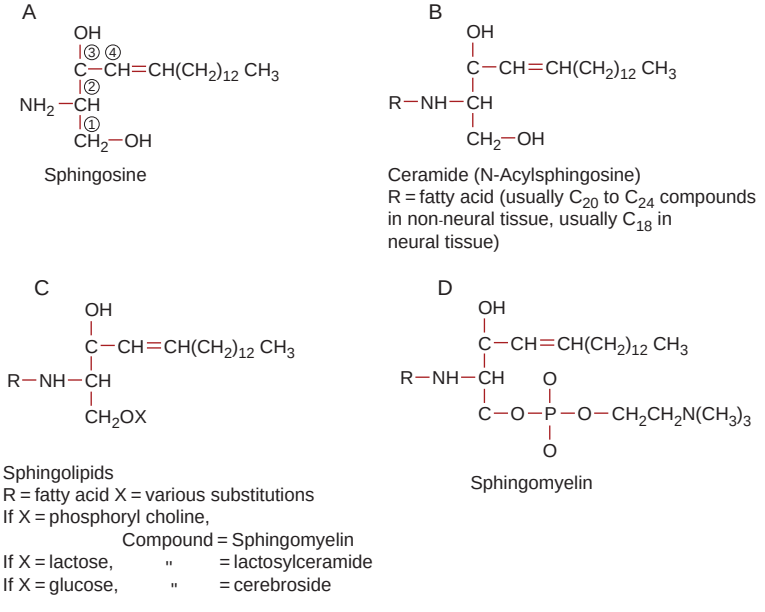

FIGURE 59.1. Formulas of some of the sphingolipids.

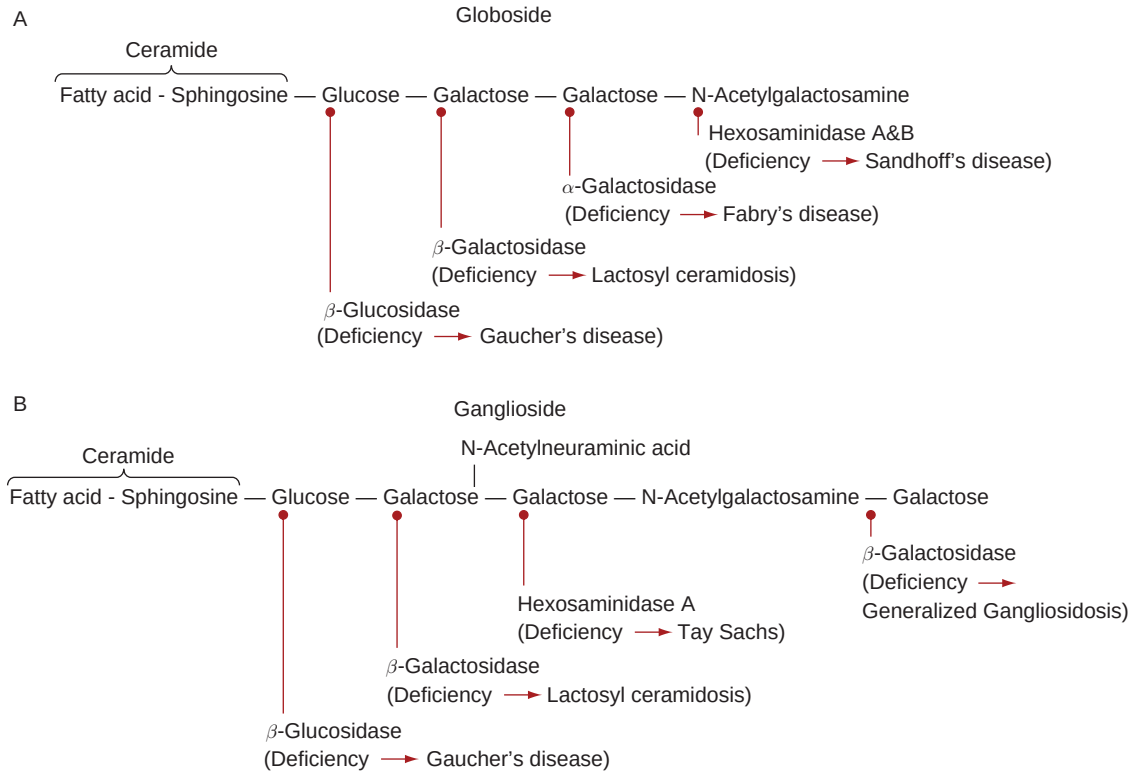

FIGURE 59.2. Schematic structure of globoside (A) and ganglioside (B) to show site of action of the several catabolic enzymes, which result in one of the storage diseases when defective.

storage disease and one of the most prevalent genetic disorders among Ashkenazi Jewish individuals, with an incidence of about 1 in 1,000 and a carrier frequency of about 1 in 15.[3]

Etiology and Pathogenesis

All three subtypes of Gaucher disease result from the deficient activity of the lysosomal hydrolase, acid β-glucosidase (Table 59.1). The major acid β-glucosidase gene mutations that cause Gaucher disease among Ashkenazi Jewish patients have been identified (Table 59.2). Genotype/phenotype correlations have been made for the different subtypes and provide insight into the molecular basis for the remarkable clinical variation in Gaucher disease. Presumably, the amount of residual enzymatic activity determines disease subtype and severity. For example, the mutations that cause the severe type 2 (infantile) disease express little, if any, enzymatic activity in vitro, whereas type 1 patients who are homozygous for the milder N370S mutation tend to have a later

TABLE 59.1

BIOCHEMICAL AND PHENOTYPIC CHARACTERISTICS OF GAUCHER AND NIEMANN-PICK DISEASES

Disease	Enzyme Deficiency	Substance Accumulated	Site	Complications
Gaucher Disease				
Type 1	Acid β-glucosidase	Primarily glucosylceramide	Macrophage–monocyte system	Infiltration of bone marrow, progressive hepatosplenomegaly, skeletal complications
Type 2	Acid β-glucosidase	Primarily glucosylceramide	Macrophage–monocyte system, CNS	Infiltration of bone marrow, progressive hepatosplenomegaly, skeletal complications, neurodegeneration
Type 3	Acid β-glucosidase	Primarily glucosylceramide	Macrophage–monocyte system, CNS	Progressive neurodegeneration
Niemann-Pick Disease				
Type A	Acid sphingomyelinase	Sphingomyelin	Monocyte–macrophage system, CNS	Hepatosplenomegaly, progressive neurodegeneration
Type B	Acid sphingomyelinase	Sphingomyelin	Monocyte–macrophage system	Progressive hepatosplenomegaly, infiltrative lung disease
Type C	Abnormal cholesterol transport	Primarily cholesterol	Most cells, especially liver, CNS	Hepatosplenomegaly, progressive neurodegeneration

CNS, central nervous system.

TABLE 59.2

MOLECULAR BASIS OF GAUCHER AND NIEMANN-PICK DISEASES

Disease	Chromosome Assignment	Molecular Characteristics	Comments
Gaucher disease	1q21	cDNA, functional and pseudogenomic sequences, >200 mutant alleles known	Four mutations (N370S, L444P, 84insG, IVS2^{+}1) account for 90 to >95% of mutant alleles in Ashkenazi Jewish patients
Niemann-Pick disease			
Types A and B	11p15.1 to p15.4	cDNA, entire genomic sequence, >70 mutant alleles known	Four mutations account for >95% of mutant alleles in Ashkenazi Jewish patients with type A disease
Type C	18q11-q12 region	cDNA, entire genomic sequence, >100 mutant alleles known	More than 100 mutations in NPC1 gene

onset and a milder course than patients with one N370S allele and another mutant allele. However, the wide variability in clinical presentation among Gaucher disease patients cannot be fully explained by the underlying acid β-glucosidase mutations, and presumably other "modifier" genes can influence disease severity.

Pathology

The pathologic hallmark in Gaucher disease is the presence of Gaucher cells in the macrophage–monocyte system, particularly in the bone marrow. These cells, which are 20 to 100 μm in diameter, have a characteristic wrinkled-paper appearance resulting from intracytoplasmic substrate deposition. These cells stain strongly positive with periodic acid-Schiff reagent, and their presence in bone marrow and/or other tissues suggests the diagnosis (Fig. 59.3). The accumulated glycosphingolipid, glucosylceramide, is derived primarily from the phagocytosis and degradation of senescent leukocytes and, to a lesser extent, erythrocyte membranes. Glucosylceramide storage results in organomegaly and pulmonary infiltration. Neuronal cell loss in patients with types 2 and 3 disease presumably results from the neural accumulation of the cytotoxic glycosphingolipid, glucosphingosine, due to the severe deficiency of acid β-glucosidase activity. Glucosylceramide accumulation in the bone marrow, liver, spleen, lungs, and kidney leads to pancytopenia, massive hepatosplenomegaly, diffuse infiltrative pulmonary disease, and nephropathy or glomerulonephritis. The progressive infiltration of Gaucher cells in the bone marrow causes thinning of the cortex, pathologic fractures, bone pain, bony infarcts, and osteopenia, particularly in type 1 disease. Central nervous system (CNS) involvement occurs only in patients with types 2 and 3 disease.

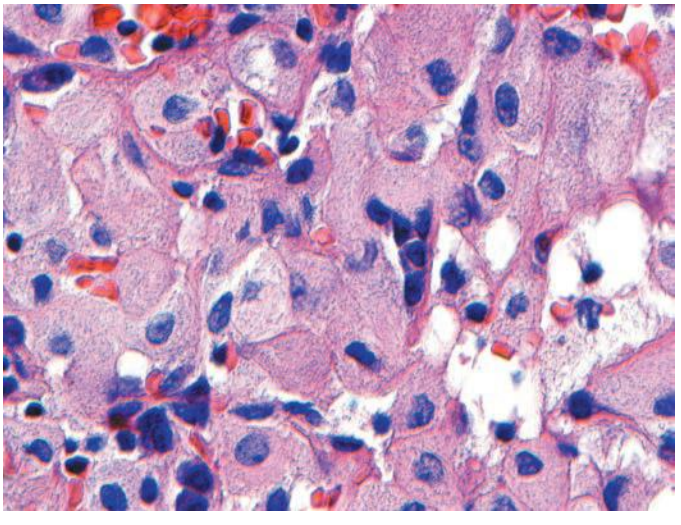

FIGURE 59.3. Splenic histopathology in Gaucher disease. There are sheets of histiocytes with bland nuclei and abundant pink cytoplasm with a fine "tissue paper" appearance.

Clinical Manifestations

Type 1 Disease

There is a broad spectrum of clinical expression among type 1 disease patients, in part because of the combination of different mutant alleles. Onset of clinical manifestations occurs from early childhood to late adulthood, with more symptomatic patients presenting in childhood or adolescence. At presentation, patients may have easy bruisability resulting from thrombocytopenia, chronic fatigue secondary to anemia, hepatomegaly with or without elevated liver function tests, splenomegaly, and bone pain or pathologic fractures. Occasional patients present with pulmonary involvement. Patients who are diagnosed in the first 5 years of life are frequently non-Jewish and typically have a more malignant disease course. Milder patients are discovered later in life during evaluations for hematologic or skeletal problems, or are found to have splenomegaly on routine examinations. In symptomatic patients, splenomegaly is progressive and can become massive. Clinically apparent bony involvement can present as bone pain or pathologic fractures. Most patients have radiologic evidence of skeletal involvement, including an "Erlenmeyer flask" deformity of the distal femur, which is an early skeletal change. In patients with symptomatic bone disease, lytic lesions can develop in the long bones, ribs, and pelvis, and osteosclerosis may be evident at an early age. Bone crises with severe pain and swelling can occur. Bleeding secondary to thrombocytopenia may manifest as epistaxis and bruising and is frequently overlooked until other symptoms become apparent. Children with massive splenomegaly are short of stature because of the energy expenditure required by the enlarged organ.

Type 2 Disease

Infants with the rare and panethnic type 2 subtype have a rapid neurodegenerative course with extensive visceral involvement and death within the first 2 years of life. The disease presents in infants with increased tone, strabismus, and organomegaly. Failure to thrive and stridor resulting from laryngospasm are typical. The progressive psychomotor degeneration leads to death, usually due to respiratory compromise.

Type 3 Disease

Patients with type 3 Gaucher disease typically present in infancy or childhood. In addition to the organomegaly and bony involvement, neurologic involvement is present. There is a high frequency of type 3 disease in Sweden (1 in 50,000), which has been

traced to a common founder in the 17th century. Type 3 has been further classified as type 3a or 3b based on the extent of neurologic involvement and whether there is progressive myotonia and dementia (type 3a) or isolated supranuclear gaze palsy (type 3b).

Diagnosis

Gaucher disease should be considered in the differential diagnosis of patients who present with unexplained organomegaly, easy bruisability, and/or bone pain.[4] In the past, bone marrow examination revealing the presence of Gaucher cells was used for diagnosis. Today, all suspect diagnoses should be confirmed by demonstrating deficient acid β-glucosidase activity in isolated leukocytes or cultured fibroblasts. For genotype/phenotype correlations, the specific acid β-glucosidase gene mutation should be determined, particularly in Ashkenazi Jewish patients. Carrier identification can be achieved by enzymatic assay, although in the Ashkenazi this can be achieved by detection of the common mutations. Testing should be offered to all family members, keeping in mind that heterogeneity even among members of the same kindred can be significant and that asymptomatic affected individuals may be diagnosed during such testing. Prenatal diagnosis is available by determining the enzymatic activity and/or the parent's specific mutations in chorionic villi or cultured amniotic fluid cells.

Treatment

Enzyme replacement with recombinant acid β-glucosidase (imiglucerase [Cerezyme, Genzyme Corporation, Cambridge, MA] or velaglucerase alfa [VPRIV, Shire HGT, Lexington, MA]) is the standard of care for the treatment of patients with type 1 disease. Clinical trials have demonstrated that most extra-skeletal symptoms are reversed within 12 to 36 months by an initial debulking dose of enzyme (60 units/kg) administered by intravenous infusion every other week. Initial higher doses may be indicated in patients with severe disease (type 3) at the time of diagnosis and in those with rapid progression or significant comorbidities.[5] Early treatment may be efficacious in normalizing linear growth and bone morphology in affected children. Experience during the last 20 years has proven enzyme replacement therapy to be safe and effective in preventing the complications of type 1 disease. However, enzyme replacement does not alter the neurologic progression of patients with Gaucher disease types 2 and 3. It has been used in these patients as a palliative measure, particularly in type 3 patients with severe visceral involvement. Alternative treatments being evaluated include therapies targeted to reducing the synthesis of glucosylceramide by chemical inhibition of glucosylceramide synthase, as well as pharmacologic chaperone monotherapy to increase the residual activity of missense mutations, and pharmacologic chaperone coadministration with the recombinant enzyme to stabilize it in the circulation and to increase its delivery to other tissues.

NIEMANN-PICK DISEASE

Definition

Niemann-Pick disease (NPD) types A and B are lipid storage disorders that result from the deficiency of the lysosomal enzyme, acid sphingomyelinase, and the subsequent accumulation of its substrate, sphingomyelin.[6] The original description of NPD referred to what is now known as type A NPD, which is a fatal neurodegenerative disorder of infancy characterized by failure to thrive, hepatosplenomegaly, and a rapidly progressive neurodegenerative course that leads to death by the age of 2 or 3 years. Type B NPD has a wide phenotypic spectrum that can include neurologic manifestations, but typically does not.[6–8] Type C NPD is a neurodegenerative disorder that results from defective intracellular cholesterol transport and accumulation of unesterified cholesterol in lysosomes.[7,8] Previously, a type D disease was identified in patients from Nova Scotia; however, these patients actually have type C disease. All the subtypes are inherited as autosomal recessive traits and display variable clinical features.

Etiology and Pathogenesis

Types A and B NPD result from the deficient activity of the lysosomal hydrolase, acid sphingomyelinase (Table 59.1). In type C NPD, the genetic defect involves the defective transport of cholesterol from the lysosome to the cytosol. Two different genes causing the altered cholesterol transport in type C disease have been identified (*NPC1* and *NPC2*), permitting more precise diagnosis, carrier detection, and prenatal diagnosis in affected families. Only types A and B are discussed here; for type C, see Refs. 7 and 8.

Pathology

Types A and B Niemann-Pick Disease

The pathologic hallmark in types A and B NPD is the histochemically characteristic lipid-laden foam cell, often referred to as the "Niemann-Pick cell." These cells, which can be readily distinguished from Gaucher cells by their histologic and histochemical characteristics, are not pathognomonic for NPD, because histologically similar cells are found in patients with Wolman disease, cholesterol ester storage disease, lipoprotein lipase deficiency, and in some patients with GM_1 gangliosidosis, type 2 (Fig. 59.4). Sphingomyelin is the major lipid that accumulates in the cells and tissues of patients with types A and B NPD. In most normal tissues, sphingomyelin constitutes from 5% to 20% of the total cellular phospholipid content; however, in patients with types A and B NPD, the sphingomyelin levels may be elevated up to 50-fold, constituting ~70% of the total phospholipid fraction. Lysosomal sphingomyelin accumulation in liver, kidney, and lungs has been documented with organs from types A and B NPD patients containing about the same amount of sphingomyelin, with the notable finding of significant sphingomyelin and psychosphingosine in the CNS of type A NPD patients. In general, patients with type A disease have <5% of normal acid sphingomyelinase activity when assayed in cultured fibroblasts and/or lymphocytes, whereas cells from type B patients typically have >5% of normal activity,

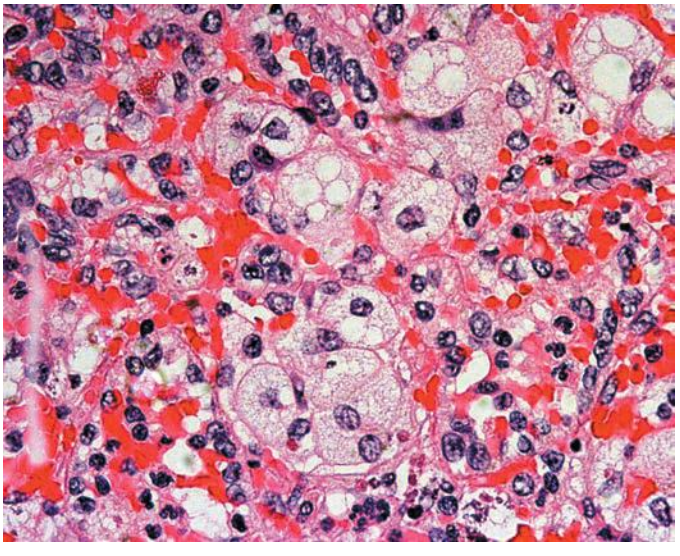

FIGURE 59.4. Splenic histology in Niemann-Pick disease type B. Aggregates of histiocytes are present with distinct vacuoles. Although some large vacuoles are seen, most are small. (Image provided by Professor Attilio Orazi, Department of Pathology, Indiana University.)

which presumably prevents the development of the neurologic symptoms.

Clinical Manifestations

Types A and B Niemann-Pick Disease

The clinical presentation and course of type A NPD is relatively uniform and is characterized by a normal appearance at birth. Hepatosplenomegaly and psychomotor retardation are evident by 6 months of life, followed by rapid neurodegeneration and death by 3 years. The loss of motor function and the deterioration of intellectual capabilities are progressive. In later stages, spasticity and rigidity are evident, with affected infants experiencing complete loss of contact with their environment.

In contrast to the stereotyped type A phenotype, the clinical presentation and course of patients with type B disease are more variable. Most patients are diagnosed in infancy or childhood, when enlargement of the liver and/or spleen is detected during a routine physical examination. At diagnosis, type B patients also have evidence of mild pulmonary involvement, usually detected as a diffuse reticular or finely nodular infiltration on chest roentgenogram. In most patients, hepatosplenomegaly is particularly prominent in childhood, but with increasing linear growth the abdominal protuberance decreases and becomes less conspicuous. In mildly affected patients, the splenomegaly may not be noted until adulthood, and there may be minimal disease manifestations. In most type B patients, decreased pulmonary diffusion resulting from alveolar infiltration becomes evident in childhood and progresses with age. Severely affected individuals may experience significant pulmonary compromise by age 15 to 20 years. Such patients have low pO_2 values and dyspnea on exertion. Life-threatening bronchopneumonias may occur, and cor pulmonale has been described. Severely affected patients also may have liver involvement leading to life-threatening cirrhosis, portal hypertension, and ascites. Clinically significant pancytopenia resulting from secondary hypersplenism may necessitate partial or total splenectomy, although removal of the spleen can exacerbate the pulmonary disease.

Cholesterol abnormalities characterized by low high-density lipoprotein cholesterol and increased total cholesterol are found in most patients and can be associated with early atherosclerotic changes. Some type B patients have neurologic involvement, which can include cerebellar signs and nystagmus, extrapyramidal involvement, mental retardation, and psychiatric disorders. As in other lysosomal storage diseases, it is evident that neurologic manifestations in acid sphingomyelinase deficiency may occur along a continuum among patients. Nevertheless, there is a distinctive, fatal neurodegenerative form (NPD-A), characterized by a brief period of normal development followed by a severe neurodegenerative course and death in early childhood.

Patients with NPD type C disease often have prolonged neonatal jaundice, appear normal for 1 to 2 years, and then experience a slowly progressive and variable neurodegenerative course. Their hepatosplenomegaly is less severe than that in patients with type A or B disease, and they may survive into adulthood.

Diagnosis

Type A NPD patients are diagnosed in the first year of life with failure to thrive, organomegaly, and severe psychomotor retardation. In type B NPD patients, splenomegaly is usually noted early in childhood; however, in very mildly affected patients, the enlargement may be subtle and detection may be delayed until adolescence or adulthood. The presence of the characteristic Niemann-Pick cells in the bone marrow supports the diagnosis. However, patients with type C disease also have extensive infiltration of these cells in the bone marrow. Thus, all suspect cases should be evaluated enzymatically to confirm the clinical diagnosis by measuring the acid sphingomyelinase activity in peripheral leukocytes, or cultured fibroblasts and/or lymphoblasts. Patients with type A or B disease will have markedly decreased levels of enzymatic activity (1% to 10% of normal), whereas patients with type C disease may have slightly decreased sphingomyelinase activities (50% to 75% of normal), and patients with Gaucher disease and other storage disorders presenting with hepatosplenomegaly and/or neurologic involvement will have normal or near-normal acid sphingomyelinase levels. Type C NPD can be documented biochemically by demonstrating the cholesterol transport defect in cultured fibroblasts or by determining the specific mutations in the *NPC1* or *NPC2* genes.

The enzymatic identification of type A and B carriers is problematic. However, in families in which the specific molecular lesion has been identified, family members can be accurately tested for heterozygote status by DNA analysis. Prenatal diagnosis of types A and B disease may be made reliably by measuring the acid sphingomyelinase activity in cultured amniocytes or chorionic villi. In families in which the specific gene mutations are known, the prenatal diagnosis can be made by DNA analysis of fetal cells. In type C disease, the cholesterol defect can be demonstrated by filipin staining, but DNA diagnosis using fetal cells is most accurate.

Treatment

Orthotopic liver transplantation in an infant with type A disease and amniotic cell transplantation in several type B patients have been attempted, with little or no success. Bone marrow transplantation of type B patients has reduced the spleen and liver volumes, the sphingomyelin content of the liver, the number of Niemann-Pick cells in the marrow, and the radiologic infiltration of the lungs. However, no long-term information is available, as these patients often lose their engraftment or have significant morbidity and mortality in the post-transplant period. To date, lung transplantation has not been reported in any severely compromised type B patient. Clinical trials of enzyme replacement therapy have begun for NPD type B. Treatment of types A and C disease is limited by the severe neurologic involvement.

CHAPTER 60

LANGERHANS CELL HISTIOCYTOSIS

Suman Malempati, H. Stacy Nicholson

Langerhans cell histiocytosis (LCH) is a disorder characterized by clonal proliferation of cells in the mononuclear phagocyte system. Since the first case was described more than a century ago,[1] LCH has often been a source of confusion, perhaps best demonstrated by the several labels given to the disorder during the past 100 years. Since 1985, *Langerhans cell histiocytosis* has been the preferred term,[2,3] replacing *histiocytosis X*, coined in 1953.[4] The *X* demonstrated the lack of knowledge about the etiology and pathophysiology of LCH, and about how the different clinical syndromes were related. The term *histiocytosis X* did serve to bind the syndromes, which included Hand-Schuller-Christian syndrome, Letterer-Siwe disease, eosinophilic granuloma, Hashimoto-Pritzker syndrome,[5] self-healing histiocytosis,[6] and pure cutaneous histiocytosis,[7] into one clinical entity. The term *Langerhans cell histiocytosis* reflects the central role of the Langerhans cell in these diseases. LCH also distinguishes these disorders from other histiocytic syndromes, which include primary and secondary hemophagocytic lymphohistiocytosis, Rosai-Dorfman disease, and neoplastic disorders such as acute monocytic leukemia, malignant histiocytosis, and true histiocytic lymphoma.[3] This chapter focuses on LCH.

HISTORY

The clinical triad of defects in membranous bone, exophthalmos, and polyuria in children, which became known as *Hand-Schuller-Christian disease*,[8] was described in 1921 in a review by Hand.[9] Hand described the first six reported cases, including those of Christian, Schuller, and his own first case reported in 1893.[1] All six patients had hepatosplenomegaly, lymphadenopathy, and bone lesions. However, not all had exophthalmos and polyuria. Attempts to link the disorder to xanthoma tuberosum, lipid storage disease, and the xanthomatoses proved unsuccessful, and to this day, no evidence exists that a specific biochemical defect is responsible for the condition. However, the foamy or xanthoma cell came to be regarded as a pathognomonic feature of the syndrome.[10]

A different syndrome, consisting of fever, bilateral otitis media, hepatosplenomegaly, and adenopathy in a young infant who died, was described by Letterer in 1924.[11] In 1933, Siwe described a 16-month-old girl who died after a 3-month illness characterized by fever, hepatosplenomegaly, lymphadenopathy, neutrophilia, and a destructive lesion in her fibula.[12] At autopsy, massive infiltrates of large cells resembling histiocytes were found. Siwe reviewed five other cases from the literature (including that of Letterer) and concluded that they constituted a single clinical entity.[12]

In 1940, two groups of investigators described a syndrome in which a characteristic feature was infiltration of bone by eosinophilic granulomas.[13,14] In 1942, Green and Farber described a series of patients with eosinophilic granulomas of bone, which usually healed promptly after irradiation or curettage.[15] They noted that these cases shared pathologic features similar to those of the Letterer-Siwe and Hand-Schuller-Christian syndromes. In 1953, because of the similarity of the histiocytes observed in these three disorders, Lichtenstein combined them into a single entity called *histiocytosis X* to indicate their unknown cause.[4] The recognition that these three disorders were related was an important contribution. The term *Langerhans cell histiocytosis,* proposed in 1985, reflects an improved understanding of these disorders.[3]

Despite our understanding of the central role played by the Langerhans cells in LCH, little is known about the etiology of LCH. Although clinical features of LCH were first recognized over a century ago, the pathogenesis remains uncertain. In 1994, two separate groups detected clonality of the involved histiocytes from LCH lesions.[16,17] Clonality was demonstrated in LCH cells from unifocal lesions as well as disseminated disease. However, debate continues as to whether LCH represents a neoplastic disorder or a reactive proliferation of histiocytes (Fig. 60.1).

EPIDEMIOLOGY

Although estimates vary by region and time period, the annual childhood incidence of LCH has been estimated to be approximately 4 to 9 cases per million.[18,19,25] The discrepancy between epidemiologic studies is likely due to variation in reporting and data collection. Across studies, there is consistently a slight

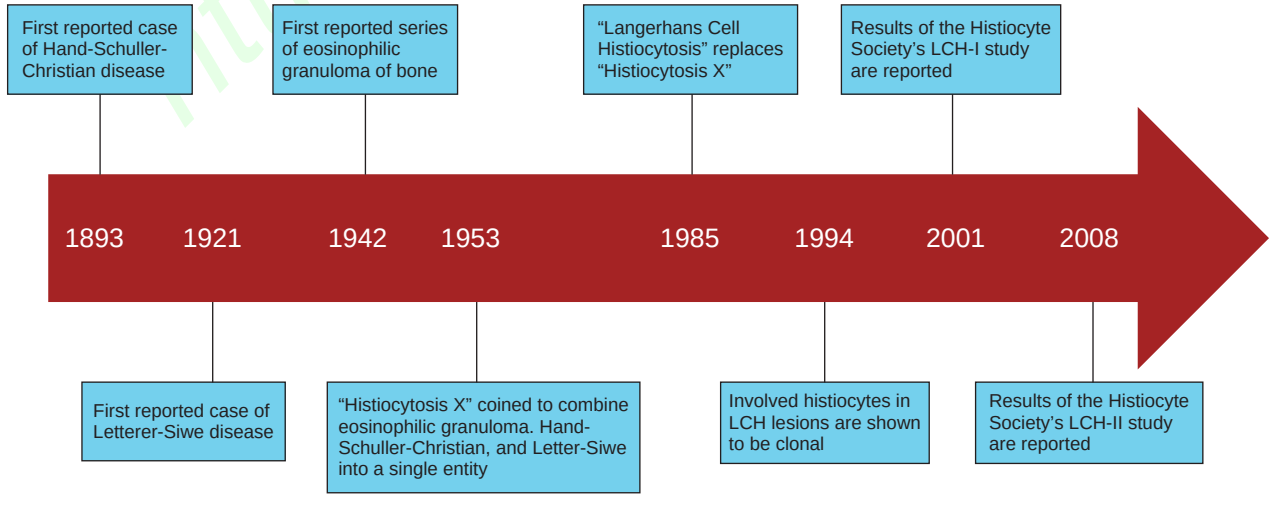

FIGURE 60.1. Historical timeline demonstrating the major discoveries regarding the pathogenesis and treatment of Langerhans cell histiocytosis (LCH).

predominance of cases in males.[18,19,20] LCH occurs less frequently in adults with an incidence of 1 to 2 cases per million per year.[21] The disease is more common and tends to be more severe in younger children. For children under 1 year of age, the annual incidence is 9.9 cases per million.[22] Almost all cases of multisystem LCH occur before 5 years of age.[23,24,25] In an exploratory case–control study comparing 177 children with LCH to children with cancer and community controls,[20] LCH was associated with a family history of benign tumors and less strongly with feeding problems during infancy. Other factors associated with LCH in this study were maternal urinary tract infections during pregnancy and blood transfusions during infancy. Factors not associated with LCH were the typical childhood viral infections and medication use. In a case–control study of 459 children with LCH, which compared risk factors in children with LCH to those in both community and cancer controls,[26] LCH was associated with neonatal infections, solvent exposure, and thyroid disease in the proband or the family. Childhood immunizations appeared to be protective. Reports of seasonal variation in incidence are conflicting[18,25] Familial clustering of LCH has been observed, suggesting that a genetic predisposition may exist.[27] The concordance rates between dizygotic and monozygotic twins are 33% and 80%, respectively. In addition, patients with LCH may have a predisposition to cancer and vice versa. Links with both solid tumors and leukemia have been documented.[28] Several cases of LCH developing in patients with acute lymphoblastic and acute myelogenous leukemia have been reported.[29–32] Patients with LCH have genetic instability and increased chromosomal breakage, which also suggests a genetic predisposition to malignancy.[33,34,35]

PATHOLOGY AND PATHOPHYSIOLOGY

The basic histologic lesion in LCH is granulomatous, with lesions containing histiocytes, mature eosinophils, and lymphocytes.[36] Other cells present may include giant cells, neutrophils, and plasma cells. Initially, lesions are proliferative and dominated by histiocytes, some of which are Langerhans cells. Although mitotic figures may occasionally be identified, the histiocytes are not neoplastic by histologic criteria. As lesions progress, necrosis may develop, and the number of eosinophils and phagocytic cells containing cellular debris increases. Ultimately, xanthomatous changes and fibrosis may occur, and late in the course of disease, Langerhans cells may no longer be demonstrable. Multinucleated giant cells occasionally are prominent, especially in bone and lymph nodes. The histologic findings do not correlate with the extent or aggressiveness of disease.[37]

The Langerhans cell is the *sine qua non* of the diagnostic lesion. Langerhans cells are dendritic antigen-presenting cells that are normally found in skin and other organs. Langerhans cells are classified as dendritic cells because of their capacity to form long cytoplasmic extensions through which they establish intimate contact with other cells. The presence of fascin, a highly selective marker of dendritic cells, on the surface of Langerhans cells confirms their derivation from dendritic cells.[38] Langerhans cells are found primarily in normal epidermis, but also are evident in lymph nodes and spleen. A hematopoietic progenitor of Langerhans cells has been identified in normal bone marrow.[39] In the skin, Langerhans cells form a trap for external contact antigens and are involved in delayed hypersensitivity. Despite low phagocytic activity, they fix antigens for presentation to other cells, especially T lymphocytes.[40]

Although its demonstration is essential for diagnosis, the Langerhans cell may constitute no more than a small proportion of histiocytes within lesions. Viewed by light microscopy, these cells appear as large mononuclear cells with few cytoplasmic vacuoles and little or no phagocytic material.[41] The nuclei are irregularly shaped and contain a fine chromatin pattern. Electron microscopic or immunohistochemical studies may be required to identify Langerhans cells with confidence. The former demonstrate structures known as *Birbeck granules* (Langerhans bodies, X granules),[42] rod-shaped organelles with a central striation and occasional terminal vesicular dilation, giving them a tennis racket appearance (Fig. 60.2). Birbeck granules are thought to be produced by invagination of the cell membrane, and their function is not known. The other feature that conclusively establishes the diagnosis of LCH is the demonstration of either CD1a antigen or CD207 (Langerin) on the surface of LCH cells by immunohistochemical staining.[36,43] Langerin is a cell-surface receptor that induces the formation of Birbeck granules.[44] Langerin expression has recently been recognized as a sensitive and relatively specific marker in establishing the diagnosis of LCH. Other distinctive features of Langerhans cells that can be demonstrated with immunohistochemical techniques include the expression of S-100 protein,[41] Ia-like antigen,[45] and CD101.[46]

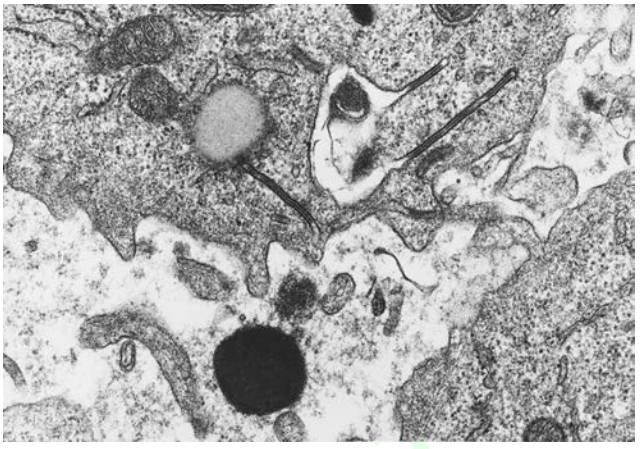

FIGURE 60.2. Electron micrograph of Langerhans cells from a bone lesion demonstrating characteristic Birbeck granules with a trilaminar structure. (Magnification ×45,000; courtesy of Roma Chandra.)

The intralesional histiocytes of LCH were previously thought to be similar to normal Langerhans cells found in skin. However, it is now recognized that pathologic Langerhans cells or LCH cells are a less differentiated and more activated type of dendritic cell.[47] CD1a-positive LCH cells from bone lesions express CD14 and CD68, monocyte antigens that are not expressed or are expressed at low levels in normal skin Langerhans cells.[48] A recent study demonstrated a gene expression profile of intralesional LCH cells that was distinct from that of normal skin Langerhans cells.[49] LCH cells also express the immature dendritic cell marker CCR6 in the absence of CCR7, which is expressed on mature dendritic cells.[50] LCH cells exhibit a degree of migration capability, which is absent in mature dendritic cells. LCH cells can be induced to differentiate in the presence of CD40 ligand in vitro.[48] However, as CD40 ligand is abundant in LCH lesions, the reason for maturational arrest is unclear.[51] Abnormal cellular adhesion molecules in LCH cells, suggested by the presence of CD2, CD11a, CD11b, and CD11d, may contribute to the migration of Langerhans cells into LCH lesions, as well as their abnormal persistence and proliferation.[52] Compared to normal Langerhans cells, LCH cells are defective in their alloantigen-presenting activity.[53]

The focal accumulation of Langerhans cells, macrophages, lymphocytes, and eosinophils suggests that LCH is immunologically mediated. This reasoning is supported by both histologic abnormalities of the thymus and disturbances of immunoregulation in patients with active disease.[54] Thymic abnormalities were noted by Letterer in his initial description of the disorder, later known as Letterer-Siwe disease.[11] Abnormalities noted on pre-therapy biopsy samples and postmortem materials include dysmorphic

changes, dysplasia, and nonspecific involution.[55,56,57] In patients with LCH, the number of normal thymocytes (expressing CD6) and late differentiating suppressor lymphocytes (expressing CD8) is decreased.[58] These abnormalities are noted even when the disease is limited in its distribution.

Recognition of the possible pathogenic significance of thymic abnormalities prompted several studies of T lymphocytes in blood. The demonstration of decreased numbers of H2 receptors on blood lymphocytes suggested loss of T-suppressor cells.[59] This loss was confirmed by quantitation of T-cell subsets in patients with active disease. Both the relative and absolute numbers of suppressor T lymphocytes ($CD8^+$ cells) are decreased, resulting in an increase in the T4-to-T8 ratio. Suppressor cell activity as measured by the concanavalin A and indomethacin stimulation assays also is poor.[59] That T-suppressor cell deficiency may be causally related to a functionally abnormal thymus is suggested by the normalization of T4-to-T8 ratios with thymic extract.[57] Moreover, the apparent ability of crude thymic extract to reverse disease activity in some patients suggests that the T-cell abnormalities may be of primary pathogenic significance.[57]

Although less consistent, other abnormalities in immune regulation also have been described, including hypergammaglobulinemia,[60] deficiency in antibody-dependent monocyte-mediated cytotoxicity,[61] and abnormal in vitro response to mitogens and antigens.[55] However, most investigators note normal mitogen-induced responses and normal delayed hypersensitivity.[62] Also, several cytokines are increased in LCH.[63,64] Cytokines serve as mediators of inflammation, regulators of lymphocyte growth and differentiation, and activators of specialized effector cells. In tissue culture, Langerhans cells purified from bony LCH lesions secrete interleukin-1 (IL-1) and prostaglandin E2, both of which induce bone resorption in vitro.[65] These lesions also secrete angiotensin-converting enzyme, transforming growth factor-β1 and IL-2.[66] These mediators are probably responsible for the osteolytic lesions that are a prominent clinical feature of LCH. Other cytokines that have been demonstrated to be increased in the serum of LCH patients include granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, IL-8, IL-10, and tumor necrosis factor-α.[67] These cytokines are related to local activation of T lymphocytes and other inflammatory leukocytes. In addition, GM-CSF receptors are expressed by Langerhans cells.[68] GM-CSF induces Langerhans cell proliferation and activation in vitro, and serum levels of GM-CSF have been correlated with the extent of disease.[68]

The link between proliferation of Langerhans cells and immune dysfunction has not been worked out entirely. One suggestion is that the disorder results from a physiologically appropriate response of the Langerhans cell to an external antigen or neoantigen, possibly infectious in origin. However, the lack of seasonal variation or geographic clustering argues against an infectious basis. In addition, no direct evidence for a viral etiology (viral particles or nuclear material) in LCH lesions has been demonstrated.[69,70] Alternatively, LCH may result from an appropriate response of the Langerhans cell to abnormal signals from other cells in the immune system, perhaps from T lymphocytes. In either event, deficiency of T-suppressor cells may disrupt the mechanism for termination of immune responses. Failure of this homeostatic mechanism could result in unrestrained macrophage proliferation. Patients with interferon-γ deficiency present with findings that mimic LCH.[71]

Whether LCH is primarily a reactive or neoplastic process has long been debated. The predominant theory has been that LCH is a reactive process to an unknown stimulus.[72] However, in 1994 two groups showed that the lesional cells are clonal[16,17]; clonality occurred in patients with all forms of LCH, including acute disseminated LCH and unifocal LCH, and in those with intermediate forms of the disease. T-cells within LCH lesions were polyclonal.[16] Interestingly, LCH occurs in some individuals with malignant disorders.[28] Most cases of malignancy occur after treatment for LCH, although acute lymphoblastic leukemia, in particular, may precede the diagnosis of LCH.[31,32] The presence of chromosomal instability and mutational events reported in a few studies support a neoplastic process.[34,35] However, at least some cases of pulmonary LCH are not clonal.[73] Moreover, the immature phenotype of LCH cells appears dependent on the microenvironment, suggesting a reactive process. Therefore, although the clonality of LCH cells has fueled the argument that LCH may be a neoplastic disorder, the debate continues.

CLINICAL FEATURES

LCH can present along a continuum of illness, ranging from indolent to explosive disease. In some patients, pathologic lesions are solitary, whereas in others they are widely disseminated. Moreover, the distribution of lesions in a given patient may vary considerably over time. Although LCH can occur at any age, it occurs with greatest frequency in infants and children. The median age at diagnosis for all disease variants is 3 to 6 years.[18,19] The acute disseminated form of the disease characteristically occurs in younger children and almost all cases occur before the age of 5 years.[25] Children younger than 1 year old, in particular, often present with multiple organ involvement.[22,74] The more indolent forms of LCH occur primarily in older children and young adults.[75] Approximately 70% of cases of LCH in children involve a single organ system, with bone being the most common site.[18,19,22,25] Table 60.1 shows the distribution of involved sites

TABLE 60.1

SYSTEMS AFFECTED ON DIAGNOSIS OF LANGERHANS CELL HISTIOCYTOSIS BY AGE

by age at diagnosis of LCH. The most commonly involved organ in adults is bone, often accompanied by an adjacent soft tissue mass.[76,77] Other organs that are involved less often in adults include the lungs and pituitary gland.[76] In adults, multisystem disease, including liver, lymph node, and bone marrow involvement, is extremely rare.

The traditional classification of clinical variants was based on patterns of organ involvement.[8] Eosinophilic granuloma was used to describe a syndrome characterized by single or multiple bone lesions in the absence of visceral involvement.[13] When granulomas involved the liver, spleen, lymph nodes, skin, central nervous system (CNS), or bone marrow as well as bones, the disorder was called *Letterer-Siwe disease*.[11,12] The triad of multiple bone lesions, exophthalmos (resulting from retro-orbital granulomas), and diabetes insipidus (DI; the result of hypothalamic or pituitary involvement) constituted Hand-Schuller-Christian disease (Figs. 60.3 and 60.4).[9] The separation of eosinophilic granuloma of bone from syndromes characterized by visceral dissemination proved to be useful prognostically. However, the distinction between Letterer-Siwe disease and Hand-Schuller-Christian disease was often subtle and clinically irrelevant. The current classification is based on the number of organ systems involved and the number of sites involved within an organ system.[23,78] The main classifications of disease are unifocal eosinophilic granuloma (i.e., single-system, single-site disease, usually in bone), multifocal eosinophilic granuloma (i.e., single-system, multiple-site disease, usually in bone), and acute disseminated histiocytosis (i.e., multisystem disease). The presence and degree of organ dysfunction are important distinctions in those with multisystem disease.[78]

Bone is the most commonly involved organ, with the skull being the most commonly involved site in both children and adults.[79,80] Unifocal eosinophilic granuloma of bone is the most common form of the disease.[10,81] Multifocal bone involvement may or may not be associated with visceral disease. Characteristically, patients note mild discomfort at the site of bone involvement. However, skull lesions are often painless and are found only because of a soft tissue mass over the bony defect. In young children, multifocal lesions of the skull are often associated with other head and neck manifestations. Gingival swelling and inflammation, usually associated with cervical adenopathy, may be the first manifestations of disease. Premature eruption or loss of teeth and breakdown of the lower alveolar ridge result from involvement of the mandible.[82] Mandibular lesions may be palpable and painful, giving rise to facial swelling.[83] The maxilla and upper gingival ridge are involved less often. Involvement of the Petrous ridge of the temporal bone and mastoid is common, predisposing to chronic otitis media. Vertebral lesions pose special problems because of the risk of injury to the spinal cord. Vertebral collapse gives rise to vertebral plana (Fig. 60.5). Extension of granulomas into the spinal space may compress the cord, causing permanent neurologic damage. Recurrent bony lesions in children, particularly those involving the craniofacial region, are often associated with DI.[84,85]

Radiographically, skeletal lesions are characterized by sharply demarcated rarefactions of the medullary portions of bone, producing a "punched out" appearance (Fig. 60.6).[79,81] Reactive sclerosis in surrounding uninvolved bone is unusual at diagnosis, but when present, signifies that healing has begun. As healing occurs, the sharp endosteal margins become less distinct, and sclerosis is often seen. Both tables of the skull characteristically are involved, the outer more so than the inner. Erosion of mandibular bone around unerupted teeth gives them the appearance of floating in space. Skeletal lesions are well delineated with conventional radiography, computed tomography, and magnetic resonance imaging.[86] The relative benefit of radionuclide bone scintigraphy, on the other hand, is controversial.[87–89] Radionuclide bone scans often are falsely negative for skull lesions, but may be more sensitive in identifying lesions in the ribs, spine, and pelvis.[90,91]

FIGURE 60.5. Sagittal magnetic resonance image of the thoracic spine showing collapse of the T8 vertebral body, more prominent in the anterior aspect, in a patient with reactivation of Langerhans cell histiocytosis.

Positron emission tomography (PET) may have greater specificity in identifying active osseous lesions, but its clinical utility in LCH requires further study.[92,93]

Skin involvement occurs in about one third of patients overall.[22,25] Although skin manifestations are seen in only 10% of patients with single-system disease, it is a much more common feature of acute disseminated histiocytosis.[81,94] Even in those with skin-only disease, the rate of progression to multisystem disease is 30% to 40%.[95] The skin lesions are typically vesiculopustular and may have a hemorrhagic crust. They are similar in appearance to those of seborrheic dermatitis. LCH is often suspected after a seborrheic rash fails to respond to treatment. The rash has a predilection for the scalp, postauricular areas, and diaper area (Fig. 60.7). The back, axillae, and intertriginous areas also may be involved.[94] With advanced stages of the disease, the entire integument may be affected. Breakdown of severely affected areas is common, and concurrent thrombocytopenia imparts a hemorrhagic component to the rash.

A rash indistinguishable from that seen in acute disseminated histiocytosis may occur as a congenital, self-limited phenomenon not associated with skeletal or visceral disease. This form of histiocytosis has been called *congenital self-healing histiocytosis* or *Hashimoto-Pritzker syndrome*.[5,96] The lesions are present at birth or appear within the first 2 or 3 weeks of life. They are most numerous over the scalp and face, but also may extend over the trunk and proximal extremities. Mucous membranes are spared. Langerhans cells present in biopsy material have the same immunophenotypic characteristics as those in the other variants of histiocytosis, although they contain fewer Birbeck granules.[96] The lesions typically undergo spontaneous regression, with complete healing by the time the patient is 3 to 4 months of age. The prognosis is generally excellent without therapy, although occasionally isolated cutaneous LCH in infants can progress to multisystem disease.[97]

Increasingly appreciated as a problem in LCH, CNS involvement[98,99] occurs by contiguous spread of skull lesions into brain substance or by granulomatous infiltration of deep structures. The disease demonstrates a predilection for the hypothalamic nuclei[100] and cerebellum,[101,102] although focal lesions may occur in the temporal lobe, occipital lobe, and spinal cord. Rarely, CNS

FIGURE 60.6. Skull radiograph showing active osteolytic lesions in a patient with disseminated Langerhans cell histiocytosis. Note absence of reactive sclerosis.

FIGURE 60.7. Erythematous maculopapular rash in a boy with disseminated Langerhans cell histiocytosis. (From Esterly NB, Maurer HS, Gonzalez-Crussi F. Histiocytosis X: A seven year experience at a children's hospital. J Am Acad Dermatol 1985;13:481–496, with permission.)

lesions are found in patients who have no other evidence of histiocytosis. Neurologic signs and symptoms include ataxia, nystagmus, dysmetria, seizures, dysphagia, cranial nerve deficits, and spastic paraparesis.[103] DI resulting from infiltration of the hypothalamus or pituitary stalk is common.[104] Whereas mass lesions are satisfactorily visualized by computed tomography or magnetic resonance imaging, infiltrative lesions within the hypothalamus and elsewhere often are of similar density to adjacent brain tissue and produce little or no mass effect. Some of these lesions may be seen with magnetic resonance imaging.[98] CNS involvement may leave survivors with permanent sequelae.[98,84]

Of the endocrinopathies associated with LCH, DI is the most common.[105] LCH is a common cause of DI in both adults and children.[106] DI is caused by infiltration of the hypothalamus, pituitary stalk, or posterior pituitary by Langerhans cells. The prevalence of DI in large series of patients ranges from 10% to 50%.[84,85,105,106,107,108,109] In a study of 1,741 children with LCH, the cumulative risk of DI was 20% at 15 years from diagnosis.[85] DI is more common in patients with multisystem disease and in those with proptosis.[109] Patients with multiple craniofacial bone lesions are also at increased risk.[85] DI is not typically a complication of unifocal bone disease not involving the skull. Characteristically, the onset of DI is after the diagnosis of LCH is made. Symptoms of DI occur at or preceding the diagnosis of LCH in only about one third of patients.[84] However, LCH should be considered in the differential diagnosis in patients who present with central DI.[106] In such cases a thickened pituitary stalk seen on MRI may be the only radiographic manifestation (Fig. 60.4).[110] For most children, symptoms occur within 2 years of diagnosis and rarely, if ever, after 4 to 5 years.[109,111] Although most affected patients have complete absence of antidiuretic hormone, partial deficiency may occur. Progression from partial to complete DI may occur, and once complete DI has developed, it cannot be reversed. Whether systemic chemotherapy for LCH may prevent the development of DI is unclear. However, more rapid response to therapy and shorter disease duration corresponds to a decreased incidence of DI.[85] Reactivation of disease after complete resolution is associated with an increased risk of DI.[85]

Neurodegenerative disease is the next most common CNS consequence of LCH after DI.[112] The typical MRI findings are diffuse, symmetrical signal changes of variable intensity in the basal ganglia or cerebellum (Fig. 60.8).[113,114] Patients with LCH-associated neurodegenerative disease demonstrate variable manifestations of disease. Some patients have no neurologic signs or symptoms, whereas others may have significant neurologic effects. Clinical signs may include tremor, ataxia, spasticity, dysarthria, and behavioral or psychiatric problems. The time course of disease progression is also variable, but neurologic deterioration may be severe and devastating. Histologic evaluation of neurodegenerative lesions show a T-cell mediated inflammatory process with tissue degeneration, and most importantly, absence of CD1a-positive cells.[115]

Growth retardation resulting from growth hormone (GH) deficiency is another complication of LCH.[105,108] GH deficiency occurs in approximately 10% of patients with LCH overall and up to 60% of patients with LCH-associated DI.[84,116] Loss of GH, along with deficiency of other anterior pituitary hormones, is usually due to involvement of the hypothalamus or anterior pituitary by Langerhans cells.[116] GH replacement has been shown to be safe and effective in children with LCH and GH deficiency.[117]

Thyroid involvement by histiocytosis gives rise to goiter and may lead to hypothyroidism.[108] Obstruction of the upper airway by diffuse enlargement of the thyroid gland has been described.[118] Most children with thyroid involvement have DI and other evidence of disseminated disease.[105]

Enlargement of the liver, often associated with abnormal liver function, is observed in many children with the disseminated form of LCH.[119–121] In some patients, liver involvement leads to portal cirrhosis or intrahepatic cholestasis.[121] Tissue from liver biopsies obtained from children with hepatomegaly infrequently shows the infiltrates of Langerhans cells, eosinophils, and lymphocytes that are hallmarks of the disease in other organs. Instead, subtle changes in the portal triads are observed, including triaditis, bile duct proliferation, and fibrosis.[122] Patients with triaditis alone at diagnosis are less likely to have abnormal liver function or progressive liver disease than those with fibrohistiocytic or cirrhotic changes. Persistent abnormality of liver function is a well-recognized adverse prognostic indicator.[123]

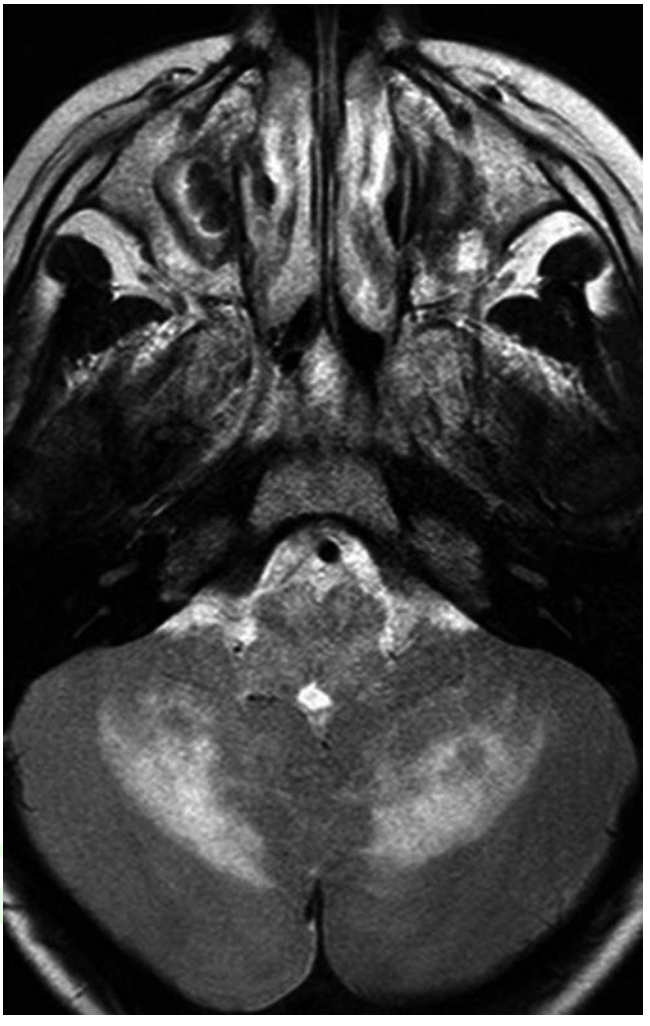

FIGURE 60.8. Axial magnetic resonance imaging scan showing diffuse bilateral signal abnormality in the cerebellum in a patient with neurodegenerative Langerhans cell histiocytosis.

Involvement of lymph nodes and spleen is often a feature of disseminated disease.[23] Lymph nodes may be involved because of contiguous bone or skin disease or as a result of widespread histiocytic dissemination. Splenomegaly is caused by portal hypertension or involvement of the spleen by large numbers of histiocytes. Curiously, Birbeck granules are rarely seen in otherwise characteristic Langerhans cells in the spleen and liver.[41,42]

Although not common, the lungs may be involved with disseminated histiocytosis.[124] As with other forms of disseminated disease, lung involvement occurs primarily in infants and young children. In contrast, primary pulmonary histiocytosis is principally a disease of young and middle-aged adults,[125–127,128,129] although it does occur in children.[130,131] Smoking is often associated with pulmonary LCH.[132,133] Affected patients are without

apparent multisystem disease at diagnosis; with further evaluation, however, some patients have asymptomatic bone lesions,[130] and as many as 10% subsequently develop DI.[134] Signs and symptoms of pulmonary involvement may be subtle or may include growth failure or weight loss, dyspnea, tachypnea, and hemoptysis. Recurrent pneumothoraces occur in as many as 20 to 25% of cases.[135] Lung involvement is characterized radiographically by diffuse micronodular densities with cyst formation, sometimes giving rise to a picture of "honeycomb lung." Lesions are usually prominent in the perihilar regions and the upper lung fields. Costophrenic angles are usually spared, and enlargement of hilar nodes is unusual. Permanent pulmonary sequelae often occur,[136] and reactivation in the lungs may be associated with smoking.[133]

Bone marrow involvement by Langerhans cells has been described most often in infants with disseminated disease.[23,24,137] It is characterized by anemia, neutropenia, and thrombocytopenia, occurring singly or together. Erythrophagocytosis may rarely be a factor in the pathogenesis of anemia.[138] Because bone marrow and splenic involvement often occur together, splenic sequestration of blood cells may further exaggerate the cytopenias of bone marrow involvement.

DIAGNOSIS

The clinical and radiographic features of LCH are distinctive enough to suggest the diagnosis in most patients. However, the diagnosis must be made pathologically, and for a definitive diagnosis, the presence of Birbeck granules or the presence of Langerin and /or CD1a on the surface of LCH cells must be demonstrated.[139]

Assessment of the extent of disease is critical. To help standardize the workup and management of LCH patients, the Histiocyte Society has published guidelines on how to evaluate and follow patients.[140] A thorough physical examination is necessary to evaluate for hepatomegaly or splenomegaly, lymphadenopathy, and any bone or soft tissue masses. Bony lesions may be diagnosed by either bone scan or skeletal survey. Each modality has been shown to discover lesions missed by the other. However, radionucleotide bone scan may miss osteolytic lesions that do not have any osteoblastic characteristics. This is particularly true for skull lesions.[90,91] Other studies required include a chest radiograph, complete blood count, assessment of liver function, and determination of renal concentrating ability. A bone marrow examination is required if cytopenias exist, and a high-resolution chest CT scan may be necessary if signs and symptoms suggest pulmonary involvement.[131] Although not required to evaluate disease, some authors have recommended studies of T- and B-cell numbers, T-cell subsets, and lymphocyte function. New imaging modalities, including PET and octreotide scans, may be useful in LCH, but they require additional study.[93,141,142]

Several staging or scoring systems have been proposed as having prognostic and therapeutic relevance. Most cite age (age younger than 2 years being a liability), extent of disease, and the function of involved organs as the important prognostic variables.[23,24,143] An important distinction made by the Histiocyte Society and proven to be highly prognostic is whether "risk" organs are involved. "Risk" organs are the hematopoietic system defined as at least two cytopenias (with or without documented bone marrow involvement), spleen, liver, and lungs. The presence of "CNS-risk lesions" results in a higher risk of developing DI. CNS-risk lesions are those involving the craniofacial bones, particularly those around the eyes, ears, and oral cavity.[85] The Histiocyte Society also recognizes "Special Sites" as being bone lesions that are located in critical anatomic sites in which lesions may cause immediate morbidity. Examples include the odontoid peg and vertebral lesions with intraspinal soft tissue extension. Stratification for treatment is defined based on these parameters. Patients are divided into those with single-system LCH or multisystem disease. Patients with multisystem disease with or without risk organ involvement and those with single-system disease and either CNS-risk, multifocal bone lesion, or special site lesions are candidates for systemic therapy.

PROGNOSIS

For most patients with LCH, the prognosis is excellent. Although LCH may wax and wane over many years, most patients improve over time. However, patients with multisystem disease may experience organ failure, which can be fatal. Outcome by single bone, multiple bone, and multiple organ involvement are shown in Table 60.2.

Most patients with unifocal bone disease experience complete resolution of lesions with or without treatment. Progression of bone erosion and recurrences at new sites are the exception rather than the rule.[144] In a study of 48 patients with single bone involvement, the recurrence rate was 8% and no deaths were reported.[74] In contrast, disease that is multifocal at the time of diagnosis is often characterized by one or more recurrences after disease control.[74,80] Patients with multiple bone lesions, particularly those with skull involvement, have a much higher incidence of disease reactivation than those with single bone lesions.[74] In addition, most patients with multiple organ involvement will experience disease recurrence. In one large series, 72% of patients with multisystem disease who initially responded to treatment experienced recurrent LCH from 2 months to more than 5 years after cessation of therapy, and most recurrences were in previously uninvolved sites.[75] Young children, especially those younger than 2 years of age at diagnosis, are at particular risk for multiple relapses. However, in most patients the disease appears to eventually burn out.[145,146]

From Jubran RF, Marachelian A, Dorey F, et al. Predictors of outcome in children with Langerhans cell histiocytosis. Pediatr Blood Cancer 2005;45:37–42, with permission.

Despite the favorable prognosis for most patients, mortality from disease progression can occur. Approximately one third of adults with pulmonary LCH die from the disease.[128] The highest incidence of mortality, however, is seen in children with involvement of the liver, lungs, hematopoietic system, or spleen at diagnosis ("risk" organs as defined by the Histiocyte Society).[140] A 5-year survival rate of only 25% has been reported in children with liver or spleen involvement at diagnosis.[75] In a series of 18 patients with "risk" organ involvement, 7 died after either disease progression or recurrence.[74] In contrast, in two separate studies, all patients 2 years of age or older without "risk" organ involvement survived.[78,146] After disease resolution, LCH survivors may be left with permanent complications, including DI, pulmonary difficulties, neurologic complications, orthopedic abnormalities, neuropsychological impairment, dental problems, chronic otitis, or hearing impairment.[72,84,145] Patients with one or more reactivations after initial therapy are more likely to have long-term sequelae from LCH.[147]

MANAGEMENT AND TREATMENT

Management is dictated by the likely natural history of the disease based on the location and extent of lesions and by the presence of specific organ involvement and/or dysfunction. Given that LCH tends to improve with time, most patients do not require treatment aimed at ablating the disease. In most patients, disease manifestations are reversed with therapy that is far less intensive than that used for neoplastic disease. As noted previously, multiple courses of treatment may be required for recurrences. DI is not ameliorated by chemotherapy. Although some authors describe reversal of DI with radiotherapy directed to the hypothalamus–pituitary region soon after the onset of symptoms,[148] the consensus is that radiotherapy, like chemotherapy, is without benefit in this situation.[108,149]

Treatment decisions should be based on the number of systems involved and on whether a particular lesion is likely to result in disability. Children with single-system disease, particularly if they have a solitary lesion of bone (e.g., eosinophilic granuloma of bone), may require no therapy other than curettage.[144] However, some patients have aggressive disease, warranting treatment with multiagent chemotherapy.[123] In addition, multiple courses of treatment may be required for recurrences. However, in contrast to neoplastic disease, patients with LCH recurrence can often be successfully re-treated with a previously received regimen. Sometimes, recurrence can be ameliorated with less intensive therapy than originally received. Rarely are aggressive approaches, such as bone marrow or liver transplantation, justified.

Because unifocal bone disease is associated with a uniformly excellent prognosis, therapy with potential late effects should be avoided. The surgical procedure required for diagnostic purposes often is definitively therapeutic as well. Lesions other than those for which curettage is performed for diagnostic purposes often heal spontaneously.[150] Lesions that progress or recur; those that threaten an important function, such as sight or hearing; and those that pose a risk of pathologic fracture or future disability may be treated effectively with low-dose radiotherapy. Doses of 600 to 1,000 cGy in three to five fractions effect local control in most patients.[148,149,151] Lesions in weight-bearing sites, such as the neck of the femur, may require curettage and autologous bone grafting. Direct steroid injection into the lesion has been used[152]; however, the benefit of this treatment has never been proven in a randomized fashion. Isolated histiocytosis of the skin in infants usually regresses spontaneously and does not require systemic therapy.[5,96,153] Skin lesions in older children or adults may respond at least temporarily to radiation with ultraviolet light.[154]

Systemic therapy is required for multisystem disease and for single-system disease in which multiple bones or CNS-risk bones are involved. Approximately 50% of patients requiring systemic therapy respond to corticosteroids alone.[155] Because of the toxicity of corticosteroids when used for more than brief periods, however, other chemotherapeutic agents are now the mainstay of management. Vinblastine, vincristine, 6-mercaptopurine, methotrexate, alkylating agents, anthracyclines, and etoposide, singly or in combinations, are effective in controlling LCH.[143] Patients with liver, lung, or bone marrow dysfunction as well as those at high risk for adverse CNS outcome are best treated with combination chemotherapy. In a clinical trial in which patients were stratified by risk, treatment included induction chemotherapy with vinblastine, etoposide, and prednisone followed by maintenance chemotherapy with etoposide, vinblastine, prednisone, 6-mercaptopurine, and methotrexate.[123] Two thirds of those patients with organ dysfunction achieved a complete remission, as did approximately 90% of those with either multisite bony disease or soft tissue disease without organ dysfunction.

The Histiocyte Society has conducted multinational randomized clinical trials in LCH.[78,156] In the first international trial (LCH I),[78] 143 patients were randomized to receive 24 weeks of vinblastine (6 mg/m^2 intravenously weekly) or etoposide (150 mg/m^2/day intravenously for 3 days, every 3 weeks); all patients received a single dose of steroids. Both of those monotherapies were equivalent. Due to the risk of secondary leukemias with etoposide, subsequent studies have been built from the vinblastine arm. One robust finding in this study was that the response at 6 weeks was strongly prognostic, regardless of initial treatment. However, LCH I did not produce superior results compared to studies from the German/Austrian Group, DAK-HX 83 and DAL-HX 90.[157] Overall survival was similar, but a lower reactivation rate, longer reaction free interval, and fewer permanent disabilities were seen in the DAL studies compared to LCH I.

The Histiocyte Society's LCH II trial demonstrated that intensified treatment increased early response in patients younger than 2 years with multisystem disease and risk organ involvement.[156] The study showed that the addition of etoposide to a regimen of vinblastine, prednisone, and daily 6-mercaptopurine reduced the risk of mortality for these patients. The most recent LCH III trial evaluated the effect of adding methotrexate to the combination of vinblastine and prednisone for patients with "risk" organ involvement. Although data from that trial are pending, the current recommendation is that patients with multisystem disease should receive a 6-week course of therapy with weekly vinblastine and daily prednisone, followed by 12 months of maintenance therapy with vinblastine and prednisone pulses every 3 weeks with daily oral 6-mercaptopurine. Treatment should be similar for patients with multifocal bone and CNS-risk lesions, except that there is no proven benefit to 6-mercaptopurine.

Newer agents that have been evaluated for LCH that are refractory to standard therapy include cladribine (2-chlorodexoyadenosine). The early promise of cladribine reported in several small studies prompted further evaluation by the Histiocyte Society.[158,159,161] In a Phase 2 study, cladribine showed benefit to patients with reactivation of disease in nonrisk organs.[162] However, cladribine proved no more beneficial than standard therapy for patients with multisystem disease and risk organ involvement. The combination of cladribine with other agents such as cytarabine or etoposide may be more effective, but carries the risk of more pronounced bone marrow suppression and hematologic toxicity.[163] Other agents that have shown promise in small series include clofarabine, bisphosphonates, and etanercept.[164,165,166,167] Etanercept inhibits TNF-α, which is highly expressed in Langerhans cells, lymphocytes, and macrophages of LCH lesions and promotes proliferation of Langerhans cells.[168,169]

Several patients with recurrent progressive LCH refractory to conventional therapy have benefited from allogeneic hematopoietic

stem cell transplantation (HSCT).[170,171,172,173,174,175,176] However, toxicity from HSCT in these patients has been an issue with high rates of transplant-related mortality. A few patients have undergone HSCT with reduced-intensity conditioning with less transplant-related morbidity and mortality.[177] The most effective conditioning regimens and appropriate timing of HSCT are yet to be determined.

CHAPTER 61

PATHOLOGY OF LANGERHANS CELL HISTIOCYTOSIS AND OTHER HISTIOCYTIC PROLIFERATIONS

Karen L. Chang, Lawrence M. Weiss

Langerhans cell histiocytosis and other dendritic and histiocytic neoplasms and related proliferations are uncommon diseases.[1] Dendritic cells, also known as classical dendritic cells, arise from the myeloid-derived common dendritic cell precursor and are divided by function and structure to include Langerhans cells, interdigitating dendritic cells, and follicular dendritic cells. Langerhans cells and interdigitating dendritic cells both show strong expression of S-100 protein and HLA-DR, with Langerhans cells positive for CD1a and langerin, and interdigitating dendritic cells negative for CD1a and langerin. Normal Langerhans cells reside primarily in the skin and migrate via lymphatics (as veiled cells) to the lymph nodes as they differentiate into interdigitating dendritic cells, which reside in the paracortical region of the lymph nodes. Langerhans cells are efficient antigen-processing presentation machines, whereas interdigitating dendritic cells interact closely with T-cells, leading to the initiation of strong cellular immunity. Follicular dendritic cells express CD21, CD35, and/or CD23, and not CD1a, langerin or S-100 protein. They are fixed cells that reside in lymphoid follicles, interacting with follicular B cells in the formation and organization of the follicles. In addition, they trap and store antigen–antibody complexes and they are important in memory cell formation and affinity maturation of follicular B-cells. Plasmacytoid dendritic cells also arise from the common dendritic cell precursor and are the main source of α-interferon upon viral infection or CD154 stimulation. Plasmacytoid dendritic cells also play an important role in immune tolerance through immune regulation and/or depletion via the uptake of self-peptides captured by the uptake of apoptotic classic dendritic cells. They express CD123 and not S100, CD1a, or langerin. A subset of plasmacytoid dendritic cells has immunoglobulin rearrangements.

Histiocytes are noncirculating cells derived from a bone marrow stem cell known as monocyte/macrophage and dendritic cell precursor, which is the same stem cell that gives rise to the common dendritic cell precursor. Histiocytes are the tissue-based equivalent of monocytes and are normally resident in a variety of organs, including the spleen, lymph nodes, and bone marrow; liver (Kupffer cells); lung (alveolar macrophages); lamina propriety of the gut; and brain (microglia). They express CD163 and CD68 (an antigenic marker of lysosomes). They play an important role in resistance to intracellular microorganisms and tumors through nonimmunologic mechanisms and in the recognition and clearance of apoptotic cells.

Each of these major dendritic and histiocytic cells has corresponding tumors, as summarized in Table 61.1 and discussed in further detail below.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis is a neoplastic proliferation of Langerhans cells, albeit at perhaps a more immature state of maturation.[2] Langerhans cells are dendritic cells that are normally resident in the basal layer of the epidermis and are characterized by immunohistochemical expression of CD1a, S-100 protein, and langerin and the presence of Birbeck granules by ultrastructural examination. Three major syndromes of involvement are recognized.[3–5] In the most common type, unifocal disease (formerly solitary eosinophilic granuloma), involvement of a single site, usually bone, is seen. This syndrome is seen primarily in adolescents and young adults. In multifocal unisystem disease (formerly many cases of Hand-Schuller-Christian disease), there is involvement of several sites within one organ system, almost always bone. This syndrome is seen primarily in children. In the least common multifocal multisystem disease (formerly many cases of Letterer-Siwe disease), multiple organs are involved, usually including the bones, skin, liver and spleen, and lymph nodes, often in a lymphoma-like distribution. These latter cases are usually seen in infants.

Langerhans cell histiocytosis represents a monoclonal proliferation, as revealed by molecular studies of the X-linked androgen receptor gene.[6] There is no association with known viruses.[7] Cytogenetic and other studies have shown abnormalities involving chromosomes 1p and 7.[8] Recurrent mutations of the oncogene BRAF have been found in a large number of LCH cases, including the allegedly polyclonal pulmonary variant of LCH.[9] Some investigators have theorized that immune dysfunction plays a role in the pathogenesis, although direct evidence is lacking. Neoplastic Langerhans cells may aberrantly express chemokines of immature dendritic cells, and abnormal reactions between Langerhans cells and macrophages may contribute to production of a cytokine "storm."[10,11]

Biopsy is essential to the diagnosis of Langerhans cell histiocytosis. The key to the diagnosis is the identification of neoplastic Langerhans cells. Langerhans cells are dendritic cells with characteristic grooved, folded, or indented nuclei, inconspicuous nucleoli, a relative bland chromatin pattern, and thin nuclear membranes[12] (Fig. 61.1). The degree of nuclear atypia or the mitotic rate in general does not correlate with outcome, with the exception that cases with frankly sarcomatous features probably represent rare cases of Langerhans cell sarcoma (see the section "Langerhans Cell Sarcoma"). The cytoplasm is usually moderately abundant and pale to intensely eosinophilic. Langerhans cells may be the only cell type, particularly as seen in cases of multifocal, multisystem disease, but most often they are found admixed in a characteristic cellular milieu that usually includes variable

TABLE 61.1

MAJOR DENDRITIC AND HISTIOCYTIC CELLS AND THEIR TUMORS

Cell	Tumor	Major Phenotype
Langerhans cell	Langerhans cell histiocytosis/sarcoma	CD1a$^+$, S-100 protein$^+$, Langerin$^+$
Follicular dendritic cell	Follicular dendritic cell sarcoma	CD21$^+$, CD35$^+$, CD23$^+$
Interdigitating dendritic cell	Interdigitating dendritic cell sarcoma	S-100 protein$^+$, CD1a$^-$

numbers of eosinophils, histiocytes, and neutrophils. Occasionally, eosinophilic microabscesses are seen. More mature lesions have greater numbers of histiocytes, which may be nonstimulated, epithelioid, or multinucleated and simulating osteoclasts. Late lesions tend to have variable numbers of foamy macrophages and plasma cells and are often associated with a significant degree of fibrosis. Ultrastructurally, neoplastic Langerhans cells have Birbeck granules, numerous lysosomes, small vesicles, and multivesicular bodies, and irregular cell membranes with an absence of cell junctions. Birbeck granules are specific to Langerhans cells and are usually "tennis racket"-shaped intracytoplasmic membranous bodies, with an osmiophilic core and a double outer sheath. The langerin antibody is an endocytic receptor associated with the formation of Birbeck granules and thus is highly specific and sensitive and has in large part supplanted the need for electron microscopy studies.[13]

Neoplastic Langerhans cells tend to have a similar (but not identical) phenotype as normal Langerhans cells, and are usually identified by expression of CD1a, langerin, and S-100 protein[14] (Fig. 61.2). In addition, Langerhans cell histiocytosis expresses vimentin, HLA-DR, placental alkaline phosphatase (in contrast to normal Langerhans cells), and peanut agglutinin lectin. The tumor has been reported to be variably positive for CD45, CD68, CD163, CD4, and lysozyme; however, expression of these antigens probably represents positivity of the intimately admixed histiocytes. The Ki-67 index is usually low (<25%). Neoplastic and normal Langerhans cells are consistently negative for B- and T-lineage markers, CD30, CD34, and follicular dendritic cell markers CD21 and CD35. By enzyme histochemistry, normal and neoplastic Langerhans cells are positive for adenosine triphosphatase, α-D-mannosidase, α-naphthyl acetate esterase, α-naphthyl butyrate esterase, and acid phosphatase.[15] There is no evidence of antigen-receptor gene rearrangements.

The differential diagnosis includes reactive proliferations of Langerhans cells, including dermatopathic lymphadenitis, so-called pulmonary Langerhans cell histiocytosis, and Langerhans cell histiocytosis-like proliferations associated with malignancy lymphoma. In dermatopathic lymphadenitis, the reactive Langerhans cells occur in the paracortex, in contrast to the sinusoidal or patchy pattern of lymph node involvement by Langerhans cell histiocytosis, and the proliferating Langerhans cells are accompanied by melanin-containing histiocytes and numerous interdigitating dendritic cells. So-called pulmonary Langerhans cell histiocytosis and Langerhans cell histiocytosis-like proliferations associated with malignant lymphoma are morphologically indistinguishable from Langerhans cell histiocytosis. Langerhans cell histiocytosis can be distinguished from most other histiocytic and dendritic disorders by their characteristic expression of CD1a, S-100 protein, and langerin.

LANGERHANS CELL SARCOMA

Langerhans cell sarcoma is an extremely rare neoplasm defined as a neoplastic proliferation of Langerhans cells that have overtly malignant cytologic features.[16–18] It usually presents de novo but may also represent progression from typical Langerhans cell histiocytosis. There is a wide age range affected, and there may be a female predominance. Typically, multifocal multisystem disease is present. An aggressive behavior is seen, with an overall survival of ~50%.

Histologically, a proliferation of cytologically malignant histiocyte-like cells is seen (Fig. 61.3). The presence of occasional nuclear features characteristic of Langerhans cells may suggest the diagnosis. The mitotic rate is high, and the characteristic cellular milieu of Langerhans cell histiocytosis is not usually seen. Given this histologic picture, the diagnosis is usually established with the identification of the CD1a (which may be focal; (Fig. 61.4) and S-100 protein, reactivities that are characteristic of Langerhans cells. The identification of Birbeck granules on ultrastructural examination is also helpful in confirming the diagnosis. None of the cases reported to date have included langerin study. The Ki-67 index is usually much higher than that seen in typical Langerhans cell histiocytosis.

FOLLICULAR DENDRITIC CELL SARCOMA

Follicular dendritic cell sarcoma is a neoplasm of cells differentiating toward follicular dendritic cells. Normal follicular dendritic cells are the antigen-processing cells of the germinal center. Follicular dendritic cell sarcoma is a very rare neoplasm, occurring in a wide age range and even gender distribution.[17,19–22] A subset of cases may occur in association with Castleman disease, and there may also be an association with schizophrenia.[17,22,23] Most cases are not associated with known viruses, although a subset of cases, particularly those arising in liver or spleen, may be associated with Epstein-Barr virus (EBV).[24–26] It most often presents in

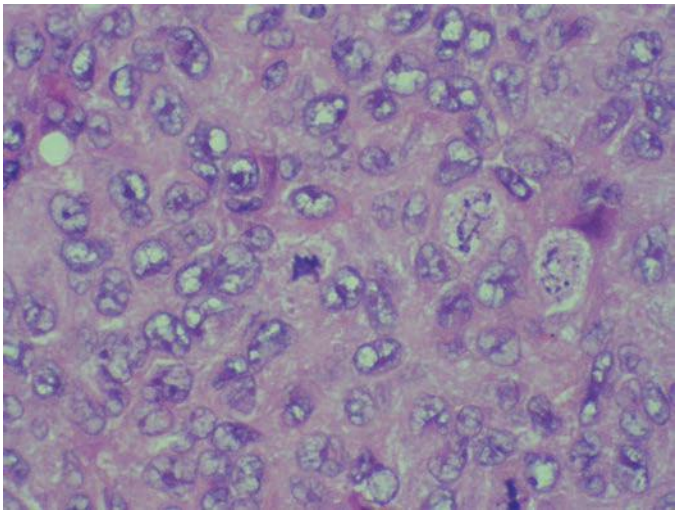

FIGURE 61.3. Langerhans cell sarcoma. Although some of the nuclei have features of Langerhans cells, the nuclear atypia is striking. Note the presence of several mitotic figures, including atypical forms.

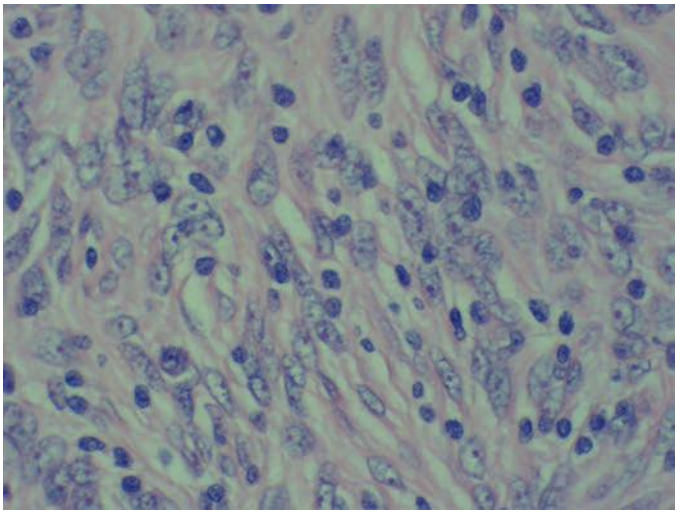

FIGURE 61.5. Follicular dendritic cell sarcoma. A bland spindle cell proliferation is seen, with scattered mature lymphocytes.

lymph nodes, but may also present in a variety of extranodal sites. Patients usually present with a slow-growing mass. Treatment usually consists of complete surgical excision, with or without adjuvant radiotherapy and/or chemotherapy. The tumor usually behaves in an indolent fashion, although local recurrence may occur in about one half of cases, and metastasis may occur in one fourth of cases.[27]

Histologically, one sees a spindle cell neoplasm, which may resemble a low-grade sarcoma (Fig. 61.5). The spindled cells may form fascicles and whorls, and there is characteristically an admixture of small mature lymphocytes, both amid the spindled cells or architecturally segregated into a second component, which may include secondary lymphoid follicles. The individual cells usually have bland spindled nuclei, although significant atypia may be seen in a minority of cases. The chromatin may vary from vesicular to granular and generally have small nucleoli. Occasional multinucleated cells may be seen. Ultrastructural studies show complex interdigitating cell processes with scattered mature desmosomes, typical of normal follicular dendritic cells, and an absence of Birbeck granules.

Immunohistochemical studies show the presence of phenotypic markers characteristic of normal follicular dendritic cells: expression of CD21, CD35, and/or CD23.[17] They are also usually positive for vimentin, desmoplakin, and HLA-DR, variably positive for S-100 protein and CD68, and negative for keratin, CD45, langerin, and specific markers of B- and T-cell differentiation (although CD20 may occasionally be aberrantly expressed). A germline configuration of the antigen-receptor genes is found.

The differential diagnosis includes other dendritic tumors as well as other sarcomas, carcinoma, and malignant melanoma. Other sarcomas and dendritic tumors lack CD21, CD35, and/or CD23, whereas carcinoma is keratin-positive and malignant melanoma expresses specific markers of melanocytic differentiation.

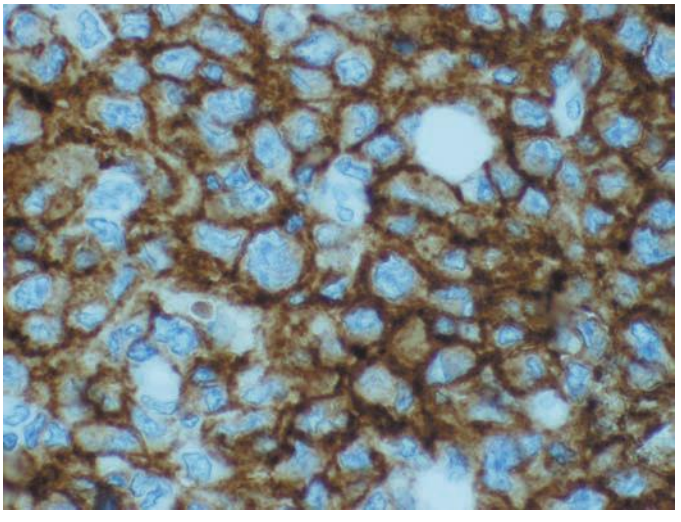

FIGURE 61.4. Langerhans cell sarcoma, CD1a (same case as Fig. 61.3). Membrane staining with CD1a is seen, characteristic of Langerhans cells.

INTERDIGITATING DENDRITIC CELL SARCOMA

Interdigitating cell sarcoma is a tumor differentiating toward normal interdigitating dendritic cells.[17,22,28,29] Normal interdigitating dendritic cells are major antigen-processing cells, usually located in the lymph node paracortical region. Interdigitating dendritic cell tumor is a very rare neoplasm usually occurring in adults, equally in men and women. Tumors may present either primarily in lymph nodes or at extranodal sites. Patients usually present with a solitary mass, although systemic symptoms may be present. The clinical course varies from benign to rapidly progressive lethal disease. Some cases may be associated with B-cell lymphoma; in such occurrences, both entities have been shown to be clonally related.[30,31]

Interdigitating dendritic cell sarcoma usually shows a paracortical pattern of distribution, with residual follicles (Fig. 61.6). It may be comprised of spindled cells and has a close resemblance to follicular dendritic cell sarcoma, although the cells may be more rounded and occasionally simulate a diffuse large-cell lymphoma. Nuclear atypia may vary widely, as does the mitotic rate. Immunohistochemical studies usually show strong expression of S-100 protein, in the absence of specific markers of follicular dendritic cells (CD21, CD35, and/or CD23), the Langerhans cell markers CD1a and langerin, or B- and T-cell markers. CD45, CD163, and CD68 may be variably positive. There is a germline configuration of the antigen-receptor genes. Ultrastructural studies show an absence of Birbeck granules or well-formed desmosomes, although complex interdigitating cell processes are seen.

Immunohistochemical studies are necessary to distinguish interdigitating dendritic cell sarcoma from follicular dendritic

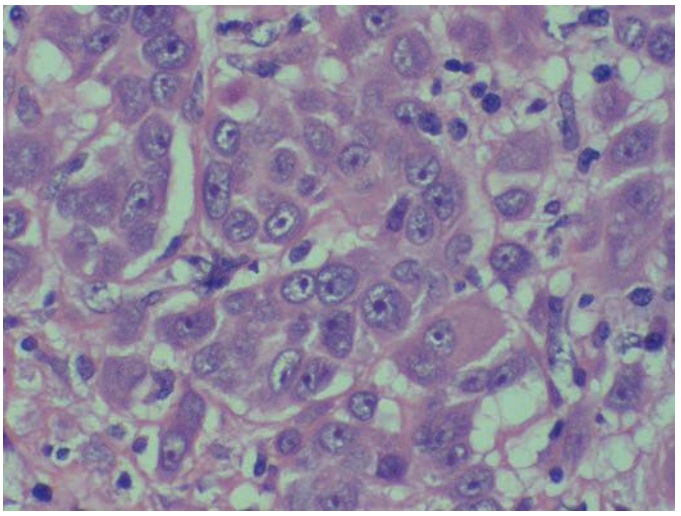

FIGURE 61.6. Interdigitating dendritic cell sarcoma. The cells are epithelioid. This case showed strong nuclear staining for S-100 protein, yet was negative for CD1a.

cell sarcoma (CD21-, CD35-, and/or CD23-positive), Langerhans cell histiocytosis (CD1a-positive and langerin-positive), malignant lymphoma (B-, T-, and/or CD30-positive), spindled carcinoma (keratin-positive), or malignant melanoma (which expresses HMB-45, MELAN-A, and/or melanoma-associated transcription factor).

OTHER RARE DENDRITIC CELL SARCOMAS

Other rare dendritic cell sarcomas described in the World Health Organization Classification of Hematopoietic and Lymphoid Tissues includes indeterminate cell tumor and fibroblastic reticular cell neoplasm. Indeterminate cell tumor is a CD1a-negative, S-100 protein-positive skin-based spindled cell tumor, which lacks Birbeck granules.[19,32,33] The tumor comprises bland spindled cells, some of which show irregular grooves and clefts (Fig. 61.7). Ultrastructural studies do not show Birbeck granules, suggesting a transitional neoplasm between Langerhans cell histiocytosis and interdigitating dendritic cell sarcoma. Obviously, such hard-to-classify cases are extraordinarily rare, and not yet well characterized. Fibroblastic reticular cell neoplasms are also extremely rare.[19,34] They generally occur in the lymph node paracortex and have a spindled to histiocytic appearance, and express vimentin, actin, and smooth muscle actin (in a heterogeneous pattern), and not S-100, CD1a, langerin, CD45, or markers of lymphoid or follicular dendritic cells.

BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM

Blastic plasmacytoid dendritic cell neoplasm (formerly, $CD4^+CD56^+$ hematodermic neoplasm or blastic NK-cell lymphoma) is a rare aggressive neoplasm that probably shows differentiation toward plasmacytoid dendritic cells (formerly known as plasmacytoid monocytes). Normal plasmacytoid dendritic cells are predendritic cells of the lymph node paracortex and are a major source of α-interferon in viral infection or CD154 stimulation.[35] The neoplasm consistently expresses CD123 (the interleukin-3 receptor), CD68, and CD4, and a subset of cells expresses CD56 (the neural cell adhesion molecule NCAM). There is no association with known viruses, including EBV.[36] Most patients with $CD4^+CD56^+$ hematodermic neoplasm are elderly and present with skin lesions.[37] Bone marrow, peripheral blood, and lymph nodes are commonly simultaneously involved. The disease is usually rapidly progressive, with the development of disseminated disease in most patients, although some cases localized to skin may have a good prognosis.

Histologically, one sees a diffuse monotonous infiltrate of medium-sized cells with fine, blastic-appearing chromatin, closely resembling a lymphoblastic neoplasm (Fig. 61.8). Immunohistochemical studies show a phenotype resembling normal plasmacytoid dendritic cells, with positivity for CD4, CD56, CD123, and CD68.[38] In addition, there is also consistent positivity for CD45, CD43, HLA-DR, CD62L, and CXCR3, and some cases show positivity for terminal deoxyribonucleotide transferase or CD34. Antigen-receptor genes are germline. The differential diagnosis includes lymphoblastic lymphoma and acute myeloid leukemia, both of which lack the characteristic CD4-, CD56-, CD123-positive phenotype of $CD4^+CD56^+$ hematodermic neoplasm.

HISTIOCYTIC SARCOMA

Histiocytic sarcoma is a neoplastic proliferation of cells showing histologic, immunohistochemical, and molecular features of histiocytes.[1,17] By definition, there is the presence of one or more

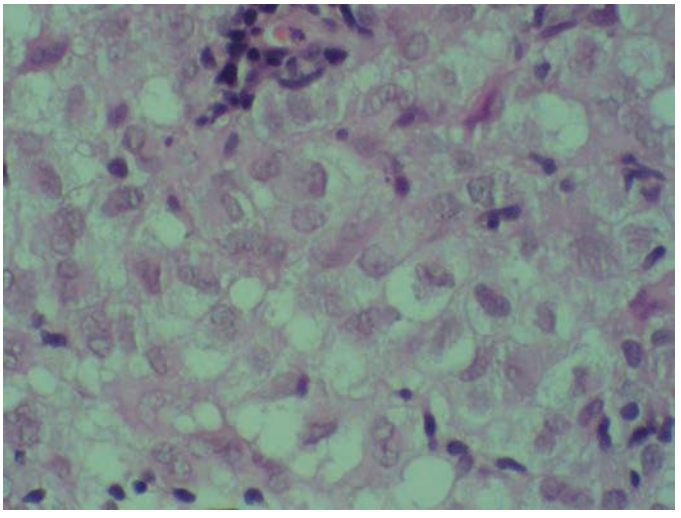

FIGURE 61.7. Indeterminate cell tumor. This cutaneous case showed positivity for CD1a and S-100 protein, yet Birbeck granules were not present on ultrastructural study.

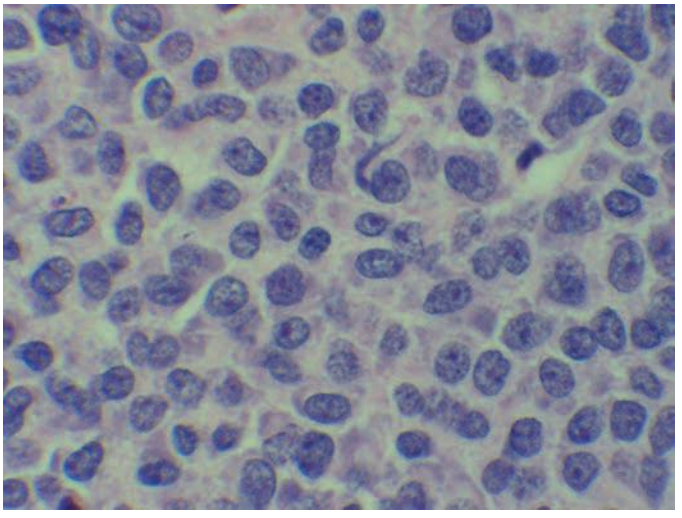

FIGURE 61.8. Blastic plasmacytoid dendritic cell neoplasm. Note the uniform proliferation of cells with a blastic chromatin pattern.

specific histiocytic markers and absence of specific B- and T-cell markers. The neoplasms are tissue-based, and neoplasms associated with monocytic leukemias are excluded.

Histiocytic sarcoma is a rare neoplasm, mostly commonly occurring in adults, although it has been reported in all ages.[17,39–42] A subset of cases may be associated with mediastinal germ cell tumor, usually malignant teratoma, with or without yolk sac tumor.[43] Lymph nodes and skin are most commonly involved, although virtually any site may be affected, including liver, spleen, bone, and intestinal tract. The bone may show lytic lesions or diffuse marrow involvement, with the latter occasionally causing pancytopenia. Some patients may show a "systemic" pattern of spread, recalling the old term, "malignant histiocytosis." Most patients present a high clinical stage. Histiocytic sarcoma is an aggressive neoplasm, generally with a poor response to therapy, with most patients dying of progressive disease.

Histologically, one usually sees a patternless diffuse infiltrate of large cells, with a close resemblance to diffuse large-cell lymphoma (Fig. 61.9). Occasionally, one sees a preferential or exclusively sinusoidal pattern of infiltration. The proliferating cells generally have irregularly shaped nuclei, sometimes eccentrically placed, often with multilobulation and occasionally with multinucleation. Nuclear atypia ranges from mild to severe. The chromatin pattern is usually vesicular, and nucleoli may vary from small to large. Cytoplasm is usually moderate to abundant and eosinophilic, and may show some spindling. There may be some cells with foamy cytoplasm. Cytophagocytosis, usually hemophagocytosis, may be present, but is not considered to be a defining feature.

Phenotyping studies are essential to distinguish histiocytic sarcoma from other malignancies. Histiocytic sarcoma shows expression of at least one specific histiocytic marker in the absence of specific B- and T-cell markers. Positive markers of histiocytic differentiation may include CD163, CD68, CD4, CD11c, CD14, and lysozyme (Fig. 61.10). Additional, albeit nonspecific, antigens expressed by the neoplastic cells of histiocytic sarcoma may include CD45 and HLA-DR. The myeloid markers CD34 and myeloperoxidase are negative, although CD33 is usually positive.[44] There may also be expression of S-100 protein, but CD1a, CD21, CD35, and langerin are negative. Antigen-receptor gene rearrangement studies show a germ line configuration, with the exception of those with an association with B cell lymphoma, and there is no association with known viruses.

The most important differential diagnostic consideration is with malignant lymphoma. Histiocytic sarcoma is ~0.1% as frequent as malignant lymphoma, which can be identified by the presence of specific B- and T-cell markers and/or CD30. The malignancy most frequently confused with histiocytic sarcoma is anaplastic large-cell lymphoma, which often has a focal or preferential sinusoidal pattern of involvement and may be comprised of highly pleomorphic cells. In fact, most cases previously diagnosed as malignancy histiocytosis on histologic grounds alone probably represent anaplastic large-cell lymphoma, which may be distinguished from histiocytic sarcoma by the former's constant expression of CD30, with or without ALK staining.[45] Rarely, carcinomas and malignant melanoma may be confused with histiocytic sarcoma. Use of keratin and specific markers of melanocytic differentiation other than S-100 protein (such as HMB-45, melanocytic-associated transcription factor, and Melan-A) should identify these cases.

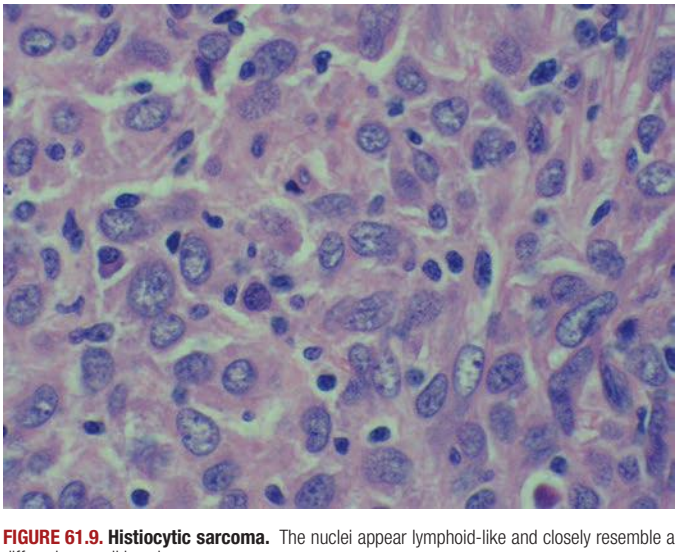

FIGURE 61.9. Histiocytic sarcoma. The nuclei appear lymphoid-like and closely resemble a diffuse large cell lymphoma.

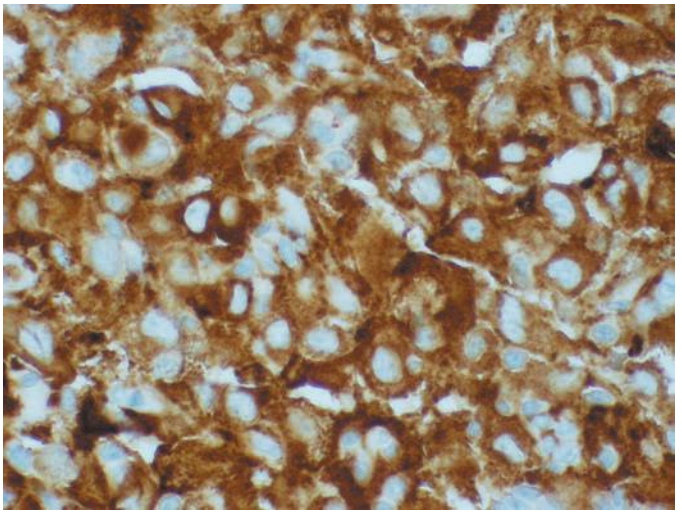

FIGURE 61.10. Histiocytic sarcoma (same case as Fig. 61.9). CD163: strong positivity for CD163 is seen, consistent with a histiocytic lineage.

DISSEMINATED JUVENILE XANTHOGRANULOMA

Juvenile xanthogranulomata are protuberant cutaneous nodules that usually present in the head and neck of children.[46–48] The lesions may measure up to 1 cm in diameter and may occasionally occur in the soft tissues or internal organs. An aggressive systemic form, known as disseminated juvenile xanthogranuloma, accounts for <5% of cases. This variant also most commonly affects children, although rarely adults are affected (Erdheim-Chester disease). The etiology of disseminated juvenile xanthogranuloma is unknown, but rare patients also have neurofibromatosis-1 and/or juvenile myelomonocytic leukemia. Of note, NF-1 and JMML are also associated with usual type juvenile xanthogranulomta.[49–51] Pathologically, the lesions of disseminated juvenile xanthogranuloma are cellular, with a mixture of histiocytic, spindled, and giant cells.[47] Nuclear pleomorphism is not prominent. The tumor cells express factor XIIIa, fascin, CD163, and CD68, and do not express S-100 protein.

ROSAI-DORFMAN DISEASE

Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy) is a probably reactive disorder of as yet unknown etiology and whose proliferating cells may derive from a surfeit of sinusoidal macrophages.[52,53] Patients usually present with

markedly enlarged, often bilateral, painless cervical lymph nodes. However, a wider variety of extranodal sites are involved in about one-half of cases, including skin, upper respiratory tract, bone, soft tissue, including orbit, and these extranodal sites may be the presenting or only site of disease.[54] Patients are generally young, presenting at a median age of 20 years, with no sex predilection, but a marked propensity for African Americans. There are usually a wide variety of laboratory abnormalities; including leukocytosis (neutrophilia), polyclonal hypergammaglobulinemia, and elevated sedimentation rate. The clinical course is usually benign, although there may be persistence or recurrence of disease, and a small subset may be associated with immune dysfunction and have a poor outcome.[55]

Involved lymph nodes are usually markedly enlarged and have a fibrotic lymph node capsule with massive dilation of the lymph node sinuses (Fig. 61.11). The sinuses show characteristic histiocytes, usually admixed with numerous plasma cells and the adjacent medullary cords also show numerous plasma cells. Extranodal sites usually show strikingly identical features, with dilated lymphatic sinuses, although surrounding fibrosis is usually more prominent. The characteristic histiocytes are very large with round nuclei that have a vesicular chromatin pattern, a delicate nuclear membrane, and one to several distinct nucleoli. Cytoplasm is abundant, amphiphilic to eosinophilic, and occasionally foamy. A distinctive feature is that the cytoplasm often contains numerous lymphocytes (lymphophagocytosis) or other cells (including neutrophils or erythrocytes).

Immunohistochemical studies show that the distinctive histiocytes are strongly positive for S-100 protein, CD163, CD68, CD11c, and CD14.[56–58] They may also be focally positive for CD30 or, and more rarely, positive for CD1a. They are consistently negative for the follicular dendritic cell markers CD21 and CD35. Molecular studies show a germline configuration of the antigen-receptor genes, and the cells have been shown to be polyclonal by analyses of the X-linked androgen-receptor gene. There is no convincing evidence of an association with any known viruses.

The differential diagnosis includes sinus histiocytosis, Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis, and histiocytic sarcoma. The key to the diagnosis of Rosai-Dorfman disease is the recognition of the peculiar proliferating histiocytes, which contain a distinctive nucleus, and prominent lymphophagocytosis. Sinus histiocytosis lacks these peculiar cells, although it may show focal lymphophagocytosis.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

Hemophagocytic lymphohistiocytosis is a clinicopathologic syndrome characterized by uncontrolled hyperinflammation caused by a variety of inherited or acquired immune deficiencies.[59] Most of the genetic defects involve defects in granule-mediated cytotoxicity and NK-cell function.[60] Familial hemophagocytic lymphohistiocytosis usually presents within the first year of life, with a symptom-free interval after birth typically seen.[59,61] EBV is the triggering agent in ~75% of cases of infection-associated hemophagocytic lymphohistiocytosis.[62] The terminal stages of any malignancy, including malignant lymphoma, may be associated with hemophagocytic lymphohistiocytosis. However, EBV-associated T/NK neoplasms are particularly common, and the accompanying hemophagocytic syndromes may occur at an early stage and may even be the presenting symptom of the lymphoma.[63,64] Patients with hemophagocytic lymphohistiocytosis usually present with fever, hepatosplenomegaly, and cytopenias, and central nervous system symptoms are also common. Laboratory abnormalities include cytopenias of two or more cell lines, hypertriglyceridemia and/or hyperfibrinogenemia, and an increase in serum ferritin and soluble CD25. The prognosis is poor, with the immediate aim of therapy being to suppress the increased inflammatory response by immunosuppressive/immunomodulatory agents and cytotoxic drugs. Hematopoietic cell transplant has been curative in a selected group of patients with primary hemophagocytic lymphohistiocytosis.[65]

Early in the disease course, biopsied lymph nodes may show a marked immunoblastic proliferation in the paracortex, with only minor hyperplasia of histiocytes noted in the sinuses. Later on, however, there is a massive infiltrating of the sinusoid by benign-appearing histiocytes. They show a normal histiocytic phenotype, with CD163 and CD68 positivity, and often show prominent hemo- and platelet phagocytosis (Fig. 61.12). There are also usually scattered to abundant plasma cells. The cortical and paracortical regions become comparatively diminished in size and stimulation. Finally, the lymph node may show lymphocyte depletion, with marked histiocytic hyperplasia with abundant phagocytosis in sinusoids. The hemophagocytic lymphohistiocytosis syndrome is usually established on clinical criteria, with lymph node biopsy performed to rule out coexisting malignant lymphoma.

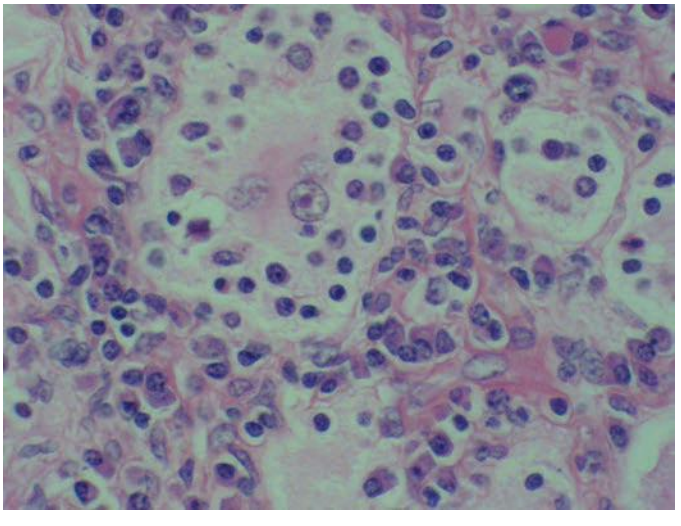

FIGURE 61.11. Rosai-Dorfman disease. Note the peculiar histiocytes with abundant lymphophagocytosis, along with the accompanying infiltrate of mature plasma cells.

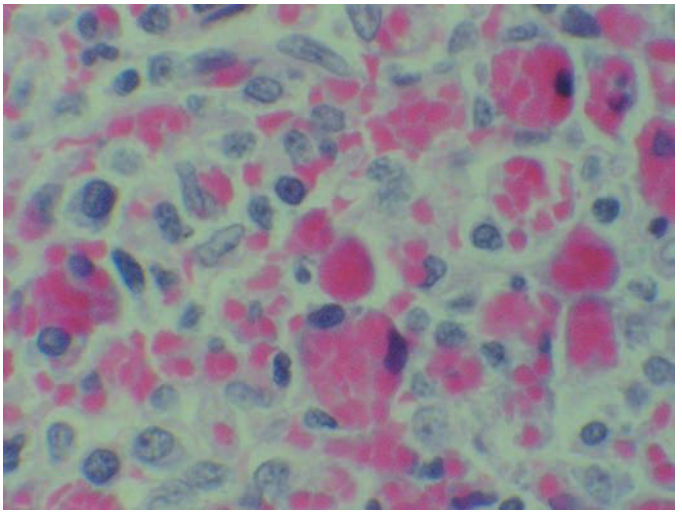

FIGURE 61.12. Lymphohistiocytic hemophagocytosis, spleen. Note the prominent hemophagocytosis. This case was associated with Epstein-Barr infection.

CHAPTER 62

INFECTIOUS MONONUCLEOSIS AND OTHER EPSTEIN-BARR VIRUS–RELATED DISORDERS

Thomas G. Gross

Epstein-Barr virus (EBV) infects the majority of human individuals but usually results in subclinical infections. EBV has been etiologically linked to a wide spectrum of human disease, but it has been shown to be the etiologic agent in relatively few. Although EBV has been identified as the etiologic agent for infectious mononucleosis (IM), the diagnosis is predicated on the presence of a well-described constellation of clinical and laboratory features. EBV has been associated with Burkitt lymphoma (BL) and nasopharyngeal carcinoma (NPC), as well as many other human malignancies, such as non-Hodgkin lymphoma (NHL; B-cell, T-cell, and natural killer [NK]-cell phenotype), Hodgkin lymphoma (HL), leiomyosarcoma, gastric carcinoma, even hepatocellular carcinoma, and breast cancer. EBV has been associated with premalignant conditions or diseases with features of malignancy, such oral hairy leukoplakia in human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) and lymphoproliferative disorders (LPDs) in patients with primary or secondary immunodeficiencies. EBV has been associated with several other nonmalignant disorders as well, such as hemophagocytic lymphohistiocytosis (HLH) and chronic active EBV infection (CAEBV), and even has been implicated in diseases such as multiple sclerosis and chronic fatigue syndrome. The role of EBV in the pathogenesis of these disorders remains to be fully understood. This chapter reviews the biology of EBV and IM in detail. The other diseases that have been associated with EBV infection are discussed, focusing on data pertaining to the role EBV may play in their pathogenesis.

HISTORICAL BACKGROUND

In the first decade of the 20th century, several cases of glandular enlargement, sore throat, and increased numbers of mononuclear cells on the blood smear were described by Turk,[1] Cabot, Marchant, and others.[2] These cases were sometimes reported as acute leukemia that apparently resulted in spontaneous remission and cure. In the 1920s, Sprunt and Evans[3] classified these cases and six of their own as infectious mononucleosis (IM), emphasizing the peculiar blastlike cells present in the blood. In 1923, Downey et al. published a detailed morphologic description of these cells.[4]

In 1958, Denis Burkitt described an unusual, rapidly growing lymphoma in children of central Africa.[5] In 1961, Dr. Burkitt gave a lecture at the Middlesex Hospital Medical School in London about the epidemiology of this lymphoma that now bears his name.[6] A young doctor named Anthony Epstein was in attendance at this lecture and upon hearing the predilection of this tumor occurring in endemic malaria areas, he hypothesized a viral etiology for this tumor. For 3 years, Dr. Epstein and his colleagues were unsuccessful in finding viruses in the tumor tissue provided by Dr. Burkitt. However, in 1964, Dr. Epstein reported, along with Achong and Barr, the presence of viral particles in lymphoblasts cultured from tumor biopsies.[7]

The discovery of EBV as the etiologic cause of IM was the result of a very astute observation made in 1967.[8] The Henles noted that blood taken from a laboratory technician who had recently contracted IM led to the spontaneous establishment of a lymphoid cell line containing characteristic EBV particles, whereas previous attempts to establish cell lines from this individual's blood had been unsuccessful. They also observed that sera obtained before the onset of IM were negative for an anti-EBV or heterophile titers, whereas after the onset of clinical IM, the anti-EBV and heterophile titers appeared and rose for a period of time.. The Henles and associates studied the sera of a number of students from Yale University, where a prospective study of IM had been in progress for many years. In all instances of clinical IM, the anti-EBV and heterophile titers rose together from a negative baseline. Of even greater interest was the observation that the anti-EBV titer remained persistently elevated, in contrast to the transient nature of the heterophile response. Confirmation of EBV as the etiologic agent in the majority of cases of IM soon followed.[9,10,11]

PATHOPHYSIOLOGY OF EPSTEIN-BARR VIRUS INFECTION

EBV is one of eight known human herpes viruses (HHVs) and is subgrouped into the γ-herpes virus subfamily. Immature virus particles that measure 75 to 80 nm can be found in both the nucleus and the cytoplasm of infected cells. Mature, fully infectious particles, with a diameter of 150 to 200 nm, are found only in the cytoplasm.[12] The infectious virus particle has three components: a nucleoid, a capsid, and an envelope. The doughnut-shaped central core, or nucleoid, contains the viral DNA in linear form. Surrounding the nucleoid is the capsid, which is icosahedral and is made up of hollow, tubular protein subunits called *capsomeres*. Finally, the nucleocapsid (the capsid and the contained viral DNA) is enclosed in a protective envelope that is derived either from the nuclear membrane or from the outer membrane of the host cell. The envelope contains a number of viral antigens that are manufactured and inserted into the host cell membrane before the assembly of mature virus particles. The EBV genome (Fig. 62.1) is a double-stranded DNA molecule of approximately 173,000 base pairs (bp) organized into a series of unique coding regions (U1 to U5), divided by interval repeat regions (IR1 to IR4)

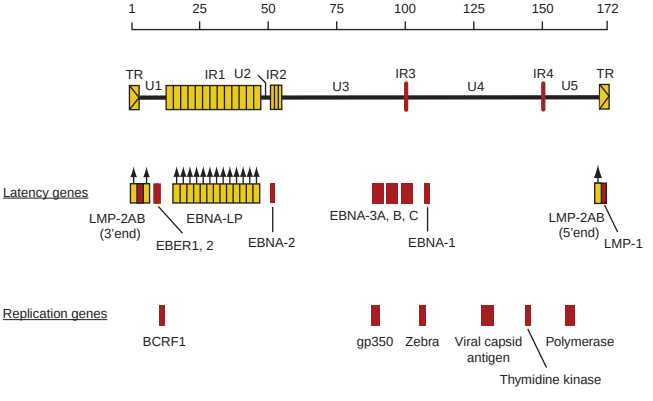

FIGURE 62.1 Epstein-Barr virus (EBV) genome and its organization. Schematic representation of linear EBV DNA showing the general organization in a series of unique (*U1* to *U5*), internal repeat (*IR1* to *IR4*), and terminal repeat (*TR*) domains. The location of several EBV genes expressed during viral latency and replication is shown. EBER, EBV-encoded RNA; EBNA, EBV-determined nuclear antigen; gp, glycoprotein; LMP, latent membrane protein; ZEBRA, Z EBV replication activator. (From Tosato G, Tata K, Angiolillo AL, et al. Epstein-Barr virus as an agent of hematological disease. Baillere Clin Hematol 1995;8(1):165–199, with permission.)

and terminal repeat domains. The genome encodes approximately 100 proteins.[13,14] Figures 62.1 and 62.2 illustrate viral genes encoded by the genome and are discussed in detail in the section, "Epstein-Barr Virus Infection." When EBV infects a cell, its linear genome circularizes to form an episome, an extrachromosomal element in the nucleus of the cell.[13,15–17]

Many variants have been reported, although the relevance to human disease pathogenesis is unclear. Two variants EBV-1 (A type) and EBV-2 (B type) exist, which are differentiated mainly by their differences in the EBV-determined nuclear antigens (EBNAs) 2, 3A, and 3C.[13,15,18] Both types of EBV are found in most populations. The relationship between these different strains and specific diseases remains to be determined. Additional EBV variants with differences in EBNA-1 have been reported to be associated with specific EBV-affiliated diseases, such as BL, but the incidence of these variants has been shown to be similar in the general population of a particular geographic region.[19] Furthermore, mutations (so-called 30-bp or 69-bp deletions) of latent membrane protein (LMP-1) have been reported to be highly associated with the development of HL, certain forms of T- and B-cell lymphoma, and NPC.[20–23] But again, when compared with EBV variants found in the geographic regions, there exists no difference between healthy individuals and those associated with tumors.[23,24] Therefore, caution must be exercised when attributing specific EBV viral strains to particular diseases in the absence of geographically matched control isolates.

Epstein-Barr Virus Infection

The only host that the virus infects naturally is the human, although lymphocytes from other species, namely New World primates (i.e., cottontop marmosets, owl monkeys, and tamarins), are infectible.[25,26] EBV has been found in a variety of human tissue types associated with disease (i.e., T lymphocytes, NK cells, HL, leiomyosarcoma, gastric carcinoma, hepatocellular carcinoma, and breast cancer).[27,28,29,30,31,32,33] The mechanism of EBV infection in these tumors remains to be fully elucidated.

Infection of B lymphocytes begins with attachment of the virus envelope glycoprotein (gp) 350/220 to the complement receptor C3d, also known as *CR2* or *CD21*.[34] For entry into B lymphocytes, a complex of three viral proteins (gH–gL–gp42) is required, and human leukocyte antigen (HLA) class II molecules serve as a coreceptor for gp42.[35] Epithelium of the oropharynx is a source of viral replication,[36] but it has been difficult to determine the mechanism of infection, inasmuch as these cells do not express CD21 or HLA class II molecules. Recent studies have demonstrated that during primary infection, the majority of virions are not internalized after binding to B lymphocytes of the oropharyngeal tissue. And these B lymphocytes can form cellular conjugates with epithelial cells that allow for transfer of EBV virions into the epithelial cells.[37] The mechanism for EBV entry into other cell types (e.g., T cells, gastric mucosa, smooth muscle cells, etc.) may also be via direct contact with B cells that have bound virions with subsequent virion internalization. Infection of epithelium leads to the replication of the virus with the release of large quantities of viral particles containing three-part complexes (gH–gL–gp42) that favor infection of HLA class II and CD21-expressing cells (i.e., B lymphocytes located in the oropharyngeal lymphoid tissues of the Waldeyer ring).[35] These B lymphocytes may remain latently infected in the oropharynx, but if viral reactivation and replication occur, cellular lysis and death result, and the virus can be shed into the saliva. Virus contained in infectious saliva is produced by B lymphocytes of the oropharynx.[38,39] Salivary virus may then be transmitted to another host.

The mechanisms underlying viral replication are not completely understood as there exist no in vitro models that recapitulate viral replication in humans. Viral replication is initiated through *oriLyt*.[40] Two key early immediate genes are first transcribed, BRLF1 and BZLF-1, encoding Z EBV replication activator (ZEBRA) protein.[13,15,41] These proteins then up-regulate the expression of early gene products essential for viral replication, including viral DNA polymerase and viral thymidine kinase. Late gene products follow, including viral capsid antigen (VCA), the major envelope glycoprotein (gp350), and the viral protein BCRF-1, which contains 70% homology to interleukin (IL)-10.[13,15,42,43] Complete viral replication results in the lysis and death of the host cell. Recently, it has been shown that viral proteins associated with type III latency (see below) are associated with viral replication.[44] What role this plays in B-cell transformation and immortalization remains to be determined.

Alternatively, infected B lymphocytes appear to undergo normal B-cell differentiation and disseminate throughout the body into secondary lymphatic organs (i.e., lymph nodes, spleen, and bone marrow).[44–47] Studies have demonstrated that the reservoir for latent EBV infection is a small percentage of postgerminal center, antigen-selected resting memory B lymphocytes.[47] The number of latently infected B cells is approximately 10^{-5} to 10^{-6} of all B cells and remains stable for the majority of the life of the infected individual.[46,48]

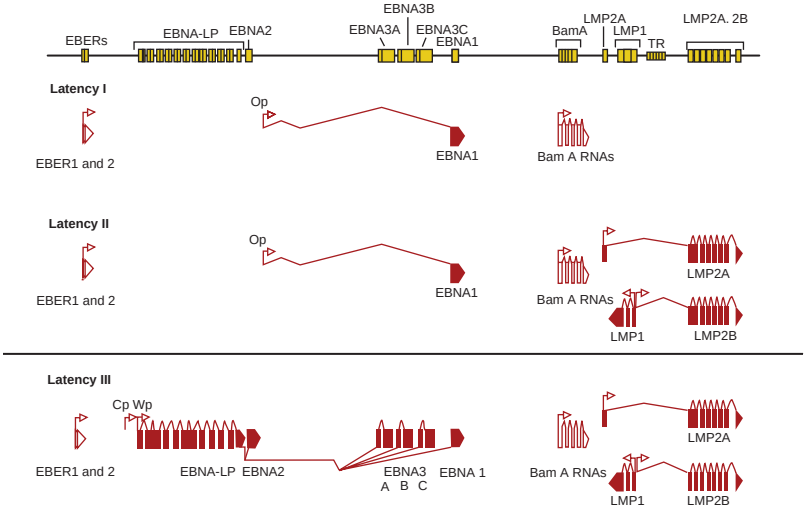

FIGURE 62.2 Epstein-Barr virus (EBV) gene transcription in the three forms of latency. The *top panel* shows the position of the exons on a linear map of the genome. The *lower panel* shows the direction of transcription from each promoter (*arrows*) and the splicing structure between the exons. Coding exons are shown in *black* and noncoding exons in *white*. EBER, EBV-encoded small RNA; EBNA, EBV-encoded nuclear antigen; LP, leader protein; LMP, latent membrane protein; TR, terminal repeat. (From Young LS, Dawson CW, Eliopoulos AG. The expression and function of Epstein-Barr virus encoded latent genes. J Clin Pathol Mol Pathol 2000;53:238–247.)

Latent infection is characterized by the expression of nine virally encoded proteins. Figures 62.1 and 62.2 illustrate the transcriptions of the nine latent proteins of EBV (EBNA-1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, EBNA leader protein [LP], LMP-1, LMP-2A, and LMP-2B).[13,15,49] Two EBV-encoded RNAs (EBER-1 and EBER-2) are expressed abundantly in all EBV-infected cells and are valuable for making the diagnosis of EBV disease, but do not code for proteins and their function remains to be determined.[13] In addition, the Bam HI-A rightward transcript (BART) is generally found in infected cells, but its function also remains to be fully delineated.[50]

The state of latent infection is maintained by EBNA-1. The function of EBNA-1 is to bind to a nucleotide sequence called *ori-P*, part of the DNA origin of EBV replication, thereby allowing the viral genome to be maintained in the nucleus of the latently infected B cell.[51,52] By this mechanism, the EBV DNA is assured of being maintained in B cells that undergo replication.

EBNA-2 and LMP-1 appear to be required for B-cell immortalization.[13] EBNA-2 transactivates the expression of LMP-1 and LMP-2.[13,53] EBNA-LP augments the ability of EBNA-2 to upregulate LMP-1. LMP-1 and LMP-2 are associated with a cellular tyrosine kinase. The function of LMP-1 is similar to that of other members of the tumor necrosis factor (TNF) receptor family and is similar—but not identical—to that of CD40. LMP-1 interacts with TNF-receptor–associated factors and the TNF-receptor–associated death domain in infected cells and activates nuclear factor-*k*B and c-Jun N-terminal kinase pathways, resulting in B-cell activation and proliferation.[49,54–57] Additionally, LMP-1 expression also induces bcl-2 expression and can prevent apoptosis in B cells.[57] LMP-2 prevents viral reactivation by blocking tyrosine phosphorylation and promotes B-cell survival.[58] The EBNA-3 proteins regulate expression of certain cellular genes, including specific cellular receptors such as CD28, CD19, CD21, CD23, and CD30; T-cell co-stimulatory molecules CD80/CD86; adhesion molecules such as intercellular adhesion molecule-1, leukocyte factor antigen-1, and leukocyte factor antigen-3, and a member of the src oncogene family, c-fgr.[15,59]

Expression of EBV genes varies along the spectrum of EBV-associated diseases and often differs from in vitro immortalized B cells or normal human resting B cells infected by EBV.[49,53] The viral gene expression of viral latency is illustrated in Figure 62.2. Briefly, in type I latency- EBNA-1, EBER-1, and EBER-2 and BART are expressed. Type I latency is observed in BL and a portion of EBV-positive gastric carcinoma. Type II latency is characterized by the expression of EBNA-1, LMP-1, LMP-2A and B, EBER-1, and EBER-2 and is observed in NPC, and other EBV-positive lymphomas, such as T- or NK-cell NHL, and the Reed-Sternberg (RS) cells of HL. EBV-infected cells of LPD observed in immunodeficient patients resemble in vitro immortalized B cells and generally express all nine of the EBV-related latent proteins (type III latency). The site of EBV latency in seropositive healthy individuals, the resting memory B cells does not appear to express EBNA-1 but only LMP-2, EBER-1, and EBER-2 together with BART (type IV latency).[60]

Immune Response to Epstein-Barr Virus Infection

Understanding the immune response to EBV infection is essential to comprehend the pathogenesis of EBV-related disease. EBV is a very potent immune stimulus. The immune system controls lymphoproliferation in the normal host and maintains a host/virus symbiosis. Figure 62.3 illustrates the delicate balance between the host T-cell immune response and control of B-cell proliferation of latently infected B cells. In a healthy individual, although only 10^{-5} to 10^{-6} B cells are latently infected with EBV, approximately 1% to 5% of all circulating $CD8^+$ T cells are capable of reacting against EBV.[48,61,62,63] Initially, there is B-cell proliferation,

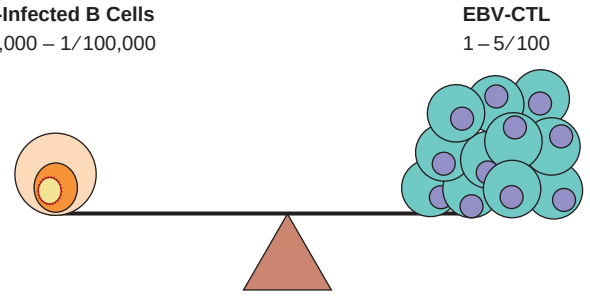

FIGURE 62.3 Balance of immune control in Epstein-Barr virus (EBV) infections. CTL, cytotoxic T lymphocyte.

producing both EBV-specific and -nonspecific antibodies. The number of these virus-containing B cells rises during the acute phase of the infection but never exceeds 0.03% to 0.1% of the circulating mononuclear cells.[64,65] A cellular immune response follows, which is composed primarily of an expansion of cytotoxic T lymphocytes (CTLs), with the vast majority being EBV-specific, although some are not EBV-specific.[66,67] Figure 62.4 illustrates the pathologic consequences of an abnormal CTL response to EBV infection. A deficient CTL response, either quantitative or qualitative, results in an EBV-driven B-cell proliferative process. The lack of an appropriate CTL response can also result in an aggressive, predominantly T-cell and histiocytic reaction that is not EBV-specific. This reaction is characterized by extensive infiltration of lymphoid and parenchymal organs with hemophagocytosis, and tissue destruction is often observed. If unchecked, this reaction can be rapidly fatal.[68,69]

The humoral response to EBV is well characterized (Fig. 62.5).[70,71,72,73] VCA antibodies are the earliest to appear: first immunoglobulin M (IgM) and, later, IgG. IgM antibodies probably arise during the incubation period, peak with symptoms, and then decline rapidly.[73] IgA anti-VCA antibodies are seen in some patients and, like IgM anti-VCA antibodies, are gone within several weeks.[74,75] IgG anti-VCA antibodies reach a peak 2 to 3 weeks after their IgM predecessors and persist for life.[74,75] The majority of patients also have a transient response to the EBV early antigen (EA), peaking usually within a month of infection.[72] Antibodies to EBNA may appear several weeks after the onset of the illness in some patients but, in general, take several months to appear, and titers rise slowly over 1 to 2 years and persist for life. The majority of normal individuals have detectable IgG to EBNA by 6 months after EBV infections, although it may take years to develop detectable anti-EBNA titers.[76] In young children, the anti-VCA and anti-EA responses may be much less intense, and anti-EBNA may take much longer to be seen.[77]

An EBV-nonspecific humoral response also occurs with EBV infection. Paul et al.[78] first described this phenomenon in 1932 when they reported that the sera of patients with IM contained heterophil antibodies against sheep erythrocytes in concentrations far above normal. The use of heterophil antibodies in the diagnosis of IM is discussed in detail in the section, "Infectious Mononucleosis: Diagnosis." Many of these EBV-nonspecific antibodies function as autoantibodies and include cold reactive anti-i antibodies, Donath-Landsteiner cold hemolysins, and antibodies against smooth muscle, thyroid, and stomach.[79–82] In addition, antinuclear antibodies have been found in the sera of some patients,[83,84] as well as rheumatoid factors,[85] including anti-Gm antibodies,[86] anticardiolipin antibodies, and antiactin and anticytoskeletal antibodies.[87] The serum of some persons with IM may contain cryoglobulins.[88] Some of these autoantibodies have been reported to be monoclonal.[84]

Although neutralizing antibodies produced after primary infection may play a role in thwarting the spread to additional B cells, EBV-specific antibodies are most useful for diagnosis,

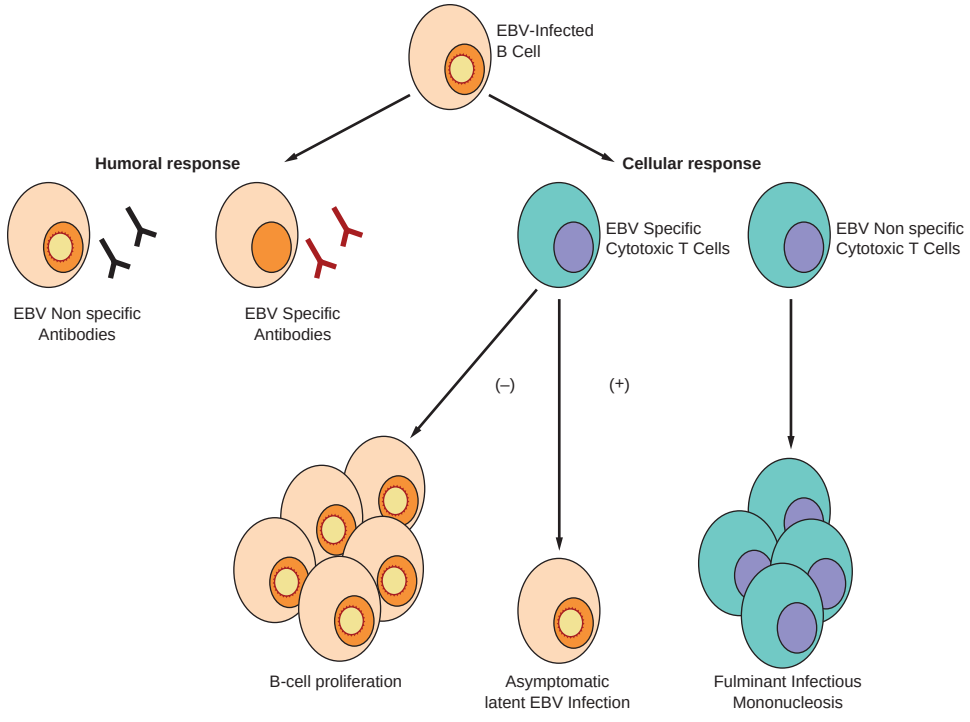

FIGURE 62.4 Immune response to Epstein-Barr virus (EBV) infection.

whereas the cellular response is the most important for control of EBV infections. NK cells and $CD4^+$ T cells have been shown to play a role, but $CD8^+$ memory cytotoxic T cells (EBV-CTLs) are the primary defense in controlling EBV infections.[66,67,89,90] The absolute number of NK cells may initially be increased, but a decrease in NK function is usually observed, returning to normal gradually over several weeks.[91] Initially, these EBV-CTLs account for the majority of cells causing the lymphocytosis and the large, pleomorphic, atypical lymphocytes, or "Downey cells," characteristic of IM.[66,67,90,92] Of note, it has been shown that the amount of these T cells in the peripheral blood correlates with symptoms seen in IM, not the number of EBV-infected B cells or the viral load.[93] Not surprisingly, at first the majority of EBV-CTLs are reactive against lytic viral antigens. During lytic infection three EBV proteins, BNLF2A, BILF1, and BGLF5, function to lower HLA I surface expression, which in effect helps EBV-infected cells evade the immune system.[94] However, over time the number of EBV-CTLs reactive against latent viral antigens predominates.[66,67]

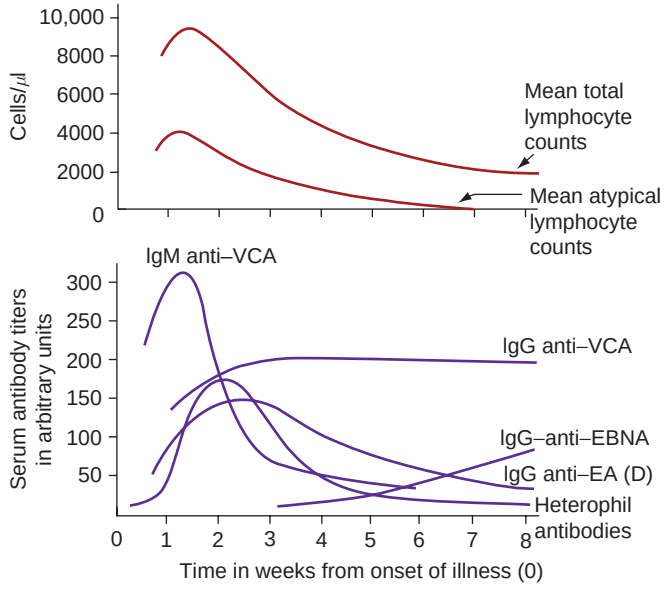

FIGURE 62.5 Laboratory tests I. Time course relationship between heterophil antibodies, various anti–Epstein-Barr virus antibodies, and the mean total and atypical lymphocyte counts. EA, early antigen; EBNA, Epstein-Barr nuclear antigen; D, diffuse component; Ig, immunoglobulin; VCA, viral capsid antigen.

This symbiosis of EBV and the infected host is maintained by interactions between viral gene expression in latently infected B cells and host EBV-CTL surveillance. The reservoir of viral latency is found among the resting memory B cells.[46,47] These resting memory B cells do not express high levels of adhesion molecules or T-cell co-stimulatory molecules, making them poor antigen-presenting cells. When these cells divide, EBNA-1 is expressed to ensure passage of viral DNA to progeny cells.[52] Although $CD4^+$ T-cell responses against EBNA-1 have been documented,[95] EBNA-1–specific cytotoxic T cells are not readily generated.[96,97] Thus, the reservoir of latent EBV infection is not recognized readily by the immune system.

Activated EBV-infected B cells express major histocompatibility complex class I antigens; various adhesion molecules make these proliferating EBV-infected B cells good antigen-presenting cells. Proliferating, latently infected B cells express all latent proteins, including EBNA-2, EBNA-3A, EBNA-3C, LMP-1, and LMP-2 (type III latency). These proliferating EBV-infected B cells are highly susceptible to cellular lysis by EBV-CTL and are eliminated during convalescence, whereas memory EBV-CTL provide lifetime immunosurveillance against EBV-driven B-cell proliferation. The immunodominant epitope of the EBV-CTL response is highly restricted by the HLA type of the individual.[98] For months after the expansion of EBV-infected B cells is controlled, virus is shed at high titers in the saliva,[99] indicated ongoing viral replication in infected B cells of the oropharanyx.[46] Recent studies have demonstrated that EBV-CTL against latent viral antigens home more efficiently to lymphoid tissue of the oropharynx than EBV-CTL against lytic viral antigens.[100] This observation helps explain that the greatest risk of acquiring primary infection is salivary exposure from a recently infected person or a person in early convalescence, although infective virions can be found in the saliva of persons with a long latent infection.

INFECTIOUS MONONUCLEOSIS

Epidemiology

The typical clinical syndrome associated with IM occurs most commonly in young adults, the peak incidence being in persons between 17 and 25 years of age (Fig. 62.6).[70,101] Children often acquire immunity to EBV without developing the typical clinical manifestations of IM, for reasons still not understood.[101–103] Because symptoms of EBV correlate with the CTL response,[93] this would suggest that young children generally respond with a less exuberant cellular response. The yearly conversion rate to EBV seropositivity among children in the United States is not known. Past studies suggest earlier conversion with lower socioeconomic status, i.e., 51% of Yale University freshmen and 86% of Marine recruits, had antibodies to EBV.[12,104] Authors of a British study concluded that 30% to 40% of children had been infected by their fifth year.[105] Generally speaking, the rate of seroconversion is high in developing countries, where standards of hygiene are relatively low compared to higher socioeconomic countries.[10,70] Under these circumstances, primary infection occurs in almost all children before 10 years of age, leaving few young adults susceptible to develop IM, and the observed incidence of IM in such countries is very low.[10,70] IM is sufficiently uncommon in individuals older than 30 years of age and is so rare in those older than 40 years of age that special care is needed when making the diagnosis in persons in their middle or late years. Nevertheless, well-documented cases of this illness in patients older than 40 years of age have been reported.[105–108] Complications such as protracted fever, jaundice, pleural effusion, and Guillain-Barré syndrome often dominate the clinical picture in these patients, detracting from the evidence that would allow the clinician to make the correct diagnosis.[107]

IM is not as contagious as is commonly believed. It is rare for members of a patient's family, roommates of the same sex, and other close associates to develop symptoms of IM.[109,110] "Kissing disease," the colloquial term for IM, underscores the association of intimate kissing with IM.[70,99,102,111] Although oral shedding occurs throughout the life of a carrier, it peaks shortly after infection but often is readily detectable for 18 months or longer.[99,112,113] Other modes of acquiring EBV infection include transplantation of organs or hematopoietic cells in which transmission to the transplant recipient is common.[114–117] Although it is not thought to occur frequently, there are anecdotal reports of transmission from blood transfusions,[118,119] in utero, or perinatally.[120,121] Although there are anecdotal reports of virus detected in cervical epithelium and semen, sexual transmission has never been demonstrated.[122]

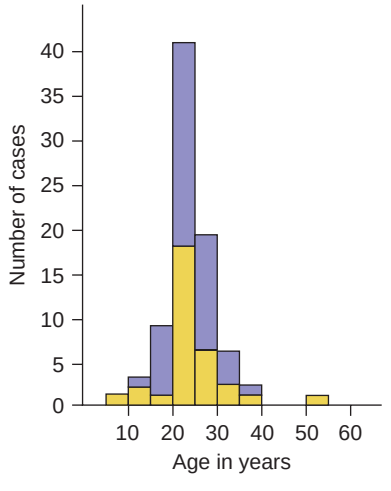

FIGURE 62.6 Age incidence. Age and sex of 82 patients with infectious mononucleosis at Johns Hopkins Hospital. Shaded columns, males; open columns, females.

Clinical Features

Many individuals have held that the manifestations of IM are protean and that many disorders may be simulated by this condition. IM is traditionally characterized by the clinical triad of fever, pharyngitis, and generalized adenopathy, with demonstration of an *atypical lymphocytosis*, defined as an absolute lymphocytosis with more than 50% lymphocytes and 10% or more atypical forms in the differential count, and the presence of heterophil antibodies.[102] Usually, IM occurs only once in the lifetime of a host, although recurrences have been reported, and exacerbations of unresolved infection or transition to a chronic course may also occur. (See the section, "Chronic Active Epstein-Barr Virus Infections.")

The signs and symptoms of IM are summarized in Table 62.1. The clinical course based on physical signs and symptoms is illustrated in Figures 62.7 and 62.8. In most young adults, the symptoms are fairly abrupt in onset, although close questioning frequently elicits vague complaints of lassitude and ill-being for several days before the onset of more pronounced symptoms. Most of the early symptoms are nonspecific. Myalgias do occur, but they are usually mild and are often confined to the neck and upper back. Excessive fatigue and general malaise may be accompanied by fever, sweating, and chills. Severe rigors rarely occur, and the patterns of fever are generally moderate and nonspecific. The fever is of no characteristic type. It may be transient and slight in degree, but in as many as one third of patients, it reaches a peak of 40°C. A secondary rise in temperature may occur after an initial drop to normal and may accompany the onset of glandular swelling or sore throat.

Anorexia is a common early symptom. Its intensity and duration are often linked to the severity of sore throat and dysphagia. The anorexia often persists for several weeks. Nausea is equally common and may be one of the earliest symptoms of IM, but

TABLE 62.1

SYMPTOMS AND SIGNS OF INFECTIOUS MONONUCLEOSIS

Symptoms	%	Signs	%
Malaise and fatigue	90–100	Adenopathy	100
Sweats	80–95	Fever	80–95
Sore throat, dysphagia	80–85	Pharyngitis	65–85
Anorexia	50–80	Splenomegaly	50–60
Nausea	50–70	Bradycardia	35–50
Headache	40–70	Periorbital edema	25–40
Chills	40–60	Palatal exanthem	25–35
Cough (mild)	30–50	Liver or splenic tenderness	15–30
Myalgia	12–30	Hepatomegaly	15–25
Ocular muscle pain	10–20	Rhinitis	10–25
Chest pain	5–20	Jaundice	5–10
Arthralgia	5–10	Skin rash	3–6
Diarrhea or soft stools	5–10	Conjunctivitis	5
Photophobia	5–10	Pneumonitis	3
Abdominal pain	5		
Epistaxis	3

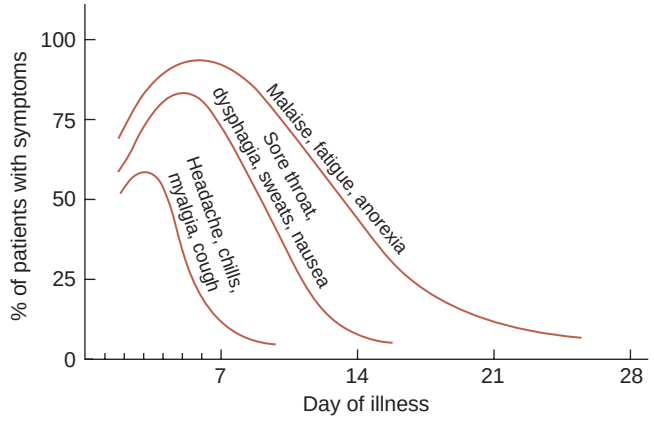

FIGURE 62.7 Major symptoms. Usual frequency and duration of major symptoms in young adults with infectious mononucleosis. (From Finch SC. Clinical symptoms and signs of infectious mononucleosis. In: Carter RL, Penman HG, eds. Infectious mononucleosis. Oxford: Blackwell Scientific, 1969.)

vomiting is rare. Sore throat and dysphagia are among the most important manifestations of IM and may be the only symptoms in some patients. These symptoms usually develop gradually and subside in 1 to 2 weeks. For most patients, the symptoms of pharyngitis are mild, but occasionally, even taking sips of water may be painful.

Lymph node enlargement is invariably present at some time.[123,124,125] Adenopathy usually appears during the first week of illness and slowly resolves thereafter. Anterior and posterior cervical node enlargement is almost always present, and palpable axillary and inguinal nodes are common. Radiographically detectable hilar adenopathy is rare (<1%).[126] Although splenomegaly is expected, the spleen is palpable in only one half to three fourths of all patients, and massive splenomegaly is rare.[127] Hepatomegaly is detected in 15% to 25% of patients and is usually accompanied by percussion tenderness over the liver and discomfort on palpation. The course of hepatomegaly closely follows that of adenopathy and splenomegaly.[127] Pharyngeal inflammation usually appears in the first week and then subsides rapidly. In approximately 25% of patients, pharyngitis first occurs after the initial week of illness, and there are no pathognomonic features. It varies in intensity, but rarely, massive tonsillar and pharyngeal edema may cause virtually complete pharyngeal obstruction.[125] Severe cough is relatively rare, although mild cough is common.

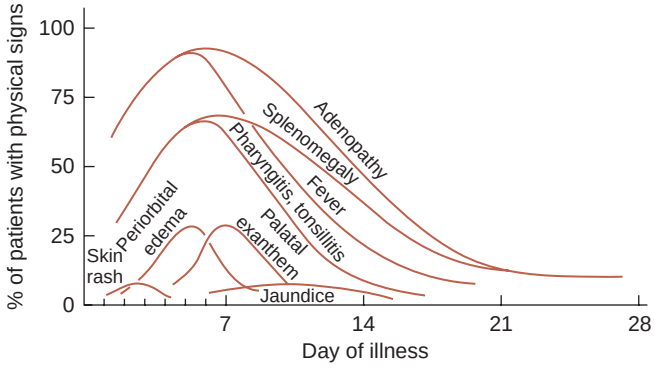

FIGURE 62.8 Physical signs. Usual frequency and duration of major physical signs in young adults with infectious mononucleosis. (From Finch SC. Clinical symptoms and signs of infectious mononucleosis. In: Carter RL, Penman HG, eds. Infectious mononucleosis. Oxford: Blackwell Scientific, 1969.)

Headaches occur early, as well as photophobia, and ocular muscle pain can occur. Ocular manifestations occur in approximately one third of patients and include eyelid edema, conjunctivitis, dry eyes, keratitis, uveitis, choroiditis, retinitis, papillitis, and ophthalmoplegia.[128] Rashes are also common with primary EBV infection and may be the only symptom in young children.[129,130] Several observers have noted that patients experiencing IM are peculiarly prone to rashes when treated with ampicillin, which appear to be the result of vasculitis caused by circulating ampicillin–antibody complexes.[131,132,133]

Laboratory Findings

Hematologic abnormalities in IM are observed in virtually all patients. The hematologic changes persist for a minimum of 2 weeks and usually persist for 1 to 2 months. One of the classic features of IM is the atypical lymphocytosis. The pleomorphism of the mononuclear cells found in the blood is usually striking. In addition to normal lymphocytes and monocytes, large mononuclear cells, or atypical lymphocytes, are observed in the blood (Fig. 62.9). Although nonspecific[4] because they may be found in the blood of patients with a variety of conditions, including other viral infections,[134] they are a prominent feature of IM. The abnormal cells vary greatly in size and shape. They possess a nucleus that may be oval, kidney-shaped, or slightly lobulated and cytoplasm that most often is nongranular and vacuolated or foamy. The nuclear chromatin forms a coarse network of strands and masses and is not clearly differentiated from the parachromatin. The identity of these cells has been shown to be $CD8^+$ T lymphocytes, as discussed previously (see the section, "Immune Response to Epstein-Barr Virus Infection'). The rapid proliferation of these activated T cells is responsible for the large numbers of atypical cells seen in the peripheral blood, whereas the proliferating B cells are primarily responsible for the generalized lymphadenopathy, hepatosplenomegaly, tonsillar and adenoidal changes, and the cellular infiltration seen in many parenchymal organs; this is discussed in detail in the section, "Infectious Mononucleosis: Histologic Findings."

Most patients with IM have slightly or moderately increased total white blood cell counts in the range of 10.0 to 20.0 $\times$ 10^9 cells/L, with approximately 15% of patients reaching levels in excess of 20.0 $\times$ 10^9/L.[111,135,136] The absolute lymphocyte count most often exceeds 5.0 $\times$ 10^9 cells/L; with atypical lymphocytes usually >20%.[111] Lymphocytosis begins toward the end of the first week of illness and reaches a peak corresponding to symptoms, as does the total leukocyte count (Fig. 62.10). Leukopenia has also been observed and can be manifested as lymphopenia or granulocytopenia.[136] Most patients with IM have normal hemoglobin levels, and severe thrombocytopenia is rare, although mild depressions of platelet counts may be found in perhaps one half of patients.[137] Severe neutropenia and thrombocytopenia may be very ominous signs, as they are frequently seen in the hemophagocytic reactions (VAHS or EBV–HLH).

Nonhematologic abnormalities are also commonly observed in patients with IM. Many patients show mild to moderate abnormal liver function tests.[136] The reported incidence varies from 40% to 100%, depending on the severity of the disease, the time of testing, and the diligence with which the changes were sought. Reported enzyme changes include elevations of lactate dehydrogenase, alkaline phosphatase, glutamic pyruvate transaminase, phosphohexose isomerase, and aldolase, in roughly that order of frequency. Perhaps one third of patients have mild to moderate elevations of serum bilirubin values; levels above 8 mg/dl (135 μmol/L) are exceedingly rare but have been reported.[136,138] Occasionally, proteinuria or hematuria is present, but renal function is usually unimpaired. When the patient is jaundiced, bile and increased concentrations of urobilinogen may be found. When

lumbar puncture has been performed to evaluate patients with severe headaches, the cerebrospinal fluid (CSF) pressure may be elevated, and pleocytosis and increased levels of protein are often noted. The sugar content is normal. In a few patients, heterophil antibodies have even been demonstrated in the CSF.[139]

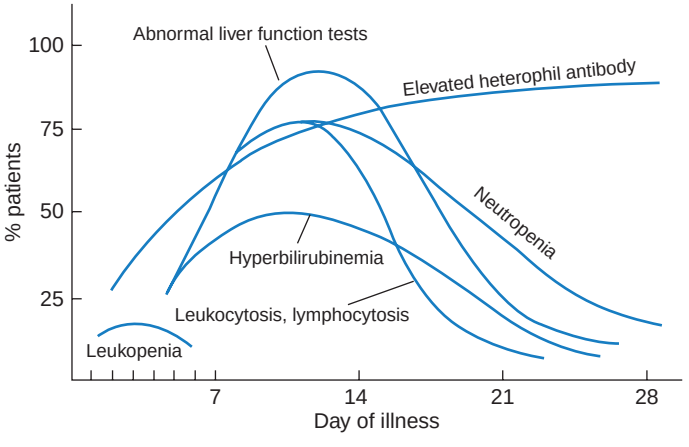

FIGURE 62.10 Laboratory tests II. Major laboratory findings in adults with infectious mononucleosis. (From Finch SC. Clinical symptoms and signs of infectious mononucleosis. In: Carter RL, Penman HG, eds. Infectious mononucleosis. Oxford: Blackwell Scientific, 1969.)

Histologic Findings

The main pathologic feature of IM is a notable proliferative response within the reticuloendothelial system, especially by the lymph nodes and the spleen. It can be difficult to distinguish between malignant lymphoma and nonmalignant disease associated with EBV infection, especially in the immunodeficient patient population.[69] In summary, the histologic diagnosis of IM is one of suspicion rather than certainty.[69,140]

The lymph node architecture is generally intact[141,142] but may be distorted.[140,141–143] Other morphologic features mimicking lymphoma include extensive immunoblastic proliferation in sheets and nodules and significant cellular atypia.[141] Clonality studies are often necessary to differentiate IM from malignant disease. The germinal centers are usually identifiable, but follicular prominence is diminished, probably because of the irregular and vaguely defined borders that result from the lymphocytic and reticuloendothelial hyperplasia of paracortical structures and, to a lesser extent, the medullary cords. This intense proliferative activity within the paracortical areas is in keeping with the characterization of atypical lymphocytes as T cells.[143] In addition, focal proliferations of macrophages are noted, as is, most characteristically, the presence of "typical" IM cells throughout the pulp, on the edges of germinal centers, and in the sinuses.[142] RS-like cells[140,141,143] are often observed in association with areas of necrosis.[69] Because the presence of EBV has been demonstrated in approximately 50% of HL specimens,[144–146] the identification of

the virus or EBV-determined antigens is not particularly helpful in the differential diagnosis of these two disorders.

The spleen is striking for infiltration of its fibromuscular structures by mononuclear cells.[147] Both the capsule and trabeculae are often thin and invaded by proliferating lymphocytes. This may explain the occurrence of splenic rupture in this disease. In vitro hybridization studies can be used to track the distribution pattern of cells carrying the viral genome.[140,148] Most labeled cells are found in the hyperplastic T-cell zones, the paracortical or interfollicular areas[140,148]; smaller numbers are found within the epithelioid venules, the lymph node sinuses, and, occasionally, the germinal centers and the mantle zone.[148] In the spleen, labeled cells are found mainly within pulp cords.[148] Most of the labeled cells are small lymphocytes, but occasional labeled blasts, dendritic cells, and macrophages can be identified.[148]

The bone marrow may be cellular with generalized hyperplasia of erythroid, myeloid, and megakaryocytic elements.[149] With special techniques, sarcoidlike granulomas may also be demonstrated.[149–151] In most instances, however, routine marrow aspiration reveals no abnormalities of note.

Diagnosis

The diagnosis of IM rests primarily on documentation of a primary EBV infection. Because EBV cannot be cultured, the humoral response to EBV infection, which has been discussed in the section, "Immune Response to Epstein-Barr Virus Infection," is the usual method to discern infection. In summary, a recent, primary EBV infection is characterized serologically by (a) a positive heterophil antibody titer; (b) high titers of anti-VCA antibodies, both IgM and IgG; (c) high titers of anti-EA antibodies; and (d) the absence of anti–EBNA-1 antibodies (Fig. 62.5) Convalescent sera demonstrate the disappearance of IgM anti-VCA antibodies and the appearance of anti–EBNA-1 antibodies.[72,73] At present, the diagnosis of IM is made by the presence of anti-IgM to EBV VCA. Rapid test systems using recombinant EBV antigens and enzyme-linked immunosorbent or other assay technologies have been developed for use in clinical laboratories,[152,153] but false-positive tests, especially for anti-EBV IgM antibodies, can occur.[154]

Because so many antibodies have been linked to the development of IM, elevation of Ig levels in association with this disease is not surprising.[155,156] Although this change is especially true for IgM, lesser elevations have also been seen in IgG and IgA. A general increase in titers of IgG antibodies and production of IgM antibodies against heterophile antigens and other infectious agents is common during the primary EBV infection[157,158] and must be taken into account when performing a diagnostic workup. Antibodies with recognized antigenic specificities make up only a small proportion of the total γ-globulins of the serum,[155,159] and the antigenic specificity of most of the increased γ-globulins remains undefined.

A serologic diagnostic test for IM has been available since Paul et al.[78] discovered that the sera of patients with IM contain agglutinins against sheep red cells. They called the antibody *heterophil* because it reacted with a heterologous antigen that obviously had not elicited its production. Historically, the heterophil antibody test was felt to be a sine qua non in the diagnosis of IM in adults. Investigators soon learned that the antibody reacted not only with sheep red cells, but also with beef and horse erythrocytes.[157,160,161] The heterophil antibody is an IgM globulin,[162–164] which, in some studies,[164] was shown to have λ light chains only. The Paul Bunnel (PB) antigen with which the heterophil antibody interacts is thermostable,[160,162] in contrast to the Forssman antigen. Its immunologically reactive sites appear to be carbohydrate in nature.[165] The carbohydrate nature of the antigen probably explains the observation that the antibody response is almost exclusively IgM. PB antigens are found also on cells other than heterologous erythrocytes.[162] Of particular interest is the demonstration of PB-like antigens on murine T lymphocytes, Thy-1–positive murine lymphoma cells, and murine neutrophilic granulocytes.[162] In addition, PB antigens have been demonstrated in various tissues of IM patients during the early stages of the disease,[162] in cultures of some lymphoid cell lines,[166] in fresh BL tissues,[167] and in the spleens of some patients experiencing lymphoma or leukemia.[162] The formation of PB antibodies by cultures of lymphocytes from IM patients also has been demonstrated.[168]

Heterophil antibodies in titers of up to 1:28 are present in most normal persons and, occasionally, in titers of 1:56.[169] A study of more than 3,000 IM patients showed the following age distribution of PB antibodies: 5 to 9 years of age, 4%; 10 to 14 years of age, 8%; 15 to 24 years of age, 80%; 25 to 29 years of age, 3%; and older than 30 years of age, 5%.[170] For these reasons, the test for heterophil antibodies has been called "presumptive,"[171] but in the presence of clinical and hematologic findings suggestive of IM and a titer of 1:256 or higher, the diagnosis of IM is likely. In patients with IM, positive heterophil reactions almost always appear during the first 2 weeks of the illness (Fig. 62.5). Highest titers usually are found during the second and third weeks. As a rule, positive reactions last 4 to 8 weeks, but they have been observed to persist for as short as 7 to 9 days or as long as 18 weeks.[169] The titer bears no relation to the severity of the disease or to the leukocyte changes. Although elevated heterophil antibody titers are quite common in EBV infection, occasionally patients with other disorders produce elevated levels.[172]

Molecular diagnostic techniques are useful for the demonstration of EBV in tissues and body fluids. In situ hybridization techniques[140,148,173] and the polymerase chain reaction (PCR)[174,175] are most commonly used. The use of quantitative EBV PCR has been evaluated for diagnostic and prognostic value in EBV-related diseases.[176,177] The detection of EBV DNA in peripheral blood or serum by PCR provides good evidence that the patient has been infected by EBV. However, interpretation of quantitative EBV DNA PCR or "viral load" results can be problematic, especially in the immunodeficient patient. Immunocompromised patients tend to have higher amounts of EBV DNA than normal healthy individuals with latent EBV infections. Also, different laboratories use different methods of detection, different specimens (blood vs. serum vs. mononuclear cells), and different measurements (copies per micrograms DNA vs. cells vs. ml of serum/blood).[177] It appears that the amount of EBV DNA detectable in the blood of a patient with EBV-related disease may be useful in monitoring response to therapy in some diseases, but its value for diagnosis or prognosis still remains to be determined. The best method to diagnose EBV as an etiologic agent is tissue biopsy and in situ hybridization.

Differential Diagnosis

The diagnosis of IM usually is not difficult. In most instances, a young adult complains of malaise, fatigue, anorexia, and a sore throat and is found to have fever, adenopathy, pharyngitis, and splenomegaly. Appropriate changes in EBV titers will confirm the diagnosis. Much has been written about complications that can be devastating or even fatal, but serious complications in IM are rare, occurring in <1% of all diagnosed patients.[125] Therefore, signs of significant respiratory, cardiovascular, intestinal, urinary, or joint disease make considerations of other diagnoses mandatory.

The fever and general malaise can be seen in many infectious diseases including salmonella infections, listeriosis, brucellosis, subacute bacterial endocarditis, the lymphadenopathic form of toxoplasmosis, and malaria.[69] Generalized lymph node enlargement, including the postauricular and occipital nodes, is also characteristic of rubella.[69] The pharyngitis of IM must be differentiated from acute streptococcal pharyngitis, diphtheria, and acute viral pharyngitis of other types. β-Hemolytic streptococci are isolated relatively often from patients with classic IM.[123] Thus, a

positive throat culture for streptococci does not make a search for an EBV infection unnecessary. In addition, a palatine exanthem may be present in patients with rubella, and atypical lymphocytes have been described in this condition. Drug fever and serum sicknesslike reactions may also suggest IM, because they often are characterized by fever, jaundice, lymph node enlargement, and atypical lymphocytes.[69] Lymphocytosis, absolute or relative, may be encountered in association with diseases other than IM. These disorders include tuberculosis, tularemia, pertussis, dengue, mumps, chickenpox, German measles, typhoid fever, infectious hepatitis, serum sickness, and various other allergic states. In association with some of these conditions, abnormal lymphocytes resembling those of IM have been observed, as mentioned previously. Leukocytosis due to small lymphocytes of normal appearance and not associated with splenomegaly, lymphadenopathy, or a positive heterophil titer is suggestive of some other acute infectious process.

The hematologist may be called on to differentiate IM from other more serious hematologic diseases, such as acute leukemia or lymphoma. Although many leukocytes of patients with IM appear abnormal, few contain nucleoli, and thrombocytopenia and anemia are rare in these patients. EBV serologies confirming primary infection can be very helpful. Bone marrow examination is rarely necessary to differentiate IM from acute leukemia. Nodal biopsy can be difficult at times to differentiate IM from a malignant process. (See the section, "Histologic Findings.") Patients who have had IM do not have a higher incidence of leukemia, but a few cases of concurrent IM and leukemia have been reported.[178–181]

A number of self-limiting diseases are associated with a peripheral blood picture that satisfies all of the morphologic criteria established for the diagnosis of IM; failure to recognize these illnesses can result in unnecessary lymph node or liver biopsies, bone marrow aspiration, or other irrelevant diagnostic tests. The most common causes include cytomegalovirus (CMV), rubella, hepatitis and adenoviruses, *Toxoplasma gondii*, trichinosis, HIV, and HHV6, as well as a number of bacterial infections, with CMV being the most common.[182,183–189]

When CMV-mononucleosis occurs, the illness can clinically be identical to IM with similar laboratory findings.[182] The diagnosis is confirmed by demonstrating the presence of IgM antibodies to CMV in virtually all cases.[123,182] A few patients have been reported to present with evidence of simultaneous CMV and EBV infection.[181]

Complications

Unusual clinical patterns and serious complications are probably seen in no more than 1% of all patients.[138] Misconceptions about a higher incidence stem from the fact that most of the medical literature concerning IM deals with complications and from impressions of subspecialists who usually do not see patients with uncomplicated disease. The most frequently reported complications are listed in Tables 62.2 and 62.3[190–215].

TABLE 62.2

HEMATOLOGIC COMPLICATIONS OF INFECTIOUS MONONUCLEOSIS[a]

Immune hemolytic anemia
Immune thrombocytopenia
Granulocytopenia
Marrow aplasia
Virus-associated hemophagocytic syndrome
Acquired immune deficiencies

TABLE 62.3

NONHEMATOLOGIC COMPLICATIONS OF INFECTIOUS MONONUCLEOSIS

Splenic Rupture[190–192]
Neurologic complications
Guillain-Barré syndrome[193–195]
Encephalitis[196–199]
Reye syndrome[200]
Meningitis/meningoencephalitis[242,200,201,429]
Cranial nerve palsies[202–204]
Optic neuritis[128]
Peripheral neuropathy[205–209]
Cerebellar ataxia[210,211]
Transverse myelitis[212,213]
Cardiac complications
Electrocardiography changes[129,243]
Pericarditis[214,215]
Myocarditis[80]
Respiratory complications
Acute airway obstruction[244,245]
Pleural effusion[247–249]
Parenchymal changes[246,247,249]
Liver failure[239,250,251,252]
Pancreatitis[253,254]
Renal failure[255]

Hematologic complications are the most common. The incidence of hemolytic anemia may be as high as 3%.[216,217] Hemolysis usually is mild; in approximately 70% of the patients with hemolytic anemia, the reaction to the antiglobulin test (or Coombs test) is positive, and in approximately the same number, the titers of cold agglutinins are increased,[217] usually with anti-i specificity.[218] Occasionally, hemolysis has been attributed to Donath-Landsteiner cold hemolysins.[219,220] In summary, anti-i antibodies are extremely common, but hemolytic anemia is rare.[218,221,222] Sometimes, however, no antibody of any kind is detectable. IM has been associated with accelerated hemolysis in patients with underlying hereditary spherocytosis,[223,224] elliptocytosis,[225] or thalassemia,[226] and in one patient, the onset of paroxysmal nocturnal hemoglobinuria coincided with the development of IM.[227]

Hematologic cytopenias are common. Although mild depression of the platelet count (100 to 140 10^9/L) may be found in perhaps one half of patients with IM,[137] thrombocytopenic purpura is a rare complication that is seen primarily in younger children.[228–230] Thrombocytopenia occurring in acute IM has been attributed to increased destruction by an enlarged spleen or the production of platelet autoantibodies.[231,232] Immune thrombocytopenia preceding the development of severe aplastic anemia has been reported.[233] Mild granulocytopenia is a common finding in patients with IM,[233] but severe granulocytopenia is rare.[233–235] When marrow examination has been performed, myeloid hyperplasia has been noted with increased numbers of promyelocytes, but with depletion of more mature neutrophilic cells.[234,235] This picture is compatible with a proliferative response to an earlier marrow injury or peripheral destruction or increased use of granulocytes. Serious suppression of the entire marrow is rare.[217,236,237] Fatal aplastic anemia has been noted after what appeared to be typical IM[219,238] but is more often related to hemophagocytic reactions (VAHS or EBV–HLH).[239]

One of the most common reported complications is splenic rupture, which has led to death in several cases[190,191] but has been reported to occur with an incidence of 0.1% to 0.2% in North America. Of the 107 cases reported in the world literature up to 1978, only 18 were considered "spontaneous" by one reviewer.[192] The diagnosis of a ruptured spleen should be entertained whenever a patient with IM has severe or even moderate pain below the left costal margin, especially if the pain is accompanied by radiation to the left shoulder and supraclavicular area, or has evidence of impending peripheral vascular collapse. Other signs include those characteristic of peritoneal irritation, abdominal tenderness, and shifting dullness if massive intra-abdominal bleeding has occurred. Frank rupture may be preceded by one or more episodes of subcapsular hemorrhage or minor capsular tears, which may be difficult to differentiate from rupture. Because potentially fatal bleeding may occur at any time, it is recommended that surgical intervention be pursued whenever the typical pain pattern is accompanied by signs of hemodynamic instability.[190,191] Delayed surgical intervention often is attributable to the misconception that abdominal pain is a common feature of the uncomplicated disease. Preservation of splenic function by surgical repair of the capsular tear (splenorrhaphy) or partial splenectomy has been recommended by some but is not generally recommended, as the altered splenic architecture in IM makes it unlikely that such interventions will be successful.[190,191]

Complications of almost all organ systems have been described in association with IM[240] and are listed in Table 62.3. Neurologic manifestations are not infrequent in IM and may occur in 1% to 2% of patients.[193,194,241] When serious neurologic complications occur, the mortality rate may be as high as 8% to 11%,[242] and, in addition, the incidence of serious residual damage may be as high as 12%.[242] Cardiac complications are rare, although electrocardiographic abnormalities may occur in approximately 10% of patients,[129,243] and fatal myocarditis has been reported in association with IM.[80] The most serious respiratory complication is acute airway obstruction, which usually is the result of extreme hyperplasia of the tonsils and other pharyngeal lymphatic tissue.[244,245] Pleural effusion and pulmonary parenchymal changes are exceedingly rare,[246–249] but occasional cases are characterized by extensive interstitial infiltrates (lymphoid interstitial pneumonitis), and severe respiratory insufficiency has been reported.[247] Evidence for some degree of hepatic involvement is found in most patients but is usually mild; the necrosis and inflammatory exudate seen in association with infectious hepatitis are encountered only rarely.[239,250,251,252] Liver failure is rare[239,250] but can be a prominent feature in fatal cases of IM [fulminant infectious mononucleosis (FIM) or EBV–HLH],[250] including those associated with subtle forms of immune deficiency.[250] Acute pancreatitis has been associated with IM.[253,254] An association between IM and irreversible renal failure was postulated in one patient.[255]

Treatment

Most patients experiencing uncomplicated acute IM require only symptomatic therapy. Bed rest is recommended for patients with fever, malaise, and myalgias. Strenuous exercises, especially contact sports, should be avoided for at least 1 month or until resolution of splenomegaly. Nonsteroidal anti-inflammatory drugs, such as acetaminophen or ibuprofen, should be used to control pain, although in patients with severe hepatitis, these agents should be used judiciously. It has been suggested that aspirin may prolong convalescence.[256] Aspirin also interferes with platelet function, potentially increasing the risk of bleeding in thrombocytopenic patients, and Reye syndrome has been reported in association with IM, albeit rarely.[200] Antibiotics are of no value in uncomplicated IM, but many patients show culture or serologic evidence of a recent streptococcal infection,[123] and these should be treated with appropriate antibiotics. Ampicillin and amoxicillin should be avoided because they often cause a severe rash.[123,130,132]

Corticosteroids have been used in cases of life-threatening complications such as airway obstruction, carditis, lymphoid interstitial pneumonitis, pleural effusions, or cerebral edema. Their efficacy is largely anecdotal and is presumably due to their anti-inflammatory and lympholytic properties. The cumulative results of several small, controlled clinical trials suggest that corticosteroids hasten the resolution of fever and tonsillopharyngeal symptoms but do not provide significant benefits in the therapy of lymphadenopathy or hepatosplenomegaly.[15,257,258,259,260] Therefore, caution should be exercised when using corticosteroids.[260] There are reports of encephalitis or myocarditis in association with steroid use in IM,[261,263] and secondary bacterial and fungal infections can occur. However, in the face of severe complications, the use of steroids may well be indicated and necessary.

Several antiviral agents such as acyclovir, ganciclovir, zidovudine, foscarnet, and the interferons (IFNs) have been shown to inhibit the replication of EBV in vitro.[262] Only the linear form of the genome, not the latent circular form, is susceptible to inhibition. The efficacy of acyclovir in the therapy of uncomplicated IM has been assessed in several controlled trials.[263–266] In general, acyclovir reduces viral shedding during the time of therapy, but viral shedding resumed when therapy was discontinued.[15] Clinical trials have documented few clinical benefits as measured by duration of illness and sore throat, weight loss, or absence from school or work, even when acyclovir was given in combination with steroids.[259,266] IFN-α has been used in a few patients experiencing persistent EBV infection with severe complications of interstitial pneumonitis, encephalitis, or genital ulcers, apparently with some success.[267] Patients with IM-associated immune thrombocytopenia have responded to therapy with large doses of intravenously administered γ-globulin.[232] A viral protein vaccine has been developed that protects marmosets from developing LPD[268,269] but not from infection. Several groups are working on the development of EBV vaccines[270,271] Although these vaccines can induce a neutralizing antibody response they do not protect against primary infection or reduce the risk of developing clinical disease, i.e., IM.

Prognosis

Complete recovery occurs within 2 months in the majority of patients. Recurrences of IM are so rare that one must question whether the initial diagnosis or the diagnosis of recurrence is accurate. It is estimated that IM is fatal in as many as 1 in 3,000 cases, or approximately 50 cases annually in the United States.[76,272] Penman,[239] in reviewing the world literature on IM, catalogued 87 fatalities attributed to the disease or its complications. Only 20 of these reports, however, contained adequate evidence for an unequivocal diagnosis. Of these 20 cases, 9 fatalities were related to be due to neurologic complications, 4 were related to respiratory failure from peripheral neuropathy of the Guillain-Barré type, and 5 were related to central respiratory paralysis; 3 were related to splenic rupture; and 3 were related to secondary infection. Other fatal complications included hepatic failure (two cases) and myocarditis (one case). In two cases, the cause of death was unrelated to IM. The majority of deaths associated with IM occur in patients who develop VAHS or EBV–HLH.[76,272]

A recent study has demonstrated that the severity and duration of the illness does not correlate with either control of viremia or rapidity of the antiviral humoral or cellular responses.[273] Therefore, in the nearly 100 years since the first description of IM and the etiologic agent (i.e., Epstein-Barr virus) countless reports of describing the spectrum of potential complications have been published. But despite enormous numbers of studies to define the pathogenesis, it remains a mystery how and why EBV causes the symptoms of IM, and a therapy that reproducibly improves symptoms remains elusive.

OTHER EPSTEIN-BARR VIRUS–RELATED DISEASES

Recently, methods for detecting infectious agents in human disease have become highly developed. Consequently, many ubiquitous infectious agents have been etiologically linked to certain human diseases (e.g., EBV infection has been associated with a wide spectrum of human diseases). Classically, EBV is associated with the development of human malignancies such as BL and NPC. EBV infection has also been associated with other human malignancies, such as NHL (B-cell, T-cell, and NK-cell phenotype), HL, gastric carcinoma, leiomyosarcoma, hepatocellular carcinoma, breast cancer, and LPDs associated with immunodeficiency. In addition, EBV infection has been associated with several nonmalignant, but potentially life-threatening human diseases, such as VAHS or EBV-HLH, and CAEBV, in which development of malignant lymphoma can occur. Also, some have linked EBV infection to chronic illnesses, such as chronic fatigue syndrome and most recently multiple sclerosis. Although association has been demonstrated, it remains controversial whether EBV is causative in these disorders (Table 62.4). The following discussion focuses on diagnosis of and evidence for the role of EBV in the pathogenesis of these diseases.

Chronic Active Epstein-Barr Virus Infection

EBV rarely causes recurrent or persistent symptomatic infections in apparently immunocompetent hosts. Diagnostic criteria for CAEBV have been proposed[274] and consist of (a) evidence of severe, progressive EBV illness beginning as a primary EBV infection and lasting more than 6 months with anti-EBV titers of IgG anti-VCA 1:5120, anti-EA 1:640, or anti-EBNA<1:2, or all three; (b) histologic evidence of major organ involvement; and (c) increased amounts of EBV in peripheral blood or affected tissues, or both. CAEBV is characterized by persistent or recurrent IM-like symptoms, such as recurrent fever, lymphadenopathy, and hepatosplenomegaly, and unusual anti-EBV antibody patterns.[274] CAEBV occurs most commonly in patients who develop IM as older children or young adults.[274–276] This entity may be more prevalent in Asia, as most of the published literature is from Japan. A cohort of 30 patients in Japan diagnosed with CAEBV presented with the following clinical manifestations: Fever (100%), liver dysfunction (90%), splenomegaly (90%), lymphadenopathy (50%), thrombocytopenia (50%), anemia (50%), hypersensitivity to mosquito bites (43%), calcification in the basal ganglia (18%), and oral ulcer (18%).[275] CAEBV can be lethal, with 30 to 50% mortality within 5 years of diagnosis.[28,276] Life-threatening complications include the hemophagocytic syndrome (21%), coronary artery aneurysm (21%), hepatic failure (18%), malignant lymphoma (16%), and interstitial pneumonia (12%).[276] The majority of deaths are due to hemophagocytic syndromes or hematologic malignancies, which may be of T-cell, B-cell, or NK-cell phenotype.[28,274,276]

It is believed that cellular immunologic abnormalities are responsible for the development of CAEBV. In the peripheral blood of patients with CAEBV, high levels of EBV DNA have been found in $CD4^+$ T cells and NK cells, but not in B cells.[277] The significance of this finding in the pathogenesis of CAEBV and the mechanism of infection of these cells remain to be elucidated. This entity may overlap with severe or fulminant IM (FIM or EBV–HLH).[68,274,277] Further studies are needed to differentiate between these enigmatic disorders and to determine the role of EBV infection in their pathogenesis.

A standard treatment approach to CAEBV has not been established. Most reports are anecdotal but include antiviral agents (acyclovir, ganciclovir, and vidarabine) and/or immunomodulating agents (IFN-α or IL-2).[274–276,277–279] Because immunochemotherapy (e.g., etoposide, corticosteroids, and cyclosporin A) has been effective in treating the EBV–hemophagocytic syndrome,[280,281] it has been used to control symptoms and treat hemophagocytic complications.[274] Hematologic malignancies have been treated with standard NHL therapy,[276] but curative therapy for the severely affected patient appears to require the replacement of the patient's immune system with a normally functioning immune system to control the EBV infection, for instance, by an allogeneic stem cell or marrow transplant[275,282] or by allogeneic adoptive T-cell therapy.[283]

CAEBV infections should be differentiated from the so-called chronic mononucleosis, or chronic fatigue syndrome. Due to the similar symptoms and reports of elevated anti-VCA and anti-EA titers, EBV has been suggested to be the etiologic agent in the chronic fatigue syndrome.[284] In controlled studies, no specific EBV serologies have been found that differentiate chronic fatigue syndrome patients from controls.[285] In a randomized, placebo-controlled trial of acyclovir, clinical improvement was seen as frequently with the placebo.[286] Chronic fatigue syndrome has been associated with other infections (viral and bacterial) and, therefore, should not be considered a disease caused by EBV.[285,287]

TABLE 62.4

DISEASES THAT HAVE BEEN ASSOCIATED WITH EPSTEIN-BARR VIRUS

Definite Etiologic Role	Strong Association Etiologic Role Unclear	Controversial Association
Infectious mononucleosis	Burkitt lymphoma	Chronic fatigue syndrome
CAEBV	Nasopharyngeal carcinoma	Multiple sclerosis
EBV–HLH	Lymphoproliferative disease of immunodeficiency	Breast carcinoma
	Leiomyosarcoma of immunodeficiency	
	X-linked lymphoproliferative disease	
	Hodgkin disease	
	Nasal NK-/T-cell lymphoma	
	Gastric carcinoma	

CAEBV, chronic active Epstein-Barr virus infection; EBV, Epstein-Barr virus; HLH, hemophagocytic lymphohistiocytosis; NK, natural killer.

Fulminant Infectious Mononucleosis or Epstein-Barr Virus–Associated Hemophagocytic Lymphohistiocytosis

The self-limited course of IM contrasts with the atypical responses that can occur in FIM, also called *VAHS* or *EBV-associated HLH*.[68] Death occurs in approximately 1 in 3,000 IM cases, or approximately 50 cases annually in the United States.[76,272] The median age at presentation of FIM/EBV-HLH is similar to that of uncomplicated IM (i.e., 13 years of age). Whereas FIM/EBV-HLH is the most common manifestation in males affected with X-linked lymphoproliferative disease (XLP), it often occurs outside the context of XLP.[68,69,272,288,289,290] Outside the context of XLP, the male-to-female ratio is approximately 1:1.[272] VAHS has been associated with CMV, herpes simplex virus, and adenovirus, but EBV is the most common.[68,280] Clinically, FIM/EBV-HLH is indistinguishable from other types of VAHS, familial HLH, and the accelerated phase of Chédiak-Higashi disease or X-linked inhibitor of apoptosis (XIAP) or sometimes referred to as XLP2.[68,69,280,291] Because FIM/EBV-HLH is rare, a search for a heritable immune deficiency in family members is mandatory.

Patients who progress to FIM/EBV-HLH initially present with the usual signs and symptoms of IM, but these symptoms usually rapidly progress in severity.[272] The EBV antibody responses vary considerably from completely lacking to unusually high; therefore, it may be difficult to differentiate FIM/EBV-HLH from other hemophagocytic syndromes, CAEBV, acute leukemia, other malignancies, or even overwhelming sepsis.[68,272] The course and progression of the disease are variable, ranging from multiorgan failure developing over hours to persistent or recurring symptoms of IM lasting for months. An atypical lymphocytosis usually is present at early stages of the disease, but patients subsequently develop severe persistent pancytopenia and/or hepatic dysfunction resulting in fulminant hepatitis and varying degrees of multiorgan failure.[69,272,288,289] The development of hepatic dysfunction, often with coagulation abnormalities secondary to liver failure or disseminated intravascular coagulation, and pancytopenia are ominous signs, as are other signs of hemophagocytic syndromes, such as hypofibrinogenemia and elevated triglyceride levels.[68,69,280,289,292]

As discussed previously, EBV is a potent stimulus to the immune system, resulting in a massive EBV-specific and -nonspecific response of both the humoral and cellular immune systems (Fig. 62.4). In FIM/EBV-HLH, the EBV-nonspecific response, primarily the cellular immune response, is uncontrolled. FIM/EBV-HLH is characterized by extensive infiltration of parenchymal organs by lymphoid cells, primarily $CD8^+$ cells in varying degrees of transformation and histiocytes with surprisingly few B cells.[69,292] The cells infected by EBV in FIM/EBV-HLH are usually T cells[68,277,292] and are generally $CD8^+$, as opposed to the $CD4^+$ or NK cells observed in CAEBV.[277,292]

If this aggressive immune reaction proceeds unabated, all organs ultimately sustain extensive and irreparable damage.[68,69,288,290,292] Early in the course of the disease, the bone marrow may be hypercellular with few infiltrating histiocytes; erythrophagocytosis is seen best in smears of marrow aspirates. The marrow later becomes hypocellular with varying numbers of infiltrating histiocytes.[288,290] Lymph nodes initially show an intense lymphoblastic proliferative response, again primarily T cells, but later, lymphoid depletion supervenes.[69,288,290] Liver biopsies reveal active portal infiltration with lymphocytes and histiocytes, with occasional erythrophagocytosis in liver sinusoids.[250] In the spleen, extensive necrosis of white pulp develops. Perivascular mononuclear cell infiltrates of the brain, mononuclear cell myocarditis, and interstitial nephritis also are observed.[69,272,288,289,290,293,294] The thymus shows thymocyte depletion and necrosis of thymic epithelia.[295] Increased serum levels of IL-2, IFN-γ, L-6, TNF-α, and soluble IL-2 receptors have been demonstrated.[68] The T cells that are activated in response to EBV are believed to be stimulated to produce proinflammatory cytokines (e.g., IL-2, IFN-γ, etc.), and it is believed this activates macrophages, which produce more proinflammatory cytokines, such as IL-6 and TNF-α, culminating in the phagocytosis, tissue destruction, and cellular depletion seen in FIM/EBV-HLH; death usually follows shortly thereafter due to multisystem organ failure.[68]

Once FIM/EBV-HLH develops, therapy is difficult and often unsuccessful, with a median survival time of approximately 4 weeks.[290] Antiviral drugs, Ig supplementation, IL-2, IFN-α, IFN-γ, plasmapheresis, corticosteroids, and most cytotoxic drugs have been ineffective.[68,76] The only therapy that has demonstrated consistent success in the treatment of FIM/EBV-HLH is with the early use of etoposide, which reduces the activity of stimulated macrophages in vitro.[281,296] The best results appear to be obtained with a combination of etoposide and concomitant immunosuppression with corticosteroids and cyclosporin A or tacrolimus (FK506).[281,297] Others have reported using rituximab (anti-CD20 monoclonal antibody) in combination with chemotherapy and immunotherapy.[298] The rationale for this approach is that the reduction of EBV (+) B cells decreases immunogenic stimulus for the abnormal T-cell response. Therapy may have to be continued for 6 to 12 months. These patients are profoundly immunocompromised from their disease and the therapy. Therefore, a successful outcome is dependent on control of FIM/EBV-HLH symptoms as well as the prevention and successful treatment of life-threatening infectious complications. Even with remission of symptoms, recurrences are common and carry a poor prognosis. Curative therapy usually involves replacement of the patient's immune system with a normal immune system by allogeneic stem cell or marrow transplantation.[289,299,300] With the advent of therapy with etoposide and immunomodulation therapy to "quiet" the disease and early intervention with allogeneic stem cell transplantation, the outcome has gone from <5% 1-year survival to approximately 50% 3- to 5-year survival.[300]

Epstein-Barr Virus–Associated Disorders in Immunodeficiency

In the mid-1970s, Purtilo et al. described XLP, in which affected males were thought to have a specific immunodeficiency to EBV, resulting in FIM, malignant lymphoma, hypogammaglobulinemia or agammaglobulinemia, or aplastic anemia.[301] Later, it was noted that patients with ataxia telangiectasia had high antibody titer responses against EBV-replicating antigens, and EBV genome positive malignant lymphomas were observed.[302,303] Similar antibody patterns and EBV-associated B-cell LPD (EBV-LPD) were also reported in patients with Wiskott-Aldrich syndrome.[304] With more efficacious immunosuppression, EBV-LPD was also observed more frequently in recipients of organ and marrow transplants, whereas stopping or decreasing the dose of immunosuppressants sometimes resulted in the regression of EBV-LPD, suggesting that a deficiency of immunosurveillance is responsible for the development of EBV-LPD in such patients.[305] In the late 1980s, an increased incidence of EBV-LPD, including BL, was reported in association with a growing number of patients with AIDS.[306] In recent years, advances in the treatment of patients with immune disorders have resulted in longer survival, and the number of patients at risk of EBV-associated diseases has increased.

In LPD of immunodeficiency, EBV has been identified predominantly in the B-cell phenotypes, but EBV (+) T-cell LPD and HL can also be observed. However, not all LPD of immunodeficiency is EBV-associated. Even in XLP, where affected boys have a very aberrant immune response to EBV infection, many of the NHLs have been found to be EBV-negative.[307,308]

Primary Immunodeficiencies

As mentioned previously, the main immune defense against EBV-driven B-cell proliferation are EBV-CTL. Patients with primary immunodeficiencies often lack T-cell functions, which may manifest as insufficient EBV-CTL activity. Immunodeficiencies primarily affecting B cells or neutrophil function are not at increased risk of EBV-associated disease unless treated with T-cell immunosuppression.[309,310] There are numerous reports of the occurrence of EBV-LPD in patients with a primary immunodeficiency disease (e.g., ataxia telangiectasia, Wiskott-Aldrich syndrome, Chédiak-Higashi syndrome, severe combined immunodeficiency, and common variable immunodeficiency).[307] Type III EBV latency is predominantly seen in these lymphomas,[27,307] suggesting a lack of appropriate EBV-CTL immunosurveillance (see the section, "Immune Response to Epstein-Barr Virus Infection"). In addition, relapses are common but may not represent failure to eradicate the original clone, instead indicating a new clonal proliferation.[311] These data underscore the role of immunosurveillance in the pathogenesis of these malignancies.

The treatment is often difficult because of the underlying serious immunodeficiency and/or genetic susceptibility to

chemotherapeutic agents. Antiviral therapy has had little effect in the treatment of EBV-LPD associated with immunodeficiency.[309,310,312] Although complete remissions can be achieved with chemotherapy, immunodeficient patients with NHL have a far inferior outcome compared to those expected for immunocompetent children with NHL receiving similar therapy.[310,313,314] These poor results are due to increased toxicity of chemotherapy, especially in defects of DNA repair such as ataxia telangiectasia patients, but infection-related deaths are also greatly increased compared to immunocompetent patients. Because recurrences can be of different clonal origin, successful treatment depends on controlling B-cell proliferation by developing appropriate EBV-CTL immunity. In the majority of cases, the only way to achieve this is allogeneic bone marrow transplantation (BMT).[300,309,310,315]

X-Linked Lymphoproliferative Disease

In 1974, there were two reports of maternally related boys dying of IM.[316,317] In 1975, Purtilo et al. described a kindred in which 6 of 18 boys died of an LPD associated with EBV infection.[317] XLP has also been called *Duncan disease*, after the original kindred, or *Purtilo disease*. XLP is a rare disorder, affecting an estimated 1 out of a million male individuals.[289] Initially, three phenotypes were described in XLP patients, and these continue to characterize the majority of patients: FIM (or EBV-HLH), malignant lymphoma (LPD), and dysgammaglobulinemia.[317] Less commonly reported manifestations include disorders such as vasculitis, pulmonary lymphomatoid granulomatosis, and hematologic cytopenias, including aplastic anemia and pure red cell aplasia.[289,308] The "disease state" is capricious, as it may feature a single phenotype or two or more phenotypes, which may develop sequentially in susceptible individuals.[289,308]

Reflecting on the ubiquitous nature of EBV infection, FIM is the most common XLP phenotype, affecting approximately 50% of patients.[289,308] FIM is decidedly the most lethal of the XLP phenotypes; historically, most of the boys died within 1 month and historically only 7% of FIM patients survived.[308] Treatment should be the same as for FIM or EBV–HLH as discussed previously. The median age of onset for XLP-associated FIM is 5 years of age, but the condition has occurred up to 40 years of age. The pathology and clinical findings of FIM associated with XLP are identical to those seen in patients with EBV-HLH but without XLP, and have been discussed previously. It is interesting that over a third of XLP patients with evidence of current or prior EBV infection never develop FIM.[308]

Dysgammaglobulinemia is the second most common XLP phenotype, affecting approximately one fourth of boys.[289,308] Most boys manifesting this phenotype demonstrate global decreases of serum Ig levels. However, some have featured increased levels of IgM or IgA, or both, as well as variable deficiencies in IgG1 and IgG3 subclasses.[318] Although hypogammaglobulinemia often occurs after EBV infection, some XLP patients develop hypogammaglobulinemia without prior evidence of EBV infection.[308] Mice with the XLP gene "knockout" can manifest progressive hypogammaglobulinemia and abnormalities in Ig switching.[319] The pathogenesis of dysgammaglobulinemia in XLP has not been delineated, but appears to be due to a defect in T-cell help and affects B-cell memory.

An LPD develops in approximately one fourth of XLP patients.[289,308] Most lymphomas are of B-cell phenotype and are characterized by Burkitt or diffuse large-cell histology.[69,320] Karyotypic analysis has not been extensively performed; however, the t(8;14) associated with classic BL is rare.[321,322] Approximately 10% of LPD are not of B-cell phenotype, including a small number of patients with HL or T-cell LPD.[69] As in other immunodeficiencies, the role of EBV in the LPD of XLP is unclear, inasmuch as approximately one half of the boys with LPD have had no evidence of prior EBV infection, and EBV is detectable in only 25% of tumor specimens.[308]

Distinct from the marrow depletion seen with FIM, a limited number (4%) of boys have developed isolated hematologic cytopenias.[289,308] Most manifest with suppression of two or more hematologic cell lines, although aplastic anemia and pure red cell aplasia have been observed.

Initially, it was thought that males affected with XLP only manifested symptoms after primary EBV infection. Although IM is, by definition, caused by EBV, other XLP phenotypes develop in EBV-seronegative patients.[308] About 10% of affected boys will manifest symptoms of XLP before exposure to EBV.[289,308] There is no difference in the age of onset of clinical symptoms between males who have or have not been previously exposed to EBV.[308] Therefore, prevention of EBV infection in boys with XLP does not avert clinical manifestations. In addition, whereas approximately 60% of the boys develop FIM after primary infection with EBV, others develop LPD, dysgammaglobulinemia, and hematologic cytopenias, and a few have no symptoms at all.[308] These data suggest that the genetic defect in XLP is more global and not EBV-specific as once thought. There must be other genetic and/or environmental factors that influence the host susceptibility to EBV and are important in determining the clinical phenotype of XLP.

Now, the diagnosis can be made easily by identifying a mutated *SH2D1A* gene[308,323,324,325] or lack of the corresponding SLAM-associated protein (SAP) protein expression.[326] Female carriers on average express SAP on only 50% of their lymphocytes, due to random X-chromosome inactivation,[327] but do not develop overt clinical manifestations of XLP. Molecular analysis should be pursued in females at risk of being a carrier to provide accurate genetic counseling. Spontaneous mutations in *SH2D1A* in affected males where mothers do not have mutations have been reported.[328]

One might predict that mutations that delete the XLP gene or truncate the protein would be more likely to be associated with a severe phenotype, whereas missense mutations would occur preferentially in mildly affected patients. Attempts to correlate mutations of the *SH2D1A* gene and the clinical manifestations of XLP found that it was not uncommon to observe different phenotypes and severities with identical mutations, even within the same family.[308] No significant differences were observed in the phenotypes or severity of disease based on the type (missense, nonsense, truncating) or localization of *SH2D1A* mutations. The age of onset of clinical manifestations of XLP varied considerably, from younger than 1 to 40 years of age, as did survival, but there was no correlation with the type of mutation. Therefore, genetic analysis does not predict the phenotype or severity of disease.[308]

The *SH2D1A* gene codes for a protein of 128 amino acid residues that consists of an SH2 domain and a 25-amino acid C-terminal tail.[323,324] *SH2D1A* is expressed throughout thymocyte development, as well as in $CD4^+$ and $CD8^+$ peripheral T cells, NK and NKT cells, but not on B cells.[291,325] SAP appears to function in the regulation of immune response by interacting with. several proteins, including SLAM (signaling lymphocyte activating protein; CD150), also called SAP.[324] SAP also has been demonstrated to interact with members of the CD2 superfamily of molecules, including CD2, CD48, CD583, CD84, Ly-9, and 2B4, and with a new family of RasGAP adapter proteins such as p62Dok (Dok [downstream of kinases]-1), p56Dok (Dok-2), and Dok-3.[329–332] The immunologic effects of SAP interactions with these proteins are under investigation but appear to be very important in NKT cell development and terminal B-cell differentiation.[291]

Mice genetically deficient in *Sh2d1a* (the murine homolog) expression have been generated.[333] Consistent with human XLP, mutant animals are viable and fertile, transmit the gene defect in an X-linked Mendelian fashion, and display no significant defects in the number and phenotype of developing thymocytes or circulating T, B, or NK cells. After infection with lymphocytic

choriomeningitis virus, *Sh2d1a*-deficient mice recapitulate important aspects of the human disease. For example, these mice exhibit abnormal lymphocyte responses to a virus resulting in a large $CD8^+$ cytotoxic T-cell response that is fatal to the mice.[333] As mentioned previously, these mice also have defects in humoral responses and develop hypogammaglobulinemia over time.[322,333]

XLP is highly lethal, with historically 75% of patients dying by 10 years of age, although the oldest known survivor with XLP is over 50 years of age and has not required allogeneic transplantation.[289,308] Antiviral therapies, including acyclovir, ganciclovir, intravenous Ig, and IFN-α, have been used to treat primary EBV infection; none has been particularly effective.[309,334] The only therapy that has been consistently beneficial for males with FIM is etoposide and immunosuppression, as discussed previously.[68,297,308] Several affected males have been treated successfully with anti-CD20 (rituximab) following primary infection with EBV but before they develop all the clinical signs and symptoms of FIM or EBV-HLH.[288] With FIM or EBV-HLH, even with remissions, relapses are invariable. Therefore, an allogeneic BMT is recommended once the patient's condition is stabilized and a suitable donor has been identified.[309–311,315] As with EBV-HLH not associated with XLP, the outcome has improved from a <10% 1-year survival to perhaps half of the boys with FIM surviving with the early initiation of etoposide, immunosuppression, and allogeneic stem cell transplantation.[300,315] Patients with hypogammaglobulinemia require regular Ig supplementation to prevent bacterial and viral infections. However, Ig infusions do not offer the guarantee of protection from primary EBV infection in an EBV-seronegative patient.[308] For patients with lymphoma or hematologic cytopenias, standard therapeutic protocols suffice. Although treatment can induce disease remissions, relapses and other XLP phenotypes invariably occur, and allogeneic BMT is recommended.[309,310,311,312,313,314,315] With definitive diagnosis by genetic mutational analysis, BMT now can be performed before the appearance of clinical manifestations of the disease[315,335] and is recommended to prevent the life-threatening complications of the disease.

In 2006, another X-linked disorder that was characterized by EBV-HLH was described to be caused by deficiency in the *BIRC4* gene.[336,337] Of note, *BIRC4* resides in close proximity to the *SH2D1A* gene. Further studies demonstrated that these patients have defects in their antiapoptotic functions and the disorder has been named deficiency of the XIAP. Because XIAP patients frequently have problems with EBV-HLH, XIAP has also been called XLP2. However, unlike SAP which is limited to T, NK and NKT cells, XIAP is widely expressed on human tissue.[291] As the name suggests, the XIAP function is to inhibit apoptosis; therefore deficiency leads to increased sensitivity to apoptosis and hypogammaglobulinemia is observed in XIAP paitents.[291] The immune mechanism for susceptibility to complications of EBV infection, including EBV-HLH is unclear, but XIAP patients do not have an increased incidence of lymphoma.[291] Therefore, it is best to differentiate XLP and XIAP as distinct clinical entities.

Secondary Immunodeficiencies

It is well recognized that patients infected with HIV, as well as transplant recipients, are at increased risk of developing LPD that are often associated with EBV. Rarely, elderly patients, malnourished patients, and those with cancer develop EBV-associated atypical lymphoproliferation.[69,312] Indeed, the World Health Organization (WHO) now recognizes a EBV-positive diffuse large B-cell lymphoma as a distinct entity.[338] EBV-induced LPD have been reported in patients without severe immunodeficiency (e.g., individuals who received methotrexate as treatment for rheumatoid arthritis).[339] Therefore, a high index of suspicion is warranted in any patient who may be immunosuppressed.

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

EBV has been found in several diseases associated with HIV infection, including oral hairy leukoplakia,[340,341] leiomyosarcoma,[33] and NHL.[342] Oral hairy leukoplakia is characterized by white raised plaques on the lateral surfaces of the tongue. EBV has been found in the lesions of oral hairy leukoplakia in HIV patients,[342,343] and these lesions have been reported to respond well to therapy with acyclovir.[343] The EBV-associated leiomyomas and leiomyosarcomas account for 3% to 15% of all cancers in HIV-infected children.[344,345] For reasons that are not clear, leiomyomas and leiomyosarcomas do not appear to be increased in HIV-infected adults. Tumors can be found in the lung, brain, adrenal glands, and spleen.[33,346—348,349,350] How EBV gains access to smooth muscle cells and its pathogenic role in tumorigenesis remains unclear. The clinical course is highly variable, but aggressive treatment with highly active antiretroviral therapy (HAART) and primary excision of tumors, if feasible, are recommended in all patients, but chemotherapy and/or radiation are often required.

The clinical spectrum of HIV-related NHL typically includes systemic NHL, primary central nervous system (CNS) NHL, and pleural effusion lymphoma (PEL). Although EBV is detected in essentially all the primary CNS NHL[349] and most PEL,[350] only approximately 50% to 60% of systemic HIV-related NHL have detectable EBV.[351] PEL is not typically associated with solid masses and is associated with HHV8, but most also have EBV present in tumor cells.[350] The relative contribution of HHV8 and EBV in the pathogenesis of PEL is unclear. Following the introduction of HAART into clinical practice in the 1990s, there has been a dramatic effect on the incidence of AIDS-defining diseases. In the HAART era, there has been a decrease in primary CNS NHL and systemic diffuse large B-cell lymphoma; however, the incidence of BL has appeared to be unchanged.[352,353,354] The outcome for patients with HIV and NHL has improved dramatically. There are some overlapping toxicities from HAART and cytotoxic agents; however, with the concurrent use of HAART and aggressive supportive care, HIV patients can now tolerate standard therapies for NHL with similar outcomes.[355]

Post-transplant Lymphoproliferative Disease

Figures 62.3 and 62.4 illustrate the importance of a qualitatively and quantitatively appropriate T-cell response in maintaining homeostasis and preventing EBV-driven B-cell proliferation. Therefore, with chronic immunosuppressive therapy following the transfer of EBV-infected B cells via blood, marrow, or organ grafts, complications due to EBV are frequently seen in transplant patients.

Post-transplant lymphoproliferative disease (PTLD) represents a spectrum of clinical and morphologic heterogeneous lymphoid proliferations.[69,309,356–360] EBV LPD post-transplant may manifest as isolated hepatitis, lymphoid interstitial pneumonitis, or meningoencephalitis, or as an IM-like syndrome with peripheral adenopathy, fever, or hepatitis, or all three. Frequently, the definition of PTLD is limited to lymphomatous lesions (localized or diffuse) that are often extranodal (often in the allograft). Although less frequent, the most fulminant presentation of PTLD is a disseminated systemic disease that clinically resembles septic shock and histologically resembles FIM.

Histologically, EBV disease is quite heterogeneous as well. There have been several histologic classifications for PTLD over the years,[356–358,360] but the WHO has now proposed a classification, which includes (a) *early lesions* not considered PTLD and that are polymorphic hyperplasia, without disruption of the normal tissue architecture and often accompanied by more classic clinical signs and symptoms of IM; (b) *polymorphic PTLD*, where T-cell infiltration and disruption of normal tissue architecture are observed; and (c) *monomorphic PTLD,* which resembles

intermediate- to high-grade NHL and tissue necrosis is more frequent[338] Distinguishing between a polyclonal and a monoclonal PTLD can be difficult as up to 50% of PTLDs do not express surface Ig.[69,338] Cytogenetic abnormalities are rare in PTLD, even with Burkitt histology, and abnormalities in genes observed in NHL (i.e., c-myc; N-, H-, and K-ras; p53; and bcl-2, etc.) are rare in PTLD.[338,358,361]

The diagnosis of PTLD should be made by biopsy and evaluated by in situ hybridization with EBER probes or immunohistochemical staining for LMP-1, although LMP-1 staining is not as sensitive as EBER staining.[362] PTLD must be distinguished from the increased background number of EBV-positive cells in lymphoid tissue in the post-transplant patient, where up to 10 EBER-positive cells per high powered field (hpf) can be observed without PTLD compared to the nontransplant patient where 0 to 1 cell/hpf is normal.[363] Perhaps the greatest difficulty in making the diagnosis of PTLD occurs in the proliferations that do not produce a mass lesion but have disseminated or infiltrative disease in solid organs. The diagnosis can sometimes be suspected upon examination of the peripheral blood, bone marrow, CSF, or other body fluids for the presence of plasmacytoid cells or large B cells. This type of PTLD is often first discovered at autopsy, with pre-mortem diagnosis being sepsis or graft-versus-host disease (GVHD).[364,365]

The majority of PTLD is CD20+,[70,369] but not all PTLD is of B-cell phenotype and not all are EBV positive. T-cell PTLD tends to occur late, often more than 10 years after transplantation.[366] PTLD with HL phenotype can also occur but tends to occur later (i.e., >4 years post-transplant) and is generally EBV positive.[367] The validity of the Hodgkin phenotype of PTLD has been questioned and it has been suggested that it may be a variant of polymorphic B-cell PTLD.[368] The diagnosis of HL in the post-transplant patient should be reserved for disease where the RS cells are CD45(–) and/or CD15 (+).[368] The reason for the long latency in non–B-cell PTLD is unknown, but probably reflects a lesser role for EBV and/or deficient immunosurveillance in the pathogenesis.

More than 90% of early (<1 year post-transplant) PTLD is EBV positive, when EBV-CTL immunity is lowest,[365,369,370] whereas late (>2 years post-transplant) PTLD are frequently EBV negative, can be of T-cell origin, and may have a poorer prognosis.[366,371—373,374] The etiology of EBV-negative PTLD is not known, and no other virus has been identified as an etiologic agent. These late PTLD may be a different disease and appear more akin to LPD observed in other immunodeficient states (e.g., AIDS and primary immunodeficiencies), in which B-cell origin and EBV association are not universal.[372]

The risk factors for PTLD are well described and in general include anything that favors B-cell proliferation and/or suppresses T-cell activity. The reported incidence of PTLD ranges from 1% to 5% in low-risk procedures (e.g., renal, heart, liver, and non–T-cell-depleted bone marrow transplants) to >10% in the high-risk procedures (e.g., lung, small bowel, and T-cell–depleted bone marrow transplants).[365,369,374] In children receiving a solid organ transplant, the effect of the type of allograft appears to be much less. This is likely due to the fact that age and EBV-seronegativity at the time of transplant are very strong risk factors.[375,376]

Successful treatment of PTLD necessitates controlling the B-cell proliferation and facilitating the development of an appropriate memory cytotoxic T-cell (EBV-CTL) response to maintain an asymptomatic state of viral latency (Figs. 62.3 and 62.4). Additional factors that contribute to the difficulty of treating these patients include increased toxicity from therapy, secondary infections, and the increased risk of organ rejection or GVHD due to the enhancement of alloreactive T-cell immunity. Surgery, radiotherapy, or both are effective in curing localized disease, but this benefits only a small percentage of patients.[309,312] The use of antiviral agents such as acyclovir or ganciclovir and/or intravenous Ig may reduce viral replication and thereby limit the number of infected B cells and may be useful in prophylaxis or preemptive therapy.[312,374,375,376,377,378] The efficacy of antiviral drugs in treating PTLD is controversial because they are seldom used without other interventions (e.g., reduction of immunosuppression); in addition, if viral replication, which is lytic to the infected B cells, is suppressed, B-cell proliferation could theoretically be enhanced.

The approach most widely used as initial therapy for PTLD is reduction of immunosuppression.[312,374] In some cases, this is sufficient for controlling the disease, especially in localized polymorphic cases or cases that present like IM. As opposed to PTLD after solid organ transplantation, reduction of immune suppression is rarely successful following BMT, because the major immunosuppression after BMT is from delayed EBV-CTL recovery, not suppression of EBV-CTL function. Patients who do not tolerate reduction of immunosuppression because of graft rejection or GVHD, or who do not respond to immunosuppression reduction, require more aggressive therapy and have a much poorer prognosis.[309,312,374]

Anti–B-cell monoclonal antibodies have been used successfully, including anti-CD21 and anti-CD23[379] and, more recently, anti-CD20.[380,381] Chemotherapy has also been used successfully for PTLD.[382,383] Chemotherapy is attractive because it kills proliferating B cells and is immunosuppressive enough to treat or prevent GVHD or organ rejection.[382,384] However, at conventional doses used in the treatment of NHL, post-transplant patients have more end-organ toxicity and susceptibility to infection, with as many as 35% of patients dying of toxicity caused by the therapy.[383] A low-dose chemotherapy approach has been shown to be at least as effective in treating PTLD in children following organ transplant with little toxicity.[384]

Because the problem in most cases of PTLD is an inadequate number of EBV-CTL,[370,385] replacement of EBV-CTL is a logical therapeutic intervention. Infusion of donor lymphocytes has been demonstrated to be successful in the treatment of PTLD post-BMT.[386] To avoid the GVHD and other associated toxicities with infusion of donor lymphocytes, ex vivo–generated EBV-specific CTL have been shown to be effective in treating and preventing PTLD post-BMT.[387] The ex vivo generation of EBV-specific CTL takes several weeks[387,388,389] and requires a high level of technology and cost. Therefore, due to the cost and regulatory oversight necessary to generate and administer the in vitro–generated EBV-CTL, this approach is not feasible for most centers. The use of adoptive T-cell therapy in an organ transplant recipient is more complex. First, cadaver organs are most widely used; therefore, donor lymphocytes are often not available. Second, as opposed to BMT, after organ transplant, the PTLD cells are usually of recipient origin, so the immunologic recognition, specificity, and efficacy of donor lymphocytes are uncertain. Third, the use of closely matched relatives' lymphocytes runs the risk of both rejection and GVHD. It has been shown that in organ transplant patients EBV-specific CTL can be given safely, and when given prophylactically no PTLD developed.[389] However, despite detection of an increased number of EBV-specific CTL, EBV DNA levels in the peripheral blood decreased very little and the infused cells persisted only 2 to 6 months.[389] EBV-specific CTL have been used to treat PTLD successfully following organ transplant, but again multiple infusions were required as the adoptively transferred EBV-specific CTL did not last.[388] Although a logical and exciting therapeutic strategy, at present adoptive cellular therapy is not available for the majority of patients with PTLD.

Epstein-Barr Virus–Associated Malignancies

Burkitt Lymphoma

The neoplastic cells in BL have a mature germinal center B-cell phenotype as demonstrated by the expression of B-cell–associated

antigens (CD19, 20, and 21) and the presence of surface Ig.[9] Approximately 95% of endemic African BL are EBV positive, as compared with 20% of sporadic BL occurring mainly in Europe and North America.[9,20,390] Regardless of EBV status, BL is characterized by specific chromosomal translocations that involve chromosomes 8 and 14 (t[8;14]) in 70% of cases, or 8 and 22 (t[8;22]) and 8 and 2 (t[8;2]) in the remaining cases.[390,391,392,393] As a result, the *MYC* oncogene becomes juxtaposed to one of the Ig gene loci (i.e., chromosome 14 [heavy chain], chromosome 22 [λ-light chain], or chromosome 2 [κ-light chain]) and is constitutively expressed.[391,392,393]

The role of EBV in the pathogenesis of BL remains to be fully defined. It has been hypothesized that chronic B-cell stimulation by EBV, HIV, and/or malaria[6,390,393] plays a key role by enhancing the chances of a *MYC* translocation.[6,390,393] The very restricted EBV viral gene expression of type I latency EBV gene expression (i.e., EBNA-1 and the EBERs only) seen in EBV-positive BL makes it difficult to explain the role of EBV in transformation of BL.[13,53,394,395] In vitro systems have demonstrated that latency III viral gene expression is incompatible with high *c-myc* expression and maintenance of BL cells,[396] and that EBV gene expression, although not promoting cellular proliferation, inhibits apoptosis in *MYC*-expressing BL cells.[397]

Nasopharyngeal Carcinoma

NPC is another important EBV-associated malignant disorder. This tumor is mainly observed in Southeast Asia, Southern China, and a few other limited regions of the world.[9] In these areas, NPC is one of the most frequent malignancies observed. A genetic predisposition appears to be a major factor in the development of this epithelial malignancy. The first generation of southern Chinese immigrants to the United States has an incidence of NPC that is approximately one half that of native Chinese, suggesting that both genetic and environmental factors contribute to the development of NPC.[398] The evidence linking EBV to NPC is more compelling than with BL, with essentially all cases being EBV positive.[399] The etiologic link between NPC and EBV was first suggested by serologic evidence, especially with anti-IgA antibodies directed against EA, present in high titers in NPC patients as compared with matched controls, IM patients, and BL patients.[9,400,401] In fact, prospective screening for these IgA antibodies or quantitative PCR of EBV DNA in the serum has been useful in detecting preclinical NPC and in anticipating recurrences after therapy.[402,403]

Despite the universal association of EBV with NPC, the role EBV plays in the pathogenesis is unclear. The finding of monoclonal EBV found in precancerous lesions of NPC is noteworthy, as it suggests EBV infection takes place early in the pathogenesis and is essential in the development of NPC.[404,406] However, all attempts to transform nasopharyngeal epithelium with EBV in vitro have failed. As stated before, NPC tumor cells demonstrate type II viral latency gene expression (i.e., EBERs, EBNA-1, LMP-1 and LMP-2, and BARF1).[399] It is hypothesized that because LMP-1 and BARF1 have effects on expression of cellular genes associated with proliferation, they are important in the pathogenesis of NPC.[399,405,406] Other studies have identified genetic defects with presumed inactivation of tumor suppressor genes on chromosomes 3p, 9p, and 14q.[407] For some time, environmental factors such as exposure to toxins contained in traditional Chinese medicines, including *Euphorbia* plant extracts, which induce EBV replication, and the ingestion of nitrosamines or other oncogenic substances in salted fish, have also been felt to play an important role in the development of NPC.[9]

Hodgkin Lymphoma

A pathologic link between EBV and HL has been suspected for some time on the basis of serologic studies that demonstrated unusually high titers of antibodies to VCA and EA, as well as the observation that individuals with high antibody titers to EBV have an increased risk of developing HL.[408,409,410] The presence of EBV has been demonstrated conclusively within the RS cells and their mononuclear variants in 40% to 50% of HL specimens.[28,144–146] The virus appears to be monoclonal in any given individual, suggesting that infection occurred before the clonal expansion of RS cells.[144,411] EBV positivity is most frequent in mixed cellularity histology, followed by nodular sclerosing, whereas lymphocyte-predominant and lymphocyte-depleted types are usually negative.[412] Again, as in NPC, the viral gene expression is latency type II.[53,145,413]

What role EBV plays in HL also remains undetermined. A large epidemiologic study demonstrated that individuals who developed signs and symptoms of IM following primary infection had a 1 in a 1,000 chance of developing HL. This risk is small, but it was found to be statistically significant compared to the general population and to individuals who did not develop IM following primary infection.[414] In addition, the increased risk was only for developing EBV-positive HL.[414] It has recently been shown that in individuals who develop IM following primary EBV, a persistent deficit in their T cells to respond to IL-15 in vitro is prevalent, although this deficit was not found in individuals who did not develop IM following primary EBV infection.[415] LMP expression in RS cells occurs at very high levels,[416] which usually are immunogenic. It is hypothesized that individuals with IM have a lessened ability in immunosurveillance for EBV-induced lymphoproliferation, and this explains the increased incidence of EBV-positive HL in IM patients.[415] Inasmuch as only 1 in 1,000 individuals with IM ever develops HL, there must be other co-factors important in the pathogenesis.

T-cell Lymphoma

EBV genome-positive T-cell lymphoma was first described unexpectedly in three patients who had extraordinarily high IgG antibody titers to EBV-VCA and EBV-EA.[417] After this report, EBV genome-positive peripheral T-cell lymphoma had been increasingly reported mainly in Asian populations.[426] Type II latency is predominantly shown in these malignancies.[53] The mechanism of EBV infection into human T cells still remains to be elucidated. CD21 expression has been reported on some T-cell lines[418,419]; however, in vitro experiments have failed to demonstrate continuous presence of EBV in such T-cell lines. Variable clinical manifestations are observed in patients with T-cell lymphoma. This may be in part due to cytokine production and cytotoxic functions that can be observed in these tumor cells. It is interesting that this type of lymphoma is often associated with severe CAEBV.[274,276] These malignancies are highly resistant to the standard therapies and the outcome is very poor despite aggressive therapy including transplantation.

Natural Killer–Cell Lymphoma/Leukemia

Patients with EBV genome-positive, $CD3^-$ NK-cell proliferations were initially reported by Japanese investigators.[420] Type II latency is predominant in these malignancies as well.[23] NK-cell lymphoma/leukemia has often been associated with mosquito bite sensitivity[421] and CAEBV (see discussion in the section, "Chronic Active Epstein-Barr Virus Infection"). Midline granuloma, which is predominantly of T-/NK-cell origin, was first reported in Asia,[422] but now cases in North America and Europe have been shown to be EBV genome positive, with monoclonal viral episomes detected in virtually all tumor cells. In general, these malignancies have the same poor prognosis as EBV-positive T-cell malignancies.

Gastric Carcinoma

Gastric carcinoma is a leading cause of death due to cancer in Japan. Shibata and Weiss initially reported the presence of the EBV genome by in situ hybridization.[29] The incidence

of the EBV genome in gastric carcinoma is 2% to 16% worldwide.[29,423,424,425] The viral gene expression pattern is unique. All EBV-positive gastric carcinomas express EBERs, EBNA-1, and BARF1 (BART) consistent with type I latency. However, some tumors express LMP-2A and/or lytic genes such as BZLF1 (ZEBRA protein).[426]

Miscellaneous Epstein-Barr Virus–Associated Human Disease

There are anecdotal reports of numerous human diseases that have been associated with EBV or that EBV DNA has been detected in pathologic tissues. The association of EBV to leiomyoma/leiomyosarcomas in immunodeficient children is strong, but the role in their pathogenesis is far from being understood.[32,33] Reports of EBV being detected in other malignancies include hepatocellular carcinoma,[30] lymphoepithelial carcinomas of the salivary glands, tonsillar carcinoma, parotid gland carcinoma, and thymoma (reviewed in Ref. 76). EBV has been found in breast carcinoma,[31] but epidemiology studies have failed to demonstrate an association.[427] One of the more intriguing associations is with multiple sclerosis (MS). There have been several epidemiology studies attempting to determine whether there is a link between the development of IM followed by MS. Published results are conflicting, but a recent meta-analysis suggested that an association does exist.[428] Because EBV is so ubiquitous in the human population, associations of disease with EBV must be interpreted with caution.

CHAPTER 63

PRIMARY IMMUNODEFICIENCY SYNDROMES

Troy R. Torgerson

INTRODUCTION

The primary immunodeficiency disease (PIDD) are a group of clinical syndromes originally described in patients with marked susceptibility to particular types of infections. This group of disorders has now expanded to include more than 150 clinically defined entities that span the full spectrum of immune dysfunction ranging from virtually absent immune responses to overwhelming uncontrolled autoimmunity.[1] In this "genomic era" we have come to understand that the majority of immunodeficiency disorders are caused by defects in single genes. There are now approximately 200 known single gene defects associated with immune deficiency. It has also become evident that mutations in different genes can lead to a similar clinical phenotype. For example, defects in more than 20 different genes have now been associated with a clinical phenotype of severe combined immune deficiency (SCID).[2] This has led to an explosion in our understanding of the role of specific molecular pathways in the human immune system but has created some confusion when discussing the clinical syndromes themselves. Consequently, it has become the practice to refer to disorders by their molecular defect, either in combination with, or in lieu of, their clinical name or eponym (i.e., "ADA-deficiency" or "ADA-SCID" rather than "SCID"). This practice is followed here.

MAJOR COMPARTMENTS OF THE IMMUNE SYSTEM

To provide a framework for this overview of immunodeficiency, it is worthwhile to divide the immune system into four major compartments: complement, phagocytes, B cells and antibodies, and T cells. The complement and phagocyte compartments are part of the "innate" arm of the immune system, whereas the B-cell and T-cell compartments are components of the "adaptive" arm of the immune system (see Table 63.1). Many immunodeficiency disorders are caused by a defect in only one compartment of the immune system, whereas others are "combined" immunodeficiencies with defects in multiple compartments. In general, defects in each compartment of the immune system are associated with susceptibilities to particular types of infections. In addition, each specific immunodeficiency typically has unique features that differentiate it from other immunodeficiencies, often making it possible to identify the disorders based on clinical and laboratory findings (see Table 63.1).

COMPLEMENT

The complement system consists of a series of proteins that are present in the plasma and become activated upon encountering pathogens. Activation of early complement components initiates a cascade of protein cleavage and activation events that ultimately leads to formation of the membrane attack complex (MAC) consisting of complement proteins C5, 6, 7, 8, and 9. A number of regulatory proteins including Factor H, Factor I, and membrane cofactor protein (MCP) control complement activation at the level of C3, thereby preventing inappropriate complement fixation. The complement cascade is activated via three major mechanisms: (1) the classical pathway, which is initiated by antigen/antibody complexes; (2) the alternative pathway, which is initiated directly by bacterial cell wall components; and (3) the lectin pathway, which is initiated by carbohydrate moieties present on bacteria.

Complement deficiencies make up only a small portion (~2%) of all primary immune deficiencies.[3] Defective activation of the entire complement cascade can be caused by the absence or dysfunction of only 1 of more than 20 complement proteins. The proteins most often affected are C2, C3, and C4.[4]

Clinical Presentation

Patients with defects in the C1 esterase inhibitor have hereditary angioedema (HAE) in which allergic or mechanical stimuli can trigger massive, localized, severe attacks of edema that can be life-threatening if they involve the airway. Patients with deficiency of early complement components in the classical pathway (C1–C4) typically present with symptoms of autoimmunity (lupus or glomerulonephritis) or with recurrent invasive infections caused by encapsulated organisms (particularly *Streptococcus pneumoniae*). Patients with defects in the late complement components (C5–C9) that are involved in formation of the membrane attack complex typically present with recurrent or severe Neisserial infections.[4] Patients with defects in complement regulatory proteins (Factor I, Factor H, and MCP) are at risk of developing familial hemolytic uremic syndrome and age-related macular degeneration (see Fig. 63.1).[5–7]

TABLE 63.1

COMMON SYMPTOMS ASSOCIATED WITH DEFECTS IN EACH OF THE FOUR MAJOR IMMUNE COMPARTMENTS

Complement	Phagocytes	B Cells/Antibodies	T Cells
• Invasive infections with encapsulated bacteria (*S. pneumoniae, H. influenzae*, etc.) • Recurrent, invasive *Neisserial* infections • Hereditary angioedema • Autoimmunity (lupus, glomerulonephritis) • Familial hemolytic uremic syndrome (HUS)	• Skin and soft tissue abscesses, boils, and lymphadenitis • Infections with Catalase$^+$ organisms (*S. aureus*, Serratia, Aspergillus, etc.) • Poor wound healing • Chronic gingivitis and periodontal disease • Mucosal ulcerations, colitis • Delayed separation of the umbilical cord/omphalitis	• Recurrent bacterial sinopulmonary infections • Unexplained bronchiectasis • Chronic or recurrent gastroenteritis (giardia, cryptosporidium, enterovirus, etc.) • Echovirus encephalomyelitis	• *Pneumocystis jiroveci* pneumonia • Recurrent, severe, or unusual viral infections (CMV, EBV, adenovirus, papillomavirus, etc.) • Invasive fungal or mycobacterial infections • GVHD (rash, abnormal LFTs, chronic diarrhea) • Failure to thrive

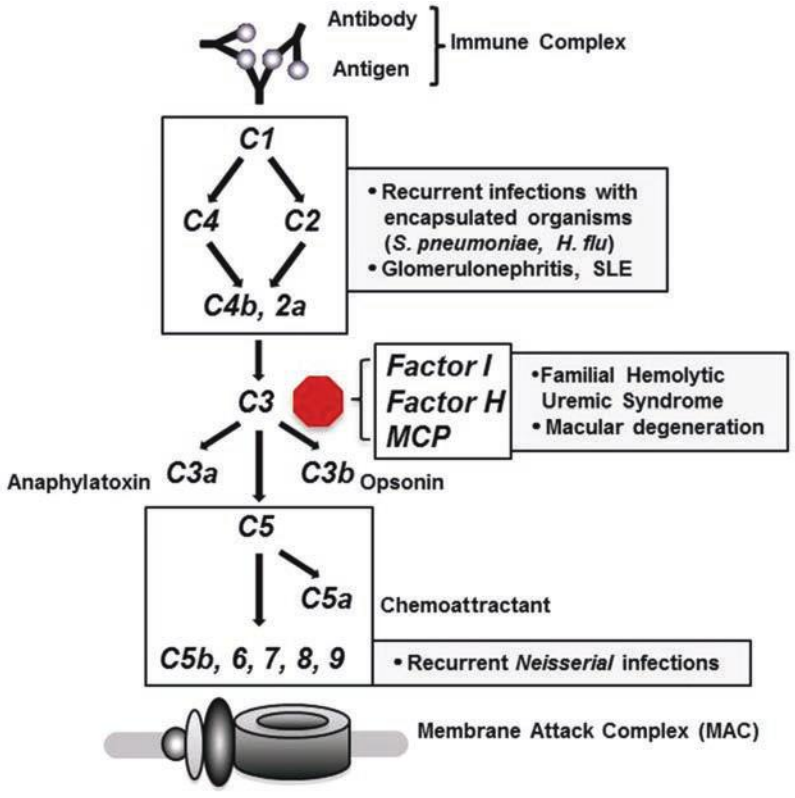

FIGURE 63.1. The classical complement pathway showing activation by immune complexes and ultimate formation of the membrane attack complex. Factor I, Factor H, and MCP (membrane cofactor protein) control complement activation primarily at the level of C3. *Boxes* indicate the clinical syndromes or infections that result from defects of the indicated complement proteins.

Specific Disorders

C1 Esterase Inhibitor Deficiency

Deficiency of C1 esterase inhibitor is the cause of HAE. Unlike many of the other early complement component deficiencies, absence of C1 esterase inhibitor does not lead to an increased risk for infection. Instead, this protein regulates the activity of kallikrein, blocking its ability to act on Factor XII and kininogen. As a consequence, minor irritants cause unabated production of bradykinin and other mediators of vascular permeability, leading to rapid swelling of the soft tissues (angioedema), severe abdominal pain, and at times, acute obstruction of the airway. Effective treatments are now available for HAE including purified C1 esterase inhibitor, a kallikrein inhibitor, and a bradykinin B2 receptor antagonist.[8,9,10] Because of the expense of these agents, they are often administered at the beginning of an attack to abort symptoms rather than being administered prophylactically to prevent the onset of an attack.

C2 Deficiency

C2 deficiency is the most common complement component deficiency associated with susceptibility to infections, occurring in approximately 1 of 20,000 people. As indicated above, patients with early complement cascade defects (C1–C4) are susceptible to invasive infections with encapsulated organisms, *S. pneumoniae* being a particularly fulminant pathogen in these patients. The infectious susceptibility is compounded by functional antibody deficiency in some patients. In addition, patients with C1, C2, or C4 deficiency are at high risk of developing autoimmunity (lupus or glomerulonephritis). In the case of homozygous C2 deficiency, approximately 50% of patients develop lupus or glomerulonephritis.[11]

Diagnosis

Screening for complement deficiency should be performed in patients with recurrent episodes of bacteremia, meningitis, or disseminated gonorrhea. Because more than 30% of patients with recurrent Neisseria infections have complement deficiency, it is imperative that prompt testing of the complement system be done in these individuals. The screening test of choice for complement deficiencies is the CH50 test, which measures functional complement activity in the plasma. The CH50 will only identify defects in the classical pathway, which is typically sufficient inasmuch as alternative pathway defects are exceedingly rare. If an alternative pathway defect is suspected, however, an analogous test (the AH50) can be performed. In order for the CH50 to give accurate results, the blood specimen needs to be handled carefully because complement is very heat labile. In general, it is recommended that any abnormal CH50 test should be repeated to confirm a complement deficiency. The CH50 is typically very low or absent in patients with a complement component deficiency. A CH50 result that is only moderately low is often seen in situations where the specimen was handled incorrectly or in patients with autoimmune disease such as lupus or mixed connective tissue disease. Once an abnormal CH50 test is confirmed, specialized testing to identify the specific complement component that is absent can be performed.

Treatment

Patients with complement deficiency are susceptible to fulminant sepsis and other deep-seated infections caused by encapsulated organisms. For this reason, patients should be given a letter or laminated card that they can keep with them at all times with contact information for their primary care physician and clinical immunologist, and a message indicating that they have a complement deficiency and there should be no delay in giving parenteral antibiotics should they be ill. For patients who live at a distance from skilled medical care, consideration should be given to providing a dose of parenteral antibiotic such ceftriaxone that can be administered by the patient or a family member when they become ill, prior to a lengthy trip to the hospital. The efficacy of

chronic prophylactic antibiotics to prevent infection in patients with complement deficiency is not well studied and remains a significant question in this group of disorders. In addition to preparing for and treating infections, patients should also be regularly screened for autoimmunity by history, physical exam (i.e., blood pressure monitoring), and laboratory testing including BUN, creatinine, and urinalysis to monitor for signs of glomerulonephritis inasmuch as this is a common autoimmune manifestation.

PHAGOCYTES

One of the major roles of phagocytic cells (neutrophils and macrophages) is to continuously survey the body for signs of infection. Upon sensing an infection, they migrate from the circulation into the tissues toward the site of the infection where they begin to ingest both opsonized and nonopsonized pathogens and debris. The ingested material is processed and fragments of digested proteins are loaded into class II MHC molecules that are presented at the cell surface where they can be recognized by cells of the adaptive immune system. Phagocytes that ingest pathogens and debris can either remain at the site of infection or migrate back to local draining lymph nodes to present antigen. Phagocytic disorders can occur in one of three ways: (1) a lack of phagocytes (congenital neutropenia); (2) defective phagocyte migration (leukocyte adhesion deficiency [LAD] and WHIM syndrome); and (3) inability of phagocytes to process or degrade organisms that have been ingested (chronic granulomatous disease [CGD]).

Clinical Presentation

Because of the role that phagocytes play in controlling bacterial and fungal pathogens, patients with phagocytic defects often present with infections and abscesses of skin, deep tissues, and organs caused by bacteria and fungi. Symptoms can include boils and/or cellulitis with or without pus, lymphadenitis, pneumonia, delayed shedding of the umbilical cord, hepatic abscesses, gastrointestinal disorders, gingivitis, and unexplained fever, malaise, and fatigue. The onset of symptoms of phagocytic cell disorders is typically in infancy or early childhood.

Specific Disorders

Severe Congenital Neutropenia

The congenital neutropenias are described in more detail elsewhere (Chapter 57) so are covered only briefly here. Mutations in five different genes have now been associated with severe congenital neutropenia (SCN): *ELANE*, which is inherited in an autosomal dominant manner, causes increased myeloid cell apoptosis and can present either with SCN or with a cyclic neutropenia phenotype; *GFI1*, which is also inherited in an autosomal dominant manner, causes defective myeloid cell differentiation; *HAX1*, which is inherited in an autosomal recessive manner, is associated with increased myeloid cell apoptosis, and is the cause of the classic "Kostmann" syndrome; *G6PC3*, which is inherited in an autosomal recessive manner, causes excessive myeloid cell apoptosis, and is associated with a variety of other congenital defects including cardiac, urogenital, endocrine, auditory, and facial anomalies; and *WAS*, in which specific activating mutations in the CDC42 binding domain are inherited in an X-linked recessive manner, leading to abnormal and dysregulated actin polymerization that causes defective neutrophil chemotaxis and increased apoptosis.[12]

In all cases, clinical management involves a heightened suspicion for infections and aggressive treatment if these arise. Treatment of acute infections may require antibiotics combined with G-CSF to increase neutrophil counts. Despite there being little evidence specifically in SCN supporting the use of prophylactic antibiotics, extrapolation from data in leukemic patients with neutropenia suggests a benefit so these are used in most patients. Prophylactic, long-term therapy with G-CSF is typically utilized only in those patients who have recurrent, severe bacterial infections in spite of antibiotic prophylaxis or in patients with fungal infections. Bone marrow transplantation is effective in SCN although there is little to no reported experience in those genetic disorders that are more rare such as G6PC3 deficiency.

Leukocyte Adhesion Deficiency

LAD is caused by the absence of functional adhesion receptors that are required for the migration of phagocytes from the circulation into the tissues. The characteristic clinical features of LAD include recurrent skin and soft tissue infections that often lead to development of deep ulcers despite there being highly elevated peripheral blood leukocyte counts. Interestingly, the inability of leukocytes to migrate to these sites of infection leads to an absence of pus in the lesions, which can be a useful diagnostic clue. Wound healing is also compromised and patients typically have marked gingivostomatitis. Three forms of LAD have been described: *LAD-I*, the most common form of LAD, is caused by mutations in the *ITGB2* gene encoding the $\beta 2$-integrin CD18. Mutations cause an absence of the CD11/CD18 integrin complex on the surface of leukocytes, which can be readily discerned by flow cytometry. *LAD-II* is caused by mutations in the *SLC35C1* gene encoding the GDP-fucose transporter. These mutations cause defective expression of Sialyl Lewis X (sLe^X), a fucose-containing ligand on neutrophils. sLe^X is the ligand for E- and P-selectins, which are expressed on the surface of cytokine-activated endothelial cells and allow neutrophil rolling. As a result of the fucose defect, all patients with LAD-II also have the rare Bombay blood group, which is a useful diagnostic test for suspected LAD-II. *LAD-III* is caused by mutations in the *FERMT3* gene that encodes Kindlin-3, a coactivator that is required for activation and function of $\beta 1$-, $\beta 2$-, and $\beta 3$-integrins. Absence of functional Kindlin-3 leads to dysfunction of CD18 and causes an LAD phenotype (see LAD-I above). In addition, patients with LAD-III also have a Glanzmann-type bleeding disorder resulting from dysfunctional integrin-mediated aggregation of platelets.[13]

Patients with LAD-I and LAD-III typically present in childhood and often have a severe course with early mortality, whereas patients with LAD-II often have milder cases and may live into adulthood. Treatment of LAD can be more complicated than some of the other phagocytic disorders because in addition to treating infections aggressively with antibiotics, active soft tissue infections may require recurrent donor white cell infusions of functional neutrophils in order to clear the infection. The primary defects of LAD are intrinsic to hematopoietic cells, thus bone marrow transplantation can be curative.[14–16]

WHIM Syndrome

WHIM syndrome (warts, hypogammaglobulinemia, recurrent bacterial infections, and myelokathexis [retention of neutrophils in the bone marrow]) is caused by autosomal dominant mutations in CXCR4, the receptor for the chemokine CXCL12 (SDF-1). Patients with WHIM typically present in childhood with recurrent bacterial otitis media, sinusitis, bronchitis, pneumonia, and cellulitis. The bacterial susceptibility is a result of the combination of hypogammaglobulinemia and neutropenia. In addition to bacterial infections, patients with WHIM have a particular susceptibility to papillomavirus infections, which can be severe and lead to early malignancy. The mechanisms that underlie the viral susceptibility are not entirely understood but are thought possibly to be intrinsic to the epithelial cells. In the hematopoietic system, CXCL12 causes homing of cells to the bone marrow and controls release of these cells from the marrow. Neutrophils and lymphocytes from patients

with WHIM have an increased chemotactic response to CXCL12, suggesting that the neutropenia and lymphopenia observed in WHIM are the result of inappropriate cell retention in the marrow.[17] Treatment with G-CSF or GM-CSF can normalize the neutrophil counts although these often cause significant bone pain at the doses required.[18] Recent studies using the CXCR4 antagonist plerixafor in adults with WHIM syndrome have shown promise for improving neutrophil counts by mobilizing neutrophils from the bone marrow.[19,20] Antibiotics and immunoglobulin replacement can significantly reduce the risk of bacterial infections. There is very little reported experience regarding bone marrow transplantation for WHIM although anecdotal evidence suggests that it may correct the neutropenia and hypogammaglobulinemia but may not alter the papillomavirus susceptibility.[21]

Chronic Granulomatous Disease

CGD is the most frequently diagnosed phagocytic cell immune defect. The most common form is X-linked, caused by mutations in the *CYBB* gene and accounting for approximately two thirds of all CGD patients. The remaining forms, caused by mutations in the *CYBA*, *NCF1*, *NCF2*, or *NCF4* genes are all autosomal recessive. All mutations affect the formation or function of the NADPH oxidase complex, on neutrophil phagolysosomes. The NADPH oxidase is required to generate a burst of reactive oxygen species in response to phagocytosis of pathogens. Reactive oxygen species activate proteases in the phagolysosomes that destroy ingested bacteria. In CGD, the oxidative burst cannot be generated, leading to defective processing of ingested organisms and an inability to eliminate bacterial and fungal pathogens appropriately. Catalase-positive organisms including *Staphylococcus* species, *Aspergillus* species, *Burkholderia cepacia*, *Serratia marcescens*, and others are the most common pathogens. The most common types of infection at presentation are pneumonia, lymphadenitis, cellulitis, and hepatic abscesses (particularly with *Aspergillus* sp.). The most common cause of premature death is *Aspergillus* infection.[22] In addition to the infectious susceptibilities of CGD, a substantial percentage of patients struggle with inflammatory complications that are common to this disorder including an inflammatory colitis that occurs in approximately 40%, hepatic dysfunction, gingivitis, and others.

Treatment of CGD revolves around aggressive management of acute infections followed by prophylaxis against future infections using a combination of daily antibiotic (typically trimethoprim–sulfamethoxazole), daily antifungal (typically itraconazole), and thrice-weekly Interferon-γ injections. This combination has dramatically improved outcomes in CGD; however, despite appropriate use of this regimen, some patients ultimately have increasing symptoms that lead to a decline in survival beginning in the late teens or early twenties. The prospects for long-term survival appear to be correlated with the amount of residual oxidative burst activity that can be generated by a particular patient's phagocytes.[23] This has led to a renewed interest in bone marrow transplantation for CGD, which has been quite successful in the modern era, likely due to improved antimicrobials and transplant-conditioning regimens with reduced toxicity. Many now recommend that for patients who have mutations that severely affect oxidative burst activity, bone marrow transplant should be considered preemptively, early in life before patients develop comorbidities.[24]

Diagnosis

Assessment of patients for a possible phagocytic disorder requires that both the number and the function of phagocytes be evaluated. Numbers are easily evaluated using a complete blood count with differential. If there is a concern for cyclic neutropenia, neutrophil counts may need to be evaluated 3 times weekly for 3 to 4 weeks to identify the nadir.[25] Functional testing includes evaluation of CD11/CD18 integrin expression on myeloid cells by flow cytometry if the patient has symptoms suggestive of leukocyte adhesion deficiency. In cases of suspected CGD, evaluation of neutrophil oxidative burst function is essential. Traditionally this was done using nitroblue tetrazoleum (NBT) but is now performed using dihydrorhodamine (DHR), a reagent that permeates neutrophils and fluoresces when reduced by a normal neutrophil oxidative burst. Fluorescence is measured by flow cytometry. The DHR test is sensitive enough to differentiate most cases of X-linked CGD from autosomal recessive CGD, making it a particularly useful clinical assay.[26,27]

Treatment

As noted above, management of phagocytic disorders revolves around having a heightened suspicion for infections, aggressively treating acute infections using antibiotics and G-CSF as necessary, and developing a prophylaxis regimen that is both effective and reasonable from a patient standpoint. At times, patients continue to have recurrent or severe infections despite these efforts and require more definitive therapy. As indicated above, hematopoietic stem cell transplantation (HSCT) has been shown to be effective in many, but not all, phagocytic disorders. Gene therapy has been attempted for both X-linked CGD[28] and for LAD-I[29] but neither has been particularly successful thus far and at this point is considered to be experimental. Ongoing research to address the challenges of gene therapy that are unique to these two disorders is underway.

B CELLS/ANTIBODIES

The predominant role of B cells in the immune system is to make antibodies (immunoglobulins) in response to antigen challenge (pathogens, vaccines, etc.). The absence of functional antibodies causes susceptibility to bacterial and viral infections. Antibody deficiency can occur in one of three different ways: (1) hypogammaglobulinemia or low levels of one or more immunoglobulin classes (IgG, IgA, IgM, or IgE) occurring as a result of decreased antibody production, often associated with a specific single-gene defect; (2) hypogammaglobulinemia as a result of excessive antibody loss, typically through the kidneys as proteinuria or through the gut as protein-losing enteropathy; or (3) functional antibody deficiency, in which immunoglobulin levels are normal but the Ig lacks the quality required to bind and opsonize pathogens.

Clinical Presentation

Patients who lack sufficient levels of functional antibody present clinically with recurrent bacterial sinopulmonary infections (sinusitis, otitis media, bronchitis, and pneumonia). In addition, patients may develop bowel infections caused by microorganisms such as Giardia or Cryptosporidium that are often only modestly pathogenic to normal individuals. In addition to these symptoms, patients with certain antibody-deficiency disorders have characteristic clinical features that can provide clues to the specific diagnosis. These are covered below.

Specific Disorders

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA) is caused by mutations in the Bruton's tyrosine kinase (*BTK*) gene. BTK is a member of the Tec family of cytoplasmic tyrosine kinases and is required for the maturation of B-cell precursors in the bone marrow.[30] Mutations in BTK therefore cause an arrest of B-cell development at the pre-B–cell stage leading to virtual absence of circulating B cells in the peripheral

blood. Mutations that only partially interfere with the enzymatic function of BTK have also been described and are associated with milder forms of the disease that only have defects in the generation of specific antibody responses.

XLA is typically suspected in male patients with recurrent bacterial sinopulmonary infections and <2% circulating $CD19^+$ B cells. Other infections that occur relatively frequently in patients with XLA prior to the initiation of IgG replacement therapy include skin infections (furunculosis, pyoderma, and cellulitis) and sepsis. The diagnosis can be confirmed either by identifying a mutation in the *BTK* gene or by demonstrating absence of the BTK protein in monocytes or platelets. A positive family history suggestive of an X-linked recessive mode of inheritance increases the suspicion for XLA. It is uncommon for patients with XLA to develop symptoms in the first months of life because newborns are protected from most infections by transplacentally acquired maternal IgG. There are few distinguishing physical features of XLA that can provide clues to the diagnosis but absence of visible tonsils or adenoids (by X-ray or CT scan) is a useful clue.

In addition to the common sinopulmonary pathogens, patients with XLA are also susceptible to infections by particular opportunistic organisms that are more rare and fastidious, which can cause unusual clinical syndromes. For example, *Helicobacter cinaedi* can cause a syndrome of dermatomyositis and cellulitis that presents with cutaneous ulcerations, particularly on the lower legs.[31,32] The organism can sometimes be recovered from the blood but is fastidious and difficult to culture using usual methods. The ability to culture the organism and evaluate its antibiotic sensitivity is crucial in many cases because it is frequently resistant to various antibiotics. A combination of antibiotics is often needed to clear the infection effectively.[33] Similarly, *Mycoplasma* species, including *M. hominis,* can cause lung, abdominal, or bone infections that are remarkably hard to eradicate and *Ureaplasma urealyticum* infections are a rare cause of arthritis, urethritis, and pneumonia.[34]

Prior to the widespread use of IgG supplementation in these patients, opportunistic viral infections, particularly with viruses that require an extracellular phase, were especially problematic. For example, echovirus encephalitis was estimated to be the cause of death in ~10% of boys with XLA in the 1970s but that number has fallen dramatically with aggressive use of IgG supplementation. There continue to be rare cases of echovirus encephalitis in patients with XLA, even in those on adequate IgG replacement therapy, but these are thought to be caused by viral strains for which there may not be high antibody titers in the particular IgG preparation being used.[35,36] Similarly, a mink astrovirus strain was recently identified by deep sequencing from the brain of an XLA patient who developed a neurodegenerative disorder as a teen.[37] Interestingly, he had lived next to a mink farm as a child but was started on immunosuppression early in his teens for inflammatory bowel disease, which may have allowed the virus to escape control. Lastly, infections with vaccine-strain poliovirus were pathogenic in undiagnosed patients with XLA who were immunized with the live-viral vaccine after transplacentally acquired maternal antibody had waned. The shift from live attenuated to killed poliovirus for immunization has essentially eliminated new cases.

Hyperimmunoglobulin M Syndromes

Under normal circumstances, binding of antigen to cell surface IgM on naive B cells induces activation of the B-cell. The antigen that is bound to surface IgM on the B-cell is ingested, proteolytically digested, and antigenic peptide fragments are displayed on the B-cell surface in MHC Class II molecules. Antigen-specific T cells then engage the B-cell via MHC II/TCR interactions. Once engaged, the activated helper T-cell (Th) provides additional costimulatory signals to the B-cell that are critical to promote immunoglobulin class-switching from IgM to IgG, IgA, and IgE. The most important of these costimulatory signals comes via the interaction of CD40 ligand on activated T cells with CD40 on B cells. Additional costimulatory signals come from ICOS on activated T cells and ICOS ligand (B7-H2) on B cells. Activation of the B-cell through CD40 and cytokines that are secreted by the helper T-cell cause it to undergo class-switch recombination (CSR) during which the μ-heavy chain gene segment within the immunoglobulin gene, is replaced by either a γ, α, or ε gene segment. This is accomplished by nicking and double-strand breakage of the DNA in the immunoglobulin heavy-chain locus, which requires a series of enzymatic steps that involve activation-induced cytidine deaminase (AID), uracil DNA glycosylase (UNG), and others. Genetic defects that affect CD40 ligand (CD40L), CD40, AID, or UNG can therefore prevent class-switch recombination thus thwarting the B-cell's ability to make significant amounts of any antibody isotype in addition to IgM.

The overwhelming majority of patients with hyper-IgM syndrome have the X-linked form caused by X-linked recessive mutations in the CD40 ligand (CD40L/CD154), which is encoded by the *CD40L* gene on the X-chromosome.[38] CD40L and its receptor CD40 are members of the tumor necrosis factor (TNF) superfamily of ligands and receptors. In lymphocytes, CD40L is expressed only on activated T cells but is also expressed on platelets where its role is unknown. Affected boys may present with recurrent bacterial sinopulmonary infections caused by low IgG, IgA, and IgE, whereas IgM is normal or elevated. In addition to the usual bacterial pathogens, patients with CD40L mutations also demonstrate unique susceptibilities to fungal infections, particularly *Pneumocystis jiroveci* (PJ) that causes pneumonia, and to a protozoan, *Cryptosporidium parvum* (CP) that causes bowel infections. B lymphocytes are present, and T-cell numbers are generally normal. In almost all cases, the diagnosis can be made by using flow cytometry to evaluate the expression and function of the CD40L protein on activated T cells. Expression is evaluated using antibodies specific to the CD40L protein and the function is evaluated by measuring the binding of a CD40-Ig heavy chain fusion protein to the expressed CD40L. Gene sequencing can then be performed in order to identify a specific mutation.

The susceptibility to *Pneumocystis* and possibly other fungal pathogens has been somewhat of a puzzle because patients do not have other signs of a significant cellular immune defect such as severe or recurrent viral infections. Interestingly, the susceptibility to *Pneumocysitis jiroveci* pneumonia (PJP) appears to go away in most patients by the age of 5. PJP is almost always diagnosed by staining bronchoalveolar lavage fluid for the presence of the organism. PJP can be readily prevented by prophylactic trimethoprim–sulfamethoxazole administration and active disease is amenable to treatment using higher doses of the same drug. Recent data have suggested that the fungal susceptibility in CD40L deficiency may be a result of defective CD40L signaling into dendritic cells and monocytes that express CD40.[39]

C. parvum bowel infections are more difficult to diagnose and manage in patients with CD40L deficiency. CP may cause abdominal pain, bloating, diarrhea, malabsorption, and weight loss. It may require multiple stool samples to identify the oocysts and occasionally, the diagnosis can only be made on endoscopically obtained biopsy specimens. Treatment with paromomycin or nitazoxanide can clear the infection although prolonged courses are typically needed in hyper IgM patients and treatment failures are not uncommon. CP infections can result in chronic inflammation of the gut and biliary tree, which seems a likely contributor to the high incidence of bile duct cancers seen in these patients.[40,41]

Treatment involves the use of IgG replacement therapy combined with prophylactic antibiotics for prevention of PJP at least until the age of 5. The role of bone marrow transplantation for CD40L deficiency is still being evaluated. Even though a number of patients have undergone successful bone marrow

transplantation, the role of BMT remains somewhat controversial in this disease although in patients with ongoing CP infection, the prognosis for the patients who develop bile duct disease is so poor that the risks of transplantation are well justified.[42,43]

CD40 deficiency is inherited as an autosomal recessive defect that has been described primarily in two cohorts from Italy and the Middle East. It results in a syndrome that is almost identical to CD40L deficiency in which both sexes are affected. Homozygosity for a null mutation occurs, but heterozygosity is more common and can result in a partial phenotype because CD40 functions as a trimer (defects of even one chain of the trimer interfere with its function).[44]

Autosomal recessive mutations in AID and UNG also cause a hyper-IgM phenotype but it tends to be milder than either CD40L or CD40 deficiency, likely because the defect is limited to B cells, whereas CD40L/CD40 signaling plays a role in other cell types including dendritic cells and monocytes.[45,46] Patients with AID or UNG typically live into adulthood and do not demonstrate the same susceptibility to PJP and CP bowel infections. Patients with mutations in AID do, however, have a significant propensity to develop autoimmunity affecting various organ systems. Patients are typically treated with IgG replacement therapy and antibiotics for acute infections. There are no reports of bone marrow transplantation for AID or UNG deficiency.

Common Variable Immunodeficiency Syndromes

Common variable immunodeficiency (CVID) is a heterogeneous disorder that is likely caused by a variety of molecular mechanisms that ultimately lead to a similar clinical phenotype. The European Society of Immunodeficiency (ESID) has proposed diagnostic criteria in an effort to standardize the diagnosis of CVID. These include: (1) plasma IgG levels that are less than 2 standard deviations below the mean for age combined with a "marked decrease" in either IgM or IgA; (2) age of onset of immunodeficiency >2 years of age; (3) absent isohemagglutinins or poor responses to vaccines; and (4) defined causes of hypogammaglobulinemia have been excluded.

The peak age of onset of CVID is in the second or third decade of life and 50% to 60% of patients have a clinical phenotype consisting almost exclusively of increased bacterial sinopulmonary infections. With IgG supplementation, this group of patients has a relatively benign course with long-term survival that is not unlike the normal population. The other half of patients have a complicated disease course with autoimmunity or lymphoproliferative disease that can involve the hematopoietic system, lungs, lymph nodes, liver, and bowel. The long-term outcome of this population is significantly worse, approaching only 40% survival over 40 years.[47]

Among the disorders seen in this population, a granulomatous, lymphoproliferative, interstitial lung disease (GLILD) affects approximately 30% to 40% of patients.[48] This often presents with decreasing lung function that is manifested by cough, decreased exercise tolerance, and sometimes hypoxemia. Typical findings on chest CT scan include diffuse nodules within the lung, opacities that have a "ground glass" appearance, bronchial wall thickening, and sometimes bronchiectasis. Lung biopsy generally demonstrates a lymphocytic interstitial pneumonitis with noncaseating granulomas and a follicular bronchiolitis with lymphoid aggregates of both B and T cells. This pattern is sometimes mistaken for sarcoidosis although there are differences. Over time, this inflammatory process in the lungs will cause destruction of alveoli and will contribute to development of bronchiectasis. There continues to be some debate among providers about whether this process should be treated if the patient is not demonstrating pulmonary compromise. If left unchecked, however, there is evidence that irreversible damage and fibrosis develops in many patients. High-dose steroids are often used as first-line therapy to treat this process and in many cases they are effective but do not typically lead to a lasting remission on their own. A recent study using a combination of anti-CD20 monoclonal antibody (rituximab) therapy and azathioprine in a small cohort of CVID patients with GLILD demonstrated dramatic responses with a prolonged remission of disease in many patients.[49]

In addition to pulmonary symptoms, gastrointestinal complaints are common in CVID, affecting 20% to 30% of patients.[47] Patients who develop disease demonstrate a hypertrophic lymphoproliferation of Peyer's patches that causes a nodular lymphoid hyperplasia in the bowel. This is associated with abdominal discomfort, diarrhea, malabsorption, and weight loss and can cause significant morbidity. A variety of approaches have been taken to treat this process but none have offered particularly dramatic results although nonabsorbable steroid preparations have shown some benefit with minimal side effects. A more troubling complication observed in 5% to 10% of patients is a hepatitis that can cause severe hepatic dysfunction with development of hepatosplenomegaly and ascites.[47] Infectious causes are almost never identified and liver biopsy demonstrates a nodular lymphoid hyperplasia in the liver parenchyma, not unlike that observed in the bowel. Liver disease is among the complications associated with a poor outcome.

Some 20% of subjects have additional clinical findings that are suggestive of autoimmunity/immune dysregulation including immune thrombocytopenia and hemolytic anemia, neuropathy, endocrinopathies, and skin disease. Skin involvement ranges from alopecia and vitiligo to psoriasis and granuloma annulare.[50,51]

In most cases of CVID, the molecular etiology of disease is unknown. There has, however, been some progress in identifying genetic defects associated with a CVID phenotype. The most common mutations identified are autosomal recessive defects in the transmembrane activator, calcium modulator, and cyclophilin ligand interactor (TACI), which are found in 7% to 10% of patients with CVID. Unfortunately, even in patients who have mutations that abrogate protein expression, the penetrance of disease seems to be highly variable with individuals from one family harboring the same mutation, having either a CVID phenotype, a selective IgA deficiency phenotype, or no disease. This inability to correlate disease phenotype or prognosis with the presence of a TACI mutation has raised the question of whether TACI genotyping offers clinical value. In addition to TACI, autosomal recessive mutations in the genes encoding the Baff receptor (*BAFFR*), the inducible T-cell co-stimulator (*ICOS*), *CD19*, *CD20*, *CD21*, *CD81*, and the LPS-responsive vesicle trafficking, beach- and anchor-containing protein (*LRBA*) have been identified in rare patients with features of CVID. These mutations have provided insight into basic immune mechanisms in humans but explain only a handful of all patients with CVID.[52,53] Lastly, hypomorphic mutations in *BTK* (X-linked agammaglobulinemia), *CD40L* (X-linked hyper-IgM syndrome), *SAP/SH2D1A* (X-linked lymphoproliferative syndrome), and *RAG1/RAG2* can be associated with a CVID-like phenotype and according to the diagnostic criteria for CVID, need to be excluded prior to making this diagnosis.[52]

B-cell numbers in peripheral blood are typically normal but a subset of CVID patients have B-cell lymphopenia. In those patients with normal B-cell numbers, B-cell maturation, memory development, and immunoglobulin class-switching are often abnormal and can be assessed by detailed flow-cytometry–based immunophenotyping of B cells. Varying classification schemes have been proposed to subtype patients according to their B-cell phenotype and these subsets have been correlated with differences in risk for autoimmunity, and the like. B-cell immunophenotyping has therefore become a useful clinical tool in caring for patients with CVID. In addition to the humoral immune deficiency, many patients with CVID have impaired T-cell function with decreased CD4 or CD8 T cell numbers as well as abnormal T-cell proliferative responses in vitro to mitogens and antigens. Regulatory T-cell numbers and function have also been found to be decreased in patients with CVID.[54,55–58]

Selective Immunoglobulin A Deficiency

There are two isoforms of IgA that are made predominantly at mucosal surfaces where they play a critical role in neutralizing pathogens and maintaining mucosal integrity. Subjects >4 years of age with serum IgA levels consistently <7 mg/dl but normal IgG and IgM levels are considered selectively IgA deficient. Selective immunoglobulin A deficiency (SIgAD) can be difficult to diagnose in childhood because adult blood levels of IgA (50 to 200 mg/dl) are not usually attained until 12 years of age or older. The molecular mechanisms by which this occurs are largely unknown. Interestingly, despite low IgA, the frequency of cell-surface IgA-positive B cells is normal in patients with SIgAD. Up to 20% of IgA-deficient subjects have reduced levels of at least one IgG subclass: mostly IgG_2.

Selective IgA deficiency is the most common immunodeficiency with an incidence as high as 1 in 300 in blood bank studies. The majority (>50%) of patients with selective IgA-deficiency have no apparent symptoms that can be directly linked to their immune defect. In the patients who do have symptoms, they are typically more suggestive of immune dysregulation and autoimmunity (allergy, arthritis, diarrhea, celiac disease, etc.) than immune deficiency (sinusitis, otitis media, bronchitis, and pneumonia). In patients who are truly IgA deficient, sensitization to IgA itself can be a problem, leading to anaphylactic reactions during infusions of blood products including IVIg, red blood cells, platelets, and so on. This is, however, quite uncommon and can often be managed by pretreatment with benadryl, acetaminophen, and steroids before the start of the infusion.[59]

Transient Hypogammaglobulinemia

Maternal IgG is actively transported across the placenta from mother to infant. The rate of transfer increases in the last month of pregnancy. Premature infants will therefore have low IgG levels but term newborns have IgG concentrations virtually equal to their mother's. Because the half-life of IgG is approximately 21 days, the levels of maternal immunoglobulin fall as the infant grows and the IgG is catabolized. For most term infants, the IgG level in the blood reaches a nadir between 200 to 400 mg/dl, typically between 3 and 4 months of age. As the infant's own immune system matures and begins to generate more IgG of its own, the immunoglobulin levels begin to rise again. There are, however, children whose IgG levels dip below 200 mg/dl and may remain low for a prolonged period of time before they begin to rise into the normal range again. Despite this, the response to protein antigen vaccines is often normal. This phenomenon is termed transient hypogammaglobulinemia of infancy (THI) and immunoglobulin levels typically return to normal by 2 to 6 years of age. There are almost no data about the mechanism by which THI occurs although it has been suggested that it may be the result of delayed B-cell maturation. This has, however, not been borne out by B-cell immunophenotyping studies.[60] The true incidence of THI is unknown because immunoglobulin levels are usually only requested if patients are having symptoms (i.e., recurrent infections). There is no consensus on how to manage THI although most would agree that if patients are having frequent infections, they might require IgG supplementation until their own IgG levels normalize. One approach has been to immunize affected infants with killed vaccines and to start supplemental IgG therapy on those who make no significant antibody response. Infants who do respond to immunization with a protective specific antibody titer are usually safe with symptomatic management or with prophylactic antibiotics alone.

Immunodeficiency, Centromere Instability, and Facial Anomalies Syndrome

Immunodeficiency, centromere instability, and facial anomalies (ICF) syndrome is a complex syndrome that includes centromeric instability, a variable immune deficiency (often with normal B-cell counts), facial anomalies including hypertelorism, a flat nasal bridge, and low-set ears, and developmental delay. The immunoglobulin deficiency is variable but IgA, IgG, and/or IgM are frequently low. Lymphocyte proliferation can also be abnormal. The centromeric instability leads to chromosomal breaks, deletions, and multiradial chromosome junctions in activated lymphocytes that typically affect chromosomes 1, 9, and 16. ICF syndrome typically presents in childhood with recurrent bacterial sinopulmonary infections and patients generally require chronic IgG supplementation. The diagnosis is usually suspected in patients who have the facial phenotype and recurrent infections. ICF syndrome is caused by mutations in the *DNMT3B* gene, which encodes one of a family of DNA methyltransferases. Hypomethylation of the DNA is hypothesized to cause disease but the precise mechanism by which this generates the facial and immune phenotypes is unknown.[61,62] Evaluating the karyotype of activated peripheral blood lymphocytes can demonstrate the characteristic chromosomal abnormalities in chromosomes 1, 9, and 16, which can be highly suggestive of the diagnosis. Ultimately, sequencing of the *DNMT3B* gene can confirm a diagnosis of ICF syndrome.

Diagnosis

The diagnosis of antibody deficiency needs to evaluate both the quantity and the quality of the antibody response. Quantity is easily evaluated by measuring quantitative immunoglobulin levels (IgG, IgM, IgA, and IgE) in the blood and comparing these to the age-appropriate normal ranges. Evaluating the quality of the antibody response can be done by measuring specific antibody titers to vaccines that the patient has received. Generally, responses to both protein antigens (tetanus, diphtheria, hepatitis B, etc.) and carbohydrate antigens (23-valent unconjugated Pneumovax) need to be assessed to confirm normal antibody responses. Patients who respond appropriately to protein antigens but do not respond to carbohydrate antigens may have specific antibody deficiency and may require additional workup. Recent guidelines regarding the interpretation and use of diagnostic vaccination have recently been published.[63]

In addition to evaluating antibody quantity and quality, it is essential to determine whether patients have normal B-cell numbers by evaluating lymphocyte subsets. The use of more detailed B-cell immunophenotyping to evaluate B-cell development, the presence of $CD27^+$ memory B cells, and the ability of memory B cells to undergo immunoglobulin class switching has become standard-of-care in many clinics as it provides valuable diagnostic and prognostic information.[64]

Flow cytometry testing to assess the expression of specific proteins that are defective in B-cell and antibody deficiency disorders including BTK, CD40 ligand, CD40, ICOS, CD27, BAFF receptor, and the like, can be performed in specialty laboratories and offer the ability to rapidly obtain a molecular diagnosis. This is typically supplemented by sequencing of specific genes.

Treatment

Immunoglobulin Replacement

In patients with antibody deficiency, replacement of IgG is critical to maintaining health and preventing long-term complications associated with recurrent infections. Immunoglobulin replacement therapy has been found to be effective when administered intravenously (IVIg), subcutaneously (SCIg), and intramuscularly (IMIg) and there are currently FDA-approved products that support administration via any of these routes. That said, because of significant discomfort associated with IMIg administration, this route is rarely used in the United States. Most patients are maintained on either IVIg or SCIg depending on patient preference and

provider recommendations related to each patient's clinical need. Because the half-life of IgG in the circulation is ~21 days under normal circumstances, IVIg is typically administered every 3 to 4 weeks providing high peak levels followed by a decline over the ensuing weeks to a trough prior to the next infusion. In contrast, SCIg is typically administered 1 to 2 times per week in smaller doses providing a more "steady-state" level of IgG in the circulation. IgG products are prepared from the pooled plasma collected from thousands of healthy donors and therefore they contain a broad range of antibodies. A reasonable starting dose of either IVIg or SCIg is 400 to 500 mg/kg/month. This can be divided into the number of doses required to administer the necessary monthly volume (IgG preparations range in concentration from 5 g/100cc (5%) to 20 g/100cc (20%)). In most patients, a trough IgG level of 600 mg/dl in the blood is a reasonable initial target but the dose can then be increased or decreased to achieve a trough IgG level that prevents both acute infections and development of progressive lung disease. There is evidence that at least for bacterial pneumonia, higher IgG trough levels are directly correlated with a decreased risk of infection.[65] Supplemental IgG is generally very effective at preventing lower respiratory tract infections (bronchitis and pneumonia), but the response of upper tract disease (particularly sinusitis) is more variable. Some patients have persistent sinus symptoms that can be a significant clinical problem despite IgG therapy. In these patients, the addition of prophylactic antibiotic therapy or increasing the frequency or dose of IgG infusions may be beneficial.

Side effects with IVIg therapy are relatively common, occurring in as many as 25% of treated patients.[66] Side effects include headaches, nausea, vomiting, chills, fatigue, fever, rash, and aseptic meningitis. These can often be managed by changing the IgG product being used, pretreating with benadryl, acetaminophen, and steroids (0.5 to 1 mg/kg) prior to infusion, or slowing the rate of infusion. Patients who have persistent symptoms despite these measures can often tolerate subcutaneous IgG supplementation (SCIg).

Prophylactic Antibiotics

It has been increasingly recognized that in many patients with antibody deficiency, replacement of IgG (even to normal levels), may not prevent all clinically significant infections. The addition of prophylactic antibiotics has been used as an adjunct to IgG therapy to try to improve control of infections and decrease morbidity. Unfortunately, to date, there have been no well-performed studies that argue strongly either for or against the use of prophylactic antibiotics to improve outcomes. Similarly, there have been virtually no studies that support a particular antibiotic regimen as being superior for prophylaxis. Many patients with antibody deficiency have evidence of bronchiectasis and chronic lung disease, therefore some providers, extrapolating from the lung transplant and cystic fibrosis literature, have utilized thrice weekly macrolide antibiotics as a prophylactic regimen in an attempt to prevent progression of lung pathology. Further studies are needed to clarify the role of prophylactic antibiotics and to define the optimal regimen.

T CELLS

Disorders characterized by the absence of T cells have been known for some time but the identification of several new genetic defects has expanded this group of disorders. Some are characterized by significant, generalized T-cell lymphopenia whereas others are characterized by the absence of specialized subsets of T cells.

Clinical Presentation

In general, absence of T cells causes susceptibility to unusual or severe infections caused by viruses including cytomegalovirus (CMV), Epstein-Barr virus (EBV), and adenoviruses, fungal infections caused by organisms such as *P. jiroveci* that commonly causes pneumonias in this group of patients, and mycobacteria such as Bacilli Calmette-Guerin (BCG) in areas of the world where this is used. In addition, patients with T-cell deficiencies frequently have symptoms of autoimmunity including diarrhea (secondary to autoimmune enteropathy), cytopenias (autoimmune hemolytic anemia [AIHA] and idiopathic thrombocytopenic purpura [ITP]), and hepatitis.

Specific Disorders

22q11.2 Deletion Syndrome (DiGeorge Syndrome)

Deletions within the 22q11.2 region of the long arm of chromosome 22 have been associated with various clinical syndromes including DiGeorge syndrome (DGS), velocardiofacial syndrome (VCFS), conotruncal anomaly face syndrome (CTFS), CATCH22 syndrome, and others. DiGeorge syndrome is the name most commonly associated with immune deficiency and thus is the focus of this discussion. Although DGS is a complex syndrome that has been associated with a wide array of symptoms, the diagnostic criteria proposed by the European Society of Immune Deficiency (ESID) are relatively straightforward. These propose that a diagnosis of DGS should be strongly considered in patients who have <500 $CD3^+$ T cells/mm^3 and any two of the following three characteristics: (1) conotruncal cardiac defect (truncus arteriosus, tetralogy of Fallot, interrupted aortic arch, or aberrant right subclavian); (2) hypocalcemia requiring therapy for >3 weeks; (3) deletion of chromosome 22q11.2. This chromosomal deletion syndrome occurs in approximately 1 in 4,000 to 5,000 births and causes haploinsufficiency of the genes encompassed in the deletion that can extend to include as much as 3 Mb of the chromosome.[67,68]

The characteristic T-cell lymphopenia of DiGeorge syndrome is thought to arise primarily from the absence of adequate thymic tissue and at times, the diagnosis is suspected when the cardiac surgeon correcting a congenital heart defect finds little or no thymic tissue in the mediastinum. Most affected infants have low, but not absent T cells and absolute counts tend to improve over the first year of life. Both $CD4^+$ and $CD8^+$ T cells are low, however, $CD8^+$ T-cell numbers tend to be more affected in most patients. Despite low T-cell counts, most patients do not have significant problems with recurrent or severe viral or fungal infections. Some patients may have recurrent candidiasis. Bacterial infections of the upper respiratory tract including otitis media and sinusitis do occur but may be related more to anatomical issues associated with the facial anomalies than to the immunodeficiency per se. Rare patients have severe T-cell lymphopenia with essentially no T cells and are termed "complete" DiGeorge. These patients may have a clinical phenotype similar to SCID.[67,68]

Other prominent clinical features include: hypocalcemia that can be severe and persistent due to parathyroid hypoplasia, dysmorphic facial features that include small low-set ears, hypertelorism, and micrognathia, renal anomalies including horseshoe kidney and a duplicated collecting system, and developmental delay including problems with speech acquisition, learning disabilities, and behavioral problems. Patients with DiGeorge syndrome have also been found to have an increased incidence of autoimmunity including cytopenias (particularly affecting red cells and platelets), juvenile idiopathic arthritis (JIA), and thyroiditis.

In symptomatic patients, the diagnosis of DiGeorge syndrome is typically made by confirming a deletion within the 22q11.2 region by fluorescence in situ hybridization (FISH) or by quantitative PCR for deletion of the *TBX1* gene that lies within the deletion.[69] In approximately 10% of patients, deletion of this region cannot be detected despite the presence of classic clinical features.

Treatment of DiGeorge initially involves supportive care that may include cardiac support and calcium supplementation. In

patients with severe T-cell lymphopenia or evidence of decreased T-cell function, prophylaxis against PJP pneumonia and IgG supplementation may be utilized. Blood for these patients should be irradiated to prevent the risk of graft-versus-host disease. For those patients with the severe "complete" form of the syndrome, grafting of allogeneic thymus slices into the thigh muscle has proven to be successful in recovering the T-cell lymphopenia, improving T-cell responses to mitogens, and correcting the infectious susceptibility.[70,71] HSCT has been utilized in a handful of patients with mixed results.[72,73] In general, HSCT restores the T-cell counts and protects patients against further infection but in the absence of a thymus, the T-cell graft is thought to consist primarily of long-lived committed lymphoid progenitor T cells and not of cells derived from donor bone marrow stem cells. As a result, there is concern that the T-cell grafts may senesce over time, once again leaving the patient lymphopenic and susceptible to infection. There are currently no long-term therapies that can successfully correct the parathyroid defect.

Severe Combined Immune Deficiency

Made famous by *The Boy in the Plastic Bubble*, a 1976 made-for-TV movie starring John Travolta, SCID is among the most severe immunodeficiencies. It is now known that this category of diseases is made up of a variety of related disorders caused by mutations in more than 20 different genes. The one thing that is common to all forms of SCID is deficiency of one or more subsets of T cells. In many cases, there are no circulating T cells. Depending on the genetic defect, patients may also lack B cells and/or NK cells. This has led to the useful convention of defining cases of SCID by their cellular phenotype (i.e., $T^{neg}B^{+}NK^{+}$, $T^{neg}B^{+}NK^{neg}$, $T^{neg}B^{neg}NK^{+}$, $T^{neg}B^{neg}NK^{neg}$, etc.). The cellular phenotype suggests what the underlying genetic defect may be (see Table 63.2).[2] Because of the absence of functional T cells, patients with SCID typically come to medical attention because of severe or chronic viral infections, fungal infections, or autoimmunity. In the overwhelming majority of SCID cases, this leads to death in infancy or early childhood if patients do not undergo curative treatment such as HSCT or gene therapy. Unfortunately, the presence of infections makes HSCT or gene therapy much more complicated and substantially decreases the chances of survival. Because of this, efforts have been underway in the United States and other countries to perform screening of all newborns using dried blood spot cards obtained at birth to identify those who may have SCID. These efforts have led to the recognition that the incidence of SCID is approximately 1 in 40,000 live births in the United States.[74,75]

X-Linked Severe Combined Immunodeficiency

The X-linked form of SCID is the most common type, accounting for ~40% of all SCID cases. It occurs as a result of mutations in the *IL2RG* gene, encoding the γ receptor chain (γc) utilized by a number of cytokine receptors including those for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 (see Fig. 63.2). In the absence of a functional γc chain, cells are unable to respond to these cytokines. Because IL-2 and IL-7 are key growth factors for T cells, and IL-15 is the key growth factor for NK cells, patients with X-SCID lack T and NK cells but usually have normal numbers of B cells in their blood. The ability to make antibodies is nevertheless severely impaired due to the lack of T-cell help.

If not identified by newborn screening, infants with X-SCID typically present with severe infections. *P. jiroveci* pneumonia is common and often accompanied by severe viral infections with cytomegalovirus (CMV), EBV, respiratory syncytial virus (RSV), rotavirus, metapneumovirus, and others. Adenovirus is particularly lethal in SCID, causing not only pneumonitis but also a severe fulminant hepatitis. In countries where BCG is still used for vaccination, X-SCID patients may develop severe, systemic BCGosis. Other symptoms that are frequently associated with X-SCID include diarrhea, failure to thrive, and candidiasis. The physical exam and associated studies offer few clues to the diagnosis of X-SCID other than a paucity of palpable lymph nodes and absence of a thymic shadow on a chest X-ray.

Flow cytometry testing to evaluate tyrosine phosphorylation of the STAT3 transcription factor in response to IL-21 stimulation can provide a rapid assessment of whether a patient may have an IL2RG or JAK3 defect (see below). Under normal circumstances, IL-21 stimulation of B cells causes rapid tyrosine phosphorylation in B cells that is absent in patients with IL2RG or JAK3 deficiency (see Fig. 63.2). The diagnosis is ultimately confirmed however by sequencing of the *IL2RG* gene.

HSCT has been the mainstay of therapy for X-SCID using a variety of pretransplant conditioning regimens. Some have strongly advocated the use of T-cell depleted grafts from one of the haploidentical parents because they are readily available but many patients transplanted using that approach have failed to obtain significant donor chimerism in the B-cell compartment, so have remained dependent on IgG supplementation posttransplant. X-SCID was also the first disorder successfully treated by gene therapy. Unfortunately, the retroviral gene therapy vector used to deliver the normal copy of the *IL2RG* gene had an unknown propensity to integrate within the T-cell oncogene *LMO2*, causing T-cell leukemias in a subset of treated patients.[76,77,78] Further studies are underway using alternative viral vectors with the hope that these may have a better safety profile.

JAK3 Deficient Severe Combined Immune Deficiency

JAK3 is the tyrosine kinase immediately downstream of the common gamma chain (γc). It transduces signals from cytokine receptors to the STAT5 transcription factor and to other intracellular signaling molecules (see Fig. 63.2). Approximately 30 different mutations have been identified that impair JAK3 function to varying degrees. Those that are severe have a $T^{neg}B^{+}NK^{neg}$ cellular phenotype similar to mutations in *IL2RG*. Approximately one third of patients have milder mutations that allow some JAK3 function.[79,80] These patients can develop some T cells although the T cells that develop are functionally abnormal. The clinical presentation is similar to that observed in γc deficiency. Sequencing of the *JAK3* gene is required to confirm the diagnosis.

Interleukin-7 Receptor, CD3 Components, and CD45-Deficient Severe Combined Immune Deficiency

Defects in the α-chain of the IL-7 receptor (IL7RA), CD3 subunits (γ, δ, ε), or CD45 can cause SCID with a $T^{neg}B^{+}NK^{+}$ phenotype. As noted above, IL-7 is one of the two key growth and differentiation factors for T cells. As a result, mutations in the IL-7 receptor α-chain (CD127) lead to selective T-cell deficiency but allow normal development of B and NK cells.

Similarly, absence of any of the CD3 subunits specifically affects the ability of T cells to develop because CD3 makes up an essential part of the T-cell receptor complex. The T-cell receptor, including CD3 subunits, assembles in the endoplasmic reticulum and Golgi complex before trafficking to the cell surface. If any of the receptor subunits are absent (including any of the CD3 chains), the receptor is recycled and never makes it to the outer cell membrane. As a result, cells are unable to receive the TCR stimulation needed as they traffic through the thymus and they die by "neglect." Because the number of T cells entering the thymus is normal, the CD3 defects are unusual among SCID disorders in that the size of the thymus is normal. Of the three known CD3 defects (γ, δ, and ε), CD3γ deficiency may have a somewhat milder clinical phenotype that can present with moderate T-cell lymphopenia and recurrent pneumonia and otitis.

CD45 is a transmembrane tyrosine phosphatase present on most white blood cells. It regulates intracellular Src-family tyrosine kinases that are important for T-cell receptor function and

TABLE 63.2

MOLECULAR DEFECTS ASSOCIATED WITH SPECIFIC CELLULAR PHENOTYPES IN SEVERE COMBINED IMMUNE DEFICIENCY (SCID)

Cellular Phenotype	Gene	Inheritance	Features
$T^{neg}B^{neg}NK^{neg}$			
• Adenosine deaminase deficiency	*ADA1*	AR	Costochondral abnormalities, neonatal hepatitis
• Purine nucleotide phosphorylase deficiency	*PNP*	AR	Progressive neurologic problems
• Reticular dysgenesis	*AK2*	AR	Also has deficiency of myeloid lineage cells, sensorineural deafness
$T^{neg}B^{neg}NK^{+}$			
• RAG1 deficiency	*RAG1*	AR	
• RAG2 deficiency	*RAG2*	AR	
• Artemis deficiency	*DCLRE1C*	AR	Radiosensitivity
• DNA-PKcs deficiency	*PRKDC*	AR	Radiosensitivity
• DNA ligase IV deficiency	*LIG4*	AR	Radiosensitivity, microcephaly, growth retardation
• Cernunnos/XLF deficiency	*NHEJ1*	AR	Radiosensitivity, microcephaly, growth retardation
$T^{neg}B^{+}NK^{neg}$			
• Common γ chain deficiency	*IL2RG*	XL	
• JAK3 deficiency	*JAK3*	AR	
• CD45	*PTPRC*	AR	Some NK cells may be present
$T^{neg}B^{+}NK^{+}$			
• IL-7 receptor-α (CD127) deficiency	*IL7RA*	AR	
• DiGeorge syndrome	*22q11.2 del*	AD	Hypoparathyroidism, cardiac defects, dysmorphic facies
• CHARGE syndrome	*CHD7*	AD	Multiple anomalies make up the clinical complex of CHARGE syndrome
• CD3δ deficiency	*CD3D*	AR	
• CD3ε deficiency	*CD3E*	AR	
• CD3γ deficiency	*CD3G*	AR	
• CD3ζ deficiency	*CD3Z*	AR	
• P56lck deficiency	*LCK*	AR	
• Coronin-1A deficiency	*CORO1A*	AR	Lymphadenopathy
$T^{+}B^{+}NK^{+}$			
• MHC II deficiency	*CIITA*	AR	$CD4^{+}$ T cells are typically decreased but not absent
	RFXANK	AR	
	RFX5	AR	
	RFXAP	AR	
• ORAI1 deficiency	*ORAI1*	AR	Myopathy, calcium flux defect in B and T cells so poor proliferation
• STIM1 deficiency	*STIM1*	AR	Myopathy, calcium flux defect in B and T cells so poor proliferation

AD, Autosomal dominant; AR, Autosomal recessive; XL, X-linked recessive.
Modified from Cossu F. Genetics of SCID. Ital J Pediatr 2010;36:76.

activation. Autosomal recessive mutations of CD45 lead to T-cell deficiency and a SCID phenotype in affected infants.

DNA Recombination and Repair Defects in Severe Combined Immune Deficiency

Rearrangement of the V, D, J, and constant regions of the T-cell receptor gene and the B-cell immunoglobulin gene requires that double-stranded breaks be made in the DNA and that these breaks then be repaired after removal of intervening chromosomal fragments. The recombinase activating genes *RAG1* and *RAG2* are expressed in T and B cells and play an essential role in creating the necessary double-stranded DNA breaks in the TCR and immunoglobulin loci. A large complex of proteins including Artemis (DCLRE1C), DNA-PKcs, Cernunnos/XLF (XRCC4-like factor), and DNA ligase IV (LIG4) then play a role in the repair of the DNA double-stranded breaks needed to create the final, recombined TCR or Ig locus. Inasmuch as productive rearrangement of the TCR or Ig locus is a necessary developmental step during T- and B-cell maturation, complete failure in one of these processes results in lymphopenia, with few if any T- or B cells

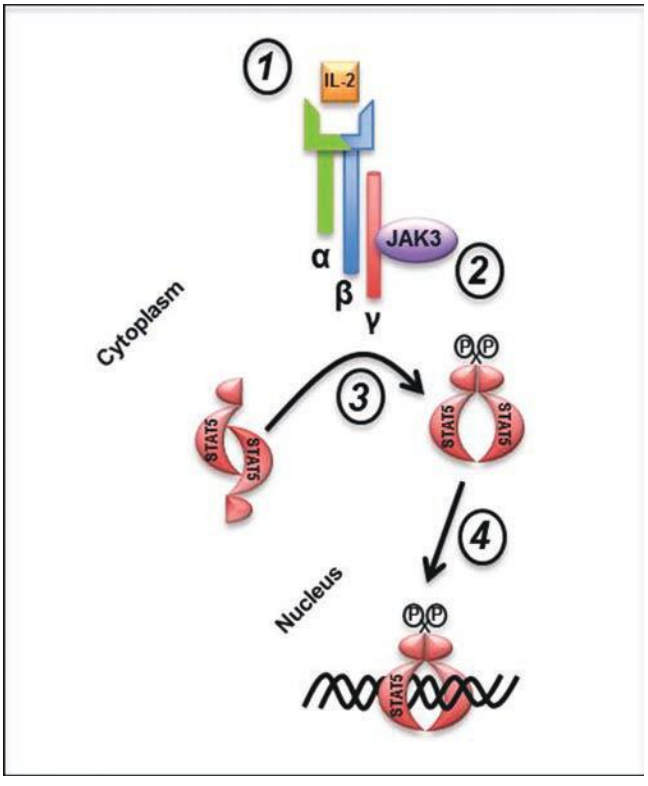

FIGURE 63.2. Interleukin-2 signaling. Under resting circumstances, the transcription factor STAT5 is present in the cytoplasm in a nonphosphorylated state. Upon binding of IL-2 to its receptor made up of α, β, and γ chains (1), the common γ chain is phosphorylated on tyrosine by the receptor-associated JAK3 kinase (2). STAT5 then binds to the phophotyrosine residues on the receptor via its Src-homology 2 (SH2) domains, where it is also phosphorylated on key tyrosine residues by JAK3 (3). After undergoing a conformational change, the phosphorylated STAT5 dimer localizes to the nucleus where it binds DNA and mediates gene transcription. Mutations in the common IL-2 receptor γ chain or in JAK3 cause severe combined immunodeficiency (SCID).

in the blood, whereas generation of NK cells is generally unaffected. Because radiation induces double-strand breaks in DNA, cells from patients with mutations in any of the proteins involved in DNA repair (Artemis, DNA-PKcs, cernunnos, ligase IV) demonstrate decreased survival in vitro after radiation exposure (radiation-sensitivity). This can be a valuable diagnostic clue in making a diagnosis.

Patients who have null mutations of any of these proteins have a clear $T^{neg}B^{neg}NK^{+}$ cell phenotype. There are, however, many mutations, particularly missense mutations or small in-frame deletions that allow expression of a partially functional protein that can occasionally productively recombine a TCR or Ig gene locus. The cell in which this occurs is then able to pass the developmental block and proliferate in an attempt to fill the lymphopenic void that is otherwise present in SCID. These forms of SCID are termed "leaky" because they allow a small number of T- (and occasionally B-) cells to "leak" past the developmental block. Omenn syndrome, originally described in leaky RAG1 or RAG2 mutants, is a clinical phenotype that results from this leaky form of SCID. Affected infants typically develop a desquamative erythroderma after birth that is associated with the presence of oligoclonal, activated T cells in the skin, hepatosplenomegaly, lymphadenopathy, eosinophilia, and elevated IgE. Some develop autoimmune enteropathy and cytopenias. Affected patients are typically treated with T-cell–directed immunosuppression such as cyclosporine or FK506, followed by bone marrow transplantation. Leaky forms of SCID have now been described in a number of SCID-associated molecular defects including RAG1, RAG2, Artemis, ligase IV, IL7RA, IL2RG, RMRP, and others.[81]

Adenosine Deaminase and Purine Nucleotide Phosphorylase Deficient Severe Combined Immune Deficiency

Adenosine deaminase (ADA) deficiency was the first molecularly defined immunodeficiency with discovery of patients with SCID who lacked the enzymatic activity of ADA in the peripheral blood in the early 1970s. ADA catalyzes the conversion of adenosine triphosphate (ATP), guanosine triphosphate (GTP), and their deoxy counterparts to adenosine diphosphate (ADP) and guanosinediphosphate (GDP). When enzyme activity is impaired or absent, intracellular levels of deoxy-ATP (dATP) rise to interfere with ribonucleotide reductase, such that DNA synthesis and repair are slowed and lymphocyte apoptosis is increased. Purine nucleotide phosphorylase (PNP) works farther down this same metabolic pathway to convert deoxyinosine to hypoxanthine. Mutations interfering with this function cause deoxy-GTP accumulation and the inhibition of ribonucleotide reductase and DNA synthesis. In both cases, affected infants typically have a $T^{neg}B^{neg}NK^{neg/low}$ cellular phenotype due to the toxic nature of the accumulated metabolites on lymphocyte development. Patients typically present with severe or recurrent viral infections or recurrent sinopulmonary infections in the first year of life.

Both syndromes are associated with other, nonimmune symptoms including skeletal abnormalities and osseochondrosis dysplasia in ADA deficiency and neurologic deficits, developmental delay, and spasticity, in PNP deficiency. In both cases, the diagnosis can be made by detecting high levels of the toxic metabolites that build up in the peripheral blood in the absence of enzymatic activity. Sequencing of the *ADA1* or *PNP* genes can be done to confirm the diagnosis. ADA deficiency accounts for 20% or more of autosomal-recessive SCID cases.

Aside from bone marrow transplantation, ADA deficient infants can be treated with polyethylene glycol–conjugated ADA, which is injected intramuscularly once per week. Treatment efficacy is gauged by measuring plasma ADA activity and red cell dATP levels. Enzyme treatment has the advantage of speed of response coupled with safety.[82,83] The treatment is very expensive and many treated patients develop antibodies to the bovine protein that may neutralize the effect of the enzyme. HSCT is effective in ADA deficiency but less so in PNP deficiency as it does not correct the neurologic deficits. Gene therapy for ADA deficiency has been quite successful and unlike X-linked SCID and WAS, there have been no reported cases of leukemia despite the retroviral gene therapy vector backbone being similar.[84]

Zap-70 Deficient Severe Combined Immune Deficiency

Zap-70 is a tyrosine kinase that is downstream of CD3 in the T-cell receptor signaling pathway. Absence of functional enzyme results in a characteristic SCID phenotype with decreased $CD4^{+}$ T cells but virtually absent $CD8^{+}$ T cells. Immunoglobulin levels are often decreased and antibody responses to vaccination are typically absent because of the lack of effective T-cell help. The $CD4^{+}$ T cells that are present do not respond to antigen or mitogen stimulation that utilizes the T-cell receptor but they do proliferate and make cytokines in response to phorbol and ionomycin stimulation, which mimics TCR stimulation by activating kinases and calcium flux through downstream mechanisms. Bone marrow transplantation is effective in this disorder.

Defects in Antigen Presentation by MHC I or MHC II

The class II MHC complex generally presents peptide antigen derived from ingested material (either by phagocytosis or via the B-cell antigen receptor). Defects that interfere with the assembly or cell-surface expression of the Class II MHC–peptide complex prevent effective antigen recognition by $CD4^{+}$ T cells, resulting in a SCID syndrome that presents in infancy with chronic diarrhea, failure to thrive, and occasionally with autoimmune cytopenias. MHC II deficiency can result from defects in one of four

DNA-binding proteins that regulate transcription of the MHC class II gene (*CIITA*, *RFXANK*, *RFX5*, and *RFXAP*). Founder mutations (particularly in *RFXANK*) that are common in the Mediterranean region have led to most affected patients having some familial ties to this geographical area. Because MHC class II presentation of antigen is abnormal, $CD4^+$ T-cell counts are often low whereas CD8 counts are normal. A rapid preliminary diagnosis can be made by evaluating peripheral blood cells for expression of the class II complex by flow cytometry, which will detect reduced expression. Some patients can have a mild disease course and can live well into adulthood with only supportive care although others with the same mutation (even in the same family) may have a more severe phenotype. Bone marrow transplantation for MHC II deficiency has been challenging with survival rates typically approaching approximately 50%. In addition, there is a high rate of severe graft-versus-host disease (GvHD) in these patients, possibly because thymic epithelial cells that play a role in positive and negative T-cell selection are not replaced by transplant and still do not express MHC II.[85]

The class I MHC complex presents peptide antigens derived from intracellular proteins where proteolytically derived peptides are bound to the MHC I complex as it is generated and trafficked through the endoplasmic reticulum. Peptides that are generated in the cytosol are transported into the inner lumen of the endoplasmic reticulum by the peptide transporters TAP1 and TAP2. Mutations in either of these, or of Tapsin to which they bind, have been identified. TAP mutations are typically associated with recurrent viral infections, and recurrent sinusitis and bronchitis. The diagnosis is usually suspected when serologic typing for HLA Class I antigens fails to give interpretable results, but molecular typing indicates intact MHC DNA. $CD8^+$ T-cell and NK-cell counts are frequently (but not uniformly) decreased in these patients. Other cell subsets are typically normal. Heterogeneity in the phenotype may reflect differences in the underlying mutation and in the gene affected. Some patients may survive into the third decade. The role of HSCT in MHC I deficiency is unclear.

Treatment of Severe Combined Immunodeficiency Syndromes

SCID was uniformly lethal in the first years of life until Good and colleagues successfully reconstituted an affected infant with a transplant of sibling bone marrow. Experience in subsequent years has shown that patients with B-cell–positive SCID (IL2RG, JAK3, IL7RA, etc.) readily reconstitute their T-cell deficiency but may not develop significant B-cell chimerism. The reasons for this are not entirely understood but various hypotheses have been put forward. From a practical standpoint, a lack of donor B-cell engraftment may lead to a chronic need for IgG replacement therapy even after transplant inasmuch as patients may not be able to mount sufficient antibody responses. Patients with B-cell–negative SCID are more likely to have successful donor engraftment of both T- and B-cell lineages and are more likely to recover full humoral immune function.

One of the most significant challenges in the treatment of SCID is that in the absence of a family history, most patients come to attention because of infections. These are most commonly PJP and severe viral infections (see above). PJP can be treated but may lead to lung damage, whereas the viral infections may or may not be controllable. In addition, many SCID infants have significant diarrhea and weight loss by the time they reach a transplant center. Together, these complications increase the risk of adverse outcomes during transplantation for SCID and have been the major impetus for adding SCID to state newborn screening panels. Initial management prior to transplant involves aggressive supportive care, antimicrobials to treat any intercurrent infections (bacterial, viral, and fungal), antimicrobial prophylaxis to prevent future infections, and IgG replacement therapy.

There is significant debate about the best pretransplant conditioning regimen for patients with SCID to balance safety and efficacy. In general, those patients that have a matched sibling donor receive no conditioning prior to receiving unmanipulated bone marrow. For other patients, a variety of conditioning regimens ranging from no conditioning to fully myeloablative regimens have been tried. Similarly, a range of manipulated and unmanipulated stem cell sources have been tried including matched bone marrow, matched peripheral blood, cord blood, and haploidentical. Last, a variety of prophylactic immunosuppressive regimens have been used in the early posttransplant period to limit GvHD and prevent graft rejection. Each option has advantages and disadvantages, which has led to the spectrum of transplant regimens that have been attempted for SCID. Current efforts are underway to assess which regimens offer the best outcomes and lowest risk.[86–88,89]

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH) is a complex disorder characterized by skeletal dysplasia with short limbs (metaphyseal chondrodysplasia), sparse hypoplastic hair, gastrointestinal problems, and a variable immunodeficiency. CHH is caused by mutations in the *RMRP* gene, which encodes the 267 base-pair RNA component of the RNase MRP complex that plays a role in processing of precursor ribosomal RNA. The mechanism by which autosomal recessive mutations in *RMRP* cause the clinical features of CHH is unknown. The largest populations of CHH patients have been identified among the Old Order Amish and Finnish populations. Virtually all patients with CHH have some degree of immunodeficiency that can range from a mild humoral defect with decreased vaccine responses to a SCID-like phenotype associated with progressive lymphopenia and severe infections with bacteria, viruses, and fungi. A leaky-SCID phenotype has also been described in RMRP deficiency. The diagnosis of CHH can be made based on the clinical phenotype and confirmed by sequencing of the *RMRP* gene. The immunologic features of CHH can be corrected by HSCT but the other features persist.[90]

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-linked Syndrome

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) is a syndrome of regulatory T-cell deficiency. Natural regulatory T cells comprise a subset of $CD4^+$ T cells that regulate immune responses and play a critical role in peripheral immune tolerance. IPEX syndrome is caused by mutations in the *FOXP3* gene located on the X chromosome that encodes a key transcription factor that is required for the generation of functional regulatory T cells (Treg). In the absence of FOXP3, patients present with severe, early-onset, systemic autoimmunity that is the result of having decreased Treg cell function. Almost all patients with IPEX syndrome present with enteropathy within the first 6 months of life. The enteropathy is typically characterized by profuse watery diarrhea (often nonbloody) and villus atrophy. The majority of patients have an eczematous dermatitis that typically begins in the first months of life. An early onset endocrinopathy that is almost exclusively either thyroiditis or Type I diabetes is also developed by 60% to 70% of patients. The most consistent laboratory abnormality among patients is a significantly elevated serum IgE level. In addition to these characteristic clinical and lab features, patients also have a high incidence of other severe autoimmune disorders including: hemolytic anemia, thrombocytopenia, neutropenia, hepatitis, renal disease, and others.

Recognition of the clinical features of IPEX syndrome is the first step in diagnosing this disorder. Sequencing of the *FOXP3* gene remains the gold standard for making a diagnosis of IPEX syndrome although sequencing needs to encompass noncoding

areas of the gene including the upstream noncoding exon and the polyadenylation signal sequence in order to cover all regions in which pathogenic mutations have been identified.[91,92] Flow cytometry to measure FOXP3 protein expression and FOXP3$^+$ Treg is a helpful adjunct to gene sequencing although only ~25% of patients have mutations that are predicted to abrogate FOXP3 protein expression completely. The remainder of patients have varying degrees of FOXP3$^+$ Treg deficiency due to the fact that mutant FOXP3 may not support normal Treg development. As a result, flow cytometry by itself is not considered to be a sufficiently reliable screening test for IPEX syndrome.

Initial therapy for IPEX syndrome typically consists of aggressive supportive care (parenteral nutrition, insulin, thyroid hormone, etc.) combined with T-cell–directed immune suppression using agents such as tacrolimus, cyclosporine, or rapamycin. HSCT is currently the only curative therapy for IPEX syndrome. Early HSCT using a nonmyeloablative conditioning regimen prior to the onset of autoimmune-mediated organ damage usually leads to the best outcome and limits the adverse effects of therapy.[93,94] Because Tregs constitutively express the high-affinity IL-2 receptor, they have a selective growth advantage in vivo. As a result, complete donor engraftment in all hematopoietic lineages may not be necessary because preferential engraftment of donor Treg cells can be sufficient to control the disease.[95]

OTHER COMPLEX OR COMBINED IMMUNODEFICIENCY DISORDERS

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is unique among immunodeficiency disorders because affected patients have both an infectious susceptibility and a bleeding disorder. The bleeding problems are caused by the platelets being small (mean platelet volume <5 fl), dysfunctional, and decreased in number (usually platelet counts <70,000/μl). Patients with WAS typically present in infancy with bloody diarrhea and/or bruising, recurrent upper respiratory tract infections, and eczema. The incidence of hematopoietic malignancies is high. IgE levels are often elevated. Serum IgG levels and T-cell counts are often normal in infancy but may decrease over time. Responses to vaccination, particularly with carbohydrate antigens such as Pneumovax are often abnormal.

WAS is caused by mutations in the *WAS* gene that is located on the short arm of the X chromosome. Inheritance is X-linked recessive. There is a distinct genotype/phenotype correlation of mutations in WAS: Mutations that destroy WAS protein (WASp) expression lead to the full syndrome of immunodeficiency and platelet dysfunction. Mutations that allow expression of a mutant WASp protein are typically associated with a milder X-linked thrombocytopenia (XLT) phenotype in which the platelet dysfunction persists but the immunodeficiency is very mild. Point mutations in the CDC42 binding domain of the WASp protein lead to a third phenotype of X-linked neutropenia (XLN) that is generally not accompanied by bleeding abnormalities.[96,97]

The WASp protein is expressed primarily in lymphoid and myeloid cells where it functions to nucleate actin polymerization in the cell. Patients with WAS therefore have problems with directed migration of neutrophils and with clustering and signaling through T-cell and B-cell antigen receptors (this causes decreased signaling into the cell and abnormal proliferative responses). A diagnosis of WAS can be confirmed by demonstrating the absence of WASp protein in cells by flow cytometry or western blotting, or by identifying a mutation in the *WAS* gene.

Treatment of WAS initially involves supportive care including treatment of any acute infections and management of any bleeding episodes. In general, repeated platelet transfusions are avoided because of the concern that patients will become sensitized to a wide array of HLA types, which may increase the risk of complications during subsequent HSCT. Splenectomy can increase platelet counts, however, it also increases the risk that patients may die of sepsis with encapsulated organisms so there continues to be significant controversy surrounding the role of splenectomy in WAS. Patients with the full WAS phenotype should be evaluated for HSCT with matched related or unrelated donor bone marrow or cord blood.[98] Haploidentical transplants have proven risky in this disease and therefore are generally avoided. The role of HSCT in XLT remains controversial.[99] Some have advocated that the benefits for curing the bleeding problems are worth the risk if a matched sibling donor is available. Gene therapy has been successful in a small number of patients with WAS but as in the X-SCID gene therapy trials, some treated patients developed T-cell leukemias as a result of integration of the viral gene therapy vector near an oncogene.[100]

Radiation Sensitive Disorders: Ataxia Telangiectasia and Nijmegen Breakage Syndrome

Ataxia telangiectasia (AT) is a disorder associated with progressive neurologic decline, immunodeficiency, and propensity to malignancy. It is caused by autosomal recessive mutations in the *ATM* gene that encodes a serine/threonine kinase that acts together with the NBS1 protein as one of the major sensors of double-stranded DNA breaks in the cell. ATM phosphorylates key proteins involved in the activation of the DNA damage repair checkpoint, leads to cell-cycle arrest, and then double-stranded DNA break repair. In the absence of functional ATM or NBS1, cells have a marked sensitivity to ionizing radiation. Because rearrangement of the TCR gene and the immunoglobulin gene loci also require double-stranded DNA break repair, these processes may be affected as well.

Patients with AT usually present in early childhood (most commonly between 2 and 5 years of age) with cerebellar ataxia that progresses to unsteady gait and over time, to choreoathetosis. Telangiectasias (small tufts of dilated blood vessels under the surface of the skin or mucus membranes) typically develop first on the conjunctivae and later are seen on the nose, ears, and shoulders. They can be an important diagnostic clue in a child with progressive ataxia. The majority of patients have immunoglobulin deficiency of varying degrees and can develop sinopulmonary symptoms and sepsis. The progressive neurodegeneration can compromise coughing, thus it is hard to determine whether respiratory infections occur more as a result of the immunodeficiency or the motor defects. Most affected individuals have elevated serum α-fetoprotein levels, which can be useful diagnostically. Malignancies are an important complication as a result of the DNA-repair defect. Acute T-cell leukemias are common and often demonstrate chromosomal translocations that affect the chromosomal regions involved in T-cell receptor gene rearrangements. B-cell lymphomas also occur and are usually associated with 11q22–23 chromosomal deletions. There is also an increase in the frequency of epithelial tumors in both homozygotes and ATM mutation carriers. Affected patients usually die in the second or third decade of life.

Other DNA repair defects that cause varying degrees of ataxia and/or mild mental retardation include an ataxialike syndrome caused by mutations in *MRE11* and the Nijmegen breakage syndrome (NBS), caused by mutations in *NBS1*. In addition to an immunodeficiency like that observed in AT, patients with NBS have marked microcephaly, mild developmental delay/

mental retardation, and a strong propensity to develop lymphomas. Another DNA repair defect, Bloom syndrome, caused by mutations in a DNA helicase (RecQ proteinlike-3), results in excess sister chromatid exchanges; it is associated principally with lymphomas and cancer. Multiple primary tumors occurring at an early age are common. Reduced growth in childhood results in a proportional dwarfism that, with cutaneous telangiectasias, is a useful physical sign. Inheritance is autosomal recessive, and the disease occurs with increased frequency in Ashkenazi Jewish populations. Chronic lung disease occurs and may be related to the low levels of IgA and IgM.[101]

Mammalian Susceptibility to Mycobacterial Disease

Under normal circumstances, intracellular pathogens such as mycobacteria induce production of IL-12 and IL-23 that play a role in driving maturation of naive T cells into activated T helper type I (Th1) cells that produce interferon-γ (IFN-γ). IFN-γ then acts on a variety of cells including phagocytes (neutrophils, monocytes, and dendritic cells) to induce a number of interferon-inducible genes. Multiple molecules in this signaling pathway have been found to be defective in patients with intact cellular immunity who have invasive, nontuberculous mycobacterial infections. Mutations in the genes encoding the IL12 p40 subunit (*IL12B*), the IL-12 receptor β1 chain (*IL12RB1*), the *TYK2* tyrosine kinase that is associated with the IL-12 receptor and required for phosphorylation of the STAT4 transcription factor (*TYK2*), the IFN-γ receptor subunits (*IFNGR1&IFNGR2*), and the STAT1 transcription factor that is activated in response to IFN-γ (*STAT1*), and the mutations in this pathway are also associated with other infections including invasive salmonellosis and severe viral infections (*STAT1*). In addition to these genetic defects, patients with invasive mycobacterial disease have now been identified with neutralizing autoantibodies to IFN-γ. Together these discoveries demonstrate a major role for the IL-12/IL-23/IFN-γ axis in normal human immunity.[102] For patients with the milder, autosomal dominant IFN-γ receptor defects, IL-12 p40 defects, IL-12 receptor defects, and TYK2 defects, antimicrobial therapy and IFN-γ treatment are often sufficient to treat invasive mycobacterial infections and to prevent future infections. For patients with the more severe, autosomal recessive IFN-γ receptor defects, IFN-γ supplementation provides no benefit and HSCT is warranted.[103,104]

Susceptibility to Hemophagocytic Lymphohistiocytosis and Severe Epstein-Barr Virus Infection

Several defects affecting intracellular trafficking of vesicles and granules are associated with susceptibility to hemophagocytic lymphohistiocytosis (HLH). This group includes some phenotypes that are quite distinctive including Chédiak-Higashi (CHS) and Griscelli (GS) syndromes, which are both associated with a partial oculocutaneous albinism. Patients with CHS have pyogenic infections and periodontitis; their neutrophils have reduced chemotaxis and contain giant inclusion bodies (lysosomes). Patients with GS also have neurologic defects ranging from developmental delay to fatal neurodegeneration. Their neutrophils are dysfunctional, but they lack the giant granules of CHS. In vitro tests show low natural killer cell and cytotoxic cell function. CHS, GS, and X-linked lymphoproliferative syndrome (XLP) share susceptibility for HLH, an accelerated inflammatory process that in the case of XLP may be triggered by EBV. The genes responsible for these syndromes are *LYST*, *RAB27A*, *SH2D1A*, and *XIAP/BIRC4*, respectively, whereas genes for a further group of proteins (Perforin, Munc 13-D, and Syntaxin 11) are associated with familial hemophagocytic lymphohistiocytosis.[105]

Toll-like Receptors and Innate Signaling Pathway Defects

The Toll-like receptors are a family of at least 10 pattern recognition receptors that are expressed in varying combinations on a broad array of immune and nonimmune cells. They recognize particular types (patterns) of molecules derived from pathogens (e.g., bacterial lipopolysaccharide, flagellin, mannan, CpGdinucleotides, viral dsDNA, etc.). Triggering of Toll-like receptors activates intracellular signaling pathways, many of which converge on a common pathway utilizing the IRAK proteins and MyD88, which in turn activate the IκB kinase complex (NEMO/IκKα/IκKβ), ultimately leading to phosphorylation and degradation of IκBα and activation of the NF-κB transcription factor complex.

Mutations in TLR signaling pathways have now been associated with major infectious susceptibilities: mutations in *IRAK4* and *MyD88* have been identified in patients with susceptibility to invasive pyogenic bacterial infections including particularly *S. pneumoniae*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*. Interestingly, patients with IRAK4 or MyD88 deficiency tend to have problems with invasive pyogenic bacterial infections in childhood but these subside over time, presumably as a result of the adaptive immune response covering for this innate defect. Mutations in *TLR3*, *TRIF*, *TRAF3*, and *UNC-93B* have been identified in patients with susceptibility to herpesvirus encephalitis. Defects in NEMO and IκBα also cause susceptibility to infections with pyogenic bacteria and mycobacteria and are associated with an anhydrotic ectodermal dysplasia phenotype. The severity of immunodeficiency and ectodermal dysplasia is quite variable and depends on the specific mutation that is present.[106]

Chronic Mucocutaneous Candidiasis Syndromes

Chronic mucocutaneous candidiasis (CMC) is a clinical syndrome associated with chronic and recurrent candidal infections of mucosae, particularly oral and vaginal, together with nailbed infections but generally without systemic infection. CMC can occur in isolation or as part of a broader clinical syndrome such as in APECED (autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy). Recent discoveries have determined that in almost all cases, CMC is associated with abnormalities in development of Th17 effector T cells or with the production of, or responses to, the cytokine IL-17. These include autosomal recessive mutations in IL-17F or the IL-17 receptor α-subunit, dominant loss-of-function mutations in STAT3, and dominant gain-of-function mutations in STAT1.[107]

Recently, the CMC associated with APECED was found to be the result of autoantibodies to IL-17 and IL-22.[108,109] APECED is caused by mutations in AIRE1, a nuclear protein that regulates the expression of self-antigens by thymic medullary epithelial cells where it plays a role in T-cell selection and maturation. Other features of this disorder include endocrinopathies (hypoparathyroidism, adrenal insufficiency, and diabetes), alopecia areata, nail dystrophy, and vitiligo.

Autoimmune Lymphoproliferative Syndrome

The clinical phenotype of autoimmune lymphoproliferative syndrome (ALPS) is characterized by massive lymphadenopathy and hepatosplenomegaly in most cases. In addition, patients have problems with recurrent episodes of autoimmune hemolytic

SUGGESTED LAB TESTS FOR BASIC EVALUATION OF EACH COMPARTMENT OF THE IMMUNE SYSTEM

Complement	Phagocytes	B Cells/Antibodies	T Cells
Numbers: • Plasma levels of specific complement components (C1 esterase inhibitor, C2, C3, C4, etc.) **Function:** • CH50—functional test for classical pathway • AH50—functional test for alternative pathway	**Numbers:** • CBC with differential: Are neutrophil counts normal? **Function:** • Expression of the CD11b/CD18 integrin on leukocytes • Neutrophil oxidative burst test: dihydrorhodamine 123 (DHR) or Nitroblue tetrazolium (NBT)	**Numbers:** • CBC with differential: Are lymphocyte counts normal? • Lymphocyte subsets: Are T-, B-, and NK-cell counts normal? **Function:** • Vaccine titers: protein antigens (tetanus or diphtheria titers, etc.) • Vaccine titers: carbohydrate antigens (Pneumococcal titers)	**Numbers:** • CBC with differential: Are lymphocyte counts normal? • Lymphocyte subsets: Are T-, B-, and NK-cell counts normal? **Function:** • T-cell proliferation to mitogens/antigens • Vaccine titers: protein antigens (tetanus or diphtheria titers, etc.)

Note: The laboratory evaluation for immunodeficiency should be individualized to each patient's clinical presentation.

anemia and thrombocytopenia. The defects that have been identified in patients with this group of disorders are all associated with abnormalities in lymphocyte apoptosis. These include *FAS* (CD95), Fas ligand (*FASL*), *FADD*, caspase 10 (*CASP10*), *NRAS*, and *KRAS*. Peripheral blood T- and B-cell counts are generally normal, but in almost all cases, there is an increased percentage of $\alpha\beta$-TCR$^+$ double-negative T cells that lack expression of both CD4 and CD8. A predisposition to developing lymphoid malignancies has been described in ALPS but is thought to be primarily in those patients who have mutations in the death domain of FAS. In addition to elevated double-negative T cells, patients with ALPS frequently have elevated levels of IL-10 and vitamin B12 in the blood, which can be valuable diagnostically in patients with suspected ALPS. Patients with mutations in caspase 8 (*CASP8*), were previously classified as ALPS but are now considered to have a unique syndrome that may include lymphadenopathy and splenomegaly, but recurrent respiratory tract infections and mucocutaneous herpesvirus infections are prominent, both unusual features in ALPS.[110,111]

A variety of immunosuppressive therapies have been tried in ALPS to control the recurrent autoimmune cytopenias and severe hepatosplenomegaly. Most of these were only modestly successful as was splenectomy. Recent studies have, however, demonstrated a dramatic response to rapamycin therapy in many patients with ALPS, often causing shrinkage of the lymph nodes and spleen back to their normal size.[112,113]

BASIC LABORATORY WORK-UP FOR IMMUNE DEFICIENCY

A basic laboratory work-up to screen for significant defects in each of the four major compartments of the immune system can be done by most practitioners prior to making a referral to a clinical immunologist for further detailed evaluation. In simple terms, this work-up should include evaluation of numbers and function for each of the four immune system compartments. A recommended work-up using this approach is outlined in Table 63.3.

CHAPTER 64

ACQUIRED IMMUNODEFICIENCY SYNDROME

Ariela Noy, Roy M. Gulick

HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

Human immunodeficiency virus (HIV) infection is a true pandemic, an infection that affects individuals in every country of the world.[1] A diagnosis of acquired immunodeficiency syndrome (AIDS) is made when a person with HIV infection progresses to develop severe immunodeficiency as demonstrated by a CD4 lymphocyte count of less than 200/μl or the development of specific AIDS-associated diseases.[2] The first cases of AIDS were described in 1981 in five young gay men in Los Angeles.[3] Since the beginning of the HIV pandemic, an estimated 70 million people worldwide acquired HIV infection and over half of them died.[1] Currently, an estimated 34 million people are living with HIV infection, with over two thirds of them living in sub-Saharan Africa. There are an estimated 1.1 million people currently living with HIV infection in the United States.[4] The development of effective antiretroviral treatment in 1996 changed the natural history and clinical course of HIV infection dramatically, with remarkable decreases in HIV-associated illnesses and deaths.[5] In parallel, many of the hematologic complications of HIV infection also occur much less commonly today. Cytopenias due to HIV disease or its treatment occurred frequently in the past, but now are uncommon. Coagulation abnormalities occur occasionally. Hematologic malignancies remain an important challenge, even in the setting of effective HIV treatment. This chapter discusses HIV infection and the diagnosis and management of associated hematologic complications. A complete discussion of antiretroviral therapy and opportunistic diseases can be found elsewhere.[6–8]

Background

HIV-1 was discovered by two independent groups in 1983 to 1984.[9] A related virus, HIV-2, was discovered in 1986, but remains localized to Western Africa and countries with historic ties to Western African countries.[10] HIV is transmitted most commonly worldwide by sexual contact and also by intravenous drug use, transfusion of infected blood or blood products, and perinatally from an infected mother to her child. HIV may be transmitted by infected blood, blood products, bloody fluids, or genital secretions, but not by saliva, sweat, urine, other nonbloody fluids, or feces. In the absence of HIV treatment, the time from initial HIV infection to the development of severe immunodeficiency and AIDS is approximately 10 years.[11] The U.S. Centers for Disease Control and Prevention define AIDS in individuals who are HIV-1 antibody positive with a CD4 cell count <200/μL (regardless of symptoms) or have one of ~25 AIDS-defining illnesses, including opportunistic infections and malignancies.[2] Effective antiretroviral therapy changes the natural history of the disease and prevents HIV disease progression and prolongs survival.

Pathophysiology

HIV-1 is a retrovirus with a genome that contains the structural genes *gag, pol,* and *env* that code for viral core proteins that control viral replication (e.g., HIV reverse transcriptase, HIV integrase, and HIV protease), as well as the envelope glycoproteins, gp 160, 120, and 41.[12] Additional regulatory genes, *rev* and *tat,* code for viral-specific proteins that control viral transcription and processing of viral messenger RNA. Other viral genes mediate infectivity and interactions with the host cell (*nef, vif, vpr, vpu).*

HIV entry is the first step in HIV-1 infection and consists of three substeps: CD4 receptor binding, co-receptor binding, and membrane fusion.[13] In the first substep, the viral outer membrane glycoprotein, gp120, binds to the CD4 receptor on the surface of the target cell. Cells that express CD4 receptors include the CD4 lymphocyte, macrophages, and dendritic cells. Following binding of gp120 to the CD4 receptor, gp120 undergoes a conformational change and allows binding to a second co-receptor, the chemokine receptor, either CCR5 or CXCR4.[14] Individuals who lack the gene that codes for the CCR5 receptor are relatively resistant to HIV infection; individuals who are heterozygotes for this gene demonstrate a slower progression of HIV disease.[15] Following binding to the co-receptor, gp120 undergoes a second conformational change that allows a second HIV membrane glycoprotein, gp41, to bind and attach to the cell surface and then allows the viral membrane to fuse with the host cell membrane.

After HIV entry, the contents of the viral particle, including viral RNA and viral proteins, are extruded into the cytoplasm of the target cell. Viral RNA is transcribed to complementary viral DNA by the viral specific enzyme, HIV reverse transcriptase. The viral DNA forms a double-stranded complex that migrates to the nucleus of the cell where the viral-specific protein HIV integrase inserts the viral DNA randomly into the host cell genome. An HIV-infected CD4 lymphocyte may enter a latency period that can extend to 70 years, constituting a long-lived viral reservoir.[16] The latently infected cell may be activated, and then genomic DNA along with incorporated viral DNA is transcribed to viral RNA that is translated to viral proteins, including *gag* and *pol* gene products that assemble at the surface of the cell and then bud off into new viral particles. Post-budding, precursor viral proteins are cleaved by another viral-specific enzyme, HIV protease, in a step that is required for viral maturation and infectiousness.[17] A single latently infected cell can produce hundreds to thousands of virions. When enough viral particles have budded off from an infected cell, the membrane becomes compromised and cell death occurs.

The characteristic decrease in CD4 lymphocytes over the course of untreated HIV disease occurs from a combination of increased apoptosis and decreased lymphopoiesis, although this is not completely understood.[18] An estimated one million latently infected CD4 lymphocytes exist in an HIV-infected individual with controlled infection on antiretroviral therapy.[19] Although the relative number of latently infected CD4 cells is small, apoptosis may occur in uninfected CD4 cells. Untreated HIV infection also was recognized early on to be associated with immune activation, CD8 cell dysfunction, B-cell dysfunction and impaired antibody production and general immune dysregulation.[20,21]

Diagnosis

The U.S. Centers for Disease Control currently recommend routine HIV testing for all individuals aged 13 to 64, not based on risk.[22] Standard HIV testing detects HIV-1 antibody by using a screening test, a repeatedly positive enzyme-linked immunosorbent assay (ELISA), followed by a confirmatory test, a Western blot that demonstrates at least two among three major HIV-1-specific bands: p24, gp41, and gp120/160.[23] False-positive ELISA may occur because of the low specificity of the test. False-negative HIV antibody tests can occur due to the window period (4 to 6 weeks), the

time between viral infection and the development of the detectable antibody response.

Newer rapid tests use a technology similar to the ELISA to detect HIV antibody in blood or oral fluids and results are available within 20 minutes. Although the rapid test is very specific (>99%) with a high positive predictive value (≥90%), a positive rapid test must be confirmed by a conventional confirmatory Western blot.[24] Some rapid tests are now CLIA-waived and may be performed in nonhealth care settings (e.g., street fairs, mobile vans or even self-administered at home) allowing more widespread testing.

Another method of HIV testing detects the virus directly, either the viral p24 antigen or HIV RNA, and reduces the window period: p24 antigen testing was added to the standard HIV antibody ELISA test, the so-called 4th generation ELISA test, to detect HIV infections earlier.[25] Nucleic-acid–based testing has been used both in individual cases and in blood bank screening programs.[26] Using these newer tests along with pre-transfusion screening, the risk of acquiring HIV infection through a blood transfusion in the United States is less than 1 per 1.5 million units transfused and is decreasing.[27]

Clinical Features of Hiv-1 Infection

Acute HIV infection can present as a nonspecific illness characterized by fever, oral ulcers, and maculopapular rash[28]; however, at least 50% of newly infected individuals may be completely asymptomatic. The clinical illness will subside over several weeks and then the patient enters an asymptomatic phase, often with nonspecific generalized lymphadenopathy, that may last years as the CD4 lymphocyte count gradually declines over time. HIV-related diseases occurring at higher CD4 counts (>300/μL) include those caused by more aggressive pathogens (e.g., tuberculosis, herpes zoster, and pneumococcal pneumonia) as well as Kaposi's sarcoma. As the CD4 cell count declines below 300, other HIV-related illnesses also occur, including oral hairy leukoplakia, oral thrush, and seborrheic dermatitis. As the CD4 cell count declines below 200, the case definition of AIDS is met and AIDS-defining illnesses may also occur including *Pneumocystis jiroveci* (formerly *carinii*) pneumonia, central nervous system (CNS) toxoplasmosis, and cryptococcal meningitis. Multiple opportunistic illnesses can occur simultaneously in a single patient.

Hematologic disorders such as leucopenia, anemia, immune and thrombotic thrombocytopenia, bone marrow failure, coagulation disorders including thrombosis, and malignancies all occurred commonly in HIV-infected individuals.[29,30] Some of these complications were due to viremia and immune dysregulation, and others were due to toxicity from HIV therapies.[31] With the development of effective antiretroviral therapy, hematologic disorders and HIV-associated malignancies have decreased markedly.[32]

Treatment

In the 1980s and early 1990s, the average life expectancy of a patient with AIDS was less than 1 year. Today, it is estimated that an individual diagnosed with HIV infection and appropriately managed with antiretroviral treatment will live close to the average life expectancy of the general population.[33] Antiretroviral therapy changes the natural history of HIV infection by inhibiting viral replication. Currently, there are 27 U.S. Food and Drug Administration–approved unique drugs for the treatment of HIV infection; combination regimens with 3 or more drugs are standard treatment. Current U.S. HIV treatment guidelines recommend starting antiretroviral therapy in all HIV-infected individuals, regardless of symptoms, HIV viral load, or CD4 cell count.[6] The life cycle of the virus and the specific sites targeted by antiretroviral therapy are shown in Figure 64.1.

The oldest mechanistic classes of drugs are the HIV reverse transcriptase inhibitors of two kinds, the nucleoside analogs and the nonnucleoside analogs. The nucleoside analogs mimic the structures of the four DNA bases and when bound to the active site and incorporated into the elongating viral DNA, result in chain termination: adenosine analogs, didanosine (ddI) and tenofovir (TDF); cytosine analogs, emtricitabine (FTC), lamivudine (3TC), zalcitabine (ddC); guanine analog, abacavir (ABC); and thymidine analogs, stavudine (d4T) and zidovudine (AZT, ZDV). The nonnucleoside analogs also inhibit the HIV reverse transcriptase enzyme, but do so by binding a site remote to the active site and include delavirdine (DLV), efavirenz (EFV), etravirine (ETR), nevirapine (NVP), and rilpivirine (RPV).

In the mid-1990s, the third antiretroviral drug class was approved, the HIV protease inhibitors that target a step late in the viral life cycle. Following budding of the viral particles from the infected cell, viral precursor proteins must be chemically cleaved by the viral-specific enzyme, HIV protease. These compounds were the most potent known against HIV and when used in combination regimens resulted in suppression of HIV RNA levels and dramatic decreases in morbidity and mortality.[5] The 10 approved protease inhibitors bind in the active site of the protease and block this cleavage: amprenavir (APV) and its prodrug fosamprenavir (FPV), atazanavir (ATV), darunavir (DRV), indinavir (IDV), lopinavir (LPV), nelfinavir (NFV), ritonavir (RTV), saquinavir (SQV), and tipranavir (TPV).

The three newer mechanistic classes of approved HIV drugs are two different HIV entry inhibitors and the HIV integrase inhibitors. The approved chemokine receptor antagonist is maraviroc (MVC) that binds to the host cell CCR5 receptor and prevents viral binding. The approved HIV fusion inhibitor is a small peptide, enfuvirtide (ENF, T-20) that targets the viral glycoprotein gp41 and prevents fusion of the viral and cellular membranes; as a

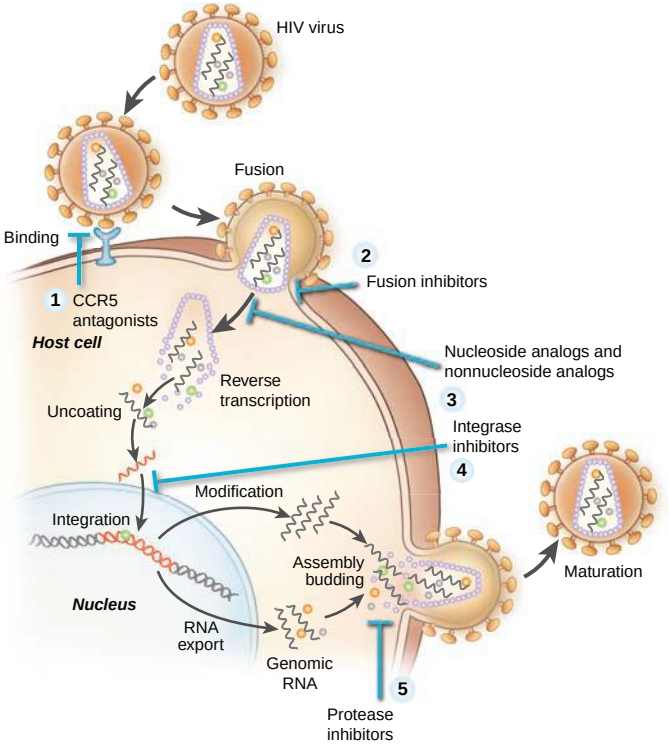

FIGURE 64.1. The human immunodeficiency virus (HIV) life cycle, deciphered with the help of genomic analyses, is unusually complex in its details, but all viruses undergo the same basic steps to infect cells and reproduce. Points at which antiretrovirals act are marked.

peptide it requires twice-daily subcutaneous dosing and is used uncommonly. Raltegravir (RAL) and elvitegravir (EVG) inhibits the viral-specific enzyme HIV integrase that inserts the viral DNA into the host cell DNA.

Current treatment guidelines recommend four preferred combination antiretroviral regimens on the basis of potency, tolerability, and convenience[6]: (1) tenofovir/emtricitabine/efavirenz (co-formulated as a single pill taken once daily); (2) tenofovir/emtricitabine (co-formulated) + atazanavir and ritonavir (given as a low-dose pharmacologic booster; 3 pills once daily); (3) tenofovir/emtricitabine (co-formulated) + darunavir and ritonavir (booster; 3 pills once daily); and (4) tenofovir/emtricitabine (co-formulated) + raltegravir (3 pills divided twice daily). The goal of current HIV treatment is maximal virologic suppression; current virologic suppression rates on initial therapy regimens approach 90%. CD4 cell counts typically increase 100/μL over baseline in the first weeks or months following initiation of therapy and then continue to increase at a slower rate.[34] The reconstituted CD4 cells generally are of the memory type ($CD45RO^+$ or $CD34RA^+$), with naïve cells increasing more slowly; thymic function also improves. Immune reconstitution may result in IRIS, the immune-related inflammatory syndrome that is usually managed symptomatically.[35] Appropriate increases in CD4 cell counts allow discontinuation of opportunistic maintenance therapy and prophylaxes. Specific immune-based therapies, including interleukin-2, have failed to demonstrate additional clinical benefits and are not recommended currently.[36]

An HIV-infected individual who is stable taking antiretroviral therapy will typically see the treating physician every 3 to 6 months to check for side effects and monitor the HIV RNA and CD4 cell count.[6] In the case of virologic failure, drug resistance testing is performed and a new regimen selected on the basis of treatment history, drug resistance testing results, and available drug options. The goal is to construct a regimen with 2 to 3 fully active drugs and this will result in resuppression of HIV RNA in the majority of patients. HIV therapy currently is lifelong. Treatment interruptions are associated with clinical events[37] and should be avoided.

Several ongoing challenges remain in the management of HIV disease. Despite suppression of virologic replication, some patients experience ongoing inflammation and immune activation and this has been linked to nontraditional HIV illnesses such as cardiac, hepatic, renal, neurologic, and non-AIDS malignancies. In addition, despite dramatic improvements in life expectancy, cure of HIV disease remains elusive. The unique case of a man with HIV disease virologically controlled on antiretroviral therapy who developed acute myelogenous leukemia necessitating total-body irradiation, cytotoxic chemotherapy, and bone marrow transplant from a donor with a deletion in the gene coding for the CCR5-receptor who ultimately experienced a course complicated by rejection and a second transplant is thought to be the only patient cured successfully of HIV disease.[38] Cure, or complete eradication of HIV, remains challenging because of the long-lived latently infected CD4 cell reservoir; much current research is focused on this goal.[39]

HEMATOLOGIC COMPLICATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Anemia

Anemia is the most frequent cytopenia observed in HIV-1 infection. Striking anemia with transfusion dependence was common early in the epidemic when high doses of zidovudine (ZDV) were in use, but severe depression of hemoglobin levels are now rarely observed, except in patients with advanced disease.[40] In several large multicenter studies, persistent anemia was associated with shorter survival, independent of the degree of immunosuppression.[41,42]

As in other persons, anemia occurs due to one of three major factors: either ineffective hematopoiesis; blood loss due to involvement of the intestines by infection such as cytomegalovirus (CMV) or Kaposis's sarcoma; or red blood cell destruction.

Red blood cell production can be affected by HIV itself due to cytokines that interfere with hematopoiesis,[43–45] highly active antiretroviral therapy (HAART) and medications used to treat HIV-associated infections (Table 64.1 including high-dose trimethoprim-sulfamethoxazole (TMP-SMX) for *P. carinii* pneumonia and ganciclovir for CMV), HIV-associated cancers such as lymphomatous infiltration of the marrow, low erythropoietin, or HIV-associated hypogonadism.[46]

The Effect of HAART on Anemia

Nucleoside analogs other than ZDV are not associated with anemia. Zidovudine is commonly associated with marrow toxicity, particularly with long-term administration. Use of lower ZDV doses in combination with other nonmyelosuppressive antiviral drugs (such as the protease inhibitors or other nucleoside analogs) has significantly decreased the frequency of anemia, although patients with advanced disease on doses of ZDV of <500 mg/day still demonstrate significantly decreased hemoglobin levels when compared to similarly immunosuppressed HIV-infected patients not taking the drug.[47] Although the mechanism responsible for ZDV-associated anemia, inhibition of thymidine kinase, and DNA chain termination should theoretically also affect cells of other lineages, neutropenia is less frequent a toxicity and thrombocytopenia is very uncommon. In contradistinction to zidovudine, protease inhibitors, such as indinavir, ritonavir, crixivan, and nelfinavir, alone or in combination with ZDV or other nucleoside

TABLE 64.1

HEMATOLOGIC TOXICITIES OF ANTIRETROVIRAL DRUGS

Medication	Type of Activity	Hematologic Toxicity
Zidovudine	Nucleoside analogs, antiviral	Anemia, neutropenia (dose dependent)
Stavudine	Nucleoside analogs, antiviral	Anemia, neutropenia (dose dependent)
Ganciclovir	Cytomegalovirus infection	Leukopenia, thrombocytopenia
Trimethoprim/ sulfamethoxazole	Antibiotic, *Pneumocystis* pneumonia	Dose-related neutropenia, anemia; methemoglobinemia especially in persons with G6PD deficiency
Primaquine	Antibiotic, *Pneumocystis* pneumonia	Rare agranulocytosis, thrombocytopenia; methemoglobinemia especially in G6PD deficiency
Pentamidine	*Pneumocystis* pneumonia	Infrequent anemia, leukopenia, thrombocytopenia
Sulfadiazine	Toxoplasmosis	Leukopenia in 40%; thrombocytopenia in 12%
Clindamycin/ pyrimethamine	Toxoplasmosis	Cytopenias in 31%
Amphotericin B	Antifungal, cryptococcal meningitis	Anemia

G6PD, glucose-6-phosphate dehydrogenase.

analogs, have little or no effect on hematopoiesis.[31,48] It is important to note that HAART itself improves anemia as shown in a single center retrospective series in the HAART era. HAART was associated with hemoglobin levels >140 g/L in 42% of patients, irrespective of use of zidovudine as part of HAART regimen, compared with 31% of patients who did not use HAART.[49]

Treatable causes of anemia include nutritional/vitamin deficiency, gastrointestinal losses, parvovirus B19 infection,[50,51] HIV related kidney disease, and low erythropoietin levels independent of normal renal function. In HIV infection, erythropoietin levels are low in some patients, in part because tumor necrosis factor-α (TNF-α) acts to block erythropoietin release in response to low hemoglobin levels.[52] Patients with low erythropoietin levels respond better to its administration than do patients with normal or elevated levels of the hormone. In one meta-analysis, patients with erythropoietin levels below 500 IU/L demonstrated significant increases in hemoglobin levels, decreases in transfusion requirements, and improvement in quality of life, whereas replacement was ineffective in patients with high erythropoietin levels.[53]

Some patients with HIV infection have significant anemia, requiring frequent transfusion. Clinical and experimental evidence suggests transfusion may be associated with substantial morbidity in HIV-infected patients. In one study, transfused patients with advanced disease had an increased incidence of CMV infection and death.[54] Laboratory data suggest transfusion may be associated with HIV viral activation. Allogeneic lymphocytes present in transfused blood components activate viral production by HIV-infected lymphocytes in vitro.[55] When quantitative polymerase chain reaction (PCR) was used to measure circulating HIV, viral load was increased in HIV-infected patents 5 days after transfusion.[56] However when leuko-depleted blood components were used, no significant differences in viremia or infectious complications occurred.[57]

Red Blood Cell Destruction

Red blood cells can be destroyed in the setting of HIV infection through a variety of mechanisms. This includes autoimmune disease,[58] hemophagocytic syndrome, disseminated intravascular coagulation typically seen with infection or cancer, sulfa use in the setting of 6-GPD deficiency, or thrombotic thrombocytopenic purpura (TTP) (dealt with separately below). Drugs can also cause hemolysis.

Parvovirus is a rare, but treatable cause of anemia. Parvovirus affects erythroid lineage cells. In immunocompetent patients this is a self-limited infection, but is serious in patients who cannot clear the infection, or have other hemolytic problems. For parvovirus infection, commercial immune globulin infusion (400 mg/kg/day for 5 to 10 days) is almost always associated with marked improvement in hemoglobin levels with resolution of anemia.[51,59] HIV-infected patients frequently develop repeated episodes of B19 infection and need repeated treatments with intravenous immune globulin.[60]

Thrombocytopenia

Thrombocytopenia occurs in the setting of HIV infection due to decreased production, increased destruction, or splenic sequestration secondary to other causes such as lymphoma or hepatitis C. Although mild to moderate thrombocytopenia is common in patients with HIV, it is rarely associated with bleeding. Thrombocytopenia is generally associated with decreased platelet survival, except in patients with advanced disease where bone marrow failure is more prominent.[61] Opportunistic infection, splenomegaly, and fever all decrease platelet survival.

Autoimmune thrombocytopenia (ITP) is a feature of HIV infection and is a diagnosis of exclusion. Notably, patients can present in advance of other symptoms of HIV. Consequently, HIV should be ruled out in new cases of ITP. $CD4^+$ lymphocyte counts in reported series of patients with HIV-ITP have averaged between 0.3 and 0.6 $\times$ 10^9/L.

Although platelet-associated antibodies increase in prevalence with HIV disease progression, it is not clear if they play a major role in most patients. Technical difficulties in detecting platelet-associated antibody have led to a very high false-positive rate.[62] Furthermore, for any condition (including sepsis and TTP) associated with platelet injury, antibody can be detected on the platelet surface. Specific platelet-associated antibody has nonetheless been carefully characterized in a limited number of patients. One study demonstrated that platelet-associated immune complexes are made up of antiplatelet integrin, glycoprotein IIIa ($\beta 3$), antibody (Ab), and its anti-idiotype blocking Ab.[63] Some of the antibodies also bound epitopes with homology to HIV-1 proteins *nef, gag, env,* and *pol,* suggesting molecular mimicry. The presence of this Ab was associated with thrombocytopenia and produced thrombocytopenia when infused into mice.[64] The associated platelet fragmentation was due to generation of the membrane-damaging peroxide and other reactive oxygen species. Antibodies to a cleavage product of talin, which can be generated by platelet activation or exposure to HIV-1 protease, have also been characterized. These may result from an immune response to talin-H, a neoantigen that may have been created by platelet fragmentation.[65]

Defective megakaryocytopoiesis may also contribute to thrombocytopenia, particularly in patients with advanced disease. Megakaryocytes can be infected with certain strains of HIV, some of which can be cytopathic for the megakaryocytes.[66] In addition, megakaryocytes arising from HIV-1–infected $CD34^+$ progenitor cells are defective in their ability to produce platelets.[67]

Treatment

Generally, patients with modest thrombocytopenia (platelet count >50 $\times$ 10^9/L) require no treatment. For others with clinically significant thrombocytopenia, short-term steroids produce rapid responses in 60% to 80% of patients. However, steroids are immunosuppressive and are associated with long-term infectious complications and can accelerate the development of Kaposi's sarcoma. HIV-specific antiretroviral therapy will result in improvements of platelet counts in most patients. Although most of the original work was done with ZDV, other antiretrovirals are effective. Both antiretroviral agents and steroids improve thrombocytopenia by increasing platelet production, without significantly affecting platelet survival.[68,69] Splenectomy will increase platelet counts in those not responding to antiretroviral therapy and does not appear to accelerate the underlying HIV disease.[70] Intravenous immune globulin also is effective but its high cost, limited availability, and short duration of action make this a less attractive treatment. Anti-Rh immune globulin has the advantages of wide availability and cheaper cost, but is also limited by its short duration of action[71] and is associated with a mild hemolysis which can be clinically problematic in patients with pre-existing anemia, requiring transfusion prior to administration of anti-Rh immune globulin. Vincristine is effective when given monthly, although its administration is complicated by neuropathy. IL-11, a cytokine that promotes megakaryocyte maturation, is licensed for treatment of chemotherapy-related thrombocytopenia, but no studies have reported efficacy in HIV-infected patients. Rituximab is effective in some patients with idiopathic thrombocytopenic purpura (ITP) without HIV but has not been studied extensively in patients with HIV infection[72] for this indication. Three newer treatments for ITP in the general population include the anti-B cell antibody rituximab, effective in 60% of patients, and the thrombopoietin mimetics, romiplostim and eltrombopag, each associated with a 60% to 85% response.[73] Remarkably, these drugs have not been systematically studied in HIV-associated ITP.

Neutropenia

Mild neutropenia is relatively common in patients with HIV infection. Although generally not of clinical significance, a deficiency in bone marrow reserve may become clinically apparent when administration of cytotoxic chemotherapy or other marrow-suppressive drugs becomes necessary. In fact it is generally held that most cytotoxic chemotherapy requires prophylactic use of hematopoietic growth factors. Antineutrophil antibodies can frequently be seen,[62] but their presence does not correlate with the degree of neutropenia. Progenitor cell numbers are generally normal except in patients with advanced disease when they are modestly decreased.[74] Parenteral treatment with ganciclovir (GCV) or cytotoxic chemotherapy results in leukopenia in the majority of patients, frequently necessitating dose reduction and cytokine treatment.

Treatment

Neutropenic (absolute neutrophil count, $<1.0 \times 10^9$/L) HIV-positive patients may experience increased frequency of significant bacterial infections. In a case-controlled study, Tumbarello et al.[75] compared the neutrophil counts of groups of HIV-infected patients with and without bacteremia. An absolute neutrophil count of $<1.0 \times 10^9$/L as present in 38% of bacteremic patients was compared with 19% of asymptomatic patients. A matched cohort study[76] found the frequency of bacteremia increased in neutropenic patients to 12.60 events per 100 patient months compared with 0.87 events per 100 patient months in the non-neutropenia controls. In another study of 1,645 patients with an absolute neutrophil count of $<0.5 \times 10^9$/L the risk of Gram-negative infection increased eightfold.[77]

A number of studies have looked at the effect of recombinant growth factors on the incidence of infection and number of hospitalizations. Granulocyte colony-stimulating factor (G-CSF) enhances the proliferation and differentiation of neutrophils and improves neutrophil function, whereas granulocyte-macrophage colony-stimulating factor (GM-CSF) stimulates the proliferation and differentiation of a variety of myeloid progenitor cells and inhibits migration of neutrophils, enhancing the function of mature neutrophils and macrophages.[71,78] G-CSF is the most widely used hematopoietic growth factor in HIV-infected patients, has fewer side effects, and increases the neutrophil count more rapidly. Although GM-CSF has been associated with an increase in HIV-1 replication in vitro, no consistent observation of acceleration of disease progression or increase in p24 antigen levels in patients receiving the drug has been demonstrated. GCSF is primarily used to increase the tolerance of patients undergoing chemotherapy.

HIV-infected patients can also have a number of defects in neutrophil function. These include reduced L-selectin shedding and decreased H_2O_2 production[79] as well as defects in leukocyte migration, chemotaxis, and chemiluminescence during phagocytosis. These defects were more prominent in patients with advanced disease.[80] G-CSF and GM-CSF both improve leukocyte function in vitro. A number of studies have looked at potential benefits of these cytokines in animal models of immunosuppression. In a murine model of *Pneumocystis jiroveci* pneumonia, $CD4^+$-depleted immunosuppressed mice that received G-CSF after experiential pulmonary infection with *P. jiroveci* demonstrated improved survival when compared with control mice receiving placebo. Similar benefits were demonstrated using mouse models of disseminated *Mycobacterium avium* infection, systemic candidiasis, and streptococcal pneumonia.[81] No clinical study using either G-CSF or GM-CSF to enhance leukocyte function has been performed.

Lymphopenia

Increases in both CD4 and CD8 cell death and impairment in function are the sine qua non of HIV infection. IL-2 partially corrects the impaired lymphocyte proliferation and cytotoxicity seen in HIV infection in vitro. It also can partially block the enhanced tendency of lymphocytes obtained from HIV-infected patients to undergo programmed cell death (apoptosis).[38] In phase I trials of IL-2 in HIV-infected patients, it increased CD4 cell number and improved lymphocyte function.[82] The development of a long-acting polyethylene glycol–modified IL-2, which increases the half-life by 10- to 15-fold, allows for intermittent administration of the drug. Administration of doses of 1 to 5 million U/m^2, two to three times weekly, resulted in modest but sustained increases in CD4 counts and improvement in natural killer activity in a patient with CD4 counts $>0.4 \times 10^9$/L[83] in 3 to 6 months. Fever, rash, and capillary leak are the most common toxicities.[84] More recently, administration of very high doses of IL-2 (7.5 million IU twice daily to patients with early HIV infection) resulted in substantial increases in CD4 counts, compared with those seen in the group administered lower doses (1.5 million IU twice daily).[85] Of greater importance is the suggestion that intermittent administration of IL-2 in combination with HAART may lead to reduction in $CD4^+$ T-lymphocyte cells that contain replication-competent HIV.[86] None of these approaches is currently standard of care.

Thrombotic Thrombocytopenic Purpura

TTP is more common among patients with HIV infection. HIV-1 infection has been reported to account for up to 30% of TTP/hemolytic-uremic syndrome.[87] The risk of microangiopathy has declined significantly after institution of HAART for unclear reasons.[88] Although no controlled studies comparing HIV-related TTP with classic TTP have been conducted, HIV-related TTP is generally thought to be associated with a milder course and a better response to therapy than classic TTP.[89]

A number of different possible pathophysiologic mechanisms have been proposed. HIV can infect endothelial cells, and viral p24 antigen has been detected by immunochemical stain in splenic endothelial cells, spinal cord specimens, and bone marrow microvascular endothelial cells.[90] Whether infection results in vascular dysfunction has not been clearly demonstrated. TNF-α and IL-1β, two cytokines that are increased in HIV infection, could potentially lead to increases in endothelial expression of certain adhesion molecules, such as vascular cell adhesion molecule-1, intercellular adhesion molecule, and E-selectin, promoting localization of inflammatory cells to the endothelium with transmigration of lymphocytes through the endothelial wall. CMV, a virus that appeared to be associated with TTP in one large AIDS Clinical Treatment Group drug study, increases procoagulant activity in cultures of endothelial cells, potentially by binding and activating coagulation factor X/Xa.[91] Endothelial cells from small vessels undergo apoptosis when exposed to plasma from patients with TTP.[91–93] Recently, severe ADAMTS13 (a disintegrinlike and metalloprotease with thrombospondin type 1 repeats) deficiency has been reported in TTP unassociated with HIV.[94]

Treatment

Although the treatment of choice of TTP is plasmapheresis or plasma exchange, successes with antiplatelet agents, vincristine, splenectomy, and plasma infusion have been reported.[95] In one study of HIV-TTP, most patients undergoing plasma exchange in addition to other therapies achieved a complete response.[89] Others have reported significant responses in patients receiving plasma infusions alone.[96] Plasma exchange may allow infusion of greater amounts of plasma to the individual. However, the success of infusion alone has important implications for those in the developing world where plasma exchange is not available.[96] Plasma exchange is currently recommended to replace 35 to 40 ml/kg per exchange using the lactate dehydrogenase (LDH) values and platelet counts to follow the course of the disease. A

platelet count above 50×10^9/L and a normalized LDH are general aims of effective therapy. Platelets should not be transfused because doing so may lead to thrombotic events.

Pathophysiology of Bone Marrow Suppression in Human Immunodeficiency Virus Infection

Diverse factors responsible for impaired hematopoiesis in HIV infection include suppression of the bone marrow by the virus or by viral proteins, immune dysregulation, actual infection of the bone marrow progenitor cells by HIV, and alteration of stromal cell elements. A number of studies demonstrate that CD34 cells have both HIV receptors necessary for infection (i.e., CD4 and the chemokine receptors CXCR4 or CCR5).[97] Chemokines are cytokines that induce chemotaxis. CD4 expression, as well as CXCR4 and CCR5 co-receptor expression, increases with maturation of the CD34 cell, and the expression of each correlates with potential infectability.[98] In addition, CXCR5 may be up-regulated by a number of different cytokines. Although it is clear that the CD34 cell can be infected by HIV under a number of conditions, it appears that bone marrow progenitor cells do not represent a significant reservoir of infection.[99] In one study, HIV was detected in CD34 cells in only 14% of HIV-infected patients recruited in the United States and in 36% of HIV-infected persons in Zaire.[100] When found, CD34 infection was present in those patients with far-advanced disease. Many investigators could not detect HIV infection in any stem cells.[101,102] In another study, purified $CD34^+$ cells were infected in vitro and cultured on allogeneic stroma for extended periods of time.[103] A highly sensitive PCR failed to detect HIV-1 in the most primitive long-term colony-initiating cells (i.e., the secondary colonies generated from clonogenic cells harvested from stroma). Thus, it appears that although some committed progenitor cells can be infected with HIV-1 under some circumstances, the most immature stem cells appear not to be susceptible to HIV-1 infection.

The effects of HIV-1 on colony formation have been studied, either using bone marrow cells derived from HIV-1–infected patients[101,104] or after in vitro infection of hematopoietic cells from bone marrow of normal donors.[67,101] Results have been surprisingly divergent. Although the growth potential of committed bone marrow progenitor cells in methylcellulose cultures after challenge with HIV-1 appears to be diminished, normal growth frequently has also been reported.[101] Similar disparity exists in the results of studies performed with patient bone marrow. Such differences may be related to techniques in assaying colony growth (total bone marrow vs. purified $CD34^+$ cells), culture conditions (use of specific cytokines or growth factors), or patient selection. In some reports, inhibition of colony formation by virus was only observed in cultures of total bone marrow cells and not with isolated $CD34^+$ cells.[105] Of interest is one report of abnormal progenitor cell function in HIV-negative infants born to infected mothers,[106] implying that direct infection was not necessary for marrow suppression.

Marrow stromal function has been examined in patients with HIV infection. Stromal cells from some HIV-1–infected patients may be infected by the virus, demonstrating the importance of stromal infection in causing dysregulation of hematopoiesis. In one study,[107] decreased colony formation has been observed when stroma infected in vitro was used to support growth of normal uninfected bone marrow progenitor cells. In another study, stroma obtained from HIV-infected patients supported growth of normal $CD34^+$ cells equally as well as stroma obtained from normal uninfected controls.[74]

Although the stem cell compartment appears to be relatively well preserved early in the disease, in patients with low CD4 counts and history of OIs, there is a modest reduction of long-term colony-initiating cell numbers.[74] However, the long-term colony-initiating cell numbers were far better preserved in this population than in patients with aplastic anemia with similar blood counts, implying that OIs; pharmacotherapy with antiparasitic, antimicrobial, antiviral, or cytotoxic agents; vitamin deficiencies; or poorly understood virally mediated immunomodulatory changes were the major contributors to bone marrow failure in patients with advanced HIV disease.

Inconsistencies in the results of experiments attempting to demonstrate the role of direct infection of HIV-1 on hematopoiesis have stimulated further search for pathophysiologic mechanisms of bone marrow suppression. Several cytokines that are released during the course of HIV-1 infection are potent inhibitors of hematopoiesis. Not only native virus and productive infection,[105,108] but also viral products, such as gp120, gp160, and viral *tat* proteins, induce the secretion of an array of cytokines, including TNF-α, lymphotoxin-β (TNF-β), and IL-6.[109] Perhaps the most prominent cytokine implicated in an array of pathophysiologic reactions in AIDS is TNF-α (or cachexin).[110,111] In addition to its effect on body metabolism and the immune system, TNF-α has inhibitory effects on hematopoiesis.[112] High levels of interferon-γ (IFN-γ) were not only associated with a poor prognosis in HIV-1 infection, but also correlated with the degree of anemia.[113] Although disordered cytokine production by both lymphoid tissue and bone marrow clearly occurs in HIV-1 infection, it is difficult to determine its ultimate role in suppression of hematopoiesis. Many inhibitory cytokines are produced in greatest quantities early in the course of HIV-1 infection when marrow suppression is least, and their levels decline as the disease progresses (when marrow suppression becomes most marked). In addition, increased levels of stimulatory cytokines have been observed in HIV-1 infection, and many cytokines never reach significant levels in the circulation. Local production of growth factors in bone marrow may be more important than systemically secreted factors. In support of this hypothesis, one study of genetically engineered stromal cells, designed to produce low levels of IFN-γ constitutively, showed significant suppression of normal hematopoietic colony growth on IFN-γ stroma, which could only be replicated by addition of large amounts of exogenous IFN-γ to marrow grown on normal stroma.

Apoptosis of hematopoietic progenitor cells through the Fas-L/Fas-R pathway is a mechanism by which activated T-cells can kill virus-infected cells.[114] It is likely that Fas-L and other cytokine products of activated T-cells contribute to the hematopoietic inhibition seen in HIV-1 infection. Increased levels of Fas-L have been reported in patients with AIDS, and triggering of Fas-R on hematopoietic cells results in apoptosis.

Bone Marrow Examination in Human Immunodeficiency Virus 1 Infection

The majority of bone marrow samples from HIV-1–infected patients will exhibit morphologic abnormalities, but most are nonspecific except in OI, in which the bone marrow examination provides valuable diagnostic information. Therefore, the bone marrow examination rarely yields substantial clinical information except in the diagnosis of concurrent *M. avium-intracellulare*, tuberculosis, or fungal infection or as part of staging for malignancy.

The histopathologic findings in the bone marrow of HIV-1–infected patients are varied. In one large study of 216 bone marrow examinations performed in 178 HIV-1–infected patients for evaluation of cytopenia, 69% of patients exhibited hypercellular marrow, 69% showed myelodysplastic changes, and 20% showed significant fibrosis; only 5% of the biopsies were hypocellular. Granulomas were found in 13% and lymphoid aggregates in 36% (but in other studies, in up to 50%) of specimens. Higher numbers of plasma cells and elevated numbers of eosinophils were also present, especially in conjunction with increased reticulum. Hyperplasia involving the granulocytic and erythrocytic lineages has been most commonly reported; the myeloid-to-erythroid ratio has varied from 2:1 to 5:1.[94]

Morphologic changes tend to be more pronounced in more immunosuppressed patients and increase in frequency as disease progresses. All lineages can be involved. Megaloblastic changes and ringed sideroblasts are frequent. Using the morphologic criteria established for primary myelodysplastic syndromes, dysplasia involving at least one lineage was diagnosed in 69% of patients. Dysplastic changes increase with disease progression. However, in one study, the numbers of erythroid precursors and the morphology of megakaryocytes clearly differentiated patients with AIDS from those with myelodysplastic syndrome.[96] The cumulative effects of drug toxicities, direct HIV-1 infection of marrow cells, and dysregulated cytokine production may be responsible for the morphologic changes that occur late in AIDS. However, the dysplastic changes in an individual lineage and specific cytopenias are not correlated.

Coagulation Abnormalities

A number of retrospective epidemiologic studies[115–124] have found that the incidence of thrombosis in HIV-infected patients was increased two- to tenfold over what would be expected in a healthy control population of the same age. However, except for isolated cases of protein S deficiency, no study has compared these patients to equally sick uninfected patients whose immobility, lymphedema, and hypoalbuminemia predispose them to hypercoagulability. Patients with HIV are more likely to develop antiphospholipid antibodies such as lupus anticoagulant (found in 1% of patients)[125] and antiphosphatidylcholine and anticardiolipin autoantibodies antibody (found in about 50% of patients with HIV infection)[126,127]; however, many of these studies were performed before HAART became standard of care. Apart from diagnostic problems related to a falsely elevated partial prothrombin time, these antibodies do not appear to be associated with an increased frequency of thrombosis, as they are in uninfected patients.[128,129]

Increased levels of complement-binding protein 4, which attaches to protein S and renders the protein inactive, can be detected in as many as 27% to 73% of patients. These patients demonstrate decreased functional protein S when a functional assay is used to measure activity. The risk of thrombosis in these patients is substantially increased. No clear guidelines are available for treatment or other protein-S–deficient patients, but most hematologists recommend anticoagulation for an undefined period of time for those with a history of unprovoked thrombosis.

ACQUIRED IMMUNODEFICIENCY SYNDROME–RELATED MALIGNANCIES

Cancer is the leading cause of death for HIV-1–infected persons on HAART. Twenty-five to forty percent of HIV-positive patients will develop a malignancy.[32,33,130,131,132,133,134,135,136,137] Although Kaposi sarcoma, aggressive B-cell lymphomas, and cervical cancer are said to be AIDS defining when occurring in the setting of HIV infection and occur more frequently in HIV infection, death from non–AIDS-defining cancers is more common. The development of malignancies is related to a number of factors, including immunosuppression and concurrent infections with other viruses such as human herpes virus 8 (HHV8) and Epstein-Barr virus (EBV), or the human papillomavirus, which foster malignant transformation. These viruses carry oncogenic proteins and cytokines that contribute to malignant pathogenesis. Additionally, HIV infection reduces the ability to clear the viral infection. The SMART study demonstrated that HAART interruptions in so-called drug conservation strategies increase the risk of cancer sixfold.[138]

Although the incidence of KS and certain lymphomas has decreased after HAART was introduced, the frequency of other tumors such as cervical cancer has undergone little change. CNS lymphoma, although once accounting for 18% of AIDS-related lymphomas, now is extremely rare. Several new drugs and therapies have been developed for KS and AIDS-related lymphomas, and these treatments, plus the development of HAART, have contributed to improvements in morbidity and mortality. Given the introduction of HAART and our increased ability to treat infections effectively, the life span of patients with HIV has increased, eventually leading to substantial increases in individuals living with HIV-1.[119] One analysis projected a median life expectancy of 75 years assuming a high rate of HIV diagnosis (median CD4 cell count at diagnosis, 0.432×10^9/L), and 71.5 years with a low diagnosis rate (diagnosis only when symptomatic, median CD4 cell count 0.14×10^9/L. Cumulative risks of death by 5 and 10 years after infection were 2.3% and 5.2%, respectively.[139] This makes treating malignancies more attractive than in the pre-HAART era. Although these malignancies also occur in the HIV-uninfected population, their presentation, as well as their appropriate treatment, is quite different in the HIV-infected patient.

ACQUIRED IMMUNODEFICIENCY SYNDROME–RELATED LYMPHOMA

Non-Hodgkin lymphoma (NHL) and Hodgkin lymphoma (HL) occur with increased frequency in patients infected with HIV.[125] Approximately 10% of HIV-positive people will develop NHL, and although the incidence has greatly reduced during HAART, it is still increased 25- to 150-fold compared to the general population.[140–143] These recent studies also demonstrate the duration and depth of the CD4 nadir and the duration of viremia increase the incidence of NHL. Decreased immune surveillance, B-cell dysregulation[144] and, in certain subtypes, infections with HHV8 and EBV, are also involved in the pathophysiology of the disorder.

A number of changes have occurred in the HIV-related lymphomas since widespread institution of HAART. The overall incidence of HIV-associated lymphomas has declined for NHL. This decrease has primarily affected lymphomas occurring at low CD4 counts, whereas NHL occurring at higher CD4 counts has been relatively unaffected.[145] Among patients with systemic, AIDS-related NHL, there has been decreased high-grade histology and improved survival.[146,147] Three types of lymphoma are now recognized as AIDS-defining by the CDC: Burkitt lymphoma, immunoblastic lymphoma which is a subtype of diffuse large B-cell lymphoma, and primary CNS lymphoma. The World Health Organization (WHO) more recently provided a classification system for the HIV-associated lymphomas (Table 64.2; Fig. 64.2). The frequency of NHL increases with the degree of immunosuppression, particularly for CNS lymphoma. Thus CNS lymphoma is rarely seen in developed countries where HAART is available, except in socioeconomic sectors where standard of care HIV therapy is not ubiquitous. In addition, patients with poorer virologic control on HAART suffer a significantly higher incidence of lymphoma and worse outcomes following therapy.[148] Some studies have suggested genetic factors play a role in the development of NHL. One study demonstrated that HIV-infected patients who are heterozygous for the CCR5D32 deletion are less likely to develop lymphoma, whereas those with stromal-cell–derived factor-1 mutations are more likely to develop lymphoma.[149]

For patients receiving combination chemotherapy, the optimal timing of HAART with combination chemotherapy is controversial.[150] Many oncologists continue antiretrovirals during chemotherapy, and some temporarily discontinue them, citing fears of drug–drug interactions and increased toxicities. The latter stance has been challenged by six randomized studies in infections showing immune reconstitution occurring within the first month of HAART leading to a decrease in infection mortality.[151] This suggests that HAART discontinuation or deferment of initiation after a concurrent HIV and lymphoma diagnosis could be detrimental. Nonetheless, in a retrospective Italian study comparing toxicities between patients receiving CHOP (cyclophosphamide, doxorubicin,

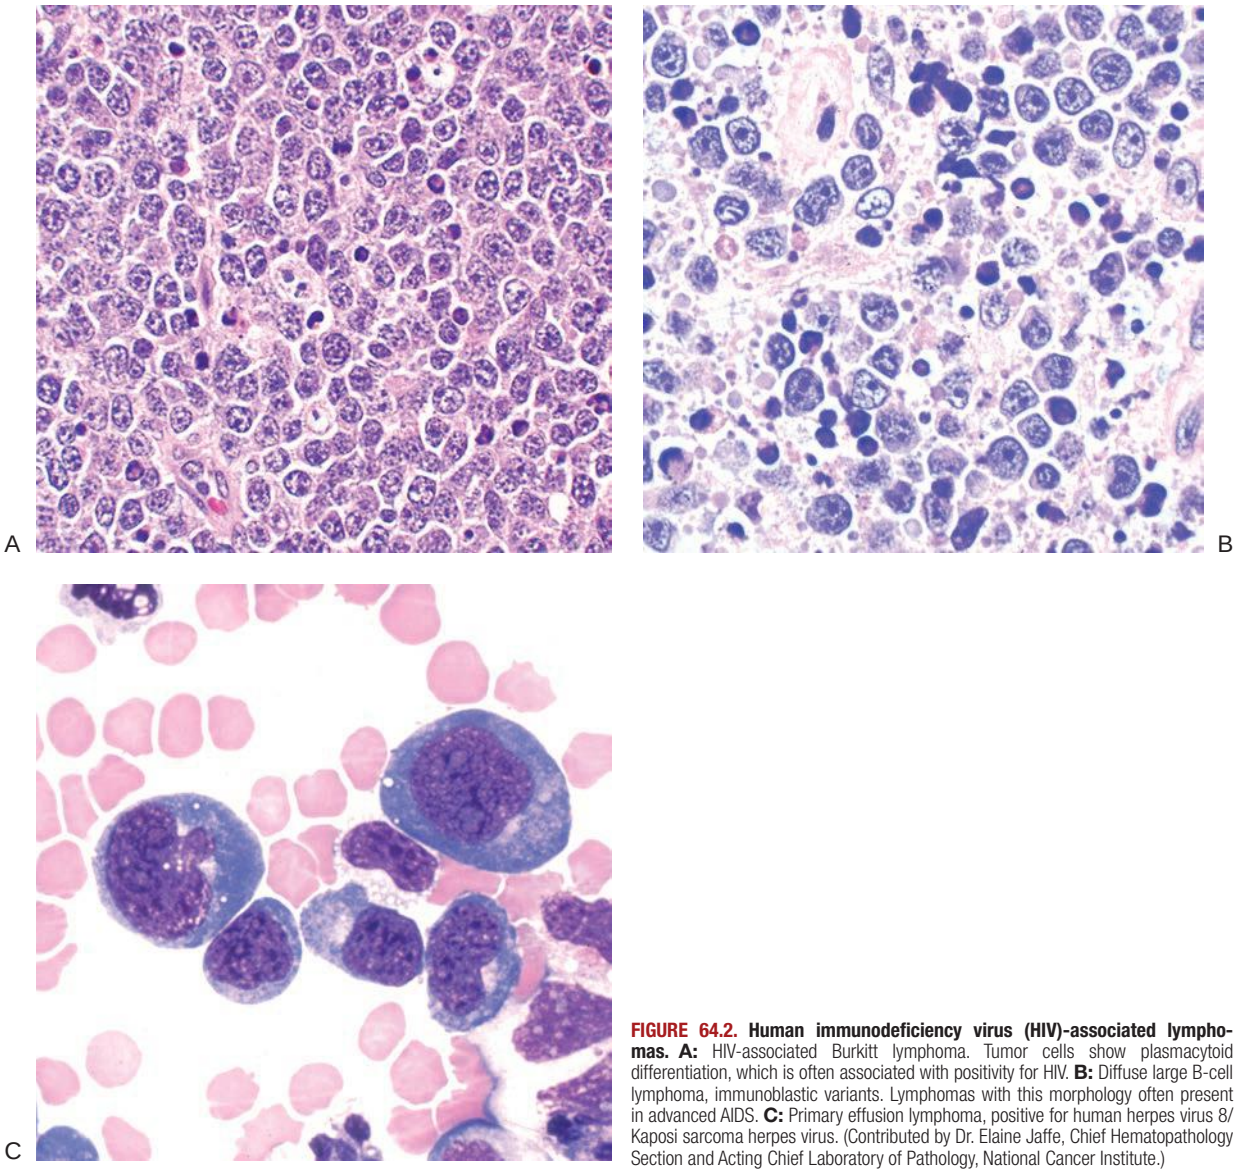

FIGURE 64.2. Human immunodeficiency virus (HIV)-associated lymphomas. A: HIV-associated Burkitt lymphoma. Tumor cells show plasmacytoid differentiation, which is often associated with positivity for HIV. **B:** Diffuse large B-cell lymphoma, immunoblastic variants. Lymphomas with this morphology often present in advanced AIDS. **C:** Primary effusion lymphoma, positive for human herpes virus 8/Kaposi sarcoma herpes virus. (Contributed by Dr. Elaine Jaffe, Chief Hematopathology Section and Acting Chief Laboratory of Pathology, National Cancer Institute.)

vincristine, and prednisone) plus HAART versus CHOP or a comparable regimen without HAART, the group receiving HAART experienced greater neurotoxicity and anemia but a decreased frequency of infection.[152] The differences in favor of HAART may have been due to improvements in supportive care gained during the 1990s. Moreover, with an expansion of the panoply of HAART medications, it is now possible to avoid specific HAART components to minimize drug–drug interaction. However, no controlled clinical trial has yet been performed to assess the contribution of continuing HAART therapy to improvement in viral replication and lymphoma control.[153] It is unlikely that such a study will be conducted.

The three main pathologic types of HIV-NHL are the Burkitt and those with Burkitt features, diffuse large B-cell lymphomas, and primary effusion lymphomas (PELs). These differ in their clinical presentations, in their underlying pathogenesis, and in their response to therapy. The majority of HIV-related lymphomas are of B-cell origin. T-cell lymphomas are rare, as are PELs, which lack B-, T-, and hematopoietic cell markers. Burkitt and lymphomas with Burkitt features usually present with widespread disease and have a risk of CNS involvement. Other less common lymphomas include polymorphic lymphoproliferative disorders resembling post-transplant–associated lymphoproliferative disease and lymphomatoid granulomatosis.

The role of viruses in the pathophysiology of HIV-related lymphomas is dependent on subtype.[154] For example, CNS lymphomas are virtually always associated with EBV infection, and PEL is associated with HHV8 infection. EBV encodes for a number of cytokines promoting cell growth. AIDS-Burkitt is variably associated with EBV, but also contains activating mutations in the *cMYC* proto-oncogene, frequent inactivation of p53, as well as point mutations in *BCL-6*. One study showed that loss of EBV-specific $CD8^+$ T-cells in subjects progressing to EBV-related NHL correlated with loss of $CD4^+$ T cells and that these cells were better preserved in equally immunocompromised patients not developing lymphoma.[155]

Patients with HIV–NHL frequently present with advanced stage III or IV disease. The majority will present with a rapidly growing mass or the development of systemic B symptoms (i.e., fever, night sweats, and unexplained weight loss). The clinical presentation is dependent on the site of involvement. Extranodal involvement including the bone marrow (25% to 40%), gastrointestinal tract (26%), and CNS (17% to 32%) is common.

TABLE 64.2

WORLD HEALTH ORGANIZATION CLASSIFICATION OF HUMAN IMMUNODEFICIENCY VIRUS (HIV)-ASSOCIATED LYMPHOMAS[125]

1. Lymphomas that occur with reasonable frequency in the absence of HIV infection
   a. Burkitt lymphoma
   b. Diffuse large B-cell lymphoma
      Centroblastic
      Immunoblastic (includes primary central nervous system lymphoma)
   c. Extranodal marginal zone B-cell lymphoma of the mucosa-associated lymphoid tissue[a]
   d. Peripheral T-cell lymphoma[a]
   e. Classic Hodgkin lymphoma
2. Unusual lymphoma occurring more specifically in HIV infection
   a. Primary effusion lymphoma
   b. Plasmablastic lymphoma
3. Lymphomas occurring in other immune deficiency states
   a. Polymorphic B-cell lymphoma

[a]Occur rarely in HIV.
From World Health Organization Classification of Tumours. Pathology and genetics: tumours of haematopoietic and lymphoid tissues. Lyon: IARC Press, 2001.

Leptomeningeal disease may be present and detected by flow cytometry only at a higher frequency than the immunocompetent population, where it is rare, with a surprising 22% among 51 newly diagnosed patients in one study in which 11 (22%) were detected by flow cytometry and only 1 by cytology.[156] Involvement of the small bowel and rectum is also prevalent, particularly in those with large cell histology. Several prognostic factors predict response to therapy and overall survival including CD4 count, Karnofsky performance, age, and LDH level.[157]

Clinical Manifestations

Therapy

Initially prior to HAART, patients with lymphoma were more debilitated and experienced significant toxicity associated with chemotherapy. Multiple trials focused on reduced-intensity chemotherapy, which generally resulted in shorter remission durations. Treatment of HIV lymphoma has changed radically after the institution of HAART and remission has been reported after institution of HAART alone. However, this is not the standard of care and most trials now focus on more intensive therapy.

The French Italian Cooperative Group recently tailored treatment to the level of pre-existing immunosuppression, examining low- versus high-dose therapy in patients with moderate and severe immunosuppression. Patients with CD4 counts over 0.2×10^9/L received a dose-intensified regimen of ACVB (doxorubicin, cyclophosphamide, vindesine, bleomycin, methylprednisolone, methotrexate) versus standard CHOP because of evidence from previous trials of NHL unrelated to HIV showing that patients receiving an intensified regimen had more durable remissions.[158] Both groups of HIV-infected patients in this trial had comparable responses, but toxicity was better in the CHOP arm. Patients with one adverse prognostic factor were randomly assigned to CHOP or dose-reduced CHOP. High-risk patients were treated with dose-reduced CHOP or vincristine plus prednisone. In the intermediate-risk group, standard-dose CHOP was superior to dose-reduced CHOP, but overall survival remained similar in the two groups. This risk-adapted approach has not been adapted universally due to the results of other trials.

A number of regimens administering chemotherapy by slow infusion appear effective without causing significant toxicity. Patients receiving cyclophosphamide, doxorubicin, and etoposide (CDE)[159] as an infusion had median survivals of 18.4 months. A multicenter phase II trial of infusional CDE in 48 systemic NHL patients not on HAART had only a 46% median survival at 8 months.[160] This infusion regimen has been combined with HAART with few problems other than increased mucositis in the HAART group.[161]

EPOCH (etoposide, prednisone vincristine, cyclophosphamide, and doxorubicin–cyclophosphamide dose adjusted to CD4 count) has produced responses of 79% in a preliminary study.[162] Antiviral therapy was suspended during treatment in this protocol, for fear of concurrent toxicities, leading to transient increases in viral load and decreases in CD4 counts. A multicenter trial by the AIDS malignancy consortium investigated EPOCH with concurrent versus sequential rituximab and found the CR rate to be higher in the concurrent arm.[163] The vast majority of patients remained on HAART during treatment, challenging the earlier assertion that HAART must be suspended.

Anti-CD20 monoclonal antibody (rituximab) has become a ubiquitous component of B-cell NHL in the general population. Preliminary studies show that it can be added to EPOCH without evidence of added toxicity.[164] Rituximab administered with CDE and concomitant HAART has yielded 2-year survivals of 80%.[165] However, a randomized phase III study of CHOP with or without rituximab failed to demonstrate any added benefit of rituximab and suggested increased toxicity in those with a CD4 count less than 0.05×10^9/L.[166] In contrast, another study, rituximab adjunction to CHOP produced a complete response rate of 77% and a 2-year survival rate of 75% in patients with AIDS-related NHL, without increasing the risk of life-threatening infections.[167] The current standard of care is to use rituximab with attention to infection including hematopoietic growth factors and antibiotic prophylaxis in those at highest risk.

Primary Central Nervous System Lymphoma

Primary CNS NHL (PCNSL) typically affects the most immunocompromised with $CD4^+$ lymphocyte counts $<0.05 \times 10^9$/L and now is rarely seen in patients receiving HAART. Most are diffuse large B-cell lymphomas and are multifocal (reviewed in Ref. 168). Confusion, memory loss, lethargy, and focal neurologic findings are the most frequent presenting symptoms and signs. The response to therapy in patients with primary CNS lymphoma has been very disappointing. Palliation with steroids and whole-brain radiation (3,000 to 5,400 Gy) has response rates of 75% and treatment with high-dose methotrexate has reportedly given similar results, but the response duration is short with a median survival of 2 to 4 months regardless of CD4 count. A pilot study using only antivirals and immunomodulation was very promising with two of five patients treated remaining in complete remission at 28 months and 52 months, respectively, but closed early due to low accrual.[169]

Primary Effusion Lymphoma

PEL comprises approximately 1% to 5% of AIDS-related lymphoma cases. Clinically, the disease is characterized by malignant effusions with the absence of nodal disease. Diagnosis is made by pericardiocentesis, thoracentesis, or paracentesis with cytologic examination of the fluid and immunohistochemical evaluation. PEL cells have pleomorphic morphology and lack expression of B-cell–associated genes, including surface immunoglobulin, although immunoglobulin gene rearrangements are usually positive, indicating a clonal B-cell origin. The gene expression profile of PEL cells suggests plasmablastic derivation.[170] The malignant clone is almost always found to be infected with HHV8, whereas concurrent infection with EBV is frequent. PEL may extend into tissues underlying the serous cavities, including the omentum, lymph nodes, mediastinum, and lung. In one study of 277 NHL

patients, PEL was diagnosed in 11 patients (4%). Patients treated with doxorubicin, vincristine, and prednisone achieved a complete response rate of 42%. However, median survival time was only 6 months.[171] The decision to undergo therapy should be based on the functional status of the patient, the degree of immunosuppression, and the likelihood that the quality of life would be improved. A report of antiviral therapy alone leading to sustained remission has been documented.[172]

Burkitt Lymphoma

Burkitt lymphoma is highly overrepresented in patients living with HIV. Before the era of HAART, treatments were curtailed due to fears of prolonged and profound neutropenia associated with the intensive therapies that had become standard in the general population. One small retrospective[173] and one small prospective study[174] initially challenged the prevailing dogma and found that intensive therapies such as CODOX-M/IVAC or hyper-CVAD with methotrexate and high-dose cytarabine could be safely given with HAART with success rates of 80% to 90%. More recent publications have also suggested the same.[175,176] Another retrospective study has supported the use of R-EPOCH as more efficacious and less toxic.[177] A recently completed clinical trial by the AIDS Malignancy Consortium was designed to reduce toxicity while maintaining efficacy, and may confirm these results prospectively in a multicenter setting.[178] The NCI has also reported early results with EPOCH–rituximab in a prospective study.[179]

Plasmablastic Lymphoma

Plasmablastic lymphoma is a very rare CD20 negative variant of HIV-associated NHL. It was originally described as almost exclusively associated with HIV and nearly always fatal in the pre-HAART era.[180] The sine qua non of stage I disease is a mass in the jaw, but disseminated disease including numerous bone lesions is common. A retrospective study suggested curability in the HAART era in both HIV-positive and HIV-negative patients.[181] Optimal management will be difficult to define due to the rarity of the disease.

Hodgkin Lymphoma

Although HL is not considered an AIDS-defining illness, a marked increase is seen in HIV.[182–184] Although risk of NHL has decreased with better therapy, the incidence of HL among patients with HIV infection has increased.[182,185] Unlike HL in HIV-uninfected patients, B symptoms are almost often present; mixed cellularity HL is the predominant pathologic subtype of disease; and advanced, extranodal disease is expected in the majority. One study showed 70% to 90% of patients present with B symptoms, and 74% to 96% of patients have advanced disease (stage III or IV) at the time of diagnosis with frequent involvement of extranodal sites (60%), including bone marrow, liver, and spleen involvement. Unlike those not infected with HIV, noncontiguous spread of disease is common and mediastinal involvement is far less. Bone marrow involvement occurs in 40% to 50% of patients and may be their first indication of the disease. Another characteristic distinguishing the HIV-associated HL from that not associated with HIV is the predominance of Reed-Sternberg cell–rich cases. AIDS-HL, like AIDS-NHL, is characterized by a high frequency of EBV infection when compared to HL in the HIV-negative population. The pathologic role of EBV in HL is evidenced by the Reed-Sternberg cell expression of EBV-transforming protein.

Treatment

Although standard multiagent chemotherapy may be curative in most HIV-negative patients with stage III or IV HL, the median survival for HIV-infected patients has been in the range of 1 to 2 years.[183] Response to standard chemotherapy ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) is lower than that of patients without HIV infection, but may be better in the HAART era. Poor tolerance to chemotherapy results in dose reduction or delay of chemotherapy, but this may be ameliorated by the use of GCSF. The median overall survival of patients is approximately 1.5 years.[184,186,187] Because 85% to 95% of HL patients have widespread disease, no data exist on the impact of radiation therapy in treatment of AIDS-HL. Recent studies in the HAART era include trials suggesting better outcomes. Currently an ongoing US intergroup study (S0816) is examining midtreatment risk adaption and regimen modification based on interim PET scan after cycle 2 of ABVD. The novel and highly potent brentuximab vedotin, an anti-CD30 antibody conjugated to an antitubulin drug approved for relapsed and refractory non-HIV Hodgkin has not yet been tested in the setting of HIV, but will be investigated in an upcoming AIDS Malignancy Consortium study of untreated advanced stage HIV-HL.

Transplantation for Hodgkin Lymphoma and Non-Hodgkin Lymphoma

Myeloablative autologous transplants have been performed in patients with both NHL and HL. The City of Hope reported the first prospective study of 12 patients with NHL beyond first complete remission.[188] Opportunistic infections were seen in three patients; transient increases in viral load were seen in seven (related to HAART noncompliance). Three patients died, including two with relapsed lymphoma, but all others were alive at 18.5 months. Another study included eight patients with relapsed or resistant lymphoma, four with HL, and four with NHL. Seven of eight continued HAART during transplant and seven engrafted successfully. Although six of seven patients engrafted, only four patients went into complete remission.[189] Another pilot of 16 patients with relapsed and refractory lymphoma reported 6/16 alive at a median of 8 months after second-line therapy, high-dose conditioning and autologous stem cell support.[190] The European Cooperative Study Group on AIDS and Tumors (GECAT) reported the largest study and the only one enrolling patients before second-line therapy with 27/50 going onto autologous transplant and a median overall survival of 33 in all 50 eligible patients.[191] In addition, two retrospective case control studies have suggested no difference in outcome between HIV-positive and HIV-negative patients undergoing autologous transplant for the same indications.[192,193] The AIDS Malignancy Consortium and Bone Marrow Clinical Trials Network have partnered in an ongoing trial to demonstrate multicenter feasibility and study biologic correlates. Finally, gene therapy pilot studies are ongoing to test the feasibility of engineered hematopoietic stem cell HIV resistance at the time of transplant for malignancy.[194]

Nonmyeloablative allogeneic transplantation has been used in patients with refractory disease and has produced short-term remissions (12 months), but was associated with little toxicity and few opportunistic infections.[195] A case has been reported of simultaneous treatment of acute myelogenous leukemia and eradication of HIV infection using a donor with homozygous CCR5 deletion, a receptor necessary for HIV infection. However, the rarity of this deletion makes this approach unique. The AIDS Malignancy Consortium and Bone Marrow Clinical Trials Network have recently opened an allogeneic transplant pilot study for HIV-infected patients with a wide variety of hematologic malignancies.

CONCLUSION

Patients with HIV infections are living longer and having better quality of life than ever before. Life expectancy can approach the general population. Treatment of HIV-infected patients with

HAART has altered the natural history of HIV infection by decreasing the frequency of opportunistic infections and altering the expected frequency of hematologic complications and AIDS-related malignancies. Cytopenia, particularly anemia, is more common in advanced stages of HIV and results both from bone marrow failure and peripheral destruction. With the development and application of HAART, both AIDS-defining and non–AIDS-defining malignancies represent an ever-increasing cause of death in this population. Lymphomas are highly prevalent among HIV-infected patients, although CNS lymphoma is now very rare on HAART. Intensive curative therapies are now the norm except in patients with advanced AIDS. In the future, different strategies directed toward controlling the underlying inciting viral infections associated with malignancy (EBV, HHV8) and focusing on immune reconstitution in addition to standard chemotherapy may improve response rates and survival.

CHAPTER 65

DISORDERS OF THE SPLEEN

Matthew R. Porembka, Majella Doyle, William C. Chapman

The spleen is a small, purplish, sponge-like organ found in the left upper abdominal quadrant.[1] Although there is no mention of the spleen in the Bible, it receives considerable attention in the Talmud and post-Talmudic literature. Classically identified as the seat of laughter, there has been much debate over whether the spleen is truly necessary.[2] It is said that Galen called it an "organ full of mystery" as early as the second century A.D. Although we have come to understand much about the structure and function of the spleen since those times, much of what intrigued Galen still remains a mystery today. The spleen has been classified into different organ systems including the circulatory system, the hematopoietic system, the mononuclear phagocyte system, or the lymphatic system. However, it is probably more accurate to describe the spleen as a clearinghouse for circulating cellular elements—a place where multiple organ systems converge in both structure and function.

DEVELOPMENT AND ANATOMY

The spleen is derived from embryonic mesoderm. The developing organ first becomes apparent during the fifth week of gestation as mesodermal cells coalesce between the leaflets of the dorsal mesogastrium, posterior to the developing stomach. As development continues, independent lobules enveloped by mesogastrium become evident. In time, they fuse to form a multilobulated mass that eventually differentiates into a well-formed organ by late fetal life.[3] Occasionally, a stray lobule may fail to fuse with the others, develop independently, and give rise to an accessory spleen, a functioning mass of splenic tissue set apart from the body of the organ proper. The mesogastrium enveloping the lobules eventually gives rise to the organ's capsule and trabecular skeleton, and the posterior and anterior attachments give rise to the primary supporting structures: the splenorenal and gastrosplenic ligaments, respectively.[4] The colonization of the cellular elements of the spleen occurs first with the erythroid and myeloid progenitors, followed by the first hematopoietic stem cells. Finally, lymphoid-tissue-inducer cells are observed and provide the necessary local cellular signals to trigger the unique architecture of the splenic cellular elements. This development is highly similar to that of lymph nodes.[5]

Gross Anatomy

Grossly, the spleen may appear in a variety of shapes. It may be wedge-shaped (44%), tetrahedral (42%), or triangular (14%), depending on its relationships with the stomach, left kidney, pancreas, and colon. The average adult spleen measures 13 to 15 cm in length, 8 to 10 cm in width, and 4 cm in thickness, with a weight of 150 g and a corresponding blood volume of ~300 mL.[4] However, the size of the spleen varies with age, immunologic status, and nutritional status.[1]

The nonperfused organ appears purplish in color with a solid, sponge-like texture throughout. It is covered by a fibrous connective tissue capsule that is 1.5 mm thick and composed of collagen and elastin fibers.[1] This capsule surrounds all but the hilum of the spleen.[4] Continuous with the capsule, involutions penetrate the body of the organ to form trabeculae, the fibrous supporting skeleton of the spleen.[3] Finally, a serosal membrane, derived from peritoneum, covers the organ externally and adheres to the capsule. This mesothelial membrane covers the entire organ except at its hilum and the reflections of its primary supporting ligaments.[1]

In the majority of people, the spleen is divided into the superior lobe and inferior lobe, but further division into subsegmental lobes can be seen.[6] Avascular planes separate each lobe and they are defined by discrete, nonanastomosing circulatory pathways.[1,3,6]

Location and Relationships

The spleen is located in the left upper quadrant of the abdominal cavity, posteriorly, at the level of the ninth to eleventh thoracic vertebrae. The superior, or diaphragmatic, surface of the organ is convex in shape, smooth, and related to the left hemidiaphragm; whereas the inferior, or visceral, surface is somewhat triangular and rests on the splenic flexure of the colon.[1,4]

The medial portion of the spleen is concave and divided by a longitudinal ridge into a gastric surface anteriorly and a renal surface posteriorly. The gastric surface contains the hilum of the organ and relates to the fundus of the stomach and the tail of the pancreas. The tail of the pancreas touches the spleen in 30% of cases and is within 1 cm of it in 73% of the population, contributing to the risk of pancreatic injury in patients undergoing splenectomy.[7] The renal surface borders the superolateral surface of the left kidney and left adrenal gland. Figure 65.1 shows the gross appearance of the spleen as well as its relationship to the adjacent pancreatic tail and branch vessels of the splenic artery.

The spleen is supported by a number of suspensory ligaments: the splenorenal posteriorly, the gastrosplenic anteromedially, the splenophrenic superiorly, and the splenocolic inferiorly.[1] The splenorenal and gastrosplenic ligaments provide the majority of support to the organ and are considered primary. The splenorenal ligament supports the organ posteriorly and serves as a conduit for the organ's neurovascular bundle, whereas the gastrosplenic ligament stabilizes the spleen anteromedially to the greater curvature of the stomach and contains the short gastric and gastroepiploic vessels. The other ligaments of the spleen play a secondary role in the support of the organ and are generally

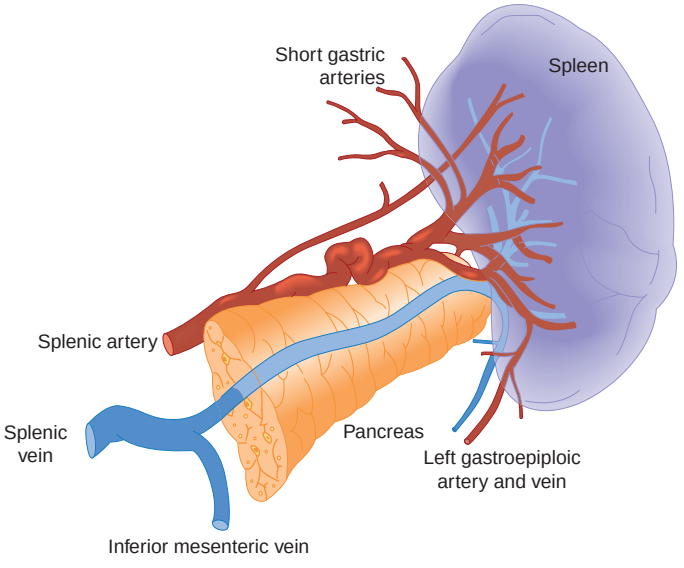

FIGURE 65.1. Illustration of the spleen and relationship to the adjacent pancreatic tail and branch vessels of the splenic artery and vein. (Redrawn and modified from Cameron JL, ed. Atlas of surgery. Philadelphia, PA: BC Decker, 1990.)

avascular.[1,4] However, in certain pathologic states, such as portal hypertension, significant collateral circulation through these planes may occur.

Vascular Supply

The spleen is a highly perfused organ. Although it represents only ~0.2% of the total body weight, it receives > 5% of the total cardiac output.[8] The main blood supply to the spleen is the highly variable splenic artery, which delivers 250 to 300 ml of arterial blood per minute. It arises as a branch of the aorta's celiac trunk in the midline and follows a tortuous course to the left, enveloped within the splenorenal ligament, to supply the organ.[1]

The splenic artery is a highly unpredictable vessel that displays variations in course and dimension. In 95% of the population, it travels along the upper border of the pancreas, but it may also travel in front of, within, or behind the pancreatic tissue. Along its tortuous course, the splenic artery gives rise to the left gastroepiploic artery and the short gastric arteries, both of which run within the gastrosplenic ligament. At its terminal end, the splenic artery branches into a number of smaller arteries, or segmental branches, before penetrating the hilum of the organ. These smaller arteries are also highly variable but are most often four in number and include the superior polar, superior middle, inferior middle, and inferior polar splenic arteries. The segmental branches penetrate the organ by traveling within the trabeculae (sheaths of fibrous connective tissue derived from the involution of the spleen's fibrous capsule) and ramify within the body of the organ. Additional sources of arterial blood to the spleen include direct tributaries and collateral circulation provided by branches of the pancreatic and short gastric arteries.[1,4]

Venous drainage is facilitated primarily by the splenic vein. It is formed by the coalescence of the segmental splenic veins, as they leave the hilum of the organ, and the left gastroepiploic vein. Occasionally, short gastric veins may also participate. The splenic vein courses toward the midline along the superior border of the pancreas, where it joins the superior mesenteric vein to form the portal vein. Along the way, the splenic vein receives venous tributaries from the pancreas and, in 60% of cases, also receives the inferior mesenteric vein.[1,4]

Lymphatics

The spleen, which is considered by many to be a lymphatic organ, has no afferent lymphatics, yet a significant amount of lymph fluid is expressed by the organ and drains via efferent vessels that form around the arterioles. The lymphatics travel with the neurovascular bundle through the trabeculae, exiting at the hilum.[3,9] In turn, the lymphatic fluid is directed toward the nodes of the splenic hilum, the splenic artery, and the pancreas (the pancreaticosplenic nodes), and eventually drains to the nodes of the celiac axis.[4]

Innervation

The spleen is innervated by fibers of the sympathetic nervous system which originate at the level of T-6 to T-8 and pass with the greater thoracic splanchnic nerve to the celiac ganglion.[15] From there, they pass to the organ via the arterial tree, with resulting vasomotor function.[1] It is believed that, similar to other mammals, the autonomic nervous system regulates changes in spleen volume, resulting in the expulsion of stored red blood cells during times of physiologic need.[18,25]

Of interest are studies that relate the sympathetic innervation of the spleen to the immune system.[10–12] These studies suggest that spleen innervation also supplies branches to the lymphocytic tissue of the white pulp, and that the innervation is plastic and able to be remodeled depending on the host's current immune state.[13] In this respect, these investigators argue, the central nervous system is hard-wired to the immune system and may mediate the observed immunosuppressive effects of stress.

Accessory Spleens

An accessory spleen is a functioning lobule of splenic tissue set apart from the body of the spleen proper. It is an anatomic variant present in 10% to 30% of the general population and appears to be found with greater frequency in patients with hematologic disorders. Figure 65.2 shows a typical example of an accessory spleen.

These supernumerary organs arise during embryologic development when an encapsulated lobule of precursor cells fails to fuse with others forming the spleen proper ; they are solitary in ~88% but can be multiple in 10% of cases.[14] In the majority of cases, accessory spleens receive their blood supply from a tributary of the splenic artery and are found most often near the hilum of the organ or within one of the primary supporting ligaments. However, they may be found within secondary supporting ligaments or within the greater omentum or even in as remote a location as the pelvis of the female or the scrotum of the male. They may be mistaken for malignancy on imaging studies, such as computed tomography (CT) or endoscopic ultrasound.

Because accessory spleens perform the same functions as the spleen proper, they are subject to the same pathologic conditions that affect the parent organ. Therefore, they may enlarge after splenectomy, causing a relapse of the disease process for which the spleen was removed. The presence of an unrecognized accessory spleen can account for failure of certain surgical procedures such as splenectomy for immune thrombocytopenic purpura (ITP).[15,16,17,18] In patients who continue to have thrombocytopenia after splenectomy, a search for a missed accessory spleen should be considered. Diagnosis may be made using abdominal sonography, CT, magnetic resonance imaging, nuclear scintigraphy, or Doppler sonography.[19]

Splenosis

In addition to accessory spleens, extrasplenic tissue may occur via traumatic autotransplantation in the form of splenosis. This is the migration and subsequent proliferation of dislodged splenic

FIGURE 65.2. Autopsy photograph demonstrating accessory spleen (*large arrow*) and its relationship to the splenic hilum, pancreas (*small arrow*), and adjacent liver. L, liver; S, spleen. (Photograph provided by Hedi Wingard, M.D., Department of Pathology, Vanderbilt University Medical Center.)

tissue, and it is reported to occur in up to 75% of patients who undergo splenectomy for traumatic injury. Rarely, splenosis may be found in the gynecologic patient or in the thorax after rupture of the spleen and left hemidiaphragm.[20–22] Histologic examination of splenetic tissue reveals the same elements of the parent organ: white pulp, red pulp, and marginal zones.[20] It follows, therefore, that splenetic tissue should preserve at least some splenic function. Indeed, it has been observed that postsplenectomy patients with splenetic tissue do retain the ability to clear erythrocytes of undesirable inclusion bodies. However, it has not been demonstrated that this provides sufficient protection from postsplenectomy infectious complications, and the practice of splenic tissue reimplantation after splenectomy has been abandoned.[23]

Wandering Spleen

Wandering spleen refers to migration of the spleen from its normal location in the left upper quadrant. With an incidence of <0.5% in splenectomy series, the major complication of an ectopic spleen is torsion, either acutely or chronically. Signs and symptoms include vague or chronic abdominal discomfort and a tender abdominal mass; and CT assessment of viability leads to the decision of splenectomy versus splenopexy.

Microscopic Anatomy

Splenic tissue is supported by a scaffold of trabeculae, a dense, fibrous connective tissue skeleton that gives rise to an intrasplenic meshwork of collagen fibers. Vascular elements enter the spleen at the hilum, branch through the trabeculae, and penetrate the body of the organ to supply the microcirculation.[1] As the arterial elements enter the parenchyma, they become surrounded by an aggregate of lymphoid tissue, which follows vessels in a sheathlike distribution. Aggregates of lymphoid tissue are collectively called the *white pulp*. White pulp may be arranged in this coaxial fashion, or it may appear as isolated follicles within the parenchyma of the organ. The balance of splenic tissue beneath the capsule is known as the *red pulp*. It is composed of vascular, circulatory, and mononuclear phagocytic elements. Additionally, an intermediate region can be observed at the junction between the white and red pulp; it is known as the *marginal zone*. Nerves and lymphatics follow the distribution of the larger vessels throughout the body of the organ.

White Pulp

The white pulp structure resembles that of a lymph node, with organized T and B cell compartments surrounding branching arterial vessels. The organization of the cellular elements within the white pulp is created and maintained by local chemokine gradients specific to T and B cells.[3,9] White pulp may be observed in one of two arrangements: a *periarteriolar lymphatic sheath* (PALS) or a *lymphoid follicle*. The PALS is a collection of T lymphocytes that surrounds intraparenchymal arterioles and follows these vessels in a coaxial fashion for several millimeters throughout their terminal distribution. Within the PALS, T cells interact with dendritic cells and passing B cells. The lymphoid follicles are spherical collections of B lymphocytes. These follicles are usually distributed along the length of the PALS in an eccentric fashion and house activated B cells undergoing clonal expansion.[9]

Red Pulp

The red pulp represents approximately three-fourths of the splenic volume and is composed primarily of vascular elements surrounded by a fibrocellular reticulum that contains mononuclear phagocytic cell lines and circulating elements of blood in transit.[1] The chief vascular component of the red pulp is the *splenic sinus,* a preliminary venous element whose structure is unique to this organ. The sinus is composed of an incomplete lining of elongated endothelial cells surrounded by a highly fenestrated basement membrane. The structure is supported externally by reticulin fibers wrapped in a transverse fashion. These *stress fibers* also have actin- and myosin-like filaments which regulate the porosity of the sinus. The unique architecture of the splenic sinus has been compared to the structure of a wooden barrel, with the elongated endothelial cells resembling the planks or staves and the external reticulin fibers representing the hoops.[3]

The splenic sinuses permeate the surrounding fibrocellular reticulum that supports them. Two-dimensional histologic observation reveals an intervening reticulum arranged in cords called *splenic cords* or *cords of Billroth*.[1] These cords actually are a three-dimensional meshwork of densely packed elements (fibroblasts, collagen fibers, and cells of the mononuclear phagocytic lines). Terminal arterioles and capillaries deliver circulating blood to this meshwork that percolates through the cord toward the sinuses. Thus, circulating elements of blood in transit are also packed within the cords: erythrocytes, platelets, macrophages, lymphocytes, plasma cells, and granulocytes.[1,3,9]

Marginal Zone

The *marginal zone* is a transitional region between the white and red pulp and contains both lymphocytic and mononuclear phagocytic elements. Within this transitional zone, three distinct regions can be identified. Moving from white to red pulp are the marginal sinus, the marginal zone proper, and the perimarginal cavernous sinus plexus.[3]

The *marginal sinus* is a vascular sinus that surrounds the white pulp and is a region where arterioles terminate into an anastomosing complex of vascular spaces. External to the marginal sinus is the marginal zone. This transitional region contains elements of both white and red pulp and is where much of the circulating blood is presented to lymphocytic and mononuclear phagocytic cells.[3,24] Figure 65.3 illustrates a schematic view of the microcirculation within the spleen.

Many different cell types reside in the marginal zone. Its foundation is a framework of reticular fibroblasts which is continuous with the reticular fibroblasts of the red pulp and the cells lining the marginal sinus. The marginal zone macrophage, metallophilic macrophage, and B cell are the key cell types in this transitional zone. The marginal zone B cell is a specialized subset of B cells that differ phenotypically and functionally from follicular B cells and are considered a bridge between the innate and adaptive immune systems.[25] Interactions between these cells are key in the marginal zone's organization and integrity. Many transient cells

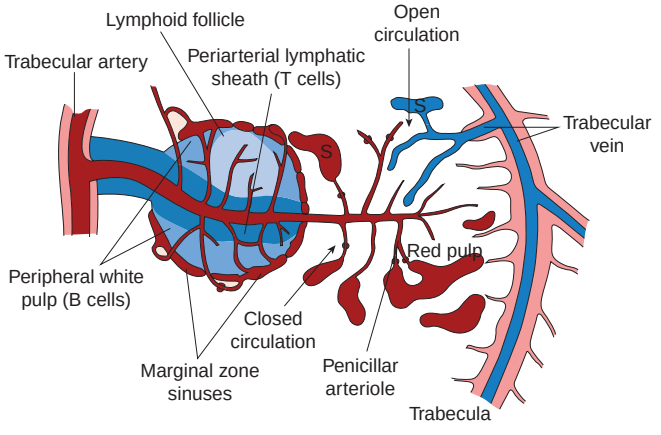

FIGURE 65.3. Schematic illustration of the microcirculation of the spleen. S, splenic sinus. (Redrawn and modified from Greep RO, ed. The spleen. New York: McGraw-Hill, 1966.)

pass though this area as they circulate into the red pulp and back into the blood stream. Diapedesis of lymphocytes and dendritic cells occurs through a barrier cell layer from the marginal sinus into the white pulp; however, the exact mechanism of this localization remains unknown.[25,26]

Microvasculature

As the splenic artery approaches the body of the organ, it divides into a series of branches, the *proper splenic arteries*. On average, four proper splenic arteries then enter the organ at the hilum and branch into *trabecular arteries,* so named because they run within the framework of the fibrous connective tissue skeleton, the *trabeculae*. Trabecular arteries leave the fibrous trabeculae and penetrate the parenchyma by branching into central arteries that immediately become surrounded by a cuff of white pulp, the PALS.[3,9]

As the central arteries pass through the white pulp, they give off lateral branches at right angles, most of which terminate in and supply the marginal sinuses, and others that terminate within the marginal zone or red pulp.[9,27] The right angle by which these lateral tributaries branch off from the central artery is thought to mediate a plasma-skimming effect which functions to hemoconcentrate the blood with a greater number of cellular elements.[27–29] This skimming effect may also help regulate plasma volume. Central arteries continue from the white pulp sheath through the marginal zone and eventually terminate in the red pulp, giving off additional lateral branches along the way that are known as *penicillar arterioles*.[1] The penicillar arterioles, which are named for their resemblance to *Penicillium* molds, terminate in one of three fashions: They may circle back and supply the marginal sinus; they may terminate in the red pulp, supplying the splenic cords; and a minority may terminate directly into the venous sinuses for direct venous return. Eventually, the central artery itself terminates within the red pulp.[24,27,29]

Circulating elements of splenic blood flow begin their return by first entering the splenic sinuses, the preliminary venous vessels. Flow may enter the sinuses directly from arterial connections in a closed circulatory fashion. Alternatively, plasma and blood cells may reach the sinuses only after percolating through the reticulum of the parenchyma in an open circulatory fashion. Eventually, the venous sinuses coalesce and drain into trabecular veins that give rise to the segmental veins and, finally, the splenic vein.[24,27,29]

The exact details of splenic microcirculation remain elusive despite much research since its first description in 1901. The currently accepted models that describe the flow of blood through the vessels of the spleen discuss this in terms of the pathway taken, or route, and the kinetics, or speed of flow. *Closed circulation* implies that blood passes directly from artery to capillary to vein. In terms of the spleen, blood traveling along a closed circulatory path follows the terminal arterioles to capillaries and, eventually, into the venous sinuses. Indeed, such direct connections have been observed.[24,27,29]

The term *open circulation* implies that cells and plasma circulate outside of endothelium-lined vascular channels. As it pertains to the spleen, circulating blood may follow one of two open pathways: It may leave the endothelium-lined marginal sinus, traverse the white pulp, and drain into the open-ended sinuses of the perimarginal cavernous sinus plexus[27]; or it may leave penicillar arterioles that terminate in stroma of the red pulp, traverse the splenic cords, and reenter the venous sinuses through their fenestrations. Indeed, the unique vascular channels and microarchitecture of the spleen can support these open circulatory pathways, which also have been observed.[9,24,29]

Another model for discussing splenic microcirculation describes it in terms of kinetics or speed of flow.[1,27] Accordingly, intrasplenic circulation may be fast, intermediate, or slow, traversing the organ in seconds, minutes, or hours.[1] Fast flow occurs along paths of low resistance, traverses the organ in seconds, and accounts for ~90% of splenic flow.[24] Pathways that support fast flow include the open circulation of the marginal zone and, to a lesser extent, the closed circulation of direct arterial, capillary, and sinus connections.[27]

Elements that flow at an intermediate speed cross the circulation within minutes rather than seconds and represent ~9% of flow across the organ. These elements are thought to follow the open circulation through the cords where red cell processing—pitting and culling—occurs.

Finally, slow-flowing elements may take more than a day to traverse the organ and represent 1% of splenic flow. This is thought to represent a pool of maturing reticulocytes, which travel to the spleen from the bone marrow and undergo maturation before being released into the circulation.[27] The role of the spleen in this function is well documented and supported by the fact that asplenic patients have a high concentration of immature reticulocytes in their peripheral circulation.[30]

SPLENIC FUNCTION

The functions of the spleen are probably best understood in terms of its unique structure. Composed of several different tissue types, it lies at the crossroads between the arterial supply and venous return. In this respect, the spleen functions as a unique lymphoid organ where elements of the circulatory, reticuloendothelial, and immune systems interact. Thus, it is ideally suited to play a critical role in the surveillance of circulating blood.

The spleen functions as a filter of the circulating blood, a coordinator of the immune response, and a reservoir for circulating cells and platelets. Additionally, the spleen may have a number of other responsibilities, including hematopoiesis, hemoglobin degradation and iron recovery, and plasma volume regulation.

Filter Function

One of the primary functions of the spleen is to filter blood. Elements removed from circulation by the spleen include aging or abnormal red cells, intraerythrocyte inclusions, and foreign particulate matter.[3]

Culling

The removal of aging or abnormal red blood cells by the spleen occurs within the cords of Billroth and is known as *culling*. Cells bound for destruction become trapped within the reticulum meshwork and, as their splenic transit time increases, they succumb to phagocytosis by resident macrophages.

Another theory contends that as erythrocytes age, they lose significant amounts of cytoplasmic membrane. Senescent cells therefore lack the deformability necessary to negotiate the meshwork and ultimately become trapped. This theory applies to red cells that are morphologically abnormal secondary to congenital disorders such as sickle cell anemia and hereditary spherocytosis. Finally, it has been proposed that as erythrocytes age, they expose surface antigens that are recognized by self-directed antibodies. Once opsonized with antibody, senescent cells are easily trapped by cordal macrophages.[3,9,30,31]

Pitting

In addition to culling, the spleen also functions to remove intraerythrocyte inclusions from circulating red cells. The ability of the spleen to clear these inclusions while maintaining the integrity of the red cell itself is known as *pitting* and is an exclusive function of splenic tissue.

Undesirable intracellular elements removed by the spleen include circulating particulate matter, Heinz bodies (denatured hemoglobin), Howell-Jolly bodies (nuclear remnants), and Pappenheimer bodies (iron granules). Pitting occurs as cells within the cords attempt to reenter the circulation through the splenic sinuses. To do this, they must pass through slit-like fenestrations of the sinus endothelium. As this occurs, the deformable portion of the cell bends to negotiate the opening, whereas the inclusion, which is nondeformable, is unable to pass through the narrow passage; thus, it is left behind to be phagocytized by resident macrophages. The passage of red cells through the slits is mediated by active changes within the sinus endothelial cell stress fibers. These cells have been shown to have cytoskeletons that include the contractile protein components actin and myosin.[3,22,31] Figure 65.4 is a schematic representation of the process of pitting.

Evidence that supports the role of the spleen in culling and pitting is found in the fact that, after splenectomy, asplenic and hyposplenic patients lose their ability to clear damaged red cells and intraerythrocyte inclusion bodies from the circulation. These patients display peripheral blood smears with an abnormal variety of erythrocytes, many with intracellular inclusions. In fact, determination of the percentage of pitted erythrocytes is a well-established method of assessing splenic function.[30,31]

Clearance of Particulate Matter

Another important filtering function of the spleen is its ability to remove particulate matter from the circulation. As blood travels through the meshwork of the cords, foreign particles are exposed to splenic macrophages that clear them by phagocytosis. Experiments with injected carbon particles have confirmed this process and have identified the cells chiefly responsible for this function: The macrophages surrounding the splenic sinuses.

Immune Function

Because the spleen is composed of lymphocytic tissue, circulatory elements, and mononuclear phagocytic cell lines, it is ideally suited to play a coordinating role in the immune response. The organ's function in this respect includes its role in the nonspecific as well as the specific arm of the immune response, making it an important organ for immune homeostasis. The nonspecific immune functions of the spleen include the clearance of pathogens, the clearance of opsonized erythrocytes and platelets, and the production of complement. The ability of the spleen to clear blood-borne microorganisms and debris combined with its highly organized lymphoid compartment makes the spleen the most important organ for antibacterial and antifungal immune reactivity.

The spleen plays a significant role in the removal of blood-borne pathogens from the circulation. Once coated with complement, bacteria and viruses become circulating immune complexes. Although the liver clears some of these complexes, many others are delivered to the spleen and eliminated by marginal zone cells expressing specific receptors including pattern-recognition receptors, C-type lectin SIGNR1, and type 1 scavenger receptor MARCO.[32] Marginal zone metallophilic macrophages also function to concentrate pathogens in the spleen, leading to their opsonization, and produce high levels of interferon-α and interferon-β

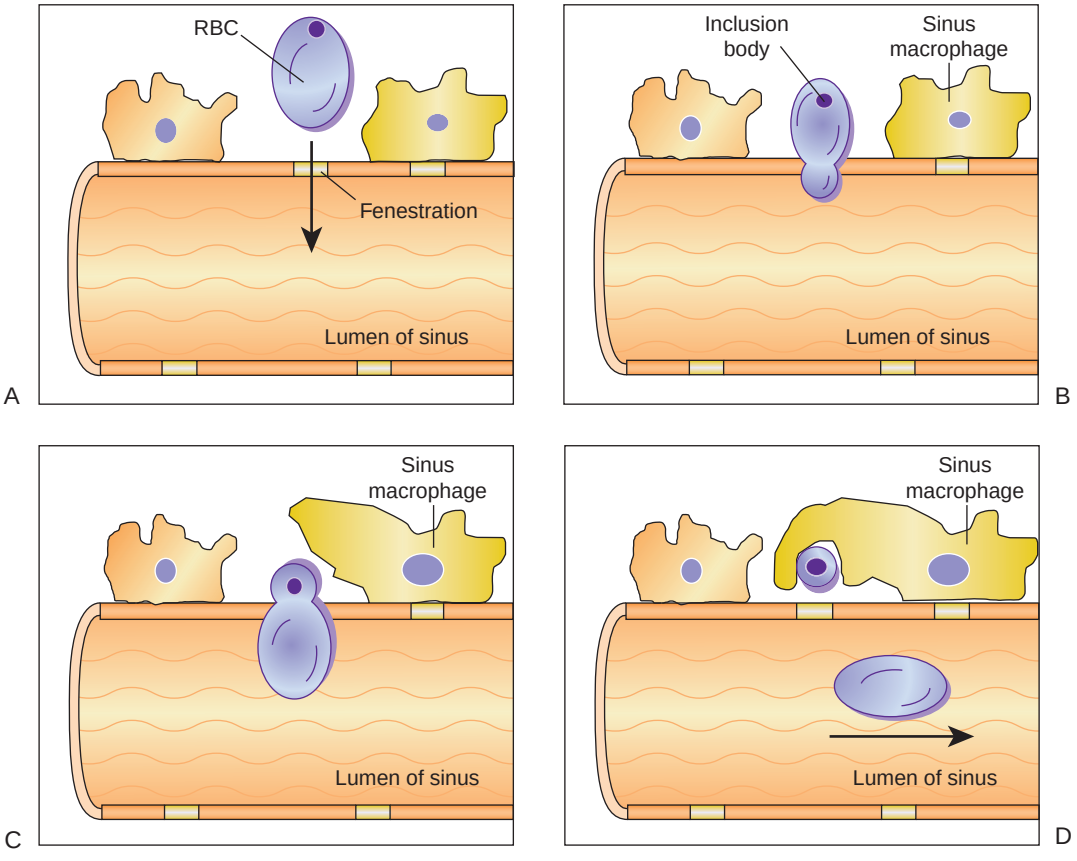

FIGURE 65.4. Schematic representation of process of pitting by the spleen. This process is believed to be responsible for removal of undesirable elements from circulation, including particulate matter, Heinz bodies (denatured hemoglobin), Howell-Jolly bodies (nuclear remnants), and Pappenheimer bodies (iron granules). **A:** Red blood cell (RBC) flows from open circulation and approaches fenestration of sinus. **B:** RBC begins to enter sinus through fenestration; note inclusion body within RBC. **C:** RBC transverses sinus; membrane-bound inclusion body lags behind. Sinus macrophage begins to approach inclusion body. **D:** RBC within sinus returns to venous circulation. Inclusion body succumbs to sinus macrophage. (Modified from Weintraub LR. Splenectomy: who, when, and why? Hosp Pract (Off Ed) 1994;29.)

after viral exposure.[26] Marginal zone B cells are specialized to detect circulating pathogens, after which they rapidly differentiate into immunoglobulin (Ig) M producing plasma cells or antigen presenting cells capable of $CD4^+$ T cell activation.[26] The contribution of the spleen to this process is supported by the fact that asplenic patients display a higher level of circulating immune complexes than do spleen-competent subjects.

The ability of the spleen to clear encapsulated bacteria is especially significant. Because these organisms have the ability to evade antibody and complement binding, their clearance depends on prolonged contact between pathogen and macrophage. It is well recognized that asplenic or hyposplenic patients are prone to a syndrome of fulminant septicemia, most often involving encapsulated bacteria: Overwhelming postsplenectomy sepsis.[31]

The spleen also plays a major role in the removal of opsonized erythrocytes and platelets from the circulation. In certain pathologic states, such as autoimmune hemolytic anemia or ITP, circulating elements become opsonized with IgG antibody. The resulting cell-antibody complexes enter the spleen and encounter Fc receptor–laden macrophages in the marginal zone, where they are destroyed.[3]

Several proteins and glycoproteins of the complement system are synthesized by mononuclear phagocytic cells in the spleen, namely properdin and tuftsin. *Properdin* is an opsonin that plays a critical role in the alternative pathway and has been detected in the monocytes of the spleen. Tuftsin stimulates interleukin-1 production and binds to granulocytes to initiate phagocytosis.[3] Although these elements are also produced at other locations including tissue macrophages and the liver, the spleen's contribution is significant, and they are found in lower concentrations in the circulation of asplenic or hyposplenic patients. Patients who have lost their spleens also display a decreased concentration of C3 and factor B.[33]

Specific Immune Response

The spleen is also uniquely suited to play a coordinating role in the specific arm of the immune response. Because white pulp and vascular elements lie adjacent to each other, this may serve as an interface between the lymphocytic populations of T and B cells and the elements of circulating blood.

As circulating blood enters the spleen, 90% of it passes through the marginal sinuses and surrounding zones.[27] Here, foreign antigens are exposed to the lymphocytic tissue of the PALS and the follicles, stimulating them to respond. After antigen-specific differentiation in the white pulp follicles, plasmablasts migrate to the bridging channels of the marginal zone within the red pulp.[34] The anatomic localization of the plasmablasts in the spleen resembles that found in lymph nodes. Antibodies produced at this location rapidly enter the circulation. The spleen also plays an important role in the induction of cell-mediated immunity. Once activated, antigen presenting cells enter the white pulp, resulting in the activation of T cells. Activated T cells then localize to the periphery of the B cell follicles where costimulatory signals are exchanged, resulting in B cell isotype switching in the follicle. These activated B cells then either migrate to the marginal zone, or remain in the germinal center. It should be noted that although these functions also occur within lymph nodes, asplenic patients demonstrate a specific response to blood-borne antigens. For example, the production of IgM in asplenic patients is both delayed and diminished. On the other hand, specific immune factors that rise in the circulation after a splenectomy include IgE and self-directed autoantibodies. This is likely due to structural differences between the lymph nodes and spleen which carry antigen to each. Antigens transported to the white pulp are from the circulating blood, whereas those delivered to lymph nodes are carried by the lymph.[35,36]

Cellular Reservoir Function

The ability of the spleen to function as a reservoir for circulating elements has been the subject of much study. Platelet sequestration by the spleen is well documented. Newer evidence supports the spleen as a primary site of production and a reservoir for white blood cells.[3]

The spleen is considered a reservoir for platelets because it can sequester large quantities of thrombocytes and, in turn, release them on demand. In nonpathologic states, the spleen sequesters ~30% of the body's platelets and can release them into the circulation in response to certain stimuli. For example, in response to an increase in circulating catecholamines, the spleen releases significant numbers of sequestered thrombocytes into the circulation.[37]

The role of the spleen as a platelet reservoir is most dramatically demonstrated by the fact that pathologically enlarged spleens sequester greater quantities of platelets. In splenomegaly secondary to portal hypertension, the organ can sequester up to 90% of the body's reserves and result in severe thrombocytopenia. On the other hand, in the postoperative period after splenectomy, there is a significant rise in circulating platelet counts. Sometimes this effect is transient, possibly because the liver compensates by increasing its ability to sequester thrombocytes.[38]

The spleen has been also demonstrated to sequester a significant portion of red cell volume during times of inactivity, reducing blood viscosity and heart workload.[39] Increases in the hematocrit after exercise reproducibly occur secondary to release of erythrocytes from the spleen. Splenic volume and the retention of erythrocytes in the splenic sinuses is thought to be mediated though the contractility of the stress fibers supporting the splenic sinuses.[3] The mechanism of splenic volume change likely involves both direct innervation by autonomic fibers as well as the hormonal effects of catecholamines. α-Adrenergic blockade abolished the responses of the spleen to norepinephrine and direct neural stimulation.[10–12]

The ability to produce and sequester various groups of leukocytes allows the spleen to act as a mediator between the different arms of the immune response. One study has shown that as blood enters the spleen, lymphocytes selectively migrate to their respective zones: T cells to the lymphatic tissue of the PALS, and B cells to the follicles and red pulp. Mitogen-stimulated B lymphocyte proliferation can be upregulated in the setting of inflammation by the serotonin-rich platelets located in the spleen.[3] The spleen is also a reservoir for granulocytes, readily mobilized under stress, and memory B cells.[40] The spleen also plays an important role in the coordination of the cellular innate immune response. It has been shown that a subset of innate immune cells including undifferentiated myeloid cells reside in the spleen and greatly outnumber those cells found in the circulation. These myeloid cells cluster in the cords of the subcapsular red pulp and can be released in response to injury, inflammation, and sepsis to regulate the host's immune response.[41] In addition, this population of undifferentiated myeloid cells has been implicated as an important mediator of tumor-induced immune suppression. In cancer patients, these cells have been termed myeloid-derived suppressor cells and are upregulated in the spleen and peripheral circulation. The degree of this upregulation correlates to the disease stage.[42]

Erythropoietic Function

The spleen produces red blood cells during fetal development and during certain pathologic states. During the fifth month of fetal development, it is a major source of red blood cell production, after which it loses this ability. Pathologic states associated with splenic hematopoiesis include myeloid metaplasia. However, the production of cells by the spleen under these abnormal conditions results not from the reactivation of fetal stem cells but from displaced bone marrow cells that take up residence in the confines of the organ.[14]

Iron Metabolism

As red blood cells are destroyed within the splenic cords, their contents are degraded in the phagolysosome of sinusoid macrophages. The hemoglobin is recycled into heme and sent to the bone marrow for use in the manufacture of new erythrocytes or stored as ferritin. Large complexes of ferritin form into hemosiderin, both of which can be mobilized into the circulation during times of iron deficiency.[43,44] The spleen's storage ability of iron is clearly demonstrated by the fact that asplenic patients display lower serum iron levels for a considerable amount of time after splenectomy.[31]

The spleen also scavenges hemoglobin that is released from intravascular destruction of erythrocytes. Intravascular hemoglobin is rapidly bound by haptoglobin, which is removed in the spleen through a receptor-mediated endocytosis directed by CD163, a hemoglobin-specific receptor on the surface of macrophages.[45]

The ability to scavenge for iron also plays an important antibacterial role. Iron is a necessary nutrient for many bacterial pathogens which secrete *siderophores* to compete for iron in the host's serum and tissues. Specialized macrophages in the red pulp of the spleen can be stimulated by these bacteria through toll-like receptors resulting in the secretion *lipocalin-2*, a molecule that complexes with siderophores limiting bacterial growth.[46]

SPLENIC DISORDERS AND INDICATIONS FOR SPLENECTOMY

The causes of splenomegaly and indications for splenectomy can often be confusing. There are many potential causes of splenomegaly that must be considered in any patient undergoing evaluation with an unknown diagnosis. It cannot be overstated that patients without a known cause of splenomegaly should rarely undergo splenectomy and then only after a thorough workup has been completed to assess the likely etiology of this finding.

Splenomegaly is often the result of some other condition, not the result of a primary pathologic state. The spleen rarely harbors a primary malignancy such as lymphoma that is not apparent at other sites after a careful survey by history, by physical examination, with limited imaging studies, and with peripheral blood studies. The temptation to perform a splenectomy for diagnostic purposes early in the workup of the stable patient should be strongly resisted. It is unlikely to yield a diagnosis, and, in some situations, may entail significant risk to the patient with no benefit (as in splenomegaly resulting from portal hypertension).

It is important to remember that splenic size is not always a reliable guide to splenic function, because palpable spleens are not always pathologic and abnormal spleens are not always palpable. In a survey of healthy first-year college students, 3% were found to have splenomegaly, and 5% of all hospitalized patients have been noted to have splenomegaly.[47] Patients with cirrhosis and portal hypertension almost always have splenomegaly, but even with significant thrombocytopenia, which is often present, no specific therapy is indicated because this condition rarely results in specific complications. The important clinical issue involves determining when abnormal splenic function is occurring, ascertaining the responsible etiology, if possible, and only then assessing therapeutic options.[48]

Chauffard introduced the concept of hypersplenism in 1907, although the exact clinical definition remains confusing in practice even today. The criteria for this diagnosis generally include four features: cytopenia with anemia, thrombocytopenia, leukopenia, or some combination; compensatory bone marrow hyperplasia; splenomegaly; and improvement or resolution in these findings after splenectomy. Hypersplenism has been further classified into *primary hypersplenism*, when no etiologic factor for splenomegaly has been found; and *secondary hypersplenism*, when splenomegaly is the result of another recognized condition (such as portal hypertension or an infiltrative process). With continued progress in diagnosis of the causes of splenomegaly, there has been a continued drop in the frequency of cases of primary hypersplenism. Given the nonspecific nature of this diagnosis and uncertainties regarding its therapeutic implications, it is used less often today.

Perhaps a more useful guide in the assessment of splenomegaly is to consider the mechanisms responsible for the splenic enlargement. Eichner et al. divided the causes of splenomegaly into six major categories, listed in Table 65.1.[47] The likely mechanisms for resulting cytopenias in specific disease states are shown in Table 65.2. It is interesting that the degree of splenomegaly on physical examination, radiographic assessment, or at the time of splenectomy does not appear to correlate with the magnitude of cytopenia.

Although most attention regarding splenic dysfunction relates to splenomegaly and related cytopenias, occasionally patients develop hyposplenic conditions, usually from splenic infarction (such as sickle cell disease). In this group, consideration should be given to vaccination against encapsulated organisms, and potential infectious complications should be considered if unexplained fever or signs of sepsis develop, similar to postsplenectomy patients.

Indications for Splenectomy

A recent review of indications for splenectomy demonstrates the evolution of surgical management for splenic disorders. Over a 10-year period, the most common indications for splenectomy (trauma, incidental, hematologic malignancy, iatrogenic, and cytopenia) saw a drop of between 30% and 50%. In addition, the

TABLE 65.1

CLASSIFICATION OF SPLENOMEGALY BY MECHANISM

Mechanism	Causative Diseases
Immune response work hypertrophy	Subacute bacterial endocarditis
	Infectious mononucleosis
	Felty syndrome
Red blood cell destruction work hypertrophy	Spherocytosis
	Thalassemia major
	Pyruvate kinase deficiency
Congestive (venous outflow obstruction)	Cirrhosis and portal hypertension
	Splenic vein thrombosis
Infiltrative	Sarcoidosis
	Amyloidosis
	Gaucher disease
Neoplastic	Lymphoproliferative
	Myeloproliferative
	Sarcoma
	Metastatic carcinoma
Miscellaneous	Trauma
	Splenic cysts
	Hemangioma

TABLE 65.2

ETIOLOGY OF SPLENOMEGALY AND CYTOPENIA IN SELECTED DISEASE STATES

Disease Condition	Probable Mechanism
Portal hypertension	Increased pooling of blood cells
Hairy cell leukemia	Retention of hairy cells in splenic pulp
Felty syndrome	Immune system work hypertrophy
Thalassemia major	Reticuloendothelial system work hypertrophy
Gaucher disease	Increased pooling and flow-induced dilutional anemia
Agnogenic myeloid metaplasia	Extramedullary hematopoiesis

Data from Eichner ER, Whitfield CL. Splenomegaly. An algorithmic approach to diagnosis. JAMA 1981;246:2858–2861; Eichner ER. Splenic function: normal, too much and too little. Am J Med 1979;66:311–320; Sheldon GF, Croom RD, Meyer AA. The spleen. In: Sabiston DC, ed. Textbook of surgery, 14th ed. Philadelphia, PA: WB Saunders, 1991:1108–1133.

absolute number of splenectomies decreased over the period of review.[70] Nevertheless, splenectomy is an accepted and often definitive treatment modality for a number of diseases, as discussed below.

Immune Thrombocytopenic Purpura

ITP is an acquired isolated thrombocytopenia in which circulating antiplatelet antibodies bind to platelets and are cleared by phagocytic cells from circulation (see Chapter 47). The humoral cause of the disease was established in 1951, when a hematologist in training infused himself with the plasma from a patient with ITP and developed thrombocytopenia and platelet destruction. Today, between 40% and 80% of patients with ITP have identified autoantibodies to platelet-specific glycoproteins, including GPIIb/IIIa and GPIb/IX. In addition, dendritic cells with upregulated costimulatory molecules appear to play a major role in the pathophysiology of the disease through the enhancement of B and T cell responses to platelets.[49] Macrophage-mediated platelet destruction is believed to play an important role in refractory disease through the presentation of new antigens.[50] The spleen likely has a dual role in this disease by both producing IgG and providing the location for removal of platelets from the circulatory system.

ITP most commonly presents in women in their 20s and 30s, and they often present with bleeding after minor trauma, with nosebleeds or petechiae. There are often no physical findings, and importantly, the spleen is almost always normal in size. The primary laboratory abnormality is thrombocytopenia with platelet counts typically $<50 \times 10^9$/L and sometimes as low as 10×10^9/L. There is evidence of immature platelets on peripheral smears, and bone marrow smears show increased numbers of megakaryocytes. ITP can occur in childhood and often follows a viral illness. Most cases are acute and resolve spontaneously within 6 months to 1 year. However, a small number is at risk for major bleeding, and ~5% of children develop chronic severe thrombocytopenia that requires treatment, including splenectomy in some cases.[50]

First-line treatment of patients with ITP and symptomatic bleeding or platelet counts $<30 \times 10^9$/L is with corticosteroids, with the goal of achieving and maintaining a hemostatic platelet count. Typical regimens include daily oral prednisone or pulses of high-dose dexamethasone. Both regimens are effective and currently are being compared in a randomized clinical trial (NCT00991939). For thrombocytopenic crises and overt bleeding, a rapid increase in platelet count may be achieved with IVIg (1 g/kg) or anti-D (for Rh-positive patients) followed by platelet transfusion and steroid administration.

Almost all patients with ITP will progress to second-line treatment as remission with corticosteroids is often not durable and the long-term side effects are unacceptable. Options for patients who fail steroid treatment include splenectomy, rituximab, and the TPO-receptor agonists. The timing of second-line treatments is not well studied, is inconsistent among recent consensus statements, and should be a shared decision between patient and physician that is tailored to fit the patient's condition and goals.[16,51,52]

Splenectomy remains the most effective treatment of ITP. Initial response to splenectomy ranges from 40% to 86%. In a systematic review evaluating the efficacy of splenectomy in patients with ITP over 58 years of age, complete remission was achieved in 66% of patients, partial response in 22%, and recurrence was uncommon.[17] Splenectomy can usually be performed electively unless patients have active, ongoing bleeding. Despite the thrombocytopenia, the circulating platelets function normally, and preoperative platelet transfusions are usually unnecessary and may be ineffective in raising the platelet count because of the rapid sequestration by the spleen.

Rituximab is a chimeric monoclonal antibody against B cells expressing CD20. Although normal platelet counts ($>150 \times 10^9$/L) were achieved in 44% of patients and a partial response was seen in 63% ($>30 \times 10^9$/L), median duration of response was only 10.5 months. Rituximab carries significant risks: 3.7% of patients experienced a severe or life-threatening toxicity and 2.9% died.[53,54,55]

TPO-receptor agonists effectively achieve durable increases in platelet counts, but require continuous treatment. Platelet counts respond in approximately 80% of patients, including those who have failed splenectomy and rituximab. Although the risk profile appears to be favorable, long-term risks have not yet been fully studied.[53,54,55]

When patients fail splenectomy or rituximab, third-line treatments with TPO-receptor agonists or immunosuppressive agents may be indicated. Failure after splenectomy should prompt a search for accessory spleens, as their removal may induce remission. Accessory spleens have been reported in 10% to 30% of patients with ITP.[15,18,99] Technetium sulfa-colloid scanning or ^{111}indium-labeled scanning is useful to demonstrate accessory splenic tissue.[19]

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) generally occurs between the ages of 10 and 40 years and is more common in women than in men (see Chapter 48). TTP is associated with genetic mutations in ADAMTS13 gene, the von Willebrand factor-cleaving protease, or acquired autoantibody inhibitors usually formed after therapy with ticlopidine or clopidogrel. The disorder occasionally occurs during pregnancy or in the postpartum period, and a familial form of the disease exists.[56] TTP is characterized by thrombocytopenia, microangiopathic hemolytic anemia, neurologic abnormalities, renal failure, and fever. TTP is likely to be the result of the abnormal presence of a platelet-aggregating agent in the circulation. Studies suggest that this agent is von Willebrand factor, which is found in excess in patients with TTP. Platelet aggregation leads to microvascular thrombi, typically in the brain, heart, spleen, kidneys, pancreas, and adrenals. Nearly 90% of adults with ADAMST13 deficiency will respond to daily plasma exchange with plasmapheresis and transfusion of fresh-frozen plasma. Patients with acquired autoantibodies can be treated with high-dose glucocorticoids, rituximab, or splenectomy. Surgical treatment is considered in patients who have frequent relapses of TTP and may prolong the disease-free interval.[56–58,59]

Hereditary Anemias

Hereditary spherocytosis is inherited as an autosomal dominant disease in which the red cell membrane includes a defective protein, spectrin (see Chapter 27). The spleen destroys the resulting

defective, spherical red cells. These patients have an anemia and significant reticulocytosis. Peripheral smears demonstrate spherocytes, and these patients have a negative Coombs test. Elective splenectomy will correct the anemia. Ideally, splenectomy is performed after the age of 5 or 6 years to minimize the potential risks of postsplenectomy infections. Because of the rapid red cell turnover, these patients often develop calcium bilirubinate gallstones, and consideration should be given to concomitant cholecystectomy at the time of splenectomy if they are present.[18]

Sickle cell anemia is an autosomal recessive condition that also results in defective red blood cells (see Chapter 33). Because of the frequency of sludging and thrombosis in small vessels, these patients more often develop infarcts in the spleen, which over time results in autosplenectomy. In rare patients, however, splenectomy may be indicated for acute splenic sequestration crisis, hypersplenism, massive splenic infarction, and splenic abscess.[60] Unlike hereditary spherocytosis, splenectomy has little effect on anemia related to the sickle cell condition.

Thalassemia major is an autosomal dominant condition in which abnormal hemoglobin forms protein precipitates in the red cell, recognized as Heinz bodies on a peripheral smear. These patients can develop significant splenomegaly with resulting cytopenia. In this condition, splenectomy can lessen the need for transfusion.

Malignant Tumors of the Spleen

Malignant diseases affecting the spleen can be divided into lymphoproliferative disorders, myeloproliferative disorders, metastatic lesions, and primary splenic neoplasms. Metastatic disease is not uncommon. Melanoma, breast, lung, renal, and ovarian lesions are the main source. Metastatic lesions usually reflect vastly disseminated disease secondary to hematogenous spread. Autopsy series have demonstrated splenic metastasis in 2.3% to 7.1% of cancer patients.[61]

Primary tumors of the spleen are exceedingly rare. They include hemangiosarcoma, hemangiopericytoma, plasmacytomas, and malignant fibrous histiocytomas. All of these conditions may present with splenomegaly and are uniformly treated with splenectomy.

Lymphoma

Lymphoma is a common tumor leading to splenomegaly or a splenic mass (see Chapters 88 and 89), although the spleen is rarely the primary site. Non-Hodgkin lymphoma, including splenic marginal zone lymphoma, can present with massive splenomegaly. Although splenectomy has been shown to be a therapeutic treatment of hypersplenism by increasing blood counts, it has not improved long-term survival.[62]

Hodgkin Lymphoma

Hodgkin lymphoma, described by Thomas Hodgkin in 1832, is a highly curable malignant lymphoma characterized by typical multinucleated giant cells (Reed-Sternberg) (see Chapters 93 and 94) and predictable stepwise progression from one lymph node basin to another. Histologic subtypes fall into five categories: lymphocyte-rich classical, lymphocyte-predominant, nodular sclerosing, mixed cellularity, and lymphocyte-depleted. Most patients initially present with asymptomatic peripheral lymphadenopathy, most often in the cervical region (60% to 80%). Other nodal regions, including the mediastinal, axillary, inguinal, and retroperitoneal regions, are less often involved at initial presentation. The presence of B symptoms, including fever, weight loss > 10%, and night sweats, is noted. Extralymphatic and splenic involvement is also used to stage patients. Below the diaphragm, the first nodal tissue involved is the spleen, with 35% of stage I or II patients having occult splenic disease.[63]

Historically, staging laparotomy was used in patients with Hodgkin lymphoma suspected of harboring subdiaphragmatic disease. In this procedure, lymph nodes were sampled from the para-aortic, paracaval, and iliac regions, and liver biopsies were performed along with splenectomy. With the enhanced accuracy of CT and other imaging studies for staging purposes, the increased effectiveness of medical treatments, and the associated surgical risk, the need for surgical staging has essentially been eliminated.[63]

Leukemia

In chronic lymphocytic leukemia and less often in chronic myelocytic leukemia, massive splenomegaly can result in significant symptoms from the mass effect of the enlarged spleen, necessitating splenectomy (see Chapters 90 and 81). Likewise, patients may develop significant cytopenia that is refractory to conventional medical measures (i.e., corticosteroids, immunosuppression) and may be candidates for splenectomy. The decision to undertake splenectomy must be made with caution, because these patients often are immunosuppressed and malnourished and have a higher operative mortality risk as well as a higher rate of perioperative complications.[64]

Hairy cell leukemia can lead to infiltrative splenomegaly and pancytopenia, which may limit cytotoxic chemotherapy (see Chapter 91). With the introduction of effective medical therapies, the indications for splenectomy are now limited to spontaneous splenic rupture and severe thrombocytopenia with bleeding. Resistant disease should prompt investigations to confirm an accurate diagnosis.[65]

Myelofibrosis

Myelofibrosis describes a group of disorders characterized by acquired mutations that target the hematopoietic stem cells, and induce dysregulation of cellular signaling, clonal proliferation, and abnormal cytokine signaling. Prominent bone marrow fibrosis and disruption of normal hematopoiesis results, and can be associated with enlargement of the liver and spleen as a result of extramedullary hematopoiesis[66] (see Chapter 83). Massive splenomegaly may lead to pancytopenia, portal hypertension, early satiety, and pain. Splenectomy remains a viable treatment for refractory, symptomatic massive splenomegaly in myelofibrosis. Approximately 50% of patients will be rendered transfusion-independent. In addition, most experience resolution of mechanical symptoms and subjective improvement in constitutional symptoms. The median response is 12 months.[67] Caution must be taken with splenectomy in patients with myelofibrosis, as the procedure carries a perioperative mortality rate of 5% to 10% and a morbidity rate of approximately 25%.[67]

Splenic Cysts

Cystic lesions of the spleen are rare and represent a challenge for physicians to diagnose and treat. The number of asymptomatic cysts incidentally diagnosed continues to rise because of increased utilization of abdominal imaging, including computer tomography, ultrasound, and magnetic resonance.

Splenic cysts are categorized based on the presence or absence of an epithelial lining. Cysts with an epithelial lining are considered primary and can be further subdivided into parasitic or nonparasitic. Secondary cysts, or pseudocysts, lack an epithelial lining and are believed to result from trauma in the majority of cases[68,69] (Fig. 65.5).

Primary cysts possess an epithelial lined lumen and can be divided into parasitic and nonparasitic. Parasitic cysts are most often multilocular, associated with hepatic cysts, and occur after infection with *Echinococcus granulosus*. They make up

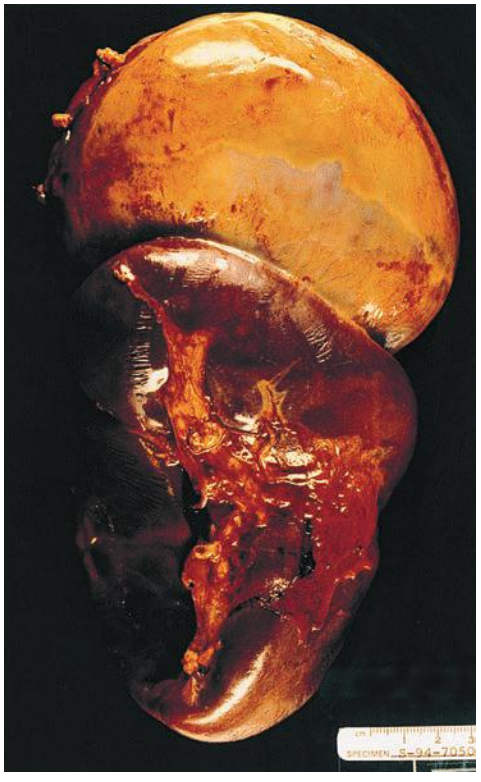

FIGURE 65.5. Large symptomatic splenic pseudocyst developing after blunt trauma to the spleen.

FIGURE 65.6. Computed tomographic scan (A) and gross photograph (B) of spleen in 35-year-old woman with marked splenomegaly from splenic hemangioma. The arrow demonstrates central hemangioma with surrounding uninvolved splenic parenchyma. This benign tumor had caused significant thrombocytopenia, resulting in spontaneous bleeding before splenectomy.

the majority of splenic cysts worldwide and are endemic in South America and the Mediterranean. Parasitic cysts, however, are rare in the Western world. Surgery must be undertaken carefully, as rupture can result in anaphylactic shock or disseminated scoliceal infection. In the presence of large numbers of cysts, surgical treatment is contraindicated and medical therapy with mebendazole, an effective antiparasitic therapy, is an alternative. Treatment of a single or few cysts can be managed sequentially with medical treatment, chemical sterilization (cetrimide 0.1%), and cyst evacuation.[70]

Nonparasitic cysts are usually congenital and can be further divided into endodermoid, dermoid, or epidermoid cysts. Epidermoid cysts are the most common congenital cysts (~90%) and present most often in children and young adults. They are derived from inclusions of splenic surface epithelial lining into the splenic parenchyma during development or from an accelerated secretion of lining cells from an unknown cause.[71] Dermoid cysts are exceedingly rare; they contain all three embryonic germ layers and make up the remainder of nonparasitic congenital cysts. Endodermoid cysts are not true cysts, but rather cystic vascular lesions composed of several ectatic vessels that are best described as lymphangioma or hemangioma (Fig. 65.6). These benign tumors are most often incidental findings when imaging studies or laparotomy are performed, or they may be found at autopsy. Occasionally, the patient may develop significant splenomegaly and cytopenia, leading to the need for splenectomy. Usually, however, the diagnosis can be made on the basis of imaging studies alone and splenectomy avoided. In cases of doubt, follow-up imaging studies demonstrating the absence of change over time should avoid unnecessary splenectomy.[68]

The spleen is the intraperitoneal organ that is most often injured after abdominal trauma. Although 75% of nonparasitic splenic cysts are posttraumatic, 30% of patients cannot recall the inciting event.[69] Pseudocysts may contain a mixture of blood and necrotic debris, as they commonly form after intraparenchymal or subcapsular hematomas organize and subsequently degenerate (Fig. 65.7). Pancreatic pseudocysts have been reported to burrow into the substance of the spleen, and this should be kept in mind in the patient with a history of pancreatic trauma or pancreatitis. Assessment of cyst fluid amylase levels may provide a clue to the pancreatic origin in such a case.[72] Management of cysts in these cases is usually directed toward treatment of underlying pancreatitis.

Splenic cysts are often asymptomatic (70%) but can also present with vague abdominal pain. The pain can be constant or intermittent, left-sided or epigastric, and occasionally radiates to the left shoulder. Physical exam can reveal a painless abdominal mass in 50% of patients. Radiologic examination with ultrasound, CT, or magnetic resonance imaging can characterize the cyst as uni- or multilocular and provide insight into anatomic relationships. Prior to any invasive procedure, determination of parasitic antibody titers are of great importance to rule out parasitic infection. Ultrasound-guided percutaneous cyst aspiration may be useful for obtaining definitive diagnosis, decreasing the size of the cyst, and excluding communicating pancreatic origin.

The majority of patients with splenic cysts are asymptomatic and do not require specific treatment. Nonoperative treatment is recommended for small cysts up to 5 cm in diameter. In patients with symptomatic cysts, surgical intervention is recommended. Although percutaneous drainage and alcohol ablation is often successful in initially reducing the size of the cyst, the procedure is often plagued with a high incidence of recurrence, necessitating

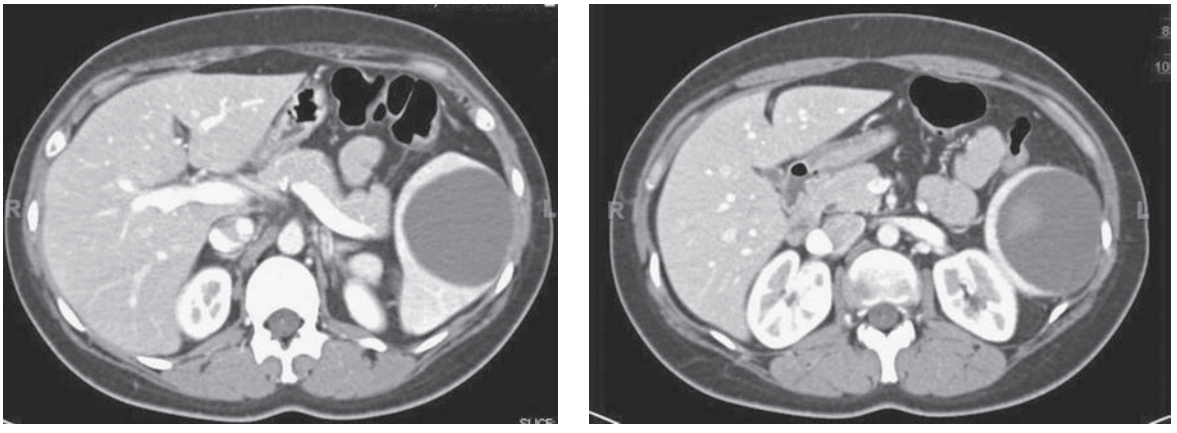

FIGURE 65.7. A: CT of a 43-year-old woman who was scanned after developing left upper quadrant pain. She had no history of trauma. CT showed a splenic pseudocyst. **B:** After aspiration, some blood is seen in the cyst lumen. The cyst rapidly reaccumulated, and the patient subsequently had a successful laparoscopic cyst deroofing.

definitive surgical correction.[73,74] For single, unilocular superficial cysts, laparoscopic marsupialization or fenestration with splenic preservation should be undertaken. Deep cysts, or those located at either splenic pole, can be resected with partial splenectomy, which provides immunologic protection and improved outcomes when compared to splenic autotransplantation. Complete splenectomy is indicated in cases of giant cysts surrounded by splenic parenchyma or multilocular cysts.[18,69,71]

Splenic Abscess

Splenic abscesses may also occur when a simple cyst is secondarily infected, for example, after aspiration, or as a primary abscess, usually from a hematogenous source. Splenic abscesses usually develop from hematogenous seeding, from a distant site of infection, in the setting of intravenous drug abuse, or after splenic infarction, as in patients with sickle cell disease. Immunocompromised patients are at higher risk. There are rarely specific symptoms present, suggesting the spleen as the specific site of infection, although left upper quadrant tenderness may be present in patients with significant abscess cavities. Abdominal CT scanning is the most helpful imaging technique, demonstrating low-density lesions in the spleen, which may contain gas and present peripheral enhancement.[74] CT can also be used to direct placement of percutaneous drainage catheters, which can provide successful treatment in the majority of cases. Multilocular abscesses with thick septations or necrotic debris generally require surgery, although percutaneous catheter drainage may lead to improvement of the patient's general condition without adverse effect on subsequent operation.[73,74] Antimicrobial therapy is based on aspirate culture data, with *Staphylococcus* and *Streptococcus* species being common pathogens.

Felty Syndrome

Felty syndrome composes a triad of rheumatoid arthritis, neutropenia, and splenomegaly in <1% of patients with rheumatoid arthritis. Clinically, patients present with severe joint destruction and other systemic manifestations such as leg ulcers, rheumatoid nodules, vasculitis, lymphadenopathy, and hepatomegaly. Antibody-coated neutrophils are cleared from the circulation in the spleen, and neutropenia can develop. Recurrent bacterial infections, a major source of morbidity, are due to the decreased granulopoiesis, increased peripheral destruction of neutrophils, and defects in neutrophil function. Methotrexate, or other disease-modifying antirheumatic drugs (DMARDs), is the first-line treatment for Felty syndrome with granulocytopenia and increased infection rate. If DMARD treatment is unsuccessful, low-dose granulocyte colony-stimulating factor is recommended. Splenectomy is indicated only in treatment-resistant cases in which splenomegaly is present; splenectomy is contraindicated in patients with large granular lymphocyte (LGL) expansion, as the procedure has no effect and may actually cause deterioration.[18,75,76]

Abdominal Trauma and Splenic Injury

Splenic preservation is the main goal of the modern management of blunt traumatic splenic injuries. Nonoperative management is often successful in about 90% of patients. The degree of splenic injury is measured using contrast-enhanced CT scans and graded according to the American Association for the Surgery of Trauma (AAST) criteria (Table 65.3). The finding of active arterial contrast extravasation from the spleen, referred to a "blush," is an indicator of failure of conservative management in adults. Most injuries of grade 3 or less are successfully managed nonoperatively, whereas the presence of a high grade injury (Grade 4 or 5) or a contrast blush predicts the need for intervention (Fig. 65.8).[77] The primary requirement for nonoperative management is hemodynamic stability, and therefore close monitoring is required in all cases. A continued transfusion requirement and/or hypotension in the face of adequate resuscitation are indications for urgent intervention. A recent meta-analysis of 24,615 patients demonstrated that 12% of patients failed conservative management, ultimately requiring intervention. It also suggested that failure

TABLE 65.3

AAST GRADES OF SPLENIC INJURY

Grade 1	Minor subcapsular tear 1 cm or subcapsular hematoma <10% SA
Grade 2	Capsular tear not involving trabecular vessels, <3 cm or subcapsular hematoma between 10% and 50% SA
Grade 3	Laceration >3 cm parenchymal depth involving trabecular vessels or subcapsular hematoma >50% S, or expanding or ruptured hematoma
Grade 4	Laceration involving the hilum with >25% devascularization of the spleen or intraparenchymal hemorrhage with active bleeding
Grade 5	Completely shattered spleen

SA, surface area.

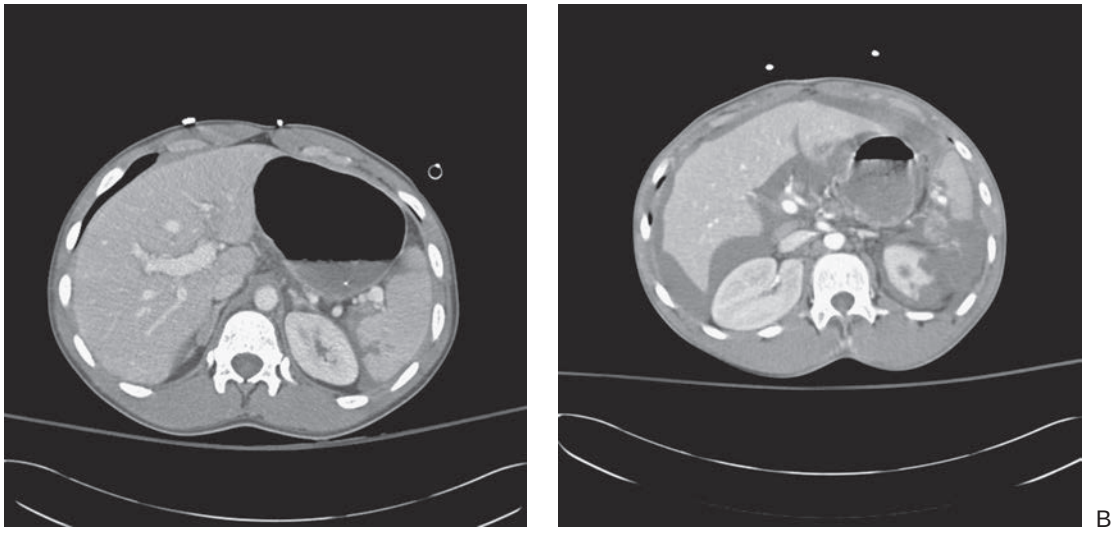

FIGURE 65.8. A: Contrast-enhanced CT showing a grade 1 splenic laceration in the inferior pole, with associated hemoperitoneum; the patient was successfully managed conservatively. B: Contrast-enhanced CT showing a grade 5 splenic laceration with evidence of active extravasation and perisplenic hematoma. This patient required urgent splenectomy.

of conservative management in older patients may be associated with increased mortality.[78,79]

Options for operative invention consist primarily of open splenectomy, with splenic repair and partial splenectomy utilized rarely. In addition to splenectomy, splenic artery embolization has become an integral adjunct in the management of high-grade splenic injuries and in patients with active contrast extravasation. With adequate patient selection, angioembolization has decreased the failure rate of nonoperative management to 4% in some recent series.[77]

Delayed Splenic Rupture

Delayed splenic rupture has been reported in patients experiencing blunt abdominal trauma, a setting in which patients develop splenic hemorrhage >7 days after their original injury.[80] This problem most likely represents an injury in evolution, when the initial imaging study (most commonly CT or ultrasound) at the time of the trauma fails to demonstrate a significant injury. These patients usually have an initial splenic contusion that continues to slowly enlarge and, at some later date, results in disruption of the splenic capsule. This is an uncommon occurrence, but should be considered in any patient who develops significant left upper quadrant pain, distention, and signs of bleeding or shock after an episode of trauma.[81,82] The treatment is urgent intervention with angiography or splenectomy, depending on the patient's clinical picture.

Spontaneous Splenic Rupture

Spontaneous rupture of the spleen is extremely rare and for unknown reasons occurs predominantly in males. Predisposing conditions include splenic infarctions, coagulation disorders, thrombocytopenia, portal hypertension, vasculitis, venous thrombosis in the spleen and focal splenic lesions, lymphoma, and leukemia. Spontaneous rupture is most often secondary to a neoplastic etiology. Overall mortality with rupture is about 12% with splenomegaly, advanced age (>40 years), and a neoplastic etiology predicting an increased risk of death.[83]

These patients usually develop acute left upper quadrant pain that may be associated with referred pain in the left shoulder. Initially, this may be contained beneath the splenic capsule as a subcapsular hematoma, but if intraperitoneal rupture occurs, patients may present with acute severe pain and hypovolemic shock. Ultrasonography or CT scanning is a confirmatory study, demonstrating intraperitoneal fluid (blood) and subcapsular hematoma. Urgent or emergent splenectomy is definitive treatment for these patients. Splenic conservation may be an option in some, because the grade of injury tends to be less severe compared to traumatic splenic injury.

SPLENECTOMY: SURGICAL TECHNIQUE

Open Splenectomy

Historically, splenectomy has been performed via a midline or left subcostal incision, depending on the surgeon's preference and the presence or absence of significant splenomegaly. In patients with massive splenomegaly (>2,000 g), a midline incision may be preferred to allow adequate mobilization and delivery of the spleen into the operative field.

Once the abdomen is entered, a careful search is made for accessory spleens, which may be found anywhere in the abdomen but are most often found in the splenic hilum or in the mesentery of the intestine.

In patients with significant splenomegaly, initial ligation of the splenic artery causes the spleen to decrease in size, lessen its distention, decrease the risk of capsular avulsions, and decrease splenic bleeding should a capsular tear occur. This portion of the procedure is performed by dividing the avascular gastrohepatic ligament above the pancreas and isolating the artery near its point of origin from the hepatic artery. Care must be taken to avoid injury to the adjacent pancreas. This step is optional and can be omitted if the artery is not readily accessible, because aggressive attempts at splenic artery ligation can result in pancreatic injury.

There are ligamentous attachments to the spleen that must then be divided before the inflow vessels in the hilum can be ligated. The phrenosplenic attachment is avascular and can be divided with sharp dissection. The gastrosplenic ligament (and short gastric vessels) and the splenocolic ligament are divided. Finally, the inflow vessels to the splenic hilum are individually ligated, taking care during this portion of the procedure to avoid injury to the tail of the pancreas. Closed suction drainage of the splenic bed is not routinely used, but a drain can be placed if there

is suspicion of a possible pancreatic injury. If this occurs, evacuation of pancreatic fluid minimizes the risk of abscess formation and allows for a controlled pancreatic fistula that will usually seal with observation alone. Conversely, if a symptomatic fluid collection develops in the bed of an undrained spleen in the postoperative period, then a percutaneous drain can be placed under CT or ultrasound guidance.

Partial splenectomy is unlikely to be a realistic option for patients with marked splenomegaly, but may be an option for patients with splenic pseudocysts in whom unroofing of the cyst is the primary objective. This may also be an option in patients with splenic trauma in whom splenorrhaphy may allow splenic preservation. Uranus et al. report successful partial splenectomy using a surgical stapler, and this may occasionally be helpful. Partial splenectomy has also been reported in patients undergoing splenectomy for Gaucher disease.

Laparoscopic Splenectomy

Since laparoscopic splenectomy was first described in 1991 by Delaitre et al.[84] it has become the standard operative approach for the elective treatment of many benign and malignant diseases of the spleen.[15,18] Numerous studies have demonstrated the advantages of the laparoscopic approach compared to open splenectomy, including decreased blood loss, shorter hospital stays, accelerated recovery, and decreased convalescence. As outcomes have continued to improve, the procedure has been applied to an increasing array of splenic pathologies, and is now one of the most common laparoscopic solid-organ procedures. The indications for laparoscopic splenectomy have been expanded and now include ITP, hereditary spherocytosis, hemolytic anemia, TTP, leukemias, splenic myelofibrosis, sickle cell disease, lymphomas, myelodysplastic syndrome, multiple myeloma, and accessory splenectomy.

Massive splenectomy is no longer an absolute contraindication for laparoscopic splenectomy. Superior outcomes over open splenectomy in patients with massive spleens have been demonstrated, including decreased blood loss, reduced transfusion requirement, fewer reoperations for bleeding, and an average reduction in hospital stay by 8 days. Decreased blood loss continues to be the greatest advantage of laparoscopic splenectomy in patients who are coagulopathic and at risk for massive hemorrhage.[62,85,86] The decision to perform laparoscopic splenectomy in a patient with splenomegaly is a multifactorial decision that depends on the underlying disease process, comorbidities, and surgeon experience. The effect of the surgeon's learning curve has been clearly demonstrated in laparoscopic splenectomy, with the average conversion rate depending on experience and ranging from 1.2% to 15%.[85]

The operative approach for laparoscopic splenectomy continues to evolve with the introduction of new surgical technology. After induction of general anesthesia, a nasogastric tube and Foley catheter are placed to decompress the stomach and bladder, respectively. The patient is placed into the right lateral decubitus position, and three or four working ports are placed for the introduction of the laparoscopic instruments, including an angled laparoscope. The lateral port is most often placed at the level of the eleventh rib tip, the medial port in midline, and the middle port halfway between the two, ~4 cm below the inferior tip of the spleen. In patients with a supramassive spleen (>22 cm in craniocaudal length or 19 cm in width), the addition of a hand port has been shown to greatly reduce operative time without increasing length of stay or convalescence. This approach allows the insertion of the surgeon's nondominant hand into the abdominal cavity while maintaining pneumoperitoneum. Positioning is slightly altered by placing the patient's side at a 45-degree angle. After positioning and setup is complete, a careful inspection of the abdomen is carried out to identify other disease or the presence of accessory spleens, focused on the hilum, omentum, and lesser sac.[86]

The dissection then proceeds in five stages: division of the short gastric vessels, division of the splenocolic ligament, ligation of the inferior polar vessels, hilar control, and division of the phrenic attachments of the spleen. Much of the dissection may be carried out with harmonic shears, and the hilar structures are ligated and divided with an endoscopic stapling device. The spleen is then placed in an extraction bag, morcellated in situ, and the fragments removed.

COMPLICATIONS OF SPLENECTOMY

The overall complication rate for laparoscopic splenectomy is ~9%. The most common complications of splenectomy include bleeding, injury to the adjacent pancreas with resulting pancreatitis, and pancreatic pseudocyst, abscess, or fistula formation. These patients can also develop injury to the adjacent stomach or splenic flexure of the colon if care is not taken in dividing the ligamentous attachments to these structures.

Postoperative thrombocytosis can occur, and aspirin (one low-dose aspirin per day) should be considered if the platelet count is $>1{,}500 \times 10^9$/L, to minimize the risks of thrombosis or embolism. The thrombocytosis is usually transient, with return of platelet counts to normal ranges by 2 years after splenectomy.

Thrombosis of the portal venous system is a unique, and potentially life-threatening, complication after splenectomy. Although this complication was once believed to be rare, improvements in radiologic techniques have demonstrated portal venous thrombosis much more frequently than previously thought, with a number of cases occurring asymptomatically. The reported incidence of portal venous thrombosis varies greatly within the literature. Initial retrospective reviews demonstrated incidences between 5% and 15%. When prospectively analyzed, however, the incidence was found to be greatly unappreciated, with 19% to 55% of patients developing portal venous thrombosis. Asymptomatic thrombosis was observed in 33% to 66% of postsplenectomy patients. Patients with larger diameter splenic veins and those operated on for hematological malignancy were found to be at increased risk for thrombosis.[87–89]

When symptomatic, portal venous thrombosis most often presents between 2 and 22 days postoperatively with vague, nonspecific complaints including decreased appetite, vague abdominal pain, nausea, and malaise. Abdominal pain is a rare sign that is present only in cases of severe ischemia. Fever and leukocytosis are common. Risk factors highly associated with portal venous thrombosis include splenomegaly, hematologic malignancy, and thrombocytosis. Normal D-dimer levels have a 98% negative predictive value. Contrast-enhanced CT scanning is the preferred method of evaluation as it can assess the portal circulation as well as other common etiologies of abdominal pain.[89,90]

Once the diagnosis of portal venous thrombosis is made, systemic anticoagulation should be started immediately. With prompt anticoagulation, recanalization can occur rapidly in over 90% of patients. However, patients who received treatment 10 days after the procedure uniformly failed.[91] Although treatment with thrombolytics and antiplatelet agents has been reported, indications for routine use are still yet to be determined.[89,92]

Infection Risk Postsplenectomy

Infectious complications are increased after splenectomy, and this can occur both in the early postoperative period and after a significant time has passed. The rate of early postoperative infections is particularly high when multiple other procedures are performed (e.g., after complex injuries in the setting of multiple trauma).[93,94] The complication of overwhelming postsplenectomy infection (OPSI) has received significant attention. In addition to

OPSI, postsplenectomy patients are at risk for multiple and recurrent episodes of severe infection requiring hospitalization.[95]

Overwhelming Postsplenectomy Infection

One of the most important developments affecting the splenectomy procedure has been the recognition of the life-long increased risk of severe infection and sepsis after splenectomy. In 1969, Diamond described a case of postsplenectomy fulminant bacteremia leading to rapid death and popularized the term OPSI.[96]

Pathophysiology

In the early postoperative period, infection is usually caused by *Staphylococci* and enteric Gram-negative bacilli. Outside this interval, the most common organisms responsible for OPSI are encapsulated bacteria, with *Pneumococcus* being most common (incidence, 50% to 90%).[97] Other responsible organisms include *Neisseria meningitidis, Escherichia coli, Haemophilus influenzae, Staphylococcus,* and *Streptococcus*; and infections occur at rates that range from 7% to 12%.[98]

The special susceptibility of the asplenic patient to encapsulated organisms is likely due to compromised humoral immunity. After splenectomy, a subset of IgM memory B cells that responds to bacterial polysaccharides is severely depleted. These memory B cells have undergone mutation, selection, and class switch in response to a specific antigen and produce antibodies rapidly on second challenge from the same antigen. The IgM memory B cells are responsible for the T cell–independent response and require a functional spleen for their generation and survival.[99,100] Studies confirm that bacteria-specific IgM production in asplenic patients is both delayed and diminished.[101]

Also, it has been demonstrated that asplenic patients have lower circulating levels of certain complement factors, including properdin, tuftsin, C3, and factor B.[102] Tuftsin is a tetrapeptide that stimulates phagocytosis by binding to specific receptors on granulocytes, monocytes, macrophages, and natural killer cell–modulating biologic activity. The spleen also produces properdin, a crucial factor in the alternative pathway of complement activation. The alternate pathway is activated in the absence of antibody and forms C3 convertase. Properdin binds to C3 convertase, preventing its rapid decay, and allows for conversion of C3 to C3b.

There is also evidence that splenectomy results in defects of cellular immunity. After splenectomy for trauma, a cohort of patients was found to have a significant reduction in the percentage of $CD4^+$ T cells, specifically in the $CD45RA^+$ subset. This was accompanied by impairment in primary immune responsiveness in a number of cellular and humoral assays.[99]

Incidence

OPSI is most common in the very young, in patients with underlying malignancies or other medical conditions, and within the first 2 years after splenectomy, although it has been reported 20 to 40 years after surgery. The precise incidence of OPSI is controversial, but is estimated between 0.18 and 0.89 person-years[95,96,97,98,102,103]; published estimates vary widely secondary to different disease definition, duration of follow-up, age stratification, indication for splenectomy, and age. OPSI is greatest in the very young and diminishes with age: 15.7% in infants, 10.4% in children <5 years old, 4.4% in children <16 years old, and 0.9% in adults.[8] Although the incidence in adults is similar to that of the general population, mortality from sepsis is increased 58-fold in the asplenic population, with a fatality rate between 50% and 90%.[95,96,97,98,102,103] Underlying pathology, like youth, also imparts an increased risk of OPSI with the highest risk associated with underlying immune disorders and Hodgkin lymphoma.[97]

Clinical Course

OPSI usually presents with fever and brief upper respiratory tract infection, and pursues a rapid course with evolution to sepsis, shock, disseminated intravascular coagulation, and multiple organ failure within hours. Any asplenic patient with fever should be evaluated for possible OPSI. Key to successful treatment is prompt administration of broad-spectrum intravenous antibiotics. A complete septic workup, including routine laboratory tests, appropriate imaging, and microbiology cultures, should be performed, but should never delay the initiation of antibiotics. In fully developed OPSI, mortality rates of 50% to 90% have been reported; 80% of deaths occur within 48 hours.[95,97] More recent information suggests that when informed patients seek medical attention promptly, mortality rates may be reduced to 10%.

Prevention of Overwhelming Postsplenectomy Infection

The guidelines for the prevention of OPSI center around vaccination, antibiotic prophylaxis, patient education, and strategies aimed at preserving splenic function. Recommended vaccines include the meningococcal vaccine, 23-valent polysaccharide pneumococcal vaccine for patients between 2 and 64 years old, and the *H. influenzae* conjugate vaccine. For patients undergoing elective splenectomy, vaccination should be performed at least 2 weeks before surgery to maximize the antibody against T cell–dependent immunogens. In emergent cases, patients should be vaccinated 14 days after their surgery.[98,104]

Repeat vaccination is safe in those who mount an antibody response based on measurement of antibody levels.[104,105] Currently, a single revaccination with the 23-valent polysaccharide pneumococcal vaccine is recommended at least 5 years after the first dose, with no further dosing recommended routinely. Reimmunization against meningococcal and *H. influenzae* are not recommended.[106] Regardless, many patients do not receive any revaccination because of a general lack of understanding about their condition and the unclear role of revaccination.[94]

Children <5 years old also require aggressive immunization and antibiotic prophylaxis after splenectomy. Initial vaccination is provided with the *H. influenzae* vaccine, meningococcal vaccine, and 7-valent pneumococcal conjugate vaccine. If not previously immunized against pneumococcus, an additional dose of the 7-valent vaccine is recommended no less than 6 to 8 weeks after the last dose, with a final 23-valent vaccine booster 3 to 5 years after the last dose. Daily antibiotic prophylaxis with penicillin V potassium (125 mg twice a day until 3 years of age and 250 mg twice a day thereafter) is recommended for all children under the age of 5 years. If no invasive pneumococcal infections are experienced, prophylaxis may be discontinued after the age of 5 after appropriate immunizations have been obtained.[106]

One of the most important, and most overlooked, aspects of prevention is patient education. Up to 50% of asplenic patients are unaware of their increased risk of serious infection, and 30% to 40% do not recall being vaccinated.[97] Few are provided with antibiotics to take empirically at the onset of fever, and one-half would not spontaneously tell an uninformed emergency department doctor about their splenectomies.[98] Asplenic patients should be extensively counseled about their health risks, the need for reimmunization, and the importance of informing future caregivers of their condition.

Autotransplantation of Splenic Tissue

Extrasplenic tissue may emerge secondary to traumatic autotransplantation, known as *splenosis*. Although this tissue appears as normal spleen, with white pulp, red pulp, and marginal zones, extrasplenic tissue is insufficient to recapitulate the host immune response and is not a recommended practice for patients undergoing splenectomy.[21,23]

CHAPTER 66

TUMORS OF THE SPLEEN

Daniel A. Arber

A variety of tumors and tumorous proliferations may involve the spleen, and there are several that are unique to this organ. This chapter focuses on the unique proliferations as well as other neoplastic causes of splenomegaly. Splenomegaly, however, is not restricted to neoplastic causes and may occur with secondary hypersplenism, which may be secondary to autoimmune or paraneoplastic causes, infectious processes, and passive congestion due to other nonneoplastic medical disorders.

PATTERNS OF TUMOROUS SPLEEN PROLIFERATIONS

Although splenomegaly is often present with splenic neoplasia, some tumors and tumorous proliferations may be found incidentally in normal-sized spleens during radiologic staging or in spleens removed due to traumatic rupture or incidentally removed during other surgical procedures. The pattern of splenic infiltration may be helpful in the differential diagnosis of splenic tumors and the gross disease patterns tend to mimic histologic patterns (Fig. 66.1 and Table 66.1).[1] The most common disease patterns are diffuse, miliary, and nodular disease. Diffuse disease generally results in splenomegaly with complete infiltration of the splenic parenchyma. This often imparts a glassy and homogeneous red appearance to the cut surface of the spleen. This usually is due to obliteration of the normal splenic white pulp by a cellular proliferation of the red pulp. This disease pattern has traditionally been attributed to leukemic infiltration, T-cell lymphomas, and histiocytic tumors. Many of the red pulp proliferations previously considered to be histiocytic, however, have now been shown to represent T-cell neoplasms. The miliary pattern shows small, punctate tan or white areas throughout the cut surface of the spleen. These usually represent expansion of the splenic white pulp, the normal B-cell compartment of the spleen. However, a similar gross appearance may occur with granulomatous infections. The white pulp expansion pattern most commonly occurs in florid reactive hyperplasia and with low-grade B-cell lymphomas. The nodular disease pattern is characterized by one or more distinct tumor nodules in the spleen which may be identified incidentally on imaging studies. These nodules are usually firm and tan or white in cases of large cell lymphoma, Hodgkin disease, or metastatic tumors, and are bloody with a beefy-red appearance in vascular proliferations. Cystic lesions of the spleen may also show a nodular pattern of involvement.

CYSTS AND ABSCESSES

Cysts of the spleen are found in <1% of splenectomy specimens.[2] They occur most commonly in men in the third decade of life. They are usually asymptomatic; however, they may cause a splenic mass and be associated with abdominal pain. Splenic cysts may be essentially any size but are on average 10 cm in diameter.[3] Splenic cysts may be designated as primary or secondary, also considered true and false cysts, respectively. Both types are usually unilocular, but some small primary cysts are multilocular. Primary cysts are reported to represent approximately 20% of all splenic cysts, but small primary cysts of the spleen are probably underrepresented in older studies and more extensive evaluation of nonparasitic cysts shows that the vast majority are true cysts.[4,5] Primary cysts have a firm, rough, and trabecular cyst wall that shows fibrosis and an epithelial lining on histologic examination (Fig. 66.2). The lining may be of mesothelial or squamous epithelium with the latter probably representing a metaplastic change.[6] The epithelial lining of primary cysts may be patchy, with denuded areas present that may simulate a secondary cyst. Primary cysts can be further subdivided into parasitic and nonparasitic types. Primary parasitic cysts related to echinococcal infection (hydatid cysts) are common worldwide, but are uncommon in Western countries. Parasitic cysts are readily identified by the presence of parasite scolices in the cyst contents. Nonparasitic primary cysts appear to arise from congenital inclusions of capsular mesothelium.[7] Small multilocular primary cysts of the spleen occurring at the splenic capsule have in the past been mistaken for lymphangiomas.[8] Patients with primary cysts may have elevations of CA19-9 and carcinoembryonic antigen.[9,10] Primary cysts are usually treated with splenectomy, and partial resection by laparoscopic methods often leads to recurrence.[11,12]

Secondary cysts are reportedly more common, representing approximately 80% of splenic cysts in most studies, but more detailed evaluation can confirm many of these as having a focal epithelial lining and thus they are really primary.[4] The true secondary cysts are often associated with a history of abdominal trauma and are probably acquired after hematoma or infection. The cysts are unilocular and usually have a smooth lining. They differ histologically from primary cysts by the complete absence of an epithelial lining, and are thus unlikely to recur even if only partially resected. The cyst wall may contain hemosiderin or calcification.

Some secondary cysts of the spleen may represent resolved abscesses. Multiple small splenic abscesses usually do not develop associated fibrosis with resolution, but larger abscesses are often single and develop a wall of surrounding fibrosis virtually identical to that seen in secondary cysts. Although relatively uncommon, splenic abscesses are most often associated with sepsis or

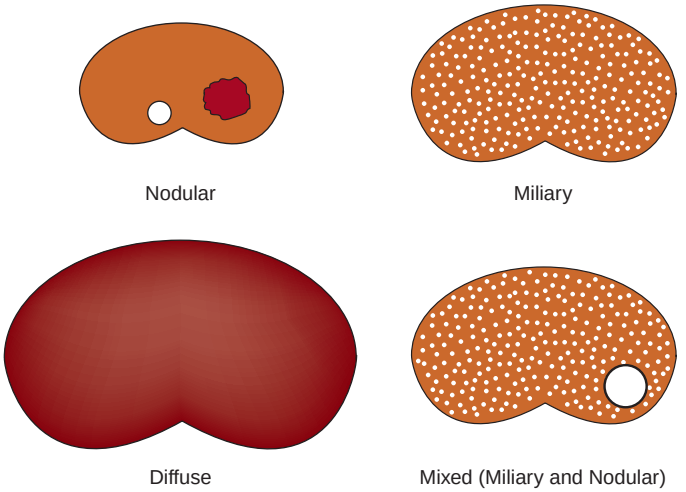

FIGURE 66.1. Gross patterns of splenic tumor involvement. Nodular tumor infiltrates may form solid firm masses or may be hemorrhagic masses. The miliary pattern shows small punctate white foci that usually correspond to expansions of the white pulp. The diffuse pattern shown is usually associated with massive splenomegaly and corresponds to a red pulp expansion. Mixed patterns may be seen when the spleen is involved by more than one process or when a low-grade lymphoma transforms to high-grade disease.

TABLE 66.1

PATTERNS OF SPLENIC TUMOR INVOLVEMENT

Diffuse (Predominantly Red Pulp) Disease	Miliary (Predominantly White Pulp) Disease	Predominantly Nodular Disease
Peliosis	Marked white pulp hyperplasia	Cysts
Hemangiomatosis	Chronic lymphocytic leukemia/small lymphocytic lymphoma	Abscess
Lymphangiomatosis	Prolymphocytic leukemia	Inflammatory pseudotumor
Acute leukemias	Most follicular lymphomas	Hamartoma
Hairy cell leukemia	Mantle cell lymphoma	Hemangioma
Hairy cell leukemia variant	Splenic marginal zone lymphoma	Sclerosing angiomatoid nodular transformation
Diffuse red pulp small B-cell lymphoma	Lymphoplasmacytic lymphoma[a]	Littoral cell angioma
Chronic myeloproliferative neoplasms	Early involvement by large B-cell lymphoma	Epithelioid hemangioendothelioma
Lymphoblastic lymphoma		Angiosarcoma
Hepatosplenic T-cell lymphoma		Metastatic tumors
Large granular lymphocytosis		Most large B-cell lymphomas
Lymphoplasmacytic lymphoma[a]		Hodgkin lymphoma

[a]More than one pattern may occur with some diseases.

endocarditis. They may also occur following abdominal trauma, including splenic rupture, by contiguous spread of infection from other organs, or in association with functional asplenia in sickle cell anemia.[13–15] Most splenic abscesses are due to polymicrobial infection, but common organisms include *Streptococcus*, *Staphylococcus*, *Escherichia coli*, and *Salmonella*.[16]

Partial splenectomy has been used successfully in the treatment of nonparasitic splenic cysts.[17]

VASCULAR PROLIFERATIONS

Vascular tumors are the most common tumors of the spleen. Vascular proliferations may be diffuse or may form a tumor mass. Peliosis is a rare, diffuse vascular proliferation that is usually an incidental finding occurring in adults.[18,19,20] It may be associated with hepatic peliosis and may occur with anabolic steroid use, in association with malignancies, and following solid organ transplantation, as well as in patients with hepatic cirrhosis, tuberculosis, and aplastic anemia. Peliosis results in dilated vascular spaces, usually 1 mm or less in diameter, that involve the entire splenic parenchyma (Fig. 66.3). Splenic peliosis appears to be associated with an increased risk of splenic rupture.[19,21,22]

Hemangiomas are benign tumors that are also usually asymptomatic, but may cause splenomegaly, abdominal pain, and hypersplenism.[2,23,24,25] Most hemangiomas are localized and form single or multiple tumor nodules that contain cystic blood-filled spaces grossly. These spaces are lined by endothelial cells, and papillary projections may occur in areas with thrombi. The tumor nodules are usually surrounded by fibrosis and may show calcification. Plain abdominal radiographs, computed tomographic scans, and sonograms are nonspecific, but all show discrete solid and cystic masses, often with evidence of calcification.[26,27] Diffuse hemangiomatosis of the spleen is less common, is often associated with systemic hemangiomatosis, results in massive splenomegaly, and may be associated with coagulopathies.[28,29] Diffuse hemangiomatosis differs from peliosis by the presence of intervening fibrosis in hemangiomatosis, which is not a feature of peliosis.

Localized lymphangiomas of the spleen may be difficult to distinguish from hemangiomas or primary cysts, but usually contain proteinaceous fluid rather than the blood of an hemangioma.[2,23,30] Diffuse lymphangiomatosis may be localized to the spleen, but is usually a systemic process and most commonly occurs in children and young adults with massive splenomegaly.[30,31,32–34] The splenic parenchyma is replaced by multiple cysts, up to 3 cm in diameter, imparting a spongy appearance (Fig. 66.4). The cysts are filled with thick pink to brown fluid. Large localized lymphangiomas and lymphangiomatosis of the spleen may be treated with splenectomy.[30]

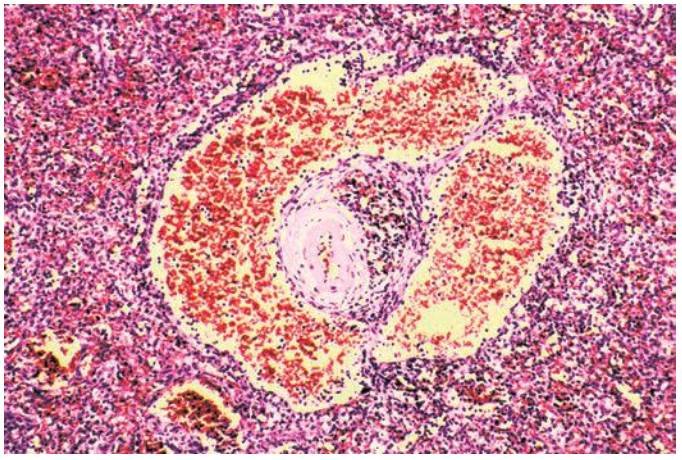

FIGURE 66.3. Splenic peliosis. Peliosis of the spleen shows expanded small vessels that diffusely involve the spleen without forming a nodular mass and without intervening fibrosis.

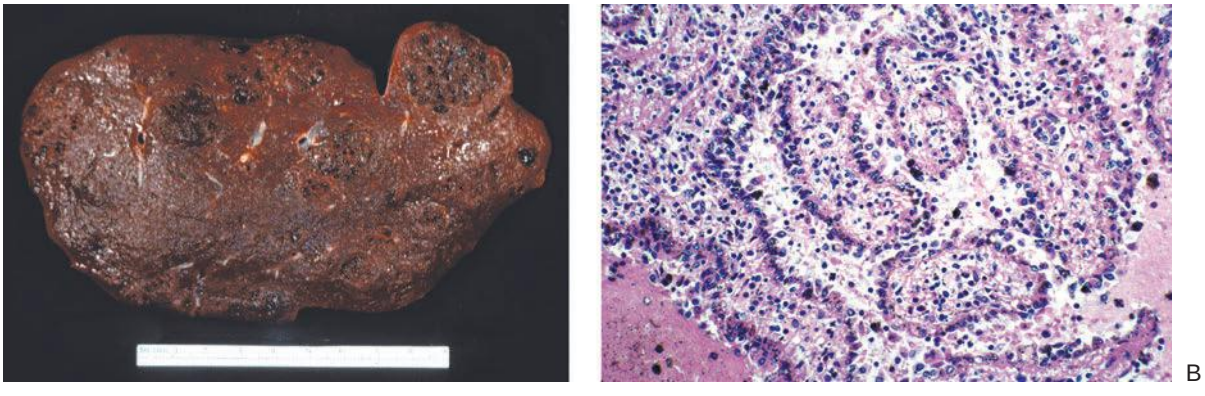
FIGURE 66.4. Lymphangiomatosis. Cut surface of a spleen. Multiple, variably sized cysts are present.

Although hemangiomas and lymphangiomas of the spleen are similar to those of other sites, there are two unique vascular proliferations of the spleen. Littoral cell angioma is a tumor presumably derived from the normal splenic lining cell, also known as the littoral cell.[24,35] These tumors may occur at any age and usually cause mild to moderate splenomegaly. Many tumors, however, are found incidentally. The tumor forms multiple spongy dark red nodules that can measure up to 9 cm in diameter (Fig. 66.5). Histologically these tumors differ from hemangiomas in that the vascular spaces are lined by plump cells with nuclear enlargement and often show papillary areas and lining cells sloughing into the vascular spaces. The lining cells of littoral cell angioma have a unique immunophenotype, expressing vascular, histiocytic, and dendritic-associated markers CD31, CD68, CD163, and CD21. In contrast to hemangiomas and normal sinus lining cells, the lining cells of littoral cell angioma do not express CD34 or CD8. Most cases of littoral cell angioma are treated with splenectomy without recurrence, but there are two reports of late abdominal and liver metastasis after 4 and 8 years.[36,37] Both cases showed solid foci of clear cells and probably represent littoral cell hemangioendotheliomas.

Sclerosing angiomatoid nodular transformation (SANT) is the other vascular proliferation unique to the spleen.[38,39,40] To date, SANT has only been reported in adults, usually presenting as an incidental mass, and less commonly with splenomegaly or abdominal pain. It usually forms a single fibrotic nodule that contains vascular spaces, including slitlike spaces, fibrosis with spindled cells, and splenic sinus lining cells without nuclear atypia, mitotic figures, or necrosis. Cases of this type have been interpreted in the past as epithelioid and spindled hemangioendotheliomas or as inflammatory pseudotumors (see below), but they have not recurred or metastasized after splenectomy. SANT is now felt to be a reactive fibrous entrapment of altered red pulp, presumably following some form of splenic injury, rather than a true neoplasm. More recent reports have described an increase in IgG4-positive plasma cells in SANT and some studies suggest an association with Epstein-Barr virus (EBV) in this proliferation.[39,41,42] However, the EBV-positive cases appear to be overlap proliferations with splenic inflammatory pseudotumor and SANT is typically EBV-negative.[43]

Angiosarcoma of the spleen occurs most commonly in adults and is usually associated with splenomegaly, abdominal pain, and cytopenias.[24,44,45,46] Splenic rupture is common in these patients. Because most angiosarcomas involving the spleen are high-grade sarcomas with dissemination, it is often difficult to determine whether the splenic tumor is primary or secondary. The tumor forms an infiltrating mass that may have areas of cystic hemorrhage. The histologic appearance may be varied; however, angiosarcomas characteristically show cytologic atypia, high mitotic activity, and necrosis. Many cases may be difficult to differentiate from other high-grade sarcomas, and immunohistochemical detection of vascular antigen expression, such as CD31, CD34,



A B

FIGURE 66.5. Littoral cell angioma. A: Multinodular hemorrhagic lesions of the spleen in littoral cell angioma. **B:** Microscopically, there are papillary vascular spaces with plump lining cells and histiocytes.

and von Willebrand factor, is necessary to diagnose such cases. High-grade angiosarcomas involving the spleen have a generally poor prognosis, with most patients dying of disease within 1 year of diagnosis; however, rare cares with long-term survival following splenectomy have been reported.[46]

Low-grade angiosarcomas, also known as epithelioid hemangioendotheliomas, are much less common than high-grade tumors.[47,48,49] These are reported to occur in both children and adults, but some of the adult cases have features similar to those more recently described for SANT (see above). Patients usually present with anemia and may have hyper- or hyposplenism. These tumors are better circumscribed than high-grade angiosarcomas with more bland epithelioid cells, vascular spaces, and prominent fibrosis. They also usually lack necrosis. The cells may show intracellular lumina and will express vascular-associated antigens. These tumors may be incidental findings, are usually localized to the spleen, and do not tend to recur after splenectomy.

LYMPHOID PROLIFERATIONS

Essentially any lymphoproliferative disorder may involve the spleen and splenic involvement may be the first evidence of disease. Despite this, most lymphoid proliferations involving the spleen are disseminated at the time of splenic involvement and are accompanied by lymphadenopathy.[50,51,52,53] Two types of splenic lymphoma, however, are unique to the spleen and present with splenomegaly without lymphadenopathy.

Splenic marginal zone lymphoma was originally described as a splenic lymphoma with features that mimicked hairy cell leukemia.[54] Although sharing some morphologic and immunophenotypic features, splenic marginal zone lymphoma appears to be distinct from both nodal and extranodal (nonsplenic) marginal zone lymphomas.[55] It is the most common lymphoma type in patients with so-called splenic lymphoma with circulating villous lymphocytes.[56,57,60] Splenic marginal zone lymphoma most commonly occurs in elderly patients with massive splenomegaly (Fig. 66.6).[53,61,62,63,64,65] Although splenic hilar lymph nodes are often involved by disease, other adenopathy is not usually present. Patients frequently have a lymphocytosis. The abnormal lymphoid cells may vary in appearance, but some cases have circulating lymphocytes with villous cytoplasmic projections that differ from hairy cell leukemia lymphocytes by having only unipolar or bipolar projections as opposed to the more uniform villous projections of hairy cell leukemia. The spleen is uniformly enlarged without a distinct mass. The white pulp is massively expanded by a biphasic population of small lymphocytes that may cause a gross miliary pattern of the spleen parenchyma. The central white pulp lymphocytes are small with scant cytoplasm and are surrounded by a bandlike proliferation of more irregular small lymphocytes with abundant clear to pink cytoplasm on histologic sections. These cells are $CD20^+$ B cells that express BCL2, but do not express CD10, or CD43. A subset of cases may express CD5. The pattern of infiltration is distinct from hairy cell leukemia, which causes a diffuse red pulp infiltrate, and splenic marginal zone lymphoma does not usually demonstrate tartrate-resistant acid phosphatase (TRAP) positivity or expression of Annexin A1, CD25, or CD103 of hairy cell leukemia.

Although peripheral blood and bone marrow involvement by splenic marginal zone lymphoma are common,[66] most cases are indolent and do well with splenectomy with or without chemotherapy.[61,67] In a series of 60 patients, all treated with splenectomy and almost half receiving chemotherapy, the overall survival was 103 months with a range of 2 to 164 months. The subset of more aggressive cases tended to show involvement of bone marrow and nonhematopoietic sites.[67] Other features reported to be associated with more aggressive disease include increased numbers of large lymphoma cells, p53 overexpression, and loss of chromosomal regions 7q and 17p.[67–70] A large series of 309 patients found a 76% 5-year cause-specific survival, with factors associated with worse survival on multivariant analysis being hemoglobin <12 g/dl, lactate dehydrogenase levels greater than normal, and albumin levels <3.5 g/dl.[71] More recently, patients have shown excellent responses to rituximab alone or with chemotherapy without splenectomy.[72,73] Rare cases have recurred in lymph nodes with transformation to diffuse large B-cell lymphoma,[74,75] and one report described cases with transformation to micronodular T-cell–rich large B-cell lymphoma.[76] Cases of splenic marginal zone lymphoma with hepatitis C virus infection and mixed cryoglobulinemia are reported to have regressed with hepatitis C antiviral therapy.[77,78] Most cases, however, occur in the absence of hepatitis C infection, and rituximab with or without chemotherapy appears to have major activity in these patients.[79] Splenic red pulp small B-cell lymphoma and hairy cell leukemia variant share some similarities with splenic marginal zone lymphoma and are both considered as provisional entities in the 2008 World Health Organization classification.[80,81] They differ from splenic marginal zone lymphoma by being primarily red pulp small B-cell proliferations. All are CD5 and CD10 negative B-cell proliferations. Hairy cell leukemia variant is typically composed of cells similar to prolymphocytes with prominent nucleoli, but these cells also show cytoplasmic projections suggestive of hairy cells. Despite the morphologic similarity to hairy cell leukemia, hairy cell leukemia variant does not usually express CD25 or Annexin A1, markers typically expressed in hairy cell leukemia. It is important to distinguish hairy cell leukemia variant from splenic

FIGURE 66.6. Splenic marginal zone lymphoma and metastatic carcinoma. A: Gross appearance of the miliary pattern of splenic involvement by splenic marginal zone lymphoma. Note the white, larger mucoid lesion at the left, which represents metastatic papillary serous ovarian carcinoma resulting in a mixed disease pattern of infiltration. **B:** The splenic marginal zone lymphoma shows biphasic white pulp with small round cells in the center and larger lymphocytes with more cytoplasm in the outer marginal zones. Similar cells with clear cytoplasm are also present in the adjacent red pulp.

marginal zone lymphoma, because hairy cell leukemia variant is a more aggressive disease.[82]

Hepatosplenic T-cell lymphoma is the other lymphoma type unique to the spleen. It also presents with massive splenomegaly as well as hepatomegaly and usually with bone marrow disease.[83,84,85,86,87,88,89] This lymphoma most commonly occurs in young adults with a male predominance. Patients present with fever, weight loss, and jaundice in addition to hepatosplenomegaly and may have pancytopenia and circulating lymphoma cells in the peripheral blood. Rare cases have occurred after solid organ transplantation,[90,91] and recently cases associated with inflammatory bowel disease and rheumatoid arthritis have been reported. These latter cases may occur in older patients and are felt to be associated with immunomodulator and tumor necrosis factor-α inhibitor therapies.[92] This tumor was originally described as erythrophagocytic Tγ lymphoma[93] and has also been referred to as hepatosplenic $\gamma\delta$ T-cell lymphoma. The lymphoma diffusely expands the spleen without a discrete mass and medium-sized cells with irregular nuclear contours and abundant cytoplasm infiltrate the splenic red pulp (Fig. 66.7), often with loss of the splenic white pulp. The liver involvement is sinusoidal rather than forming a tumor mass. Hemophagocytosis may also be present and some cases in the past may have been interpreted as malignant histiocytosis. The cells express T-cell–associated markers, such as CD2, CD3, CD5, CD7, and CD43, but may show aberrant loss of one or more of these markers. The cells also usually express CD16, CD56, and TIA-1, but do not show other features of natural killer cells. The cells are negative for EBV, granzyme B, and perforin. Most cases are neoplasms of $\gamma\delta$ T-cells, which do not express CD4, CD8, or T-cell receptor β-chains. However, some cases are $\alpha\beta$ T-cell neoplasms and there appears to be no significance to subdividing this lymphoma by T-cell type[89]; cases with both immunophenotypes show the characteristic combined cytogenetic abnormalities of isochromosome 7q and trisomy 8.[94,95,96] Hepatosplenic T-cell lymphoma is an aggressive disease that may show initial improvement following splenectomy and/or chemotherapy, but usually behaves aggressively with a median survival of 8 months (range 0 to 42 months) reported in one study. Patients with longer survival have received a variety of combination chemotherapy and hematopoietic stem cell transplantation approaches.[89,97]

Secondary involvement of the spleen by lymphoproliferative disorders is also common.[53] Hairy cell leukemia is one that frequently presents with splenomegaly without lymphadenopathy. The patients are usually elderly, with pancytopenia that includes monocytopenia. Peripheral blood and bone marrow are virtually always involved to some degree, although blood involvement may be minimal. The spleen is enlarged by a diffuse or red pulp infiltrate of small lymphocytes. The white pulp is decreased or absent and dilated blood-filled spaces, often termed red blood cell "lakes," are common in the red pulp. The blood, bone marrow, and splenic lymphocytes are monotypic B cells that lack CD5 and express CD11c, CD25, Annexin A1, and CD103, as well as being positive by cytochemistry or immunohistochemistry for TRAP. A subset of cases shows expression of CD10 or lacks expression of CD11c, CD25, or CD103.[98] In the past TRAP cytochemistry was considered the gold standard for diagnosis of hairy cell leukemia, but it has been largely replaced by immunophenotypic evaluation. The blood changes of circulating lymphocytes with villous cytoplasmic projections may be difficult to distinguish from splenic lymphoma with villous lymphocytes, usually secondary to splenic marginal zone lymphoma. However, the pattern of the splenic infiltration between the two diseases differs, with a red pulp or diffuse pattern in hairy cell leukemia and a predominantly white pulp expansion in splenic marginal zone lymphoma.

Other lymphomas of small B lymphocytes may secondarily involve the spleen resulting in splenomegaly, and include chronic lymphocytic leukemia/small lymphocytic lymphoma, lymphoplasmacytic lymphoma, mantle cell lymphoma, and follicular lymphoma. With the exception of a subset of cases of lymphoplasmacytic lymphoma, these disorders all infiltrate and expand the splenic white pulp. The majority of large B-cell lymphomas and virtually all cases of Hodgkin lymphoma involving the spleen form distinct tumor nodules with adjacent uninvolved splenic tissue. A subset of large B-cell lymphomas and lymphoplasmacytic lymphomas will primarily involve the splenic red pulp and before immunophenotyping may mimic other disorders, including leukemic infiltrates in the case of red pulp large B-cell lymphoma and possibly hairy cell leukemia in the case of red pulp lymphoplasmacytic lymphoma. T-cell lymphomas and the rare histiocytic tumors typically enlarge the spleen by expanding the splenic red pulp in a diffuse manner.

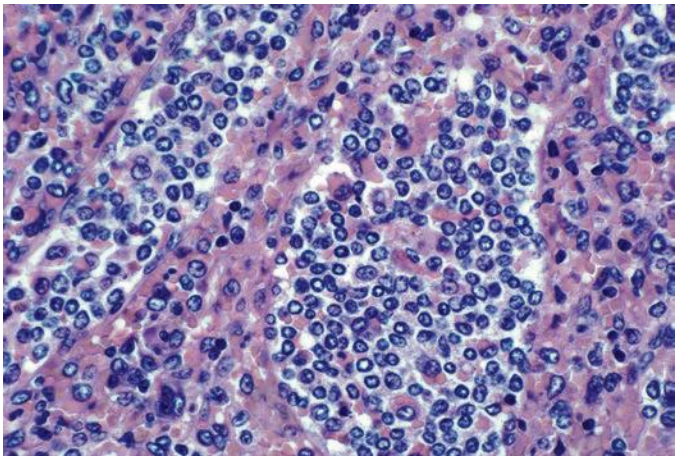

FIGURE 66.7. Hepatosplenic T-cell lymphoma. Medium-sized lymphoma cells are infiltrating the splenic red cords and sinuses of the red pulp.

ACUTE LEUKEMIA AND MYELOPROLIFERATIVE NEOPLASMS

In acute leukemia, splenomegaly may be due to an increase in either lymphoblasts or myeloblasts in the red pulp. This is rarely an isolated finding, and does not usually create diagnostic difficulty. Myeloproliferative neoplasms characteristically cause splenomegaly, and in some cases this enlargement is massive. Primary myelofibrosis most commonly causes massive splenomegaly, usually over 1,000 g.[99,100] The splenomegaly may be associated with a wasting syndrome that is improved with splenectomy. Splenectomy in this disorder, however, is associated with an increased risk for blast transformation.[101] The cause of splenomegaly in most myeloproliferative neoplasms is expansion of the splenic red pulp by abnormal hematopoiesis. The red pulp cords and sinuses are filled with varying numbers of nucleated red blood cells, maturing granulocytes, and atypical megakaryocytes (Fig. 66.8). There may be other causes of noticeable splenomegaly in patients with myeloproliferative neoplasms. A rapidly enlarging spleen may signal accelerated phase or blast transformation. Detection of increased numbers of $CD34^+$ immature cells in the red pulp may be a useful clue to such transformation. In essential thrombocythemia, the spleen may be enlarged due to increased numbers of platelet-filled macrophages in the red pulp. In the early phase of polycythemia vera, massive congestion by red blood cells may be the cause of splenomegaly.[102]

OTHER TUMOROUS PROLIFERATIONS

Splenic hamartomas are also known as splenomas or spleen-in-spleen syndrome, and are benign splenic proliferations.[103,104,105,106,107] They may occur at any age and are usually incidental findings,

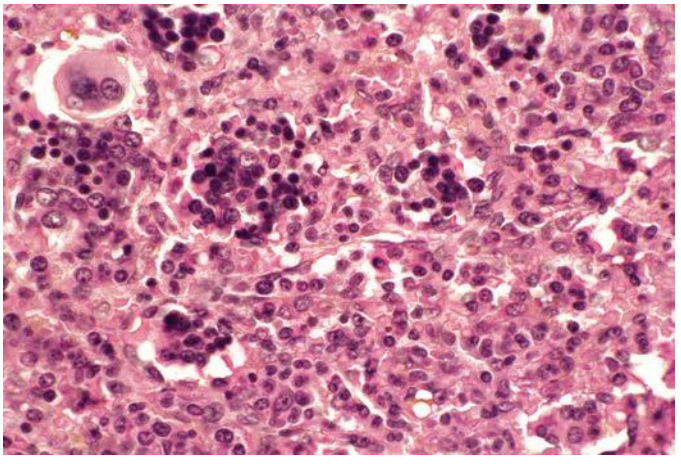

FIGURE 66.8. Chronic myelogenous leukemia involving the spleen. The red pulp is expanded by aggregates of erythroid and myeloid precursors admixed with scattered megakaryocytes.

although up to 30% of patients have cytopenias due to hypersplenism. They form single or multiple, sometimes scarring masses of the splenic parenchyma. They are grossly bulging masses when the spleen is cut (Fig. 66.9), but are more indistinct on histologic sections because these proliferations represent a reduplication of splenic red pulp tissue with normal splenic sinus lining cells and a lack of normal white pulp. They are also associated with fibrosis, which may include bizarre stromal cells, but these proliferations have no malignant potential. It is not clear whether splenic hamartomas are actually neoplasms or represent an unusual reparative process.

Inflammatory pseudotumor of the spleen and liver are distinct from inflammatory pseudotumors or inflammatory myofibroblastic tumors of other sites.[108] In the spleen, these tumors occur more commonly in adult women who may present with symptoms that may include fever, weight loss, malaise, anemia, leukocytosis, thrombocytosis, polyclonal hypergammaglobulinemia, and an elevation of the erythrocyte sedimentation rate.[109–113] Infectious disease evaluations are usually negative. The splenic mass is usually solitary and may be up to 12 cm in diameter. The tumor is a dense nodule containing a mixed inflammatory infiltrate and fibrosis. The spindled fibrotic cells of this unique tumor contain evidence of clonal EBV and the infected spindled cells in most cases express the follicular dendritic cell marker CD21. Some hepatic cases have recurred, but splenic cases treated with splenectomy have not. Some authors have suggested that these proliferations represent an unusual type of follicular dendritic cell tumor[114] termed inflammatory pseudotumor-like follicular dendritic cell sarcoma, although other follicular dendritic cell tumors are not associated with the EBV.

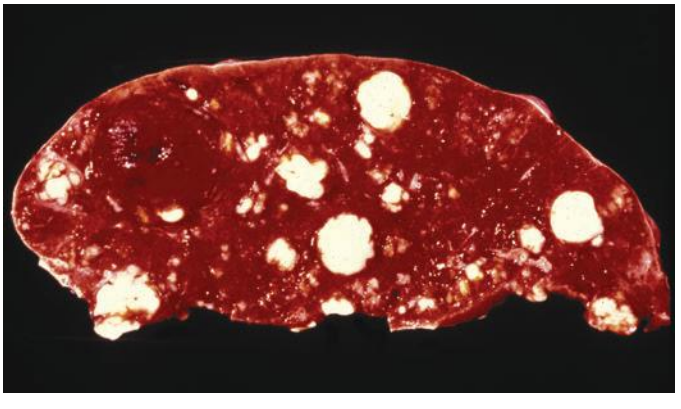

FIGURE 66.9. Splenic hamartoma and splenic involvement by classical Hodgkin lymphoma. The hamartoma represents a bulging red mass to the left, whereas the Hodgkin lymphoma forms multiple firm white nodules throughout the spleen. Hamartomas are often incidental findings in spleens removed for other reasons.

Primary sarcomas, other than angiosarcoma, and carcinomas of the spleen are extremely uncommon. Reported cases of sarcoma include malignant fibrous histiocytoma, fibrosarcoma, leiomyosarcoma, rhabdosarcoma, histiocytic sarcoma, interdigitating dendritic cell sarcoma, and fibroblastic reticular cell tumor.[3,115,116–121] Primary carcinomas reported include squamous cell carcinoma arising in a cyst, mucinous cystadenocarcinoma and carcinosarcoma both possibly arising from peritoneal surface epithelium, and primary transitional cell carcinoma.[122–125] Although still rare, carcinoma of the spleen from metastasis or direct tumor extension is more common than primary disease. One third of metastatic tumors are only identified on microscopic examination,[126] so the frequency of splenic involvement may be underestimated by imaging studies. Lung, gastric, ovarian, and breast carcinoma primaries are the most common to involve the spleen, and splenectomy may be performed for solitary splenic metastases.[127,128,129]

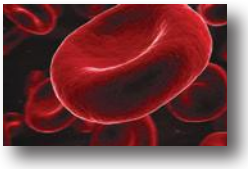
PART VII

Hematologic Malignancies

SECTION 1 GENERAL ASPECTS



CHAPTER 67

HEMATOPOIETIC NEOPLASMS: PRINCIPLES OF PATHOLOGIC DIAGNOSIS

Daniel A. Arber

The hematopoietic neoplasms consist of acute and chronic leukemias, Hodgkin and non-Hodgkin lymphomas, plasma cell tumors, and the rare histiocytic and dendritic neoplasms. Each of these disease categories is now recognized to represent various heterogeneous disease groups that include a large number of distinct biologic entities.[1,2] With the great advances in targeted therapies and molecular genetic discoveries in the area of hematopoietic tumors, the number of distinct entities will continue to grow. Although the diagnosis and classification of these tumors were originally based primarily on morphologic features, sometimes supplemented by cytochemical studies,[3–7] the diagnosis of hematopoietic tumors now requires a complex battery of specialized tools that almost always include immunophenotyping and frequently require cytogenetic and molecular genetic studies. Despite these advances, morphologic evaluation remains the cornerstone for the pathologic diagnosis for most diseases. Morphologic evaluation allows for cost-effective tissue processing and triaging for appropriate ancillary tests, which becomes increasingly important as the number of molecular genetic tests grows in this area.

PREOPERATIVE CONSIDERATIONS

Special considerations are often needed prior to sampling of tissue that is suspected to contain a hematopoietic neoplasm.[8–12] The testing that will be needed depends on the clinical differential diagnosis as well as the initial pathologic impression of the sample. However, if the correct specimen types for ancillary tests are not saved prior to the initial pathologic review, the tissue may not be sufficient for these additional tests. Therefore, the hematologist, pathologist, or surgeon performing the procedure should have a clear understanding of the specimen requirements for the various tests that might be needed to rule in or out all suspected diseases. This often requires direct communication with the surgical pathologist or hematopathologist who will ultimately receive the sample prior to obtaining tissue. The submission of fresh tissue on saline-soaked gauze is ideal for tissue samples; however, this may not be feasible if the sample is taken at night or in a clinic that is physically separate from where the sample will be processed. Even in the latter setting, however, the sample may be sent by courier to a remote location quickly so that the tissue can be correctly triaged. In the absence of central processing of the sample, the physician performing the procedure must be aware of how to collect samples that are adequate for immunophenotyping studies, molecular and cytogenetic studies, and possible cultures. This problem is even more complicated when reference laboratories are used for different types of testing, an increasingly common practice, resulting in the need to split what may be very small samples prior to sending them out for these studies.

Ideally, the entire fresh sample is submitted to the pathology department within minutes of removal. There it may be received by a resident, technician, pathology assistant, or pathologist. No matter who receives the specimen, the clinical indication for the biopsy as well as any special clinical concerns or testing requirements needs to be clearly communicated. For tissues removed to rule out lymphoma, the specimens should be sampled in the fresh state. One protocol for lymph node sampling is provided in Figure 67.1[8] and is discussed in more detail below. Hematologists and pathologists should work together to establish a suitable protocol for their institution. Special needs should be communicated to the pathologist in advance of obtaining the sample, to ensure that the supporting testing areas, such as cytogenetics or microbiology, are prepared to receive the sample or to make arrangements to send samples quickly to the appropriate reference laboratory. It is worth noting that surgical pathologists receive lymph node specimens for a variety of indications, most of which do not require special processing and are simply formalin fixed. Without adequate clinical information and communication to alert them to a possibility of lymphoma or another hematopoietic tumor, tissue may not be sent for flow cytometry or cytogenetic studies, or saved for possible molecular genetic studies. Because the differential diagnosis of malignant lymphoma often includes infectious etiologies, the need for cultures or other infectious disease testing requiring fresh tissue or other special tissue preparation must also be communicated.

SPECIMEN PROCESSING

Triaging Protocols

How a sample for a suspected hematologic disorder is triaged often depends on the specimen type. Peripheral blood, bone marrow aspirate, and fine needle aspirate samples are often

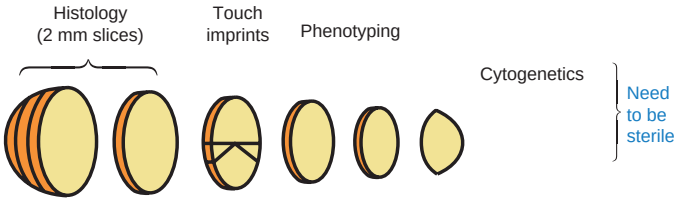


FIGURE 67.1. Schematic of protocol for processing lymph node biopsies from patients suspected of having lymphoid malignancies.

triaged at the bedside by the physician collecting the sample. In this setting, the treating physician often orders flow cytometry immunophenotyping, cytogenetics, molecular genetics, and even cultures on samples collected in different tubes. Because the diagnosis of most disorders is still based in large part on morphologic features, it is advisable to use the initial bone marrow aspirate material for fresh smears, prepared at the bedside, or to make touch preparations for morphology in all cases with inadequate aspirate material (see Chapter 1). Subsequent aspirations may be more hemodiluted, but are usually still suitable for ancillary studies. In contrast, the triaging of tissue biopsy specimens is usually performed after the sample is submitted to the laboratory, as mentioned above and illustrated in Figure 67.1.[8,9] If lymphoma is suspected, sections of fresh material should be fixed for morphologic evaluation. If enough tissue is obtained, a portion of fresh tissue may also be sent for flow cytometry, and possibly for cytogenetics or cultures. Additional material may be frozen for future molecular genetic studies. In the rare instance where electron microscopy may be needed, a small portion of fresh tissue should be saved in glutaraldehyde. The exact tests performed, however, will depend on the clinical indication for the biopsy and communication between the pathologist and the treating hematologist.

Tissue Fixation and Processing

Proper specimen fixation and processing are essential for morphologic evaluation as well as for the optimal performance of ancillary studies.[10–12] If lymphoma is suspected, thin sections of fresh material should be fixed for morphologic evaluation. In the past, special fixatives containing heavy metals such as mercuric chloride were used to improve cell morphology, but these fixatives are less commonly employed today due to difficulties in disposing of the mercury. Such fixatives also disrupt nucleic acids, making molecular studies often impossible. More routine formalin fixation will usually provide appropriate sections, as long as the tissue is fixed adequately, usually meaning overnight fixation of thin sections in fresh neutral buffered formalin. Formalin-fixed tissue is satisfactory for many DNA-based molecular assays, but some tests cannot be performed on fixed tissue. Tissue that is frozen should be stored at the lowest possible temperature (preferably −70°C to −80°C) and should not be stored in defrostable freezers.

Bone marrow aspirate specimens should be sent fresh after collection with minimal anticoagulant. Bone marrow biopsies should also be submitted fresh, or in fixative if delivery to the laboratory may be delayed. Again, heavy metal fixatives are less commonly available today and formalin or Bouin fixation is more frequently used. Bone marrow biopsies also must undergo decalcification, which may degrade some antigens and may reduce the ability to perform some assays. Decalcification in ethylenediaminetetraacetic acid is considered the most gentle for antigen preservation,[13] but some methods take several days to obtain adequate decalcification and this method is not routinely performed in most laboratories.

SAMPLING METHODS AND THEIR LIMITATIONS

Open Biopsy

The ideal specimen for pathologic evaluation is a large portion of tissue, received fresh and taken from an open biopsy. Such samples allow the maximum amount of tissue for morphologic analysis and ancillary studies. However, the increasing use of less-invasive procedures requires different approaches for different specimen types.

Peripheral Blood

Peripheral blood is often the easiest sample to obtain for an initial evaluation for a hematologic malignancy. Analysis of blood may allow for a diagnosis of leukemia or even peripheral blood involvement by lymphoma, although the absence of neoplastic cells in the blood cannot exclude disease elsewhere. Limitations to blood analysis include the inability to classify blast proliferations with <20% circulating blasts, and the lack of architecture needed for classification of some lymphomas involving blood. Despite these limitations, when the blood is involved by a hematopoietic tumor, morphologic, immunophenotypic, and molecular genetic studies of the blood may be of value in some patients. However, if a bone marrow is to be performed, duplication of testing on both the blood and marrow is usually unnecessary.

Bone Marrow Aspirate and Biopsy

Evaluation of marrow material will often provide much more information than peripheral blood alone in terms of classifying leukemic processes and determining the marrow blast percentage. In addition, some acute leukemias with monocytic features will have an increase in marrow blasts, but show maturation of neoplastic cells in the blood that may mimic chronic myelomonocytic leukemia; therefore, bone marrow assessment is essential in that setting. Both aspirate and biopsy materials provide critical information. Some diseases, such as lymphomas and metastatic tumors, may focally involve the marrow and are often associated with fibrosis, both factors that may make them undetectable on aspirate smears alone. When such focal disease processes are suspected, biopsies from more than one site will produce a higher yield for disease detection.[14]

Fine-Needle Aspirate and Core Biopsy

Fine-needle aspiration has become common as an evaluation tool for solid tumors and even lymphoma due to it being a relatively noninvasive procedure. The technique is ideal for the evaluation of relapse of disease but is now often used for initial patient evaluation. Although fine-needle aspiration coupled with flow cytometry immunophenotyping is ideal for the diagnosis of many low-grade lymphomas,[15,16] it has significant limitations due to the inability to determine architectural features of the lymphoma, to grade some lymphomas properly, and to identify focal disease or transformation. The addition of needle biopsies with or without aspiration and immunophenotyping overcomes some of these limitations, but a significant number of cases will need to go on to open biopsy for diagnosis and/or classification. Because of these limitations, excisional biopsy of easily accessible lymph nodes, when available, is preferred over lymph node aspiration or needle biopsy as an initial diagnostic procedure.

Laparoscopic Biopsy

Laparoscopic biopsies and other more invasive biopsy techniques often obtain more tissue than core biopsies, but often fragment

the specimen, especially with laparoscopic splenectomy specimens.[17] Despite this, the fragments are usually large enough to determine the architectural pattern of the lymphoid infiltrate.

IMMUNOPHENOTYPING

Immunophenotyping is now essential in the diagnosis and classification of most hematopoietic tumors.[2] It is necessary to distinguish precursor B- from precursor T-lymphoblastic leukemia/lymphoma, to detect aberrant immunophenotypes in both lymphoid and myeloid leukemias, and to determine B-cell clonality and aberrancies in malignant lymphomas. Flow cytometry and immunohistochemistry are the primary methods currently used, and they have different advantages in the evaluation of these diseases.

Flow Cytometry

Flow cytometry is ideal for tumors involving blood and bone marrow because the cells are already in a cell suspension, a necessary factor for this analytic technique. This method, however, is also ideal for nonsclerotic lymph node specimens, in which a cell suspension can often be made easily. The method requires the processing of unfixed tissue, either fresh or in transport media. As described in Chapter 2, flow cytometry is ideal for evaluating surface antigen expression on cell suspensions and allows for the evaluation of multiple antigens on a given cell. This method is most helpful for acute leukemias and low-grade lymphomas in which aberrant antigen expression in combinations is common on the neoplastic cells.[18,19] Detection of nuclear and cytoplasmic antigens, such as cyclin D1 and BCL2, is more difficult with this methodology.[16]

Immunohistochemistry

Immunohistochemistry can be performed on fixed, paraffin-embedded tissue and allows for morphologic correlation with antigen expression. This is most useful in tumors with only scattered tumor cells, such as Hodgkin lymphoma, which is usually not detectable by current flow cytometry methods. Paraffin section immunohistochemistry also allows for detection of cytoplasmic and nuclear antigens that do not routinely work well by flow cytometry and allows fairly complete immunophenotyping of disorders that do not have fresh tissue available,[20] although the number of markers detectable by this method is still less than can be assessed by flow cytometry immunophenotyping. Table 67.1 lists the most commonly used antibodies in paraffin section immunohistochemistry for hematopoietic tumors.

GENETIC TESTING

Genetic analysis has become increasingly important in the diagnosis, classification, and prognosis assessment of hematopoietic tumors.[21,22] These techniques are described in more detail in other chapters; however, it is important to understand the general utility of the various assays that are currently available. Gene array analysis has contributed greatly to our understanding of a variety of hematopoietic tumors in recent years, but it is not used as a diagnostic tool in most laboratories and is being largely supplanted by sequencing methods in the research setting. Karyotype analysis is still the best overall screening method for most tumors and will detect most gross chromosomal abnormalities, including translocations, deletions, and aneuploidy. This method has the advantage of an overall screen of all chromosomes, compared to the more targeted detection of abnormalities with the other molecular genetic methods, and should be performed on all suspected acute leukemias or myeloproliferative neoplasms. The submission of samples for karyotype analysis in cases of suspected malignant lymphoma shows more institutional variability.

Many important genetic abnormalities, however, are cryptic at the karyotype level of detection and these include some translocations, such as the t(12;21)(p13;q22) of pediatric acute lymphoblastic leukemia; B- and T-cell antigen-receptor rearrangements of malignant lymphomas; and gene mutations, such as those seen in many acute myeloid leukemias. Karyotype analysis is also difficult on slower-growing tumors, such as low-grade lymphomas, and will not work on fixed tissues. Therefore, a variety of other techniques is also commonly used to evaluate the molecular genetic changes of these tumors. Although Southern blot analysis has traditionally been considered the gold standard for the detection of many abnormalities, gene rearrangement studies, the need for large amounts of fresh or frozen tumor tissue, the complexity of the assay, and the relatively long turnaround time of this assay have resulted in most diagnostic laboratories abandoning this method. Fluorescence in situ hybridization (FISH) is a commonly used technique that can be performed on metaphases or intact cell nuclei, and this method is ideal for the detection of translocations, deletions, and trisomies. FISH panels to detect common, disease-specific abnormalities with prognostic significance are now routine assays performed at diagnosis for cases of suspected chronic lymphocytic lymphoma and plasma cell myeloma and are becoming more common for other neoplasms. The various polymerase chain reaction (PCR) methods are rapid means of detecting translocations and gene rearrangements, and can detect lower tumor volumes than FISH methods. Quantitative PCR assays are used to determine levels of minimal residual disease, such as to monitor patients being treated for chronic myelogenous leukemia. Other in situ hybridization methods are useful to localize infectious agents, in particular the Epstein–Barr virus, in specific cell types and this method is often used in the diagnosis of classical Hodgkin lymphoma and nasal natural killer (NK)/T-cell lymphoma. The introduction of next-generation sequencing platforms into clinical laboratories will increase the number of genetic targets for a given case in the near future. Therefore, a variety of molecular diagnostic tools is now available to supplement karyotype analysis in the evaluation of hematopoietic tumors.

OTHER ANCILLARY METHODS

New molecular genetic technology will certainly become available for diagnostic use in the future, yet other more traditional ancillary techniques are actually becoming less common in the routine diagnosis of hematopoietic tumors. Specifically, electron microscopy is rarely used and has been largely supplanted by immunophenotypic methods. Similarly, the diagnostic utility of many histochemical and cytochemical assays has also diminished. Although the proper classification of some of the acute myeloid leukemias in the "not otherwise specified" group of the World Health Organization (WHO) classification still have cytochemical criteria, it is now generally recognized that subgroups of acute myeloid leukemia defined solely by these methods have little clinical relevance.[23,24]

THE DIAGNOSTIC REPORT

The diagnostic report for hematopoietic tumors should ideally summarize all diagnostic material and testing from a sample.[25] This would include a combination of peripheral blood, marrow aspirate, and marrow biopsy for bone marrow samples. The morphologic review should be performed and interpreted in combination with immunophenotyping and cytogenetic and molecular genetic studies. The report should state the relevant

TABLE 67.1

COMMONLY USED MARKERS FOR THE CHARACTERIZATION OF HEMATOPOIETIC AND LYMPHOID NEOPLASMS IN PARAFFIN-EMBEDDED TISSUE SECTIONS

Category	CD Antigen or Antibody	Reactivity in Normal Cells[a]	Reactivity in Neoplasms[a]
Pan-leukocyte	CD45	B cells, most T cells, macrophages, and granulocytes	Most NHLs and leukemias
T cell	CD1a	Cortical thymocytes and Langerhans cells	Precursor T-cell lymphoblastic leukemia/lymphoma, Langerhans cell histiocytosis
	CD3	T cells	Most T-cell neoplasms
	CD5	T cells and subset of small B cells	Many T-cell lymphomas and leukemias and subset of diffuse small B-cell neoplasms, such as small lymphocytic lymphoma/chronic lymphocytic leukemia and mantle cell lymphoma
	CD7	Most T cells and NK cells	Many T-cell lymphomas and leukemias
	CD43	T and NK cells, some macrophages, granulocytes, and plasma cells	Most T-cell lymphomas, some B-cell lymphomas, acute myeloid leukemias, and plasma cell neoplasms
	CD45RO	Most T and NK cells, some macrophages, some myeloid cells	Most T-cell lymphomas, some B-cell lymphomas
	CD57	Some NK cells, subset of T cells	Some NK- and T-cell lymphomas/leukemias and some lymphoblastic lymphomas
	TCRβ	α/β T cells	Many T-cell lymphomas
	TCRγ	γ/δ T cells	γ/δ T-cell lymphomas
B cell	CD10	Precursor B cells and germinal center B cells, some germinal center T cells	Many precursor B-lymphoblastic leukemias/lymphomas, some precursor T-lymphoblastic leukemias/lymphomas, angioimmunoblastic T-cell lymphoma, many follicular lymphomas, Burkitt lymphoma
	CD20	B cells	Most B-cell NHLs, L&H cell in LPHD; RS cells in some cases of classic Hodgkin disease
	CD21	Mantle and marginal zone B cells, FDC	Some mantle and marginal lymphomas, FDC tumors
	CD23	Mantle zone B cells, some FDC	Chronic lymphocytic leukemia/small lymphocytic lymphoma, some follicular lymphomas
	CD45RA	B cells and subset of T cells	B-cell NHL, L&H cells in LPHD, some T-cell lymphoid and myeloid leukemias
	CD79a	B cells	Most B-cell NHLs and many B-cell leukemias
	PAX5	B cells	Most B-NHL, L and H cell in LPHD; RS cells in classic Hodgkin disease, some acute myeloid leukemias
	Anti-immunoglobulin	B cells, plasma cells	B-cell NHL and plasma cell neoplasms
Hodgkin related	CD15	Granulocytes and some macrophages	RS cells in classical Hodgkin lymphoma; some T- and B- large cell lymphomas; some carcinomas
	CD30	Activated B and T cells	RS cells in classical Hodgkin lymphoma; most cases of ALCL; other T- and B-cell NHLs
Miscellaneous	CD34	Progenitor cells	Some acute myeloid leukemias and some precursor lymphoblastic leukemias/lymphomas
	CD56	NK cells, few T cells	Many NK-cell neoplasms
	CD123	Plasmacytoid dendritic cells	Blastic plasmacytoid dendritic cell tumors; some acute leukemias; hairy cell leukemia
	CD138	Plasma cells	Multiple myeloma and plasmacytoid lymphomas
	CD163	Macrophages and granulocytes	True malignant histiocytosis; some myeloid leukemias
	S100	Langerhans cells, interdigitating dendritic reticular cells, sometimes FDC	Langerhans cell histiocytes, sinus histiocytosis with massive lymphadenopathy, rare T-cell lymphomas, myeloid leukemias
	Terminal deoxyribonucleotidyl transferase	Precursor marrow cells, cortical thymocytes	Most precursor B- or T-lymphoblastic leukemias/lymphomas, some acute myeloid leukemias
	Ki-67	Proliferating cells (not in G_0 phase of cell cycle)	Proliferating cells
	Myeloperoxidase	Myeloid cells	Myeloid leukemias
	BCL2	Nonfollicular center B cells, T cells	Most follicular lymphomas, many other diffuse NHLs and leukemias
	BCL6	Germinal center B cells	Most follicular lymphomas and some diffuse large B-cell lymphomas
	ALK1	No expression in normal lymphoid cells	Subset of ALCL, DLBCL and inflammatory myofibroblastic tumor cases
	Cyclin D1	Minimal to no expression in normal lymphoid cells	Mantle cell lymphoma, hairy cell leukemia, and some cases of plasma cell myeloma

ALCL, anaplastic large cell lymphoma; FDC, follicular dendritic cell; L&H, lymphocyte and histiocytic; LPHD, lymphocyte-predominant Hodgkin disease; NHL, non-Hodgkin lymphoma; NK, natural killer; RS, Reed-Sternberg.

[a]In most cases the immunoreactivity of each antibody is not exclusive to the cell type or neoplasm listed and positive results must be interpreted in the context of the entire immunophenotype.

clinical information and indication for biopsy/aspiration. In addition, the report should clearly define the methodology used for any special studies (such as flow cytometry vs. immunohistochemistry; PCR vs. FISH, etc.), the antibodies studied and their results, a summary of the interpretation of each special study, and a final interpretation of the significance of all of the assays performed. The final diagnosis should clearly identify the site from which the specimen was obtained, and should, when possible, provide a diagnosis using the most current version of the WHO classification of hematopoietic tumors which is summarized in Table 67.2. Such comprehensive reports are more complicated to produce, but are necessary to classify most hematopoietic neoplasms properly. This approach may require amending initial interpretations, based on morphology and immunophenotyping, to provide the complete assessment that includes cytogenetic and molecular genetic results.

The pathologic diagnosis of hematopoietic tumors now requires a broad approach that involves very close interactions between hematologists and pathologists as well as interactions with a variety of laboratories. Excellent communication between the physician performing the diagnostic procedure and the laboratories is needed to ensure that the specimen is handled in the most efficient manner and to obtain the most accurate and rapid diagnosis for the patient.

TABLE 67.2

2008 WORLD HEALTH ORGANIZATION CLASSIFICATION OF HEMATOPOIETIC AND LYMPHOID NEOPLASMS

Myeloproliferative Neoplasms
Chronic myelogenous leukemia, *BCR-ABL1*
Chronic neutrophilic leukemia
Polycythemia vera
Primary myelofibrosis
Essential thrombocythemia
Chronic eosinophilic leukemia, not otherwise specified
Mastocytosis
Myeloproliferative neoplasms, unclassifiable
Myeloid and lymphoid neoplasms associated with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*

Myelodysplastic/Myeloproliferative Neoplasms
Chronic myelomonocytic leukemia
Atypical chronic myeloid leukemia, *BCR-ABL1* negative
Juvenile myelomonocytic leukemia
Myelodysplastic/myeloproliferative neoplasm, unclassifiable

Myelodysplastic Syndromes
Refractory cytopenia with unilineage dysplasia
Refractory anemia with ring sideroblasts
Refractory cytopenia with multilineage dysplasia
Refractory anemia with excess blasts
Myelodysplastic syndrome with isolated del(5q)
Myelodysplastic syndrome, unclassifiable
Childhood myelodysplastic syndrome

Acute Myeloid Leukemia (AML) and Related Precursor Neoplasms
AML with recurrent genetic abnormalities
- AML with t(8;21) (q22;q22) (*RUNX1-RUNX1T1*)
- AML with inv(16)(p13.1q22) or t(16,16) (p13.1;q22) (*CBFB-MYH11*)
- Acute promyelocytic leukemia with t(15;17)(q24.1;q21.1) (*PML-RARA*)
- AML with t(9;11)(p22;q23) (*MLLT3-MLL*)
- AML with t(6;9)(p23;q34) (*DEK-NUP214*)
- AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2) (*RPN1-EVI1*)
- AML (megakaryoblastic) with t(1;22)(p13;q13) (*RBM15-MKL1*)
- Provisional entity: AML with mutated *NPM1*
- Provisional entity: AML with mutated *CEBPA*

AML with myelodysplasia-related changes
Therapy-related myeloid neoplasms
AML not otherwise specified
- AML minimally differentiated
- AML without maturation
- AML with maturation
- Acute myelomonocytic leukemia

(*Continued*)

TABLE 67.2

2008 WORLD HEALTH ORGANIZATION CLASSIFICATION OF HEMATOPOIETIC AND LYMPHOID NEOPLASMS (CONTINUED)

- Acute monoblastic and monocytic leukemia
- Acute erythroid leukemia
- Acute megakaryocytic leukemia
- Acute basophilic leukemia
- Acute panmyelosis with myelofibrosis

Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Blastic plasmacytoid dendritic cell neoplasm

Acute Leukemias of Ambiguous Lineage

Precursor Lymphoid Neoplasms

B-lymphoblastic leukemia/lymphoma, not otherwise specified
B-lymphoblastic leukemia/lymphoma with t(v;11q23)(*MLL*)
B-lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22) (*ETV6-RUNX1*)
B-lymphoblastic leukemia/lymphoma with t(5;14)(q31;q32) (*IL3-IGH@*)
B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3) (*TCF3-PBX1)*
B-lymphoblastic leukemia/lymphoma with hyperdiploidy
B-lymphoblastic leukemia/lymphoma with hypodiploidy
T-lymphoblastic leukemia/lymphoma

Mature B-Cell Neoplasms

Chronic lymphocytic leukemia/small lymphocytic lymphoma
B-cell prolymphocytic leukemia
Splenic B-cell marginal zone lymphoma
Hairy cell leukemia
Splenic B-cell lymphoma/leukemia, unclassifiable
Lymphoplasmacytic lymphoma
Heavy-chain diseases
Plasma cell neoplasms
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
Nodal marginal zone lymphoma
Follicular lymphoma
Primary cutaneous follicle center lymphoma
Mantle cell lymphoma
Diffuse large B-cell lymphoma (DLBCL), not otherwise specified
T-cell/histiocyte–rich large B-cell lymphoma
Primary DLBCL of the central nervous system
Primary cutaneous DLBCL, leg type
EBV-positive DLBCL of the elderly
DLBCL associated with chronic inflammation
Lymphomatoid granulomatosis
Primary mediastinal (thymic) large B-cell lymphoma
Intravascular large B-cell lymphoma
ALK-positive large B-cell lymphoma
Plasmablastic lymphoma
Large B-cell lymphoma associated with HHV8-associated multicentric Castleman disease
Primary effusion lymphoma
Burkitt lymphoma
B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma
B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma

Mature T- and NK-Cell Neoplasms

T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Chronic lymphoproliferative disorder of NK cells
Aggressive NK-cell leukemia
EBV-positive T-cell lymphoproliferative diseases of childhood

Adult T-cell leukemia/lymphoma
Extranodal NK/T-cell lymphoma, nasal type
Enteropathy-type T-cell lymphoma
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides
Sézary syndrome
Primary cutaneous CD30-positive T-cell lymphoproliferative disorders
Primary cutaneous $\gamma\delta$ T-cell lymphoma
Primary cutaneous $CD8^+$ aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous CD4-positive small/medium T-cell lymphoma
Peripheral T-cell lymphoma, not otherwise specified
Angioimmunoblastic T-cell lymphoma
Anaplastic large cell lymphoma, *ALK*-positive
Anaplastic large cell lymphoma, *ALK*-negative

Hodgkin Lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma
Nodular sclerosis classical Hodgkin lymphoma
Mixed cellularity classical Hodgkin lymphoma
Lymphocyte-rich classical Hodgkin lymphoma
Lymphocyte-depleted classical Hodgkin lymphoma

Immunodeficiency-Associated Lymphoproliferative Disorders

Lymphoproliferative diseases associated with primary immune disorders
Lymphomas associated with HIV infection
Posttransplant lymphoproliferative disorders
Other iatrogenic immunodeficiency-associated B-cell lymphoproliferative disorders

Histiocytic and Dendritic Cell Neoplasms

Histiocytic sarcoma
Langerhans cell histiocytosis/sarcoma
Interdigitating dendritic cell sarcoma
Follicular dendritic cell sarcoma
Other rare dendritic cell tumors
Disseminated juvenile xanthogranuloma

AML, acute myeloid leukemia; DLBCL, diffuse large B-cell lymphoma; EBV, Epstein-Barr virus; HHV8, human herpes virus-8; HIV, human immunodeficiency virus; NK, natural killer.

CHAPTER 68

PRINCIPLES AND PHARMACOLOGY OF CHEMOTHERAPY

Kenneth R. Hande

PRINCIPLES OF CHEMOTHERAPY

To optimally treat cancer patients, clinicians should understand the principles of cancer chemotherapy as well as the pharmacology of the drugs they are administering. The first section of this chapter reviews our understanding of (a) cancer biology, (b) mechanisms of antineoplastic drug action, (c) mechanisms of drug resistance, (d) drug toxicities, (e) pharmacologic principles (common and unique), and (f) potentials and limitations of therapy for individual patients. Specific drugs used to treat hematologic malignancies, their mechanism of action, and their toxicities are summarized in the second section of this chapter.

Cancer Biology

Most cancers are detected when there are 10^4 to 10^{11} neoplastic cells present.[1] The large number of cells present at diagnosis usually requires multiple courses of treatment or a long duration of therapy to result in a cure. Even if a drug, or a combination of drugs, is quite effective in killing cancer cells, such that it kills 999 of every 1,000 cells present (99.9% cell kill), one treatment will reduce a tumor population from 10^{11} to 10^8 cells. At least four treatments are therefore necessary to eliminate the final cancer cell, assuming there is no tumor cell growth during the treatment period. In fact, because of toxicity to normal tissues and the time needed for normal tissue recovery, cancer chemotherapy must be spaced out in treatment cycles. During the period between cycles, tumor regrowth occurs. Thus, most curative treatment regimens require prolonged therapy, often using multiple courses of chemotherapy, with the number of courses depending on the tumor mass at the time of diagnosis and the sensitivity of the tumor to the drugs. The fraction cell kill (e.g., 90%, 99%, 99.99% cell kill) depends on the sensitivity of cells to the antineoplastic drug and the dose of drug administered. Rapidly dividing cells are generally more sensitive to antineoplastic agents while nondividing cells are generally resistant.

Most cancers do not grow at a fixed rate throughout their course. Initial growth rates may be exponential. Gompertzian growth is sigmoid. In the Gompertzian model, the growth fraction of the tumor reduces as the tumor enlarges.[2] Because a significant proportion of cells in a large tumor mass are often in a resting or dormant phase, presumably as a result of lack of adequate nutrients or oxygen, they may not be affected by chemotherapy. The best opportunity for cell kill by chemotherapy is in the early portion of the growth curve, when all cells are dividing.

Recurrence of cancer after "complete remission" (disappearance of all detectable disease) can be explained by the inability of current staging methods to detect fewer than 10^3 to 10^4 tumor cells in the body even by the most sensitive means. Chemotherapy that kills several logs of tumor cells (e.g., from 10^{11} to 10^4) eliminates all visible evidence of cancer and prolongs survival, but the malignancy will recur at a later time. Examples of possible clinical courses associated with cancer chemotherapy are illustrated in Figure 68.1.

The growth fraction of a cancer represents the percentage of cells progressing actively through the cell cycle. A cell cycle is marked by two observable events. In *S-phase* (synthesis), DNA replication occurs; during *M-phase* (mitosis), cellular division into two daughter cells is noted.[1] G_1 (gap) is the time between the end of mitosis and the start of the next S-phase. G_2 is the time between the completion of S-phase and the start of M-phase. Cells that have ceased to proliferate for prolonged periods have entered a G_0 phase (or resting phase) of the cell cycle (Fig. 68.2). Some drugs are cytotoxic when exposed to cancer cells in any phase of the cell cycle. Other drugs are phase-specific; that is, they are cytotoxic to cells only in a particular phase of the cell cycle. Cytarabine, for example, is an S-phase–specific agent, whereas vincristine is M-phase–specific. For cells to be killed by cytarabine, the drug must be present when the cell is synthesizing DNA.

Mechanisms of Antineoplastic Drug Action

Antineoplastic agents have been discovered by many methods. Exposing cancer cells in culture to natural or synthetic compounds to screen for materials with antineoplastic activity has identified a number of active antineoplastic agents (drugs such as paclitaxel). Since DNA is important in cell division, compounds blocking DNA synthesis have been developed. Over the past 20 years, genes and their protein products that regulate cell division have been identified. The molecular pathways by which these oncogenes cause cellular proliferation have been determined.[3] Knowledge of molecular pathways critical to the growth of cancer cells has led to the targeted development of molecules altering specific pathways (e.g., tyrosine kinase inhibitors, angiogenesis inhibitors). During the past two decades, the development of cancer drugs has shifted from a screening process where active agents are identified and their mechanism of action later defined, to first identifying a targetable pathway, finding a compound to block that pathway, and then testing for antineoplastic activity.

No matter how an antineoplastic has been developed, these drugs interfere with an essential step required for cell growth or division. The initial target of antineoplastic drugs varies widely, from direct attack on the DNA molecule to inhibition of signal transduction molecules. However, all antineoplastic agents cause a disruption in a cellular process so significant to the cancer cell that it requires the cell to either quickly repair the damage or to initiate the process of apoptosis (programmed cell death). Essentially, all antineoplastic agents result in cancer cell death through initiation of apoptosis.[4] *Apoptosis* is the normal physiologic process of cellular suicide, which occurs in all living organisms to eliminate unwanted, functionally abnormal, or harmful cells. In apoptosis, in contrast to cellular necrosis, the cell shrinks and condenses, fragmenting into multiple membrane-bound bodies (apoptotic bodies) that are engulfed by surrounding cells without inflammation or damage to the surrounding tissues. Biochemically, apoptosis is characterized by fragmentation of nuclear DNA, demonstrated by a typical ladder pattern on agarose gel electrophoresis.

To understand how cytotoxic agents initiate apoptosis, an understanding of the events that occur during the normal cell cycle is important. As previously mentioned, DNA synthesis is not continuous from one mitosis to the next but takes place in only a specific period of the cell cycle, the S-phase. Similarly, mitosis or the M-phase takes up only a small part of the cell cycle.[1] In most, if not all cells, the cell cycle is temporarily halted during the G_1–S-phase checkpoint and at the G_2–M-phase checkpoint. At these times, cells determine whether to continue into the S-phase, initiate the process of apoptosis, or undergo DNA repair. Passage into a new phase of the cell cycle requires activation of a series of enzymes called *cyclin-dependent kinases*, which activate another group of enzymes (the cyclins).[5] If cells are damaged by

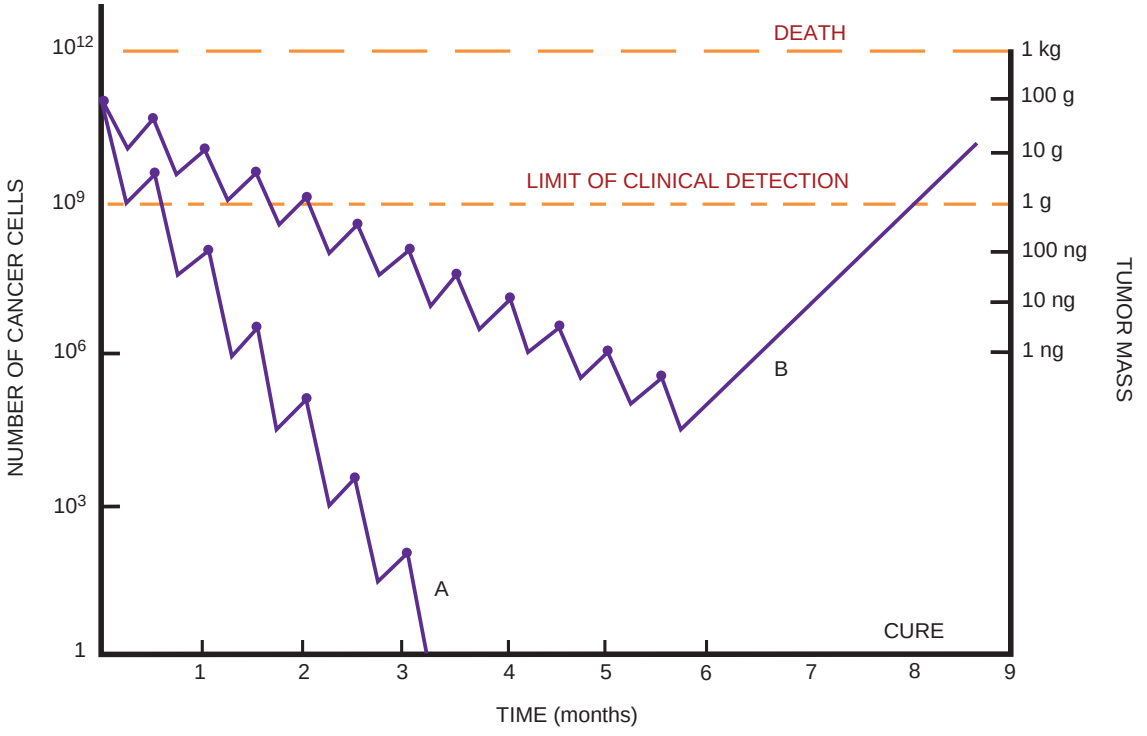

FIGURE 68.1. Schematic representation of clinical course of two patients with Hodgkin disease. Both patients A and B are diagnosed with a clinically detected tumor mass (10^{11} cells). Both patients are treated with ABVD (doxorubicin, bleomycin, vincristine, and DTIC) every 2 weeks. One course of therapy for patient A results in a 2-log tumor cell kill. Patient B's therapy results in only a 1-log tumor cell kill. Some tumor growth occurs while waiting for normal tissue recovery before initiation of the next treatment. Three months into therapy, neither patient A nor B has clinically detectable disease. Treatment is stopped after 6 months of therapy. Patient A is cured, whereas disease recurs in patient B 3 months after stopping therapy.

chemotherapeutic agents and are unable to repair the damage, apoptosis is initiated at the G_1–S or G_2–M checkpoint, provided the mechanisms for apoptosis are in place. Several critical factors are needed for apoptosis to occur such as p53, p63, and p21. P53 is a nuclear phosphoprotein capable of binding to specific DNA sequences and activating selected target genes triggering apoptosis. Cells with a mutated *P53* gene have a relative resistance to cancer chemotherapeutic agents and are unable to initiate apoptosis properly.[6] *P21* is a protein induced by p53 that binds to and inactivates the cyclins required for progression of cells into the S-phase. Other factors are known to affect the apoptotic pathway. A protein originally found in B cell lymphomas, bcl-2, blocks apoptosis. Caspases are the key machinery causing the breakdown of DNA and proteins. *Caspases* are specialized proteases existing as proenzymes, which can be rapidly activated by a number of factors. The Fas ligand and tumor necrosis factor stimulate the protease cascade. It is clear that antineoplastic agents provide the initial trigger for beginning the pathway to programmed cell death (Fig. 68.3). However, the presence, or absence, of apoptotic proteins is as important as the initial interaction between a cytotoxic drug and its effecter in determining whether tumor cell kill occurs.[4]

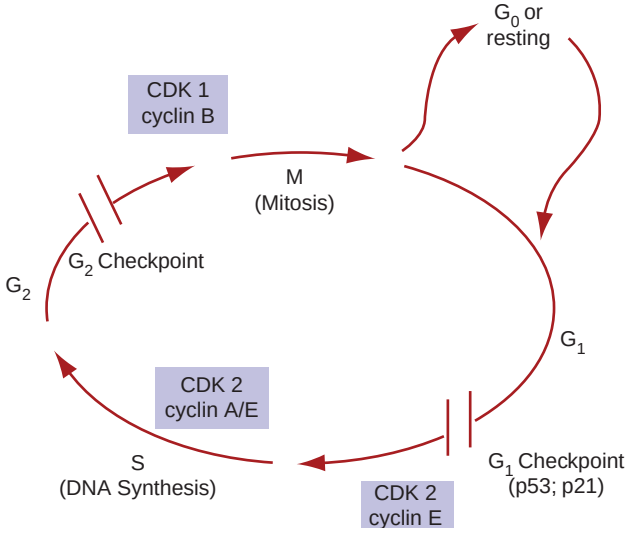

FIGURE 68.2. The cell cycle. The cell cycle is marked by two observable events. During S-phase (synthesis), DNA replication occurs; and during M-phase (mitosis), cells divide. G_1 and G_2 (gap) are times between completion of M-phase and start of S-phase and between completion of S-phase and start of M-phase, respectively. During G_1 and G_2, the cell prepares for the S- and M-phases of the cell cycle. Cells may temporarily cease to divide and enter a resting or G_0 phase of the cell cycle. The G_1–S checkpoint is a critical phase in the cell cycle, when directions for entering S-phase or committing to apoptosis (programmed cell death) are given.

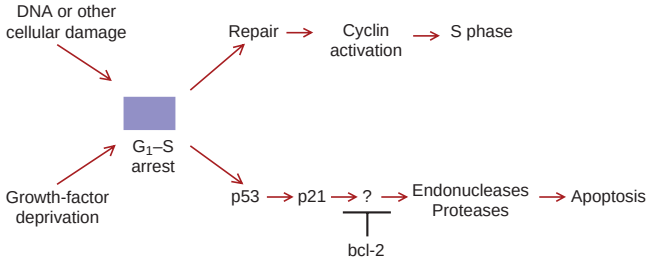

FIGURE 68.3. Potential pathways involved in cytotoxicity induced by chemotherapy. Chemotherapeutic drugs or growth factor deprivation damages cells. Cells are arrested at the G_1–S checkpoint. If the damage is sublethal, it may be repaired and the cell proceeds to S-phase. If significant DNA damage is present, the process of programmed cell death is initiated. Critical factors, such as p53 and p21 gene products, are required for the cell to undergo apoptosis.

Resistance to Anticancer Drugs

The presence of cancer cells that are resistant to chemotherapeutic agents is a common clinical occurrence. It has been postulated that by the time the number of cancer cells reaches 10^3 to 10^6, a resistant clone has developed.[7] Unfortunately, there are many ways in which cells can become resistant to an antineoplastic agent. Steps in antineoplastic drug disposition within the cell are represented schematically in Figure 68.4. For an anticancer drug to be active, it must (a) be taken up into a cancer cell and (b) be converted into an active agent. It must then make its way within the cell to its target without being (c) metabolically inactivated, (d) chemically inactivated, or (e) excreted from the cell. Once it interacts with its cellular target, the cell must *not* be able to (f) alter the target or (g) repair the damage to the target. Finally, (h) mechanisms for apoptosis must be in place, as discussed in the preceding section. Examples of drug resistance at all of these steps have been described.[8] Not only are there multiple potential mechanisms for drug resistance, but an individual tumor cell can become resistant to a particular drug in many ways. For example, resistance to methotrexate (MTX) has been described in some cell lines with altered folate transport that limits MTX uptake into cells.[9] In other cell lines, MTX resistance results from the overexpression of the target enzyme, dihydrofolate reductase (DHFR).

Cancer cells may become simultaneously resistant to several types of chemotherapeutic drugs. Cells that express the multidrug resistance gene (*MDR*) produce a glycoprotein of 170-kDa weight known as *p-glycoprotein* or *p170*.[8] Originally described in 1976, this protein is a drug transporter that sits in the cell wall of resistant tumor cells. P-glycoprotein transports a number of antineoplastic agents, most of which are hydrophobic, including vinca alkaloids, epipodophyllotoxins, anthracyclines, actinomycin, and taxanes. Cells in which the *MDR* gene is activated develop simultaneous resistance to these antineoplastic agents. The presence of *p*-glycoprotein on tumor cells has been correlated with poor prognosis in hematologic tumors.[10] Efforts have been directed at inhibiting p-glycoprotein. However, MDR inhibitors often block either the hepatic or renal excretion of anticancer drugs, thereby increasing drug toxicity.[11] Clinical effectiveness of these MDR inhibitors has not been demonstrated. Cancer cell lines have been characterized that do not overexpress *p*-glycoprotein but do display a similar cross-resistance pattern. These lines have different types of transport proteins, such as MDR-related protein (MRP) or breast cancer resistance protein (BCRP). MRP and BCRP, like *p*-glycoprotein, are members of the adenosine triphosphate (ATP) binding cassette gene superfamily, but are structurally dissimilar to *p*-glycoprotein and with different inhibitors.[12,13] In summary, tumor cells can develop resistance to antineoplastic drugs by numerous mechanisms. Resistance occurs as a result of random mutational changes in a population of cancer cells. Mutations to a drug-resistant cell line are estimated to occur at a population size of 10^4 to 10^6 tumor cells, a size smaller than is clinically detectable. Therefore, drug-resistant cancer cell populations will be present in the majority of tumors at diagnosis. The early presence of resistant tumor cells leads to the rationale for (a) early treatment of cancers to avoid multiple resistant populations and (b) use of multiple agents with differing mechanisms of action.

Drug Toxicity

As opposed to many other classes of drugs, the therapeutic window for chemotherapeutic agents is narrow (Fig. 68.5). The dose of drug needed to achieve adequate tumor cell kill often causes toxicity to normal tissues. For many antineoplastic agents, a sigmoidal curve defining the relationship between toxicity and the dose of drug administered (or the area under the plasma drug concentration [AUC] versus time curve) has been demonstrated. At low drug concentrations, no cytotoxicity is observed. With increasing concentration, cell kill is proportional to dose. At higher concentrations, the effect plateaus. Similar relationships correlating the dose of drug and the antitumor response have also been demonstrated.[14] A positive relationship between the drug dose administered and the tumor response rate has been found for many tumors, including the lymphomas. Higher response rates and an increased chance for cure are achieved with higher doses of selected agents.[15,16] For this reason, clinicians generally try to push doses of agents to toxicity to maximize the chance for cure. The optimal dose or AUC for an individual patient with a particular cancer is unknown.

Chemotherapeutic agents cause a wide variety of toxicities (Table 68.1). Myelosuppression and nausea are seen, to some degree, with many anticancer drugs. Nausea and vomiting, although generally self-limited and not life-threatening, are very distressing to patients. The emetogenic potential of antineoplastic

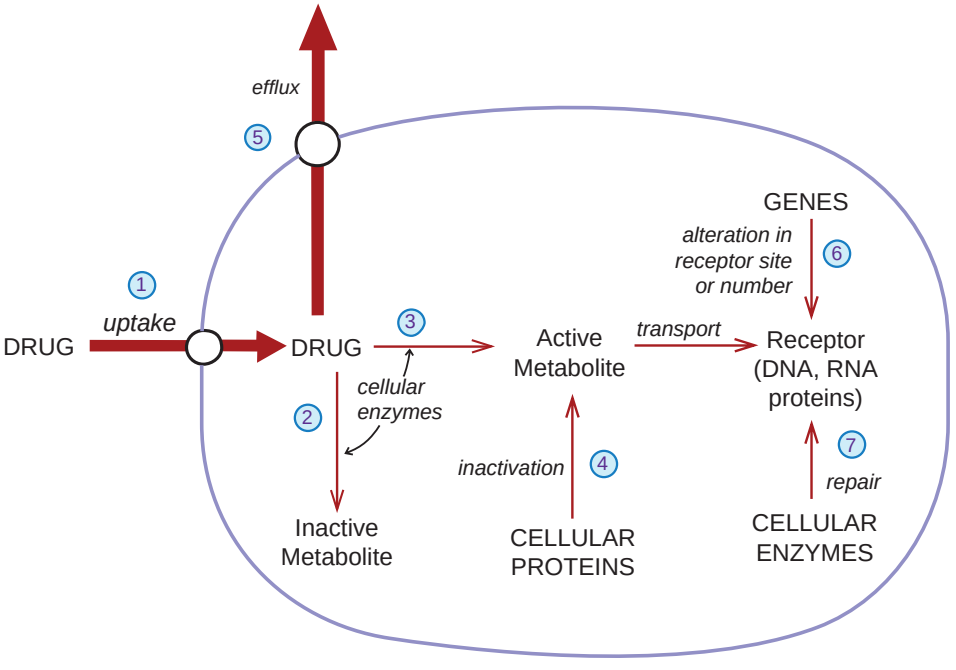

FIGURE 68.4. Potential pathways for antineoplastic drug disposition in tumor cells. For a drug to be effective, the drug, or its active metabolite, must reach its target site within the cell. Possible steps required for a drug to reach its receptor or to be inactivated include: *(1)* uptake into a cell through a particular transport protein; *(2)* enzymatic conversion of the drug to an inactive metabolite; *(3)* enzymatic conversion of the drug to its active metabolite; *(4)* binding of an active metabolite by a cellular protein or thiol, thereby inactivating drug; *(5)* excretion of the drug from the cell via an efflux transport pump; *(6)* alteration in the genetic makeup of the cell, changing the drug receptor site or number; and *(7)* changes in the ability of a cell to repair damage of a drug at its receptor.

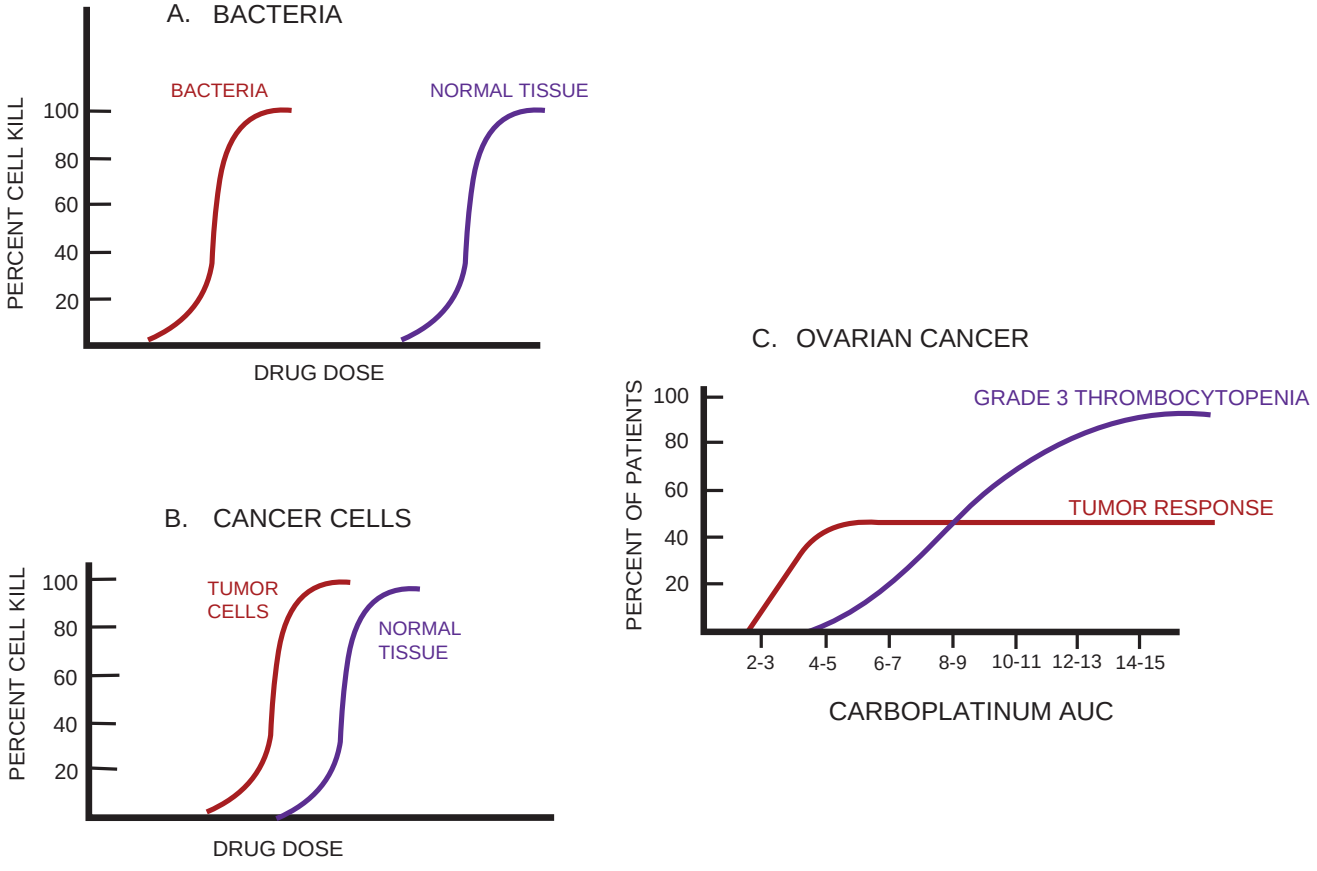

FIGURE 68.5. Schematic representation curves relating drug concentrations to response. Antibacterial agents **(A)** have a wide therapeutic window, with a significant difference in the dose that produces bacterial cell kill and the dose that causes toxicity to normal tissues. For antineoplastic drugs **(B)**, the therapeutic window is narrow (e.g., doses adequate to produce tumor cell kill usually produce toxicity to normal tissues). For a few cancers, such as ovarian **(C)**, the shape of the dose–response curve has been defined.[14] For most tumors, however, a specific dose–response (or AUC–response curve) has not been defined.

agents varies from drug to drug and is dose-dependent[17] (Table 68.2). Serotonin receptors, located within the vagal and splanchnic nerves of the gastrointestinal system and in the brain, are critical in the initiation of nausea by chemotherapeutic agents. The development of specific type 3 serotonin (5-hydroxytryptamine or $5HT_3$) receptor blockers, such as ondansetron, dolasetron, and granisetron, and NK-1 inhibitors, such as aprepitant, has resulted in major improvement in control of chemotherapy-induced emesis.[17,18]

Myelosuppression is the most common dose-limiting antineoplastic agent toxicity. The suppression of hematopoietic cell lines is determined by the kinetics of the specific cell line in the peripheral compartment. Anemia occurs as a late effect because of the long half-life of red blood cells (120 days). Thrombocytopenia occurs in an intermediate time frame (platelet half-life 5 to 7 days), whereas granulocyte suppression occurs earliest. Granulocytopenia is a more frequent occurrence than thrombocytopenia or anemia. The white blood cell count usually drops 5 to 14 days after drug administration, with recovery by 7 to 21 days. Several exceptions are recognized, such as a predominant thrombocytopenia seen with carboplatin and delayed myelosuppression with busulfan and the nitrosoureas (occurring 4 to 5 weeks posttherapy). The degree and duration of bone marrow suppression are related directly to the dose of drug administered. High-dose chemotherapy regimens, used with stem cell transplantation, generally result in 10 to 25 days with neutrophils $<500/mm^3$ and thrombocytopenia lasting for a more extended period. The length of cytopenias depend upon the stem cell source with peripheral blood shorter (10 to 14 days) than bone marrow (20 to 25 days). An increased risk of infectious complications occurs that is related directly to the degree and duration of granulocytopenia.[19] The development of recombinant hematopoietic colony-stimulating factors (CSFs), such as erythropoietin, thrombopoietin, granulocyte-macrophage CSF, and granulocyte-CSF, has shortened the duration of bone marrow suppression but not eliminated it. CSFs are now commonly used prophylactically with regimens expected to produce an incidence of febrile neutropenia >20%. Guidelines for the use of these important, yet expensive, factors are available and should be followed.[20]

The range of toxicities associated with antineoplastic agents is too great to review in detail in this chapter. Readers are referred to reviews on endocrine,[21] oral,[22] renal,[23] neurologic,[24] hepatic,[25] pulmonary,[26] cardiac,[27] and cutaneous[28] toxicities of antineoplastic agents. Physicians must also remember that most antineoplastic agents have teratogenic and mutagenic potential. Alkylating agents are the most damaging to testicular and ovarian function. Damage is dependent on drug dose, the age of the patient (older patients are more likely to experience toxicity), and sex (males more than females).[29] Second malignancies (primarily acute leukemia) have been associated with alkylating agents, epipodophyllotoxins, nitrosoureas, and anthracyclines.[30] Concomitant radiation therapy increases the risk of second malignancies (such as sarcomas or breast cancer) 5 to 20 years following therapy.

General Pharmacologic Principles

Antitumor activity of an antineoplastic agent is best correlated with the concentration of drug that reaches the site of drug action within the cancer cell (Fig. 68.5A). Several factors may affect what

TABLE 68.1

ANTINEOPLASTIC DRUG TOXICITY

Irinotecan	Irinotecan	Vinblastine		Vincristine[a]							
Mechlorethamine[a]	Lenalidomide	Vincristine		Vinorelbine[a]							
Methotrexate	L-PAM[a]										
Mitomycin	Methotrexate										
Mitoxantrone	Mercapto purine[a]										
Mustard[a]	Mitomycin[a]										
Nitrosoureas	Mitoxantrone[a]										
Irinotecan	Mustard[a]										
Pentostatin	Nelarabine										
Procarbazine	Nitrosoureas[a]										
Romidespin	Paclitaxel[a]										
Streptozocin[a]	Pentostatin										
Thioguanine	Procarbazine										
Thiotepa	Romidespin										
Topotecan	Teniposide[a]										
Vorinostat	Thioguanine										
	Thiotepa										
	Tositumomab										
	Vinblastine										
	Vinorelbine										
	Vorinostat										

Ara-C, cytosine arabinoside; ATRA, all-*trans* retinoic acid; DTIC, decarbazine; HMM, hexamethylmelamine; L-PAM, L-phenylalanine mustard.
[a]Major toxicity.

TABLE 68.2

EMETIC POTENTIAL OF SELECTED ANTINEOPLASTIC AGENTS

High (>90% risk)	
Carmustine	Dactinomycin
Cisplatin	Mechlorethamine
Cyclophosphamide (>1.5 mg/m^2)	Streptozocin
Dacarbazine	
Moderate (30–90% risk)	
Alemtuzumab	Doxorubicin
Azacytidine	Epirubicin
Bendamustine	Idarubicin
Carbazitaxel	Ifosfamide
Carboplatin	Irinotecan
Clofaribine	Methrotrexate (>250 mg/m^2)
Cyclophosphamide (>1.5 g/m^2)	Oxaliplatin
Cytarabine (>1 g/m^2)	Pralatrexate
Daunorubicin	Temozolomide
Low (10–30% risk)	
Bortezomib	Mitomycin
Cytarabine (<1 g/m^2)	Mitoxantrone
Docetaxel	Paclitaxel
Eribulin	Panitumumab
Etoposide	Pegylated liposomal doxorubicin
5 Fluorouracil	Pemetrexed
Chlorambucil	Romidesin
Gemcitabine	Temsirolimus
Ixabepilone	Topotecan
Hydroxyurea	Trastuzumab
Melphalan	Vorinostat
Methotrexate (<250 mg/m^2)	
Minimal (<10% risk)	
Bevacizumab	2-Chlorodeoxyadenosine
Bleomycin	Fludarabine
Busultan	Rituximab
Cetuximab	Vinca alkaloids

happens to a drug following administration until it reaches its site of action (Fig. 68.6). Pharmacokinetics describes what happens to a drug following administration (what the body does to the drug). Pharmacokinetics represents an attempt to predict quantitatively how a patient will handle a given dose of drug.[31] Important pharmacokinetic parameters include (a) bioavailability or absorption, (b) volume of distribution, (c) clearance or drug elimination, and (d) drug half-life (Fig. 68.7). Pharmacodynamics describes what effect the drug has on a particular tissue (what the drug does to the body).

Bioavailability, the percentage of a dose of drug that reaches the plasma compartment, defines drug absorption (Fig. 68.7). Drugs given intravenously have, by definition, 100% bioavailability. Factors that decrease the bioavailability of orally administered drugs include poor solubility in aqueous solutions or metabolism of the drug by the intestine or liver before entry into the systemic circulation (first-pass effect). Bioavailability of poorly soluble drugs, such as etoposide, decreases at high oral drug doses.[32] Bioavailability of orally administered 6-mercaptopurine (6-MP) and 5-fluorouracil is low because of extensive first-pass hepatic drug metabolism.[33,34] With poor or widely variable bioavailability of a particular agent, an intravenous route of administration is preferred. The most important factor regarding bioavailability is the variation from patient to patient in the amount of oral drug absorbed (coefficient of variation). If bioavailability of an oral anticancer drug were 50% in all patients, simply doubling the drug dose would produce an equivalent response to intravenously administered drug. However, the variation from patient to patient in the AUC achieved is usually greater with oral than with intravenously administered drug.[35] Therefore, variation in toxicity is also greater.

After a drug reaches the bloodstream, it is distributed into tissues. Figure 68.8 illustrates a plasma concentration-versus-time curve for a drug with a typical two-phase (distribution and elimination) decline in plasma concentration. Distribution may be affected by drug binding to plasma proteins (usually albumin or α_1-acid glycoprotein). Only free drug is biologically active. Decreasing the amount of bound drug by having a low serum albumin concentration or displacing drug from its binding site may increase toxicity (as seen with etoposide).[36] Distribution of drug into a "third space," such as ascites or a pleural effusion, may slow clearance and increase toxicity, as is noted with MTX.[37]

Clearance is expressed as the volume of biologic fluid (usually plasma) from which a drug can be removed per unit of time. Clearance of most drugs is constant over a range of plasma concentrations, which means that the mechanism for elimination is not saturated. However, some drugs, such as paclitaxel, demonstrate saturable elimination at high plasma concentrations.[38] This means that a greater proportional drug effect is noted when high drug doses are employed. Clearance measurements allow physicians to maintain a particular plasma concentration because the dosage rate = clearance × desired plasma concentration.

Removal of drugs from the circulation occurs primarily by metabolism, renal elimination, or hepatic excretion. If urinary excretion is an important route of elimination, renal failure results in slower removal of the drug from the body. Administration of the usual dosage of a drug cleared by the kidney to a patient with renal insufficiency leads to greater drug accumulation and an increased likelihood of toxicity. In such cases, drug dosage needs to be modified to prevent excess toxicity. Using available data on drug clearance, the appropriate dose in renal insufficiency may be calculated as follows: *Dose in renal insufficiency = normal dose × (clearance in renal insufficiency ÷ normal clearance)*

In contrast to a predictable decline in renal drug clearance when glomerular filtration is reduced, it is not possible to make a general prediction of the effect of liver disease on hepatic biotransformation of drugs. Even in advanced hepatocellular disease, the magnitude of impairment in drug clearance usually is only two- to fivefold. The extent of such changes cannot be predicted by common tests of liver function. Consequently, even when it is suspected that drug elimination is altered in liver disease, there is no quantitative base on which to adjust the dosage regimen other than assessment of clinical response. Antineoplastic drugs for which dose modifications are indicated for renal or hepatic insufficiency are listed in Table 68.3.

The hepatic metabolism of drugs may be altered by genetic deficiency of a metabolizing enzyme or by inhibition of metabolism by another drug. Pharmacogenomics is the study of how a particular patient's genetic makeup affects drug metabolism. It is now recognized that some patients inherit a mutated gene which produces an inactive or much less active enzyme important in clearing a drug from the body.[39] Such patients have a markedly lower drug clearance and a higher incidence of toxicity. Examples include the inherited deficiencies of dihydropyrimidine dehydrogenase, the enzyme that degrades 5-fluorouracil[40]; UGT1A1, the enzyme that inactivates irinotecan[41]; and thiopurine methyltransferase, the enzyme that degrades azathioprine and 6-MP.[42]

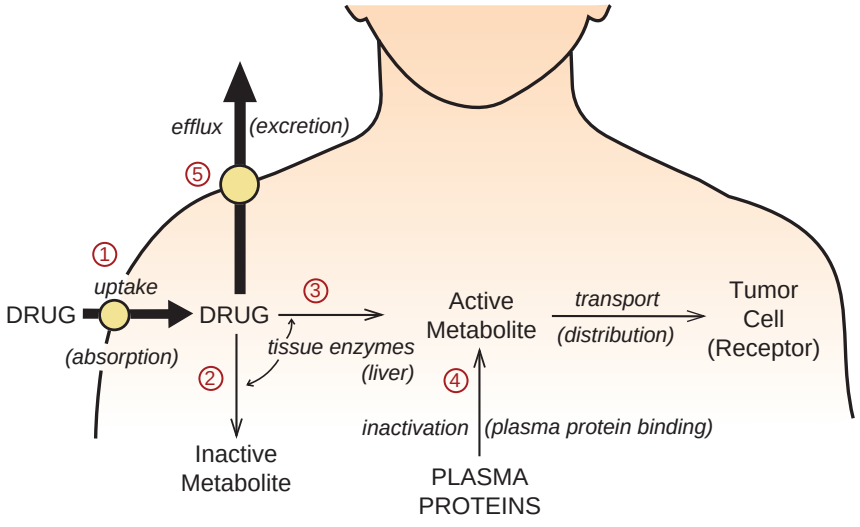

FIGURE 68.6. Schematic representation of drug disposition in the body. For a drug to function, it must be taken into the body *(1)* and the drug must avoid being cleared from the body by metabolism *(2)* or excretion *(5)*. It must reach its site of action in active form *(3)*, without being inactivated by protein binding *(4)*.

Certain antineoplastic drugs are metabolized by the hepatic P-450 microsomal enzyme system (vincas, epipodophyllotoxins, cyclophosphamide, tyrosine kinase inhibitors, and the taxanes). The activity of the microsomal enzyme systems may be increased with concomitant use of phenobarbital, phenytoin, or other drugs. Use of anticonvulsants has been shown to increase the catabolism of teniposide, a drug eliminated from the body through hepatic microsomal metabolism.[43] Clearance of drugs metabolized by the hepatic P-450 enzyme system, such as paclitaxel or Taxotere, can be decreased with concomitant use of P-450 inhibitors, such as ketoconazole or selected antiretroviral agents.

It is important to recognize the unpredictable variation in the way chemotherapeutic drugs are handled by the body. Mean values for bioavailability, clearance, and volume of distribution of anticancer agents have standard deviations of 20%, 50%, and 30%, respectively. This means that target drug concentrations may vary widely from patient to patient, even those whose renal and hepatic function appears similar. This is particularly important for drugs with a low therapeutic index and necessitates that all patients receiving chemotherapy must be carefully monitored.

Approach to the Patient with Cancer

Before initiating cancer chemotherapy, a physician should (a) verify the accuracy of the diagnosis, (b) understand the natural history of the illness, and (c) identify, with the patient, the goals of therapy. Verification of the diagnosis, in nearly every case, requires histologic documentation of cancer. Once the diagnosis is established, the physician and patient must decide whether cure is possible or palliation is the optimal goal. If cure is the goal, the patient and physician may be willing to tolerate more severe toxicity. The patient must be a partner in such decisions. In many cases, several options may be reasonable and an informed patient can direct the physician as to whether intensive, potentially toxic therapy should be tried for a relatively small chance of cure.[44,45]

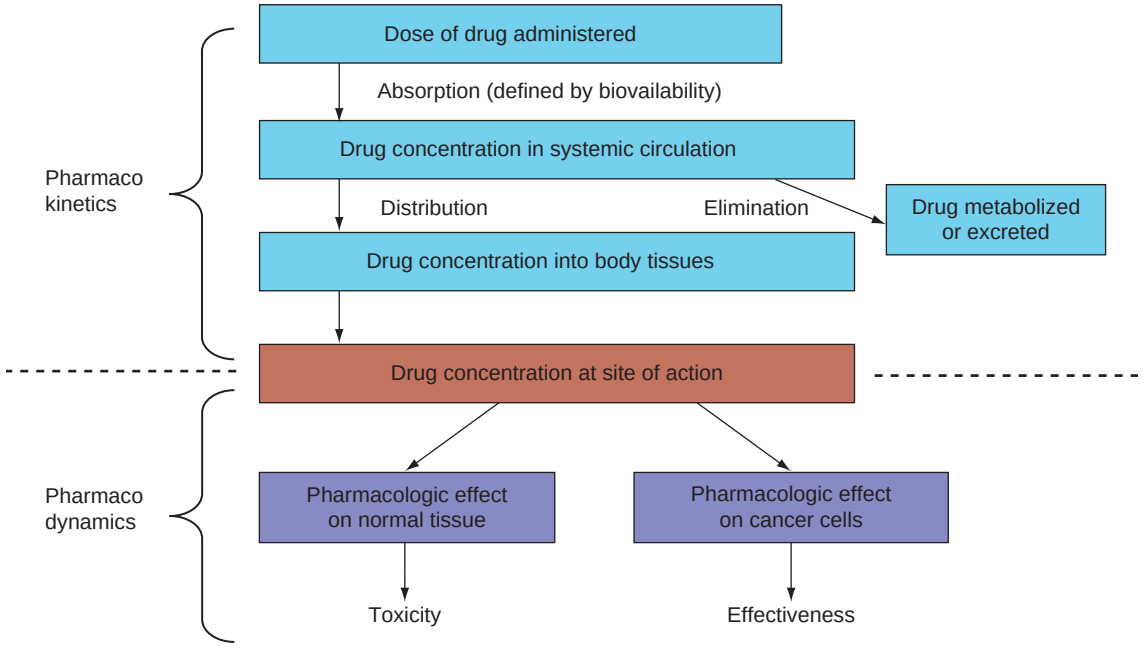

FIGURE 68.7. Pathway of a drug administered to a patient. Pharmacokinetics describes what the patient's body does to a drug. Pharmacodynamics describes what the drug does to the patient's tissues or cancer cells.

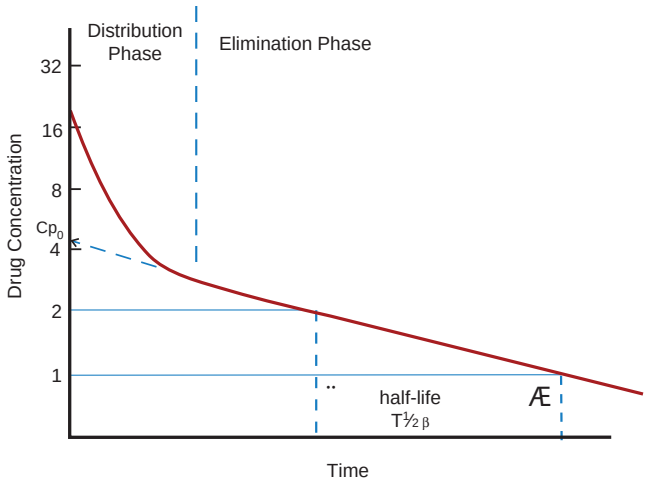

FIGURE 68.8. Plasma concentrations of a typical drug at various times following intravenous administration. Following an early distribution phase, drug concentrations decrease in a log-linear manner. Cp0 is the hypothetical drug plasma concentration at time zero if equilibrium were achieved instantaneously. The drug's half-life is the time required for its concentration to decrease by half.

TABLE 68.3

DRUGS REQUIRING DOSE ALTERATIONS FOR ORGAN TOXICITY

Nephrotoxicity	Hepatic Toxicity
Arsenic trioxide	Bortezomib
Bleomycin	Cytarabine
Capecitabine	Daunorubicin[a]
Carboplatin[a]	Doxorubicin[a]
Cisplatin[a]	Docetaxel[a]
Cladribine	Epirubicin[a]
Cyclophosphamide (if CrCl < 20 ml/min)	Etoposide
Daunorubicin[a]	Everolimus
Deoxycoformycin	5 Fluorouracil
Etoposide	Idarubicin
Fludarabine	Imatinib
Hydroxyurea	Irinotecan[a]
Ifosfamide	Ixabepilone
Irinotecan	Nilotinib
Lenalidomide	Paclitaxel[a]
Methotrexate[a]	Procarbazine
Mithramycin	Temsirolimus
Mitomycin[a]	Vinblastine[a]
Nitrosoureas[a]	Vincristine[a]
Oxaliplatin (if CrCl < 20 ml/min)	Vinorelbine[a]
Pemetrexede	
Pentostatin	
Sorafenib	
Streptozocin	
Topotecan[a]	
Vandetanib	

[a]Major dose adjustment.

Fortunately, curative therapy, even for disseminated disease, is available for many hematologic malignancies, including Hodgkin and non-Hodgkin lymphomas, and acute and chronic leukemia. In some illnesses, such as chronic lymphocytic leukemia and low-grade lymphomas, curative therapy may not be available, but the disease is often indolent. A discussion of these illnesses and their natural histories can reassure patients and help them understand why chemotherapy is not being immediately initiated. If high-dose, aggressive curative chemotherapy is planned, patients and their families need to be aware of anticipated and potential toxicities.

The use of chemotherapy for treatment of an individual requires a detailed knowledge of the patient, including his or her medical and psychological status, specific knowledge of the drugs to be used, and the availability of appropriate laboratory and hospital support services. Combination chemotherapy (use of several drugs simultaneously) is usually employed and multiple cycles of drugs administered to achieve adequate tumor cell kill without life-threatening toxicity or the development of tumor cell resistance. Certain patient selection factors are important in planning treatment. Age alone is seldom a reason to exclude patients from chemotherapy.[46] However, age-related changes in organ function, including reduced marrow reserve, abnormal liver function tests, and decreased renal function, are commonly seen and may increase the risk of toxicity. The performance status of a patient (either Karnofsky or American Joint Committee on Cancer scale) usually correlates with response and tolerance to chemotherapy (Table 68.4).

The nutritional state of a patient is important. Malnourished patients with hypoalbuminemia may have increased toxicity when highly protein-bound drugs are used.[36]

Guidelines for dosing of chemotherapy drugs in obese patients have been developed.[47] Doses based on actual body weight are generally recommended, as myelosuppression is the same or less pronounced in the obese than the non-obese cancer patient given full-weight–based doses. Fixed dosing of carboplatin, vincristine, and bleomycin is appropriate. Altered organ function may eliminate the opportunity to use certain drugs (e.g., doxorubicin in patients with heart failure or bleomycin in patients with severe pulmonary toxicity). Drug doses may require modification for decreases in blood counts (Table 68.5) and also for changes in renal and hepatic function (see General Pharmacologic Principles).

It is common to re-evaluate patients after two to four cycles of chemotherapy to determine treatment effectiveness. If a response is seen, therapy is usually continued for a set number of courses or two cycles past a complete response. If tumor progression is noted, therapy should generally be discontinued. For patients with stable disease, an assessment of drug toxicity is important. If therapy is tolerable, a decision to continue treatment is reasonable, with the understanding that disease progression will eventually occur. Physicians administering potentially toxic chemotherapy must make certain that they have appropriate monitoring and support facilities available for their patients in the event of untoward toxicity.

DRUGS USED TO TREAT CANCER

A comprehensive review of the pharmacology of all chemotherapeutic agents is beyond the scope of this chapter. This section focuses on those agents most commonly used in the therapy of hematologic malignancies. Important information necessary for the optimal use of these drugs requires knowledge of their (a) mechanism of action; (b) pharmacology, including bioavailability, routes of elimination, and important drug interactions; and (c) toxicities. Table 68.6 summarizes this information for the majority of antineoplastic agents. A more detailed review of the agents commonly used to treat hematologic malignancies follows.

TABLE 68.4

KARNOFSKY AND AMERICAN JOINT COMMITTEE ON CANCER (AJCC) PERFORMANCE STATUS SCALES

Karnofsky Description	Karnofsky Scale (%)	AJCC Scale	AJCC or ECOG Description
Normal; no complaints; no evidence of disease	100	0	Normal activity
Able to carry on normal activity; minor signs or symptoms of disease	90		
Normal activity with effort; some signs or symptoms of disease	80	1	Symptomatic and ambulatory; cares for self
Cares for self; unable to carry on normal activity or to do active work	70		
Requires occasional assistance but is able to care for most of own needs	60	2	Ambulatory >50% of time; occasionally needs assistance
Requires considerable assistance and frequent medical care	50	3	Ambulatory 50% or less of time; nursing care needed less of time
Disabled; requires special care and assistance	40		
Severely disabled; hospitalization indicated although death not imminent	30		
Very sick; hospitalization necessary; active supportive treatment necessary	20	4	Bedridden; may need hospitalization
Moribund, fatal processes progressing rapidly	10		
Dead	0		

Alkylating Agents (Actinomycin-D, Bendamustine, Busulfan, Chlorambucil, Cyclophosphamide, Dacarbazine, Hexamethylmelamine, Ifosfamide, Melphalan, Mechlorethamine, Mitomycin C, Nitrosoureas (BCNU, CCNU), Procarbazine, Streptozocin, Temozolomide, Thiotepa)

Mechanism of Action

Alkylating agents covalently bind alkyl groups (one or more saturated carbon atoms) to cellular molecules, including DNA, RNA, and proteins. Alkylating agents form reactive carbonyl groups in plasma and within tissues. Attack at electron-rich sites on adenine or guanine (S_N 1 agents) in DNA is the primary mechanism for cytotoxicity.[48] The pattern of DNA lesions generated by an alkylating agent depends on the number of reactive sites within the alkylating agent, its particular reactivity, the type of alkyl group addition (methyl or chloroethyl) and the DNA substrate (double- or single-strand). Many alkylating agents (bendamustine, chlorambucil, cyclophosphamide, ifosfamide, mustard, melphalan) contain two reactive nitrochlorethyl groups, which allow them to react with both strands of DNA, forming cross-linkage (Fig. 68.9). Other agents (procarbazine, dacarbazine, temozolomide) produce single-strand alkylation. Most alkylators preferentially attack the N^7 position of guanine. Nitrosoureas, procarbazine, and dacarbazine (DTIC) attack the 0^6 position. Depending on the site of DNA binding, the base adducts produced by alkylating agents block DNA replication and transcription, leading to cell death. However, alkylating agents may also compromise genome integrity, inducing mutagenesis. Alkylating agents are cell cycle–nonspecific.

There are multiple enzymes that have been identified that can repair the genomic damage caused by alkylating agents.[48] An example is the repair of alkylation sites on DNA by 0^6 methyl transferase; the overexpression of this enzyme in a cancer cell produces resistance to nitrosoureas but not to nitrogen mustard or cyclophosphamide.[49] An imbalance of any one repair enzyme can increase or decrease the alkylation sensitivity of a cell. Inhibitors of DNA-repair enzymes (such as Poly ADP ribose polymerase or PARP) may increase cell sensitivity to alkylating agents.

The most widely used alkylating agents in hematology are the nitrogen mustards: mechlorethamine, cyclophosphamide, ifosfamide, melphalan, and chlorambucil. Thiotepa is an aziridine that is closely related to the mustards. Busulfan is an alkyl sulfonate that has a poorly understood selective toxicity for myeloid precursors. Procarbazine and DTIC are metabolized to reactive intermediates that decompose to produce methyl diazonium, which covalently binds DNA. The basis of cytotoxicity of these nonfunctional alkylating agents is probably the formation of DNA strand breaks and inhibition of DNA polymerase.[50] Bendamustine, a recently FDA-approved alkylating agent for treatment of chronic lymphocytic leukemia and lymphomas, regulates different genes compared to other alkylating agents.[51] It is not cross resistant with other alkylators and is effective against both quiescent and dividing cells. It produces more durable and extensive DNA double-stand breaks than do cyclophosphamide or melphalan.

Cellular thiols can provide nucleophilic targets, which bind alkylating agents before they reach their DNA target. Increasing or decreasing the concentration of thiols can decrease or increase antineoplastic drug activity and/or toxicity. Buthione sulfonamide (BSO) decreases glutathione synthesis (a naturally occurring thiol) and increases alkylating agent cytotoxicity.[52] Amifostine (WR2721) provides an exogenous nucleophilic thiol that can decrease alkylating agent toxicity.[53]

TABLE 68.5

GENERALIZED DOSE ADJUSTMENT GUIDELINES FOR HEMATOLOGIC TOXICITY[a]

	100% Dose	75% Dose	50% Dose	Omit
Granulocyte	>2,000	1,500–1,999	1,000–1,499	<1,000
White blood cell	>3,500	3,000–3,500	2,500–2,999	<2,500
Platelet	>100,000	75,000–100,000	50,000–75,000	<50,000

[a]In selected circumstances, such as the treatment of leukemia, these guidelines do not apply. Specific guidelines accompanying individual protocols should be sought.

TABLE 68.6

CHEMOTHERAPEUTIC AGENTS (EXCLUDING HORMONAL AGENTS)

Name (Synonym)	Drug Class	Action	Clearance Route[a]	Major Toxicity
Alemtuzumab (Campath®)	Radioactive monoclonal antibody	Binds to CD_{52} to target radioactivity	Radioactive extinction	Myelosuppression Hypersensitivity reaction Infection
Altretamine (Hexalen®, hexamethylmelamine)	Nonclassical alkylating agent	Unknown, may alkylate DNA	Hepatic metabolism	Hypersensitivity reaction, deficient synthesis of key proteins (clotting factors, insulin), CNS depression, pancreatitis
Anagrelide (Agrylin®)	Phospholipase inhibitor	Prevents megakaryocytes from maturing	Metabolism via CYP/A2	Palpitations, headache, nausea, abdominal pain, dizziness
Arsenic trioxide (Trisenox®, ATO)	Targeted drug	Degrades PML-RAR fusion protein	Hepatic metabolism	APL differentiation syndrome, Q–T prolongation, nausea, fatigue
Asparaginase (Elspar®, Oncaspar®, pegasparaginase)	Enzyme	Breaks down the amino acid asparagine; sensitive lymphocytes lack ability to synthesize asparagine	Hepatic metabolism	N&V, neurotoxicity, myelosuppression, diarrhea, diabetes, anticoagulation
Azacitidine (Vidaza®)	Hypomethylating agent	Inhibitor of DNA methylation	Hepatic metabolism	Myelosuppression
Bexarotene (Targretin®)	Retinoid	Binds to the retinoid X receptor to induce cellular differentiation	Oxidative hepatic metabolism	Hepatotoxicity, hyperlipidemia, hypothyroidism, photosensitivity, teratogenicity
Bendamustine (Trenda®)	Alkylating agent	Forms DNA cross-links	Hydrolysis in plasma to inactive metabolites	Nausea, fatigue, myelosuppression, fever
Bevacizumab (Avastin®)	Monoclonal antibody to VEGF	Decreases angiogenesis	Protein degradation	Hypertension, headache, bleeding, thrombosis, proteinurea
Bleomycin (Blenoxane®)	Antibiotic	Single-strand DNA breaks	Renal	Hypersensitivity reaction, pulmonary fibrosis, skin and mucocutaneous reactions, fevers
Bortezomib (Velcade®)	Proteosome inhibitor (targeted agent)	Inhibits protein destruction blocking NFK-β	Oxidative hepatic metabolism	Nausea, fatigue, diarrhea, peripheral neuropathy, thrombocytopenia
Brentuximab vedotin	Monoclonal antibody	Binds with CD30 antigen with toxin then internalized	Hepatic	Hypersensitivity reaction, neuropathy, fatigue, fever, diarrhea, neutropenia
Busulfan (Myleran®, Busulfex®)	Alkylating agent	Forms DNA cross-links.	Metabolism	Myelosuppression, hepatotoxicity (venoocclusive disease), pulmonary fibrosis
Capecitibine (Xeloda®)	Antimetabolite	A 5-FU prodrug	Hepatic metabolism	Diarrhea, myelosuppession, palmar-plantar erythrodysethesia
Carboplatin (CBDCA, Paraplatin®)	Platinum complex	Produces DNA cross-links	Renal	Thrombocytopenia, leukopenia, nephrotoxicity, ototoxicity, neuropathy, N&V
Carmustine (BCNU)	Nitrosourea	Alkylates DNA at O^6 position of guanine	Hepatic metabolism	Delayed (4–6 wk) myelosuppression, pulmonary toxicity, hepatotoxicity
Cetuximab (Erbitux®)	Monoclonal antibody	Binds to the epidermal growth factor receptor	Binding of antibody to receptor	Anaphylactic reaction, skin rash, fevers
Chlorambucil (Leukeran)	Alkylating agent	Cross-links DNA	Metabolism	Myelosuppression, pulmonary toxicity, hepatotoxicity
Cisplatin (CDDP) (Platinol®)	Platinum complex	Produces DNA cross-links	Protein binding	Nephrotoxicity, N&V, ototoxicity, alopecia, neuropathy
Cladribine (Leustatin™) (2-chlorodeoxy adenosine)	Antimetabolite (purine analog)	Incorporation into DNA; NAD consumption	Renal	Myelosuppression, fever, renal toxicity (high-dose)
Clofarabine (Clolar®)	Antimetabolite	Incorporates into DNA; inhibits DNA polymerase	Renal	Nausea, hepatotoxicity, palmar-plantar erythrodysesthesia
Cyclophosphamide (Cytoxan®, Neosar®)	Alkylating agent	Cross-links DNA strands	Hepatic metabolism (renal)	Myelosuppression, N&V, cystitis, cardiac (high-dose)
Cytarabine (Cytosar®, ara-C, cytosine arabinoside, DepoCyt™)	Antimetabolite (pyrmidine analog)	Incorporates into DNA; inhibits DNA polymerase	Hepatic metabolism	Myelosuppression, N&V, mucositis, ocular, hepatic

Name (Synonym)	Drug Class	Action	Clearance Route[a]	Major Toxicity
Dacarbazine (DTIC)	Nonclassical alkylating agent	DNA methylation	Renal (hepatic metabolism)	Vesicant, myelosuppression, N&V, hepatic
Dactinomycin (Cosmegen®) (actinomycin-D)	Antibiotic	DNA intercalation	Biliary	Myelosuppression, N&V, vesicant, mucositis
Dasatinib (Sprycel™)	Targeted agent, signal transduction inhibitor	Inhibits the tyrosine kinase of several growth factor receptors including bcr-abl	Hepatic metabolism (CYP 3A4) and biliary excretion	Fluid retention, N&V, diarrhea, myelosuppression, hypothyroidism
Daunorubicin (Cerubidine®, Dauno Xome®)	Antibiotic (anthracycline)	Topoisomerase inhibition, DNA intercalation, free-radical formation	Biliary excretion, hepatic metabolism	Myelosuppression, N&V, cardiomyopathy, vesicant, red urine, mucositis
Decitabine (Dacogen®)	Hypomethylating agent	Allows activation of tumor suppressor genes	Hepatic deamination	Myelosuppression, fatigue, nausea, teratogen
Denileukin diftitox (Ontak®)	Toxin-fusion protein	Binds to the IL-2 receptor, where the diphtheria toxin is internalized	Proteolytic degradation	Infusion reactions (fever, hypotension, myalgias), skin rash, transaminitis, vascular leak syndrome, hypothyroidism
Docetaxel (Taxotere®)	Tubulin binder	Mitotic spindle inhibitor	Hepatic metabolism, biliary excretion	Myelosuppression, hypersensitivity (steroids needed), fluid retention, neuropathy
Doxorubicin (Adriamycin®, Rubex®, Myocet™, Doxil®)	Topoisomerase inhibitor (Anthracycline)	Topoisomerase inhibition, free-radical formation	Biliary excretion, hepatic metabolism	Myelosuppression, N&V, cardiomyopathy, vesicant, red urine, mucositis
Epirubicin (Ellence™)	Topoisomerase inhibitor (Anthracycline)	Inhibits topoisomerase II	Hepatic metabolism and excretion	Nausea, vomiting, myelosuppression, cardiac toxicity
Erlotinib (Tarceva®)	Targeted agent	Inhibits the tyrosine kinase of the epidermal growth factor receptor	Hepatic oxidative metabolism	Skin rash, diarrhea
Etoposide (VePesid®, VP-16, Etopophos®, Toposar®, etoposide phosphate)	Topoisomerase inhibitor	Inhibits topoisomerase II	Renal (hepatic metabolism)	Myelosuppression, mucositis, hypersensitivity reaction
Everolimus (Affinitor®)	Targeted therapy	Blocks oncogenic pathway through m-TOR inhibition	Hepatic metabolism through CYP3A4	Edema, rash, stomatitis, diarrhea, myelosuppression, infection
Fludarabine (fludarabine phosphate, Fludara®)	Antimetabolite (purine analog)	Inhibits DNA polymerase, incorporation into DNA and RNA, NAD depletion	Renal	Myelosuppression, mucositis, hypersensitivity reaction, neurologic
Fluorouracil (5-FU, Adrucil®, FUDR®)	Antimetabolite (pyrimidine analog)	Inhibits thymidylate synthetase, incorporated into DNA and RNA	Hepatic metabolism	Myelosuppression (more with bolus), diarrhea & mucositis (more with continuous infusion), stomatitis, cardiac ischemia, CNS (cerebellar ataxia)
Gefitinib (Iressa®)	Targeted therapy	Block the tyrosine kinase of EGFR	Hepatic metabolism via CYP3A4	Rash, diarrhea
Gemcitabine (Gemzar®)	Antimetabolite	Inhibits ribonucleotide reductase, incorporated into DNA as false nucleotide	Metabolism	Myelosuppression, nausea, diarrhea, hepatic, fever
Hydroxyurea (Hydrea®, Droxia™, Mylocel™)	Antimetabolite	Inhibits ribonucleotide reductase	Hepatic metabolism, renal	Myelosuppression, mucositis
Idarubicin (Idamycin®)	Topoisomerase inhibitor (anthracycline)	Similar to doxorubicin	Hepatic	Similar to doxorubicin
Ifosfamide (Ifex®)	Alkylating agent	Cross-links DNA strands through alkyl groups	Hepatic metabolism, renal excretion.	Myelosuppression, N&V, neurologic, alopecia, cystitis (must be given with MESNA)
Imatinib mesylate (Gleevec™, STI-575)	Targeted agent	Inhibits the tyrosine kinase of the bcr-abl and c-kit oncogenes	Hepatic metabolism	Nausea, diarrhea, fluid retention, abnormal LFTs, hypothyroidism
Interferon-α (INF-α, Intron A®, Roferon®)	Biologic	Degradation of messenger RNAs, modulation of oncogene expression, increase in NK cells and other immunoregulatory elements	Renal metabolism	Fever, chills, myalgias, headache, fatigue, anorexia, myelosuppression, hepatic, CNS, depression
Ibritumomab (Zevalin™)	Monoclonal antibody	Antibody to CD20 coupled to Y^{90}	Radioactive decay	Myelosuppression, allergic reactions, hypothyroidism
Irinotecan (Camptosar®, CPT-11)	Topoisomerase I inhibitor	Inhibits topoisomerase I	Metabolism, biliary excretion	Myelosuppression, diarrhea, pneumonitis, stomatitis

(*Continued*)

TABLE 68.6

CHEMOTHERAPEUTIC AGENTS (EXCLUDING HORMONAL AGENTS) (CONTINUED)

Name (Synonym)	Drug Class	Action	Clearance Route[a]	Major Toxicity
Lenalidomide (Revlimid®)	Immunomodulator	Uncertain—possible TNF-α inhibitor; inhibits angiogenesis	Renal	Teratogenicity, myelosuppression, DVTs, diarrhea, fatigue
Lomustine (CeeNU®, CCNU)	Alkylating nitrosourea	Same as carmustine	Same as carmustine	Same as carmustine
Mechlorethamine (nitrogen mustard, Mustargen®)	Alkylating agent	Cross-links DNA via alkylation	Tissue binding	Vesicant, ototoxicity, myelosuppression, N&V
Melphelan (Alkeran®, L-PAM, phenylalanine mustard)	Alkylating agent	Cross-links DNA strands via alkylation	Spontaneous degradation, protein binding	Myelosuppression, pulmonary fibrosis (rare), N&V (high-dose)
Mercaptopurine (6-MP, Purinethol®)	Antimetabolite (purine analog)	Incorporation into DNA	Hepatic metabolism	Myelosuppression, hepatotoxicity
Methotrexate (MTX)	Antimetabolite (folic acid analog)	Inhibits dihydrofolate reductase with decreased thymidylate and protein synthesis	Renal excretion	Myelosuppression, mucositis, hepatotoxicity (chronic low-dose), renal (high-dose), pulmonary
Mitomycin (Mutamycin®)	Antibiotic	Cross-links DNA strands	Hepatic metabolism	Myelosuppression, N&V, vesicant, pulmonary, hepatic, renal
Mitoxantrone (Novantrone®, DHAD)	Anthraquinone	Similar to doxorubicin	Hepatic metabolism	Similar to doxorubicin, blue-green urine
Nelarabine (Arranon®)	Antimetabolite (purine analog)	Incorporated into DNA and blocks DNA replication	Hepatic demethylation	Neurotoxicity including somnolence, fatigue, dizziness, headache, myelosuppression
Nilotinib (Tasigna®)	Targeted therapy	Inhibits the tyrosine kinase of BCR/ABL	Hepatic metabolism via CYP3A4	Myelosuppression, QT prolongation, N & V, hepatic toxicity, edema
Ofatumumab (Arzerra®)	Monoclonal antibody	Binds to CD20	Proteolytic degradation	Infusion reaction, infection, myelosuppression, HBV reactivation
Oxaliplatin (Eloxatin®)	Platinum complex	Produces DNA cross-links	Renal and tissue binding	Hypersensitivity reaction, neuropathy, hepatitis, pulmonary fibrosis
Paclitaxel (Taxol®, Abraxane®)	Plant alkaloid	Mitotic spindle inhibitor, stabilizes microtubulin.	Hepatic metabolism, biliary excretion	Myelosuppression, hypersensitivity syndrome (use with steroids and antihistamines), mucositis, neuropathy, myalgia
Panitumumab (Vectibix™)	Monoclonal antibody	Binds to EGFR	Proteolytic degradation	Rash, infusion reaction, diarrhea
Pazopanib (Votrient®)	Targeted agent	Inhibits the TKI of VEGF receptors	Hepatic metabolism via CYP3A4	Hypertension, hair color change, diarrhea, myelosuppression, QT prolongation, hepatotoxicity
Pemetrexed (Alimta®)	Antimetabolite	An antifolate that inhibits dihydrofolate reductase, and thymidylate synthetase	Renal	Myelosuppression, fatigue, N&V
Pentostatin (Nipent®, 2-deoxycoformycin)	Antimetabolite (purine analog)	Adenosine deaminase inhibitor.	Renal	Myelosuppression, fever, rash, hepatotoxicity, pulmonary, CNS
Prelatrexate (Folotyn®)	Antimetabolite	Inhibits DHFR (see methotrexate)	Renal	Myelosuppression, mucositis
Procarbazine (Matulane)	Nonclassical alkylating agent	Alkylates DNA; DNA strand breaks	Hepatic metabolism	Myelosuppression, N&V, CNS (confusion, depression), MAO inhibition, hepatic, pulmonary
Rituximab (Rituxan®)	Monoclonal antibody	Binds to CD20 on lymphocytes and initiates complement-mediated cytotoxicity	Proteolytic degradation	Fevers, hypersensitivity reaction, Hepatitis B reactivation, infection
Sorafenib (Nexavar®)	Targeted therapy	Inhibits the tyrosine kinase of VEGER, PDGFR, c-kit, and FLT-3	Heptic metabolism: Oxidation and glucuronidation	Fatigue, palmar-plantar erythrodysethesia, hypertension, hyperphosphatemia, rash proteinuria
Streptozocin (Zanosar®)	Alkylating nitrosourea	Methylation of O^6-guanine of DNA	Renal	Myelosuppression, N&V, renal, diabetes, vesicant
Sunitinib (Sutent®)	Targeted therapy	Inhibits the tyrosine kinases of VEGFR, PDGFR, c-kit; inhibits angiogenesis	Hepatic oxidative metabolism	Hypertension, bleeding, diarrhea, mucositis, fatigue
Temozolomide (Temodar®)	Atypical alkylating agent	Methylates DNA guanine resulting in strand breaks	Metabolism by hydrolysis	Myelosuppression, N & V, fatigue
Teniposide (VM-26, Vumon®)	Microtubulin inhibitor	Binds to topoisomerase II, causing DNA strand breaks	Hepatic metabolism	Myelosuppression, hypersensitivity reactions

Name (Synonym)	Drug Class	Action	Clearance Route[a]	Major Toxicity
Temsirolimus (Torisel®)	Targeted agent	Inhibits m-TOR	Hepatic metabolism and biliary excretion	Edema, hyperlipidemia, myelosuppression, hepatic toxicity, hyperglycemia
Thalidomide (Thalomid®)	Immunomodulatory agent	Suppresses TNF, blocks angiogenesis, increases IL2 and interferon	Nonenzymatic hydrolysis	Birth defects, thrombosis, fatigue, somnolence, neuropathy
Thioguanine (6-thioguanine, 6-TG, Tabloid®)	Antimetabolite (purine analog)	Incorporates into DNA as fraudulent nucleotide	Hepatic metabolism	Myelosuppression, hepatic venoocclusive disease
Thiotepa (Thioplex®)	Alkylating agent	Trifunctional alkylating agent, cross-links DNA	Metabolism	Myelosuppression, stomatitis
Topotecan (Hycamtin®)	Topoisomerase I inhibitor	Inhibits the enzyme topoisomerase I, causing DNA stand breaks	Renal	Myelosuppression, N&V
Tositumomab (Bexxar®)	Monclonal antibody	Radioactive drug that binds to CD20	Proteolytic degradation	Myelosuppression, fever, nausea, hypersensitivity reaction
Trastuzumab (Herceptin®)	Monoclonal antibody	Binds to the $Her2^{neu}$ oncogene, resulting in apoptosis	Protein binding and proleotytic degradation	Hypersensitivity reaction, cardiomyopathy, fever, diarrhea
Tretinoin (ATRA, Vesanoid®)	Targeted retinoid therapy	Induces maturation of promyelocytes	Hepatic oxidative metabolism and glucuronidation	Fever, dyspnea, pulmonary infiltrates (retinoic acid symdrome), headache, fever, neurologic, hepatic
Venmurafanib (Zelboraf®)	Targeted agent	Inhibits the tyrosine kinase of the BRAF oncogene	Hepatic metabolism	Rash, erythema, squamous cell skin cancers, photosensitivity, abnormal LFTs, fatigue
Vinblastine (Velban®, VLB)	Microtubulin inhibitor	Binds to tubulin, prevents formation of mitotic spindle	Hepatic	Myelosuppression, vesicant, neurotoxin
Vincristine (Oncovin®, Vincasar®, VCR)	Microtubulin inhibitor	Binds to tubulin, prevents formation of mitotic spindle	Hepatic	Neurotoxin, vesicant, CNS
Vinorelbine (Navelbine®)	Microtubulin inhibitor	Binds to tubulin, prevents formation of mitotic spindle	Hepatic	Myelosuppression, vesicant, neuropathy
Vismodegib (Erivedge®)	Targeted agent	Inhibits the Hedgehog signaling pathway	Hepatic metabolism and excretion	Teratogenic, fatigue, muscle spasms, diarrhea, alopecia
Vorinostat (Zolinza®)	Histone deacytlase inhibitor	Inhibits histone deacytelase to unmask DNA methylation	Hepatic	Fatigue, diarrhea, N&V pulmonary emboli

Clinical Pharmacology

Binding of alkylating agents or their reactive intermediates to sulfhydryl groups on glutathione or proteins is the primary route of drug clearance. Dosage alterations for hepatic or renal function impairment are usually not needed. Mechlorethamine rapidly degrades in solution and must be reconstituted just before administration. Cyclophosphamide and ifosfamide require activation via the cytochrome P-450 system to produce 4-hydroxy derivatives, which are taken up in tumor tissue[54] and decompose to form the active metabolite, phosphoramide mustard (Fig. 68.10). Drugs that alter the microsomal enzyme system, such as phenobarbital, can alter the plasma kinetics of cyclophosphamide and its metabolites. However, these kinetics changes do not appear to affect the toxicity of this drug. Ifosfamide, a structural analog of cyclophosphamide, is activated less readily than cyclophosphamide, so higher drug doses are required.[55] Although only a small amount of a dichlorethyl metabolite is formed with cyclophosphamide,

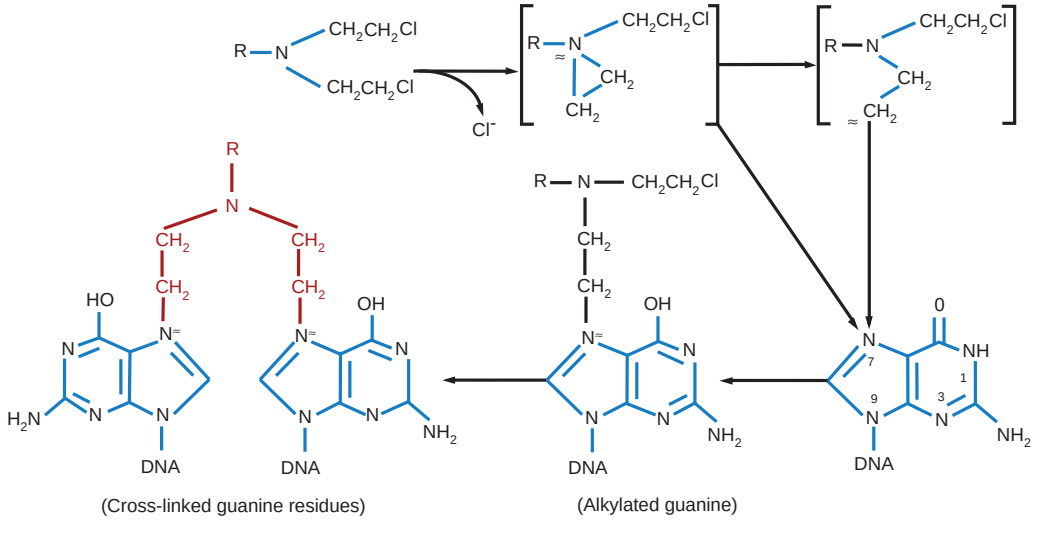

FIGURE 68.9. Mechanism of attachment of alkylating agents to DNA. Alkylating agents (in this case, those with two nitrochloroethyl groups) form reactive intermediates that bind to the N7 position of guanine. Bifunctional alkylating agents can bind to two guanine molecules, resulting in cross-linkage of DNA strands.

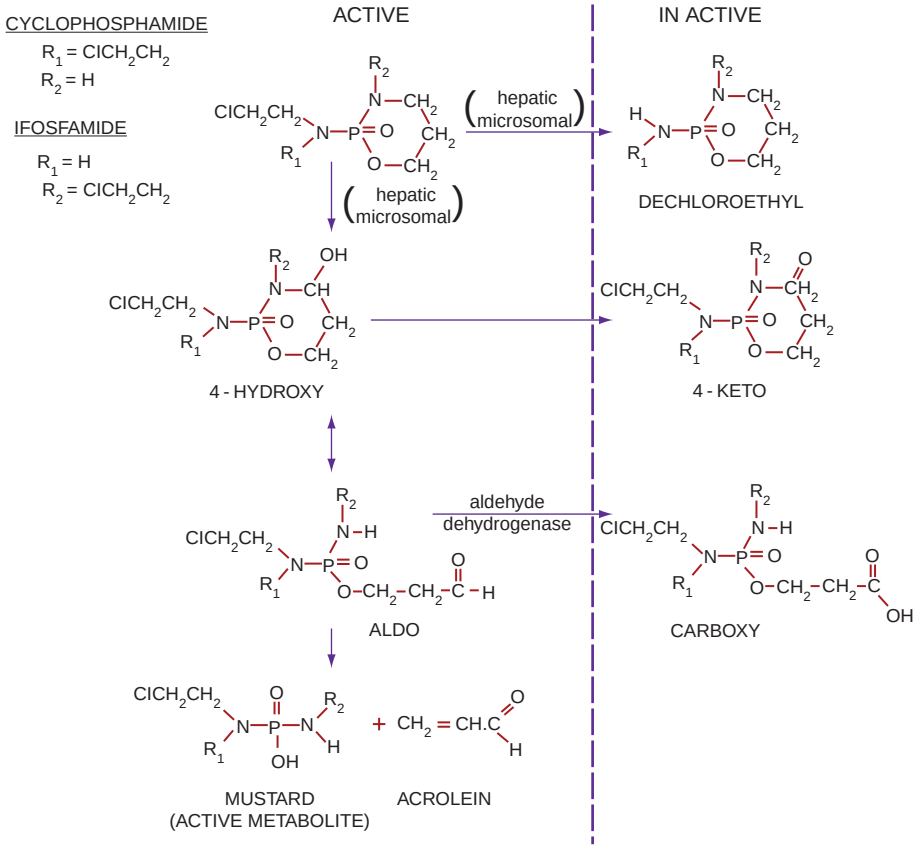

FIGURE 68.10. Metabolism of cyclophosphamide and ifosfamide. These drugs can be metabolized to the active agents (vertical metabolism) or to inactive metabolites (horizontal metabolism).

this metabolite is generated to a significant extent with ifosfamide and may account for the central nervous system (CNS) toxicity seen with this drug. The release of acrolein and dichlorethyl metabolites into the bladder results in cystitis with both cyclophosphamide and ifosfamide. Mercaptoethane sulfonate (MESNA) is administered to all patients receiving ifosfamide and to patients receiving high-dose cyclophosphamide. MESNA binds to reactive urinary metabolites of these alkylating agents and prevents cystitis.[56] In plasma, MESNA circulates in an inactive dimesna form so that antineoplastic activity is not altered. Oral bioavailability of cyclophosphamide is excellent, whereas the bioavailability of melphalan (30%) and chlorambucil (50%) are reduced and variable. The AUC of melphalan is reduced by concomitant use of cimetidine.[57]

Toxicity

Although alkylating agents share a common mechanism of action, toxicity of alkylating agents varies significantly because of differences in pharmacokinetics, lipid solubility, membrane transport properties, and the presence of specific DNA-repair mechanisms. Marrow suppression occurs in all hematopoietic cell types. However, the pattern of suppression varies from drug to drug. A relative platelet- and stem cell–sparing effect occurs with cyclophosphamide. In contrast, busulfan is especially damaging to stem cells. The hematopoietic depression produced by the nitrosoureas is delayed (3 to 6 weeks). Nausea and vomiting are frequent with high doses of alkylators, but decrease with low-dose oral regimens. Alopecia is seen primarily with cyclophosphamide. Pulmonary fibrosis can be seen with all alkylating agents, but particularly with busulfan and the nitrosoureas.[58] Bladder toxicity is seen with ifosfamide and cyclophosphamide. Hepatic toxicity is noted with high-dose thiotepa, cyclophosphamide, busulfan, or BCNU therapy used in stem cell transplant regimens.[59] Ifosfamide, busulfan, and the nitrosoureas cause CNS toxicity, more frequently at high doses.[60] Renal toxicity is seen with the nitrosoureas and ifosfamide.[61] High-dose cyclophosphamide produces water retention. All of the alkylating agents result in gonadal atrophy, and permanent loss of reproductive function can occur.[62] All alkylating agents are teratogenic and carcinogenic. An increased risk of second cancers (usually acute myelogenous leukemia) has been reported with melphalan, procarbazine, and cyclophosphamide.

Antimetabolites (Azathioprine, Cladribine, Clofarabine, Cytarabine, Fludarabine, Gemcitabine, Hydroxyurea, Mercaptopurine, Methotrexate, Pentostatin, Thioguanine)

Antimetabolites prevent the synthesis of molecules required for DNA synthesis. Antimetabolites are cell cycle–specific agents that must be present during the S-phase of the cancer cell cycle for cytotoxicity. The schedule of drug administration is very important with these agents. Many antimetabolites are prodrugs that require metabolism to an active molecule. The pharmacology of selected antimetabolites most frequently used in the treatment of hematologic malignancies is reviewed in the following.

Methotrexate and Pralatrexate (Folotyn®)

Mechanism of Action

MTX, an analog of folic acid (Fig. 68.11), and pralatrexate are tight-binding inhibitors of DHFR, the enzyme required for converting folate to its active (tetrahydrofolate) form.[63] In the presence of MTX, tetrahydrofolates, needed as cofactors for purine and thymidine formation, are depleted, leading to inhibition of DNA synthesis and subsequent cell death. Cytotoxicity is related to the time MTX or MTX polyglutamate is present within the cell at

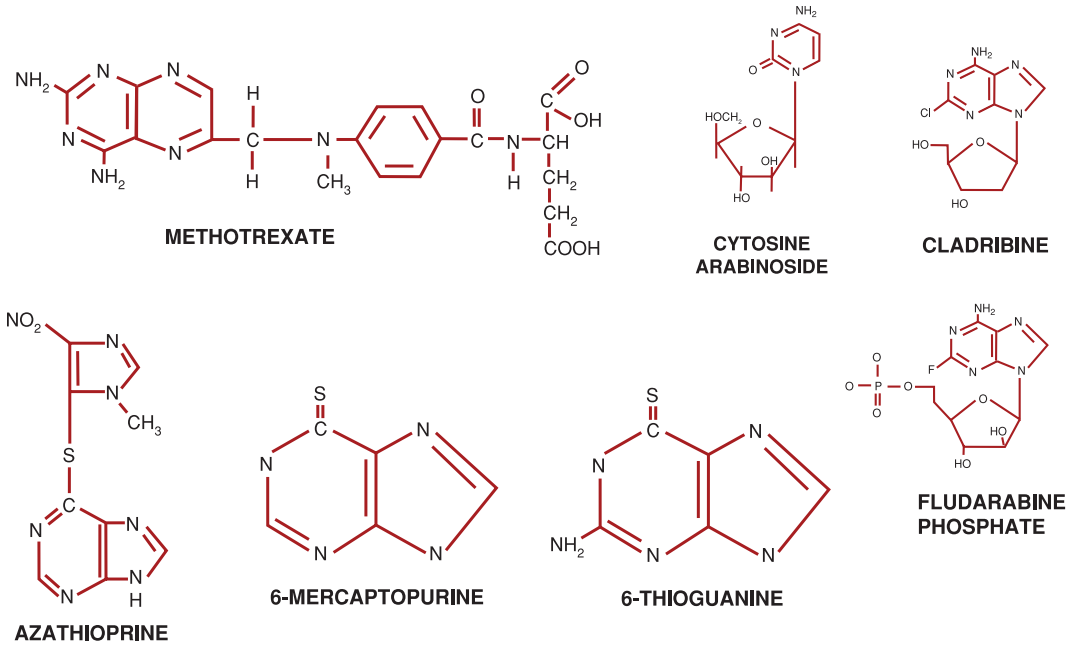

FIGURE 68.11. Structures of selected antimetabolites used for treatment of hematologic malignancies.

concentrations great enough to inhibit DHFR.[64] 5-Formal tetrahydrofolate (calcium leucovorin or citrovorum factor), administered 24 hours after the administration of MTX, can rescue normal cells from the effects of MTX by providing a reduced form of folic acid to the cells. Resistance to MTX has been related to the presence of increased levels of the target enzyme, DHFR, as the result of increased expression or amplification of the DHFR gene.

Clinical Pharmacology

MTX can be given orally, intravenously, or by intrathecal injection. With standard oral doses (7.5 to 20 mg/m^2), absorption is variable, with bioavailability decreasing at higher doses.[65] MTX is primarily eliminated by glomerular filtration and renal tubular secretion. In patients with renal dysfunction, MTX clearance is delayed, resulting in prolonged exposure and increased toxicity.[66] Patients with renal insufficiency should not be given MTX or must have plasma drug concentrations closely monitored, with leucovorin rescue employed if clearance is delayed. Retention of drug in ascites or pleural effusions can prolong MTX half-life and increase toxicity.[37]

Toxicity

The primary toxicities associated with MTX are myelosuppression and mucositis.[63] High-dose MTX can result in renal failure as a consequence of drug precipitation in renal tubules in the presence of acidic urine. The routine use of adequate prehydration, alkalinization of the urine, and measurement of MTX concentrations is required with high-dose MTX therapy.[67] Chronic MTX administration can be associated with liver disease, manifested by portal fibrosis and occasional cases of cirrhosis.[68] MTX is also associated with the development of pulmonary toxicity.[69] CNS toxicity has been reported with MTX, particularly with high doses of MTX and concomitant cranial irradiation. Intrathecal MTX administration may cause arachnoiditis.[70]

Pyrimidine Analogs (Cytosine Arabinoside [ara-C and Liposomal ara-C], Gemcitabine, 5-Azacytidine, Decitabine)

The drugs listed above are all analogs of the naturally occurring pyrimidine, cytosine. Gemcitabine is occasionally used as third-line therapy for lymphomas but will not be further discussed. 5-Azacytidine and decitabine, although cytidine analogs, are believed to function through inhibition of histone deacetylase (HDAC) and will be discussed in a later section.

Mechanism of Action

Cytosine arabinoside (ara-C, cytarabine, liposomal ara-C, or DepoCyt™) is an analog of deoxycytidine with substitution of an arabinose sugar for the normally occurring deoxyribose sugar (Fig. 68.11). Once it enters a cell, ara-C must undergo metabolic activation to cytosine arabinoside triphosphate by a series of enzyme-mediated phosphorylation steps (Fig. 68.12). Cytosine arabinoside triphosphate competitively inhibits DNA polymerase-α. Cytosine arabinoside triphosphate is also incorporated into DNA, a feature that correlates closely with cytotoxicity. Incorporated ara-C inhibits both DNA template function and chain elongation.[71] Ara-C–mediated DNA damage then induces apoptosis. Several mechanisms of resistance to ara-C have been described, including: (a) deletion of deoxycytidine kinase, the initial enzyme involved in ara-C activation; (b) increased levels of cytidine deaminase in tumor cells, resulting in rapid conversion of ara-C to inactive uracil arabinoside; and (c) decreased presence of nucleoside transport sites on tumor cells.

Clinical Pharmacology

Ara-C is rapidly converted to the inactive metabolite, ara-U, by the degradative enzyme, cytidine deaminase, present in the liver. The large capacity of the liver for metabolizing ara-C results in (a) a short plasma half-life of ara-C (2 to 3 hours), (b) adequate capacity for clearance of ara-C even in the presence of hepatic damage,

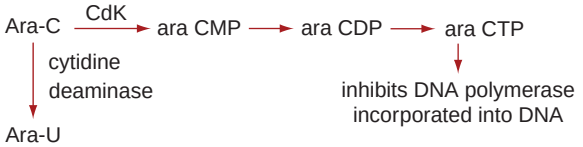

FIGURE 68.12. Metabolism of cytosine arabinoside (ara-C) by tumor cells. Ara-C is phosphorylated to its active metabolite, cytosine arabinoside triphosphate (ara-CTP), by a series of enzymatic steps, beginning with deoxycytidine kinase (CdK). Metabolism via the enzyme cytidine deaminase converts ara-C to the inactive metabolite, uracil arabinoside (ara-U).

and (c) urinary excretion of high concentrations of ara-U.[72] Because of the short drug half-life and the S-phase specificity of ara-C, prolonged infusion or multiple-day administration schedules are required for cytotoxicity. Cytarabine encapsulated into multivesicular lipid-based capsules (DepoCyt™) has been developed as a means of sustaining cytotoxic ara-C concentrations at the tumor site. Liposomal ara-C acts as a depot form of ara-C and has been found useful in the therapy of neoplastic meningitis.[73]

Toxicity

Single high-dose boluses of ara-C are well tolerated but clinically ineffective because of the rapid inactivation of the agent. Continuous infusion or repeated administration of ara-C for 24 to 48 hours results in significant myelosuppression.[74] Nausea, vomiting, and diarrhea may occur after ara-C administration, especially with high-dose regimens. These symptoms typically subside quickly after the treatment. High-dose ara-C regimens (doses of 3 g/m^2 every 6 to 12 hours for 8 to12 doses) have been associated with the development of cholestatic jaundice and elevations of hepatic transaminases. In addition, cerebral and cerebellar dysfunction has been reported in ~20% of patients receiving high-dose ara-C.[75] This toxicity is more common in patients >50 years of age and in patients with renal insufficiency. A steroid-responsive conjunctivitis noted after high-dose ara-C has led to the routine prophylactic use of saline or steroid eye drops in patients receiving the high-dose regimens. Intrathecal injection of liposomal ara-C is associated with chemical arachnoiditis (headache, fever, nausea, vomiting) which can be treated with steroids.

Hydroxyurea

Mechanism of Action

Hydroxyurea inhibits ribonucleotide reductase, the enzyme responsible for the conversion of ribonucleotide diphosphates to the deoxyribonucleotides required for DNA synthesis and repair.[76] Hydroxyurea kills cells selectively in the S-phase of the cell cycle. Doses of 0.5 to 2.0 g/day result in a rapid (2 to 5 days) decrease in peripheral white blood counts. The rapid onset of effect on circulating leukemia cell populations and the brief duration of action have led to the routine use of this agent in patients with significantly elevated leukemic blast counts or in those with elevated platelet counts.[77]

Clinical Pharmacology

Hydroxyurea is well absorbed orally (90% to 100% bioavailability), with minimal patient-to-patient variability.[78] It is excreted primarily in the urine with a plasma half-life of 4 hours.[79] Although precise guidelines are not available, patients with renal failure should have drug doses reduced.

Toxicity

Hydroxyurea's primary toxicity is myelosuppression.[80] Myelosuppression occurs 2 to 5 days following drug administration and is generally not severe. Reversal of myelosuppression is rapid following discontinuation of drug. Nausea, vomiting, anorexia, and diarrhea can be seen, but are typically mild. Uncommon toxicities include pulmonary fibrosis, hepatotoxicity, fever, and leg ulceration.

Purine Antimetabolites (6-Mercaptopurine, 6-Thioguanine, Azathioprine, Nelarabine, Cladribine, Clofarabine, Fludarabine)

6-Mercaptopurine, 6-thioguanine, azathioprine, nelarabine, cladribine, clofarabine, and fludarabine are all purine nucleoside analogs used in therapy of hematologic malignancies. The first four are guanine analogs, while the last three are analogs of adenine. All share many similarities. Nucleoside analogs are transported across cell membranes and phosphorylated to a triphosphate metabolite which is then incorporated into DNA. Once incorporated, nucleoside analogs interfere with DNA synthesis, lead to termination of DNA chain elongation, and inhibit DNA-repair mechanisms.[81] Similarities and differences among these drugs are reviewed below.

Mechanism of Action of Guanine Nucleotides

6-Mercaptopurine is used in maintenance therapy for children with acute lymphoblastic leukemia. 6-Thioguanine is a second-line agent for therapy of acute myelogenous leukemia. Azathioprine, a prodrug of 6-MP, is used as an immunosuppressant. Nelarabine (Arranon®) is approved for the treatment of relapsed T cell acute lymphoblastic leukemias (ALL) and lymphoblastic lymphomas. The mechanism of action of these three agents is similar. These nucleoside analogs enter cells, are converted to triphosphates, and incorporated into DNA where they terminate DNA synthesis. 6-MP is an analog of hypoxanthine (Fig. 68.11). It is converted to 6-MP ribose triphosphate, which is incorporated into DNA (Fig. 68.13). 6-Thioguanine is activated in a manner similar to that outlined for 6-MP. Azathioprine is rapidly cleaved by nonenzymatic mechanisms to 6-MP and methyl-4-nitro-5-imidazole derivatives. The imidazole derivatives react with thiol and cysteine residues. Alkylation of lymphocyte thiol groups may be important in inducing immunosuppression.[82] Ara-GTP, the active metabolite of nelarabine, is incorporated into T cell lines 20- to 40-fold more efficiently than into B cell lymphoblasts.[83]

Clinical Pharmacology of Guanine Nucleotides

Azathioprine is rapidly cleaved to 6-MP after absorption. Clearance of 6-MP occurs primarily through two routes of catabolism. 6-MP is oxidized to the inactive metabolite, 6-thiouric acid, by xanthine oxidase (Fig. 68.13). 6-MP also undergoes S-methylation by the enzyme thiopurine methyl transferase (TPMT) to yield less active 6-methyl mercaptopurine.[84] Oral absorption of 6-MP is incomplete and highly variable. The low bioavailability (5% to 37%) is a result of a large first-pass effect as drug is absorbed into the portal circulation and metabolized by xanthine oxidase in the liver. The use of concomitant allopurinol (an inhibitor of xanthine oxidase) increases 6-MP bioavailability fivefold, increasing toxicity.[85] This important drug interaction must be remembered for 6-MP and azathioprine. Patient-to-patient variation in TPMT activity can result in significant changes in 6-MP metabolism and in drug toxicity. One in 300 subjects has absent TPMT activity. Patients with low TPMT activity are susceptible to severe 6-MP– and azathioprine-induced myelosuppression.[86] Patients with high TPMT concentrations may be a higher risk for relapse as a result of rapid drug inactivation. Genetic testing for the TPMT gene is available. Nelarabine is a water-soluble prodrug of ara-G. Following intravenous administration, nelarabine is rapidly metabolized (<1 hour) by O-demethylation to ara-G, which is primarily transported into

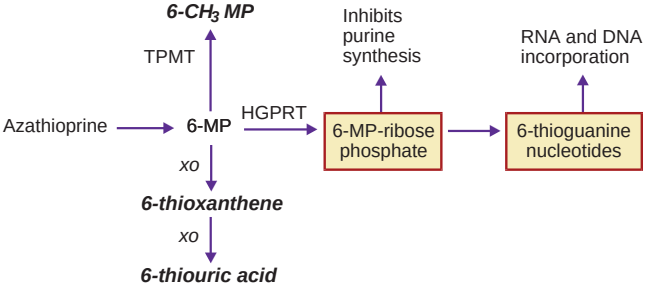

FIGURE 68.13. Mechanism of activation and catabolism of azathioprine and 6-mercaptopurine. Active metabolites are indicated by surrounding boxes. Inactive (or less active) metabolites are indicated by italic print. HGPRT, hypoxanthine-guanine phosphoribosyltransferase; TPMT, thiopurine methyltransferase; xo, xanthine oxidase.

lymphoblasts, phosphorylated, and incorporated into DNA.[83] A small amount of ara-G is cleared via the kidneys so that increased toxicity may be expected in patients with creatinine clearance less than 50 ml/min. As an adenosine deaminase inhibitor, pentostatin can reduce conversion of nelarabine to ara-G, thereby reducing efficacy. Pentostatin and nelarabine should not be used in combination.

Toxicity of Guanine Nucleotides

The dose-limiting toxicity of 6-MP, 6-thioguanine, azathioprine, and nelarabine is myelosuppression, occurring 1 to 4 weeks following onset of therapy and reversible when the drugs are discontinued.[83,84] Immunity to infectious agents or vaccines is subnormal. Gastrointestinal mucositis and stomatitis are modest but appear to be more common in adults than in children. Hepatotoxicity, seen in a small number of patients receiving 6-MP, is usually mild and reversible, with a clinical picture of cholestatic jaundice, although elevations of transaminases may be seen.[87] Frank hepatic necrosis and venoocclusive disease can occur. 6-MP and azathioprine are potentially teratogenic. Neurologic events (seizures, peripheral neuropathy) have been associated with nelarabine use.

Mechanism of Action of Adenine Nucleosides (Fludarabine, Cladribine, Clofarabine)

Fludarabine (Fludara®) (Fig. 68.11) is a fluoridated analog of 9-β-D-arabinofuranosyladenine (ara-A) used to treat CLL and refractory indolent lymphomas. When administered, fludarabine is dephosphorylated in plasma, enters cells, and then is again phosphorylated to 2-fluoro-ara-ATP (Fig. 68.14).[88] F-ara-ATP inhibits DNA polymerase, ribonucleotide reductase, DNA primase, and DNA ligase I, resulting in DNA deletions and mutations.[89] Fludarabine is also incorporated into DNA, where it is an effective DNA chain terminator. Cladribine (Leustatin® or 2-chlordeoxyadenosine, 2CdA), an adenosine analog found to be more cytotoxic to lymphocytes than fludarabine, is used to treat hairy cell leukemia. The 5′-triphosphate metabolite (2-chloro-2′-deoxyadenosine 5′-triphosphate, 2-CdATP) accumulates in cells that are rich in deoxycytidine kinase, primarily lymphoid cells. 2-CdATP is incorporated into DNA, producing DNA strand breaks and inhibition of DNA synthesis in dividing cells.[90] Clofarabine, 2-chloro-9(2-deoxy-2-fluoro β-D arabinosyl) 9H purine-6 amine, is similar in structure to cladribine with the addition of a fluorine at the 2-carbon position of the sugar moiety.[91] The addition of the fluorine molecule increases resistance to the cleavage of the glycosidic bond compared to cladribine. As with cladribine and fludarabine, clofarabine is phosphorylated intracellularly to the active triphosphate form. Clofarabine triphosphate inhibits DNA synthesis though its inhibitory action on ribonucleotide reductase and DNA polymerase. Clofarabine is approved for treatment of refractory ALL and AML.

Although the effects of F-ara-A and 2CdA on DNA synthesis account for their activity in dividing cells, these nucleosides are also cytotoxic to cancers with very low growth fractions, such as indolent lymphomas. Although the specific mechanism by which they induce cell death among quiescent cells is still under investigation, several proposed mechanisms of action include the ability to inhibit RNA polymerase and to deplete nicotinamide adenine dinucleotide (NAD), with resultant decrease in cellular energy stores and interference with normal DNA-repair processes.[92]

Clinical Pharmacology of Adenine Nucleosides

Fludarabine undergoes rapid (2 to 4 minutes) conversion to 2F-ara-A. 2-F-ara-A is excreted primarily in the urine, with few metabolites noted. In patients with renal function impairment, clearance of 2-F-ara-A decreases significantly.[89] Dose reduction is recommended for patients with renal dysfunction. Oral bioavailability is ~75%. Bioavailability of subcutaneously administered cladribine is excellent. Oral bioavailability averages 50%.[93] Cladribine is cleared primarily by the kidneys (50% of total dose) via a cation organic carrier system. Although dose adjustment guidelines for patients with renal insufficiency are not available, caution should be used in giving cladribine to patients with renal failure. Significant patient-to-patient variability (+/–28%) exists in the AUC achieved following administration of drug by any method.[94] Roughly 50% of an administered clofarabine dose is excreted unchanged in the urine within 24 hours. This suggests that dose alteration will be needed for renal insufficiency, but studies in patients with renal failure have not been completed. The drug half-life is 5.2 hours.

Administration of clofarabine prior to cytarabine increases intracellular accumulation of ara-CTP in AML blasts.[95]

Toxicity of Adenine Nucleosides

The dose-limiting toxicity of fludarabine is myelosuppression occurring a median of 12 to 16 days after beginning therapy. Cytopenias may be prolonged.[96] Other toxicities include mild nausea and vomiting (36% of patients), fever (60%), infection (33%), peripheral sensorimotor neuropathy (rare), autoimmune hemolytic anemia (rare), and hepatocellular toxicity with elevations in serum transaminases (rare).[81,89] An irreversible neurotoxicity syndrome has occurred in patients receiving high doses (>40 mg/m^2/day for 5 days). Mild, reversible neurotoxicity has been seen at lower doses, with increased frequency and severity in older patients.[97] Pulmonary toxicity, characterized by fever, cough, hypoxia, and diffuse interstitial pneumonitis, has also been reported. Fludarabine is immunosuppressive and is associated with an increased risk of opportunistic infections.[98] CD4 and CD8 T-lymphocyte subpopulations drop to 150 to 200/mm^3 after therapy.

The dose-limiting toxicity of cladribine is myelosuppression. Grade 3 or 4 neutropenia occurs in half of treated patients at standard doses. Fever (>100°F) has been seen in two-thirds of patients, often beginning 5 to 7 days into therapy or during the period of neutropenia.[99] Cladribine suppresses CD4$^+$ lymphocytes. The CD4:CD8 ratio may remain depressed for up to 16 months after therapy, with associated opportunistic infections including *Candida* or *Aspergillus*.[98] After high-dose cladribine therapy (5 to 10 times the recommended therapeutic dose), renal failure and progressive irreversible motor weakness with paraparesis have been reported. Betticher et al.[100] have shown that

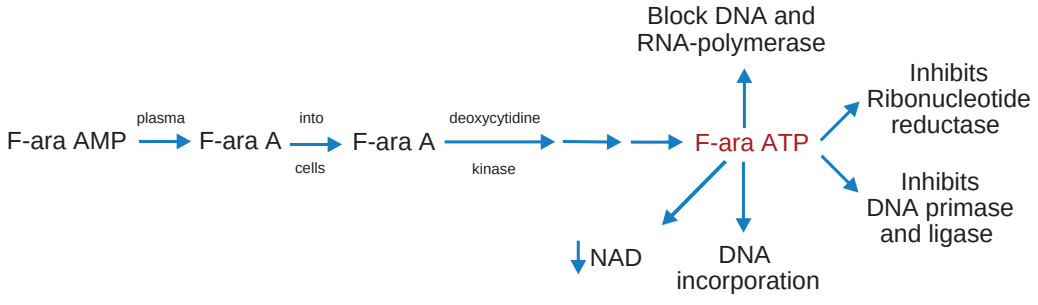

FIGURE 68.14. Activation pathway and mechanism of action of fludarabine.

reducing the dose of cladribine from 0.7 to 0.5 mg/kg per cycle decreases both the rate of grade 3 myelosuppression (33% to 8%) and the risk of infection (30% to 7%). No change in lymphoma response rate was noted with this dose reduction. The primary toxicity of clofarabine is myelosuppression leading to an increased risk of infection. Nausea and vomiting are seen but are generally mild. Severe reversible hepatic toxicity is noted in 15% to 40% of patients receiving clofarabine.[96,101]

Pentostatin

Mechanism of Action

Pentostatin (deoxycoformycin, DCF) is a potent inhibitor of adenosine deaminase. It is active in the treatment of chronic lymphoid malignancies, particularly hairy cell leukemia.[102] Inhibition of adenosine deaminase results in inability of the cell to catabolize adenosine and deoxyadenosine. Intracellular concentrations of deoxy-ATP increase and exert a negative feedback on ribonucleotide reductase, resulting in an imbalance in deoxynucleotide pools. This imbalance inhibits DNA synthesis and impairs replication, with arrest of cells in the G_1 and S phases of the cell cycle. The malignant cells of hairy cell leukemia and CLL have low levels of adenosine deaminase, making them particularly sensitive to the effects of pentostatin.[103]

Clinical Pharmacology

Plasma pentostatin concentrations greatly exceed those needed to inhibit adenosine deaminase. Pentostatin's terminal half-life is 3 to 15 hours in humans. Forty to 80% of the drug is excreted unchanged in urine within 24 hours.[104] Plasma clearance correlates with creatinine clearance. Dosage reduction should be considered for patients with impairment in renal function. Pentostatin is not bioavailable by the oral route, because of its acid lability.

Toxicity

At doses used in hairy cell leukemia (4 mg/m^2 biweekly), therapy is usually well tolerated.[105] Toxicities include worsening of neutropenia, mild to moderate lethargy, anorexia, rash, and reactivation of herpes zoster late in therapy. Nausea, although usually mild, can occasionally be severe. Delayed emesis is seen.

Histone Deacetylase Inhibitors (Vorinostat, Romidepsin) and Hypomethylating Agents (5-Azacytidine, Decitabine)

Eukaryotic DNA is organized in a macromolecular complex wrapped around histone proteins. Amino acid residues on the histone tail can be modified by acetylation and by methylation. These modifications change the structure of the histone-DNA complex. Histone acetyltransferases (HATs) are enzymes that acetylate histone molecules, resulting in opening of the chromatin, thereby allowing transcription factors access to DNA promoter regions. In contrast, HDACs remove acetyl groups from histone proteins, leading to condensation of DNA and inactivation of gene transcription.[106] Increased HDAC activity has been associated with a decrease in tumor suppressor gene expression, alterations in intrinsic and extrinsic apoptotic pathways, and decreased apoptosis. Romidepsin (Istodax®) and vorinostat (Zolinza®) are HDAC inhibitors approved for treatment of cutaneous T cell lymphomas.

Similarly, a large number of genes are silenced by methylation in some cancers. This methylation may block the gene promoter region of tumor suppressor genes.[107] 5-Azacytidine (Vidaza®) and decitabine (Dacogen®) are methyltransferase inhibitors which block the methylation of DNA with the hope of activating tumor suppressor genes. 5-Azacytidine and decitabine have been approved for treatment of MDS and are being used in AML.

Mechanism of Action

Vorinostat is a potent inhibitor of several HDACs (1, 2, 3, and 6), while romidepsin inhibits class 1 HDAC enzymes.[106,108,109] It is uncertain whether specificity of any HDAD inhibition impacts antineoplastic activity. Inhibition of HDAC induces genes that cause apoptosis or differentiation. Clinical studies have demonstrated hyperacetylation in tumor cells following vorinostat administration. However, no correlation between tumor acetylation status and response has been seen, suggesting that other mechanisms of action may impact on antineoplastic activity.[108] HDAC inhibitors also induce oxidative damage, have antiangiogenic effects, and disrupt cell cycle checkpoints. The specific mechanism of antineoplastic activity remains uncertain.

5-Azacytidine and decitabine (5-aza-deoxycitidine) are both nucleoside analogs. Like cytarabine, they undergo phosphorylation within the cell to a triphosphate form and then are incorporated into DNA. Once incorporated into DNA, these agents bind the enzyme DNA methyltransferase, inhibit methyltransferase activity, and result in DNA hypomethylation.[110] Hypomethylation reverses silenced tumor suppressor gene loci. The silenced genes may play an important role in terminal differentiation, apoptosis, or senescence of leukemic cells.[111]

Clinical Pharmacology

Vorinostat is available as an orally administered, 100-mg capsule that is generally given with food. Both vorinostat and romidepsin are primarily inactivated by metabolism (glucuronidation and hydrolysis) with metabolites excreted in the urine. Vorinostat has a short half-life (2 hours); despite the short plasma half-life, accumulation of acetylated histones continues for over 10 hours after administration.[106] Use of vorinostat or romidepsin in patients with renal or hepatic insufficiency has not been studied. However, since drug clearance is primarily via metabolism, dose adjustment for renal insufficiency is not thought to be needed.

Following IV or subcutaneous administration, decitabine and 5-azacytidine are rapidly inactivated by hepatic metabolism (primarily via the enzyme cytidine deaminase). There is little protein binding. The half-lives of 5-azacytidine and decitabine are 4 hours and 30 minutes, respectively. The drugs do not have oral bioavailability because of rapid decomposition in acidic solutions. Because of an association between the length of drug exposure with DNA methylation and the short half-life of these drugs, continuous treatment of azanucleosides over several days is recommended.[111] Dose adjustments for hepatic or renal insufficiency have not been studied but are unlikely to be needed.

Toxicity

The most common toxicities of HDAC inhibitors include nausea, vomiting, diarrhea, thrombocytopenia, anemia, and taste disorders. Dose-limiting side effects are generally thrombocytopenia and dehydration.[112] Pulmonary emboli have been reported in 4% to 5% of cancer patients receiving vorinostat. QT prolongation is noted with both vorinostat and romidespin.[106] The primary toxicity of decitabine and azacytidine is myelosuppression. Gastrointestinal toxicities, including nausea, vomiting, and constipation, are seen, usually transient in nature (1 to 4 days), and improve over time.[113]

Hormonal Therapies

A comprehensive review of all hormonal therapies is beyond the space limitation of this chapter. Of the several types of hormonal agents used in cancer therapy, corticosteroids are the class of drugs used to treat hematologic malignancies. Corticosteroids are also useful in managing complications of cancer, including chemotherapy-induced emesis, hypercalcemia, and increased

intracranial pressure. Prednisone and dexamethasone are synthetic glucocorticoids most commonly used in oncology. They are respectively 4- and 30-fold more potent than the naturally occurring glucocorticoid, cortisol. Prednisone and cortisol have roughly equivalent mineralocorticoid effects while dexamethasone lacks significant mineralocorticoid activity.

Mechanism of Action

Several cancers depend on specific hormones for growth and cellular integrity. Altering the hormonal balance can cause tumor regression in patients. The mechanism of corticosteroid cytotoxicity to lymphocytes is mediated via binding to the glucocorticoid receptors, which induces apoptosis in these hormone-sensitive cells.[114]

Clinical Pharmacology

Prednisone is an inactive prodrug that requires hepatic activation to produce prednisolone, the active moiety. Oral bioavailability of corticosteroids is excellent (>80%). The plasma half-life of prednisone is 1 hour for prednisolone and 4 hours for dexamethasone. In contrast to cortisol, synthetic glucocorticoids have little protein binding. Drugs activating the microsomal enzyme system (such as phenytoin) increase degradation, while cytochrome P450 inhibitors (such as aprepitant) increase glucocorticoid concentrations.[115]

Toxicity

Prednisone and dexamethasone have little mineralocorticoid activity; therefore most side effects are related to suppression of the hypothalamic-pituitary-adrenal (H-P-A) axis and the development of iatrogenic Cushing's syndrome. In general, suppression of the H-P-A axis is not seen in patients who have received glucocorticoids for less than 3 weeks. A gradual tapering of glucocorticoids is recommended for those on these agents for longer periods. Side effects are dose- and schedule-related.[116] Commonly affected systems include: skin (purpura, thinning, acne), eye (cataracts), heart (hypertension, hyperlipidemia), endocrine (diabetes, adrenal insufficiency), GI (PUD, steatohepatitis), bone (osteoporosis), muscle (myopathy), psychiatric (euphoria, psychosis), and an increased risk of infections. Many of these toxicities are seen only with long-term therapy.

Microtubulin Agents

Two general classes of microtubulin inhibitors are used in cancer therapy: the vincas and the taxanes. The vinca alkaloids block microtubulin formation, while the taxanes (docetaxel, ixabepilone, and paclitaxel) stabilize microtubulin bundles, leading to their dysfunction. Since taxanes are not generally used in therapy of leukemias and lymphomas, only the vinca alkaloids will be reviewed here.

Vinca Alkaloids (Vinblastine, Vincristine, and Vinorelbine)

Mechanism of Action

The vinca alkaloids vinblastine, vincristine, and vinorelbine bind to tubulin and prevent the formation of microtubulin, a protein that is essential for maintenance of cellular shape and for formation of the mitotic spindle.[117] Vinca alkaloids bind to a site on microtubulin distinct from the taxanes. Cells treated with vinca alkaloids are arrested in metaphase.[118] Disruption in microtubular formation leads to initiation of apoptosis. Differences in activity and toxicity of the vinca alkaloids result from variation in their pharmacokinetics, their differential effects on various tubulin isoforms, and variations in tissue penetration and cellular retention. Resistance is a result of the presence of *p*-glycoprotein or reduced tubulin binding resulting from mutations in tubulin.

Clinical Pharmacology

All vincas are rapidly taken up into cells. However, vincas differ in cellular retention (vinblastine greater than vincristine). All vincas are extensively bound to tissues and to proteins with long terminal half-lives (20 to 60 hours).[119] CNS penetration is poor. All of the vinca alkaloids are metabolized by the liver via hepatic cytochrome P450 3A4 (CYP 3A4) and excreted into the bile. Drugs that block CYP 3A4 may inhibit vinca clearance, causing increased toxicity.[120] Doses of the vinca alkaloids should be reduced in patients with hepatic dysfunction, but not in patients with renal insufficiency. Specific dose reduction guidelines with impairment of hepatic function are not available.

Toxicity

Vincristine causes little myelosuppression. Its dose-limiting and most frequent toxicity is neurotoxicity,[118,121] manifested by a symmetric, distal, sensory-motor neuropathy. Loss of deep tendon reflexes in the lower extremities and paresthesias of the fingers and toes are common early findings. Continued use of the drug can result in further motor neuropathy, which may be only partially reversible when the drug is stopped. Neuropathies of the motor cranial nerves have also been reported, as have constipation, cramps, and paralytic ileus. Hair loss is commonly seen following vincristine administration. The dose-limiting toxicity of vinblastine is hematopoietic, with thrombocytopenia and leukopenia commonly occurring after administration of the drug.[122] The onset of myelosuppression tends to occur earlier with this agent than with other antineoplastic agents, with the leukocyte nadir typically seen by day 4 to 7 and recovery by day 10 to 14. Severe neurotoxic symptoms are unusual with vinblastine, but use of the drug is associated with myalgias and an autonomic neuropathy manifested by orthostatic hypotension or paralytic ileus. The dose-limiting toxicity of vinorelbine is myelosuppression.[123] Vinorelbine is less neurotoxic than vincristine. Injection-site reactions of erythema, pain, and vein discoloration occur in one-third of patients, with severe vein toxicity seen in 2% of patients treated with vinorelbine. Respiratory reactions have been reported. All vincas are potent vesicants, with severe local tissue damage associated with extravasation of these drugs into soft tissues.

Monoclonal Antibodies

Monoclonal antibodies have been used in cancer therapy over 30 years. Initial monoclonal antibodies were produced in mice. The development of techniques to convert portions of the murine antibody to a human subclass (chimerization), to convert all of the antibody, except the hypervariable region, to human amino acid sequences (humanization), or to make a totally human monoclonal antibody have advanced the field.[124] The humanized proteins have a longer half-life and can better activate human complement stimulating complement-mediated cytotoxicity or activate antibody-dependent cell-mediated cytotoxicity (ADCC). Seven monoclonal antibodies (alemtuzumab, brentuximab vedotin, gemtuzumab, ibritumomab, ofatumumab, rituximab, and tositumomab) have been approved for treatment of hematologic malignancies and are briefly reviewed.

Rituximab (Rituxan®) and Ofatumumab (Arzerra™)

Mechanism of Action

Both rituximab and ofatumumab bind to the protein CD20. CD20 is a nonglycosylated protein of 33 to 35 daltons that is expressed on the surface of human B lymphocytes. CD20 is expressed on all B cell malignancies except most ALL and myeloma. Rituximab is a genetically engineered mouse/human chimeric IgG monoclonal

antibody with human constant regions and mouse variable regions. Several mechanisms of cytotoxicity have been demonstrated.[124,125] Antibody-mediated cellular toxicity (ADCC), resulting from the ligation of the Fc portion of the monoclonal antibody to Fc receptors expressed by accessory cells, occurs. Rituximab is also capable of binding complement and triggering complement-dependent cell lysis (CDC) of human B cells. Cross-linking of CD20 molecules can trigger apoptosis. Ofatumumab is a fully human monoclonal antibody which binds to a site on CD20 different from rituximab. Compared to rituximab, ofatumumab enhances in vitro CDC and ADCC due to greater reactivity with human complement and effecter cells.[126,127] Head-to-head clinical trials comparing of rituximab to ofatumumab have not been performed.

Clinical Pharmacology

Rituximab and ofatumumab antibody concentrations in plasma following drug administration are proportional to the dose of drug administered, although there is marked inter-individual variation in maximal drug concentration (5- to 50-fold). Antibody half-life ranges from 30 to 400 hours for rituximab and 7 days for ofatumumab.[128,129] With weekly administration schedules, there is progressive accumulation of rituximab from week 1 to week 4. Drug clearance is not affected by chemotherapy. Drug elimination probably occurs by protein binding and proteolytic degradation. Clearance may be related to variable amounts of tumor cells present in the body and the concentration of CD20 antigens to which the drug binds.[129]

Toxicity

Mild toxicity is seen in the majority of patients receiving rituximab or ofatumumab, but severe toxicity (NCI grade 3 or 4) is rare. Infusion reactions, resulting from release of cytokines occurring when antibody binds to CD20 cell, result in mild nausea, chills, rigors, tachycardia, fever, and skin rash within 1 to 3 hours following treatment in some patients. Slow drug administration is recommended for patients receiving their first cycle of drug to minimize such reactions. Serious infusion-related reactions (bronchospasm, hypotension, acute respiratory distress syndrome, and shock) have been reported during drug infusions in less than 1% of infusions. The incidence of infusion-related reactions decreases with subsequent infusions. Grade 3 to grade 4 neutropenia (2% to 6%), anemia (1% to 3%), and thrombocytopenia (1% to 2%) are uncommon. B cell lymphocyte counts are reduced for ~6 months.[128,129] Late onset neutropenia, occuring 40–350 days following therapy, has been noted in 3–7% of patients. Multifocal leukoencephalopathy has been reported with rituximab.[130] Interstitial lung disease and reactivation of hepatitis B have been noted with rituximab therapy. A late occurring neutropenia has been noted following rituximab therapy.

^{90}Y-Ibritumomab Tiuxetan (Zevalin®) and ^{131}I-Tositumomab (Bexxar®)

Mechanism of Action

^{90}Y-ibritumomab and ^{131}I-tositumomab are also monoclonal antibodies directed at the CD20 antigen but have an attached radioactive moiety designed to result in radiation-induced cytotoxicity to cells expressing the CD20 antigen.[131,132] Ibritumomab is a monoclonal antibody combined with tiuxetan, which acts as a chelation site for Indium-111 and Yttrium-90 (Y-90). Indium-111 is a gamma-emitter used to assess biodistribution of ibritumomab while Y-90 emits beta particles. Beta-emission induces cellular damage through the formation of free radicals (in both target cells and surrounding cells). Roughly 85% of non-Hodgkin lymphomas express the CD20 antigen on their surface.[133] A pretreatment therapy of unlabeled antibody to CD20 is given prior to administration of radioactive-tagged antibody to minimize targeting of radio labeled antibody to normal B cells in the circulatory system. ^{131}I-Tositumomab is a radio-iodinated derivative of a murine IgA lambda monoclonal antibody covalently liked to iodine 131.

Clinical Pharmacology

^{90}Y-Ibitumomab is a pure β-emitter with a half-life of 64 hours. ^{131}I-Tositumomab has both β and α radiation. Clearance of ^{131}I-tositumomab–labeled antibodies varies significantly among patients, and dosing for an individual patient is derived from quantitative whole-body imaging of a test dose. The half-life of elimination averages 67 hours. More rapid clearance is noted in patients with a more extensive tumor burden.

Toxicity

The primary toxicity of both ^{131}I-tositumomab and ^{90}Y-ibitumomab is myelosuppression occurring about 1 month after dosing. The median platelet and neutrophil nadirs are 43,000 and 690, respectively, with tositumomab. Using ^{90}Y-ibitumomab, grade 4 neutropenia, thrombocytopenia, and anemia occur in 35%, 14%, and 8% of patients, respectively.[131,133] Nadirs occur 7 to 9 weeks posttherapy. Nonhematologic toxicity includes asthenia, hypothyroidism, infusion reactions, and fevers. Infusion reactions including anaphylaxis are seen in 25% to 30% of patients (anaphylaxis less common). Myelodysplasia and mucocutaneous reactions (erythema multiforme) have been noted days to months following therapy.[134]

Alemtuzumab (Campath®)

Alemtuzumab is a humanized monoclonal antibody directed against the CD52 antigen expressed not only by most lymphomas and lymphoid leukemias but also by normal B and T lymphocytes, NK cells, monocytes, macrophages, dendritic cells, and neutrophils. The CD52 antigen is not internalized after antibody binding; antitumor effects are mediated by antibody-dependent cell-mediated cytotoxicity.[135] Alemtuzumab also alters signal transduction, which may contribute to cytotoxicity. Because it binds to normal B and T cells and normal neutrophils (triggering complement lysis), transfusion reactions are frequent. The drug is therefore administered by slow infusion or by subcutaneous injection. Patients receiving subcutaneous alemtuzumab have local skin reactions which may be severe. Treatment results in myelosuppression and long-term immunosuppression. There is a high risk of opportunistic infections.[136]

Brentuximab Vedotin—(Adcetris™)

Mechanism of Action

Brentuximab vedotin is a conjugate of a chimeric IgG1 monoclonal antibody against CD 30 linked to a cytotoxic drug, monomethyl auristatin E. CD 30 is a member of the TNF family expressed on the tumor cells of Hodgkin's lymphoma and anaplastic large cell lymphoma. Monomethyl auristatin E (MMEA) is a synthetic inhibitor of tubulin polymerization. After binding to cells expressing CD30, the antibody-drug conjugate is internalized in lysosomes. The peptide linking the antibody to the drug is then cleaved, releasing MMEA into cells where it binds to tubulin and causes cell cycle arrest and apoptosis.[140] A small fraction of MMEA diffuses out of tumor cells where it results in cytotoxicity to cells in the microenvironment.[141]

Clinical Pharmacology

Brentuximab is administered intravenously every 3 weeks. The half-life of the antibody- drug conjugate is 4 to 6 days, while the half-life of MMEA is 3 to 4 days.[137] Steady state plasma levels are achieved in 21 days. Most MMEA is cleared via the liver into the stool (72%) as intact drug. There is modest metabolism via CYP 3A4. Information regarding dose adjustments or renal or hepatic insufficiency is not yet available, but it is unlikely that renal impairment would affect drug clearance.

Toxicity

As with many monoclonal antibodies, infusion reactions can be seen during drug infusion (10%) with occasional anaphylaxis.[138,139] Peripheral neuropathy, which often improves with drug discontinuation, is noted in 20% to 50% of patients. Other toxicities seen with brentuximab vedotin include fatigue, fever, nausea and diarrhea, and neutropenia. Progressive multifocal leukoencephalopathy (PML) due to reactivation of JC virus has been seen. A high incidence of pulmonary toxicity was noted when brentuximab has been combined with bleomycin.

Gemtuzumab Ozogamicin (Mylotarg®)

Gemtuzumab is a monoclonal antibody to the CD33 antigen, found on myeloid cells, linked to the antibiotic calicheamicin. The postulated mechanism of action is through binding of the antibody to myeloblast with internalization of calicheamicin. Calicheamicin binds to DNA, resulting in DNA strand breaks. Because of lack of clinical studies clearly demonstrating antineoplastic activity, gemtuzumab was withdrawn from clinical use in the United States in 2010.

Molecularly Targeted Therapies

In the early years of cancer drug development, antineoplastic agents were often discovered by testing biologics or chemicals for ability to kill cancer cells in culture. If activity was identified, then the mechanism of action of that material was later determined. With advances in cancer biology and sequencing of the human genome, our understanding of how cancers develop and what processes are critical in cancer proliferation has grown. For the past two decades, most cancer drugs have been developed by identifying a critical pathway needed by a particular cancer and then identifying a drug which blocks that critical pathway. Molecular targeted therapies are drugs which selectively target specific molecular features of cancer cells such as aberrations in genes or proteins which regulate tumor cell growth. The best of these drugs target genes or proteins which are critically responsible for tumor growth or survival, such as the BCR-ABL protein in CML. Of the many target agents developed in the past 15 years, those used in treatment of hematologic malignancies will be reviewed here. The targets include: the IL-2 receptor (denileukin diftitox), the BCR-ABL oncoprotein (imatinib, dasatinib, nilotinib), the retinoic acid pathway (ATRA, arsenic trioxide), and the proteosome (bortezomib).

Denileukin Diftitox

Mechanism of Action

Denileukin diftitox (Ontak®) is a fusion protein containing peptide sequences for human interleukin (IL-2) and diphtheria toxin.[140] The IL-2 portion of this fusion protein binds to cells that express IL-2 receptors. Once bound to the IL-2 receptor, the diphtheria toxin protein is internalized, inhibits cellular protein synthesis, and results in cell death. Three types of IL-2 receptors exist: high-, intermediate-, and low-affinity. The fusion protein is internalized only with intermediate- or high-affinity IL-2 receptors. Expression of high-affinity IL-2 receptors is normally restricted to activated T lymphocytes and lymphomatous cells of T or B cell origin. Denileukin diftitox has been approved for use in cutaneous T cell lymphomas.[141]

Clinical Pharmacology

There is wide variation in serum concentrations of denileukin diftitox after intravenous administration (coefficient of variation >50%).[141] A terminal half-life of ~75 minutes is seen with initial therapy, but this decreases to 43 minutes with continued therapy, as antibodies to denileukin diftitox appear. Animal studies have shown that the drug is cleared via hepatic protein degradation.

Toxicity

Hypersensitivity reactions, such as dyspnea, back pain, rash, hypertension, and chest tightness, occur during or within 24 hours of drug infusion in 60% of patients.[141,142] These symptoms resolve within 48 hours and can usually be controlled with use of steroids, antihistamines, or slowing of drug infusion. Constitutional and gastrointestinal symptoms (nausea/vomiting, asthenia, myalgias, headache, diarrhea) are seen in 92% of patients (grade 3 or 4 in one-third). A vascular leak syndrome (hypotension, edema hypoalbuminemia) occurs up to 2 weeks postinfusion in 25% of treated patients. The drug should not be given if the serum albumin is less that 3.0 g/dL. Myelosuppression is uncommon.

Retinoids

All-Trans Retinoic Acid or Tretinoin

Mechanism of Action. In acute promyelocytic leukemia, the retinoic acid receptor (RAR) is translocated next to a nuclear protein gene (PML). Fusion of RAR protein with the nuclear protein, PML, prevents normal differentiation of myeloid cell.[143] Retinoids are vitamin A derivatives that are essential for normal controlled cellular growth and development. ATRA binds to one or more nuclear receptors to decrease proliferation and induces differentiation of APL cells.[144] Pharmacologic concentrations of ATRA (1 μM) reverse the inhibition of differentiation of the promyelocytes and induce remission of APL by providing retinoic acid to activate repressed genes.

Clinical Pharmacology. Tretinoin is well absorbed. Peak plasma ATRA concentrations of 350 ng/mL are achieved 1 to 2 hours following ATRA dosing and drop rapidly ($t_{1/2} = 50$ minutes). ATRA is metabolized by the hepatic P450 microsomal enzyme system. Use of ATRA stimulates this degradative pathway. ATRA plasma concentrations, therefore, decrease with prolonged drug use.[145] Variation in hepatic microsomal metabolism accounts for significant patient-to-patient and day-to-day variation in ATRA clearance.[146]

Toxicity. Many patients tolerate tretinoin with minimal morbidity. However, 20% to 25% of patients may develop a syndrome characterized by unexplained fever, leukocytosis, dyspnea with interstitial pulmonary infiltrates, peripheral edema, pleuropericardial effusions, hypotension, and acute renal failure.[147] Patients with 4 of these symptoms are classified as having a severe differentiation syndrome (also call retinoic acid syndrome), while those with 3 symptoms have intermediate syndrome. The differentiation syndrome occurs more frequently in patients with elevated WBC or renal insufficiency. Steroids are used to treat and prevent this syndrome. Pseudo-tumor cerebri, hyperlipidemia, and abnormal liver function tests have been observed with therapy. ATRA, like other retinoids, has significant teratogenic properties, particularly during the first trimester of pregnancy.[148]

Bexarotene

Mechanism of Action. Bexarotene (Targretin®) is a retinoid approved for therapy of cutaneous T cell lymphoma. Retinoid modulation of tumor growth is mediated though binding to nuclear receptors that function as transcription factors to regulate gene expression in T cells. Two receptor families, retinoic acid nuclear receptors (RARs) and retinoid X nuclear receptors (RXRs) have been identified.[149] Bexarotene selectively binds and activates RXR receptors, inducing apoptosis in selected cell types through triggering of a variety of downstream events.[150]

Clinical Pharmacology. Bexarotene is available as a topical gel for application to skin lesions or as an oral capsule for systemic therapy. Peak plasma concentrations are seen 2 to 3 hours after oral administration. Drug half-life is 4 to 7 hours. Bexarotene, like

other retinoids, undergoes metabolism by the hepatic cytochrome P450 enzyme system (CYP3A4). Drug interactions with other CYP 3A4–metabolized drugs may occur. Gemfibrozil increases bexarotene concentrations and toxicity.

Toxicity. The most common bexarotene-associated toxicities are hyperlipidemia (82%), hypercholesterolemia (30%), central hypothyroidism (29%), headache (20%), asthenia (16%), pruritus (13%), and leukopenia (11%).[151,152] Side effects are more common at higher drug doses. Pancreatitis may result from hyperlipidemia. Use of lipid-lowering agents and thyroid replacement are often required. Thyroid function tests must be monitored.

Signal Transduction Inhibitors

Several antineoplastic agents have been FDA approved that inhibit a tyrosine kinase associated with signal transduction molecules activated in cancer cells. Inhibitors of the BCR-ABL (imatinib, dasatinib, nilotinib), PDGFR (sunitinib and sorafenib), EGFR (erlotinib, gefitinib), BRAF (vemurafenib), hedgehog (vismodegib), and VEGFR (sunitinib, pazopanib, and sorafenib) tyrosine kinases are clinically available. Imatinib mesylate, nilotinib, and dasatinib are currently approved for treatment of chronic myelogenous leukemia (CML). Other approved tyrosine kinase inhibitors are used primarily for treatment of solid tumors and will not be discussed in this chapter.

Imatinib Mesylate

Mechanism of Action

CML is characterized by a reciprocal exchange of genetic material between chromosomes 9 and 22 (t9; 22). A new gene is formed, the BCR-ABL proto-oncogene, which encodes a signal transduction protein that is autonomous. Increased activity of the BCR-ABL proto-oncogene leads to cellular proliferation, decreased apoptosis, or both.[153] The intracellular component of the BCR-ABL signal transduction protein contains a tyrosine kinase that activates subsequent signaling molecules by taking a phosphate from ATP and transferring it to a second signaling molecule. Imatinib mesylate (Gleevec®) binds to the ATP-binding site of the BCR-ABL oncoprotein and prevents transfer of phosphate from ATP to the second messenger (Fig. 68.15). Imatinib inhibits the tyrosine kinase of the BCR-ABL, c-kit, and PDGF oncogenes.[154]

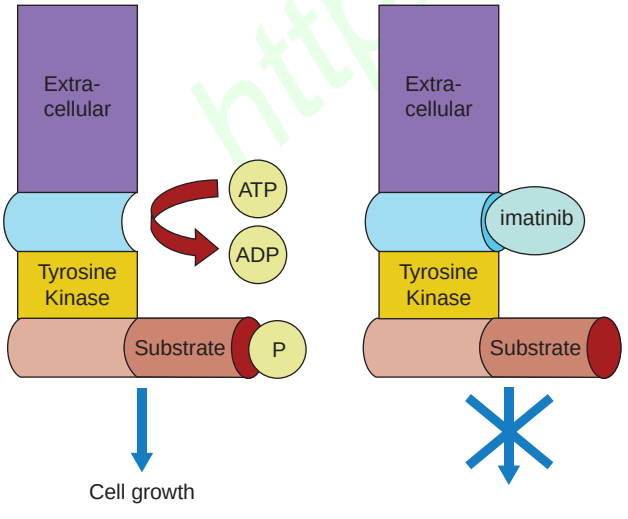

FIGURE 68.15. The BCR-ABL oncoprotein is shown schematically. This is a transmembrane protein with a tyrosine kinase on the intracellular part of the molecule. Imatinib mesylate binds to the tyrosine kinase, preventing activation of second-messenger proteins.

Clinical Pharmacology

Imatinib mesylate is given orally at doses of 400 to 800 mg/day. Bioavailability is 98%, with a drug half-life of 18 hours. Imatinib is cleared by hepatic microsomal cytochrome P450 metabolism (CYP 3A4) to a metabolite that has similar potency.[155] Biliary excretion of parent drug and metabolite account for 70% of drug clearance. However, no evidence of decreased clearance or increased drug toxicity has been seen in patients with hepatic or renal dysfunction.[156,157] Drugs that alter the hepatic CYP 3A4 metabolism have the potential to alter clearance of all BRC-ABL TKIs.[158]

Toxicity

Mild nausea (70%), diarrhea (56%), and fluid retention are the most common toxicities associated with imatinib.[154,159] Edema can usually be managed with diuretics or dose reductions. Hematologic toxicity is mild and associated with a more advanced stage (e.g., CML blast crisis). Severe toxicity (grade 3 or 4) is rare (15% of patients). Abnormal liver function tests have been reported but require discontinuation of therapy in <0.5% of patients.

Dasatinib (Sprycel®)

Mechanism of Action

Roughly 25% to 45% of CML patients given imatinib discontinue this drug within 5 years either due to development of tumor resistance or to drug intolerance. To address this problem, several additional BCR-ABL TKIs have been developed. Dasatinib inhibits the ABL kinase present in patients with CML but differs from imatinib in that it can bind to both active and inactive conformations of the ABL kinase domain.[160] This less exacting requirement for binding allows dasatinib to inhibit BCR-ABL mutations resistant to imatinib. Dasatinib also inhibits the SRC kinase.[161] Dasatinib is a 100- to 300-fold more potent ABL kinase inhibitor than imatinib.

Clinical Pharmacology

Dasatinib is metabolized primarily by the hepatic cytochrome enzyme system (CYP 3A4). Concurrent use of drugs that induce or inhibit CYP 3A4 should be avoided if possible.[161] Dasatinib's solubility is pH-dependent, so H_2 blockers and proton pump inhibitors should not be used with dasatinib. Antacids can be used, but 2 hours before or after administration of dasatinib.

Toxicity

Fluid retention, nausea, vomiting, and diarrhea are the most common toxicities seen with dasatinib use. Pleural effusions are noted in 8% of treated patients. Myelosuppression is common (50% grade 3 or 4).[162] Grade 3 to 4 thrombocytopenia is seen in 35% to 80% of patients. Dasatinib may prolong the Q-T interval, increasing the risk of arrhythmias. Correcting hypokalemia and hypomagnesemia to minimize this effect is recommended.

Nilotinib (Tasigna®)

Mechanism of Action

Nilotinib is a second generation BCR-ABL TKI. It is similar in structure to imatinib but allows a better topologic fit with the ABL kinase and a 30-fold increase in potency.[163] Nilotinib also inhibits the KIT and platelet-derived growth factor tyrosine kinases, again more potent than imatinib.[164] Although both nilotinib and dasatinib are effective in most BCR-ABL mutants associated with resistance to imatinib (75% response rates), neither are effective against the T315I mutant.[163,164]

Clinical Pharmacology

Nilotinib is given orally at a dose of 400 mg twice daily. The plasma half-life is 15 to 17 hours and 98% of the drug is protein-bound. The metabolism of nilotinib is mainly hepatic. Drugs that inhibit CYP3A4 or prolong the QT interval should be avoided.

Toxicity

Mild skin rash (28%), nausea (24%), pruritus (24%), and headache (19%) are common side effects, but rarely are severe.[163] Peripheral edema and pleural effusions seldom occur with nilotinib. Grade 3/4 neutropenia and thrombocytopenia were each reported in 29% of patients.[164] Typical biochemical abnormalities include increased serum lipase, hyperbilirubinemia (usually indirect), hyperglycemia and elevated transaminases. Prolongation of the Q-T interval is noted.

Proteosome Inhibitors—Bortezomib (Velcade®)

Mechanism of Action

Bortezomib targets and blocks the action of the proteosome. The proteosome is a large enzyme complex which breaks down proteins that have been selected for degradation.[165] The degradation process requires the proteins to transverse the regulatory gate of the proteosome. Bortezomib is a modified boronic peptide. It inhibits the chymotryptic site of the 26S proteosome, an enzyme that regulates protein degradation.[166] Bortezomib inhibits the degradation of proteins involved in regulation of cell proliferation and survival. It deregulates signaling molecules that are critical to the interaction of myeloma cells with the bone marrow microenvironment, leading to growth inhibition and apoptosis. Several intracellular molecules important in apoptosis, including NF-κB, JNK, Bcl-2, p53, and gp130 are modulated by proteosome degradation.

Clinical Pharmacology

The primary mechanism of bortezomib clearance is oxidative metabolism via the cytochrome P450 enzyme system (CYP 3A4, 2D6, 2C19, 2C9, and 1A2). Bortezomib penetrates poorly into the CNS. Dose adjustments are not needed with renal insufficiency.[167] Information regarding dose adjustments for hepatic insufficiency is lacking. Drug interactions could be expected with agents that inhibit cytochrome P450 metabolism.[168]

Toxicity

The most frequent toxicities (>30%) associated with bortezomib treatment include fatigue/weakness, GI disturbances (nausea/anorexia/diarrhea/constipation), myelosuppression (neutropenia/thrombocytopenia), and peripheral neuropathy.[168] Peripheral neuropathy may be seen in up to 35% of patients; however, many myeloma patients have an underlying neuropathy prior to starting bortezomib. The neuropathy is related to the duration of treatment. Dose reductions based on the presence of neuropathy are needed and can result in improvement of neuropathy in 65% to 70% of patients.[169]

Topoisomerase II Inhibitors (Doxorubicin, Daunorubicin, Epirubicin, Idarubicin, Mitoxantrone, Etoposide, and Teniposide)

Mechanism of Action

Topoisomerases are nuclear enzymes that make the transient strand breaks in DNA to allow the cell to manipulate DNA topology by passing an intact helix through a transient break in the DNA backbone.[170] This is a mechanism to relieve super coiling and tension on the DNA molecule. DNA topoisomerase I makes single-strand breaks in the DNA, whereas topoisomerase II makes double-strand breaks and passes double-stranded DNA through the break. Topoisomerase enzymes are needed for DNA replication, chromosome condensation, and chromosome segregation. Topoisomerase II inhibitors (doxorubicin, daunorubicin, epirubicin, idarubicin, mitoxantrone, etoposide, and teniposide) act by poisoning this enzyme to prevent it from relegating cleaved DNA

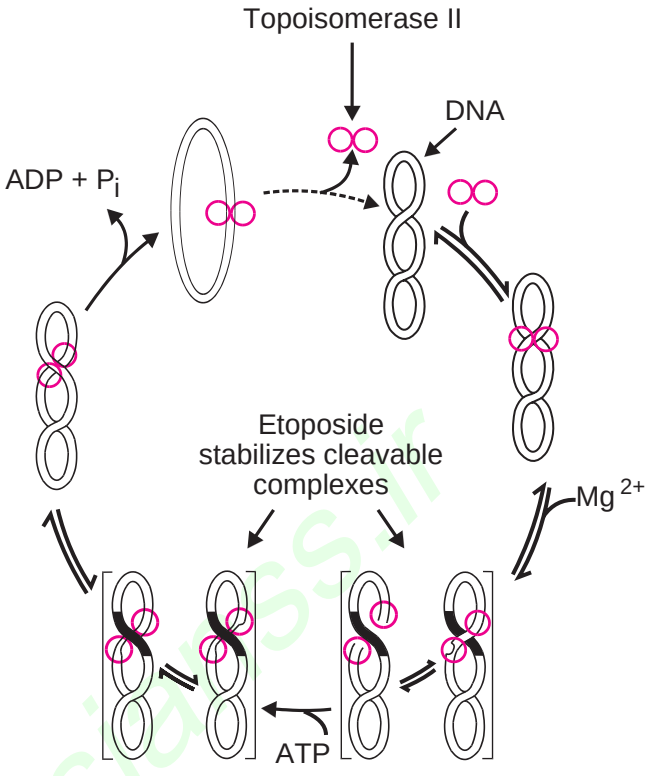

FIGURE 68.16. The catalytic cycle of topoisomerase II. Topoisomerase II binds to DNA. In the presence of magnesium and ATP, an intact DNA helix can pass through a temporary break in DNA with subsequent relegation. Topoisomerase II inhibitors block this cycle at the stage of DNA cleavage. (From Osheroff N, Zechiedrich EL, Gale KC. Catalytic functions of DNA topoisomerase II. Bioassays 1991;12:269–275.)

(Fig. 68.16).[171] This converts topoisomerase II into a toxin, by introducing high levels of transient protein-associated breaks in the genome of treated cells. Failures to repair the DNA break by the cell results in apoptosis. Currently available topoisomerase I inhibitors are irinotecan (CPT-11) and topotecan. As these agents are not frequently used in treatment of hematologic neoplasms, they will not be further discussed in this section. Topoisomerase II inhibitors include the anthracyclines, epipodophyllotoxins and mitoxantrone.

Anthracyclines (Doxorubicin, Daunorubicin, Epirubicin, and Idarubicin)

Clinical Pharmacology

Clearance of all anthracyclines occurs through hepatic metabolism and biliary excretion. Urinary excretion accounts for only ~10% of anthracycline clearance.[172–174] Dose reduction is required for patients with jaundice, although specific dose reduction guidelines are not available. Use of doxorubicin in patients with hepatic dysfunction does not appear to increase cardiac toxicity, but an increase in mucositis and myelosuppression occurs. Liposomal-encapsulated anthracyclines (liposomal doxorubicin [Doxil®, Myocet™] or liposomal daunomycin [DaunoXome®]) act as depot forms of drug.[175,176] The delayed release of the anthracyclines from the liposome produces lower peak plasma concentrations and less cardiotoxicity.

Toxicity

The acute dose-limiting toxicity of the anthracyclines is myelosuppression, with a nadir in leukocytes expected around day 10 to 14, with recovery usually by day 21 to 28.[171] Other acute systemic toxicities include nausea, vomiting, alopecia, and

mucositis. Anthracyclines cause severe local tissue reactions if extravasation occurs during infusion. The most serious toxicity associated with anthracyclines is cardiotoxicity. Anthracyclines cause a dose-dependent congestive cardiomyopathy that often leads to congestive heart failure. Late-onset cardiomyopathy can appear months to years after treatment is completed.[177] The mechanism underlying the cardiotoxic effects of anthracyclines remains uncertain but is thought to be via formation of free radicals, generated by iron-doxorubicin complexes that damage cardiac cellular membranes[178]; cardiotoxicity may also be related to anthracycline damage to cardiac stem cells. The cardiac damage caused by anthracyclines is cumulative. With total doses of doxorubicin <350 mg/m^2, heart failure is seen in <5% of cases. The risk of toxicity is related to the peak plasma concentration, so continuous infusions reduce the risk of heart failure compared to administration by large bolus injections. At equally myelosuppressive doses, epirubicin may be less cardiotoxic than doxorubicin.[178] Liposomal formulations of doxorubicin and daunorubicin have been investigated in the hopes of increasing tumor selectivity, which would allow an increase in the tolerated dose. The liposomal formulation of doxorubicin has reduced cardiotoxicity. Liposomal formulations of doxorubicin and daunorubicin are, however, associated with palmar-plantar erythrodysesthesia syndrome.[175,176]

Mitoxantrone

Clinical Pharmacology

Efforts to synthesize compounds with better antineoplastic activity and less toxicity than doxorubicin led to the discovery of mitoxantrone. Hepatic metabolism is the primary mechanism for mitoxantrone clearance, with only 6% to 11% being cleared by the kidney.[179]

Toxicity

The primary dose-limiting toxicity of mitoxantrone is myelosuppression. Other potential toxicities include nausea, vomiting, alopecia, and cardiotoxicity. At doses that produce equivalent drops in white blood cell and platelet counts (75 mg/m^2 of doxorubicin vs. 15 mg/m^2 of mitoxantrone), nausea, vomiting, and alopecia are less frequent with mitoxantrone than with doxorubicin.[179,180] With commonly used dosages, approximately twice as much mitoxantrone can be given before heart failure develops as compared to doxorubicin. Acute leukemia is also a potential serious side effect of therapy using mitoxantrone.

Epipodophyllotoxins (Etoposide and Teniposide)

Clinical Pharmacology

Etoposide is poorly soluble in water. It is dissolved in a solubilizer composed of polysorbate 80, polyethylene glycol, and alcohol (Tween 80) and diluted to a concentration <0.4 mg/mL to avoid precipitation. These additives are believed to induce the hypersensitivity reactions occasionally seen with etoposide infusion. Approximately one-third of administered intravenous etoposide is excreted in the urine, and hepatic glucuronidation may account for another 25% of etoposide's metabolism.[181] Etoposide is also hepatically metabolized to O-demethyl metabolites.[182] Etoposide clearance is modestly decreased in patients with renal dysfunction, but not with hepatic obstruction. Biliary drug excretion is minimal so that only modest dose adjustment is required in the presence of obstructive jaundice. Etoposide is highly bound to plasma proteins, with only 6% to 8% of drug nonbound. Because free drug is biologically active, conditions that decrease protein binding or decrease albumin increase the pharmacologic effect of a given drug dose. Teniposide has less water solubility, decreased renal clearance (10%), and is even more tightly bound to plasma proteins than etoposide. Teniposide has a longer drug half-life and increased biliary clearance compared to etoposide. Anticonvulsants, such as phenobarbital and phenytoin, increase teniposide clearance, presumably by increasing hepatic metabolism.[183] This increased clearance results in a lower efficacy of chemotherapy in children with ALL receiving teniposide chemotherapy plus anticonvulsants. Etoposide is available as an oral capsule. Bioavailability of oral etoposide ranges from 40% to 80% and varies with the drug dose.[32] Oral etoposide absorption is linear up to doses of 250 mg, but decreases with doses of >300 mg. Oral etoposide administration results in significantly greater variability in drug exposure than does intravenous administration.[184] Etoposide phosphate is a water-soluble prodrug that is rapidly changed to etoposide by endogenous phosphatases.[185]

Toxicity

Common toxicities of etoposide and teniposide include bone marrow suppression, dose-dependent nausea or vomiting, and alopecia.[181] Myelosuppression is the dose-limiting toxicity at usual therapeutic doses. At very high doses, such as those used with bone marrow transplantation regimens, mucositis becomes dose-limiting. Liver toxicity, fever, and chills are also seen with high-dose therapy. Hypersensitivity reactions, including vasomotor changes related to the pulmonary and gastrointestinal systems, although infrequent, can be life-threatening. These reactions may be due to hypersensitivity to the Tween 80 needed to solubilize the intravenous etoposide preparation. Hypersensitivity reactions can usually be ameliorated with histamine blockade and/or by using a slower infusion rate. Etoposide phosphate may reduce the risk of a hypersensitivity reaction, because no solubilizer is required. The most serious adverse event associated with etoposide and teniposide is the development of AML.[186] Therapy-related AML also occurs with other topoisomerase II inhibitors, but at a lower frequency. Leukemia develops relatively early after topoisomerase II inhibitor therapy (2 to 5 years) and can be distinguished from other therapy-related malignancies by a unique molecular marker: A balanced translocation involving the MLL (mixed-lineage leukemia) gene on chromosome 11 band q23.

Platinum Analogs (Cisplatin, Carboplatin, Oxaliplatin)

Mechanism of Action

The platinum analogs, cisplatin, carboplatin, and oxaliplatin, are heavy-metal complexes that induce tumor cell kill by cross-linking DNA strands in a manner analogous to the alkylating agents. Reactive aquated platinum intermediates are formed within cells, which directly and covalently bind to DNA, leading to DNA

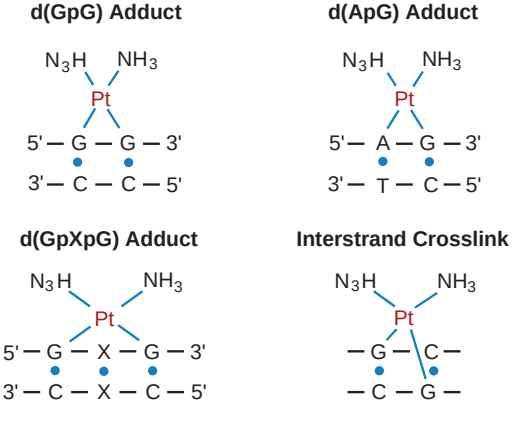

FIGURE 68.17. Sites of covalent binding of cisplatin to DNA. After forming an aquated reactive intermediate, cisplatin binds to guanine (and occasionally adenine) bases within the DNA molecule. Some adducts result in intrastrand DNA cross-links.

cross-links[187] (Fig. 68.17). Cisplatin is more reactive in water than carboplatin or oxaliplatin. The difference in aqueous stability, differences in the reactive groups, and spatial differences between platinum compounds appear to account for the variations in pharmacokinetics and toxicity among platinum agents. The amount of platinum bound to DNA after cisplatin, carboplatin, and oxaliplatin administration is similar, although the time frame for forming DNA adducts varies, with oxaliplatin and carboplatin taking more time than cisplatin.[188] Platinum compounds are effective in the treatment of solid tumors and are used as second-line agents in the treatment of lymphomas.[189]

Clinical Pharmacology

The reactive intermediates of the platinum analogs rapidly bind to proteins and other nucleophilic compounds. Only the free (unbound) species are cytotoxic.[190] Over 90% of cisplatin is protein-bound and inactivated within 2 to 4 hours.[191] Thus, protein binding represents the major route of cisplatin elimination. In contrast, only 20% to 40% of platinum is protein-bound at 2 hours following carboplatin administration. Renal excretion is the primary route of carboplatin elimination (70% to 90% of total clearance). Carboplatin clearance is highly correlated with creatinine clearance. Carboplatin doses should be calculated based on an individual patient's creatinine clearance.[192] Oxaliplatin is also extensively cleared by the kidney (50%), but to a lesser degree than carboplatin. Increased toxicity following oxaliplatin therapy is not seen in patients with renal function impairment unless a patient's creatinine clearance falls to <20 mL/minute.[193]

Toxicity

The toxicity profiles of cisplatin, oxaliplatin, and carboplatin differ. Myelosuppression is rare with cisplatin, although moderate anemia is common. Nausea and vomiting are common cisplatin toxicities, but the incidence can be reduced with decadron and serotonin antagonists.[77] Nephrotoxicity, manifest by azotemia and electrolyte disturbances (primarily hypomagnesemia and hypokalemia), is dose-related.[194] Although pre- and posttreatment hydration (with chloride-containing solutions) and diuresis reduce the incidence and severity of cisplatin nephrotoxicity, moderate and permanent reductions in glomerular filtration rate (GFR) may still occur.[195] Neurotoxicity from cisplatin is cumulative, dose-related, and usually begins as a "stocking-glove" type of peripheral neuropathy. The toxicity profile of carboplatin differs from cisplatin, with dose-limiting myelosuppression being the major toxicity following carboplatin administration.[196] Renal and ototoxicities noted with cisplatin are infrequent after carboplatin administration, although peripheral neuropathy is still seen. Nausea and vomiting after carboplatin usually are mild to moderate. Oxaliplatin results in neurotoxicity that is both acute and chronic. Reversible, cumulative peripheral sensory neuropathy is the primary dose-limiting factor of oxaliplatin therapy. Hematologic and gastrointestinal toxicities occur but are mild to moderate. Ototoxicity and nephrotoxicity are uncommon.[197]

Other Chemotherapeutic Agents Used in Hematology

Anagrelide (Agrylin®)

Mechanism of Action

Anagrelide is an oral imidazoquinazoline found to result in thrombocytopenia in the 1980s.[198] The precise mechanism of action is not known but anagrelide and its metabolite, 3-hydroxy anagrelide, block the maturation of platelets and reduce platelet counts. In contrast to hydroxyurea, anagrelide does not affect DNA or induce angiogenesis.[199]

Clinical Pharmacology

Anagrelide is rapidly (2 hours) absorbed and then metabolized via the CYP1A2 to an active (3-hydroxy anagrelide) and inactive metabolite. Its half-life is 2 hours and that of the active metabolite is 4 hours.[200]

Toxicity

Because anagrelide and 3-hydroxy anagrelide inhibit phosphodiesterase, the main side effects (vasodilatation, tachycardia, headache, palpitations) are related to the positive ionotropic effects of this drug.

Asparaginase

Mechanism of Action

Certain cells, particularly those of lymphocytic origin, lack the capacity to synthesize the amino acid asparagine. L-Asparaginase is an enzyme derived from bacteria that reduces blood asparagine to undetectable levels, thereby depriving cells of this amino acid. The cytotoxic effects of L-asparaginase on lymphoblasts result from the inhibition of protein synthesis when cells are depleted of asparagine.[201]

Clinical Pharmacology

After intravenous enzyme administration, plasma asparagine levels fall rapidly and remain low for up to 10 days.[200] Asparaginase can be detectable in the blood for 1 to 3 weeks, but as antibodies are formed, clearance of the drug is greatly accelerated. Asparaginase is degraded by protein metabolism. Trough asparaginase concentrations of 0.3 IU/ml are recommended for all leukemic patients.[202]

Toxicity

Toxic effects of asparaginase related to inhibition of protein synthesis include a decrease in circulating levels of albumin, clotting factors, insulin, and lipoproteins.[203] Synthesis of anticoagulant proteins, such as antithrombin III, protein C, and protein S, is also reduced. Hypersensitivity reactions (urticaria, anaphylaxis, serum sickness) are common, with frequencies ranging from 20% to 40%. Conjugation of polyethylene glycol to asparaginase (pegasparaginase, Oncaspar®) prevents uptake of the drug by the reticuloendothelial system, making it less immunogenic and prolonging its circulating half-life. The incidence of hypersensitivity reactions to pegasparaginase in patients who have had reactions to *Escherichia coli* asparaginase is ~30%. The relative effectiveness and toxicity of asparaginase and pegasparaginase remain to be established.[201] Toxic reactions to both asparaginase and pegasparaginase include cerebral dysfunction (25% of patients), vomiting, chills (often an immediate reaction), pancreatitis (15% of patients), and liver function abnormalities.[203]

Arsenic Trioxide

Mechanism of Action

Arsenic trioxide (ATO, Trisenox®) is used for treatment of promyelocytic leukemia.[204] Trivalent arsenic interacts with thiol groups in cells, primarily proteins that contain cysteine residues.[205] The outcome of this interaction depends on the cell type and the dose and duration of arsenic exposure. The specific mechanism for ATO effects in APL has not clearly been defined, but As_2O_3 stimulates differentiation of APL cells, induces apoptosis, and inhibits NF-κB.

Clinical Pharmacology

Arsenic trioxide is methylated presumably in the liver and then excreted in the urine as metabolites.[205] The antineoplastic effect of these metabolites is unknown. ATO has a half-life of 17 hours and distributes throughout the body. Drug penetration into the CNS is seen (14% of plasma concentrations).[206] No dosage guidelines for patients with hepatic or renal insufficiency are currently available.

Toxicity

The most common ATO side effects include nausea, rash, fatigue, fever, headaches, diarrhea, and mild hepatotoxicity.[204,205,206] The most common life-threatening toxicities include hypokalemia (13%), hyperglycemia (10%), the APL differentiation syndrome, and cardiac toxicity. Cardiac toxicity is primarily manifest by Q–T prolongation on the EKG, but Torsades de Pointe and sudden death have been reported. The "retinoid acid syndrome," similar to that noted following ATRA treatment, is frequently seen (25% of patients). The incidence of myelosuppression is low. Although arsenic is a known carcinogen, neurotoxin, and renal toxin, secondary malignancies, renal toxicity, and neuropathy have rarely been complications of arsenic trioxide therapy to date.

Bleomycin

Mechanism of Action

Bleomycin is a mixture of low-molecular-weight glycopeptides of which bleomycin A_2 is the major species. Bleomycin can be administered subcutaneously, intramuscularly, or intravenously and has been instilled into pleural and pericardial spaces to act as a sclerosing agent in patients with malignant effusions. Bleomycin produces single- and double-strand DNA breaks, which result in chromosomal deletions and fragmentation.[207] The DNA strand breaks are generated by production of free radicals by a Fe (II)–bleomycin complex, which intercalates into DNA and allows one bleomycin molecule to cleave both strands of DNA.[208]

Clinical Pharmacology

Absorption after intramuscular or subcutaneous injection of bleomycin is nearly complete. Renal clearance accounts for 65% of total drug clearance. Patients with renal failure have a prolonged drug half-life and an increased risk of developing pulmonary toxicity.[209,210] A 75% dose reduction has been recommended for patients with a creatinine clearance <25 mL/minute. Approximately 45% of an intracavitary dose of bleomycin is absorbed into the systemic circulation, and 30% is excreted in urine.[211]

Toxicity

Bleomycin is not myelosuppressive. Fever occurs within 48 hours of drug administration in ~25% of patients. Rare acute allergic reactions have been noted with this drug.[212] The most prominent toxic effect of bleomycin is a chronic interstitial pneumonitis, which may continue on to fibrosis, hypoxia, and death.[213] Pulmonary toxicity, manifested by cough, dyspnea, and pulmonary infiltrates, occurs more often at higher cumulative drug doses but can occur following any dose. Approximately 10% of patients who receive a total drug dose of >400 mg develop pulmonary toxicity. Risk factors for pulmonary toxicity include individual doses >25 U/m^2, advancing age, underlying lung disease, and previous radiation therapy to the chest.[214] Patients who receive high oxygen concentrations during anesthesia following bleomycin therapy have been associated with increased frequency of bleomycin lung toxicity in some studies but not others. No specific therapy is effective, other than stopping the drug. Bleomycin can also result in cutaneous toxicities of hyperpigmentation, erythema, desquamation, nail changes, and alopecia. Reynaud's phenomena have been reported.

Interferon Mechanism of Action

Interferons (IFNs) are a family of glycoproteins of which some are inhibitors of viral replication and tumor growth. Type I interferons include α, β, and ω subtypes while type II interferon has only INFγ. Type I interferon α is used for treatment of hematologic malignancies. IFN-α2b (Intron A®) and IFN-α2a (Roferon®) are recombinant products that differ by one amino acid of 166. A pegylated interferon is also available. IFNs have multiple effects on cytokine production and regulation of tumor oncogenes and antioncogenes. The specific mechanism of antitumor activity of the IFNs is unclear, but the IFNs produce direct antiproliferative effects on tumor cells, increase host-mediated immune defenses, and inhibit angiogenesis.[215–217] They stimulate activity of T cells, natural killer cells, dendritic cells, monocytes, and macrophages.

Clinical Pharmacology

The IFNs can be administered subcutaneously, intramuscularly, or intravenously. Following exposure to IFN, expression of >20 genes is altered. The optimal dose and administration route of IFN are not clear. IFN-$\alpha 2a$ is metabolized by the liver and filtered through the glomeruli, while INF-α2b is metabolized and cleared by the kidney. The half-life of interferon α is 2 to 3 hours,[218] although its biologic effect is much longer. The half-life of pegylated interferon is 177 hours.

Toxicity

IFN-α use is associated with many toxicities, including a flulike syndrome manifested by myalgias and fatigue in patients who are not premedicated with antipyretics.[219,220] The severity of myalgias decreases with continued drug use. Nausea and vomiting are noted less often. Somnolence and lethargy occur when higher doses of IFN are used. Other, less common side effects include myelosuppression, diarrhea, mild alopecia, skin rashes, and elevated hepatic enzymes. Depression, anxiety, and suicidal ideation may occur with IFN therapy.[221] These toxic effects are readily reversed when administration of the IFN is stopped. Some of the immediate systemic toxicity associated with the use of this agent can be prevented by administration of acetaminophen or megestrol.

Thalidomide (Thalomid®) and Lenalidomide (Revlimid®)

Mechanism of Action

Thalidomide and lenalidomide are immunomodulatory drugs with a wide range of potential antineoplastic actions. Both drugs have similar immunomodulatory effects. Lenalidomide was developed after thalidomide and is more potent with fewer side effects. Thalidomide and lenalidomide activate T cells and stimulate endogenous cytokine release including IL-2, and IFN-α production.[222] They inhibit TNF-α synthesis and block the activation of NF-κB kinase. They increase NK cell number and function. Thalidomide and lenalidomide also inhibit the action of vascular endothelial growth factor (VEGF) and block angiogenesis. The specific mechanism of antineoplastic immunomodulation of these two agents remains uncertain.

Clinical Pharmacology

The structure of thalidomide and its analog, lenalidomide, are shown in Figure 68.18. Thalidomide is a mixture of R and S enantiomers. It undergoes rapid spontaneous hydrolysis in plasma to multiple hydroxylated metabolites. Very little thalidomide undergoes hepatic metabolism via the cytochrome P450 system, so CYP-directed drug interactions are unlikely. Absorption of oral thalidomide is slow (3 to 4 hours) but extensive

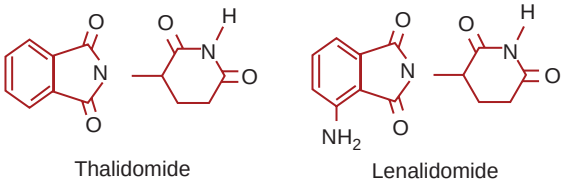

FIGURE 68.18. The chemical structures of thalidomide and lenalidomide.

(80% bioavailability). Drug half-life is 6 hours. Ninety percent of the drug is excreted in the stool or urine within 48 hours, mostly as metabolites. The effect of food on thalidomide absorption is minimal. Repeat dosing does not affect kinetics. Because thalidomide is mainly hydrolyzed and passively excreted, its clearance is not expected to be altered in patients with impaired liver or renal function.[223] Lenalidomide is rapidly absorbed when given by mouth (t_{max} = 1.0 hour). Food does not alter drug absorption but does slow oral absorption. In normal volunteers, two-thirds of an administered dose is excreted unchanged in the urine.[224] Drug half-life is 3 hours. Lenalidomide is effective in myeloma patients with renal insufficiency but increased toxicity (myelosuppression and neuropathy) is noted in this population. Dose reductions may be needed for individuals with renal insufficiency.[225]

Toxicity

Thalidomide is a potent teratogen. Use of thalidomide as a sedative in the late 1950s resulted in birth defects in >10,000 infants.[226] Birth defects include absent or hypoplastic limbs, ear or eye deformities, and heart defects. Thalidomide administration to pregnant women is absolutely contraindicated. Women of childbearing age must have a negative pregnancy test before starting thalidomide, use two effective forms of birth control, and have a pregnancy test every 4 weeks. Breastfeeding is prohibited. Men must use a condom or refrain from intercourse. Common thalidomide toxicities include neuropathy, somnolence, and constipation. The incidence of neuropathy is 38% at 6 months and 73% at 12 months.[227] Clinical features are tingling or painful distal paresthesias affecting primarily the feet but sometimes the hands. The duration of thalidomide therapy correlates directly with the development of neurotoxicity. Some degree of sedation is universal, dose-dependent, and usually appears 2 weeks after initiation of therapy. Some patients suffer from depression. Tremors and/or headaches occur in 5% to 20% of patients. Venous thrombosis is seen in 2% to 23% of patients, with higher risk in patients >60 years of age. Sinus bradycardia is noted in 5% of patients. Constipation develops a few days after starting treatment in >50% of patients. Hypothyroidism occurs in 20% of patients occurring 1 to 6 months after starting therapy. A maculopapular skin rash or pruritus is seen in 20% to 50% of patients. Stevens-Johnson syndrome is occasionally seen (<1%).

Although lenalidomide does not cause birth defects in animal models, because of its similarity to thalidomide, this drug should not be given to pregnant women. The most common lenalidomide toxicity is a reversible myelosuppression (neutropenia and thrombocytopenia). Sedation is not seen with lenalidomide. Neuropathy has been noted but is felt to occur less frequently than with thalidomide.[227] Skin rash and itching are seen in 25% of patients. Deep-vein thrombosis has been noted when lenalidomide has been used with dexamethasone.[228] Hypothyroidism occurs in 5% to 10% of patients receiving lenalidomide. An increased risk of development of second malignancies has been reported with both thalidomide and lenolidomide.[229]

The Future

Additional genes, signaling pathway molecules, and posttranslational events important in the development and growth of hematologic cancers will continue to be discovered. Accruing knowledge of cancer biology identifies potential new pathways for therapy. In 2012, over 900 potential antineoplastic agents were in development. Readers are referred to websites: http://www.clinicaltrials.gov and www.phrma.org/research/new-medicines for details of potential antineoplastic agents in clinical development. While it is hard to predict the future, it is likely that drugs targeting additional signal transduction pathways[230–234] and additional monoclonal antibodies or antibody-drug conjugates[235] are likely to be developed. Drugs targeting new pathways such as the Flt-3 tyrosine kinase, present in one-third of AML patients,[236] phosphatidylinositol kinase (PI3K), upregulated in B cell malignancies,[237] and Bruton's tyrosine kinase (Btk)[238] appear promising. New, less toxic and more specific IMiDs (pomalidamide) and proteosome inhibitors (carfilzomib)[238] appear close to FDA review. Innovative immunomodulatory therapies are under development.[239,240] Readers will need to continue to monitor the medical literature to keep pace with these rapidly changing developments in treatments for hematologic cancers.

CHAPTER 69

SUPPORTIVE CARE IN HEMATOLOGIC MALIGNANCIES

Andrew J. Moore, Mary A. Vu, Stephen A. Strickland

Patients with hematologic neoplasms are at significant risk for complications both from the malignancy as well as the required therapy. The morbidity and mortality associated with the expected cytopenias, the therapeutic modalities, as well as the potential organ impairment present significant challenges to patients and health care providers alike. The frequency and severity of these complications vary among patients and according to the underlying disease process. Continued investigation and advances in antibiotics, antiemetics, and palliative therapies are allowing us to better meet the ever changing needs of our patients and ensure the provision of quality care. This chapter provides an overview of current recommendations and recent advances in the management of challenges encountered in the care of patients with hematopoietic malignancies.

INFECTIOUS DISEASE ISSUES RELATED TO HEMATOLOGIC MALIGNANCY

Deficits in Host Defense

Patients with hematologic malignancies are at increased risk for infection due to impaired host defense from the underlying malignancy along with concomitant illnesses or extrinsic factors including marrow-suppressive therapy. Hematologic malignancies are often associated with specific or global immune abnormalities that result in increased frequency of infections or opportunistic infections even in the absence of treatment. Understanding the different risk factors in the individual patient allows appropriate preventive strategies and treatments to be implemented more effectively. Defects in host defense mechanisms associated with specific malignancy are outlined in Table 69.1, whereas Table 69.2 identifies opportunistic infections by the host defects, such as those caused by impairment of phagocytosis (mainly neutropenia), defective production of circulating antibody (humoral immunity), and impaired cellular immunity. Concomitant illnesses, such as diabetes, nephrotic syndrome, cardiac disease, and liver disease contribute to infection risk and influence management decisions.[1]

Neutrophil Defects

Neutrophils play a critical role in the innate immune response, mediating both antimicrobial and inflammatory responses. They are produced in the bone marrow under the influence of an array of cytokines. Mature neutrophils circulate in the peripheral blood for only 3 to 6 hours, placing a demand on the marrow for an impressive capacity for constitutive neutrophil production that can be rapidly upregulated in response to acute bacterial, fungal, or inflammatory stresses.[2] Deficits in neutrophil number and functional defects of mature neutrophils predispose to life-threatening infections, while disruption of the maturation sequence underlies the pathophysiology of myelodysplasia and leukemia.

Neutropenia, defined as a decrease of the peripheral blood neutrophil count below 0.1×10^9/L, predisposes to bacterial and fungal infections. The severity (0.1×10^9/L) and length of neutropenia (>2 weeks) contribute to the risk of serious infections.[3] Neutropenia is usually caused by decreased production. Localizing signs and symptoms are often absent in the setting of severe neutropenia because of a lack of inflammatory response from absent granulocytes. Fever remains the most common sign of infection associated with neutropenia.

Neutropenia is a common complication of acute leukemia (AL) and is often prolonged during induction therapy.[4] In chronic myeloid leukemia (CML), neutropenia typically occurs with the development of blast crisis, with the evolution of myelofibrosis (MF), or with therapy. Mild neutropenia is observed in patients with MF and multiple myeloma (MM), but it is uncommon during untreated phases. Neutropenia occurring in patients with Hodgkin lymphoma (HL) or non-Hodgkin lymphoma (NHL) is typically a result of marrow invasion with tumor or marrow fibrosis and occurs in conjunction with other cytopenias. Hairy cell leukemia patients may become neutropenic secondary to tumor cell invasion, splenomegaly, or both, but may also result from defects in cell-mediated immunity, monocytopenia, and decreased T cells after nucleoside analog therapy.[5] In patients with T cell large granular lymphocytic leukemia, neutropenia may be the primary problem.

Functional defects in morphologically normal neutrophils have been described in hematologic malignancies, particularly myeloproliferative neoplasms (MPNs) and myelodysplastic syndrome (MDS).[6] Such defects increase the susceptibility to infection.[7] Neutrophils from untreated patients with CML may be mildly defective with respect to phagocytosis, oxygen consumption, and bactericidal capacity, and tend to have decreased concentrations of lactoferrin, elastase, collagenase, and peroxidase.[8] Myeloblasts and lymphoblasts found in AL patients are of no benefit to the host against infection.

Deficient Immunoglobulin Production

The humoral immune response is one of the two main arms of the immune system. In this response, the immune system triggers specific B cells to proliferate and secrete their specific antibodies. Impaired humoral immunity is a major cause of frequent and severe infection in patients with hematologic malignancies. A decrease in Th2 CD4 T-lymphocyte–B-lymphocyte interaction results in decreased antibody production, complement-mediated damage, and phagocytosis. Diminished immunoglobulin synthesis is a major contributor to infection in patients with CLL, MM, and some B cell types of NHL.[9,10,11] Myeloma and other plasma cell dyscrasias are often functionally hypogammaglobulinemic despite elevated total immunoglobulin. Splenectomized patients have impaired antibody response, reduced levels of tuftsin (natural activator of phagocyte cells), and are at increased risk for infections similar to those of patients with hypogammaglobulinemia, particularly encapsulated organisms (*Streptococcus pneumoniae, Haemophilus influenzae, and Neisseria meningitidis*).[12]

Defects in Cellular Immunity

Cellular immunity comprised of T lymphocytes, macrophages, and natural killer cells recognizes and combats pathogens that proliferate intracellularly. Cellular immune mechanisms are important in immunity to all classes of infectious agents, including most viruses and many bacteria (e.g., *Mycoplasma*, *Chlamydophila*, *Listeria*, *Salmonella*, and *Mycobacterium*), parasites (e.g., *Trypanosoma*, *Toxoplasma*, and *Leishmania*), and fungi (e.g., *Histoplasma*, *Cryptococcus*, and *Coccidioides*).[13] T lymphocytes are activated by dendritic cells, macrophages, and B lymphocytes, which present foreign antigens in the context of the host's own major histocompatibility complex antigen to the T cell receptor. Activated T cells then act in several ways to fight infection. *Cytotoxic* $CD8^+$ T cells directly attack and lyse host cells that express foreign antigens. *Helper* $CD4^+$ T cells stimulate the proliferation of B cells and the

TABLE 69.1

HOST DEFECTS PREDISPOSING TO COMPLICATIONS IN HEMATOLOGIC MALIGNANCIES

Disease	Host Defect	Complications
Acute myeloid leukemia	Neutropenia	Bacterial infections, including perirectal abscess, typhlitis, sinusitis; superinfections when hospitalized; increasing problem of methicillin-resistant *Staphylococcus aureus* and coagulase-negative staphylococci; *Clostridium difficile* colitis; aspergillosis with prolonged neutropenia; viral infections (herpes simplex)
	Thrombocytopenia, disseminated intravascular coagulation	Hemorrhage
	Hyperleukocytosis	Leukostasis, tumor lysis
Acute lymphoblastic leukemia	Neutropenia	Bacterial infections (see Acute myeloid leukemia)
	Cellular immunity while on maintenance therapy	*Pneumocystis jirovecii*, disseminated varicella
	Thrombocytopenia	Hemorrhage
	Hyperleukocytosis	Tumor lysis, leukostasis
Chronic myeloid leukemia	Mild defects in neutrophil function	No increased risk of infections except in blast crisis
	Thrombocytosis, platelet dysfunction	Increased risk of thrombosis and hemorrhage, similar to other myeloproliferative disorders
Chronic lymphocytic leukemia	Decreased immunoglobulins	Infections with encapsulated organisms (pneumococcus, *Haemophilus influenzae*, meningococcus)
	Cellular immunity	Mycobacteria, fungal, viral (herpetic), *Salmonella*
	Immune dysfunction	AIHA, ITP, red cell aplasia
Hodgkin lymphoma	Cellular immunity	Viral (herpes zoster, other), *P. jiroveci*, fungal, mycobacteria, listeriosis, *Salmonella*
	Cytokine production	B symptoms, pruritus, eosinophilia
	Splenectomized	Encapsulated organisms (above), increased risk of leukemia
	Immune dysfunction	ITP, AIHA
	Mediastinal disease	SVC syndrome
Non-Hodgkin lymphoma		
Small B cell lymphoma	Decreased Igs	Similar infections to CLL
PTCL, particularly angioimmunoblastic and subcutaneous panniculitis like PTCL	Immune dysfunction	AIHA
	Cytokine production	B symptoms, hemophagocytic syndrome, eosinophilia
Large B cell lymphoma	Mediastinal disease	SVC syndrome, pericardial disease
T-lymphoblastic lymphoma	Mediastinal disease	SVC syndrome, tumor lysis, CNS disease
Mantle cell lymphoma	Colonic polyposis	Gastrointestinal bleed
Burkitt lymphoma	Gastrointestinal primary	Obstruction, perforation, tumor lysis, CNS disease with advanced-stage disease
Multiple myeloma	Paraprotein	Hyperviscosity, hemorrhage
	Decreased Igs	Similar infections to CLL
	Osteoclast overactivity	Hypercalcemia
Waldenström macroglobulinemia	IgM paraprotein	Hyperviscosity, hemorrhage
Hairy cell leukemia	Neutropenia	Bacterial and fungal infections
	Cellular immunity	*P. jirovecii*, atypical mycobacteria
	Immune dysfunction	Periarteritis nodosa, lymphocytic vasculitis
	Monocytopenia	—
T cell large granular lymphocyte leukemia	Neutropenia	Bacterial infections
	Immune dysregulation, positive rheumatoid factor, antinuclear antibody	ITP, AIHA, red cell aplasia
Adult T cell leukemia/lymphoma	Cellular immunity	Opportunistic infections (*Strongyloides stercoralis, P. jirovecii*)
	Parathyroid hormone–related protein	Hypercalcemia

AIHA, autoimmune hemolytic anemia; CLL, chronic lymphocytic leukemia; CNS, central nervous system; Ig, immunoglobulin; ITP, immune thrombocytopenic purpura; PTCL, peripheral T cell lymphoma; SVC, superior vena cava.

production of immunoglobulins. Defects in cell-mediated immunity characterized by impaired Th1 $CD4^+$ T lymphocytes and/or macrophage function results in increased risk of infections with intracellular bacteria, fungi, parasites, and viruses (Table 69.2).

Multiple factors determine the severity and frequency of impaired cellular immunity. There may be differences in the stages of disease studied, the therapy used, and the sensitivity of the tests used to measure cellular immunity. Patients with HL often do not respond to new antigens and lose prior sensitivity as well.[13,14] Patients with CLL usually show reduced or absent lymphocyte transformation with phytohemagglutinin but do not lose skin hypersensitivity to antigens such as old tuberculin.[15] Patients with HL do not mount

TABLE 69.2

OPPORTUNISTIC INFECTIONS ASSOCIATED WITH DEFECTS IN IMMUNITY IN HEMATOLOGIC NEOPLASIA

Defect	Infections
Neutropenia	Gram-negative bacteremia (*Escherichia coli, Pseudomonas, Klebsiella, Proteus*)
	Gram-positive bacteremia (methicillin-resistant *Staphylococcus aureus*, coagulase-negative staphylococci, *Streptococcus viridans*)
	Fungemia (*Candida* species, aspergillosis)
Humoral immunity	Encapsulated organisms *Streptococcus pneumoniae* *Haemophilus influenzae* *Neisseria meningitidis*
Cellular immunity	Bacteria *Listeria monocytogenes* Mycobacteria *Legionella* species *Nocardia* species *Salmonella* species
	Viruses Herpes simplex Varicella zoster Parainfluenza, respiratory syncytial virus, cytomegalovirus
	Fungi *Cryptococcus neoformans* *Coccidioides immitis* *Histoplasma capsulatum* *Pneumocystis jirovecii*
	Parasites *Toxoplasma gondii* *Strongyloides stercoralis*

either a primary or a secondary immune response, whereas those with CLL maintain secondary responses but cannot mount a primary response. Depressed cellular immunity is uncommon in AL[16] except during maintenance therapy in ALL.[17]

Approach to Infection in the Immunocompromised Host

The initial assessment of a febrile immunocompromised host is dependent on the underlying hematologic condition and other associated risk factors. It should focus on determining the potential sites and causative organisms and assessing the patient's severity of illness. Although fever remains the most important clue to an infectious process, the characteristic signs and symptoms of infection may be absent in more than one-half of infected neutropenic patients, and routine cultures are often negative.[3] It is estimated that 60% or more of neutropenic patients who become febrile have an established or occult infection.[18] No known factors accurately predict which patients with fever and neutropenia are most likely to have bacteremia. As a result, a careful history and screening physical examination must be performed with special attention to the most common sites of infection: skin, oropharynx, nares, sinuses, lungs, GI tract (including perianal area), soft tissues, and indwelling catheter devices.

Risk assessment should be performed as part of the initial evaluation as it helps stratify the severity and facilitate goal-directed therapies. Assessing risk may determine the type of empiric antibiotic therapy (oral vs. intravenous), venue of treatment (inpatient vs. outpatient) and duration of antibiotic therapy. The most commonly used index for the stratification of risk for complications in febrile neutropenic patients is the Multinational Association for Supportive Care in Cancer (MASCC) index (Table 69.3).[19] The following independent factors were found to be predictive of lower risk for complications: (1) burden of illness characterized by low or moderate symptoms, (2) absence of hypotension, (3) absence of chronic obstructive pulmonary disease, (4) presence of solid tumor or absence of previous fungal infection in patients with hematologic malignancies, (5) outpatient status, (6) absence of dehydration, and (7) an age less than 60 years. These variables predicting low risk were assigned an integer weight, and a risk index score consisting of the sum of these integers was derived. A score of 21 or greater identified low-risk patients with a positive predictive value of 91%, specificity of 68%, and sensitivity of 71%; whereas those with scores less than 21 are at higher risk for complications.[19]

In general, most experts consider high-risk patients to be those with anticipated prolonged (>7 days duration) and profound neutropenia (ANC $< 0.1 \times 10^9$/L) or significant medical comorbid conditions, including hypotension, pneumonia, new abdominal pain, or neurologic changes. High-risk patients warrant inpatient therapy with intravenous antibiotics. Lower-risk patients, including those with anticipated brief (<7 days duration), neutropenic periods, and few comorbidities, are candidates for empiric oral therapy.

Initial evaluation of neutropenic fever (Table 69.4) should include blood cultures, a urinalysis and urinary Gram stain, complete blood count with a differential, and blood chemistry tests to assess liver and renal function. Chest radiographs should be obtained for all patients with respiratory signs or symptoms, as well as viral swabs, and cultures of aspirated or biopsy material from accessible body sites that appear infected. At least two sets of blood cultures are recommended, with a set collected simultaneously from each lumen of an existing central venous catheter (CVC), if present, and from a peripheral vein site according to the updated guidelines from the Infectious Diseases Society of America (IDSA).[3] An aggressive diagnostic workup is warranted if any localizing signs or symptoms are elicited. Patients who are unable to undergo invasive diagnostic procedures to determine an infectious etiology should be treated with empiric antibiotics until the appropriate diagnostic workup can be safely performed, or until the neutropenia resolves. Additional radiographic tests, such as computed tomography (CT) scans of the sinuses, chest, and abdomen, as well

TABLE 69.3

THE MASCC RISK INDEX SCORE: DETERMINING THE RISK OF SERIOUS COMPLICATIONS IN FEBRILE NEUTROPENIA

Category	Weight
Burden of illness: no or mild symptoms	5
No hypotension	5
No chronic obstructive pulmonary disease	4
Solid tumor or no previous invasive fungal infection	4
Outpatient status	3
Burden of disease: moderate symptoms	3
No dehydration	3
Age < 60 y	2

as examination of cerebrospinal fluid, may be necessary in selected patients. Noninfectious causes such as drug reactions, mucositis, graft-versus-host disease (GVHD) should be considered in patients with persistent fever. Superinfection with fungi or *Clostridium difficile* needs to be considered as well. Frequent reassessment of the patient's clinical status will help determine whether there is a need for additional coverage or changes to the ongoing antimicrobial regimen.

Empiric Antibiotic Therapy: Current Guidelines and Regimens

The goal of initial empiric antibiotic therapy is to prevent serious morbidity and mortality due to bacterial pathogens until further culture results are available. In the early 1970s combination regimens incorporating two or three additive or synergistic drugs were used, such as antipseudomonal penicillin and an aminoglycoside. Subsequent regimens included beta-lactam and beta-lactamase inhibitor such as ticarcillin-clavulanic acid and piperacillin-tazobactam. Decades of well-studied clinical trials have not yet identified a superior empiric therapeutic regimen for the initial treatment of febrile neutropenic patients.[20] Effective regimens (combination or monotherapy) share certain essential features, including bactericidal activity, antipseudomonal activity, and minimal toxicity. Initial choice of antimicrobials should be based on the risk status of the patient (low vs. high), on localizing signs or symptoms of infection, and on the epidemiology of pathogens and antibiotic susceptibility patterns in individual centers. Evidence-based guidelines are available for additional guidance on antibiotic therapy for neutropenic patients with fever.[3,21,22] An algorithm for managing patients with febrile neutropenia is provided in Figure 69.1.

Initial Antibiotics for High-risk Patients

Monotherapy with selected broad-spectrum beta-lactams with activity against *Pseudomonas* species is as effective as combination antibiotic regimens (beta-lactam plus aminoglycoside) for empiric therapy of uncomplicated fever and neutropenia, and has fewer toxicities.[23,24] Antibiotics recommended by the IDSA as appropriate monotherapy include the following: cefepime, imipenem-cilastatin, meropenem, and piperacillin-tazobactam.[3] Many centers have found that ceftazidime is no longer reliable as empiric monotherapy for neutropenic fever because of decreasing potency against gram-negative organisms and poor activity against many gram-positive pathogens, such as streptococci.[25–27] Other antimicrobials (aminoglycosides, fluoroquinolones, and/or vancomycin) may be added to the initial regimen for management of complications such as hypotension and pneumonia, or there are specific clinical indications including suspected catheter-related infections, skin or soft-tissue infections, or if antimicrobial resistance is suspected or proven.

A meta-analysis of randomized trials involving cefepime reported that cefepime was associated with increased 30-day mortality when used for empiric therapy for neutropenic fever; however, no increase in infection-related mortality was noted.[28] Subsequent analysis by the FDA failed to demonstrate a statistically significant increase in 30-day mortality for cefepime-treated

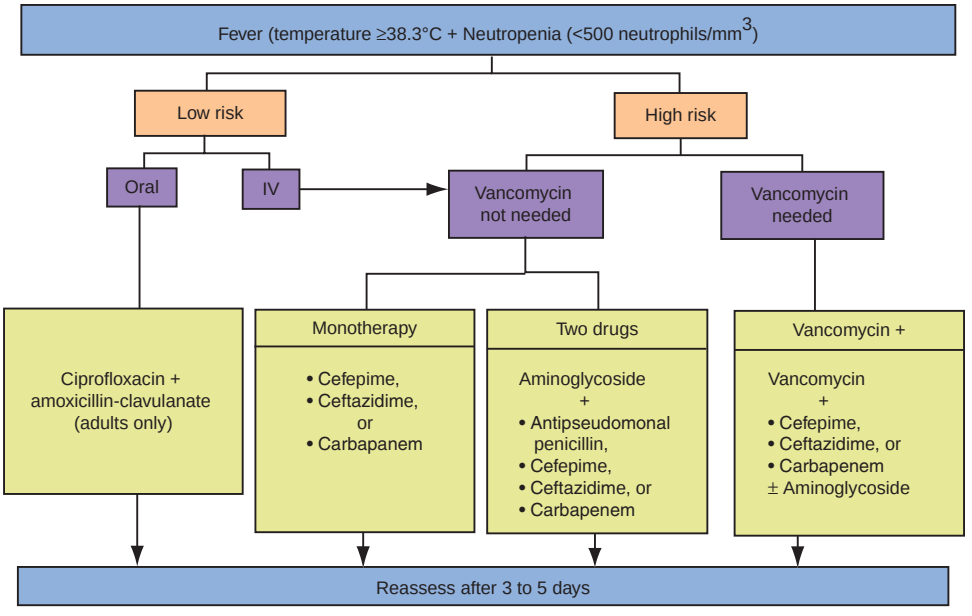

FIGURE 69.1. Empiric antibiotic regimens in febrile neutropenia.

patients compared with controls, and thus concluded that cefepime remains a reasonable option for treating febrile neutropenia.[28,29]

Empiric combination therapy should be used in cases of severe sepsis or septic shock, or high prevalence of multidrug-resistant gram-negative bacilli. Effective antibiotic combinations include one of the aforementioned beta-lactams plus an aminoglycoside (choice based on local resistance, typically amikacin). Fluoroquinolones may be an acceptable alternative to aminoglycosides at institutions where prevalence of quinolone-resistant bacteria is low, or in patients with renal insufficiency. Febrile neutropenic patients with candiduria or oral thrush should also be covered by empiric antifungal therapy.

Role of Vancomycin and Other Agents in Gram-positive Coverage

Empiric vancomycin use in febrile neutropenia has led to considerable debate and concern, as the uncontrolled use of vancomycin facilitates vancomycin-resistant organisms. Randomized trial data provided by the European Organization for Research and Treatment of Cancer (EORTC) failed to demonstrate a true clinical advantage for empiric vancomycin in adults.[30] It decreased the number of days the patient had fever, but did not improve survival and was associated with increased incidence of nephrotoxicity and hepatotoxicity. Empiric vancomycin should therefore be reserved for specific settings during neutropenia, including (1) hypotension or septic shock without an identified pathogen, (2) clinically apparent catheter-related infection, (3) positive blood cultures with a gram-positive organism prior to identification and susceptibility testing (linezolid or daptomycin are reasonable alternatives in environments with high prevalence of vancomycin-resistant enterococcus [VRE]), or (4) known colonization with methicillin-resistant *Staphylococcus aureus* (MRSA) or penicillin-resistant *S. pneumoniae*. Consideration should also be given to discontinuation of the empiric vancomycin after 2 to 3 days if the initial cultures are negative. Vancomycin plus aztreonam is an acceptable regimen in febrile neutropenic patients with allergies to beta-lactams.[31]

Lower-risk Patients with Fever and Neutropenia

Patients with fever and neutropenia can be stratified according to their risk of developing life-threatening infectious complications.[21,22] Outpatient management with close monitoring and follow-up may be feasible for patients with MASCC scores of 21 or greater given the lower risk of complications. The IDSA, the American Society of Clinical Oncology (ASCO), and the National Comprehensive Cancer Network (NCCN) support the use of outpatient oral antibiotic therapy in carefully selected lower-risk patients with neutropenic fever. Ciprofloxacin plus amoxicillin/clavulanate is recommended for adult patients. Clindamycin can be substituted for amoxicillin/clavulanate in patients allergic to penicillins.[3] Fluoroquinolones have an importance in the outpatient management of febrile neutropenic adults since they are the only class of oral antibiotics with activity against *P. aeruginosa*.

Evaluation of Response and Duration of Therapy

Modifications of the initial antimicrobial regimen are made based on new physical findings, microbiologic data, or persistent fever that indicates a resistant organism. It often takes 3 to 5 days to determine the efficacy of the initial antibiotic regimen (Fig. 69.2). Low-risk patients may become afebrile as early as 2 days, and high-risk patients may take as long as 7 days to have a response to the antibiotics. Antibiotics should be continued for a minimum of 7 days or until the documented infection has been eradicated. It is preferable to have neutrophil recovery (ANC $> 0.5 \times 10^9$/L) before discontinuing therapy. If the patient continues to be febrile 3 to 5 days after the initiation of empiric antibiotics, one of three choices can be made: continue the same antibiotics if the patient is stable and no source of infection has been found; change or add antibiotics if the patient develops a new complication, there are new findings on evaluation, or the patient appears to worsen clinically; or add an antifungal drug.[3,32]

Empiric amphotericin B has been replaced with the use of less toxic antifungals, such as caspofungin, micafungin, voriconazole, posaconazole, and the lipid formulations of amphotericin B. Risk of fungal infection (*Aspergillus* and *Candida*) rises precipitously in patients with profound neutropenia and persistent fevers after 7 to 10 days. Empiric antifungal therapy has been shown to reduce infectious mortality in patients with new or persistent fever occurring after 1 week of antibiotic therapy.[33,34] Fluconazole is highly effective in the treatment of oropharyngeal and esophageal candidiasis and may be as effective as amphotericin B for systemic candidiasis in patients who are hemodynamically stable and have not been on antifungal prophylaxis. Broader spectrum antifungal agents are indicated in the setting of suspected *Aspergillus,*

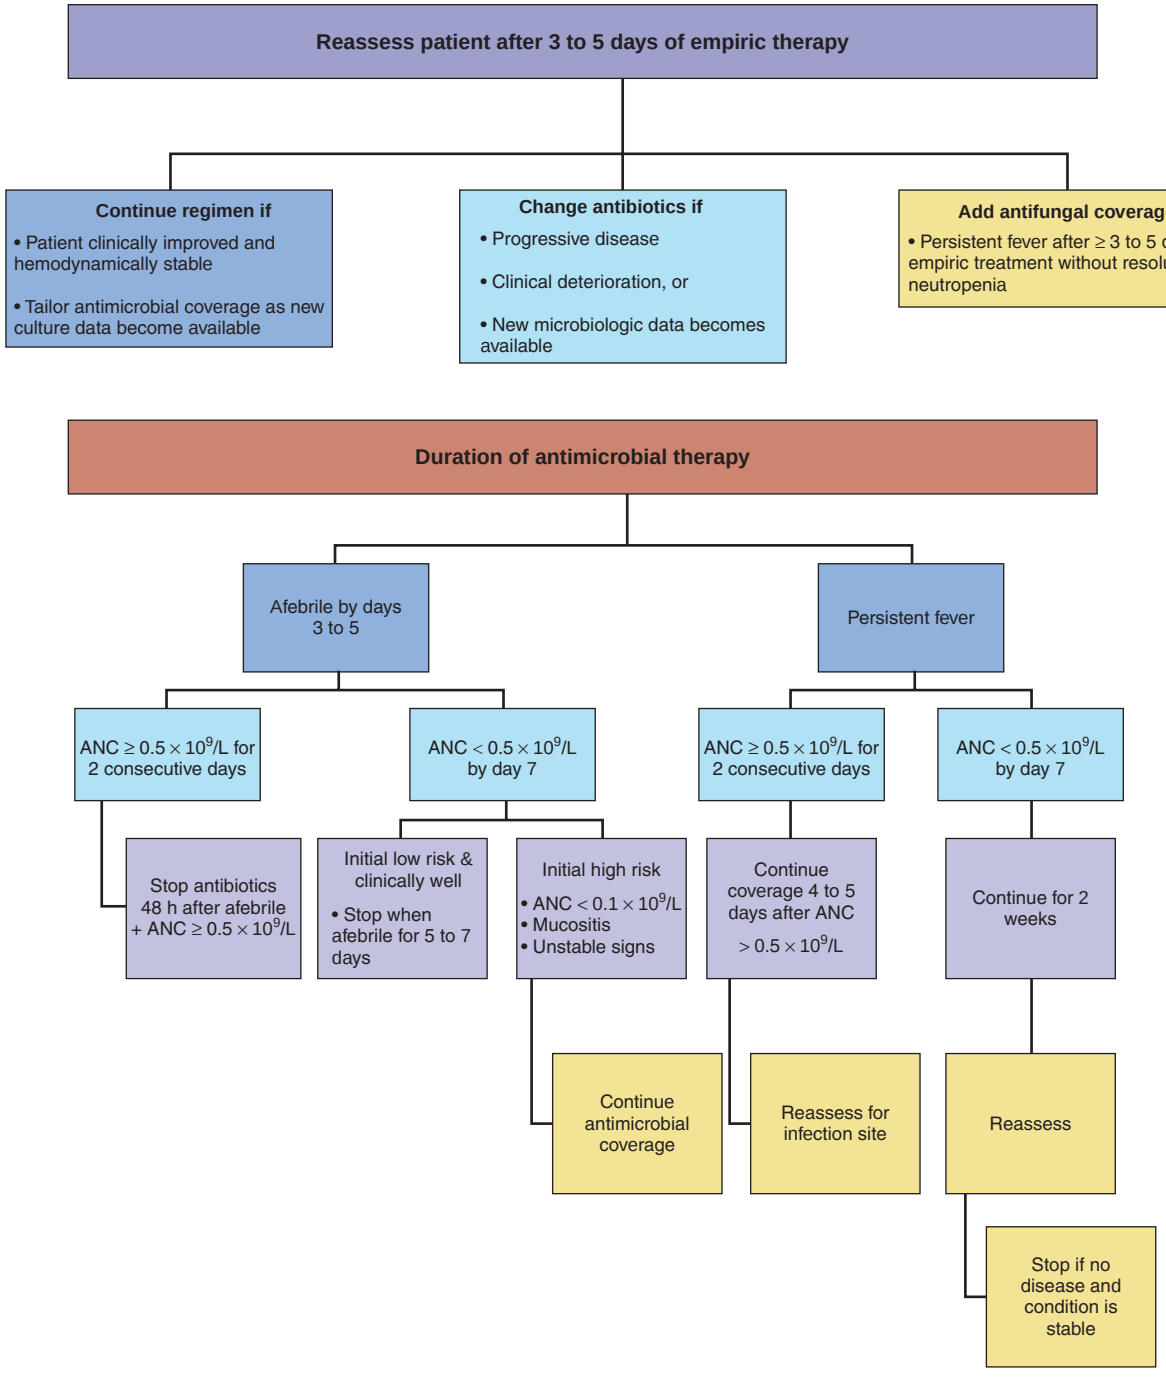

FIGURE 69.2. Common modifications of empiric antimicrobial therapy in the febrile neutropenic patient.

atypical fungi, and several clinically relevant *Candida* species (*C. krusei, C. tropicalis, C. lusitaniae,* and *Torulopsis glabrata*) due to the absent or poor activity of fluconazole against these organisms.

Echocardiography is recommended for *S. aureus* bloodstream infections to determine the presence or absence of endocarditis, and thus clarify the need for prolonged antibiotic therapy. Transesophageal echocardiography is more sensitive and preferred when compared with a transthoracic approach.[35]

Myeloid Colony-stimulating Factors

Prophylactic use of myeloid colony-stimulating factors (CSFs) is common in the setting of intensive chemotherapy regimens such as stem cell transplantation. Multiple randomized clinical trials of prophylactic recombinant granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) have shown benefits in reducing the time to neutrophil recovery and the duration of fever and hospitalization in patients with hematologic neoplasms.[36,37] Prophylactic G-CSF and GM-CSF in autologous and allogeneic *hematopoietic stem cell transplantation (HSCT)* recipients have been associated with a small reduction in the risk of documented infections but do not appear to affect infection-related or treatment-related mortality.[38] Empiric use of CSFs in the management of neutropenic fever is not standard practice, as no consistent benefit has been demonstrated in terms of morbidity or mortality among randomized controlled trials of their use in patients with febrile neutropenia.[39,40] Neither ASCO nor EORTC recommend the routine use of growth

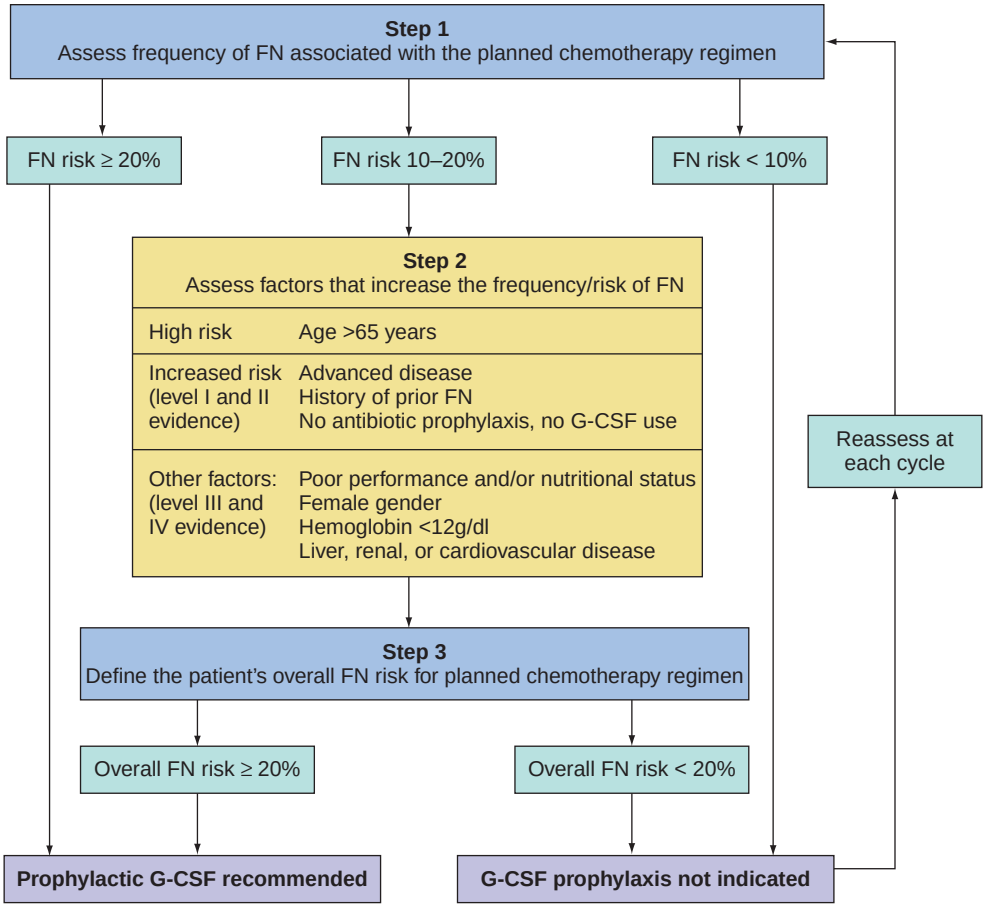

FIGURE 69.3. Algorithm to decide prophylactic G-CSF usage. FN, febrile neutropenia; G-CSF, granulocyte colony-stimulating factor. (With permission from Aapro MS, Bohlius J, Cameron DA, et al. 2010 update of EORTC guidelines for the use of granulocyte colony-stimulating factor to reduce the incidence of chemotherapy-induced febrile neutropenia in adult patients with lymphoproliferative disorders and solid tumours. Eur J Cancer 2011;47:8–32.)

factors to treat episodes of febrile neutropenia unless patients are at high risk for infection-related complications, such as those older than 65 years, or those with prolonged (>10 days) and profound ($<0.1 \times 10^9$/L) neutropenia, active infection, hypotension, and/or multiorgan dysfunction[39,40] (Fig. 69.3).

G-CSF has a mild toxicity profile, with bone pain occurring 1 to 2 days prior to neutrophil recovery being the most common side effect. Recombinant yeast–derived GM-CSF reportedly has a better side effect profile than *E. coli*–derived GM-CSF (less fever, rash, and myalgias), although a randomized trial failed to reveal statistically significant differences.[41] High-dose GM-CSF has been associated with hepatic transaminase elevation, serositis, fluid retention, venous thrombosis, and reactivation of autoimmune disease. A syndrome of hypoxemia, flushing, cardiovascular instability, musculoskeletal pain, nausea, and vomiting has also been described with intravenous GM-CSF.[42]

Pegfilgrastim offers once-per-cycle administration compared to the required daily doses of the nonpegylated CSFs, and a single dose of pegfilgrastim has been shown to exert a prolonged effect lasting for approximately 14 days or until neutrophil recovery.[43] Two small phase II trials involving lymphoma patients demonstrated similar efficacy of pegfilgrastim versus filgrastim in regards to reduction of febrile neutropenia after chemotherapy administration.[44,45]

Granulocyte Transfusions

The role of granulocyte transfusions in the management of neutropenic fever is poorly defined. Although some small series and case report studies have attributed benefit to granulocyte transfusions in profoundly neutropenic patients with documented severe bacterial and fungal infections, others have failed to demonstrate significance.[46,47] A Cochrane Review of 8 randomized controlled trials found the data inconclusive.[46,48] The rationale for granulocyte transfusions is to provide support for the neutropenic patient with a life-threatening infection by augmenting the number of circulating neutrophils until autologous myeloid regeneration occurs. Rare adverse events associated with granulocyte transfusions include transmission of infections (commonly CMV), HLA alloimmunization, fever, potential transfusion associated graft-versus-host disease if granulocytes are not irradiated, and progressive platelet refractoriness. Appropriate patient selection is necessary prior to administration of granulocyte transfusions, given the risks and the marginal benefits reported.

SPECIFIC FEBRILE SYNDROMES, SELECTED PATHOGENS, AND TREATMENTS

Sepsis and Septic Shock

Severe sepsis and septic shock are associated with a high mortality rate. Published mortality rates vary between 20% and 60%.[49,50] Common sequelae include acute respiratory distress syndrome (ARDS) and multisystem organ failure, which accounts for the high mortality of this syndrome. The source of septicemia is not apparent in 30% of cases, despite positive identification of an organism.[50,51]

Sepsis is defined as the presence of systemic inflammatory response syndrome (SIRS) associated with a confirmed infectious process.[52] SIRS can be self-limited or can progress to severe sepsis and septic shock. Along this continuum, circulatory abnormalities (intravascular volume depletion, peripheral vasodilatation, myocardial depression, and increased metabolism) lead to an imbalance between systemic oxygen delivery and oxygen demand, resulting in global tissue hypoxia or shock. SIRS criteria include two or more of the following: (1) temperature greater than 38°C or less than 36°C, (2) heart rate greater than 90 beats per minute, (3) respiratory rate greater than 20 breaths per minute or a PCO2 less than 32 mm Hg, or (4) white blood cell count greater than 12×10^9/L or less than 4×10^9/L, or the presence of more than 0.1×10^9/L immature band neutrophils.[52]

Bloodstream Infections

Bloodstream infection is a common complication of patients undergoing cytotoxic chemotherapy. Common sources include skin breakdown, intravenous catheters, as well as the digestive and respiratory tracts. Following documented bacteremia, repeat blood cultures should be obtained to confirm the effectiveness of therapy. Evaluation to identify the source of the infection should also be performed.

Gram-positive Bacteria

Staphylococcus species are the most common cause of bacteremia. *Staphylococcus aureus* is a coagulase positive bacteria, which commonly colonizes the nares and the skin of many individuals, and can cause both local disease (wound infection, cellulitis) and systemic disease (bacteremia, endocarditis, septic arthritis, and osteomyelitis). Removal of intravascular catheters should be considered in patients with *S. aureus* bacteremia. The risk of endocarditis following *S. aureus* bacteremia warrants a transesophageal echocardiogram to determine the absence or presence of heart valve vegetations and thus define the necessary duration of therapy.[35,53,54,55,56] A 2-week course of intravenous antibiotics may be sufficient for *S. aureus* bacteremia with a negative transesophageal echocardiogram.[35] Nafcillin is the drug of choice for treating methicillin-susceptible *S. aureus,* whereas vancomycin should be reserved for MRSA or the treatment of penicillin-allergic patients.[57]

Methicillin-resistant *S. aureus* (MRSA) is recognized as a major cause of infection in the health care setting and is now emerging in the community.[58] MRSA isolates are resistant to all beta-lactam antibiotics as well as cross-resistant to multiple classes of antibiotics. Community-acquired MRSA strains are generally susceptible to clindamycin and TMP/SMX. The standard treatment for MRSA is vancomycin. Clinical infections caused by vancomycin-intermediate and vancomycin-resistant *S. aureus* have been reported sporadically and generally occur only in patients receiving prolonged courses of vancomycin.[58] Failure of vancomycin in MRSA bacteremia has been associated with increasing vancomycin minimum inhibitory concentrations well within what is currently considered the susceptible range.[59] New guidelines on vancomycin dosing and therapeutic monitoring have been published based on these observations. Serum vancomycin trough concentrations should be maintained above 10 mg/L to avoid development of resistance.[60]

Linezolid and daptomycin are active against the majority of gram-positive organisms, including MRSA[61–65]; however, the use of these drugs should be limited to specific situations. Daptomycin, a bactericidal lipopeptide (6 mg/kg daily) is an acceptable option for *S. aureus* bacteremia.[66] Daptomycin is inactivated by lung surfactant and therefore should not be used to treat pneumonia. Linezolid should be used cautiously in patients with compromised bone marrow function, as myelosuppression has been associated with prolonged exposure. Thrombocytopenia occurs in 0.3% to 10% of those on linezolid and increases with the duration of use. Myeloid recovery of neutropenic cancer patients is not delayed with short courses; however, data for prolonged exposure (greater than 14 days) is limited.[41,61] Linezolid is not approved for treatment of catheter-related infections or gram-negative infections, as these patients have a higher chance of death compared with those receiving vancomycin or oxacillin for intravascular catheter-related infection with gram-positive and gram-negative organisms.[67] Linezolid seems at least as effective as vancomycin against nosocomial MRSA pneumonia in most published studies, although a controversial post hoc subgroup analysis suggests linezolid has a slight advantage over vancomycin on survival and cure rates.[68,69] The American Thoracic Society and IDSA guidelines on nosocomial MRSA pneumonia consider linezolid and vancomycin to each be acceptable options for suspected or proven MRSA pneumonia.[70]

Neutropenic patients with severe mucositis are at increased risk for bacteremia with viridans group streptococci (VGS), a commensal normal oral flora. Other risk factors for VGS include prophylaxis with TMP/SMX or fluoroquinolones and the use of histamine-2 blockers.[71] Neutropenic patients with VGS bacteremia may have a low-grade fever and facial flushing prodrome followed by high fever and chills. Complications include toxic-shock–like syndrome characterized by hypotension, respiratory distress, renal failure, and a centrifugal maculopapular rash usually starting on the trunk with subsequent desquamation of the palms and soles. Septic shock may be more common in children than in adults.[72] Resistance of VGS to beta-lactams has been recognized and empiric use of vancomycin as initial therapy is recommended pending susceptibility testing.

Vancomycin-resistant enterococcus (VRE) bloodstream infection is an important cause of morbidity. The portal of entry for enterococcal bacteremia may be an indwelling central catheter or mucositis from chemotherapy or radiation toxicity. Risk factors for VRE include prolonged hospitalization, neutropenia, chemotherapy-induced mucositis, and use of vancomycin, cephalosporins, and metronidazole.[73] VRE bloodstream infections in cancer patients are associated with significant reduction in survival and frequent microbiologic failure, despite treatment with linezolid and/or daptomycin.[74] Optimal therapy for VRE infection in cancer patients is not well defined. Catheter removal from patients with indwelling lines and VRE bacteremia should always be considered. Linezolid, quinupristin-dalfopristin, and daptomycin have been used with variable success rates[41,75,76]; and tigecycline has demonstrated activity in vitro.

Quinupristin/dalfopristin (a 30:70 mixture of two semisynthetic streptogramin antibiotics) has been shown to be safe and effective in serious vancomycin-resistant *E. faecium* infections, but is not active against *E. faecalis.* Common adverse effects including arthralgias, myalgias, and conjugated hyperbilirubinemia may limit its use in certain patients.[75]

Gram-negative Bacteria

Infections caused by gram-negative bacilli typically occur in the lungs, in the urinary tract, and in the bloodstream and are a significant cause of morbidity and mortality.[77] Gram-negative bacilli most commonly responsible for infection in humans are *Enterobacter* species*, Klebsiella pneumoniae, Pseudomonas aeruginosa*, *Escherichia coli*, *Acinetobacter* species, and *Serratia marcescens*. Mortality related to infections caused by gram-negative bacilli ranges from 20% to 60% depending on the site of infection and a patient's comorbid conditions. Inappropriate initial antimicrobial therapy and a delay in drug administration are associated with poorer patient outcomes.[78,79] Prompt treatment with adequate coverage, especially for *P. aeruginosa,* should be initiated until susceptibility results are available, to minimize mortality and morbidity.

Double coverage for gram-negative bloodstream infections in combination with an aminoglycoside has been shown to result in increased toxicity and no improvement in overall survival.[24,80,81] Empiric use of an aminoglycoside should therefore be limited to patients with hemodynamic instability and those in whom there is a high suspicion for antibiotic-resistant gram-negative bacterial infections. Fluoroquinolones with adequate antipseudomonal activity may be an acceptable alternative to an aminoglycoside as part of a combination regimen, depending on local susceptibility patterns.

Infections caused by *P. aeruginosa* remain the most lethal gram-negative pathogens in neutropenic patients. Empiric combination of an antipseudomonal beta-lactam antibiotic plus an aminoglycoside or antipseudomonal fluoroquinolone is recommended until susceptibility data is available, since no single antimicrobial is effective against 100% of *Pseudomonas* isolates.[75,82] Infections due to strains of *P. aeruginosa* resistant to all common antipseudomonal agents are an increasing problem.[83] Ecthyma gangrenosum is the most characteristic skin lesion associated with systemic *P. aeruginosa* infection.

Escherichia coli and *Klebsiella* species are common gram-negative pathogens in neutropenic patients. The use of prophylactic antibiotics such as ciprofloxacin or TMP/SMX may increase the prevalence of resistant enteric organisms such as *Enterobacter*, *Citrobacter*, and *Serratia* species which may carry an inducible beta-lactamase that may contribute to treatment failure with third-generation cephalosporins like ceftazidime. Carbapenems, fluoroquinolones, and piperacillin-tazobactam may be used in this setting. *Stenotrophomonas maltophilia* is an increasingly common cause of infection in patients who have been on broad-spectrum antibiotics or who have intravascular catheters.[75] TMP/SMX is the treatment of choice for patients with this infection but ticarcillin-clavulanate or moxifloxacin may be effective in patients intolerant to TMP/SMX. *Acinetobacter baumannii* bacteremia is frequently associated with infected intravascular catheters and is often resistant to multiple antibiotics, including imipenem-cilastatin.[84] Ampicillin-sulbactam, tigecycline, or colistin may be effective, but consultation with an infectious diseases specialist is encouraged when dealing with *Acinetobacter* infections.

Fungemia

Pathogenic fungi include yeasts and molds. *Candida* species are yeasts that form part of the normal flora and typically gain access to the bloodstream through disruption of anatomic barriers (mucositis or indwelling catheters). Molds are ubiquitous soil inhabitants whose conidia or spores are inhaled. Aspergillosis is the most common mold infection in cancer patients, but other pathogenic fungi (e.g., zygomycetes, *Fusarium* and *Scedosporium* species) have also been reported.

Candidemia and Invasive Candidiasis

Candida species are the fourth most common cause of nosocomial bloodstream infections in the United States.[85,86] Mortality rates of candidemia range between 20% and 40%.[86] *C. albicans* is the most common, although the frequency of non-*albicans* candidemia is increasing, presumably as a consequence of widespread fluconazole prophylaxis. Clinical findings vary from asymptomatic to full-blown septic shock. *C. tropicalis* is highly virulent in neutropenic hosts. *C. krusei* is generally resistant to fluconazole, and *C. glabrata* has variable susceptibility. *C. parapsilosis* is associated with the vascular catheters and lipid formulations used for total parenteral nutrition.

Comparison of IV fluconazole with amphotericin B as therapy for candidemia in neutropenic and nonneutropenic patients has found similar overall response rates, but less toxicity with fluconazole.[87,88] Anidulafungin appears to be similar to fluconazole in treating invasive candidiasis.[89] Voriconazole provides equivalent benefit and has less nephrotoxicity compared to the sequential combination of amphotericin B followed by fluconazole in nonneutropenic patients.[90] Caspofungin has a slightly higher response rate and is less toxic than amphotericin B as initial therapy for invasive candidiasis, and micafungin has been shown to be as effective as amphotericin B.[91,92,93]

IDSA guidelines for management of candidiasis recommend an echinocandin (caspofungin, micafungin, or anidulafungin) for treatment of candidemia in neutropenic patients.[94] Lipid formulations of amphotericin B are recommended in complicated infections such as endocarditis and meningitis or in hemodynamically unstable patients where invasive mold infection is suspected.[94] Echinocandins are also advised in patients who develop breakthrough candidemia while receiving an azole. Voriconazole should be considered for treatment of *C. krusei*, which is generally resistant to fluconazole, and when a mold-active agent is warranted. Patients with candidemia should undergo ophthalmologic evaluation with fundoscopic exam, and it is recommended that intravascular catheters be removed from patients with candidemia.[94]

Aspergillosis is addressed in the pneumonia section; zygomycosis (mucormycosis) is covered under sinus infection; and cryptococcosis is under central nervous system (CNS) infections.

CENTRAL NERVOUS SYSTEM INFECTIONS

Infection of the CNS can present with subtle nonspecific findings such as fever, headache, photophobia, changes in mental status, or more dramatic findings such as loss of consciousness and seizure. Prompt diagnosis and initiation of therapy are crucial to minimize negative clinical outcomes. CNS infections can be divided into surgical- and nonsurgical-related complications and infections. The IDSA has published guidelines on the management of CNS infections.[95,96]

Central Nervous System Infections Unrelated to Neurosurgery

Meningitis and encephalitis are part of a clinical spectrum of CNS disorders causing fever and meningismus. Encephalitis may manifest with signs and symptoms of meningeal inflammation, but is distinguished by the predominance of alterations of consciousness and neurologic deficits. Initial evaluation generally involves head CT to rule out intracranial bleeding in addition to brain MRI and lumbar puncture (assuming no contraindication). Cerebrospinal fluid (CSF) studies should be tailored to specific host factors, epidemiologic exposures, and clinical presentation, but should generally include a cell count with differential, glucose, protein, Gram stain, cryptococcal antigen, fungal culture, and bacterial culture. Noninfectious causes of meningitis include carcinomatous meningitis, nonsteroidal antiinflammatory medications, TMP/SMX, and serum sickness (e.g., associated with antilymphocyte gammaglobulin or intravenous immunoglobulin [IVIG]).

Empiric treatment for suspected bacterial meningitis should include antimicrobial agents that penetrate the blood-brain barrier and enter the CSF, such as ceftriaxone, ampicillin, and vancomycin.[95] This regimen provides coverage against the most common causes of bacterial meningitis, including penicillin-resistant pneumococci and listeriosis. The combination of vancomycin and TMP/SMX may be used in patients allergic to penicillins.[95] Cefepime or meropenem should be used instead of ceftriaxone in patients at risk for *P. aeruginosa* meningitis (e.g., neutropenia, neurosurgery within the past 2 months, allogeneic HSCT, prior history of *P. aeruginosa* infection). Meropenem should also provide appropriate coverage against *Listeria*. Conflicting results have been reported regarding the use of dexamethasone as an adjuvant therapy in the management of bacterial meningitis. Data

from a large meta-analysis found dexamethasone to not provide significant reductions in death or neurologic sequelae, although a statistically significant reduction in hearing loss was observed among surviving patients.[97] ISDA guidelines for the management of bacterial meningitis support the incorporation of adjuvant dexamethasone in pediatric patients with *H. influenzae* type B meningitis and in adult patients with pneumococcal meningitis.[95]

Encephalitis in patients with cancer is most commonly caused by HSV. Intravenous acyclovir should be considered as empiric therapy for HSV in patients with suspected encephalitis (fever, mental status changes, CSF pleocytosis, and focal changes on EEG or MRI, especially in the temporal lobes). CSF studies should include PCR for HSV and CSF cytology. PCR for arboviruses should be considered in patients with exposure to endemic areas. The CSF should also be sent for nucleic acid amplification, adenosine deaminase level, and culture for tuberculosis in patients with known or suspected encephalitis. Patients with severe impairment of cellular immunity (e.g., allogeneic HSCT recipient, advanced AIDS) should be evaluated with PCR for CMV, VZV, HHV-6, and toxoplasmosis as well as culture for *Nocardia*. Most cases of encephalitis occur in HSCT patients and are due to reactivation of latent viral, bacterial, or parasitic infections: herpesviruses (HSV, VZV, CMV, EBV, human herpes virus [HHV]-6), adenovirus, mycobacteria, and *Toxoplasma gondii*.

Herpes viruses

HSV meningoencephalitis has been associated with older age, steroid therapy, and brain irradiation. The diagnosis is usually made by viral PCR from the CSF and enhancement of the temporal lobe on MRI. Intravenous acyclovir should be considered as empiric therapy for HSV.[96] Other, less common herpesvirus infections can also be diagnosed by PCR of viral DNA in the CSF. Detection of high levels of EBV DNA should raise suspicion of EBV-related lymphoproliferative disorder, but primary EBV encephalitis and myelitis have been described.[98,99] HHV-6 has been associated with a characteristic syndrome in HSCT patients consisting of confusion, lethargy, fever, rash, and hippocampal enhancement on T2-weighted MRI FLAIR images.[100] The diagnosis is made by detection of HHV-6 DNA in the CSF by PCR. Ganciclovir or foscarnet may be used in treating HHV-6 infections.[101] Adenoviral encephalitis in HSCT patients has been reported as part of disseminated adenoviral infection and treatment with cidofovir may be attempted.[96]

Other uncommon but important causes of meningoencephalitis are due to new primary infections rather than reactivation. Advanced age and cancer are risk factors for encephalitis from West Nile virus (WNV) transmitted by mosquitoes and for which there is no proven therapy.[102]

Brain Abscess

Brain abscesses that develop during neutropenia are typically caused by fungi (commonly *Aspergillus* and *Candida*).[103] Bacterial abscesses may occur as a local extension of infection of the sinuses or dental caries and are often caused by a mixed aerobic and anaerobic flora (streptococci, *Staphylococcus, Bacteroides).* Other causes of CNS abscesses in patients with impaired cellular immunity include toxoplasmosis, nocardiosis, cryptococcosis, and mycobacterial infections.[103]

Noninfectious etiologies include CNS malignancies, including secondary lymphomas and EBV-associated posttransplant lymphoproliferative disease (PTLD) in patients with impaired cellular immunity. Given the broad differential diagnosis of new focal CNS lesions in the highly immunocompromised patient, a brain biopsy is recommended if feasible. Cultures and stains should include bacteria, fungi, mycobacteria, and *Nocardia* species. Serum galactomannan, CSF galactomannan, and beta-d-glucan testing are useful to facilitate a diagnosis of CNS aspergillosis.

Brain abscesses usually manifest with headache, focal neurologic findings, or seizures.[104,105] MRI typically shows single or multiple lesions with edema and ring enhancement. Manifestations of CNS aspergillosis include focal seizures, hemiparesis, cranial nerve palsies, and hemorrhagic infarcts due to vascular invasion.[106] *Aspergillus* brain abscesses are typically multiple, hypodense, and nonenhancing with little mass effect. CT scans with contrast enhancement may initially fail to reveal focal lesions, but subsequently evolve focal ring-enhancing or hemorrhagic lesions.[107]

Initial therapy with ceftriaxone plus metronidazole is advised in immunocompetent patients with a bacterial brain abscess.[3,104,105,108] Patients with prolonged neutropenia should be treated with the combination of meropenem or cefepime plus metronidazole and voriconazole[3,104] Adjustments may be needed for patients requiring certain antiseizure agents (e.g., phenytoin) due to the potential for significant drug–drug interactions with voriconazole (as well as itraconazole and posaconazole).[109] Empiric high-dose TMP/SMX (trimethoprim component: 5 mg/kg every 8 hours) should be considered to cover toxoplasmosis and nocardiosis in allogeneic HSCT recipients and patients with severe T cell impairment. Retrospective analysis of CNS aspergillosis treated with voriconazole as either primary or salvage therapy indicated that 34% had a complete or partial response[110] and compares favorably to previous reports in which frequency of successful responses to amphotericin B in CNS aspergillosis was close to zero.[111]

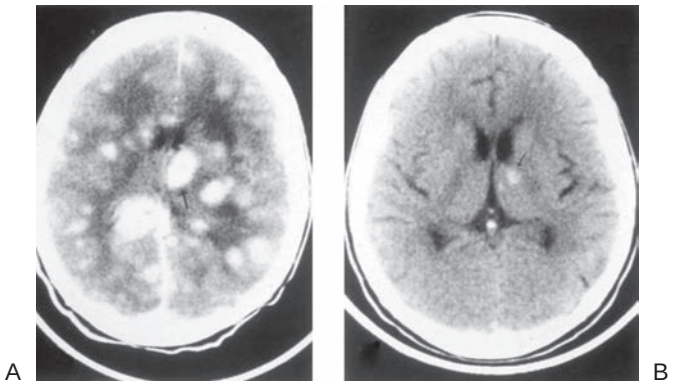
Cryptococcosis

Lymphoid malignancy and corticosteroid therapy are major risk factors for cryptococcal infection.[112] Host defense against cryptococcal infection is dependent on T cell immunity. Isolated neutropenia is rarely associated with cryptococcal infection. The principal portal of entry of this organism is by inhalation. Spread to the blood and then to the central nervous system is a prerequisite for subsequent development of cryptococcal meningitis. Although meningitis is the most common presentation of cryptococcal infection, other manifestations include pneumonia, fungemia, cutaneous infections, and visceral dissemination. Visual loss may be a consequence of endophthalmitis (a space-occupying lesion in the visual pathway), direct invasion of the optic nerve, and elevated intracranial pressure.[113]

The IDSA recommends a regimen of amphotericin B (0.7 to 1 mg/kg daily) plus 5-fluorocytosine (100 mg/kg daily) for the first 2 weeks, followed by life-long maintenance fluconazole therapy in AIDS-associated cryptococcal meningitis.[114] In the absence of modern randomized studies, the same induction regimen is recommended in non-AIDS–associated cryptococcal meningitis, followed by fluconazole for at least 10 weeks or until immunosuppressive agents have been discontinued.[114] Reduction of the dosage of 5-fluorocytosine may be considered to minimize delay of myeloid recovery in neutropenic patients.

Toxoplasmosis

Reactivation of previously acquired infections is responsible for the majority of opportunistic CNS infections caused by *T. gondii.* The organism can be acquired by ingestion of undercooked meat or through contact with feline feces. CNS toxoplasmosis is typically associated with disseminated infection, and risk factors include therapy with corticosteroids, alemtuzumab, cytotoxic agents, and/or radiation therapy, and poorly controlled malignancy. Although toxoplasmosis is an uncommon complication of HSCT, nearly all occurrences are associated with seropositivity prior to transplantation.[115] It tends to occur in the presence of moderate to severe GVHD with a median day of onset of disease at 64 days post-HSCT.[116]



A B

FIGURE 69.4. Central nervous system toxoplasmosis: magnetic resonance imaging study of the brain before therapy (A) and after therapy (B) with pyrimethamine and sulfadiazine.

Common clinical findings for CNS toxoplasmosis include altered mental status, coma, seizures, cranial nerve abnormalities, and motor weakness.[117] MRI typically shows two or more lesions that may be ring-enhancing (Fig. 69.4). The differential diagnosis includes bacterial infection, invasive aspergillosis, nocardiosis, and malignancy. Differentiating toxoplasmosis from lymphoma is particularly difficult; [18F] fluorodeoxyglucose positron emission tomography typically shows increased metabolism in lymphoma.[118] CSF in toxoplasmosis is usually normal but mononuclear pleocytosis and elevated protein levels may occur. In addition to CNS involvement, toxoplasma may also present with myocarditis, interstitial pneumonitis, culture-negative sepsis, and hemophagocytic syndrome. Definitive diagnosis of toxoplasmosis relies on demonstration of tachyzoites and cysts in histopathologic sections, but PCR testing of serum and CSF may facilitate earlier diagnosis.[117,119] Oral sulfadiazine 1 to 1.5 g every 6 hours plus pyrimethamine (loading dose of 200 mg, followed by 75 mg daily) is the initial treatment of choice for toxoplasmosis. Folinic acid (10 to 20 mg daily) should be administered to reduce myeloid toxicity. At 4 to 6 weeks after resolution of symptoms and signs of infection and radiologic improvement, switching to a maintenance regimen (sulfadiazine 0.5 to 1 g four times daily plus pyrimethamine 50 mg/day) is reasonable. Maintenance therapy should be continued for the duration of immunosuppression and until radiologic resolution. Clindamycin and primaquine may be used instead, after verifying normal glucose-6-phosphate dehydrogenase activity in patients intolerant of sulfonamides. Atovaquone may also be used after exhausting other options.[96]

Dementias

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease associated with lytic infection of oligodendrocytes by the human polyomavirus JC virus.[40] Patients may develop rapidly progressive dementia as well as focal motor neuropathy or cerebellar degeneration. This disease is most commonly seen in patients with advanced AIDS. However, PML is also seen in severely immunocompromised persons with hematologic malignancies and in HSCT recipients. Several reports have linked the use of rituximab with the development of PML and prompted an FDA advisory regarding a possible association.[120] PML has also been reported with other immunosuppressants and biologics including belatacept,[121] brentuximab,[122] efalizumab,[123] fludarabine,[124] infliximab,[125] and mycophenolate.[126] Brain MRI typically reveals unilateral or bilateral white matter disease without mass effect or enhancement. Diagnosis is generally confirmed by detection of the JC virus in spinal fluid by PCR (90% sensitivity) or by brain biopsy. There is no established therapy for PML and the prognosis is poor.

Infections Related to Neurosurgical Procedures and/or Devices

Neurosurgical procedures such as resection of tumor, insertion of a shunt for hydrocephalus, or insertion of an Ommaya reservoir each carry a risk for infectious complications. Infection risk is further increased with use of steroids and brain irradiation. Early postoperative infections after placement of intraventricular devices are usually caused by skin flora: coagulase-negative staphylococci, *S. aureus*, streptococci, and *Propionibacterium acnes*. Enterobacteriaceae and *P. aeruginosa* account for approximately 10% of infections. Coagulase-negative staphylococci and *P. acnes* usually cause indolent late postoperative infections.

Infection of a shunt or an Ommaya reservoir may manifest with malfunction of the device, fever, or altered mental status. Overt signs of meningitis, such as meningismus and photophobia are often absent. CT imaging may suggest meningitis, ventriculitis, or a brain abscess if the device is infected at the proximal end. Evaluation of the CSF is required for diagnosis confirmation. Infections occurring in the distal region of the device may manifest as a soft tissue infection. In cases of ventriculoatrial shunts, distal infections may cause persistently positive blood cultures, thrombophlebitis, endocarditis, or septic pulmonary emboli. Distal ventriculoperitoneal shunt infections are associated with peritonitis and intraabdominal collections. Removal of the entire device plus systemic antibiotics is the most effective approach to eradicate infection. Use of parenteral and intraventricular instillation of antibiotics without hardware removal has demonstrated variable success, and recurrence of infection is common, particularly those caused by *S. aureus*.[127] Antibiotic therapy should be tailored to the specific pathogen isolated. In acutely ill patients with meningitis suspected to be related to prior neurosurgery, empiric therapy with parenteral vancomycin should be administered to cover *Staphylococcus*, *Streptococcus*, and *Propionibacterium* species in combination with an agent with activity against Enterobacteriaceae and *P. aeruginosa* such as ceftazidime or meropenem.[95]

OROPHARYNGEAL AND SINUS INFECTIONS

The mucosal linings of the gastrointestinal and respiratory tracts constitute the first line of host defense against a variety of pathogens. During the course of treatment for hematologic malignancy these barriers often are compromised and expose patients to infections and invasions by local flora, resulting in bacteremia and candidemia. Chronic GVHD may further compromise mucosal immunity, including defective salivary immunoglobulin secretion.

Mucositis may extend into the esophagus, causing retrosternal chest discomfort. Mucosal lesions are usually caused by HSV and/or *Candida* species, but are occasionally caused by CMV, fungal (i.e., *Histoplasma*), or bacterial pathogens such as viridans group streptococcal infections and oral anaerobes (i.e., *Pseudomonas* species).

Oral mucosal candidiasis or thrush is common with T cell immunodeficiency. Cytotoxic chemotherapy, corticosteroids, and antibiotics predispose to oral candidiasis. The most common presentation is white adherent plaques on the palate, buccal mucosa, tongue, or gingiva. Pseudohyphae on a wet mount or Gram stain establish the diagnosis. Therapy includes local treatments such as clotrimazole troches or oral fluconazole.

Esophageal candidiasis may present as odynophagia and initial therapy with fluconazole is advised. Therapeutic options for fluconazole-resistant mucosal candidiasis include an echinocandin, voriconazole, posaconazole, or amphotericin B. Most fluconazole-resistant *Candida* isolates are susceptible to voriconazole and posaconazole, but cross-resistance may occur.

Congestion, sinus tenderness, and fever are common nonspecific signs of sinusitis. Respiratory bacterial pathogens, including *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* predominate the etiology of sinusitis in immunocompetent patients. Common pathogens in those that are immunocompromised include *P. aeruginosa*, *S. aureus*, Enterobacteriaceae, and molds, and warrant investigation with sinus and facial imaging. Treatment of sinusitis in immunocompetent patients involves standard antibiotic regimens, such as amoxicillin-clavulanate, azithromycin, clarithromycin, or a cephalosporin with activity against respiratory pathogens. In addition to standard antibiotic therapy, neutropenic patients with symptoms or signs of sinusitis should have a CT scan of the sinuses and an otolaryngologist consultation and consideration of endoscopy to assess the possibility of invasive mold. Endoscopy with or without mucosal biopsy is often helpful in distinguishing these entities when there is no response to empiric antifungal or antiviral therapy or if clinical deterioration follows initial response to therapy. Systemic azole or amphotericin B therapy is preferred in patients with AIDS, neutropenic cancer patients, patients with recurrent perineal candidiasis, or those with refractory proven oropharyngeal candidiasis.[87]

The presence of a heterogeneous mass or bony erosion on CT is highly suggestive of invasive fungal sinusitis. Periorbital swelling and diplopia may be observed late in the course of infection. *Aspergillus* species are the most common isolate, but zygomycetes (e.g., *Mucor, Rhizopus*) as well as less common molds such as *Fusarium* are also being recognized. Aggressive surgical debridement in addition to antifungal therapy with two broad-spectrum antifungals is usually required to optimize the chances of recovery. Empiric therapy should include a lipid formulation of amphotericin B (5 mg/kg/d) to ensure treatment against *Aspergillus* species and zygomycetes.[128] Antifungal therapy should be continued for weeks to months even if all of the visualized necrotic tissue is fully resected. Voriconazole may be substituted for many cases of fungal sinusitis, but should be avoided in zygomycetes (*Mucor*, *Rhizopus*) infections which are not susceptible to voriconazole. Posaconazole is an oral azole with activity against zygomycetes and may provide a useful alternative to an amphotericin B formulation for long-term therapy.[129] Posaconazole therapy does require adequate food intake for optimal absorption to reach therapeutic levels.[130]

LUNG INFECTIONS

Pneumonia is the most common infectious cause of death in immunocompromised patients. Numerous noninfectious processes should also be considered in patients with pulmonary infiltrates: malignancy, its treatment (drug toxicity, radiation pneumonitis), congestive heart failure, pulmonary hemorrhage, pulmonary embolism with infarction, cryptogenic organizing pneumonia (also known as bronchiolitis obliterans organizing pneumonia), and acute respiratory distress syndrome. It is imperative that prompt empiric therapy should be initiated when an infectious cause is suspected. The differential diagnosis of pulmonary infiltrates in patients with hematologic malignancies is shown in Table 69.5. Noninfectious causes of interstitial pneumonitis (IP) in the febrile patient are diagnosed only after exclusion of infectious etiologies.

Pulmonary Infiltrates in Neutropenic Patients

Diagnosing the etiology of pulmonary infiltrates in neutropenic patients can be challenging for many clinicians. Physical findings of consolidation and sputum production may be absent as a result of the neutropenia. General work-up for suspected pneumonia should include routine blood cultures, a chest radiograph, and if possible, sputum culture and Gram stain. Respiratory viral pathogens should be considered during peak season and local pattern of infections. Rapid testing for influenza A and B may be performed using a throat or nasopharyngeal swab but viral culture is more definitive. Nasopharyngeal wash may also be used to diagnose respiratory viral infections. Legionellosis can be diagnosed based on urine antigen testing or sputum culture. While the urine antigen testing is more easily obtained, it only detects *Legionella pneumophila* type I.[131] Broad-spectrum antibiotics should be initiated immediately and therapy tailored once culture data become available.

Initial Antimicrobial Therapy

In patients with less than 7 days of neutropenia, pulmonary infections are likely to be caused by Enterobacteriaceae, *P. aeruginosa*, and *S. aureus*. Community respiratory viruses should also be considered during winter months. If community-acquired pneumonia is suspected, a macrolide or fluoroquinolone should be given to cover for atypical pneumonia organisms. The addition of TMP/SMX should be considered if PJP is suspected. Vancomycin or linezolid should be added for pneumonia in patients colonized with MRSA and for nosocomial pneumonia. If clinical improvement occurs within 48 to 72 hours of therapy, the antibiotic regimen should be tailored based on available culture data and continued for at least 10 to 21 days and until neutropenia resolves. In the absence of clinical improvement, resistant bacterial and nonbacterial pathogens including filamentous fungi should be considered.

Pulmonary Infiltrates in Patients with Defects in Cell-mediated Immunity

In addition to the common bacterial causes of pneumonia, patients with defects in cell-mediated immunity are at risk for infections with *P. jirovecii*, *Nocardia* species, and viruses, as well as *Legionella*, mycobacteria, mold, and fungi. Invasive procedures, including bronchoscopy for bronchoalveolar lavage (BAL) and/or biopsy, should be considered to aid in diagnosis.

Fungal Pneumonia

Patients with allogeneic HSCT, prolonged high-dose systemic corticosteroids, immunosuppression with T cell suppressants and neutropenia for more than 10 days are at increased risk of fungal pneumonia. Chest CT imaging is recommended in patients failing to respond to initial empiric treatment or those in whom there is a high suspicion for fungal or mold infection.[132] CT may disclose lesions missed by the chest radiograph as well as findings characteristic of invasive fungal disease: well-circumscribed, dense infiltrates, the "halo sign," and/or cavitation.[133] Other angioinvasive infections including *P. aeruginosa* may cavitate. The galactomannan assay is specific for invasive aspergillosis,[134] whereas the beta-d-glucan assay detects aspergillosis and other invasive fungal infections including invasive candidiasis, PJP, and fusariosis.[135] Galactomannan assay testing is associated with a sensitivity of 70% and specificity of 89% for invasive aspergillosis.[136] False-positive results may be more common in children and allogeneic HSCT recipients with concomitant use of piperacillin/tazobactam.[137,138] Rising serum galactomannan levels correlate with failure of antifungal therapy, whereas decreasing levels are associated with positive outcomes in patients with invasive aspergillosis.[139,140]

Aspergillus species are by far the most common invasive mold infections (Fig. 69.5). Voriconazole is currently the treatment of choice for invasive aspergillosis.[34,137] Amphotericin B is active against *Aspergillus* species (with the exception of *Aspergillus terreus*), but may be inferior to voriconazole in aspergillosis.[137] Initial antifungal therapy should be either with voriconazole or a lipid formulation of amphotericin B in patients at high risk for invasive mold diseases or with suspected pneumonia of unknown etiology. Echinocandins have not been evaluated as initial monotherapy for invasive aspergillosis, but have favorable response

TABLE 69.5

DIFFERENTIAL DIAGNOSIS OF PULMONARY INFILTRATE IN THE IMMUNOCOMPROMISED PATIENT

Cause	Diagnosis
Infectious Causes	
Bacterial pneumonia	Lung infiltrate: positive culture from blood, BAL, or pleural fluid; resolution with antibiotics.
CMV pneumonia	Intranuclear or intracytoplasmic CMV inclusions in pulmonary epithelial cells in TBB specimen or BAL fluid, or positive BAL culture for CMV. Quantitative PCR can be monitored for response.
Other viral pneumonias	May be preceded by rhinorrhea, sore throat, and cough; diffuse interstitial pattern. Most common are RSV, influenza, parainfluenza, and adenovirus. Diagnosis can be made by detection of virus or viral antigen on throat swabs, nasal washes, or BAL fluid; immunologic and molecular techniques (PCR) are available.
Legionella pneumonia	Positive culture of *Legionella* species from sputum, BAL fluid, or pleural fluid, or positive test for *Legionella* antigen by DFA test in BAL fluid, or a positive urinary *Legionella pneumophila* antigen or *Legionella* titer ≤1:256 with compatible clinical features.
Invasive pulmonary aspergillosis	Halo or crescent sign on high-resolution chest CT; positive galactomannan assay; pathologic evidence of invasion of lung tissue by acutely branching septate hyphae consistent with *Aspergillus* species, or isolation of *Aspergillus* species from BAL fluid or bronchial washing with consistent clinical and radiologic features.
Pneumocystis jirovecii Pneumonia	Fever and dyspnea may precede interstitial pneumonia. Detection of cysts or trophic forms of the organism in cytocentrifuge preparation in BAL fluid.
Candida and other fungal pneumonia	Histologic evidence of tissue invasion by *Candida* or other fungal species.
Mycobacterium tuberculosis	Positive culture of *M. tuberculosis* from sputum, bronchial washing, BAL fluid, or lung biopsy showing caseating granuloma with acid-fast organisms.
Nontuberculous mycobacteria (NTM) infection	Consistent clinical and radiologic findings with either: (a) isolation of NTM from sputum, bronchial washing, or BAL fluid and lung biopsy showing mycobacterial histopathology features; or (b) isolation of NTM from lung tissue, blood, or bone marrow culture.
Nocardia pneumonia	Presumptive diagnosis can be made if acid-fast filamentous rods are visualized on TBB or BAL fluid; also, *Nocardia* species are gram-positive rods. Requires 5–21 d for culture. Disseminated disease occurs in one-third of patients, with brain abscess as the most common site.
Noninfectious Causes	
Diffuse alveolar hemorrhage	≥20% hemosiderin-laden macrophages in BAL fluid or hemosiderin-laden macrophages in lung tissue.
Chemotherapy-induced pneumonitis	History of receiving chemotherapeutic agent, with BAL or lung biopsy showing atypical type II pneumocytes with consistent clinical features and no evidence of lung infection.
Radiation pneumonitis	History of receiving radiation, with BAL lymphocytosis with consistent clinical and radiologic features and no evidence of lung infection.
Congestive heart failure (CHF)	Clinical diagnosis of CHF (bibasilar rales, left ventricular third sound, and radiologic evidence of pulmonary edema with resolution of symptoms with diuretics), or pulmonary artery occlusion pressure >18 mm Hg. Older age and prior chemotherapy, particularly with anthracyclines, are contributing factors.
Pulmonary emboli	Diagnostic confirmation strategy varies among institutions; suspected with clinical features, elevated D-dimer, and V/Q scan and confirmed by spiral CT pulmonary angiography.
Leukoagglutinin reaction	Sudden onset of respiratory distress after transfusion. The incidence of transfusion-related lung injury (TRALI) is 0.04%–0.1%; mortality is estimated at 5%–8%.
ARDS/diffuse alveolar damage	Acute-onset, bilateral lung infiltrates on chest radiography, pulmonary artery wedge pressure ≤ 18 mm Hg, or the absence of clinical evidence of left atrial hypertension, and PaO_2/FiO_2 ≤ 300 (acute lung injury) or ≤ 200 (ARDS).
Nonspecific pneumonitis	Lung biopsy showing nonspecific inflammation and variable fibrosis with no evidence of lung infection, and without alternative clinical diagnosis.
Pulmonary infiltrates of unclear etiology	Data from imaging, cultures, serology, and FB inconclusive for a firm diagnosis.

ARDS, acute respiratory distress syndrome; BAL, bronchoalveolar lavage; CMV, cytomegalovirus; CT, computed tomography; DFA, direct immunofluorescent antibody; FB, fiberoptic bronchoscopy; PCR, polymerase chain reaction; RSV, respiratory syncytial virus; TBB, transbronchial biopsy.

rates in patients refractory or intolerant to triazoles or amphotericin B.[141] Posaconazole has been used successfully as salvage therapy for a variety of invasive fungal infections refractory to standard therapy.[142] Posaconazole is currently approved by the FDA for prophylaxis of invasive *Aspergillus* and *Candida* infections, and in the European Union is indicated for treatment of invasive aspergillosis and other invasive fungal infections refractory to standard antifungal agents.[143]

Endemic Fungi

Commonly known endemic fungi include *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis*. These dimorphic fungi exist in nature in the fruiting mycelial stage and then convert to the yeast stage at body temperature. Endemic mycoses in the central United States include histoplasmosis and blastomycosis. Immunocompetent hosts are typically asymptomatic following inhalation of *Histoplasma microconidia* but may manifest acute fever, pulmonary infiltrates, and hypoxia. Immunocompromised patients have a higher risk of disseminated histoplasmosis involving the liver, spleen, lymph nodes, bone marrow, adrenal glands, mucocutaneous tissues, gastrointestinal tract, and CNS. Chest radiographs may show a miliary reticulonodular appearance similar to that seen with tuberculosis. Blood cultures may be positive in disseminated histoplasmosis. Antigen detection in blood, urine, and BAL is both

sensitive and specific.[144] Antibody detection may also be useful, but false-negative results may occur in immunocompromised patients.[145] Biopsy specimens showing small intracellular or narrow budding yeast are suggestive of the diagnosis and should be confirmed by culture. IDSA guidelines recommend amphotericin B for severe pulmonary or disseminated histoplasmosis.[145] Prolonged therapy with itraconazole may be initiated after stabilization of disease, and should be continued for the duration of immunosuppression.[145]

Coccidioides immitis is endemic in the southwestern United States. *C. immitis* is more likely to be pathogenic in patients with compromised cell-mediated immunity. High rates of treatment failure and death have been reported in patients with hematologic malignancies.[146] The diagnosis is most often established by finding the fungus in BAL, sputum, or biopsies. Serology is positive in only 55% of patients. Coccidioidomycosis can involve virtually any organ in disseminated disease but has trophism for bone and the CNS. Therapy for disseminated disease generally requires amphotericin B followed by maintenance fluconazole.[147]

Pneumocystis Jirovecii Pneumonia (PJP)

Pneumocystis jirovecii (formerly *P. carinii*) is classified as a fungus rather than a protozoan based on gene sequence data, although it lacks ergosterol, the main fungal cell-wall component. Defective T cell immunity and steroid use are risk factors for PJP. *Pneumocystis jirovecii* can have a fulminant course with rapid progression to respiratory failure in immunocompromised patients.[148] Patients with pneumonia from *P. jirovecii* usually present with rapid onset of dyspnea, nonproductive cough, hypoxemia, and fever. Radiologic studies generally show diffuse bilateral interstitial infiltrates but can show focal infiltrates. Pleural effusion is uncommon. Diagnosis of PJP relies on visualization of the organism microscopically, as it does not grow in culture. BAL is the standard diagnostic modality for PJP, but induced sputum has acceptable yield in some institutions.[149] Immunofluorescent staining with monoclonal antibodies is more sensitive than silver staining or Wright-Giemsa staining.[150] PJP frequently results in positive serum beta-d-glucan testing.[151] Treatment should be started based on clinical suspicion, and TMP-SMX (5 mg/kg IV every 8 hours) remains the treatment of choice.[3] Prednisone should be added to the empiric treatment regimen if the pO2 is <70 mmHg.[152] Alternatives for TMP/SMX-allergic/intolerant patients include dapsone, atovaquone, or clindamycin-primaquine for infections of moderate severity and IV pentamidine for infections of high severity.

Viral Pneumonia

Pneumonia due to respiratory viruses (respiratory syncytial virus [RSV], influenza, parainfluenza, adenovirus) is more common in patients with defects in cell-mediated immunity. Treatment with ribavirin (RSV, parainfluenza)[153,154] with or without immunoglobulins or cidofovir (adenovirus)[155] has not been shown to change outcome. Prompt treatment of RSV upper respiratory illnesses in HSCT recipients with a combination of aerosolized ribavirin and IVIG prevents progression to pneumonia in a pilot study.[156] Oseltamivir and zanamivir are effective in HSCT and immunocompromised patients with influenza and are recommended in documented or suspected influenza infections.[3,157]

CMV pneumonia is a significant complication of allogeneic HSCT. It typically develops between 40 and 100 days posttransplant and presents with fever, dyspnea, hypoxemia, and diffuse interstitial infiltrates (Fig. 69.6). CMV pneumonia after day 100 is becoming more common and should be considered in patients with a history of previous CMV reactivation. In transplant patients the diagnosis is established by a compatible clinical syndrome with detection of CMV in BAL (by culture or cytopathology showing characteristic intracytoplasmic and intranuclear inclusions) or tissue (by culture or histologic diagnosis). CMV pneumonia is rare in nontransplant patients and the culture alone is not considered sufficient to make the diagnosis, as CMV can be shed from pulmonary secretions without causing invasive disease.[158,159] Frontline treatment of CMV pneumonia typically consists of ganciclovir 5 mg/kg IV every 12 hours with IVIG 500 mg/kg every 48 hours for 3 weeks, although foscarnet (90 mg/kg every 12 hours) is an acceptable alternative to the ganciclovir.[160]

Hospital-Acquired Pneumonia

Hospital-acquired pneumonia (HAP) is considered "early" when it happens within 4 days of admission or "late" when it occurs 5 days or more after admission.[70] Late HAP is more likely to be caused by multidrug-resistant pathogens. Risk factors for

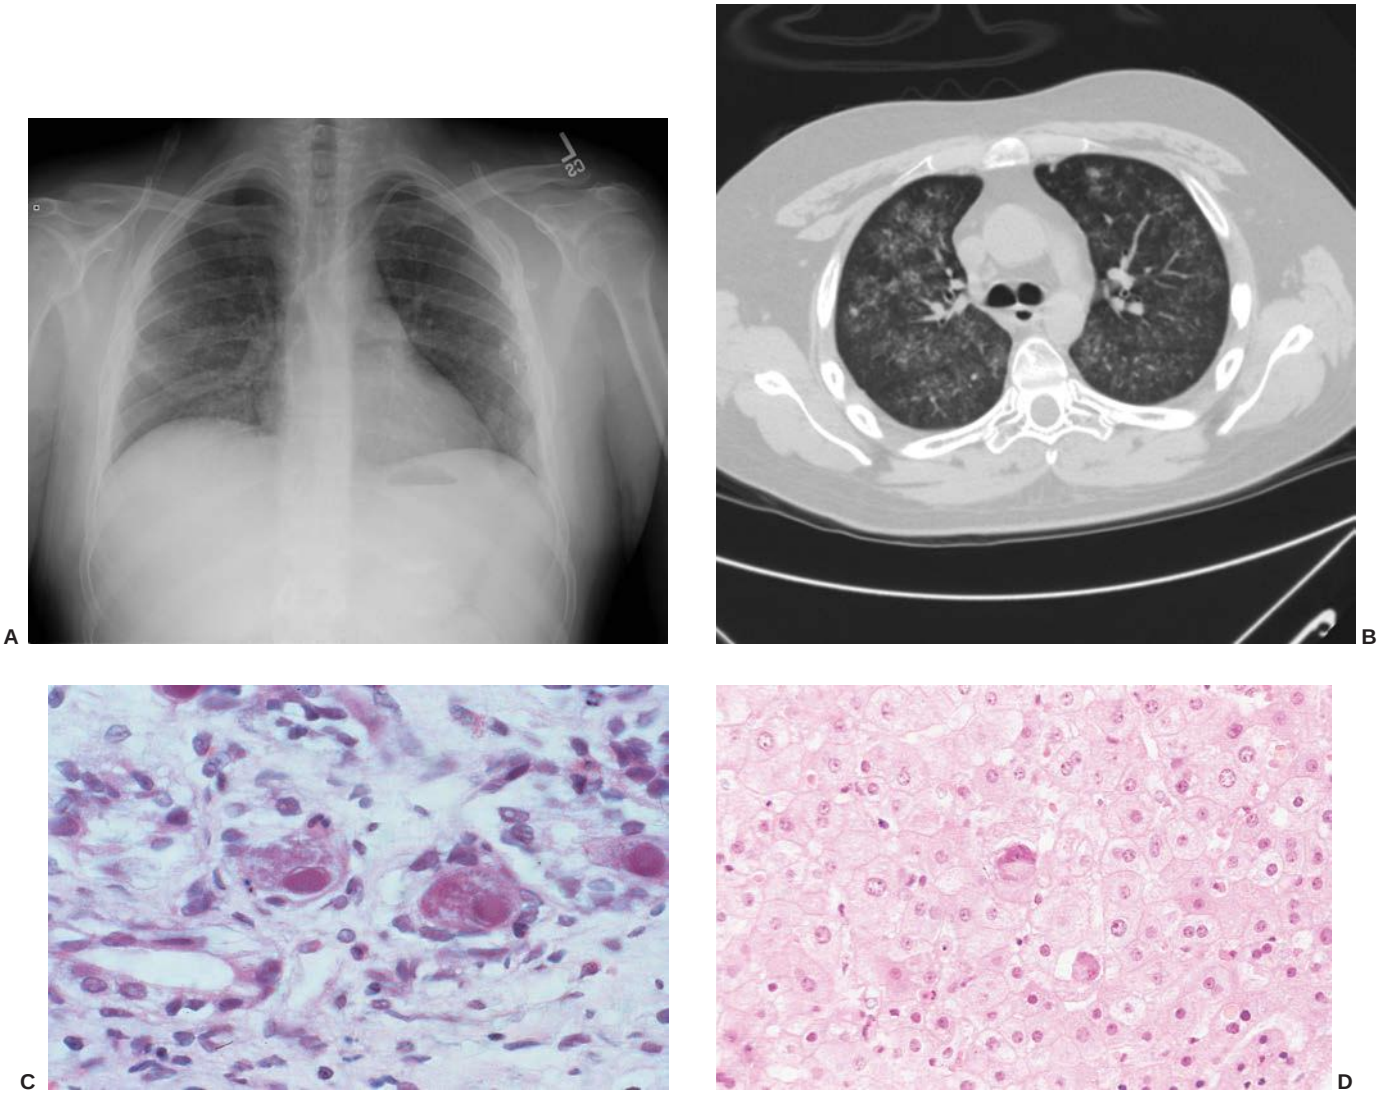

FIGURE 69.6. The spectrum of cytomegalovirus (CMV) disease in the abnormal human host. A: Chest radiograph demonstrating diffuse interstitial infiltrates in patient 60 days after cord blood transplant. **B:** Chest CT showing bilateral fine nodular infiltrates. **C:** CMV inclusion disease of the colon. Typical infected cells show cellular ballooning with dense primary nuclear inclusions surrounded by a thin, cleared rim; secondary inclusions appear as cytoplasmic granules after the nucleus has filled with virions. **D:** CMV hepatitis demonstrated on liver biopsy. Viral cytopathic effect may be difficult to establish, but rare viral inclusions with surrounding parenchymal changes are diagnostic of CMV. Hematoxylin and eosin stain ×400. (Photomicrographs courtesy of Margie Scott.)

multidrug-resistant pathogens include previous antimicrobials in the preceding 90 days, hospitalization for 2 days or more in the preceding 90 days, residing within a nursing home, chronic dialysis, home wound care, and exposure to others with multidrug-resistant pathogens.[70] Initial therapy for HAP depends on severity of illness of the patient, previous antimicrobial exposures and hospitalizations, and institutional antibiogram data. Empiric therapy should include an antipseudomonal beta-lactam plus an antipseudomonal fluoroquinolone, or an aminoglycoside plus either linezolid or vancomycin to cover MRSA with subsequent tailoring of regimen once culture data becomes available.[70]

GASTROINTESTINAL INFECTIONS

Neutropenic Enterocolitis (Typhlitis)

Typhlitis refers to inflammation of the cecum and results from a combination of neutropenia and defects in the bowel mucosa related to cytotoxic chemotherapy. When it extends beyond the cecum, the broader term neutropenic enterocolitis is used.[110] Differential diagnosis for etiology of typhlitis includes *C. difficile* colitis, CMV enteritis, bowel ischemia, and GI tract GVHD.[161] Typhlitis is pathologically characterized by ulceration and necrosis of the bowel wall, hemorrhage, and masses of organisms. Clinical signs include fever, abdominal pain and tenderness, and radiologic evidence of right colonic inflammation. Nausea, vomiting, and diarrhea (bloody or nonbloody) are the most common associated symptoms. Abdominal distention, tenderness, and a right lower quadrant fullness or mass reflect a thickened bowel. Bacteremia with bowel flora, *P. aeruginosa*, and polymicrobial sepsis may occur. *Clostridium* species are the most common anaerobic pathogens. Typhlitis should be suspected if right lower quadrant pain and bloody diarrhea are present. Surgical intervention may be required in the event of an intraabdominal catastrophe.

An abdominal and pelvic CT scan should be performed in patients with suspected typhlitis or undiagnosed abdominal pain in the setting of neutropenia. Positive CT scan findings are present in about 80% of cases[162] and include a right lower quadrant inflammatory mass, pericecal fluid, soft tissue inflammatory changes, localized bowel wall thickening and mucosal edema,

and a paralytic ileus. All patients should be assessed for *C. difficile* infection. Treatment requires broad-spectrum antibiotics with activity against aerobic gram-negative bacilli and anaerobes (e.g., ceftazidime plus metronidazole, imipenem, meropenem, or piperacillin/tazobactam) and supportive care, including intravenous fluids or parental nutrition and bowel rest. The majority of patients will respond to antibiotic therapy and supportive care without the need for surgery. Indications for surgery often include (1) persistent gastrointestinal bleeding after resolution of neutropenia, thrombocytopenia, and clotting abnormalities; (2) intraperitoneal perforation; (3) uncontrolled sepsis despite fluid and vasopressor support; and (4) an intraabdominal process (such as appendicitis) that would require surgery in the absence of neutropenia.[163]

Clostridium Difficile Colitis

Pseudomembranous enterocolitis that is caused by *Clostridium difficile* may occur as a complication of antibiotic therapy, and stool should be assayed for the *C. difficile* toxin.[164] The clinical presentation includes asymptomatic carriage, colitis without pseudomembrane formation, pseudomembranous colitis, and fulminant colitis with toxic megacolon. In severe *C. difficile* disease, paralytic ileus, toxic dilatation of the colon, and bowel perforation may occur. Abdominal radiographs may show nonspecific dilation of the colon with mucosal edema ("thumbprinting"). The mainstay of diagnosis is detection of *C. difficile* toxin A, toxin B, or both, in the stool with a cytotoxin test, enzyme immunoassay, or PCR for the toxin gene. Enzyme immunoassays have variable sensitivity, while DNA amplification testing for *C. difficile* has a reported sensitivity greater than 95%.[165] Empiric therapy for *C. difficile* enterocolitis should be instituted despite a negative stool evaluation if suspicion remains high and other causes of diarrhea have been excluded. Traditional options for the treatment of *C. difficile* include oral or intravenous metronidazole and oral vancomycin.

Metronidazole is recommended as frontline therapy for uncomplicated cases, as its efficacy is similar to oral vancomycin, and the selection pressure on other flora is less dangerous.[166] Oral vancomycin may be more efficacious in severe and refractory *C. difficile* colitis and should be considered for treatment in these cases.[167,168] Fidaxomicin has also been found to be equivalent to oral vancomycin and is FDA approved for the treatment of *C. difficile*–associated diarrhea.[169] Nitazoxanide and rifaximin are under investigation. Patients in whom oral agents cannot be administered should receive intravenous metronidazole. In cases involving toxic dilatation of the colon or perforation, subtotal colectomy, diverting ileostomy, or colostomy may be required.

GENITOURINARY INFECTIONS

Neutropenic patients with a urinary tract infection often do not show pyuria and are far more likely to become bacteremic compared with nonneutropenic patients. While treatment is typically reserved for symptomatic episodes in nonneutropenic patients, intervention should be considered in neutropenic patients with asymptomatic bacteruria. Candiduria may represent colonization in a patient with an indwelling urinary catheter, particularly in the setting of broad-spectrum antibiotics. Removal of the urinary catheter is frequently sufficient therapy. Patients with neutropenic fever and candiduria should receive systemic antifungal therapy over concerns of potential occult invasive candidiasis. Fluconazole 400 mg/day for 1 to 2 weeks is the treatment of choice. In the case of non-*Albicans* candiduria, another azole or amphotericin should be used. Echinocandins are minimally present in the urine, and they are not effective in the treatment of candiduria.[170]

Hemorrhagic cystitis is a common consequence of some cytotoxic regimens, particularly cyclophosphamide. A viral etiology should be considered in HSCT recipients and other immunocompromised patients with unexplained hematuria. Adenovirus, the polyomavirus BK, and CMV have been associated with hemorrhagic cystitis. Adenovirus hemorrhagic cystitis is usually self-limiting, but low-dose cidofovir (1 to 3 mg/kg/week, without probenecid) is occasionally used with the aim of preventing disseminated adenoviral disease.[171] BK virus commonly reactivates after allogeneic HSCT, but only a minority of patients (typically those with high viral loads) develop hemorrhagic cystitis. Treatment consists of supportive care and reduction of immunosuppressants if possible.

SKIN AND SOFT TISSUE INFECTIONS

Skin eruption caused by infections must be distinguished from noninfectious ones such as drug reactions (including chemotherapy-induced hand-foot syndrome), Sweet syndrome, erythema multiforme, vasculitis, leukemia cutis, pyoderma gangrenosum, tumor, and GVHD. When evaluating the potential for a skin/soft tissue infection, careful examination of all line sites and perineal areas are essential. Early biopsy of skin lesions for histology and culture is recommended. Antimicrobial therapy should be tailored to the probable organisms: staphylococci and streptococci for catheter-associated processes and gram-negative and anaerobic organisms for perineal processes, respectively. Vancomycin may be considered for cellulitis, disseminated papules/lesions, and wound infections. Acyclovir, famciclovir, or valacyclovir should be considered for vesicular lesions after appropriate diagnosis is made for HSV or VZV.

VZV and herpes simplex virus (HSV) generally present as vesicular lesions and may be indistinguishable. Scrapings from the base of vesicles should be sent for direct fluorescent antibody (DFA) testing to diagnose VZV and for shell-vial culture to diagnose HSV. Intravenous acyclovir is the treatment of choice for VZV and HSV in the immunocompromised host.[172] In immunocompetent patients, oral acyclovir, valacyclovir, and famciclovir have been used successfully.

Gram-positive bacteria that cause skin and soft tissue infections include *Streptococcus* (group A and B) and *S. aureus*. Gram-negative bacilli with propensity to cause dermatologic infections include *P. aeruginosa*, *Stenotrophomonas maltophilia*, *Aeromonas hydrophila*, and *Vibrio vulnificus*. The latter classically presents with septicemia and secondary cellulitis with hemorrhagic bullae following ingestion of contaminated seafood by patients with underlying liver disease. *V. vulnificus* may also present as a primary cellulitis with bacteremia when an open wound is exposed to seawater.

Ecthyma gangrenosum is typically a manifestation of *P. aeruginosa* or other gram-negative bacilli. It can be variable in its appearance but often presents as a dark, necrotic lesion in neutropenic patients. Antibiotic therapy with an antipseudomonal agent should be initiated and early surgical consultation for possible debridement is imperative.[173]

A rapidly progressive deep soft tissue infection with gas formation suggests clostridial myonecrosis (or polymicrobial necrotizing fasciitis) caused by *Clostridium* species. The lesions may become necrotic, bullous, and hemorrhagic. Systemic toxicity including fever, malaise, and mental status changes occur early. Extensive surgical debridement may be life-saving if initiated early, but the mortality rate remains high. Polymicrobial sepsis with enteric flora is commonly observed in association with clostridial bloodstream infection. In neutropenic patients, metronidazole plus an antipseudomonal cephalosporin or single-agent therapy with imipenem, meropenem, or piperacillin/tazobactam are recommended.[174]

Skin lesions of disseminated candidiasis are small, raised discrete erythematous papules.[175] The lesions resemble those of heat rash early in their presentation. They are usually not tender.

Concurrent myalgias raise the possibility of *Candida* myositis. Biopsy and fungal staining of cutaneous lesions can provide an immediate clue to the diagnosis, prompting the early addition of antifungal therapy. Blood cultures are typically positive.

VIRAL INFECTIONS

Respiratory viruses include influenza, parainfluenza, respiratory syncytial virus, human metapneumovirus, adenoviruses, rhinoviruses, and coronaviruses. Most respiratory viruses typically cause self-limited infection in healthy persons, but cause significant morbidity and mortality in immunocompromised patients with hematologic malignancies and HSCT recipients.[176] The role of empiric antiviral therapy in the treatment of neutropenic fevers is not well defined. Antiviral drugs are indicated in the management of neutropenic fevers only if there is clinical and laboratory evidence of active viral infection.[3] Respiratory virus testing (including testing for influenza, parainfluenza, adenovirus, respiratory syncytial virus [RSV], and human metapneumovirus) and chest radiography are indicated for patients with upper respiratory symptoms such as cough and coryza. Although aerosolized and oral administration of ribavirin has been used, no antiviral agent has been proven to be effective against parainfluenza virus. Similarly, there is no clear indication for aerosolized or oral ribavirin or other antiviral against RSV pneumonia though modest effect has been observed in retrospective analysis.[154]

Influenza Virus

Influenza results in annual epidemics of respiratory viral illness during the winter. Unlike the mild and typically self-limited disease seen in immunocompetent patients, immunocompromised patients frequently have a more severe course. Several existing antiinfluenza agents are commercially available. Amantadine and rimantadine are active against influenza A, but not influenza B. Resistance to these agents may rapidly develop during therapy. The neuraminidase inhibitors, zanamivir and oseltamivir, are active against both influenza A and B. They are effective in reducing the duration of influenza illness if started early after onset of symptoms, and they have a prophylactic benefit during community outbreaks.[177,178] Oseltamivir appears to be both safe and effective against influenza infections among HSCT recipients. If influenza is suspected, empiric therapy with an antiinfluenza agent (e.g., oseltamivir and zanamivir) should be initiated while awaiting test results[3,178] Choice of drug should be based on the susceptibility patterns of the predominant influenza strain(s).

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) infection can cause high mortality in patients with acute leukemia and in HSCT recipients.[179] Upper respiratory symptoms (sinusitis, coryza, rhinorrhea) usually precede lower respiratory tract involvement (dyspnea, wheezing) and pneumonia, but may be absent. Uncontrolled studies suggest that aerosolized ribavirin and IVIG containing high RSV neutralizing titers for at least 24 hours prior to respiratory failure prevent respiratory failure and result in much better outcomes.[180] Inhaled ribavirin and immunoglobulin should be considered in patients with RSV infection at highest risk for severe complications, such as allogeneic HSCT recipients, patients with acute leukemia, and those with persistent neutropenia.[3]

Adenovirus

The spectrum of adenoviral infections in immunocompromised patients extends from asymptomatic shedding to fatal multisystem disease and includes upper respiratory tract infection, pneumonia, renal parenchymal disease, hemorrhagic cystitis, hepatitis, small and large bowel disease, and encephalitis. Viral shedding from throat secretions, urine, and stool is common, occurring in approximately 5% to 20% of HSCT recipients, and should not be equated with disease. Gastroenteritis and hemorrhagic cystitis are usually self-limited, whereas pneumonia and disseminated disease are associated with a high mortality rate. Adenoviral infection is more common in young transplant patients, those who receive T cell–depleted transplants, and those who receive stem cells from unrelated donors.[155] Supportive care is important, though cidofovir may be beneficial.[171]

Parvovirus B19

Parvovirus B19 is a DNA virus that is transmitted via respiratory secretions and blood products. Infection in immunocompromised persons unable to mount a protective antibody response may cause prolonged fever, chronic pure red cell aplasia, thrombocytopenia, or pancytopenia. Predisposing conditions include acute and chronic leukemias, myelodysplastic syndrome, lymphoma, HSCT, potent antineoplastic chemotherapy, and systemic steroids. Diagnosis of parvovirus B19 infection in the immunocompromised patient relies on PCR detection of viral DNA from serum; these patients may be incapable of antibody responses. Treatment often consists of IVIG.[181]

INFECTIONS IN HEMATOPOIETIC STEM CELL TRANSPLANTATION PATIENTS

Autologous and allogeneic HSCT recipients have a unique set of infectious disease problems. Infection is reported as the primary cause of death in 8% of autologous HSCT patients and 17% to 20% of allogeneic HSCT recipients.[182] High-dose chemotherapy or chemoradiotherapy preparative regimen causes short-term cytopenias and often mucositis, followed by profound immunosuppression with weeks to months of defective T cell–mediated immunity. All HSCT recipients experience profound immunosuppression at some point and the degree of immunosuppression experienced by individual patients varies greatly and is influenced by several factors. GVHD severity correlates with the degree of immunosuppression and infectious complications. This correlation is due to a variety of factors, including damage to lymphoid microenvironments, adverse effects of GVHD on homeostatic peripheral expansion, as well as the impact that chronic immunosuppression has on a reconstituting immune system. Recipient factors such as age, comorbidities, and infectious exposure prior to transplant contribute substantially to the risk for posttransplant infectious complications. Graft-associated factors also play an important role. Peripheral blood stem cell graft recipients show more rapid immune reconstitution,[183] whereas umbilical cord blood transplantation in adults,[184,185] and transplantation of profoundly T cell–depleted haploidentical grafts result in poor immune reconstitution and higher rates of infectious complications.

Most infections in autologous HSCT recipients occur during neutropenia or within the first few months after transplantation before reconstitution of cellular immunity. Recipients of $CD34^+$ cell-enriched autografts appear to have a similar risk to allogeneic HSCT recipients for CMV and other opportunistic infections.[186] Recipients of allogeneic peripheral blood stem cell grafts undergo more rapid immune reconstitution than those who receive marrow.[187] Reconstitution of cellular and humoral immunity in allogeneic transplant patients occurs gradually over a period of 1 to 2 years. Duration of T cell immunity defects varies, depending on factors such as cancer type, manipulation of the stem cells preinfusion, and the age of the recipients.[188] Infectious disease risk profiles vary depending on the type of transplant as well as the many variants associated with an HSCT (conditioning regimen,

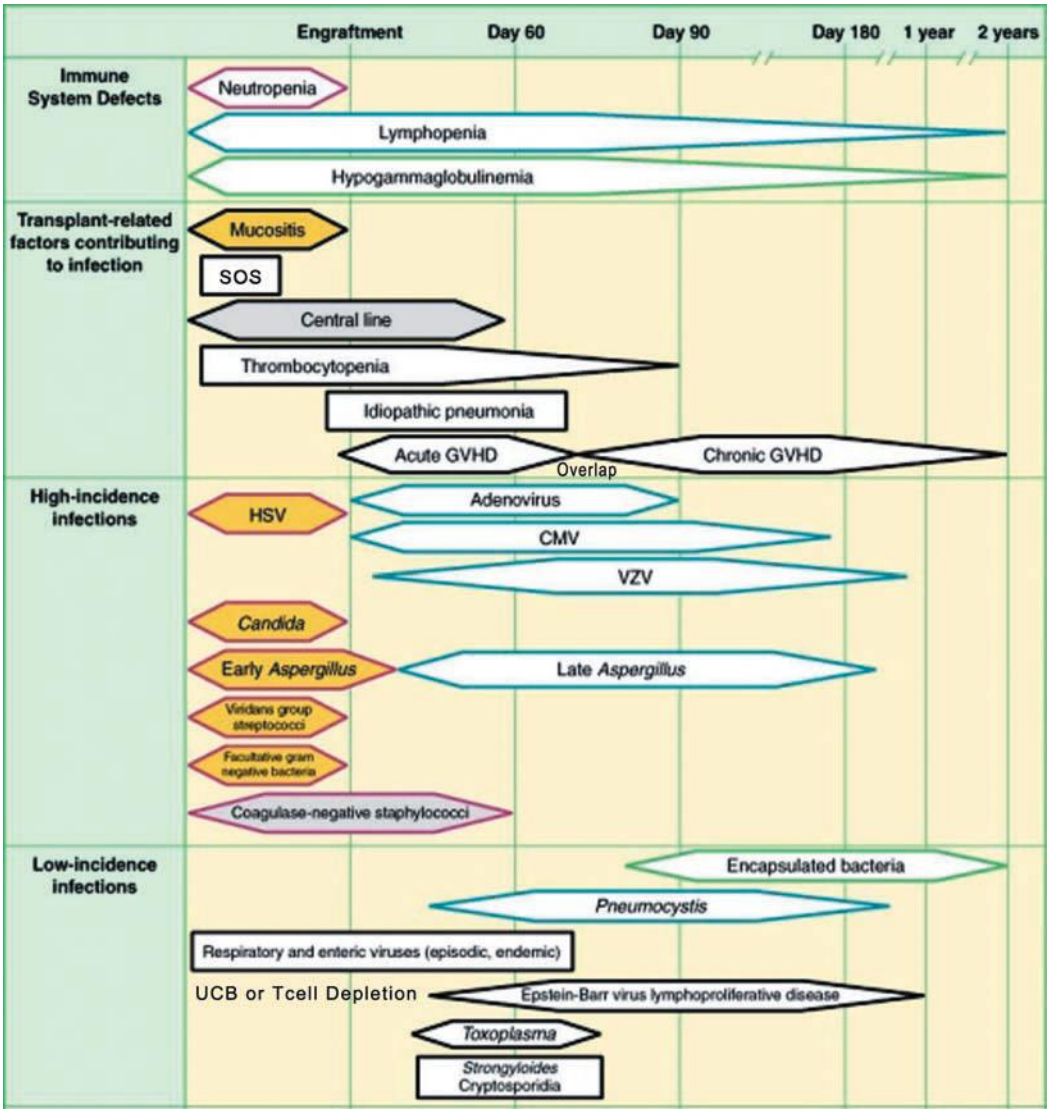

FIGURE 69.7. Phases of predictable opportunistic infections and complications among patients undergoing hematopoietic stem cell transplantation. CMV, cytomegalovirus; GVHD, graft-versus-host disease; HSV, herpes simplex virus; SOS, sinusoidal obstruction syndrome; UCB, umbilical cord blood; VZV, varicella zoster virus. Adapted from Van Burik J-AH, Freifeld AG. Infection in the severely immunocompromised host. In: Abeloff MD, Armitage JO, Niederhuber JE, et al., eds. Clinical oncology, 3rd ed. Philadelphia, PA: Churchill Livingstone; 2004:942.

degree of HLA matching, stem cell source, and GVHD prophylaxis). The spectrum of pathogens to which HSCT recipients are most susceptible follows a time line corresponding to the predominant immune defects as outlined in Figure 69.7.

Neutropenia is the principal host defect in the first few months after HSCT and predisposes patients to bacterial, fungal, and viral infections. The risk of bacterial infection, central venous catheter (CVC) infection, and reactivation of herpes simplex are highest in the preengraftment period. Prolonged neutropenia and antibiotic therapy leads to a steady rise in the risk of invasive fungal infection, which then decreases after engraftment. After myeloid engraftment, qualitative dysfunction of phagocytes persists because of immunosuppressive agents and corticosteroid. Cellular immune dysfunction peaks at approximately day 40 after engraftment and the typical onset of GVHD. The risk of opportunistic viruses and molds during this period is associated with the severity of GVHD and immunosuppressive regimens. Long-term venous access catheters continue to give rise to infection as long as the access is maintained. Continuation of prophylactic antimicrobials beyond 1 year depends on the individual patient's infection history and the ability to wean immunosuppressive therapy.[182]

Preventing Early Infectious Disease (0 to 100 days after HSCT): Early after HSCT, neutropenia is the principal host defense defect, predisposing mainly to bacterial and fungal infections. Presence of a CVC remains as a risk factor for bacterial infection even after myeloid engraftment. Management of bacterial infections in the early neutropenic phase of the transplant is similar to the management of febrile neutropenia seen with any other myelosuppressive therapy. Bacterial infections account for over 25% of fevers in the preengraftment phase of allogeneic HSCT.[189] The source of infection is usually the gut and oral flora due to mucositis, even though the increased use of CVCs has increased the risk of gram-positive bacteremias from skin flora. Streptococcal infections may be seen in patients with severe mucositis. The risk of late bacterial infections (those that occur after engraftment) depends on the immune status of the patient. Allogeneic HSCT recipients are at risk for bacterial infections with encapsulated organisms (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*) if they develop chronic GVHD or profound hypogammaglobulinemia.[190] Prophylactic fluoroquinolones are often maintained until marrow engraftment. This practice has been shown to reduce the incidence of infections, particularly

those due to gram-negative organisms, but has not been shown to definitively decrease infection-related mortality.[81,176] Antibiotic prophylaxis has been found to significantly decrease the risk for all-cause mortality when compared with placebo or no treatment in neutropenic patients,[81,191] IDSA and ASBMT guidelines do recommend prophylactic fluoroquinolone in high-risk patients with expected duration of neutropenia >7 days.[182]

Viral Infections

Cytomegalovirus

CMV infection has been a major source of morbidity and mortality in transplant recipients prior to the era of proper prophylaxis and monitoring for reactivation. Transplant recipients are at risk for reactivation (if CMV seropositive pre-HSCT) and also primary infection (from stem cells or blood products from CMV seropositive donors). Incidence of primary infection has decreased with the increasing use of leukofiltered blood products.

CMV infection is defined as the reactivation of the virus and the detection of the virus in the blood or other body fluids in the absence of organ-specific abnormalities (pneumonitis, hepatitis, colitis, and retinitis). *CMV disease* is defined as the isolation of the virus from body fluids or tissues in a symptomatic patient or the histopathologic evidence of CMV on tissue biopsy (see Fig. 69.6). Risk factors for the development of CMV disease include older recipient age, pretransplant seropositivity of the recipient or donor, or both, and severe acute GVHD.[192,193] T cell depletion of the stem cell graft or treatment of the recipient with antithymocyte globulin for GVHD increases the likelihood of CMV reactivation.[194]

The incidence of CMV reactivation in allogeneic transplant recipients who are seropositive before transplant is 60% to 70%, as compared to a 10% to 30% incidence of primary infection in seronegative recipients.[195–197] Prior to the use of ganciclovir, CMV interstitial pneumonitis occurred in 15% to 30% of HSCT allograft recipients and the ensuing mortality was as high as 85%; however, mortality remained high at 30% to 50% even with the combined use of ganciclovir and CMV-specific immune globulin (Ig).[194]

Administration of CMV-safe or leukofiltered blood products is recommended to all seronegative autologous or allogeneic HSCT recipients to prevent primary CMV infection.[195,198] CMV surveillance starting at the time of engraftment is recommended in instances of recipient and/or donor CMV seropositivity. Tests used for CMV surveillance include CMV pp65 antigenemia assay, DNA PCR detection methods, or CMV blood cultures.[199] Detection of CMV in the blood is the strongest predictor of CMV disease, but 12% to 20% of patients with negative surveillance cultures still develop CMV disease. While high-dose intravenous acyclovir significantly reduces the incidence of all forms of CMV disease or delays the onset of CMV infection, it does not prevent CMV viremia.[200,201]

There are two recommended strategies for prevention of CMV disease. One strategy is prophylaxis with ganciclovir, valganciclovir, or valacyclovir, starting from engraftment until day 100, or longer if the patient remains at risk for CMV reactivation (active GVHD, high-dose steroids, low CD4 count).[199,202] The other strategy is close surveillance and preemptive therapy with ganciclovir or foscarnet when CMV reactivation is detected. Both strategies reduce the incidence of CMV disease in the first 100 days; however, the median onset of CMV disease has shifted from 50–60 days to 160–176 days post-HSCT in the preemptive era.[197]

Preemptive therapy with ganciclovir for patients with positive CMV surveillance cultures (blood, urine, throat, or bronchoalveolar lavage fluid) has demonstrated improved survival at 100 and 180 days post-HSCT, but has failed to provide an overall survival advantage.[203] Protracted ganciclovir prophylaxis can lead to emergence of resistant strains and the failure of natural immunity against CMV to develop, thus resulting in late recrudescence.[196,204,205] Optimal preemptive therapy appears to be 1 to 2 weeks of twice-a-day induction followed by maintenance until PCR or antigen negativity.[182]

Ganciclovir is the drug of choice for CMV infection and disease, but its myelosuppressive effects may preclude its use in patients with significant cytopenias. Foscarnet is an equally effective alternative and can be used to treat ganciclovir-refractory CMV infections or in patients with significant cytopenias. Although it is not myelosuppressive, foscarnet is associated with renal toxicity and electrolyte imbalances.[160] Cidofovir is another nephrotoxic antiviral with efficacy against CMV, but there are few data on its use in the stem cell transplant patient population.[206] Maribavir is the latest antiviral in the armamentarium of drugs available for management of CMV and has been found to decrease rates of CMV infection when used as prophylaxis in the stem cell transplant setting,[207] but has failed to prevent CMV disease in a randomized phase III study.[208]

Herpes Simplex Virus

HSV reactivation occurs in as many as 80% of seropositive allogeneic transplant recipients, causing mucocutaneous oral or genital lesions, esophagitis, and, occasionally, pneumonia or encephalitis. Testing all transplant recipients for herpes simplex virus exposure (HSV IgG) is recommended. Antiviral prophylaxis with acyclovir, valacyclovir, or famciclovir is recommended for all seropositive patients until the time of engraftment. Although its use is not recommended past 1 month after transplant, some patients with recurrent lesions might benefit from longer use of the prophylaxis.[209,210]

Varicella Zoster Virus

Impaired cellular immunity is the principal risk factor for VZV disease. Current recommendations are to test every transplant patient for varicella zoster virus serostatus (IgG). VZV reactivation may occur at any time after engraftment in autologous and allogeneic transplant recipients. Disseminated VZV is seen in as many as 30% of cases and is associated with a high mortality. Many centers administer oral acyclovir or valacyclovir for ~12 months after transplant to VZV-seropositive patients.[210] Seronegative patients should be given varicella zoster immune globulin within 96 hours of exposure to a VZV vaccine or upon contact with active infection.

Fungal Infections

Most fungal infections in the SCT population are due to *Candida* or *Aspergillus*. The etiology in the remaining <10% are uncommon fungi, such as *Fusarium*, *Scedosporium*, *Blastomyces*, and *Histoplasma.* Prevention of fungal infections in these patients is key. Fluconazole prophylaxis at a dose of 400 mg/day, beginning at the time of transplant and until the time of engraftment, provides adequate protection against invasive yeast infections.[189,211,212] Failure of fluconazole prophylaxis against *Candida* is usually a result of the emergence of resistant yeast forms (*C. krusei*, *C. glabrata*). Empiric therapy for fungal infections in febrile neutropenic patients is considered the standard of care, and several studies are examining the preemptive approach.[33,141] The toxicity of intravenous amphotericin B is substantial and it is no longer recommended for prophylaxis. Lipid formulations of amphotericin (Abelcet, Amphotec, and AmBisome) have fewer renal and infusional toxicities. Newer antifungal agents have changed the approach to prevention and treatment of fungal infections in SCT patients. Caspofungin, micafungin, and anidulafungin are echinocandins with a broad spectrum of activity against several species of *Candida* and *Aspergillus*. Triazoles such as voriconazole, posaconazole, and ravuconazole also have activity against *Aspergillus* and a wide variety of yeasts and molds.[137]

Pneumocystis jirovecii pneumonia (PJP) is not a protozoan, but resembles a fungus based on molecular studies. Prophylaxis against PJP is recommended in all allogeneic HSCT recipients from the time of engraftment until 6 months after transplant, or even longer if the patient is on high doses of immunosuppressive drugs for chronic GVHD. Oral TMP-SMX is the drug of choice, but aerosolized pentamidine, dapsone, dapsone in combination with trimethoprim or pyrimethamine, pyrimethamine and sulfadoxine, and atovaquone can be used as alternatives.[213,214,215,216] Patients should be tested for glucose 6-phosphate dehydrogenase deficiency before initiation of dapsone. Guidelines for PJP prophylaxis in autologous SCT patients are less clear and should be considered in patients who are deemed high-risk, such as those who receive fludarabine or cladribine and those who have had prolonged steroid use before transplant.

Toxoplasmosis reactivation or infection is rare but can be life-threatening and usually occurs within the first year post-transplant. Toxoplasmosis prophylaxis is recommended for seropositive allogeneic recipients or those with a prior history of toxoplasmic infection.[182] Oral TMP-SMX is the prophylactic agent of choice,[182] but pyrimethamine-sulfadoxine (Fansidar) prophylaxis can be used.[217] For patients who are TMP-SMZ–intolerant, a combination of clindamycin, pyrimethamine, and leucovorin can be substituted. Prophylaxis is recommended from the time of engraftment until 6 months after transplant.[182] Pyrimethamine does not eradicate the cyst form of *T. gondii*.

STRATEGIES TO PREVENT INFECTIONS

Measures and practices to prevent nosocomial pathogen acquisition as well as the spread of infections play critical roles in the overall picture of managing febrile neutropenia as well as the well-being of all exposed to hospital settings.

Hand hygiene is the most effective means of preventing transmission of infection in the hospital.[218] All persons should sanitize their hands upon entering and leaving the rooms of neutropenic and other hospitalized patients.

No specific protective gear (e.g., gowns, gloves, and masks) is required during the routine care of neutropenic patients, but standard isolation and barrier precautions should be followed when specific infections occur or contact with body fluid is anticipated.[219] Single patient room occupancy is common practice, especially for HSCT.

Neutropenic diets are typically given to patients with neutropenia, though data are lacking. Studies comparing diets of cooked and uncooked foods indicate that avoidance of raw fruits and vegetables does not prevent major infection or death.[220,221] While well-cooked foods are generally recommended, well-cleaned, uncooked raw fruits and vegetables are acceptable.

Many patients with neutropenia do not require specific room ventilation, but laminar airflow rooms and HEPA filtration are still considered important for certain high-risk patients, such as those undergoing HSCT. The use of laminar flow and HEPA filtration has been reported to decrease the incidence of *Aspergillus* infections.[222,223] However, the use of reverse isolation has not been shown to significantly reduce the acquisition of nosocomial pathogens.[224]

Molds, including *Aspergillus* and *Fusarium* species, have been isolated from plants and dried or fresh flowers and therefore these should not be allowed in the rooms of neutropenic patients.[225,226] Pets should also not be allowed in the area with neutropenic patients.[212]

Prevention of Infections

Infection prophylaxis in cancer patients involves broad-spectrum antimicrobial therapy against the common bacterial, viral, and fungal pathogens in high-risk patients. Knowing the spectrum of infection-causing pathogens at individual hospitals or treatment centers is key to appropriate prophylaxis. A summary of prophylactic strategies in this patient population is provided in Table 69.6.

Antibacterial Prophylaxis

Historically, TMP-SMX has been used for many years for prophylaxis against bacterial infections. Initial studies showed efficacy in preventing PJP, whereas later studies demonstrated benefit in reducing the incidence of bacterial infections in patients with hematologic malignancies.[227–231] Fluoroquinolones are the most commonly used antibiotics for prophylaxis against bacterial infections in neutropenic patients. They are broad-spectrum derivatives of nalidixic acid that are orally bioavailable with a broader spectrum of activity, preserve colonization resistance, and are well tolerated. Quinolone-based prophylaxis has been successful in reducing the risk of aerobic gram-negative infections in neutropenic patients undergoing cytotoxic chemotherapy for AL and HSCT in several studies.[232,233] An increased frequency of breakthrough gram-positive bacteremias, predominantly by viridans streptococci (*Streptococcus mitis*, *S. sanguis*) and coagulase-negative staphylococci, has been observed.[71,233–235] The newer fluoroquinolones (ciprofloxacin, levofloxacin) have broader gram-positive activity and have been variably effective in preventing infection with α-hemolytic streptococci when coadministered with roxithromycin or amoxicillin-clavulanate.[236] Viridans group streptococcal bacteremia breakthroughs have been reported with ciprofloxacin prophylaxis.[71] In comparison to placebo, fluoroquinolone prophylaxis significantly reduced the incidence of gram-negative infections.[191] Fluoroquinolone prophylaxis was also associated with a statistically nonsignificant, yet clinically relevant, decrease in mortality in neutropenic patients.[191,237] Gram-positive and fungal infection rates were not significantly affected by fluoroquinolone prophylaxis.[191]

Prophylactic levofloxacin in neutropenic patients with intermediate or high risk of infection has been shown to lead to a reduction in infections,[176] whereas the major benefit in low-risk neutropenic patients relates to the reduction in febrile episodes.[238]

Both the IDSA and NCCN recommend the consideration of fluoroquinolone prophylaxis (levofloxacin is preferred) in patients with an expected duration of neutropenia of more than 7 days. TMP/SMX should be used in specific patients at high risk for *P. jirovecii*. No antibiotic prophylaxis is recommended for patients with neutropenia expected to last 7 days or less and who are not receiving immunosuppressive regimens.[3,239]

Emergence of secondary resistance remains a valid concern regarding the use of antibiotic prophylaxis. Gram-negative bacteremias in patients who receive fluoroquinolone prophylaxis are often caused by resistant *P. aeruginosa*, but infections that are caused by non–*P. aeruginosa* species, especially *E. coli*, and *Enterobacter* species, are being increasingly reported.[240,241] The potential risks of quinolone prophylaxis regarding the development of *Clostridium difficile* colitis also warrants consideration[77,164] and underscores the importance of judicious use of antimicrobial prophylaxis.

Prophylaxis against Pneumococcal Infection

Pneumococcal prophylaxis should be considered in asplenic patients and in allogeneic HSCT recipients with chronic GVHD. The risk of pneumococcal sepsis is greatest within the first 2 years after splenectomy, but a third of events may occur up to 5 years out, and cases of fulminant sepsis have been reported at more than 20 years.[242] Pneumococcal disease among allogeneic HSCT recipients typically occurs in the later transplant period, from 3 months to several years after transplant. Pneumococcal

TABLE 69.6

PROPHYLAXIS OF INFECTIONS IN HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS AND HEMATOLOGIC CANCER PATIENTS

Prophylaxis	Indication	Agent	Duration/Comments
BACTERIA			
Antibacterial prophylaxis	Patients who are expected to be neutropenic for >7 days	Levofloxacin 500 mg orally daily or TMP/SMX may be used for those allergic to or intolerant of fluoroquinolones	Start when ANC $< 1.0 \times 10^9$/L and continue until resolution of neutropenia
FUNGAL AND MOLDS			
Antifungal prophylaxis	Induction therapy for AML and MDS	Posaconazole 200 mg orally tid is drug of choice if high risk for aspergillosis. Alternatives include itraconazole, voriconazole, lipid formulation of amphotericin B, or an echinocandin (may choose to use fluconazole prophylaxis if incidence of aspergillosis is low.)	Begin with initiation of chemotherapy and continue until resolution of neutropenia.
	Acute lymphoblastic leukemia	Fluconazole[a] or an echinocandin Azoles are inhibitors of cytochrome P-450 isoenzymes, and are expected to interfere with metabolism of vinca alkaloids and other drugs; close monitoring is recommended	Continue prophylaxis for duration of neutropenia
	Autologous HSCT recipient during neutropenia	Fluconazole[a] or echinocandin	Continue prophylaxis for duration of neutropenia
	Allogeneic HSCT recipient during neutropenia	Fluconazole,[a] itraconazole, voriconazole, and micafungin have each been evaluated in this setting	Continue prophylaxis for duration of neutropenia
	Allogeneic HSCT with significant GVHD receiving intensive immunosuppressive therapy[b]	Posaconazole 200 mg orally tid is drug of choice. Alternatives include voriconazole, itraconazole, lipid formulation of amphotericin B, or an echinocandin	Continue prophylaxis for 16 wk and for at least the duration of intensive immunosuppressive therapy,[b] whichever occurs later
Pneumocystis jirovecii Prophylaxis	Acute lymphocytic leukemia, allogeneic HSCT recipients, alemtuzumab recipients, fludarabine recipients, or patients receiving corticosteroids (≥20 mg of prednisone equivalent) for ≥1 mo in the presence of other immunosuppression or myelotoxic chemotherapy.	TMP/SMX 1 DS (TMP 160 mg + SMX 800 mg) orally daily or 3 days per week OR dapsone 100 mg orally daily OR inhaled pentamidine 300 mg every 4 wk OR atovaquone 1,500 mg/d.	In allo-HSCT, continue prophylaxis for 2 mo after stopping immunosuppression. In patients treated with alemtuzumab, continue prophylaxis for 2 mo after the last dose or until the CD4 count is >200.
VIRUSES			
Prophylaxis for HSV	HSCT recipients (HSV-seropositive recipients) Induction chemotherapy for acute leukemia (HSV-seropositive) Patients treated with alemtuzumab, or in patients with recurrent HSV reactivation following chemotherapy	Acyclovir 400 mg orally bid or tid OR 800 mg orally bid OR 250 mg/m^2/12 h or valacyclovir 500 mg orally once or twice (higher doses have been used up to 1,000 mg tid) or famciclovir 250 mg orally tid	Continue prophylaxis for HSV until resolution of neutropenia and mucositis. In patients treated with alemtuzumab, continue prophylaxis for 2 mo after the last dose or until the CD4 count is >200
Prophylaxis for VZV	Allogeneic HSCT recipients with a history of chicken pox or shingles	Acyclovir 800 mg orally bid OR valacyclovir 500 mg orally daily	
Prophylaxis for CMV (preemptive therapy)	Patients requiring CMV surveillance 1. Allogeneic HSCT recipients who are CMV$^+$ or whose donor is CMV$^+$ (standard of care) 2. Autologous SCT recipients receiving a CD34-enriched autograft 3. Patients treated with alemtuzumab	Induction for 1 wk followed by maintenance for 1 wk as follows: Ganciclovir 5 mg/kg IV q12h for 7 days (induction), followed by Ganciclovir 5 mg/kg IV daily 5 times a week (maintenance) OR Foscarnet[a] 60 mg/kg IV q12h times 7 days (induction) followed by Foscarnet[c] 60 mg/kg IV daily (maintenance) Oral valganciclovir (900 mg bid) is an acceptable alternative to IV formulations in patients who do not have severe gut GVHD (see text)	CMV surveillance: 1. Allogeneic HSCT recipients: day 30 to at least 6 mo after allogeneic HSCT, during periods of GVHD, and until the CD4$^+$ count is >100 μL. 2. Recipients of CD34-enriched autologous grafts: day 30 to day 100 and until the CD4$^+$ count is >100 μl. 3. Alemtuzumab recipients: time of initiation until at least 2 mo after completion of therapy and until the CD4 count is >100 μl. The level of CMV reactivation that triggers preemptive therapy varies with the method. The CDC recommends any positive CMV antigenemia (pp65) or two consecutive qualitative PCR results within the first 100 days, and five cells per slide after the first 100 days

TABLE 69.6 (CONTINUED)

PROPHYLAXIS OF INFECTIONS IN HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS AND HEMATOLOGIC CANCER PATIENTS

Prophylaxis	Indication	Agent	Duration/Comments
Prophylaxis against CMV		Ganciclovir or foscarnet at the same dose as in preemptive regimen	Treatment is given for the first 100 days, then weekly or biweekly monitoring and preemptive management is initiated

ANC, absolute neutrophil count; AML, acute myelogenous leukemia; bid, twice daily; CDC, Centers for Disease Control and Prevention; CMV, cytomegalovirus; DS, double strength; GVHD, graft-versus-host disease; HSCT, hematopoietic stem cell transplant; HSV, herpes simplex virus; IV, intravenous; MDS, myelodysplastic syndrome; tid, 3 times a day; PCR, polymerase chain reaction; SCT, stem cell transplant; TMP/SMX, trimethoprim/sulfamethoxazole; VZV, varicella zoster virus.

[a]Fluconazole is effective as prophylaxis against candidal, but not mold, infections. If prophylactic fluconazole is used in patients with prolonged neutropenia, a strategy of empirical modification to a mold-active drug in patients with persistent neutropenic fever should be considered. Doses apply to adults with normal renal function.
[b]Criteria include acute grade II to IV GVHD, or extensive chronic GVHD, or treatment with intensive immunosuppressive therapy consisting of either high-dose corticosteroids (1 mg/kg of body weight per day for patients with acute GVHD or 0.8 mg/kg every other day for patients with chronic GVHD), antithymocyte globulin, or a combination of two or more immunosuppressive agents.
[c]Doses apply to adults with normal renal function.

Adapted from the NCCN Clinical Practice Guidelines in Oncology. Prevention and Treatment of Cancer-Related Infection. NCCN. Version 1.2012, the clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America (IDSA), and the comprehensive guideline cosponsored by the Center for International Blood and Marrow Research, the National Marrow Donor program, the European Blood and Marrow Transplant Group, the American Society for Blood and Marrow Transplantation, the Canadian Blood and Marrow Transplant Group, the Infectious Diseases Society of America (IDSA), the Society for Healthcare Epidemiology of America, the Association of Medical Microbiology and Infectious Disease Canada, and the CDC makes evidence-based recommendations for HSCT that may be applicable to other cancer patients. Tomblyn M, Chiller T, Einsele H, et al. J Am Soc Blood Marrow Transplant 2009;15:1143–1238.

prophylaxis with an oral penicillin or TMP/SMX is recommended for at least 6 months post-HSCT or until discontinuation of immunosuppressive therapy.[243] Vaccination against *S. pneumoniae* is recommended for all HSCT recipients, preferably with pneumococcal 7-valent conjugate vaccine.[243]

Antifungal Prophylaxis

Antifungal prophylaxis should be based on risk stratification and should target specific pathogens in different patient groups. Patients with hematologic malignancies or HSCT recipients have several risk factors for fungal infections: defects in cellular immunity, prolonged profound neutropenia, immunosuppressive therapy, use of broad-spectrum antibiotics, use of parenteral nutrition, and use of indwelling vascular devices. The Transplant Associated Infections Surveillance Network (TRANSNET) prospectively analyzed HSCT recipients with proven or probable invasive fungal disease. Aspergillosis (43%), candidiasis (28%), and zygomycosis (8%) were the most common.[244] Preventive efforts should be directed toward the reduction of *Candida* and *Aspergillus* species, as they have traditionally been the most common causes of fungal disease in immunocompromised patients.[196,244] Patients should be counseled to avoid dust or soil exposure when traveling to areas that are endemic for organisms such as *Blastomyces dermatitidis*, *Coccidioides immitis*, and *Histoplasma capsulatum* when possible. Most other pathogens such as *Aspergillus* species, *C. neoformans*, and the Mucorales order (Zygomycetes class) are ubiquitous in the environment. Hospital outbreaks of *Aspergillus* are more likely to occur during periods of construction or renovation.[245,246] HEPA filtration, regular maintenance of ventilation systems, and floor-to-ceiling barriers around construction sites are important measures in reducing the risk of invasive aspergillosis.[247]

Prior to the development of the triazole class of drugs, few effective antifungal agents other than amphotericin B were available. Nystatin and clotrimazole may prevent oropharyngeal candidiasis but are not well tolerated in patients with severe mucositis. Oral polyenes (nystatin and oral amphotericin B) are not orally bioavailable and have failed to demonstrate a reduction of systemic fungal infections.[248,249] Inhaled amphotericin B has shown promise in preventing colonization and infection with *Aspergillus* but tolerability remains a concern and direct comparison to systemic mold-active azoles has not been studied.[250–252]

Multiple randomized trials in patients with leukemia and patients undergoing allogeneic HSCT have demonstrated that fluconazole prophylaxis at a dosage of 400 mg/day reduces the incidence of superficial and invasive candidal infections, excluding *C. krusei*.[211,253,254] Fluconazole prophylaxis has also been found to confer improved survival in HSCT recipients,[189,255] but may increase the risk of colonization by azole-resistant *Candida* strains.[189] Itraconazole prophylaxis for candidiasis has been shown to provide similar efficacy and may additionally reduce the risk of aspergillosis. However, itraconazole has also demonstrated higher toxicity (drug-drug interactions due to cytochrome P450 3A4 inhibition) and gastrointestinal intolerance. It is also contraindicated in patients with a decreased cardiac ejection fraction or a history of congestive heart failure.[256] Micafungin appears to be as effective as fluconazole in prevention of candidiasis in HSCT recipients[257] and may also reduce the risk of *Aspergillus*.

Prevention of aspergillosis requires prophylaxis with broader spectrum antifungals. Comparison of standard prophylaxis (fluconazole or itraconazole) versus posaconazole in AML/MDS patients receiving myelosuppressive induction therapy revealed that posaconazole prophylaxis led to fewer invasive fungal infections, including aspergillosis, and to improved survival.[142] A similar comparison in HSCT recipients with severe GVHD demonstrated that prophylactic posaconazole also led to fewer cases of invasive aspergillosis but failed to impact overall survival.[142] Comparison of voriconazole versus fluconazole prophylaxis in allogeneic HSCT recipients showed a trend toward reduction of aspergillosis infections in voriconazole recipients, but no difference in overall or fungal infection–free survival.[3]

Fluconazole is a well-studied agent and remains the standard drug of choice to prevent invasive candidiasis, but it has no activity against molds.[258] Mold-active agents should be considered when there is significant risk of aspergillosis. Posaconazole is an oral agent with antimold activity and requires administration with food or enteral preparations to enhance bioavailability. The mold-active azoles (i.e., itraconazole, voriconazole, posaconazole) are potent inhibitors of cytochrome P450 3A4 isoenzymes and may lead to reduced clearance of other drugs, such as calcineurin inhibitors and vinca alkaloids. Close monitoring of drug-drug interactions and appropriate dose modifications are required.[109]

Histamine blockers and proton pump inhibitors, such as omeprazole, should be avoided, and serum levels must be monitored during therapy.[259]

Antiviral Prophylaxis

Opportunistic viral disease may occur by primary infection or by reactivation of latent infection. Herpesviruses, including CMV, VZV, and HSV-1 and -2, are by far the most common infection-causing viruses. Antiviral prophylaxis (acyclovir, valacyclovir, or famciclovir) against HSV is advised during the period of neutropenia in seropositive patients receiving chemotherapy for acute leukemia, and during neutropenia and at least 30 days after HSCT for both allogeneic and autologous transplant recipients.[3,239] Prolonged prophylaxis should be considered in allogeneic HSCT recipients with GVHD or with frequent HSV reactivation before transplantation.[210] Acyclovir is an effective prophylaxis against reactivated HSV infections (gingivostomatitis, esophagitis) in patients who are receiving intensive chemotherapy for acute leukemia or BMT.[260–262] Acyclovir or valacyclovir are each commonly used as prophylaxis, treatment, and suppressive therapy against HSV and VZV in immunocompromised patients.[263,264] Although acyclovir has proven to be highly effective as prophylaxis, there are reports of acyclovir-resistant HSV developing while on therapy.[265,266] Treatment with foscarnet or cidofovir is recommended in the setting of acyclovir-resistant HSV. Foscarnet-resistant HSV strains have been reported in allogeneic stem cell transplant patients and such patients have been treated with cidofovir.[267] Newer nucleoside analogs (such as BV-ara U, Brovavir) are being studied. Acyclovir-related prodrugs (valacyclovir, famciclovir) appear as effective as acyclovir for HSV and VZV prophylaxis.[160,172,268] Avoidance of close contact with infected or exposed individuals is advisable for immunocompromised seronegative patients. Prophylaxis should also be considered in patients receiving T cell–depleting agents (e.g., fludarabine, calcineurin inhibitors, and proteasome inhibitors).

Prevention of Viral Hepatitis

Reactivation of latent hepatitis B virus occurs in various settings (e.g., HSCT, cytotoxic chemotherapy, anti-CD20 monoclonal antibodies treatments). The immunosuppressive effect of the chemotherapy allows virus reactivation in the liver, and the subsequent immune reconstitution may result in hepatocellular damage.[269] Patients with lymphoma, or who use steroids or receive anthracycline chemotherapy, seem to be at higher risk.[270] Fulminant hepatitis and death may occur following HBV reactivation in immunocompromised patients. Evaluation of HBV surface antigen, core antibody, and surface antibody should be considered for those in whom intensive immunosuppressive therapy in planned.[271] Lamivudine prophylaxis has been shown to be relatively effective in the prevention of hepatitis B reactivation, though randomized trials are still needed.[204,270,272]

Baseline quantitative PCR for HBV DNA should be obtained in HBsAg-positive individuals. Antiviral therapy should be strongly considered in patients with active HBV infection undergoing HSCT or other intensive immunosuppression therapies, but an optimal antiviral treatment regimen remains unclear.

Augmentation of Host Defense

Optimization of patients' immune status via prophylactic immunization is another consideration to assist in the reduction of infection risk. Table 69.7 summarizes the recommended vaccine schedule of patients with hematologic malignancies and HSCT recipients as per the Advisory Committee on Immunization Practices (ACIP), ASBMT, and EBMT.[182,212,239,273,274]

Active Immunization

Patients with hematologic neoplasms are at increased risk for infection with polysaccharide-encapsulated bacteria, viruses, and fungi due to impaired T cell, granulocyte, and reticuloendothelial cell function, as well as to defective antibody responses. Immunization as a means of preventing infectious morbidity has been best studied in children with ALL or solid tumors, patients with HL with or without splenectomy, and marrow transplant recipients. Although the optimal timing of immunizations in these patients and specific recommendations for each type of cancer are still unclear, general guidelines have been established.

If indicated, the administration of inactivated vaccines should be completed more than 10 days before initiation of chemotherapy or 3 months after completion of chemotherapy in adults with hematologic malignancies, including acute leukemia and myeloproliferative diseases.[239] CDC recommendations require all infants to be vaccinated for *Haemophilus influenzae* type B (Hib) and thus almost all adults in theory should possess adequate immunity against this organism. However, splenectomized Hodgkin's disease patients who were receiving antineoplastic therapy were found to have a significantly greater decrease in Hib titer at a 6- to 12-month period after the primary vaccination (given before starting chemotherapy) as compared to normal controls.[275] Most children who receive maintenance chemotherapy for leukemia or lymphoma are able to generate protective antibody responses to a single dose of conjugate polysaccharide Hib vaccine, although responses are less than those that are seen in healthy children.[276] Recommendations for children are therefore to continue the primary series of Hib-conjugate vaccinations during chemotherapy treatment and to administer a booster immunization 1 year after completion of chemotherapy.[277] For adults with hematologic malignancies, it is recommended that a dose of Hib vaccine be given before initiation of chemotherapy or before splenectomy, if one is planned.[278] The need for a booster a year after chemotherapy in adults has yet to be determined, and further studies are warranted.[275,278,279]

Pneumococcal vaccines are available as either a conjugate vaccine (PCV-7, PCV-13) or a polysaccharide vaccine (pneumococcal polysaccharide vaccine 23-valent, PPSV23). Conjugated vaccines elicit improved immune responses in HSCT recipients compared with pure polysaccharide vaccines, and are therefore preferred.[274,280–283] Conjugated vaccines induce a robust T cell–dependent immune response and generate long-term memory loss. It is recommended that HSCT recipients receive 3 sequential doses of PCV-13 starting 3 to 6 months after transplant. A fourth vaccination with PPSV-23 is given 8 weeks after the third dose of PCV-13 to broaden the immune response to include serotypes not included in PCV-13. Given that patients with active chronic GVHD are likely to have a poor response to PPSV-23, a fourth dose of PCV-13 should be considered in these patients.[182] One-time revaccination with PPSV-23 at 5 years after the first dose is currently recommended for immunocompromised patients.[278] The ACIP recommends that adults 19 years of age or older with immunocompromising conditions who have not previously received PCV13 or PPSV23 should receive a dose of PCV13 first, followed by a dose of PPSV23 at least 8 weeks later. Complete protection might not be achieved if the vaccine is given within 3 years after antineoplastic therapy.[284,285]

Immunization for *N. meningitidis* by using a polysaccharide vaccine is recommended in cancer patients requiring splenectomy.[286] However, this vaccine offers no protection from serogroup B (which is responsible for one-third of cases). Ongoing studies are being conducted to test new meningococcal serogroup B vaccine.[287]

Children undergoing chemotherapy and who have not completed all of the diphtheria-tetanus (DT) (or diphtheria, pertussis, and tetanus; pertussis is included if the child is <7 years of age)

TABLE 69.7

RECOMMENDATIONS FOR ACTIVE IMMUNIZATION OF ADULTS WITH MALIGNANCIES

Vaccine	Persons Who Should Receive Vaccine	Timing in Relation to Chemotherapy	Regimen[a]
Haemophilus influenzae type b	Lymphoma patients	Before staging splenectomy, >10 d before initiation of chemotherapy, or 3 mo after completion of chemotherapy	Single-dose
Hepatitis B[b]	Cancer patients with hepatitis B surface antigen (+) household contacts	Not during immunosuppressive therapy	3 doses: second dose 1–2 after the first, third dose 4–6 mo after the first
Influenza	All cancer patients	>2 wk before initiation or between cycles of intermittent chemotherapy	Annually each fall/winter
Measles, mumps, rubella	Nonimmune leukemic patients in remission and household contacts of all immuno-suppressed individuals	For leukemic patients in remission, >3 mo after completion of therapy; otherwise contraindicated in patients with leukemia, lymphoma, or those undergoing immuno-suppressive therapy	Once
Meningococcal (*Neisseria meningitides*)	Lymphoma patients	Before staging splenectomy	2 doses; second dose 3–5 y after the first
Poliomyelitis (inactivated poliovirus vaccine only)[c]	Adults at increased risk of infection; all susceptible household contacts of cancer patients	No data available; recommend each dose >10 d before initiating chemotherapy	3 doses; second dose 4–8 wk after the first, third dose 6–12 mo after the second
23-Valent polysaccharide pneumococcal (*Streptococcus pneumoniae*)	Any nonimmune cancer patient, especially lymphoma and multiple myeloma a patients	Before staging splenectomy, >10 d before initiation of chemotherapy, or 3 mo after completion of chemotherapy	2 doses; second dose at least 5 y after the first
PCV13 (Pneumococcal Conjugate) Vaccine	19 yr of age or older with immunocompromising conditions who have **not** previously received PCV13 or PPSV23; 19 y of age or older with immunocompromising conditions, who have previously received one or more doses of PPSV23	Give a dose of PCV13 first followed by a dose of PPSV23 at least 8 wk later. Subsequent doses of PPSV23 should follow current PPSV23 recommendation. Give a dose of PCV13 one or more years after the last PPSV23 dose was received	
Tetanus and diphtheria toxoids combined	All cancer patients	No data available; recommend administration >10 d before initiating chemotherapy	Primary 3-dose series if not previously immunized; second dose 4–8 wk after the first, third dose 6–12 mo after the second; booster doses at 10-y intervals throughout life or with dirty wound if >5 y since last dose
Varicella	Nonimmune household contacts of cancer patients	Not applicable—contraindicated in patients with leukemia, lymphoma, or those undergoing immunosuppressive therapy	For persons >13 y of age, 2 doses separated by 4–8 wk

[a]Adapted from the Centers for Disease Control and Prevention.

[b]May be used in conjunction with hepatitis B immunoglobulin prophylaxis.

[c]Live oral polio vaccine is no longer available for general use in the United States and is contraindicated in immunosuppressed persons or their household contacts.

and polio immunization series should complete the boosters as scheduled, although aggressive and prolonged chemotherapy may blunt the response. Only the inactivated polio vaccine (IPV) should be given to immunocompromised patients because of the risk of acquiring polio from the live attenuated oral polio vaccine. Booster doses of DT or diphtheria, acellular pertussis, and tetanus and the IPV should be administered 1 year after chemotherapy completion. It is recommended that adult cancer patients receive DaPT immunization boosters in the same dose and schedule as for healthy individuals, as responses can be elicited in immunocompromised patients.[239]

The inactivated influenza vaccine is generally recommended in immunocompromised patients on a yearly basis.[278] Several studies have evaluated the efficacy of this vaccine in cancer patients; there is definite efficacy in patients with solid tumors, but the response may be blunted in patients with hematologic malignancies.[288] Despite a lack of a clear-cut benefit in immunocompromised patients, the likelihood of at least partial protection has urged physicians to vaccinate all cancer patients with the inactivated influenza vaccine.

The live attenuated measles, mumps, and rubella (MMR) vaccine may be considered in previously unimmunized children with leukemia who are in remission, or who have been off or not received chemotherapy for at least 3 months; but it is otherwise contraindicated in immunocompromised individuals.[239,277] The live attenuated varicella vaccine is not recommended for use in immunocompromised patients, except in seronegative children with HIV.[239,289,290]

Protective antibodies to common childhood diseases (polio, tetanus, diphtheria, mumps, measles) wane after ablative therapy and autologous or allogeneic transplantation and thus necessitate revaccination.[291–293] All HSCT patients should be vaccinated with combined tetanus-diphtheria toxoids at 12, 14, and 24 months after transplant.[243,292,294–296] Antibody levels against *H. influenzae* gradually decline after transplant, and revaccination using the Hib-conjugate vaccine is recommended at 12, 14, and 24 months after transplant to restore immunity.[243] The oral polio vaccine is contraindicated in all immunocompromised individuals.[278] IPV and hepatitis B vaccines are recommended at 12, 14, and 24 months after transplant, owing to the loss of immunity against

the virus by 1 year after transplant in the majority of transplant recipients.[297,298] Vaccination against *Meningococci*, rabies, and hepatitis A is not routinely recommended in this patient population.[182] Annual seasonal administration of inactivated influenza vaccine is recommended following 6 months posttransplant.[182] The MMR vaccine, a live attenuated vaccine, may be given to BMT patients about 2 years after transplant and may be administered to household contacts before then. Patients with GVHD who are continuing to receive immunosuppressive therapy should not be given the MMR vaccine.[291] The varicella vaccine is a live attenuated vaccine and is contraindicated in transplant recipients. Use of the Bacille Calmette-Guérin vaccine is contraindicated during the first 2 years posttransplant.[299,300]

Passive Immunization

Intravenous immunoglobulins (IVIG) therapy for prevention of infection has been evaluated primarily in patients with lymphoproliferative disorders and multiple myeloma and SCT recipients. Currently available IVIG preparations are safe, well tolerated, and consist primarily of IgG, although small amounts of IgA and IgM are present.[301] IgA-poor preparations must be used to prevent anaphylaxis in patients with known or suspected congenital IgA deficiency and/or those with high anti-IgA titers. IVIG (400 mg/kg given every 3 weeks) has been shown to reduce frequency of moderately severe bacterial infections in patients with CLL who have hypogammaglobulinemia or a history of recurrent infections.[302–304] However, this practice has not been proven to be cost-effective, to prolong survival, or to demonstrably improve the quality of life of patients with CLL.[194] Reduction in the number of symptomatic and life-threatening infections has also been reported in patients with multiple myeloma receiving monthly infusions of IVIG.[201,305] A meta-analysis of multiple trials involving prophylactic IVIG in patients with CLL and MM illustrated a significant decrease in occurrence of major infections and reduction in clinically documented infections, but no survival benefit.[306] Thus, prophylactic use of IVIG for patients with CLL or MM with hypogammaglobulinemia and/or recurrent infections should be considered on an individual basis.

In allogeneic HSCT patients, prophylactic use of IVIG has been shown to prevent grades II–IV acute GVHD,[307,308] decrease gram-negative septicemia, and decrease local infections; but it does not improve mortality.[309,310] Decisions to use IVIG in allogeneic transplant patients should be made on an individual basis because of the cost of IVIG and the availability of suitable antimicrobial alternatives. Autologous transplant recipients do not appear to benefit from prophylactic globulin therapy, and its use may actually lead to increased incidence of fatal hepatic venoocclusive disease in these patients.[311]

IVIG and CMV hyperimmune globulin can confer passive immunity against CMV infection, but other methods of CMV prophylaxis, such as leukofiltration of blood products, may be more cost-effective.[312]

Passive immunization with varicella zoster immune globulin is indicated in seronegative immunosuppressed patients who are exposed to an active case and should be given within 72 to 96 hours of the exposure.[313] Patients who are exposed to measles, mumps, or rubella may benefit from passive Ig prophylaxis if it is given within 6 days of exposure.[314,315] Intramuscular Ig is recommended for patients who travel to areas that are endemic for hepatitis A or for postexposure prophylaxis.[316] Two doses of hepatitis B Ig, given 1 month apart, are recommended for postexposure prophylaxis.

MANAGEMENT OF CATHETER-RELATED INFECTIONS

Catheter-related bloodstream infections (CRBSI) are associated with prolonged hospitalizations, increased healthcare costs, and increased morbidity and mortality.[317,318] The incidence of device-associated infection varies depending on the type of device inserted, its length of use, and the extent of the patient's immunosuppression. Neutropenic patients, particularly those with a hematologic malignancy, have a greater risk for developing CRBSI and bacteremia.[317,319,320] Overall, the incidence of port-associated infections is low at 0.1 per 1,000 port-days, and that of tunneled catheters is approximately 1 to 3 per 1,000 days of patient use. Cumulative incidence of PICC-related blood stream infections is 1.1 per 1,000 PICC-days (range 0.9 to 1.3), but higher in the inpatient setting (2.1 per 1,000 PICC-days).[318] Number of lumens is an independent risk factor for CRBSI and multiple-lumen catheters have higher infection rates.[142,321] Standardized infection control procedures as recommended by the CDC are increasingly being used to help reduce catheter-related bloodstream infections.[322]

Several types of catheter-related infections have been defined: exit site infection, tunnel infection (or pocket infection in the case of ports), septic phlebitis, and CRBSI (Table 69.8).[55] The majority of these infections are caused by gram-positive pathogens, with coagulase-negative staphylococci recovered most frequently.

TABLE 69.8

DEFINITION OF CATHETER-ASSOCIATED INFECTIONS

Localized catheter colonization	• Significant growth of a microorganism (greater than 15 CFU) from the catheter tip, subcutaneous segment of the catheter, or catheter hub.
Exit site infection	• Erythema, or induration within 2 cm of the catheter exit site, in the absence of concomitant bloodstream infection (BSI) and without concomitant purulence.
Tunnel infection	• Tenderness, erythema, or site induration of more than 2 cm from the catheter exit site along the subcutaneous tract of a tunneled catheter (i.e., Hickman or Broviac) in the absence of concomitant BSI.
Pocket infection	• Purulent fluid in the pocket of a totally implanted intravascular catheter that may or may not be associated with spontaneous rupture and drainage or necrosis of the overlaying skin in the absence of concomitant BSI.
Catheter-related bloodstream infection (CRBSI)	• Bacteremia or fungemia in a patient with an intravascular catheter with at least one positive blood culture obtained from a peripheral vein, clinical manifestations of infections (e.g., fever, chills, or hypotension) and no apparent source for the BSI except the catheter. • One of the following should be present: a positive semiquantitative (greater than 15 CFU/catheter segment) or quantitative (greater than 10^2 CFU/catheter segment) culture whereby the same organism (species and antibiogram) is isolated from the catheter segment and peripheral blood; simultaneous quantitative blood cultures with a 3:1 ratio for CVC versus peripheral; or differential period of CVC culture versus peripheral blood culture positivity of more than 2 hours.

Catheter-related infections with *S. aureus,* gram-negative bacteria, corynebacteria, bacillus species, and mycobacterial and fungal organisms have also been reported.

Simultaneous cultures from peripheral sites and all catheter ports are helpful in distinguishing infection of the catheter itself from infection arising from another source. Successful treatment of CRBSIs caused by coagulase-negative staphylococcal or even gram-negative organisms does not always require catheter removal. Infections of the skin pocket of an implanted port also resolve in ~70% of patients without removal of the device.[55] Appropriate intravenous antibiotics should be administered for 1 to 3 weeks and should be rotated through all lumens. If clinical improvement is observed and surveillance cultures from each lumen remain negative after 3 days of antibiotic therapy, the catheter sterilization is likely.[55] Uncomplicated exit site infections will also usually resolve with aggressive local care and systemic antibiotic therapy. However, some bacterial infections (e.g., *S. aureus*, some *Bacillus* species, *Corynebacterium* group, and *Stenotrophomonas* species) will require catheter removal in order to increase the likelihood of successful treatment. Other indications for immediate removal of the catheter include evidence of complicating endocarditis, osteomyelitis, septic thrombosis, septic pulmonary embolism, or sepsis with signs of shock/end-organ dysfunction. Certain organisms, such as *Candida* and fungi, are extremely difficult to eradicate and necessitate prompt catheter removal to avoid the complications of disseminated infection. Fungemia caused by *Malassezia furfur* (*Pityrosporum orbiculare*) tends to occur in patients who receive parenteral lipids and may be resistant to amphotericin B. This infection often manifests as fever, pulmonary infiltrates, and thrombocytopenia; discontinuation of the lipid, as well as removal of the catheter, is needed.[323]

Occlusion and Venous Thrombosis of Catheters

Although a clot is the most common cause of occlusion, inability to aspirate blood from the port or catheter does not always suggest clot formation. Other causes of impaired catheter flow include a malpositioned Huber needle, catheter compression on the wall of the vein, catheter kinking, catheter pinch-off, precipitation of drug solutions in the catheter lumen, development of fibrin sheaths, and catheter migration resulting in a malpositioned tip.[324] Fibrin blockage is common, and simple repositioning of the patient and/or Valsalva maneuvers may allow blood to be withdrawn. If these strategies fail, the catheter position should be confirmed by chest radiograph after injection of contrast dye through the catheter. Patients in whom there is no contraindication to thrombolytic therapy may be given an infusion of urokinase at 200 U/kg/hour for as long as 12 hours to reopen the catheter. Otherwise, 5,000 U of urokinase (in 2 ml of sterile water) may be injected into the catheter, and a blood draw may be attempted again in 30 minutes. This procedure may be repeated twice in 24 hours if necessary. Recombinant tissue plasminogen activator (alteplase) at a dose of 2 mg/2 ml instilled for 30 minutes may also restore function in occluded venous catheters.[325,326]

Contrary to early reports, data from two randomized studies failed to demonstrate a benefit of low-dose warfarin[327] or LMWH[328] to reduce the incidence of symptomatic catheter-associated thrombotic events in patients with cancer. Prophylactic use of urokinase (5,000 IU/ml) every 1 to 2 weeks into long-term CVADs has shown reduced incidence of thrombosis and also of catheter-related infections.[329]

Thrombosis can occur in the catheter itself or in the superior vena cava or veins of the upper extremity. While asymptomatic thromboses have been reported in rates up to 60%, recent studies show a variable incidence of symptomatic catheter-related thrombosis of 4% to 5% up to 28% of adults and 12% of children with a CVC.[325,330,331] Almost all central indwelling venous access devices become coated with a fibrin sheath within days of insertion and the majority of CVC-related thrombi arise within 30 days of initial placement.[332] Pain, ipsilateral extremity edema, and superficial venous dilation require evaluation with venography or noninvasive contrast imaging techniques. The catheter should be removed if it is no longer needed or if treatment with systemic anticoagulation fails. If the catheter remains functional and needed for clinical use, then the recommendation from the 2012 American College of Chest Physicians is to keep the catheter in place and to continue systemic anticoagulation with warfarin or low molecular weight heparin (LMWH) as long as the catheter remains indwelling. If the catheter is removed, it is recommended to continue systemic anticoagulation for a total of 3 months regardless of diagnosis.[333] Another recommendation has a variable length of anticoagulation, from 6 weeks to 6 months depending upon the size of the clot and whether the patient is considered prothrombotic[331] (Fig. 69.8).

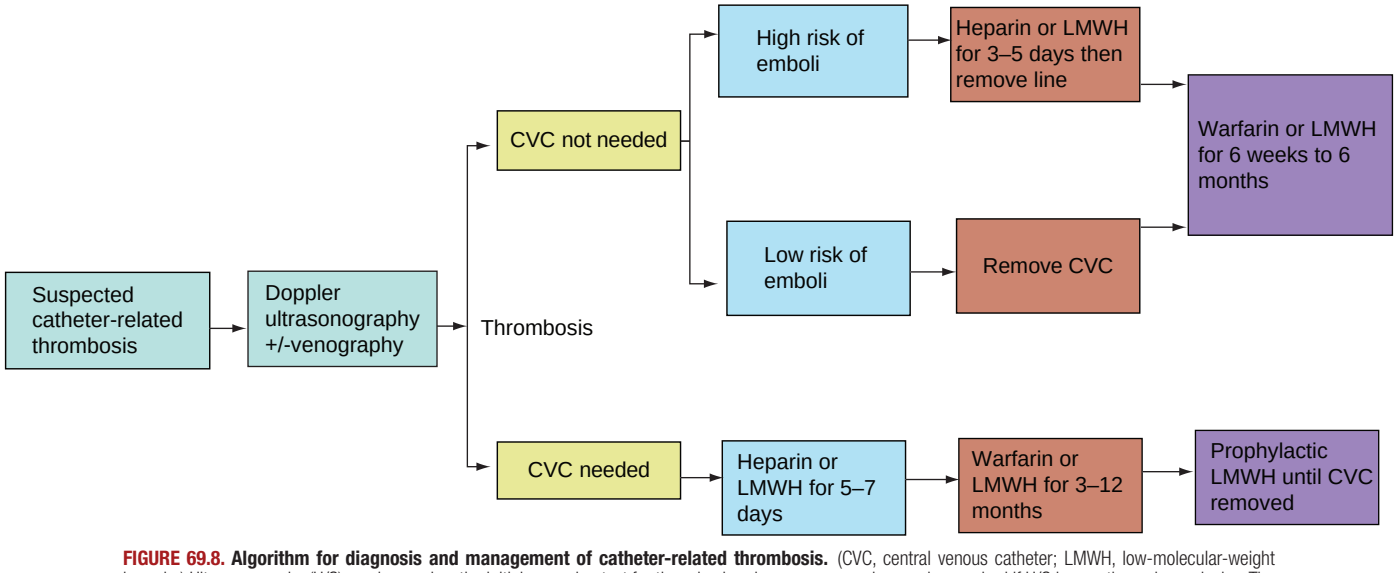

FIGURE 69.8. Algorithm for diagnosis and management of catheter-related thrombosis. (CVC, central venous catheter; LMWH, low-molecular-weight heparin.) Ultrasonography (U/S) can be used as the initial screening test for thrombosis, whereas venography may be required if U/S is negative or inconclusive. The duration of anticoagulation depends upon clinical factors, including the need for the CVC, the size of the clot, and the presence of a prothrombotic state. In patients with cancer, LMWH is preferred over warfarin, and duration of anticoagulation should be 6 months or longer. (Adapted from Baskin JL, Pi C-H, Reiss U, et al. Management of occlusion and thrombosis associated with long-term indwelling central venous catheters. Lancet 2009;374:159–169.)

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

Chemotherapy-induced nausea and vomiting (CINV) is a common adverse effect of cancer therapies. Nausea and vomiting can be very distressing to both patients and their caregivers. Nausea can have a negative impact on quality of life, both physical and cognitive functions, and may lead to critical delays in the administration of potentially curative therapy.[334,335] Nausea and emesis can be induced by a number of factors besides chemotherapy, and thus it is important to investigate the underlying etiology. Radiation therapy, especially in those undergoing total body irradiation (TBI) prior to HSCT, infections, metabolic derangements, electrolyte abnormalities, metastases (especially brain and liver), medications (antibiotics, antifungals, opiates), and other psychological factors can all lead to nausea and vomiting in patients with cancer.[336] Based upon the emetogenic potential of the chemotherapy administered and specific patient characteristics, personalized therapeutic decisions can be made to try to prevent CINV.[337] A breakdown of the relative emetogenicity of commonly used chemotherapeutic agents can be found in Chapter 68, Table 68.2. Patient characteristics associated with increased risk for CINV include: age < 50, female gender, history of motion sickness, history of low prior chronic alcohol intake, and emesis during pregnancy.[335] Coadministration of chemotherapeutic agents and repeated cycles of chemotherapy can also increase the potential for CINV.[338]

CINV can be broken down into 5 distinct yet related syndromes: (1) acute CINV, (2) delayed CINV, (3) anticipatory CINV, (4) breakthrough CINV, and (5) refractory CINV.[338] Acute CINV is typically defined as occurring within the first 24 hours of chemotherapy administration. Delayed CINV is typically defined as occurring 1 to 5 days after chemotherapy administration. Anticipatory CINV occurs prior to the chemotherapy administration, and has been associated with just one episode of nausea and vomiting with a prior regimen. Breakthrough CINV occurs despite the use of appropriate preventative strategies, and refractory CINV occurs due to failure of preventative and rescue therapies.[338]

To understand the rationale behind different strategies for the prevention and treatment of CINV, it is helpful to understand the physiology of the emesis response. The current model of the emesis response (Fig. 69.9) is primarily mediated through neurotransmitters in the gastrointestinal (GI) system and the central nervous system (CNS).[338] Afferent signals from the chemotherapy trigger zone (CTZ), cerebral cortex, and GI tract converge on the vomiting center (VC) within the medulla oblongata. Ultimately, the VC sends out efferent signals to the organs responsible for completing the motor events of emesis (esophagus, stomach, abdominal musculature).[339] Serotonin and substance P are the main neurotransmitters implicated in CINV; however dopamine, histamine, endorphins, acetylcholine, and GABA have also been shown to be involved. Based upon the identification of active neurotransmitters and their receptors within the VC, control of CINV may depend ultimately upon blocking the neurotransmitter receptors in the VC from afferent inputs of the GI tract and CNS.[338]

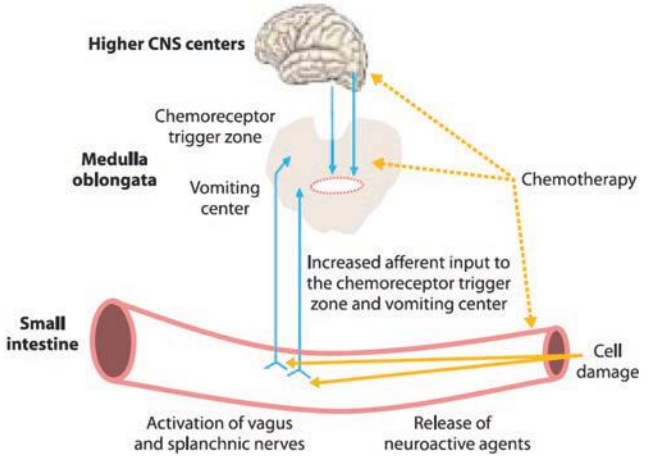

FIGURE 69.9. Model of the emesis response. (With permission from Navari RM. Pathogenesis-based treatment of chemotherapy-induced nausea and vomiting–two new agents. J Support Oncol 2003;1:89–103.)

Prevention is the key treatment of CINV. Development of effective preventative antiemetic regimens requires consideration of the emetic potential of the chemotherapy, dosing and duration of the chemotherapeutic regimen (1 day vs. multiday), single vs. multi-drug regimens, personal risk factors, and the mechanism of action of the prescribed antiemetic therapy. Maximum benefit from antiemetic therapy is achieved when it is initiated prior to chemotherapy and continued throughout the duration of the emetic response to each chemotherapeutic agent. Multiple organizations, including ASCO, NCCN, and MASCC, have developed guidelines for antiemetic prevention, and a summary of these recommendations is listed in Table 69.9.

Agents

5-HT3 Receptor Antagonists

Perhaps the most significant advance in antiemetic therapy, as well as supportive therapy in general, has been the development of the 5-HT3 receptor antagonists. Agents in this class (e.g., granisetron, ondansetron, palonosetron, and dolasetron mesylate) have all shown efficacy in controlling acute nausea associated with chemotherapy.[340–342] As well, both IV and PO routes of administration of these medications are effective when appropriate doses are given.[343] While all 5-HT3 receptor antagonists have been shown to be effective in controlling acute nausea and vomiting caused by chemotherapy, palonosetron has recently been shown to be much more effective than other available 5-HT3 receptor antagonists in preventing delayed nausea and vomiting.[344,345,346] A recent meta-analysis of randomized controlled trials comparing palonosetron with other 5-HT3 receptor antagonists revealed that it was significantly more effective in preventing acute and delayed nausea and vomiting for highly emetogenic and moderately emetogenic chemotherapy.[347] Palonosetron's half-life of 40 hours is much longer than that of the other 5-HT3 receptor antagonists and it has an approximately 100-fold higher binding affinity to the 5-HT3 receptor. These qualities likely explain palonosetron's superiority in preventing chemotherapy-induced nausea and vomiting, especially delayed onset nausea and vomiting.[348] Palonosetron is currently FDA approved for use as a single infused dose on day 1 for the prevention of acute and delayed nausea and vomiting associated with highly and moderately emetogenic chemotherapy. While repeat dosing is considered safe based on NCCN guidelines, the additional benefit of repeated dosing for multiple-day chemotherapy regimens is unknown.

Adverse effects of 5-HT3 receptor antagonists are usually mild and transient. Headache is the most common side effect, followed by gastrointestinal side effects of abdominal discomfort, diarrhea, and constipation, which occur less frequently.[349] Association of IV dolasetron with increased risk for cardiac arrhythmias has been reported by the FDA, and thus IV dolasetron is not recommended.

Neurokinin 1 Receptor Antagonists

Substance P is a mammalian tachykinin found in vagal afferents that send impulses to the vomiting center and thus are involved in the vomiting response. Substance P induces emesis through its binding to neurokinin 1 (NK-1) receptors in the brainstem nucleus tractus solitarius, the area postrema, and the abdominal vagus nerves.[338,350] Two randomized, double-blind, multicenter

TABLE 69.9

SUMMARY OF GUIDELINES FOR THE PREVENTION AND TREATMENT OF CINV

	High		Moderate		Low	Minimal
Group	**Acute CINV[a]**	**Delayed CINV**	**Acute CINV**	**Delayed CINV**	**Acute/Delayed CINV**	**Acute/Delayed CINV**
NCCN[b1]	-5-HT3 RA[c] (palonosetron preferred) + dexamethasone + (fos)aprepitant ± lorazepam ± H2[d] blocker or PPI[e]	± 5-HT3 RA (unless palonosetron given day 1) +Dexamethasone (8 mg po daily days 2–4 with aprepitant or fosaprepitant 150 mg IV day 1) (8 mg po day 2, then 8 mg po BID days 3 and 4 with fosaprepitant 150 mg IV day 1) + Aprepitant 80mg po days 2 and 3 if aprepitant given on Day 1 ± lorazepam day 2–4	-5-HT3 RA (palonosetron preferred) +Dexamethasone ± Aprepitant or Fosaprepitant 150 mg IV day 1 ± lorazepam ± H2 blocker or PPI	-5-HT3 RA on days 2 and 3. (unless palonosetron given day 1) Or Dexamethasone Daily day 2–3 Or Aprepitant 80 mg po day 2–3 (if aprepitant given day 1) ± dexamethasone ± Lorazepam ± H2 blocker or PPI	(repeat daily for multiple-day regimens) -Dexamethasone 12 mg po/IV daily Or -Metoclopramide 10–40 mg PO/IV Or -Prochlorperazine 10 mg PO/IV ± lorazepam ± H2 blocker or PPI	No routine prophylaxis before or after chemotherapy is recommended
ASCO[f2]	-5-HT3 RA + Dexamethasone +(fos)aprepitant ±Lorazepam ±diphenhydramine	-Dexamethasone Day 2–3, or day 2–4 + Aprepitant day 2–3 if Fosaprepitant is NOT used day 1.	-5-HT3 RA (palonosetron preferred) + Dexamethasone ±aprepitant ±lorazepam ±diphenhydramine	-Dexamethasone daily day 2–3 ± aprepitant (if used on day 1)	-Dexamethasone 8 mg PO/IV prior to chemotherapy	No antiemetic should be administered routinely before or after chemotherapy
MASSC/ESMO[g3]	For HEC[h] and AC[i] regimens: -5-HT3 RA + Dexamethasone + (fos)aprepitant	-Dexamethasone day 2–4 + aprepitant day 2–3 if aprepitant given day 1	Non-AC regimens: -Palonosetron + Dexamethasone	-Dexamethasone day 2–3	-Dexamethasone or 5-HT3 RA or Dopamine antagonist prior to chemo	-No routine prophylaxis is recommended

controlled studies found the addition of aprepitant (125 mg po on day 1 and 80 mg po daily on days 2 and 3) to standard therapy (5-HT3 receptor antagonist on day 1) and dexamethasone (prechemotherapy on day 1 and daily on days 2 to 4) improved rates of acute N/V and delayed N/V when compared to standard therapy alone in patients receiving cisplatin chemotherapy.[351,352] Thus, in 2003, aprepitant became the first neurokinin-1 receptor antagonist to be approved for the prevention of acute and delayed nausea and vomiting with highly-emetogenic chemotherapy. Fosaprepitant, a parenteral NK-1 receptor antagonist, has since become available for the prevention of CINV associated with highly emetogenic chemotherapy. Unlike aprepitant, fosaprepitant is given at a dose of 150 mg IV 30 minutes prior to chemotherapy on day 1 only.[353] Important to note is that NK-1 receptor antagonists are moderate inhibitors of the enzyme CYP34A, the enzyme responsible for glucocorticoid metabolism, and thus in clinical trials the dosing of concurrent dexamethasone was reduced to 12 mg on day 1 and 8 mg on days 2 and 3.[351,352]

Olanzapine

Olanzapine is an atypical antipsychotic with an affinity to multiple neurotransmitter receptors involved in the emetic response, including: dopaminergic, serotonergic, adrenergic, histaminergic, and muscarinic receptors, thus suggesting a potential benefit for the prevention and treatment of nausea and vomiting.[354,355] In a pilot study, Passik et al. explored the antiemetic activity of olanzapine in patients with advanced cancer, with their results suggesting benefit. Subsequent trials, including a randomized phase III trial, confirmed these results.[356–358] Navari et al. conducted a randomized phase III trial comparing the efficacy of olanzapine vs. aprepitant, both in combination with palonosetron and dexamethasone, for the prevention of CINV in patients receiving highly emetogenic chemotherapy. Complete response rates, no emesis, and no need for rescue medications were similar results for both groups during the acute and delayed period; however, nausea was better controlled in the olanzapine group.[358] The total dose of dexamethasone was also less in the olanzapine group, as this group received only a one-time dose of dexamethasone on day 1 vs. 4 days of dosing in the aprepitant group. This finding led the authors to conclude that the use of olanzapine for the prevention of CINV with highly emetogenic chemotherapy may be more beneficial, since the exposure to steroids and potential adverse effects of their use with multiple rounds of chemotherapy would be much less.

An increase in extrapyramidal symptoms (EPS) associated with olanzapine use has not been seen in studies evaluating olanzapine's efficacy in the prevention of CINV, and this lack of increase in EPS as compared to other neuroleptic drugs used for the treatment of nausea (e.g., prochlorperazine and metoclopramide) is another reason to consider its use. These preliminary studies also found an improvement in mood and appetite in patients who were treated with olanzapine.[354] At this time, expert guidelines recommend the use of aprepitant along with 5HT-3 receptor antagonists and steroids for the prevention of CINV associated with highly emetogenic chemotherapy; however, further studies evaluating olanzapine's benefit in this group of patients are ongoing and the results of these studies may alter recommendations in the future.

Chemotherapy-induced Nausea and Vomiting with High-dose Chemotherapy/Hematopoietic Stem Cell Transplant

Controlling nausea and vomiting in patients undergoing HDC with HSCT rescue is a challenge. Many factors, including HDC, total body irradiation (TBI), medications to prevent graft-versus-host disease, antimicrobials, and opioids, can induce nausea and vomiting.[359] Multiple studies have shown a benefit of 5-HT3 receptor antagonists along with steroids in the prevention of CINV in patients undergoing HDC; however, complete responses with these regimens were seen in only 15% to 50% of patients.[360–363] Given the suboptimal rate of control seen with 5HT-3 receptor antagonists and steroids, studies examining the addition of aprepitant, an NK-1 antagonist, to 5HT-3 receptor antagonists have been conducted.

The role of newer agents, such as aprepitant, in the prevention and treatment of CINV in patients undergoing HDC with stem cell rescue is less clear. There is data to support the efficacy and safety of aprepitant along with 5HT-3 receptor antagonists and steroids, albeit from small, single institution studies. Despite the small sample sizes, these studies have shown efficacy for a number of preparative regimens, including: BEAM (BCNU [carmustine] + etoposide + ARA-C [cytarabine] + melphalan), T-ICE (paclitaxel + ifosfamide + carboplatin + etoposide), BuCy (busulfan + cyclophosphamide), Cy/TBI (cyclophosphamide + total body irradiation), Cy/TBI/VP16, and BCV (BCNU + cyclophosphamide + VP16). The data so far has looked at multiple different dosing regimens for aprepitant, including the traditional 3-day regimen (125 mg po on day 1 followed by 80 mg po on days 2 and 3) and a 12-day regimen (125 mg po on day -7 followed by 80 mg po daily thereafter until day +4) conducted in a pilot study by Bubalo et al.[364] As aprepitant is a moderate inhibitor of CYP34A, busulfan doses need to be followed closely, and in pilot studies all patients required dose adjustments.[365,366,367,368,369] These studies support the added benefit of aprepitant to standard antiemetic therapy without increasing toxicity. Because of the limited amount of data, ASCO guidelines currently recommend considering the use of aprepitant in patients undergoing HDC with HSCT until the results of larger phase III studies become available.

Miscellaneous

Multiday chemotherapy regimens and highly emetogenic radiation regimens are both commonly used in the management of hematologic malignancies. ASCO guidelines recommend the use of antiemetics appropriate for the emetogenic risk class of the chemotherapy being administered for each day of chemotherapy and for 2 days after, if appropriate.[370] Both MASCC and ASCO guidelines recommend the use of a 5HT-3 receptor antagonist along with steroids for the treatment of highly emetogenic radiation therapy, such as TBI, with ASCO guidelines recommending a minimum of 5 days of steroid therapy.[343,370]

CANCER-RELATED FATIGUE

Fatigue is one of the most common symptoms reported by cancer patients, and has a reported incidence of 60% to 90% among patients with cancer. Cancer-related fatigue (CRF) is defined as an unusual sense of tiredness that is persistent and not improved with rest, that can occur with cancer or cancer treatment, and that may affect physical and/or mental functioning.[371] Fatigue can negatively impact a patient's quality of life by interfering with their ability to perform activities of daily living, keep employment, and maintain financial stability.[372] CRF is more intense and more unpredictable than fatigue that was experienced before the cancer diagnosis.[373]

Multiple etiologies for CRF are often present in patients with cancer and include anemia, sleep disorders, depression, endocrinopathies, nutritional deficiencies, and uncontrolled pain. Anemia is likely the most common reversible cause of fatigue during active cancer treatment. Although CRF is often attributed to the initiation of cancer therapies, this fatigue may persist long after the completion of treatment with up to 30% of cancer survivors reporting loss of energy years after completion of treatment.[372,374] Escalante and Manzullo recommend using the question "How

would you rate your fatigue on a scale of 0 to 10 over the past week?" along with a simple visual analog scale from 0 to 10 (with 0 as no fatigue and 10 as the worst imaginable fatigue) to screen patients and to follow response to interventions. Specific causes for fatigue should be sought out, and once specific therapies for fatigue are initiated, then assessments for response should take place as the identified cause is being corrected.[372]

Multiple pharmacologic and nonpharmacologic interventions have been employed to treat CRF. Nonpharmacologic interventions include exercise programs, nutritional assessments, and sleep analysis. Exercise has been the most studied nonpharmacologic strategy for treating fatigue.[372] Schwartz et al. evaluated the effect of a moderate-intensity home exercise regimen in women with newly diagnosed breast cancer receiving active treatment with chemotherapy. Low- to moderate-intensity exercise significantly decreased fatigue in these patients, and the intensity of fatigue declined as exercise tolerance increased.[373] Initiation of an exercise program should begin at low intensity levels and shortened intervals with gradual increase in intensity and duration based on the patient's physical conditioning. Patients with severe debilitation and extensive disease may require consultation with a physical therapist or a physical medicine and rehabilitation specialist to assist in developing a safe and effective exercise program.[372]

Pharmacologic strategies that have been used to combat CRF include stimulants, antidepressants, and low-dose steroids. Well-designed clinical trials evaluating the efficacy of these pharmacologic interventions to guide treatment decisions are unfortunately lacking. Methylphenidate, a stimulant, has been studied in CRF and may have a beneficial effect. Sarhill et al. studied the efficacy of methylphenidate for the treatment of fatigue in patients with advanced cancer. In this open labeled pilot study, 9 of 11 patients studied achieved benefit regardless of whether anemia was present. Only 1 patient stopped treatment because of adverse effects.[375,376] Therapy is typically initiated at 5 mg in the morning and 5 mg in the early afternoon. Methylphenidate should not be administered in the late afternoon as it may interfere with sleep patterns. Patients may require titration of dosing over time in order to maintain a clinical benefit because of the potential development of tolerance. Tachycardia and hypertension are known adverse effects of methylphenidate and it is therefore not recommended for use in patients with known coronary artery disease, uncontrolled hypertension, or tachyarrhythmias.[372]

Modafinil, a nonamphetamine psychostimulant, has been studied in a randomized phase III trial to evaluate its effectiveness in the treatment of cancer-related fatigue.[377] Jean-Pierre et al. reported a benefit from modafinil 200 mg daily in patients with severe fatigue at baseline; however, there was no statistically significant improvement in fatigue in patients with mild to moderate fatigue at baseline. Thus, it is recommended that intervention with modafinil be limited to those with severe fatigue at baseline.[377]

The inability of current pharmacologic interventions to produce significant improvements in CRF for the majority of cancer patients underscores the importance of a multidisciplinary approach to CRF that incorporates assessments for fatigue, recognition of underlying etiologies, coping strategies, nonpharmacologic therapies, and intervention with pharmacologic therapy only when necessary.

CANCER PAIN

Pain is one of the most feared symptoms of cancer by patients and family members.[378] Sixty to eighty percent of patients with advanced cancer experience moderate to severe pain on a monthly basis, and control of cancer-related pain is one of the most important goals of supportive care. Management of cancer pain can be quite complex because the etiologies are diverse and can adversely affect multiple domains of quality of life, including activities of daily living, psychological well-being, physical functioning, and social interactions.[379] Coexisting cancer symptoms, such as weakness, fatigue, nausea, dyspnea, constipation, and impaired cognition, can magnify the perception of and exacerbate cancer pain. Modifying the source of the pain, altering the perception of pain, and blocking the transmission of pain to the central nervous system can effectively treat cancer pain in 85% to 95% of cases.[380] A comprehensive patient-centered approach to pain management that assesses the patient's pain, barriers to pain control, concurrent medical problems, response to pharmacologic interventions, and psychosocial status is key to achieving adequate pain control.[381–384]

Types of Cancer Pain

To adequately address and control pain, it is imperative that the treating physician understand the pathophysiology of cancer pain. The majority of cancer-related pain can be classified as nociceptive, neuropathic, or both. The distinction between these 2 types of pain is important, as neuropathic pain is often refractory to opioid therapy. Nociceptive is the term used to describe pain that is propagated by continual tissue injury, and it is classified into somatic or visceral pain. Nociceptive pain is termed somatic when the continual tissue injury is relayed via primary afferent nerves in somatic tissues such as those of the musculoskeletal system. Somatic pain is classically described as being sharp or aching and localized to the area of tissue damage. Nociceptive pain is termed visceral when tissue injury is relayed via primary afferents of the viscera. Visceral pain tends to be poorly localized and intermittent, many times described as dull or aching.[378,385,386] Neuropathic pain is a result of injury to peripheral or central nerves and typically causes paroxysmal burning, shooting, or aching sensations that may or may not be associated with paresthesias. In patients with malignancy, neuropathic pain can be caused by a number of different etiologies, such as direct nerve injury from the tumor itself, or the result of anticancer treatments such as surgery, radiation, and chemotherapy. Identification of neuropathic pain often indicates that nontraditional adjuvant therapies may be required to achieve adequate pain relief.[385,387]

Barriers to Pain Control

Up to 50% of patients with cancer have uncontrolled pain.[388] Several reasons for inadequate treatment of pain exist and can be classified as physician barriers or patient barriers to pain control.

Multiple studies have identified physician-related barriers to cancer pain management, and all have a recurring theme.[389,390] Two large studies surveying US medical oncologists' attitudes and practices in cancer pain management have been undertaken over the past 20 years.[391,392] Despite the almost 20-year time between the 2 studies, both concluded that knowledge deficits, inadequate training in pain management, inadequate opioid prescribing as recommended by established guidelines, and poor pain assessment are the main physician-related barriers to adequate pain management. The potential for addiction, the development of tolerance, scrutiny by regulatory agencies, and inadequate side effect management are other potential reasons for nonadherence to established pain management guidelines.

There are also many patient-related barriers that hinder patients' use of appropriate analgesics for cancer pain. Reluctance of patients to report pain and take pain medications have been shown to be the most prominent patient-related barriers to cancer pain management.[393,394] The Barriers Questionnaire, a tool designed to identify patient-related barriers to cancer pain management, has identified 9 areas of concern that patients may have in reporting and taking pain medications. (1) Fatalism, belief that cancer pain is inevitable; (2) fear of addiction; (3) "desire to be a

good patient" and not complain; (4) fear of distracting one's physician from treating the disease; (5) concern that increasing pain signifies disease progression; (6) concerns about drug tolerance; (7) concerns about side effects; (8) religious fatalism, the religious belief that pain is caused or given by a deity and that patients have to tolerate the pain in order to avoid carrying the pain into their next life; and (9) concerns that pain medications are better when given on an as needed basis.[393]

Patient education is one way to overcome patient barriers to cancer pain management. Multiple studies have proven the effectiveness of pain education programs in improving patient adherence to analgesic therapy and ultimately decreasing pain intensity.[395–397] Educational interventions for both physicians and patients will likely lead to more appropriate guideline-based analgesic prescribing and patient adherence to prescribed therapies.

Pain Assessment

A comprehensive pain assessment is crucial to adequate pain control and includes a detailed pain history that evaluates pain intensity, location, and type, as well as an assessment of psychological stressors and the patient's network of social support. A detailed physical exam paying close attention to impending oncologic emergencies is also important in determining the etiology of pain so that timely and appropriate interventions can be initiated. Pain is subjective, and thus patient report is the "gold standard" for measurement. In order to try and make pain measurement objective and reliable, a number of scales have been developed.

Pain intensity has been shown to have an inverse correlation with quality of life and functioning. Pain intensity can be measured by a number of validated scales.[398,399] Some scales are available to assess pain intensity for those with limited literacy as well as those who are cognitively impaired.[378,400–402] Other scales, such as the Memorial Pain Assessment Card and the Wisconsin Brief Pain Inventory, have been developed to assess pain intensity as well as psychological distress. These two scales are not only multidimensional but also practical, given the efficiency in which they can be completed in a clinical setting.[403,404] Numerical ratings of pain intensity obtained from the different scales can then be used to guide analgesic therapy.

Analgesic Management: World Health Organization Analgesic Ladder

The World Health Organization (WHO) "three-step analgesic ladder" (Fig. 69.10) developed in the 1980s continues to provide the framework for the management of cancer-related pain. The analgesic ladder introduced a stepwise approach to pain management and selection of appropriate analgesia based on pain intensity. Based on WHO recommendations, mild pain, rating 1 to 4, is treated with nonsteroidal antiinflammatory drugs (NSAIDs) and acetaminophen plus adjuvant analgesics; moderate pain, rating 5 to 6, is treated with weak opioids such as codeine and tramadol; and for severe pain, rating 7 to 10, strong opioids such as hydromorphone, morphine, fentanyl, oxycodone, and methadone are recommended.[405,406] Additional principles endorsed by the WHO for optimal pain management include: (1) oral administration of pain medications if possible; (2) around-the-clock dosing for chronic pain; (3) pain severity should determine drug choice; (4) individualized treatment plans because of variability of response to analgesic agents among patients; and (5) frequent reassessments of patient's pain.[406]

NSAIDs and acetaminophen are the initial nonopioid step 1 analgesics recommended for use by the WHO guidelines for mild pain. NSAIDs block cyclooxygenase 1 and cyclooxygenase 2 enzymes (COX-1 and COX-2), thus decreasing prostaglandin synthesis. Prostaglandins and other inflammatory cytokines are produced within the tumor microenvironment and are responsible for pain associated with local tumor growth and infiltration.[406,407] The benefit and role of NSAIDs in the treatment of cancer-related pain has been shown in two large meta-analyses.[407,408] There does seem to be a ceiling effect for analgesia with NSAIDs and doses beyond the daily recommended maximum dose are not advised. Doses of nonopioid analgesics should be titrated to maximal daily doses or until adverse effects emerge, as long as mild to moderate pain persists. NSAIDs do carry a risk for GI toxicity, and cancer patients may be particularly susceptible to these toxicities, given concurrent medications that can lead to mucositis, gastritis, and anorexia. Selective COX-2 inhibitors are available and have been associated with less GI toxicity than nonselective NSAIDs; however, there have been reports of adverse GI effects with their use in cancer patients.[409] For acetaminophen, it is not recommended to dose more than 6 g per day; however, for those with underlying

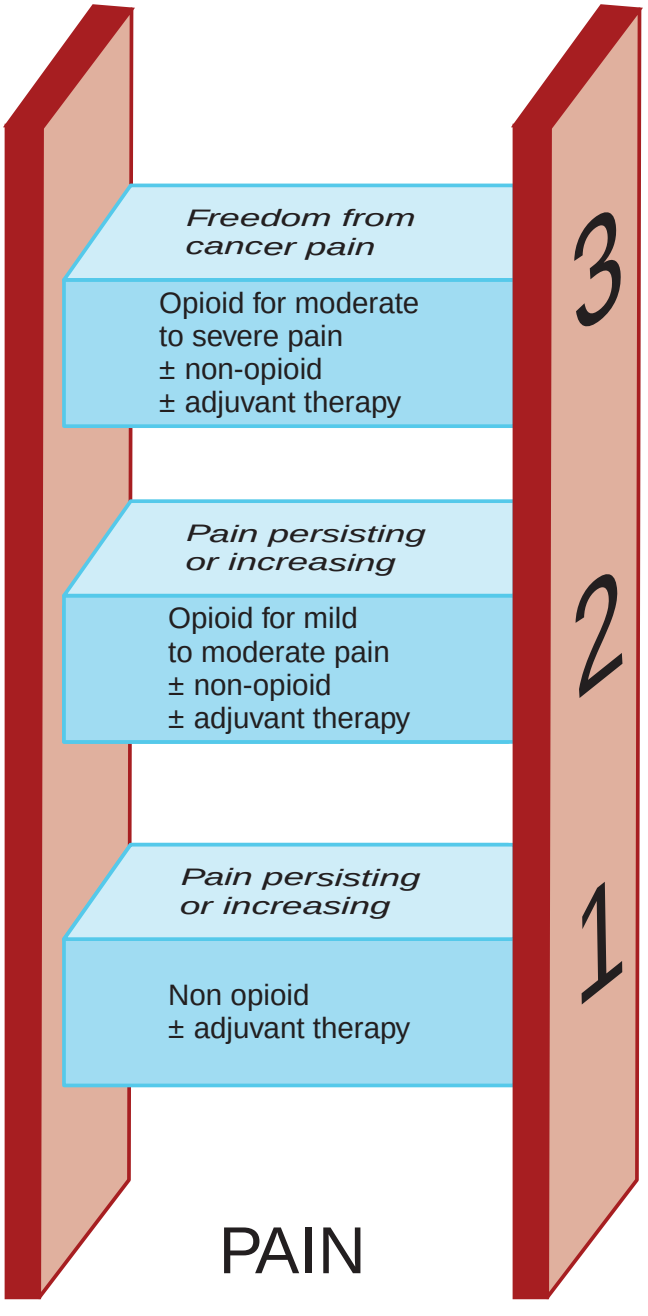

FIGURE 69.10. The WHO "three-step analgesic ladder."

hepatic dysfunction or those taking concomitant potentially hepatotoxic medications, 4 to 6 g per day may be more appropriate.

If pain remains uncontrolled with appropriate step 1 interventions, then the introduction of opioid therapy into the management of cancer pain is recommended by step 2 of the WHO analgesic ladder. Opioids are the backbone of pain management in patients with cancer. Interindividual variation in opioid receptors (polymorphisms of the mu, kappa, and/or delta receptors), absorption, intensity of the painful stimulus, administration of concurrent medications, and enzymes responsible for opioid metabolism underscore the importance of an individualized approach to opioid prescribing for patients experiencing cancer pain.[410,411,412] Step 2 opioids, previously referred to as "weak opioids," include codeine, tramadol, hydrocodone, and oxycodone. These opioids are typically combined with nonopioid analgesics such as NSAIDs or acetaminophen which limit their total daily dose. Codeine has a weak affinity for mu opioid receptors and its analgesic activity requires metabolism to morphine by CYP2D6. The time-to-peak effect for codeine is typically 1 to 2 hours, and it has an effective half-life of approximately 3 hours. Like many other opioids that require CYP2D6 metabolism to produce active metabolites, medications that induce or inhibit the CYP2D6 enzyme can alter the analgesic effects of codeine. In addition, some patients are "fast" or "slow" metabolizers, further adding to the variability in effectiveness.[413] Tramadol, a synthetic analog of codeine, is also considered a "weak opioid." Tramadol is unique because it not only has analgesic properties that are mediated through mu receptor activation, but it also has serotonin and norepinephrine reuptake inhibitor activity. This dual mechanism is felt to be responsible for its effectiveness, especially in selected patients with chemotherapy-induced neuropathic pain.[414,415] O-desmethyl tramadol, the active metabolite of tramadol, requires metabolism via the CYP2D6 enzyme and is thus subject to interactions to CYP2D6 inducers and inhibitors. Maximal daily dose is 400 mg per day, as doses above this can lead to neurotoxicity and seizures. Hydrocodone is an oral opiate that is indicated for the treatment of moderate pain and is available only as a combination product with an NSAID or acetaminophen. The metabolism of hydrocodone is through the CYP2D6 enzyme as well; however, its active metabolite, hydromorphone, is a very strong mu receptor agonist.[416] Given hydrocodone's prodrug properties, analgesic response is affected by different polymorphisms in the CYP2D6 gene, as well as inducers and inhibitors of this enzyme.[410]

If pain persists at a level of 5 or greater after achieving the maximal daily dose of the step 2 analgesic, then the addition of a step 3 analgesic is recommended. Morphine, fentanyl, oxycodone, and hydromorphone are the most commonly used step 3 analgesics used for the management of moderate to severe cancer pain.

Morphine has classically been the opioid of choice for the treatment of moderate to severe cancer pain. Due to morphine's multiple routes of administration (oral tablets, oral solutions, parenteral, and rectal), formulations are available to appropriately treat acute pain crisis, chronic stable pain, and those in a terminal condition. Morphine can cause adverse effects that are classic for all opioids; however, it can also produce adverse effects that are unique to itself. Morphine can cause a histamine release, which can lead to bronchospasm and rash. Morphine can also decrease sympathetic tone that leads to peripheral vasodilatation and resultant orthostatic hypotension.[410,413] It is metabolized through glucuronidation, producing active metabolites morphine-6 glucuronide (M6G) and morphine-3 glucuronide (M3G). M3G is associated with neurohyperexcitability and hyperalgesia. Both metabolites are excreted in the urine; thus, renal insufficiency can lead to an accumulation of these metabolites and result in oversedation and increased adverse effects.[417,418]

Oxycodone is available in its pure form as well as in combination with acetaminophen or an NSAID. Combination products limit oxycodone's titration due to maximal daily doses of the nonopioid analgesic partner medication, thus limiting its efficacy to that of other step 2 analgesics. In its pure form, oxycodone has no ceiling effect, the same as the other step 3 opioids. Oxycodone is metabolized by CYP2D6 to oxymorphone, thus making it susceptible to drug-drug interactions that induce or inhibit CYP2D6.[410]

Hydromorphone is a semisynthetic opioid that is approximately 5 times more potent than morphine once steady state oral and parenteral dosing is reached.[419] Hydromorphone has multiple routes of administration: intravenous, intramuscular, subcutaneous, oral, and rectal, and is extensively metabolized by the liver; thus its use may be preferred in patients with renal failure.[410]

Fentanyl is another step 3 opioid that is a very strong opiod agonist, approximately 80 times more potent than morphine. Fentanyl is unique in that it not only has a parenteral form, but also has transdermal and transbuccal formulations. These preparations are particularly useful for patients with stable chronic pain who are unable to swallow pills, are noncompliant, or are in the terminally ill phase when swallowing may be difficult. When transitioning to transdermal fentanyl preparations it is important to note that there is a delay of 8 to 16 hours until the onset of analgesia, and thus initial overlap with other opioid medications may be required. Steady state of transdermal fentanyl is not reached until approximately 72 hours.[410,420]

Fentanyl undergoes extensive metabolism in the liver, thus making it an attractive option for use in those with renal failure. There is some controversy as to the appropriate relative potency ratio to be used when converting oral morphine to transdermal fentanyl. Donner et al. showed that an oral morphine to transdermal fentanyl ratio of 100:1 was safe and effective in converting patients with cancer pain from oral morphine to fentanyl; however, they noted that this ratio was too low and that the true ratio determined by their study was 70:1. Thus, if one uses 100:1 as a conversion ratio, then one should be aware that this will likely lead to insufficient dosing, and supplemental breakthrough medications will likely be necessary until appropriate doses can be achieved.[421]

Oxymorphone, a newer strong opioid multireceptor agonist, is available in oral preparations and is 10 times more potent than morphine. Oxymorphone is not metabolized by CYP2D6 and thus is not as susceptible as some of the other aforementioned opioids to drug-drug interactions.[422]

Methadone is another effective opioid receptor agonist that has been used to treat chronic cancer pain. Due to its long half-life, erratic metabolism, and propensity for drug-drug interactions, it is recommended that methadone only be managed by providers with knowledge of its pharmacology and experience in its prescribing.[410]

The oral route of administration is the most preferred as long as patients are able to swallow, and this route of administration is controlling the pain. Acute pain exacerbations should be treated with short-acting medications around the clock along with breakthrough dosing in order to ultimately come up with a total 24-hour opioid dose that will control the pain. As long as patients are experiencing severe unrelieved pain, the total opioid dose should be increased by 50% to 100% every 24 hours until the pain is controlled. If patients are experiencing unrelieved moderate pain, the total opioid dose should be increased by 25% to 50% every 24 hours until the pain is controlled. Once the patient's pain is adequately controlled, then long-acting preparations of oral opioid therapy can be incorporated. Appropriate doses of long-acting opioid medications can be calculated by taking the 24-hour total oral opioid requirement to control the pain and converting this into a long-acting opioid dose. Because of the individualized nature of the metabolism of different formulations of opioid pain medications, as a general rule it is safe to start with 75% of the total dose of the previous opioid when transitioning between opioids, and titrate the dose up as necessary. Once scheduled long-acting opioids are instituted, short-acting breakthrough

medications should be made available to the patient on an as needed basis with dosing intervals determined by the medications' time to peak effect. Again, frequent reassessment of pain control is of paramount importance, especially during times of transition between different formulations of opioid medications.[386]

Despite aggressive and appropriate management with opioid and other adjuvant analgesic medications, a minority of patients will continue to have uncontrolled pain related to their malignancy. In these circumstances, a referral to an anesthesiologist or a neurosurgical pain specialist is warranted. Epidural nerve blocks, spinal cord stimulation, or implantable epidural catheters with opioid pain pumps may be needed to achieve adequate pain control.[423,424]

Adjuvant Therapies

Opioid therapy alone may not be adequate to control all types of cancer-related pain, and thus throughout all steps of the WHO analgesic ladder adjuvant analgesic treatments are recommended when they are felt to benefit the patient (Table 69.10). Corticosteroids have long been used to treat pain due to spinal cord compression associated with metastatic disease; however, their benefit has been shown in the treatment of bone and neuropathic pain as well.[425–427] Anticonvulsants such as gabapentin and lamotrigine, as well as antidepressants such as amitriptyline and nortriptyline, have been shown to improve neuropathic pain and can be used in combination.[428,429,430] As pain can be exacerbated by depression, and depression can be influenced by pain, it is crucial that prompt recognition and treatment of depressive symptoms occur when identified.[431] Pain that is caused by malignant bone involvement may respond to therapy with agents that limit osteoclast activity, such as bisphosphonates and Miacalcin, as well as agents such as NSAIDs and corticosteroids, which can decrease local inflammation caused by tumor invasion.[432,433]

TABLE 69.10

ADJUVANT ANALGESICS

Indication/Drug Class	Examples
Multipurpose Analgesics	
Tricyclic Antidepressants	Amitriptyline, Nortriptyline, Desipramine
Selective Serotonin Reuptake Inhibitors	Paroxetine, Citalopram
Noradrenaline/serotonin Reuptake Inhibitors	Venlafaxine
Others	
Corticosteroids	Dexamethasone, Prednisone
Neuroleptics	Olanzapine
For Neuropathic Pain	
Anticonvulsants	Gabapentin, Topiramate, Lamotrigine, Levetiracetam, Pregabalin
N-methyl-D-aspartate receptor antagonists	Ketamine, Dextromethorphan
Topical Drugs	Lidocaine/Prilocaine
For Bone Pain	
Corticosteroids	Dexamethasone, Prednisone
Calcitonin	Calcitonin
Bisphosphonates	Pamidronate, Zoledronic Acid
For Musculoskeletal Pain	
Muscle Relaxants	Cyclobenzaprine, Orphenadrine, Carisoprodol, Metaxalone
Baclofen	
Tizanidine	
Benzodiazepines	Diazepam, Lorazepam, Clonazepam

Adapted from Lussier D, Huskey AG, Portenoy RK. Adjuvant analgesics in cancer pain management. Oncologist 2004;9:571–591.

There is some evidence to suggest that complementary therapies such as massage, acupuncture, and yoga are beneficial in the treatment of cancer-related pain; however, larger studies are needed to confirm these possible benefits.[434–436]

Adverse Effect Management

Despite the efficacy of opioids in the treatment of pain, almost all patients who use opioids for analgesia will experience side effects. The most common adverse effects of opiates are listed in Table 69.11. Prevention is the key to the management of these adverse effects; however, once side effects emerge, aggressive measures to abate these undesired effects, along with opioid titration and possible rotation, are necessary. Constipation is one of the most psychologically distressing side effects from opioid therapy that patients may experience and can lead to anorexia and bowel obstruction.[437] All patients taking opioids should be on a prophylactic bowel regimen to try and prevent constipation. Methylnaltrexone, a peripheral opioid antagonist, has been demonstrated in multiple studies to be effective in relieving opioid-induced constipation. Weight-based subcutaneous dosing can be given as needed, however not to exceed 1 dose per 24-hour period. Inclusion criteria for randomized clinical trial enrollment were either < 3 bowel movements within the preceding week or >2 days without a bowel movement.[438–441] As methylnaltrexone is unable to cross the blood-brain barrier, it is able to reverse peripheral inhibition of opioid receptors of the GI tract without affecting analgesia.[442] Respiratory depression is a potentially fatal yet uncommon adverse effect of opioid treatment. Naloxone, a nonselective opioid antagonist, is the only therapy currently available for the reversal of opioid-induced respiratory depression.[443] Due to its low bioavailability, naloxone is given by intravenous infusion. The extent and duration of naloxone's effect depends on the receptor affinity of the opioid being reversed. Due to its rapid elimination, naloxone many need to be dosed repeatedly or by continuous infusion to maintain reversal of respiratory depression.

Since naloxone is a nonselective opioid antagonist, reversal of respiratory depression results in reversal of analgesia, and thus research into therapies that can reverse respiratory depression while preserving analgesia are currently underway.[444] Urinary retention can be relieved with insertion of a Foley catheter into the bladder. Excessive sedation can be combated by dose reduction of the opioid or with addition of a psychostimulant such as caffeine or methylphenidate.[445] There is preliminary data that opioid-induced neurotoxicity, specifically hyperexcitability, can be managed with medications such as lorazepam, baclofen, valproic acid, and midazolam. Small studies have shown improvement in opioid-induced nausea with centrally acting antiemetics such as

TABLE 69.11

ADVERSE EFFECTS OF OPIOID TREATMENT

Common Adverse Effects of Opioid Therapy	
Constipation	Hallucinations
Respiratory Depression	Impotence
Hyperexcitability	Fatigue
Urinary Retention	Sweating
Nausea	Vomiting
Pruritus	Myoclonus
Sedation	Xerostomia

metoclopramide and phenothiazines, as well as antipsychotics such as olanzapine and chlorpromazine.[354,446]

MUCOSITIS

Mucositis is a common toxicity related to systemic chemotherapy, especially in those patients receiving HDC and HSCT, in which mucositis affects 80% to 100% of patients undergoing preparative regimens.[447] Mucositis can make the host susceptible to infection, modulate the intensity of treatment able to be given, and hinder the ability for oral intake, all of which can have a negative impact on quality of life (QOL).[448] The choice of chemotherapeutic agent (e.g., methotrexate, bleomycin, infusional 5-FU, cytarabine, etoposide), preexisting oral disease, and concurrent use of radiation therapy are all factors that can increase the likelihood of a patient developing treatment-related mucositis.[449,450]

As with nausea, prevention is key; unfortunately, the data for effective preventative interventions is sparse. Pretreatment prophylactic oral care, consisting of a comprehensive oral examination that includes caries treatment, endodontic therapy, and tooth extraction if necessary, has been shown to decrease the frequency of treatment-related oral complications.[451] Other preventative therapies such as cryotherapy, palifermin, and low-level laser therapy have data to support their use in patients undergoing treatment for hematologic malignancies. The strongest data supporting oral cryotherapy (ice chips swished around the mouth for 30 minutes) for the prevention of treatment-related mucositis has been in patients receiving bolus 5-FU treatments.[452] There is also data supporting the use of oral cryotherapy in patients receiving high-dose melphalan and stem cell transplantation, and thus MASCC guidelines recommend the use of oral cryotherapy for the prevention of oral mucositis in this patient population.[453]

Palifermin is a recombinant human keratinocyte growth factor that stimulates the growth and differentiation of epithelial cells. Spielberger et al. evaluated the effectiveness of palifermin in preventing the development of severe mucositis in patients undergoing HDC and TBI followed by autologous HSCT in a double-blind phase III randomized controlled trial.[454] Palifermin (60 μg/kg of body weight per day intravenously for 3 days before the initiation of conditioning therapy and for 3 days after autologous HSCT) was shown to decrease the incidence of WHO grade 3 or 4 mucositis, duration of mucositis, use of opiod analgesics, and need for total parenteral nutrition (TPN). These results led to clinical practice guidelines recommending the use of prophylactic palifermin in patients with hematologic malignancies who are undergoing high-dose chemotherapy with autologous HSCT.[453,455] Palifermin's utility in allogeneic HSCT is not as well defined. Retrospective data from Goldberg et al. evaluated the safety and efficacy of palifermin in patients who underwent T cell–depleted allogenic HSCT and found a benefit in those patients undergoing TBI-based conditioning regimens but not those undergoing chemotherapy-based conditioning regimens.[456] Prospective studies to evaluate palifermin's role in allogenic HSCT are currently underway and thus guideline-based recommendations currently advocate for palifermin's use in patients undergoing HDC with autologous HSCT.[453,455,456]

Low-level laser therapy (LLLT) has also been reported to be an effective treatment for the prevention of oral mucositis associated with HDC and TBI conditioning regimens prior to HSCT. This type of low energy radiation therapy has been shown to have analgesic, antiinflammatory, and wound healing properties.[457] MASCC guidelines currently recommend the use of LLLT to reduce the incidence of oral mucositis associated with HDC or TBI conditioning regimens and HSCT. Unfortunately, LLLT requires expensive equipment and expert training, and thus few centers have the capability to support such therapy.[453]

Supersaturated calcium phosphate rinses (SCPRs) have been evaluated in the prevention of treatment-related oral mucositis. In a small randomized single-institution study of patients undergoing allogeneic HSCT comparing SCPR 4 times daily to a control group consisting of a solution made of saliva leaf extract, iodine-povidine, and fluconazole administered at the same frequency, SCPRs were found to decrease the incidence, severity, and duration of oral mucositis, as well as the need for analgesic and TPN interventions. Larger multicentered trials are needed to confirm these results.[458]

Once oral mucositis occurs, treatment is supportive and consists of appropriate oral care, mucosal protectants, and analgesia (topical and/or systemic); however, data to validate these interventions is limited. Routine oral care should focus on limiting trauma which could further damage the oral mucosa. Soft toothbrushes and gentle cleansing rinses such as salt and soda rinses (½ teaspoon of salt and 1 teaspoon of baking soda in a quart of water every 4 hours) should be used. In an open labeled pilot study conducted by Innocenti et al., Gelclair, a mucosal protectant, was found to be beneficial in reducing oral pain. Of note, only 3 of the 30 patients in this trial had chemotherapy-related mucositis.[459] Studies of analgesic mouthwashes have documented pain relief with topical lidocaine and morphine preparations; however, if these preparations do not control the mucositis-related pain, patients should be treated with systemic analgesia by the oral route if possible, and if unable, through parenteral routes.[460,461]

ANOREXIA

Cancer-related anorexia (CRA) leads to weight loss as a result of decreased appetite from the systemic effects of advanced cancer.[462] Anorexia is one of the most frequent and troubling symptoms experienced by patients and their family members, occurring in more than half of patients with advanced cancer.[463,464] CRA and cachexia are provoked by metabolic changes induced by advanced malignancies in the host, with a milieu of proinflammatory cytokines felt to be responsible.[465] Dramatic changes in weight and body habitus can occur when the hypermetabolic state of malignancy is coupled with decreased caloric intake associated with CRA. The resultant changes in body habitus can be quite psychologically distressing to patients and their families, and thus patient education and attempts to improve anorexia are of utmost importance.[466]

There are multiple nonpharmacologic and pharmacologic interventions that are effective in the treatment of CRA; however, the first step in the management of CRA is to evaluate for any reversible causes. Reversible causes of anorexia in patients with advanced cancers and those receiving directed therapies for advanced cancers include constipation, uncontrolled pain, nausea, vomiting, gastroparesis, depression, stomatitis, mucositis, and delirium. Evaluation for a possible reversible cause and its treatment should be the first step in management of CRA.[466] If no reversible cause can be identified, then interventions directed toward management of CRA should be initiated. Nonpharmacologic measures include nutritional counseling, increasing physical activity, and encouraging the intake of calorie-dense foods and supplements.

Corticosteroids, megestrol acetate (Megace), and cannabinoids have all been evaluated in the treatment of anorexia. Megestrol acetate at doses of 800 mg/day have been the most extensively studied and have been shown to be effective in treating anorexia associated with advanced malignancy and acquired immune deficiency syndrome (AIDS).[467–472] Jatoi et al. performed a large randomized controlled trial of more than 400 patients with advanced cancer, comparing the effectiveness of megestrol acetate (800 mg/day) vs. dronabinol (2.5 mg twice a day) vs. a combination of both agents for the treatment of cancer-associated anorexia. Megestrol acetate was found to improve appetite and induce weight gain more than dronabinol. Combination therapy did not provide an additional benefit over megestrol acetate therapy

alone.[471] A study conducted by Navari et al. found that the addition of olanzapine (5 mg/day) to megestrol acetate (800 mg/day) led to improvements in weight gain, anorexia, and quality of life (QOL) when compared to megestrol acetate alone. No additional grade III or IV toxicities were observed in the group receiving megestrol acetate and olanzapine.[473] Megestrol acetate is fairly well tolerated, with increased risk for thromboembolism being the most worrisome adverse effect. A prospective study of dexamethasone 4 to 16 mg daily has been shown to be effective in treating anorexia; however, given the multiple potential adverse effects of corticosteroids, the lowest effective dose should be used and treatment discontinued if no benefit is observed within 3 to 5 days of starting treatment.[466,474] For patients unable to consume all of their caloric needs by mouth, enteral tube feedings are the treatment of choice, as this method of delivery can help prevent mucosal atrophy of the gastrointestinal tract.

COMPLICATIONS OF HEMATOLOGIC MALIGNANCIES

There are numerous complications secondary to hematologic neoplasms, and selected topics on thrombocytopenia, anemia, and tumor burden are described in the subsequent section. Neutropenia was addressed in the preceding sections on neutrophil defects, febrile neutropenia, and myeloid colony-stimulating factors. Problems due to tumor burden include hyperleukocytosis, acute tumor lysis, hypercalcemia, and cord compression.

Thrombocytopenia

Thrombocytopenia may develop as a result of direct marrow infiltration, chemotherapy, infection, DIC, immune-mediated platelet destruction, and hypersplenism, as well as other idiopathic etiologies, and is considered the most common cause of serious hemorrhagic events in patients with acute or chronic leukemia.[475] The relationship between spontaneous bleeding events and decreased platelet counts in the setting of induction chemotherapy or HSCT has been well described.[476,477] As a result, prophylactic and/or therapeutic platelet transfusion to reduce bleeding risk is a generally accepted practice in these settings.[478–481] The optimal threshold for prophylactic platelet transfusion remains controversial, but levels in the 10 to 20 $\times$ 10^9/L range have commonly been utilized with no major differences in outcome demonstrated between these levels.[476,477,482] However, the risk of bleeding events in thrombocytopenia has been estimated to be increased 8-fold when counts are $< 5 \times 10^9$/L and 2-fold with counts from 5 to 15 $\times$ 10^9/L compared to platelets in the 20 to 29 $\times$ 10^9/L range.[483] Therapeutic (in the presence of bleeding) versus prophylactic (platelet count $< 10 \times 10^9$/L) platelet transfusion strategies have been compared in patients undergoing intensive chemotherapy for AML or autologous HSCT.[484] The therapeutic platelet transfusion strategy led to a reduced number of platelet transfusions without an increased risk of major hemorrhage in autologous HSCT patients. However, nonfatal grade 4 (mostly CNS) bleeding was increased among AML patients, suggesting a continued role for prophylactic strategies in this population. Clinical practice guidelines set forth by ASCO currently recommend a threshold of 10×10^9/L for prophylactic platelet transfusion in adult patients receiving therapy for acute leukemia.[485]

Patients with either chronic or recurrent thrombocytopenia requiring multiple platelet transfusion exposures are at increased risk for experiencing platelet refractoriness due to alloimmunization. The presence of fever is also associated with increased refractoriness to platelet transfusions[486] and further compounds the risk of bleeding in this setting. When administering platelet transfusions to this population, the use of ABO-compatible platelet products is important in reducing alloimmunization as well as improving the incremental response to a given platelet transfusion.[487,488] Platelets are generally available in the form of either single-donor apheresed products or pooled from multiple random donors. Each of these products may also be modified by either leukoreduction or irradiation. Reduction of leukocytes from platelet products by filtration has been demonstrated to be equally as effective as irradiation in the prevention of alloimmunization-related platelet refractoriness.[489] Similarly, there is no difference in alloimmunization risk to support empiric use of leukoreduced single-donor (apheresed) platelet products compared to random-donor platelets in this setting.[489] Leukoreduction provides additional benefits by preventing CMV transmission[490] and by reducing the incidence of febrile transfusion reactions.[491] The benefit of platelet irradiation for the prevention of transfusion-associated graft-versus-host disease (GVHD) appears limited. Use of irradiated platelet products should be restricted to patients receiving allogeneic HSCT, those receiving blood products from related donors, and those who are severely immunocompromised.[492]

Thrombocytopenia caused by accelerated platelet consumption can occur in patients with hematologic malignancies. ITP has been well described in the setting of CLL[493–495] and has been reported in patients with HL, NHL, MM, and ALL.[494–498] The mechanisms that contribute to the initiation of ITP in each of these situations are largely unknown, but it is presumed that pathogenic autoantibodies are produced and react to antigens present on the platelets. The prognostic significance of ITP in the setting of the various hematologic malignancies is unclear. Standard therapeutic interventions for ITP (Chapter 47) with steroids, intravenous immunoglobulin (IVIG), and/or splenectomy are typically employed in addition to definitive treatment for the underlying malignancy.

Diffuse intravascular coagulation (DIC) is well recognized to cause a consumptive thrombocytopenia associated with hematologic malignancies, most notably APL (Chapter 78). DIC is characterized by widespread intravascular activation of coagulation, intravascular fibrin deposition, and simultaneous consumption of coagulation factors and platelets which increase bleeding risk.[499] APL-associated DIC is characterized by marked hyperfibrinolysis with a clinical presentation of severe bleeding and laboratory parameters consistent with hypofibrinogenemia, elevated fibrin split products, elevated fibrinogen degradation, quantitative D-dimers, and consumption of plasminogen and á2-antiplasmin.[500] It is suspected that the hyperfibrinolytic state in APL-associated DIC is superimposed on the prothrombotic characteristics known to occur in DIC as a result of coagulation activation and fibrin deposition, providing concurrent risk for both thrombotic and hemorrhagic complications. Chemotherapy administration to treat an underlying malignancy may transiently increase thrombotic risk by causing endothelial damage as well as release of procoagulant factors, cytokines, and proteases from damaged malignant cells.[501,502,503,504] Therapeutic intervention for DIC remains largely supportive, with the focus on treatment of the underlying malignancy in these situations. Limited data exists to provide recommendations for the management of DIC-related complications. Transfusion support of platelets or plasma products is typically determined by active bleeding and/or the risk of hemorrhagic complications.[505] The use of therapeutic heparin should be considered on an individual patient basis and may benefit those at risk for thrombotic complications.[503,506]

Thrombocytopenia as a direct result of the malignant condition, or the aggressive chemotherapy that may be required, poses significant challenges in the treatment of patients. Recombinant human IL-11 (Oprelvekin) has been approved for the treatment and prevention of chemotherapy-induced thrombocytopenia in nonmyeloid malignancies.[507] Randomized placebo-controlled testing in breast cancer patients receiving chemotherapy demonstrated reduced platelet transfusion events.[508] Use of rIL-11 has

also been shown to improve platelet nadirs and shorten duration of thrombocytopenia in patients receiving chemotherapy for hematologic malignancies.[509] It is not indicated for use in children or in patients receiving myeloablative chemotherapy. Despite its proven effectiveness, the use of rIL-11 has been limited in part because of the potential for hypersensitivity reactions, ventricular arrhythmias, and papilledema associated with visual field defects and possibly blindness. Genetically modified recombinant human IL-11 (mIL-11) is under active investigation, but early reports suggest that it is able to provide equivalent thrombopoietic activity with an improved safety profile.[510]

Romiplostim is a thrombopoietin (TPO) peptide mimetic which increases platelet counts by binding to and activating the TPO receptor (Chapter 47). Although approved for use in chronic ITP, off-label use has been reported for chemotherapy-induced thrombocytopenia[511] and romiplostim's role in this setting is under active investigation (NCT01676961; NCT01516619). Eltrombopag is a nonpeptide TPO agonist also approved for chronic ITP. Eltrombopag increases platelet production by binding to and activating the TPO receptor, but also increases proliferation and differentiation of marrow progenitor cells by activation of intracellular signal transduction pathways. Increased platelet numbers have been reported with its use in patients with radiation-induced thrombocytopenia,[512] patients receiving chemotherapy for advanced solid tumors,[513] and patients with refractory aplastic anemia.[514] Eltrombopag use in patients undergoing chemotherapy for hematopoietic malignancies is also an area of active investigation (NCT01656252, NCT01488565).

Anemia

Anemia commonly occurs as a result of the presence of a hematologic malignancy and/or the subsequent therapeutic interventions. Marrow infiltration and replacement with neoplastic cells is the primary cause, but other mechanisms must be considered.

Patients with inflammatory and/or malignant conditions commonly present with normocytic, normochromic or microcytic, hypochromic anemia. Laboratory findings are typically suggestive of a hypoproliferative state characterized by low reticulocyte counts and the absence of appropriate erythroid hyperplasia in the marrow in response to the anemia. Serum erythropoietin (EPO) levels tend to be inappropriately low in response to the malignancy-associated anemia,[515] which is suspected to result from proinflammatory cytokines that interfere with the regulation of EPO gene expression.[516] Erythroid marrow response to EPO is blunted, and higher doses of EPO supplementation are often required to improve anemia associated with hematologic neoplasms.[475,517] The use of EPO stimulating agents has been curtailed because of an inferior survival in randomized trials for cancer patients and an increased risk for thrombosis.[518]

Inflammatory cytokines have been demonstrated to increase hepcidin production,[519,520] causing decreased intestinal iron absorption and impaired iron release from the reticuloendothelial system.[521] Increased IL-6 levels have been implicated in stimulating hepcidin production in patients with HL, MM, ALL, and AML, and provides insight into the pathophysiology of anemia commonly found in patients with various malignancies.[522–524] Targeting IL-6 in the treatment of cancer-related anemia has shown promise and remains an area of active investigation.[525,526]

Macrocytic anemia is often seen in association with MDS and AML and is also commonly caused by exposure to cytotoxic chemotherapy. Agents such as cytarabine, hydroxyurea, methotrexate, and 6-mercaptopurine inhibit DNA syntheses and are frequently associated with the development of macrocytic anemia in exposed patients. In the absence of exposure to these types of agents, abnormal nucleated red cells may occur in AML or as part of the terminal phase of myeloproliferative disorders. Certain morphologic features allow their differentiation from the megaloblasts resulting from vitamin deficiencies. The nuclear chromatin is typically not as fine as in true megaloblasts, and a greater proportion of the erythroid precursors are more immature in most patients with erythroleukemia than in those with vitamin B12 or folate deficiencies. In addition, the neutrophils characteristic of these vitamin deficiencies, such as hypersegmentation, giant metamyelocytes, and macropolycytes, are usually absent in the macrocytic anemia seen in AML/MDS.

Hemolytic anemias have been observed in association with various hematologic malignancies and may precede diagnosis of the malignant condition. While their presentation may be dramatic, concomitant hemolytic anemias do not carry prognostic significance. Warm antibody–mediated hemolytic anemia has been classically described to occur in 10% to 20% of patients with CLL but has also been observed in association with various other hematologic cancers.[527–530] Therapy is directed at decreasing the production of antibody and the splenic destruction of red blood cells (Chapter 29). Glucocorticoids, transfusion support, and/or splenectomy are used in autoimmune hemolytic anemia of warm antibody type, in addition to therapy directed toward the underlying neoplasm. Anemia is usually mild in cold agglutinin disease, and intervention with steroids and splenectomy is of little benefit. Avoiding cold exposure, plasmapheresis, and treatment of the underlying lymphoproliferative disorder may be effective in improving the anemia associated with cold agglutinin disease. Microangiopathic hemolytic anemia is seen most often as part of the DIC syndrome but has been reported in patients with hematologic neoplasms without evidence of DIC. Erythrocyte trapping and/or destruction in the spleen may contribute to anemia in hematologic cancers such as low-grade lymphomas and CLL. Splenectomy has been used for treatment of nonautoimmune hemolytic anemias in lymphoid malignancies when this hypersplenism occurs.[531,532]

Hemophagocytic syndrome is a rare but often dramatic cause of anemia in patients with a variety of hematologic malignancies. Its presence has been described in association with acute leukemias, lymphomas, and myeloma,[533–537] as well as a result of infectious complications of both bacterial and viral origin.[538,539] The mechanism by which this potentially devastating macrophage activation occurs is poorly understood, but is felt to result from the inability to turn off the inflammatory response of the immune system to the particular inciting factor (malignancy, infection, etc.).[540] Prognosis in these patients is quite poor.

Hyperleukocytosis and Leukostasis

Hyperleukocytosis has been variably defined as a white blood cell (WBC) count greater than 50×10^9/L or 100×10^9/L (Table 69.12).

TABLE 69.12

MANAGEMENT OF HYPERLEUKOCYTOSIS

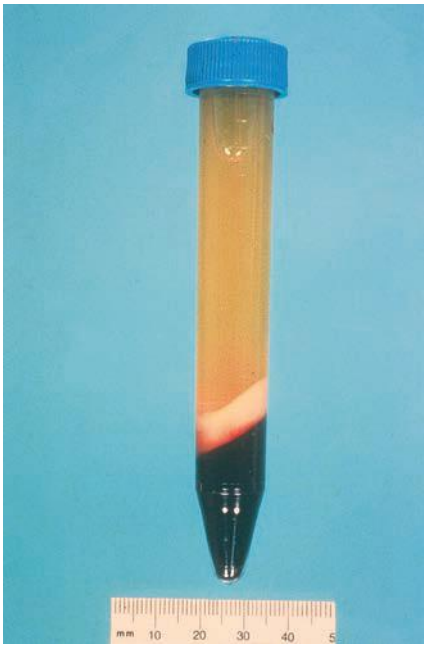
1. Risk of leukostasis depends upon disease and level of WBC ($\times 10^9$/L). AML (monocyte variants) and CML, blast crisis (>50–100) > ALL (>150–300) > CML (>150–250) > CLL (300–500)
2. Target organs for leukostasis are: brain (stupor, blurred vision), lungs (dyspnea), kidneys(azotemia), penis (priapism), heart (arrhythmia)
3. Spurious lab may occur with hyperleukocytosis: elevated platelet count, pseudohypoxemia ("leukocyte larceny"), pseudohyperkalemia, pseudohypoglycemia, prolonged coagulation tests
4. Transfusion: limit red cells due to risk of increasing viscosity; transfuse platelets due to increased risk of bleeding and loss of platelets with leukapheresis
5. Therapy: hydration, allopurinol or rasburicase, hydroxyurea, consider leukapheresis if symptomatic, dexamethasone, institute chemotherapy, manage tumor lysis

It is typically associated with increased morbidity and mortality in patients with leukemic diagnoses as a result of associated leukostasis and/or tumor lysis syndrome. The absolute count at which the hyperleukocytosis becomes clinically relevant is somewhat dependent on the specific underlying leukemic process. For instance, patients with AML may develop severe complications at a WBC count of 50×10^9/L, whereas patients with CLL may tolerate WBC counts above 400×10^9/L. Hyperleukocytosis has been estimated to occur in approximately 5% to 13% of AML and between 10% to 30% of ALL,[541] and has historically been associated with a poor prognosis when occurring in patients with acute leukemia.[542–544] Supportive care measures such as aggressive intravenous fluid support, allopurinol, and hydroxyurea are typically employed as temporizing measures until some form of cytoreductive therapy can be initiated.

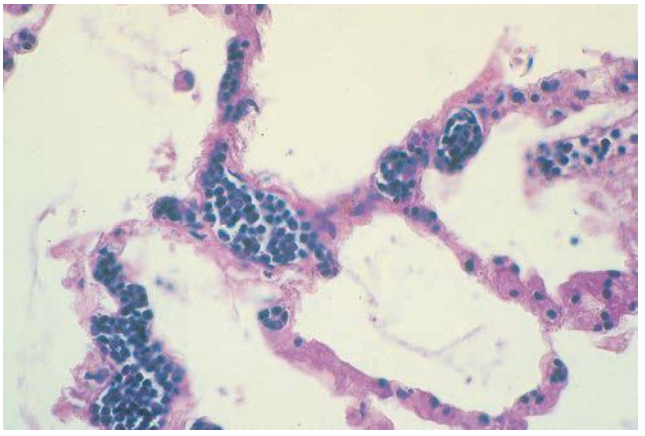
Leukostasis is a symptomatic manifestation of hyperleukocytosis which qualifies as a medical emergency caused by the "sludging" of the leukemic cells within the capillaries, leading to vascular obstruction and resultant tissue hypoxia (Fig. 69.11). Presenting symptoms of leukostasis are reflective of the location where this tissue hypoxia is occurring. CNS manifestations of confusion, headaches, visual disturbances, somnolence, delirium, or ataxia may occur. Respiratory findings may include bilateral infiltrates on chest imaging and associated dyspnea, tachypnea, hypoxia, and rhonci on physical exam. Leukostasis remains a diagnosis of clinical suspicion rather than one confirmed by a laboratory test. Given the potential for catastrophic consequences, reasonable clinical suspicion of diagnosis should prompt emergent intervention. Hydroxyurea is an oral antimetabolite with the ability to rapidly lower leukocyte counts and whole blood viscosity.[545,546] Definitive antileukemic therapy should be initiated as soon as possible. Some centers prefer to initiate leukapheresis prior to the initiation of chemotherapy in order to reduce the peripheral leukemic burden, ameliorate the symptoms of leukostasis, and minimize the risk of tumor lysis syndrome upon initiation of the chemotherapy.[547,548] While retrospective data has shown that leukapheresis may reduce early mortality, it has failed to provide improvements in remission or overall survival.[549]

Acute Tumor Lysis Syndrome

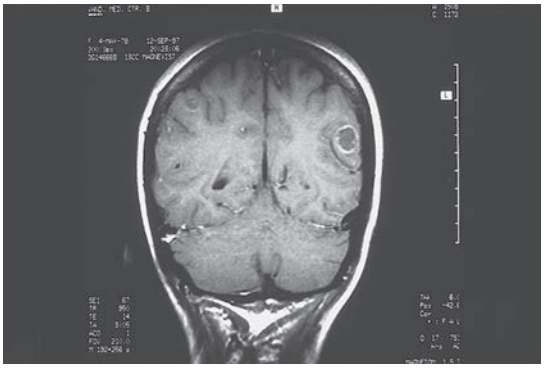
ATLS occurs most frequently in patients with rapidly proliferating neoplasms such as high-grade lymphomas (e.g., Burkitt) and acute leukemias (Fig. 69.12). ATLS may occur spontaneously and be observed at the time of initial diagnosis or in response to the initiation of cytotoxic chemotherapy. Tumor lysis results from the rapid breakdown of malignant cells and the subsequent abrupt release of the cellular contents (intracellular ions, nucleic acids, proteins, etc.) into the extracellular space. Laboratory evidence of tumor lysis is more commonly seen than the clinical manifestations. Laboratory tumor lysis requires at least 2 of the following metabolic abnormalities occurring simultaneously within 3 days prior to or up to 7 days after the



A



B



C

FIGURE 69.11. Hyperleukocytosis and leukostasis. A: An elevated leukocrit is present in this tube of centrifuged peripheral blood from a patient with T cell acute lymphoblastic leukemia who had a peripheral blood blast count of 250×10^9/L. **B:** Pulmonary alveolar capillaries are expanded by leukocyte aggregates indicative of leukostasis in patient with acute myeloid leukemia (hematoxylin and eosin stain). **C:** Ring-enhancing lesions on magnetic resonance imaging were attributed to hemorrhage in a patient with chronic granulocytic leukemia, hyperleukocytosis, and blurred vision (TI-weighted image).

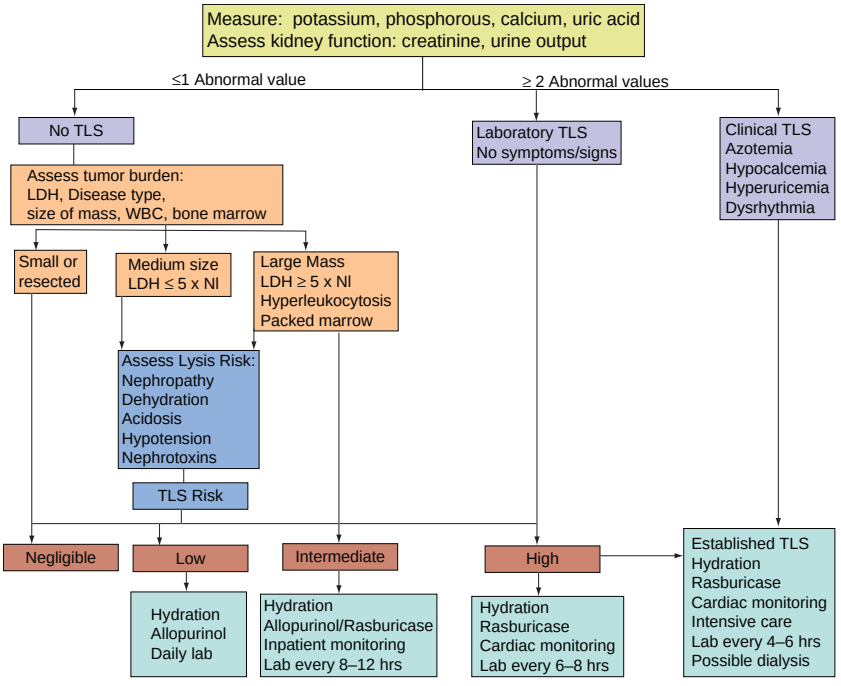


FIGURE 69.12. Management of tumor lysis syndrome (TLS). Serum chemistries and renal function are assessed when instituting therapy in any patient with a hematologic neoplasm. The risk of TLS is based on assessing laboratory values, disease type, and tumor burden. Patients at a high risk for TLS include the acute leukemias with hyperleukocytosis and the aggressive lymphomas with large masses or elevated LDH (lactate dehydrogenase). Volume repletion, agents to lower uric acid, and laboratory monitoring are warranted in all patients. As the risk of TLS increases, the interval of monitoring shortens and the level of care intensifies with cardiac monitoring and the possible requirement for dialysis. (Adapted from Howard SC, Jones DP, Pui C-H. The tumor lysis syndrome. N Eng J Med 2011;364:1844–1854.)

initiation of therapy: hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia.[550,551,552] The clinical tumor lysis syndrome is defined as the above abnormal laboratory findings in combination with acute renal failure, seizures, cardiac dysrhythmias, or death.

Hyperuricemia plays a major role in the development of the acute renal failure seen in ATLS. The etiology of the renal failure is presumably from crystal-induced tissue injury that occurs when calcium, uric acid, and xanthine precipitate in the renal tubules and lead to crystal-induced obstruction (Fig. 69.13). Allopurinol is commonly used in the prevention and treatment of ATLS. Allopurinol is a competitive inhibitor of xanthine oxidase and prevents the formation of uric acid. Allopurinol is available in both oral and IV preparations. If uric acid levels remain elevated despite allopurinol, rasburicase (recombinant uric acid oxidase) may be administered. Rasburicase converts uric acid to allantoin which is highly water soluble. Randomized data from high-risk pediatric patients receiving rasburicase versus allopurinol demonstrated reduction of uric acid levels by 86% within 4 hours of rasburicase administration versus only a 12% reduction in the allopurinol group ($P < 0.0001$).[553] The FDA approved dosing schedule for rasburicase is 0.2 mg/kg intravenously over

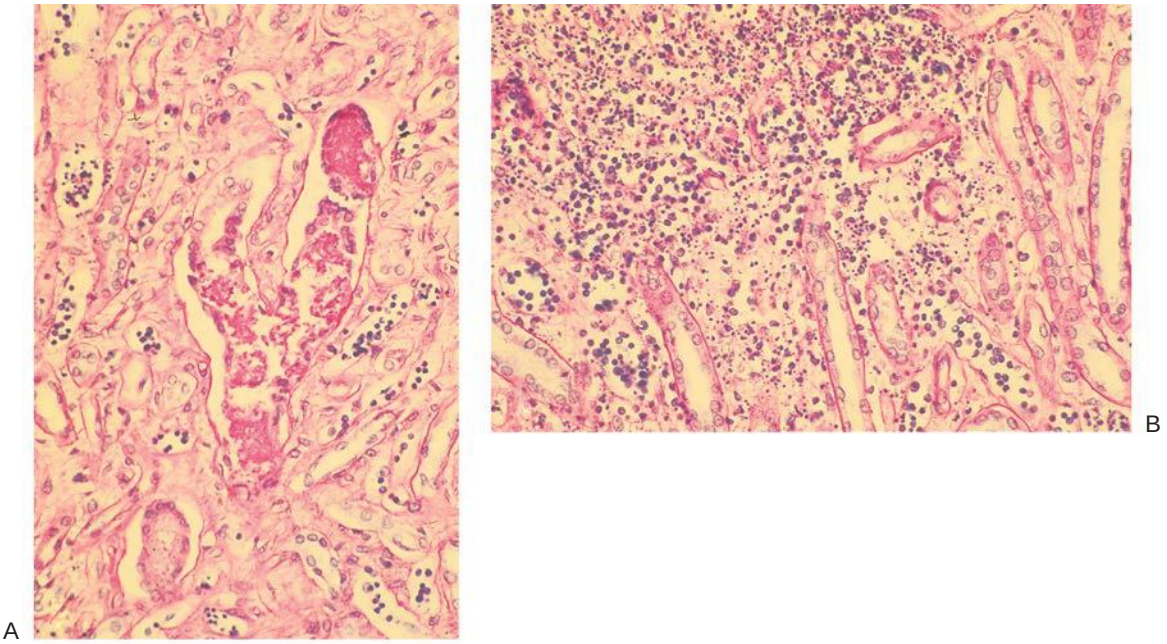

FIGURE 69.13. Tumor lysis: A: Karyorrhectic lymphoblast nuclei are present throughout the kidney in a patient with acute tumor lysis syndrome in whom cytolysis was initiated by administration of corticosteroids. **B:** Renal tubules contain calcium phosphate precipitates that contributed to acute lysis-associated renal failure (hematoxylin and eosin stain). (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.)

30 minutes daily for up to 5 days. Multiple reports in the literature suggest that lower fixed dose strategies may be sufficient and more cost-effective.[554,555–557]

Patients with significant electrolyte imbalances and/or renal insufficiency may require therapeutic dialysis support until resolution of the ATLS. Prophylactic dialysis prior to initiation of chemotherapy should also be considered in high-risk patients such as those with bulky high-grade tumors.

Hypercalcemia

Hypercalcemia can occur in association with many various hematologic malignancies but is more commonly seen in patients with either MM or human T cell leukemia virus type-1 (HTLV-1)–associated adult T cell leukemia/lymphoma (ATL). Hypercalcemia in patients with cancer is primarily due to increased bone resorption and release of calcium from bone. The 3 main mechanisms leading to hypercalcemia are increased osteolytic activity, tumor secretion of parathyroid hormone-related protein (PTHrP), and ectopic production of calcitriol (1, 25-dihydroxyvitamin D). The symptoms of hypercalcemia are generally nonspecific and include fatigue, anorexia, nausea, constipation, pain, frequent urination, and altered mental status. Correction of the calcium levels typically leads to rapid and effective palliation of these symptoms.[558]

MM has an affinity for diffuse bone involvement and releases osteoclast activating factors leading to osteoclast-induced bone resorption that present as lytic lesions which may occur throughout the skeleton.[559] Myeloma has also been associated with osteoblast inhibition leading to decreased bone formation.[560] This impaired bone formation in the setting of increased destruction disrupts calcium homeostasis and results in the hypercalcemia. Numerous molecules have been implicated in the development of lytic disease and hypercalcemia, including interleukin (IL)-6, the receptor activator of nuclear factor kappa-B ligand (RANKL), macrophage inflammatory protein 1a, osteoprotegerin, and IL-3.

Calcium homeostasis in the normal host involves conversion of 1-OH vitamin D to calcitriol in the kidney. Calcitriol leads to increased calcium absorption from the gastrointestinal tract as well as increased bone resorption and results in hypercalcemia. Ectopic production of calcitriol has been described in both HL and NHL.[561,562]

Normal calcium metabolism is mediated by parathyroid hormone. In cases of HTLV-1–associated ATL,[563] as well as other hematologic malignancies (AML,[564] CML,[565,566] HL,[567] NHL,[568] and MM[569]), the secretion of PTHrP stimulates osteoclasts, causing increased calcium release from the bone and resulting in a process known as humeral hypercalcemia of malignancy (HHM). Endogenous PTH is typically suppressed secondary to the hypercalcemia, and serum PTH levels will be very low. Unlike PTH, PTHrP does not typically stimulate production of calcitriol[570] and thus does not increase intestinal calcium absorption. The uncoupling of bone resorption and formation that occurs in HHM results in the influx of calcium into the circulation and resultant hypercalcemia.

Regardless of the mechanism leading to the cancer-related hypercalcemia, successful treatment ultimately requires antineoplastic therapy directed toward the underlying malignancy. The severity of the patient's symptoms and the prevention of catastrophic consequences will typically require interventions with more rapid impact. Patients with hypercalcemia often experience significant volume depletion as a result of an osmotic diuresis. Thus, aggressive volume repletion with isotonic intravenous fluids (e.g., normal saline) should be initiated upon discovery of the hypercalcemia. Once the patient is appropriately volume replete, loop diuretics may be added to increase calciuresis. Thiazide diuretics increase calcium resorption and should be avoided.

The effectiveness and availability of bisphosphonates have made them a mainstay of hypercalcemic therapy. These agents inhibit calcium release by disrupting osteoclast-mediated bone resorption.[571] Multiple intravenous bisphosphonate choices are available for the treatment of malignancy-associated hypercalcemia: pamidronate, zoledronic acid, and ibandronate. Intravenous administration of the bisphosphonates is generally well tolerated, but patients may experience flu-like symptoms (fever, arthralgias, myalgia, fatigue, and bone pain), uveitis, hypocalcemia, hypophosphatemia, impaired renal function, and osteonecrosis of the jaw.[572] Calcitonin results in rapid lowering of serum calcium levels and may be combined with bisphosphonates,[573–575] but calcitonin tachyphylaxis is common and limits the benefit of repeated dosing. Cases of renal insufficiency have been reported in association with bisphosphonates, and caution should be employed with their use in the treatment of hypercalcemia in patients with impaired renal function.[576]

Denosumab is a fully human monoclonal antibody that targets RANKL and inhibits osteoclast maturation, activation, and function, leading to reduced bone resorption. It is approved for the treatment of osteoporosis and prevention of skeletal-related events in at-risk patient populations. Its effectiveness has been reported in the treatment of malignancy-associated hypercalcemia refractory to bisphosphonates.[577] Denosumab has also demonstrated less nephrotoxicity than bisphosphonates,[578,579] and its use has been reported in the setting of renal insufficiency.[580] Common side effects of denosumab include fatigue, headache, hypophosphatemia, hypocalcemia, nausea, weakness, dyspnea, and cough.

Cord Compression

Spinal cord impingement is a medical emergency requiring rapid recognition and intervention in the hopes of minimizing complications. It has been frequently reported in patients with MM and is also known to occur in association with HL and NHL. Cord compression as a result of a leukemia diagnosis is rare but has been reported.[581–583] Pain is the most common presenting symptom of patients with cord compression and may precede neurologic symptoms by several weeks. Radicular pain, pain not relieved with lying down, and proximal muscle weakness are of particular concern for the possibility of an underlying cord impingement. The development of autonomic symptoms such as urinary retention and fecal incontinence typically occurs late in the course and is predictive of poor outcomes.

Patients with known hematologic malignancies that complain of severe back pain and/or any neurologic symptom warrant urgent imaging to rule out cord compression. Emergent referrals for the possibility of surgical intervention should be considered for patients in whom there is a reasonable index of suspicion. Empiric steroids may be appropriate in clinical contexts of concern, or if there are unavoidable delays in being able to obtain imaging. It should be noted, however, that the initiation of steroids may cause rapid necrosis of the tumor and impair the ability to make a tissue diagnosis. Magnetic resonance imaging (MRI) is the imaging modality of choice and should include the entire spine, as multiple areas of compression can occur simultaneously[584] (Fig. 69.14).

Intervention for cord compression is directed at pain control, avoidance of complications, and the preservation or improvement of neurologic function. Frontline therapy typically consists of urgent initiation of corticosteroids (dexamethasone). The optimal dose of steroids is not known. High-dose dexamethasone (up to 100 mg) has been shown to improve neurologic recovery and ambulatory status,[426,585] but carries the risk of serious adverse events such as psychosis and gastrointestinal complications.[586,587] In general, it is recommended that patients with suspected or confirmed cord compression be started on dexamethasone at an

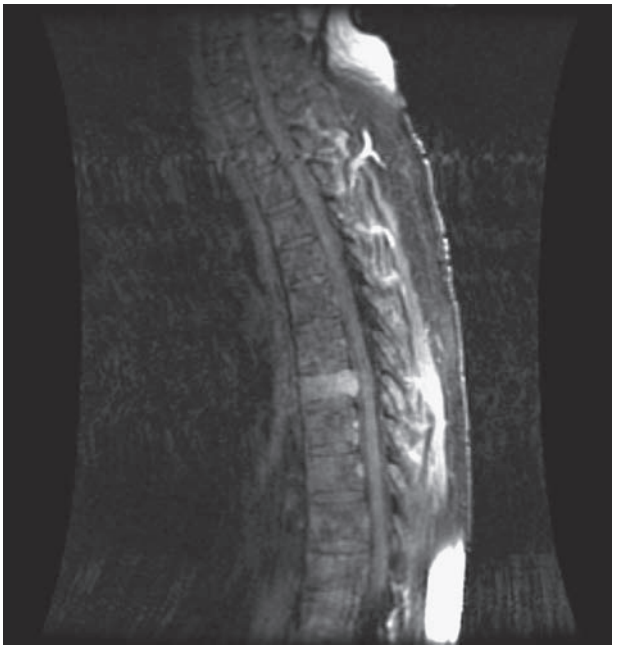

FIGURE 69.14. Spinal cord involvement shown by magnetic resonance imaging. Epidural mass on sagittal view with evidence of cord compression and cord impingement at &7 level (T1-weighted image). The diagnosis by biopsy was multiple myeloma.

initial dose of 10 to 100 mg followed by at least 16 mg daily (in divided doses).[588] Following the initiation of steroids and confirmation of cord impingement, definitive treatment with surgical intervention, radiation therapy, and/or chemotherapy should be initiated.[588,589] Surgery should be considered in those who are medically and surgically appropriate and/or those in whom a tissue diagnosis has not yet been established. Radiation therapy should be administered to those who are not candidates for surgical intervention.

SUMMARY

This chapter has addressed selected aspects of supportive care in hematologic malignancies. The improved prognosis for leukemias, lymphomas, and myeloma has been attributed to better drugs, including targeted therapy and immunotherapy; however, progress could not have occurred without the concomitant advances in supportive care, particularly in the management of infections and in transfusions.

The goals of supportive care are to prevent and reduce the toxicities of therapy and the complications of the diseases. There is an emphasis on survivorship, including rehabilitation after therapy and recognition of the long-term risks of therapy. When therapeutic options no longer offer survival benefit, access to palliative care and end-of-life issues take precedence over other components of supportive care.

CHAPTER 70

IMMUNOTHERAPY

Adetola A. Kassim, Sattva S. Neelapu, Larry W. Kwak, Luc Van Kaer

HISTORY

There probably is no field in medicine that has provided as much hope, or as much disappointment, as the field of tumor immunology. A major relationship between the immune system and the oversight of neoplasms was postulated in the early part of the last century by Paul Ehrlich.[1] This theory of immunosurveillance envisioned that, in long-lived animals, inheritable genetic changes in somatic cells must be common, and some proportion of these changes must represent steps toward malignant transformation. It was considered an evolutionary necessity, therefore, that some mechanisms exist for eliminating or inactivating such potentially dangerous mutant cells. This mechanism was thought to be immunologic. The theory of immunosurveillance was restated in the 1950s by Lewis Thomas, then popularized and championed by Sir Macfarlane Burnet.[2] Supported by these powerful figures in medicine, the theory of immunosurveillance was so inherently appealing that it often was accepted uncritically, and evidence to the contrary often overlooked.[3] For instance, although patients or animals who are immunosuppressed tend to have an increased incidence of tumors, these tumors are disproportionately of lymphoid origin or associated with an oncogenic virus. The development of common epithelial neoplasms (with the exception of certain skin cancers) in these patients occurs with much less impressive frequency.[4]

The most obvious evolutionary necessity of the immune system was to survey a variety of infections, especially viral infections. Early evidence seemed to indicate that immunity played a significant role in eradicating virally induced tumors.[4,5] On the other hand, it appeared to play a less significant, or less effective, role in prevention of tumors induced by physical or chemical carcinogens.[6,7]

Experimentation in the early part of the 20th century demonstrated that spontaneously arising tumors in outbred animals could occasionally be transplanted from one animal to another of the same species and propagated in that fashion. Attempts to immunize against transplantable tumors soon followed. Animals injected with a small number of tumor cells often were able to eliminate those tumor cells—that is, there appeared to be a threshold number of tumor cells required for tumor propagation. Animals that had eliminated a sublethal inoculum of tumor cells were often able to withstand inoculation with a large number of tumor cells that would have been lethal in a naive animal. Furthermore, preexposure to normal tissue of the donor often rendered the recipient resistant to challenge with a lethal number of tumor cells.[8] These experiments brought into question the idea of tumor-specific antigens and ultimately led to the discovery of major histocompatibility complex (MHC) genes and their products.[9,10]

Modern tumor immunology finds its roots in the classic experiments of Prehn and Main.[11] These investigators demonstrated, in genetically identical mice, that previous exposure to a chemically induced sarcoma rendered animals resistant to challenge with the same tumor, but that these animals would accept normal, nonneoplastic tissues transplanted from the tumor donor animal. Similarly, prior exposure to normal tissues from the donor animal did not render the recipient animal resistant to tumor challenge. These experiments revived the notion that tumor-specific (transplantation) antigens did exist. Subsequent experiments demonstrated that protection afforded by prior exposure to tumor cells was tumor specific.[12] Thus, the host response to transplanted tumors behaved like an adaptive immune response, demonstrating memory and specificity.

Tumor immunity could be passively conveyed from one animal to another by transfer of lymphoid cells.[13] The relevant cells for protection were shown to be T lymphocytes.[14] Thus, it should have been clear to workers in the field that the relevant tumor antigens were those that could be recognized by T lymphocytes. However, as this work was beginning there was little understanding of how T lymphocytes recognized antigens or how those antigens were processed and presented to the T lymphocyte by antigen-presenting cells (APCs) or the tumor target cells. Much time and effort were expended in search of membrane structures or tumor cell products that would distinguish the tumor from all others. Particularly after the description of monoclonal antibody technology,[15] a fervent search was undertaken to define structures on tumor cells that would be tumor specific and potential targets for therapeutic intervention. Although many cell surface structures were defined, and the contribution to the understanding of biology cannot be overstated, this adventure produced only a single truly specific tumor antigen, the idiotype (Id) of clonally distributed immunoglobulin present on certain lymphomas.

Only recently has convincing evidence for an effect of immunosurveillance been produced.[16,17,18] This new evidence relies, in great measure, on the availability of genetically manipulated animal systems. A variety of knockout mice with defects in components of immune activation or effector function develop, at high frequency, spontaneous tumors or tumors after carcinogen exposure. Interferon-γ receptor–deficient mice are more likely to develop methylcholanthrene-induced sarcomas and are more susceptible to spontaneous development of sarcomas and lymphomas after loss of p53 alleles.[19,20] One in two aged perforin-deficient mice develops disseminated lymphomas.[21] These tumors are rejected by histocompatible wild-type mice through a mechanism dependent on $CD8^+$ T lymphocytes. A high incidence of lymphoma is also seen in aged mice deficient in Fas/Fas ligand interactions.[22] Aged mice doubly deficient in signal transducer and activation of transcription (*Stat*) 1 and recombination activating gene (Rag) 2 develop adenocarcinomas (colon, breast, and lung) with high frequency.[23] The frequency and distribution of tumors are increased in the doubly deficient mice over the frequencies and distributions seen in singly deficient mice. Many of these observations have been interpreted as evidence that the primary (both first and predominant) mechanism underlying tumor immunosurveillance is the system of innate immunity.[16,17,18]

INNATE IMMUNITY AGAINST TUMORS

The innate immune system is a widespread and evolutionarily ancient form of host defense against infection. In recent years, there has been an explosion of information regarding innate immunity, including its role in host defense and its regulation of inflammation and adaptive immunity.[24,25,26] The innate immune system is made up of many cells. These include dendritic cells (DCs), macrophages, mast cells, neutrophils, eosinophils, natural killer (NK) cells, natural killer T (NKT) cells, and certain subsets of $\gamma\delta$ T cells. Each of these cell types has been implicated in immune responses against tumors.

Phagocytic Cells

Many cells of the innate immune system, including neutrophils, macrophages, and DCs, bear receptors that detect "danger"[27]

in the form of pathogen-associated molecular patterns (PAMPs). Examples of PAMPs include bacterial lipopolysaccharide, lipoprotein, peptidoglycan, and lipoteichoic acids; bacterial CpG DNA; and viral RNA and DNA. These PAMPs are recognized by a variety of pattern recognition receptors (PRRs) expressed by cells of the innate immune system.[26,28] The innate immune system is said to distinguish "infectious nonself" from "noninfectious self." The PRRs of the innate immune system are encoded in the germline. Unlike genes of the T cell antigen receptor and the immunoglobulins, these genes do not undergo rearrangement. They are fixed and detect critical microbial components. Engagement of PRRs with PAMPs can result in pathogen uptake and/or cellular activation.[26,28] One important group of PRRs is the family of evolutionary conserved Toll-like receptors (TLRs), which are critically important for innate immune cell activation. Thirteen TLRs, each with specificity for a different PAMP, have been described in mammals. Other PRR families include the nucleotide-binding domain leucine-rich repeats (NLR) receptors and the caspase recruitment domain helicases.

Neutrophils and macrophages typically exert little antitumor activity, unless these cells are activated by bacteria, their products, or cytokines produced by tumor-specific T cells.[29,30] Recent studies have suggested that dying tumor cells or damaged tissues can release damage-associated molecular patterns (DAMPs) that can interact with PRRs and thus serve as danger signals.[31] NLR receptors such as NLRP3 (NLR family pyrin domain-containing 3), which form large cytoplasmic signaling complexes called inflammasomes, are thought to play a critical role in detecting DAMPs and might regulate the development of tumors either positively or negatively.[32–34] Macrophages can kill tumor cells using the same mechanisms utilized for killing of microorganisms. These mechanisms include phagocytosis and release of cytotoxic molecules such as reactive oxygen intermediates and nitric oxide.[35] Activated macrophages also produce a variety of cytokines. Among these cytokines, tumor necrosis factor (TNF)-α plays a major role in the tumoricidal effects of macrophages in vitro.[36]

Another important role of phagocytes in tumor immunity is to present tumor antigens to T lymphocytes. DCs (and other APCs such as macrophages) can phagocytose tumor cells and present tumor antigens in the context of MHC molecules and costimulatory signals to T lymphocytes.[37]

Natural Killer Cells

It has been recognized for a long time that NK cells kill MHC class I–deficient tumor cells in vivo and in vitro.[38] However, the identity and characterization of receptors mediating NK activation proved elusive for many years. Activation of NK cells now is understood to be dependent on the balance of activating and inhibitory signals emanating from activating and inhibitory receptors on the NK cell surface.[39,40] These receptors fall into two major structural classes, those of the immunoglobulin superfamily (KIRs and LIRs) and those of the C-type lectin-like family (NKG2D, CD94/NKG2A, and Ly49). Most inhibitory receptors (e.g., CD94/NKG2A, KIR, and Ly49) recognize classic or nonclassic MHC molecules. An activating receptor on NK cells, NKG2D (also called KLRK1), has now been shown to recognize a variety of stress-induced MHC class I–like molecules (e.g., Rae-1, H60, and MICA/B). Of note, activated $CD8^+$ T cells and mucosal $\gamma\delta$ T cells also express NKG2D. Another activation receptor on NK cells is FcγRIII, which can target NK cells to immunoglobulin G (IgG) antibody-coated tumor cells and induce antibody-dependent cell-mediated cytotoxicity.

NK cells can also discriminate between different allelic variants of MHC molecules.[41] This phenomenon was originally identified in the context of the hybrid resistance transplant model in mice, where parental bone marrow grafts were rejected by a subset of host F1 NK cells. When faced with mismatched allogeneic targets, a subset of donor NK cells can sense the missing expression of self–human leukocyte antigen (HLA) class I alleles and mediate alloreactions. These alloreactive NK cells can improve engraftment and control the relapse of acute myeloid leukemia (AML) in mismatched hematopoietic transplants.[41,42]

Natural Killer T Cells

NKT cells are a subset of T lymphocytes that share receptor structures and functions with the NK cell lineage.[43] Prototypical NKT cells, often referred to as invariant (i)NKT cells, express a semi-invariant T cell receptor (TCR), which is specific for glycolipid antigens presented by the MHC class I–like protein CD1d. Although NKT cells express an antigen-specific receptor that is generated by somatic DNA rearrangement, these cells belong to the innate rather than the adaptive arm of the immune system.[44] The invariant TCR expressed by NKT cells recognizes a limited set of self- and foreign antigens and, therefore, bears similarity to the PRRs expressed by cells of the innate immune system. Further, NKT cells have a natural, activated phenotype and are unable to generate classic memory responses against their cognate glycolipid antigens.

Mice that are deficient in NKT cells have increased susceptibility to MCA-induced sarcomas, indicating that these cells contribute to natural immunity against tumors.[45] NKT cells in mice and humans respond to the marine sponge–derived glycosphingolipid α-galactosylceramide (α-GalCer), which has potent antimetastatic activities in mice.[45] α-GalCer and related NKT cell antigens are being explored as potential cancer immunotherapies.[46]

Mucosal $\gamma\delta$ T Cells

T cells expressing the $\gamma\delta$ TCR are enriched in mucosal tissues such as the mucosa of the gut and skin.[47] These mucosal $\gamma\delta$ T cells have a highly restricted TCR repertoire, suggesting specificity for a limited set of antigens selectively expressed in their respective epithelial compartments. Like NKT cells, mucosal $\gamma\delta$ T cells can be classified as being at the interface between innate and adaptive immunity.[44] Epidermal and intestinal $\gamma\delta$ T cells express NKG2D and become activated when NKG2D binds to stress-induced MHC class I–related molecules.

$\gamma\delta$ T cells play a crucial role in immune surveillance against malignant epidermal cells. The incidence of cutaneous malignancies after treatment with a combination of initiator and promoter carcinogens was substantially increased in mice lacking the TCR δ-chain.[48] Activation of $\gamma\delta$ T cells required both NKG2D and the $\gamma\delta$ TCR, suggesting that engagement of NKG2D with its ligand(s) synergizes with signals received through the autoreactive $\gamma\delta$ TCR.

ADAPTIVE IMMUNITY AGAINST TUMORS

The adaptive immune system is composed of B and T cells that express diverse antigen-specific receptors, immunoglobulins, and TCRs, respectively. Diversity of these receptors is generated by somatic DNA rearrangement, in a process referred to as VDJ recombination.[49,50] Currently, there is little evidence that adaptive immunity plays a major role in natural immunity against tumors (with the exception of tumors induced by viruses). Although mice lacking T lymphocytes have increased susceptibility to the development of MCA-induced sarcomas, this might be largely due to the lack of iNKT cells and/or $\gamma\delta$ T cells.[18,51] Nevertheless, it is clear that tumors can induce adaptive immune responses (Fig. 70.1), which can be exploited for the development of cancer immunotherapies.

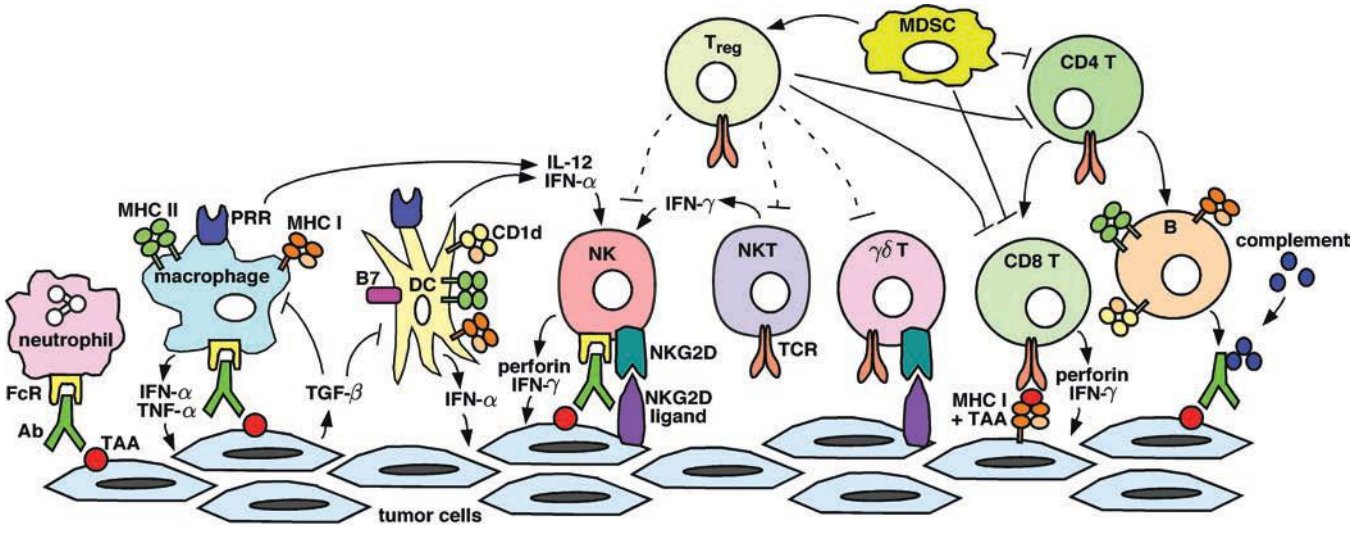

FIGURE 70.1. Immune responses against tumors. A variety of cells and soluble factors of innate and adaptive immunity can participate in immune responses against tumors. Examples of mechanisms that can suppress immune responses against tumors (i.e., production of TGF-β by tumor cells and induction of T_{reg} cells) are also depicted. Ab, Antibody; FcR, Fc receptor; IFN, interferon; MDSC, myeloid-derived suppressor cell; MHC I, major histocompatibility complex class I; MHC II, major histocompatibility complex class II; NK, natural killer; NKT, natural killer T; PRR, pattern recognition receptor; TAA, tumor-associated antigen; TCR, T cell receptor; TGF, transforming growth factor; TNF, tumor necrosis factor; T_{reg}, regulatory T cell.

Antibodies and B Cells

The role of B cells in regulating tumor immunity remains poorly understood. In some tumor models, B cells appear to be important for priming of T cell responses and tumor resistance, whereas in other models, B cells have an inhibitory effect on the generation of cytotoxic T lymphocyte (CTL) responses and tumor rejection.[52] Nevertheless, it is clear that tumor-bearing hosts can produce antibodies against a variety of tumor antigens.[53] However, strong humoral responses rarely correlate with tumor resistance. Nevertheless, antibodies can be utilized for immunotherapy of cancer, in particular tumors of hematopoietic origin. Antibodies may kill tumor cells by activating complement and promoting phagocytosis by macrophages. Alternatively, antibody-coated tumor cells may be killed by antibody-dependent cell-mediated cytotoxicity, in which Fc receptor–bearing NK cells, macrophages, or neutrophils mediate the killing. In addition, in certain cases, antibodies may directly interfere with the growth of tumor cells, as illustrated by the beneficial effects of anti–HER-2/neu antibodies against breast cancer, which likely involves downregulation of the HER-2/neu growth factor receptor.[54]

T Lymphocytes

Classic studies with transplantable tumors have demonstrated a critical role of T lymphocytes in tumor immunity.[11] CTLs play a particularly important role in tumor rejection, as these cells can directly lyse malignant cells that display tumor antigens in association with MHC class I molecules.[55,56] The importance of $CD4^+$ T cells in tumor immunity is less clear. $CD4^+$ T cells may secrete cytokines that promote the development of $CD8^+$ T cell responses, increase the sensitivity of tumor targets to CTL lysis by inducing MHC class I expression, and activate macrophages. Because of their critical role for the development of tumor immunotherapies, we will briefly describe the mechanisms that lead to the induction of T cell responses to tumors.

Antigen Processing and Presentation

T lymphocytes recognize peptide antigens in the context of MHC molecules. These peptides are derived from two distinct pathways.[57] Peptides representing proteins sampled from the extracellular world are generally presented in the context of class II MHC proteins, whereas peptides resulting from intracellular synthesis of proteins are presented in the peptide groove of the class I MHC proteins (Fig. 70.2). The binding cleft of MHC molecules has a β-pleated sheet floor and α-helical sides. An immunogenic peptide must be capable of forming noncovalent attachments to key residues along the cleft and interacting with the T cell antigen receptor with other residues. The MHC contact residues of the peptide tend to be near the amino and carboxy terminal ends of the peptide. The cleft of the class I MHC molecule has closed ends and accommodates only a peptide of proper length, 9 to 11 amino acids. The cleft of the class II MHC molecule, on the other hand, is open-ended and can bind peptides of more diverse lengths, 10 to 30 amino acids, with most being 12 to 19.[58]

Peptides located in class II MHC molecules are derived from proteins that have been consumed by APCs[59] (Fig. 70.2A). The proteins are taken up by phagocytosis, or receptor-mediated endocytosis in clathrin-coated pits, or engulfed by pinocytosis. Once internalized, the antigens are located in membrane-bound vesicles called endosomes. The endosomes then become continuous with lysosomes. The enzymology of the endolysosome has been described in some detail.[59,60] There, in an acidic environment, disulfide bonds in proteins are first reduced by the enzyme GILT (gamma interferon-inducible lysosomal thiol reductase), and the resulting products are subsequently cleaved to peptides by proteases, predominantly cathepsins. The endosome fuses with an exocytic vesicle budding from the Golgi apparatus that contains newly made class II MHC molecules associated with invariant chain, which has been shown to play a critical role in the assembly, intracellular transport, and function of MHC class II molecules.[61] In addition, a chaperone, HLA-DM, plays a critical role in the loading of peptides onto MHC class II molecules. HLA-DM is a peptide exchange factor that binds with empty and peptide-loaded class II molecules in endosomal and lysosomal compartments.[61] In the fused vesicle, peptides are loaded into the class II MHC molecules. Fusion of the endosome with the plasma membrane ultimately displays the class II MHC molecule–peptide complexes on the cell surface.

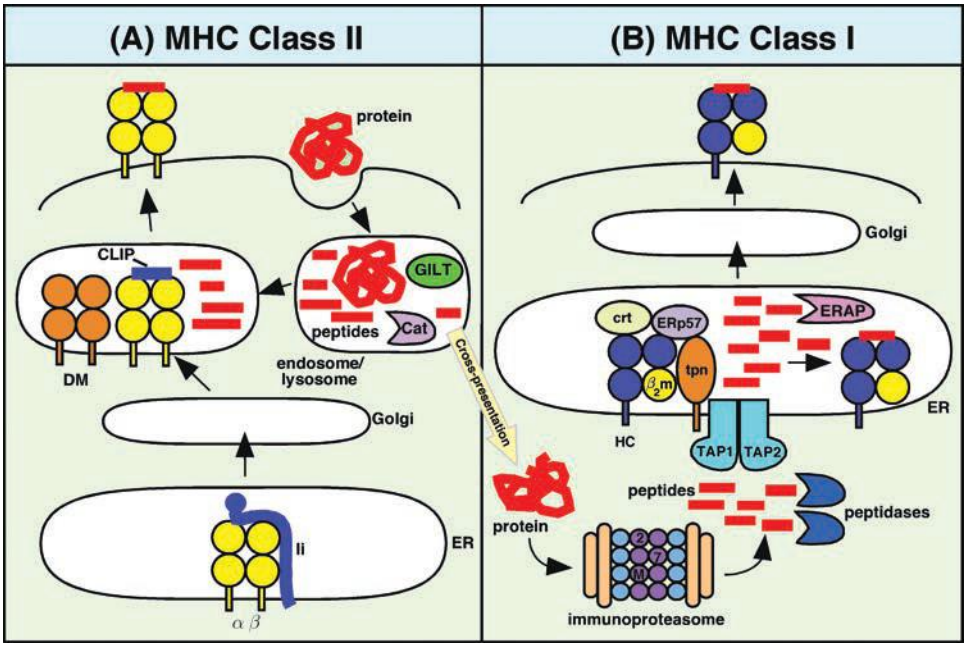

FIGURE 70.2. Presentation of peptides by major histocompatibility complex (MHC) molecules. A: MHC class II–restricted antigen processing and presentation to CD4 T cells. Exogenous protein antigens are taken up by antigen-presenting cells, disulfide bonds are reduced by the interferon (IFN)-γ-inducible lysosomal thiol reductase (GILT), and the proteins are then degraded in endosomal/lysosomal compartments by cathepsins (Cat). MHC class II α and β are synthesized in the endoplasmic reticulum (ER) and associate there with the MHC class II–associated invariant chain (Ii). The class II/Ii complexes then egress to endosomal compartments, where Ii is degraded by cathepsins, until only its class II–associated invariant chain (CLIP) region remains bound by class II. CLIP is then removed from class II by the human leukocyte antigen (HLA)-DM peptide exchange factor. Finally, class II is loaded with peptide and delivered to the cell surface for presentation to class II–restricted CD4 T cells. **B:** MHC class I–restricted antigen processing and presentation to CD8 T cells. Cytosolic proteins, derived from endogenously synthesized proteins or from cross-presented antigens (as indicated by the *arrow*), are degraded by immunoproteasomes that contain the interferon IFN-γ–inducible subunits LMP2 (2), LMP7 (7), and MECL-1 (M). Some of the resulting peptides are further processed in the cytoplasm by peptidases and then transported to the lumen of the endoplasmic reticulum (ER) by the transporter of antigen processing (TAP). Some of the peptides undergo further processing in the ER by ER-associated aminopeptidases (ERAP). Peptide-receptive MHC class I heavy chain (HC)/β_2-microglobulin (β_2m) heterodimers in the ER associate with a variety of chaperones, including calreticulin (crt), ERp57, and tapasin (tpn). After binding with peptides, class I molecules undergo a conformational change, permitting their egress to the cell surface for presentation to class I–restricted CD8 T cells.

Peptides are prepared for presentation on class I molecules in a different fashion (Fig. 70.2B). These peptides are derived from intracellular protein synthesis.[62,63] After protein synthesis, proteins introduced into the cytoplasm become the target of the proteasome, a cytoplasmic organelle whose major function is the degradation of proteins tagged for turnover by the addition of ubiquitin.[64,65] During conditions of interferon-γ production such as infection, several proteasome subunits (LMP2, LMP7, and MECL-1) become upregulated and are incorporated into newly assembled proteasomes. Proteasomes that include these IFN-γ–inducible subunits are referred to as immunoproteasomes, whereas those that lack these subunits are called constitutive proteasomes. The IFN-γ–inducible proteasome subunits favor the generation of peptides that have increased affinity for MHC class I molecules.[66–68] In addition to the proteasome, several cytoplasmic peptidases (e.g., TPPII, LAP, TOP) have been implicated in the generation of antigenic peptides, although they can cleave some epitopes as well.[65,69] These peptides are then transported into the lumen of the endoplasmic reticulum (ER) by the transporter associated with antigen processing (TAP) proteins.[62] Within the ER, peptides may be further trimmed by ER-resident aminopeptidases (i.e., ERAP1 and ERAP2).[65,69,70] Assembly of class I MHC heavy chain molecules with β_2-microglobulin requires the presence of peptides. Within the ER, empty MHC class I molecules are associated with a variety of chaperones, including calnexin, calreticulin, ERp57, and tapasin. Tapasin is a transmembrane protein that tethers empty class I molecules in the ER to TAP.[71] Emerging evidence suggests that tapasin retains unstable MHC class I molecules within peptide-loading compartments until they bind with high-affinity peptides. The assembled MHC class I–peptide complex transits the Golgi apparatus, proceeds in a vesicle to the cell surface, and is displayed on the cell surface after fusion of the vesicle membrane with the plasma membrane.

There has been a lot of interest in the mechanisms whereby tumor cells initiate $CD8^+$ T cell responses. Few tumors are derived from professional APCs and, therefore, do not effectively prime naive $CD8^+$ T cells. It has now been established that tumor cells can be processed and presented by host APCs, particularly DCs, in a process that is referred to as cross-presentation (Fig. 70.2).[72,73] Tumor antigens are then processed inside the APC, and peptides derived from these antigens are displayed on MHC class I molecules for recognition by $CD8^+$ T cells. These APCs also express MHC class II molecules and can prime naive $CD4^+$ T cells, which may be important for the generation of effective $CD8^+$ memory responses. Once tumor antigen-specific CTLs are generated, they can kill tumor cells without the requirement for costimulation. While the precise mechanisms of cross-presentation remain poorly understood,[74] the concept of cross-presentation has important applications in the development of tumor vaccines.[72,75]

T lymphocyte Activation

The goal of antigen processing and presentation is the activation of appropriate T lymphocytes to proliferate, produce cytokines, and promote an immunologic reaction or become cytotoxic cells. Although the interaction of the T cell antigen receptor with antigen-MHC provides specificity of response and initiates the crucial events of activation, the interactions are few and have low affinity.[76] The interaction between T lymphocytes and APCs or target cells is initially stabilized by a number of nonspecific

receptor–counterreceptor interactions, leading to development of an immunologic synapse with its central supramolecular activation cluster.[77,78,79] Chief among these interactions is the coupling of CD2 on the T lymphocyte with lymphocyte function antigen-3 on the APC. Also involved is the interaction of the lymphocyte function antigen-1 molecule with intercellular adhesion molecule-1 and intercellular adhesion molecule-2. Once the cells have been apposed, the specific interaction of the T cell antigen receptor and the antigen-MHC can occur. It now appears that the T cell proceeds toward activation only if certain threshold numbers of TCR-MHC/antigen interactions occur.[80]

The signal transduction pathways that result in T cell activation have been extensively reviewed,[81–83,84] and we will focus here on the most salient features (Fig. 70.3). Ligation of the TCR with an agonist peptide/MHC complex results in phosphorylation of the cytoplasmic portions of the CD3 and ζ components of the TCR. The cytoplasmic domains of CD3 and ζ contain several conserved peptide sequences called immunoreceptor tyrosine-based activation motifs (ITAMs) that are targets for intracellular protein tyrosine kinases that catalyze the phosphorylation of tyrosine residues in various protein substrates. The tyrosine kinase lck interacts with the cytoplasmic domains of CD4 and CD8 and the tyrosine kinase fyn interacts with the TCR–CD3 complex. Binding of the TCR with peptide/MHC complexes results in receptor clustering, bringing CD4/CD8 and lck in close proximity of the ITAMs within the CD3 and ζ-chains. Lck and fyn subsequently phosphorylate tyrosine residues within the ITAMs, which become docking sites for the ζ-associated protein, ZAP-70, a member of the syk family of protein tyrosine kinases. The bound ZAP-70 then becomes a substrate for lck, and phosphorylation of ZAP-70 results in its activation. Activated ZAP-70 phosphorylates several scaffolding proteins, including LAT (linker of activated T cells) and SLP-76, which, when phosphorylated, serve as docking sites for other proteins that, in turn, activate multiple signaling pathways. One of these signaling pathways involves changes in inositol lipid metabolism. Phospholipase Cγ1 (PLCγ1) becomes tyrosine

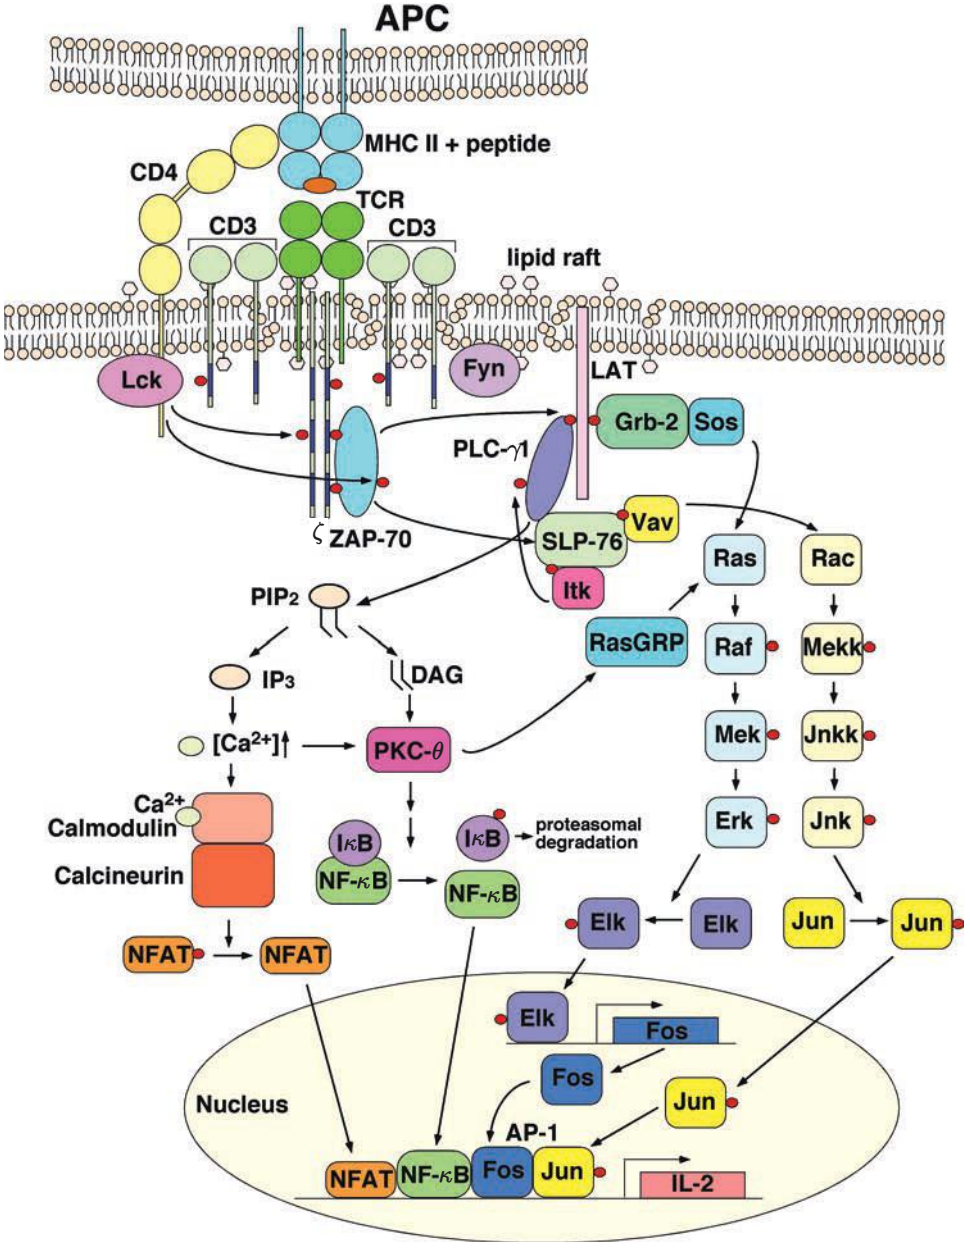

FIGURE 70.3. Overview of signal transduction events involved in T lymphocyte activation. Interaction of the T cell receptor (TCR) and coreceptors with major histocompatability complex (MHC)–peptide complexes on antigen-presenting cells (APCs) results in multiple signaling events that lead to the activation of several transcription factors that stimulate expression of numerous genes (e.g., the interleukin-2 [IL-2] gene). Note that the precise interactions between different adaptor proteins that participate in proximal TCR signaling events remain incompletely understood. AP, activated protein; DAG, diacylglycerol; Elk, Ets-like transcription factor; Erk, extracellular signal-regulated kinase; Grb, growth factor receptor-bound protein; IκB, inhibitor of κB; IP_3, inositol triphosphate; Itk, interleukin-2-inducible tyrosine kinase; Jnk, Jun N-terminal kinase; Jnkk, Jnk kinase; LAT, linker of activated T cells; Lck, lymphocyte-specific protein tyrosine kinase; Mek, Mapk/Erk kinase; Mekk, Mapk/Erk kinase; NF, nuclear factor; NFAT, nuclear factor of activated T cells; PIP_2, phosphatidylinositol biphosphate; PKC, protein kinase; PLC, phospholipase C; RasGRP, Ras guanyl nucleotide-releasing protein; SLP-76, SH2 domain-containing leukocyte protein, 76-kD; Sos, son of sevenless; ZAP-70, ζ-associated protein kinase, 70-kD.

phosphorylated and activated as it associates with LAT. Activation of PLCγ1 leads to the hydrolysis of a minor membrane lipid, phosphatidylinositol biphosphate (PIP_2), to yield inositol triphosphate (IP_3) and diacylglycerol (DAG). Each of these products activates downstream events. IP_3 induces a rapid increase of free Ca^{2+} by release from membrane-sequestered Ca^{2+} stores, whereas DAG and Ca^{2+} activate protein kinase C (PKC) θ. T cell activation also results in the activation of the ras and rac signaling pathways. Adapter proteins that are activated by phosphorylated LAT and SLP-76 result in the activation of the guanine nucleotide exchange factors SOS (son of sevenless) and vav, which activate the ras and rac signaling pathways, respectively.

These signaling events ultimately result in the activation of a number of transcription factors, including NFAT, NF-κ B, and AP-1. Cytosolic Ca^{2+} binds with the Ca^{2+}-dependent protein calmodulin, and Ca^{2+}-calmodulin complexes subsequently activate several enzymes, including the serine/threonine phosphatase calcineurin. Calcineurin then dephosphorylates NFAT, which uncovers a nuclear localization signal that permits NFAT to translocate to the nucleus. Activation of NF-κB is dependent, at least in part, on activated PKCθ. NF-κB is normally found in the cytoplasm in association with a protein called inhibitor of κB (IκB). TCR signals result in phosphorylation of IκB, which is then targeted for degradation by the proteasome. Release of IκB uncovers a nuclear translocation signal in NF-κB that permits its translocation to the nucleus. AP-1 is a transcription factor composed of the proteins Fos and Jun, which are activated by the ras and rac signaling pathways, respectively.

The net result of this extremely complex activation system is the expression of new proteins, the acquisition of functional capacity, or the ability to proliferate. T lymphocyte activation is best understood as a culmination of events leading to IL-2 production.[85] The constraints on production of this cytokine are more rigorous than those relevant for production of other gene products (such as IL-2 receptor α-chain and transcription factors). The promoter of the IL-2 gene is made up of a number of binding sites for transcription factors, including two NFAT sites, an NF-κB site, and an AP-1 site.[86] The combination of production of IL-2 receptor α-chain and IL-2 provides an adequate stimulus for the T lymphocyte to successfully proliferate, giving rise to the antigen-specific clonal expansion of lymphocytes characteristic of immunologic responses. However, there are extraordinary controls against inappropriate activation of T lymphocytes.[87] In addition to a first signal delivered via the T cell antigen receptor complex, full activation of T cells also requires a second signal.[88] The best characterized origin of these second signals is the interaction of CD28 on the T lymphocyte surface with its cognate ligands CD80 (B7–1) and CD86 (B7–2) on the APC, the most potent of which is the DC. Failure to receive a second signal can lead the T lymphocyte to undergo anergy or apoptosis. Activation of T cells is also regulated by a variety of negative signals, including inhibitory receptors of the CD28 family such as CTLA-4 (cytotoxic T lymphocyte-associated protein 4), which interacts with CD80 and CD86, and PD-1 (programmed death-1), which interacts with PD-L1 and PD-L2.[88]

TUMOR-ASSOCIATED ANTIGENS

Tumor antigens are like all other antigens of adaptive immunity. That is, with few exceptions, they are peptides that are presented to T lymphocytes in the cleft of an MHC-encoded protein.[55] The nature of peptide antigens responsible for immune responses to tumors has been described in a classic set of experiments.[55] In essence, two approaches were used. Neither made assumptions regarding the nature of the antigenic peptides. In the first approach, tumor-derived cloned CTLs were established. Next, a library of tumor complementary DNA or genomic DNA was constructed and used to transfect cells expressing appropriate MHC molecules but lacking the tumor-specific epitope. Transfected cells were tested for their ability to activate the tumor-specific CTLs. The transfected DNA was then recovered and sequenced, thus identifying the gene of origin. In the second approach, MHC molecules were isolated from tumor cells. Subsequently, peptides were eluted from the MHC molecules and fractionated chromatographically. These peptide fractions were then used to load APCs and presented to tumor-specific CTLs. Peptide fractions that stimulated T cell responses were then sequenced using conventional Edman degradation or tandem mass spectrometry. These approaches have revealed some surprising characteristics of tumor-specific antigens. Most tumor-specific antigenic peptides discovered thus far have been derived from proteins not usually expressed in any normal adult tissues[89] (with the exception of testis and ovary), such as P1A[90,91] and MAGE-1,[92,93] or they represent differentiation antigens characteristic of the cellular lineage of the tumor, such as tyrosinase,[94–96] gp100,[97–99] and MART1/Aa[100,101] in melanoma.

Early definition of tumor antigens focused on MHC class I–restricted peptides.[102] This seemed to be the obvious approach because most tumors express MHC class I structures, but few express MHC class II molecules. Also, the point of immunotherapy was to eliminate tumors—a job for cytolytic cells (i.e., for $CD8^+$ cytotoxic lymphocytes that recognize antigen in the context of class I MHC molecules). Early clinical immunization trials[103–105] demonstrated the feasibility and the potential efficacy of immunotherapy with peptides recognized by $CD8^+$ T cells. However, immune responses were, in general, weak and short-lived. At the same time that the trials were being conducted, there was a growing realization of the importance of $CD4^+$ T cells in the immune response against tumors.[102,106,107] Techniques similar to those used to define antigens recognized by CTLs have been used to define antigens for $CD4^+$ T cells. However, these techniques are slow and labor intensive. A genetic targeting expression system has been designed to expedite antigen screening.[107] It is likely that incorporation of both MHC class I– and II–restricted epitopes in tumor vaccines will be required to generate potent antitumor responses.[108]

While this direct approach to tumor antigen recognition has proceeded, other investigators have asked whether certain appealing target proteins could be immunogenic. In particular, molecules involved in the process of malignant transformation provide attractive targets for therapeutic intervention.[109] Because loss variants of tumor cells bearing these oncogenic proteins would presumably be nonmalignant,[110] an immunologic assault on these proteins might be particularly effective. Evidence has been provided that immune responses to both mutated and overexpressed oncogenic proteins can occur in patients with malignancy or can be elicited in animals. Target oncogenic proteins include mutated Ras,[111] HER-2/Neu,[112,113] BCR-ABL,[114,115] PML-RARα,[116] and mutated p53.[117]

A newer approach to definition of tumor-specific antigen targets for humoral immunity, termed SEREX, has been introduced.[118] In the SEREX approach, a complementary DNA library is prepared from a patient's tumor specimen, packaged into phage vectors, and expressed in bacteria. Recombinant proteins from bacterial clones are transferred to nitrocellulose membranes and identified as relevant antigens by reactivity with IgG antibodies present in the patient's serum. Early studies defined three classes of antigens: (a) known tumor antigens, such as MAGE-1, MAGE-4a, and tyrosinase; (b) products of known genes, such as restin; and (c) unknown gene products.[119,120] Because the cellular and humoral arms of immunity work in concert, it is likely that targets of antibody production will also prove to be targets of cellular immunity. The SEREX method provides a direct approach to the definition of potentially relevant tumor antigens.

TUMOR-HOST INTERACTIONS: BEYOND IMMUNOSURVEILLANCE

While the immune system can protect against the development of tumors, interactions between developing tumors and the host are complex. Tumors often develop means to evade immune responses, and tumors that develop in immunocompetent hosts are often more immunogenic than those that develop in immunodeficient hosts. Finally, it is now also well-recognized that the immune system can play both tumor-suppressing and tumor-promoting roles.

IMMUNE EVASION BY TUMORS

Many tumors have devised ways to evade immune responses.[18,56,121] First, tumors may lose expression of the antigens that were recognized by antibodies or CTLs. Second, many tumors downregulate expression of MHC class I molecules, rendering these cells resistant to lysis by CTLs.[122,123] Third, tumors may fail to induce effective CTL responses because of the absence of costimulatory molecules and/or resistance to uptake by APCs and cross-presentation.[124] Instead of inducing an effective immune response, some tumors may actively promote tolerance induction, by inducing anergy, exhaustion, or deletion of tumor antigen-specific T cells.[125,126] This might involve the generation of tumor antigen-specific regulatory T cells (T_{regs}),[127] induction of inhibitory costimulatory molecules such as CTLA-4 and PD-1 on tumor antigen-specific T cells,[126] and/or expansion of myeloid-derived suppressor cells, a heterogeneous group of myeloid progenitor cells and immature myeloid cells that can inhibit lymphocyte function.[128] Fourth, tumor cells may actively suppress immune responses by secretion of suppressive cytokines such as TGF-β or by expression of the Fas ligand, which may engage with Fas on lymphocytes to induce apoptosis.[125] Fifth, the tumor microenvironment, most notably the tumor stroma, may be critical in preventing immunologic destruction of tumor cells by effectively generating an immune privileged site.

Immune Sculpting of Tumors

In 2001, an important study showed that the immune system not only can protect against the development of tumors, but also can influence the quality of tumors—that is, the immune system of the host in which a tumor develops influences the immunogenicity of the tumor.[23] These investigators showed that RAG2-deficient mice not only develop MCA-induced tumors at higher frequency, but that a substantial portion of these tumors was spontaneously rejected upon transplantation in syngeneic immunocompetent mice. In sharp contrast, tumors derived from immunocompetent mice usually grew progressively in immunodeficient mice. Thus, these findings demonstrated that the immune system not only protects the host from tumor formation but also sculpts the immunogenicity of the tumors, in a process that is now referred to as cancer immunoediting.[17,18,129] Cancer immunoediting has been posited to proceed through three sequential stages: (a) an elimination phase where the immune system recognizes and destroys tumors before they become clinically apparent, (b) an equilibrium phase where tumor cells that escaped the elimination phase are continuously destroyed, with emergence of resistant tumor cell variants due to immune pressure, and (c) an escape phase where tumor cells that have successfully evaded immune responses progressively grow. The cancer immunoediting hypothesis represents an extension or modern version of the immunosurveillance hypothesis.

Tumor-promoting Immune Responses

Discussion of tumor–host interactions would not be complete without at least a mention of the tumor-promoting role of the immune system.[130] Many environmental factors, including chronic infections, tobacco smoke, and inhaled pollutants, as well as dietary factors and obesity, are associated with a low-level chronic inflammation and represent risk factors for cancer development. Chronic inflammation can contribute to tumor genesis at all stages, by generating nontoxic stress during the initiation of cancer, inducing cellular proliferation to promote cancer development, and enhancing angiogenesis and tumor invasion to promote cancer progression.[130]

APPROACHES TO IMMUNOTHERAPY

Immunotherapy is the use of the immune system or its components to target and eradicate tumors. B cell lymphomas are considered to be the most immune responsive of all human cancers.[131] They can undergo spontaneous regression,[132] and partial responses have been elicited through the use of nonspecific immune activators, such as bacillus Calmette-Guérin and IL-2.[133,134] Thus, follicular B cell lymphomas represent excellent candidates for immunotherapy.

Antibody Approaches

The most common form of immunotherapy employed in the treatment of cancer is passive immunotherapy, which involves the administration of manufactured antibodies that target a particular antigen (Table 70.1). Monoclonal antibodies have emerged as a potent and effective molecularly targeted therapy for human cancer, usually in combination with chemotherapy.[135,136] Therapeutic mAbs, such as rituximab and alemtuzumab, are examples of a passive approach. Currently, several B lymphocyte antigens, including CD20, CD22, and CD52, have been utilized as targets for immunotherapy. These targets, while found uniformly on lymphoma cells, are also expressed on normal immune system components, such as normal B lymphocytes.[134,137,138] Personalized immunotherapy, also referred to as Id vaccine therapy, is a patient- and tumor-specific approach. This modality targets unique protein determinants of the immunoglobulin molecules produced by the malignant B cell clone and does not appear to result in depletion of normal lymphocytes or subsequent impairment of the immune system. This technique stimulates the patient's immune system to attack the tumor through the use of both the humoral and cellular arms of the immune system. As a result, immunologic memory may be established which could translate into long-term remission. Some of these are being tested in phase II and III trials (Fig. 70.4).[139]

TABLE 70.1

PERSONALIZED ACTIVE IMMUNOTHERAPY VERSUS PASSIVE IMMUNOTHERAPY

Personalized Active Immunotherapy	Passive Immunotherapy
Tumor-specific	Not tumor-specific
Stimulates host immune response	Does not stimulate host immune response
Induces immunologic memory	Temporary antitumor effect
May produce long-term immunity	Requires retreatment
Induces both the cellular and humoral arms of the immune system	Induces the humoral arm of the immune system only (ADCC, CDC)
Requires patient tumor sample for production	Does not require patient tumor sample

ADCC, antibody-dependent cellular cytotoxicity; CDC, complement-dependent cytotoxicity.

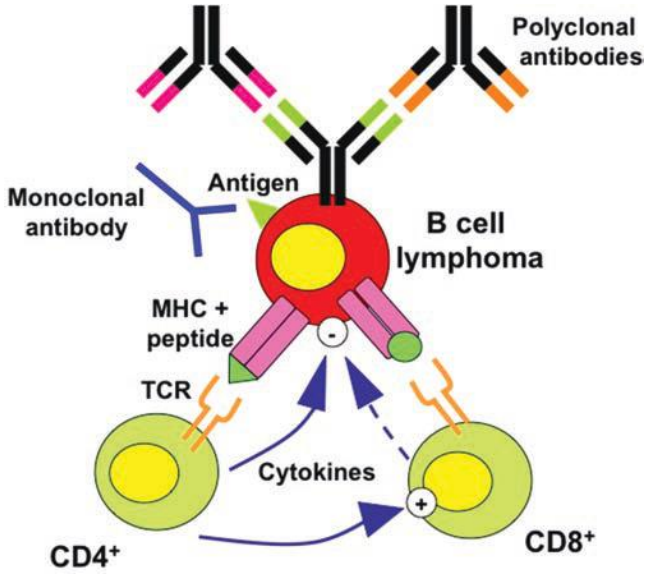

FIGURE 70.4. Idiotype as a tumor-specific antigen for B-lymphoma cells. Each B lymphocyte expresses an immunoglobulin molecule on its surface, the idiotype (Id) protein, which is capable of recognizing and binding to a unique antigen. When B lymphocytes undergo malignant transformation, the Id sequences are maintained by the malignant clones and can thus serve as tumor-specific antigen. MHC, major histocompatability complex; TCR, T cell receptor. (Adapted from Vose JM. Personalized immunotherapy for the treatment of non-Hodgkin's lymphoma: a promising approach. Hematol Oncol 2006;24:47–55.)

Unconjugated Antibodies

Unaltered antibodies have been used since the earliest trials of monoclonal antibody therapy in humans.[140–142] In early trials, success was limited by the absence of suitable tumor cell surface targets, antigenicity of first-generation (murine) mAbs in humans, modulation of the target structure from the tumor cell surface, and poor recruitment of immune effector mechanisms.[143,144] However, enthusiasm for this approach was rekindled by the enormous success of genetically engineered, chimeric, or fully humanized versions of mAbs, most notably rituximab for lymphoid malignancies and trastuzumab in solid tumors.[144]

Rituximab is a chimeric monoclonal antibody with humanized framework and Fc regions. It is directed against the CD20, pan B cell antigen. CD20 is present on pre-B cells and mature B cells, but not on precursor cells or terminally differentiated plasma cells. The function of CD20 remains poorly understood,[145] although it has been implicated in B cell activation, regulation of B cell growth, and regulation of transmembrane calcium flux. The antibody fixes human complement and elicits antibody-dependent cellular cytotoxicity (ADCC). Rituximab was approved for use as monotherapy in patients with low-grade or follicular $CD20^+$ non-Hodgkin lymphoma (NHL) in 1997. In the pivotal trial involving 166 patients, reported by McLaughlin et al.,[146] patients had relapsed or chemotherapy-resistant disease. Patients received four weekly infusions of rituximab at 375 mg/m^2. Rituximab produced a tumor response in one-half of the patients, with a median duration of response of 11.8 months, comparable to the patients' response duration on the last chemotherapy treatment. Human antichimeric antibody responses were uncommon. The most common adverse experience associated with rituximab was a constellation of acute infusion-related events, including chills, fever, headache, rhinitis, pruritus, vasodilation, asthenia, and angioedema. This syndrome can progress to hypotension, urticaria, bronchospasm, and, rarely, death. The risk is particularly great in patients with high circulating white cell counts.[147] Other toxicities were, in general, mild and infrequent.[148] Neutropenia and thrombocytopenia were unusual. Circulating B cells were depleted and remained low until recovery at a median of 12 months. Immunoglobulin levels, however, remained normal. No increased incidence of infections was seen. Rituximab was evaluated again in the relapsed, refractory, low-grade, or follicular NHL patient population, using eight weekly infusions rather than four.[149] This extended regimen produced a response rate of 57% and a time to progression (TTP) in responding patients of more than 19.4 months. Adverse event reporting was commensurate with the longer treatment period.

Davis et al.[150] reported a response rate of 43% and a TTP of 8.1 months in the patients with a significant poor prognostic factor, importantly in patients with low-grade or follicular NHL who had bulky disease, using the standard 4-infusion regimen. These investigators also showed an overall response rate (ORR) of 40% in patients who had progressed after an initial response to rituximab, with an estimated median TTP for responding patients of 17.8 months.[151]

Rituximab has been used in the first-line treatment of patients with indolent lymphoma, both as monotherapy and in combination with chemotherapy. Hainsworth[150] reported the results of rituximab as monotherapy in 39 previously untreated patients. Patients received rituximab x 4 at the usual dose and schedule, with an ORR of 54%. Patients who had responded or who had stable disease were treated with an additional four weekly treatments of rituximab at 6 months intervals to a maximum of 4 treatment cycles. The ORR rose to 72% after the second course of treatment. Progression-free survival (PFS) at 1 year was 77%. The addition of rituximab to cyclophosphamide, hydroxyldaunomycin, oncovin (vincristine), and prednisone (CHOP) chemotherapy produced impressive results. Patients were treated with six infusions of rituximab, one associated with each of six cycles of CHOP. In 40 patients with newly diagnosed ($n = 31$) or relapsed/refractory ($n = 9$) low-grade or follicular NHL, rituximab plus CHOP produced an ORR of 95% and complete response (CR) rate of 55%. With a median follow-up of 29 months, median duration of response and median TTP had not been reached. Eight of 18 patients tested for the *BCL-2* [t(14;18)] translocation by PCR testing were positive at initiation of therapy. Seven of these 8 patients, after therapy, became negative for the translocation. The authors concluded that the addition of rituximab to CHOP produced benefits in efficacy parameters without significant additional toxicity. Elimination of PCR positivity for the t(14;18) translocation had not been previously reported with CHOP alone.

Rituximab also has been used with success in patients with more aggressive lymphomas. Vose et al.[151] reported the results of rituximab plus CHOP chemotherapy (again using 6 infusions of rituximab in association with 6 cycles of CHOP) in 33 previously untreated patients with advanced aggressive B cell NHL. The combination produced an ORR of 94% and a CR rate of 61%. With a median observation time of 26 months, 29 of 31 patients achieving a remission were in continuing remission at the time of the report. Thirteen patients were BCL-2 positive at study entry. Eleven of these 13 patients became BCL-2 negative after treatment, and 10 of the 11 remained BCL-2 negative. The authors concluded that the results were achieved without significant added toxicities above those expected with CHOP. The Groupe d'Etude des Lymphomes de l'Adulte undertook a study to compare the utility of CHOP with that of rituximab plus CHOP in elderly patients with diffuse B cell lymphoma.[152] Patients between the ages of 60 and 80 years with untreated, diffuse large B cell lymphoma were eligible for the study. Patients were randomly assigned to receive 8 cycles of CHOP chemotherapy (197 patients) or to receive 8 cycles of CHOP, each given after an infusion of rituximab (202 patients). Rituximab plus CHOP produced a superior rate of remission, 76% versus 63% ($P = 0.005$). With

a median follow-up of 2 years, event-free and overall survivals (OSs) were significantly higher in the rituximab plus CHOP group ($P < 0.001$ and $P = 0.007$, respectively). These results were achieved without a significant incremental increase in toxicity. The addition of rituximab to CHOP reduced the risk of treatment failure (risk ratio, 0.54; 95% confidence interval [CI]: 0.44, 0.77) and the risk of death (risk ratio, 0.64; CI: 0.45, 0.89). The addition of immunotherapy to standard chemotherapy had accomplished what 25 years of chemotherapy manipulation had failed to do (i.e., improve on the results of CHOP chemotherapy).[153,154] Maintenance rituximab has also been found to prolong event-free survival (EFS) and response duration in follicular lymphoma.[155] In subsequent ongoing randomized phase III studies,[156,157] rituximab maintenance regimen provided significant PFS and OS at 3-year[156] and 4-year[157] follow-up assessments in both previously treated[156] and untreated[157] patients with follicular NHL, compared with no further treatment, though no difference in OS has been reported by other investigators.[158]

The mechanism by which rituximab produces these impressive results is less clear. A number of possible mechanisms have been considered: initiation of complement-mediated cell lysis, induction of ADCC, and signaling via CD20 leading to programmed cell death and/or sensitization to cytotoxic drugs. Pretreatment lymphoma cells from 29 patients were examined by flow cytometry for expression of complement inhibitors CD46, CD55, and CD59.[159] Expression of these cell surface inhibitors of complement activation was not predictive of outcome to rituximab therapy. Considerable evidence suggests that induction of ADCC plays an important role in rituximab's antilymphoma effects. A rituximab-like antibody for which an IgG4γ framework was substituted for the IgG1 framework of rituximab was incapable of producing B cell depletion in primates.[160] Rituximab was relatively ineffective in eliminating Raji B cell implants in Fc$R\gamma^{-}/^{-}$/nu/nu knockout mice compared to nu/nu mice.[161] These mice lack the activating receptor for Fc portions of antibodies, a critical component of the antibody-dependent cell-mediated cytotoxicity mechanism. In patients, response to rituximab has been shown to be associated with homozygosity for the high-affinity allotype of the FcγRIIIa receptor.[162] Evidence also exists that rituximab signaling or interference with normal signaling via CD20 may directly induce apoptosis or sensitize cells to the deleterious effects of chemotherapeutic agents.[163] A direct, growth inhibitory effect of rituximab, with accompanying apoptosis, on cell lines cultured in the absence of complement was demonstrated.[164] Anti-CD20–associated apoptosis has been associated with upregulation of the proapoptotic protein, Bax[165] and downregulation of antiapoptotic protein BCL-2 through inactivation of STAT3.[166] Downregulation of STAT3 appears to be a result of downregulation of an IL-10 autocrine pathway.[167] These changes and/or others may be responsible for increased sensitivity to chemotherapeutic agents.[168]

In the wake of the success of rituximab, a number of other antilymphoma mAbs have entered the clinic.[169] Alemtuzumab is a humanized IgG1κ monoclonal antibody directed against the CD52 cell surface antigen.[144] CD52 is expressed on normal and malignant lymphocytes of B- and T cell lineage, as well as NK cells, monocytes, and macrophages. Alemtuzumab is indicated for the treatment of B cell chronic lymphocytic leukemia (CLL) in patients who have been treated with alkylating agents and who have failed fludarabine therapy. The pivotal clinical trial was carried out in 93 patients with fludarabine-refractory CLL .[170] Alemtuzumab produced a response rate of 33%. Virtually all of the responders were partial responders; the CR rate was 2%. Median duration of response was 7 months. Median TTP was 4.7 months for the group as a whole; 9.5 months for responders. The most common adverse events were infusion related—most were grade 1 or 2 in severity, including rigors in 90% of patients (grade 3 in 14%), fever in 85% of patients (grade 3 or 4 in 20%), nausea in 53% of patients, and vomiting in 38% of patients. Infusion-associated side effects declined with subsequent infusions. During the study, 28% of patients experienced dyspnea, 17% experienced hypotension, and 3% experienced hypoxia. Overall, 55% of patients developed an infection during the study. Approximately one-half of these infections were considered serious (grade 3 or 4). Septicemia occurred in 15% of patients, and two deaths resulted. Opportunistic infections occurred in 12% of patients. Ten percent of patients died during or within 30 days of treatment—one-third of these were attributed to progressive disease. Twenty-four percent of patients discontinued treatment because of a drug-related side effect. Most patients who discontinued had not responded to therapy. Serious infusion-related events associated with alemtuzumab appear to result from ligation of CD16 on NK cells resulting in what has been termed *cytokine storm*—release of IL-6, TNF-α, and interferon-γ.[171] Prolonged immunosuppression after use of alemtuzumab can result in opportunistic infections.[172] Treatment schemas now include the routine use of prophylaxis with both antibiotics and antivirals.

To improve on the immunogenicity and efficacy of rituximab, the last few years have seen the development of new generations of anti-CD20 monoclonal antibodies (mAbs) with enhanced antitumor activity resulting from increased complement-dependent cytotoxicity (CDC) and/or ADCC and increased Fc binding affinity for the low-affinity variants of the FcγRIIIa receptor (CD16) on immune effector cells. These second-generation mAbs, such as ofatumumab, veltuzumab, and ocrelizumab, are in clinical development. They are humanized or fully human to reduce immunogenicity, but with an unmodified Fc region. Ofatumumab is a fully human anti-CD20 IgG1 mAb in clinical development for hematologic malignancies and autoimmune diseases. Ofatumumab specifically recognizes an epitope encompassing both the small and large extracellular loops of the CD20 molecule, and is more effective than rituximab at CDC induction and killing target cells. Veltuzumab (IMMU-106, hA20) is a humanized anti-CD20 mAb with complementarity-determining regions similar to rituximab. This antibody has enhanced binding avidities and a stronger effect on CDC compared to rituximab. Ocrelizumab is a humanized mAb with the potential for enhanced efficacy in lymphoid malignancies compared to rituximab because of increased binding affinity for the low-affinity variants of the FcγRIIIa receptor. Third-generation mAbs are also in clinical development. They are also humanized mAbs, but in addition they have an engineered Fc to increase their binding affinity for the FcγRIIIa receptor. Third-generation mAbs also in clinical development include AME-133v, PRO131921, and GA-101 (Table 70.2), with enhanced affinity for the FcγRIIIa receptor and an enhanced ADCC activity compared to rituximab.[173]

Two other mAbs with potential utility in the treatment of lymphoma are in early clinical development.[169,174] Epratuzumab is a humanized IgG1 monoclonal antibody directed against the CD22 antigen. CD22 is a pan–B cell antigen with distribution similar to that of CD20. Epratuzumab has a favorable safety profile in early trials. Approximately 50% of follicular lymphoma patients and 25% of diffuse large-cell lymphoma patients responded in a small phase II trial. Some of the responses have been long-lived. A recent phase II trial testing the safety and efficacy of combining epratuzumab with R-CHOP (ER-CHOP) in untreated DLBCL showed that the addition to standard R-CHOP, E 360 mg/m^2 intravenously, administered for 6 cycles in 107 patients, showed similar toxicity to standard R-CHOP. ORR in the 81 eligible patients was 96% (74% CR/ CR unconfirmed [Cru]) by computed tomography scan and 88% by positron emission tomography. By intention to treat analysis, at a median follow-up of 43 months, the EFS and OS at 3 years in all 107 patients were 70% and 80%, respectively. Comparison with a cohort of 215 patients who were treated with R-CHOP showed improved EFS in the ER-CHOP

TABLE 70.2

ANTI-CD20 MONOCLONAL ANTIBODIES (mAbs) APPROVED OR POTENTIALLY USEFUL FOR LYMPHOID MALIGNANCIES

mAb	Company	Antibody characteristics	ADCC	CDC	Direct effects	Comparison with rituximab
Rituximab (Rituxan®, Mabthera®)	Hoffman La Roche	Type I, first-generation mouse/human chimeric IgG1	++	++	+	
Rituximab (Rituxan®, Mabthera®)	GlaxoSmithKline plc/ Genmab A/S	Type I, first-generation, human IgG1	++	++++	+	Binding to different CD20 epitope; more effective at CDC
Veltuzumab (IMMU-106, hA20)	Immunomedics Inc.	Type I, second-generation, humanized IgG1	++	++	+	Slower off-rate, enhanced binding avidity, a superior CDC
Ocrelizumab	Genentech Inc./Biogen Idec Inc./Chugai Pharmaceutical Co. Ltd/Roche Holding Ag	Type I, second-generation, Humanized fusion IgG1	+++	+/–	+	Binding to different CD20 epitope, enhanced ADCC, reduced CDC, enhanced affinity for FcγRIIIa RIIIa
PRO131921	Genentech, Inc.	Type I, third-generation, humanized fusion IgG1	+++	+++	+	Improved binding to FcγRIIIa, better ADCC, superior antitumor efficacy
AME-133 v (LY2469298)	Lilly	Type I, third-generation, humanized fusion IgG1	+++	++	++	Enhanced affinity for FcγRIIIa, superior ADCC
GA-101 (RO5072759)	Glycart Biotechnology AG, Genentech, F Hoffmann-La Roche Ltd	Type II, third-generation, humanized IgG1	++++	–	++++	Superior ADCC and direct cell killing
TRU-015	Trubion Pharmaceuticals Inc., Pfizer Inc.	SMIP-derived humanized fusion protein	+++	+	?	Single-chain polypeptide, enhanced ADCC, reduced CDC

ADCC, antibody-dependent cellular cytotoxicity; CDC, complement-dependent cytotoxicity; IgG, immunoglobulin G; SMIP, small modular immunopharmaceutical; + indicates low cytotoxicity; ++ indicates intermediate cytotoxicity; +++ indicates high cytotoxicity; ++++ indicates very high cytotoxicity; +/– indicates very low cytotoxicity; – indicates lack of cytotoxicity; ? indicates cytotoxicity unknown.

patients. ER-CHOP was well tolerated and results appear promising as a combination therapy.[175]

Apolizumab is a humanized IgG1 monoclonal antibody that binds to a variant of the HLA-DR β-chain. The antibody induces complement-mediated lysis, ADCC, and tyrosine phosphorylation signaling events in cell lines in vitro. The antibody binds to approximately 70% of lymphoma specimens. Administration of the antibody to patients results in typical infusion-related side effects. Four of 8 patients with follicular lymphoma responded to apolizumab. A phase I/II dose-escalation study of thrice-weekly apolizumab (1.5, 3.0, 5.0 mg/kg/dose) for 4 weeks in relapsed CLL resulted in significant toxicity and lack of efficacy; thus, further clinical trials of apolizumab were discontinued, as were other trials in lymphoma and solid tumors.[176] Milatuzumab (hLL1, IMMU-115; Immunomedics) is a fully humanized mAb specific for CD74, a cell surface–expressed epitope of the HLA class II–associated invariant chain. CD74 plays an important role as an accessory signaling molecule and survival receptor in the maturation and proliferation of B cells by activating the PI3K/Akt and the NF-κB pathways.[177] Milatuzumab demonstrated antiproliferative activity in transformed B cell lines, improved survival in preclinical models, and is presently being evaluated for the treatment of several hematologic malignancies.

Inroads are being made in other hematologic cancers. In multiple myeloma, it was recently reported that the cell surface glycoprotein CS1 (CD2 subset 1, CRACC, SLAMF7, CD319) was highly and universally expressed on myeloma cells while having restricted expression in normal tissues. Preclinical studies showed that elotuzumab (formerly known as HuLuc63), a humanized mAb targeting CS1, could induce patient-derived myeloma cell killing within the bone marrow microenvironment using a SCID-hu mouse model and that the CS1 gene and cell surface protein expression persisted on myeloma patient-derived plasma cells collected after bortezomib administration. In vitro bortezomib pretreatment of myeloma targets significantly enhanced elotuzumab-mediated ADCC, both for OPM2 myeloma cells using NK cells or peripheral blood mononuclear cells from healthy donors and for primary myeloma cells using autologous NK effector cells. In an OPM2 myeloma xenograft model, elotuzumab in combination with bortezomib exhibited significantly enhanced in vivo antitumor activity. Elotuzumab is currently in a phase I clinical trial in relapsed/refractory myeloma.[178] In AML, one strategy for the development of mAbs targeting human AML stem cells involves first identifying cell surface antigens preferentially expressed on AML LSC (leukemia stem cell) compared with normal hematopoietic stem cells. In recent years, a number of such antigens have been identified, including CD123, CD44, CLL-1, CD96, CD47, CD32, and CD25. Moreover, mAbs targeting CD44, CD123, and CD47 have demonstrated efficacy against AML LSC in xenotransplantation models. Hopefully, these antibodies will ultimately prove to be effective in the treatment of human AML.[179]

Anti-idiotype Therapy

Much time and energy were expended searching for tumor antigens, particularly after the development of mAb techniques.[17] These brute-force immunization, hybridization, and screening procedures yielded little. They defined only a single truly tumor-specific antigen. That was the Id of clonally distributed antibody expressed on the surface of certain B cell lymphomas. Because it represents a unique protein structure within the combining site of the antibody, the Id can serve as an antigen for antibody production. This fact was demonstrated by Sirisinha and Eisen[180] in the early 1970s. Furthermore, they demonstrated that an immunologic response to Id could lead to tumor protection.[181]

Levy and Miller[182] have explored the utility of anti-Id strategies in indolent B cell lymphoma over many years. Initially, these investigators raised custom-made anti-Id mAbs[183] for passive administration. A first patient with far advanced,

chemotherapy-refractory disease received anti-Id mAbs. Gradual reductions in serum Id and tumor volume were noted. The patient then entered a long-term complete remission.[184] In an initial series of patients treated with anti-Id therapy, 11 patients were reported.[185] In this group, a second near-complete remission, four partial remissions, and five insignificant responses were seen. There was little toxicity associated with administration of the anti-Id antibodies. The most common side effects were chills and fever. Transient shortness of breath, headache, nausea, emesis, diarrhea, and myalgias were occasionally observed. Unusual toxicities included transient leukopenia or thrombocytopenia and transient elevations of hepatic enzymes. Several interesting problems of anti-Id therapy were noted in this early series: the interfering effect of circulating Id, the development of human antimouse antibody, and the emergence of Id-negative tumor cell variants.[186–189] An attempt to reduce the incidence of emergence of Id-negative lymphoma variants with a short course of chlorambucil was unsuccessful.[190] The cumulative experience suggests that anti-Id therapy can result in a 15% CR rate and a 50% partial response rate. The mechanism of tumor response in these trials remains unclear. However, response in these trials correlated with anti-Id–induced signal transduction events in the lymphoma cells, suggesting that activation of apoptotic pathways may lead to lymphoma cell death after interaction of the anti-Id antibody with the lymphoma surface-bound immunoglobulin receptor.[191] This group has turned to active immunization strategies in indolent lymphoma (see section "Immunization Strategies").

Radioimmunotherapy

The use of immunoglobulin–radionuclide conjugates in cancer treatment represents appropriation of a classic guided-missile strategy. In theory, the antibody homes to its antigenic target and delivers a cytotoxic assault on the cell to which it attaches. Radionuclides offer certain advantages over other cytotoxic agents. They do not have to be internalized. Radioactive particles can deliver their effects over distances of 1 to 5 mm, thus limiting collateral damage to normal tissues while still potentially providing antitumor effects against antigen-negative variants in the vicinity in what has been termed a *cross-fire effect*. The principles of radiation physics underlying radioimmunotherapy (RIT) have been reviewed by Press and Rasey.[192] Radiolabeled antibodies deliver continuous, exponentially decreasing, low-dose-rate radiation. Traditional external beam radiotherapy delivers intermittent, fractionated radiation at higher dose rates. The most commonly used isotopes for RIT have been iodine 131 (I-131) and yttrium 90 (Y-90). These radionuclides kill cells primarily through emission of β particles, resulting in DNA strand breaks. The β particles of Y-90 are more energetic than those of I-131. They affect cells in a radius of approximately 5 mm compared to approximately 1 mm for those of I-131. I-131 also emits γ rays. This allows direct imaging of the distribution of the radioconjugate but raises issues regarding shielding and health care worker and family member safety.

Several recent reviews attest to the evolution of this field.[193,194] A number of theoretical and experimentally generated concerns with RIT appear to have been overcome in the successful clinical studies described below. There had been concern that effective delivery of radioimmunoconjugates would be impeded by heterogeneous tumor vasculature, slow diffusion of these large molecules in interstitial spaces, heterogeneous biodistribution in tumor nodules, and high intratumoral pressures.

The two products in clinical use presently, Y-90 ibritumomab tiuxetan (Zevalin) and I-131 tositumomab (Bexxar), are both directed against the anti-CD20 antigen of B lymphocytes, the same structure targeted by rituximab. Both products are based on murine mAbs. Both are administered after infusion of unconjugated anti-CD20 antibodies—rituximab in the case of Zevalin and tositumomab in the case of Bexxar. Both have used nuclear medicine imaging as a preparatory step to administration, but it is no longer required for Y-90 ibritumomab. Simple dosimetry is accomplished for I-131 tositumomab by capturing whole-body gamma counts after infusion of a 5 mCi "dosimetric dose" of the agent. Imaging was carried out in Y-90 ibritumomab tiuxetan–treated patients to assure normal biodistribution. Whole-body dosimetry is carried out in I-131 tositumomab–treated patients to allow calculation of a patient-specific activity (mCi) to deliver a desired total-body dose of radiation (cGy). Both have been studied most extensively in indolent lymphoma and have been approved for treatment of patients with relapsed or refractory follicular, including rituximab refractory, or transformed B ($CD20^+$) NHL.

The approval for ibritumomab tiuxetan rested primarily on two clinical studies. The first was a randomized controlled comparison of the effectiveness of Y-90 ibritumomab tiuxetan to that of rituximab in patients with relapsed or refractory, follicular, or transformed B cell NHL.[195] The study involved 143 patients; 73 randomized to Y-90 ibritumomab tiuxetan (single administration), and 70 randomized to rituximab (weekly × 4). The median number of prior therapies was 2. Approximately one-half of the patients failed to respond to or had a TTP of less than 6 months to their last chemotherapy regimen. Y-90 ibritumomab tiuxetan produced a statistically superior response rate (using the response definitions of the International Workshop), 80% versus 56% ($P = 0.002$). The number of durable responders at 6 months favored Y-90 ibritumomab tiuxetan–treated patients, but the significance of the observation was lost at 9 months and 12 months. Median TTP (estimated by Kaplan-Meier methods) was 11.2 months for patients treated with Y-90 ibritumomab tiuxetan and 10.1 months for patients treated with rituximab ($P = 0.173$). Grade 3 and 4 nonhematologic adverse events were unusual in both groups. Y-90 ibritumomab tiuxetan produced grade 3 or 4 neutropenia in 57% of patients, grade 3 or 4 thrombocytopenia in 60% of patients, and grade 3 or 4 anemia in 2% of patients. One patient in the Y-90 ibritumomab tiuxetan–treated group developed myelodysplasia. One patient in the rituximab-treated group developed pancreatic carcinoma. The second trial was a phase II experience in 57 patients who had failed to respond to rituximab or had a TTP of ≤6 months.[196] These patients had a median of 4 prior therapies, and 74% had bulky tumors (greatest diameter ≥ 5 cm). In this patient population, Y-90 ibritumomab tiuxetan produced a response rate of 74% and CR rate of 15%. The median TTP was estimated at 6.8 months. Grade 4 neutropenia occurred in 35% of patients, grade 4 thrombocytopenia in 9% of patients, and grade 4 anemia in 4% of patients.

The pivotal study for I-131 tositumomab enrolled 60 patients with refractory or transformed low-grade NHL who had been treated with at least two different qualifying chemotherapy regimens.[197] Patients must also have failed to achieve an objective response or relapsed within 6 months after completion of their last qualifying chemotherapy (LQC) regimen. Median age was 60 years, and other poor prognostic features included: median of 4 prior therapies, bulky disease, bone marrow involvement, elevated serum lactate dehydrogenase, advanced stage, and transformation from an initial low-grade histology to a higher-grade histology in 38% of the patients. A statistically significant improvement in the primary endpoint was achieved, with a longer duration of response (>30 days) after I-131 tositumomab therapy ($n = 26$) compared to patients after their LQC ($n = 5$; $P < 0.001$). Improvements in secondary efficacy endpoints after I-131 tositumomab compared to those after LQC were also achieved: overall response (47% vs. 12%; $P < 0.001$), duration of response (11.7 vs. 4.1 months; $P < 0.001$), and CR (22% vs. 2%; $P = 0.002$). Fifteen of 60 patients (25%) were classified as long-term responders (patients with a MIRROR Panel–assessed TTP of a year or more). Nine (15%) of the 60 patients remained in CR, with TTP ranging from 41+ to 57+ months.

A second trial examined the incremental benefit of the radioconjugate (I-131 tositumomab) compared to the nonradioactive antibody (tositumomab).[198] This study was a randomized, two-arm, open-label, multicenter study that enrolled patients with chemotherapy-relapsed or refractory low-grade or transformed low-grade NHL. Patients were randomized to receive either I-131 tositumomab therapy or unlabeled tositumomab alone. The primary endpoint was a comparison of the rates of CR. Secondary endpoints included ORR, duration of responses, and TTP. A total of 78 patients (18% with transformation) participated in the study. Patients had been previously treated with one to three chemotherapy regimens. One or more therapies must have included an anthracycline, anthracenedione, or alkylating agent. A significant difference was observed for the primary efficacy endpoint. The CR rate was 33% (14 of 42 patients) for the patients treated with I-131 tositumomab compared to 8% (3 of 36) for patients treated with unlabeled tositumomab ($P = 0.012$). In addition, the ORR was greater after treatment with I-131 tositumomab: 23 of 42 patients (55%) compared to 7 of 36 patients (19%; $P = 0.002$). Nineteen patients initially treated with the unlabeled antibody crossed over to receive I-131 tositumomab after disease progression. A CR then was observed in 42% (8 of 19 patients) and an ORR in 68% (13 of 19 patients) in the crossover patient population. A total of 20 patients (33%) from the I-131 tositumomab–treated populations, including patients in the crossover arm, were classified as having a long-term response, including ten patients continuing in CR, with TTP ranging from 23+ to 59+ months.

The efficacy of I-131 tositumomab was also evaluated in patients who had progressed after rituximab.[199,200] Patients must have had prior treatment with at least four doses of rituximab without an objective response, or to have progressed during or after treatment. Twenty-four patients did not respond to their last treatment with rituximab, and, of the 16 patients who did respond to rituximab, five patients had a duration of response exceeding 6 months. A response occurred in 27 of 40 patients (68%), with a median duration of response of 14.7 months (95% CI; 10.6 months no response). A CR occurred in 12 of 40 patients (30%); the median duration of CR had not been reached (95% CI; 11 months no response). Twenty-four patients had a longer (at least 30 days) duration of response after I-131 tositumomab than after rituximab; 5 patients had a longer duration of response after rituximab than after I-131 tositumomab; 9 patients had equivalent durations of response; and 2 patients were censored ($P < 0.001$). A total of 14 patients (35%) had a TTP of 12 months or longer. The median PFS was 10.4 months (95% CI, 5.7 to 8.6) for all patients and 24.5 months for confirmed responders (95% CI, 16.8 to not reached [NR]). PFS for 15 confirmed CR patients was NR with an estimated 3 years PFS of 73%. Prior response to rituximab did not significantly affect the confirmed OR rate, duration of response, or median PFS.

Radioiodinated tositumomab and Y-90 ibritumomab tiuxetan have also been used at myeloablative doses, with stem cell rescue in patients with relapsed B cell lymphomas.[201,202,203,204] Radioiodinated tositumomab was used initially as a single agent.[202] Twenty-five patients were imaged after a tracer dose of radioiodinated tositumomab. Twenty-two of these 25 patients achieved favorable biodistributions (i.e., had tumor doses in excess of doses to normal organs). These 21 patients received therapeutic infusions of radioiodinated tositumomab (345 to 785 mCi) followed by reinfusion of autologous hematopoietic stem cells. All patients achieved bone marrow engraftment (19 with bone marrow stem cells, two with peripheral blood stem cells). However, two patients died before full neutrophil recovery; one of sepsis, one of progressive lymphoma. Nonhematologic toxicities included nausea in most patients, mild mucositis in five patients, and partial alopecia in four patients. One patient experienced reversible cardiomyopathy and interstitial pneumonitis. Eighteen patients responded to this therapy; 16 patients experienced a CR. With a median follow-up of 2 years, 2 years PFS was estimated at 62%, with OS estimated at 93%. Press et al. then combined radioiodinated tositumomab with chemotherapy and autologous stem cell transfusion in a series of patients with relapsed B cell lymphomas.[203] Fifty-two patients received the planned therapy. Patients were again given tracer doses of radioiodinated tositumomab and underwent sequential gamma camera imaging. Absorbed doses of radiation to tumor sites and normal organs were determined. Thereafter, patients received a therapeutic infusion of radioiodinated tositumomab calculated to deliver between 20 and 27 Gy to normal organs (e.g., liver, kidneys, and lungs). Patients then received etoposide, 60 mg/kg, and cyclophosphamide, 100 mg/kg, followed by reinfusion of autologous hematopoietic stem cells. The maximal tolerated dose of radioiodinated tositumomab to be combined with chemotherapy was determined to be that dose that delivered 25 Gy to normal organs. Eight patients experienced 13 grade 3 or 4 toxic events. These included 3 patients with acute respiratory distress syndrome, 3 patients with severe mucositis or gastrointestinal toxicity, 1 patient with venoocclusive disease, and 4 patients with fatal infections. At 2 years, the Kaplan-Meier estimates of OS and PFS for all treated patients were 83% and 68%, respectively. These findings were considered superior to results previously observed in patients who had undergone conventional external beam total-body radiation with etoposide/cyclophosphamide preparation for transplantation in the same institution. Thirty-one patients with $CD20^+$ NHL were treated with high-dose Y-90 ibritumomab tiuxetan in combination with high-dose etoposide and cyclophosphamide and were followed by autologous hematopoietic cell transplantation (HCT).[204] Treatment also was well tolerated; there were 2 deaths and 5 relapses. At a median follow-up of 22 months, the 2 years estimated OS rates are 92% and 78%, respectively. Retreatment with tositumomab and I-131 tositumomab, has also been found possible in patients with progressive disease after treatment with I-131 tositumomab, who were able to receive subsequent therapy, including cytotoxic chemotherapy and stem cell transplantation.[205] In patients with prior response, I-131 tositumomab can produce second responses that can be durable.[206]

Use of RIT is also being investigated in the allogeneic HCT setting.[207,208,209] RIT with β-emitters has been successfully used for further dose intensification of myeloablative conditioning regimens for HCT. Using a canine model of nonmyeloablative HCT, Bethge et al. used pretransplant RIT with the α-emitter bismuth-213 coupled to anti-CD45 or anti-TCR$\alpha\beta$ mAb together with postgrafting immunosuppression with mycophenolate mofetil and cyclosporine, which resulted in stable engraftment and long-term mixed chimerism.[208] In 2 relapsed patients with NHL, Y-90 ibritumomab tiuxetan was given as part of the conditioning for an HLA-matched donor transplant. Rituximab 250 mg/m^2 was given on days −21 and −14, 0.4 mCi/kg Y-90 ibritumomab tiuxetan on day -14 and fludarabine (30 mg/m^2) plus cyclophosphamide (500 mg/m^2) on days −7 and −3, resulting in fast and reliable engraftment, offering an attractive new therapeutic option for relapsed lymphoma patients.[209] A method of dose-intensified RIT called "pretargeting" RIT (PRIT) dissociates the slow distribution phase of the antibody molecule from the delivery of the therapeutic radionuclide. This might achieve improved outcomes with less toxicity, and is being explored in preclinical studies of hematologic malignancies.[210] In a preclinical study using an acute leukemia xenograft model, comparing conventional and pretargeted anti-hCD45 RIT, investigators showed clearly that anti-CD45 PRIT provided rapid tumor localization and improved biodistributions of radioactivity with significant improvements in efficacy compared with conventional anti-CD45 RIT.[211]

In allogeneic HCT, RIT is being explored to reduce toxicity associated with external γ-beam radiation. RIT with an anti-CD45 mAb labeled with the α-emitter astatine-211 has been used as a conditioning regimen in dog leukocyte antigen-identical HCT, resulting in good engraftment and minimal toxicity.[212]

Immunotoxins and Fusion Toxins

This category of treatment reagents resembles those guided missiles of RIT. In this case, however, the warheads are chemical rather than nuclear, and the targeting is provided by antibodies or by lymphokines, growth factors, and so on, that specifically bind receptors on the surfaces of target tumor cells. Attached to the targeting moiety is the cytolytic moiety. This is usually a toxin, derived from plants or bacteria, which works by inhibiting protein synthesis. They kill either resting or dividing cells and require fewer than ten molecules in the cytosol to be effective.[213,214] Toxins of this type tested in phase I trials include ricin A-chain, blocked ricin, saporin, pokeweed antiviral protein, *Pseudomonas* exotoxin A, and diphtheria toxin. Recently, calicheamicin, a highly potent antitumor antibiotic that cleaves double-stranded DNA at specific sequences,[215] has been successfully targeted to leukemia cells.[216]

A number of factors influence the efficacy of immunotoxins. These include the binding affinity of the ligand for its target and the target density on the tumor cell surface.[217] The epitope to which binding occurs can affect the potency of the immunotoxin.[218] Membrane-proximal epitopes appear to confer greater efficacy. Immunotoxin binding must lead to internalization of the target structure and the attached immunotoxin.[219] Once internalized, the toxin moiety must translocate to the cytoplasm to be effective. This process is aided by certain translocation sequences in the toxin. The need for translocation signals provides the rationale for using blocked ricin toxin; targeting via the binding subunit is eliminated but translocation signals are preserved.[220] The site of translocation may vary for different toxins. Increasing lysosomal pH protects cells from *Pseudomonas* exotoxin and diphtheria toxin but increases sensitivity to ricin,[221–223] suggesting that ricin may undergo translocation in the Golgi apparatus. Finally, these toxins affect protein synthesis by ADP-ribosylating elongation factor 2[224] in the case of diphtheria toxin and *Pseudomonas* toxin, or by alteration of the 60S ribosomal subunit in the case of ricin.[225]

A number of phase I clinical trials using ricin-based, anti-pan B cell antibody immunotoxins have been reported in B cell lymphoma.[226–233] These trials demonstrated that therapeutic doses of immunotoxins can be delivered with tolerable, reversible side effects. Toxicities include systemic symptoms of fever, nausea, vomiting, headache, and muscle aches; evidence of hepatocyte damage with transaminase elevations; and significant problems with capillary leak syndrome.[234] Again recognized were the problems of human antimouse antibody formation and rapid clearance of immunotoxin in the presence of circulating antigenemia. Sporadic responses were seen in these trials, with response rates perhaps approaching 25% and CRs approaching 10%. There were hints that targeting via CD22 might be more useful than targeting via CD19.[235] Some experts have suggested that these agents will not become useful clinical tools until problems of their immunogenicity have been solved.[143,214]

However, recent success has been reported for two agents of this class. A recombinant immunotoxin containing the anti-CD22 variable domain (Fv) fused to a truncated *Pseudomonas* exotoxin has produced CRs in patients with hairy-cell leukemia (HCL).[236] Sixteen patients whose disease was resistant to nucleoside analogs were treated by intravenous infusion every other day for three doses. Thirteen of 16 patients responded—11 had CRs. The treatment was generally well tolerated. Common side effects included transient elevations of liver enzymes and hypoalbuminemia. Median follow-up was 16 months, during which 3 of the 11 complete responders relapsed. These three patients were retreated with the immunotoxin. Two of the three developed hemolytic uremic syndrome. Moxetumomab pasudotox, is an improved, more active form of a predecessor recombinant immunotoxin, BL22 (also called CAT-3888), and is up to 50-fold more active on lymphoma cell lines and leukemic cells from patients with CLL and HCL. A phase I trial was recently completed in HCL patients, who achieved response rates similar to those obtained with BL22 but without dose-limiting toxicity. In addition to further testing in HCL, moxetumomab pasudotox is being evaluated in phase I trials in patients with CLL, B cell lymphomas, and childhood ALL. Moreover, protein engineering is being used to increase its activity, decrease nonspecific side effects, and remove B cell epitopes.[237]

Gemtuzumab ozogamicin (Mylotarg) is an immunotoxin composed of a recombinant human IgG4κ monoclonal antibody conjugated with a cytotoxic antitumor antibiotic, calicheamicin,[238] and was previously approved for the treatment of elderly patients with CD33-positive AML in first relapse. The antibody is directed against the CD33 antigen found on the surface of leukemic blasts and normal immature cells of myelomonocytic lineage, but not on hematopoietic stem cells. CD33 is a sialic acid–dependent adhesion molecule. In a phase I dose-escalation trial, treatment with gemtuzumab ozogamicin resulted in elimination of leukemic cells from peripheral blood and bone marrow in 8 of 40 patients.[239] The basis for approval of the drug was the experience in 142 patients participating in one of three similar trials designed to examine the efficacy and safety of gemtuzumab ozogamicin in patients in first relapse of AML.[216] Across the three studies, 80 patients were 60 years of age or older. The median duration of first remission for the group was 11.1 months. All 142 patients received a first dose of drug, 109 patients received two doses (the recommended treatment course), and five patients received three doses. Roughly 40% of patients were treated as outpatients. Median duration of hospitalization was 24 days. The ORR was 30%. This included patients achieving a CR (defined as [a] leukemic blasts absent from peripheral blood, [b] bone marrow blasts <5% of cellular elements, [c] recovery of neutrophils and platelets, and [d] rbc transfusion independence) and patients achieving a CRp (CR as defined, except delayed platelet recovery). Median survival for the group as a whole was 5.9 months. Median relapse-free survival for responders was 6.8 months. Essentially, all patients had grade 3 or 4 neutropenia and thrombocytopenia. Fifteen percent of patients experienced grade 3 or 4 bleeding events. Infusion-associated events occurred in approximately 10% of patients. Sepsis occurred in 16% of patients; pneumonia in 7%. Grade 3 or 4 hypotension was seen in 9% of patients. Twenty-three percent of patients experienced grade 3 or 4 elevation of serum bilirubin levels, and 17% of patients had grade 3 or 4 elevations of hepatic transaminases. Two deaths were associated with liver abnormalities. Eleven patients died during the treatment period of causes other than disease progression. There was no treatment-associated cardiotoxicity, cerebellar dysfunction, or alopecia. Gemtuzumab ozogamicin was withdrawn from the United States market in 2010 due to lack of clinical benefit in subsequent trials, but it remains available in Japan and for selected investigator-initiated research. Inotuzumab ozogamicin is a similar immunotoxin linking calicheamicin to an IgG4 antibody against CD22, and is in phase III trials in B cell lymphoma.[240]

Neoplasms bearing the high-affinity IL-2 receptor have been approached with a genetically engineered, bacterially expressed IL-2-diphtheria toxin fusion protein, denileukin diftitox.[241] Denileukin diftitox was approved in 1998 for the treatment of patients with relapsed cutaneous T cell lymphoma (CTCL). This was the first approval for drugs of the recombinant fusion toxin class. The development of this molecule is detailed in a recent review.[242] The basis of approval was a pivotal trial conducted in 73 patients with disease that was refractory to other therapy (patients having received three or more previous treatments).[243] Patients were randomized to either a low dose (9 μg/kg/day) or high dose (18 μg/kg/day) of the fusion toxin. Patients were treated on 5 consecutive days in 21-day cycles for up to 8 cycles.

Seventy-one patients received a drug. The ORR was 30%, and CR rate was 10%. Rates and durations of response did not differ between the two treatment groups. Adverse events included flu-like symptoms, acute infusion-related events, and vascular leak syndrome. Approximately three-fourths of the patients experienced transient elevations of hepatic transaminase levels and hypoalbuminemia; approximately 15% of patients experienced grade 3 or 4 elevations of liver enzymes or hypoalbuminemia. The success of this trial, to some extent, allays concern that a major problem with this family of fusion toxins would be previous immunization of most of the American population with diphtheria toxoid in childhood. Although approximately one-half of patients had antibodies against diphtheria toxin at baseline and almost all patients had antibodies after treatment, these did not appear to affect treatment outcome.[243,244]

An anti-CD30 antibody, brentuximab vedotin, an antibody-drug conjugate composed of the anti-CD30 chimeric IgG1 monoclonal antibody cAC10 and the potent antimicrotubule drug monomethylauristatin E connected by a protease-cleavable linker, is increasingly being used in hematologic malignancies.[245] Several trials have shown durable antitumor activity with a manageable safety profile in patients with relapsed/refractory Hodgkin lymphoma,[246] systemic anaplastic large-cell lymphoma, or primary cutaneous CD30-positive lymphoproliferative disorders.[247] Treatment with single-agent brentuximab vedotin resulted in objective response rates and CR rates of 75% and 34%, respectively, in relapsed or refractory Hodgkin lymphoma; and of 86% and 57%, respectively, in relapsed or refractory systemic anaplastic large-cell lymphoma patients.[247] Peripheral sensory neuropathy and neutropenia were observed with brentuximab vedotin but were generally grade 1 and 2 in severity and manageable. In August 2011, brentuximab vedotin was approved in the United States for the treatment of Hodgkin lymphoma after failure of autologous stem cell transplant (ASCT) or after failure of at least two prior multiagent chemotherapy regimens in ASCT-ineligible candidates, and for the treatment of systemic anaplastic large-cell lymphoma after failure of at least one prior multiagent chemotherapy regimen.

Bispecific Antibodies

Bispecific antibodies are antibody constructions that recognize a tumor-associated antigen (TAA) with one arm and recognize and activate an immune effector cell structure with the other arm.[248,249,250] In theory, approximation of a tumor cell with an activated immune effector could result in tumor cell elimination. These bispecific antibodies can be obtained either by chemical heteroconjugation or by fusion of 2 hybridomas of desired specificity to yield a tetradoma. With either approach, chromatographic or other separation techniques are required to isolate the desired product.

Strategies using antibodies to activate phagocytic cells, NK cells, and T lymphocytes have been examined. In preclinical models, anti-Id x anti-CD3 bispecific antibodies have demonstrated the ability to inhibit tumor cell growth.[251–253] Recognizing the need for costimulation in T cell response, other investigators have used a combination of bispecific antibodies, anti-CD3 x anti-TAA and anti-CD28 x anti-TAA, with interesting results.[248]

Blinatumomab, a new novel class of T cell engaging bispecific single-chain antibody (BiTE® antibodies) engages T cells for redirected lysis of CD19 positive target cells.[254] CD19 is stably expressed on the majority of B cell malignancies. A phase I trial in patients with indolent NHL showed efficacy.[255] A phase II study of blinatumomab patients with B-lineage ALL, with persistent or relapsed MRD, resulted in an 80% MRD response rate. After a median follow-up of 33 months, the RFS of the whole evaluable study cohort of 20 patients was 61%, while 9 patients who received allogeneic hematopoietic stem cell transplantation (HSCT) after blinatumomab treatment had a hematologic RFS rate of 65% (Kaplan-Meier estimate). Amongst patients who were Philadelphia (Ph)–negative, 4/6 MRD responders with no further therapy after blinatumomab were in ongoing hematologic and molecular remission. Thus, blinatumomab may have a role in inducing long-lasting CRs in B-lineage ALL patients with persistent or recurrent MRD.[256]

Bispecific antibodies have been used in the treatment of patients with refractory Hodgkin lymphoma.[257,258] In an initial phase I/II trial,[258] 15 patients were treated with an NK cell–activating bispecific monoclonal antibody directed against the Fcγ-receptor III (CD16 antigen) and the Hodgkin-associated CD30 antigen. The antibody was administered every 3 to 4 days x 4. Dose-limiting toxicity was not encountered up to and including the highest dose administered, 64 mg/m^2. Side effects were unusual, but included fever, pain in involved lymph nodes, and maculopapular rash. Nine of 15 patients developed a human antimouse antibody response that resulted in allergic reactions in four patients who were retreated. Duration of one CR was 16 months, and partial responses endured for a median of 3 months. These results prompted a second trial to investigate the effects of different administration schedules and the concomitant administration of cytokines on the effectiveness of the bispecific antibody.[259] Sixteen patients were treated with 25 mg of the construct four times, either as a continuous infusion for 4 days or a 1 hour infusion every other day. Patients who exhibited response were retreated at 4-week intervals, if possible. Patients with stable disease received retreatment after administration of IL-2 and granulocyte-macrophage colony-stimulating factor (GM-CSF). Four patients responded to the treatment (three partial remissions and one complete remission). Durations of response were from 5 to 9 months.

Bispecific antibodies, as an approach to immunotherapy, appear to have garnered more enthusiasm and engendered more activity in the treatment of solid tumors.[260] This approach as an immunotherapeutic strategy is also being explored in overcoming drug resistance cell lines in B cell malignancies,[261] as well as the allogeneic HCT setting, to enhance the graft-versus-tumor effect, while minimizing graft-versus-host disease (GVHD).[262] Relatively minor results have not given rise to large-scale trials. Gupta et al. in a preclinical study showed that two bispecific HexAbs (IgG-[Fab]4 constructed from veltuzumab [anti-CD20 IgG] and milatuzumab [anti-CD74 IgG]) show enhanced cytotoxicity in mantle cell lymphoma (MCL) and other lymphoma/leukemia cell lines, as well as patient tumor samples without a crosslinking Ab, compared with their parental mAb counterparts, alone or in combination. They may thus constitute a new class of therapeutic Abs by invoking the juxtaposition and engagement of 2 independent targets on a cancer cell.[263] A trifunctional bispecific antibody, FBTA05, is now in preclinical studies.[264] It is designed to target human CD20 and human CD3, simultaneously binding B cells and T cells by its variable regions and recruiting FcγR-positive accessory immune cells by its intact Fc region. The cytotoxicity of FBTA05 on ex vivo cells from patients with CLL was comparable with that induced by alemtuzumab, exceeded the antineoplastic effects of rituximab, and was effective in elimination of malignant B cells even if CD20 surface expression was low. Importantly, a high grade of cytotoxicity was associated with the induction of T cell proliferation and the concomitant release of interferon-γ and IL-6, thus overcoming the detrimental effects of an unfavorable effector:target cell ratio.[265] These unique approaches appear to further improve the antineoplastic efficacy of mAbs in hematologic malignancies.

Cytokines

Interferons

The interferons (IFNs) constitute a family of cytokines that were initially recognized by their abilities to interfere with viral replication.[199] Two major classes of IFNs exist: type I,

consisting primarily of IFN-α and IFN-β; and type II, consisting of IFN-γ. Type I IFNs are produced by many cell types. Type II IFN is produced by T lymphocytes. Signaling in this system involves the janus kinase (JAK) family and the STATs.[266] Transmission of IFN-specific signals results in induction of a number of genes, including several transcription factors, MHC class I and class II (primarily in response to IFN-γ) molecules, and a number of proteins that are responsible for the antiviral activity of the IFNs, including the (2′ to 5′) oligoadenylate synthase–nuclease system.[267] Promoters for these genes share an IFN-stimulated response element that has a consensus structure of AGTTTCNNTTTCNC/T.[268] The nature of the IFN antitumor action is as yet ill defined. Early observations involving virally induced tumors demonstrated that IFNs could inhibit tumor growth.[269] These observations were later extended to nonvirally induced tumors.[270] The marriage of molecular biology and the entrepreneurial biotechnology industry produced recombinant IFNs early on, and these molecules have been used extensively in clinical trials since the early 1980s. IFN-α has found its way into the therapeutic armamentarium, but IFN-γ has not. The most successful applications of these substances have been in chronic myelogenous leukemia (CML) and HCL.

In chronic-phase CML, IFN-α has demonstrated the ability to control blood counts and to induce complete hematologic response in perhaps 70% of patients, and complete cytogenetic responses in 25% of patients.[271,272–275,276,277,278] Typical administration schedules have been 5×10^6 U/m^2/day or three times weekly. These results have been achieved with significant side effects, including initial flu-like symptoms that abate at approximately 2 weeks, then later fatigue, weight loss, neurotoxicity, depression, and insomnia. Rare cardiac and autoimmune side effects have occurred, including arrhythmias and congestive heart failure as well as hemolytic anemia, thrombocytopenia, rheumatologic disorders, hypothyroidism, and nephrotic syndrome. The role of IFN-α in the treatment of CML and its effect on remission duration and survival are controversial. One large multicenter trial failed to demonstrate a correlation between cytogenetic response to IFN-α and remission duration or survival,[274] but in a head-to-head comparison of IFN-α with hydroxyurea, significantly improved survival was seen in the IFN-α–treated group.[276,279,280] In this study, most of the benefit of IFN-α appeared to accrue to the patients who achieved a major cytologic response, all of whom were in the IFN-α–treated group. In the era of imatinib mesylate, the role for IFN-α remains to be defined.[277,278]

In HCL, IFN-α became the first effective, nonsurgical treatment; splenectomy was the first treatment approach. A number of studies conducted with partially purified, then recombinant IFN-α demonstrated that approximately 75% of treated patients achieved a complete or partial response.[281–285] Median durations of response were 12 to 24 months, with virtually all patients eventually relapsing. However, most patients responded to a second treatment course of IFN-α. The mechanism of IFN-α action in this disease is unknown. Both antiproliferative[286] and immunomodulatory[287,288] events have been demonstrated in treated patients. Although IFN-α is an active agent in HCL, the remarkable effectiveness of short courses of cladribine in inducing sustained complete clinical remissions in this disease make it the treatment of choice for most patients with the disease.

Interferon-α also has been used in the treatment of NHL.[143] As a single agent, interferon-α has modest activity in indolent lymphomas, but toxicities are significant (at the doses generally used) and remission durations are generally short, with little effect on response rates and perhaps a reduction in the rate of transformation to higher-grade lymphoma,[289] moderate prolongation of remission durations, but, with one exception,[290] no effect on OS.

IFN-α may also be a useful agent in the treatment of multiple myeloma.[291,292] When used in combination with chemotherapy, IFN-α may improve initial response rate and PFS. A pilot trial conducted by the Eastern Cooperative Oncology Group suggested that IFN-α treatment in combination with chemotherapy led to increased response rates and prolonged disease-free interval by 12 months over that expected,.[293] In a large randomized trial of 256 patients,[294] IFN-α maintenance treatment produced improved disease-free survival of 17.8 versus 8.2 months for the control group and OS of 50.6 versus 34.4 months. Both differences were statistically significant. Inclusion of IFN-α during induction therapy appeared to confer further benefit. However, in a large cooperative group trial,[295] no benefit was seen to IFN-α maintenance therapy. A meta-analysis of 24 randomized studies involving more than 4,000 subjects indicated that IFN-α improves relapse-free survival to a moderate degree and OS to a marginal degree in multiple myeloma. Therefore, the role of IFN-α in the treatment of multiple myeloma remains controversial. Its cost and side effects must be considered when contemplating the use of IFN-α. Furthermore, its usefulness has been questioned in melphalan-prednisone–treated patients,[296] in patients receiving high-dose steroids,[297] and in the elderly.[298] Recombinant IFN-γ1b has been used to enhance the immune system in high risk cancer patients treated with granulocyte transfusions, as well as to treat fungal infections in the allogeneic hematopoietic stem cell transplant setting.[299] Type I IFN (HLBI, IFN-α2b and IFN-β) has been shown to enhance antileukemic cytotoxicity of $\gamma\delta$ T cells in in vitro models.[300] IFN-α is effective in polycythemia rubra vera, particularly in the young or pregnant patient.[301]

Interleukin-2

IL-2 was first recognized as a growth factor for T lymphocytes.[302,303] Its discovery allowed the cloning and long-term propagation of antigen-specific T cell clones.[304,305] In addition, it was determined that IL-2 treatment led to gain of function, particularly increased cytotoxicity in T lymphocytes[306] and NK cells.[307] The possibility of generating or potentiating specific immune responses for clinical applications made the production of IL-2 one of the earliest targets of the biotechnology industry. Recombinant IL-2 was available for clinical application by 1983,[308] only 5 years after the activity was first described.

IL-2 binds specifically to receptors (IL-2R) on target cell surfaces.[309] Most resting lymphocytes display only intermediate-affinity receptors made up of IL-2Rβ and IL-2Rγ polypeptide chains. A number of stimulatory signals lead to production of IL-2Rα chains and the display of high-affinity heterotrimeric receptors of IL-2Rα, IL-2Rβ, and IL-2Rγ chains. IL-2Rα contributes a rapid association rate with IL-2, whereas the IL-2Rβ and IL-2Rγ chains provide a slow dissociation rate. The resulting rapid on rate and slow off rate results in an equilibrium dissociation constant ($K_d = 10^{-1}$ mol).[310] With approximately 750 receptors per cell surface, an endocytosis-related half-life of approximately 15 minutes, and an apparent requirement of 10,000 occupied receptors before commitment to cell cycle progression, it is likely that optimal treatment strategies will require prolonged, continuous administration of the cytokine.[311]

Early experience with IL-2 used increasing doses, seeking optimal effect. However, at high intravenous dose (greater than 10^{-8} mol peak concentration, attempting to saturate intermediate-affinity IL-2R on target cells), IL-2 produced significant, life-threatening toxicities.[312] These side effects included fever and chills initially followed by a constellation of problems resulting from a capillary leak syndrome, including hypotension requiring pressor support in a majority of patients, significant weight gain, respiratory distress occasionally requiring intubation, oliguria, renal dysfunction, and death in approximately 1% of patients. Additional side effects included nausea, vomiting, diarrhea, cardiac arrhythmia, liver dysfunction, mental status changes, anemia, and thrombocytopenia. Because of

these severe side effects, arbitrary ad hoc dose adjustments and well-controlled clinical trials have attempted to reduce dose while maintaining clinical efficacy. At doses approximately 300 to 500 times less than those initially used, marked increases in circulating levels of NK cells without induction of immune-mediated pathology have been demonstrated.[313] Continuous intradermal and intermittent subcutaneous administration schedules have been evaluated.[311]

IL-2 has been used in the treatment of AML. A few studies have been conducted in patients with active disease.[314–317] Of these patients, a small minority had complete remissions, which were generally of brief duration. However, in several instances the IL-2–induced/maintained remission duration exceeded that of previous remission durations. This experience prompted an examination of IL-2's ability to prolong remission after chemotherapy.[318] Seventeen patients with AML were treated with IL-2 or IL-2 plus lymphokine-activated killer (LAK) cells after autologous bone marrow transplantation (BMT). Five of these patients relapsed between 2 to 10 months, one died in therapy, but 11 remained in complete remission 12 to 54 months after BMT. All of the surviving patients demonstrated remission inversion. Similar results were reported in seven patients treated with polyethylene glycol–conjugated IL-2 administered as the sole postremission therapy after induction of a second complete remission.[319] More recently, a pilot study of IL-2 in patients in first remission has been reported.[320] The results suggest that more patients were alive at 3 years than would have been predicted by observations in historical controls. These results suggest that consolidative IL-2 administered early in remission induction can decrease relapse rate and suggest that prospective randomized comparisons are warranted.

Despite difficulty meeting accrual goals in several studies,[321] some experience has been gained using IL-2 in NHL, Hodgkin disease, and CTCL. In general, response durations in these diseases are brief and clinically insignificant.[143] However, a few remissions of prolonged duration have been reported. European investigators examined continuous-infusion high-dose IL-2 alone in patients with heavily pretreated lymphomas of various subtypes.[322] In 24 patients with low-grade lymphomas resistant to anthracycline-containing regimens, one CR was seen. In 23 patients with intermediate- or high-grade lymphomas refractory to primary therapy or salvage therapy, three complete remissions and two partial remissions were documented. No responses were seen in seven patients with Hodgkin disease. In seven patients with mycosis fungoides refractory to chemotherapy, one complete remission and four partial remissions were seen. These authors concluded that further testing with IL-2 in patients with aggressive lymphoma and CTCL was warranted. This experience with CTCL is particularly provocative because a direct effect of IL-2 on tumor cells, which often bear the IL-2R, is likely and may relate to the mechanism by which the IL-2 effect was manifest in this trial.

Use of IL-2 has been investigated in myelodysplastic syndrome (MDS).[323] Its utility, in this setting, remains to be defined. IL-2 is critical for Treg cell development, expansion, activity, and survival.[324,325] Investigators found that the administration of daily subcutaneous low-dose IL-2 in patients with active chronic GVHD rapidly induced preferential and sustained Treg cell expansion, reversed advanced manifestations of chronic GVHD, and permitted a substantial reduction in the glucocorticoid dose.[326] Conversely, the binding of basiliximab and daclizumab, two IL-2 receptor antagonists (IL-2RAs) that bind to the α-subunit of the IL-2R (CD25), found predominantly on the surface of activated cytotoxic T cells, induced proliferation and provides selected immunosuppression, prevents GVHD efficiently and feasibly following unrelated donor-peripheral blood stem cell transplantation (URDPBSCT) and contributes to favorable outcome.[327]

Cellular Approaches

Graft-versus-leukemia Effect

Despite the fact that early studies in murine leukemia suggested that allogeneic HCT would confer a lower risk of relapse than syngeneic HCT,[328] and this information was used as part of the rationale for early clinical HCT,[329] the reality of a graft-versus-leukemia (GVL) effect in human transplantation was slowly recognized.[330,331] Significant indirect evidence for a GVL effect can now be cited.[332] Anecdotal reports have documented remission reinduction after a flare of GVHD[333] or on rapid withdrawal of immunosuppression.[334] Furthermore, a number of studies have confirmed that syngeneic HCT is associated with a higher risk of relapse than allogeneic HCT.[335,336] Other studies, including large retrospective analyses by the International Bone Marrow Transplant Registry,[337] have demonstrated a protective effect of GVHD. Non-T cell–depleted transplant recipients with acute, chronic, and acute plus chronic GVHD had a lower likelihood of relapse than did patients receiving non-T cell–depleted HCT who had no GVHD. Patients who received non-T cell–depleted HCT and experienced no GVHD still had a lower likelihood of relapse than patients receiving syngeneic HCT. These data have been interpreted to support the notion that graft-versus-leukemia effects can be seen in the absence of GVHD. Of note, it appears that the potency of the graft-versus-tumor effect differs among neoplasms.[338] The graft-versus-tumor effect is obvious in AML and CML, has been suggested in lymphoma,[339] but at least in one study was absent in ALL,[340] and has been less apparent in myeloma.[341]

The molecular and cellular mechanisms that underlie the GVL effect are becoming better understood.[332,338,341,342] Furthermore, the relationship between the GVL effect and GVHD is becoming better defined. Some antigens relevant to these processes have been identified. Although MHC differences have long been associated with GVHD, the role of minor histocompatibility antigen expression in GVHD and the GVL effect is becoming apparent[338,340,341,343,344,345] (Fig. 70.5). In a murine model, administration of allogeneic T cells specific for a single minor histocompatibility antigen resulted in an antileukemic response without a graft-versus-host response.[346] Other antigens may be important as well.[346] Immune responses against the neoantigens expressed from the *BCR/ABL* fusion in CML[347,348] and the *PML/RαRα* fusion in acute promyelocytic leukemia[349] have been demonstrated. Their relevance is suggested by the disease-specific efficacy of DLI, but their true relevance in the clinical setting remains to be defined.

The immunologic effectors of GVHD and GVL are also being dissected. It is apparent that T lymphocytes must play a large role in these reactions, for their removal results in a marked decrease in GVHD and marked increases in relapse frequencies.[350] The role of NK cells in mediating the GVL effect is increasingly being investigated.[351,352] Preclinical studies in mice have shown that different combinations of activating and inhibitory receptors on NK cells can reduce GVHD, promote engraftment, and provide superior graft-versus-tumor responses. Emerging clinical data have shown that the use of KIR-ligand incompatibility produces a potent graft-versus-leukemia effect in patients with AML at high risk of relapse.[352] Recent evidence suggests that $CD4^+$ T lymphocytes may be particularly important in the GVL effect.[353,354] Allografts selectively depleted of $CD8^+$ T lymphocytes ($CD4^+$ T lymphocytes preserved) demonstrated a low incidence of GVHD yet a preserved GVL effect similar to that seen with unfractionated HCT in patients with CML. These clinical findings are supported by similar findings in animal models[355] and by the demonstration of donor-derived, HLA-identical, cytotoxic $CD4^+$ T cell clones of multiple specificities in a patient with severe GVHD after transplantation for CML.[356] T-helper subset 2 and T-cytotoxic subset 2 may be particularly important in the regulation of GVHD and

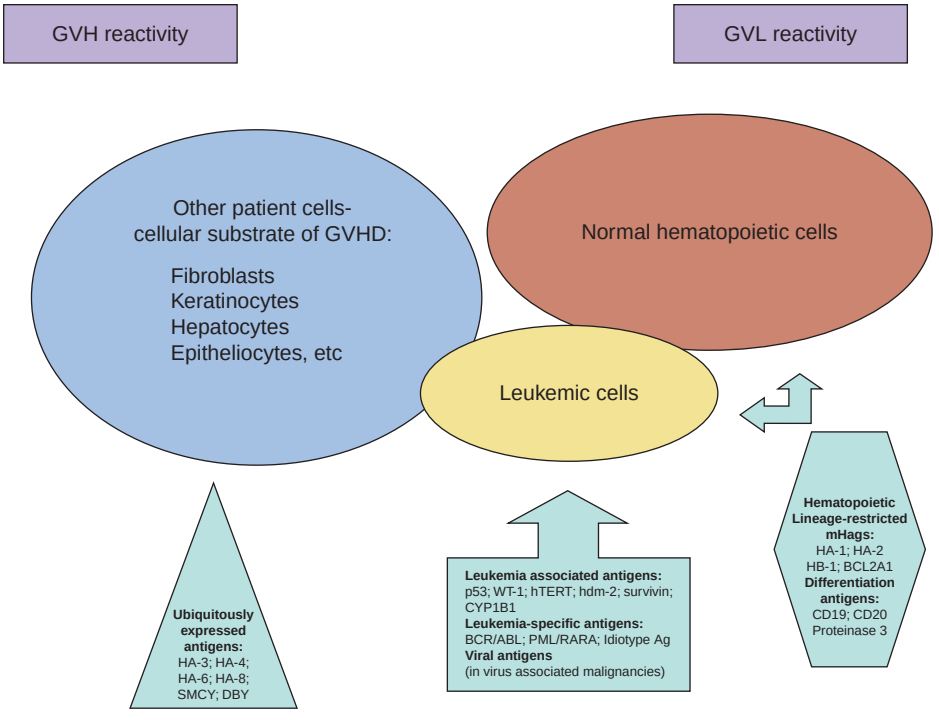

FIGURE 70.5. Antigenic basis of graft-versus-leukemia (GVL) and graft-versus-host (GVH) immune responses. Graft-versus-leukemia reactivity is mediated by immune responses specific to antigens with expression restricted to leukemic cells (leukemia-specific and certain viral antigens) and patient hematopoietic cells (hematopoietic lineage–restricted minor histocompatibility antigens, hematopoietic differentiation antigens). Reactivity to leukemia-associated antigens contributes to GVL mostly, although these antigens are expressed at low levels in normal tissues. Ubiquitously expressed antigens are a substrate of GVH disease. Ag, antigen; GVHD, graft-versus-host disease; mHags, minor histocompatibility antigens. (Adapted from Ivanov R, Hagenbeek A, Ebeling S. Towards immunogene therapy of hematologic malignancies. Exp Hemat 2006;34:251–263).

mediation of GVL effects.[357] Development of MHC-tetramer technology has provided a means to visualize antigen-specific T cell responses.[358] This technology can be used to correlate individual T cell responses with a clinical course. In an early application of the approach, Mutis et al.[359] demonstrated that the frequencies of T cells specific for the HY and HA-1 minor histocompatibility antigens correlated with the severity of GVHD.

A number of strategies have been proposed to enhance the GVL effect and reduce GVHD.[338,360] These include a reduction in the total number of T lymphocytes used in transplantation, delayed transfusion of donor lymphocytes,[361] $CD8^+$ T lymphocyte depletion, ablation of thymidine kinase gene–transfected donor T lymphocytes with ganciclovir administration in case of GVHD,[362,363] administration of IL-2[364] and use of IL-2 receptor antagonists,[327] functional depletion of antihost lymphocytes without depletion of antimyeloid lymphocytes,[365,366] and ex vivo generation of leukemia-specific T lymphocytes.[367]

The approach that has garnered the most attention recently has been mini-allografting.[368,369,371] High-dose chemotherapy with stem cell rescue has proven to be an effective, potentially curative approach to the treatment of several malignancies. However, this technique is associated with significant morbidity and mortality. The success of DLI (see section "Donor Leukocyte Infusions") for the treatment of CML and other hematologic malignancies has suggested that much of the benefit of allogeneic HCT is mediated by the graft-versus-malignancy effect. Several groups have evaluated the effects of safer, less toxic approaches to HCT. Shimoni et al.[369] described their experience with allogeneic HCT using nonmyeloablative regimens in 116 patients. These low-dose regimens were designed, not to eradicate host hematopoiesis, but to allow induction of the GVL effect as the primary treatment mechanism. Forty-six patients with advanced age or significant organ dysfunction and diagnoses of CML, AML, or myelodysplasia, were treated with purine analog/cytarabine combinations to provide sufficient immunosuppression to allow engraftment of allogeneic progenitor cells. Thirty-six of 40 evaluable patients receiving related-donor HCT engrafted with donor cells—23 patients—achieved complete donor chimerism, and 13 patients were mixed chimeras. Death attributed to treatment-related causes occurred in 8 patients. Twenty-eight of 31 evaluable patients with AML or MDS achieved a CR. Three patients died in remission. Fifteen patients relapsed. Six of the 15 patients received donor leukocyte infusion, but none responded. Eleven patients had CML. Eight of nine patients who received related-donor grafts achieved complete hematologic and cytogenetic remission. Two-thirds of patients treated in chronic phase were alive at 2 years. Seventy patients were treated with purine analog/melphalan nonmyeloablative regimens in an attempt to improve outcomes for patients with active chemorefractory leukemia at the time of HCT. Sixty-two of 64 evaluable patients had engraftment of donor hematopoietic cells. Treatment-related mortality was estimated at 45%. Median survival for the group was 4.5 months. Survival at 1 year was 37% and at 2 years was 31%. Investigators at the Center for International Blood and Marrow Transplant Research (CIBMTR) found that following HCT using myeloablative conditioning (MAC), GVHD had an adverse effect on transplant-related mortality (TRM) with early modest augmentation of GVHD-associated GVL. While following reduced-intensity conditioning (RIC), GVL may be important in limiting both early and late leukemia recurrence.[372]

Donor Leukocyte Infusions

A number of authorities consider the success of DLI to be the most compelling proof of a GVL effect.[373] In 1990, Kolb et al.[374] reported three patients with relapsed CML after marrow transplantation that were treated with infusion of buffy coat leukocytes from the donor and IFN-α. Complete hematologic and cytogenetic responses were seen in these patients. Since then, the phenomenon has been replicated and extended by many investigators.[373,375,376] A broad experience of 25 North American transplant centers has been reported,[377,378] confirming the remarkable efficacy of this approach in patients with relapsed chronic-phase CML and the less impressive response rates in advanced CML and acute leukemia. The collective experience suggests that in cytogenetic relapse or clinical chronic-phase relapse of CML,

complete cytogenetic remission can be attained in 80% of patients. However, patients with more advanced disease have a much lower, perhaps 25%, chance of remission. When the technique has been applied to patients with AML relapsing after allogeneic BMT, response rates have been only 15% to 20%.[376]

The timing and application of DLI in other hematologic malignancies following hematopoietic stem cell transplant is still being explored. The clinical benefit of DLI in AML was explored in a retrospective analysis on the role of DLI in the treatment of relapsed AML after allogeneic HSCT by the European Group for Blood and Marrow Transplantation (EBMT) Acute Leukemia Working Party. They analyzed the data of 399 patients with AML in the first hematologic relapse after HSCT whose treatment did (n = 171) or did not (n = 228) include DLI. After a median follow-up of 27 to 40 months, respectively, estimated survival at 2 years was about 21% for patients who received DLI and 9% for patients who did not receive DLI. Improved outcome was associated with younger age (<37 years; P = 0.008), relapse occurring more than 5 months after HSCT (P < 0.0001), and use of DLI (P = 0.04). Among DLI recipients, a lower tumor burden at relapse (<35% of bone marrow blasts; P = 0.006), female sex (P = 0.02), favorable cytogenetics (P = 0.004), and remission at time of DLI (P < 0.0001) were predictive for survival in a multivariate analysis. Two-year survival was 56% if the DLI was performed in remission or with favorable karyotype, compared to 15% if the DLI was given in aplasia or with active disease.[378] Anecdotal reports of responses have been generated in multiple myeloma, CLL, Fanconi anemia, and polycythemia vera.[376] When applied to patients with ALL, Hodgkin lymphoma, and NHL, few responses have been seen.[376]

DLI are not without complications. The two most worrisome are GVHD and pancytopenia occurring weeks after infusion. Predictors of GVHD after donor leukocytes were T lymphocyte depletion in the original transplant marrow and concomitant IFN-α usage. The GVHD induced by DLI appears to respond more readily to immunosuppressive measures than does the GVHD seen with transplantation. Predictors of myelosuppression include frank hematologic relapse and T lymphocyte depletion.[373,377,378,379]

The optimal dose and timing of DLI have yet to be determined.[380] Administered dosage of leukocytes does not necessarily correlate with response,[373,381,382] but there is some evidence that the incidence of GVHD does correlate with dosage,[382] making the notion of infusing fewer cells attractive. Regarding timing, the ability to detect relapse with molecular biologic techniques, such as PCR, allows definition of relapse long before it becomes hematologically apparent. Yet whether DLI should be used before hematologic relapse remains a matter for clinical investigation because transient molecular relapses have been documented.[379] Similarly, the requisite concomitant use of IFN-α has been questioned. In the European trials, use of IFN-α did not appear to improve the response rate to DLI,[337] and a number of studies have documented responses without the use of the cytokine.[379,382]

Adoptive Cellular Immunotherapy

The field of immunotherapy was rejuvenated in the early 1980s by reports of clinical trials with transfer of antitumor cells to tumor-bearing patients.[383,384] Rosenberg et al. pioneered the use of LAK cells plus IL-2.[385,386] LAK cells were derived from resting, autochthonous, peripheral blood mononuclear cells by culture ex vivo in high concentrations of IL-2. After culture, these cells were capable of lysing fresh tumor cells in an MHC-nonrestricted fashion.[387] They were returned to tumor patients with concomitantly administered high-dose IL-2. Although the tumor target structure remains undefined, these determinants appear to be broadly distributed on fresh and culture tumor cells and not expressed on normal cells in vivo. LAK cells appear to be derived from the NK subset of human lymphocytes bearing the NK markers CD16 and CD56, and usually lacking the CD3 structure.[388,389] Initial reports with LAK plus IL-2 in patients suggested a significant response rate in NHL, but most emphasis has been given to solid tumors, particularly renal cell carcinoma and melanoma.[390,391] Studies suggested that LAK cells do not consistently home to the site of tumor involvement, significantly limiting their therapeutic efficacy,[392] and have demonstrated no advantage for the administration of LAK plus IL-2 over administration of IL-2 alone.[390]

A search for more potent killer cells resulted in the description of tumor-infiltrating lymphocytes (TILs).[393] These cells could be isolated and grown from single-cell suspensions of tumor specimens in IL-2. They have the phenotype of classical cytotoxic T cells and kill tumor cells in an MHC-restricted manner. In animal studies, TILs are approximately 50 to 100 times more potent killers than are LAK cells. TILs also more efficiently home to and accumulate in tumor deposits.[394,395] Pilot trials[386,396] have demonstrated a response rate of approximately 35% in patients with melanoma.

The rather modest response rates, the extremely labor-intensive nature of these treatments, and the serious toxicity of systemically administered IL-2 have markedly limited enthusiasm for these approaches to treatment, but they stand as important milestones on the road to effective immunologic treatments for neoplastic hematologic diseases and solid tumors. The remarkable success of adoptively transferred, virally specific, ex vivo expanded T lymphocytes for control of cytomegalovirus infection in patients after allogeneic HCT[397–398,399] suggests that, if appropriate tumor cell antigens can be found and exploited, this form of therapy may become a useful modality in the treatment of hematologic malignancies.[400,401]

Engineered cells, using autologous chimeric antigen receptor-modified T cells reinfused into a patient with refractory CLL, expanded to a level that was more than 1,000 times as high as the initial engraftment level in vivo, with delayed development of the tumor lysis syndrome and with complete remission. A specific immune response was detected in the bone marrow, accompanied by loss of normal B cells and leukemia cells that express CD19. Remission was ongoing 10 months after treatment. Hypogammaglobulinemia was an expected chronic toxic effect.[402] Also, transplants using lectin-separated, E-rosette–depleted (SBA-E-) allogeneic marrow– or granulocyte colony-stimulating factor–mobilized $CD34^+$ peripheral blood progenitor cells, which were adequately depleted of T cells and administered without posttransplant immunosuppression, have been shown to induce consistent engraftment with low incidences of acute and chronic GVHD, both in HLA-matched and HLA-disparate recipients. Furthermore, the incidence of relapse posttransplant is not increased in patients transplanted for AML, MDS, or ALL.[403]

Immunization Strategies

The central hypothesis of active immunotherapy for cancer is that either the tumor cell itself or antigens derived from the tumor cell (which are specific, or at least selective, for the tumor cell) can be modified and injected back into the patient as a therapeutic vaccine. The desired result is activation of both major arms of the immune response, the host antibody response and a host T cell response, against the target tumor cell or antigen, to aid in the eradication of the disease (Fig. 70.6).

Active Immunotherapy for Lymphomas

Vaccine strategies targeting NHL have largely focused on using the tumor-specific Id as an antigen. The variable regions of the heavy and light chains of the immunoglobulin molecules expressed on the surface of B cells contain unique determinants termed Id that can be recognized as an antigen. Since malignancies of mature and resting B cells arise from clonal proliferation of cells that

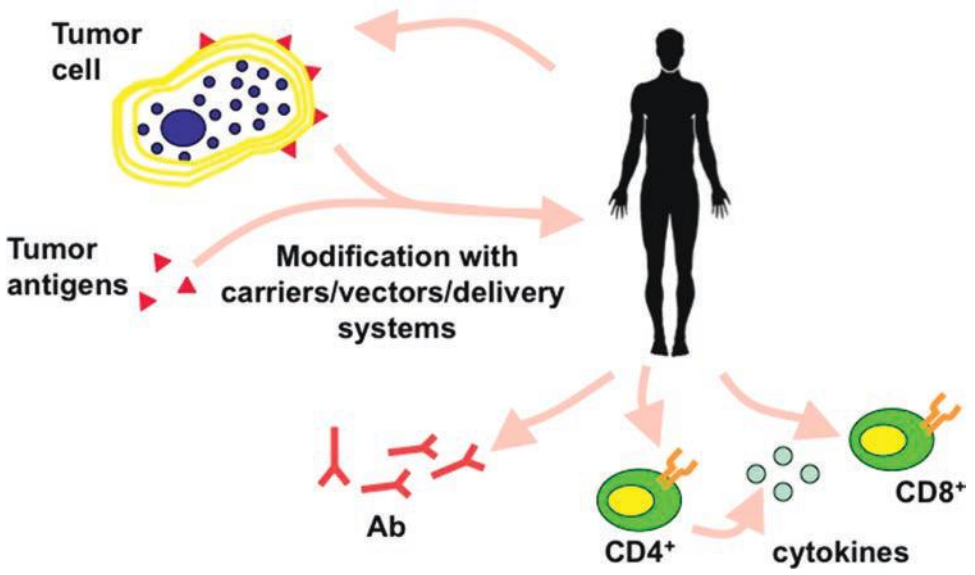

FIGURE 70.6. Therapeutic vaccination against cancer. Active immunotherapy against cancer typically involves the use of tumor cells or antigens derived from the tumor cells that are modified and injected back into the patients to elicit a potent host $CD4^+$ and $CD8^+$ T cell response and possibly a host antibody response against the targeted tumor to aid in the eradication of the disease. Ex vivo modification of tumor antigens or tumor cells may involve the use of conjugation to a carrier molecule, incorporation into viral vectors, transduction of tumor cells with cytokine genes, and/or administration with adjuvants. Ab, antibody.

express immunoglobulins with unique variable region sequences on their surface, the Id of a given B cell malignancy can serve as a tumor-specific antigen and has been exploited as a target for active specific immunotherapy.

Preclinical Studies of Idiotype Vaccines

In the early 1970s, Lynch and Eisen demonstrated in mice that active immunization with purified immunoglobulins from mineral oil–induced plasmacytomas induced Id-specific tumor resistance.[180,181] This phenomenon has been reproduced subsequently in a number of lymphoma, myeloma, and leukemia models.[404–409] In 1987, Kaminski et al. demonstrated that optimal immunization required conjugation to a strongly immunogenic carrier protein, such as keyhole limpet hemocyanin (KLH).[407] Subsequently, Kwak et al. demonstrated that the use of GM-CSF factor as an adjuvant facilitated the induction of tumor-specific $CD8^+$ T cells and enhanced the efficacy of the vaccine in a murine 38C13 lymphoma model.[409] GM-CSF likely acts by recruiting and promoting maturation of professional APCs such as DCs, which may in turn activate pathways of antigen processing that allow exogenous proteins to be presented by class I molecules. Animal studies also demonstrated that idiotypic vaccination conferred protection against tumor challenge and could cause regression of established tumors. Taken together, these results provided the rationale for testing autologous tumor-derived idiotypic surface immunoglobulin as a therapeutic "vaccine" against human B cell NHL.

Pilot Clinical Trial of Idiotype Vaccine

The first human study of Id vaccination was pioneered by Kwak et al., in patients with follicular lymphoma (Table 70.3), which was a pilot study designed to determine whether it was possible to immunize against the Id portion of the protein.[410] Follicular lymphoma patients, in minimal residual disease or complete remission after chemotherapy, were immunized with subcutaneous injections of autologous purified tumor-derived immunoglobulin, conjugated to KLH. Because no Id-specific immune responses were observed before the addition of an immunologic adjuvant to the first group of patients, patients (9 patients) subsequently received the entire series of immunizations with a standard emulsion adjuvant (Syntex adjuvant formulation-1 [SAF-1]). In all, 41 patients were treated in this pilot study, and 41% demonstrated specific anti-Id antibody and 17% demonstrated cellular proliferative responses.[411] Of the 20 patients with residual disease following chemotherapy, two patients had complete regression of the tumor in association with the development of a specific immune response. Thus, these results were important because they demonstrated that patients with lymphoma could be induced to make sustained Id-specific immune responses by active immunization with purified autologous tumor-derived surface immunoglobulin conjugated to the immunogenic carrier KLH. Furthermore, the induction of Id-specific immune responses was demonstrated in the setting of minimal tumor burden after conventional chemotherapy. However, it is important to recognize that convincing T cell responses ($CD8^+$) were not observed, and this single-arm trial was not designed to answer the question of clinical efficacy.

Idiotype Keyhole Limpet Hemocyanin + Granulocyte-macrophage Colony-stimulating Factor Vaccine–induced Molecular Remissions in Follicular Lymphoma

Based on the preclinical observation that the addition of GM-CSF as an adjuvant to the vaccine-induced tumor-specific $CD8^+$ T cells,[409] Bendandi et al. conducted a phase II clinical trial where 20 previously untreated follicular lymphoma patients were treated with autologous tumor-derived Id-KLH + GM-CSF vaccine (in normal saline) following induction of clinical remission with a uniform chemotherapy regimen (prednisone, doxorubicin, cyclophosphamide, and etoposide [PACE])[412] (Table 70.3). This produced a homogeneous group of patients, all in first CR, who were given vaccine treatment in the setting of minimal residual disease. The vaccine was injected subcutaneously in 5 monthly doses starting approximately 6 months after completing chemotherapy to allow time for immunologic recovery. The vaccine was well tolerated, with the main adverse effects being injection site reactions such as erythema, induration, and pruritus. There were no long-term adverse effects due to the vaccine.

Following vaccination, anti-KLH antibody and cellular responses were induced in all patients. Anti-Id antibody responses were induced in 15 of 20 patients (75%) and Id-specific and/or tumor-specific $CD4^+$ and $CD8^+$ T cell responses were observed in 19 of 20 patients (95%).[412] Further characterization of anti-Id cellular immune responses demonstrated that the T cells specifically recognized multiple unique immunodominant epitopes within the hypervariable complementarity-determining

regions, but not framework regions of immunoglobulin heavy chain.[413]

Monitoring of the patients for minimal residual disease showed that 8 of 11 patients with PCR-positive t(14;18) chromosomal translocation breakpoints converted to PCR negativity in their blood immediately after completing vaccination, and sustained their molecular remissions for a median of 18+ months (range: 8+ to 32+ months).[412] Thus, these results provided the first convincing evidence for an antitumor effect of Id vaccination.

Analysis of time to relapse also provided an independent indication of clinical benefit. With a median follow-up of 9.2 years, median DFS is 8 years, and the OS rate is 95%.[414] While definitive statements cannot be made because this was not a randomized trial, the DFS appears superior to that of a historical, ProMACE chemotherapy-treated control group (median DFS, about 2.2 years).[415] Additional studies have also shown that Id vaccines may have potential clinical utility.

Idiotype Vaccine Improved Disease-free Survival in Follicular Lymphoma in a Phase III Trial

The encouraging immunologic and clinical outcome of the Id-KLH + GM-CSF vaccine in the phase II clinical trial led to the initiation of a randomized double-blind placebo-controlled multicenter phase III clinical trial sponsored initially by the National Cancer Institute (NCI) and later by Biovest International, Inc. to definitively answer the question of clinical benefit induced by Id vaccination in patients with follicular lymphoma (Table 70.4).[416] Patient population, induction chemotherapy, vaccine formulation, and trial design were similar to the phase II trial. Following induction of PACE chemotherapy, patients that achieved a CR or CRu were randomized 2:1 to receive either the specific vaccine, Id-KLH + GM-CSF, or the nonspecific immune stimulant, KLH + GM-CSF. Of 117 vaccinated patients, 76 received Id vaccine and 41 received control. After a median follow-up of 56.6 months, median DFS was 44.2 months for the Id vaccine arm and 30.6 months for the

control arm ($P = 0.047$). Interestingly, in an unplanned subgroup analysis, the clinical benefit appeared to be restricted to the group of patients that had IgM isotype on their tumors. Median DFS for IgM-Id vaccinated group *v* control was 52.9 *v* 28.7 months ($P = 0.001$), and for IgG-Id vaccinated group *v* control was 35.1 *v* 32.4 months ($P = 0.807$). In summary, this trial showed for the first time that therapeutic vaccination could induce meaningful clinical benefit in patients with lymphoma.[416]

However, two other phase III clinical trials of Id vaccine in follicular lymphoma sponsored by Genitope and Favrille failed to show clinical benefit (Table 70.4).[417,418] Differences in the nature of vaccine products, trial design, and requirement for complete remission status after induction therapy may explain differences in outcomes between these 3 trials. For example, the NCI/Biovest study used the traditional hybridoma technology to generate the vaccine for each patient.[419] This results in production of the native IgM or IgG-Id, depending on the isotype of the Id on each tumor. In contrast, the Favrille and Genitope studies used recombinant DNA technology to clone the variable regions of the tumor Id and fuse them to a common IgG Fc.[420] Ids that have switched to IgG were previously shown to be tolerogenic, whereas Ids of their IgM progenitors were highly immunogenic.[421,422] Moreover, the Fc fragment of IgG has been shown to have highly promiscuous MHC class II T cell epitopes that specifically activate T_{regs} and tip the immune responses toward tolerance rather than immunogenicity.[423] The use of less intensive induction chemotherapy and vaccinating patients with partial remission and/or stable disease may also have contributed to persistence of tumor-induced immunosuppression at the time of vaccination in the Genitope and Favrille studies.

Idiotype Vaccination in Combination with Rituximab

Although the NCI/Biovest study demonstrated that Id vaccination might improve clinical outcome, demonstration of vaccine efficacy after rituximab-containing induction therapy is necessary to integrate Id vaccination into standard of care for lymphomas. Rituximab is an anti-CD20 monoclonal antibody that depletes both normal and malignant B cells.[146,424] Consequently, patients treated with rituximab are unlikely to have peripheral blood B cells and therefore unlikely to generate humoral immune responses following active immunotherapy. Animal studies have yielded conflicting results on the role of B cells in the priming of naive T cells.[52,425–429] To determine the effects of B cell depletion induced by rituximab on immune responses to Id vaccines, twenty-six previously untreated mantle cell lymphoma patients were treated with 6 cycles of dose-adjusted rituximab, etoposide, vincristine, doxorubicin, cyclophosphamide, and prednisone (EPOCH-R), followed 12 weeks later with 5 monthly cycles of autologous tumor-derived Id-KLH + GM-CSF vaccination (Table 70.3).[430] As expected following EPOCH-R, peripheral blood B cells were completely depleted in all patients, began to recover at approximately 6 months, and returned to baseline levels by 1 year in most patients. In contrast, $CD4^+$ T cell numbers decreased only slightly and recovered by the start of vaccination with a median time of 3 months; $CD8^+$ T cell numbers did not change substantially.[430]

Unexpectedly, despite rituximab administration, antibody responses against the carrier molecule KLH and Id were detected in 17 of 23 (74%) and 7 of 23 (30%) evaluable patients, respectively. The humoral responses were delayed and correlated with B cell recovery, with most detected after the fourth or fifth vaccination, compared with after the first or second vaccination in the follicular lymphoma study in which rituximab was not administered.[412] In contrast, vigorous $CD4^+$ and $CD8^+$ antitumor and KLH T cell responses were not delayed and were induced in 20 of 23 patients (87%) and 23 of 23 (100%), respectively, in the absence of circulating B cells,[430] suggesting that professional APCs such as DCs may effectively present antigen to T cells in the absence of B cells. This result was independently confirmed in another clinical trial where induction of anti-KLH and anti-Id or tumor T cell responses was observed in >70% of follicular lymphoma patients vaccinated with autologous tumor-derived Id-KLH + GM-CSF vaccine following treatment with rituximab.[431] Although the median PFS of 24 months was not significantly different from historical controls of mantle cell lymphoma, the median OS of 104 months was markedly better. More interestingly, an antitumor T cell GM-CSF response but not antibody response was significantly associated with OS and time to next treatment, suggesting that antitumor cellular immune responses may significantly delay tumor growth.[432] Taken together, these results indicate that Id vaccines could be administered in the setting of B cell depletion induced by rituximab and may potentially improve clinical outcome.

The Relative Role of Humoral versus Cellular Immunity in Idiotype Vaccine Efficacy

While some murine lymphoma models have demonstrated that the antitumor efficacy of Id vaccine is dependent on the induction of an antibody response,[407,433,434] other lymphoma models have shown that protection against tumor challenge or eradication of established tumors requires a $CD4^+$ and/or a $CD8^+$ T cell response.[409,435,436] An analysis of 136 patients with follicular lymphoma treated with Id vaccination showed that the induction of specific anti-Id antibody responses was associated with significantly prolonged PFS.[437] This study also demonstrated that patients with a favorable FcγRIIa polymorphism that predicts stronger binding of the Fc of antibodies to effector cells had a longer PFS. Thus, patients with FcγRIIa 158 valine/valine (V/V) genotype had a longer PFS than those with valine/phenylalanine (V/F) or phenylalanine/phenylalanine (F/F) genotypes. In contrast, no significant correlation was observed between the development of a cellular anti-Id immune response and PFS. However, it is possible that this study may have underestimated the value of an antitumor T cell response for several reasons. First, cellular responses on this study were measured by a T cell proliferation assay, which is relatively insensitive, compared with assays such as ELISPOT and cytokine flow cytometry.[438] Second, the proliferation assay detects primarily a $CD4^+$ T cell response and may fail to detect a $CD8^+$ T cell response. Third, immunologic assays that demonstrate recognition of native tumors (tumor-specific) may be more clinically relevant to assess T cell responses following cancer vaccination, compared with assays that demonstrate recognition of tumor antigens presented on appropriate APCs (antigen-specific). Finally, 86 of 136 patients (63%) in this study received a chemical adjuvant with the Id vaccine that predominantly induced a humoral immune response.[410,411] In contrast, Id vaccine formulations using DCs[439,440] or cytokines such as GM-CSF[412,430] or IL-2[441] as adjuvants significantly enhanced the induction of cellular immune responses.

Following Id-pulsed DC vaccinations, clinical tumor regressions were associated with the induction of cellular responses, but without an antibody response[439,440] (Table 70.3). Similarly, following Id-KLH + GM-CSF vaccination, patients achieved molecular remissions[412] or CR[442] without a detectable antibody response, suggesting that cell-mediated antitumor immune responses are important for vaccine efficacy. Clinical tumor regression was also observed in a follicular lymphoma patient after administration of a novel liposomal Id/IL-2 vaccine (OncoVAX-Id/IL-2) in the absence of an antibody response.[441] The liposomal vaccine study also showed that the tumor-specific $CD4^+$ and $CD8^+$ T cell responses induced by the vaccine were sustained 18 months beyond the completion of vaccination and were associated with prolonged DFS[441] (Table 70.3). In another study, Nelson et al. demonstrated that the precursor frequency of tumor-specific CTL correlated with freedom from progression following Id vaccination.[443] In treatment of naive indolent B cell lymphoma patients, cellular responses after immunization with Id Fab fragment correlated with tumor

regression andPFS.[444] As mentioned above, antitumor cellular but not humoral immune responses were associated with prolonged survival in mantle cell lymphoma.[432] Taken together, these results suggested that T cell responses could induce tumor regression independent of a humoral response and support the use of lymphoma vaccines in the setting of B cell depletion induced by rituximab-based induction regimens. However, because the relative role of cellular versus humoral immunity for vaccine efficacy is uncertain, it may be advisable to administer booster vaccinations following B cell recovery to optimize humoral responses.

Second-generation Lymphoma Vaccines

The results of clinical trials described above suggest that Id vaccination is safe, induces antitumor humoral and cellular immune responses, and is associated with improved disease-free survival in patients with follicular lymphoma. However, rapid progress in the development of active immunotherapeutic approaches for lymphoma has been hindered by the need to generate a custom-made product for each patient, by a process that is expensive, laborious, and time consuming. An alternative to Id protein vaccination is to directly extract selected membrane proteins from the tumor cells and incorporate them into liposomes along with IL-2. This novel membrane proteoliposome vaccine (Oncoquest-L) could be produced within 24 hours, was observed to be safe in a pilot clinical trial in follicular lymphoma patients, and induced tumor-specific $CD4^+$ and $CD8^+$ T cell responses.[445] Other individualized tumor vaccine formulations in development for NHL include GM-CSF–transduced tumor/bystander cells,[435] CD40-activated tumor cells,[446] and tumor lysate-pulsed DCs.[447,448] However, as with Id protein vaccination, these vaccine formulations also require generating a custom-made product for each patient and therefore may limit the broad applicability of this approach.

Identification of universally expressed lymphoma-specific antigens would lead to development of vaccine formulations that can be used in all lymphoma patients and are therefore easier and less costly to produce. Recently, T cell leukemia lymphoma 1 (TCL1), a coactivator of Akt that promotes cell proliferation and survival and has been shown to be aberrantly expressed in multiple B cell lymphomas, has been suggested as a possible shared TAA for common B cell lymphomas, including follicular lymphoma, CLL, mantle cell lymphoma, diffuse large B cell lymphoma, and splenic marginal zone lymphoma.[449] $TCL1_{71–78}$ peptide-specific $CD8^+$ T cells were shown to lyse autologous primary tumor cells in an HLA-A*0201-restricted manner, suggesting that TCL1 is naturally processed and presented on the surface of lymphoma cells for recognition by cytotoxic T cells. Additional preclinical studies are needed to determine the safety of TCL1 vaccine prior to evaluation in clinical trials.

Active Immunotherapy for Myeloma

Multiple myeloma is characterized by clonal proliferation of plasma cells, all of which secrete the same immunoglobulin molecule (M-protein). Similar to B cell lymphomas, the variable regions of the heavy and light chains of the immunoglobulin molecule secreted by the myeloma tumor cells contain unique idiotypic sequences that can be recognized as an antigen. Therefore, the Id of the myeloma can serve as a tumor-specific antigen and has been exploited as a target for active specific immunotherapy in animal models.[181,405] In addition, the M-protein can be easily isolated from human plasma and purified into a highly refined, safe protein vaccine. Id-specific CTL lines generated from myeloma patients by repeated in vitro stimulation with Id-pulsed DCs specifically recognized and lysed autologous primary myeloma cells,[450,451] validating human myeloma cells as targets of an Id-specific T cell response.

Immunization of myeloma patients with Id vaccine following autologous stem cell transplantation was generally safe. However, Id-specific cellular immune responses were weak and clinical responses were transient or rare,[452–454,455,456] possibly due to the immunocompromised state of myeloma patients from the underlying disease or treatment. Immunization with human telomerase reverse transcriptase and survivin-derived peptides similarly showed low immunogenicity.[457] An alternative strategy is to immunize HLA-matched healthy donors prior to stem cell harvest and transfer the resulting tumor antigen-specific immunity to the patients by stem cell transplantation, with the goal of enhancing the graft-versus-tumor effect without increasing the risk of GVHD. This approach was tested in HLA-matched donor–recipient pairs in the setting of allogeneic stem cell transplantation.[458–460] These studies demonstrated that immunization of healthy HLA-matched stem cell donors with the Id purified from the plasma of the myeloma patients conjugated to KLH was safe, induced KLH and Id-specific T cell immunity in the donors, and could be transferred passively to recipients. Interestingly, donor-derived KLH- and Id-specific humoral, and central and effector memory T cell responses were detectable relatively early after allotransplant, within the first 30 days, despite iatrogenic immunosuppression for GVHD prophylaxis, and were boosted by posttransplant vaccinations in most recipients.[460] Furthermore, transfer of Id-specific immunity from the donors to the recipients was associated with prolonged DFS in the recipients.[458–460] However, a randomized study is necessary to definitively determine whether Id vaccination of the donors is associated with improved clinical outcome in myeloma patients. Nevertheless, vaccination of stem cell transplant donors may represent a safe and novel strategy to improve outcomes of allotransplant by reducing relapse in malignancies for which tumor-specific antigens have been defined, and by protecting against infectious pathogens.

Recently, Dickkopf-1 (DKK1) has been suggested as a shared TAA for myeloma.[461,462] DKK1 is highly expressed by the tumor cells of almost all myeloma patients, and is absent from normal tissues and organs except placenta, uterus, testis, and prostate.[461] DKK1 was shown to suppress osteoblast formation and increase bone destruction in myeloma; and inhibiting DKK1 activity by specific antibodies resulted in increased osteoblast number and bone formation, reduced osteoclast activity, and inhibited myeloma growth in a myeloma mouse model, suggesting a major role for DKK1 in the pathogenesis of myeloma.[463] DKK1 peptide-specific T cell lines and clones generated from HLA-$A*0201^+$ blood donors and myeloma patients effectively lysed primary myeloma cells in vitro and eradicated myeloma xenografts mice.[461] Furthermore, DKK1 vaccine protected mice from developing myeloma and had therapeutic effects against established myeloma in a murine myeloma model, suggesting its potential utility for myeloma patients.[462]

Active Immunotherapy for Leukemias

The identification of several leukemia-associated antigens has generated interest in developing vaccines for leukemia. One of the most studied leukemia antigens is the CML-associated BCR-ABL fusion protein resulting from the reciprocal translocation t(9;22). The demonstration of binding of the peptides derived from the fusion region to several HLA molecules and the induction of T cells that recognize peptide-pulsed target cells in vitro validated this fusion protein as a potential target for immunotherapy. Immunization of the CML patients with the peptides derived from the fusion region in clinical trials showed induction of specific BCR-ABL cellular immune responses and was associated with improved cytogenetic responses in some of the patients.[464,465,466,467] However, additional trials are needed to determine the clinical efficacy of these vaccines, since most patients also received IFN and/or imatinib at the time of vaccination.

Active immunization strategies have also been evaluated in patients with AML and MDS using peptides derived from

overexpressed proteins in leukemia cells such as the WT1, proteinase 3, and neutrophil elastase. A nonamer peptide PR1 derived from both proteinase 3 and neutrophil elastase that had high-affinity binding for the HLA-A*0201 molecule was tested in a phase I/II study in 66 patients with AML, CML, or MDS. Preliminary data suggest a significant increase in the PR1-specific T cells in 25 of 53 patients (47%) with measurable disease and clinical remission in 9 of 25 immune responder patients (36%), including durable molecular remissions in patients with refractory AML.[468] Immunization of patients with AML or MDS with WT1 peptide-based immunotherapy showed a correlation between CTL immune responses and reduction of leukemic blast cells and/or WT1 transcripts.[469,470,471,472,473]

FUTURE DIRECTIONS

The demonstration of induction of antitumor T cell responses by Id vaccination following B cell depletion induced by rituximab[430,431] suggests that active immunotherapy strategies may be combined with passive immunotherapy strategies. Indeed, the use of passively administered antitumor mAbs such as rituximab with vaccines is likely to be complementary. Compared with mAbs, vaccines are likely to target different tumor antigens, can induce immunologic memory, and can induce polyclonal humoral and cellular immune responses, thereby minimizing the emergence of immune escape variants. However, with the increased use of rituximab for the treatment of B cell NHL, further improvement in the potency of the vaccines would require strategies to enhance the T cell responses, since rituximab depletes normal B cells and impairs the generation of antibody responses following vaccination. As described below, several strategies are being explored to achieve this goal.

Over the past two decades, preclinical studies have demonstrated that the induction of an optimal antitumor immune response requires the incorporation of tumor antigen, carrier molecule, and adjuvant as essential components of a cancer vaccine. Consequently, several cancer vaccine clinical trials were conducted to test and define a better tumor antigen, carrier molecule, and adjuvant. While such strategies were successful in enhancing the potency of the cancer vaccines and in inducing remissions in patients with minimal residual disease or small-volume disease, they do not appear to be effective for the treatment of patients with large tumor burdens. Although novel adjuvants such as TLR ligands may prove to be more potent than cytokine adjuvants,[474–476] further improvement of the cancer vaccines would probably also require disruption of the immunoregulatory pathways that modulate the magnitude and duration of the immune response.

Studies in animal models suggest that the T cell immune responses against foreign or self-antigens are regulated by several immunoregulatory pathways and/or peripheral tolerance mechanisms.[121,477,478] For example, T_{regs} have been shown to downregulate T cell responses against foreign antigens as well as tumor antigens.[479] Similarly, CTLA-4, a molecule that is expressed on activated T cells and T_{regs}, was shown to downregulate T cell responsiveness and prevent the initiation and/or limit the magnitude of autoreactive T cell responses.[480] A host of other mechanisms such as PD-1, B7-H1, and B7-H4 were recently described to negatively regulate T cell responses.[121,481] These new insights have led several investigators to hypothesize that the potency of cancer vaccines can be further enhanced by concurrent suppression or blocking of peripheral tolerance mechanisms and/or suppressive immunoregulatory pathways. Dannull et al. have demonstrated that vaccine-mediated antitumor immunity is significantly enhanced in renal cell cancer patients after depletion of T_{regs} using denileukin diftitox[482] (a recombinant IL-2 diphtheria toxin conjugate; also known as Ontak), a Food and Drug Administration–approved drug for the treatment of CTCLs. Similarly, blockade of CTLA-4 in combination with peptide vaccination has resulted in enhanced cancer immunity and durable objective responses in patients with metastatic melanoma.[483,484] Another strategy to enhance the potency of vaccines is to combine them with novel immunomodulatory agents. Lenalidomide, an immunomodulatory drug used for the treatment of myeloma, has been shown to enhance immune responses to pneumococcal vaccine in myeloma patients.[485] Lenalidomide was also demonstrated to augment effects of Id vaccine by enhancing T cell responses and reversing systemic immunosuppression in a mouse model of lymphoma.[486] Taken together, these preclinical and early-phase clinical results support the evaluation of combination immunotherapy strategies in future clinical trials with the cancer vaccine to stimulate an antitumor T cell response, and the simultaneous suppression of immune regulatory pathways to augment the induced T cell response. The existence of multiple immune regulatory pathways necessitates systematic evaluation of these approaches in clinical trials to determine the optimal combination immunotherapy regimen.

CHAPTER 71

GENE THERAPY FOR HEMATOLOGIC DISORDERS

Andre Larochelle, Cynthia E. Dunbar, John Tisdale

INTRODUCTION

The molecular characterization of congenital and acquired human disease over the past several decades has stimulated scientists and clinicians to envision genetic therapy as a new and exciting possibility.[1] By the 1990s, gene transfer technologies had progressed sufficiently to offer real hope for successful widespread clinical application.[2–4] The first replication-defective retroviral vector was described in 1983, offering a safe and feasible route for transfer of exogenous genes to nontransformed human cells.[5] By 1989–1990, clinical studies using gene transfer began.[6,7,8] Hundreds of clinical trials have been completed or are in progress (Fig. 71.1). Although surrounded by expectations, none of the early trials had even minimal evidence for clinical benefit, and in 1996 an expert panel convened by the director of the National Institutes of Health was critical of the premature initiation of clinical gene therapy trials and the subsequent overselling of results by investigators and the media.[9] At the time of the report, no clinical gene "therapy" trial had shown clinical efficacy. The focus thus turned to rationally designed, small-scale clinical trials in diseases for which the pathophysiology is well understood, as well as the more important need for continued basic science investigations into vector systems and target cell biology.[10–12]

Hematopoietic stem cells (HSCs) and lymphocytes have remained central target cell populations for two major reasons: first, they are relatively easy to manipulate ex vivo, and, second, many acquired and congenital diseases are potentially curable by their genetic correction.[13,14] A significant fraction of ongoing human clinical trials target hematopoietic cells or are designed to treat congenital or acquired diseases of the hematopoietic or immune system (Fig. 71.2). Moreover, many important experimental advances in our understanding of hematologic physiology have resulted from the application of gene transfer techniques in vitro or in animal models.[15,16,17–20,21] For instance, retroviral tagging of HSCs has allowed tracking and quantitative analysis of murine and nonhuman primate stem cell behavior, and experiments overexpressing oncogenes or cytokines in primary hematopoietic

cells using similar techniques has helped elucidate the in vivo role of these proteins. Significant advances in gene transfer technology have occurred through systematic preclinical testing in large animal models, and clinically relevant gene transfer levels have now been achieved in these models. These results predicted success in humans, at least for disorders for which modest transfer rates of genes not requiring complex regulation could be curative, and unequivocal efficacy has since been realized.[22,23] These long-anticipated results represented a significant advance for the field, providing not only restoration of immunity in children with severe combined immunodeficiency (SCID), but proof of principle in the context of a human disorder, and a great deal of enthusiasm for returning to the clinic for these and other disorders quickly developed. However, serious adverse events arising as a direct result of insertional mutagenesis have since been reported and efforts to understand these events more fully, develop additional safeguards, and adjust the risk–benefit assessment have now become necessary. Thus, it is particularly important for hematologists to have a general understanding of the field, even if widespread clinical applications may be a decade or more in the future. This chapter reviews the fundamental features of gene transfer technologies and their applications in preclinical and early clinical trials. The pace of the field is rapid, and many details may become obsolete, but the central concepts should remain relevant to any future gene therapy applications.

OVERVIEW OF BASIC CONCEPTS

Gene therapy can be defined as the transfer of a gene or genetic material (DNA or RNA) into a cell with therapeutic intent (Fig. 71.3). The *genotype* of the cell is thus altered, with subsequent gene expression altering the *phenotype* of the cell. The therapeutic agent is the gene product, generally a protein, or less frequently RNA, for example, ribozymes or antisense molecules. This is in contrast to conventional therapies that act by directly altering the phenotype, even if the congenital or acquired defect is a genetic one. Three examples illustrate the conventional approach to underlying genetic disorders. Dietary avoidance of phenylalanine can prevent the consequences of phenylketonuria by circumventing the genetic deficiency of phenylhydroxylase. Cancer chemotherapy acts by preferentially killing tumor cells based on their cell cycle characteristics, thus removing cells with an acquired genetic defect. And factor replacement in hemophilia directly replaces the defective or missing gene product by infusion of an exogenously manufactured or isolated protein. Gene therapy strategies instead attempt to alter the underlying genetic abnormality to circumvent the need for these therapies.

The identification and cloning (isolation) of genes responsible for many congenital disorders, as well as of the cellular genes mutated in acquired disorders such as cancer has led to the concept of genetic correction of affected cell populations. Ideally, actual substitution of a defective gene with a therapeutic gene would be the most desirable method for returning target cells to a normal genotype and phenotype (*gene replacement*). However, this goal requires *homologous recombination*, a complex and inefficient process, and current gene transfer methods predominantly rely on either insertion of new genes into the chromosomes, or on extrachromosomal (*episomal*) maintenance of a newly introduced gene (*gene addition*).[24–26] To date, efforts have focused on *somatic* (nongerm cell) therapy, with genotypic alteration of only the diseased target tissue. Manipulation of germ cells, with transmission of altered genetic material to subsequent generations, is not yet feasible in humans, but the profound ethical and societal implications need to be addressed through the political process before the technology progresses much further.[27] The recent development of induced pluripotent stem cells (iPS cells), whose behavior is analogous to embryonic stem cells (ESCs) but can be derived from somatic cells, has introduced the possibility of genetic manipulation of autologous pluripotent stem cells, circumventing the ethical issues surrounding ESCs.

The vehicle for transferring new genetic material into a target cell is called a *vector*. At a minimum, a vector contains the gene or genes of interest along with regulatory elements such as promoters or enhancers that govern expression of the gene product.

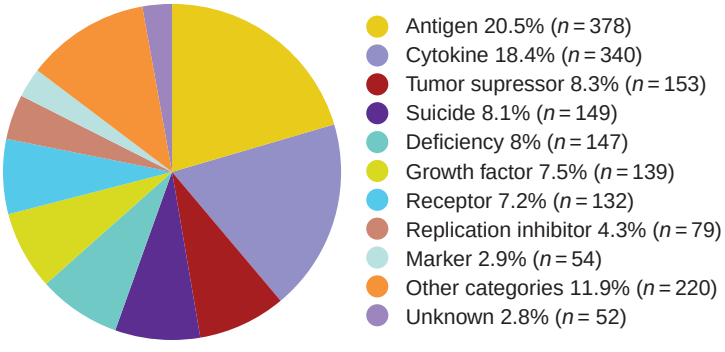

FIGURE 71.3. Gene types transferred in gene therapy clinical trials. (From The Journal of Gene Medicine, © 2012 John Wiley and Sons Ltd, www.wiley.co.uk/genemed/clinical. Reproduced with permission of John Wiley and Sons, Inc.)

A vector may be a simple particle consisting of a fragment of DNA encapsulated within a liposome or conjugated to proteins that facilitate uptake into cells, or may be a more complex viral vector, capitalizing on the ability of viruses to enter cells easily and express genes robustly. Characteristics of the major vector systems are summarized in Fig. 71.4 and Table 71.1, and are detailed in subsequent sections. The successful interaction of a vector with a target cell, leading to an alteration in that cell's genotype, is termed *transduction*.

Vector production procedures are unique to each system, but a number of considerations are common to all, especially those being developed for actual clinical use. A clinical vector must be feasible and practical to produce safely at pharmaceutical grade.[28,29] To prevent indiscriminate spread of viral genomes, most viral vectors designed for clinical applications must be rendered *replication-defective* meaning that once a viral vector enters a target cell, the cell will produce no new viral particles. High-*titer* vector preparations, containing a high concentration of functional vector particles, are also very important, allowing exposure of target cells to the highest possible *multiplicity of infection* (MOI), defined as the ratio of vector particles to target cells; this increases the probability of successful vector–cell interaction.

Exposure of target cells to vectors can occur either ex vivo or in vivo. Autologous hematopoietic targets such as stem cells or lymphocytes are generally transduced ex vivo, because these cells can be easily collected, manipulated in culture, and then reinfused intravenously. Ex vivo transduction allows for a controlled exposure of only the desired target cells to large concentrations of vector, and is less likely to generate an inflammatory or immune response or be hindered by vector inactivation by complement. Other cellular targets for ex vivo transduction have included hepatocytes, keratinocytes, tumor cells, and muscle progenitor cells.

In vivo gene transfer has been used for applications involving cells that cannot successfully or easily be harvested and manipulated ex vivo, such as airway epithelium, vascular endothelium, differentiated muscle cells, retinal pigment epithelium, and neurons. The ideal in vivo system would allow intravenous injection of a vector followed by rapid and safe specific transduction of target cells around the body.

A number of important steps must occur between exposure of a target cell to a vector and successful transduction of that cell, with persistence of the transferred genetic material in the correct cellular compartment and expression of the gene of interest or *transgene*. The vector must cross the plasma membrane efficiently and without damaging the cell. Most viral vectors enter cells via specific cell-surface receptors, and an important consideration is the number of functional receptors on the proposed target cell for the vector being used.[30] A process called *pseudotyping* can be used to redirect viral vectors to different cell-surface receptors by substituting alternative viral envelope proteins during the vector production process.[31,32,33,34] Nonviral vectors may cross the plasma membrane without need for a specific receptor.

After crossing the plasma membrane, the vector must then travel through the cytoplasm and cross the nuclear membrane in order to enter the nucleus and utilize the cell's transcriptional machinery for expression of the transgene. Nuclear entry of some vectors may be dependent on mitosis, with temporary breakdown of the nuclear membrane; others carry nuclear localization determinants that result in specific conveyance across the intact membrane. The transferred genetic material may *integrate* permanently into the target cell's own chromosomal DNA, ensuring passage of the new gene to all daughter cells with every cell division. The need for integration depends on the target cell and therapeutic application: it is absolutely required for gene transfer into HSCs where the transgene must be transmitted to all progeny cells, but is superfluous for cellular targets such as neurons or muscle cells that are not mitotic.

Alternatively, the gene may remain *episomal*, or nonintegrated. Some vectors are very stable as nuclear episomes, with prolonged persistence of transgene expression as long as the cell does not undergo mitosis. Unless the episome can reproduce itself, cell division will eventually dilute out episomal DNA, limiting the application of nonintegrating vectors to nonmitotic tissues or to situations requiring only transient expression.

The level of transgene expression and the ability to restrict expression to specific target cell types are also important factors to consider. Expression of the transduced gene is dependent on both vector and target cell determinants. Transcriptional promoters must be included along with the actual transgene protein coding sequences in the vector, and often *lineage or tissue-specific* promoter and enhancer elements are used to limit expression to a particular cell lineage derived from a target cell population.[35–37] For instance, hemoglobin gene regulatory sequences are required to drive transgene expression specifically in erythroid cells in strategies targeting the globin disorders. In other situations, *constitutive* control elements that can drive transcription continuously in most cell types can be used. Genetic control elements that are *inducible*, or turned on by some exogenous manipulation such as the administration of an antibiotic, are also under development for inclusion in gene transfer vectors.[38,39] Endogenous cellular factors may shut off expression of transferred genes in some situations.[40,41] These factors have not been fully elucidated, and vary from vector to vector. Silencing of transferred genes via methylation of vector sequences is one possible mechanism.[42] The level of expression necessary for the desired therapeutic effect is very important to determine during in vitro and animal experiments and varies greatly depending on the target cell type and the proposed clinical application.

Nonviral Vectors

The simplest approach to gene transfer is to use only the DNA of the transgene, with the necessary control sequences, as the vector.[29,43] Recombinant DNA production in bacteria can result in purified plasmids containing the gene(s) of interest along with regulatory elements. For over two decades, scientists have introduced purified DNA into target cells ex vivo by a variety of physical and chemical means. The least complex technique is direct microinjection into individual cells, which has little clinical

TABLE 71.1

GENE TRANSFER VECTOR SYSTEMS

Vector System	Integration	Cell Cycle Dependence	Insert Size Limit	Clinical Experience	Advantages	Disadvantages	Major Applications
Murine retrovirus	Yes	Yes	8–10 kb	Extensive	Stable producer lines No viral genes in vector Low immunogenicity Well-understood biology Efficient entry and integration in many cell types Proven clinical safety	Low titer, fragile vector Requirement for cycling Erratic expression Insertional mutagenesis	Ex vivo—stem cells, lymphocytes, tumor cells, hepatocytes, myoblasts In vivo—producer cell or vector injection into tumors
HIV-based lentivirus	Yes	No		None	Faithful delivery of complex genes Well understood Efficient entry and integration Pseudotyping allows broad tissue range	Production labor-intensive Erratic expression Insertional mutagenesis Recombination with wildtype HIV	Ex vivo—stem cells, lymphocytes, tumor cells, nondividing cells
Adenovirus	No	No	8–10 kb	Moderate	High titer, stable vector High-level transgene expression Efficient entry into many cell types	No stable producer lines Potential for recombination and replication-competent virus Multiple viral genes expressed from vector High immunogenicity (may be advantage as a vaccine vector!) Pre-existing immunity Inflammatory responses	In vivo—pulmonary epithelium, tumor cells, muscle, liver
AAV	Yes—inefficient	Yes—controversial	4.5 kb	Minimal	Stable vector, extra- and intracellularly High titer High-level transgene expression No expressed viral genes in vector	No stable producer cell lines High percentage of defective particles Requirement for helper adenovirus during production Very limited insert size Pre-existing immunity	Undefined
Naked DNA	No	No	No limit	Moderate	Ease of production High level of safety No extraneous expressed vector genes No immunogenicity of vector	Inefficient cell entry, uptake into nucleus Poor stability within cell Low-level expression	In vivo—tissues accessible to injection, for transient expression or vaccination
Facilitated DNA (liposomes, polylysine conjugates, inactivated adenovirus, etc.)	No	No	No limit	Moderate	Same as naked DNA plus: Can be targeted to specific cell types More efficient uptake and intracellular stability	No mechanism for persistence	Same as naked DNA, plus in vivo tumor cells, vascular endothelium

AAV, adeno-associated virus, kb, kilobases.

utility due to the impossibility of injecting enough cells to produce most of the desired effects. One exception is the observation that direct DNA injection into muscle or skin can stimulate a very potent immune response against antigens introduced as plasmid transgenes.[44,45] This observation led to preclinical and clinical development of genetic vaccination strategies against bacterial and viral pathogens.[46]

A number of other methods have been explored for getting plasmid DNA into cells. *Liposomes*, composed of phospholipid bilayers enclosing an aqueous space loaded with DNA, can directly fuse with the plasma membrane, releasing DNA into the cytoplasm.[47] The *gene gun* technique involves bombardment of the cell membrane with gold microparticles complexed to DNA.[48,49–52] Electroporation and calcium phosphate precipitation are generally too toxic and inefficient for use in gene transfer strategies aimed at primary human cells.[53–55]

All of these methods lack mechanisms to stabilize intracellular vector DNA, nor do they allow transport into the nucleus; they therefore rarely result in chromosomal integration or long-term persistence and expression. The development of *cationic liposomes* has improved cellular uptake of plasmid DNA and has circumvented cytoplasmic degradation.[56,57] In aqueous solution these positively charged liposomes bind with up to 100% of negatively charged DNA without size restrictions and can deliver DNA to the cell nucleus, albeit inefficiently, where it remains primarily episomal.[58] If administered in vivo, liposomes demonstrate no target cell tropism and are rapidly cleared by the reticuloendothelial system. However, after intravenous injection of cationic liposomes, long-term low-level persistence of vector sequences in many murine organs has been demonstrated.[59,60]

Nonviral plasmid DNA transfer has been improved by conjugation of vector DNA to substances that improve cellular transport

and allow target cell specificity via cell-surface receptors.[61,62] For example, adenoviral capsid elements (especially the penton base protein) help disrupt endosomes, releasing DNA more efficiently into the cytoplasm, and inclusion of transferrin or other ligands in DNA–polylysine conjugates allows specific uptake via cell-surface receptors.[63–67]

Manufacturing nonviral vectors is much simpler than manufacturing viral vectors, and cannot generate potentially dangerous replication-competent infectious particles.[29,68] Transduction is not dependent on target cell cycling, and no viral proteins are present to induce an antivector immune response. There are no size constraints. Limitations include a generally lower transduction efficiency than with viral systems. Most important, transgene integration is poor and persistent expression rare, limiting utility to situations allowing transient transgene expression.

Viral Vectors

Viral vectors are Trojan horses, taking advantage of the viral capsid or envelope and of the viral machinery to deliver nonviral transgene sequences efficiently to target cells.[69] In general, the external capsid or envelope of the virus is unaltered in a viral vector, but the genome of the virus is in large part replaced by a transgene or genes. This strategy is limited by the space available in a viral particle for new genetic material. Viral vectors also depend on the presence of a specific viral receptor on target cells. The efficiency of gene transfer utilizing viral vectors is the main advantage when compared to some of the physical and chemical cell entry methods described above. Furthermore, the relatively low toxicity of transduction of cells with certain viral vectors (e.g., retroviruses, lentiviruses, and adeno-associated viruses [AAV]) is another advantage when compared to physical or chemical methods. In order to modify a virus into a vector system, detailed understanding of the viral genome and life cycle is necessary to retain viral genome sequences required for packaging of vector nucleic acids into viral particles and for appropriate trafficking in the target cell, while removing sequences that might allow production of replication-competent viral particles.

Retroviral Vectors

The murine retroviruses exemplified by the Moloney murine leukemia virus (MLV) were the basis of the first practical viral vector system.[70–72] These retroviruses consist of two single strands of linear viral RNA bound to protein core and coated by a lipid envelope that is acquired from the plasma membrane of the infected cell upon viral release. The linear RNA genome can contain 2 to 9 kilobases (kb) of coding and regulatory sequences, flanked on each end by sequences termed long terminal repeats (LTRs) that permit integration into chromosomes and contain strong promoter/enhancer elements that normally drive expression of full-length viral RNA genomes, or via alternative splicing, the individual retroviral genes. These simple murine retroviruses contain only three genes necessary for viral replication and packaging: *gag*, *pol*, and *env*. The retrovirus enters a cell after binding to a specific cell-surface receptor via the *env* gene product. These receptors are large, widely expressed proteins involved in phosphate transport and other cellular homeostatic functions.[30] The *amphotropic receptor* is found on both rodent and primate cells, and is the entry site for most murine retroviral vectors directed at human cells.[73–75]

After cell entry, the viral RNA is reverse transcribed via the *pol* gene product into *proviral* cDNA and enters the nucleus. The LTR sequences allow random integration of the viral cDNA into the host chromosomes. The integrated retroviral genome, or *provirus*, relies on the host cell's transcriptional machinery for expression of proviral genes and production of full-length viral RNA. The *gag*, *pol*, and *env* gene products are packaged along with the new viral RNA into viral particles, dependent on the presence of a *packaging* (ψ) sequence in the viral RNA, and viral particles are released from the cell via budding through the plasma membrane, without damaging the infected cell.

Recombinant retroviral vectors are constructed by removing the *gag*, *pol*, and *env* gene sequences from the viral nucleic acid backbone and replacing them with up to 7 to 8 kb of a gene or genes of interest, retaining only the LTRs and the packaging signal (ψ).[5] The resulting recombinant viral vector can integrate and express the gene or genes of interest, but cannot replicate and produce new retrovirus once within a target cell, because of the lack of *gag*, *pol*, and *env* genes within its genome. Thus it is termed *replication defective*. Figure 71.5 diagrams the steps involved in making a retroviral vector. A *packaging cell line* is created by introducing a plasmid containing *gag*, *pol*, and *env* sequences but no ψ sequence into an immortalized cell line such as NIH3T3. The lack of the ψ sequence prevents these *helper* genes from being packaged into viral particles. A second plasmid containing the recombinant vector sequences (LTRs flanking the transgene or genes) is then introduced into these cells to create a *producer cell* line. Full-length vector RNA is transcribed from the vector plasmid sequences and packaged into viral particles using the *gag*, *pol*, and *env* proteins encoded by helper plasmid sequences. In this way, producer cell lines release helper-free replication-defective vector particles containing the recombinant genome into cell culture media at a titer of up to 107 particles/ml. These particles contain the full-length vector RNA, consisting of the viral LTRs flanking the transgene or genes, and the *env*, *gag*, and *pol* proteins, but because they do not contain any actual *gag*, *pol*, or *env* viral gene sequences, no further infectious virus can be made once the vector infects the target cell.

The potential for generation of replication-competent virus through recombination events between the vector and helper sequences in the producer cell line is a significant safety concern.[28,76] In order to allow packaging of replication-competent viral particles these recombination events must result in the transfer of an intact ψ packaging sequence being transferred into the helper sequences containing the *gag*, *pol*, and *env* genes. The presence of replication-competent virus could allow spread of vector and helper particles indiscriminately to nontarget cells in vivo, thus greatly increasing the risk of insertional mutagenesis by repeated infection of susceptible cell populations.[76,77] The absolute need for avoidance of replication-competent viral particles in clinical vector preparations was inadvertently demonstrated when high-grade lymphomas occurred in rhesus monkeys transplanted with HSCs transduced with a vector preparation contaminated with high levels of replication-competent virus.[78] Over the next several years, a number of modifications in the organization of genetic sequences included in the packaging cell lines has greatly decreased the risk of recombination events, and sensitive systems for detecting replication-competent virus have been developed.[28,79,80,81] A number of investigators have used packaging cell lines derived from human instead of murine cells to make producer cell lines, in hopes that lower levels of endogenous retroviral sequences in human cells would also decrease recombination events and thus replication-competent viral contamination.[82,83]

As described below, retroviral vectors are capable of stable integrated transduction of a large number of cell types, including repopulating stem cells, but have a number of important limitations. Stable transduction and integration requires passage of the target cell through the S phase of the cell cycle, preventing transduction of quiescent cells.[84] The amphotropic receptor density on certain target cell types may be too low to allow efficient transduction.[85] Thus, redirection of receptor specificity via pseudotyping with alternative envelope proteins has been explored, with some success.[32,86–90]

Biophysical considerations may also limit vector–target interactions. Vector particles are very fragile, and degrade quickly in

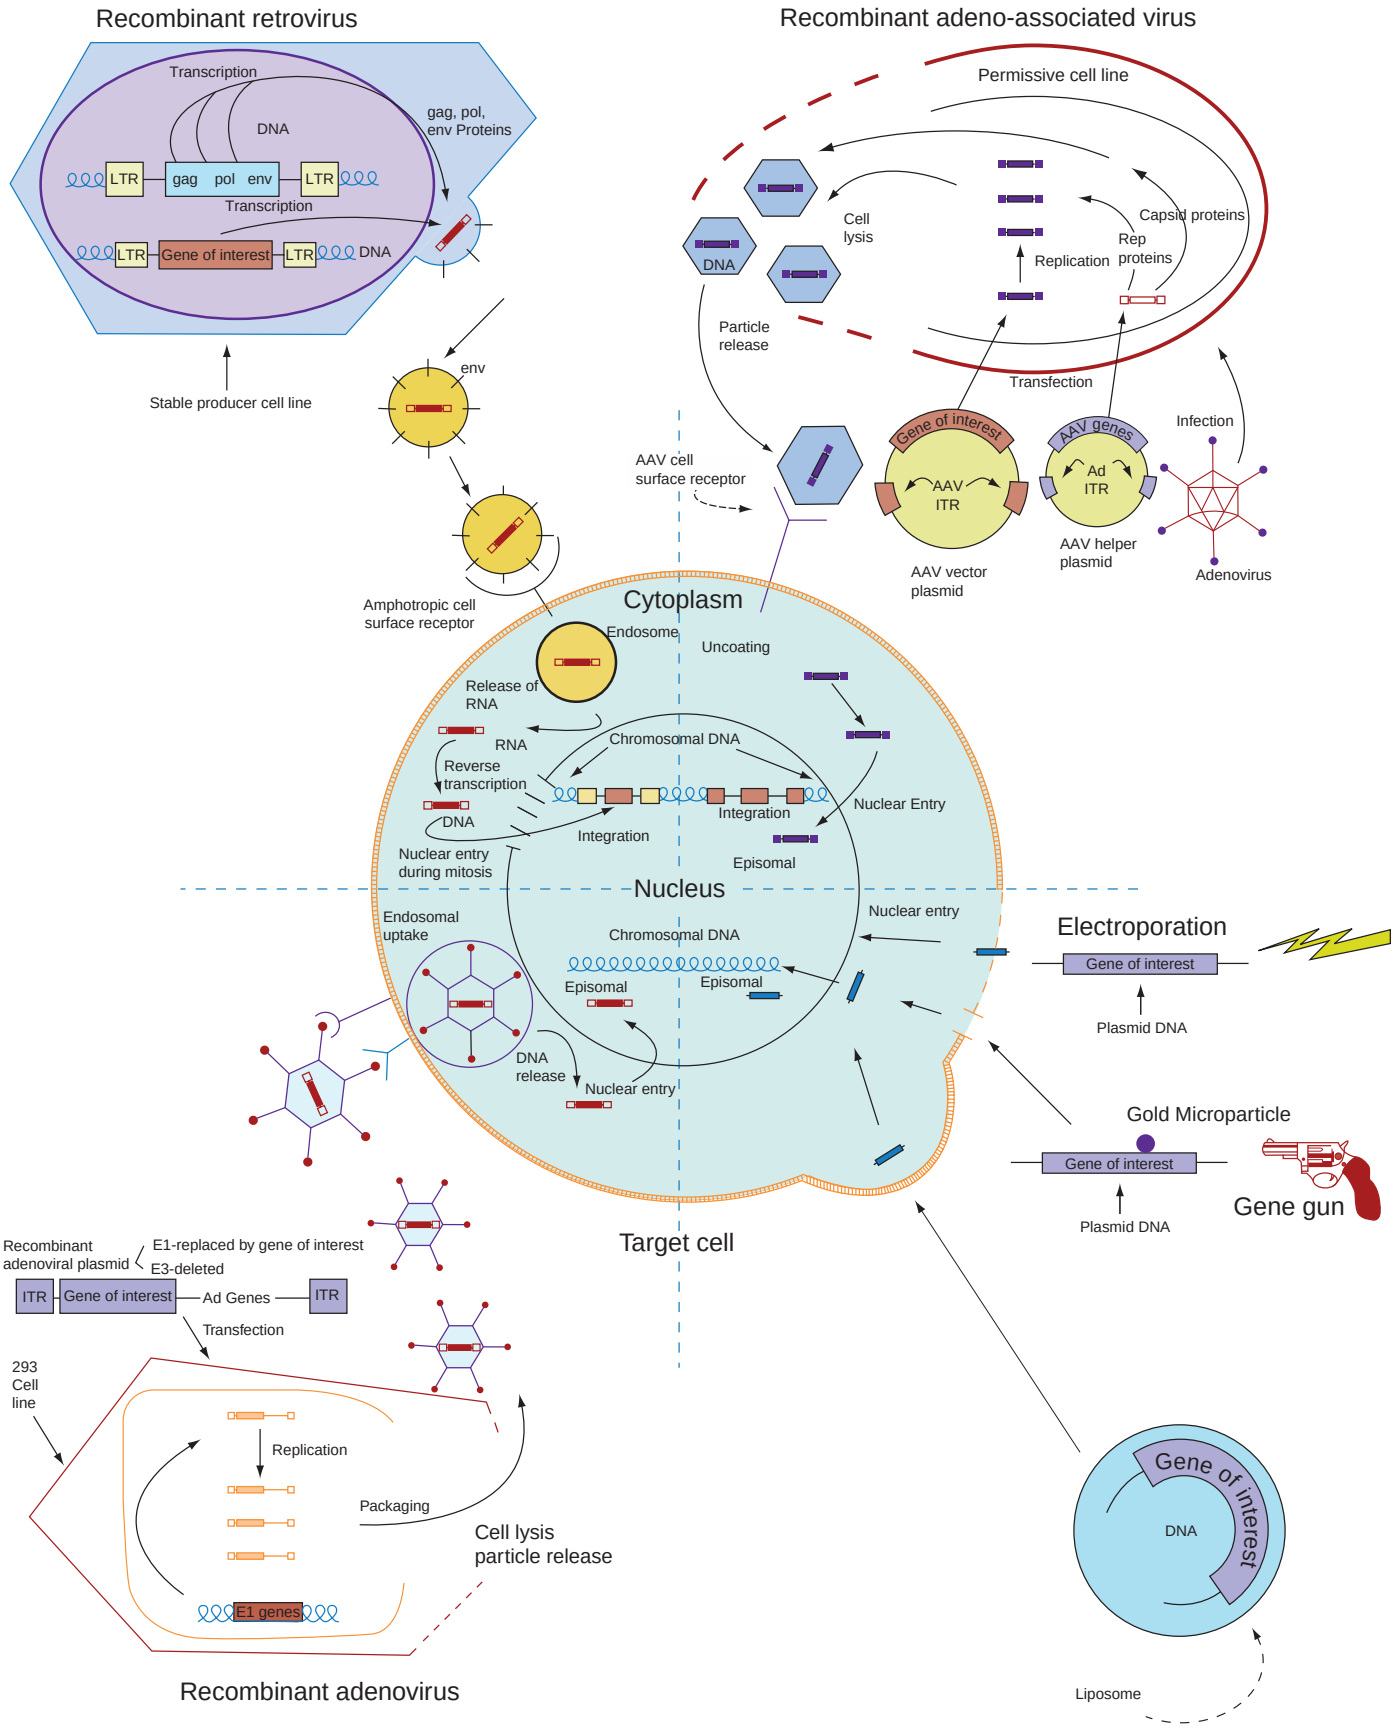

FIGURE 71.5. Schematic representation of transduction of a generic target cell by the four major gene transfer vector systems. The same "gene of interest" is shown being transferred with each vector. AAV, adeno-associated virus; Ad, adenovirus; ITR, inverted terminal repeat; LTR, long terminal repeat.

solution or within cells if cell division allowing nuclear entry and integration does not occur. A number of investigators have tried to increase the likelihood of successful transduction by flowing vector solution continuously over target cells or co-localizing vector and target cells using culture dishes coated with fibronectin fragments.[91,92] New methods of concentrating and stabilizing vector preparations are also under development.[33,87,93]

Lentiviral Vectors

There has been real progress toward the development of alternative retroviral systems that may overcome some of the limitations of the MLV vectors. HIV-derived lentivirus vectors have been most actively pursued. Relatively high-titer vectors have been reported using production strategies with numerous safeguards against recombination events that could result in generation of wildtype HIV.[94,95,96] Vectors retaining the HIV gp120 envelope protein could be used to transduce $CD4^+$ T-cells, monocyte/macrophages, or glial cells, and pseudotyping with alternative envelope proteins such as vesicular stomatitis virus (VSV) or amphotropic leukemia virus envelope proteins could be used for transduction of a wider range of cells. Lentiviral vectors can traverse an intact nuclear membrane, requiring the HIV *gag* protein and an accessory VpR protein, thus allowing transduction of nondividing cells.[97,98] The promise for more efficient HSC transduction using lentiviral vectors remains an attractive feature, however, other features of HIV-based vectors have also stimulated interest. Specifically, the faithful delivery of nonrearranged genes with complex regulatory elements appears superior, and success in delivering the human β-globin gene along with large portions of the locus control region has finally been achieved with HIV-based vectors.[99] A number of additional safety modifications have been employed, including deletions in the 3′ LTR reducing the risk of insertional mutagenesis by self-inactivation of the integrated LTRs. Indeed, the first clinical trial employing lentiviral vectors for the treatment of HIV have been carried out,[100,101] and subsequent trials have demonstrated clear efficacy in adrenoleukodystrophy (ALD)[102] and thalassemia.[103]

Human Foamy Viral Vectors

The other member of the *retroviridae* under consideration as a gene transfer vector is the human foamy virus (HFV). HFV, a poorly characterized retrovirus, has three potential advantages. It has never been associated with pathology in animals or humans, it infects a wide variety of primate cell types, and it has the capacity to package longer transgene(s).[104] It does not appear, however, to transduce nondividing cells, although it may be more stable than conventional retroviruses within a target cell, tolerating a more prolonged period before cell division and then integration.[105] Virologists are trying to define the packaging signal and other important elements necessary for engineering a replication-incompetent HFV vector,[106,107] and a method for the production of helper-free vector stocks has recently been described.[108] Third-generation vectors have now been developed, and these foamy virus vectors appear efficient for transducing HSCs, with high gene transfer rates observed in human cord blood (CB) in vitro, and in murine BM (BM) in vivo after a single, overnight vector exposure.[109] Recently, HFV vectors have proven highly efficient in a canine model of leukocyte adhesion deficiency (LAD).[110]

Adenoviral Vectors

Adenoviruses are nonenveloped double-stranded large DNA viruses.[111] The linear adenovirus genome contains 36 kb with an inverted terminal repeat (ITR) of 100 to 165 base pairs at each terminus. A set of early genes encodes for regulatory proteins that serve to initiate cell proliferation, DNA replication, and down-modulation of host immune defenses, whereas the late genes encode for structural proteins. Adenovirus readily crosses the plasma membrane of many cell types, whether replicating or not, via receptor-mediated endocytosis[112] through the receptor, common to two distinct viral pathogens, coxsackie B and adenovirus 2 and 5, termed the coxsackie and adenovirus receptor.[113] Adenovirus escapes the endosome by altering the pH and then enters the nucleus where it remains as a linear episome. In permissive cells, adenovirus replicates and then enters a lytic cycle, destroying the host cell and releasing daughter viral particles. Of the 42 adenovirus serotypes, most are known to cause mild respiratory, gastrointestinal, and conjunctival infections in immunocompetent humans; no associated malignancies in humans have been reported, although some serotypes can transform cells in culture. The human embryonic kidney cell line HEK293 was, in fact, immortalized by transfection of kidney cells with sheared adenovirus serotype 5 DNA; the E1 gene that is integrated into the cellular genomic DNA is apparently responsible for the immortalization of the cell line.

Recombinant adenovirus vectors have been engineered from adenovirus (usually serotype 5) by the removal of the E1 and E3 genes (regulating replication and immune recognition) and replacement by the gene or genes of interest, with space for 7 to 8 kb of new genetic material.[114,115,116,117,118] High-titer adenovirus vectors, up to 10^{12} plaque-forming units (pfu) per ml, can be reliably packaged through the use of a human embryonic kidney transformed cell line,[293] which provide the helper or replication E1 genes, followed by purification and concentrating procedures. The final product is a replication-defective adenovirus vector which is free of helper or wildtype virus that can efficiently transduce nondividing cells.[116] These vectors do not integrate into the target cell genome, avoiding insertional mutagenesis and resulting in only transient transgene expression in proliferative tissues. Because of the tropism of adenovirus for epithelial cells, these vectors were initially investigated for the treatment of pulmonary diseases and diseases in which liver gene transfer is desirable.[119,120]

Transient transgene expression also may result from host cellular and humoral immune responses directed at either transgene-encoded antigens or adenovirus proteins expressed from the large portions of the adenovirus genome retained in these vectors.[121,122] Another concern is inflammation resulting from in vivo transduction of certain cell types, especially airway epithelium.[123] In vivo use may also be compromised by pre-existing or new antiviral neutralizing antibodies, limiting the efficacy of repeated dosing, which may be required for applications directed at mitotic tissues.[124] Nonessential adenoviral sequences are being gradually eliminated from the vectors.[125,126] The use of adenovirus vectors in which essentially all viral genes are removed is the ultimate goal of such a strategy. Unfortunately, although these vectors have little except the capsid proteins to mark themselves as foreign, there is evidence that they can trigger innate immunity by recognition through the toll-like receptor 9 pathway in target cells.[127] Further technical issues that are important include the decreased efficiency of vector production as more viral genes are deleted, inasmuch as these functions need to be provided by accessory plasmids through transfection of vector-producing cells. Hence, these highly deleted vectors are often called "helper-dependent." Specific dosage schedules (e.g., neonatal or embryonic exposure) or co-administration of immune modulators such as cyclosporine or IL12 may also prevent sensitization.[128–132] Another strategy being explored is use of different vectors based on adenovirus serotypes other than adenovirus 5. One survey of unusual group B and group D adenovirus serotypes that might be considered for use as HIV vaccines indicates that in a target population in sub-Saharan Africa the existing immunity to adenovirus serotypes 11, 35, and 50 from group B and adenovirus serotypes 26, 48, and 49 from group D are substantially less than that of the commonly studied adenovirus 5 serotype from group C.[133] By employing alternatives to adenovirus 5, it might be possible to get around the barrier of pre-existing antivector antibodies for vaccination

efforts. Furthermore, it might be possible to alternate the vector type with subsequent vaccinations to thwart neutralizing antiadenovirus immunity to the vaccine vector. Recently, investigators developing HIV vaccination strategies have reported an adenovirus 41 serotype vector that can express HIV envelope protein.[134] The adenovirus 41 serotype virus is an enterotropic pathogen that causes diarrhea in its wildtype form; the use of a gene transfer vector with tropism for a mucosal surface may present advantages for vaccination against HIV, a pathogen that is normally encountered by the host in the mucosa. This vector has not yet been clinically tested.

In initial clinical trials, adenovirus vectors were used to transfer a normal cystic fibrosis transmembrane conductance regulator (*CFTR*) gene into airway cells (bronchial or nasal) of patients with cystic fibrosis.[135–137] Despite the demonstration that airway cells could be transduced with these vectors in vivo with correction of the chloride transport defect, clinical utility has been precluded by the harmful immune and inflammatory responses noted above. However, the active immune response induced by adenoviral vectors is also being explored as a possible advantage for adenovirus vectors when they are used to transduce tumor cells with cytokines or other immune modulators for tumor vaccine protocols.[138–140] The fact that most adenoviral gene transfer results in transient transgene expression (in contrast to retroviral-mediated gene transfer) has limited their use for congenital diseases in which permanent expression of a missing protein is desirable, such as hemophilia, ornithine transcarbamylase (OTC)-deficiency, or α-1-antitrypsin inhibitor deficiency. The use of alternating serotypes for repeated administration can only increase the number of administrations so much before immunity to the vectors neutralizes further administration. The powerful and often toxic immune reaction against viral vectors makes their use for vaccination or antitumor therapy more likely than for correction of metabolic disorders.[141] The tragic death of a subject who received the OTC-adenovirus vector was mediated in a large part by the "cytokine storm" and resultant systemic immune response that led to widespread capillary leak multiorgan failure.[141]

Adeno-Associated Viral Vectors

AAV are small nonenveloped single-stranded DNA viruses in the parvovirus family, dependovirus subfamily, that require a helper virus (typically a double-stranded DNA virus such as adenovirus or herpes simplex virus) for production of new viral particles.[142–144] The linear AAV genome is approximately 4.7 kb long and consists of two homologous ITRs of 145 bp flanking two groups of genes: the *rep* or nonstructural genes and the *cap* or structural genes. There are at least eleven serotypes of AAV that differ mainly on the basis of their external capsid proteins. AAV-2 is the best characterized serotype. AAV-2 enters host cells primarily through interaction with the heparin sulfate proteoglycan protein on the cell-surface, and by interaction with the $\alpha_V\beta5$ integrin and fibroblast growth-factor receptor proteins. AAV has oncoprotective and HIV-suppressive properties, and is not known to cause disease in humans or other animals.[145–147] Prior infection with AAV-2 in humans is common: seroepidemiologic studies demonstrate that 80% of the adult population has antibodies.[143,148]

After cell entry mediated by the capsid protein, wildtype AAV integrates within the host chromosome.[149] Integration of multiple copies in tandem occurs in a site-specific manner within a relatively small area on chromosome 19: this site specificity appears to require rep protein.[150,151] Specifics of replication and integration are less well understood than for retroviruses.

Recombinant AAV vector DNA contains the AAV ITRs flanking a gene of interest replacing the *rep* and *cap* genes. This plasmid is introduced into a cell line permissive for adenovirus, along with a helper plasmid containing the AAV *rep* and *cap* genes but no ITRs. Upon exposure to adenovirus or transfection with adenovirus genes such as E4 (particularly open reading frame 6), the cell line packages the recombinant vector sequences using the *rep* and *cap* gene products produced by the helper plasmid, and recombinant vector particles are released as the producer cell lyses.[152,153–156] Recombinant AAV vectors have size constraints: vector sequences longer than 115% of the wildtype length are not packaged or encapsidated efficiently. Very high titers of recombinant AAV particles can be produced, but often a significant percentage of capsids are empty or otherwise defective.

The need for replication-competent adenovirus during AAV vector production complicates the manufacturing and safety issues, inasmuch as the adenovirus must be inactivated or (preferably) removed before use. Some progress is being made toward introducing only the specific adenovirus genes necessary for AAV replication into producer cell lines, avoiding live adenovirus. The inability to harvest AAV vector without actual lysis and death of the producer cells also complicates production of pure and defined vector preparations. Generation of stable packaging cell lines is also hindered because the AAV *rep* gene product harms most cell types; but recently producer cell lines expressing *rep* from an inducible promoter have been isolated.[157,158] Another approach to avoid the issue of helper-virus contamination is to transfect cells with multiple plasmids that separately encode the desired transgene nucleic acid as well as the structural and replication proteins.[159,160]

Integration of the recombinant vectors into target cell chromosomes appears to be very inefficient, and thus these vectors prove more useful in situations not requiring integration, inasmuch as they have been shown to be stable as episomes for long periods.[156,161,162] Site-specific integration in chromosome 19, very desirable to avoid random insertional mutagenesis, does not occur with the recombinant AAV vectors, presumably due to lack of *rep* protein in the vector particle.[162] Many cell types can be efficiently transduced, including nondividing cells such as neurons, but integration and increased efficiency of transduction still appears to depend on cell division or other DNA-disrupting events, although this conclusion is very controversial.[163–167]

Recently, there has been a great deal of interest in the use of vectors based on serotypes other than AAV-2, especially AAV-6, AAV8, and AAV-9, although the work thus far has consisted of in vitro vector production development[160] and preclinical animal studies.[168–170] It is possible that a number of other parvoviruses can be developed as vectors, including AAV-3, nonpathogenic strains of B19, or novel autonomous parvoviruses isolated from nonhuman primates or other animal species.[171–173] These viruses are similar to AAV, but some, such as B19, never integrate. Self-complementary AAV vectors based upon serotypes with high-efficiency delivery to liver cells have been utilized recently to deliver factor IX as a potential treatment for hemophilia B in the canine model with correction of the bleeding abnormalities.[174,175] These results supported the first successful clinical trials in humans described in detail below.[176]

Miscellaneous Other Vectors

Herpes viruses are large DNA viruses with marked neurotropism, generating intense interest in their potential as vectors targeted at the nervous system.[177–180] They can accommodate very large DNA sequences (up to 30 kb). More recently, these vectors have been reported to transduce some types of hematopoietic cells, including monocytes, leukemic blasts, and progenitor cells.[181,182] However, these vectors result in only transient expression in dividing cells, and cause cytotoxicity, limiting clinical utility, at least for hematologic applications.

Vaccinia virus, a large DNA virus that replicates cytoplasmically, has also been considered for gene therapy applications.[183,184] It can accommodate very large transgenes (up to 30 kb) and expresses these genes at very high levels, but expression is

transient, and production of replication-incompetent vectors has not yet been possible. Very high immunogenicity limits most clinical applications, but may be advantageous for in vivo vaccination with vaccinia-transduced tumor cells.[184–187]

Genome Editing

Current vectors and protocols have attempted phenotypic correction or modification by gene addition, generally randomly in the genome. A different process, gene correction by homologous recombination, in hematopoietic tissues has been proposed as an alternative.[188] Correction of the genetic defect in lymphoblastoid cell lines derived from patients with sickle cell disease was described[189] using a RNA–DNA oligonucleotide, yet the applicability of this approach remains elusive.

An alternative corrective approach for some disorders has recently been described. Constructs targeting aberrant splice sites in the form of oligonucleotides, morpholinos, or U7 snRNAs lead to increased levels of correctly spliced β-globin mRNA by effectively blocking the aberrant splice site through the use of sequences complementary to the corrected sequence.[190–192] A major problem with this approach has remained the difficulty in delivering such constructs in vivo with sufficient efficiency to correct the phenotype and recently, lentiviral vectors designed to deliver modified U7 snRNAs permanently have been tested in cell lines and in primary cells from individuals with thalassemia with encouraging early results.[193]

Targeted DNA double-strand breaks through the use of artificial nucleases was recently shown to increase the efficiency of homologous recombination by several logs, renewing enthusiasm for this approach. The development of zinc finger nucleases (ZFNs) that allow cleavage of DNA in a sequence-specific manner allows the potential for genome editing at virtually any site. These artificial endonucleases mediate DNA cleavage at targeted sites and have been utilized successfully in a broad range of experimental systems including plants, flies, worms, rodents, ESCs, and primary human cells.[194] The ideal set of ZFNs would target double-strand DNA breaks at high efficiency, and more importantly, with high specificity. Specificity has thus far been difficult to achieve. ZFNs can also be utilized to modify normal genes, such as the *CCR5* (required for HIV entry), and a clinical trial is now underway testing this approach as a potential therapy for HIV.[195] Transcriptional activatorlike effector nucleases are a new class of nucleases that allow tailored genome editing in a variety of cell types with the potential for increased specificity.[196] The advent of iPS cells that can be generated from individuals with genetic diseases raises the possibility of genome editing followed by differentiation to a cell type of interest as a form of therapy for a number of diseases, and proof of concept has already been achieved in a murine model of sickle cell disease in which iPS cells were corrected with homologous recombination and transplanted after differentiation into hematopoietic progenitors.[197]

HEMATOPOIETIC STEM AND PROGENITOR CELLS AS TARGETS FOR GENE TRANSFER

Since the development of helper-free retroviral gene transfer technology, now decades ago, the HSC has been a primary target for gene therapy applications. The curative potential of HSCs carrying corrective genes has been well established through the use of allogeneic bone marrow (BM) transplantation in genetic disorders whereby an individual carrying a normal genotype serves as the stem cell donor, yet procedural toxicities and finite donor availability limit this approach. The prospect of a curative, one-time therapy using genetically modified autologous stem cells for the treatment of a wide variety of congenital disorders such as hemoglobinopathies, immunodeficiencies, or metabolic storage diseases, and of a new weapon against malignancies and HIV infection, has proven irresistible.[13,14,198–201] Gene therapy directed at HSCs must utilize an integrating vector, because ongoing self-renewal or proliferation/differentiation would rapidly dilute out an episomal vector in daughter cells. Initial preclinical studies in the 1980s reported the introduction of genetic markers and clinically relevant genes into mouse HSCs using integrating retroviral vectors, providing both conceptual and methodologic insights that led to first-, second-, and third-generation human gene therapy clinical trials (Fig. 71.6).

Gene Therapy Preclinical Evaluation Using Standard Mouse Transplantation Models

Retroviral gene transfer into murine hematopoietic repopulating stem cells has become routine in many laboratories.[202,203,204] The isolation and availability of various hematopoietic growth factors has allowed ex vivo maintenance and increased retroviral gene transfer into hematopoietic target cells. Several different combinations of growth factors have been successful, including at least two or three cytokines that are active on primitive cells, such as interleukin-3 (IL-3), interleukin-6 (IL-6), and stem cell factor (SCF). Their mechanism of action probably includes both induction of cell cycling, a necessity for retroviral transduction and integration, and up-regulation of retroviral cell-surface receptors.[85,205,206–209] Other manipulations that have been found to increase gene transfer efficiency to murine stem cells include co-culture of target cells directly on a layer of retroviral producer cells, use of high-titer ($>10^5$ viral particles/ml) vectors, induction of stem cell cycling by pre-treatment of donor mice with 5-fluorouracil, and co-localization of vector and target cells using fibronectin-coated culture dishes.[92,210–213] Using these techniques, successful gene transfer can now be achieved in virtually all mice transplanted with transduced syngeneic BM stem cells, with long-term persistence of the vector sequences in 10% to 100% of cells from all hematopoietic lineages.[206,210,211,213,214] The continued presence of vector sequences in short-lived granulocytes for the lifespan of the mouse and in multiple lineages of the blood of serial transplant recipients indicates that murine repopulating stem cells can be successfully modified with retroviral vectors.[15,17,206,215,216,217] Documentation of the shared single-cell ancestry of gene-modified cells from different lineages by examining retroviral integration sites among transduced cell progeny has also supported this contention.

The ability of retroviral vectors to introduce marker genes permanently into murine cells with lifelong repopulating ability led investigators to test whether this approach was feasible when clinically relevant genes were used. Genetic disorders with high morbidity and mortality and with no effective conventional treatments were considered prime candidates for preclinical evaluation.

Severe Combined Immunodeficiency Disease

SCID resulting from adenosine deaminase (ADA) deficiency was initially chosen and stable expression of functional human ADA was demonstrated in all hematopoietic lineages at levels near endogenous murine levels in reconstituted murine transplants.[202,218–222] The efficiencies of gene transfer and ADA levels achieved in these preclinical models, together with the anticipated in vivo selective survival advantage of transduced T-cells, were thought to be predictive of successful correction of lymphoid dysfunction in patients with ADA deficiency.[13] Retroviral vector-mediated gene transfer has also been used successfully to evaluate gene therapy strategies in several murine models of human immunodeficiencies, including those caused by deficiency

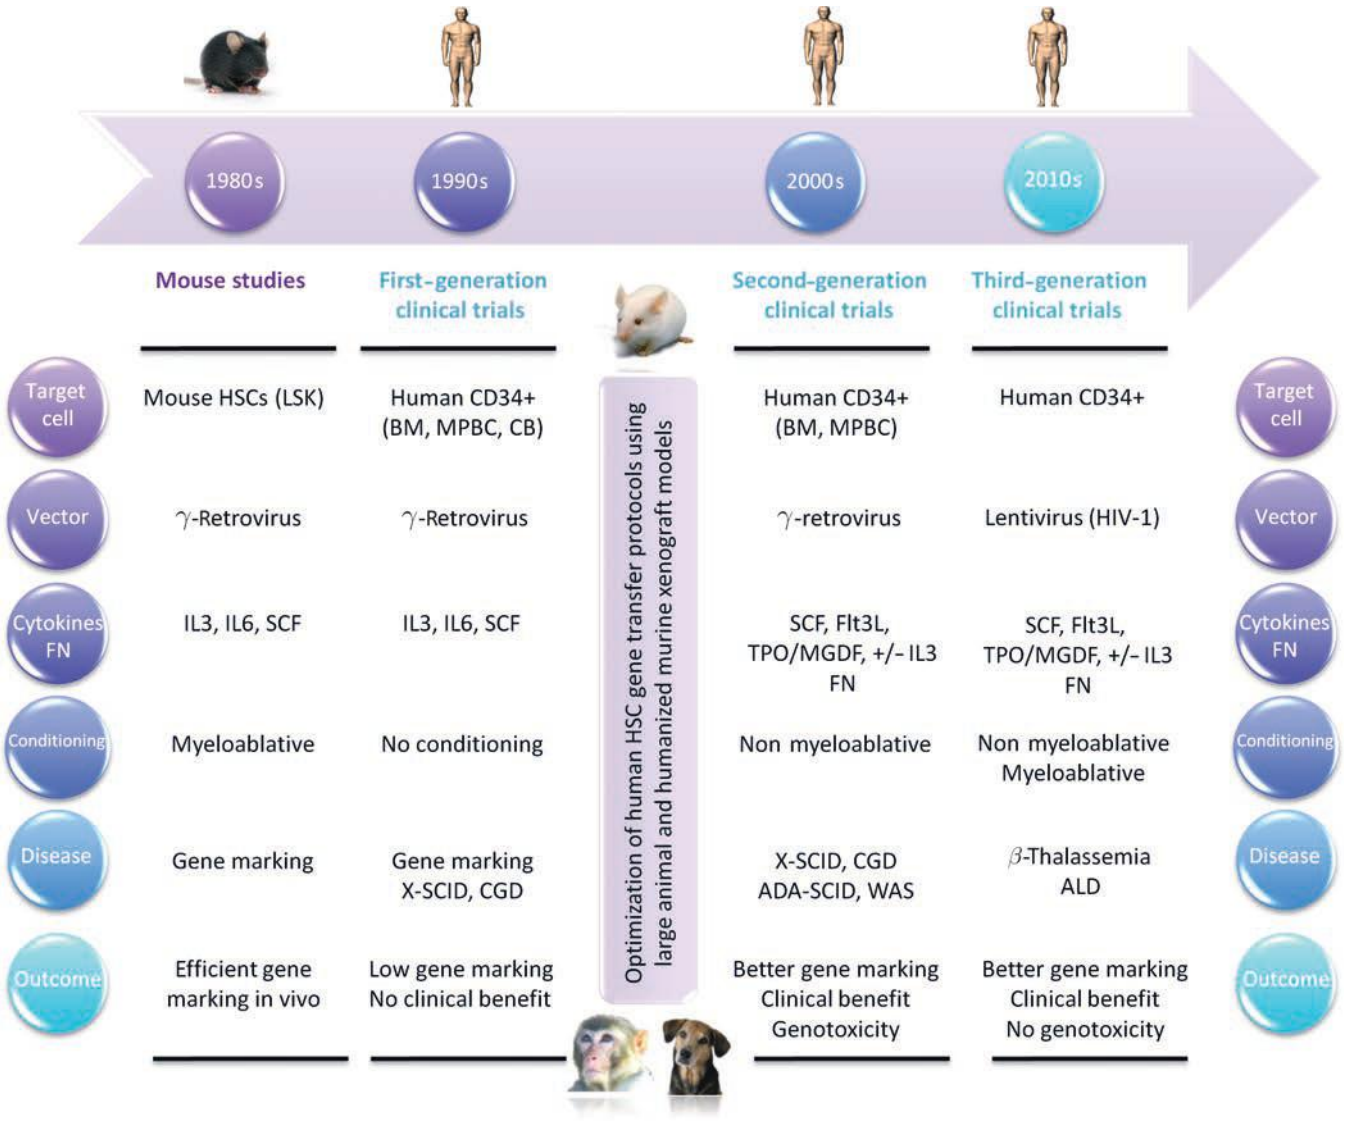

FIGURE 71.6. Timeline for the development of human gene therapy protocols targeting hematopoietic stem cells (HSCs). The main phases in the evolution of HSC gene therapy clinical trials are ordered chronologically. The six principal features defining each phase are outlined. ADA (adenosine deaminase); ALD (adrenoleukodystrophy); BM (bone marrow); CB (cord blood); CGD (chronic granulomatous disease); Flt3L (*fms*-related tyrosine kinase 3 ligand); FN (fibronectin); HIV (human immunodeficiency virus); IL3 (interleukin 3); IL6 (interleukin 6); LSK (Lin^-, $Sca1^+$, Kit^+); MGDF (megakaryocyte growth and development factor); MPBC (mobilized peripheral blood cells); SCF (stem cell factor); SCID (severe combined immunodeficiency disease); TPO (thrombopoietin); WAS (Wiskott-Aldrich syndrome).

of the common γ-chain expressed in T-cell cytokine receptors (X-SCID),[223–224,225] JAK3 kinase deficiency,[226] deficiency in the ZAP70 protein,[227] and recombination-activating gene-2 (*RAG-2*) deficiency.[228]

Gaucher Disease

Gaucher disease is an inherited deficiency of the lysosomal enzyme glucocerebrosidase (GC) and the associated accumulation of glucocerebroside in the lysosomes of macrophages results in multisystem damage, including hepatosplenomegaly, gradual replacement of bone marrow (BM), skeletal deterioration, and neuropathology in some cases of Gaucher disease. Correction of enzyme deficiency in macrophages by HSC gene therapy has been considered an attractive therapeutic option for these patients. Mouse BM transplant models have been invaluable for initial evaluation of retrovirus-based gene transfer vectors developed for Gaucher disease.[206,214,229–232] These studies established the feasibility of efficient transfer of the GC gene to normal mouse HSCs and long-term expression in their progeny after reconstitution, strengthening the rationale for gene therapy as a treatment option for Gaucher disease.

Hemoglobinopathies

Hemoglobinopathies, including β-thalassemia and sickle cell disease, were also among the first diseases selected as targets for genetically based therapeutic approaches. Transfer of the human β-globin gene into murine HSCs proved more challenging due to the requirement to include specific endogenous regulatory elements from the β-globin locus that were obligatory to achieve clinically relevant expression. Early preclinical studies demonstrated that retroviral vectors containing the β-globin gene and its promoter could transduce murine HSCs. However, human β-globin gene expression was either absent or very low, usually varying between 0% and 2% of mouse β-globin RNA levels.[205,233–238] As outlined below, it is not until new vector designs became available that successful genetic correction of β-thalassemia was first demonstrated in murine preclinical models, laying the foundation for a recent clinical trial of gene therapy for β-thalassemia.[103]

Chronic Granulomatous Disease

Chronic Granulomatous Disease (CGD) results from mutations in any one of four genes encoding the essential subunits of the phagocytic antimicrobial system NADPH phagocyte oxidase (phox),[239] including gp91phox, p22phox, p47phox, and p67phox, rendering individuals born with CGD particularly susceptible to bacterial and fungal micro-organisms. Retrovirus-based gene transfer vectors have been tested in two CGD knockout mouse models.[240–242] These studies indicated that gene transfer into murine HSCs is feasible and that partial reconstitution of NADPH oxidase activity achieved after retroviral gene transfer can improve host defense if an adequate number of phagocytes exhibit enzyme activity.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich Syndrome (WAS) is an X-linked complex primary immunodeficiency disorder caused by mutations in the gene that encodes the WAS protein (*WASP*).[243] It is characterized by an increased susceptibility to recurrent infections associated with adaptive and innate immune deficiency, thrombocytopenia, eczema, and autoimmunity.[244,245] The generation of two *Wasp*-deficient mice has facilitated preclinical safety and efficacy studies of retroviral vectors for the treatment of WAS. In one study,[246] vector-mediated WASP expression was shown to correct the T-cell defect in *Wasp* mice. In another study, investigators demonstrated rescue of T-cell signaling and amelioration of colitis upon transplantation of transduced WAS HSCs in mice, supporting the development of gene therapy approaches for WAS.[247]

First-Generation Human Gene Therapy Trials

Because of the absence of in vivo assays that measure the repopulating capacity of human HSCs, gene transfer protocols employed in early clinical trials were adapted from the murine studies described above, and initially tested using human in vitro colony-forming cell (CFC) assays that detect committed progenitor cells, and long-term BM culture assays that detect a cell capable of maintaining production of CFC for at least 5 weeks on a layer of stromal cells. Notwithstanding the fact that progenitors do not have the same biologic properties as stem cells, investigators were initially encouraged when high gene transfer efficiency (up to 100%) was observed in these in vitro progenitor assays using gene transfer vectors and transduction conditions comparable to those employed in the mouse.[248,249,250] Demonstration of correction of GC and ADA deficiency after retroviral vector-mediated gene transfer into progenitors from patients with Gaucher disease[251] and ADA-SCID,[252] respectively, provided even further impetus to regulators and investigators to initiate a first generation of human HSC gene transfer clinical trials, including gene marking studies and gene therapy trials with therapeutic intent (see Table 71.2.

Genetic Marking Trials

The first human clinical gene transfer trials used retroviral vectors carrying nontherapeutic marker genes, and were critical for establishing proof of principle and allaying safety concerns (Table 71.2).[7,253] Patients already undergoing autologous transplantation as therapy for an underlying malignancy received genetically marked hematopoietic stem and progenitor cells to determine whether re-infused tumor cells contribute to relapse after autologous transplantation and to establish if transduced HSCs could contribute to long-term hematopoietic reconstitution.[254,255,256–258] Genetically marked tumor cells were unequivocally demonstrated in several patients at the time of relapse, suggesting that the re-infused marrow had contributed to progression, and that investigation of therapeutic purging strategies was worthwhile. The presence of the marker gene was also followed in nonmalignant hematopoietic cells. Gene-marked cells contributed only 0.1% to 1% of the total BM but detection of the marker gene in T-cells and B-cells for as long as 18 months after transplantation was consistent with low-level transduction of primitive hematopoietic cells with multilineage capacity.

In a similar marking study, investigators determined that autologous BM used for transplantation in patients with chronic myelogenous leukemia following intensive therapy also contained cells that contributed to relapse.[259] Other gene marking trials involving patients with multiple myeloma,[260,261,262] breast cancer,[261,262] follicular lymphoma,[263] and AML[264] failed to show stable levels of marked cells of more than 0.1% after transplantation with autologous gene-marked grafts, contrasting with the high-level marking observed in preclinical mouse models. Although valuable in the early stages, the perceived level of risk related to retroviral-marking clinical trials was altered dramatically after the first report of leukemia in a patient receiving retroviral gene therapy for X-SCID,[265] and given the lack of any possible benefit to the patient related to use of marking vectors, this type of trial has been completely abandoned.

Gene Therapy Trials with Therapeutic Intent

Despite the low efficiencies of gene transfer into long-term repopulating stem cells achieved in early human marking trials, several Phase I/II clinical trials investigating the transfer of potentially therapeutic genes were initiated (Table 71.2). Important information was obtained on both the safety and feasibility of stem cell engraftment without ablation, and although these initial trials were largely disappointing, there were glimmers of hope regarding clinical benefit.

Severe Combined Immunodeficiency Disease

SCID due to ADA deficiency has been a prototype target disease for gene therapy since the initial development of retroviral vectors over a decade ago,[266] and children with ADA-deficient SCID were the subjects of the first clinical trial utilizing a vector carrying a therapeutic gene directed at T-lymphocyte targets (see below). HSCs would be theoretically preferable to T-cells as gene-correction targets in this and other immunodeficiency disorders, because of the potential for permanent and complete reconstitution of the T-cell repertoire.

To address this hypothesis directly, two ADA-deficient children received autologous BM and mature lymphocytes transduced with two different retroviral vectors carrying the therapeutic ADA gene and the Neo gene and then repeatedly re-infused without conditioning.[267] In the first year after initiation of these infusions, vector-containing T-cells originating from the transduced T-cells were observed, but with time, there was a shift to vector-containing T-cells originating from transduced BM cells. The proportion of gene-corrected clonable T-cells was 2% to 4%, and analysis of T-cell–receptor gene rearrangements indicated a wide repertoire of corrected clones. A surprisingly high number of marrow myeloid colonies resistant to neomycin were also reported, despite lack of conditioning, and an in vivo selective advantage for gene-corrected cells of all lineages was hypothesized.

For genetic disorders diagnosed in utero, the use of CB cells as targets for gene transduction represents an exciting alternative approach[268,269] CB may contain greater numbers of primitive reconstituting cells with higher proliferative potential that may prove more susceptible to retroviral transduction. Moreover, early treatment is crucial in diseases that progress to irreversible damage before a child is old enough to allow collection of mobilized peripheral blood or BM cells.[270] Three infants diagnosed in utero with ADA deficiency allowed the testing of this concept, and CB was collected at the time of delivery. The cells were $CD34^-$enriched and transduced with an ADA/Neo

retroviral vector and infused in the absence of conditioning.[271] Vector sequences were initially detected in circulating myeloid and lymphoid cells at low levels of <0.1% in all three children for >18 months. As expected if corrected lymphocytes have an in vivo advantage, 4 years after the newborns were given infusions of transduced autologous CB $CD34^+$ cells, the frequency of gene-containing T lymphocytes rose to 1% to 10%, whereas the frequencies of other hematopoietic and lymphoid cells containing the gene remained <0.1%. Cessation of polyethylene glycol-conjugated ADA enzyme replacement in one subject led to a decline in immune function, despite the persistence of gene-containing T lymphocytes. Thus, despite the long-term engraftment of transduced HSCs and selective accumulation of gene-containing T lymphocytes, this study indicated that improved gene transfer and expression were needed to attain a therapeutic effect.[267]

Fanconi Anemia

Fanconi Anemia (FA) is another genetic disorder of the hematopoietic system that appears to be an excellent candidate for gene therapy. This congenital syndrome is characterized by BM failure, physical anomalies, and an increased susceptibility to marrow failure and leukemias. Cells from these patients are abnormally sensitive to chemically induced DNA cross-linking. Many of the complementation groups have been cloned and sequenced, making a genetic approach feasible for this disorder.[272] Phenotypic correction of this abnormality in cells from one patient group was successful after transduction with viral vectors carrying the Fanconi anemia complementation group C gene (*FACC*).[273,274] A possible in vivo survival advantage for gene-corrected primitive cells and their progeny has made FA an attractive candidate disease for stem cell gene therapy. Even a very low efficiency of transduction might result in gradual in vivo expansion of corrected progenitor and stem cell populations. A clinical trial testing this hypothesis using granulocyte-colony stimulating factor (G-CSF)–mobilized peripheral-blood $CD34^+$ cells as targets yielded disappointing results, in part because of the very poor mobilization in these subjects,[275] yet engraftment with corrected progenitor cells was demonstrated.[276]

Gaucher Disease

Modeling preclinical murine transplantation models, gene therapy was also attempted for Gaucher disease.[277] Akin to the previous gene therapy trials, no conditioning was used in these patients prior to infusion of G-CSF mobilized or BM $CD34^+$ cells transduced with standard retroviral vectors carrying a normal GC cDNA. Unlike results obtained in the mouse, low numbers of gene-corrected cells were again detected, with little or no expression and no disease correction following transplantation.

Chronic Granulomatous Disease

Similar results were obtained in a clinical trial for an autosomal recessive form of CGD.[278] Five patients received transduced G-CSF mobilized $CD34^+$ cells without pre-conditioning. Corrected granulocytes were detected in the peripheral blood of all individuals for up to 6 months after infusion but the levels (0.004% to 0.05%) were below the desired 5% to 10% required for therapeutic effects.

Optimization of Human Gene Therapy Protocols

Although the first-generation human gene therapy trials established the proof of principle of transduction of primitive human repopulating hematopoietic cells, they uniformly failed to reach and maintain therapeutically relevant levels of genetically modified cells. This striking difference in outcome observed between mouse and human studies was proposed to result from intrinsic differences between mice and humans, resulting in a different susceptibility to retroviral transduction and a different ability of transduced HSCs to engraft. Other considerations included loss of stem cell activity by forced ex vivo division, immune recognition of cells expressing foreign transgene products, toxicity from the constitutive expression of the transferred gene products on HSC differentiation in vivo, lack of conditioning in the clinical settings, and the minimal expression of amphotropic surface receptors used by retrovirus-based gene transfer vectors on human HSCs.[85]

The recognition of differences in HSC behavior between mice and humans and the disappointing results in the early human HSC gene therapy clinical trials underscored the need for alternative assays similar to those available in mice that permit direct identification and characterization of human long-term reconstituting cells and their susceptibility to gene transfer. These alternative assays provided the necessary platform for the optimization of human gene therapy protocols, leading to the first clinical trials with therapeutic benefits.

Development of Preclinical Animal Models for Investigating Gene Transfer into Human Hematopoietic Stem Cells

Large Animal Models

Inasmuch as prolonged follow-up of in vivo hematopoiesis is the most reliable parameter to identify human HSCs, large animals are more adapted than mice for evaluation of gene transfer to long-term repopulating cells, given their lifespan and their size, allowing repetitive blood and marrow sampling.

Fetal Sheep

The group of E. Zanjani, capitalizing on the immunologically tolerant environment of the fetal sheep between 50 and 60 days of gestation, successfully showed engraftment and persistence of human cells several years after intraperitoneal administration in utero of primitive human hematopoietic cells from CB or BM.[279,280,281] Among fetuses reaching maturity, at least 50% showed long-term persistence of human cells and demonstration that retrovirally transduced human cells could be detected,[282] suggesting transduction of primitive human HSCs. However, the procedure was hampered by low-level engraftment, a high rate of fetal loss, and impracticality for most research groups.

Nonhuman Primates

Given their phylogenetic proximity to humans, nonhuman primates, including baboons and Old-World rhesus macaques, have been employed extensively for the preclinical testing of promising gene therapy strategies.[283,284] The cross-reactivity of reagents employed for human application adds to the practicality of these models. In contrast to murine studies, much lower levels of gene-modified circulating cells than in the murine experiments were reported using similar vector systems and transduction conditions, generally <0.01% to 1%.[285–288] These results were very similar to data obtained in first-generation clinical trials, validating the importance of large animal models for the optimization of gene therapy strategies in humans. The value of these models for preclinical testing was also illustrated when aggressive T-cell lymphomas developed in 3 of 10 rhesus macaques as a result of insertional mutagenesis following transplantation with BM cells transduced with retroviral vector stocks contaminated with replication-competent helper virus capable of continued gene transfer in vivo.[78,289] This setback led to a reassessment of safety issues and increased regulatory oversight of human clinical trials, with consensus that it is absolutely necessary to use producer cell lines and vector stocks that have been confirmed to be free of helper-virus contamination in any clinical application.

Canine Models

The canine autologous transplantation model has also been used to test retroviral gene transfer strategies. Successful transduction of G-CSF–mobilized peripheral-blood engrafting cells was first demonstrated in the dog, as was the importance of partially or fully ablative conditioning radiation or chemotherapy for detectable engraftment with transduced primitive hematopoietic cells.[290–292] Cross-reactivity of human reagents has proven more problematic in the dog model, yet continued progress in this model has led to a clinically relevant gene transfer technique.[293,294] Recently, further progress in this model has allowed the attainment of very high levels of genetically modified cells, approaching 100%.[293,295–297,298,299] The value of the dog model as a large animal model is further strengthened by the presence of several disease states that mimic those in humans, which could

allow stringent preclinical testing, as recently shown in a canine model of LAD[110] and pyruvate kinase deficiency.[300]

Large animal models thus became a focus, but outbred animals introduce significant experimental variability and the high costs limit the breadth of experiments that can be performed. For this reason, a competitive re-population model in which each animal serves as its own control has been utilized for the majority of subsequent comparative studies. In this model, hematopoietic progenitors are isolated and divided equally for transduction under two (or more) distinct experimental conditions using marking vectors that can be distinguished in vivo following reconstitution. Loss of stem cell activity during the ex vivo culture required to achieve gene transfer was a major concern generated by the early human clinical trials, a concern supported by studies in the mouse in which ex vivo culture of HSCs resulted in a significant engraftment defect.[301] Competitive experiments in the nonhuman primate tracking genetically modified cells subjected to either short or extended ex vivo culture supported this notion.[302]

Immunodeficient Mice

Although results from the large animal models have correlated better with results from early human clinical trials, the rhesus and canine experiments are expensive, slow, and technically difficult, not allowing large-scale testing of new approaches. Over the past 20 years, xenograft mouse models have gained in popularity, in part due to access, and investigators have begun to employ engraftment of transduced human hematopoietic cell populations in immunodeficient mice as an alternative experimental model.[303–307] Initially, large numbers of human BM cells were intravenously injected into sublethally irradiated mice lacking a functional immune system to prevent rejection of the injected human cells, including severe combined immunodeficient (*Scid*) and beige/nude/xid (*bnx*) mice.[308,309] With regular treatment of engrafted *Scid* mice with a combination of human hematopoietic cytokines, human BM cells that migrated to the mouse marrow and spleen gave rise to a small but sustained pool of myeloid progenitors and B-cells for several months, indicating that the engraftment was long-term and multipotent, fulfilling two key criteria used to define HSCs.

The *Scid* mouse used in these initial studies can spontaneously generate murine T- and B-cells with age and has high levels of natural killer (NK) cell activity, both impeding efficient and prolonged xenograft. To improve upon the available immunodeficient mouse strains, the Scid mutation was backcrossed onto the nonobese diabetic (NOD) background.[310] The resultant NOD-*Scid* mouse had reduced innate immunity and superior engraftment of human hematopoietic cells. However, further improvements were sought due to the high incidence of spontaneous thymic lymphomas that shortened their lifespan, a striking preferential development of human B-cells after transplantation, and a persistence of murine NK-cells resulting in a lack of human T- and NK-cell differentiation in this strain. By reducing or abolishing NK activity in NOD-*Scid* mice a new strain, NSG or NOG mice, was developed and is currently the most widely used humanized mouse model for gene therapy preclinical testing.[311,312,313,314]

The immunodeficient mouse model assays a human cell population, operationally defined as *Scid* repopulating cells (SRCs), that is distinct from hematopoietic progenitors identified using in vitro methodology, including long-term culture initiating cells and CFCs.[250] Using a gene marking approach similar to that used in mouse transplant studies and early clinical trials, Guenechea et al.[315] showed that individual engrafted and marked human SRCs could produce a large clone of differentiated progeny with engraftment potential in secondary NOD-*Scid* recipients, demonstrating the proliferative and self-renewal capacity of SRCs, respectively. Although this study did not contain a direct analysis of individual lineages, a recent investigation by the same group[316] successfully tracked self-renewal and multilineage output of single human cells purified using a complex set of markers (CD34+CD38–CD45RA–CD90+CD49f+Rholo) for at least 8 months after transplantation in NSG mice. Together, these studies fulfilled the proliferative, self-renewal, and multipotential criteria previously used to define murine HSCs, providing a compelling characterization of human HSCs. Although, in practical terms, the above studies served to validate the murine xenotransplant model as a sound surrogate assay system for human stem cells, the predictive value of these xenograft models remains questionable, as a direct comparison of engraftment of genetically modified autologous baboon cells in both the baboon and the NOD/SCID mouse suggests distinct populations contributing to hematopoiesis, with short-term progenitors only read out in the immunodeficient mouse.[317]

The development of better assays for evaluating gene transfer efficiency in human repopulating cells has culminated over the past two decades in various strategies to improve gene transfer protocols, including: (1) new retroviral vector designs, (2) optimized transduction conditions, and (3) use of conditioning regimens to favor engraftment of transduced cells.

Use of Alternative Gene Transfer Vectors

Standard retroviral vector systems have been used extensively in small and large animal models and have dominated clinical trials based on ex vivo transduction of autologous $CD34^+$ cells. However, the dependence of these vectors on cell cycling for efficient transduction has limited their utility in quiescent HSCs. Thus, alternative viral vector systems have been explored, including AAV and retroviral vectors based on various members of the Retroviridae family (e.g., lentiviruses and spumaviruses). The need for integration has precluded extensive investigation of nonviral delivery systems for hematopoietic applications requiring long-term expression.

Adeno-associated Viruses

Despite a great deal of initial enthusiasm for the use of AAV as a clinical gene transfer vector, more recent data argue against the use of AAV for most applications requiring stable integration in hematopoietic cells and their progeny. Several laboratories have reported high transduction efficiency of both human and murine hematopoietic progenitors, as assayed by PCR or transgene expression analysis on individual CFC.[162,318,319] These are difficult to interpret, however, given the stability of the AAV vector DNA and the very high efficiency of transient expression of transgenes for days to weeks without integration.[161,318,319] Although these studies indicate no advantage over retroviral vectors in terms of gene transfer into repopulating stem cells, efficient transfer to hematopoietic cells can be obtained by using AAV vectors.[320,321]

Human Foamy Viruses

HFV are retroviruses that specifically belong to the genera Spumavirus. The nonpathogenic nature of HFV makes vectors based on this virus more palatable. Because problems encountered in the production of replication-competent, retrovirus-free vector have been overcome, vectors based on the HFV have been used to transduce hematopoietic cells efficiently. They were employed to phenotypically correct CD18 integrin deficiency in a canine model of LAD,[110] gp91phox deficiency in a mouse model of X-CGD,[322] and hemolytic anemia in a canine model of pyruvate kinase deficiency[300] but it has not yet been used in clinical trials. However, they do not appear to transduce hematopoietic stem and progenitor cells more efficiently than standard retroviruses.

Lentiviral Vectors

Unlike vectors based on standard retroviruses, lentiviral vectors harbor a pre-integration complex that appears more stable and

able to cross an intact nuclear membrane, thus allowing transduction of nondividing cells such as HSCs. However, it is also generally agreed that cells must exit G0 and enter G1 for efficient transduction by HIV-1 based vectors.

Self/inactivating Feature of Lentiviral Vectors

Because of safety concerns regarding recombination with endogenous HIV, a safety or "self-inactivating (SIN)" feature was incorporated in these vectors by eliminating a portion of the 3′-LTR, which on proviral integration replaces and thus inactivates the 5′-LTR. For these SIN vectors, the efficiency of transgene expression is highly dependent on the addition of ubiquitous internal promoters, such as the murine stem cell virus (MSCV), the human elongation -1a (EF1-a), human phosphoglycerate kinase (PGK), spleen focus forming virus (SFFV), gibbon ape leukemia virus (GALV), or the hybrid chicken actin promoter containing the CMV enhancer region (CAG).

Altering Tropism of Lentiviral Vectors through Pseudotyping

Wildtype HIV-1 virions infect cells that express the CD4 receptor and an appropriate co-receptor. Expansion of the cellular tropism of HIV-1–based vectors can be accomplished by substituting the wildtype envelope protein with an envelope protein from a different virus, a process referred to as pseudotyping.[323] The MLV amphotropic envelope used in most clinical gene therapy trials employing standard retroviral vectors was also chosen in early experiments with HIV-derived vectors.[95] However, its receptor, Pit-2, is only present at very low levels on HSCs, correlating with the low efficiency of lentiviral transduction in this cell type.[85] Screening of an extensive panel of pseudotyped MLV-based vectors using the xenograft murine and nonhuman primate models established the superiority of the GALV, the cat endogenous retroviral glycoprotein (RD114) and the VSV-G protein for the transduction of HSCs.[89,324–326] However, pseudotyping lentiviral vectors with alternate envelope proteins, namely GALV and RD114, has proven more difficult due to refractory residues within the cytoplasmic tail of both envelopes that limits their cleavage by lentiviral proteases. To improve the lentiviral packaging efficiency of GALV and RD114, chimeras of each envelope have been constructed by replacing the tail region of GALV and RD114 with the corresponding region from MLV. The resulting chimeras, GALV-TR and RD114-TR, have been shown to pseudotype lentiviral vectors with increased efficiency.[327–329]

In contrast to native GALV and RD114, VSV-G is efficiently incorporated in HIV-1 virions. VSV-G pseudotyping confers high vector particle stability, allowing for repeated freeze–thaw cycles and concentration by ultracentrifugation to titers exceeding 10^9 particles/ml.[32,95,330] Pseudotypes based on VSV-G have broad tropism long thought to be conferred by interaction with phosphatidylserine (PS), a ubiquitous cellular lipid, but the role of PS as a cell "receptor" for VSV-G particles has been refuted.[331] When directly compared to amphotropic or RD114-pseudotyped lentiviral vectors using the NSG preclinical assay, vectors bearing the VSV-G envelope protein showed higher efficiency of transduction in human repopulating cells.[332] Toxicity of the VSV-G protein to cells in which it is expressed is perhaps the most significant shortcoming of this envelope protein. However, success has been obtained in deriving a stable packaging cell line by expressing VSV-G from a tetracycline-inducible promoter although this methodology has not yet been used clinically.[333,334] Moreover, notwithstanding the observed toxicity of VSV-G and the demonstration that VSV-G-pseudotyped vectors produced in human cells were rapidly inactivated by human serum,[335] two recent gene therapy trials[102,103] have reported successful long-term transduction of human HSCs using HIV-1-based vectors pseudotyped with VSV-G.

Altering the Tropism of Lentiviral Vectors for Selective Targeting of CD34$^+$ Cells

Envelope proteins made chimeric by the addition of a ligand, such as the early-acting cytokines SCF and thrombopoietin (TPO), have been explored as a mechanism for specifically targeting lentiviral vectors to primitive hematopoietic cells expressing the SCF receptor KIT. These vectors could be used for in vivo targeted gene delivery to HSCs, eliminating the risk of inducing cell differentiation and loss of the homing/engraftment potential of these cells as observed in ex vivo targeted HSC gene delivery approaches. The selective transduction of HSCs by VSV-G/TPO/SCF–displaying vectors was demonstrated by their capacity to promote selective transduction of long-term NOD/SRCs.[336] However, the fusion glycoprotein VSV-G in VSV-G/TPO/SCF–co-displaying lentiviral vectors is sensitive to human immune/complement system, rendering these vectors unsuited for in vivo gene delivery.[329] Recently, complement-resistant vectors capable of specifically targeting the very rare immature progenitor cells in an immunodeficient murine model were produced by substituting VSV-G for the complement-resistant glycoprotein mutant RD114-TR.[337] Completely obviating ex vivo manipulation of HSCs may be of particular interest for gene therapy of BM failure syndromes for which the number of stem cells is limited.

Preclinical Evaluation of Lentiviral Vectors

Given the established lack of predictability of standard murine transplantation models for evaluation of HSC transduction efficiency in humans, investigators initially chose the murine xenotransplant assay to validate the ability of HIV-1–based vectors to efficiently transduce human hematopoietic cells, including CD34$^+$ cells and the more primitive CD34$^+$/CD38$^-$ subset. Several groups reported efficient gene transfer of SRC derived from human CB,[338,339,340,341,342] BM[338] and mobilized peripheral blood[343,344] under conditions where standard retroviral vectors were ineffective. High-level green fluorescent protein (GFP) transgene expression in SRC capable of secondary[342] and tertiary[341] multilineage re-population in NOD-*Scid* mice suggested transduction of primitive human HSCs with pluripotential, proliferative, and self-renewing capabilities. As outlined below, these preclinical data have recently been confirmed in the context of clinical trials for ALD[102] and β-thalassemia.[103]

Demonstration of the utility of HIV-1–based lentiviral vectors to transduce hematopoietic cells with long-term repopulating potential was initially met with limited success in rhesus macaques[345,346] and baboons.[347] These Old-World monkeys were found to possess cellular antiviral factors responsible for the observed resistance to HIV-1 infection. In contrast, HIV-1–based lentiviral vectors could mediate efficient gene transfer to long-term repopulating cells in the canine[295] and pigtailed macaque models.[348] The restriction to HIV-1 infection in rhesus macaques was alleviated by modification of HIV-1-based vectors[349–351] or by the use of an alternative lentiviral vector based on the simian immunodeficiency virus (SIV).[352,353–356]

Despite the lack of predictability of standard murine transplantation studies for evaluation of gene transfer into human HSCs, mouse disease models developed by gene targeting or arising from spontaneous gene mutations may represent the only available option for preclinical testing of the impact of gene transfer vectors on disease phenotype; large animal disease models do not exist for most disorders treated by gene therapy, and for a number of orphan diseases that are common targets of gene transfer protocols, it is impractical to obtain biospecimens from a large cohort of patients to perform preclinical murine xenotransplant efficacy studies. All disorders with active HSC gene therapy clinical trials have employed murine models of human diseases to evaluate efficacy of lentiviral vectors for correction of disease phenotype, including ALD,[102] WAS,[357–362] β-thalassemia,[363–366] SCID,[367–371] and CGD[372].

Gene Transfer Vectors with In Vivo Selectable Markers

One strategy to increase the efficiency of gene transfer entails the inclusion of selectable genes in vectors to confer an in vivo advantage to transduced cells. Successful in vivo selection has previously been documented in murine HSC transplantation models using several drug resistance genes, including multidrug resistance protein-1 (MDR-1),[213,373] dihydrofolate reductase (DHFR),[374] and O6-methylguanine-DNA methyltransferase (MGMT)[375–377] However, in more clinically relevant large animal models, in vivo selection using DHFR[378] and MDR-1[379,380] was variable and transient, with levels of gene-modified cells returning to baseline within a few weeks. MGMT is one of the most promising drug resistance genes that encodes for the DNA repair protein O6-alkylguanine-DNA-alkyl-transferase (AGT). This protein confers resistance to the cytotoxic effects of alkylating agents, including nitrosoureas (e.g., BCNU) and temozolomide. Incorporation of a mutant form of MGMT in the gene transfer retroviral vectors can facilitate a greater selective advantage for primitive hematopoietic cells containing the vector after in vivo administration of an alkylating agent. In vivo selection of HSCs using MGMT was successfully achieved in murine,[376,377] nonhuman primate[298,381] and canine models,[297,298,382,383] and in human NOD/SRCs.[384,385] However, results in large animals were not uniformly positive[354] and, although no evidence of leukemic transformation was seen using this approach, the cumulative genotoxicity resulting from the combined use of alkylating agents and retroviral vectors needs to be considered.

Gene Transfer Vectors with Ex Vivo Selectable Markers

Positive selection of transduced cells in vitro before re-infusion is another strategy to increase re-population with gene-modified cells. Vectors containing genes for various cell-surface proteins have allowed flow cytometric sorting of successfully transduced cells. A number of studies have utilized the human cell-surface protein CD24, or the murine homolog heat-stable antigen (HSA). There is limited sequence homology between the murine and human forms, and noncross-reactive antibodies are available for selection. Their small size means they take up little space in the vector construct. Murine marrow cells transduced with a vector-containing human CD24 and sorted before re-infusion resulted in greatly increased long-term reconstitution with vector-containing cells.[386] A vector expressing murine HSA allowed enrichment for transduced human progenitor cells.[387] However, CD24 and HSA are GPI-linked surface proteins, a class of proteins that has been shown to be transferred from cell to cell both in vitro and in vivo, clouding the specificity of this marker and raising concerns about ectopic expression of these genes in vivo.[161,386,387]

Retroviral vectors carrying a truncated nonfunctional form of the human nerve growth-factor receptor have also been developed as a selectable marker for use on hematopoietic targets, because hematopoietic cells do not express endogenous nerve growth-factor receptor. The introduction of new cell-surface proteins has the theoretical disadvantage of altering trafficking or cell–cell interactions upon infusion of transduced cells. Alternative cytoplasmic markers such as GFP and mutated murine protein are naturally fluorescent, avoiding the need for pre-selection antibody staining.[388] However, prolonged stable expression of these proteins has proved difficult, and there is evidence that these proteins are toxic to primary mammalian cells.[389,390] The use of selection for GFP after retroviral-mediated transduction in the nonhuman primate model to increase engraftment by genetically modified cells resulted in increased short-term engraftment only, raising another concern that expression of transferred genes may be more efficient in differentiated rather than stem cells, effectively enriching for progenitors with only short-term potential.[391]

Low transduction efficiency of primitive human HSCs may preclude post-transduction sorting for a marker gene if, after sorting, too few stem cells remain to allow safe and rapid hematopoietic reconstitution; this is especially problematic after ablative chemotherapy. A potential solution to this problem would be ex vivo expansion of selected transduced cells prior to re-infusion. However, when ex vivo cultured cells compete against endogenous stem cells in a nonablative model, a significant engraftment defect is evident,[301,392] indicating that true long-term repopulating cells cannot be expanded efficiently or even maintained ex vivo using current culture conditions.[302,393–396]

Gene Transfer Vectors with Genes Promoting Selective Growth Advantage to Transduced Cells

In most diseases considered to be suitable targets for gene therapy, corrected cells do not themselves have an inherent growth advantage, providing an impetus to arm retroviral vectors with genes capable of conferring a selective growth advantage to transduced HSCs and their progeny. For example, mouse HSCs transduced with the homeobox gene, HOXB4, possess more than tenfold greater repopulating ability than that of nontransduced BM.[397] Furthermore, transgenic overexpression of the antiapoptotic protein Bcl-2 results in increased HSC numbers,[398] and expression of a truncated form of the human erythropoietin (Epo) receptor can augment HSC engraftment through the use of exogenous Epo.[399] Blau et al. have utilized inactive monomeric signaling domains derived from receptors such as Epo or TPO to permit controlled growth of genetically modified cells through the use of chemical inducers of dimerization.[400,401] Another approach involves selective enrichment of genetically modified cells using vectors encoding a fusion protein between the growth-signaling portion of the G-CSF receptor and the hormone-binding domain of the estrogen receptor. This approach allows controlled growth of genetically modified cells using exogenous estrogen, and preclinical testing in the nonhuman primate demonstrated the feasibility of this approach.[402,403]

However, the risk of combining integrating vectors and growth-promoting genes for clinical applications has recently been highlighted in large animal model preclinical studies. Investigators transduced monkey $CD34^+$ cells with either a *HOXB4*-expressing vector or a control vector expressing only a marker gene and analyzed the competitive repopulating ability of these cells in vivo. As hoped, there was an early very significant advantage for the *HOXB4*-transduced cells following engraftment of the monkeys, but in contrast to mouse studies, a much less significant advantage for the *HOXB4*-transduced cells was observed long-term after transplantation.[404] However, approximately 2 years after transplant, they reported the first instances of leukemia linked to HOXB4 expression, both in the original group of monkeys and in dogs that received cells transduced with HOXB4-expressing vectors.[405] Myelodysplasia in two additional nonhuman primates was subsequently reported in association with retroviral vector-mediated insertional mutagenesis and overexpression of HOXB4.[406] Overall, these studies strongly indicated that overexpression of HOXB4 using integrating retroviral vectors is much too risky to be contemplated in any clinical settings.

Optimization of Transduction Conditions

Cytokine Combination

Various procedures have been refined by different laboratories to optimize retrovirus-mediated transduction in HSCs. A delicate balance must be reached to reconcile the needs for cell cycling for

productive transduction without impairing the repopulating ability of HSCs. The current consensus based on large animal and murine xenograft models favors a transduction step in the presence of an early-acting cytokine cocktail composed of SCF, FLT-3L, and TPO, with the optional addition of IL-3. The mechanism of action of these early-acting cytokines is generally related to their effect on cell cycle status but they have also been proposed to enhance transduction by down-regulating proteasome activity in HSCs.[407,408] Transduction with standard retroviral vectors is typically performed over 72 hours with an obligatory 24-hour cytokine-mediated prestimulation step to favor cell cycling. For lentiviral vectors, a 24-hour prestimulation followed by a single 24-hour transduction in serum-free medium with cytokines has been proposed as an optimal protocol for transduction of human $CD34^+$ cells using the humanized NSG mouse xenograft model.[409,410]

Use of Fibronectin during Transduction

The function of HSCs depends upon the signals from surrounding stromal cells (e.g., fibroblasts, osteoblasts) and extracellular matrix molecules (e.g., fibronectin) found within the highly specialized BM microenvironment. In murine studies, co-culture of the hematopoietic target cells with the fibroblast-derived retroviral producer cells has been shown to be the most efficient gene transfer method. However, this approach is inappropriate for use in human clinical trials because of the risk of co-infusing the producer cells into patients along with the transduced hematopoietic cells.

To expand clinical applicability of murine gene transfer protocols, several investigators showed increased gene transfer to human hematopoietic cells adherent to autologous or allogeneic BM stromal cells using in vitro assays.[411–413] Similarly, addition of autologous stromal cells during the transduction period promoted gene transfer into HSCs in the rhesus macaque model.[302] However, the technical difficulties associated with extensive scale-up have limited widespread clinical application of this approach. Moritz et al. took a different tactic by transducing human hematopoietic cells cultured in vessels coated with the chemotryptic 35-kd carboxy-terminal fragment of human fibronectin (FN35) and noted enhanced transduction by retroviral vectors.[414] A recombinant version of this fragment (CH-296), commercially available as Retronectin (Takara Biomedical, Otsu, Japan), was shown to enhance gene transfer in human $CD34^+$ cells by co-localization of the cells with the vector,[212,415,416] unless an excess of retroviral particles was used during transduction.[417] The co-localization of vectors and target cells can be enhanced using spinoculation, a neologism coined to describe low-speed centrifugation used at the start of transduction to augment gene transfer.[93] The enhancement effect achieved with fibronectin was also attributed to biologic effects on HSCs, such as preservation of repopulating potential[212,418–420] and decreased apoptosis.[421] Extensive preclinical studies showed successful gene transfer into murine long-term repopulating stem cells as well as into human and nonhuman primate $CD34^+$ cells derived from BM, CB, or mobilized peripheral blood when transduction was performed in vitro[421,422,423,424] or in vivo[424] with retroviral vectors and Retronectin. Correspondingly, in all recent clinical gene therapy trials showing therapeutic benefits, retroviral transduction of human $CD34^+$ cells was conducted in the presence of human recombinant fibronectin.

Conditioning Regimens to Enhance In Vivo Gene Marking

Engraftment of HSCs is a competitive process between endogenous and infused stem cells. For disorders such as SCID, a growth advantage conferred on genetically corrected cells enables engraftment without conditioning, yet for the majority of disorders in which HSC gene transfer may be applicable, no such advantage to the modified cells is conferred and most investigators have relied instead on toxic myeloablative conditioning to damage or destroy endogenous stem cells and thus provide a competitive advantage to the infused genetically modified stem cells. In preclinical models[302] and in patients with malignancies,[254,261,262] myeloablative regimens have been used routinely to enable engraftment of gene-modified primitive hematopoietic cells. However, many of the diseases that could be targeted by gene therapy are chronic indolent disorders in which the risks of myeloablative regimens may outweigh the potential benefits.

Preclinical Evaluation of Nonmyeloablative Conditioning Regimen in Murine Models

Reduced intensity (nonmyeloablative) conditioning regimens were tested in preclinical models to assess engraftment of marked HSCs while reducing transplant-related toxicities. Engraftment of corrected cells can be achieved in mice in the absence of conditioning by using extremely large BM grafts but this approach is not clinically feasible.[353–357] Moderate-dose irradiation or antimetabolite-based nonmyeloablative conditioning allowed correction of CGD[242,425–428] and X-SCID[429] in mouse models of these disorders. Alternative conditioning strategies to promote engraftment of infused HSCs with increased safety have been investigated in mice and are of potential relevance for gene therapy applications. For instance, administration of an antibody that blocks c-kit, the receptor for SCF, transiently reduced endogenous murine stem cells, facilitating engraftment with donor HSCs in immunodeficient $Rag2^{-/-}/\gamma c^{-/-}$ mice but not in immunocompetent mice.[430] Combination of this antibody with low-dose irradiation profoundly decreased endogenous repopulating activity, enabling efficient and durable engraftment of fresh or lentivirus-transduced BM cells in wildtype and CGD mice.[431] In another study, HSC mobilization with AMD3100, a CXCR4 antagonist with a favorable safety profile in clinical studies, was shown to vacate niches in the mouse BM microenvironment and thus could be used in this model as a preparative regimen for stem cell transplantation (SCT).[432]

Preclinical Evaluation of Nonmyeloablative Conditioning Regimen in Large Animal Models

In large animal models, no engraftment with genetically modified cells has been observed without conditioning. In one study using a nonmyeloablative regimen, 12% gene-marked leukocytes persisted in the peripheral blood of a rhesus macaque for up to 33 weeks after transplant.[433] In other studies, autologous transplantation of transduced HSCs in nonhuman primates conditioned with low-dose irradiation or busulfan have generally resulted in low but measurable (~1%) long-term marking,[355,434–437] providing proof of principle that partial marrow cytoreduction allows engraftment of gene-modified cells without significant toxicity. A possible concern, however, is the unexpected finding that in partially ablated recipient mice, where the BM is a more competitive environment for re-population compared to the fully ablated marrow, HSCs carrying survival- or proliferation-activating lentiviral insertions had an advantage for engraftment, perhaps increasing the risk of leukemic progression.[438]

Conditioning Regimen in Gene Therapy Clinical Trials

Initial gene therapy efforts using HSCs did not administer preparative regimens to avoid potential toxicities from chemotherapy agents when benefits of the procedure were unproven.[271,278,439] It was hypothesized that the low marking levels achieved in HSCs in these trials could only lead to clinical benefits if the cells derived from the transduced HSCs had a biologic selective advantage in vivo. Modeling conditioning protocols developed in preclinical models, subsequent gene therapy trials for ADA-SCID,[23,440,441,442,443] X-CGD,[444–446] WAS,[447] and

β-thalassemia[103] introduced partial myeloablation with busulfan or melphalan prior to infusion of the genetically corrected cells. As outlined below, in most cases, successes were detected after nonmyeloablative conditioning when augmented by a recognized biologic selection for successfully treated cells in vivo or by retroviral-mediated clonal expansion. It appears that reduced intensity regimens employed to date for disorders that lack a biologic selective advantage in gene-corrected cells, such as CGD, may be insufficient to mediate substantial HSC engraftment and that more ablative approaches may be necessary. The recent clinical success achieved in X-linked ALD using a conventional myeloablative conditioning (cyclophosphamide 200 mg/Kg and busulfan 16 mg/Kg) is a useful example of a suitable regimen that resulted in clinically relevant levels of HSC marking and long-term myeloid engraftment (10% to 15%).

Optimized Gene Therapy Protocols

The preclinical studies above, augmented by the clinical experience of the early gene therapy efforts, have led to an optimized protocol for ex vivo manipulation of HSCs that has been employed with success in recent clinical trials (Fig. 71.7). Hematopoietic stem and progenitor cells expressing the CD34 cell-surface marker are purified from BM harvests or G-CSF–mobilized peripheral blood cell collections. Following a brief (24 hours) ex vivo culture in conditions that favor cell cycle transition from G_0 to G_1 (e.g., culture medium supplemented with SCF, Flt3L, and TPO), the $CD34^+$ cells are incubated on a surface coated with the C-terminal fragment of fibronectin in the presence of the same cytokines for an additional 72 hours with standard retroviral vectors or, preferably, for an additional 24 hours with VSV-G pseudotyped SIN HIV-1–based vectors expressing the desired therapeutic gene from an internal promoter. For disorders in which corrected cells do not have a competitive repopulating advantage over uncorrected endogenous HSCs and their progeny, the patient is conditioned with a reduced intensity or myeloablative regimen prior to intravenous re-infusion of the treated cells. After autologous transplantation, transduced cells home to the BM where they initiate hematopoiesis. Transduction efficiency and safety of the procedure are evaluated by periodic collection of peripheral blood samples over extended periods of time.

Second-Generation Gene Therapy Trials

The advances derived from preclinical models were rapidly applied in a second generation of clinical trials, with actual therapeutic intent, for immunodeficiency disorders, including X-SCID, ADA-SCID, CGD, and WAS (Fig. 71.6 and Table 71.2).

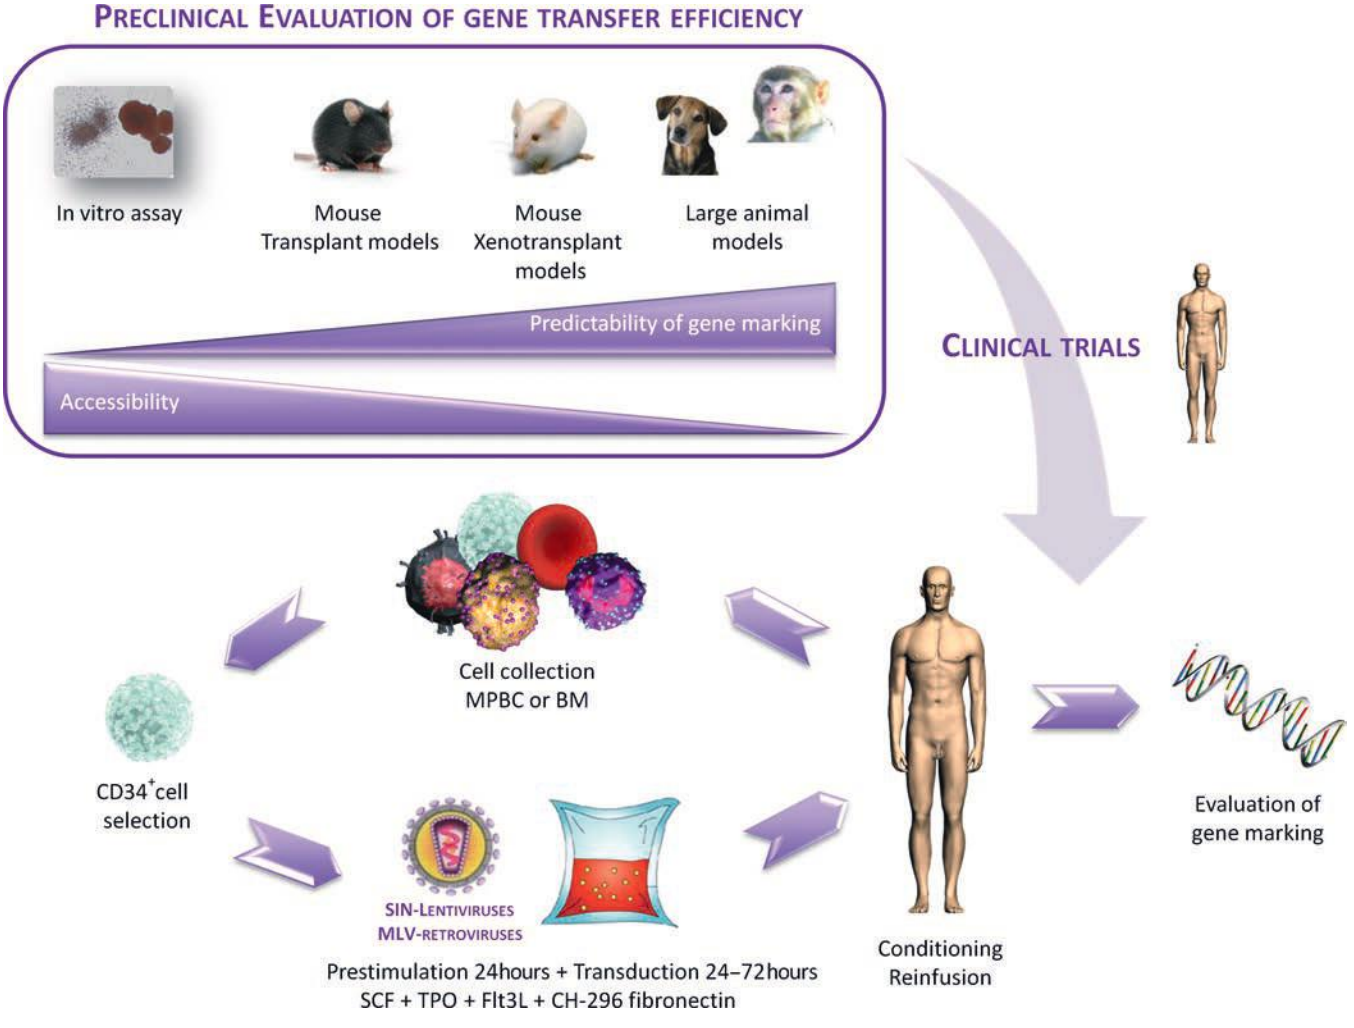

FIGURE 71.7. Approach for the genetic manipulation of hematopoietic stem cells (HSCs). The upper panel compares the predictive value and accessibility of various preclinical models in the evaluation of gene transfer efficiency of vectors used in HSC gene therapy trials. The lower panel depicts the optimized protocol for transduction of hematopoietic stem and progenitor cells, as used in recent clinical trials. BM (bone marrow); Flt3L (*fms*-related tyrosine kinase 3 ligand); MLV (murine leukemia virus); MPBC (mobilized peripheral blood cells); SCF (stem cell factor); SIN (self-inactivating); TPO (thrombopoietin).

Severe Combined Immunodeficiency Disease

The first HSC gene therapy trial demonstrating unequivocal clinical benefit was led by Fischer and Cavazzana-Calvo at the Necker Hospital in France.[22,448,449] Eleven boys with X-SCID were treated, and each patient received autologous $CD34^+$ BM cells, transduced with a standard retroviral vector expressing the corrective IL2Rγ gene and re-infused without conditioning. Rapid functional B- and T-cell immune reconstitution and clinical improvement were observed in all but one child. The same vector insertion site could be detected in both myeloid and lymphoid cells, suggesting that at least some true HSCs had been corrected. Unfortunately, as outlined in details below, the elation after this success was short-lived; four subjects in the trial developed acute T-cell leukemia as a result of insertion of the gene therapy vector near proto-oncogenes resulting in increased expression of these genes through the vector's enhancer activity.[265,450,451]

A similar gene therapy trial was also conducted in London on 10 children with X-SCID. All patients experienced substantial immunologic recovery and in most patients this was accompanied by recovery of humoral immunity and withdrawal of immunoglobin supplementation.[442,452,453] Similar to the first clinical study of gene therapy for X-SCID, a single insertion of the gene transfer vectors caused substantial overexpression of proto-oncogenes in 1 of 10 patients, resulting in leukemogenesis.[454] These data indicated that conventional murine retroviral vectors (based on MLV) present a high risk of leukemogenesis as a result of their powerful enhancer sequences in the intact LTR regions. Although gene therapy has been effective in infants with X-SCID, minimal clinical improvement was detected in 2 of 3 pre-adolescents despite effective transduction and engraftment of G-CSF mobilized $CD34^+$ cells,[455] and complete failure of gene therapy in 2 adult patients was reported after transplantation of transduced BM $CD34^+$ cells.[456]

Bordignon's and Thrasher's group also reported sustained engraftment of engineered HSCs and good immune reconstitution in patients with SCID resulting from ADA enzyme deficiency following transplantation of BM-derived transduced $CD34^+$ cells.[23,440,441] No cases of leukemia have been reported to date in these trials consistent with the long-term analysis of integration sites revealing a polyclonal pattern along with a lack of in vivo skewing for risky insertions.

Chronic Granulomatous Disease

In an attempt to genetically correct the defect in CGD patients, investigators obtained G-CSF mobilized $CD34^+$ cells from two CGD patients and, using a vector similar to that used in the X-SCID trials, inserted a corrective copy of one gp91phox gene needed to make a functional NADPH oxidase.[446] Unlike other CGD trials,[278,444,445] 3 weeks after the cells were re-infused into the patients, a surprisingly large fraction of circulating myeloid cells, more than 20%, carried the corrective gene. This sustained engraftment of functionally corrected cells with therapeutically relevant levels of NADPH oxidase was unexpectedly followed by further in vivo expansion of cell clones containing insertionally activated growth-promoting genes. Clinically, the patients were doing well, clearing chronic infections after engrafting with corrected cells. However, as outlined below, a progressive decline in blood counts was observed in both CGD patients at 15 and 28 months, respectively, after gene therapy as a result of genotoxicity from the gene transfer vectors.[457,458]

Wiskott-Aldrich Syndrome

A German group has recently reported long-term (up to 5 years) correction of WAS in 9 of 10 patients through standard retroviral infection of G-CSF mobilized $CD34^+$ cells transfused after busulfan-induced transient myelosuppression, as evidenced by a decreased frequency and severity of infections, and resolution of signs and symptoms of autoimmunity, including autoimmune hemolytic anemia, thrombocytopenia, neutropenia, and eczema.[447] However, as described in more detail below, leukemia has now developed in several patients as a result of gene transfer vector activation of a growth-promoting gene.

Third-generation Gene Therapy Clinical Trials

Third-generation HSC gene therapy trials have recently emerged, supported by preclinical data suggesting that HIV-derived lentiviral vectors may be safer and more efficient for transduction of stem cells than vectors based on γ-retroviral vectors.[340,348,353,459,460,461,462,463] This new generation of clinical trials has pioneered the use of SIN-lentiviral vectors for correction of ALD[102] and β-thalassemia[103] (Fig. 71.6 and Table 71.2)

Adrenoleukodystrophy

The first use of a lentiviral vector for HSC gene therapy was reported for the treatment of two children with X-linked ALD.[102] This is also the first study using a conventional myeloablative conditioning regimen before re-infusion of the genetically manipulated G-CSF mobilized $CD34^+$ cells. Functional myelomonocytic cells derived from corrected $CD34^+$ cells migrated into the patient's central nervous system to replace diseased microglia cells. At 24 and 30 months post-transplantation, both patients had highly polyclonal reconstitution of hematopoiesis and normal levels of ALD protein, which appeared to retard the progressive cerebral demyelination process. No evidence of genotoxicity has yet been reported in this trial.

β-Thalassemia

Cavazzana-Calvo and colleagues[103] have recently provided another example of the clinical potential of gene therapy using lentiviral vectors by treating an 18-year-old male patient suffering from transfusion-dependent β^E/β^0-thalassemia. $CD34^+$ cells were isolated from the individual's BM and transduced with an HIV-derived lentiviral vector containing a functional β-globin gene. Compared to previous trials, a conditioning regimen with higher doses of busulfan was used in this study. The levels of genetically modified cells gradually rose up to 11% at 33 months post-transplant with concomitant increases in levels of the normal β-globin protein and improved production and quality of normal RBCs. Remarkably, a year after treatment, the patient no longer needed RBC transfusions. This therapeutic benefit, however, was observed in the setting of clonal expansion resulting from integration of lentiviral vectors in the high mobility group AT-hook 2 (*HMGA2*) gene.[464] Marked expansion of a single corrected clone, persisting without malignant transformation for many years, has been documented in an early ADA–SCID gene therapy trial,[465] suggesting that clonal expansion does not irrevocably progress to malignancy, but the known association between HMGA2 overexpression and benign/malignant neoplasias imposes further caution.[464,466,467]

LYMPHOCYTES AS TARGETS FOR GENE TRANSFER

T lymphocytes have several features that make them potentially attractive targets for gene and cell therapies. T-cells circulate in large numbers and are easily harvested, functional subsets have been identified and can be purified via cell-surface antigen selection, and immune responsiveness against specific organisms or target cells can be enhanced via manipulation of culture conditions or genetic modification. A great deal has been learned in the past two decades regarding the optimal culture conditions

for enhancing proliferation while retaining function and in vivo survival.[468] Ablative conditioning is not necessary for persistence of infused T-cells, however, lymphodepletion and/or hematopoietic stem cell transplantation prior to lymphocyte infusion has been reported to improve the persistence and antitumor efficacy of adoptive T-cell therapies.[469,470] These characteristics have stimulated investigators to target lymphocytes for many gene therapy applications. A series of in vivo human clinical trials have yielded very important and often surprising information on the lifespan of these "terminally" differentiated cells in the body, but also worrisome evidence of a strong immune response against exogenous genes expressed by these cells. Striking evidence for clinical efficacy has been obtained in studies redirecting immune reactivity of T-cells toward specific antigens.[471,472]

Gene Marking Studies

The first infusion of genetically modified cells into a human enrolled in a clinical trial used genetic marking to monitor the fate of tumor-infiltrating T lymphocytes (TIL) in vivo. Persistence of low-level gene-marked T-cells was demonstrated, including within tumor deposits, although marking levels were too low to assess whether preferential trafficking of TIL cells to residual tumor occurred.[7] More recently, gene marking studies in humans undergoing allogeneic SCT have helped to further characterize the behavior of lymphocytes that have been cultured ex vivo. Epstein-Barr virus (EBV)-specific donor T-cells from SCT donors used to transplant patients at high risk for post-allogeneic SCT EBV-lymphoproliferation were isolated, expanded, and gene-marked ex vivo during co-culture with EBV-transformed donor lymphoblasts.[473,474] After transplantation, the EBV antigen exposed donor T-cells were infused into the patients, and gene-marked cells were detectable at levels suggesting expansion of two- to threefold in vivo. EBV-specific cytotoxicity in the peripheral blood was greatly enhanced after the infusions. Although circulating marked cells fell below the limit of detection 4 to 5 months later, the continued presence of memory cells derived from the infusion product was inferred in one patient who had an increase in marked lymphocytes in the blood after reactivation of latent EBV.[474]

Suicide Gene Modification of T-cells

The next iteration of genetically modified T-cell therapies in patients undergoing allogeneic SCT incorporated the herpes thymidine kinase (tk) gene into the retroviral vector.[475] This "suicide gene" encoded viral protein converts the nontoxic pro-drug ganciclovir to a toxic metabolite that kills the cell by interfering with DNA synthesis.[476,477] A major cause of morbidity and mortality post-allogeneic SCT is graft-versus-host disease (GVHD). By incorporating the tk suicide gene into donor T-cells, high doses of T-cells can be administered to confer antiviral or antitumor immunity. If and when significant GVHD occurs, donor T-cells can be destroyed by an infusion of ganciclovir. This strategy depends on inclusion of a cell-surface marker gene or a drug resistance gene within the vector to allow enrichment of transduced cells by flow cytometry or drug selection, before re-infusion, so that almost all infused cells will contain the tk suicide gene.[475,478]

A landmark study demonstrating the safety and feasibility of this approach in patients following allogeneic SCT from matched donors was reported from Italy, and confirmed in several similar trials in Europe and the United States.[479] Most recently, this approach has been shown to be very promising in haplo-identical SCTs, transplants with an extremely high risk of both severe GVHD and poor immune reconstitution.[480]

One issue that has arisen in these trials is development of immunity against the foreign tk protein, with eventual destruction of vector-containing cells even in the absence of ganciclovir in some.[481] Anti-tk immunity also developed in a subset of patients with HIV infection who received autologous HIV-reactive cytotoxic T-cells expanded ex vivo and transduced with a tk vector.[482] These observations serve as an important caveat that foreign proteins such as tk introduced via lymphocytes may stimulate immune recognition and rejection. Use of ganciclovir as the suicide activator is not ideal, given that this drug is a powerful antiviral agent and the drug of choice to treat some common viral infections in SCT- or HIV-infected patients. To circumvent both of these problems, the gene encoding the endogenous human cellular proapoptotic protein caspase 9 was modified to allow dimerization and activation by the small molecule AP1903.[483] In a recent trial, patients received a T-depleted haplo-identical stem cell transplant, followed by infusion of donor T-cells transduced with the inducible caspase 9 transgene. These cells persisted and expanded in vivo, but with the development of GVHD, more than 90% of T-cells were ablated within 30 minutes of AP1903 infusion, resulting in abrogation of GVHD.[484]

Therapy of Immunodeficiency Disorders

T lymphocytes were the targets in the first human clinical gene transfer trial utilizing a potentially therapeutic gene, initiated in 1990.[8,485] Two children with SCID due to ADA deficiency received multiple infusions of autologous T-cells transduced with a retroviral vector encoding human ADA.[6] Both patients showed improvements in circulating T numbers and some evidence for improvement in cellular and humoral immunity. In one child, over 30% of the circulating T-cells were positive for the transgene and ADA levels approached the normal range for more than 2 years. The second child had only 0.1% to 1% of circulating T-cells containing the vector even after multiple infusions, clouding interpretation of how much of the clinical improvement in the initial patient was due to the gene transfer, and how much to other factors, including the ex vivo lymphocyte expansion. The more convincing results and theoretical advantages of correcting HSCs as compared to T-cells, as detailed above, combined with the impossibility of obtaining target T-cells to correct in patients with many forms of SCID, has resulted in a shift to HSC instead of T-cell targets for the gene therapy of immunodeficiency disorders.

T-cell Gene Therapy for HIV Infection

A number of ongoing and completed human T-cell gene therapy clinical trials have enrolled patients with HIV disease, based on identification of a number of potential targets for genetic intervention.[486] The concept of *intracellular immunization* against HIV, conceived more than two decades ago, hypothesizes that an effective gene therapy strategy for HIV could be to confer nonimmunologic HIV resistance to mature cell populations by introducing a gene that interferes with the HIV life cycle or prevents infection of progeny cells into HSCs or lymphocyte precursors.[487] Striking proof of principle of this concept was reported when an HIV patient with leukemia received an allogeneic SCT from a donor with a CCR5 variant, preventing HIV cellular entry into all donor hematopoietic cells. The patient had complete disappearance of HIV post-transplantation.[488] A second approach uses gene transfer to introduce genes that will result in killing of infected cells, either directly or via enhanced immunity, thus destroying the HIV viral reservoir.

A number of T-cell gene therapy approaches to HIV were tested in a unique clinical model pursued at the United States National Institutes of Health. A cohort of syngeneic twins with one infected and one uninfected twin was identified. T-cells from the uninfected twin were collected by apheresis, and then transduced with vectors encoding potential anti-HIV genes. Comparison of survival of these transduced cells in the infected twin with survival of cells transduced with a control vector was an elegant approach to testing various anti-HIV gene therapy strategies.[489] Marked

cells could be detected and studied in the HIV-infected twin.[490] Unfortunately, none of the anti-HIV strategies tested in this model were shown to result in preferential survival of the genetically modified cells or clear improvement of viral control.[491]

Mutant HIV Rev proteins have been reported to interfere with Rev function, either by binding to and inactivating wildtype Rev, or by competitively blocking binding of wildtype Rev to the RRE.[55,492] Production of HIV either from normal lymphocytes exposed to HIV in culture, or from HIV-infected patient lymphocytes, was decreased after either retroviral or gene gun particle-mediated transduction of T-cells with a vector expressing the Rev M10 mutant, compared to a nontranslated inactive control Rev mutant.[50] A clinical trial used the gene gun to transduce autologous lymphocytes from HIV-infected patients with either the active Rev M10 vector or the inactive control Rev vector. These cells were then expanded in vitro and re-infused. The lymphocytes containing the active Rev M10 sequences survived preferentially in vivo, suggesting that the Rev M10 transgene improved T-cell survival in infected individuals.[493] In another protocol, individuals with HIV infection and a refractory hematologic malignancy were offered allogeneic peripheral blood SCT and an aliquot of the allogeneic graft was CD34 selected, transduced with a transdominant Rev encoding vector, and infused along with the unmanipulated allograft. Overall marking was also low in the only recipient of genetically modified cells, however, rising vector copy number and nondetectable HIV over extended follow-up was encouraging.[494]

Another anti-HIV T-cell gene therapy strategy involved the use of "defective-interfering viruses" known to interfere with wildtype HIV replication and spread.[495] The first lentiviral gene therapy trial in humans transduced T-cells with a "defective-interfering" vector that incorporated an antisense sequence targeting the HIV envelope gene.[496] The use of a lentiviral vector in patients with HIV infection generated concern regarding the potential for recombination between the vector and endogenous HIV virus in patients or HIV genes in the packaging cells, or the inadvertent transfer of a mobilized lentiviral vector to others via sexual or other modes of transmission, requiring further development of sensitive RCR testing development prior to clinical use and extensive safety testing of patients enrolled in the trial.[100] Preliminary results in the first five patients demonstrated the feasibility of this approach, with all patients tolerating the infusion well. In one subject, a sustained decrease in viral load was observed.[497]

T-cell Gene Therapies for Cancer

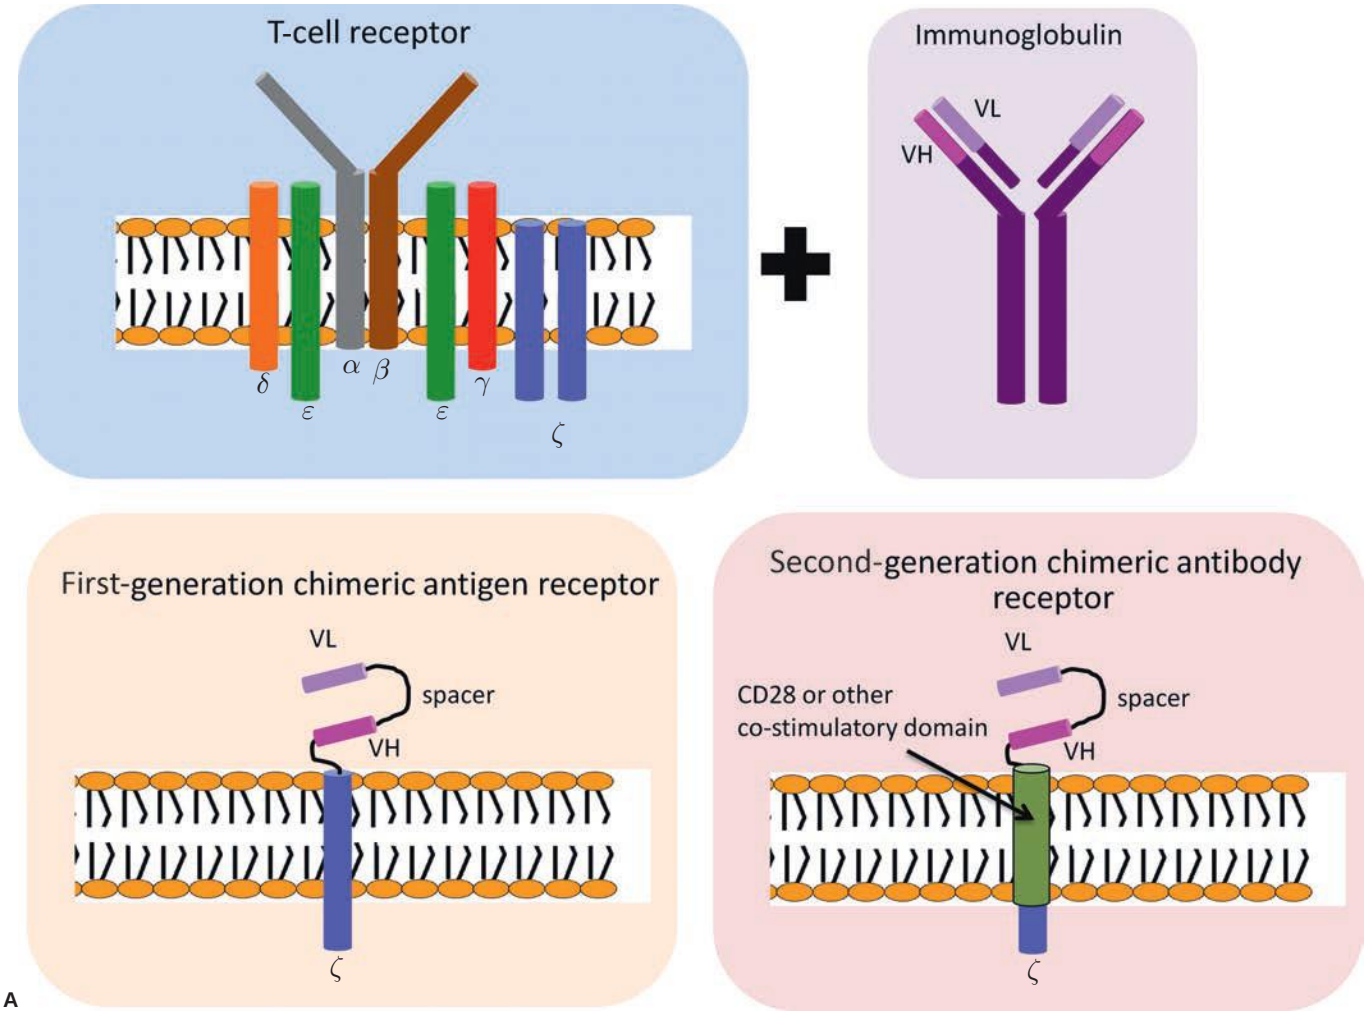
The most common clinical application for genetically modified T-cells has been for tumor immunotherapy. There are a number of challenges for cancer immunotherapies, most notably the low frequency of tumor-specific autologous T-cells, negative selection against high-affinity T-cell receptors (TCRs) binding to autologous tumor antigens during T-cell development, and the myriad mechanisms tumor cells have evolved to evade and cripple antitumor immune responses. Although early studies of the adoptive transfer of ex vivo expanded T-cells or in vivo stimulated T-cells with cytokines such as IL2 resulted in proof of principle that antitumor immunity existed and could be effective, investigators began searching for ways to enhance specific antitumor immunity via genetic modification.[498]

One approach begins by cloning high-affinity TCRs from cytotoxic T-cells shown to be reactive with tumor-specific antigens, generally from T-cells initially isolated from tumors (TILs), then further expanded and selected in vitro. The cloned transgenic α and β TCR subunit genes can then be incorporated into a retroviral or lentiviral vector and used to transduce patient T-cells, resulting in large numbers of T-cells reactive with a specific tumor antigen. Four of 31 melanoma patients receiving autologous T-cells transduced with a cloned high-affinity TCR reactive with a melanoma antigen (MART1) had objective tumor responses, as did one of three patients with colon cancer receiving T-cells transduced with a CEA-reactive TCR.[470,499]

One major drawback of this approach is the HLA-restriction of TCRs, thus requiring a different TCR construct for each HLA class 1 target, and effectively limiting this approach to patients with common HLA haplotypes. There is also the potential for mispairing between the transgenic TCR and the endogenous TCR chains that are still expressed by the target T-cell, resulting in unpredictable adverse events such as autoimmunity/ GVHD.[500] Although this complication was observed in a murine model, there is no evidence to date for a similar phenomenon in hundreds of patients enrolled in transgenic TCR clinical trials.[501] However, administration of large numbers of high-avidity TCR-expressing T-cells reacting with tumor antigens that may also be expressed at low levels on normal tissues can result in toxicity such as colitis following anti-CEA T-cells given to target colon cancer, or skin/eye and ear toxicity following administration of TCR chimeric T-cells reactive with melanoma antigens.[499,502]

A second and perhaps more promising approach to enhancing antitumor activity of T-cells was first conceptualized in 1993, and involves transduction of T-cells with genes encoding fusion molecules termed "chimeric antigen receptors" (CARs)[503,504] (Fig. 71.8A). Engineered cell-surface molecules consisting of a specific antigen-binding domain from a monoclonal antibody, or some other specific ligand-binding domain, fused to intracellular signaling moieties from the T-cell receptor (generally the ζ chain) or the FcεRI receptor are introduced into T-cells via retroviral or lentiviral vectors. When the CAR binds to antigen or ligand, the T-cell signaling cascade is activated, resulting in cytotoxicity toward the antigen-bearing target cell. There are a number of advantages of CARs as compared to TCRs for genetic enhancement of T-cell antitumor immunity. Most important, the CAR approach is "universal" and not MHC-restricted, thus the same CAR can recognize the target in any patient. Second, tumors often down-regulate MHC molecules, and thus can evade TCR-dependent recognition, in contrast to CARs, which do not require MHC engagement for their activity. Third, nonprotein targets can be recognized by CARs. One disadvantage of CARs in comparison to TCRs is that intracellular antigens cannot be targeted by CARs, because these antigens require presentation as peptides on the cell surface via MHC molecules. A recent review catalogs the large diversity of CARs that have been developed for preclinical and clinical applications.[505]

Initial CAR clinical gene therapy studies were completed in the late 1990s, utilizing autologous or syngeneic T-cells transduced with constructs fusing the gp120 binding domain of CD4 to the TCR ζ chain, to promote killing of HIV-infected T-cells. Despite encouraging animal model and in vitro data, the infused cells were present at very low levels, disappeared over time, and were not associated with clinical benefit.[491,506] A series of clinical trials in patients with cancer, targeting cell-surface proteins on ovarian cancer, neuroblastoma or lymphoma tumor cells were also disappointing, with no evidence for in vivo expansion and little persistence of infused CAR-modified cells.[503] There was some evidence that CARs themselves could be immunogenic, and that ex vivo culture conditions used during transduction and expansion were suboptimal, but a more important difference between CAR-mediated and endogenous TCR-mediated signaling is the lack of co-stimulatory signaling during CAR engagement. T-cell stimulation in the absence of co-stimulatory signals, normally provided by antigen-presenting cells, results in T-cell death or tolerance, instead of expansion and a productive immune response (Fig. 71.8B). Therefore, a second generation of CARs was designed, incorporating co-stimulatory signaling domains as part of the CAR fusion molecule itself, for instance, domains from CD28 or CD137. T-cells transduced with these enhanced CARs were found to be more effective in vitro and in animal models.[507]



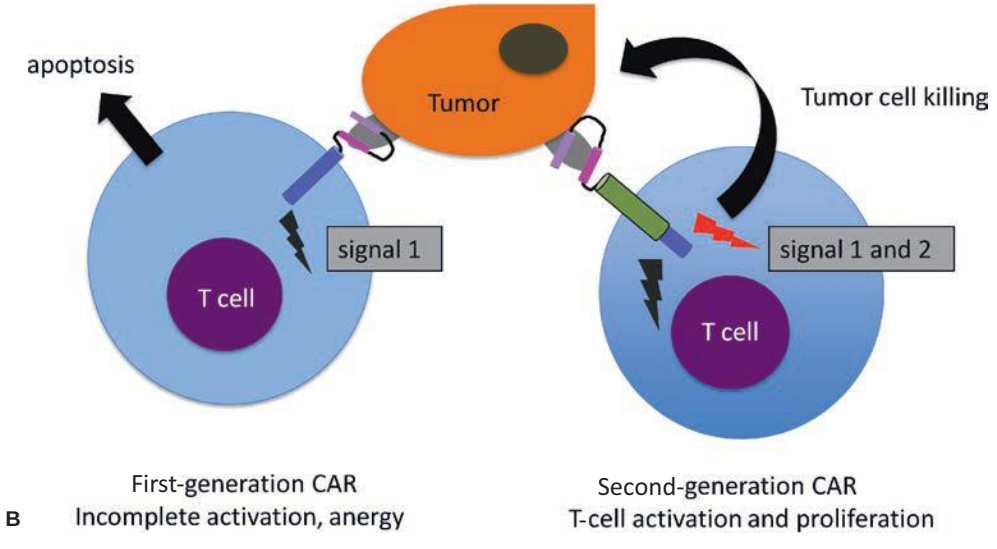


FIGURE 71.8. Gene transfer of chimeric antigen receptors for tumor immunotherapy. A: The sources of components used to construct an artificial chimeric antigen receptor are shown. The signaling ζ subunit of the T-cell receptor is connected to the variable heavy chain(VH) and variable light chain(VL) domains of a monoclonal antibody generated against the desired tumor antigen. In the second-generation CARs, an additional transmembrane domain from CD28 or an alternative co-stimulatory molecule is added between the cytoplasmic signaling domain of the TCR ζ subunit and the extracellular VH/VL antigen-binding moieties. **B:** When a T-cell transduced with a first-generation CAR encounters a tumor cell bearing an antigen recognized by the VH/VL domain of the CAR, the ζ subunit is stimulated to signal (signal 1) but in the absence of a co-stimulatory signal, the T-cell is often diverted to an apoptosis or anergy pathway. In contrast, the inclusion of a co-stimulatory signaling domain in the second-generation CAR ensures that when tumor antigen is encountered, both signal 1 generated from the ζ subunit and signal 2 generated from the CD28 domain are activated, and the T-cell proliferates and is stimulated to kill the tumor cell.

A number of other strategies have also been pursued to enhance co-stimulation and in vivo survival of CAR-modified T-cells, including targeting CARs to T-cells already primed to respond to a common antigen such as EBV, administering T-cell supportive cytokines such as IL2, IL7, or IL15, or lymphodepleting the patient prior to CAR-T administration (Fig. 71.8A,B).[503]

A series of clinical trials utilizing CARs targeting CD19 in patients with chronic lymphocytic leukemia (CLL) or other advanced chronic B-cell malignancies have provided proof of principle for the potential efficacy of this approach. A lentiviral vector expressing an anti-CD19 antibody domain fused to a CD137 co-stimulatory region and the CD3 ζ signaling component of the TCR was used to transduce autologous T-cells from a patient with CLL, and following re-infusion, there was rapid 1,000-fold in vivo expansion of the cells, tumor lysis, and complete remission of the CLL, persisting for at least 10 months to date.[471] A dramatic response was also reported in a patient with follicular lymphoma.[508] Larger case series confirmed these encouraging results.[509,510] However, the potent and persistent anti-CD19 response also resulted in profound depletion of normal B-cells and hypogammaglobulinemia. This very promising approach is now being developed for treatment of a variety of tumors.

GENE THERAPY FOR BLEEDING DISORDERS

The primary bleeding disorders most commonly result from genetic deficiencies of specific clotting factors. Classic hemophilia, or hemophilia A, results from a deficiency of factor VIII, which is normally produced by hepatocytes and vascular endothelial cells. Hemophilia B results from a deficiency of factor IX, which is normally made by hepatocytes. Thus, both diseases are hematologic disorders resulting from deficiencies of soluble plasma proteins synthesized by nonhematopoietic cells. Each of these coagulation factors may be found in circulating platelets' storage granules[511] but the megakaryocyte is not likely a site of synthesis of either factor, and granule storage is likely to occur after uptake of the protein from plasma.

Hemophilia A and B have attracted a significant amount of attention from those interested in gene therapy, for a variety of reasons. First, they are monogenic diseases for which numerous mutations are known[512,513] (http://europium.csc.mrc.ac.uk/WebPages/Main/main.htm, http://www.kcl.ac.uk/ip/petergreen/haemBdatabase.html) and their cDNAs were cloned decades ago.[514,515] Second, functional factor VIII and factor IX gene products may be produced in nearly any cell type as long as the appropriate post-translational modifications are made and the protein is secreted into the circulation. Most important, epidemiologic data and experience with factor replacement therapy have demonstrated that the level of circulating factor VIII or factor IX required to prevent clinically significant bleeding may be as little as 1% to 2% of normal plasma levels. And finally, there may be a substantial margin for error with regard to overexpression of these factors, due to regulation of the "tenase" (factor VIII/factor IX) enzyme complex and "prothrombinase" (factor V/factor X) complex by the protein C/protein S anticoagulant proteins and antithrombin III. Epidemiologic analyses suggests that elevated factor VIII or factor IX levels may be risk factors for thrombotic diseases,[516,517] but thus far it seems unlikely that overshooting to supraphysiologic levels of factor VIII or factor IX could occur following gene therapy.

Preclinical testing of hemophilia gene therapies have been facilitated by the existence of several animal models of hemophilia, including factor VIII and factor IX knockout mice[518–521] and inbred dog colonies with spontaneous hemophilia A and B mutations.[522–526] Furthermore, it has proved possible to detect epitope-tagged human factor VIII[527] or normal human factor IX[528–531] in normal rhesus macaques after gene transfer with various vectors, which permits not only safety testing of gene transfer, but also some assessment of gene expression in vivo.

Potential cell types targeted to become "cell factories" for gene transfer of factor VIII or IX include skin fibroblasts or keratinocytes, myocytes, hepatocytes, and BM stem and progenitor cells. Skin fibroblasts are readily propagated in tissue culture and can be transduced by vectors that may include selectable markers. Cells selected in vitro can then be re-introduced to the host, resulting in secretion of the therapeutic protein into the bloodstream. Preclinical studies utilizing skin fibroblasts transduced with factor IX or factor VIII retroviral vectors[532–538] in rodents have achieved therapeutic levels of factor IX or factor VIII (>1% of normal). However, a recurring issue in these models has been lack of sustained expression of the transgene, which may be due to loss of transduced cells due to cell-mediated immunity or to promoter shutdown in implanted cells.[539] One clinical trial has been performed in which factor VIII transfected skin fibroblasts were implanted in the omentum. The peak factor VIII levels achieved were marginally therapeutic and were not sustained.[540]

Gene transfer of secreted proteins to muscle cells can be performed using muscle-specific and/or nonspecific constitutive promoters to direct gene expression, with direct in vivo delivery of vectors to muscle cells via intramuscular injection. The most extensively studied and successful application of this approach has been through gene transfer utilizing adeno-associated virus vectors. AAV vectors can only package DNA with a total length of ~4.5 kb or less, which is sufficient for transfer of the small factor IX gene, but of limited use for transfer of the much larger factor VIII gene. AAV vectors form stable and long-lasting episomes, and in nondividing tissues such as muscle and liver, can produce long-term stable transgene expression. In vivo preclinical studies with AAV vectors in hemophilia B knockout mice and dogs have shown that it is possible to achieve clinically relevant levels of factor IX and correction of the bleeding phenotype for significant periods of time following intramuscular injection of fIX-AAV vectors.[541–549] These encouraging animal results led directly to a clinical trial of AAV-factor IX gene transfer, involving multiple intramuscular injections of fIX-AAV particles in patients with severe hemophilia B. Plasma factor IX levels (~1% of normal) at doses of 2×1011 vector genomes per kg were achieved.[550] Although the trial was an open label study and a placebo effect cannot be ruled out, there was a lower frequency of joint bleeds as reported by patients.[550] Unfortunately, higher doses of the vector did not result in a greater therapeutic effect, perhaps due to binding of factor IX to type IV collagen present in muscle, and the intramuscular injection route, requiring very large numbers of individual injections, is impractical and potentially risky in patients with bleeding disorders, even with exogenous factor administration at the time of the procedures.[551] Very prolonged expression from the AAV vector construct was documented on muscle biopsy specimens obtained more than 3 years following the injection of vector.[552]

Liver hepatocytes synthesize most of the plasma proteins including factors VIII and IX, and synthesize certain proteins (e.g., albumin) in tremendous quantities, thus they are natural factories for secreted proteins. Hepatocytes are readily transducible by various vectors in vitro and in vivo, and gene transfer to liver is currently the most promising approach under investigation for gene therapy of hemophilia. Adenovirus vectors are capable of near-quantitative gene transfer to hepatocytes in vivo when administered intravenously and can accommodate large genes such as factor VIII. It is not surprising that adenovirus vectors have been used for in vivo gene transfer of factor VIII or factor IX to liver cells in various animal models, including mice,[131,553–561,562,563,564] monkeys,[527,528,530] and hemophilic dogs.[130,565–568] Unfortunately, adenovirus-mediated gene transfer is typically characterized by gradual loss of gene expression because these vectors do not

form stable episomes and do not integrate, and the presence of the adenovirus vector proteins in immune-competent animals induces a cytokine cascade[569] and has a significant adjuvant effect that may induce antibodies to the expressed gene.[528,566,567,570] Based on the observation that deletion of adenovirus vector genes may result in longer periods of gene expression and a decreased immune response,[570] efforts have been made to create and test vectors with most or nearly all of the adenovirus genes removed for gene therapy of hemophilia.[558,561,571–574] Any clinical use of adenovirus vectors will be limited by neutralizing antibodies to most common serotypes that are routinely present in most humans and which would be boosted substantially with administration of an adenovirus vector.[575]

Vectors based on various serotypes of AAV have been studied for gene delivery to hepatocytes in hemophilia A and B mice and dogs, and in humans with hemophilia B. The earliest reports of AAV-mediated hepatocyte gene transfer focused on serotypes 1 and 2 vectors expressing factor VIII[576–578] and factor IX[42,267,531,579,580,581–589] in mice, dogs, and nonhuman primates. These preclinical studies demonstrated levels and duration of factor IX expression sufficient to justify clinical trials of hepatic artery infusion of AAV-2 factor IX vector in patients with severe hemophilia B. The initial trial was temporarily put on hold due to vector shedding in the semen of the first subject enrolled.[590] After demonstration that the AAV vector was not incorporated in germline DNA, the trial was resumed. The results showed peak expression of 11% of normal factor IX levels in one of seven subjects who was treated with the maximum 2×1012 vector genomes/kg dose.[591] Unfortunately, although no inhibitor antibody to factor IX developed, factor IX expression declined and plasma factor IX activity levels returned to baseline within a period of 8 weeks. The decline in factor IX levels was associated with transient elevation of liver transaminases likely due to cell-mediated immune elimination of AAV-transduced hepatocytes. One other subject treated at the maximum achieved a factor IX plasma level of 3% of normal, but also had loss of factor IX expression and elevation of liver enzymes. T-cell responses to the AAV2 capsid protein but not to factor IX were documented in these patients, and it is likely that transient presence of the AAV-2 capsid, brought into the hepatocytes during transduction, stimulated a potent recall immune response in patients previously exposed to wildtype AAV2 viruses in the environment, resulting in immunologic elimination of transduced hepatocytes.[592] This finding had not been predicted from preclinical studies in large animals, which are not naturally infected by AAV2, underscoring the need for caution in predicting results of clinical trials from animal studies.

Alternative strategies to circumvent these problems tested in animal models have included transient immunomodulation at the time of vector administration, use of alternate AAV serotypes such as 6, 8, or 9 not known to normally infect humans and thus rarely associated with seropositivity, and design of optimized vectors able to express much higher levels of factor IX per genome.[168–170,593] The combination of all these strategies has finally resulted in what appears to be unequivocal clinical success. Six patients with hemophilia B received intravenous infusions of AAV8 vectors expressing codon-optimized and self-complementary factor IX genes.[176] All had sustained levels of factor IX of 2% to 11%, and four of the six were able to discontinue prophylactic factor IX infusions. Two patients had transient elevations of liver enzymes, in one associated with detection of AAV capsid-specific T-cells, but a brief course of methylprednisolone in both led to rapid decrease in transaminases, and no loss of factor IX expression.

Although typical Moloney-based retroviral vectors are not particularly effective at in vivo gene transfer to hepatocytes due to the relatively low rate of cell division, lentivirus vectors (which do not require cell division for gene transfer) may prove to be useful for hemophilia gene therapy, and can accommodate larger transgenes and thus are more conducive to factor VIII gene therapy than AAV vectors, particularly B domain-deleted factor VIII, encoding a smaller but still functional protein. Several groups have used pseudotyped lentiviral vectors to transfer the factor VIII cDNA to liver.[594–597] The efficiency of in vivo gene transfer with lentivirus vectors has been far less than that of adenovirus or AAV vectors, but persistent expression has been achieved in some animal models. In some cases, injection of vector into the portal vein is employed to improve efficiency.[598]

Cells of hematopoietic origin are also logical targets for ex vivo gene transfer and re-introduction by marrow transplantation to treat hemophilia, because these cells circulate in the blood and, in the case of platelets, are concentrated at the site of vascular injury. This approach may be particularly relevant in patients with existing factor VIII or IX inhibitors, who have been excluded from all prior muscle and hepatocyte gene therapy trials. Ex vivo Moloney-based retroviral gene transfer of the human factor VIII gene into hemophilia A knockout mouse BM was not efficient enough to result in detectable plasma levels of human factor VIII after transplantation; however, the animals were rendered tolerant to human factor VIII.[599] Expression of xenogenic or otherwise completely foreign genes in hematopoietic stem and progenitor cells via gene transfer is known to result in induction of tolerance.[600,601] Investigators have been able to show expression of factor VIII in platelets produced from lentivirus-transduced BM in hemophilia A mice.[602,603] The latter approach utilized a promoter for the α IIb glycoprotein (normally expressed on the surface of platelets) to restrict expression of factor VIII to the platelet, and to target expression of factor VIII to sites of vascular injury.

Future issues to be addressed in the field of hemophilia gene therapy include minimizing the risk of inhibitor formation or immune rejection of transduced cells (especially with viral gene transfer vectors), development of vectors capable of sustained high levels of coagulation factor expression, and avoidance of unintentional germline transmission of vector sequences. Strategies are being explored allowing expression of functional factor VIII despite its prohibitory large gene size, including deletion of certain nonfunctional domains (B domain deleted), splitting of the gene into two portions encoded by two independent AAV vectors with transcripts that are spliced in vivo prior to protein translation, or expression of the light and heavy chain of factor VII in two independent vectors.[604,605]

SAFETY AND FEASIBILITY HURDLES TO CLINICAL GENE THERAPY

Immune Responses to Vectors and Transgenes

Immune responses against vector proteins or the transgene-encoded protein itself have only recently become the focus of intensive investigation. For in vivo vector administration, preexisting immunity to a vector such as adenovirus is at least a theoretical concern. Repeated in vivo administration of complex vectors clearly stimulates an active immune response to vector proteins, and greatly hinders success. The expression of viral genes remaining in the vector sequences could also stimulate an immune response against transduced target cells. This is not a problem for retroviral vectors; as well, newer modifications of adenoviral vectors have been developed that no longer contain or express residual adenoviral genes.[125,126] Nonhuman marker genes such as the neomycin resistance gene, or viral suicide genes such as tk included in vectors for positive or negative selection may also induce an immune response.[606] Finally, the therapeutic gene product itself may induce an immune response if the patient completely lacks the endogenous gene product or the transgenic protein is processed or post-translationally modified.[121]

Rejection of the foreign transgene itself can be the primary problem, even when highly immunogenic adenoviral vectors are

used. Recombinant adenoviral vectors encoding either murine or human Epo genes or a control vector without an expressed gene were injected into murine muscle and the mice were followed for several months for Epo expression and presence of the vector sequences in muscle.[121] Mice expressing either human or murine Epo transgenes developed high hematocrits, but the effect was transient in those expressing human Epo, as profound anemia, surprisingly, developed after the transient polycythemia. Immune responses to both the vector-expressed human Epo and endogenous murine Epo were documented in these animals, indicating that the active immune reaction against the human Epo had also generated cross-reactivity toward endogenous Epo. Adenoviral genomes were detectable long term in the muscles of the murine Epo and of the control mice, but not in the human Epo mice. This suggested that the immune response was elicited by expression of the foreign transgene, not by viral proteins.

In a murine model of allogeneic skin graft survival, foreign genes expressed by HSCs and their progeny may be capable of inducing tolerance even across MHC barriers.[607] This evidence, and documentation in mice of very long-term persistence of expression of completely xenogeneic genes such as human GC, suggests that immune responses against genes introduced via repopulating stem cells will not induce immune responses.[206,608] On the other hand, immune responses to a retroviral vector-introduced transgene in the canine MPS-1 autologous transplantation model have been shown to limit efficiency.[609]

In the murine model, tolerance to xenogeneic genes can be achieved by introduction through the hematopoietic compartment.[610] Long-term persistence of genetically modified cells at clinically relevant levels can be achieved after very low-dose irradiation with 100 cGy, even when highly immunogeneic genes are transferred. Large animal testing in the nonhuman primate confirmed these observations, with equivalent levels of long-term engraftment of cells transduced with either a vector encoding the neomycin phosphotransferase (neo) or a vector carrying but not expressing this gene product, but the overall levels of engraftment were much lower.[611] Transduction of lymphocytes in the absence of conditioning, however, resulted in rapid clearance of the neo expressing cells. However, if HSCs were transduced and transplanted first, long-term persistence of lymphocytes transduced with the neo expressing vector were observed.[600]

Various methods of immunosuppression have been at least partially successful in avoiding immune rejection of transduced cells. Neonatal exposure to vector has allowed repeated treatments with adenoviral vectors.[131] Treatment with cyclosporine, cyclophosphamide, or IL-12 have all been reported to prolong survival of transduced cells.[128–132] But these general pharmacologic approaches are not desirable or practical for most gene therapy applications, which are attractive only if they prevent lifelong reliance on toxic pharmacologic agents. Instead, improved vector design and possible inclusion of antirejection mechanisms in the vectors themselves are more attractive approaches.

Safety Considerations

The number of individuals who have safely received genetic material in the form of vectors or vector-modified cells now numbers in the many thousands, suggesting that current gene transfer approaches generally carry a low risk to subjects, however, all but a small minority of these patients likely had no clinical benefit, and risks must therefore be considered in this context. Only recently have trials moved beyond safety testing into pilot studies of efficacy for a number of hematologic diseases. Pioneering trials, as detailed above, have provided encouraging results regarding efficacy of gene therapy for congenital immunodeficiency disorders, hemophilia, thalassemia, and metabolic disorders. However, very serious and in some cases fatal severe adverse events directly linked to gene therapy have occurred, and have had significant repercussions from regulatory, clinical, and scientific standpoints.

Phase 1 Gene Therapy Trial for Ornithine Transcarbamylase

Side effects of gene transfer can result from all aspects of the process, including those inherent to a specific vector system, vector production methodology, target cell identification and manipulation, vector integration, transgene expression, or selective pressure applied after transfer.[612] The first reported serious complication of gene therapy occurred when an 18-year-old patient with relatively mild manifestations of OTC deficiency volunteered for a Phase 1 dose escalation gene therapy trial and received a catheter-directed infusion of a high dose of an adenoviral vector encoding the corrective gene into the hepatic artery. Within hours of the infusion, signs and symptoms of a systemic immune response syndrome appeared, and soon thereafter the patient died from multiorgan system failure. Studies infusing similar adenoviral vectors into nonhuman primates have shown evidence for activation of the innate immune response attributable to the adenovirus capsids as well as a vigorous proinflammatory IL-6 and IL-1 cytokine response, with evidence for endothelial damage and disseminated intravascular coagulation.[528,530,613] The induction of acute phase reactants was anticipated from the preclinical data in nonhuman primates; however, the severity and duration of the fatal reaction observed in this patient was not expected at the dose level reached. As a result of the death, many clinical gene therapy trials were temporarily put on hold and the maximum doses of adenovirus (or other) vectors to be given to humans were scaled back as a precautionary measure. Furthermore, a number of issues with respect to the pace of clinical gene therapy trials, the informed consent process, subject eligibility, reporting of adverse events, and oversight of clinical gene therapy trials were raised, and measures to increase the protection of research subjects were uniformly instituted across all gene therapy trials.[614,615]

Gene Therapy for X-SCID

Soon after the first unequivocal demonstration of clinical efficacy in a human gene therapy trial in which 10 of 11 children with SCID who received retrovirally transduced autologous BM cells were apparently cured,[22] two patients developed a precipitous rise in T-cell counts which progressed to overt leukemia 3 years following infusion of gene-corrected autologous $CD34^+$ cells.[265] Retroviral integration site analysis in the leukemia cells from both patients demonstrated vector insertions within or just upstream of the *LMO2* gene activating expression.[451] LMO2 is a transcription factor required for fetal hematopoietic development and was already known to be activated by chromosomal translocations in some cases of spontaneous childhood T-cell leukemia.[616] Since that time, an additional two of the eleven X-SCID patients enrolled in the original French trial and one of ten patients enrolled in a similar trial in England have developed clonal vector-associated T-cell leukemias.[448,454] Strikingly, four of the five patients had vector insertions activating *LMO2,* and the fifth had a vector insertion activating the *CCND2* gene, encoding cyclin D, a protein known to control cell cycle entry and to be associated with cancer when dysregulated. One of the four patients has died of complications related to the leukemic process and its treatment, and the others have been successfully treated with chemotherapy.

The first report of these adverse events in 2003 resulted in a rapid response from investigators and regulatory agencies worldwide, with most gene therapy trials utilizing integrating MLV-derived retroviral vectors to transduce hematopoietic stem and progenitor cells put on hold. The occurrence of these events was not predicted. Prior to the sequencing of the murine and human genomes, retroviral insertion was thought to be random,

based on the lack of any specific motif at the few insertion sites that had been mapped. It was predicted that just one or a few insertions into a cell's genome was unlikely to activate a proto-oncogene, based on the size of the genome and assumed random insertion.[617] Vector-containing leukemias and lymphomas had previously been reported in animal models utilizing HSC gene transfer, but were attributed to contamination by replication-competent viruses in a nonhuman primate study, resulting in multiple proviral insertions and eventual activation of a proto-oncogene, or overexpression of a signaling receptor in a murine model.[78,618]

There was initially an intense focus on whether specific aspects of X-SCID patients themselves or constitutive expression of the IL2Rγ transgene predisposed to vector-associated leukemia. One murine study suggested a greatly increased risk of leukemia when an *Il2rγ* transgene was overexpressed, and another reported a nonrandom relationship between activation of the *Lmo2* and *Il2rγ* genes and leukemias and lymphomas in susceptible neonatal mice.[619,620] Other unique aspects of the X-SCID clinical situation were proposed to have contributed to increasing risk, including the rapid expansion of lymphoid progenitors and mature T-cells into an "empty" lymphoid compartment, very high doses of transduced $CD34^+$ cells, and impaired antitumor immunity. To date none of the patients enrolled in ADA gene therapy trials, even those receiving transduced $CD34^+$ cells, have developed leukemia. A large survey of rhesus macaques, dogs, and baboons transplanted with $CD34^+$ cells transduced with standard retrovirus vectors containing marker genes or drug resistance genes failed to document any hematologic abnormalities, or progression to clonal or oligoclonal hematopoiesis, with a median follow-up of over 3 years.[621] And it is of interest that there have been no vector-related clonal expansions or malignant transformations detected in patients receiving transduced T-cells, or undergoing in vivo gene therapy targeting hepatocytes, muscle cells, or other nonhematopoietic targets. It appears that HSCs are much more susceptible than differentiated cells to vector-related tumorigenesis.[622]

Large-Scale Mapping of Gene Transfer Vector Insertion Sites

Concurrent with these adverse events, the entire human and murine genome sequences were published and new technologies were developed that permitted large-scale mapping of vector insertion sites. The insertion of a vector proviral form into the genome can affect gene expression and thus potentially promote malignant transformation via several different mechanisms, as detailed in Fig. 71.9 and discussed in detail in a number of reviews.[462,623] The Moloney MLV proviral LTR contains a strong promoter and enhancer, able to activate expression of upstream or downstream genes at distances of up to 200 kb, or directly drive expression of gene via fusion or replacement of the endogenous promoter. Internal promoters or enhancers, included to enhance transgene expression, can also activate nearby genes. A proviral insertion can inactivate a tumor-repressor gene. Vector insertion can disrupt normal exon splicing and alter

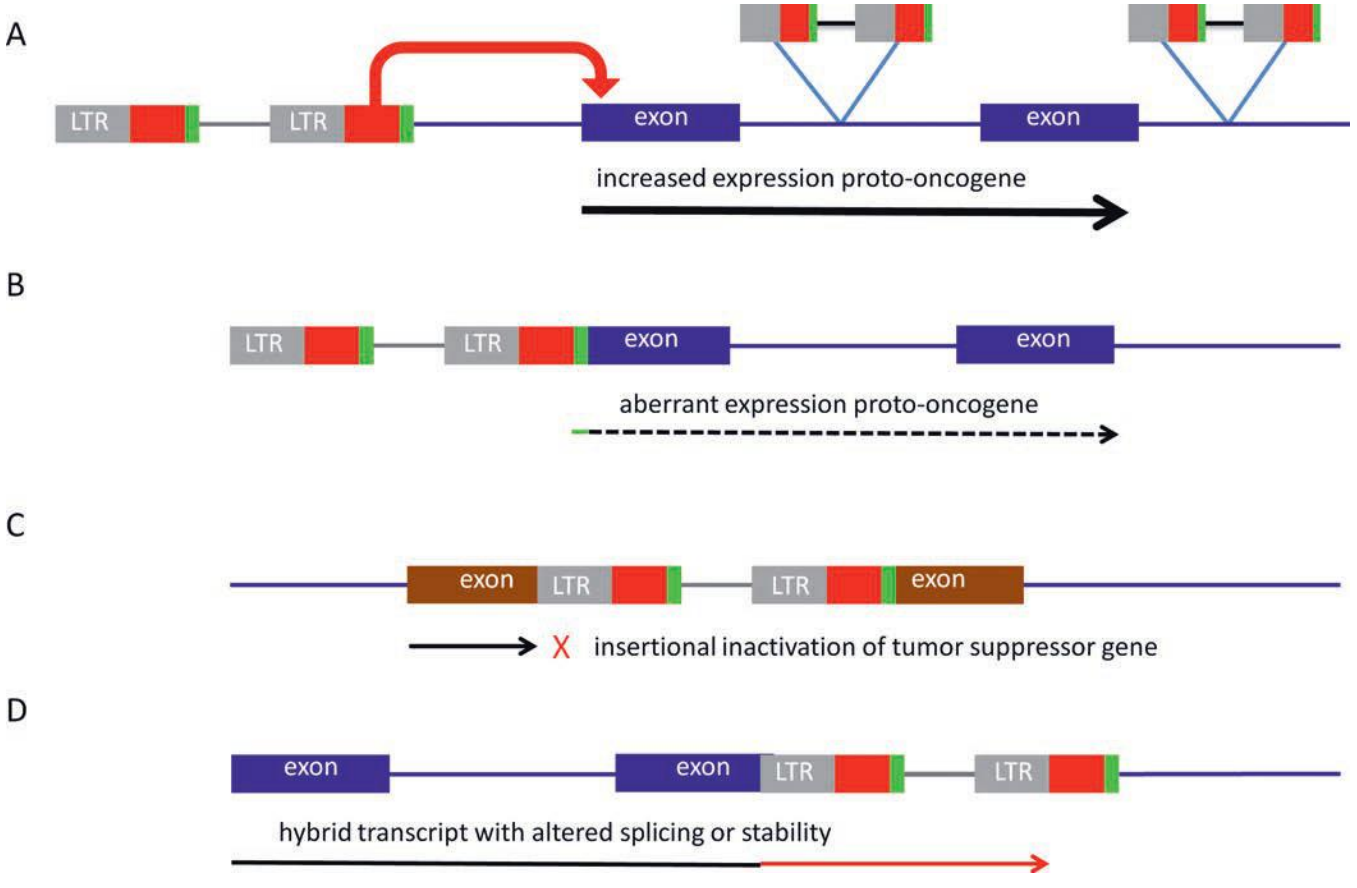

FIGURE 71.9. Mechanisms of gene dysregulation and oncogenesis via vector integration into genomic DNA. The reverse-transcribed retroviral or lentiviral DNA permanently integrates into the genome, and can disrupt endogenous gene expression via a number of mechanisms. The integrated vector consists of two identical long terminal repeats (LTR) that contain a strong enhancer (*red*) and a promoter (*green*). **A:** If the vector lands upstream, downstream, or within an intron of a proto-oncogene, the LTR enhancer can up-regulate expression of the proto-oncogene. **B:** If the vector integrates within the first exon of a proto-oncogene, a constitutively expressed fusion transcript can result, with loss of endogenous control of expression. **C:** Vector integration within an exon can completely inactivate expression of a tumor suppressor gene via production of a truncated or fusion transcript. **D:** Vector integration can disrupt normal exon/intron or isoform splicing, resulting in an aberrantly regulated transcript, and up-regulation of a proto-oncogene or down-regulation of a tumor suppressor gene.

relative levels of transcript isoforms or stability. Detailed large-scale mapping studies in cell lines and in primary hematopoietic cells revealed clear biases in integration site preferences for both standard retroviral as well as lentiviral vectors. MLV retroviral vectors were more likely to integrate near transcription start sites of genes, and HIV and SIV vectors were likely to integrate in gene-rich regions and within actual genes.[624–626]

Integration patterns were also assessed over time in mice, large animals, and patients receiving transduced cells. Murine studies using high-titer retroviral vectors and performing much longer follow-up than previous studies documented a high rate of progression to clonal or oligoclonal hematopoiesis, specifically from clones with insertions into proto-oncogenes or other growth-altering loci, and frequent leukemias in secondary and tertiary recipients of transduced cells, associated with insertions into proto-oncogenes.[627,628] A rhesus macaque transplanted 5 years previously with retroviral vector-transduced $CD34^+$ cells developed a clonal myeloid leukemia containing a vector insertion in the antiapoptotic gene *BCL2A1*.[629] A large-scale survey of retrovirus vector insertion sites in long-term repopulating cells of rhesus macaques uncovered one locus that was markedly overrepresented, with nine independent insertions into the *MDS1/EVI1* proto-oncogene, accounting for 2% of all insertions mapped.[626] Proviral insertions at this locus were also identified in immortalized myeloid cell lines generated in vitro from retrovirus vector transduced primary murine BM cells.[630]

Gene Therapy for Chronic Granulomatous Disease

Even more striking dominance of myeloid hematopoiesis derived from progenitors with vector insertions in the *MDS1/EVI1* locus was reported in a clinical trial for CGD. As described above, two patients received $CD34^+$ cells transduced with a retroviral vector expressing the corrective phox91 transgene. Initially the patients did very well but the level of vector-containing cells began to increase in the myeloid lineage beginning several months after transplantation, eventually reaching levels of 60% to 70%. This expansion was found to be almost entirely accounted for by contributions from clones with insertions in the *MDS1/EVI1* locus.[446] Both patients then progressed to clonal myelodysplasia/myeloid leukemia, derived from one of their MDS1/EVI1 clones, and associated with a secondary loss of chromosome 7 in the malignant cells.[458] Despite the persistent high frequency of vector-corrected neutrophils, expression of NADPH oxidase dropped precipitously in both subjects over time. The silencing of NADPH oxidase occurred through progressive CpG methylation of the promoter contained in the LTR of the vector. These events led to a series of infections and eventual death of one patient. The second subject was referred for unrelated donor SCT while still infection free.

Gene Therapy for Wiskott-Aldrich Syndrome

In nine of ten patients with WAS treated by gene therapy, clinical improvement was initially demonstrated. However, in a subsequent report, two of nine patients who achieved an efficient correction of the disease developed T-ALL 5 years and 16 months after gene therapy, respectively. Two additional patients also developed T-ALL more recently (unpublished data). In three of four patients with T-ALL analyzed to date, an increase of a cell clone harboring an integration site upstream of LMO2 could be observed at the onset of leukemia, the same gene locus activated by vector insertion in most of the X-SCID patients that developed T-ALL. One patient underwent an allogeneic stem cell transplant and the other individuals have responded to chemotherapy with recovery of a polyclonal integration site pattern.

Approaches to Decreasing the Risk of Insertional Genotoxicity

The insertion pattern of lentiviral vectors based on HIV or SIV is potentially safer, given that transcription start sites are not targeted. HIV/SIV vectors also have all endogenous promoter/enhancer elements deleted from the LTR, and thus should be much less likely to activate an adjacent proto-oncogene. A lower rate of leukemic transformation or cellular immortalization with HIV as compared to standard MLV-based retroviral vectors has been reported using several preclinical models, and long-term follow-up of nonhuman primates receiving SIV-transduced cells has not revealed any clonal dominance.[353,631,632] Highly polyclonal patterns have persisted long-term in several patients receiving HIV vector-transduced $CD34^+$ cells on a clinical trial for ALD.[102] However, a single patient enrolled in a lentiviral vector-based gene therapy trial for thalassemia has developed clonal expansion of cells containing an insertion in the *HMG2A* gene,[103] indicating that we do not yet fully understand the possible pathways to clonal dominance and associated risks with any integrating vector system.

The clinical adverse events and these laboratory findings strongly support the need for long-term toxicity assessment in predictive preclinical models, development of vector systems less likely to activate or otherwise alter the behavior of adjacent genes, and careful risk–benefit analysis of gene therapy target diseases and patient populations. Use of standard retroviral vectors with strong enhancers in their LTRs is no longer considered prudent for HSC-targeted gene therapy, but whether lentiviral vectors, enhancer-deleted retroviral vectors, novel vector systems such as HFV or avian leukosis sarcoma virus, or gene targeting approaches will be safer and sufficiently efficacious is not yet known, and may vary depending on patient, target cell, and disease-specific characteristics. Well-designed pilot clinical trials in patients with sufficient disease severity to justify participation in a potentially risky protocol and a level of understanding allowing authentic informed consent will in the end provide the relevant path forward for gene therapy, no matter how many careful preclinical studies have been performed.

CONCLUSIONS

A wide variety of imaginative approaches involving genetic manipulation of hematopoietic or other targets have led to the first clinical successes of gene therapy approaches to hematologic diseases such as the hemophilias and the immunodeficiencies and are certain to eventually revolutionize therapy for a number of currently fatal or disabling conditions. Continued basic scientific investigation of target cell biology and vector systems along with carefully designed clinical trials will drive the eventual application of gene therapy on a large scale.

CHAPTER 72

MOLECULAR GENETICS OF ACUTE LEUKEMIA

Mary Ann Thompson, Utpal P. Davé

INTRODUCTION

Acute leukemia results when a normal hematopoietic stem or progenitor cell sequentially acquires mutations which confer clonal growth advantage. This clonal evolution model of cancer development involves gain of function of oncogenes and loss of function of tumor suppressor genes that cooperate to induce fulminant disease. The earliest view of the genome of acute leukemia was provided by cytogeneticists who karyotyped leukemic blasts, revealing recurrent chromosomal translocations. Cloning these translocation breakpoints led to the identification of genes whose altered activity could be directly linked to leukemogenesis. More recently, the genomes of acute leukemias have been probed at an unprecedented depth, revealing various lesions at the base pair level, such as amplifications, deletions, insertions/deletions, and point mutations, that can deregulate oncogene or tumor suppressor gene function. Acute leukemias of either myeloid or B-cell origin (i.e., acute myeloid leukemia [AML] and B-cell acute lymphoblastic leukemia [B-ALL]) have been classified by the World Health Organization (WHO) by the presence of recurrent chromosomal rearrangements which affect the choice of therapy and have significant prognostic value. Acute leukemias without recurrent chromosomal rearrangement have been traditionally classified by their cell of origin, but recently these leukemias have been subjected to whole genome analyses, revealing the presence of novel recurrent molecular lesions. As clinical data matures, the list of oncogenes and tumor suppressors deregulated by mechanisms other than chromosomal rearrangement may be incorporated into a new classification schema. In this chapter, we focus on the more common recurrent genetic abnormalities found in acute leukemias, with special emphasis on how the genetic defects inform our concept of leukemia pathogenesis. We provide specific examples where the genetic lesions have led to the development of targeted therapies with fewer side effects than traditional cytotoxic chemotherapy. This is truly an exhilarating time for hematologic oncology, where laboratory findings have direct relevance to current treatment modalities.

Reasons for Studying Molecular Genetics of Acute Leukemia

A major reason for understanding the molecular genetics of acute leukemia is to develop novel molecular treatments for this disease. The paradigm for the translation of basic research knowledge to clinical treatment has been chronic myelogenous leukemia (CML). The first leukemia to be associated with a recurrent translocation, t(9;22)(q34;q11.2) (the Philadelphia chromosome),[1] CML was also the first leukemia where the product of the translocation, breakpoint cluster region *(BCR-ABL1)* was characterized.[2] In addition, CML was the first leukemia for which a specific molecular inhibitor, imatinib (Gleevec), was designed.[3] Research and clinical trials are currently underway to increase the armamentarium of targeted molecular therapies. An additional benefit of being able to identify the molecular lesions in a given acute leukemia is the ability to carry out more accurate risk stratification of newly diagnosed patients. Numerous clinical studies have correlated clinical prognosis with the set of genes that are altered in a patient's leukemic blasts. Results from the initial cytogenetic and molecular studies on a patient's leukemic blasts are used to stratify the leukemia as favorable or unfavorable, as listed in Tables 72.1 and 72.2 for adult AML and pediatric B-cell ALL, respectively. Finally, the particular array of mutated genes in the leukemic blasts provides a very sensitive method for determining efficacy of treatment by using these aberrant molecular markers to quantify minimal residual disease after treatment.

A large number of the genes altered by translocation encode transcriptional regulatory proteins that often preserve the original DNA-binding specificity of one of the fusion partners, but have altered properties of transcriptional activation or repression. The search to understand these altered properties has led investigators to basic discoveries of how transcriptional regulatory proteins modify chromatin structure to open up or inhibit the transcription of target genes. However, the genes that are recurrently mutated in acute leukemias also belong to other functional classes of proteins. Kinases which are rendered constitutively active by mutation can deregulate the cell's signal transduction pathways and lead to uncontrolled proliferation. Mutations in genes encoding proteins involved in modification of histones or methylation of DNA can lead to altered expression of groups of genes that can have effects as dramatic as those caused by mutations in transcription factors. Additional functional categories of genes that are recurrently mutated in leukemia are inhibitors of apoptosis and nuclear pore proteins. This chapter will focus on the mechanisms by which mutations in genes in each of these major functional classes may contribute to the pathogenesis of leukemia. If we understand the mechanism by which "driver" mutations work, we may be able to reverse or inhibit their actions to develop novel treatment modalities for leukemia.

Multiple Hit Model of Leukemia

Another theme that emerges from the study of the molecular genetics of leukemia is that usually more than one genetic hit is necessary for the development of leukemia.[4] This principle has been repeatedly demonstrated in mouse models, where introduction of the fusion gene found in acute leukemia by transgenic technology or retroviral transduction results in predisposition to acute leukemia with long latency, unless the accumulation of additional genetic hits is facilitated by treatment with a mutagenic agent. The multistep model of carcinogenesis is not limited to leukemias, and is reviewed in Hanahan and Weinberg's recent update[5] of their original paper[6] first outlining the six hallmarks of cancer. These hallmarks, now updated to eight, are properties that cancer cells must acquire through multiple mutations in order to become malignant: sustained proliferative signaling, evading growth suppression, enabling replicative immortality, resisting cell death, inducing angiogenesis, activating invasion and metastasis, avoiding immune destruction, and deregulating

TABLE 72.1

RISK GROUPS IN ADULT ACUTE MYELOID LEUKEMIA BASED ON CYTOGENETIC AND MOLECULAR ANALYSIS

Cytogenetic Classification	Cytogenetic Abnormality	Mutation in *FLT3*	Other Mutations	Overall Risk Profile
Favorable	*RUNX1-RUNX1T1* *CBFB-MYH11*	*FLT3*-ITD-neg or positive	Any	Favorable
Intermediate-I and -II	Normal karyotype *MLLT3-MLL* Unclassified cytogenetics	*FLT3*-ITD-neg	Mutant *NPM1* or *IDH1/2*	
		FLT3-ITD-neg	Wild-type *ASXL1*, *MLL*-PTD, *PHF6*, or *TET2*	Intermediate
		FLT3-ITD-neg or positive	Mutant *CEBPA*	
		FLT3-ITD-positive	Wild-type *MLL*-PTD, *TET2*, and *DNMT3A*, or trisomy 8-negative	
		FLT3-ITD-neg	Mutant *TET2*, *MLL*-PTD, *ASXL1*, or *PHF6*	Unfavorable
		FLT3-ITD-positive	Mutant *TET2*, *MLL*-PTD, *DNMT3A*, or trisomy 8, without mutant *CEBPA*	
Unfavorable	*RPN1-EVI1* *DEK-NUP214* *MLL* rearranged −5 or del(5q), −7 Abnl (17p) Complex karyotype	*FLT3*-ITD-neg or positive	Any

cellular energetics.[5] In the field of leukemia research, attention has been focused on deregulation of proliferation (Class I mutations), and a block in differentiation (Class II mutations).[4] The block in differentiation is visually striking under the microscope, as blasts have morphologic characteristics of hematopoietic stem cells (HSCs). However, what is relevant to leukemogenesis is that HSCs have self-renewal. Many of the well-characterized recurrent translocations in acute leukemia produce fusion genes that encode mutant transcription factors that can no longer activate the genes required for differentiation. However, some translocations (notably *BCR-ABL1*), and some of the genes most commonly affected by point mutations (*FLT3*) encode kinases that cause deregulated proliferation.[4] Through new advances in technology outlined in the next section scientists have discovered a host of additional gene mutations that occur in leukemia, suggesting many more than two hits in the path toward leukemia. In addition, a further layer of regulation at the epigenetic level has been hypothesized due to the number of genes mutated in leukemia that are active in modification of histones or in regulation of DNA methylation.

TABLE 72.2

RISK GROUPS IN PEDIATRIC B-CELL ACUTE LYMPHOBLASTIC LEUKEMIA BASED ON CYTOGENETIC AND MOLECULAR ANALYSIS

Risk Group	Cytogenetic or Molecular Abnormality	Target Genes
Favorable	t(12;21)(p13;q22.3)	*ETV6-RUNX1*
	Hyperdiploid > 50 chromosomes	
	Simultaneous trisomies of 4, 10, and 17	
Unfavorable	t(9;22)(q34.1;q11)	*BCR-ABL1*
	t(4;11)(q21.3;q23)	*MLL-AFF1*
	Hypodiploidy < 44 chromosomes	
	iAMP21	*RUNX1*
	Deletion 7(q13)	*IKZF1*
	Mutation in *JAK1/2*	*JAK1/2*
	Deletion/translocation of *CRLF2*	*CRLF2*

Advances in Technology: A Genomic Perspective of Acute Leukemia

The tremendous advances in technology in the few years since the previous version of this chapter have revolutionized our ability to analyze individual genomes (Table 72.3). As mentioned above, G-banding of chromosomes was our first view of the leukemia genome and is still highly informative in identifying translocations, aneuploidy, and other gross chromosomal rearrangements (>4 megabases).[7,8] More focused analyses such as interphase fluorescence in situ hybridization (FISH) have improved the resolution of standard cytogenetics so that amplifications or deletions of 100 kilobases may be visualized.[9] In the last 10 years, oligonucleotides covering the entire human genome have been printed onto arrays allowing hybridization of fluorescently labeled leukemic and control genomic DNA.[10,11] This array comparative genomic hybridization (CGH) can identify copy number variation (CNV), and has been powerfully employed in identifying recurrent

TABLE 72.3

RESOLUTION OF TECHNOLOGIES AVAILABLE TO IDENTIFY GENETIC ALTERATIONS IN ACUTE LEUKEMIA

Technique	Resolution	Molecular Lesion	References
Whole genome sequencing	1 bp	Point mutations, amplifications, insertions, deletions, translocations	13,325
Whole exome sequencing	1 bp	Point mutations, amplifications, deletions	326,327

FISH, fluorescence in situ hybridization; SNP, single nucleotide polymorphism.

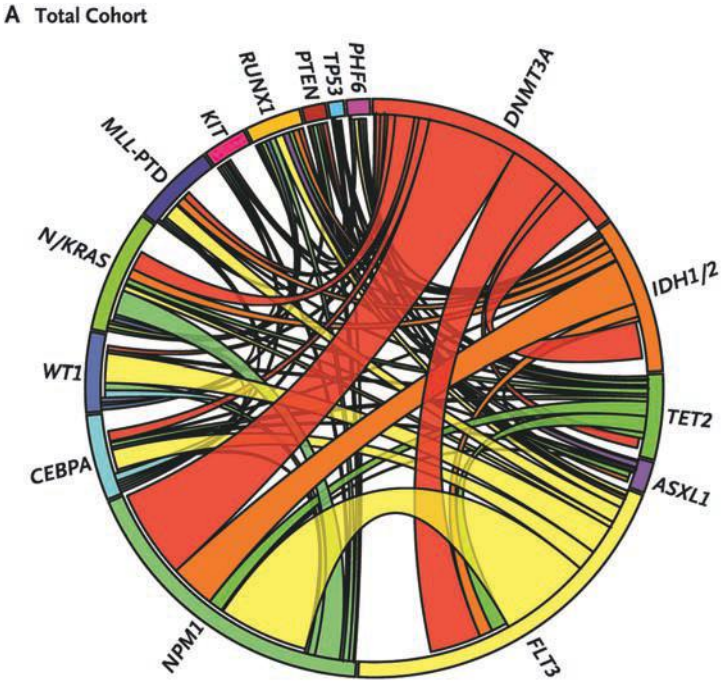
deletions and amplifications in acute leukemias. Similar microarrays were designed to cover common single nucleotide polymorphisms (SNPs) for genotyping purposes, but they too have been used to identify CNVs, particularly copy number neutral loss of heterozygosity (also known as uniparental disomy) in leukemia.[12] Array CGH and SNP arrays display the human genome as small probes and will not detect balanced translocations. Most excitingly, major advances in whole genome sequencing now provide single base pair resolution so that point mutations may be identified as well as chromosomal rearrangements.[13] These powerful technologies are readily deployed in the diagnosis of acute leukemia and provide a complete genomic perspective of the disease; however, there are important caveats. Human genomes are full of rare and common structural variants and SNPs.[14–18] Therefore, mutations can only be interpreted as being acquired in leukemogenesis if they are not present in normal somatic tissue. Thus, matched normal somatic tissue is frequently subjected to the same genomic analyses as leukemic blasts.

The sequence of the human genome was completed in 2001 at 90% coverage after 10 years of collaborative and arduous work from multiple laboratories for a cost of 1 billion dollars; the draft genome sequence contained gaps that were filled in 2004, resulting in a highly accurate reference sequence currently at build 37(2012).[19–21] At this writing, a sample human genome can be sequenced in 6 weeks for approximately 40 thousand dollars.[22] This remarkably short processing time and reduction in cost were made possible by massively parallel sequencing technologies, collectively known as next generation (or second generation) sequencing.[23] The original draft human genome sequence was generated by Sanger sequencing or dideoxynucleotide chain termination and capillary electrophoresis, first generation technologies. In second generation technologies, the addition of nucleotides occurs in parallel on multiple DNA strands and is multiplexed frequently on microchips or beads.[24] This has resulted in an incredible information glut. As DNA sequencing technologies race toward the $1,000 genome, the burden has shifted toward efficient and timely informatics analysis. Some of the complexity of genome assembly can be avoided by targeted sequencing or whole exome sequencing. Here, capture technologies utilize DNA hybridization to purify all the exons of a given genome. These are then fully sequenced; of course, in this case the mutations discovered are limited only to the coding regions of the genome, and mutations within regulatory regions may also be present. Besides mutation analysis, next generation sequencing has expedited our ability to define whole genome chromatin marks,[25] CpG methylation,[25,26] microRNAs,[27] and noncoding RNAs.[28] For chromatin analysis, immunopurification can enrich for genomic DNA that is associated with specific histone marks that denote active or inactive gene expression. These tools will be important in analyzing the effects of mutant leukemia proteins that modify histone residues.

In 2008 the entire genome sequence of a cytogenetically normal AML patient was completed for the first time.[29] In 2009 further refined techniques were used to sequence a second AML genome to a higher level of coverage (98%),[30] and in 2010 DNA from the first patient was subjected to deeper sequencing.[31] In each patient multiple acquired somatic mutations were identified by comparison to normal skin from the same patient. Somatic mutations unique to the leukemia cells were found in coding sequences, as well as in conserved or regulatory portions of genes. All of the mutations were shown to be heterozygous and were present in the majority of the blasts. Screening of a large panel of AML samples for novel coding region mutations identified in the two sequenced genomes demonstrated two genes not previously thought to be involved in leukemogenesis that were recurrently mutated: *IDH1,* (mutated in 16% of cytogenetically normal AML samples),[32] and *DNMT3A* (mutated in 22% of AML samples).[31]

A recent study greatly expanded this breakthrough work by deep sequencing the genomes of 12 patients with AML with a normal karyotype and 12 patients with acute promyelocytic leukemia (APL) with the t(15;17).[33] Again, bone marrow and skin samples were compared, and all single nucleotide variations (SNVs) were validated by Illumina sequencing. An average of 440 SNVs per genome were identified. The number of SNVs per genome was not different between the cytogenetically normal leukemia cases and the t(15;17) leukemia cases, and the number was proportional to age. Interestingly, the number of mutations detected in HSCs from normal patients was similar and also varied with age, suggesting that mutations randomly accumulate in stem cells and that the hundreds of mutations in the AML genomes most likely preexisted before the initiating mutation that gave growth advantage to the AML clone.[33] Thus only a few mutations may be relevant to the pathogenesis of the clone. An average of 11 mutations with translational consequences were present in cytogenetically normal AML genomes and 10 in APL (counting promyelocytic leukemia-retinoic acid receptor-α [*PML-RARA*] itself). Only a few were recurring in other AMLs, with an average of 3 recurring mutations in each cytogenetically normal AML genome and 2 recurring mutations, including *PML-RARA,* in the AML genomes with t(15;17).[33]

The complexity of mutations that contribute to the leukemic phenotype is visually appreciated in Figure 72.1, a summary of coexpression of mutations in a cohort of 398 patients with AML that were screened for mutations of eighteen gene loci.[34]



Gene	Overall Frequency (%)
FLT3 (ITD, TKD)	37 (30, 7)

FIGURE 72.1. Mutational complexity of acute myeloid leukemia (AML). The Circos diagram depicts the relative frequency and pairwise co-occurrence of mutations in patients with newly diagnosed AML who were enrolled in the Eastern Cooperative Oncology Group E1900 clinical trial. The length of the arc along the outer circle corresponds to the frequency of mutations in the first gene, and the width of the ribbon corresponds to the percentage of patients who also had a mutation in the second gene listed on the opposite end of the ribbon. Pairwise co-occurrence of mutations is denoted only once, going in the clockwise direction. The frequency of occurrence in the test cohort of the 18 genes in the test panel is listed to the right of the Circos diagram. From Patel JP, Gonen M, Figueroa ME, et al. Prognostic relevance of integrated genetic profiling in acute myeloid leukemia NEJM 2012;366:1079–1089, Copyright 2012 Massachusetts Medical Society. ACUTE MYELOID LEUKEMIA

World Health Organization Classification

A subset of the new WHO classification of acute myeloid leukemia is entitled "acute myeloid leukemia with recurrent genetic abnormalities"[35] (see Table 72.4). These recurrent translocations occur most often in de novo acute leukemia, but are not restricted to this category. Another major category of acute myeloid leukemia is AML with myelodysplasia-related changes,[35] where genetic mutations and chromosomal deletions occur secondary to the mutator phenotype of the underlying myelodysplastic syndrome (MDS) in some cases.

Whole genome sequencing has clarified our understanding of the clonal evolution from MDS to AML. Walter et al compared seven sets of samples from patients for whom there were paired samples of normal skin, preleukemic bone marrow diagnosed as MDS, and bone marrow involved by secondary AML.[36] In each genome there were 304 to 872 somatic point mutants in coding regions or consensus splice site regions, and those point mutations with translational consequences comprised an average of 24 mutations per genome. These functional mutations occurred in a total of 168 genes over the 7 genomes. The strength of the study was that the number of mutations allowed study of clonal evolution from MDS to secondary AML. The clonal evolution described by the sequential acquisition of mutations (defined as five mutation clusters by unsupervised clustering analysis) is visually shown in Figure 72.2. A majority of the cells in the MDS sample contained the same cluster of mutations, meaning that before blasts were even detected morphologically, the marrow was involved by a clonal process. At the secondary AML stage, all the samples contained several clones, all of which had the original set of mutations, but which were defined by acquisition of new sets of mutations as well. Presumably most of these somatic mutations are "passenger" mutations, but the multiplicity of mutations tracked adds credence to the description of clonal evolution.[36] The mutations that were in characterized genes ranged the gamut of genes involved in adhesion, cell death, cell cycle, differentiation, metabolism, motility, signaling, transcription, and transporters.[36] In the subsequent sections, we will discuss how alterations of genes that fall in these functional classes contribute to leukemogenesis.

TABLE 72.4

WORLD HEALTH ORGANIZATION CLASSIFICATION OF ACUTE MYELOID LEUKEMIA

- AML with recurrent genetic abnormalities
  - AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*
  - AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
  - Acute promyelocytic leukemia with t(15;17)(q24.1;q21.1); *PML-RARA*
  - AML with t(9;11)(p22;q23); *MLLT3-MLL*
  - AML with t(6;9)(p23;q34); *DEK-NUP214*
  - AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*
  - AML (megakaryoblastic) with t(1;22)(p13;q13); *RBM15-MKL1*
  - AML with mutated *NPM1*
  - AML with mutated *CEBPA*
- AML with myelodysplasia-related changes
- Therapy-related myeloid neoplasms
- AML, NOS
- Myeloid sarcoma
- Myeloid proliferations related to Down syndrome

AML, acute myeloid leukemia; NOS, not otherwise specified.

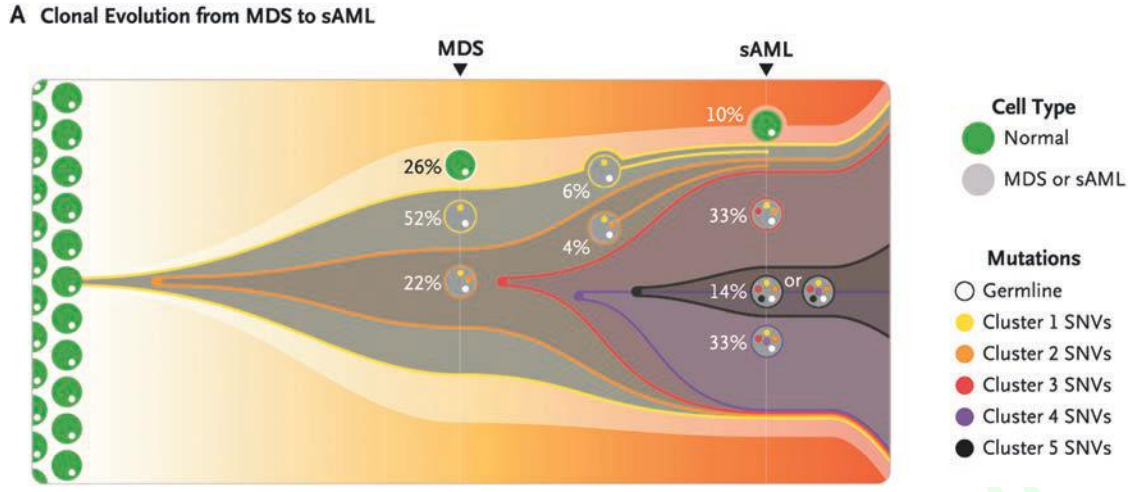

FIGURE 72.2. Clonal progression of MDS to secondary acute myeloid leukemia (AML). This model summarizes the clonal evolution from MDS to secondary AML (sAML) in one patient. Cells in clone 1 (*yellow*) contain cluster 1 mutations, 323 somatic single nucleotide variants (SNVs) present in approximately 74% of the bone marrow cells. Cells in clone 2 (*orange*) originated from a single cell in clone 1 and therefore contain all cluster 1 and 2 mutations. This clone became dominant in the sAML sample, in which three subsequent subclones (*red, purple,* and *black*) evolved through serial acquisition of SNVs (clusters 3, 4, and 5). Transcription Factors

Promyelocytic Leukemia-Retinoic Acid Receptor-α

One of the most elegant examples of the interaction between clinical and molecular advances in the treatment of acute leukemia is APL. The association between the t(15;17)(q24.1;q21.1) translocation and the characteristic morphology of APL (hypergranular blasts with frequent Auer rods or microgranular variant with dumbbell-shaped nuclei) has been known for a long time. The ability to treat APL with retinoic acid (RA) and the understanding of the molecular basis for this treatment is a compelling example of the power of molecular medicine. The initial report from China[37] that all-*trans* retinoic acid (ATRA) could induce complete remission (CR) in APL patients actually preceded the discovery that the t(15;17) translocation involved the *RARA* gene on chromosome 17.[38,39,40]

Of four translocations associated with APL, the most common is t(15;17)(q24.1;q21.1), in which the 5′ portion of the fusion protein is encoded by the *PML* gene from 15q24.1 and the 3′ portion is encoded by the *RARA* gene from 17q21.1. The *RARA* gene is a ligand-dependent steroid receptor that mediates the effects of the ligand, RA, on the cell. The breakpoint is invariant in intron 2 of *RARA,* yielding the C-terminal portion of the fusion protein, which includes the DNA-binding, ligand-binding, dimerization, and repression domains of RARA. There are three major breakpoints in the *PML* gene. The most common generates *PML(L)-RARA,* which includes the first six exons of *PML* encoding 554 amino acids of PML.[41]

The wild-type RARA is a nuclear receptor that acts as a transcription factor and binds to retinoic acid response elements (RAREs) in the promoters of many genes, including genes important in myeloid differentiation. RARA binds as a heterodimer with retinoid X receptor protein (RXR) and acts as a transcriptional repressor until ligand (RA) binding occurs, changing the conformation of the protein and resulting in transcriptional activation.[42] Target genes important for myeloid differentiation include colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF]), colony-stimulating factor receptors (G-CSFRs), neutrophil granule proteins (leukocyte alkaline phosphatase, lactoferrin), cell-surface adhesion molecules (CD11b, CD18), regulators of the cell cycle, regulators of apoptosis (BCL2), and transcription factors (RARs, STATs, HOX genes) (reviewed in Ref. 43). Expression of a dominant negative RARA in either a murine hematopoietic cell line or primary murine bone marrow cells, followed by stimulation with granulocyte–macrophage colony-stimulating factor (GM-CSF), results in arrest of granulocytic differentiation at the promyelocyte stage.[44]

In the absence of RA, the wild-type RARA, present as a heterodimer with RXR on the RARE, binds to the corepressor proteins SMRT, N-CoR, mSin3, and histone deacetylases (HDACs). Deacetylation of the histones at the target gene promoter results in transcriptional repression. Ligand binding at physiologic concentrations of ATRA causes a conformational change that results in release of corepressors and recruitment of a coactivator complex (SRC-1), which associates with histone acetyltransferases (Fig. 72.3A).[45] Acetylation of the histones at the target gene promoter is associated with transcriptional activation (reviewed in Ref. 43).

Wild-type PML protein is normally localized in subnuclear PML oncogenic domains, also called nuclear bodies (NBs), in which other nuclear factors colocalize.[46] PML may act as a tumor suppressor protein and is involved in growth suppression as well as in induction of apoptosis (reviewed in Ref. 43). Although it does not bind DNA directly, it influences transcription by interacting with both CREB-binding protein (CBP),[47] a transcriptional activator, and HDACs, transcriptional repressors, possibly within the NBs. The protein encoded by the *PML-RARA* fusion transcript resulting from the t(15;17) is delocalized from the NBs to a microspeckled nuclear pattern.[48]

In APL, the PML-RARA protein binds to RAREs with similar affinity to the RARA protein and is able to heterodimerize with RXR. It acts in a dominant negative manner, competing with wild-type RARA for binding to the RAREs. It binds corepressor proteins in the absence of ligand (via the RARA portion of the protein). However, physiologic levels of ATRA (10^{-8} M) are not able to convert PML-RARA into a transcriptional activator; pharmacologic concentrations are required (10^{-6} M; Fig. 72.3B).[45,49] This provides the mechanistic basis for the efficacy of treatment of APL patients with ATRA to include differentiation of the promyelocytes.

Understanding of the mechanism of the response of APL to ATRA was furthered by studies of an alternative translocation, t(11;17)(q23;q21.1), which is rarely seen in patients with APL.[50] Patients with this translocation are resistant to treatment with pharmacologic doses of ATRA. The fusion partner gene on chromosome 11q23 encodes *ZBTB16* (previously known

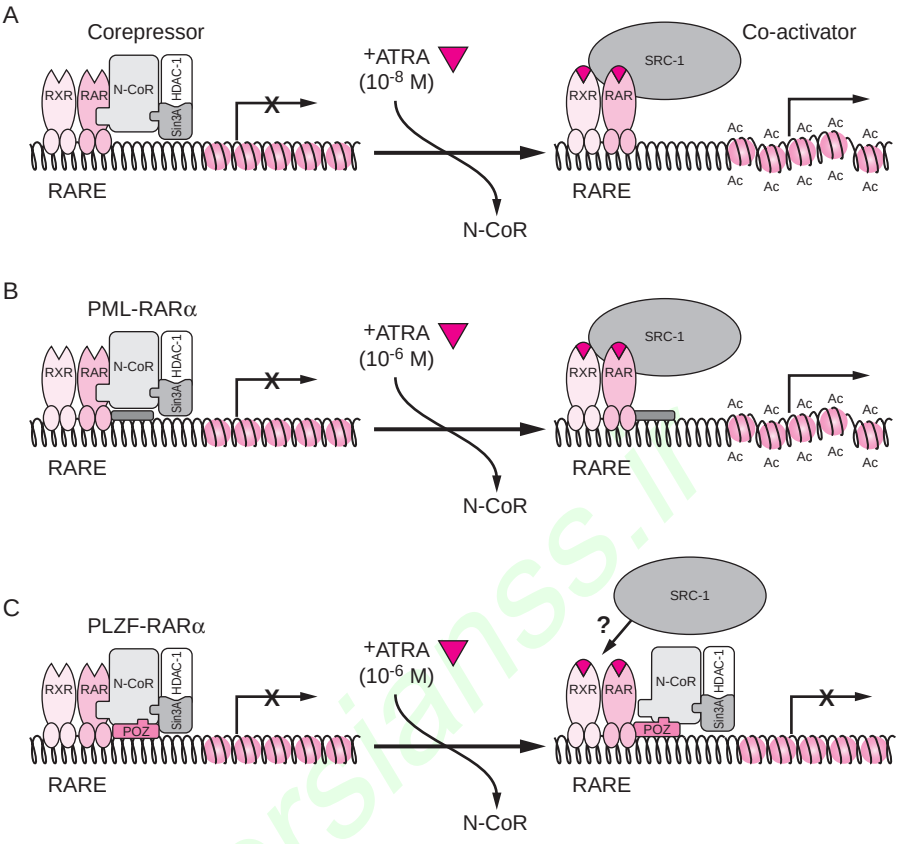

FIGURE 72.3. Model for the role of nuclear corepressors and retinoid acid receptor α (RARA) fusion proteins in the pathogenesis and treatment of acute promyelocytic leukemia. A: In the absence of all-*trans* retinoic acid (ATRA), RARA, promyelocytic leukemia (PML)-RARA, and promyelocytic leukemia zinc finger (PLZF; now known as ZBTB16)-RARA associate with N-CoR/sin3A/HDAC1 corepressor complex, which deacetylates histone tails, resulting in a compressed chromatin and transcriptional repression. Binding of ATRA at a physiologic concentration induces a conformational change in RARA, causing release of the corepressor complex and binding of coactivator (SRC-1) with histone acetyltransferase activity. Acetylation (Ac) of histone tails opens up the chromatin, facilitating transcriptional activation. **B:** In the case of PML-RARA protein, pharmacologic doses of ATRA are required to achieve dissociation of the N-CoR repressor complex. **C:** Because of additional interactions of the PLZF (ZBTB16) moiety of PLZF-RARA fusion protein with corepressors, they do not dissociate even in the presence of pharmacologic doses of ATRA. Therefore, the chromatin still remains in the repressed state. From Guidez F, Ivins S, Jhu J, et al. Reduced retinoic acid-sensitivities of nuclear receptor corepressor binding to PML- and PLZF-RARα underlie molecular pathogenesis and treatment of acute promyelocytic leukemia. Blood 1998;91:2634–2642, with permission.

as promyelocytic zinc finger), a transcriptional repressor. The N-terminal portion of the fusion protein encoded by *ZBTB16* includes the N-terminal POZ/BTB protein interaction domain, transcriptional activation and repression domains, and a variable number of zinc fingers important for protein and DNA interactions (reviewed in Refs. 43,45). ZBTB16 interacts with N-CoR, SMRT, mSin3A, and HDAC1 via the POZ/BTB domain,[51,52] and therefore contributes a second binding site for corepressor proteins. Therefore, although pharmacologic doses of ATRA induce release of corepressors from the RARA portion of the fusion protein, the corepressors binding to ZBTB16 are unaffected (Fig. 72.3C).[43,53] Significantly, concomitant treatment of cells with HDAC inhibitors such as trichostatin A (TSA) restores ATRA sensitivity, since TSA inhibits the deacetylase activity of the corepressors on the ZBTB16 moiety.[49,52]

Subsequent studies have demonstrate that PML-RARA recruits the polycomb-repressive complex 2 (PRC2) to the promoters of its gene targets. The PRC2 has a H3K27 methylase activity and can initiate gene repression through trimethylation of H3K27.[54] ZBTB16-RARA additionally recruits polycomb-repressive complex 1 (PRC1); treatment with RA releases PRC2 from both PML-RARA and ZBTB16-RARA, but does not release PRC1 from ZBTB16-RARA.[55]

Core-Binding Factor Translocations

The t(8;21) is present in approximately 15% of patients with acute myeloid leukemia,[56,57] and the *RUNX1* (runt-related transcription factor 1, formerly called *AML1*) gene, cloned from the t(8;21)(q22.3;q22) breakpoint,[58,59] is mutated in another 3% of AML. The activity of the murine counterpart of RUNX1 was first described as part of the core-binding factor (CBF), which binds to a core enhancer sequence of the Moloney murine leukemia virus long terminal repeat.[60] Another component of CBF, the non-DNA-binding CBFβ was found to be associated with inversion 16 in AML.[61]

Finally, the fusion partner of *RUNX1* in t(8;21), named *RUNX1T1,* or *ETO* (eight-twenty-one), also encodes a transcriptional regulator.[62] A gene related to *RUNX1T1, CBFA2T3* (or *MTG16),* is involved in yet another translocation involving *RUNX1,* t(16;21).[63] The structures of the fusion proteins resulting from these CBF translocations are shown in Figure 72.4.

RUNX1 is located at chromosome 21q22.3 and is encoded by 12 exons over 260 kb of DNA. The N-terminal portion of the protein contains the runt homology domain (RHD), which is homologous to the *Drosophila runt* protein[64] and is responsible for the official HUGO name, *RUNX1*. This is the DNA-binding domain and it is mutated in familial platelet disorder (FPD) and in AML associated with *RUNX1* mutations.[65,66] CBFB interacts via this domain and changes the conformation of RUNX1 to increase DNA-binding affinity.[67] C-terminal to the RHD are potential MAP kinase phosphorylation sites, followed by three weak activation domains, a nuclear matrix target signal, a dimerization domain, and sequences that are recognized by corepressor proteins (reviewed in Ref. 68).

The CBFs are essential for hematopoietic development. Gene deletion of either *Runx1*[69] or *Cbfb*[70] in mice results in fetal death at E11.5 to 12.5. These embryos lack all fetal hematopoiesis. Further transgenic experiments have demonstrated that Runx1 is essential for development of HSCs in the aorta/gonadal/mesodermal (AGM) region, the source of definitive hematopoiesis.[71] The essential role of RUNX1 in hematopoietic development appears to be through its function as a transcriptional activator. It regulates lymphoid genes such as B-cell tyrosine kinase, T-cell receptor α and β,[72] cytokines (interleukin-3 [IL3],[73] GM-CSF[74]), and granulocyte proteins (myeloperoxidase and neutrophil elastase),[75] to name a few. In addition, RUNX1 acts as a transcriptional repressor of genes such as $p21^{Waf1/Cip1}$ via interactions with the mSin3a corepressor[76] and with SUV39H1, a histone methyltransferase.[77]

The *ETO* gene, now called *RUNX1T1,* was cloned from the t(8;21) fusion[58] and is the mammalian homolog of the *Drosophila*

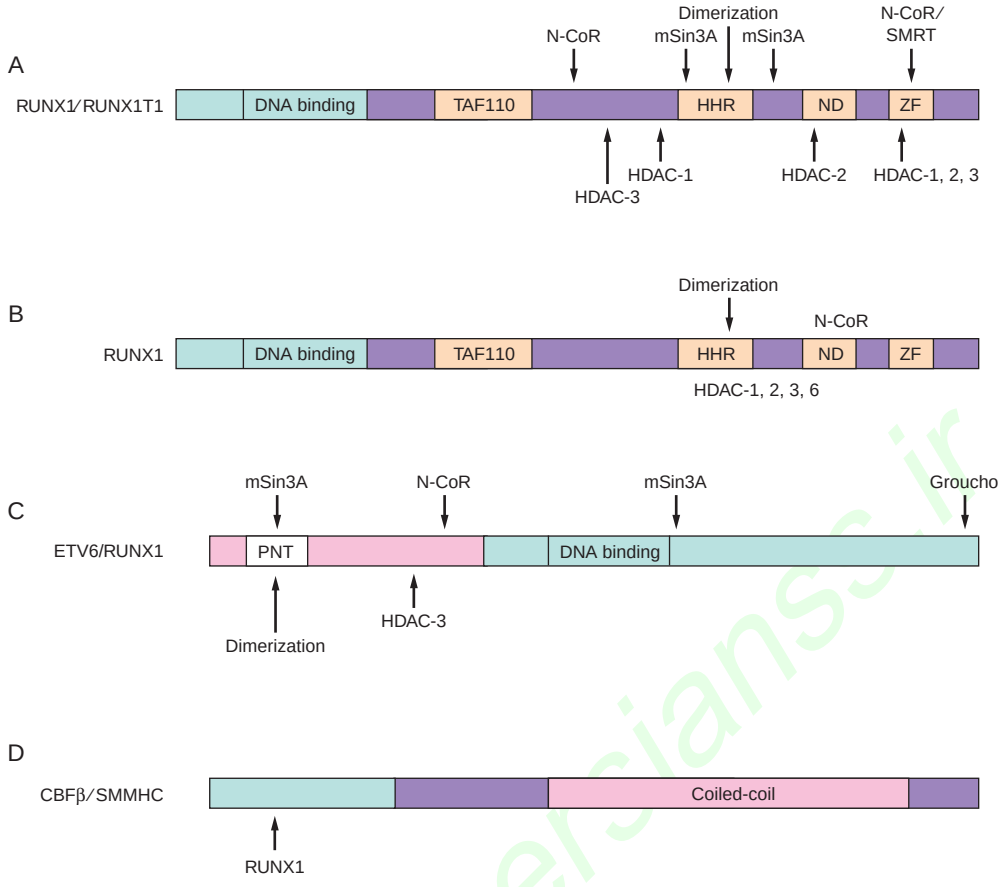

FIGURE 72.4. Schematic diagram of the t(8;21), t(16;21), t(12;21), and inv(16) fusion proteins with known corepressor contacts. A: t(8;21) RUNX1/RUNX1T1. The RUNX1 portion is shown in light pink, with the DNA-binding domain indicated. The RUNX1T1 portion is the dark pink box with domains conserved between RUNX1T1 and its *Drosophila* homolog in light gray boxes. Known contacts with corepressors and histone deacetylases are shown. **B:** t(16;21) RUNX1-MTG16 (now known as CBFA2T3). RUNX1 is shown as a light pink box, and MTG16 is shown in a similar manner to RUNX1T1 in A. **C:** t(12;21) ETV6-RUNX1. ETV6 is the dark pink box, with the conserved pointed (PNT) domain indicated. The RUNX1 portion is the light pink box. Interactions with corepressors and HDACs are shown. **D:** Inv(16) CBFB-SMMHC (now known as MYH11). The CBFB portion, which interacts with RUNX1, is light pink, and the SMMHC is dark pink, with the coiled-coil domain indicated as well as the C-terminal portion, which is necessary for interaction with mSin3A and HDAC8.[77] HHR, hydrophobic heptad repeat; ND, nervy domain; TAF110, a domain with homology to the TAF110 coactivator; ZF, zinc finger domain. From Hiebert SW, Lutterbach B, Amann J. Role of corepressors in transcriptional repression mediated by the t(8;21), t(16;21), t(12;21), and inv(16) fusion proteins. Curr Opin Hematol 2001;8:197–200, with permission.

nervy gene.[78] The four homology domains shared with the Drosophila protein include a region of similarity to TAF110, a hydrophobic heptad repeat (HHR), an ND domain of undetermined function, and two zinc finger motifs that may be a protein–protein interaction domain (Fig. 72.4A).[68] RUNX1T1 does not appear to bind DNA specifically on its own. However, it may act as a corepressor protein.[79] It associates with N-CoR and mSin3A, and directly binds to the Class I HDACs, HDAC-1, HDAC-2, and HDAC-3 (Fig. 72.4A).[80]

In the t(8;21) translocation, the *RUNX1* gene is fused to the *RUNX1T1* gene on chromosome 8. The breakpoint in the *RUNX1* locus is between exons 5 and 6,[81] yielding a fusion protein with the N-terminal 177aa of RUNX1.[58] In this fusion protein, the DNA-binding domain is present, but the C-terminal activation domains, corepressor interaction sites, and nuclear localization signals (NLSs) of the wild type are not present (Fig. 72.4A).[68] The breakpoint in the *RUNX1T1* gene occurs in the introns between the first two alternative exons of *RUNX1T1,* resulting in the inclusion of almost all of the coding region for RUNX1T1 in the fusion transcript.[58]

The RUNX1-RUNX1T1 protein specifically binds to the same DNA-binding site as RUNX1 and can heterodimerize with CBFB.[82] Therefore, the RUNX1-RUNX1T1 protein can act as a dominant negative inhibitor of wild-type RUNX1. However, cotransfection experiments demonstrated that RUNX1-RUNX1T1 can also function as an active transcriptional repressor, not only inhibiting activation of a reporter gene containing the GM-CSF receptor promoter by cotransfected RUNX1, but also reducing the expression of the reporter gene below baseline.[83] The ability of RUNX1-RUNX1T1 to act as a transcriptional repressor depends on its association with HDACs (via RUNX1T1; Fig. 72.4A), since the HDAC inhibitor TSA can abrogate effects of RUNX1-RUNX1T1 on the cell cycle.[80] In addition, examination of the M-CSFR gene in Kasumi-1 cells (high expressors of RUNX1-RUNX1T1) reveals an increase in histone H3Lys9 methylation.[84] Targets of RUNX1-RUNX1T1 repression are presumed to include genes important for granulocyte differentiation. In addition, RUNX1-RUNX1T1 represses the tumor suppressor genes *P14ARF* and *NF1*.[85,86] P14ARF stabilizes TP53 by antagonizing MDM2, an inhibitor of TP53.[87] Therefore, repression of *P14ARF* reduces the checkpoint control path of TP53, and may be a key event in t(8;21) leukemogenesis. The promoter of *P14ARF* has eight RUNX1 DNA-binding sites, and wild-type RUNX1 can activate *P14ARF*. However, transfection of *RUNX1-RUNX1T1* into cells that have only low levels of RUNX1 and high endogenous levels of P14ARF results in repression of *P14ARF*. Samples of bone marrow from patients with t(8;21) leukemia have low levels of *P14ARF* transcript by quantitative real-time polymerase chain reaction analysis.[85] Surprisingly, expression of RUNX1-RUNX1T1 in myeloid progenitor cells inhibits cell cycle progression. However, this may contribute to leukemogenesis by allowing time for accumulation of mutations in a cell immune from TP53-induced apoptosis due to inactivation of P14ARF.[85]

Finally, inversion 16, present in about 8% of AML cases, involves the CBF complex member CBFB and is associated with a morphologically distinct subset of AML, previously considered M4Eo in the French-American-British Cooperative Group Classification. This disease is a myelomonocytic leukemia with abnormal eosinophils that have dark purple as well as orange granules.[35] This cytogenetic abnormality in which the *CBFB* gene is fused to the smooth muscle myosin heavy-chain (SMMHC) gene, *MYH11,* results in fusion of the first 165aa of CBFB to the C-terminal coiled-coil region of SMMHC protein (Fig. 72.4D).[61] A C-terminal region of SMMHC/MYH11 is necessary for the activity of CBFB/MYH11 as a transcriptional corepressor, and this region also associates with mSin3a and HDAC8. Presumably CBFB/MYH11, which cannot bind DNA on its own, interacts with RUNX1 to form a transcriptional repressor complex.[88]

A number of experiments demonstrate that the CBF translocations are necessary but not sufficient for induction of leukemia. In order to determine whether expression of RUNX1-RUNX1T1 is sufficient to produce leukemia, mice were generated with a conditional *Runx1-Runx1t1* knock-in allele using the Lox-Cre system. This obviates the embryonic lethality that results when *Runx1-Runx1t1* is introduced into transgenic mice (recapitulating the phenotype of the *Runx1* null mouse). No leukemia developed in 20 *Runx1-Runx1t1*+ mice in 11 months, and no hematologic abnormality was detected except for a slight increase in the number of hematopoietic colony-forming cells. Interestingly, expression of *Runx1-Runx1t1* did not cause a significant block in differentiation of hematopoietic precursors. When the mice were mutagenized with the DNA alkylating agent, ethylnitrosourea (ENU), 31% of the mice developed granulocytic sarcoma or AML.[89] This supports the hypothesis that several genetic "hits" are necessary for the development of leukemia.

Another study used retroviral transduction of $CD34^+$ human hematopoietic progenitor cells to investigate the effect of *RUNX1-RUNX1T1* on proliferation and differentiation.[90] In mice reconstituted with RUNX1-RUNX1T1 expressing HSCs there was an expansion of the HSC population and immature myeloid cell populations, although the mice did not develop acute leukemia.[91] Therefore, the expression of RUNX1-RUNX1T1 promotes accumulation of immature cells and prolongs the period of time during which progenitor cells may accumulate additional mutations.

Further support for the hypothesis that genetic mutations besides a mutant *RUNX1* locus are necessary for development of acute leukemia comes from the study of patients with FPD with a propensity to develop AML (FPD/AML). These patients have mutations in one allele of *RUNX1*.[92] They have defective platelets and progressive pancytopenia, and develop myelodysplasia and a high incidence of AML with age. However, second mutations appear to be necessary before progression to AML occurs. This implies that acquisition of additional mutations is necessary for development of leukemia.

CCAAT/Enhancer Binding Protein-α

CCAAT/enhancer binding protein-α (CEBPA) is a transcription factor that regulates granulocytic differentiation.[93] Cytogenetically silent mutations of *CEBPA* have been identified in about 10% of AML cases.[94] In addition, mutations in other oncogenes in leukemia often lead to *CEBPA* downregulation. For example, RUNX1-RUNX1T1 represses the *CEBPA* promoter.[95] FLT3-ITD activation of ERK leads to modification of CEBPA which reduces its activity.[96] In addition, the *CEBPA* promoter is methylated in half of AML cases.[97]

The importance of CEBPA in granulocyte differentiation is demonstrated by the lack of mature granulocytes in *Cebpa* knockout mice,[98] while its conditional expression triggers granulocyte differentiation in bipotential precursors.[99] CEBPA transactivates the genes for G-CSF and GM-CSF receptors and several granulocyte-specific proteins. The gene produces two proteins using alternative start sites. The larger and predominant 42-kD protein consists of two N-terminal transactivating domains, with a C-terminal bZIP domain consisting of a basic (b) region that mediates DNA sequence binding and a leucine zipper (ZIP) domain that mediates dimerization.[100] The shorter 30-kD protein is transcribed from an alternative internal start site, and retains its bZIP domain but lacks the first transactivation domain. Mutations in *CEBPA* are of two types: C-terminal bZIP domain mutations and N-terminal truncating mutations that lead to enhanced production of the 30-kD protein.[101,102,103] The former type inhibits dimerization and DNA binding. The latter type dimerizes with the long form, but inhibits transactivation by the dimer, functioning in a dominant negative manner. In two-thirds of AML with *CEBPA* gene mutations, one allele has an N-terminal mutation and the other allele has a C-terminal variant. Several families with familial AML have been documented to have germline *CEBPA* N-terminal mutations, and progression to AML has been shown to correlate with a somatic mutation in the C-terminus.[104] *CEBPA* mutations most often occur in intermediate-risk AML with normal cytogenetics, and these patients have a significantly improved outcome.[94] Interestingly, mutation of *CEBPA* at both alleles is associated with a better overall survival than mutation of *CEBPA* at a single allele.[105] Approximately one-third of AML with *CEBPA* mutations also have *FLT3* mutations, and the *CEBPA* mutation confers a more favorable prognosis in this group of AML patients as well.[34]

GATA1

GATA1 is a zinc finger transcription factor that regulates erythroid and megakaryocytic differentiation. In the acute megakaryoblastic leukemia (AMkL) that occurs in children with Down syndrome (DS), mutations of *GATA1* have been described in all tested cases.[106,107,108] Familial missense mutations in *GATA1* result in a syndrome of dyserythropoietic anemia and thrombocytopenia, while conditional knockout of *Gata1* in megakaryocyte precursors in mice leads to thrombocytopenia and megakaryoblast proliferation. Approximately 10% of DS patients develop transient myeloproliferative disorder (TMD) in the neonatal period (usually in the first week, almost always within the first 2 months of life), and these patients have mutations in *GATA1*.[106,109] About one-third of DS patients with TMD later develop AMkL within 5 years, and identical *GATA1* mutations have been identified in the AMkL blasts as were present in the TMD. A large study demonstrated that there is no difference in the *GATA1* mutations present in patients who just developed TMD compared to patients who went on to AMkL.[110] The mutations in *GATA1* result in transcription of a truncated form that lacks its N-terminal transactivation domain, GATA-1s. This shorter form has similar DNA-binding activity but reduced transactivation compared to wild-type, and it therefore can act in a dominant negative manner. By introducing the truncated *GATA1* into *GATA1*-deficient fetal liver progenitor cells by retroviral transduction, Muntean and Crispino demonstrated that GATA-1s restored terminal differentiation but that abnormal proliferation occurred.[111] Interestingly, analysis of a knock-in mouse model where *Gata-1*s replaces wild-type *Gata-1* demonstrates that fetal liver megakaryocytes abnormally proliferate, but that megakaryocyte proliferation is normal in adult bone marrow.[112] This may explain why TMD occurs in the neonatal period in DS patients. Research into the gene(s) on chromosome 21 that cooperate with mutant *GATA1* to produce AMkL in DS children is ongoing; a recent mouse study reported evidence that Dyrk1a (dual-specificity tyrosine-phosphorylation-regulated kinase 1A) can cooperate with mutant Gata1 to promote megakaryoblast expansion.[113]

AMkL in Down syndrome is sensitive to cytosine arabinoside/anthracycline-based chemotherapy, with event-free survival rates of 80% to 100%.[114] Interestingly, a putative target of GATA1 regulation is cytidine deaminase (*CDA*), which inactivates ara-C by deamination to the inactive uridine arabinoside. Presumably failure of GATA-1s to transactivate *CDA* increases the efficacy of ara-C treatment.[111]

Epigenetic Factors Modifying Chromatin and DNA

IDH1/2 and TET2 Mutations

In the whole genome sequencing of blasts from a patient with cytogenetically normal AML, mutations in isocitrate dehydrogenase 1 (*IDH1*) were detected and were found to be present in 16% of a panel of 80 cytogenetically normal AML samples.[30] *IDHI* mutations had previously not been described in AML, though *IDH1/2* mutations are common in gliomas.[115] In a further screen of AML DNA, it was found that *IDH1/2* mutations are mutually exclusive with mutations in *TET2* (ten-eleven translocation 2) in de novo AML (Fig. 72.5). Additional findings suggesting a functional link between the products of these two genes are that AMLs with mutations in *IDH1* have similar patterns of DNA hypermethylation as AMLs with mutations in *TET2*.[116] In addition, these two mutational categories of AML share patterns of aberrant gene expression at the level of 93%.[116] The link became clear upon further investigation of the enzymatic activity of IDH1/2 and TET1/2. Wild-type IDH1/2 catalyzes production of α-ketoglutarate (α-KG), whereas the neomorphic enzymatic activity of mutant IDH1/2 produces 2-hydroxyglutarate (2-HG). α-KG–dependent enzymes such as histone demethylases and TET1/2 are inhibited by 2-HG, which is structurally similar enough to α-KG that it can bind in place of α-KG and inhibit these enzymes.[117] The TET proteins catalyze the conversion of 5-methyl cytosine (5mC) to 5-hydroxymethyl cytosine (5hmC), which is thought to be a first step in demethylation of the cytosine.[118] Experiments using a fluorescent-tagged antibody to 5hmC demonstrate that cotransfection of plasmids encoding *IDH1* and *TET2* result in a global increase in 5hmC, whereas cotransfection of plasmids encoding mutant *IDH1* and wild-type *TET2* fail to demonstrate an increase in 5hmC.[117] Therefore, mutations in *IDH1* and *TET2* both produce increased DNA methylation: mutant IDH1 by inhibiting TET2, and mutant TET2 by loss of its ability to convert 5mc to 5hmC, and thereby promote demethylation.[116–119] The significance of these changes for pathogenesis of AML is demonstrated by experiments in which either stable expression of mutant IDH1 or shRNA-mediated knock-down of TET2 in primary mouse bone marrow cells resulted in increased c-kit expression and decreased expression of the mature myeloid markers Mac-1 and Gr-1 by flow cytometric analysis.[116] Therefore, the hypermethylation and resultant silencing of genes as a result of *IDH1* and *TET2* mutations presumably inhibit myeloid differentiation and thereby promote development of AML. This mechanism suggests new avenues of molecular therapy in that drugs that mimic α-KG or that inhibit the mutant IDH1/2 may restore proper enzymatic function to histone demethylases and TET2, promoting normal histone and DNA methylation patterns.[117] In studies performed to date, mutations in *IDH1* and *TET2* have not been shown to have a significant impact on survival.[105]

DNMT3A

Deep sequencing of DNA from the first AML patient with a normal karyotype revealed additional mutations, including a mutation in DNA methyltransferase (*DNMT3A*). Sequencing of the *DNMT3A* gene in DNA from 281 AML patients revealed a mutation rate of 22.1%. The *DNMT3A* mutations were found in patients with intermediate-risk cytogenetics. As a group these patients had a mean overall survival significantly shorter than the patients with wild-type *DNMT3A:* 12.3 months compared to 41.1 months.[31] The mutations detected in patients with AML map predominantly at the interface where they disrupt tetramerization of the DNMT3A molecules. Dimeric DNMT3A molecules still have methylase activity, but they dissociate from DNA more quickly than wild-type, so

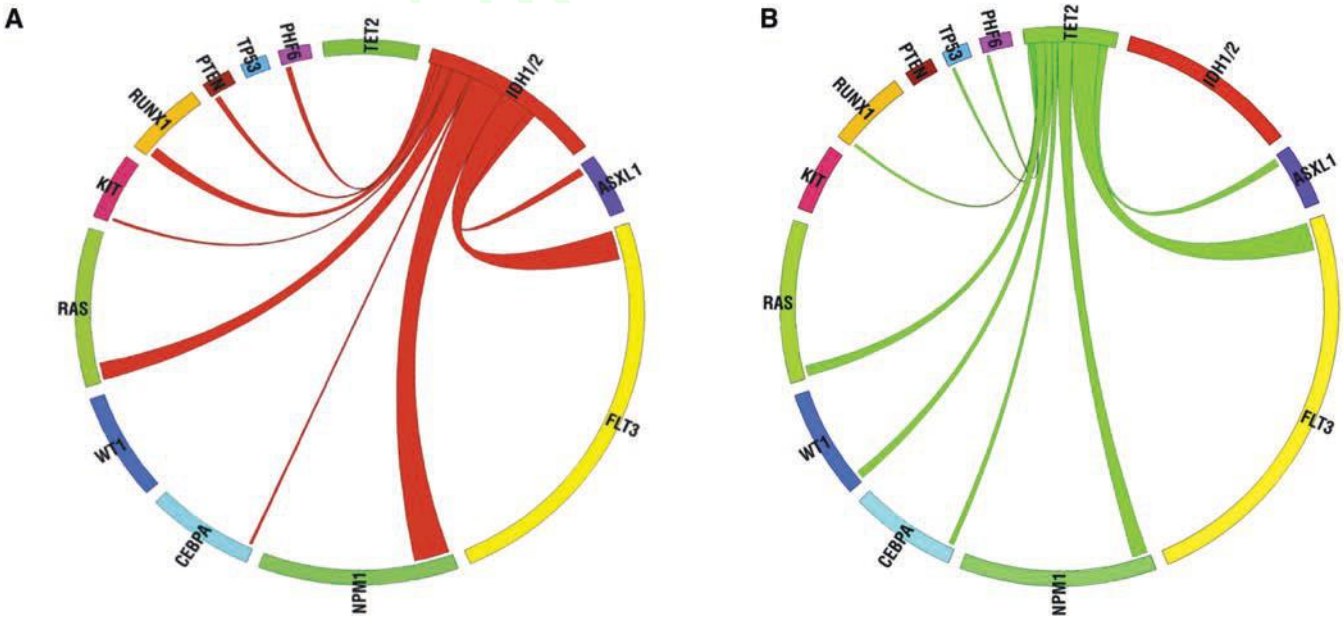

FIGURE 72.5. *IDH1/2* mutations are mutually exclusive with mutations in *TET2* in de novo AML. Reprinted from Figueroa ME, Abdel-Wahab O, Lu C, et al. Leukemic *IDH1* and *IDH2* mutations result in a hypermethylation phenotype, disrupt TET2 function, and impair hematopoietic differentiation. Cancer Cell 2010;18:553–567, with permission from Elsevier.

that fewer cytosines in a CpG island are methylated.[120] The effect on tetramerization explains why the *DNMT3A* mutations are dominant negative, usually occurring in just one allele. Global methylation does not seem to be affected in DNA from AML with mutated *DNMT3A,* but analysis of DNA methylation by MeDIP-Chip (methylated DNA immunoprecipitation-Chip) analysis in a matched set of DNAs from 5 AML patients with mutated *DNMT3A* and 5 AML patients with wild-type *DNMT3A* demonstrated 182 genomic sites where the DNA from patients with mutated *DNMT3A* was hypomethylated.[31] Studies of DNA methylation in *Dnmt3a*-null murine HSCs demonstrated a complex story with poor correlation between changes in methylation sites and changes in gene expression comparing wild-type to *Dnmt3a*-null HSCs. However, changes in gene expression patterns may be due to changes in methylation of regulatory regions of directly affected genes, whose expression then alters regulation of many other genes by mechanisms other than methylation. Transcriptional profiling of *Dnmt3a*-null HSCs did reveal that genes involved in the multipotency of normal HSCs were upregulated, whereas genes necessary for differentiation of the HSCs were downregulated. This suggests that the *DNMT3A* mutations may contribute to the block in differentiation that occurs in leukemic blasts. Interestingly the *Dnmt3a*-null mice have not yet developed leukemia, suggesting that *DNMT3A* mutation alone is not sufficient for leukemogenesis.[121]

Mixed Lineage Leukemia: 11q23 Translocations

A transcriptional activator that is characteristically rearranged in infant leukemia, therapy-related leukemia, and mixed phenotype acute leukemia is the mixed lineage leukemia gene (*MLL*), which maps to chromosome 11q23 (reviewed in Ref. 122). The *MLL* gene consists of 34 exons over 100 kb encoding a 3,969 aa protein.[122] *MLL* is the mammalian homolog of *trithorax,* a *Drosophila* transcriptional regulator that positively regulates homeobox genes.[123] Homeobox genes are a large family of genes which are developmental regulators essential for growth and differentiation. They were first identified in *Drosophila* during the study of genes whose mutations led to developmental abnormalities involving misassignment of body segment identity.[124] The mammalian homologs consist of 39 *HOX* genes, which are important in mammalian development and cell fate determination.[125] Analysis of chimeric mice reconstituted with *Mll*-deficient embryonic stem cells demonstrates that MLL expression is required for definitive hematopoiesis and expansion of HSCs in the AGM region.[126] Wild-type MLL appears to be responsible for the regulation of homeobox gene expression during development, including *HOXA9, HOXC8, HOXA7, HOXA10, HOXC6,* and *HOXC9.*[126,127,128,129] Wild-type MLL regulates *HOX* gene expression by methylation of histone H3 lysine (H3K4), requiring the SET domain. The SET domain is a protein domain shared by a number of transcriptional regulators that have histone methyltransferase activity.[130] H3K4 methylation is associated with transcriptional activation.

MLL rearrangements involve approximately 10% of chromosomal rearrangements overall in patients with ALL, AML, and MDS, and are associated with poor prognosis.[131] More than 60 different partner loci have been identified[132]; the 10 most common translocation partners are listed in Figure 72.6, along with a pie chart demonstrating the frequency of the translocation in pediatric vs. adult leukemia and AML vs. ALL. In pediatric and adult ALL, the most common translocation partners are the *AFF1* gene (previously known as *AF4)* at 4q21.3 in t(4;11), the *MLLT3* gene (previously known as *AF9*) at 9p22 in t(9;11), and the *MLLT1* (*ENL)* or *ELL* genes at 19p13.3 and 19p13.1, respectively, in t(11;19). Interestingly, the t(9;11) and t(11;19) are also associated with AML[133]; thus the name mixed lineage leukemia, since the gene is involved with leukemias of both myeloid and lymphoid origins.

The breakpoints of 11q23 usually occur between exons 8 and 11 of *MLL* (Fig. 72.7),[122] leaving approximately the N-terminal 1,400 amino acids of the MLL protein.[134] The retained protein contains three AT-hook sequences thought to bind DNA at the minor groove,[135] the CxxC domain that specifically binds unmethylated DNA, and a lysine-rich RD2 region. The conserved C-terminal SET domain is usually lost, though it is the domain that has the H3K4 histone methyltransferase activity that is the mechanism by which the wild-type protein activates *HOX* gene transcription (Fig. 72.7).[122]

There has been much investigation as to the role of the multiplicity of fusion partners of *MLL.* Two of the most common fusion partners, *MLLT10* (*AF10)* and *MLLT1,* associate with DOT1L, which is a histone methyltransferase with a different activity than wild-type MLL, as it methylates histone H3 lysine 79 (H3K79me).[136] This histone modification is also associated with transcriptional activation, however. DOT1L is one of many proteins in a Dot.com complex, which consists of DOT1L, AF10 (MLLT10), AF17 (MLLT6), and ENL (MLLT1) (Fig. 72.8).[122,136] Thus the plethora of *MLL* fusion partners begins to make sense, as many of them normally associate together in complexes that regulate transcription. Therefore the fusion protein associates with its usual partners, but the H3K79me marking occurs at different sites than usual, as the N-terminal MLL protein has the DNA-binding sites that bring the activating histone methyltransferase activity to *MLL* target genes. Demonstration of an abnormal increase in the H3K79 methylation pattern at target *HOXA* genes confirms this hypothesis, and this increase was shown to be dependent on DOT1L function.[137] Dependence on functional DOT1L not only for the H3K79 methylation pattern but also for the development of leukemia has been demonstrated with a conditional knockout mouse model for Dot1L expression.[137] If cells

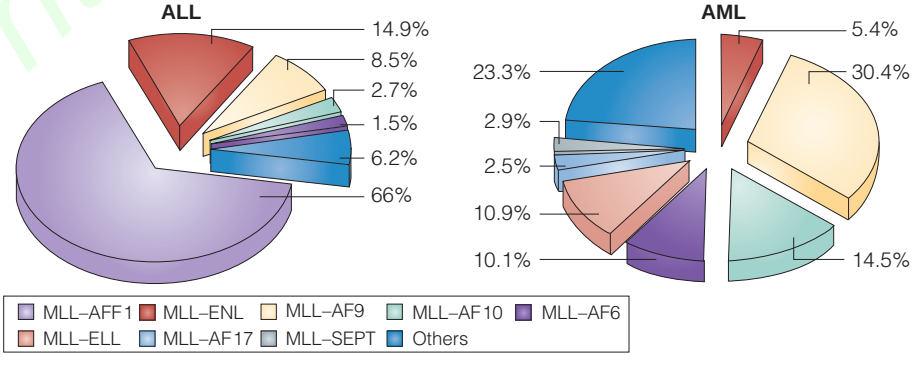

FIGURE 72.6. The distribution of the most common *MLL* chimaeras in acute lymphoid and myeloid leukemias. In *MLL*-rearranged ALL, *AFF1, AF9* (now known as *MLLT3*), *ENL* (now known as *MLLT1*), and *AF10* (now known as *MLLT10*) account for 90% of all the translocations, and in AML 70% of MLL translocations involve *AF9 (MLLT3*), *ENL (MLLT1*), *AF10 (MLLT10*), *ELL*, and *AF17* (now known as *MLLT6). AFF1* is the most frequent translocation partner of *MLL*, which is typically associated with ALL. Reprinted by permission from Macmillan Publishers Ltd: Mohan M, Lin C, Guest E, Shilatifard A. Licensed to elongate: a molecular mechanism for MLL-based leukaemogenesis. Nat Rev Cancer 10:721–728, copyright 2010.

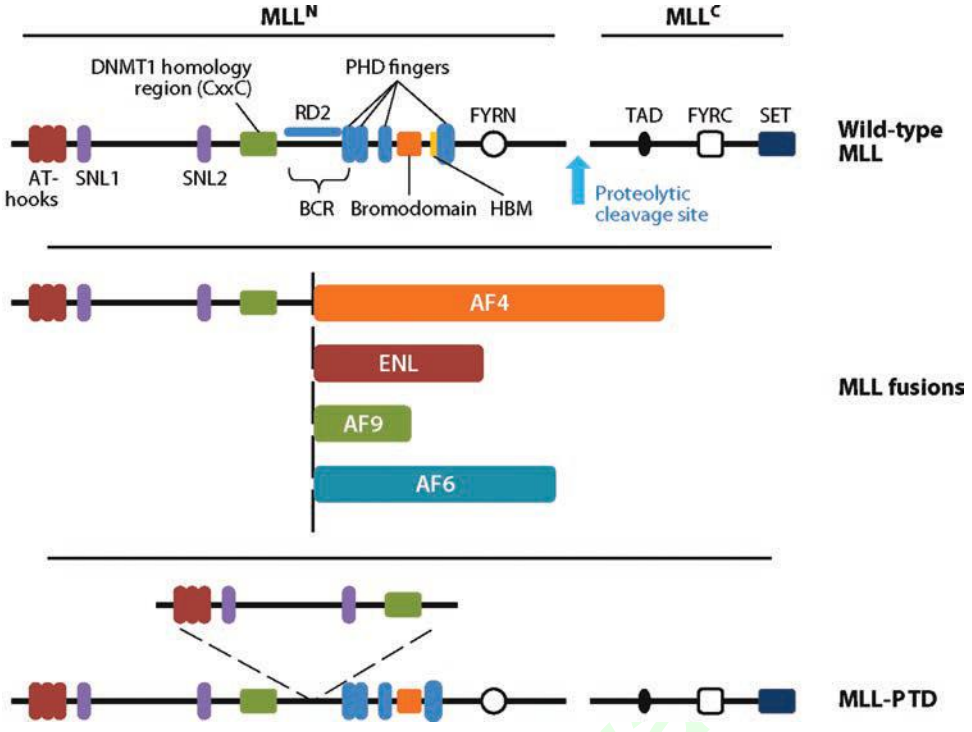

FIGURE 72.7. Structure of wild-type and leukemia-associated mixed lineage leukemia (MLL) proteins. Top: Domain architecture of wild-type MLL. Cleavage of MLL (denoted by the *blue arrow*) results in 320-kDa MLL^N and 180 kDa MLL^C fragments, which noncovalently associate. Domains within MLL^N include three AT-hooks (*red*), two subnuclear localization motifs (SNL1 and -2) (*purple*), a DNMT1 homology region (CxxC) (*green*), four plant homeodomain (PHD) fingers (*blue*), an atypical bromodomain (*orange*), and a FYRN domain (*open circle*). The breakpoint cluster region (BCR) spans an 8.3-kb region encompassing exons 7 to 13 (according to the new nomenclature) and is the site of chromosomal translocations involving *MLL*. Between the CxxC and the first PHD finger is repression domain 2 (RD2). A host cell factor-binding motif (HBM) (*yellow*) is found between the bromodomain and PHD3. MLL^C contains a transactivation domain (TAD) (*filled oval*), a FYRC domain (*open square*), and a C-terminal SET domain (*dark blue*). **Middle:** Chromosomal translocations involving *MLL* result in chimeric MLL-fusion proteins that include the N-terminal sequence of MLL up to the BCR (*dotted vertical line*), followed by one of several different fusion partners. Also shown are examples of fusion partner proteins. MLL-fusion proteins invariably retain AT-hooks, SNL and -2, and the CxxC domain of MLL^N, while losing the downstream PHD fingers and further C-terminal domains, including the SET domain. **Bottom:** *MLL* is also prone to internal partial tandem duplications (MLL-PTD), leading to duplication of MLL sequences comprising the AT-hooks, SNL1 and -2, and the CxxC domain, that are inserted at the BCR. Republished with permission of Annual Reviews, Inc. Muntean AG, Hess JL. The pathogenesis of mixed lineage leukemia. Annu Rev Pathol Mech Dis 2012;7:283–301.

are transduced by a retrovirus expressing *MLL-MLLT3,* smaller colonies of blast-like cells grow if the *Dot1L* is inactivated by the introduction of Cre. In addition, the colonies then demonstrate morphologic signs of differentiation. If the *MLL-MLLT3* cells are transplanted into irradiated mice, in vivo colonies are also reduced if *Dot1L* is inactivated, and these colonies have more differentiation and fewer proliferating cells.[137] In addition, methylation analysis of *HOXA* and *MEIS1,* target genes of MLL, demonstrate reduced H3K79me2 modification after disruption of *DOT1L.* Even more dramatic is the effect of a small molecule inhibitor of DOT1L, EPZ004777, which specifically inhibits DOT1L and prevents its H3K79 methylase activity.[138] The growth of *MLL*-rearranged cell lines such as MV4-11 and MOLM-13 is inhibited by EPZ004777 after several days of exposure in cell culture, and levels of HOXA9 and MEIS1 expression are decreased. However, the growth of a leukemia cell line in which *MLL* is not rearranged (Jurkat) was not affected by EPZ004777. In addition, treatment of a mouse xenograft model of *MLL* with EPZ004777 resulted in a statistically significant increase in median survival. Therefore, inhibition of DOT1L holds promise for targeted treatment of *MLL* leukemia.[138]

Data also exists for participation of *MLL* fusion proteins with other transcriptional regulatory complexes. Purification of the proteins involved in the super elongation complex (SEC) revealed participation of several of the *MLL* translocation partners, including *AFF1* (*AF4*), *MLLT3* (*AF9*), *MLLT1* (*ENL*), and *ELL* (Fig. 72.8).[139] The SEC complex also contains elongation factors such as ELL2, ELL3, P-TEFb, EAF1, and EAF2, and it functions to promote transcriptional elongation by RNA polymerase II. Therefore, interaction of this complex with the MLL fusion protein may provide another mechanism for increasing *HOX* target gene transcription.[122,139]

The end result of the recruitment of these transcriptional regulatory complexes by the MLL fusion protein is thought to be abnormally sustained homeobox (*HOX*) gene expression. Usually *HOX* genes are expressed highly during early development, but then are downregulated during hematopoiesis. However, the MLL fusion protein inappropriately activates the *HOX* genes.[122] Microarray analysis of *MLL* leukemia cells supports this hypothesis, as high levels of *HOXA9, HOXA5, HOXA4*, and *HOXA10*, as well as *MEIS1*, characterize the gene expression profile of leukemias with *MLL* translocations.[140,141]

MLL rearrangements are associated with several unique types of leukemia. First, in infant acute leukemia (birth to 1 year), there is a 60% to 80% incidence of 11q23 rearrangement.[142] Second, in acute leukemias related to treatment with DNA topoisomerase II inhibitors, there is a 70% to 90% incidence of *MLL* rearrangements, particularly t(4;11)(q21;q23) and t(9;11)(p21-22;q23).[143,144] Topoisomerase II is an enzyme involved in unwinding of DNA during replication and transcription. It does so by producing double-stranded in the DNA, after which (ds) breaks the ends are rejoined by a ligase activity of topoisomerase II. Topoisomerase II inhibitors such as epipodophyllotoxins inhibit this ligase function so DNA double strand breaks accumulate, triggering apoptotic events. In *MLL* there are 11 sites similar to topoisomerase II consensus binding sites in the breakpoint cluster area.[145] Therefore, if DNA ds breaks created by the topoisomerase II are incorrectly religated, translocations in *MLL* are likely to

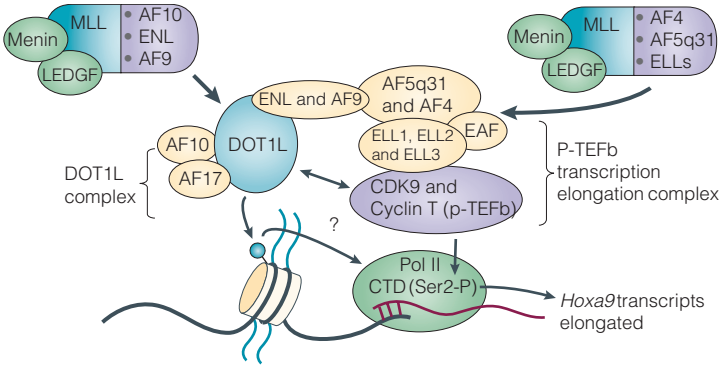

FIGURE 72.8. Proposed mechanism by which mixed lineage leukemia (MLL) fusion proteins increase transcription of HOXA9. MLL fusion proteins lose a large carboxy-terminal portion that includes the H3K4me3 writing methyltransferase SET domain, retain the chromatin-targeting property, and also acquire aberrant transactivation mechanisms through MLL fusion partners. On the left, a subset of MLL fusions MLL-AF10 (MLLT10), MLL-ENL (MLLT1), and MLL-AF9 (MLLT3), directly interact with DOT1L through the MLL fusion partner and induce the methylation of H3K79 at *HOXA9*. Some other MLL fusions, MLL-AF4 (AFF1), MLL–AF5q31 (AFF4), and MLL-ELL, interact with and recruit the P-TEFb transcription elongation complexes to *HOXA9*. On the right, DOT1L complexes (DOT1L–AF10-AF17-ENL [or AF9]) associate with P-TEFb complexes through the shared component ENL. Reprinted by permission from Macmillan Publishers Ltd: Chi P, Allis CD, Wang GG. Covalent histone modifications-miswritten, misinterpreted and mis-erased in human cancers. occur. Interestingly, infant leukemia with *MLL* translocations has a similar distribution of breakpoints, whereas sporadic cases of acute leukemia have more random breakpoints.[146] This observation has triggered speculation that in utero exposure to environmental topoisomerase II inhibitors such as flavonoids may have a role in the etiology of infant leukemia.[147]

Recently a different type of *MLL* gene alteration involving an in-frame partial tandem duplication of exons 5 to 11 has been described in approximately 4% to 7% of patients with AML[148] (Fig. 72.7). This occurs in the absence of visible chromosome abnormalities and is often associated with *FLT3* mutations.[148] This mutation retains the C-terminal SET domain, unlike all known *MLL* fusions resulting from balanced translocations. A mouse knock-in model replacing one copy of *Mll* with the *Mll-PTD* (*Mll*$^{PTD/WT}$ mice) results in overexpression of *Hoxa7*, *Hoxa9*, and *Hoxa10* in bone marrow, blood, and spleen.[149] Inspection of the promoter of *Hoxa7* and *Hoxa9* by chromatin immunoprecipitation assay demonstrates an increase in H3K4 methylation, as would be predicted due to the retention of the SET domain (Fig. 72.7).

The latency of development of leukemia appears to be shorter for *MLL* rearrangements than for other leukemogenic rearrangements. In studies of twins who develop infant leukemia, those bearing a shared *MLL* rearrangement have a concordance of nearly 100% in the first year of life, whereas in twins sharing another rearrangement, the concordance is 25% and the time to development of leukemia may be years instead of months.[150,151] Similarly, therapy-related leukemias based on *MLL* rearrangement occur sooner after therapy than those occurring after alkylating agents or radiation, usually with 7q- or 5q-cytogenetics.[144,152] This suggests that the oncogenic fusion protein produced by the *MLL* rearrangement can deregulate the cell without the accumulation of many secondary mutations. However, in genetic experiments in mice where the *Mll-Mllt3* fusion gene is knocked in, there is still a latency of 6 months before development of acute leukemia, suggesting that some secondary mutations are necessary.[153] An additional reflection of the potency of *MLL* rearrangements is that they are a poor prognostic indicator in infant leukemia, ALL, and most AML cases.[142]

This section demonstrates that mutations in genes involved in epigenetic regulation have emerged as a significant mechanism of leukemic transformation. In addition to the genes discussed above, mutations in *ASXL1* (addition of sex combs-like 1), a member of the polycomb-repressive deubiquitylase complex, and mutations in *EZH2* (enhancer of zeste homolog 2), an H3K27 methyltransferase in the PRC2, have been found in AML that is secondary to MDS or myeloproliferative diseases. This enlarging group of genes has led Shih et al. to propose two additional categories of genes involved in the pathogenesis of AML besides the Class I genes promoting proliferation and the Class II genes promoting block in differentiation. These two additional categories are: (1) Mutations in genes involved in the hydroxymethylation pathway (*IDH1/2, TET2*), and (2) Mutations in genes involved in epigenetic modification (*DNMT3A, ASXL1, MLL*).[154]

Kinases

FLT3 Mutations

FLT3 may be the single most commonly mutated gene in AML (reviewed in 155). Originally cloned from CD34$^+$ HSCs, it encodes a type III receptor tyrosine kinase. FLT3 ligand (FL) is a type I transmembrane protein that is expressed on the surface of support and hematopoietic cells in the bone marrow. It normally stimulates growth of immature myeloid cells and stem cells.[156] When FL ligand binds to the FLT3 receptor, FLT3 dimerizes and autophosphorylates intracytoplasmic tyrosine residues. The phosphorylated, activated FLT3 then activates downstream signal transduction pathways, including PI3K/AKT, MAPK/ERK, and STAT5.[157,158] Several types of mutations in *FLT3* have been cloned from leukemic cells. The most common are internal tandem repeat (ITD) mutations, in which head-to-tail duplications of various lengths and positions occur in the juxtamembrane (JM) portion of the molecule (Fig. 72.9).[159] These elongation mutations may occur due to DNA replication errors as a result of a potential palindromic intermediate that may form at that site.[160] The JM domain is an autoinhibitory domain whose inhibitory function is usually relieved by autophosphorylation after ligand binding.[155] The in-frame insertions in the JM domain produce mutant proteins that are constitutively activated; they are able to dimerize

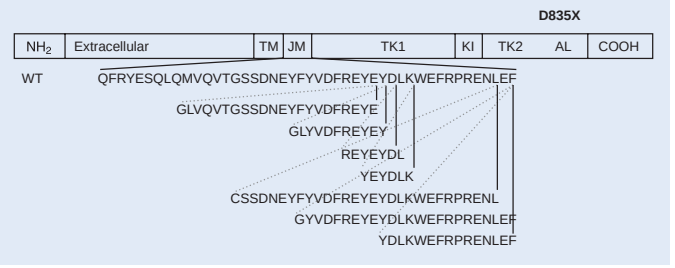

FIGURE 72.9. Schematic of the internal tandem repeat (ITD) and activation loop *FLT3* mutations in acute myelogenous leukemia (AML). The structure of the FLT3 receptor tyrosine kinase is shown, with the position of the transmembrane domain (TM), the juxtamembrane (JM) domain, the kinase domains (TK1 and TK2), kinase insert (KI), and activation loop (AL). The amino acid sequence of the wild-type JM domain is listed, and underneath are the tandem duplication sequences found in individual patients with AML. These are always in-frame insertions. The position of the amino acid that is commonly substituted in activation loop mutations is indicated above the schematic of the protein domains. From Mizuki M, Fenski R, Halfter H, et al. FLT3 mutations from patients with acute myeloid leukemia induce transformation of 32D cells mediated by the RAS and STAT5 pathways. Blood 2000;96:3907–3914 and Kelly LM, Liu Q, Kutok JL, et al. FLT3 internal tandem duplication mutations associated with human acute myeloid leukemias induce myeloproliferative disease in a murine bone marrow transplant model. Blood 2002;99:310–318.

and autophosphorylate in the absence of ligand.[160] Other types of mutations include activation loop mutations, usually an Asp825Tyr substitution resulting from a point mutation in the second tyrosine kinase domain (TKD), producing constitutive activation of FLT3.[155]

The overall frequency of *FLT3*-ITD in adult AML is 24% of patients, while in pediatric AML the frequency is somewhat lower at 10% to 15% (reviewed in Ref. 155). The frequency is very low in MDS and ALL. In contrast, the *FLT3* activation loop mutation is reported in 7% of AML, 3% of MDS, and 3% of ALL patients.[161] *FLT3*-ITD is detected most frequently in APL, but has been detected in all AML subtypes.[155] In addition, FLT3 is overexpressed at the mRNA and protein levels in many cases of AML and ALL.[162]

The role of the *FLT3*-ITD in leukemogenesis has been investigated by retroviral transduction of murine bone marrow stem cells followed by transplantation into mice. These mice develop a myeloproliferative disease with predominantly maturing myeloid elements, but they do not develop acute leukemia.[163] Therefore, the *FLT3* mutations may confer the proliferative signal in patients with acute leukemia, whereas a concomitant balanced translocation or other genetic defect confers the block in differentiation necessary for development of acute leukemia.[155]

Mutation of *FLT3* is a significant independent prognostic factor for poor outcome in patients younger than 60 years. In a study of 91 pediatric AML patients on the Children's Cancer Group (CCG) protocol, the remission induction rate was 40% in patients with *FLT3*-ITD compared to 74% with wild-type *FLT3*. The difference in event-free survival at 8 years was even more striking, at 7% for patients with *FLT3*-ITD compared to 44% for patients with wild-type *FLT3*.[164] In a study of 398 patients younger than 60 with AML, *FLT3*-ITD mutations were the primary predictor of outcome in patients with intermediate-risk cytogenetics and were associated with reduced overall survival.[34] As with *BCR-ABL1* for CML, the implication of a mutant constitutively active tyrosine kinase receptor in the pathogenesis of AML opens up the possibility of identifying a selective kinase inhibitor as a specific treatment for AML patients with a mutant *FLT3*. Several kinase inhibitors have been identified by inhibition of IL3-independent growth of cell lines expressing *FLT3*-ITD in culture.[165,166] Eight of these FLT3 inhibitors (FLT3-TKI) have been tested in phase I/II trials as single agents (reviewed in Ref. 167). In each study a majority of patients achieved >50% reduction in peripheral blast count, but these reductions were transient, lasting several weeks to months. The partial efficacy may be in part due to the refractory nature of the phase I/II patient population. However, a study performed by Piloto et al.[168] on resistant human cell lines developed through prolonged coculture with FLT3 tyrosine kinase inhibitors demonstrated that although FLT3 phosphorylation was still inhibited, downstream signaling pathways were activated. In two cell lines, activating *NRAS* mutations were detected. No mutations in *FLT3* were detected. However, in other studies, SMRT sequencing was used to demonstrate secondary *FLT3* kinase domain mutations in 4 of 8 patients who relapsed after treatment with FLT3-TKI. The mutation frequency in the patients' blasts was 20% to 50%, consistent with most of the leukemic blasts having a mutation on one allele. This degree of mutation in relapsed patients supports the idea that *FLT3* mutations are "driver" mutations necessary for growth of the leukemic clone. From the crystal structure of FLT3 several of the mutations would force the molecule into an active kinase confirmation which is not recognized by the AC220 type II kinase inhibitor used in the study.[169]

Nuclear Pore Proteins

Nucleophosmin

Nucleophosmin (NPM) is a molecular chaperone that shuttles between cytoplasm and nucleus, with particular nucleolar concentration of protein.[170] While NPM appears to function to transport preribosomal particles from the nucleolus to cytoplasm, other functions have also been described, including regulation of centrosome duplication, regulation of p53, and functional regulation and stabilization of P19ARF (reviewed in Ref. 171). Cytogenetically silent mutations of *NPM1* have now been identified in 35% of adult AML with normal karyotype. The frequency is less (9% to 27%) in pediatric AML with normal karyotype.[171,172,173] The *NPM1* mutation is stably expressed, being consistently present in leukemic blasts at relapse.[174] The wild-type NPM has two NLSs and two nuclear export signals (NES) that mediate the nuclear–cytoplasmic shuttling of wild-type NPM. Over 50 different mutations in *NPM1* have been found in patients with AML; all of these mutations cause changes in the C-terminus of the NPM protein, including generation of a new NES motif, and loss of tryptophan residues 288 and 290, or 290 alone, causing unfolding of the C-terminal domain and disruption of binding to the nucleolus.[174,175] The presence of a mutation correlates absolutely with abnormal subcellular localization of NPM, with relocation from its normal predominantly nucleolar location to the cytoplasm; this can be detected in tissue sections by immunohistochemistry. The mutation is always heterozygous, which may be related to the fact that the homozygous mutant is embryonic lethal.[176] The mutant NPM appears to function in a dominant negative manner through heterodimerization with normal NPM, to cause relocation of some of the normal NPM, as well as the mutant NPM, to the cytoplasm.[177] The mechanism by which the cytoplasmically located NPM promotes leukemia is under investigation. Conditional expression of mutated NPM in transgenic mice results in overexpression of HOX genes in Lin^- marrow progenitor cells.[178] Another mechanism by which mutant *NPM1* may promote leukemogenesis is by destabilizing the tumor suppressor protein P14ARF, which regulates the TP53 response. P14ARF colocalizes with NPM to the nucleolus, and their interaction stabilizes P14ARF. Without this interaction and nuclear location, p19Arf (the mouse homolog) is more rapidly degraded by proteasomes. By this mechanism, mutant NPM may indirectly cause decreased amounts of the tumor suppressor protein P14ARF.[174] *NPM1* mutations frequently occur in conjunction with *IDH1* and *IDH2* mutations and with *DNMT3A* mutations (see Fig. 72.1).[34,173] Several studies have shown that patients with *NPM* mutations in the absence of *FLT3* mutations have a favorable response to chemotherapy.[173,175] Patients with intermediate-risk cytogenetics and mutations in *NPM1* and either *IDH1* or *IDH2* mutations have an improved rate of overall survival and are considered to have an overall favorable risk.[34]

Risk Stratification of Acute Myeloid Leukemia

A major purpose of molecular genetic testing performed on clinical AML samples in the molecular diagnostics laboratory is to have enough information to choose the optimal therapy and to assess the prognosis of the patient. Besides determining information about *BCR-ABL1* or *PML-RARA* rearrangements that have an obvious impact on treatment decisions, the risk stratification of the patient helps the doctor determine whether it is best to treat with aggressive therapy, to adopt a gentler chemotherapy regimen, or to rush the patient to transplant. A recently published attempt to integrate the newly expanded knowledge of molecular defects, both mutations and translocations, that occur in AML reported the results of testing for mutations in a panel of 18 genes in 398 patients with AML at diagnosis. 97.3% of the patients had at least one somatic mutation. The frequency of each of the 18 mutations tested is demonstrated in Figure 72.1, as well as the Circos diagram depicting the interrelationships between the mutations.[34] The Circos diagram visually conveys the multiplicity of mutations that occur in most patients. This integrated mutational analysis demonstrated patterns of co-occurring mutations and

also mutually exclusive mutations. Some of the more important co-occurrences are *KIT* mutations and CBF alterations, co-occurrence of *IDH1/2* mutations and *NPM1* mutations, and *DNMT3A* mutations with *NPM1, FLT3,* and *IDH1* mutations. As mentioned previously, *IDH1/2* mutations do not occur in patients with *TET2* mutations (Fig. 72.5). In addition, *IDH1/2* and *WT1* mutations are mutually exclusive, as well as *DNMT3A* mutations and *MLL* translocations.[34] The effect of multiple mutations and the interplay with underlying cytogenetic changes on risk stratification are shown in Table 72.1.[34,179] The most statistically significant predictors of overall survival are as follows: *FLT3*-ITD and *MLL*-PTD mutations are associated with reduced overall survival. *CEBPA* mutations and CBF translocations are associated with improved overall survival. *PHF6* and *ASXL1* mutations are associated with reduced survival. *IDH2* mutations (R140Q) confer a favorable outcome. In intermediate-risk AML, *FLT3*-ITD mutations are the primary factor influencing outcome. In this cohort of patients the group with favorable risk had a 3-year overall survival of 64%, whereas the group with intermediate risk had a 3-year overall survival of 42% and the group with adverse risk had a 12% overall survival. Multivariate analysis demonstrated that outcomes predicted from the risk stratification are independent of age, WBC, induction dose, transplantation status, and post-remission therapy.[34]

Grossman et al.[105] developed a similar prognostic model based entirely on molecular mutational analysis rather than karyotype, in which they constructed an algorithm with 5 prognostic subgroups based upon analysis of 1,000 patients for mutations in: *PML-RARA, RUNX1-RUNX1T1, CBFB, MYH11, FLT3*-ITD, *MLL*-PTD, *NPM1, CEBPA, RUNX1, ASXL1,* and *TP53*. The very favorable prognostic group (overall survival at 3 years of 82.9%) consisted of patients with *PML-RARA* rearrangement or *CEPBA* double mutations, and the very unfavorable group with an overall survival of 0% at 3 years consisted of patients with *TP53* mutations. *TP53,* a well-characterized tumor suppressor gene, is mutated in many cancers, and mutations in *TP53* are the basis of the cancer-prone Li-Fraumeni syndrome.[180] However, this study is the first to characterize the frequency of *TP53* mutations in AML (11.5%) and its prognostic significance.[105]

The particular combination of mutations and percentage survival will change with the discovery of additional mutations, new treatment trials, and additional patient cohorts, but the principle is important that risk stratification must take into account a multiplicity of genetic events, both translocations and mutations. The role of the molecular diagnostics lab will certainly increase; the difficult question will be what is the most prognostically significant and cost effective panel of molecular tests to perform on an AML patient at diagnosis.

B-ACUTE LYMPHOBLASTIC LEUKEMIA

Introduction

Table 72.5 outlines the WHO classification for B-ALL, which lists several of the major translocations that have been repeatedly seen in B-ALL. Recent genome-wide analysis of DNA from multiple B-ALL cases has demonstrated, as in AML, that there are multiple deletions and mutations in many other genes besides the well-characterized translocations. A recent survey of 242 cases of pediatric ALL using Affymetrix SNP arrays identified an average of 6.46 somatic copy number alterations per case, predominantly deletions.[181] Interestingly, alterations in genes regulating B-lymphocyte differentiation were noted in 40% of B-ALL cases. The B-cell differentiation genes most commonly translocated or mutated include *EBF1, PAX5,* and *IKZF1*. Copy number changes in *PAX5* occurred in 29.7% of this series, with the most common alteration being mono-allelic deletion of *PAX5*. *PAX5* is essential for B-cell development, and it controls B-cell–specific transcription of B-lineage–specific genes such as CD19, CD79a, BLNK, and

B-ALL, B-cell acute lymphoblastic leukemia; NOS, not otherwise specified.
From Swerdlow SH, Campo E, Harris NL, et al., Eds. WHO classification of tumours of haematopoietic and lymphoid tissues. Lyon, France: IARC Press, 2008.

CD72.[181] In Pax5$^{-/-}$ mice, B-cell development is arrested prior to the B220^{+} pro–B-cell stage, and these pro-B cells are uncommitted lymphoid progenitors.[182] Mutations in genes necessary for B-cell differentiation are a perfect example of Class II mutations that cause a block in cell differentiation in the classic model of acute leukemia pathogenesis.

Transcription Factors

PAX5

In the above-mentioned study, the *PAX5* gene was altered by deletion or mutation in 31.7% of cases in a series of 242 B-ALLs.[181] It is rearranged in 2.6% of pediatric B-ALL cases, with 17 different fusion partners documented. PAX5 is a paired box domain (PRD) transcription factor, encoded by the *PAX5* gene at chromosome 9p13, and consists of 10 exons that encode a 391 amino acid protein. In all the fusion proteins, the paired box domain DNA-binding region and nuclear localization region are retained, but the C-terminal transactivation domain is deleted.[183] The C-terminal fusion proteins may act in contrast as transcriptional repressors, which would be brought to PAX5 target gene promoters by the retained PAX5 DNA-binding region. The PAX5 fusion proteins may act as dominant negative molecules in conjunction with the product of the wild-type *PAX5* allele, and in this way may repress genes whose products are necessary for B-cell differentiation. The *PAX5* translocations are correlated with a relatively normal karyotype, suggesting that they have a major role as a driver mutation; *PAX5* deletions, however, are usually associated with a complex karyotype.[184]

Core Binding Factors

RUNX1 is also involved in a translocation that is present in 25% of pediatric B-ALL, t(12;21)(p13;q22.3).[185] This translocation is associated with a good prognosis, although it is often missed by standard karyotype analysis. In this translocation, the N-terminus of *ETV6,* formerly called *TEL* (translocation-ETS-leukemia), is fused to most of the coding region of *RUNX1*.[186] ETV6 contains a DNA-binding ETS domain and a "pointed" domain homologous to the Drosophila development protein, *pointed*.[187] ETV6 is a transcriptional repressor and as such it contains a DNA-binding ETS domain and domains that interact with mSin3A (pointed domain), N-CoR, and HDAC-3 (Fig. 72.4C).[188] The functional significance of these interactions with HDACs was demonstrated by the ability of TSA to inhibit two properties of 3T3 fibroblast cells transformed with ETV6 and Ras: expression of the stromelysin-1 gene and aggregation.[188]

Another chromosomal alteration involving the *RUNX1* locus that occurs in approximately 2% of pediatric patients with B-ALL is the intrachromosomal amplification of chromosome 21 (iAMP21). The significance of recognizing this cytogenetic abnormality is that it is associated with a dismal prognosis if treated with standard chemotherapy. There is a 6.6 Mbp common region of amplification (CRA) on chromosome 21, and in the majority of cases an associated 3.3 Mbp common region of deletion at the telomere. The average copy number of this CRA is 4.8, and the amplification is usually detected by FISH using the *RUNX1* probe. Although *RUNX1* is in the CRA, gene expression studies do not reveal increased transcription of *RUNX1*. This cytogenetic abnormality is associated with a complex karyotype and multiple mutations; however, clonal analysis indicates that the precipitating genetic event is the iAMP21 amplification.[189]

TCF3 (E2A) Translocations

A common translocation in childhood B-ALL, present in 5% of pre–B-ALL cases,[190] is the t(1;19)(q23.3;p13.3) translocation, which fuses the *TCF3* (*E2A*) gene on chromosome 19p13.3 with the *PBX1* gene on chromosome 1q23.3 (Fig. 72.10).[191,192] The *TCF3* locus encodes three transcripts, E12, E47, and E2-5, which are generated by alternative splicing.[193] They belong to class I of the basic helix-loop-helix (bHLH) family of transcription factors which bind to specific E-box (CANNTG) sequences in promoters and enhancers, the first of which were identified in the enhancer regions of the immunoglobulin heavy-chain and κ-chain genes.[193] Usually the ubiquitous E2A proteins heterodimerize through the HLH domain with members of the class II bHLH proteins, most of which are tissue specific in expression. These heterodimers are crucial in transcriptional regulation of tissue-specific genes during development. Although E2A proteins are ubiquitous, they are preferentially expressed in B lymphocytes,[194] and E47 forms homodimers exclusively in B cells.[195] The requirement for E2A proteins in B-cell development is demonstrated by $Tcf3^{-/-}$ null mice, which exhibit a complete block in B-cell differentiation at the pro–B-cell stage prior to immunoglobulin gene rearrangement, as well as defective thymocyte differentiation.[196,197] These mice have an increased frequency of T-lymphoblastic lymphoma.[196]

PBX1 (pre–B-cell leukemic homeobox 1), identified as the fusion partner of *TCF3* in t(1;19),[198] encodes a member of the homeodomain family of transcription factors, encoded by homeobox (*HOX*) genes. The *PBX1* gene is the mammalian homolog of the *Drosophila* gene *Extradenticle,* whose protein product cooperates with other homeodomain proteins during development.[199] Likewise, PBX1 forms heterodimers with other homeodomain proteins via the homeodomain and the C-terminal HOX cooperativity motif (HCM).[200] Cotransfection experiments with reporter genes containing DNA-binding sites for PBX1 have demonstrated that PBX1 is not a strong transcriptional activator.[201] The $Pbx1^{-/-}$ mice have late embryonic lethality associated with multiple organ abnormalities,[202] supporting the hypothesis that PBX1 interactions regulate homeodomain protein function. PBX1 is not normally expressed in lymphocytes.

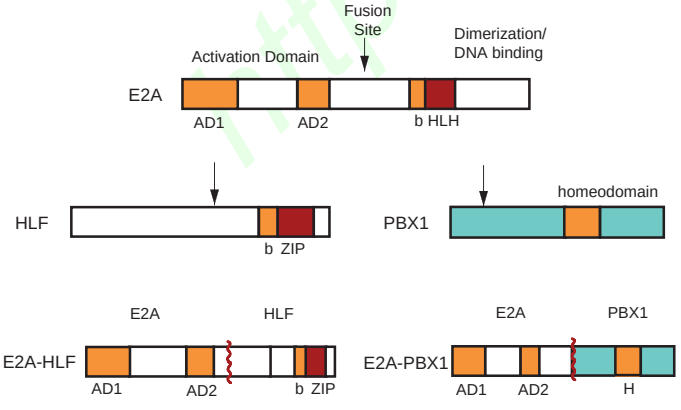

FIGURE 72.10. Structural features of E2A (TCF3) fusion proteins. The N-terminus of the *E2A (TCF3)* gene encodes a transcriptional activation domain that is translocated to hepatic leukemia factor *(HLF)* or pre–B-cell leukemic homeobox1 *(PBX1)* by chromosome translocations in acute lymphoblastic leukemia. In the case of E2A (TCF3)-HLF, the DNA-binding and dimerization domains of E2A (TCF3) are replaced by similar domains in HLF. For E2A(TCF3)-PBX1, the same DNA-binding and dimerization domains of E2A (TCF3) are replaced with the DNA-binding homeodomain of PBX1. AD, activation domain; b HLH, basic helix-loop-helix; bZIP, basic leucine zipper domain; H, homeodomain.

In the t(1;19) translocation, the breakpoint on chromosome 19 occurs within the intron between exons 13 and 14 of *TCF3,* so that the N-terminal two-thirds of TCF3 (E2A), aa1-483, are included in the fusion protein.[192] This includes both of the transcriptional activation domains (AD1 and AD2), but excludes the bHLH DNA-binding and dimerization domains (Fig. 72.10). Therefore, the TCF3-PBX1 fusion protein depends on the homeodomain of PBX1 for DNA-binding specificity. The most straightforward model for how expression of the TCF3-PBX1 fusion protein results in the development of leukemia is that fusion of the *TCF3* activation domains onto the *PBX1* sequence results in abnormally strong transactivation of target genes recognized by the PBX1 homeodomain.[203] These target genes would be activated in lymphocytes, where PBX1 is usually not expressed. Mapping experiments demonstrate that the activation domains AD1 and AD2 of TCF3 are necessary for transactivation of reporter genes containing PBX1 binding sites, and they are also necessary for transformation of NIH 3T3 cells.[204] Gene expression profiling of a pre–B-cell line inducibly expressing TCF3-PBX1 demonstrated upregulation of *BMI1,*[205] a gene which is expressed in normal HSCs, but whose expression normally decreases during hematopoietic development.[206] $Bmi1^{-/-}$ mice have a reduced number of HSCs, with defective adult self-renewal of HSCs.[206] Cells from $Bmi1^{-/-}$ mice are resistant to transformation by *Tcf3-Pbx1,*[205] suggesting that the mechanism by which *TCF3-PBX1* transforms cells is through overexpression of BMI1. Interestingly, BMI1 is a transcriptional repressor of the *CDKN2A* locus,[205] which encodes the two tumor suppressor genes *P16INK4A* and *P14ARF.*[207] *P16INK4A* binds to CDK4 and 6, preventing association with cyclins and phosphorylation of Rb. Therefore, repression of *P16INK4A* results in increased phosphorylation of Rb, which loses its affinity for the transcription factor E2F, increasing expression of E2F target genes necessary for progression to the S phase and proliferation.[208,209] The tumor suppressor P14ARF inhibits MDM2, a repressor of TP53[87]; therefore, inhibition of *P14ARF* results in increased MDM2, repression of TP53, and loss of the checkpoint functions of TP53 in preventing propagation of cells with DNA damage.[87] Therefore, activation of *BMI1* by TCF3-PBX1 results in downregulation of two powerful tumor suppressor pathways.

Another translocation involving *TCF3* occurs in approximately 1% of pediatric ALL, t(17;19)(q22;p13.3), which fuses *TCF3* to *HLF* (hepatic leukemia factor).[210,211] Clinically, these patients are adolescents; they may present with disseminated intravascular coagulation and hypercalcemia and usually have a poor prognosis. *HLF* encodes a transcription factor of the basic leucine zipper (bZIP) family, in which the basic region is the DNA-binding region and the leucine zipper refers to an amphipathic α-helical domain through which HLF can homodimerize or heterodimerize with other bZIP proteins. HLF is usually expressed in liver, kidneys, and central nervous system neurons, but not in hematopoietic cells.[212]

The TCF3-HLF fusion protein is homologous to the TCF3-PBX1 fusion protein, in that the N-terminal 483 amino acids of TCF3, contributing the activation domains AD1 and AD2, are fused to the C-terminal portion of HLF, which contains the bZIP DNA-binding and dimerization domains (Fig. 72.10).[213] Unlike PBX1, wild-type HLF is a strong transactivator, but the alteration in cell type expression and alterations in DNA-binding affinity and protein interactions by virtue of fusion to TCF3 may contribute to the transforming properties of TCF3-HLF.[214]

Recent experiments using BaF3 cells inducibly expressing TCF3-HLF have implicated *LMO2* and *BCL2* as transcriptional targets of the abnormal TCF3-HLF transcription factor.[215] Microarray analysis was performed on RNA from the cell lines before and after induction of TCF3-HLF expression; subsequent ChIP experiments demonstrated that TCF3-HLF directly binds to the promoters of these two genes to transcriptionally activate them. Relevant to potential new therapies of this poor prognosis leukemia is the finding that knock-down of *LMO2* expression or inhibition of BCL2 activity in the cells expressing TCF3-HLF reduces the proliferation of these immortalized cells.[215] LMO2 is a transcription factor expressed in hematopoietic progenitors and is known to play a role in development of T-ALL[216] BCL2 is an antiapoptotic protein with a well-known role in the pathogenesis of B-cell lymphoma (reviewed in Ref. 217).

IKAROS

SNP array studies first demonstrated that *IKZF1,* encoding the transcription factor IKAROS, is deleted in 76.2% of pediatric Ph^+ B-ALL and 90.9% of adult Ph^+ B-ALL.[218] A subsequent study of adult B-ALL cases demonstrated that 75% of adult Ph^+ B-ALL cases had alterations of the *IKZF1* gene, compared to 58% of adult Ph^- B-ALL cases.[219] IKAROS is a zinc finger–containing transcription factor that is required for lymphoid lineage commitment. It is expressed in multipotent, self-renewing HSCs and is necessary for induction of genes important for the lymphoid lineage, as well as repression of genes responsible for self-renewal and multipotency in the differentiating progeny of HSCs.[220] Deletions are usually of one allele, and in most cases the deletion involves a subset of exons, most commonly exons 4 to 7.[219] Sequencing of the deletion sites demonstrates the presence of heptamer recombination signal sequences that are recognized by RAG enzymes during immunoglobulin gene recombination.[218] These deletions result in loss of the DNA-binding domain but preservation of the dimerization domain of the protein, creating a dominant negative molecule.[219] Use of gene expression arrays to compare RNA from B-ALL cases with intact or mutated *IKZF1* loci demonstrates that *IKZF1* mutations are associated with downregulation of several genes in the B-cell differentiation pathway and upregulation of genes involved in cell cycle regulation, apoptosis regulation, DNA damage, and the JAK-STAT signaling pathway. In addition, in B-ALL with *IKZF1* mutations, there is downregulation of *RAG* and *EBF1,* two genes whose products are involved in IgH VDJ recombination.[219] Downregulation of genes involved in normal B-cell differentiation may cause the arrest of B-cell maturation that occurs in B-ALL. As the gene expression patterns in B-ALL with mutations in *IKZF1* are similar to gene expression patterns in *BCR-ABL1* positive ALL, these cases are referred to as Ph-like ALL.[221] Though the prognosis of these cases is poor, discovery of frequent concomitant mutations in cytokine receptors such as *CRLF2* and other signaling molecules such as *JAK2* suggests that use of kinase inhibitors may play a role in treating this subset of B-ALL.[222]

Kinases

BCR-ABL1

The Philadelphia chromosome is the result of the t(9;22)(q34;q11.2) translocation in which the 5′ domain of the *BCR* gene from chromosome 22 is fused with the 3' TKD of the *ABL1* gene from chromosome 9.[223,224] The Philadelphia chromosome is the resultant shortened chromosome 22. It is the most frequent recurring translocation in adult ALL, occurring in 15% to 30% of patients,[225] and also is present in 5% of pediatric B-ALL.[226] Unfortunately, it is an adverse prognostic factor in children and adults.

The *BCR-ABL1* fusion gene is associated most commonly with CML. The pathogenesis of CML will be discussed in Chapter 81. A lymphoid blast crisis arising from CML may be difficult to distinguish from a Philadelphia chromosome–positive (Ph^+) ALL. The size of the BCR-ABL1 fusion protein and whether it is restricted in expression to lymphoid cells may be helpful in making this distinction. The most common breakpoint region, the major breakpoint cluster region (M-bcr), spans almost 6 kb between exons 12 and 16 of *BCR* and results in a fusion protein of 210 kD, referred to as $p210^{bcr\text{-}abl}$.[227] A minor breakpoint, the m-bcr, is farther 5′, after exon 2 of *BCR,* resulting in a truncated fusion protein of 190 kD that contains only the first two exons of *BCR* ($p190^{bcr\text{-}abl}$).[2] Interestingly, $p210^{bcr\text{-}abl}$ is much more common in CML and CML with lymphoid blast crisis, whereas $p190^{bcr\text{-}abl}$ is much more commonly expressed in Ph^+ ALL. $p190^{bcr\text{-}abl}$ is present in 80% to 90% of pediatric Ph^+ ALL and 50% of adult Ph^+ ALL.[225] However, some cases of Ph^+ ALL contain both $p190^{bcr\text{-}abl}$ and $p210^{bcr\text{-}abl}$. Transgenic mice expressing $p190^{bcr\text{-}abl}$ develop an aggressive leukemia restricted to pre–B cells, whereas transgenic mice expressing $p210^{bcr\text{-}abl}$ develop a more chronic disease involving B and T cells and myeloid lineages.[228] In some cases of Ph^+ ALL the aberrant fusion protein is present in lymphoid and myeloid marrow cells, whereas in other cases the aberrant fusion protein, usually $p190^{bcr\text{-}abl}$, is restricted to lymphoid cells. Those cases in which $p210^{bcr\text{-}abl}$ is present in both lymphoid and myeloid cells are most likely to represent a CML lymphoid blast crisis.[229]

Studies of BCR-ABL1 expression in CML have demonstrated the leukemogenic properties of BCR-ABL1 as a constitutive tyrosine kinase.[230] This constitutive kinase activates by phosphorylation multiple downstream signal transduction intermediates, including RAS, PLCγ, and PI3 kinase.[231] Activation of these pathways results in proliferation and resistance to apoptosis.[232] Presumably similar mechanisms are at work in Ph^+ ALL. Restriction of expression of BCR-ABL1 to the lymphoid lineage would explain the development of ALL. However, in those cases of Ph^+ ALL in which BCR-ABL1 is expressed in the stem cell compartment, it is unclear why ALL has resulted instead of CML. A high percentage of Ph+ ALL, as well as B lymphoid blast crisis of CML, have concomitant mutations in *IKAROS,* as described above.[218,219,233]

Treatment of Ph^+ ALL remains problematic. Initial response to chemotherapy is similar in Ph^+ ALL and Ph^- ALL, but remissions tend to be short lived. Transplantation appears to be the best means of attaining a lasting remission. In a phase II trial of imatinib in relapsed or refractory Ph^+ ALL, 60% of patients achieved a hematologic response, but it was usually short lived.[234] However, trials using imatinib in conjunction with standard chemotherapy followed by bone marrow transplant in CR have proven more successful. The combination approach induces CR in 96% of patients with a 30% incidence of relapse and 65% overall survival rate at 18 months.[235,236] Posttransplant *BCR-ABL1* positivity has a poor prognosis; therefore in current protocols imatinib therapy is usually reinitiated 6 to 8 weeks after transplant.[233]

Secondary resistance to imatinib is common, however, and occurs in approximately 70% of relapse patients with CML blast crisis or Ph^+ ALL. In 50% to 90% of relapse patients, point mutations have been identified in the adenosine triphosphate–binding pocket of BCR-ABL1 that is targeted by imatinib.[237] New kinase inhibitors that can bind to the mutated as well as wild-type BCR-ABL1, such as dasatinib and nilotinib, are being utilized in patients who develop resistance to imatinib.[233]

T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA/LYMPHOMA

T-ALL is an uncommon acute leukemia but its genetics have been studied in considerable depth. The driver mutations in T-ALL were first identified by cloning the breakpoints at chromosomal

translocations.[238,239,240,241] These experiments revealed oncogenes whose expression was deregulated by rearrangement with the promoters and enhancers of T-cell receptor genes. Subsequently, it was shown that these same oncogenes are overexpressed by mechanisms other than translocation.[242,243,244,245] Indeed, gene expression clustering based on these oncogene signatures has been highly informative in classifying T-ALL into distinct subtypes that relate to cell of origin.[244,246,247] Whole exome sequencing and targeted sequencing have revealed numerous important mutations in T-ALL. As shown in Table 72.6, these oncogenes and tumor suppressor genes are divided into major gene classes. The *CDKN2A* locus encodes cell cycle regulatory genes *P14ARF* and *P16INK4A,* and is the most commonly inactivated gene in human T-ALL.[238] *CDKN2A* is located on 9p21 which shows homozygous deletion in more 72% of patients.[182,241] *CDKN2A* is also inactivated by other mechanisms.[248,249] Deletions of 13q14.2 including the *RB1* gene occur in up to 12% of T-ALL patients[182]; these deletions are found in patients with intact *CDKN2A,* an expected finding since both of these tumor suppressors act in the same pathway.[244,250] Mutations in *TP53* and *CDKN1B* (p27) are uncommon, each occurring in less than 1% of T-ALL patients.

Notch
