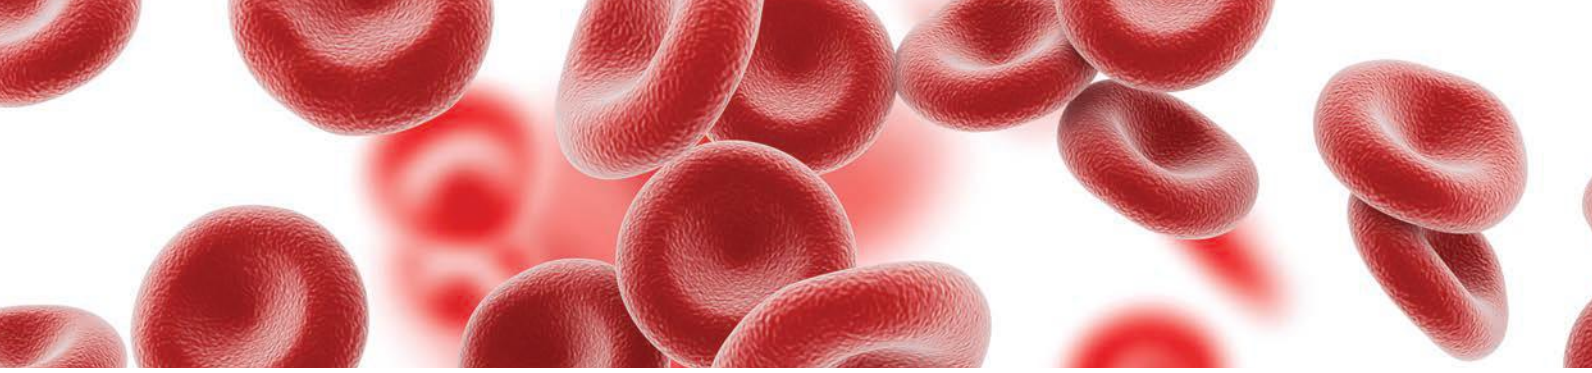
Wintrobe's Clinical Hematology

THIRTEENTH EDITION



Wintrobe's Clinical Hematology

THIRTEENTH EDITION

Editors:

John P. Greer, MD
Professor
Departments of Medicine and Pediatrics
Divisions of Hematology/Oncology
Vanderbilt University Medical Center
Nashville, Tennessee

Daniel A. Arber, MD
Professor and Vice Chair
Department of Pathology
Stanford University
Director of Anatomic and Clinical Pathology Services
Stanford University Medical Center
Stanford, California

Bertil Glader, MD, PhD
Professor
Departments of Pediatrics and Pathology
Stanford University Medical Center
Stanford, California
Lucile Packard Children's Hospital
Palo Alto, California

Alan F. List, MD
Senior Member
Department of Malignant Hematology
President and CEO
Moffitt Cancer Center
Tampa, Florida

Robert T. Means, Jr., MD
Professor of Internal Medicine
Executive Dean
University of Kentucky College of Medicine
Lexington, Kentucky

Frixos Paraskevas, MD
Professor of Internal Medicine and Immunology (Retired)
University of Manitoba Medical School
Associate Member
Institute of Cell Biology—Cancer Care Manitoba
Winnipeg, Manitoba, Canada

George M. Rodgers, MD, PhD
Professor of Medicine and Pathology
University of Utah School of Medicine
Health Sciences Center
Medical Director, Coagulation Laboratory
ARUP Laboratories
Salt Lake City, Utah

Editor Emeritus:

John Foerster, MD, FRCPC
Professor and Physician Emeritus
Winnipeg, Manitoba, Canada

Professor of Medicine
Department of Medicine
University of Utah School of Medicine
Director of Graduate Medical Education
Intermountain Medical Center and LDS Hospital
Salt Lake City, Utah

Ashkan Emadi, MD, PhD
Associate Professor
Department of Medicine
Division of Hematology/Oncology
Leukemia and Hematologic Malignancies
University of Maryland School of Medicine
Marlene and Stewart Greenebaum Cancer Center
Baltimore, Maryland

Stephen J. Everse, PhD
Associate Professor
Department of Biochemistry
University of Vermont
Burlington, Vermont

Rafael Fonseca, MD
Professor of Medicine
Hematology/Oncology
Mayo Clinic
Scottsdale, Arizona

Magali J. Fontaine, MD, PhD
Assistant Professor
Department of Pathology
Stanford University
Associate Medical Director
Department of Pathology, Transfusion Service
Stanford, California

Haydar Frangoul, MD
Professor
Director
Pediatric Blood and Marrow Transplant Program
Division of Pediatric Hematology/Oncology
Vanderbilt University School of Medicine
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

Paul S. Frenette, MD
Chair and Director
Ruth L. and David S. Gottesman Institute for Stem Cell and Regenerative Medicine
Albert Einstein College of Medicine
New York, New York

Richard C. Friedberg, MD, PhD
Professor and Deputy Chairman
Department of Pathology
Tufts University School of Medicine
Western Campus
Chair
Department of Pathology
Baystate Medical Center
Springfield, Massachusetts

Debra L. Friedman, MD, MS
Associate Professor
Department of Pediatrics
Vanderbilt University School of Medicine
Director, Division of Pediatric Hematology/Oncology
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

Michael M. Fry, DVM, MS, DACVP
Associate Professor
Department of Biomedical and Diagnostic Sciences
College of Veterinary Medicine, University of Tennessee
Knoxville, Tennessee

Vijayakrishna K. Gadi, MD, PhD
Assistant Member
Clinical Research Division
Fred Hutchinson Cancer Research Center
Assistant Professor
Medical Oncology
University of Washington
Seattle, Washington

Renzo Galanello, MD
Professor of Pediatrics
Department of Biomedical Sciences and Biotechnologies
University of Cagliari
Head, 2nd Pediatric Clinic
Thalassemia Unit
Cagliari, Italy

Susan A. Galel, MD
Associate Professor
Department of Pathology
Stanford University
Stanford, California
Director of Clinical Operations
Stanford Blood Center
Palo Alto, California

Patrick G. Gallagher, MD
Professor
Department of Pediatrics and Genetics
Yale University School of Medicine
Attending Physician
Yale—New Haven Hospital
New Haven, Connecticut

Jacob R. Garcia, MD
Associate Hematologist/Oncologist
Pediatric Hematology/Oncology
Children's Hospital and Research Center Oakland
Oakland, California

Guillermo Garcia-Manero, MD
Professor
Department of Leukemia
University of Texas MD Anderson Cancer Center
Houston, Texas

Amy E. Geddis, MD, PhD
Associate Professor
Pediatric Hematology/Oncology
University of Southern California, San Diego
Rady Children's Hospital San Diego
San Diego, California

Tracy I. George, MD
Associate Professor of Pathology
Chief, Hematopathology Division
Director, Hematopathology Fellowship
University of New Mexico Health Sciences Center
Albuquerque, New Mexico

Morie A. Gertz, MD, MACP
Professor and Chair
Department of Medicine
Mayo Clinic
Rochester, Minnesota

Spencer B. Gibson, PhD
Professor
Biochemistry and Medical Genetics
Manitoba Institute of Cell Biology
University of Manitoba
Provincial Director of Research
Manitoba Institute of Cell Biology
CancerCare Manitoba
Winnipeg, Manitoba
Canada

Bertil Glader, MD, PhD
Professor
Departments of Pediatrics and Pathology
Stanford University Medical Center
Stanford, California
Lucile Packard Children's Hospital
Palo Alto, California

Christopher L. Gonzalez, MD
Assistant Clinical Professor
Department of Pathology
Assistant Medical Director
Stanford Blood Center
Stanford University
Palo Alto, California

Lawrence T. Goodnough, MD
Professor
Department of Pathology and Medicine
Division of Hematology
Stanford University
Director
Transfusion Service
Stanford University Medical Center
Stanford, California

Siamon Gordon, MB, ChB, PhD, FRS
Glaxo Professor of Cellular Pathology Emeritus
Sir William Dunn School of Pathology
University of Oxford
Oxford, United Kingdom

Jason Gotlib, MD, MS
Associate Professor of Medicine (Hematology)
Department of Medicine/Division of Hematology
Stanford University School of Medicine
Stanford, California

John P. Greer, MD
Professor
Departments of Medicine and Pediatrics
Divisions of Hematology/Oncology
Vanderbilt University Medical Center
Nashville, Tennessee

Michael R. Grever, MD
Professor
Department of Internal Medicine
The Ohio State University
Chairman
Department of Internal Medicine
Arthur G. James Cancer Hospital and Richard J. Solove Research Institute
Columbus, Ohio

Thomas G. Gross, MD, PhD
Professor
Department of Pediatrics
The Ohio State University Medical Center
Gordon Teter Chair for Pediatric Cancer Hematology/Oncology/BMT
Nationwide Children's Hospital
Columbus, Ohio

Roy M. Gulick, MD
Professor
Department of Medicine
Chief, Division of Infectious Disease
Weill Cornell Medical College
New York, New York

Kenneth R. Hande, MD
Professor
Departments of Medicine and Pharmacy
Division of Hematology/Oncology
Vanderbilt University Medical Center
Nashville, Tennessee

Jane S. Hankins, MD, MS
Associate Member
Hematology
St. Jude Children's Research Hospital
Memphis, Tennessee

Suzanne R. Hayman, MD
Assistant Professor of Medicine
Department of Internal Medicine/Hematology
Mayo Clinic College of Medicine
Consultant
Department of Internal Medicine/Hematology
Mayo Clinic
Rochester, Minnesota

Nancy M. Heddle, MSc
Professor
Department of Medicine
McMaster University
Hamilton, Ontario
Canada

Derralynn A. Hughes, MA, DPhil, FRCP, FRCPath
Senior Lecturer
Department of Haematology
University College London
London, United Kingdom

Caron A. Jacobson, MD
Instructor
Department of Medicine
Harvard Medical School
Clinical Instructor
Medical Oncology
Division of Hematologic Malignancies
Dana-Farber Cancer Institute
Boston, Massachusetts

Madan Jagasia, MBBS, MS
Associate Professor
Department of Medicine
Division of Hematology/Oncology
Section Chief, Hematology and Stem Cell Transplant
Vanderbilt University Medical Center
Nashville, Tennessee

Vandita P. Johari, MD
Assistant Professor
Department of Pathology
Tufts University School of Medicine
Western Campus
Chief, Clinical Pathology
Department of Pathology
Baystate Health
Springfield, Massachusetts

James B. Johnston, MD
Professor
Department of Internal Medicine
University of Manitoba
Hematologist/Oncologist
Department of Medical Oncology and Hematology
CancerCare Manitoba
Winnipeg, Manitoba
Canada

Dan Jones, PhD
Medical Director
Cancer Diagnostics
Quest Diagnostics Nichols Institute
Chantilly, Virginia

Adetola A. Kassim, MD
Associate Professor
Department of Medicine
Division of Hematology/Oncology
Vanderbilt University Medical Center
Nashville, Tennessee

John G. Kelton, MD
Dean and Vice President
Faculty of Health Sciences
Professor
Department of Pathology and Molecular Medicine and Department of Medicine
McMaster University
Hamilton, Ontario
Canada

Annette S. Kim, MD, PhD
Assistant Professor
Department of Pathology, Microbiology, and Immunology
Vanderbilt University Medical Center
Nashville, Tennessee

Rami Komrokji, MD
Clinical Director
Associate Member
Department of Malignant Hematology
H. Lee Moffitt Cancer Center & Research Institute
Tampa, Florida

Ashish Kumar, MD, PhD
Assistant Professor of Pediatrics
Division of Bone Marrow Transplantation and Immune Deficiency
University of Cincinnati College of Medicine
Staff Physician
Division of Bone Marrow Transplantation and Immune Deficiency
Cancer and Blood Diseases Institute
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Shaji Kumar, MD
Professor of Medicine
Division of Hematology
Mayo Clinic
Rochester, Minnesota

Thomas J. Kunicki, PhD
Senior Scientist II
Department of Hematology Research
CHOC Children's Hospital
University of California—Irvine
Orange, California

Gary M. Kupfer, MD
Professor
Department of Pediatrics
Yale School of Medicine
Chief, Pediatric Hematology/Oncology
Department of Pediatrics
Yale New Haven Children's Hospital
New Haven Connecticut

Paul J. Kurtin, MD
Professor of Pathology
Mayo Medical School
Department of Laboratory Medicine and Pathology
Mayo Clinic
Rochester, Minnesota

Larry W. Kwak, MD, PhD
Professor and Chairman
Department of Lymphoma/Myeloma
The University of Texas MD Anderson Cancer Center
Houston, Texas

Robert A. Kyle, MD
Professor of Medicine
Laboratory Medicine and Pathology
Department of Internal Medicine
Division of Hematology
College of Medicine
Mayo Clinic
Rochester, Minnesota

Paige Lacy, PhD
Associate Professor
Department of Medicine
University of Alberta
Edmonton, Alberta
Canada

Martha Q. Lacy, MD
Department of Hematology
Mayo Clinic
Rochester, Minnesota

Jeffrey E. Lancet, MD
Associate Professor
University of South Florida
Section Chief—Leukemia
Associate Member of Malignant Hematology/Oncology
H. Lee Moffitt Cancer Center & Research Institute
Tampa, Florida

Andre Larochelle, MD, PhD
Principal Investigator, Hematology Branch
The National Heart, Lung and Blood Institute
National Institutes of Health
Bethesda, Maryland

Christopher M. Lehman, MD
Professor (Clinical)
Pathology Department
University of Utah
Medical Director of Hospital Laboratories
Pathology Department
University of Utah Health Care
Salt Lake City, Utah

Meghan S. Liel, MD
Fellow
Department of Hematology and Medical Oncology
Oregon Health and Science University
Portland, Oregon

Jeffrey M. Lipton, MD, PhD
Professor
Pediatrics and Molecular Medicine
Hofstra North Shore—LIJ School of Medicine
Hempstead, New York
Chief
Hematology/Oncology and Stem Cell Transplantation
Steven and Alexandra Cohen Children's Medical Center of New York
New Hyde Park, New York

Frederick L. Locke, MD
Assistant Professor
Oncologic Sciences
University of South Florida
Assistant Member
Blood and Marrow Transplantation
H. Lee Moffitt Cancer Center
Tampa, Florida

Mignon Lee-Chuen Loh, MD
Professor of Clinical Pediatrics
Department of Pediatrics
University of California
San Francisco Benioff Children's Hospital
San Francisco, California

John A. Lust, MD, PhD
Associate Professor of Medicine
Mayo Clinic College of Medicine
Consultant
Division of Hematology
Department of Internal Medicine
Mayo Clinic
Rochester, Minnesota

William R. Macon, MD
Professor of Pathology
Mayo Medical School
Consultant
Department of Laboratory Medicine and Pathology
Mayo Clinic
Rochester, Minnesota

Suman Malempati, MD
Assistant Professor
Department of Pediatrics
Oregon Health and Science University
Doernbecher Children's Hospital
Portland, Oregon

Kenneth G. Mann, PhD
Professor Emeritus, Biochemistry
University of Vermont
Burlington, Vermont

Catherine A. Manno, MD
Chair
Department of Pediatrics
Pat and John Rosenwald Professor of Pediatrics
New York University Langone Medical Center
New York, New York

Peter Maslak, MD
Professor of Clinical Medicine
Department of Internal Medicine
Weill Cornell Medical College
Chief
Hematology Laboratory Service
Laboratory Medicine
Memorial Sloan-Kettering Cancer Center
New York, New York

Thomas L. McCurley, MD
Associate Clinical Professor
Department of Pathology
Vanderbilt University Medical Center
Nashville, Tennessee

Laura Y. McGirt, MD
Assistant Professor of Medicine/Dermatology
Division of Dermatology
Department of Medicine
Vanderbilt University School of Medicine
Nashville, Tennessee

Margaret M. McGovern, MD, PhD
Professor and Chair
Department of Pediatrics
Stony Brook University School of Medicine
Physician in Chief
Stony Brook Long Island Children's Hospital
Stony Brook, New York

Kelly M. McNagny
Professor
Medical Genetics
The Biomedical Research Centre
University of British Columbia
Vancouver, British Columbia
Canada

Robert T. Means, Jr., MD
Professor of Internal Medicine
Executive Dean
University of Kentucky College of Medicine
Lexington, Kentucky

Dean D. Metcalfe, MD
Chief
Laboratory of Allergic Diseases
Division of Intramural Research
National Institute of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, Maryland

Joseph R. Mikhael, MD
Associate Professor
Department of Medicine
Mayo Clinic
Scottsdale, Arizona

Andrew J. Moore, MD
Clinical Fellow
Department of Medicine
Division of Hematology/Oncology
Vanderbilt University Medical Center
Nashville, Tennessee

Redwan Moqbel, PhD, FRCPath
Professor and Head
Department of Immunology
Faculty of Medicine
University of Manitoba
Winnipeg, Manitoba, Canada

David S. Morgan, MD
Associate Professor
Department of Medicine
Division of Hematology/Oncology
Vanderbilt University Medical Center
Nashville, Tennessee

William G. Morice II, MD, PhD
Associate Professor
Laboratory Medicine and Pathology
Mayo School of Graduate Medical Education
Consultant
Division of Hematopathology
Department of Laboratory Medicine and Pathology
Mayo Clinic
Rochester, Minnesota

Claudio A. Mosse, MD, PhD
Assistant Professor of Pathology
Department of Pathology
Vanderbilt University School of Medicine
Chief of Pathology and Laboratory Medicine
Department of Pathology and Laboratory Medicine
Tennessee Valley Health Systems VA
Nashville, Tennessee

Affiliate Member
Affiliate Professor
Clinical Division/Medical Oncology
Fred Hutchinson Cancer Research Center
University of Washington
Seattle, Washington
Transplant Physician
Colorado Blood Cancer Institute
Presbyterian/St. Luke's
Denver, Colorado

Sattva S. Neelapu, MD
Associate Professor
Department of Lymphoma and Myeloma
The University of Texas MD Anderson Cancer Center
Houston, Texas

Elizabeta Nemeth, PhD
Associate Professor
Department of Medicine
David Geffen School of Medicine
University of California, Los Angeles
Los Angeles, California

Huong (Marie) Nguyen, MD
Hematology/Oncology Fellow
Department of Medicine
Stanford School of Medicine
Stanford Hospital and Clinics Cancer Institute
Stanford, California

H. Stacy Nicholson, MD, MPH
Professor and Chair
Department of Pediatrics
Oregon Health and Science University
Physician-in-Chief
Doernbecher Children's Hospital
Portland, Oregon

Ariela Noy, MD
Associate Member, Associate Attending
Department of Medicine
Memorial Sloan-Kettering Cancer Center and Cornell Weill Medical College
New York, New York

Diane J. Nugent, MD
Pediatric Hematology
Chief of Hematology
Department of Hematology
CHOC Children's Hospital
University of California—Irvine
Orange, California

Maureen M. O'Brien, MD
Assistant Professor
Department of Pediatrics
University of Cincinnati
Associate Director
Leukemia/Lymphoma Program
Department of Oncology
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Robin K. Ohls, MD
Professor
Department of Pediatrics
University of New Mexico
Director of Pediatric Integration
Clinical Translational Science Center
University of New Mexico Health Sciences Center
Albuquerque, New Mexico

Mihaela Onciu, MD
Hematopathologist
OncoMetrix
Memphis, Tennessee

Attilio Orazi, MD, FRCPath (Engl.)
Professor of Pathology and Laboratory Medicine
Vice Chair for Hematopathology
Department of Pathology and Laboratory Medicine
Weill Cornell Medical College
Director
Division of Hematopathology
Department of Pathology and Laboratory Medicine
New York, New York

Thomas Orfeo, PhD
Research Associate
Department of Biochemistry
University of Vermont
Colchester, Vermont

Eric Padron, MD
Assistant Member
Department of Malignant Hematology
H. Lee Moffitt Cancer Center & Research Institute
Tampa, Florida

Frixos Paraskevas, MD
Professor of Internal Medicine and Immunology (Retired)
University of Manitoba Medical School
Associate Member
Institute of Cell Biology—Cancer Care Manitoba
Winnipeg, Manitoba
Canada

Charles J. Parker, MD
Professor
Department of Medicine
University of Utah School of Medicine
Salt Lake City, Utah

Robert C. Pendleton, MD, FACP
Associate Professor
Department of Medicine
University of Utah
Director
Hospitalist Program
Medical Director
Thrombosis Service
Department of Medicine
University of Utah Healthcare
Salt Lake City, Utah

Professor of Hematology
Department of Pathology
University of Utah
Salt Lake City, Utah

Joseph Pidala, MD, MS
Assistant Professor
Oncologic Sciences
College of Medicine—University of South Florida
Assistant Member
Blood and Marrow Transplantation
H. Lee Moffitt Cancer Center
Tampa, Florida

Annette Plüddemann, PhD
Senior Researcher
Department of Primary Care Health Sciences
University of Oxford
Oxford, United Kingdom

Michael R. Porembka, MD
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Anna Porwit, MD, PhD
Professor
Department of Laboratory Medicine and Pathobiology
University of Toronto
Hematopathologist
Department of Laboratory Hematology
University Health Network
Toronto General Hospital
Toronto, Ontario
Canada

Jerry S. Powell, MD
Professor of Medicine
Division of Hematology/Oncology
University of California
University of California Davis Medical Center, Davis
Sacramento, California

John G. Quigley, MB, FRCPC
Associate Professor
Department of Medicine
University of Illinois at Chicago
Attending Physician
Division of Hematology/Oncology
Department of Medicine
University of Illinois Hospital and Health Sciences System
Chicago, Illinois

Charles T. Quinn, MD, MS
Associate Professor
Department of Pediatrics
University of Cincinnati College of Medicine
Director of Hematology
Clinical and Translational Research
Department of Hematology
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Elizabeth A. Raetz, MD
Associate Professor
Department of Pediatrics
Division of Hematology/Oncology
New York University
New York, New York

S. Vincent Rajkumar, MD
Professor of Medicine
Division of Hematology
Mayo Clinic
Rochester, Minnesota

Michael Recht, MD, PhD
Associate Professor of Pediatrics and Medicine
Pediatric Hematology-Oncology
Oregon Health & Science University
Portland, Oregon

Nishitha M. Reddy, MD
Assistant Professor
Department of Medicine
Division of Hematology/Oncology
Vanderbilt University Medical Center
Nashville, Tennessee

Matthew M. Rees, MD
Rutherford Hospital
Rutherford, North Carolina

George M. Rodgers, MD, PhD
Professor of Medicine and Pathology
University of Utah School of Medicine
Health Sciences Center
Medical Director
Coagulation Laboratory
ARUP Laboratories
Salt Lake City, Utah

Stephen J. Russell, MD, PhD
Dean for Discovery and Experimental Research
Department of Molecular Medicine
Richard O. Jacobson Professor of Molecular Medicine
Mayo Clinic
Rochester, Minnesota

John T. Sandlund, Jr., MD
Member
Department of Oncology
St. Jude Children's Research Hospital
Professor
Department of Pediatrics
University of Tennessee College of Medicine
Memphis, Tennessee

Bipin N. Savani, MBBS
Associate Professor of Medicine
Director
Long Term Transplant Clinic, Hematology and Stem Cell Transplant
Vanderbilt University Medical Center
Nashville, Tennessee

Matthew Seftel, MD
Assistant Professor
Department of Internal Medicine
University of Manitoba
Hematologist
Department of Medical Oncology and Hematology
CancerCare Manitoba
Winnipeg, Manitoba
Canada

Paul J. Shami, MD
Professor of Medicine
Division of Hematology and Hematologic Malignancies
Adjunct Professor
Department of Pharmaceutics and Pharmaceutical Chemistry
University of Utah
Salt Lake City, Utah

Luke R. Shier, MD
Assistant Professor
Department of Pathology
University of Ottawa
Hematopathologist
Pathology and Laboratory Medicine
The Ottawa Hospital
Ottawa, Ontario
Canada

Akiko Shimamura, MD, PhD
Associate Member
Clinical Research Division
Fred Hutchinson Cancer Research Center
Associate Professor of Pediatrics
Pediatric Hematology/Oncology
Seattle Children's Hospital
Seattle, Washington

Keith M. Skubitz, MD
Professor
Division of Hematology, Oncology and Transplantation
Department of Medicine
Musculoskeletal Tumor Program, Masonic Cancer Center
University of Minnesota
Attending Physician
University of Minnesota Medical Center
Minneapolis, Minnesota

James W. Smith, MT, BSc
Assistant Professor
Department of Medicine
McMaster University
Coordinator/Technical Director
Platelet Immunology Laboratory
Hamilton Health Sciences
Hamilton, Ontario
Canada

Kristi J. Smock, MD
Assistant Professor
Department of Pathology
University of Utah Health Sciences Center
Medical Director
Hemostasis/Thrombosis Laboratory
ARUP Laboratories
Salt Lake City, Utah

Susan S. Smyth, MD, PhD
Professor and Chief
Division of Cardiovascular Medicine
University of Kentucky
Attending Physician
Medical Services
Lexington VA Medical Center
Lexington, Kentucky

Steven L. Soignet, MD
Arcus Advisory
New York, New York

Nicole I. Stacy, DVM, DrMedVet
Adjunct Clinical Assistant Professor
Department of Large Animal Clinical Sciences
University of Florida
College of Veterinary Medicine
Gainesville, Florida

Martin H. Steinberg, MD
Professor of Medicine
Department of Pediatrics, Pathology and Laboratory Medicine
Boston University School of Medicine
Director
Center of Excellence in Sickle Cell Disease
Boston Medical Center
Boston, Massachusetts

A. Keith Stewart, MBChB
Dean for Research
Division of Hematology/Oncology
Mayo Clinic
Scottsdale, Arizona

Stephen A. Strickland, MD, MSCI
Assistant Professor
Department of Medicine
Division of Hematology/Oncology
Vanderbilt University Medical Center
Nashville, Tennessee

Mary Ann Thompson, MD, PhD
Associate Professor
Department of Pathology
Vanderbilt University Medical Center

Assistant Professor of Medicine/Dermatology
Division of Dermatology
Department of Medicine
Vanderbilt University School of Medicine
Nashville, Tennessee

Welcome to the thirteenth edition of Wintrobe's *Clinical Hematology*. This textbook strives to continue the Wintrobe tradition of being comprehensive yet accessible to all who seek to understand the history, science, and clinical practice of hematology. We have brought together clinicians and scientists who have given their time and expertise to produce a state-of-the-art resource which includes an online presence with expanded bibliographies, appendices, and updates.

THE WINTROBE LEGACY

Few have appreciated the wealth of information to be gained by the study of blood more than Maxwell Myer Wintrobe (1906 to 1986). He cited poets, including John Donne's "pure and eloquent blood" and Goethe's "Blood is a juice of a very special kind"; but he added that "It is for the scientist that the blood has been especially eloquent."[1] It has been over 70 years since Wintrobe wrote the first edition of *Clinical Hematology* (1942); and at the time, he was uncertain if it would have much readership owing to the priorities of World War II. His objective was "to bring together the accumulated information in the field of hematology in a systematic and orderly form." He felt the book should be "comprehensive, complete, and authoritative." He emphasized the importance of "an accurate diagnosis as a prerequisite to efficacious treatment." His goals were to link science to the clinical practice of hematology and to provide the best therapy possible for an individual patient. We have recruited an outstanding group of scientists and clinicians who have given their expertise and time to accomplish similar goals for the thirteenth edition of *Wintrobe's Clinical Hematology*.

Wintrobe's career included medical school at the University of Manitoba (1921 to 1925) and academic appointments at Tulane University (1927 to 1930), The Johns Hopkins University (1930 to 1943), and the University of Utah (1943 to 1986). His interests were broad and his contributions to medicine and hematology were many.[2] He had access to an abundance of clinical material at Charity Hospital (New Orleans, LA), where he invented the hematocrit glass tube, which came to bear his name and allowed him to collect information about the blood (Figure 1). The Wintrobe hematocrit tube not only allowed determination of the volume of packed red blood cells after centrifugation but also allowed measurement of the erythrocyte sedimentation rate, determination of the volume of packed white cells and platelets, and detection of changes in the appearance of the plasma.

At Johns Hopkins University, Wintrobe made peripheral smears available to the clinic, reorganized the teaching of the third-year student laboratory course, and established himself as an investigator and leader in hematology.[3] He and his colleagues showed that hypochromic anemia responded to iron,[4] gave the first account of cryoglobulin in the blood,[5] and provided the first evidence that thalassemias were inherited.[6] He became chief of the Clinic for Nutritional, Gastrointestinal, and Hematologic Disorders in 1933 and was promoted to the position of Associate in Medicine in 1935. During World War II, he was assigned to study chemical warfare agents and his efforts led to a landmark paper with Louis Goodman et al. on the efficacy of nitrogen mustard as a chemotherapeutic agent.[7]

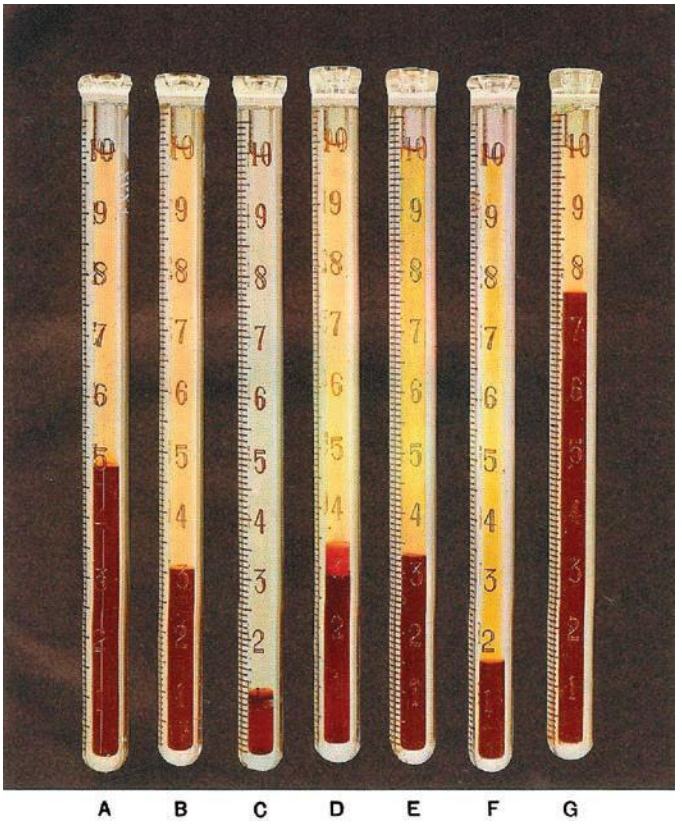

FIGURE 1. Original illustration of Wintrobe tubes depicting the appearance of centrifugal blood in various conditions, as published in the seventh edition.

In 1943, Wintrobe was offered the first Chair of Medicine at the University of Utah. He served as Chair for 24 years and in 1970 was named Distinguished Professor of Internal Medicine. He studied the role of nutritional factors, particularly the B vitamins, in hematopoiesis, and attempted to develop an animal model for pernicious anemia.[3,8] His work with pig's nutritional requirements resulted in discovering the effects of pyridoxine deficiency and the role of copper in iron metabolism.[3] He studied the effects of the newly discovered adrenocorticosteroids on hematopoiesis,[9] described the association of chloramphenicol with aplastic anemia,[10] and became an advocate for reporting the adverse reactions to drugs.[11]

Wintrobe's clinical interests extended beyond hematology, and he received the first research grant ever awarded by the National Institutes of Health. The grant was to study hereditary muscular dystrophy (a disorder that affected a number of Utah families) and was renewed annually for 23 years.[2,3] He directed the Laboratory for the Study of Hereditary and Metabolic Disorder and Training Institute (1969 to 1973). Together with George Cartwright, he established a premier hematology training program at Utah. They trained 110 fellows, 85% of whom became associated with medical schools or research institutes.[12]

Wintrobe was the sole author of the first six editions, and he recruited former fellows to assist him on the seventh and eight editions: Jack Athens, Tom Bithell, Dane Boggs, John Foerster, and Richard Lee with John Lukens joining them on the eighth edition (1981), the last one to involve Wintrobe. Lee, Bithell, Foerster, Athens, and Lukens were the editors for the ninth edition (1993). John Greer, Frixos Paraskevas, and George Rodgers joined Lee, Foerster, and Lukens for the tenth edition (1999) and Bert Glader was added for the eleventh edition (2004). Robert Means, Jr., and Daniel Arber joined Foerster, Glader, Greer, Paraskevas, and Rodgers for the twelfth edition (2009). We welcome Alan List as a new editor for this edition and honor John Foerster as the editor emeritus.

IN MEMORY OF JOHN N. LUKENS

We remember our friend, John Nevius Lukens, Jr. (1932 to 2010), who was dedicated to the Wintrobe legacy and committed to the education of the next generation of health care providers. He was a graduate of Princeton University (1954) and Harvard Medical School (1958). After an internship in Medicine and Pediatrics at the University of North Carolina, he completed his residency at The Children's Hospital in Cincinnati (1959 to 1961). He served 2 years in the U.S. Army Medical Corps at the Letterman General Hospital in San Francisco and became a research fellow at the University of Utah School of Medicine with Eugene Lahey and Wintrobe (1964 to 1967). His research contributed to the understanding of the anemia of chronic disease and iron deficiency. John was a founding member of the Children's Cancer Group and was among the pioneers of pediatric hematology who contributed to a steady and marked increase in the curability of childhood acute lymphoblastic leukemia and other cancers. He held faculty appointments at the University of Missouri School of Medicine (1967 to 1971), Tufts Medical School (1971 to 1973), and the Charles R. Drew Postgraduate Medical School (1973 to 1975) before becoming Director of Pediatric Hematology/Oncology (1975 to 1997) at Vanderbilt University's Children's Hospital. He became an Emeritus in 2001 until his death in 2010. John is remembered as a role model as a physician, a loving husband to his wife Cauley of 51 years, a father devoted to their daughters, Ann, Rachel, and Betsy, and a grandfather to five.

THIRTEENTH EDITION

Our goal in the thirteenth edition is to continue Wintrobe's commitment to link the past accomplishments in hematology to the present state of the art and to future developments. We are honored to have some of the best hematologists in the world contribute to this edition. They have continued the Wintrobe tradition of providing historical perspective and combining basic science with clinical practice. There are 74 new authors, and all of the chapters are new or have been completely revised. All of the authors are worth singling out, but space limits our ability to thank them individually. One of the new contributors is Michael Deininger, who is the Maxwell M. Wintrobe Professor of Medicine at the University of Utah Huntsman Cancer Institute.

The audience for the book encompasses the entire spectrum of health care providers, including medical students, nurses, residents, clinicians, and scientists, who seek answers about hematology. The textbook reviews the science, the methods of diagnosis, and the evidence for the basis of therapeutic decisions. The artwork has been extensively redrawn for color and consistency and there are numerous photomicrographs, which illustrate the role of hematopathology in diagnosis.

The book is divided into eight parts: Laboratory Hematology; The Normal Hematologic System; Transfusion Medicine; Disorders of Red Cells, Hemostasis, and Coagulation; Benign Disorders of Leukocytes; The Spleen and/or Immunoglobulins; Hematologic Malignancies; and Transplantation. Throughout the chapters, there is an emphasis on the four components in hematology that contribute to diagnosis: the morphological exam of the peripheral blood smear, bone marrow, lymph nodes, and other tissues; flow cytometry, cytogenetics, and molecular markers.

The expanding role of molecular genetics and flow cytometry is not only improving diagnosis but also providing targets for novel therapies. The role of tyrosine kinase inhibitors in chronic myeloid leukemia serves as a model for molecularly targeted therapy. The detection of minimal residual disease by either flow cytometry or polymerase chain reaction techniques is impacting therapeutic decisions. Chapters on gene therapy and immunotherapy are up-to-date reviews on these unique therapies for a variety of hematologic disorders. The role of stem cell transplantation is addressed in chapters on specific diseases and in an entirely new part, which reviews its application for both benign and malignant disorders, graft–versus-host disease, and the importance of long-term follow-up of transplantation survivors.

For a textbook to meet its audience needs in the 21st century, there must be an online presence and a way to interact with and update its readers. The online text has a complete reference list for each chapter and two appendices, one reviewing the clusters of differentiation molecules by Dan Arber and Frixos Paraskevas and another by veterinarians Nicole Stacy, Kirstin Barnhart, and Michael Fry, who review lab values and photomicrographs of the blood of animals. We plan to issue updates online when there is either unique or sufficient information that influences the practice of hematology.

We are indebted to the efforts of Jonathan Pine, who has kindly supported us as Senior Executive Editor at Lippincott Williams & Wilkins since the 10th edition; Emilie Moyer, Senior Product Manager; and Frannie Murphy, Development Editor.

ACKNOWLEDGMENTS

Thanks to my wife, Gay, for her support and our grown children, Lesley, Adam, and Scott; Pamela Johnson, who diligently and kindly prepared manuscripts; Billi Bean, who worked on editions 9 through 12 and handed the reins to Pamela; Meera Kumar, P.A., the nurse practitioners and nurses who provide extraordinary care to the patients at Vanderbilt University Medical Center; and mentors and colleagues: Robert Collins, John Flexner, Stanley Graber, Marsha Kinney, Mark Koury, Sanford Krantz, Friedrich Schuening, Richard Stein, and Steven Wolff; and a special thanks to John Lukens, who brought me into the world of Maxwell M. Wintrobe, and my lifelong friend, Thomas McCurley.

John P. Greer, MD

I wish to thank my wife, Carol Park, for her constant support. I also thank my current and past trainees, colleagues, and mentors, all of whom are continuous sources of knowledge.

Daniel A. Arber, MD

I wish to acknowledge the many outstanding colleagues, both chapter authors and fellow editors, whom I have had the privilege to work with in the development of this new edition. I also want to acknowledge my students, residents, and fellows who continue to make the teaching of clinical hematology so meaningful. Lastly, but most of all, I want to recognize the understanding and support of my wonderful wife Lou Ann, my children, and their families.

Bertil Glader, MD, PhD

As I am sure our readers understand, creating a state-of-the-art reference text is by no means a simple task. It begins with the authors who graciously give their time, often juggling deadlines with immediate demands from their own research, clinical duties, etc. I thank them for their diligence and perseverance to create an outstanding reference. Individuals at Lippincott Williams & Wilkins such as Emilie Moyer, Franny Murphy, and Jonathan Pine worked ever so patiently in providing the guidance and focus necessary to see this to completion. Finally, my sincere thanks to our senior editor and master medical coordinator of Wintrobe, Dr. John Greer, for his faith in the process, admirable leadership, and sensitivity to the mission.

Alan F. List, MD

I wish to thank my wife Stacey and our children, Casey, Robert, and Patrick, for their support and tolerance during the preparation of this book; the many teachers and colleagues who have guided me as mentors and examples in science and medicine, particularly Shu-Yung Chen, Joachim Pfitzner, James B. Walker, Robert D. Collins, Roger M. DesPrez, Richard Borreson, Richard Vilter, Herbert Flessa, John Flexner, and Sanford B. Krantz; and above all my late parents, Ann and Bob Means, who were my first and best teachers.

Robert T. Means, Jr., MD

I am deeply indebted to my pathologist wife, Dr. Maria Paraskevas, for her unwavering support, encouragement, and advice throughout the writing of my chapters.

Frixos Paraskevas, MD

I acknowledge Stephen Kling for expert word processing and my numerous contributors for their outstanding chapters. This is the fourth edition of this textbook I have been involved with; it has been a pleasure working with my coeditors and publishing colleagues on this edition.

George Rodgers, MD, PhD

I wish to thank my wife Gisela, who bore my commitments to this tome for seven editions with encouragement, patience, and grace. Deeply felt gratitude is extended to my mentors, Dr. L. G. Israels and Dr. M. M. Wintrobe, both now regrettably deceased, and Dr. B. Benacerraf, who nurtured my interests in Immunology. Dr. Israel's enthusiasm for Hematology and his ability to combine effectively clinical excellence, teaching, and research drew me to this specialty as a medical student. Dr. Wintrobe taught me in his own unique way and gave me the opportunity to contribute as author and associate editor to this great textbook. Special thanks to my colleagues who have contributed valuable chapters to this text.

John Foerster, MD

SECTION 3: MYELOPROLIFERATIVE DISORDERS 1688

SECTION 4: LYMPHOPROLIFERATIVE DISORDERS 1770

THE DIAGNOSTIC AND THERAPEUTIC APPROACH TO HEMATOLOGIC PROBLEMS

Maxwell M. Wintrobe

The study of the blood has a long history. Humankind probably always has been interested in the blood because it is likely that even primitive peoples realized that loss of blood, if sufficiently great, was associated with death. In biblical references, *to shed blood* meant to *kill*.[1]

THE FOUNDATIONS OF DIAGNOSIS

When and in what manner blood was first examined is unknown, but before the days of microscopy only the gross appearance of the blood could be studied. Blood allowed to clot in a glass vessel can be seen to form several distinct layers: at the bottom a dark red, almost black, jellylike material is seen; above this is a red layer; and still nearer the top of the clot is a pale green or whitish layer. Above these is the transparent, yellow serum. It has been suggested that perception of these layers in the blood after its removal from the body may have given rise to the doctrine of the four humors (black bile, sanguis, phlegm, and yellow bile), which were believed to constitute the substance of the human body. Health and disease were thought to be the result of the proper mixture or imbalance, respectively, of these four humors. This doctrine corresponding to the pervading concept of matter founded on the interrelationship of the four elements—earth, water, air, and fire—was set out clearly in the Hippocratic writings and was systematized into a complex metaphysical pattern by Galen in the 2nd century AD. It dominated medical thinking even into the 17th century.

Microscopic examination of the blood by Leeuwenhoek and others in the 17th century, and subsequent improvements in their rudimentary equipment, provided the means whereby theory and dogma would gradually be replaced by scientific understanding. The advance of knowledge was slow; however; those who were willing to observe and to seek greater understanding were few compared with the multitudes who repeated the age-old formulations. In the 18th century, William Hewson (1739 to 1774) made many important observations, and over the next 150 years or more, others gradually left their mark, including Gabriel Andral (1797 to 1876), Alexander Donné (1801 to 1878), Georges Hayem (1841 to 1933), and Paul Ehrlich (1854 to 1915), as well as Virchow, Aschoff, Maximow, Pappenheim, and still others in more recent times.[2]

However, it was not until the 1920s, beginning with the investigations of Whipple, Minot, and Castle, that the modern era of hematology started. From that time on, the field of hematology has flourished, and knowledge and understanding have grown at an ever-accelerating pace. The story has been told elsewhere.[2] The reader will find revealing the comparison of the first edition of this textbook published in 1942, with subsequent editions.

At one time, hematology was a purely laboratory endeavor concerned with quantitation of the formed elements of the blood and the study of their morphology and that of the bone marrow, spleen, and lymphoid tissues. In the past 70 years, however, hematology has become a broad-based science that, in seeking to understand the normal and pathologic physiology of the hematopoietic system, uses all the methods of diverse scientific disciplines such as biochemistry, cell biology, immunology, physical chemistry, molecular biology, genetics, and nuclear medicine. As a consequence, the study of a hematologic problem can involve the use of procedures of great complexity.

Nevertheless, in the majority of patients whose illness may be regarded as being directly or indirectly related to the blood or blood-forming organs, examination requires only simple procedures. These begin with the steps fundamental and essential in the study of any clinical problem: a carefully taken history and a meticulous, discerning physical examination. It should be emphasized that the hematologist must be conversant with illness on a broad scale because, although certain diseases affect primarily the blood and blood-forming tissues, more often, disorders of other organ systems result in alterations in the hematopoietic system. A sound and thorough background is essential for the hematologist because modern oncologic therapy affects tissues other than those of the hematopoietic system and can be associated with diverse complications.

The symptoms of hematologic disorders are so varied and nonspecific that in themselves they may not suggest a hematologic problem. Thus, unexplained fever, extreme fatigability, or recurrent infections may or may not be caused by a hematologic condition. Likewise, physical examination may or may not direct attention to the hematopoietic system. The physical signs may be mainly those of congestive heart failure when the primary condition is pernicious anemia in relapse, adenopathy and splenomegaly when the underlying condition is a self-limited childhood infection, or nothing other than pallor when leukemia or aplastic anemia is the underlying disorder. In other instances, sternal tenderness, or bone tenderness elsewhere, hemorrhages, or spoon nails may direct attention to the hematopoietic system.

Certain details of history must receive special inquiry. These include exposure to physical or chemical agents, which may have caused injury, and to drugs, prescribed or self-medicated. Often overlooked are substances used at work and in the home, such as pesticides and solvents. Especially misleading is the fact that only the exceptional individual is harmed by most of these agents, thereby giving the patient and the physician a false sense of security. For example, in patients given chloramphenicol, only rarely did aplastic anemia develop. Also deserving special inquiry is the diet, the degree and frequency of menstrual blood loss, evidence of intestinal blood loss, and the presence or the absence of fever.

In addition, family history is important in the differential diagnosis of hematologic disorders. Knowledge of ethnic origin or a history of jaundice, anemia, cholelithiasis, splenectomy, or bleeding in male rather than in female members of the family, for example, may offer useful clues. Furthermore, history alone may be insufficient. Although symptoms may be denied, a palpable

spleen on physical examination or morphologic changes seen in the blood smear, such as target cells and basophilic stippling, may direct attention to the hitherto unsuspected hereditary disorder. A family history is only as good as the thoroughness of the inquiry.

In the physical examination, careful attention should be given to the color of the skin, the sclerae and the nails, the presence of lymphadenopathy, sternal or other bone tenderness, splenomegaly, and petechiae in the mouth, ocular fundi, or skin. Unless the patient has been examined while lying on his or her right side, with the abdomen relaxed, as well as in the usual manner in the supine position, a search for an enlarged spleen cannot be considered complete. One also should be careful not to miss a renal tumor or mistake it for an enlarged spleen.

In addition to the history and physical examination, it is necessary to determine whether anemia is present, to calculate the red cell indices, and to measure the concentrations of the leukocytes and platelets. The erythrocyte sedimentation rate may be included as a useful, nonspecific indicator of acute or chronic conditions. Blood chemical examinations, especially those for blood urea nitrogen, creatinine, and uric acid, are also essential. Usually, in an automated laboratory, it is faster, equally accurate, and less costly in time and money to obtain a battery of such data as part of the initial evaluation.

The stained blood smear must be examined not only to determine the differential leukocyte count but also to search for other signs of abnormality. The latter, at least, should be done by the hematologist. Even if one could count on perfect laboratory examinations and reports (which one cannot, even with the best laboratories), nothing can replace the careful scrutiny of the blood smear by a physician who knows the patient's complaints and physical findings. Subtle abnormalities in red cell morphology may have been overlooked or a rare nucleated red cell or an immature or abnormal leukocyte may have been missed; a platelet count may have been reported as being low, but the blood smear may show otherwise.

The indiscriminate selection of a battery of hematologically oriented tests, such as obtaining a Coombs test and levels of serum iron, B_{12}, and folic acid, in every anemic patient is wasteful, unwise, and unnecessary. In particular, bone marrow examination, which too often is done almost automatically in conditions suspected to be hematopoietic, is unjustified as a routine part of the hematologic examination. Bone marrow examination is useful in certain situations but cannot be expected to be helpful in others.

Again, the tendency to order procedures such as red cell survival studies, liver and spleen scans, or other costly or time-consuming examinations when the same information can be obtained or inferred by simpler means only taxes the financial resources of the patient and the health care system.

Results of the initial investigation often direct further study in one of three or four areas, the approaches to which are described in later chapters. Thus, if anemia appears to be the outstanding feature, refer Chapter 22 for steps to follow in investigating its nature and cause. The investigation of patients with bleeding disorders is outlined in Chapter 45. Abnormalities in the numbers or morphologic characteristics or leukocytes, splenomegaly, lymphadenopathy, recurrent infection, or other signs of abnormal immunologic or phagocytic function are explored in Chapter 56. If all of the formed blood elements are deficient (pancytopenia), consult Chapters 37 and 38. The steps outlined in these chapters, along with the guidance of a provisional diagnosis on the basis of evidence disclosed to that point, make the diagnostic process a logical and orderly procedure. In such a stepwise fashion, an accurate diagnosis can be reached with a minimum of trouble to the patient and at minimal cost. Only in the most complex cases is an exhaustive investigation justified.

PRINCIPLES OF MANAGEMENT

The successful and intelligent management of disease depends on three elements: accuracy of diagnosis, understanding of the nature of the abnormalities discovered and their ultimate prognosis if unchecked, and appreciation of the character of the patient and his or her reaction to the illness. Other important factors that must be considered in this connection are the patient's age, responsibilities, concerns, and fears.

Accuracy of diagnosis obviously is fundamental and influences the treatment of the patient. If the diagnosis is uncertain, one must consider what additional steps must be undertaken in seeking the diagnosis; whether the suspected possibilities justify those steps; whether consultation might be helpful; whether one is justified in waiting to allow the disease process to progress without interference, thereby permitting it to declare itself more clearly; and whether a therapeutic trial based on the most likely diagnosis is justified. One must avoid diffuse testing and data gathering, which may be expensive and of limited value.

Physicians should regard the discovery of anemia in a patient as a challenge. Anemia is a manifestation of disease, not a disease in itself. The anemia may be a subtle sign of chronic renal insufficiency, of malignancy, or of chronic infection that has not otherwise declared itself. In such cases, management depends on the nature of the underlying cause. If the anemia is of the iron-deficient type, it is a signal to search for its cause and eliminate it if possible; moreover, the anemia can usually be relieved by appropriate iron therapy.

In addition, it is essential that the physician understand the nature of the abnormality or the disease that has been discovered. It is as wrong to alarm the patient when this is not justified as it is to fail to discover some disorder that should have been recognized and treated. It is especially important to be cautious in the way one uses terms such as *leukemia* that have life-threatening implications. Some forms of chronic lymphocytic leukemia, for example, are so slow in their progress (even requiring no treatment for many years) that this term is misleading. Likewise, other terms that have serious implications and yet refer to diseases with wide ranges of prognostic implication must be used most cautiously.

Accurate diagnosis and knowledge of the prognosis, both with and without various modes of therapy, should guide the physician in answering the three major questions of therapy:

WHETHER to treat
WHEN to treat
with *WHICH* modality

The therapeutic measures, particularly the chemotherapeutic agents available to hematologists, carry a substantial potential for harm. Potential gain must be weighed against potential risks. This is especially true when therapeutic expectation is palliation rather than cure of the disease.

Although it is self-evident that the physician must be mindful of the patient's fears and hopes and those of his or her family, it is too easy to overlook this need. The physician must take the time to give the patient and his or her family some understanding of the illness (if there is one) with sensitivity and sympathy. The physician must choose carefully each word he or she uses and consider how comments may be interpreted or misinterpreted. The nature and course of certain hematologic disorders are such that in some patients reassurance may be far more helpful than any other measure the physician can offer. Consultation with another physician, preferably an expert, may be of value to the emotional well-being of certain patients, even when the physician is certain of the diagnosis and the appropriate treatment.

Undertaking meaningless therapy, treating only because of the magnitude of the white blood cell count, for example, without considering the psychologic effects of such attention to what may be a minor manifestation of the disease, and risking the possibility

of injury by the therapeutic agents used without considering the normal course of the disease are common errors in judgment.

Dealing with the terminally ill patient and his or her family requires compassion, wisdom, and tact. One must be truthful and also understanding; what is especially important is how the truth is told. Furthermore, it is rare that a patient wants to know the whole truth. It is wise to give the patient and his or her family an opportunity to ask questions. In that way, the facts come out more gradually, and a blunt announcement of the likely outcome is avoided.

Patients and their families often ask how long the patient will live. No physician is able to predict this with any accuracy. On the one hand, the stamina of patients and their will to live vary greatly; on the other, it is difficult to guess what unexpected events may occur that will bring closer, or postpone, the ultimate end.

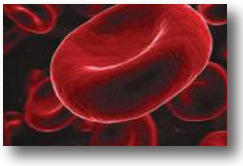
PART I

Laboratory Hematology



CHAPTER 1

EXAMINATION OF THE BLOOD AND BONE MARROW

Kristi J. Smock, Sherrie L. Perkins

Careful assessment of the blood is often the first step in assessment of hematologic function and diagnosis of related diseases, and many hematologic disorders are defined by specific blood tests. Examination of blood smears and hematologic parameters yields important diagnostic information about cellular morphology, quantification of the blood cellular components, and evaluation of cellular size and shape that allows formation of broad differential diagnostic impressions, directing additional testing. This chapter introduces the fundamental concepts and limitations that underlie laboratory evaluation of the blood and outlines additional testing that may aid in evaluating a hematologic disorder, including special stains and bone marrow examination.

Blood elements include erythrocytes or red cells, leukocytes or white cells, and platelets. *Red blood cells (RBCs)* are the most numerous blood cells in the blood and are required for tissue respiration. RBCs lack nuclei and contain hemoglobin, an iron-containing protein that acts in the transport of oxygen and carbon dioxide. *White blood cells (WBCs)* serve an immune function and include a variety of cell types that have specific functions and characteristic morphologic appearances. In contrast to mature red cells, WBCs are nucleated and include neutrophils, lymphocytes, monocytes, eosinophils, and basophils. *Platelets* are cytoplasmic fragments derived from marrow megakaryocytes that function in coagulation and hemostasis.

Blood evaluation requires quantification of each of the cellular elements by either manual or automated methods. Automated methods, using properly calibrated equipment,[1,2] are more precise than manual procedures. In addition, automated methods may provide additional data describing cellular characteristics such as cell volume. However, the automated measurements describe average cellular characteristics but do not adequately describe the scatter of individual values around the average. Hence, a bimodal population of small (microcytic) and large (macrocytic) RBCs might be reported as normal cell size. Therefore, a thorough blood examination also requires microscopic evaluation of a stained blood film to complement hematology analyzer data, especially when new findings are identified.[3–5]

SPECIMEN COLLECTION

Proper specimen collection is required for acquisition of reliable and accurate laboratory data for any hematologic specimen. Before a specimen is obtained, careful thought as to what studies are needed will aid in optimal collection of samples. Communication with laboratory personnel analyzing the specimen is often helpful in ensuring proper handling and test performance.

A number of factors may affect hematologic measurements, and specimens should be collected in a standardized manner to reduce data variability. Factor example, patient activity, level of hydration, medications, sex, age, race, smoking, and anxiety may significantly affect hematologic parameters.[6,7,8] Similarly, the age of the specimen may affect the quality of the data collected.[9,10] Thus, data such as patient age, sex, and time of specimen collection should be noted, as well as pertinent correlative clinical information.

Most often, blood is collected by venipuncture into collection tubes containing anticoagulant.[11] The three most commonly used anticoagulants are tripotassium or trisodium salts of ethylenediaminetetraacetic acid (EDTA), trisodium citrate, and heparin. EDTA and disodium citrate act to remove calcium, which is essential for the initiation of coagulation, from the blood.[11] Heparin acts by forming a complex with antithrombin in the plasma to prevent thrombin formation. EDTA is the preferred anticoagulant for blood counts because it produces complete anticoagulation with minimal morphologic and physical effects on cells. Heparin causes a bluish coloration of the background when a blood smear is stained with Wright-Giemsa stains, but does not affect cell size or shape. Heparin is often used for red cell testing, osmotic fragility testing, and functional or immunologic analysis of leukocytes. Heparin does not completely inhibit white blood cell or platelet clumping. Trisodium citrate is the preferred anticoagulant for platelet and coagulation studies.

The concentration of the anticoagulant used may affect cell concentration measures if it is inappropriate for the volume of blood collected and may also distort cellular morphology. Most often, blood is collected directly into commercially prepared negative-pressure vacuum tubes (Vacutainer tubes; Becton Dickinson, Franklin Lakes, NJ), which contain the correct concentration of anticoagulant when filled appropriately, thereby minimizing error.[11] Anticoagulated blood may be stored at 4°C for a 24-hour period without significantly altering cell counts or cellular morphology.[9] However, it is preferable to perform hematologic analysis as soon as possible after the blood is obtained.

RELIABILITY OF TESTS

In addition to proper acquisition of specimens, data reliability requires precise and reproducible testing methods. Both manual and automated testing of hematologic specimens must be interpreted in light of expected test precision, particularly when evaluating the significance of small changes. All laboratory tests

are evaluated with respect to both accuracy and reproducibility. *Accuracy* is the difference between the measured value and the true value, which implies that a true value is known. Clearly, this may present difficulties when dealing with biologic specimens. The National Committee for Clinical Laboratory Standards (NCCLS) and the Clinical and Laboratory Standards Institute (CLSI) have attempted to develop standards to assess the accuracy of blood smear examination[11] and automated blood cell analyzers.[2] Automated instrumentation requires regular quality assurance evaluations and careful calibration to reach expected performance goals and the ability to collect accurate and reproducible data.[2,12,13] In addition, the International Consensus Group for Hematology Review has suggested criteria that should lead to manual review of a specimen after automated analysis and differential counting.[3]

CELL COUNTS

Cell counts are important parameters in evaluating the blood. Cell counts may be determined either manually or by automated hematology analyzers. Whether performed by manual or automated methodologies, the accuracy and precision of the counts depend on proper dilution of the blood sample, even distribution of cells, and precise sample measurement. As blood contains large numbers of cells, sample dilution is usually required for accurate analysis. The type of diluent is dependent on the cell type to be enumerated. Thus, red cell counts require dilution with an isotonic medium, whereas in white cell or platelet counts, a diluent that lyses the more numerous red cells is often used to simplify counting. The extent of dilution also depends on the cell type. In general, red cell counts need more dilution than is required for the less abundant WBCs. Errors in cell counts are caused primarily by errors in sample measurement, dilution, or enumeration of cells. The highest degree of precision occurs when a large number of cells can be evaluated. Clearly, automated methods are superior to manual methods for counting large numbers of cells and minimizing statistical error. Table 1.1 lists the comparable values of reproducibility for automated and manual (hemocytometer) counting methods.

Manual counts are done using a microscope after appropriate dilution of the sample in a *hemocytometer*, a specially constructed counting chamber that contains a specific volume. Red cells, leukocytes, and platelets may be counted. Due to the inherent imprecision of manual counting and the amount of technical time required, most cell counting is now performed by automated instruments that increase the accuracy and speed of analysis by the clinical laboratory, thereby minimizing levels of human manipulation for test entry, sampling, sample dilution, and analysis.[16] With increasing automation, some hematology analyzers can be coupled with instruments performing other laboratory tests using the same tube of blood.[17] There is a variety of different automated hematology analyzers available, dependent on the volume of samples to be tested and the specific needs of the physician ordering testing. The analyzers range in price and workload capacity from those that would be appropriate for an individual physician's office or point-of-care facility to those needed in a busy reference laboratory with capacity for over 100 samples to be analyzed per hour.[16]

Most automated hematology analyzers perform a variety of hematologic measurements, in addition to cell counting, such as hemoglobin concentration (Hb), red cell size, and leukocyte differentials. Many instruments also perform more specialized testing, such as reticulocyte counts.[18] The ability of analyzers to perform accurate WBC differential counts, particularly those that can perform a five-part differential (enumerating neutrophils, lymphocytes, monocytes, eosinophils, and basophils), has been a significant technologic advance over the past 15 years. Automated methods for white cell counts and differentials use several distinct technical approaches, including measurement of electrical impedance, differential light scatter, optical properties, or surface antigen/cytochemical staining either alone or in combination.[19,20]

Most of the newer-generation hematology analyzers utilize optical flow cytometric technologies with or without additional cytochemical staining to detect specific cell types such as red cells, white cells, and platelets (Fig. 1.1).[19,21,22] The newer analyzers have the additional ability to detect reticulocytes as part of the normal complete blood count (CBC) differential using a fluorescent RNA dye and many will also enumerate nucleated red blood cell numbers based on their optical properties.[23] In addition, many of the current analyzers do auto sampling directly from tubes

TABLE 1.1

REPRODUCIBILITY OF BLOOD COUNTING PROCEDURES

	Two Coefficients of Variation	
Cell Type Counted	Hemocytometer[a] (%)	Automated Hematology Analyzer (%)
Red cells	±11.0	±1.0
White cells	±16.0	±1.5
Platelets[b]	±22.0	±2.0
Reticulocytes	±33.9	±5.0

[a]Minimum error. Usual error.
[b]Error may be greater with low ($<35 \times 10^9$/L) or very high ($>450 \times 10^9$/L) platelet counts.
Data derived from Bentley S, Johnson A, Bishop C. A parallel evaluation of four automated hematology analyzers. Am J Clin Pathol 1993;100:626–632[14] and Wintrobe M. A simple and accurate hematocrit. J Lab Clin Med 1929;15:287–289[15].

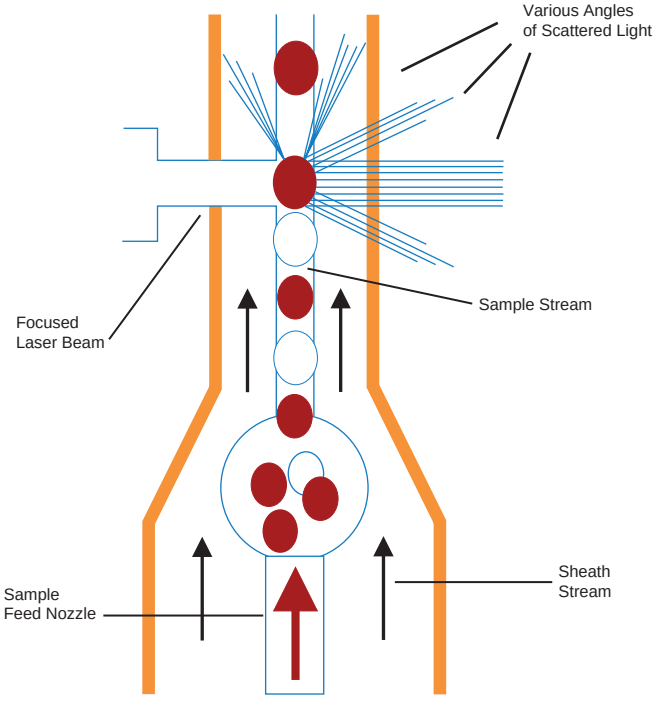


FIGURE 1.1. Optical flow cytometric type of automated hematology analyzer. A suspension of cells is passed through a flow chamber and focused into a single cell sample stream. The cells pass through a chamber and interact with a laser light beam. The scatter of the laser light beam at different angles is recorded, generating signals that are converted to electronic signals giving information about cell size, structure, internal structure, and granularity. (Adapted and redrawn from Cell-Dyn 3500 Operator's Manual. Santa Clara, CA: Abbott Diagnostics, 1993.)

and use a very small sample ranging from 35 to 150 μl for a full CBC analysis. Using flow cytometric technologies, some analyzers also have the ability to detect specific blood cell populations by specific antigen expression, such as detection of CD34 peripheral blood stem cells or leukemic blasts.[24–26] Integration of data from cytochemical or antigenic staining and light scatter properties has improved the accuracy of the five-part differential and decreased the numbers of unidentifiable cells requiring technician review for identification.

Instruments from Abbott Laboratories (CELL-DYN),[16,27] Horiba Medical (ABX Pentra series), and Sysmex (XE series, XT series, and XS series)[16,28,29] primarily utilize fluorescent-based flow cytometry as the modality for analysis. Each system has slightly different fluorochrome staining combinations that aid in the identification of white cells, red cells, and platelets in combination with light scatter characteristics. All provide integrated reticulocyte counts and five-part differentials. Workload capacities range from 70 to 106 samples analyzed per hour. When reticulocytes are ordered as a part of the differential, the capacity falls to between 40 and 60 samples per hour (allowing for the staining and detection of the RNA dye fluorescence). Instruments by Siemens (Advia 120 and 2120 series) use a combination of flow cytometric techniques and a cytochemical peroxidase stain for the five-part differential. This instrument integrates electrical impedance data, flow cytometric light scatter, characteristic fluorescent staining, and cytochemical staining to generate an accurate white blood cell differential. Siemens technology also calculates hemoglobin levels, claiming that this causes less interference by high white blood cell counts or lipemia in the specimen.[16,30,31] Instruments from Beckman/Coulter (Coulter DxH series, LH 500 series, LH 750 series, LH 780 series) also utilize electrical impedance or conductivity in combination with light scatter approaches, integrating these technologies to provide full analysis and five-part differentials (Fig. 1.2). The Beckman/Coulter series includes nucleated RBCs and reticulocyte counts in every differential. Its capacity is 45 samples per hour when reticulocytes are included and 100 samples per hour for a CBC without reticulocyte counts.[16]

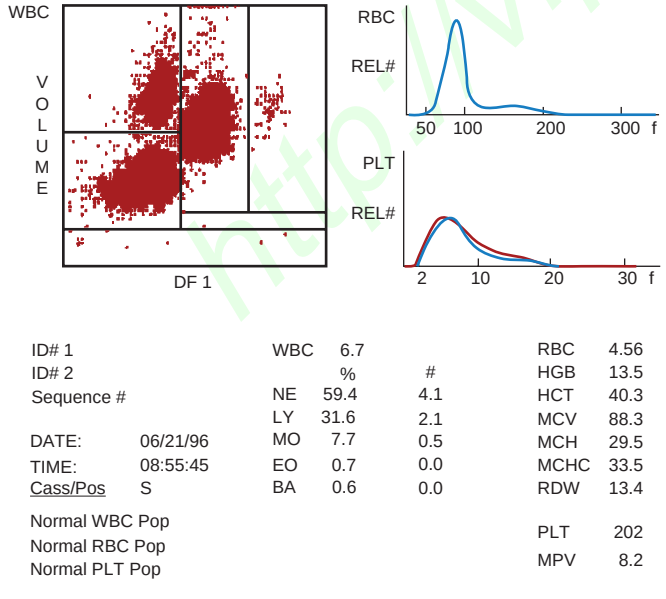

FIGURE 1.2. Histograms and printout generated by the Coulter automated hematology analyzer utilizing light scatter and electrical impedance. BA, basophil; EO, eosinophil; HCT, hematocrit; HGB, hemoglobin; LY, lymphocyte; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; MO, monocyte; MPV, mean platelet volume; NE, neutrophil; PLT, platelet; RBC, red blood cell; RDW, red cell distribution width; WBC, white blood cell.

RED BLOOD CELL ANALYTIC PARAMETERS

RBCs are defined by three quantitative values: the volume of packed red cells or hematocrit (Hct), the amount of hemoglobin (Hb), and the red cell concentration per unit volume. Three additional indices describing average qualitative characteristics of the red cell population are also collected. These are mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). All of these values are routinely collected and calculated by automated hematology analyzers, largely replacing many of the previously used manual or semi-automated methods of RBC characterization, with certain exceptions as noted below. The use of hematology analyzers imparts a high degree of precision compared to manual measurements and calculations (Tables 1.1 and 1.2).

Volume of Packed Red Cells (Hematocrit)

The hematocrit is the proportion of the volume of a blood sample that is occupied by red cells. Hct may be determined manually by centrifugation of blood at a given speed and time in a standardized glass tube with a uniform bore, as was originally described by Wintrobe.[15] The height of the column of red cells after centrifugation compared with total blood sample volume yields the Hct. Macromethods (using 3-mm test tubes) with low-speed centrifugation or micromethods using capillary tubes and high-speed centrifugation may also be used.

Manual methods of measuring Hct are simple and accurate means of assessing red cell status. They are easily performed with little specialized equipment, allowing adaptation for situations in which automated cell analysis is not readily available or for office use. However, several sources of error are inherent in the technique. The spun Hct measures the red cell concentration, not red cell mass. Therefore, patients in shock or with volume depletion may have normal or high Hct measurements due to hemoconcentration despite a decreased red cell mass. Technical sources of error in manual Hct determinations usually arise from inappropriate concentrations of anticoagulants,[32] poor mixing of samples, or insufficient centrifugation.[15] Another inherent error

TABLE 1.2

REPRODUCIBILITY OF RED CELL INDICES

Index	Method Used	% Error (±2 Coefficients of Variation)
Hemoglobin concentration	Spectrophotometric Automated	1.0–2.0 <1.0
Mean corpuscular volume	Hemocytometer Automated	9.5 <1.0
Mean corpuscular hemoglobin	Hemocytometer Automated	10.0 0.6–1.2
Mean corpuscular hemoglobin concentration	Automated	1.0–1.5

Reference and standard procedure for quantitative determination of haemoglobin in blood, 2nd ed. Document H15-A2. Villanova, PA: NCCLS, 1994 and International Committee for Standardization in Haematology. Recommendations for reference method for haemoglobinometry in human blood (ICSH Standard 1986) and specifications for international haemoglobincyanide reference preparation, 3rd ed. Clin Lab Haematol 1987;9:73–79.

in manual Hct determinations arises from trapping of plasma in the red cell column. This may account for 1% to 3% of the volume in microcapillary tube methods, with macrotube methods trapping relatively more plasma.[33,34] It should be noted that abnormal red cells (e.g., sickle cells, microcytic cells, macrocytic cells, or spherocytes) often trap higher volumes of plasma due to increased cellular rigidity, possibly accounting for up to 6% of the red cell volume.[34] Very high Hcts, as in polycythemia, may also have excess plasma trapping. Manual Hct methods typically have a precision coefficient of variation (CV) of approximately 2%.[33]

Automated analyzers do not depend on centrifugation techniques to determine Hct, but instead calculate Hct by direct measurements of red cell number and red cell volume (Hct = red cell number × mean red cell volume). Automated Hct values closely parallel manually obtained measurements, and the manual Hct is used as the reference method for hematology analyzers (with correction for the error induced by plasma trapping). Errors of automated Hct calculation are more common in patients with polycythemia[35] or abnormal plasma osmotic pressures.[36] Manual methods of Hct determination may be preferable in these cases. The precision of most automated Hcts is <1% (CV).[16]

Hemoglobin Concentration

Hemoglobin (Hb) is an intensely colored protein, allowing its measurement by spectrophotometric techniques. Hemoglobin is found in the blood in a variety of forms, including oxyhemoglobin, carboxyhemoglobin, methemoglobin, and other minor components. These may be converted to a single stable compound, cyanmethemoglobin, by mixing blood with Drabkin solution (containing potassium ferricyanide and potassium cyanide).[37,38] Sulfhemoglobin is not converted but is rarely present in significant amounts. The absorbance of the cyanhemoglobin is measured in a spectrophotometer at 540 nm to determine Hb. This technique is used both in manual determinations and automated hematology analyzers. Hb is expressed in grams per deciliter (g/dl) of whole blood. The main errors in measurement arise from dilution errors or increased sample turbidity due to improperly lysed red cells, leukocytosis, or increased levels of lipid or protein in the plasma.[39–41] With automated methods the precision for hemoglobin determinations is <1% (CV).[16]

Red Cell Count

Manual methods for counting red cells have proven to be very inaccurate, and automated counters provide a much more accurate reflection of red cell numbers.[42] Both erythrocytes and leukocytes are counted after whole blood dilution in an isotonic solution. As the number of red cells greatly exceeds the number of white cells (by a factor of 500 or more), the error introduced by counting both cell types is negligible. However, when marked leukocytosis is present, red cell counts and volume determinations may be erroneous unless corrected for white cells. The observed precision for RBC counts using automated hematology analyzers is <1% (CV)[16] compared with a minimum estimated value of 11% with manual methods.[42]

Mean Corpuscular Volume

The average volume of the red blood cell is a useful parameter that is used in classification of anemias and may provide insights into pathophysiology of red cell disorders.[43–45] The MCV is usually measured directly with automated instruments but may also be calculated from the erythrocyte count and the Hct by means of the following formula[15]:

$$\text{MCV} = \text{Hct (L/L)} \times 1{,}000/\text{red cell count } (10^{12}/\text{L})$$

The MCV is measured in femtoliters (fl, or 10^{-15} L). Using automated methods, this value is derived by dividing the summation of the red cell volumes by the erythrocyte count. The CV in most automated systems is approximately 1%,[16] compared to ~10% for manual methods.[33]

Agglutination of cells, as in cold agglutinin disease or paraproteinemia, may result in a falsely elevated MCV.[46] Most automated analyzers gate out MCV values above 360 fl, thereby excluding most red cell clumps, although this may falsely lower Hct determinations. In addition, severe hyperglycemia (glucose >600 mg/dl) may cause osmotic swelling of the red cells, leading to a falsely elevated MCV.[36,47]

Mean Corpuscular Hemoglobin

MCH is a measure of the average hemoglobin content per red cell. It may be calculated manually or by automated methods using the following formula[15]:

$$\text{MCH} = \text{hemoglobin (g/L)/red cell count } (10^{12}/\text{L})$$

MCH is expressed in picograms (pg, or 10^{-12} g). Thus, the MCH is a reflection of hemoglobin mass. In anemias secondary to impaired hemoglobin synthesis, such as iron deficiency anemia, hemoglobin mass per red cell decreases, resulting in a lower MCH value. MCH measurements may be falsely elevated by hyperlipidemia,[41] as increased plasma turbidity will erroneously elevate hemoglobin measurement. Centrifugation of the blood sample to eliminate the turbidity followed by manual hemoglobin determination allows correction of the MCH value. Leukocytosis may also spuriously elevate MCV values.[39] The CV for automated analysis of MCH is <1% in most modern analyzers, compared with approximately 10% for manual methods.[33]

Mean Corpuscular Hemoglobin Concentration

The average concentration of hemoglobin in a given red cell volume or MCHC may be calculated by the following formula[15]:

$$\text{MCHC} = \text{hemoglobin (g/dl)/Hct (L/L)}$$

The MCHC is expressed in grams of hemoglobin per deciliter of packed RBCs, representing the ratio of hemoglobin mass to the volume of red cells. With the exception of hereditary spherocytosis and some cases of homozygous sickle cell or hemoglobin C disease, MCHC values will not exceed 37 g/dl. This level is close to the solubility value for hemoglobin, and further increases in Hb may lead to crystallization. The accuracy of the MCHC determination is affected by factors that have an impact on measurement of either Hct (plasma trapping or presence of abnormal red cells) or hemoglobin (hyperlipidemia, leukocytosis).[39] The CV for MCHC for automated methods ranges between 1.0% and 1.5%.[16]

As noted above, the MCV, MCH, and MCHC reflect average values and may not adequately describe blood samples when mixed populations of red cells are present. For example, in sideroblastic anemias, a dimorphic red cell population of both hypochromic and normochromic cells may be present, yet the indices may be normochromic and normocytic. It is important to examine the blood smear as well as red cell histograms to detect such dimorphic populations.[3] The MCV is an extremely useful value in classification of anemias,[16,45,48] but the MCH and MCHC often do not add significant, clinically relevant information. However, the MCH and MCHC play an important role in laboratory quality control because these values will remain stable for a given specimen over time.[49]

Red Cell Distribution Width

The red cell distribution width (RDW) is a red cell measurement that quantitates cellular volume heterogeneity reflecting the range of red cell sizes within a sample.[43,50,51,52] RDW has been proposed to be useful in early classification of anemia as it becomes

abnormal earlier in nutritional deficiency anemias than other red cell parameters, especially in cases of iron deficiency anemia.[43,53] RDW is particularly useful in characterizing microcytic anemia, allowing discrimination between uncomplicated iron deficiency anemia (high RDW, normal to low MCV) and uncomplicated heterozygous thalassemia (normal RDW, low MCV),[43,53–55] although other tests are usually required to confirm the diagnosis.[56] RDW is also useful in identifying red cell fragmentation, agglutination, or dimorphic cell populations (including patients who have had transfusions, have sideroblastic anemias, or have been recently treated for a nutritional deficiency).[53,57]

Reticulocyte Counts

Determination of the numbers of reticulocytes or immature, nonnucleated RBCs that still retain RNA provides useful information about the bone marrow's capacity to synthesize and release red cells in response to a physiologic challenge, such as anemia. In the past, reticulocyte counts were performed manually using supravital staining with methylene blue that will stain precipitated RNA as a dark blue meshwork or granules (at least two per cell), allowing reticulocytes to be identified and enumerated manually.[58] Normal values for reticulocytes in adults are 0.5% to 1.5%, although they may be 2.5% to 6.5% in newborns (falling to adult levels by the second week of life). Because there are relatively low numbers of reticulocytes, the CV for reticulocyte counting is relatively large (10% to 20%).[59]

To increase accuracy of reticulocyte counting, automated detection methods to detect staining allow for many more cells to be analyzed, thereby increasing accuracy and precision of counts.[18,60,61] Most of the newest automated hematology analyzers have automated reticulocyte counting as part of the testing capabilities and allow reticulocyte counts to be included with routine complete blood count parameters. Reticulocytes are detected by a fluorescent dye that binds to RNA. Comparisons of stand-alone instruments and integrated hematology analyzers demonstrate superior accuracy when compared to manual counting methods, with CVs of 5% to 8%.[16,62]

LEUKOCYTE ANALYSIS

White Blood Cell Counts

Leukocytes may be enumerated by either manual methods or automated hematology analyzers. Leukocytes are counted after dilution of blood in a diluent that lyses the RBCs (usually acid or detergent). The much lower numbers of leukocytes present require less dilution of the blood than is needed for red blood cell counts (usually a 1:20 dilution, although it may be less in cases of leukocytopenia or more with leukocytosis). Manual counts are done using a hemocytometer or counting chamber. As with red cell counts, manual leukocyte counts have more inherent error, with CVs ranging from 6.5% in cases with normal or increased white cell counts to 15% in cases with decreased white cell counts. Automated methods characteristically yield CVs in the 1% to 3% range.[16] Automated leukocyte counts may be falsely elevated in the presence of cryoglobulins or cryofibrinogen,[63] aggregated platelets,[64] and nucleated RBCs, or when there is incomplete lysis of red cells, requiring manual counting. Falsely low neutrophil counts have also been reported due to granulocyte agglutination secondary to surface immunoglobulin interactions.[65,66]

Leukocyte Differentials

White cells are analyzed to find the relative percentage of each cell type by a differential leukocyte count. Uniform standards for performing manual differential leukocyte counts on blood smears have been proposed by the CLSI[67] to ensure reproducibility of results between laboratories. It is important to scan the entire blood smear at low power to ensure that all atypical cells and cellular distribution patterns are recognized. In wedge-pushed smears, leukocytes tend to aggregate in the feathered edge and side of the blood smear rather than in the center of the slide. Larger cells (blasts, monocytes) also tend to aggregate at the edges of the blood smear.[68] Use of coverslip preparations and spinner systems tends to minimize this artifact of cell distribution. For wedge-pushed smears, it is recommended that a battlement pattern of smear scanning be used in which one counts fields in one direction, then changes direction and counts an equal number of fields before changing direction again to minimize distributional errors.[67]

In manual leukocyte counts, three main sources of error are found: distribution of cells on the slide, cell recognition errors, and statistical sampling errors. Poor blood smear preparation and staining are major contributors to cell recognition and cell distribution errors.[69] Statistical errors are the main source of error inherent in manual counts, due to the small sample size in counts of 100 or 200 cells. The CV in manual counts is between 5% and 10% and is also highly dependent on the skill of the technician performing the differential. Accuracy may be improved by increasing the numbers of cells counted, but for practical purposes, most laboratories will do a differential on 100 white cells.[70,71]

Automated leukocyte differentials markedly decrease the time and cost of performing routine examinations as well as increasing accuracy to a CV of 3% to 5%.[70,71,72] However, automated analysis is incapable of accurately identifying and classifying all types of cells and is particularly insensitive to abnormal or immature cells. Therefore, most analyzers will flag possible abnormal white cell populations, indicating the need for examination by a skilled morphologist for identification.[72] The capacity for performing automated leukocyte differentials is incorporated into hematology analyzers, which identify cells on the basis of cellular size, cell complexity, or staining characteristics as part of the complete blood count, allowing for generation of a five-part differential count that enumerates neutrophils, monocytes, lymphocytes, eosinophils, and basophils.[16]

Most systems perform cell counts on specimens via continuous-flow cytometric analysis of blood samples in which the red cells have been lysed and white cells fixed. The cells are suspended in diluent and passed through an optical flow cell in a continuous stream so that single cells are analyzed for cell size (forward scatter) and complexity (dark-field light scatter) (Fig. 1.1) or cytochemical characteristics of myeloperoxidase staining (bright-field detector). The data are plotted as a scattergram (Fig. 1.2), which allows white cells to be divided into a five-part differential (neutrophils, lymphocytes, monocytes, eosinophils, and basophils) and also indicates large unstained or unclassified cells. Lymphocytes are characterized as small (low-scatter) unstained cells. Larger atypical lymphocytes, blasts, or circulating plasma cells fall into the larger cell with a low-complexity channel. Neutrophils have higher complexity and appear as larger cells. Eosinophils appear smaller than neutrophils because they tend to absorb some of their own light scatter. Monocytes have lower levels of complexity and are usually found between neutrophils and lymphocytes. To enumerate basophils, which lack specific staining characteristics and are difficult to enumerate with automated flow-through techniques, a basophil-nuclear lobularity channel may be utilized. For this determination, RBCs and WBCs are differentially lysed, leaving bare leukocyte nuclei, with the exception of basophils, which are resistant to lysis and can then be counted based on relatively large cell size due to the retained cytoplasm. Light scatter data obtained from the leukocyte nuclei may also help identify blasts, which have a lower light scatter than do mature

lymphocyte nuclei. Abnormal cell populations will generate a flag, indicating a need for morphologic review of the peripheral smear.[3] Analysis using this technique examines thousands of cells per sample, increasing statistical accuracy.[16]

Most of the current hematology analyzers have settings that will allow for evaluation of very hypocellular specimens, such as body fluids. They may be used for analysis of these fluids for enumeration of red cells and white cells, as well as providing a five-part differential count of the white cells. Because of the sampling of higher numbers of cells in these relatively hypocellular specimens, accuracy of cell counts and differential counting is improved.[30,31,73–75]

A few instruments, such as the Advia 2120 and the Coulter LH755, also have integrated automated blood smear preparation technology allowing smear preparation directly from the tube upon which the CBC analysis is performed. Thus, the tube is loaded once into a single machine to allow for CBC analysis as well as peripheral blood smear preparation.[16] Many manufacturers also have automated slide makers and stainers, which provide wedge smears from up to 80 slides per hour directly from CBC tubes; however, these are generally free-standing instruments separated from the hematology analyzer. The automated push smear technology helps to provide technical uniformity in blood smear preparation as well as staining. However, there is less flexibility in adjusting stain characteristics. These instruments sample directly from the tube, also minimizing handling of samples by technical staff.

In addition to technology that has the ability to make and stain slides, some automated differential technology via imaging is now available. For instance, Sysmex (CellaVision) has an automated image analyzer that by pattern recognition will capture digital images of 100 to 500 cells in a smear and classify them into morphologic categories to provide a five-part differential. Depending on the model utilized, these technologies have the abilities to perform between 20 and 60 automated digital differentials per hour. The systems have the capacity to store images and are useful in training technologists in the recognition of the specific cell types as well as providing an easily accessible means whereby smears obtained at different times from a single patient may be compared morphologically.[76] These systems have limitations in ability to identify morphologically abnormal cells, so specimens with dysplastic changes, unusual morphologic variants, or significant artifacts may not be evaluable or may provide false data.[77,78,79] Often these systems will place a certain percentage of cells in an unclassifiable area, requiring review by a technologist for definitive identification of the cell type and completion of the differential. As microscopy is automated, there is a uniform scanning of each slide and images are presented on a computer screen, decreasing technician microscope time and scanning pattern variability, and also allowing for the ability to greatly enlarge digitally captured images.[78,80]

PLATELET ANALYSIS

Platelets are anucleate cytoplasmic fragments that are 2 to 4 μm in diameter. As with the other blood components, they may be counted by either manual or automated methods. Manual methods involve dilution of blood samples and enumeration in a counting chamber or hemocytometer using phase contrast microscopy. Sources of error are similar to other manual counting techniques and include dilution errors and low numbers of events counted. The CV, especially in patients with thrombocytopenia, may be >15%.[81,82] Platelets are counted in automated hematology analyzers after removal of red cells by sedimentation or centrifugation, or using whole blood. Platelets are identified by light scatter, impedance characteristics, or platelet antigen staining.[16,83] These give highly reliable platelet counts with a CV of <2%. Falsely low platelet counts may be caused by the presence of platelet clumps or platelet agglutinins[64] or adsorption of platelets to leukocytes.[84,85] Fragments of red or WBCs may falsely elevate the automated platelet count, but this usually gives rise to an abnormal histogram that identifies the spurious result.[86,87]

Automated hematology analyzers also determine mean platelet volume (MPV), which has been correlated with several disease states.[88,89,90] In general, MPV has an inverse relationship with platelet number, with larger platelet volumes (secondary to new platelet production) seen in thrombocytopenic patients in whom platelets are decreased due to peripheral destruction (as in idiopathic thrombocytopenic purpura).[90,91,92] MPV is also increased in myeloproliferative disorders.[93] However, it should be noted that platelets tend to swell during the first 2 hours in EDTA anticoagulant, shrinking again with longer storage.[94,95] Decreased MPV has been associated with megakaryocytic hypoplasia and cytotoxic drug therapy.[96]

Reticulated platelets are newly released platelets that retain residual RNA, analogous to red cell reticulocytes. Reticulated platelet counts give an estimate of thrombopoiesis and may be useful in distinguishing platelet destruction syndromes from hypoplastic platelet production.[97,98] Reticulated platelets can be detected by flow cytometric methods using thiazole orange dyes that bind to RNA[99] or by automated hematology analyzers,[100,101] although they are not routinely measured. Normal values vary between 3% and 20%, and 2.5- to 4.5-fold increases in reticulated platelet counts are seen in the clinical setting of idiopathic thrombocytopenic purpura.[102] Increased reticulated platelets may herald the return of platelet production after chemotherapy.[103]

ADVANTAGES AND SOURCES OF ERROR WITH AUTOMATED HEMATOLOGY

Clearly, the use of automated hematology analyzers has reduced laboratory costs and turnaround time coincident with improving the accuracy and reproducibility of blood counts. The CV for most of the parameters measured is in the range of 1% to 2%. This level of reproducibility is not achievable with the use of most manual techniques (Tables 1.1 and 1.2).

Despite this high degree of accuracy, several potential errors may invalidate automated collection of data. Proper calibration of instrumentation is essential for collection of accurate data. Faulty current settings, which determine threshold counting values as well as variation in either the counting volumes or flow characteristics of a sample, negatively affect data accuracy. Electrical or mechanical failures as well as minor voltage fluctuations may induce marked errors in data collection. Careful calibration of the instrumentation initially, followed by frequent evaluation of reproducibility by analysis of samples with known cell concentrations, is an essential quality control measure.[104] Reference methods for instrument calibration have been developed by both the NCCLS and the ICSH and are widely used by hospital and clinical laboratories to ensure regulatory compliance.[49,67,105]

Certain disease states are also associated with spuriously high or low results, although some of these are specific to a particular type of instrumentation (summarized in Table 1.3). Therefore, the individual values obtained from the automated hematology analyzer must be interpreted in context with the clinical findings. In addition, careful examination of the stained blood film often imparts additional information that may not be reflected in the average values that constitute the automated data. For example, decreased red blood cell counts, macrocytosis, and extremely high MCHC have been observed in patients with cold agglutinin disease with a higher thermal amplitude and in some patients with elevated serum viscosity.[63] High levels of paraprotein may lead to falsely elevated hemoglobin levels, therefore affecting MCH and

TABLE 1.3

DISORDERS AND CONDITIONS THAT MAY REDUCE THE ACCURACY OF BLOOD CELL COUNTING[a]

Component	Disorder/Condition	Effect on Cell Count	Rationale
Red cells	Microcytosis or schistocytes	May underestimate RBC	Lower threshold of RBC counting window is greater than microcyte size
	Howell-Jolly bodies	May spuriously elevate platelet count (in whole blood platelet counters only)	Howell-Jolly bodies are similar in size to platelets
	Polycythemia	May underestimate RBC	Increased coincidence counting
White cells	Leukocytosis	Overestimate RBC	Increased coincidence counting
	Acute leukemia and chronic lymphocytic leukemia, viral infections	May spuriously lower WBC	Increased fragility of leukocytes, including immature forms
	Chemotherapy of acute leukemia	May artifactually increase platelet count	Leukemic cell nuclear or cytoplasmic fragments identified as platelets
Platelets	Platelet agglutinins	May underestimate platelet count, sometimes with spurious increase in WBC	Platelet clumping Aggregates may be identified as leukocytes
Plasma	Cold agglutinins	May underestimate RBC with spurious macrocytosis	Red cell doublets, triplets, and so forth have increased volume
	Cryoglobulins, cryofibrinogens	Variation in platelet count	Protein precipitates may be identified as platelets

RBC, red blood cell count; WBC, white blood cell count.
[a]Some of these examples affect counts only when certain instruments are used. The effects depend on dilution, solutions used, and specimen temperatures.

MCHC calculations.[40] Older analyzers reported spurious increases in hemoglobin levels when white cell counts exceeded 30×10^9/L due to increased turbidity, but this is decreased with newer flow systems so that hemoglobin levels remain extremely accurate in the face of white blood cell counts as high as 100×10^9/L.[16] Extremely high white cell counts may also falsely raise the red cell count and Hct as the white cell count is incorporated into the red cell count. High glucose levels (>400 to 600 mg/dl) and the associated hyperosmolarity cause red cell swelling and generate a high MCV and Hct with a falsely low MCHC.[36,106] Increased turbidity associated with hyperlipidemia may also cause falsely elevated hemoglobin determinations, MCH, and MCHC.[41]

Despite the high level of accuracy and precision, the automated hematology analyzers usually have data that create a warning flag in 10% to 25% of samples, requiring manual examination of the blood smear.[3,4,16,107] Blood smear examination still plays an important role in characterizing these samples or showing findings outside the preset parameters for the laboratory. In addition, some cells require morphologic examination to identify, such as Sézary cells,[108] and red cell morphology is best analyzed by direct smear examination.[45,48]

MORPHOLOGIC ANALYSIS OF BLOOD CELLS

Careful evaluation of a well-prepared blood smear is an important part of the evaluation of hematologic disease. Although a specific diagnosis may be suggested by the data obtained from an automated hematology analyzer, many diseases may have normal blood counts but abnormal cellular morphology. Examples of abnormal red cells that may be seen in the peripheral blood smear examination and which are associated with specific disease states are found in Table 1.4. However, morphologic analysis may be greatly hampered by poorly prepared or stained blood smears. Preparation of satisfactory blood smears requires careful attention to preparation of the blood smear and staining techniques and familiarity with the morphologic appearances of normal and pathologic cells.

Preparation of Blood Smears

Blood films may be prepared on either glass slides or coverslips. Each method has specific advantages and disadvantages.[2,109,110,111] Blood smears are often prepared from samples of anticoagulated blood remaining after automated hematologic analysis or prepared at the time of analysis. However, artifacts in cell appearance and staining may be induced by anticoagulant.[11] Optimal morphology and staining are obtained from nonanticoagulated blood, most often from a fingerstick procedure. Mechanical dragging of the cells across the glass of the slide or coverslip and uneven distribution of blood may also distort the cells; however, these artifacts may be minimized with proper technique.[2]

Coverslip smears (Fig. 1.3A) are prepared using a good grade of flat, no. 1, 0.5-inch square (or 22 × 22 mm) coverslips that are free of lint, dust, and grease. Such coverslips allow optimal spreading of the blood over the surface and minimal artifact. Usually, high-quality coverslips do not require additional cleaning, although there may be some deterioration with age. Plastic "nonwettable" coverslips are not satisfactory for these preparations. The smear is prepared by holding the coverslip by two adjacent corners between the thumb and index finger. A small drop of either fresh or anticoagulated blood is placed in the center of the coverslip. The size of the drop of blood is critical. If the drop is too large, a thick smear results. If the drop of blood is too small, a very thin smear is obtained. A second coverslip is then grasped in a similar fashion with the other hand, placed across the first coverslip, and rotated 45° with a steady, rapid, and gentle motion. The two coverslips are then immediately pulled apart and allowed to air dry. If done properly, this procedure produces two coverslips with even dispersion of blood without holes or excessively thick areas.[112,113]

Blood smears may also be prepared on clean glass slides by the wedge method (Fig. 1.3B). This often leads to irregular distribution of cells on the slide, a distinct disadvantage over the coverslip procedure. However, glass slides are less fragile, are easier to handle, and may be labeled more easily than coverslips. To prepare a slide blood smear, a drop of blood is placed in the middle of the slide approximately 1 to 2 cm from one end. A second spreader slide is placed at a 30° to 45° angle and moved

TABLE 1.4

PATHOLOGIC RED CELLS IN BLOOD SMEARS

Red Cell Type	Description	Underlying Change	Disease State Associations
Acanthocyte (spur cell)	Irregularly spiculated red cells with projections of varying length and dense center	Altered cell membrane lipids	Abetalipoproteinemia, parenchymal liver disease, postsplenectomy
Basophilic stippling	Punctuate basophilic inclusions	Precipitated ribosomes (RNA)	Coarse stippling: Lead intoxication, thalassemia
			Fine stippling: A variety of anemias
Bite cell (degmacyte)	Smooth semicircle taken from one edge	Heinz body pitting by spleen	Glucose-6-phosphate dehydrogenase deficiency, drug-induced oxidant hemolysis
Burr cell (echinocyte) or crenated red cell	Red cells with short, evenly spaced spicules and preserved central pallor	May be associated with altered membrane lipids	Usually artifactual; seen in uremia, bleeding ulcers, gastric carcinoma
Cabot rings	Circular, blue, threadlike inclusion with dots	Nuclear remnant	Postsplenectomy, hemolytic anemia, megaloblastic anemia
Ovalocyte (elliptocyte)	Elliptically shaped cell	Abnormal cytoskeletal proteins	Hereditary elliptocytosis
Howell-Jolly bodies	Small, discrete, basophilic, dense inclusions; usually single	Nuclear remnant (DNA)	Postsplenectomy, hemolytic anemia, megaloblastic anemia
Hypochromic red cell	Prominent central pallor	Diminished hemoglobin synthesis	Iron deficiency anemia, thalassemia, sideroblastic anemia
Leptocyte	Flat, waferlike, thin, hypochromic cell	—	Obstructive liver disease, thalassemia
Macrocyte	Red cells larger than normal (>8.5 μm), well filled with hemoglobin	Young red cells, abnormal red cell maturation	Increased erythropoiesis; oval macrocytes in megaloblastic anemia; round macrocytes in liver disease
Microcyte	Red cells smaller than normal (<7.0 μm)	—	Hypochromic red cell (see Chapter 27)
Pappenheimer bodies	Small, dense, basophilic granules	Iron-containing siderosome or mitochondrial remnant	Sideroblastic anemia, postsplenectomy
Polychromatophilia	Grayish or blue hue often seen in macrocytes	Ribosomal material	Reticulocytosis, premature marrow release of red cells
Rouleaux	Red cell aggregates resembling stack of coins	Red cell clumping by circulating paraprotein	Paraproteinemia
Schistocyte (helmet cell)	Distorted, fragmented cell; two or three pointed ends	Mechanical distortion in microvasculature by fibrin strands, disruption by prosthetic heart valve	Microangiopathic hemolytic anemia (disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, prosthetic heart valves, severe burns)
Sickle cell (drepanocyte)	Bipolar, spiculated forms, sickle shaped, pointed at both ends	Molecular aggregation of HbS	Sickle cell disorders, not including S trait
Spherocyte	Spherical cell with dense appearance and absent central pallor, usually decreased diameter	Decreased membrane surface area	Hereditary spherocytosis, immunohemolytic anemia
Stomatocyte	Mouth or cuplike deformity	Membrane defect with abnormal cation permeability	Hereditary stomatocytosis, immunohemolytic anemia
Target cell (codocyte)	Targetlike appearance, often hypochromic	Increased redundancy of cell membrane	Liver disease, postsplenectomy, thalassemia, hemoglobin C disease
Teardrop cell (dacryocyte)	Distorted, drop-shaped cell	—	Myelofibrosis, myelophthisic anemia

Adapted from Kjeldsberg C, Perkins SL, ed. Practical diagnosis of hematologic disorders, 5th ed. Chicago: ASCP Press, 2010.

backward to make contact with the blood drop. The blood drop will spread along the slide edge, and then the spreader slide is moved rapidly forward. This technique creates a film of blood that is 3 to 4 cm long. Artifact may be introduced by irregular edges in the spreader and by the speed at which the spreader is moved. Glass slide preparations have increased incidence of accumulation of the larger white cells at the edges of the film, introducing cellular distribution errors. Fast movement of the spreader results in a more uniformly distributed population of cells.[112,113,114]

Automated techniques for blood smear preparation have also been developed. Two major types of approaches are used: centrifugation and mechanical spreaders. Centrifugation techniques are often most useful when a small number of cells must be concentrated in a small area, as in preparing smears of cells in fluids such as cerebrospinal fluid.[112,115] Mechanical spreaders mimic the manual technique and are useful when large numbers of blood smears are prepared.[116] In general, smears made by automated techniques are often inferior to those made by an experienced technician.

Routine Staining of Blood Smears

Blood smears are usually stained with either Wright or May-Grünwald-Giemsa stains. Both stains are modifications of the Romanowsky procedure.[113,114] The stain may be purchased commercially or may be made in the laboratory. The basic stain is formulated from methylene blue and eosin. Giemsa stains use known quantities of acid bichromate to form the converted azure compounds. The Wright stain formulation uses sodium bicarbonate to convert methylene blue to methylene azure, which stains

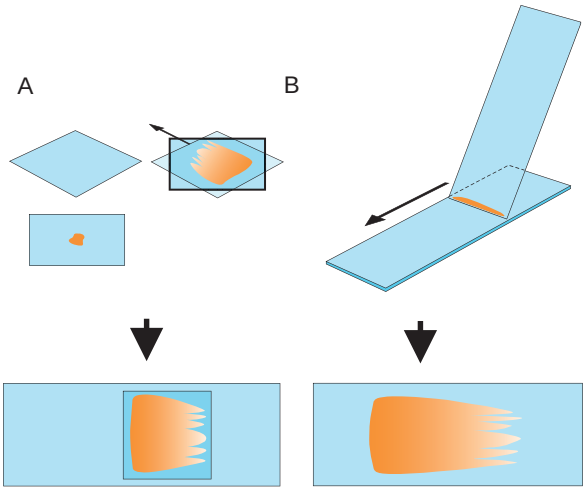

FIGURE 1.3. Preparation of blood smears. Blood smears may be prepared by the coverslip **(A)** or slide wedge method **(B)**. Coverslip smears are prepared by placing a drop of blood in the center of a coverslip and spreading the blood by rotating a second coverslip over it. Wedge smears are prepared by placing a drop of blood on a slide and using a second slide to push the blood out along the length of the slide. (Adapted and redrawn from Bauer J. Clinical laboratory methods, 9th ed. St. Louis: C.V. Mosby, 1982.)

the cell. All types of Romanowsky stains are water insoluble but can be dissolved in methyl alcohol. The stain must be free of water, which induces red blood cell artifacts. Water artifacts may be avoided by fixation of slides or coverslips in anhydrous methanol before staining.[113]

Optimal staining conditions must be established for each new batch of stain. The methylene blue conversion to azure compounds continues to occur while the stain is in the bottle, so staining conditions may change over time. Methyl azures are basic dyes that impart a violet-blue coloration when binding to the acidic components of the cell, such as nucleic acids and proteins. The eosin reacts with the basic cellular elements, imparting a reddish hue to cytoplasmic components and hemoglobin. A properly stained slide has a pink tint. The red cells will have an orange to pink coloration, and leukocytes have purplish-blue nuclei. The Romanowsky stains differentially stain leukocyte granules, which aids in morphologic analysis of the cells. Thus, neutrophil granules are slightly basic and stain weakly with the azurophilic component. The eosinophils contain a strongly basic spermine derivative and stain strongly with eosin. In contrast, basophil granules contain predominately acidic proteins and stain a deep blue-violet. No precipitate should overlie the cells because this indicates use of slides or coverslips that were not cleaned properly. Dust on slides may also induce artifacts. Staining solutions should be filtered or replaced weekly if used heavily to avoid precipitation.[113,114]

Occasionally, an excessive blue coloration of the cells is seen. This may be caused by excessive staining times, improperly prepared or aged buffer that is too alkaline, old blood smears, or blood smears that are too thick. The quality of the staining may be improved by quick and vigorous rinsing with distilled water. If the areas of the slide between cells are staining, it usually indicates inadequate washing of the slide, heparin anticoagulation, or possible paraproteinemia. When the staining appears too pink or red, the usual problem is buffer that is too acidic. This results in pale-stained leukocyte nuclei, excessively orange-RBCs, and bright red eosinophil granules. Other causes of excessive red or pink coloration include inadequate staining times or excessive washing of the slide. Most often, problems with staining are caused by problems with the pH of the solutions, and use of new buffer solutions often corrects the problem.[113]

Examination of the Blood Smear

The blood smear should be initially examined under an intermediate power (10 to 20× objective) to assess the adequacy of cellular distribution and staining. An estimate of the white blood cell count may also be made at this power, and scanning for abnormal cellular elements, such as blasts or nucleated RBCs, can be performed. It is important to scan over the entire blood smear to ensure that abnormal populations, which may be concentrated at the edges of the smear, are not missed. Use of an oil immersion lens (50 or 100×) or high-power dry lens (40×) is usually sufficient for performing leukocyte differential counts, although a 100× oil lens may be necessary for identification of cellular inclusions or abnormal cytoplasmic granules. Systematic evaluation of the blood smear is essential so that all cell types are examined and characterized. Each cell type should be evaluated for both quantitative and qualitative abnormalities.[117,118]

It is difficult to evaluate quantitative abnormalities of red cells on a blood smear; however, the RBCs should be evaluated for variations in size, shape, hemoglobin distribution, and the presence of cellular inclusions. The red cells are usually unevenly distributed throughout the blood film. Optimal red cell morphology is seen in an area of the smear where the red cells are close together but do not overlap. Areas where the red cells are spread too thinly or thickly have increased artifacts. In some blood smears, the red cells appear to stick together, forming what appear to be stacks of RBCs, termed *rouleaux*. This finding may be mimicked in normal patients in areas of the smear where the red cells are too closely packed. However, if rouleaux are seen even in thinner areas of the blood film, it suggests the presence of a paraprotein coating the red cells and causing agglutination due to loss of normal electrostatic repulsion between red cells. Areas of the blood smear that are too thin will have loss of red cell central pallor, mimicking spherocytes.[117]

Red cells should be uniform in size and shape with an average diameter of 7.2 to 7.9 μm. This may be evaluated by use of a micrometer or by comparison with the diameter of a small lymphocyte nucleus, which is approximately the same size or slightly smaller. Variations in red cell size is called *anisocytosis*. Cells that are larger than 9 μm and well hemoglobinated are considered *macrocytes*. Less mature erythrocytes are macrocytic and have a bluish tint to the hemoglobin (polychromatophilia) or have fine basophilic stippling of the cell due to remnant RNA and ribosomes. *Microcytes* are cells with a diameter of <6 μm.[117,118]

Normal erythroid cells are round. Variations in red cell shape are called *poikilocytosis*. The red cell should have a pale central area (central pallor) with a rim of red to orange hemoglobin. Hypochromia reflects poor hemoglobinization and results in a very thin rim of hemoglobin or an increased area of central pallor. Abnormal distribution of hemoglobin may result in formation of a cell with a central spot of hemoglobin surrounded by an area of pallor, called a *target cell*. Abnormal hemoglobins may also form crystals. Spherocytes and macrocytes lack an area of central pallor because of increased thickness of the cell. Red cells may also contain inclusions, such as remnants of nuclear material (Howell-Jolly bodies), remnants of mitochondria or siderosomes (Pappenheimer bodies),[118] or infectious agents (malarial parasites, babesiosis).[119,120] In addition, red cell fragments or *schistocytes* suggestive of red cell mechanical destruction are more easily detected by blood smear examination.[121]

Platelet numbers and morphology are then evaluated. Platelets appear as small blue cytoplasmic fragments with red to purple granules. Platelets are usually 1 to 2 μm in diameter with wide variation in shape. Platelet numbers may be estimated from the blood film. Normal platelet counts should have several (5 to 15) platelets per oil immersion field or approximately 1 platelet for 10 to 20 RBCs.[122] It should be noted that platelets may aggregate if blood is not anticoagulated, properly, or a fingerstick preparation

is used, and this may cause the spurious impression of a low platelet count.[122,123]

Leukocyte morphology and distribution are analyzed last. The number of leukocytes may be estimated by scanning the blood film at an intermediate power. Mechanical effects leading to abnormal distribution of larger cells should be excluded by examination of the edges of the blood film in particular.[2,117] White cells at the edges of the blood smear may appear artifactually smaller (because of cellular shrinkage and poor spreading of the cell) or larger (because of cell disruption and excessive spreading). Care must be taken when making the smear because cells, particularly neoplastic cells, may be more easily disrupted by excessive mechanical pressure than normal leukocytes. Optimal morphology of the leukocytes requires that blood smears be made promptly. Significant artifacts begin to be observed in blood that has been held for several hours and include cytoplasmic vacuolation, nuclear karyorrhexis, and cytoplasmic disruption.[11]

The WBCs normally seen in the blood smear include neutrophils, eosinophils, basophils, lymphocytes, and monocytes. The presence of immature myeloid cells (myelocytes, metamyelocytes, promyelocytes, and blasts) is distinctly abnormal.[118,124,125] At least 100 cells should be identified and counted to yield a manual white blood cell differential.[117,118] In addition to identifying relative populations of white cells by performing a differential count, the cells should be closely examined for morphologic abnormalities of the cytoplasm and nucleus. For example, infection or growth factor therapy often leads to increased prominence of the primary (azurophilic) granules in neutrophils, termed *toxic granulation.*[126,127] In contrast, many myelodysplastic disorders are characterized by hypogranularity of neutrophils in addition to abnormal nuclear segmentation.[128] Cytoplasmic inclusions may be seen in some storage disorders, lysosomal disorders, or infections.[118,120,129]

Other Means of Examining Blood

Occasionally, it is necessary to examine fresh blood as a wet mount. Wet preparations are made by placing a drop of blood on a slide, covering the drop with a coverslip, and surrounding the coverslip with petroleum jelly or paraffin wax to seal the edges. If needed, the blood may be diluted with isotonic saline, or in some cases, it may be fixed with buffered glutaraldehyde for later examination. The blood may then be viewed with light or phase contrast microscopy. Some organisms, such as spirochetes and trypanosomes, may be detected by movement in wet mount preparations although more definitive testing, such as serology or molecular organism detection is more frequently used.[130]

Supravital staining is performed on living motile cells and helps avoid artifacts induced by smear preparation, fixation, and staining.[131] However, such preparations are not permanent, a distinct disadvantage. Supravital stains are often used to detect red cell inclusions. These include crystal violet staining that detects Heinz bodies or denatured hemoglobin inclusions that appear as irregularly shaped purple bodies within the red cell. Brilliant cresyl blue may be used to precipitate and stain unstable hemoglobins, such as hemoglobin Zurich and hemoglobin H.[132] The most commonly used supravital stain is new methylene blue or brilliant cresyl blue, used for manual reticulocyte determinations,[60,133] although the use of automated methods of reticulocyte determination by CBC analyzers has largely replaced manual methods.[61] Reticulocytes are not identified positively on Wright-stained blood smears, although their presence is suggested by polychromatophilia of RBCs. Automated reticulocyte counts may have increased errors in the presence of Heinz bodies [134] or Howell-Jolly bodies [135] in the red cells. Normal reference values for reticulocytes are influenced by patient age, sex, and physical activity level.[136]

BONE MARROW EXAMINATION

Diagnosis and management of many hematologic diseases depend on bone marrow evaluation. Bone marrow examination usually involves two separate, but interrelated, specimens. The first is a cytologic preparation of bone marrow cells obtained by aspiration of the marrow and a smear of the cells, allowing excellent visualization of cell morphology and enumeration of the marrow cellular elements.[137] The second specimen is a needle biopsy of the bone and associated marrow, which allows optimal evaluation of bone marrow cellularity, fibrosis, infections, or infiltrative diseases.[111]

Indications for bone marrow examination include further work-up of hematologic abnormalities observed in the peripheral blood smear; evaluation of primary bone marrow tumors; staging for bone marrow involvement by metastatic tumors; assessment of infectious disease processes, including fever of unknown origin; and evaluation of metabolic storage diseases. Before a bone marrow examination is performed, clear diagnostic goals about the information to be obtained from the procedure should be defined and decisions made about whether any special studies are needed, to ensure that all necessary specimens may be collected and handled correctly.[111]

Several sites may be used for bone marrow aspiration and biopsy.[138,139] In part, the site chosen reflects the normal distribution of bone marrow with the age of the patient. At birth, hematopoietic marrow is found in all of the bones of the body. However, by early childhood, fat cells begin to replace the bone marrow hematopoietic cells in the extremities so that adults have hematopoiesis limited to the axial skeleton and proximal portions of the extremities.[138] Thus, younger children may have marrow examinations from the anterior medial tibial area, whereas adult marrow is best sampled from the sternum at the second intercostal space or from either the anterior or posterior iliac crest areas. Sternal marrows do not allow a biopsy to be performed, and several possible complications, including hemorrhage and pericardial tamponade, may occur if the inner table of the sternum is penetrated by the needle at areas other than the second intercostal space. The sternal marrow space in an adult is only approximately 1 cm thick at the second intercostal space, so care must be taken to avoid penetrating the chest cavity, although sternal bone marrow needles have guards to prevent penetration of the needle beyond the sternal plate. In contrast, little morbidity is associated with iliac crest aspiration and biopsy, and the posterior iliac crest is the most common site for bone marrow sampling.[140] The anterior iliac crest may be used if previous radiation, surgery, or discomfort does not allow a posterior approach.[139]

Bone Marrow Aspiration and Biopsy

Bone marrow is semifluid and easily aspirated through a needle. Many types of needles have been used for performing marrow aspiration. Most are 14 to 18 gauge, and many have a removable obturator, which prevents plugging of the needle before aspiration, and a stylet that may be used to express the bone marrow biopsy sample (Fig. 1.4). Some models, primarily used for sternal bone marrow aspiration procedures, have adjustable guards that limit the extent of needle penetration and reduce morbidity.[140] Most bone marrow needles are disposed of after one use, and specific longer needles that may be used for obese patients and mechanical drills to aid in bone penetration are available commercially.

In most cases, marrow aspiration and biopsy may be carried out with little risk of patient discomfort, provided adequate local anesthesia is used. Apprehensive patients may be sedated before the procedure.[139,141] The procedure is performed under sterile conditions. The skin at the site of the biopsy is shaved,

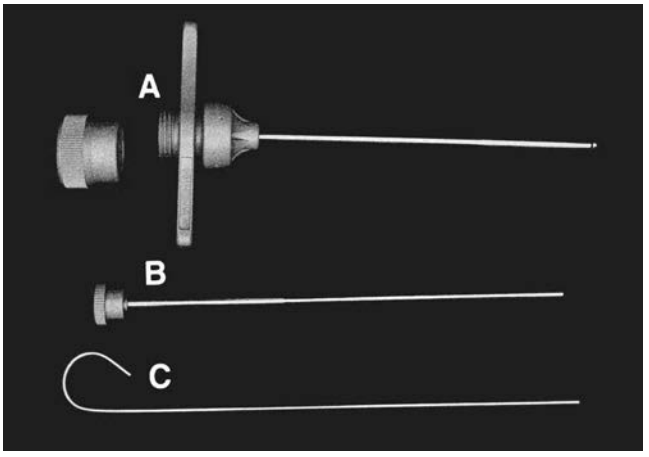

FIGURE 1.4. Jamshidi bone marrow aspiration and biopsy needle. This type of hollow needle with a beveled tip **(A)** is satisfactory for percutaneous biopsy of the bone marrow. The needle is inserted with the obturator **(B)** in place. The biopsy is expressed from the needle using the stylet **(C).**

if necessary, and cleaned with a disinfectant solution. The skin, subcutaneous tissue, and periosteum in the area of the biopsy are anesthetized with a local anesthetic, such as 1% lidocaine, using a 25-gauge needle. Care must be taken to fully anesthetize the periosteum, where most of the bone pain fibers are located. After the anesthetic has taken effect, a small cut is made in the skin overlying the biopsy site, and the marrow aspiration needle is inserted through the skin, subcutaneous tissues, and bone cortex with a slight rotating motion. Entrance of the needle into the bone marrow cavity should be sensed as a slight give or increase in the speed of needle advancement. The needle obturator is removed, and the needle is attached to a 10- or 20-ml syringe. Aspiration of the marrow is achieved by rapid suctioning with the syringe so that 0.2 to 2.0 ml of bloody fluid is obtained. Aspiration may cause a very brief, sharp pain. If no pain is noted and no marrow is obtained, the needle may be rotated and suction applied again. If no marrow is obtained, relocation to another sampling site may be required.[137,139]

The aspirated material is usually given to a technical assistant, who makes smears of the material (Fig. 1.5) and assesses the quality of the material by noting the presence of marrow spicules. The smears must be made quickly to avoid clotting in a manner similar to that described for blood smears using either coverslips or slides to spread the marrow (Fig. 1.3). After smears are made, the aspirate may be allowed to clot to form a histologic clot section for processing. In some cases, where immediate slide preparation is not available, the bone marrow may be aspirated into a tube containing a small amount of anticoagulant to impede clotting. The aspirate may later be filtered and submitted for histologic processing into a particle clot section. EDTA is the best anticoagulant to use because it introduces the least amount of morphologic artifact to the specimen.[137] If additional material is needed for flow cytometry, cytogenetics, culture, or other special studies, additional aspirations may be performed by withdrawing the needle and repositioning it in a new site and drawing marrow into tubes containing anticoagulant. Morphologic examination requires the best sample and the aspirations for ancillary studies should be made subsequent to the initial aspiration for such an examination. Occasionally, a portion of an anticoagulated marrow aspirate is spun down to obtain a buffy coat, thereby concentrating the cellular elements. In some instances, no marrow can be aspirated (dry tap). In these cases, it is essential to make smears from material at the tip of the needle and also to make touch preparations from the biopsy, as outlined below, to allow cytologic examination of the bone marrow elements.[137,139]

The bone marrow biopsy (Fig. 1.6) may be performed using the same skin incision if the aspirate has been performed in the iliac crest area. A separate biopsy needle that is slightly larger than the needle used for aspiration may be used, or the same needle that was used for the bone marrow aspiration may be reused. Care must be taken to reposition the needle biopsy site away from the area where the aspiration was performed to avoid collection of a specimen with extensive artifact induced by the aspiration procedure.[139,142] Use of a biopsy needle may require more pressure to enter the bone because of the larger-bore size. Once the needle is in place in the bone, the stylet may be inserted to give an approximation of the size of the bone core within the needle. The biopsy needle is rotated and gently

The preparation allows for optimal evaluation of cytologic features of the bone marrow precursor cells. **Panel A** (low power) demonstrating distribution of hematopoietic cells near the darkly staining bone marrow spicule in a bone marrow aspirate. **Panel B** (high power) demonstrating cytologic features of bone marrow aspirate hematopoietic cells.

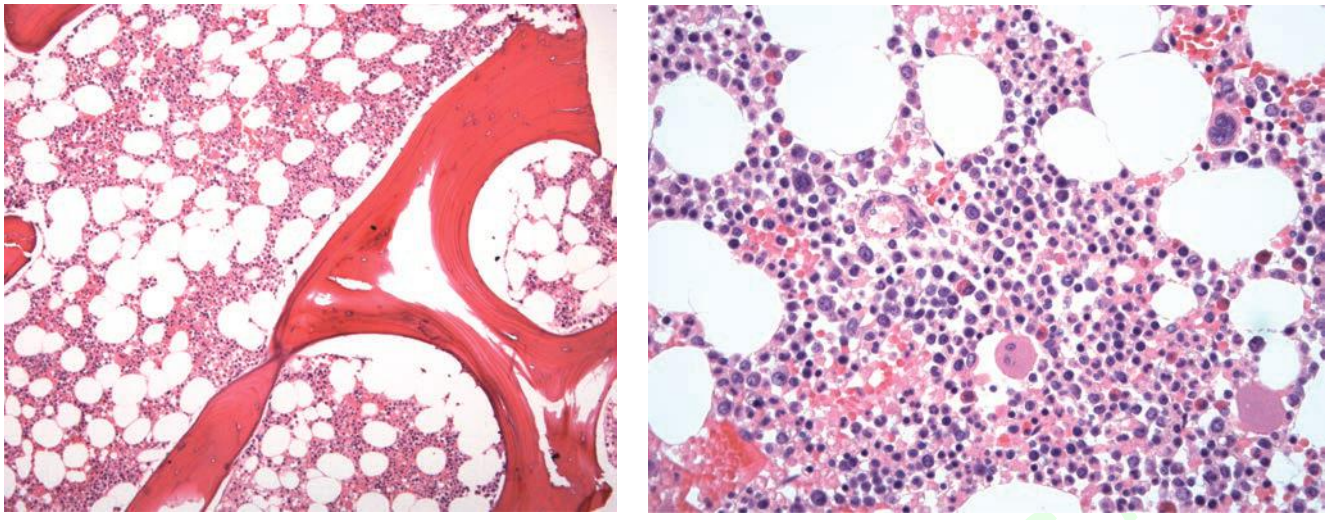

FIGURE 1.6. Bone marrow core biopsy. Histologic preparation of the bone marrow core biopsy following fixation and decalcification. The biopsy is stained with hematoxylin and eosin. This preparation allows for optimal evaluation of bone marrow cellularity and interaction of bone marrow cells with bony trabeculae and is helpful in evaluating extrinsic features such as metastatic tumor or fibrosis in the marrow. **Panel A** (low power) shows bony spicules and marrow in section of bone marrow core biopsy. **Panel B** (high power) shows morphologic detail of hematopoietic tissue within the section.

rocked to free the biopsy from the surrounding bone and then advanced slightly farther. The biopsy is then removed from the bone by withdrawing the needle, and slight positive pressure may be applied using a syringe. The biopsy is expressed from the needle by the stylet. Touch preparations of the bone biopsy should be made, particularly if no aspirate was obtained, to allow cytologic examination of the bone marrow elements. The bony core is then fixed, decalcified, and processed for histologic examination.[138,143] Ancillary testing can often be performed on additional bone marrow cores when no material can be aspirated, so collection of more than one core biopsy may be necessary.

Once the biopsy is completed, manual pressure is applied to the site for several minutes to achieve hemostasis. The site is then bandaged and the patient instructed to remain recumbent so as to apply further pressure for approximately 30 to 60 minutes. If a patient is thrombocytopenic, pressure bandages should be applied and the site checked frequently for prolonged bleeding.

Staining and Evaluation of Bone Marrow Aspirates and Touch Preparations

The bone marrow aspirate or touch preparation slides are stained with either Wright or May-Grünwald-Giemsa stains, similar to blood smears. These stains allow excellent morphologic detail and allow differential counts to be performed. Unstained smears should be retained for possible special stains if indicated.[137,139]

Evaluation of bone marrow aspirates gives little information about the total cellularity of the bone marrow because of fluctuations in cell counts induced by peripheral blood contamination of the bone marrow specimen and preparation artifacts. An overall impression of the cellularity may be given (i.e., cellular or paucicellular). More accurate evaluation of bone marrow cellularity requires examination of the bone marrow biopsy or particle clot section, although the biopsy represents a tiny fraction of the total marrow and may also be subject to sampling error.[111,139,144] The stained aspirate smear will have a central zone of dark marrow particles and stroma surrounded by a thinner area of dispersed bone marrow cells and red cells (Fig. 1.5). Low-power examination allows evaluation of the adequacy of cellularity and of the presence of megakaryocytes. Tumor cells or granulomas may also be seen by scanning the aspirate smear at low power.[137]

The aspirate smear allows cytologic examination of the bone marrow cells. A minimum of 500 nucleated cells should be evaluated under oil immersion magnification in most marrows. Only intact cells are evaluated; all bare nuclei are excluded. Counting is performed in an area where few bare nuclei are present and the cells are not overlapping, found in clusters, or artifactually distorted due to spreading artifact. This is usually in the dispersed cell zone adjacent to the spicule. It should be noted that spicules may be absent in pediatric marrows where marrow cells will be uniformly dispersed. Reference ranges for the percentage of bone marrow cell types vary widely between laboratories and are used only as guides for what is to be expected in normal bone marrow samples[137] (see Table 1.5 for example reference ranges). The proportions of each cell type and progression of the maturational sequence for myeloid and erythroid elements are determined from the differential counts. In addition, the myeloid-to-erythroid ratio may be calculated.

Differences in cell differential results among infants, children, and adults exist (Table 1.6).[137,139,144,145] In general, lymphocytes are more commonly seen in the marrow of children, especially those younger than 4 years of age, where they may compose up to 40% of the marrow cellularity.[146] Plasma cells are rare in the marrow of infants and children. Lymphocytes are much less numerous in adult bone marrows, usually making up <20% of adult marrow cellularity. Lymphocyte and plasma cell counts in adults tend to be quite variable, perhaps reflecting the tendency of these cells to be unevenly distributed in the bone marrow of adults. Often, lymphoid cells are found in nodular aggregates in older adults, and plasma cells tend to be associated with blood vessels.[111]

During the first month of life, bone marrow erythroid cells are prominent because of high levels of erythropoietin[147]; thereafter, the erythroid cells make up 10% to 40% of the marrow cells. Relatively few early erythroid precursors (normoblasts) are usually seen, and more mature forms predominate. Erythroid cells should be examined for abnormalities in morphology as well as iron content as these features are often deranged in pathologic states. Myeloid cells are usually the predominant bone marrow element, and more mature cells predominate over myeloblasts. Children tend to have higher

TABLE 1.5

DIFFERENTIAL COUNTS OF BONE MARROW ASPIRATES FROM 12 HEALTHY MEN

	Mean (%)	Observed Range (%)	95% Confidence (%)
Neutrophilic series (total)	53.6	49.2–65.0	33.6–73.6
Myeloblast	0.9	0.2–1.5	0.1–1.7

Myeloid-to-erythroid ratio	2.3	1.5–3.3	1.1–3.5

numbers of eosinophils and eosinophilic precursor cells than do adults, although many medications or allergies may increase the bone marrow eosinophil count. Megakaryocytes constitute the least abundant cell type seen in the bone marrow, usually making up <1% of the cells.[137,139]

In addition to the hematopoietic cells mentioned above, a variety of other cells may be seen in bone marrow aspirates in varying proportions. These include macrophages, mast cells, stromal cells, and fat cells. In children, osteoblasts and osteoclasts may be seen, although these cells are rare in adults and their presence may indicate metabolic bone disease.[137,139,144] Normally, these other cells make up <1% of the total marrow cellularity; however, they may be increased in a variety of reactive and pathologic processes. Aspirate smears are excellent for evaluation of macrophage hemophagocytosis[148] or storage disorders.[137]

Examination of Bone Marrow Histologic Sections

Bone marrow core biopsies and the clot obtained from the aspiration procedure are usually fixed in formalin or in a coagulative fixative, such as B5 or zinc formalin. The bony core will require decalcification before histologic processing. The fixed materials are processed and embedded in paraffin or plastic, and sections are made for examination. The bone marrow biopsy and clot sections are stained with either hematoxylin and eosin or Giemsa stains for morphologic examination[139,144] (Fig. 1.6).

Bone marrow biopsies are useful in evaluation of the cellularity of the bone marrow sampled. Several caveats must be kept in mind when assessing cellularity. Studies show variations in cellularity even within the same biopsy site[145] as well as between different anatomic sites. However, comparisons of the relative proportions of myeloid, erythroid, and megakaryocytic cells appear to be constant even in widely separated biopsy sites.[139,145] In older patients, the subcortical area is often hypocellular, and care must be taken to obtain a large enough biopsy to allow adequate evaluation of the marrow away from this area.[145] The bone marrow biopsy section provides the best representation of the bone marrow and its anatomic relationships, such as normal localization of immature myeloid cells adjacent to bony trabeculae. Evaluation of nonhematopoietic elements, such as bony trabeculae, blood vessels, and stroma, requires a biopsy specimen.

The clot section, which is prepared from the bone marrow aspirate material, has a degree of inherent artifact because the bone marrow is removed from its normal relationships with bone, blood vessels, and other stromal elements. In particular, cellularity estimations may be falsely elevated secondary to collapse of the normal stromal network in a clot section.[139]

In addition to providing information about the anatomic distribution and relationships of hematopoietic cells, the bone marrow biopsy is useful for evaluation of infiltrative processes such as carcinoma, lymphoma, other tumors, granulomatous inflammation, and fibrosis.[111,139] Occasionally, the marrow is so involved with an infiltrative process that no aspiration can be obtained (dry tap), and the biopsy provides the only diagnostic material.[149,150]

SPECIAL STAINS

Several special stains may be performed on peripheral blood smears, bone marrow aspirate smears, bone marrow touch preparations, and bone marrow biopsy materials and will provide additional information about the cell lineage beyond what is obtained by standard staining with Giemsa or hematoxylin

TABLE 1.6

CHANGES IN DIFFERENTIAL COUNTS OF BONE MARROW WITH AGE

		Birth	1 Mo–1 Y	1–4 Y	4–12 Y	Adult
Neutrophilic series	Mean (%)	60	33	50	52	57
	95% limits	42–78	17–47	32–68	35–69	39–79
Eosinophilic series	Mean (%)	3	3	6	3	3
	95% limits	1–5	1–5	2–10	1–5	1–5
Lymphocytes	Mean (%)	14	47	22	18	17
	95% limits	3–25	34–63	8–36	12–28	10–24
Erythrocytic	Mean (%)	14	8	19	21	0
	95% limits	2–28	2–16	11–27	11–31	10–30
Myeloid-to-erythroid	Mean ratio	4.3	4.0	2.6	2.5	2.6

The means and 95% confidence limits in this table were calculated by combining data published in Osgood EE, Seaman AJ. The cellular composition of bone marrow as obtained by sternal puncture. Physiol Rev 1939;24:105–114, with the data in Table 1.5.

and eosin stains. Special stains generally fall into two categories: cytochemical stains that use cellular enzymatic reactions to impart staining and immunocytochemical stains that identify cell-specific antigen epitopes. These stains are particularly useful in characterization of primary hematologic or metastatic malignancies.

Cytochemical Stains

Cytochemical stains are extremely useful in the diagnosis and classification of acute leukemias, although this utility has been lessened by identification of lineage-specific markers by flow cytometry. They allow identification of myeloid and lymphoid acute leukemias, as well as providing one basis for subclassification of the acute myeloid leukemias. These stains were widely used in morphologic subclassifications, such as the French–American–British (FAB)[151] but with wide usage of flow cytometric and other ancillary tests are not as widely used for classification purposes in the current era of the World Health Organization (WHO) classification.[152] Cytochemical stains are usually performed on peripheral blood films, bone marrow aspirates, or touch preparations made from bone marrow biopsies. Best results are obtained by using freshly obtained materials; however, some reactions may be carried out on materials that are several years old.[153]

Myeloperoxidase

Primary granules of neutrophils and secondary granules of eosinophils contain myeloperoxidase. Monocytic lysosomal granules are faintly positive. Lymphocytes and nucleated RBCs lack the enzyme.[154] Staining is due to oxidation of 3-amino-9-ethylcarbazole or 4-chloro-1-naphthol[155] substrates by myeloperoxidase in the cell to form a brown-colored precipitate.

The myeloperoxidase enzyme is sensitive to light, and smears should be stained immediately or sheltered from light. Enzymatic activity in cells may diminish over time, so the stain should not be performed in blood or marrow aspirate smears older than 3 weeks. Permount coverslip mounting medium (Fisher Scientific, Pittsburgh, PA) may cause fading of the stain. Myeloperoxidase is also sensitive to heat and methanol treatment. Erythroid cells may stain for peroxidase after methanol treatment due to a nonenzymatic interaction between the staining reagents and hemoglobin (*pseudoperoxidase* or *Lepehne reaction*). Antibodies to myeloperoxidase are available for both flow cytometric analysis and immunohistochemical staining in fixed tissue sections.[156]

Sudan Black B

Sudan black B stains intracellular lipid and phospholipids. The pattern of staining closely parallels the myeloperoxidase reaction, with positive staining of granulocytic cells and eosinophils, weak monocytic staining, and no staining of lymphocytes, although some positivity may be seen in azurophilic granules of lymphoblasts. Sudan black B has an advantage over myeloperoxidase in that it may be used to stain older blood or bone marrow smears, and there is little fading of the stain over time.[154]

Specific (Naphthol AS-D Chloroacetate) Esterase

The specific (naphthol AS-D chloroacetate) esterase stain, also called the *Leder stain*, is used to identify cells of the granulocytic series.[154] It does not stain lymphocytes and monocytes. Because of enzymatic stability in formalin-fixed, paraffin-embedded tissues, this stain is extremely useful for identifying granulocytes and mast cells in tissue sections and is particularly helpful in diagnosis of extramedullary myeloid tumors (granulocytic sarcoma, chloroma) of blasts found in tissues.[153] The cellular esterase enzyme hydrolyzes the naphthol AS-D chloroacetate substrate.[154] This reaction product is then coupled to a diazo salt to form a bright red-pink reaction product at the site of enzymatic activity. The enzyme activity is inhibited by the presence of mercury, acid solutions, heat, and iodine that may give rise to false-negative staining results.

Nonspecific (α-Naphthyl Butyrate or α-Naphthyl Acetate) Esterases

Nonspecific (α-naphthyl butyrate or α-naphthyl acetate) esterase stains are used to identify monocytic cells but do not stain granulocytes or eosinophils.[154,157] Mature T-lymphocytes stain with a characteristic focal, dotlike pattern. The stain also reacts with macrophages, histiocytes, megakaryocytes, and some carcinomas. The α-naphthyl butyrate stain is considered to be more specific, although slightly less sensitive, than the α-naphthyl acetate stain.[154] Differential staining with the different esterases is seen in megakaryoblasts, which do not stain with the α-naphthyl butyrate, but stain with the α-naphthyl acetate substrate.[153]

Terminal Deoxynucleotidyl Transferase

Terminal deoxynucleotidyl transferase (TdT) is an intranuclear enzyme that catalyzes the addition of deoxynucleotide triphosphates to the 3′-hydroxyl ends of oligonucleotides or

polydeoxynucleotides without need for a template strand.[158] TdT is found normally in the nucleus of thymocytes and immature lymphoid cells within the bone marrow, but is not found in mature lymphocytes, and it is a useful marker in identifying acute lymphoblastic leukemias and lymphomas.[152] TdT activity is found in approximately 90% of acute lymphoblastic leukemias as well as in a small subset of acute myelogenous leukemias.[159,160] TdT levels may be measured biochemically, by cytochemical staining with an immunofluorescent detection technique, by flow cytometry after permeabilization of freshly collected cells, or by immunohistochemical methods.[161–163] Indirect immunofluorescent staining is very sensitive and may be applied to air-dried samples several weeks after collection, although it is no longer used as often with the widespread use of flow cytometry.[162] Immunohistochemical methods of TdT detection are useful in paraffin-embedded tissue sections and can be used on touch preps.[161]

Leukocyte Alkaline Phosphatase

Alkaline phosphatase activity is found in the cytoplasm of neutrophils, osteoblasts, vascular endothelial cells, and some lymphocytes. The alkaline phosphatase level of peripheral blood neutrophils is quantitated by the leukocyte alkaline phosphatase (LAP) score and is useful as a screening test to differentiate chronic myelogenous leukemia from leukemoid reactions and other myeloproliferative disorders.[164] The LAP score is usually performed using the Kaplow procedure.[165] This method uses a naphthol AS-BI phosphate as the substrate, which is coupled to fast violet B salt by the enzyme to produce a bright red reaction product that is visualized over neutrophils. The LAP score is determined by evaluation of the staining intensity (ranging from 0 to 4+) of 100 counted neutrophils or bands. Normal LAP scores range from 15 to 130, but there may be variation in these ranges between laboratories. Many different disease states may cause elevation or depression of the LAP score (Table 1.7). Patients with chronic myelogenous leukemia have low LAP scores (usually between 0 and 13). Paroxysmal nocturnal hemoglobinuria and some myelodysplastic syndromes may also be characterized by low LAP scores. Leukemoid reactions in response to infection and other myeloproliferative disorders (myelofibrosis with myeloid metaplasia and polycythemia vera) often have an elevated LAP score.[93,164] There is rapid loss of alkaline phosphatase activity in samples drawn in EDTA anticoagulant.[165] The test is optimally performed on fresh capillary blood fingerstick smears or on blood anticoagulated with heparin and should be performed within 48 hours after collection of the sample. The blood smears may be held in the freezer for 2 to 3 weeks with little loss of activity.

TABLE 1.7

CONDITIONS ASSOCIATED WITH ABNORMAL LEUKOCYTE ALKALINE PHOSPHATASE (LAP) SCORES

Low LAP Score (<15)
CML
Paroxysmal nocturnal hemoglobinuria
Hematologic neoplasms (rare)
Myelodysplastic neoplasms
Rare infections or toxic exposures
High LAP Score (>130)
Infections
Growth factor therapy
Myeloproliferative neoplasms other than CML
Inflammatory disorders
Pregnancy, oral contraceptives
Stress
Drugs (lithium, corticosteroids, estrogen)

CML, chronic myelogenous leukemia.

Acid Phosphatase

Acid phosphatase is found in all hematopoietic cells, but the highest levels are found in macrophages and osteoclasts. A localized dotlike pattern is seen in many T-lymphoblasts, but this staining pattern is not reliable. The tartrate-resistant acid phosphatase (TRAP) is an isoenzyme of acid phosphatase that is found in high levels in the cells of hairy cell leukemia [166] and osteoclasts. Several methods of measuring TRAP activity have been described, but one using naphthol AS-BI phosphoric acid coupled to fast garnet GBC is reliable and reproducible.[167] Not all cases of hairy cell leukemia stain for TRAP, and staining intensity may be variable. Positive TRAP staining may also be seen in some activated T-lymphocytes, macrophages, some histiocytes (such as Gaucher cells), mast cells, and some marginal zone lymphomas.[168] TRAP staining may also be detected by immunohistochemical methods in fixed tissue sections.[169]

Periodic Acid–Schiff

The periodic acid–Schiff (PAS) stain detects intracellular glycogen and neutral mucopolysaccharides, which are found in variable quantities in most hematopoietic cells.[154,170] PAS staining is seen in blasts of both acute lymphoblastic and acute myelogenous leukemias, although there is great variability between cases.[170] Erythroleukemias demonstrate an intense diffuse cytoplasmic positivity with PAS, which may be helpful in diagnosis.[152] In addition, PAS staining is very useful in demonstrating the abnormal glucocerebrosidase accumulation in Gaucher disease.[171]

Iron

Cellular iron is found as either ferritin or hemosiderin. It is identified in cells by the Perls or Prussian blue reaction, in which ionic iron reacts with acid ferrocyanide to impart a blue color.[154,170,172] The stain is used to identify iron in nucleated RBCs (sideroblastic iron) and histiocytes (reticuloendothelial iron) or to identify Pappenheimer bodies in erythrocytes. Normally, red cell precursors contain one or more small (<1 μm in diameter) blue granules in 20% to 50% of the cells. When increased numbers of these granules surround at least two thirds of the nucleus of the red cell precursor, the cell is called a *ringed sideroblast*.[173] The stain is best used on bone marrow aspirate smears but can also be used on blood films and aspirate clot tissue sections. Decalcification of the bone marrow core biopsy may lead to loss of iron from the cells, leading to a false impression of low iron.

Toluidine Blue

Toluidine blue specifically marks basophils and mast cells by reacting with the acid mucopolysaccharides in the cell granules to form metachromatic complexes. Malignant mast cells or basophils may have low levels of acid mucopolysaccharides and may not react with this stain.[174] Specific immunohistochemical markers, such as staining for mast cell tryptase may be more specific in identification of mast cells than toluidine blue staining.[175]

Immunocytochemical Stains

Immunocytochemical staining is based on the use of an antibody that recognizes a specific antigenic epitope on a cell. There is a high level of specificity. In general, these stains may be applied to

blood smears, bone marrow aspirates, cellular suspensions, or tissue sections. Not all antibody preparations are equally effective on all types of specimens, and staining procedures may vary depending on the specimen type. A wide variety of antibodies specific to hematopoietic cellular antigens is available commercially. Some of the newer antibodies have replaced classical cytochemical stains and may be useful on older or fixed specimens.

Immunocytochemical staining of fresh blood or bone marrow cell suspensions or cell suspensions from tissues and analysis by flow cytometry is a common ancillary testing modality that is employed when a hematologic malignancy is suspected.[176,177] The flow cytometer detects both light scatter data and the presence of specific fluorochrome-labeled antibodies that have bound to the cell surface. Use of different fluorochromes can allow more than one antibody to be studied simultaneously on the same cell by means of different excitation wavelengths. The study of these cell-surface markers allows rapid and accurate analysis of lymphomas and leukemias, enumeration of T-cell subsets, and identification of tumor cells. In addition, recent advances have allowed detection of intracytoplasmic or nuclear antigens, such as myeloperoxidase and TdT, by flow cytometric analysis.[176] In many cases, particularly in the acute leukemias, the flow cytometric analysis of an acute leukemia provides important prognostic information that is not available through cytochemical staining and is useful in detection of minimal residual disease.[159,178] Clinical and technical aspects of flow cytometric analysis of hematologic tumors are covered in detail in Chapter 2.

Immunohistochemical staining is the use of specific antibody probes on tissue sections or smears of blood and bone marrow. This allows the localization of a specific antigenic epitope to the cell surface, cytoplasm, or nucleus. The antigen binding may then be detected by immunofluorescence, which requires a special fluorescence microscope, or by enzymatic formation of a colored reaction product linked to the antigen–antibody complex. Immunoenzymatic staining techniques include immunoperoxidase, immunoalkaline phosphatase, and avidin–biotin techniques.[179,180] These procedures allow study of the specimen with standard light microscopy and provide a permanent record of staining that may be re-examined. In the past, the repertoire of antibodies available for use on paraffin-embedded tissues was limited, and many antibodies required frozen sections of fresh tissues to be used. Over time, however, there has been a large increase in the number of antibodies that can be used on fixed and processed tissues.[181,182] Automated immunostaining instruments have become available that allow highly reproducible results and require less technician time and expertise for highly reproducible staining.[179,183]

OTHER LABORATORY STUDIES

Cytogenetic Analysis

Many hematologic malignancies and premalignant conditions are associated with specific cytogenetic changes.[152,184,185,186,187] These include distinctive changes in chromosome number, translocations, and inversions of genetic material. These chromosomal changes are often associated with activation or increased transcription of oncogenes and may contribute to acquisition of a malignant phenotype.[188] Cytogenetic analysis is an important element in the diagnosis of hematologic disorders, identifying specific prognostic subgroups, and monitoring for progression of disease or residual disease after therapy, and is integral to the most current classification of hematologic malignancies, such as the WHO classification.[152,159,189,190,191] Both standard chromosomal preparations and fluorescent-labeled in situ hybridization techniques may be used for cytogenetic analysis of chromosomal changes.[192,193] Further details about cytogenetic techniques and analysis are provided in Chapter 3.

Molecular Genetics

In addition to standard morphologic analysis and cytogenetics, technology has been developed that allows analysis of molecular changes in hematologic malignancies.[189,190,194,195] By use of Southern blot and polymerase chain reaction (PCR) techniques, hematopoietic proliferations may be studied for genetic alterations associated with the development of malignancy.[196] Molecular genetic analysis was initially used to identify monoclonality in lymphoid neoplasms by identifying either immunoglobulin (B-cell) or T-cell-receptor gene rearrangements.[197,198] This finding is extremely useful in classification of lymphoproliferative disorders that may be difficult to diagnose on morphologic grounds alone or that lack specific phenotypic markers.[197] In the past few years, there has been an explosion in the use of molecular techniques to detect translocations that previously had been detected only by conventional cytogenetics. Common tests include the *BCR-ABL1* translocations seen in chronic myelogenous leukemia and acute leukemia and used to monitor efficacy of treatment,[189,199] *BCL2* translocations characteristic of follicular lymphomas,[200] the t(15;17) translocation associated with acute promyelocytic leukemia,[201,202] *JAK2* translocations associated with myeloproliferative disorders,[203,204] and *NPM1* and *FLT3* mutations, which are prognostic factors in acute myeloid leukemia.[205–207] In chronic myelogenous leukemia, *BCR-ABL1* kinase domain mutation analysis can be performed to detect mutations that lead imatinib resistance[208,209]. As molecular characterization and genetic profiling of specific hematologic disorders expand, such as through microarray analysis,[210–212] it may be anticipated that more PCR and molecular tests will be developed. Molecular studies have an advantage over conventional morphologic and cytogenetic analyses in that they may detect very small populations of malignant cells (as few as 1% to 5% of the cells in a sample), may allow for quantification of low levels of transcripts to allow monitoring of disease status, and can lead to more rapid test completion (especially with PCR-based testing).[199,201] Molecular tests are most useful when a known specific entity is being tested for or in monitoring residual disease as they do not provide effective screening capability for additional genetic alterations that may affect prognosis, as does conventional cytogenetic analysis.[184,192,213]

The high degree of sensitivity makes molecular testing, particularly by PCR or in situ hybridization, very attractive for the purpose of monitoring for tumor persistence or recurrence after therapy. Previously, molecular genetic studies required collection of fresh or frozen diagnostic material; however, many of the newer assays can make use of formalin-fixed materials with sensitivity similar to that of fresh or frozen materials.[214,215] This allows analysis to be performed on a wider range of cases, including archival materials. The topic of molecular genetics is covered in further detail in Chapter 4.

Electron Microscopy

The electron microscope allows examination of ultrastructural details of a cell. In the past, electron microscopy was used as a research tool and, occasionally, as a diagnostic tool for difficult hematologic diagnoses. However, with the advent of increasing numbers of specific immunocytochemical stains, the use of the electron microscope as a diagnostic tool for hematopathologic processes has been largely discontinued.

Erythrocyte Sedimentation Rate

The erythrocyte sedimentation rate (ESR) is a common but nonspecific test that is often used as an indicator of active disease. It reflects the tendency of RBCs to settle more rapidly in the face of some disease states, usually because of increases in plasma fibrinogen, immunoglobulins, and other acute-phase-reaction proteins. In addition, changes in red cell shape or

numbers may affect the ESR. Sickle cells and polycythemic disorders tend to decrease the ESR, whereas anemia may increase it. ESR also increases with age in otherwise healthy people (although it tends to fall in adults older than age 75)[216] and tends to be higher in women. People with liver disease, carcinomas, or other serious diseases may have a normal to low ESR because of an inability to produce the acute-phase proteins.[217]

A common cause of ESR elevation is infection, but monoclonal gammopathy must be ruled out in patients who have a persistent unexplained elevation in ESR. Elevated ESRs are also seen with pregnancy, malignancies, collagen vascular diseases, rheumatic heart disease, and other chronic disease states, including human immunodeficiency virus infection.[218–220] The ESR is a poor screening test in asymptomatic individuals, detecting elevations in 4% to 8% of normal adults and, hence, should not be used to screen asymptomatic people for disease.[220] The test is probably best used in the clinical scenario of a patient with vague complaints to aid in the clinical decision to undergo further testing or as a tool to follow the clinical disease course in temporal arteritis, rheumatoid arthritis, polymyalgia rheumatica, or lymphomas.[220]

The ESR is measured by the Westergren or Wintrobe method or by a modification of these tests.[221] Both are measured in millimeters per hour, but the normal values for each method vary because of differences in tube length and shape. Both methods require correction for patient anemia. Several technical variations to the method of ESR determination have been introduced, including micromethods, sedimentation at a 45° angle, and the zeta sedimentation rate. The zeta sedimentation rate measures erythrocyte packing in four 45-second cycles of dispersion and compaction in capillary tubes. This requires a special instrument, the Zetafuge (Coulter Electronics, Hialeah, FL), but gives reproducible results on very small amounts of blood and is not affected by patient anemia.[222]

Plasma and Blood Viscosity

Plasma viscosity measurements are advocated by some authors as being superior to ESR measurements for monitoring disease states, particularly in autoimmune diseases and diseases characterized by the secretion of large amounts of immunoglobulin into the plasma (such as plasma cell dyscrasias).[223] Plasma viscosity measurements have the advantage of no red cell influences on the value obtained and yield a narrower reference range of normal values than observed with ESR.[224] However, plasma viscosity is used more rarely than ESR, probably reflecting clinical familiarity with the latter test. As with ESR, plasma viscosity may increase with age.[223] Direct measurement of acute-phase proteins, such as C-reactive protein, may also be used to monitor the course of inflammatory diseases and cardiac risk.[225,226] However, these tests are usually more expensive than ESR determinations and may not provide sufficient additional clinical information to justify the added expense.[227] Whole blood viscosity measurements are of limited clinical use because the measured blood viscosity may have little bearing on the viscosity of the blood in the circulation. Increased blood viscosity may contribute to the morbidity and mortality of patients with sickle cell disease, polycythemia, and ischemic vascular disease.

Blood Volume Measurement

In most cases, the total number of erythrocytes is closely related to the red cell concentration of the blood or Hct. However, blood volume may not always reflect erythrocyte concentration, including immediately after severe hemorrhage, severe dehydration, or overhydration. To accurately assess the blood volume in these patients, plasma volume or red cell mass or volume must be determined,[44,228] although these tests are rarely performed. The plasma volume is measured by dilution methods using a substance that is confined to the intravascular plasma compartment, such as Evans blue dye,[229] ^{131}I-labeled albumin, or radioactive indium-labeled transferrin, is injected and the volume of distribution calculated from the degree of dilution of the injected substance over 15 to 30 minutes. Radiolabeled albumin is the most commonly used, but corrections must be made because the label is gradually removed from the circulation into the extravascular space, leading to errors of 10% or more in plasma volume determinations.[230] Plasma volume may also be estimated from red cell volume.[231]

Total red cell volume is calculated by the Ashby technique, which uses radiolabeled RBCs. A number of radioisotopes may be used, but ^{51}Cr and ^{99}mTc are the most common. Biotinylated cells may also be used.[232] The red cell volume is then calculated by the dilution of the labeled cells over time using the following formula:

$$\text{Red cell volume} = \frac{\text{cpm of isotope injected}}{\text{cpm/ml red cell concentration per unit volume in sample}}$$

Usually, the measurements are made after a 15-minute interval, although longer periods may be needed with high blood viscosity due to high Hcts to ensure complete labeled cell mixing. Total red cell volume measurements must be corrected with splenic enlargement secondary to sequestration of the labeled cells within this organ. Red cell volume may also be calculated from the total plasma volume and measured Hct by means of the following equation:

$$\text{Red cell volume} = \text{Hct} \times \text{plasma volume}/100 - \text{Hct}$$

Total plasma volume may be useful in monitoring fluid and blood replacement. Red cell volume measurements are used to document true polycythemia, although some authors advocate the use of erythropoietin levels and red cell colony growth as less invasive surrogate tests for red cell volume or red cell mass measurements.[44] Total blood volume may be calculated from the sum of total red cell volume and plasma volume measurements.

CHAPTER 2

CLINICAL FLOW CYTOMETRY

Anna Porwit

DEFINITION

One of the meanings of the word *flow* is "to move with a continual shifting of the component particles." The term cytometry refers to counting (*metry*) cells (*cyto*). Thus, flow cytometry (FCM) is a method that employs a fluid stream to carry cells through a counter. FCM evaluates multiple parameters of individual cells (or other particles) by measuring the characteristics of light they scatter or the photons they emit as they stream through a light source. The strength of this technology lies in its high throughput (measurement of high numbers of cells in short time) and in its ability to capture many parameters per cell, assessing them individually. Currently, the principal applications of FCM in the clinical practice are routine cell counters and immunophenotyping. This chapter focuses on clinical application of FCM in hematology, mainly in diagnosis of hematologic malignancies. However, some functional assays (e.g., phosphorylation, cytokine secretion, apoptotic) that are being introduced into clinical practice are also briefly discussed.

HISTORICAL BACKGROUND

FCM dates back to the work done in Stockholm by T. Caspersson and coworkers, who in the 1930s demonstrated that DNA content, measured by ultraviolet and visible light absorption in unstained cells, doubled during the cell cycle.[1,2] In 1950, Coons and Kaplan reported on the detection of antigens in tissues using fluorescein conjugated antibody methods, which prompted wide use of fluorescence microscopes.[3] In 1953, W. H. Coulter patented the so-called Coulter principle and built the first FCM machine, in which blood cells in saline suspensions passed one by one through a small orifice and were detected by changes of electrical impedance at the orifice.[4] After the first paper in *Science* by M. Fulwyler,[5] the era of standard use of FCM for cell sorting started, beginning with publications from the L.A. Herzenberg Laboratory at Stanford University, CA, USA in the early 1970s.[6] Soon after, the first flow cytometers became commercially available from Becton Dickinson (now BD Biosciences), followed by other companies. FCM came into clinical use in the late 1980s, at first only in specialized laboratories. In the 1990s and early 2000s, three- and four-color analysis became a standard diagnostic method for immunophenotyping of hematologic samples. Many clinical solutions and standardization efforts were initialized by A. Orfao and coworkers, from the University of Salamanca, Spain.[7,8] In 2010, eight- and ten-color FCM became a standard clinical method.[9,10] In research settings, applications using 19-parameter FCM combining 17 fluorescence channels with forward scatter (FS) and side scatter (SS) have been reported.[11]

PRINCIPLES OF FLOW CYTOMETRY

For reliable analysis, the specimen must be in a monodisperse suspension. In a flow cytometer, isotonic fluid is forced under pressure into a tube that delivers it to the flow cell, where a fluid column with laminar flow and a high flow rate is generated (so-called sheath fluid). The sample is introduced into the flow cell by a computer-driven syringe in the center of the sheath fluid, creating a coaxial stream within a stream (the so-called sample core stream). The pressure of the sheath stream hydrodynamically aligns the cells or particles so that they are presented to the light beam one at a time. Flow cytometers measure the amount of light emitted by fluorochromes associated with individual cells or particles (Fig. 2.1). New flow cytometers have three to four lasers.[12] For application in FCM, antibodies are conjugated with fluorochromes, dyes that absorb the light from the laser and emit light at longer wavelengths. The list of fluorochromes commonly used in clinical FCM is given in Table 2.1.[13] The emitted light is focused by a lens onto fiberoptic cables and transmitted to octagonal detectors (Fig. 2.1). Filters in front of each of a series of detectors restrict the light that reaches the detector to only a small particular range of wavelengths (referred to as channels). The sensors convert the photons to electrical impulses that are proportional to the number of photons received and to the number of fluorochrome molecules bound to the cell. The fluorescent emissions are of low intensity and have to be amplified by photomultiplier tubes (PMT). PMTs count the specific photons and the remaining light is reflected to the next filter, where the process is repeated. Thus, most of the cell-associated fluorescence detected in a given channel is emitted by fluorochrome-coupled antibodies or other fluorescent reagents of interest. Electrical impulses from photoelectrons collected by PMTs are converted to digital signals. Acquired FCM data are electronically stored in so-called list-mode files that are a part of the medical record of the patient.[14]

A pair of light scatter channels provides an approximate measure of cell size (FS) and granularity (SS). FS and SS are used to set the threshold for separating debris, erythrocytes, and platelets from viable nucleated cells. Live cells scatter more light than dead and apoptotic cells and therefore have higher FS. SS is collected together with fluorescent light at right angles to the beam and is due to light reflected from internal structures of the cell. Cells with high granularity or vacuoles such as granulocytes or monocytes will have higher SS than ones with no granules such as lymphocytes or blast cells.

Most cells have low numbers of native fluorescent molecules that define their background fluorescence. Some of the light may come from spillover fluorescence emitted by a reagent measured

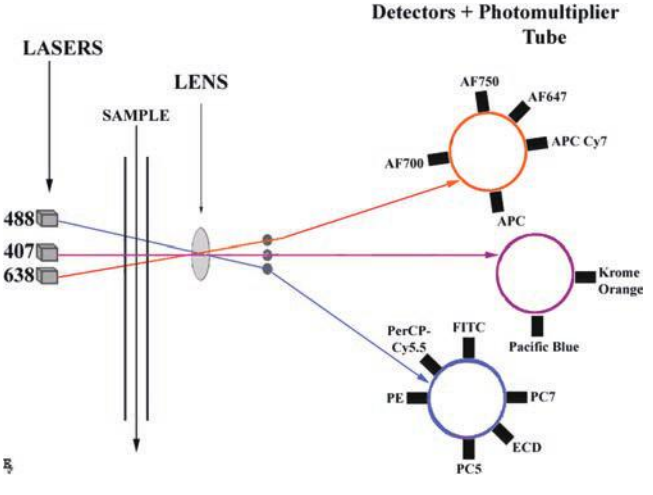

FIGURE 2.1. Principles of multicolor flow cytometry. A single cell suspension is hydrodynamically focused with sheath fluid to intersect lasers (three-laser system is shown). Fluorescence signals are collected by multiple fluorescence emission detectors, separate for every laser. Examples of fluorochromes detected by different lasers are given according to Table 2.1. Detected signals are amplified by photomultiplier tubes and converted to digital form for analysis.

TABLE 2.1

TABLE OF FLUOROCHROMES COMMONLY USED IN CLINICAL FLOW CYTOMETRY

Probe	Ex (nm)	Em (nm)	MW	Acronym/Comments
Reactive and Conjugated Probes				
R-Phycoerythrin	480;565	578	240 k	PE
Red 613	480;565	613		PE-Texas Red
Fluorescein isothiocyanate	495	519	389	FITC
Rhodamine isothiocyanate	547	572	444	TRITC
X-Rhodamine	570	576	548	XRITC
Peridinin chlorophyll protein	490	675		PerCP
Texas Red	589	615	625	TR
Allophycocyanin	650	660	104 k	APC
TruRed	490,675	695		PerCP-Cy5.5
Alexa Fluor 647	650	668	1250	
Alexa Fluor 700	696	719		
Alexa Fluor 750	752	779		
Cyanine 5	(625);650	670	792	Cy5
Cyanine 5.5	675	694	1128	Cy5.5
Cyanine 7	743	767	818	Cy7
PE-TR-X	595	620	625	ECD
PE-Cy5 conjugates	480;565;650	670		Cychrome, Tri-Color, Quantum Red
PE-Cy7 conjugates	480;565;743	767		PE-Cy7
APC-Cy7 conjugates	650;755	767		APC-CY7
Nucleic Acid Probes				
4′,6-Diamidino-2-phenylindole	345	455		DAPI ,AT-selective
SYTOX Blue	431	480	~400	DNA
SYTOX Green	504	523	~600	DNA
Ethidium bromide	493	620	394	
7-Aminoactinomycin D	546	647		7-AAD, CG-selective
Acridine Orange	503	530/640		DNA/RNA
Thiazole Orange	510	530		TO (RNA)
Propidium iodide	536	617	668.4	PI

Em, peak emission wavelength (nm); Ex, peak excitation wavelength (nm); MW, molecular weight.

in a different channel. The interference is corrected by applying fluorescence compensation based on data from single-stained samples. This is usually done using cells or beads before or during the data acquisition phase. However, modern FCM data analysis software also allows collection of uncompensated data and applying compensation during analysis. Before data acquisition, standard reference particles (fluorescent microspheres) should be used to adjust the PMT voltage settings so that the beads fall in approximately the same location or the same "target channels," predetermined for each fluorochrome.

Cell Sorting

Some flow cytometers are capable of physically separating the cells (fluorescence activated cell sorter, FACS) based on differences in any measurable parameters. Sorting is achieved by droplet formation. The basic components of any sorter are:

- A droplet generator
- A droplet charging and deflecting system
- A collection component
- The electronic circuitry for coordinating the timing and generation of droplet-charging pulses

The flow chamber is attached to a piezoelectric crystal, which vibrates at a certain frequency so that when the fluid carrying the cells passes through the nozzle, forming a jet in air with a velocity of 15 m/s, the vibration causes the jet to break up in precisely uniform droplets, approximately 30,000 to 40,000/s. Each droplet, when separated from the jet, can be charged and deflected by a steady electric field and is collected in a receptacle. Almost every cell is isolated in a separate droplet. When the cell is analyzed a sorting decision is made, and until the proper electrical charge pulse is applied to the droplet containing the cell, there is a transit time determined by several factors, such as flow velocity, droplet separation, and the cell preparation. If two cells cannot be separated the sorting is aborted.

Monoclonal Antibodies

Advances of FCM would not be possible without development of monoclonal antibodies (MAbs). By the Nobel Prize winning hybridoma technology developed in 1975 by Köhler and Milstein,[15] lymphocytes from the spleen of an immunized mouse can be immortalized by fusion to myeloma cells that have lost the ability to make their own immunoglobulins (Igs) but are capable of unlimited mitotic divisions. Through limited dilutions, individual

cell lines (hybridomas) that produce an antibody of unique specificity, avidity, and isotype can be established. In the early days of the application of MAbs to immunology, many laboratories were immunizing mice with leukocytes. The obtained hybridomas produced many antibodies that reacted with leukocytes, but the identities of the molecular targets were not known. The reactivity spectrum of the antibody could be described by staining multiple different cell types, and in most cases the target antigen could be isolated by immunoprecipitation or Western blotting and its molecular weight and other structural characteristics determined.

The first round of multilaboratory, blind, comparative analyses of antibodies was performed during the first Human Leukocyte Differentiation Antigen (HLDA) Workshop 1982 in Paris, France.[16] Statistical analysis of data from several laboratories revealed "clusters of differentiation," named for the statistical procedure of cluster analysis and for the focus on leukocyte differentiation. Antibodies thought to be detecting the same molecule, and the molecule itself, were given a "CD" designation.[17] An organization called the Human Leukocyte Differentiation Antigen Council has been established and nine subsequent HLDA workshops have characterized 350 CD antigens. The HLDA council reviewed and modified the objectives of HLDA in 2004, and changed the name of the organization to Human Cell Differentiation Molecules (HCDM). The reasoning behind the name change to HCDM was to break with tradition while retaining the letters "CD," to maintain emphasis on molecules of human origin, to extend focus from leukocytes to other cell types interacting with leukocytes such as endothelial cell or stromal cell molecules, and to broaden the scope from cell-surface molecules to any molecule whose expression reflects differentiation, recognizing the growing values of intracellular molecules. The HCDM council keeps a comprehensive database of CD molecules (www.hcdm.org). CD antigens, which are most often applied in hematologic immunophenotyping are listed in Table 2.2 and are described in Appendix A.

Sample Preparation

Appropriate samples for clinical FCM include peripheral blood (PB), bone marrow (BM) aspirate, disaggregated tissue including lymph node (LN) and other soft tissue biopsies as well as fine needle aspirations (FNA) and BM core biopsies, cerebrospinal fluid (CSF), other body fluids including effusions and lavage fluids, and nuclei from paraffin-embedded tissue for DNA ploidy assays. With the exception of the latter, all other clinical FCM specimens should be considered biohazardous and labeled as such in accordance with national or regional safety standards. A test requisition form, whether printed or electronic, should accompany all specimens. This form should include unique patient identifiers, age, sex, diagnosis (if previously established) or suspect condition under consideration, name of the physician submitting the specimen, pertinent medication or recent treatment (including dates of chemotherapy or radiation), date and time of specimen collection, and source of the specimen (e.g., bone marrow aspirate, CSF, etc.). The requested test should appear on the specimen label or on the requisition accompanying the specimen. Complete blood count (CBC) should be provided for PB and BM samples. For PB, ethylene-diaminetetraacetic acid (EDTA), sodium heparin, or acid citrate dextrose (ACD) may be used. For BM aspirates, sodium heparin is the preferred anticoagulant, and is required if cytogenetic testing is to be performed on the same specimen. All tissue biopsies intended for FCM evaluation, including LN or other tissue biopsies should be transported in an adequate volume of an appropriate transport medium in a sterile container to optimize cell viability. CSF samples should be stabilized or analyzed immediately due to potential toxic effect on cell viability.[18]

All clinical samples should be analyzed as soon as possible. As a general rule, 24 hours is preferred but 48 hours is considered the longest acceptable time frame for analysis. If transport time is longer, a viability report is mandatory and the results should be interpreted cautiously. Room temperature (18°C to 25°C) is recommended for storage and transport. For specimens that are not highly degenerated, nonviable cells can be excluded from the analysis by meticulous FS versus SS gating. Dead cells trap fluorochrome-conjugated antibodies and increase background fluorescence. Fluorescent, DNA-binding dyes (Table 2.1) that are excluded from viable cells with intact plasma membranes and thus positive in nonviable cells, can also be applied.

Whole PB/BM analysis with erythrocyte lysis is recommended for clinical immunophenotyping. Immunophenotyping of density gradient (Ficoll) separated mononuclear cells should not be used due to selective cell loss. For surface(s) staining, the so-called "stain–lyse–wash" method gives the best signal discrimination. Cells are first incubated with appropriate amounts of titrated MAb, then erythrocytes are lysed and cells finally are washed before acquisition. Several commercial lysis reagents, most of which also contain a fixative, are available. Samples to be stained for sIg should be thoroughly washed before incubation with MAb, in order to avoid false negative results due to the presence of serum Igs.

Evaluation of intracellular epitopes, including proteins, epigenetic protein modifications (e.g., protein phosphorylation, methylation, etc.), DNA, or RNA generally require that the target cell population be fixed and permeabilized in order to allow antibodies or target-binding dyes to cross the cytoplasmic and nuclear membranes. Commercial fixation and permeabilization kits, with recommended protocols, are available from several manufacturers.[19,20] For newly developed tests, it is useful to check whether the obtained intracellular staining is associated with an expected localization, using fluorescence microscopy. The specificity of the applied antibody should also be ensured. For cytoplasmic (cyt.) or nuclear (n) staining, it is important to use antibody conjugates that are free of unconjugated fluorochrome molecules that can stick to intracellular proteins nonspecifically. When simultaneous detection of surface and intracellular epitopes is necessary, the surface staining is performed first, then cells are fixed and permeabilized, and finally intracellular epitopes are stained.

Fluorochromes and Panels

Panel selection should be based on specimen type with consideration of information provided by clinical history, medical indication, and morphology.[21] Several guidelines and consensus papers giving lists of antigens proposed for diagnosis of hematologic malignancies have been published.[21,22] Selecting which antibody combinations best delineate, distinguish, and measure key differences within the target populations of interest and the number of simultaneously measured antibodies is a critical step for FCM assays. Serial dilution antibody titrations against both positive and negative cellular targets are necessary for antibody optimization. Choice of fluorochrome conjugate can affect background, specificity, and dynamic range of measurement. Typically, one would choose a fluorochrome with the best quantum efficiency/yield as the antibody conjugate to identify the lowest antigen density so as to obtain the best possible signal-to-noise ratio possible. It is of high importance to reliably distinguish between antigen-positive and antigen-negative cell populations in order to accurately measure the population of positive cells. This can be a challenge in populations of cells weakly expressing antigens. Florescence-minus-one (FMO) controls give the maximum fluorescence expected for a given population in a given channel when the reagent used in that channel is omitted.[23] These controls include both autofluorescence of the cells and the spillover that may be present even after compensation corrections and therefore such controls are best suited to determine boundaries between positive and negative cells for each subset.

TABLE 2.2

LIST OF CD ANTIGENS MOST COMMONLY USED IN FLOW CYTOMETRY IMMUNOPHENOTYPING OF HEMATOLOGIC SAMPLES

CD	Expression in Normal Hematopoietic Cell Types	MW (kD)	Function
CD1a	Cortical thymocytes, Langerhans cells, dendritic cells	49	Antigen presentation, w/β2m
CD2	Thymocytes, T-cells, NK cells	50	CD58 ligand, adhesion, T-cell activation
CD3	T-cells, thymocyte subset		w/TCR, TCR surface expression/signal transduction
CD4	Thymocyte subset, T-cell subset, monocytes, macrophages	55	MHC class II coreceptor, HIV receptor, T-cell differentiation/activation
CD5	Thymocytes, T-cells, B-cell subset	67	CD72 receptor, TCR or BCR signaling, T–B interaction
CD7	Thymocytes, T-cells, NK cells, small subset of hematopoietic progenitors	40	T costimulation
CD8	Thymocyte subset, T-cell subset, NK subset	32–34	MHC class I coreceptor, receptor for some mutated HIV-1, T-cell differentiation/activation
CD9	Eosinophils, basophils, platelets, activated T-cells	22–27	Cellular adhesion and migration
CD10	B-precursors, germinal center B-cells, thymocyte subset, neutrophils	100	Zinc-binding metalloproteinase, B-cell development
CD11a	Lymphocyte subsets, granulocytes, monocytes, macrophages	180	CD11a/CD18 receptor for ICAM-1, -2,-3, intercellular adhesion, T costimulation
CD11b	Granulopoietic cells, NK cells	170	Binds CD54, ECM, and iC3b
CD11c	Dendritic cells, granulopoietic cells, NK cells, and B-cell and T-cell subsets	150	Binds CD54, fibrinogen, and iC3b
CD13	Granulopoietic cells, monocytes	150–170	Zinc-binding metalloproteinase, antigen processing, receptor for corona virus strains
CD14	Monocytes, macrophages, Langerhans cells	53–55	Receptor for LPS/LBP, LPS recognition
CD15	Neutrophils, eosinophils, monocytes		Adhesion
CD16	Neutrophils, macrophages, NK cells	50–65	Component of low-affinity Fc receptor, phagocytosis, and ADCC
CD19	B-cells, plasma cells	95	Complex w/CD21and CD81, BCR coreceptor, B-cell activation/differentiation
CD20	B-cells	33–37	B-cell activation
CD21	B-cells and T-cells subsets	145, 110	Complement C3d and EBV receptor, complex w/CD19 and CD81, BCR coreceptor
CD22	B-cells	150	Adhesion, B-mono, B–T interactions
CD23	B-cells, eosinophils, platelets	45	CD19-CD21-CD81 receptor, IgE low-affinity receptor, signal transduction
CD24	Thymocytes, erythrocytes, lymphocytes, myeloid cells	35–45	Binds P-selectin
CD25	Activated B-cells and T-cells	55	IL-2Rα, w/IL-2Rβ, and γ to form high affinity complex
CD33	Granulopoietic cells, monocytes, dendritic cells	67	Adhesion
CD34	Hematopoietic precursors	105–120	Stem cell marker, adhesion, CD62L receptor
CD36	Platelets, monocytes, erythropoietic precursors	88	ECM receptor, adhesion, phagocytosis
CD38	High expression on B-cell precursors, plasma cells and activated T-cells, low on granulopoietic cells	45	Ecto-ADP-ribosyl cyclase, cell activation
CD41	Platelets, megakaryocytes	125/22	w/CD61 forms GPIIb, binds fibrinogen, fibronectin, vWF, thrombospondin, platelet activation and aggregation
CD42a	Platelets, megakaryocytes	22	Complex w/CD42b, c and d, receptor for vWF and thrombin, platelet adhesion to subendothelial matrices
CD45	Hematopoietic cells, multiple isoforms from alternative splicing	180–240	Tyrosine phosphatase, enhanced TCR and BCR signals
CD56	NK subset, T-cell subset	CD175–185	Neural cell adhesion molecule
CD57	NK subset, T-cell subset	110	HNK-1
CD59	Ubiquitous	18–20	Complement regulatory protein
CD61	Platelets, megakaryocytes	105	Integrin β3, adhesion, CD41/CD61 or CD51/CD61 mediate adhesion to ECM
CD62L	B-cells, T-cells subsets, monocytes, granulocytes, NK-cells, thymocytes	74, 95	CD34, GlyCAM, and MAdCAM-1 receptor, leukocyte homing, tethering, rolling
CD64	Monocytes, neutrophils	72	FCγRI, increases on neutrophils in sepsis
CD65	Granulopoietic cells		Phagocytosis
CD66	Neutrophils	90	Cell adhesion
CD68	Monocytes, neutrophils, basophils, mast cells,	110	Macrosialin

CD	Expression in Normal Hematopoietic Cell Types	MW (kD)	Function
CD71	Proliferating cells, erythroid precursors, reticulocytes	95	Transferrin receptor, iron uptake
CD79	B-cells, plasma cells	33–37	Component of BCR, BCR surface expression and signal transduction
CD103	B- and T-cell subsets	150, 25	w/integrin $\beta 7$, binds E-cadherin, lymph homing/retention
CD117	Hematopoietic progenitors, mast cells	145	Stem cell factor receptor, hematopoietic progenitor development/differentiation
CD123	Basophils, dendritic cell subset, hematopoietic progenitors	70	IL-3Rα, w/CDw131
CD133	Hematopoietic stem cells subset	120	
CD159c	NK	40	w/MHC class I HLA-E molecules, forms heterodimer with CD94
CD235a	Erythropoietic precursors	36	Glycophorin A

For a comprehensive list and characteristics please see www.hcdm.org.

Often the same anchor gating antibodies are used in every tube thereby allowing consistent population gating strategies across all tubes of a panel. In immunophenotyping of lymphocyte subsets and in the diagnosis of leukemia/lymphoma, CD45 anchor gating has been shown to provide differential population identification correlated to morphologic microscopic differentials (Fig. 2.2) [24,25]:

- Mature lymphocytes are characterized by low side scatter and strong CD45 expression (lymph region, Fig. 2.2 plot B).
- Monocytes have higher SS and strong CD45 expression (monocyte region, Fig. 2.2 plot B).
- Erythropoietic precursors are CD45 negative and have low SS (CD45− ery region, Fig. 2.2 plot B).
- Granulopoietic precursors and granulocytes are weakly CD45 positive and have high SS (CD45 dim, gran region, Fig. 2.2 plot B).
- Early hematopoietic precursors of various lineages, including CD34+ stem cells, are characterized by low CD45 expression and low SS (blast region, Fig. 2.2, plot B).

The localization of these subpopulations on the CD45/SS plot can be confirmed by multicolor staining of various lineage-associated antigens together with CD45 (Fig. 2.2, plots C–K) and visualization of cell clusters positive for given antigen combinations on the CD45/SS plot (Fig. 2.2, plot B) by so-called back-gating using color-coding.[25]

In multicolor FCM, lineage-associated antigens that are broadly expressed through maturation of investigated cell lineage can be used for gating in conjunction with SS and CD45 (e.g., CD19 for B-cells, CD3 for T-cells Figs. 2.2 and 2.3). Examples of 10-color panels for leukemia and lymphoma, currently used at the Flow Cytometry Laboratory at the Department of Laboratory Medicine, University Health Network, Toronto General Hospital, Toronto, Ontario, Canada are given in Table 2.3.

Data Analysis and Reporting

Fluorescence data may be presented using either linear or logarithmic amplification. In linear amplification, fluorescence differences are directly proportional to differences of fluorochrome concentration between cells. Logarithmic amplification compresses a wide input range, which may cause difficulties in resolving populations with similar fluorescence intensities. "Logicle" (or "biexponential") displays have recently been designed for the display of FCM data so that they incorporate the useful features of logarithmic displays but also provide accurate visualization of populations with low or background fluorescence.[12] During analysis, data is presented in form of:

- Histograms (for one parameter), where relative fluorescence or scatter is on the x-axis and the number of events with given characteristics on the y-axis
- Two-parameter dot plots, where each signal is visualized by one dot and given a parameter on the x- and y-axes; various cell populations can be then "painted" with different colors
- Density plots, where hotspots indicate large numbers of events resulting from discreet population of cells and colors can give the graph a three-dimensional feel
- Contour diagrams, where joined lines represent similar numbers of cells

New software where multiparameter data can be analyzed using principal component analysis is also available.[9,26]

Analysis is usually focused on identifying and quantifying subsets of cells. Successful analysis will depend on correct marker selection and panel design. Cell counts and percentages are typically reported. The choice of gating strategy depends on the panel used and specific populations of interest. In immunophenotyping of PB and BM, the analysis can be focused on lymphocytes (CD45 bright gate, Fig. 2.4), B-lymphocytes (Fig. 2.3), blasts (CD45 dim gate, Figs. 2.2 and 2.5), T-lymphocytes and natural killer (NK) cells, on monocytes, or include all living cells in the sample (debris excluded). In tissue samples (lymph nodes, FNA, body fluids) a broad lymphocyte gate is usually applied. The parent population should be clearly identified when percentages are reported: a fraction may represent a percentage of all living cells in the sample (debris excluded), a percentage of lymphocytes, a percentage of B-cells, a percentage of T-cells, or a percentage of blasts.

In hematology, assays are usually designed to characterize abnormal cell populations or stages of cell development. In these tests, marker intensities are used to identify the immunophenotype of the cells at various stages of differentiation. Therefore, markers with good dynamic range and proper spillover compensation are critical. Intensity results are typically reported as medians or geometric means. A comparison to control populations either external such as beads or internal such as normal mature cells is often used. If fluorescence intensity is comparable to normal mature cells, it is reported as "normal": positive if it corresponds to normal cells, "dim" if it is weaker than in normal cell population, or "bright" if it is stronger than in normal cells.

Most currently used analysis software allows cross-platform application for analysis and makes it possible to create analysis templates that are a useful tool for assuring that the analysis is always performed in the same way.[9,26] Templates help to include all critical elements, and they can serve as an example of how the analysis should be performed. Due to the highly complex nature of multiparameter analysis, it is recommended that experienced interpreters with knowledge of instrumentation, software, and data analysis produce the templates and supervise the reporting. The final report should contain:

1. Demographic identification of patient
2. Identification of the hospital or division sending the sample

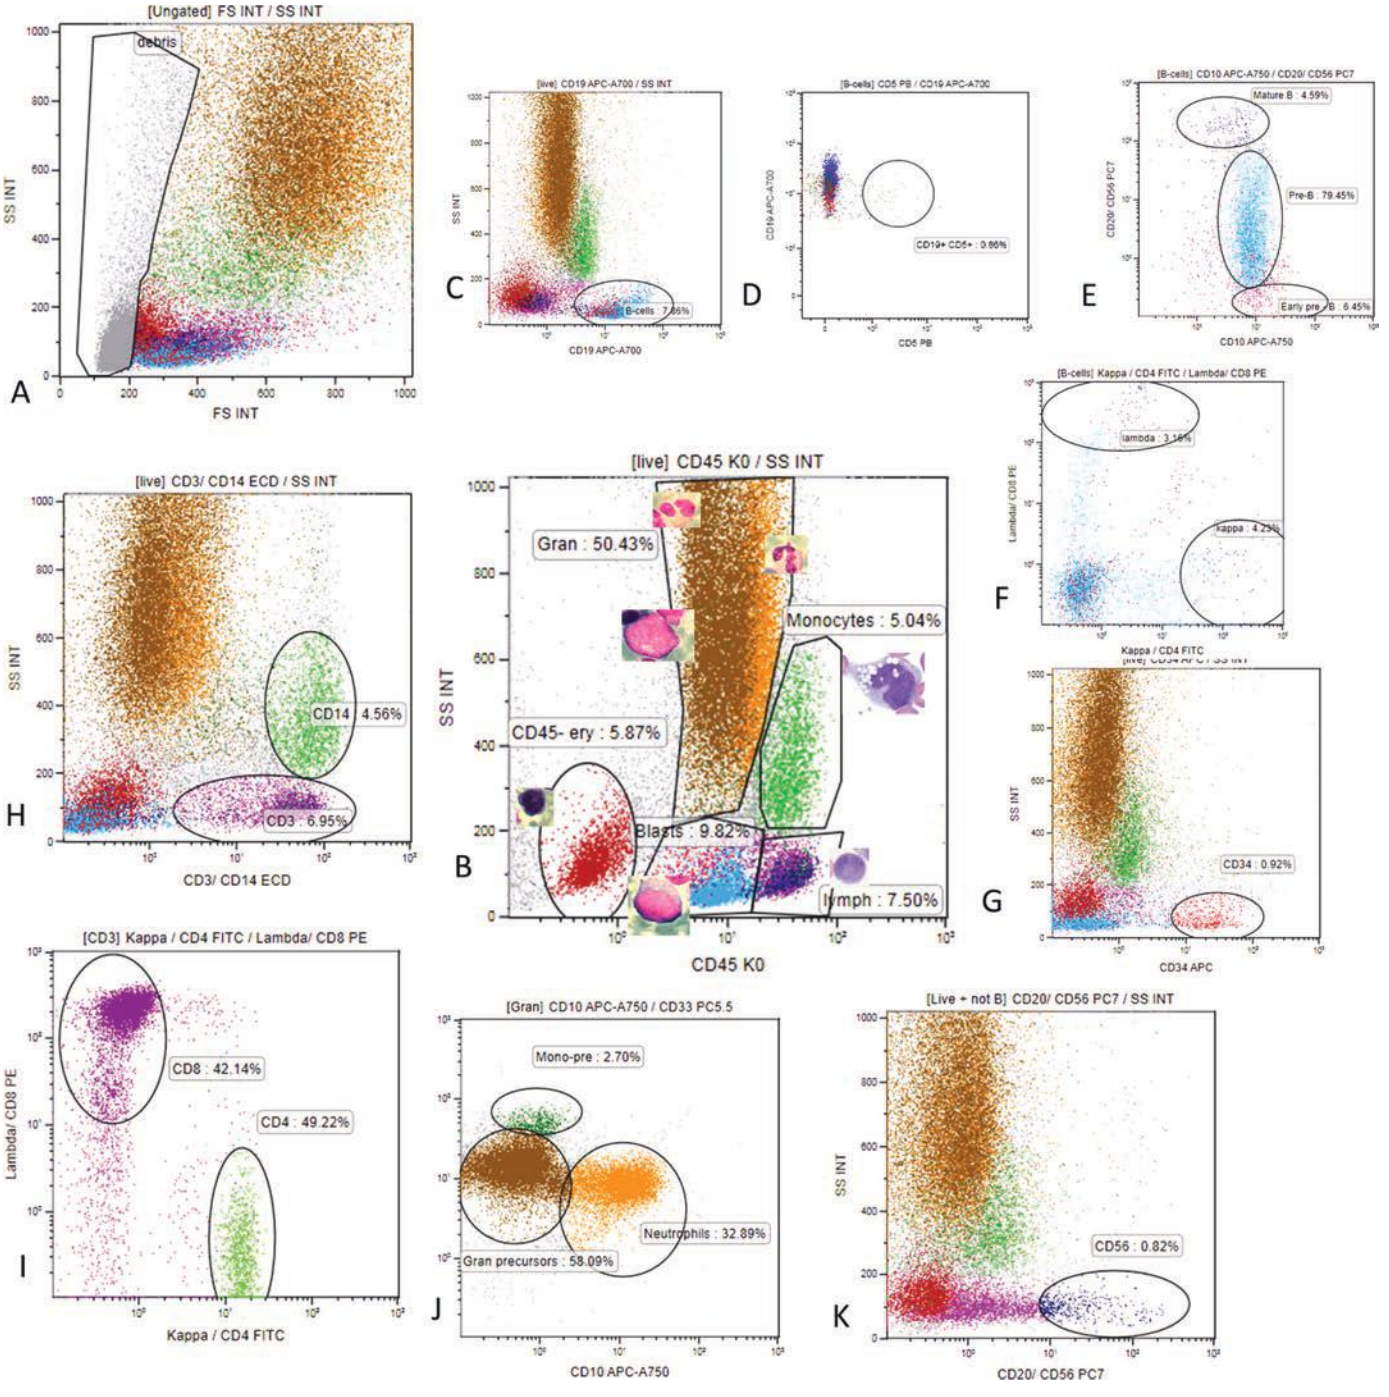

FIGURE 2.2. Bone marrow mapping with polychromatic flow cytometry. Reactive bone marrow sample from a young patient was analyzed with a screening ten-color 14 MAb panel on a Navios flow cytometer and Kaluza software (Beckman Coulter). The MAb panel consisted of kappa+CD4 FITC/Lambda+CD8-PE/CD3 + CD14 ECD/CD34 APC/CD20+CD56–PC7/CD10–APC–A750/CD19–APC–A700/CD33 PC5.5/CD5–Pac Blue/CD45 Krom Orange. Analysis starts with the creating of the "live cells" gate by removal of dead cells, erythrocyte, and platelet aggregates on FS/SS plot **(A)**. A CD45/SS plot is created within the live cell gate **(B)**. Regions for lymphocytes (CD45bright/low SS), monocytes (CD45 bright/high SS), granulopoietic cells (CD45 dim/high SS), CD45dim/low SS blasts, and CD45-low SS erythropoietic cells are determined. The B-cell gate is created from the live cell gate on the CD19/SC plot **(C)**. Presence of CD5 positive B-cells is investigated using a CD5/CD19 plot **(D)**. The presence of CD10+ B-cells is looked for by analysis of CD20 and CD10 expression within the B-cell gate **(E)**. In this patient, no CD5+ B-cells were detected but a significant fraction of B-cells showed B-precursor immunophenotype with normal maturation pattern **(E)**. If a CD5+ or CD10+ B-cell population is present, a new gate can be created within plot D or E. B-cell clonality is analyzed within the B-cell gate **(F)**. In this patient most B-cells are negative for light chain expression, consistent with B-cell precursors. Note that most of CD10+/CD20 dim B-cell precursors (cyan dots) fall into the blast gate in the CD45/SS plot (B). Kappa and lambda positive B-cells have normal kappa to lambda ratio. If CD5 and/or aberrant CD10+ B-cells were present, clonality of B-cells would be analyzed within the specific CD5+/CD19+ or CD10+/CD19+ gate. The fraction of CD34+ cells (red dots) is estimated within the live cell gate on the CD34/SS plot **(G)**. If increased numbers of CD34+ cells are found, they are further analyzed for CD33, CD19, and CD10 expression. CD3+ T-cell and CD14+ monocyte gates are created on the CD45/CD3+CD14 plot within the live cell gate **(H)**. Fractions of CD4+ (violet dots) and CD8+ T-cells (light green dots) are estimated within the CD3+ gate **(I)**. CD4/CD8 ration was normal (1.16). Granulopoietic cells are analyzed on CD33/CD10 plot within the "Gran" gate and fractions of mature neutrophils (CD33+CD10, orange dots) and granulopoietic precursors (CD33+ CD10, brown dots) are estimated **(J)**. CD14-CD33bright monocytic precursors can also be enumerated (green dots). Finally the fraction of CD56+ NK cells (dark blue dots) can be evaluated on a CD20+56/SS plot using the Boolean gate of live cells + non-B–cells to exclude CD20+ B-cell from analysis **(K)**. Various cell populations are back-gated and visualized on both FS/SS and CD45/SS plots **(A** and **B)**.

3. Type of specimen (bone marrow aspirate, peripheral blood, other biologic fluids)
4. Timing of observation (first diagnosis or follow-up)
5. Diagnostic hypothesis made by the sender
6. List of antigens and type of immunofluorescence analysis carried out
7. Absolute number of cells in the sample
8. Quality of the sample, in terms of viability
9. General description of the gating procedure
10. Immunophenotype of abnormal cells present in the sample
11. Description of other (normal) cells
12. Diagnostic conclusions
13. Comments and/or recommendations for further testing.[21,27]

Validation of Assays and Quality Assurance

In clinical settings, the results obtained in FCM must be interpreted in relation to clinical information and to the results of other techniques (morphology, cytogenetics, molecular genetics, fluorescence in situ hybridization [FISH]), which are used as a validation of the information provided by FCM.[21] Newly established panels have to be validated by comparison to reference

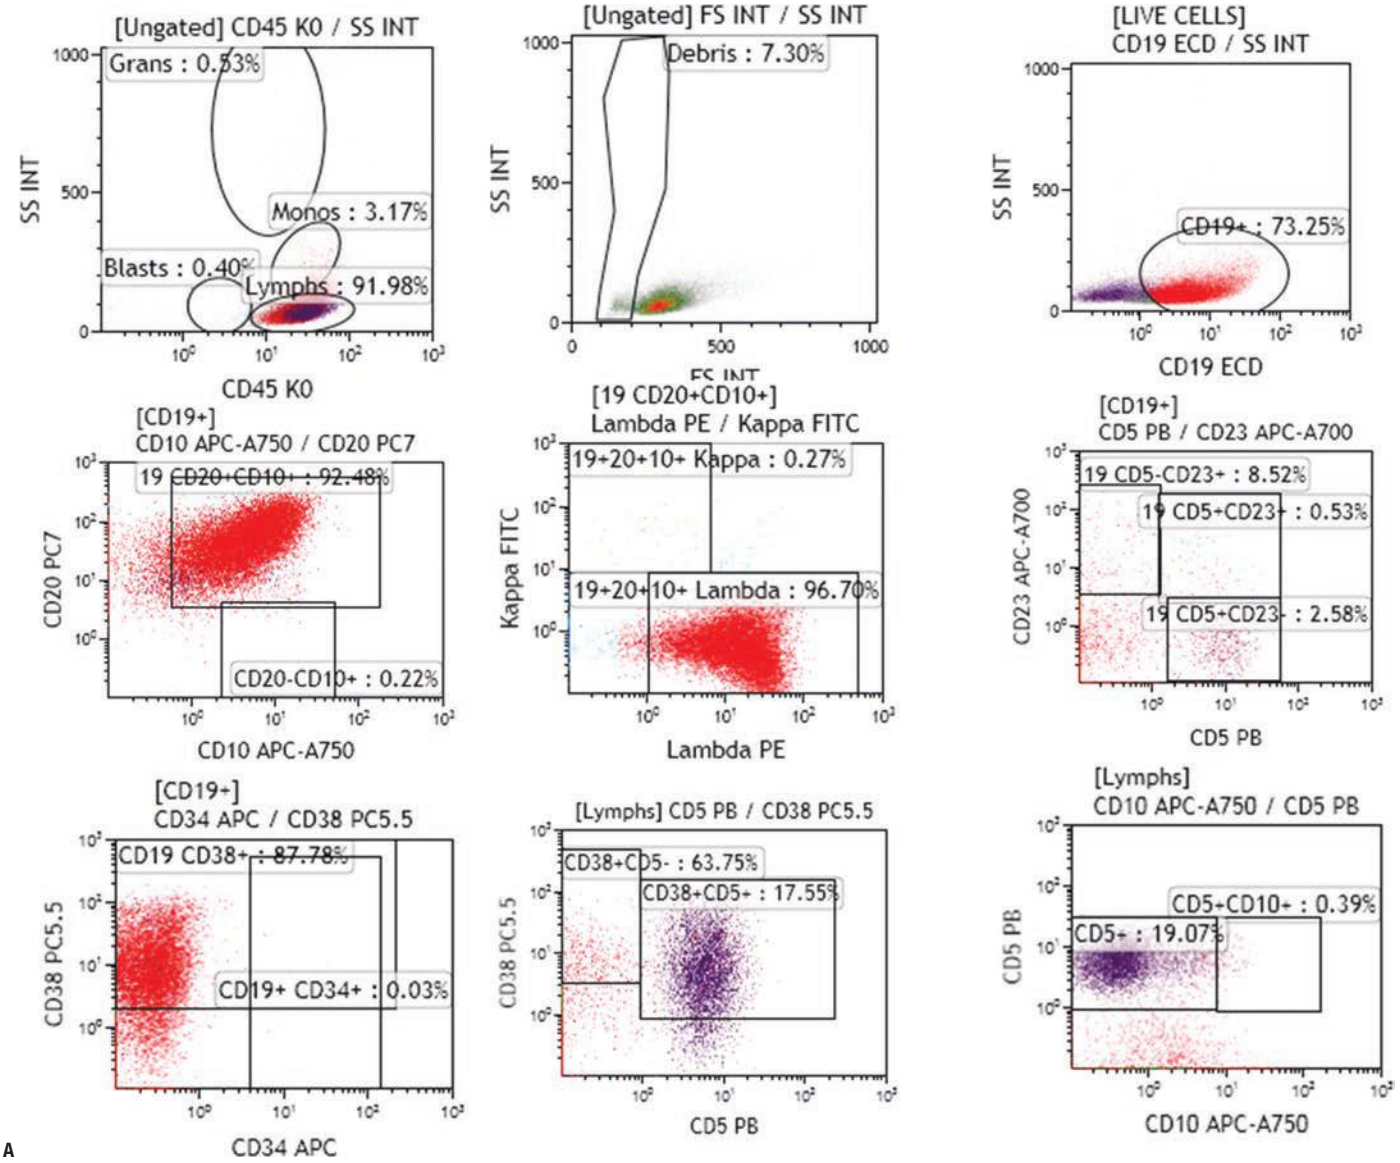

FIGURE 2.3. A. Examples of analysis of B-cell compartment in bone marrow samples. Ten-color MAb panel, Navios flow cytometer, and Kaluza software (Beckman Coulter) were applied. Panel consists of Kappa-FITC/Lambda-PE/CD19 ECD/CD34–APC/CD10–APC-A750/CD23–APC–A700/CD20–PC7/CD38-PC5.5/CD5 Pc Blue/CD45-Krom Orange. The live cell gate is created and fractions of lymphocytes, granulocytes, monocytes, and the like are evaluated as shown in Figure 2.2. The B-cell gate is created on a CD19/SS plot and expression of CD5, CD23, and CD10 is analyzed within the B-cell population. Kappa and lambda light chain expression is analyzed within total B-cell, CD5+ B-cell, or CD10+ B-cells as appropriate. Expression of CD34 and CD38 within the C19+ B-cell population can also be analyzed (see Fig. 2.3B). The fraction of plasma cells can be estimated using CD38 bright expression and high SS on the CD38/SS plot (not shown). Upper row: population of B-cells with B-CLL/small lymphocytic lymphoma-related phenotype (CD19+, CD5+, CD23+, CD20 dim, kappa dim, CD10–) consistent with bone marrow involvement in a patient who was diagnosed with small lymphocytic lymphoma in a lymph node biopsy and had no peripheral lymphocytosis. Bone marrow biopsy showed rare nodular lymphoid infiltrates. Middle row: CD5–CD10–CD23– lambda+ B-cell population in a patient with Waldenström macroglobulinemia. Lower row: population of CD19+ CD10+ B-cells strongly expressing CD20 and kappa in a patient with bone marrow involvement by a follicular lymphoma. **B.** Examples of analysis of B-cell compartment in a lymph node cell suspension. Ten-color MAb panel, Navios flow cytometer, and Kaluza software (Beckman Coulter) were applied. Panel consists of Kappa-FITC/Lambda-PE/CD19 ECD/CD34–APC/CD10–APC–A750/CD23–APC–A700/CD20–PC7/CD38–PC5.5/CD5 Pc Blue/CD45–Krom Orange. The live cell gate is created and fractions of lymphocytes, granulocytes, monocytes, and the like are evaluated as shown in Figure 2.2. The B-cell gate is created on the CD19/SS plot and expression of CD5, CD23, and CD10 is analyzed within the B-cell population. Most B-cells were positive for CD20, CD38, and CD10, and showed monotypic lambda expression.

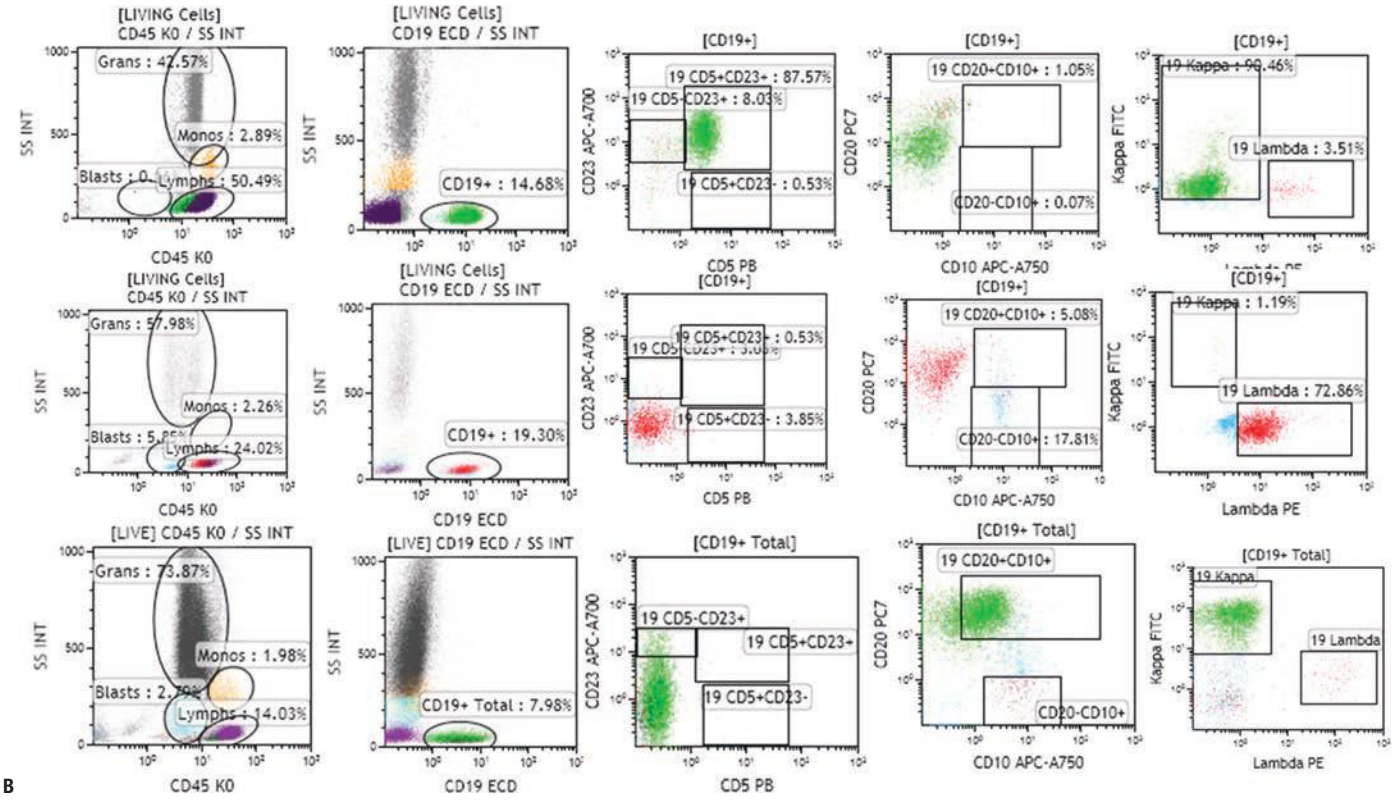

FIGURE 2.3. **(Continued)**

methodology, interlaboratory comparison, or verification with specimens obtained from patients with a confirmed diagnosis. A minimum of 10 to 20 samples (10 normal, 10 abnormal) is recommended for accuracy assessment. The acceptance criteria will also be variable depending on the required degree of accuracy for the intended use, nevertheless should be clearly defined for each assay. Ninety percent, or greater, agreement between methods is generally required for accuracy.

All instruments have to follow daily quality checks according to manufacturers' recommendations. Participation in a suitable external quality assurance (EQA) program should be undertaken. Many proficiency testing programs are in existence operating at local, national, or international levels. The more common uses of FCM should be subjected to EQA and many of the larger international programs such as those operated by UK NEQAS for Leukocyte Immunophenotyping[28] and the College of American Pathologists offer FCM EQA programs for leukemia and lymphoma diagnosis, lymphocyte subset monitoring, paroxysmal nocturnal hemoglobinuria (PNH), and CD34+ stem cell enumeration. Many of these programs use stabilized material enabling samples to be transported long distances such that data from large international cohorts can be examined to search for any instrument or reagent bias. The frequency of the samples issued by such programs is recommended to be at least four times per year to ensure continued performance monitoring.

NORMAL HEMATOPOIESIS

Knowledge of levels and expression patterns of various antigens in normal hematopoietic cells at different stages of development provides a frame of reference for recognition of abnormal differentiation

TABLE 2.3

EXAMPLES OF 10-COLOR FLOW CYTOMETRY PANELS[a] IN IMMUNOPHENOTYPING OF LEUKEMIA AND LYMPHOMA

Panel	FITC[b]	PE	ECD	PC5.5	PC7	APC	APC-AF700	APC-AF750	PB	KO
B-cell	kappa	lambda	CD19	CD38	CD20	CD34	CD23	CD10	CD5	CD45
T-cell	CD57	CD11c	CD8	CD3	CD2	CD56	CD7	CD4	CD5	CD45
AML-granulo	CD65	CD13	CD14	CD33	CD34	CD117	CD7	CD11b	CD16	CD45
AML-mono	CD36	CD64	CD56	CD33	CD34	CD123	CD19	CD38	HLA-DR	CD45
AML-ery-ly	CD71	CD11c	CD4	CD33	CD34	CD2	CD10	CD235a	CD15	CD45
ALL-B	CD58	CD22	CD38	CD33	CD34	CD123	CD10	CD19	CD20	CD45

AL-cytoplasmic	TdT	MPO	CD14	CD33	CD34	cytCD79	cytCD22	CD19	cytCD3	CD45

[a]These panels are in current clinical use at the Flow Cytometry Lab., Department of Laboratory Medicine, University Health Network, Toronto General Hospital, Toronto, Ontario, Canada.
[b]Characteristics of fluorochromes are given in Table 2.1.

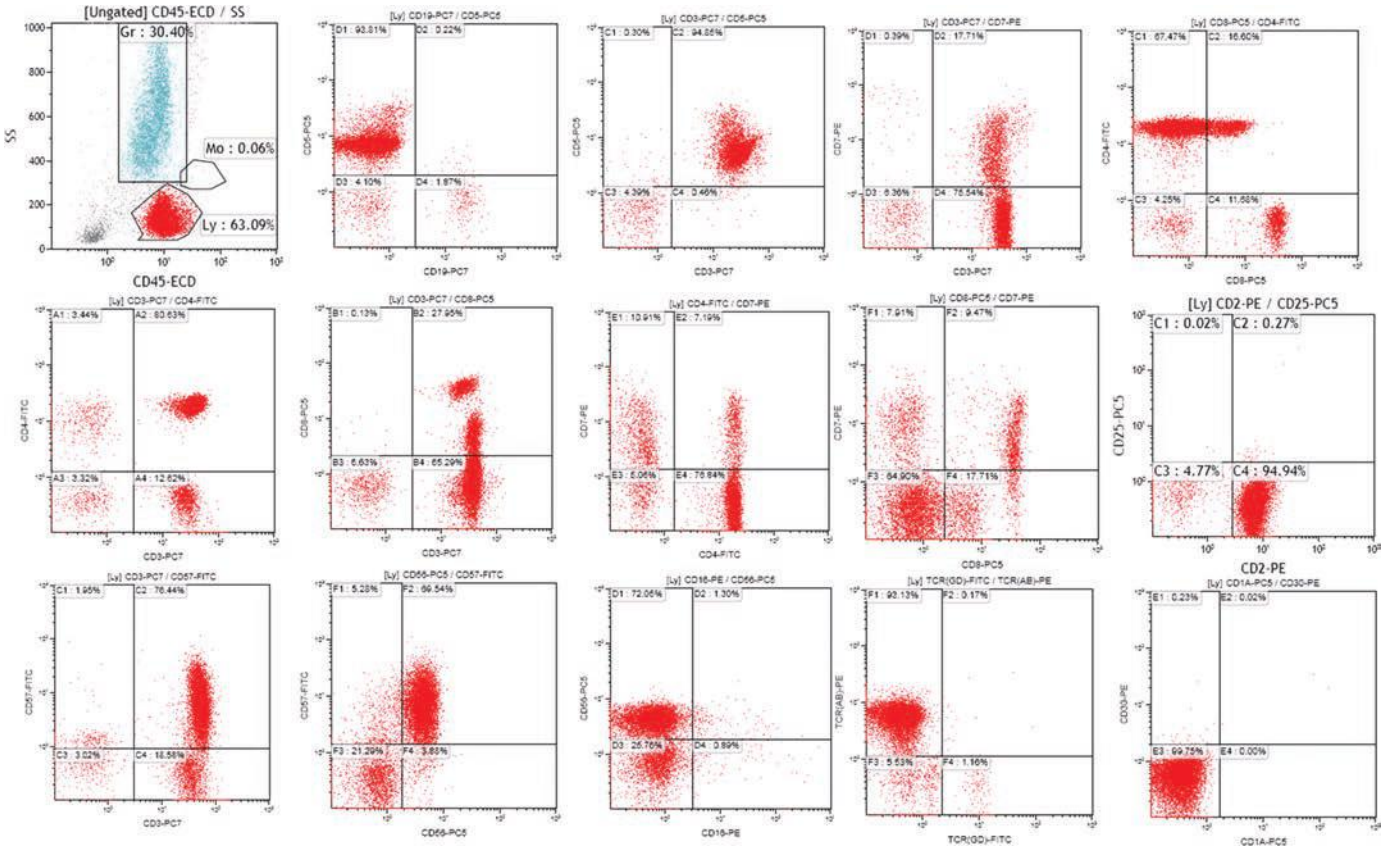

FIGURE 2.4. Example of aberrant T-cell population detected in peripheral blood of a patient with lymphocytosis. Five-color MAb panel and FC500 flow cytometer (Beckman Coulter) were used. Analysis shows that 63% of blood cells were lymphocytes (Ly, red dots on upper left plot). Analysis was performed within lymphocyte gate. Analysis revealed an aberrant population of CD3+ T-cells (75% of lymphocytes) that lack CD7 are positive for CD5 and CD4 with partial co-expression of CD8 (upper row). Small populations of normal CD4+CD7+ and CD8+CD7+ T-cells are also noted (7% and 9% of lymphocytes, respectively, middle row). All T-cells were positive for CD2 and negative for CD25 (left middle row). Further analysis that showed that the aberrant T-cell population was positive for NK-cell–associated antigens CD56 and CD57 (lower row) and had large granular lymphocyte morphology (not shown). MAb to TCR alpha/beta was positive and TCR gamma/delta negative. No expression of CD30 or CD1a was noted (left lower plot).

patterns. Following reports by Terstappen et al.,[29–31] several groups provided descriptions of clearly delineated differentiation stages of various hematopoietic cell lineages.[32,33–36,37,38] A detailed review of all available data is beyond the scope of this chapter; a summary of the most important and well-established issues is provided below.

Immature Cells of Normal Bone Marrow

CD34+ hematopoietic progenitor and precursor cells (HPC) that constitute most cells of the CD45/dim (blast) region are a heterogeneous cell population. A small fraction of pluripotent stem cells with long-term repopulating cell activity have been associated with the CD34/CD38− phenotype.[39,40] These cells are very rare in normal BM (usually <0.1%)[41], but may increase in regenerating BM and in myelodysplastic syndromes (MDS).[42,43] CD34/CD45dim cells also include a major fraction of HPC already committed to different hematopoietic lineages (erythroid, neutrophil, monocytic, dendritic cell (DC), basophil, mast cell (MC), eosinophil, and megakaryocytic) and variable numbers of CD34+ B-cell precursors (BCP).[35] Human stem cells are defined by expression of CD90 and CD49f and are CD45RA negative. Early myeloid progenitors were isolated based on the expression of IL-3 receptor, a chain (CD123) or FLT3 (CD135), and CD45RA. Myeloid, but not erythroid, progenitors express CD123 and CD135, and the transition from common myeloid to granulocyte-macrophage progenitor is marked by acquisition of CD45RA [reviewed in Ref. 44].

Granulocytic Differentiation

Several antigens change their expression intensity during maturation of granulopoiesis. Characteristic normal patterns for various antigen combinations have been identified using multicolor analysis.[25,36,37,45] Continuous variation in the expression of CD13, CD11b, and CD16 that occurs as the blasts/promyelocytes mature to neutrophils makes the combinations of these antigens very useful in delineating granulocyte maturation (Fig. 2.6). CD13 is expressed at high levels on CD34+ HPCs and CD117+ precursors (promyelocytes). CD13 is then down-regulated and dimly expressed on intermediate precursors (myelocytes) and it is gradually up-regulated again as the granulocytic cells develop into segmented neutrophils. CD11b and CD16 are initially expressed at low levels, but their expression increases during maturation (Fig. 2.6).

Expression of CD33 is particularly useful if followed together with expression of HLA-DR. CD34+ cells are HLA-DR positive and become weakly positive for CD33. With maturation, CD34 disappears and CD33 expression is up-regulated, followed by down-regulation of HLA-DR and slight down-regulation of CD33 in most mature forms.[37] CD15 and CD65 appear when cells are restricted to neutrophil differentiation. CD66, CD16, and CD10 are the markers of mature, band, and segmented neutrophil granulocytes and can be applied to evaluate blood contamination of aspirate.[46–48] The sequence of marker expression during neutrophil differentiation is summarized in Table 2.4. It has been confirmed by cell culture studies and sorting experiments.[36,49,50]

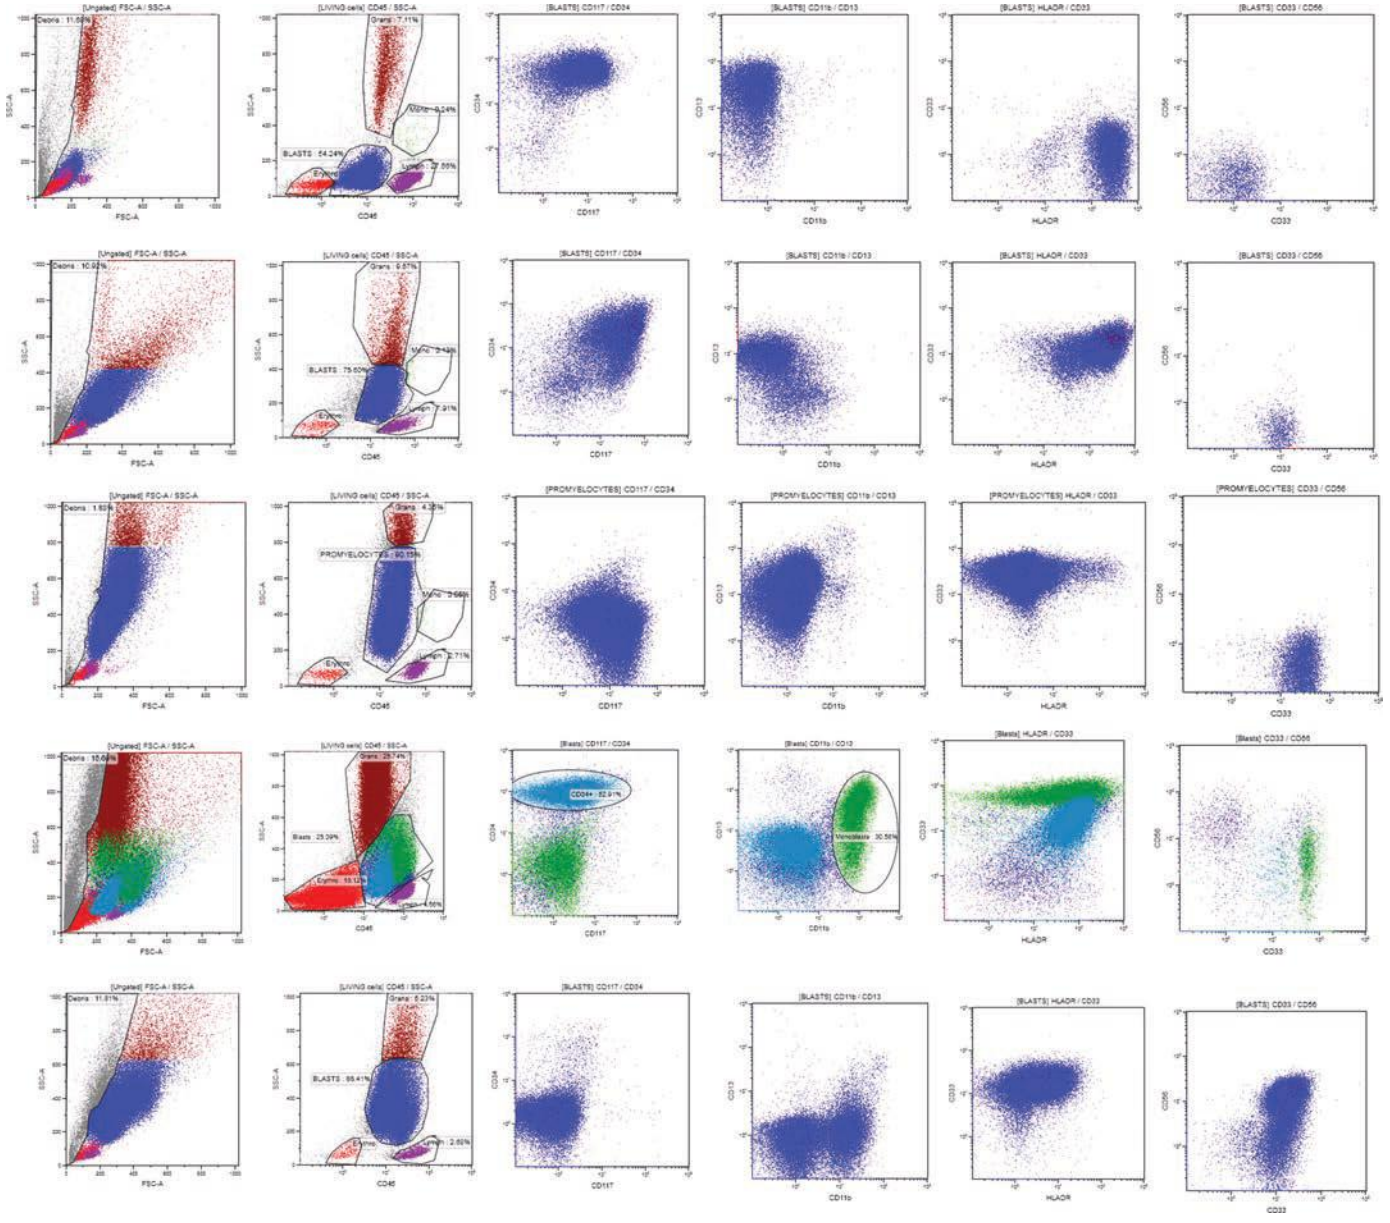

FIGURE 2.5. Examples of various scatter characteristics of CD45 dim blast population and patterns of antigen expression in acute myeloid leukemia. Bone marrow samples were stained with an eight-color MAb panel and acquired on a FACS-CANTOII flow cytometer (BD Bioscience). Panel consisted of CD56–FITC/CD13–PE/CD34 PerCP–Cy5.5/CD117–PE–Cy7/CD33–APC/CD11b APC–Cy7/HLA–DR Pac Blue/CD45 AmCyan. Analysis was performed using Kaluza software (Beckman Coulter). After removal of dead cells and debris, blasts, lymphocytes, monocytes, and granulopoietic precursors/granulocytes were gated on the CD45/SS plot. Further analysis of antigen expression was performed within the blast population (dark blue dots) except for myelomonocytic leukemia (fourth row) where the monocyte gate was added (green dots). The upper row of plots shows an example of AML without differentiation showing agranular blasts, positive for CD34, CD117, CD13, and HLA-DR, but negative for CD33 and CD56. The second row shows an example of AML with granulocytic differentiation as demonstrated by partial expression of CD11b and SS characteristics. Blasts are strongly positive for CD34, CD117, CD13, CD33, and HLA-DR but negative for CD56. The third row shows an example of APL with characteristic high SS and negative CD34, HLA-DR, CD11b, heterogeneous CD13, strong CD33, and no expression of CD56. The fourth row shows an example of myelomonocytic AML where a population of blasts (dark blue) and a population of aberrant monocytes were detected. Blasts were positive for CD34, CD33, CD11b, and HLA-DR but negative for CD117 and CD13. Both blasts and monocytes showed aberrant expression of CD56. The lower row shows an example of monoblastic leukemia, which was negative for CD34, CD117, and CD13 but showed strong expression of CD33 and CD56, dim HLA-DR, and partial expression of CD11b.

Monocytic Differentiation

CD14, CD36, and CD64 are considered as monocyte-associated markers, CD14 being the most specific. During maturation toward promonocytes, progenitors down-regulate CD34 and CD117 and gain the expression of CD64, CD33, HLA-DR, CD36, and CD15, with an initial mild decrease in CD13 and an increase in CD45. Maturation toward mature monocytes leads to a progressive increase in CD14, CD11b, CD13, CD36, and CD45, with a mild decrease in HLA-DR and CD15. Mature monocytes show expression of bright CD14, bright CD33, variably bright CD13, bright CD36 and CD64, and low CD15.[36,51]

Erythropoietic Differentiation

Early erythropoietic precursors are found in the blast area and can be identified by very bright CD44, bright CD71, intermediate CD36, positivity for HLA-DR, and expression of CD117 with "dim" CD45. Glycophorin A (CD235a) is expressed at a low level at this stage. Maturation to the basophilic erythroblast is accompanied

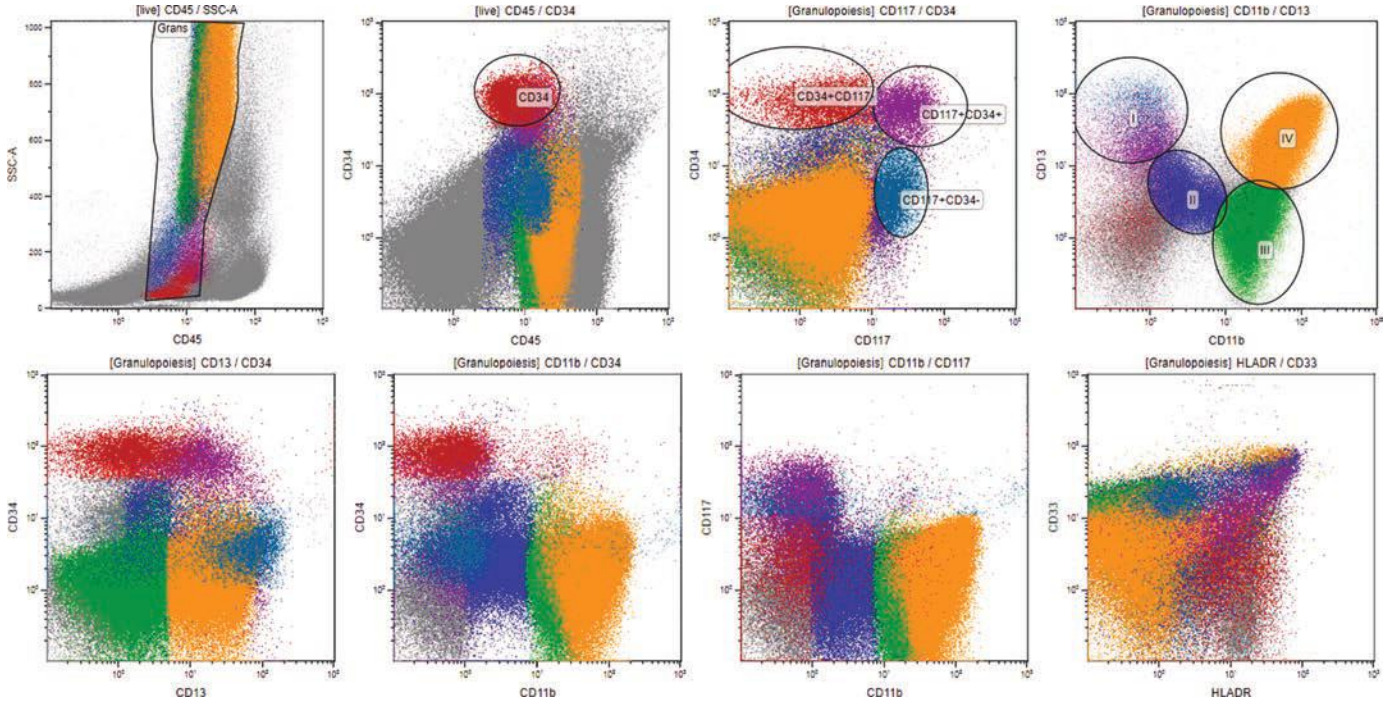

FIGURE 2.6. Flow cytometry analysis of maturation in granulopoiesis. Reactive bone marrow samples were stained with an eight-color MAb panel and acquired on a FACS-CANTOII flow cytometer (BD Bioscience). Panel consisted of CD56-FITC/CD13–PE/CD34 PerCP–Cy5.5/CD117–PE–Cy7/CD33–APC/CD11b APC–Cy7/HLA–DR Pac Blue/CD45 AmCyan. Analysis was performed using Kaluza software (Beckman Coulter). Granulopoietic cells and blasts were gated on CD45/SS plot within a live cell gate (upper left). CD34+ cells were gated in a live cell gate and a Boolean gate was created by adding both gates (called granulopoiesis). Expression of CD34 and CD117 showed three populations: CD34+/CD117−CD34+/CD117+ and CD117+/CD34−. The right upper plot shows maturation in granulopoiesis corresponding to promyelocytes (I: CD13+ CD11b−), myelocytes (II: CD13+/dim, CD11b dim), metamyelocytes/bands (III: CD13 dim, CD11bright), and mature neutrophils (IV: CD13bright, CD11b bright). The lower row of plots illustrates the position of these various subsets in other antigen expression plots. All granulopoietic cells were negative for CD56 (not shown).

by a decrease in CD44, disappearance of CD45 and acquisition of bright CD235a expression. At transition to the polychromatophilic/orthochromatophilic stage, erythroblasts show loss of HLA-DR, further decrease in CD44, and a mild decrease in CD36.[51,52]

Lymphocyte Differentiation

The average reported relative frequencies of major lymphoid subsets in various types of tissues are given in Table 2.5. Each laboratory should establish its own ranges.

B-cells

B-cell differentiation in the normal human bone marrow has been extensively studied by several groups that described characteristic patterns of antigen expression on consecutive stages of B-cell precursors (Table 2.6, Fig. 2.7).[33,36,53–56] The changes in antigen expression in B-lineage committed cells can be summarized as follows [57]:

- CD34+CD10+ Terminal deoxynucleotidyl transferase (TdT)+CD79a+CD19neg common lymphoid progenitor (CLP): early B (E-B) stage.
- CD34+CD19+CD10+TdT+CD20-cytIgM- pro-B-cell stage.
- After down-regulation of CD34 and TdT they become CD34–CD19+ CD10+ CD20 heterogenous pre-B that can be further subdivided in I and II subsets.
- CD34–CD19+CD20+CD10dim/− IgM+ immature (IM)-B-cells.
- After expression of light chains, cells become CD10-CD19+ CD20+ IgM+ IgD+ mature B-cells.

Pre-B and IM B-cells constitute the majority of B-cells in BM of children, whereas mature B-cells are most frequent in adult BM.[33,36]

In children with BM regeneration after infection or chemotherapy and in transient hyperplasia of B-cell progenitors, subpopulations of IM and mature B-cells co-expressing CD5 have been identified.[58] CD5+ B-cells are the major population of B-cells in fetal life, and their percentage decreases with age.[53] Knowledge of antigen expression patterns of B-cell subsets in normal BM is essential for follow-up studies of minimal residual disease (MRD) in patients treated for B-precursor acute lymphoblastic leukemia (ALL).[33,59,60]

T-cells

T-cell production is maintained throughout life by thymic seeding of BM-derived progenitors. Rare (<0.1%) T-cell–restricted precursors, which express pre-Tα protein on the cell surface and are CD34+CD7+CD45RA+, were identified in human BM.[57,61] Recently, it has been suggested that CD34+ CD10+ CD24– progenitors present in both BM and thymus constitute a thymus-seeding population and may replace CD34+ CD7+ CD45RA+ cells in the post-natal period.[62] However, frequency of these cells in normal BM is lower than $1/10^{-4}$.[34] No TdT-positive T-cells expressing cytoplasmic CD3 are found in normal BM.[34] Most mature T-cells in the BM co-express CD7, CD5, CD2, and membrane CD3 and are either CD4 or CD8 positive. However, minor subsets of CD7+ cells lacking other "pan-T" antigens, small subsets with co-expression of CD4 and CD8, and a subset lacking CD4 and CD8 have been identified.[34] A small population of CD7− T-cells (<10% of T-cells) can also be seen in normal and reactive conditions.[63]

Minor Bone Marrow Cell Subsets

In healthy donors, ***eosinophils*** represent 2% to 3% of blood leukocytes. Numbers of eosinophilic precursors may vary considerably

in reactive BM. Eosinophilic myelocytes can be identified by high side scatter, intermediate CD45 (at a level slightly higher than neutrophilic myelocytes), low to intermediate CD11b, intermediate CD13, and low CD33 with bright CD66b and no CD16 expression. Mature eosinophils show increased levels of CD45 and CD11b with a decrease in CD33 and are negative for CD16.[51,64]

Basophils are the least common granulocyte subset (0.5% of total blood leukocytes and about 0.3% of nucleated BM cells in

healthy individuals). Basophils are positive for CD9, CD13, CD22 (dimmer than mature B-lymphocytes), CD25 (dim), CD33, CD38 (bright), CD45 (dimmer than lymphocytes and brighter than myeloblasts), and CD123 (bright), and are negative for CD3, CD4, CD19, CD34, CD15, CD64, CD117, and HLA-DR. In some individuals, basophils are positive for CD11b.[65]

Bone marrow ***mast cells*** (BMMCs) are present in normal BM at a very low frequency 0.021% +/− 0.0025% of the nucleated cells.[66] BMMCs are clearly identifiable on the basis of their light scatter properties and strong CD117 expression. Normal BMMCs are virtually always positive for the CD9, CD11c, CD29, CD33, CD43, CD44, CD45, CD49d, CD49e, CD51, CD54, CD71, and FcεRI antigens. Other markers such as CD11b, CD13, CD18, CD22, CD35, CD40, and CD61 display a variable expression in normal individuals. BMMC are negative for the CD34, CD38, and CD138 antigens.[67,68]

Dendritic cells (DCs) comprise two main subpopulations: conventional DCs (cDCs) and interferon-producing plasmacytoid (p) DCs. Human cDCs are Lineage (Lin) negative HLA-DR+ cells that express high levels of CD11c and consist of a major blood dendritic cell antigen (BDCA)3− and a minor BDCA3+ population. Human Lin-HLA-DR+ pDCs are defined by absence of CD11c expression and by high levels of CD123 (the IL-3Rα chain) and BDCA2.[69] The CD11c+HLA-DR+BDCA3− population can be further subdivided into CD16+ and CD16− populations. Recent studies indicate that cDCs in lymphoid tissues arise from a distinct population of committed cDC precursors (pre-cDCs) that originate in bone marrow and migrate via blood. Spleen cDCs arise from a distinct population of Lin neg CD11c+ major histocompatibility complex (MHC) class II neg immediate cDC precursors (pre-cDCs). Pre-cDCs originate from bone marrow Lin neg CD117int FLT3+ CD115+ common DC progenitors.[70] The direct progenitor of pDCs is contained within the CD34 low compartment of cord blood, fetal liver, and bone marrow. These progenitors (pro-pDCs) co-express CD45RA, CD4, and high levels of CD123.[57]

NK cells are positive for CD2 and CD7 but negative for CD3 and CD5. In humans, there are two major subsets of NK cells: one expressing high levels of CD56 and low or no CD16 (CD56hiCD16+/−), and the second that is CD56+CD16hi [71] CD56hiCD16+/− cells display relatively lower cytolytic activity and produce more cytokines than the CD56+CD16hi cells. A putative committed NK precursor has been found within CD34lo CD45RA+ α4β7hiCD7+/−CD10− BM population and gives rise to CD56hi CD16− NK cells in vitro. The immature NK cells developing from committed NK-cell precursors are defined by expression of CD161 (NKR-P1).[72] These cells do not express CD56 or CD16. Immature NK cells can be induced to express these markers as well as the activating and inhibitory receptors, CD94 (NKG2A) and killer inhibitory receptors (KIR), upon culture with stromal cells and cytokines such as IL-15 or Flt3-L.[57] A total of 30% to 60% of CD56dim CD16bright NK cells in healthy adults express CD57, which is not expressed on immature CD56bright NK cells. CD57+ NK cells express a repertoire of NK-cell receptors, suggestive of a more mature phenotype, and proliferate less when stimulated with target cells and/or cytokines.[73]

MULTICOLOR ANALYSIS OF HEMATOLOGIC MALIGNANCIES

Detailed immunophenotypic information necessary for diagnosis and prognosis of various hematologic diseases, based on both FCM and immunohistochemistry, are provided in their respective chapters. The FCM findings important for diagnosis of most common entities are summarized below.

Immunophenotyping of B-Cell Lymphoproliferative Disorders

Normal/reactive B-cell populations in blood, bone marrow, and lymphatic tissue are polyclonal with an average Igκ/Igλ ratio of 1.5 (range 0.9–3) (Fig. 2.2).[74] An increase of polyclonal B-cells in blood, called the persistent polyclonal B-cell lymphocytosis (PPBL) is characterized by a chronic, stable, persistent, and polyclonal increase of B-cells (median 5×10^9/L), the presence of binucleated lymphocytes in the PB, and a polyclonal increase in serum immunoglobulin-M (IgM). Most patients are asymptomatic but isochromosome 3q and development of malignant lymphoma has been described in some cases.[75]

B-cell malignancies are clonal expansions of B-cells that express only one type of Ig light chain (κ or λ). Analysis of light chain expression in total B-cell population and in CD5/CD19 or CD10/CD19 positive cells forms the basis for B-cell lymphoma diagnosis (Fig. 2.3). Typical immunophenotypes found in various

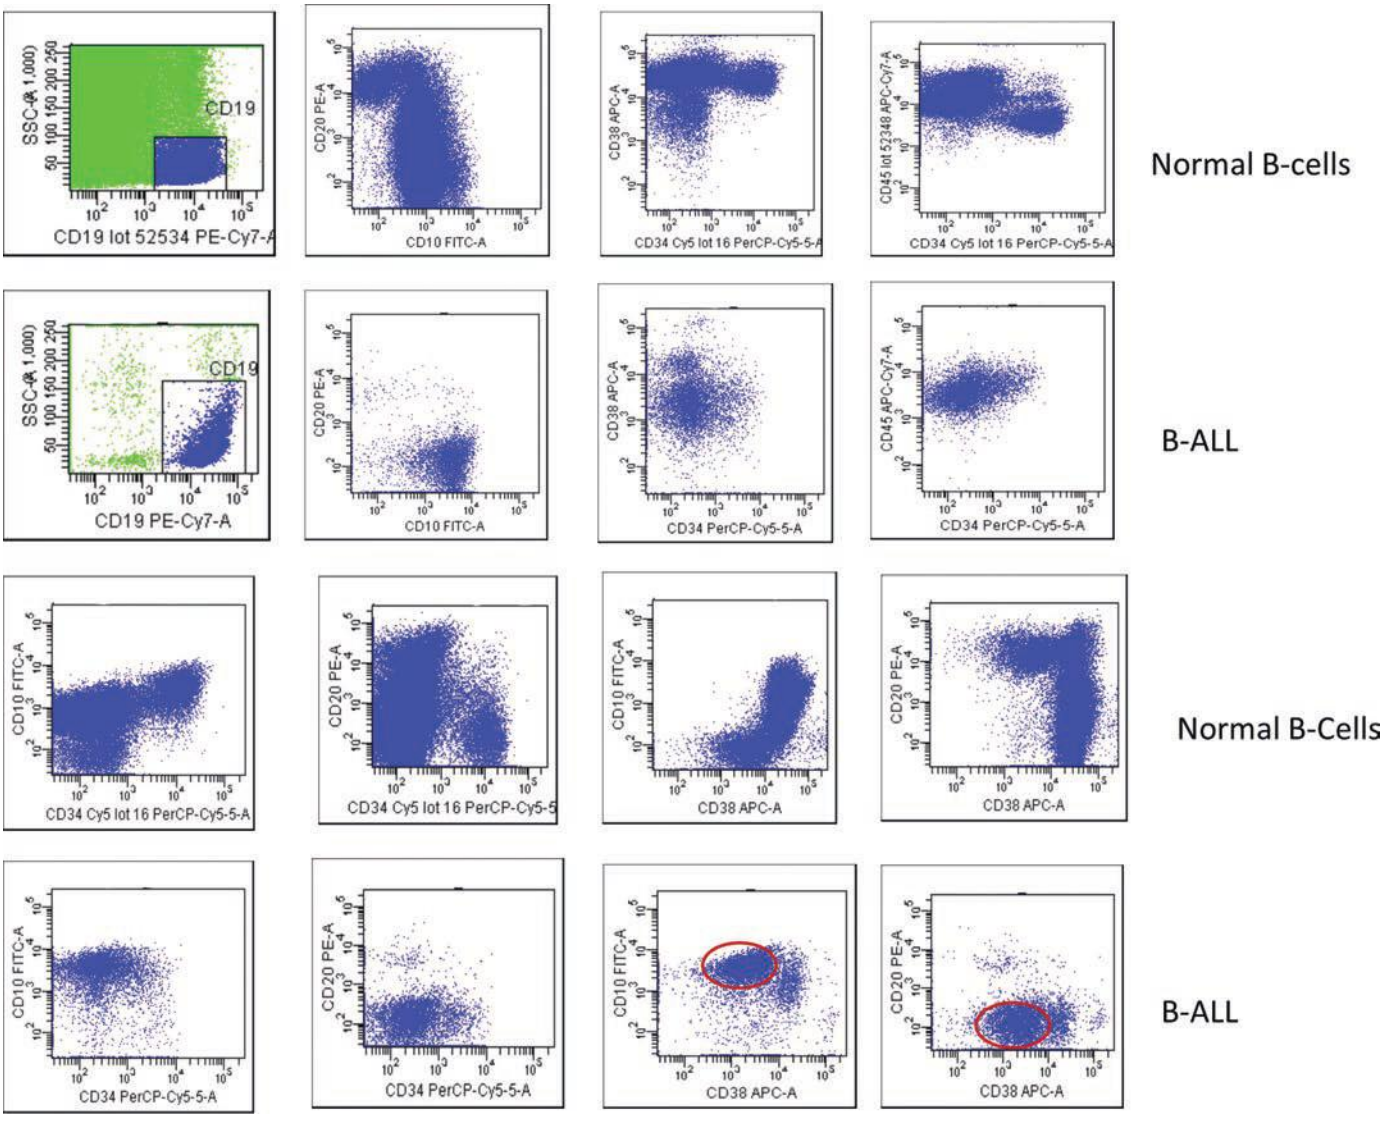

FIGURE 2.7. Example of antigen expression in a case of B-precursor lymphoblastic leukemia/lymphoma in comparison to normal bone marrow B-cells in a child. Bone marrow samples were analyzed with a six-color MAb panel, FACS-CANTOII flow cytometer, and Diva software (BD Bioscience). The panel consisted of CD10 FITC/CD20–PE/CD34 PerCp–Cy5.5/CD38–APC/CD19–PE–CY7/CD45 AmCyan (not shown). To acquire a sufficient number of B-cells, 500,000 events were analyzed on a normal bone marrow sample and 30,000 cells were acquired on the B-ALL sample. CD19+ B-cells were gated on the CD19/SS plot. Normal antigen expression patterns are shown in the upper and third row and corresponding plots for the B-ALL case are shown below (in the second and lower rows). In two lower right plots leukemic cells are found in "empty spaces," areas where normal cells are not found (red circles).

mature B-cell lymphoma subtypes are summarized in Table 2.6. An issue that may cause diagnostic problems is the demonstration of small monoclonal B-cell populations in the BM samples taken during investigations for staging of lymphoma. As FCM sensitivity increases, it becomes more likely that small abnormal populations are detected; how these relate to the neoplastic cells found in other organs is not clear. In some cases a clonal relationship to the diagnostic lymphoma sample has been demonstrated.[76] However, if the histopathologic signs of lymphoma involvement are missing, these cells may represent sc. monoclonal B-cell lymphocytosis (MBL, see below). Therefore, interpretation of FCM results in BM samples should be always integrated with clinical findings and BM biopsy analysis.

B-cell Chronic Lymphatic Leukemia

The characteristic immunophenotype of chronic lymphatic leukemia (CLL) includes positivity for CD19, CD5, CD23, and CD200, weak expression of CD20 and Ig light chains, and often expression of IgM with or without IgD. FMC7 (antibody recognizing one of CD20 epitopes[77]) is negative or only partially expressed in most cases; CD79b and CD22 are absent or weakly expressed in the cell membrane (reviewed in Ref. 78). CD11c, CD25, and other markers that recognize adhesion molecules are variably positive in CLL. CD52 is often included in the panel of markers in CLL diagnosis inasmuch as Alemtuzumab (anti-CD52) is increasingly used in therapy.[79]

Monoclonal B-cell Lymphocytosis

Monoclonal B-cell lymphocytosis (MBL) is an asymptomatic hematologic condition defined by the presence of monoclonal B-lymphocytes detected in PB of persons who do not have CLL, other B-lymphoproliferative disorders, or underlying conditions such as infectious and autoimmune diseases.[80] Initial criteria have been based on detection of a monoclonal B-cell population in the PB with an overall κ:λ ratio >3:1 or 0.3:1, or >25% of B-cells lacking or expressing low-level surface Ig in conjunction

with a specific phenotype.[80] Three different types of MBL have been described, defined on the basis of CD19 positivity, CD5 presence or absence, and CD20 intensity. The most common MBL type is the CLL-like MBL that co-express CD19 and CD5, and CD23 with dim expression of CD20. The second type is similar to CLL but shows bright CD20 expression. B-cells in the third type of MBL do not express CD5; these are classified as CD5-MBL or non-CLL-like MBL.[81] The reported prevalence depends on the sensitivity of applied FCM methodology. Studies performed using four-color FCM with a sensitivity of detection commonly used for detection of MRD in patients with CLL (1 clonal cell per 1×10^5 events) showed a 5% prevalence of CLL-like MBL in adults aged over 60.[82,83] A more recent study, using a much higher sensitivity of FCM, analyzed 5×10^6 PB cells per individual and identified CLL-like MBL in 12% of all tested subjects and in 20% of adults over 60 years old.[84] Finding of peripheral MBL should always be correlated with clinical data and interpreted in the absence of peripheral lymphadenopathy, splenomegaly, and extensive lymphatic bone marrow infiltrates.

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) cells typically express bright CD20, CD5, FMC7, and bright to moderate sIg but lack CD23 and CD200 (Table 2.7).[85,86] However, MCL cases positive for CD23 and negative for FMC7 as well as rare CD5 negative cases have been found.[87,88] Therefore, confirmation of MCL diagnosis by FISH for t(11,14) is recommended. Cyclin D1 expression can also be detected by FCM [89] but this method is not routinely applied in most diagnostic laboratories.

Lymphoplasmacytic Lymphoma and Marginal Zone Lymphoma

These two entities are difficult to differentiate by FCM. The typical immunophenotype findings include the strong expression of sIg and cyt. Ig (IgM in Waldenströms macroglobulinemia [WM], IgG, or IgA in lymphoplasmacytic lymphoma [LPL]). The characteristic antigen expression pattern includes: sIgD+/– CD19+ CD20+ CD22+ CD79a+ FMC7+CD38+ CD103-CD5– CD10– CD23– CD25-CD11c+/– CD43+/– CD27+/–.[90] A minority of splenic marginal zone lymphoma (SMZL) cases express CD5, which often correlates with higher WBC.[91] However, leukemic presentation of MCL should be excluded. Some cases are CD23 positive. In LPL, a monotypic plasma cell population that is strongly CD38/CD138 positive and also positive for CD19 and CD45 can be found.[92] Splenic diffuse red pulp small B-cell lymphoma cells in blood and BM are characterized by similar phenotype as given above but are usually CD11c positive.[93]

Hairy Cell Leukemia and Hairy Cell Leukemia Variant

Both hairy cell leukemia (HCL) and HCLv strongly express CD103, CD11c, CD20, CD22, CD19, and are negative for CD5, CD23, and in most cases negative for CD38.[94] HCL cells are often large (can be found in the monocyte region) and are positive for CD25 and CD123 in contrast to HCLv cells that are smaller and CD25 negative.[94,95]

Follicular Lymphoma

The follicular lymphoma (FL) cells usually express sIg, more frequently IgM +/−IgD than IgG or rarely IgA, together with B-cell–associated antigens (CD19, CD20, CD22, CD79a, and CD79b), and in most cases CD10. Expression of CD19 and CD22 is often weaker than in normal B-cells.[96,97] FL cells are usually CD5−, CD43–, and CD23−/+, CD11c−/+. The weaker expression of CD38 helps to differentiate FL cells from CD10 positive B-cell precursors.

Burkitt Lymphoma

Burkitt lymphoma (BL) cells display often similar phenotype to FL cells (CD19+, CD20+, CD10+), but have bright CD38 expression. The CD23–/FMC7+ immunophenotype have recently been reported as significantly associated with *MYC* rearrangement.[98] BL cells usually lack CD44 and CD54 expression, which are often expressed in CD10 positive diffuse large B-cell lymphomas (DLCB).[99,100] So-called double-hit lymphomas with two translocations including *MYC* [e.g., t(8;14)] and *BCL2* [t(14;18)] or *BCL6* (involving chromosome 3q27), which can present in the leukemic phase, have recently been shown to display a common phenotype including a marked decrease in expression of CD20 ranging from dim to absent as compared to normal follicle center B-cells. Other common features of this immunophenotype include positivity for CD10, variably decreased expression of CD45; and variably increased expression of CD38. In addition, Ig light chain restriction with decreased intensity or complete absence of light chain expression was noted in these cases.[101] The latter cases have to be tested for nuclear TdT expression and differential diagnosis of B-precursor lymphoblastic leukemia/lymphoma should be considered.

Diffuse Large B-cell Lymphoma

Two major subgroups of diffuse large B-cell lymphoma (DLBCL) (germinal center type, usually CD10+, and activated B-cell type, usually CD10–) have been described. Rare CD5 positive cases have been reported.[102] Pathologic findings may include high-scatter, low/negative expression of sIg, CD20, and CD45 (Fig. 2.7). Recent studies suggested that FCM may improve prognostic value of BM staging procedures.[103,104] However, small populations of pathologic large cells that are easily seen in BM biopsies may in some cases be difficult to delineate by FCM against a background of reactive BM cells. In staging of DLCB it is important to analyze high numbers of BM cells to be able to evaluate B-cell light chain sIg expression even in cases where B-cells represent only a minor portion of the BM cell population.

Immunophenotyping of T-Cell Lymphoproliferative Disorders

FCM detection of aberrant T-cell populations requires good understanding of T-cell biology and knowledge of normal T-cell subsets (Fig. 2.5). Reactive conditions may cause predominance of some T-cell subpopulation, which can be interpreted as immunophenotypic "aberrancy." Also, reactive T-cell populations, particularly in the setting of chronic stimulation, may comprise a limited number of clonotypes (i.e., are oligoclonal) and therefore are prone to producing clonal TCR rearrangement results. A characteristic dynamic of CD8+ immune response including CD8+ lymphocytosis with increase of CD38 and HLA-DR expression in acute phase and expansion of CD57+CD8+ subset in chronic phase was described in viral infections such as Epstein–Barr virus (EBV) and human immunodeficiency virus (HIV).[105,106] Chronic activation of the immune system may lead to an increase of CD8+ cells with NK-markers.[107]

An integrated approach combining morphology, immunophenotyping, and molecular analysis is necessary to differentiate between reactive and malignant T-cell lymphoproliferations. Immunophenotypic findings in the most common T-cell lymphoproliferative disorders are summarized in Table 2.8.

T-cell Prolymphocytic Leukemia

Leukemic cells are usually positive for CD7, CD2, CD5, and CD3 although about 20% express cytoplasmic (cyt.CD3) but not membrane CD3 (mCD3). CD7 negative cases have been reported. T-cell prolymphocytic leukemia (T-PLL) cells are usually CD4 positive and CD8 negative (60%) but in a fraction of cases T-PLL cells may express both CD4 and CD8, are CD4 negative, and CD8 positive or negative for both CD4 and CD8.[108] CD25 and NK-cell markers (CD56, CD57, CD16) as well as T-precursor-related markers CD1a and TdT are negative.

Adult T-cell Leukemia/Lymphoma

In most patients, adult T-cell leukemia/lymphoma (ATLL) cells express CD2, CD5, CD25, CD45RO, CD29, T-cell receptor $\alpha\beta$, and HLA-DR (the phenotype of activated CD4+ memory T-cells). ATLL cells usually lack CD7 and CD26 and exhibit lower CD3 expression than normal T-cells.[109]

Sézary Syndrome

The typical immunophenotype of Sézary Syndrome (SS) cells in blood includes positivity for CD2, CD3, CD4, and CD5. CD7 is expressed in only 50% of patients. Loss of CD3, CD2 and unusually bright CD5 expression has been reported.[110] CD8 and CD25 are usually negative. Recent studies have shown that Sézary cells have an immunophenotype characteristic for T-central memory cells (CD4+CD27+ CD26–CD45RA–). By comparison, CD4+ cells in patients with inflammatory erythroderma are CD27 negative.[111]

Angioimmunoblastic T-cell Lymphoma

A predominant T-cell population is usually positive for CD2, CD4, CD5, CD7, and CD45 but negative for CD8, CD19, CD20, CD30, CD38, and CD56. Lack of one or more of the "pan-T" cell markers in a subset of T-cells may be found. Aberrant expression of CD10 in at least a fraction of CD4+ T-cell population is a characteristic feature.[110,112]

T-cell Large Granular Lymphocyte Leukemia

Most cases of T-cell large granular lymphocyte (T-LGL) leukemia are characterized by an expansion of CD3+ CD8+ TCR$\alpha\beta$ T-cells. Rarely CD3+CD4+ CD8+ TCR$\alpha\beta$ or CD4– CD8–TCR$\gamma\delta$ T-cells may be found. It has recently been shown that leukemic T-LGLs have CD3+CD8+CD45RA+ CD62L– phenotype consistent with

d (dim), weak positive staining; b (bright) strong positive staining; (+) or (−) some cases positive or negative.

effector/memory RA T-cells (TEMRA). Leukemic T-LGLs often express CD57.[113] Loss of CD5 and/or CD7 may occur.[110] Correlation of the flow cytometric and molecular genetic results with the other clinical and laboratory findings is critical before the final diagnosis of T-LGL leukemia is established.[114] The level of aberrant T-cell population $\geq 2 \times 10^9$/L is the suggested level for diagnosis of T-LGL leukemia. However, in appropriate clinical settings lower counts ($>0.4 \times 10^9$/L) may be compatible with diagnosis.[113]

Chronic NK-cell proliferations are characterized by CD3–CD56+ and/or CD16+ cells [113] (Fig. 2.5). Further information can be obtained by investigation of expression pattern of killer cell Ig-like receptors (KIRa, CD158) on these cells. These receptors are encoded by at least two distinct families of genes and gene products, which are members of the Ig gene superfamily.[115] In NK-LGL, approximately one third of cases exhibit restricted expression of a single (or multiple) KIR isoform. The remaining NK-LGL cases lack detectable expression of the three ubiquitously expressed KIRs, CD158a, CD158b, and CD158e. The uniform absence of these KIRs on NK cells is aberrant because in normal NK-cell populations, there are subsets positive for each.[116] In contrast to normal NK cells that show variable staining intensity, NK lymphoproliferations also often show uniform bright expression of CD94 exclusively paired with NKG2A to form an inhibitory receptor complex. Abnormal loss of CD161 expression is also frequent in NK-LGL.[116]

Aggressive NK-cell Leukemia

The typical immunophenotype in aggressive NK-cell leukemia is: CD2+, CD16+, and CD56+, with loss of CD7 and variable expression of CD8 and CD57, but blasts are negative for myeloid markers and CD123.[117,118]

Hepatosplenic T-cell Lymphoma

The most common immunophenotype is CD2+, CD3+, CD4–, CD5–, CD7+, CD8–, $\gamma\delta$ TCR+, but CD8+ positive cases do occur. Decreased expression of CD3 and/or CD7 has also been reported. Usually some NK-cell markers (CD56 and/or CD16) are present. The normal T-cell counterpart for hepatosplenic T-cell lymphoma (HSTCL) is thought to be a functionally immature cytotoxic $\gamma\delta$ T-cell of the splenic pool with Vδ1 gene usage. A "variant form" showing $\alpha\beta$ TCR+ and similar clinical features has been described.[119]

Immunophenotyping of Plasma Cell Myeloma

Recently, the European Myeloma Network has reported consensus recommendations about the clinical utility of FCM in multiple myeloma (MM) and other clonal plasma cell (PC)-related disorders and instructions how to apply FCM in a routine diagnostic laboratory.[120] Simultaneous assessment of the expression of CD38 and CD138 is recommended as the best combination of markers for the specific identification of BM PC, due to the bright CD38 and CD138 expression.[121] It is recommended to acquire at least 100,000 "events" to ensure that at least 3,000 "events" with broad gated CD38bright/CD138+ characteristics and at least 100 PC are analyzed. At least four-color analysis panels are recommended.[121] Clonality of PC should be evaluated by analysis of cytoplasmic Ig expression.[122]

The most common aberrant features of PC in myeloma in comparison to normal PC are:

- Decreased or absent expression of CD19, CD27, CD38, and CD45
- Overexpression of CD28, CD33, and CD56
- Asynchronous expression of CD20, CD117, and sIg [121]

It is important to enumerate the fraction of aberrant PC within the total BM PC population because it has been shown that in most (>80%) patients with monoclonal gammopathy of unknown significance (MGUS) at least 5% of PC are normal, whereas in patients with symptomatic myeloma most PC are aberrant.[123] The presence of >5% normal PC in patients with symptomatic MM is of good prognostic significance and patients with MGUS or smoldering myeloma who have <5% normal PC usually rapidly progress.[123]

Immunophenotyping of Acute Leukemia

The use of CD45/SS gating is widely used for the identification of pathologic cells in acute leukemia because blasts usually appear in a position where only few cells are located in the SS/CD45 dot plots of normal BM (Figs. 2.2 and 2.4). In rare cases CD45 is not suitable for gating purposes because of the marked heterogeneity of the leukemic population or the limited number of blasts present in the hemodiluted sample. In such cases other markers such as CD34, CD117, CD13, or CD33 may be of help. A good correlation between frequencies of blasts determined by FCM and by morphology has been reported.[124] Lower blast counts by FCM in comparison to percentages of cells with blast morphology in BM smears may be due to enrichment of blasts in BM fragments (spicules). A possible bias can also be introduced by hematopathologists who choose "representative" areas of the smear for blast counting or by a relative hemodilution of samples submitted for FCM analysis.[46,125] In patients with ≥20% of blasts in smears required for acute leukemia diagnosis, immunophenotyping gives information needed for lineage assignment, analysis of the degree of heterogeneity of the abnormal cell population due to either the existence of different pathologic clones or the presence of cells in different stages of maturation, and further characterization of aberrant phenotypes for MRD follow-up.

Lineage Assignment and Mixed-Phenotype Acute Leukemias

One of the major changes in the 2008 revision of the WHO classification was to simplify the definition of biphenotypic acute leukemia (BAL).[126] The new entity of mixed phenotype acute leukemias (MPAL) among leukemias of ambiguous lineage have been defined.[126] The FCM patterns observed in most cases are characterized by co-expression of the markers on the same cells. In cases of biclonal/bilineal proliferations, two different blast populations can be detected. In other cases, transitional patterns with only part of the blast population being biphenotypic can be seen.[127] For the myeloid lineage, cytoplasmic myeloperoxidase (MPO) detected by cytochemistry, or immunohistochemistry, or by FCM with an anti-MPO antibody is considered as the most significant marker. FCM allows for the detection of MPO even in some cases of minimally differentiated acute myeloid leukemia (AML) that are negative by cytochemistry.[128] It has to be pointed out that MPO positivity is not required for myeloid lineage assignment in leukemias that are not MPAL, i.e., that lack B- and T-lineage–associated markers. To establish differentiation toward monocytic lineage, which may lack MPO, the presence of nonspecific esterase by cytochemistry, or the detection of surface CD14, CD11c, CD36, CD64 or intracytoplasmic lysozyme can be used.[129] B-lineage assignment is based on CD19 expression. If the CD19 labeling is bright, the presence of another B-lymphocyte marker is considered enough to establish B-lineage. If CD19 expression is of low intensity, the presence of two other B-lineage–associated markers will be necessary. Cytoplasmic CD79a, CD22, CD24, CD10, intracytoplasmic μ chains, or (less frequently expressed in MPAL) CD20 or CD21 can be applied. The strongest marker indicating T-lineage is the

strong cytoplasmic expression of CD3. The presence of other T-cell–associated markers such as CD2, CD5 or CD7 can add to the diagnosis of MPAL, although some of these markers can be seen on myeloid cells in AML and MDS.

Acute Myeloid Leukemia

The utility of individual myeloid-associated markers (Table 2.4) for AML diagnosis is limited due to aberrant expression of these markers in many cases of ALL. Immunologic diagnosis of AML is established by expression of at least two myeloid-associated markers in the absence of criteria for diagnosis of B-ALL, T-ALL, and MPAL.[130] Immunophenotyping by FCM is especially useful in differential diagnosis between ALL and minimally differentiated AML [131] and in diagnosis of plasmacytoid dendritic cell neoplasms that are characterized by co-expression of bright CD123, bright HLA-DR, CD4, CD56, and the absence of other lineage-associated markers (MPO–, cyt. CD3–, CD19–).[132]

Characteristic antigen expression patterns have been associated with AML with recurrent chromosomal abnormalities (Table 2.9).[133] These patterns may help in planning directed FISH or PCR studies in cases with limited material.

Several attempts at immunologic classification of AML have been published, however showing limited clinical utility.[134–136] Most prognostic implications are most probably due to immunophenotypes reflecting underlying genetic aberrancies. However, due to the genetic complexity of AML clear-cut correlations are difficult to establish. Even in homogeneous and genetically not complex groups of AML categories such as AML with normal karyotype, *NPM1* mutation, and lack of *FLT3* mutation, immunophenotypic heterogeneity for some markers such as CD56 expression was demonstrated.[137]

In general, immunophenotypic patterns of AML (Fig. 2.4) can be described as less differentiated (blastic) or as showing signs of maturation toward one or several lineages. Consequently AML can show one single or two or more populations of malignant cells. AML showing maturation toward granulocytic lineage usually displays (at least on a fraction of cells) markers associated with myeloid immaturity (CD34 and CD117) combined with variable expression of other myeloid lineage (CD13 and/or CD33) and positivity for markers associated with granulocytic maturation such as CD15 and/or CD65 (again, at least on a fraction of cells). AMLs with myelomonocytic differentiation also display a population of cells demonstrating expression of CD14, co-expression of CD36 and CD64, or bright expression of CD33, CD4, CD11b,

TABLE 2.9

IMMUNOPHENOTYPIC PATTERNS ASSOCIATED WITH RECURRENT SPECIFIC CYTOGENETIC ABNORMALITIES IN LEUKEMIA

	Cytogenetic Abnormality	Characteristic Flow Cytometry Findings
AML	t(8;21) (q22;q22), *RUNX1-RUNX1T1*	At least a fraction of blasts with CD34^{bright}, often co-expressing CD19 and TdT but not CD10 Granulocytic differentiation (CD13, CD33, MPO and CD15), aberrant expression of CD56 common No monocytic differentiation
AML	Inv.(16)(p13.1q22) or t(16;16)(p13.1(q22) *CBF-MYH11*	Distinct populations of blasts, granulocytic and monocytic (CD14, CD4, CD64) precursors Co-expression of CD34 and CD64 common Eosinophils can be delineated by high SS and low FS than neutrophils and CD16 neg Often CD2 on blasts and precursors
AML	t(9;11)(p22;q23) *MLLT3-MLL*	MAb 7.1 positivity Monocytic differentiation (HLA-DR, CD4dim, CD11b, CD13, CD15, CD36, CD33, and CD64)
AML	*NPM1* mutated	Most often blasts CD34–, often HLA-DR–, CD117+, CD123+, CD33 ^{bright}, CD110+ Show granulocytic differentiation (CD15+) Monocytic differentiation in 30% of cases Some cases only CD33 ^{bright} and MPO ^{bright} with no differentiation
AML	Inv.(3)(q21;q26.2) or t(3;3)(g21;q26.2) *RPN1-EVI1*	Positive for CD34, CD117, CD13, CD33, HLA-DR, and MPO
AML	t(6,9)(p23;q34) *DEK-NUP214*	CD9+, CD13+, CD33+, CD117+, and HLA-DR+, May be CD34– at presentation but CD34+ at relapse Basophils are often increased (CD123++, HLA-DR–)
AMkL	t(1;22)(p13;q13) *RBM15-MKL1*	Megakaryocytic differentiation CD41+, CD61+ often together with CD34, HLA-DR
APL	t(15;17)(q22;q12) *PML-RARα*	Hypergranular: most cases CD34–, HLA-DR–, CD11b–, CD11c–, CD117+, MPO+, CD33 ^{bright}, CD13 heterogenous,CD15−/^{dim}, Hypogranular: often CD2+, subsets positive for CD34 and/or HLA-DR present
ALL (B)	t(4;11)(q21;q23) *AF4-MLL*	CD34+, CD19+, CD10−, CD20−, CD13 and/or CD33 may be positive, often CD15 and/or CD65+, 7.1+ , cyt.IgM−
ALL (B)	t(9;22)(q34;q11.2) *BCR-ABL1*	CD34++, CD19+, CD10+, CD20−/+, CD13, CD33, CD66c often positive, CD15−, CD65−, 7.1–, cyt.IgM-
ALL (B)	t(12;21)(p12;q22) *TEL-AML1*	CD34+ or −, CD19+, CD10+, CD20−/+, CD13, and/or CD33 often positive, CD66c−, CD15−, CD65−, 7.1−, cyt.IgM−
ALL (B)	hyperdiploid	CD34+ or subset, CD19+, CD10+++, CD123++, CD20−/+, CD13−, CD33−, CD66c−/+, CD15−, CD65−, 7.1–, cyt.IgM−
ALL (B)	t(1;19)(q23;p13.3) *TCF3-PBX1*	CD34− or subset, CD19+, CD10− or subset, CD20+, CD13−,CD33− CD66c−/+, CD15−, CD65−, 7.1–, cyt.IgM+
ALL (T)	*FLT3* activating mutation	Expression of CD117

and/or CD11c. By contrast, acute monoblastic and monocytic leukemias usually show a single population of aberrant cells with evidence of monocytic differentiation (bright CD36, CD64, CD14, and/or CD4), which are usually CD34 and/or CD117 positive. Positivity for megakaryocytic [CD41a, CD42b, and CD61] or erythroid lineage involvement [glycophorin A, CD36, CD71++] must be interpreted cautiously inasmuch as the possible adherence of platelets or red cell membrane fragments to the blast cells may lead to unspecific positivity and misclassification. Correlation with morphologic and immunohistochemical findings is necessary. The rare cases of acute basophilic leukemia reported have shown expression of common myeloid antigens such as CD13 and CD33, as well as CD9, CD11b, CD22, and CD123.[138,139]

Using modern FCM, aberrant phenotypes (also called leukemia-associated immunophenotypes, LAIP) can be detected in >90% of patients with AML.[140,141] For correct interpretation of follow-up samples and detection of MRD, the immunophenotypic pattern of diagnostic sample and thorough knowledge of immunophenotype of various cell populations in normal and regenerating BM is necessary.[25] Most approaches used in reported studies included construction of patient-specific panels dependent on immunophenotype at diagnosis.[142,143,144] New 8–10 color approaches rely on common comprehensive panels applied at both diagnosis and follow-up, allowing detection of aberrant cells in most patients using sequential gating strategy.[145,146]

Acute Lymphoblastic Leukemia

Leukemic cells in ALL clearly disclose their belonging to a B- or T-cell lineage. As in AML, specific immunophenotypes in ALL have been associated with major groups of chromosomal aberrations (Table 2.9).

B-lymphoblastic leukemia/lymphoma (or B-ALL) is characterized by expression of CD19, HLA-DR, and TdT together with several B-cell markers such as membrane and/or cytoplasmic CD22 and cyt. CD79a. In many cases, CD45 is negative. Five immunologic subtypes, roughly corresponding to sequential stages of B-cell differentiation have been recognized. However, the existence of CD10 negative normal early B-cell progenitors is controversial. B-ALL can be immunologically classified into [130,138]:

- B I/Pro-B/Early B: CD10– CD20–, cyIgM–, sIg–
- B II/common/Early B: CD10+, CD20+/– , cyt. IgM–, sIg–
- B III/Pre-B: CD10+, CD20+/–, cyt IgM+, sIg–
- B III/Pre-B/B (very rare): CD10+, CD20+/–, cyt. IgM+, sIg+ (κ or λ–)
- B IV/B-mature: Tdt+/–, CD10+/−, CD20+, cyt. IgM–, SIg+ (κ or λ–).

T-cell lineage in ***T-lymphoblastic leukemia/lymphoma*** (or T-ALL) is established by expression of cyt. CD3, TdT,[147] and CD7, which is found in most cases.[34] Other T-cell–associated markers are variably expressed. In some cases, weak expression of cyt CD79b has been reported.[148] There is no clear consensus concerning immunologic classification of T-ALL. The European Group for the Immunologic Classification of Leukemia (EGIL) classification included:

- pro-T (or T-I) positive for only CD7
- Pre-T (or T-II) positive for CD2 and/or CD5 and/or CD8
- Cortical T (or T-III) positive for CD1a (irrespective of other markers)
- Mature T (T-IV) positive for surface CD3 and negative for CD1a (irrespective of other markers)[130]

An early T-precursor subtype, characterized by an aggressive clinical course and carrying immunophenotype associated with early T-cell precursors (ETPs) has recently been identified.[149] ETPs are a subset of thymocytes that recently migrated from the BM to the thymus; they retain multilineage differentiation potential, suggesting their direct derivation from hematopoietic stem cells. The immunophenotype of ETP subtype of T-ALL includes a lack of CD1a and CD8, very weak or negative CD5, and expression of one or more early precursor or myeloid-associated markers: CD117, CD34, HLA-DR, CD13, CD33, CD11b, and/or CD65.[149]

In >95% of both B- and T-ALL cases, leukemic blasts display aberrant immunophenotypes that allow us to distinguish them from normal B-cell precursors (Fig. 2.7) and normal bone marrow T-cells.[34,150] MRD detection by FCM is well established and already included in some clinical trials.[151] Characteristic immunophenotypes must be identified at diagnosis for each patient by comparing the cell marker profile of leukemic blasts to that of normal and regenerating bone marrow samples. Transient changes in immunophenotypes of residual leukemic cells have been reported, but some aberrant features are usually retained.[152] Sensitivity of MRD detection at 0.01% can be achieved, provided that sufficient numbers of cells are analyzed (5 to 10 $\times$ 10^5) in each antibody combination.

Myelodysplastic Syndromes and Chronic Myelomonocytic Leukemia

Although several authors described various aberrant immunophenotypic features in the bone marrow of patients with MDS, the WHO 2008 classification recommended that, only if three or more phenotypic abnormalities are found involving one or more of the myeloid lineages, the aberrant FCM findings can be considered as suggestive of MDS.[153] Standardization efforts concerning FCM diagnostics in MDS were started under the auspices of the European Leukemia Network's Work Packages 8 (MDS) and 10 (Diagnostics) (www.leukemia-net.org). The report resulting from the first International Workshop on Standardization of FCM in MDS reached consensus concerning standard methods for cell sampling, handling, and processing.[125] As well, it was recommended that standards be set that would define a minimum panel of antibody combinations, which could provide effective characterization of aberrant immunophenotypes.[125] These minimal criteria have been further refined as a result of the second and third workshops.[154] During all three workshops it was stressed that FCM results should not be reported alone but rather as a part of an integrated MDS diagnostic approach.

A detailed knowledge of normal immunophenotypes of BM cells is necessary for evaluation of aberrant features suggestive of MDS. Findings in CMML are similar to those described in MDS, the high numbers of monocytes and monocytic precursors being the main difference. Some of most important immunophenotypic characteristics of dysplasia are summarized below.

Progenitor cells: Both lymphoid and myeloid progenitor cells are found in the CD45dim/SS low region (Fig. 2.2). A large study by Kern et al. found a very good correlation between numbers of blasts counted by morphology and FCM in MDS patients.[155] Several authors consider 3% of blasts as a significant limit for increased blast number in the bone marrow.[153] Regardless of the numbers, aberrant phenotypes of blasts give very important diagnostic information.[156] Of note, the CD34+CD38− cell population, which is responsible for the long-term repopulating activity in human stem cells [40] is often increased in MDS patients.[43,157] This cell population has also been recognized as the leukemic stem cell compartment in acute myeloid leukemia (AML) and displays aberrant phenotypes in MDS.[42,158]

Maturing myeloid compartment: The most consistently reported aberration of the maturing myeloid cell compartment is the lower SS that is due to lower than normal granularity seen also by morphology in BM smears. The aberrant maturation patterns detected using CD13 and CD16 and/or CD13 and CD11b MAb combinations, altered expression of CD45, CD33, asynchronous expression of CD34, expression of lineage infidelity markers such as CD2, CD7, and CD56 are the frequently reported

changes.[153] However, it has to be pointed out that various aberrant features observed in MDS patients can occasionally be found in patients with nonclonal cytopenias and some authors suggest that aberrant FCM findings in the immature precursor population are more specific for MDS than those in maturing granulopoietic cells.[159]

Monocytes: The numbers of monocytes in BM and PB of MDS patients are usually not increased, but this population may show aberrant features in approximately 25% of patients.[155,160] The finding of two or more aberrant features is very rare in reactive monocytes.[161] Aberrant features described in MDS are similar to those found in CMML.[161] Increased expression of CD56 is most frequently reported. However, this feature is not specific for MDS and could be found in 9% of patients with nonclonal cytopenia and after growth-factor treatment.[155,161] Findings that were only rarely found in monocytes from patients with reactive monocytosis are: decreased expression of CD13, CD11b, CD43, and/or HLA-DR, and aberrant expression of CD2.[155,162]

Erythropoietic cells: The erythropoietic fraction is often increased in MDS patients.[163] Asynchronous aberrant expression of the three markers CD71 (transferrin receptor), CD45, and CD235a (glycophorin A) was detected in 20% to 77% of MDS patients in various studies.[38,45,155,163] The most often observed feature is a decreased CD71 expression in CD235a positive erythropoietic precursors. However, FCM signs of erythropoietic dysplasia have also been found in single patients with hemolytic anemia and aplastic anemia (AA).[38,45]

Lymphoid Cells

B-cell lymphoid progenitors (CD19+/CD10+/CD34±) are usually markedly diminished or absent in MDS bone marrows.[35,164–169] This has recently been confirmed by multicenter studies, in which FCM files have been obtained using different flow cytometers and antibody combinations. Files have been analyzed in a standardized way to validate a simple model to distinguish International Prognostic Scoring System (IPSS) low-risk MDS from nonclonal cytopenias.[168,170] Analysis of the mature B-cell compartment should be carried out to exclude underlying B-cell lymphoma.[125,22]

Myeloproliferative Neoplasms

In chronic myelogenous leukemia (CML) reported abnormalities include aberrant expression of CD56 on blasts and myeloid cells,[171] decreased CD16 on granulocytes,[172] decreased L-(CD62L) and P-selectin (CD62P) expression on CD34+ cells,[173,174] and aberrant expression of lymphoid antigens such as CD2, CD5, and CD7 on the blasts in CML blast crisis.[175] In non-CML MPN, the most common changes were aberrant expression of CD13, CD33, HLA-DR, and/or CD16 on maturing granulopoietic precursors. BM eosinophils, identified by expression of relatively bright CD11b, CD13, CD15, and CD45, without CD16, are expanded markedly in the patients with putative chronic eosinophilic leukemia. A higher rate of basophils with abnormal immunophenotype was also detected in different MPNs.[176]

Increased CD56 expression and small size of granulocytes as measured by FS were described in primary myelofibrosis.[177] Increase of cells in the blast gate and emerging aberrant phenotypes in the blast population herald transformation to AML.

OTHER APPLICATIONS OF FLOW CYTOMETRY IN HEMATOLOGY

Paroxysmal Nocturnal Hemoglobinuria

FCM is a standard method for diagnosis of paroxysmal nocturnal hemoglobinuria (PNH). In PNH, the somatic mutation of the X-linked phosphatidylinositol glycan complementation Class A (*PIGA*) gene causes a partial or absolute inability to make GPI-anchored proteins. Antigens such as CD55, CD58, CD59, CD14, CD16, and CD24 are affected. The channel-forming toxin aerolysin and its preform pro-aerolysin bind selectively and with high affinity to GPI anchor. An inactive aerolysin variant conjugated with Alexa Fluor 488 (FLAER-A) is now widely used to detect GPI-anchor-deficient cell populations.[178,179] Current guidelines include a combination of CD235a-FITC and CD59-PE for detection of GPI-deficient RBC, FLAER-A/CD24-PE/CD15-PECy5/CD45-PECy7 for detection of GPI-deficient granulocytes, and FLAER-A/CD14–PE/CD64–PECy5/CD45-PECy7 for GPI-deficient monocytes [180] (Fig. 2.8). High-resolution assays allow detection of GPI-deficient RBC at sensitivity level 10^{-5} and GPI-deficient WBC at 10^{-4},[180] which has been noted in patients with aplastic anemia and MDS.

Red Blood Cell Analysis

Clinical application of FCM to study erythropoiesis and nonclonal RBC disorders has been reviewed by Chesney et al..[181] Enumeration of reticulocytes and detection of hemoglobin F (HbF) positive erythrocytes are briefly summarized below.

Reticulocyte Enumeration

Several RNA dyes may be applied in hematology analyzers and flow cytometers to enumerate reticulocytes (e.g., Oxazine 750, CD4K 530, New Methylene Blue, Auramine O, and Thiazole Orange [TO]). Dyes show differing sensitivities to stain the RNA of reticulocytes. Various analyzers use different technologies to identify positive cells (fluorescence, light scattering, absorbance), and the software that is more or less capable of separating reticulocytes from erythrocytes (because there is a physiologic continuum between these populations) and from other cells, such as platelets or nucleated RBCs.[182] Fluorescence intensity will depend on the RNA content and is correlated to reticulocyte maturity. The immature reticulocyte fraction (the sum of reticulocyte fractions with medium and high fluorescence) gives information on activity of erythropoiesis.[183] TO can also be applied together with CD59-PE for detection of GPI-deficient reticulocytes, which may be of advantage in transfused PNH patients.[184]

Hemoglobin F (Fetal-Maternal Hemorrhage and Sickle Cell Anemia)

Fetal-maternal hemorrhage from a rhesus factor positive (Rh+) fetus to an Rh-mother may lead to immunization of the mother against fetal alloantigens. Therefore, standard clinical practice is to administer Rh immune globulin to all Rh-women at 28 weeks of gestation and within 72 h of delivery of an Rh+ infant. Measurement of the amount of HbF in the maternal circulation helps to determine the amount of Rh immune globulin to administer. FCM method for fetal-maternal hemorrhage detection uses a fluorochrome conjugated anti-HbF MAb to detect HbF inside permeabilized RBCs.[185] Weakly positive red cells (termed F cells) may be found in genetic disorders such as hereditary persistence of fetal hemoglobin (HPFH), sickle cell anemia, and thalassemia major. In patients with sickle cell anemia treated with hydroxyurea, monitoring the percentages of F cells can be applied to determine treatment efficacy.[186]

Fetal cells can be distinguished from F cells by much higher fluorescence intensity. Adequate gating is necessary to determine the percentage of fetal cells in the mother's RBCs, where only the "bright" cluster is considered as fetal cells. In order to determine the quantity of fetal hemorrhage (in ml of fetal blood) the percentage of fetal RBC is multiplied by a factor of 50 (assuming that maternal blood volume is 5.0 L).[181]

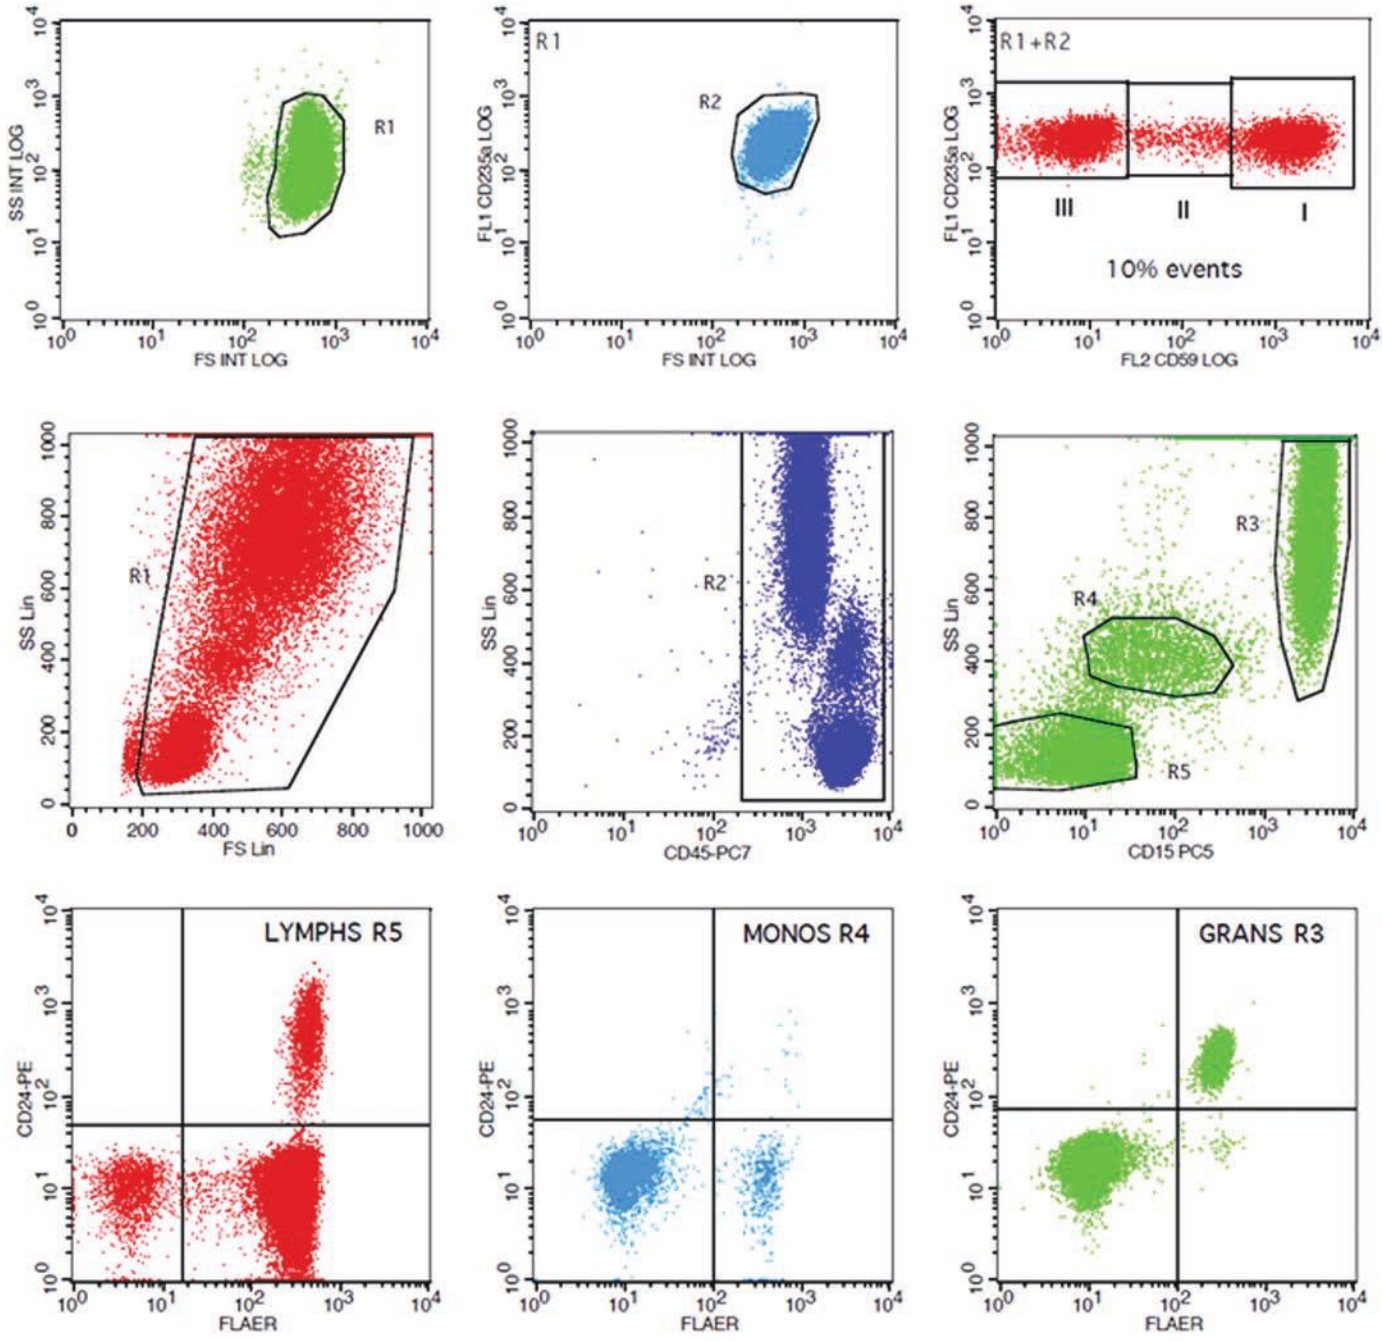

FIGURE 2.8. Enumeration of blood for markers associated with paroxysmal nocturnal hemoglobinuria (PNH). Upper row: the red blood cell (RBC) assay using CD23a–FITC/CD59-PE staining. RBCs are gated on FS and SS (R1, Upper left plot) and displayed on FCS versus CD235a–FITC plot (upper middle). CD235a positive RBCs are gated (R2). RBCs from region R1 + R2 are analyzed for CD59 expression (right upper plot). Normal RBCs (CD59 bright) are in region I. RBCs with PNH-related phenotypes (i.e., with CD59dim expression or CD59 negative) are in regions II and III, respectively. Middle and lower row: white blood cell (WBC assay) using staining with FLAER, CD24PE, CD15PECy5, and CD45PECy7. Light scatter voltages were established so that all nucleated cells were visible above the forward scatter threshold (middle left) and debris was excluded with a combination of light scatter and CD45 gating (middle plot). CD45+ events were displayed on CD15 versus SS plot (middle right plot) and granulocytes (bright CD15, high SS), monocytes (dim CD15 and intermediate SS) and lymphocytes (CD15-negative, low SS) were gated. Each of these populations was displayed on a FLAER versus CD24 plot (bottom row). PNH granulocytes (FLAER-negative, CD24-negative) were enumerated in the bottom right plot (lower left quadrant). Normal granulocytes were enumerated in the upper right quadrant. Gated monocytes were similarly displayed (bottom row middle) and the PNH monocytes (FLAER-negative, CD24-negative) were enumerated in the lower left quadrant. Gated lymphocytes (bottom row left) were assessed for PNH phenotypes in the lower left quadrant. Normal T-lymphocytes (FLAER+, CD24-negative) are visible in the lower right quadrant and normal B-lymphocytes (FLAER+, CD24+) are visible in the upper right quadrant. (Courtesy of Dr. D. Robert Sutherland, Laboratory Medicine Program, University Health Network, Toronto General Hospital, Toronto, Ontario, Canada.)

Analysis of Platelets

FCM analysis of platelets is usually performed on whole blood drawn into 3.2% to 3.8% citrate anticoagulant. Other anticoagulants can also be applied for platelet enumeration but EDTA and heparin are not recommended for analysis of platelet activation or activity due to interference with glycoprotein (GP) IIb–IIIa complex. Blood samples should not be subjected to cold and should be processed within 15 min of drawing. Platelets can be

differentiated from other blood cells by their FS and SS properties and/or expression of platelet-specific antigens (e.g., CD41, CD42, or CD61). FCM analysis of platelets can help to establish a diagnosis of specific platelet disorders (reviewed in Ref. 187) such as:

- Bernard–Soulier syndrome, inherited deficiency of the GPIb-IX-V complex, where decreased expression of GPIb (CD42b), GPIX (CD42a), and GPV (CD42d) is noted
- Glanzmann thrombasthenia, inherited deficiency of integrin αIIbβ3, where aberrant expression of CD41 (GPIIb) and CD61 (GPIIIa) is found
- Dense granule storage pool deficiency can be detected by studying uptake and release of mepacrine as fluorescent marker [188]
- von Willebrand disease where the FCM method is used for the determination of the von Willebrand factor (VWF) activity, utilizing formalin-fixed platelets, FITC-conjugated chicken anti-VWF antibodies (Fab-fragments), and PE-conjugated anti-GPIIb/IIIa antibodies.[189]

Immature platelets (also called reticulated platelets) may be identified using TO dye. This method can be applied to differentiate regenerative versus nonregenerative thrombocytopenia and assess regeneration after BM transplant.[190]

Several antibodies bind to activated but not to resting platelets (activation-dependent antibodies). Markers of platelet activation include PAC1 (detecting conformational changes in integrin $\alpha I_{Ib}\beta_3$), CD62P (P-selectin), and formation of platelet-derived microparticles (PMPs). Measurements of platelet activation by FCM may assist in diagnosis and treatment of acute coronary syndromes, acute cerebrovascular ischemia, and several other conditions. Studies of platelet activation have also been widely employed in monitoring of specific anti-platelet therapies (reviewed in Ref. 187).

Heparin-induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a rare but potentially serious complication of heparin use. Prompt diagnosis is crucial and requires the integration of clinical assessment and laboratory testing. FCM detection of leukocyte-platelet aggregates (defined as events positive for both the presence of CD45 and platelet glycoprotein IIb) as a marker of platelet activation with different heparin concentrations, using plasma from HIT-positive patients detected leukocyte-platelet aggregates in 75% of HIT-positive patients, and correlated with levels of anti-H-PF4 antibodies. An FCM-based platelet microparticle generation assay as a marker of platelet activation in HIT has also been described. Platelet microparticles ranged in size from 0.5 to 1.0 μm, and were also defined by the expression of platelet glycoprotein Ib, CD41, and annexin V. However, another FCM-based functional assay measuring CD62 has been reported as a more reliable marker of platelet activation as a result of the presence of pathogenic H-PF4 antibodies than the procoagulant phospholipid annexin V (reviewed in Ref. 191).

STEM CELL TRANSPLANTATION

CD34+ Cell Enumeration

Enumeration of CD34+ cells is an essential tool for peripheral blood stem cell (PBSC) harvest, providing a rapid assessment of graft adequacy.[192] Most transplant centers determine graft adequacy based on the number of CD34+ cells/Kg of patient body weight. Mobilization of PBSC is typically done using granulocyte colony stimulating factor (G-CSF) alone or in combination with chemotherapy. Peripheral blood (PB)-CD34+ counts have been shown to correlate with PB-CD34 apheresis collections and have been utilized to decide when apheresis should start. Mobilization success is influenced by several factors such as prior therapy, mobilization strategy, and underlying disease. Clinical guidelines for CD34+ cell quantitation in peripheral blood and PBSC for the International Society for Hematotherapy and Graft Engineering (ISHAGE) based CD34+ cell enumeration on four parameters: FS, SS, CD45, and CD34 staining intensity.[193] A viability dye 7-amino actinomycin D (7-AAD) and fluorescent counting beads were subsequently added to create a single platform assay (Fig. 2.9) and to avoid potential calculation errors from using FCM and hematology analyzer.[194] UK-NEQUAS surveys showed that methodology is still in need of standardization and that several laboratories did not perform the gating correctly.[195] New flow cytometers allowing direct volumetric cell analyses (CD34+ cells/μL) and quantitation without the need of the beads has recently been introduced and shown to give comparable results as the standard single platform protocol.[196]

Human Leukocyte Antigen Antibody Detection

The primary goal of human leukocyte antigen (HLA) antibody testing for transplant patients is to assess potential risk for graft rejection. The selection of a matched donor and appropriate post-transplant treatment is determined by patient HLA antibody status. Post-transplant formation of antibodies against HLA Class I and II antigens heralds graft rejection. FCM cross-match (FCXM), introduced in the 1980s, involves incubation of purified donor mononuclear cells with the patient's serum and subsequent detection of cell-bound antibodies by fluorochrome-conjugated antihuman Ig serum (reviewed in Ref. 197). By varying the type of secondary antibody, the isotype of antibody (IgG, IgM, or IgA) can be determined, and by adding MAbs to B- and T-associated markers, reactivity in B- and T-lymphocytes can be evaluated separately.

Solid-phase immunobinding assays utilized purified HLA proteins as targets. Beads that can be identified by a unique level of fluorescence are coated with HLA class I or II proteins to create a screening pool of HLA antigens. By using multiple different phenotypes distributed over several arrays, patient-specific HLA specificities can be determined (reviewed in Ref. 197). However, these assays are every cumbersome and require up to 15 tubes per patient. Recently, a new type of FCM platform (Luminex Corp, Austin, TX, USA) has been developed that allows up to 100 individual beads to be evaluated in a single multiplexed assay. Each bead has a unique fluorescent signature and is coated by a different antigen. A PE-conjugated antihuman IgG is used to detect the binding of patient serum to the beads. However, a fraction of patients display very broadly reactive HLA antibodies making all beads positive. Introduction of recombinant technology and coating the beads with single HLA antigens make it possible to clearly delineate the antibody reactivity of each patient (reviewed in Ref. 197). Combination of the highly sensitive antibody assessment with FCXM contributes to better selection of donor/recipient pairs and better transplant outcomes.

SOME APPLICATIONS OF FLOW CYTOMETRY IN IMMUNODEFICIENCY, AUTOIMMUNE, AND INFECTIOUS DISEASES

Primary Immunodeficiency Diseases

Over 200 primary immunodeficiency diseases (PIDs) have been clinically identified.[198] The majority of PIDs have an abnormality that could be detected by FCM assay, such as:

- Mutations in genes that affect the relative representation of a specific cell subset

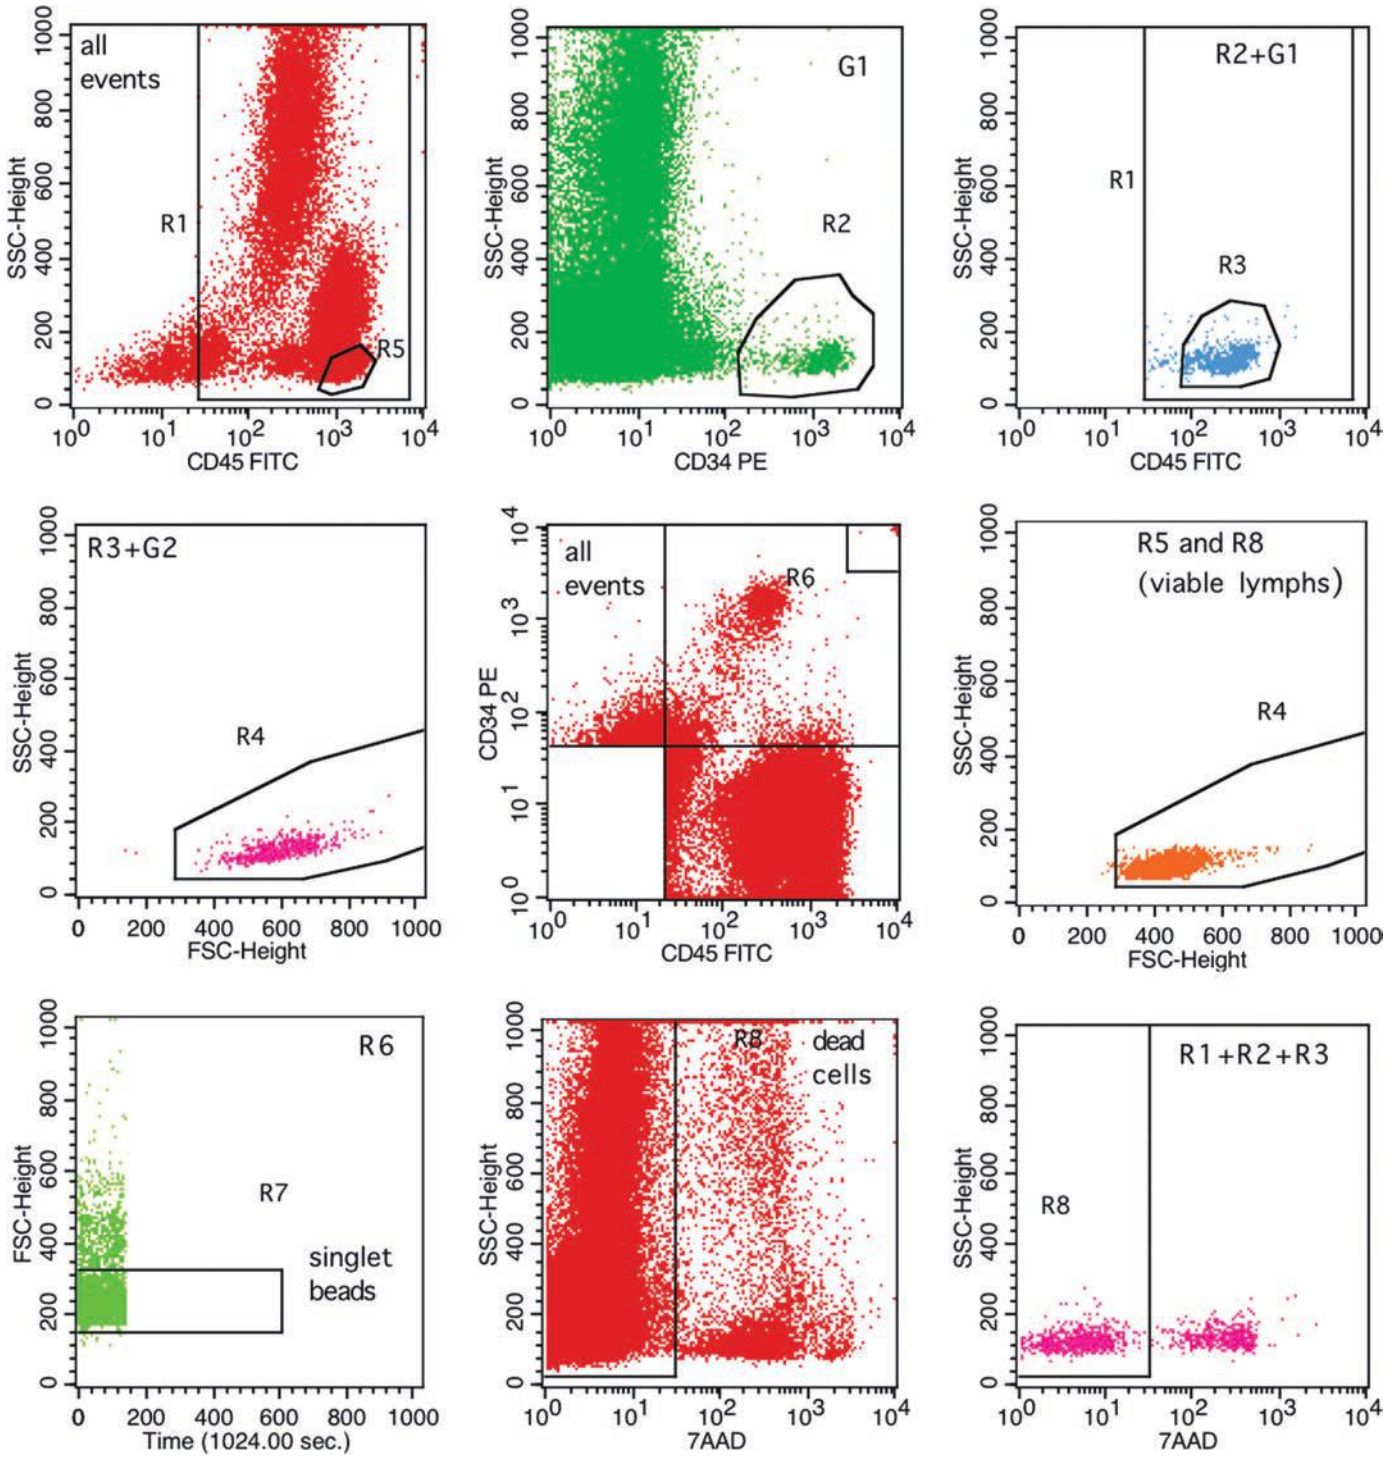

FIGURE 2.9. Enumeration of viable CD34+ cells according to ISHAGE protocol. An apheresis sample that had been stored overnight at room temperature was stained with the Stem-Kit reagent set and analyzed on a BD Biosciences FACSCalibur cytometer equipped with CellQuest™. Viable CD34+ cells were identified using Boolean gating and regions R1 through R4 (all upper plots and left middle row plots), including only viable (7-AAD−) cells from region R8 (right lower row plot). Viable lymphocytes from region R5 (left upper plot) and R8 are displayed on left middle plot and the duplicate blast-lymphocyte region R4 adjusted to include the smallest viable lymphocytes. Duplicate gating region R4 on plot 4 self-adjusts accordingly. Middle plot shows the position of a "live" gate in the bottom left corner, which excludes debris resulting from lyse-no-wash sample processing of PB, CB, and BM sample types. The number of CD34+ cells in region R4 is compared with the total number of singlet beads counted during the same acquisition and present in the same listmode file. In the example shown, total beads are gated in region R6 in the middle plot and displayed in the left lower plot (time versus forward scatter). Singlet beads are then delineated and enumerated in gating region R7. Sample analysis was performed using Cellquest Pro™ software using semi-automated Expression Editors. For earlier versions of Cellquest, the absolute number of viable CD34+ cells/μl is calculated as follows:

$$\frac{\#\,\text{CD34+ cells} \times \text{bead concentration} \times \text{DF}}{\#\,\text{singlet beads}}$$

where #CD34+ cells are determined from logical gate G4 (vCD34 in gate stats = R1+R2+R3+R4+R8), the bead concentration is specified by the manufacturer, DF is the sample dilution factor, and the singlet bead count is determined from plot 7 (singlet beads in gate stats = R6 + R7). The right lower plot shows the total CD34+ cells (viable and nonviable) from gating regions R1 + R2 + R3 only and shows viable cells onscale in about the first decade of fluorescence. This plot is useful when samples with poor viability are to be analyzed as it is easier to set region R8 in this plot versus the middle lower plot. Additionally, it shows that the fluorescence compensation between PMT 2 (CD34PE) and PMT 3 (7-AAD) is optimally set. (Courtesy of Dr. D. Robert Sutherland, Laboratory Medicine Program, University Health Network, Toronto General Hospital, Toronto, Ontario, Canada.)

- Mutations in genes that affect the expression of a specific antigen
- Mutations in genes that affect a particular cell function

Routine immunophenotyping of blood lymphocyte subsets, detection of CD154 up-regulation, and oxidative burst assay for the screening diagnosis of granulomatous diseases are most commonly employed FCM assays in PID diagnosis (reviewed in Ref. 199). FCM findings in the most common PID categories are summarized in Table 2.10 (reviewed in Ref. 200).

Flow Cytometry Detection of HLA-B27

HLA-B27, an MHC class I molecule is related to a major risk factor for a group of diseases now called spondyloarthritis that consists of consists of psoriatic arthritis, reactive arthritis, arthritis related to inflammatory bowel disease, a subgroup of juvenile idiopathic arthritis, and ankylosing spondylitis [the prototype of spondyloarthritis [201]]. This association is present in many genetically diverse populations and across all major HLA-B27 subtypes.

The presence of HLA-B27 in 80% to 90% of patients with ankylosing spondylitis and the spontaneous spondyloarthritis-like disease in HLA-B27 transgenic rats suggests a direct and dominant effect of the gene encoding this molecule. However, only a small proportion of people in the general population who harbor HLA-B27 (5% to 6% in Caucasians) develop ankylosing spondylitis, and HLA-B27 explains only 20% to 40% of the genetic susceptibility to ankylosing spondylitis, suggesting the contribution of additional genes. Genomewide association studies (GWASs) have allowed the identification of several of these additional genes. HLA-B27 typing using MAbs and FCM analysis of their reactivity in a gated T-cell population is used extensively. However, the cross-reactivity of anti-"B27"murine MAbs, particularly with the common HLA-B7 antigen has been a problem. Recently a one-tube test, employing two "B27" MAb reagents, has been developed.[202] This test securely detects the HLA-B*27 allele product B*2705, B*2702, and B*2708 and reacts with many of the other rare B*27 allele products tested. In addition, other HLAB antigens, notably HLA-B7, do not interfere with accurate HLA-B27 assignment. However, even when using the recommended dual anti-B27 typing reagents, patients reacting with one antibody only should be retested using a DNA-based technique.

Human Immunodeficiency Virus Infection

FCM studies provide important clinical information that helps predict disease outcome and guide treatment decisions in HIV+ patients. CD4+ T-cell counts are, together with viral load, the strongest predictors of disease progression. Single platform technology (SPT) is designed to enable determinations of both absolute and percentage lymphocyte subset values using a single tube. Previously, most absolute T-cell numbers were derived from three measurements determined with two different instruments, a hematology analyzer and a flow cytometer (dual-platform technology [DPT]). A gating strategy for identifying lymphocytes using CD45 fluorescence and side-scattering characteristics is now the preferred method for identifying lymphocytes. The preferred

TABLE 2.10

FLOW CYTOMETRY (FCM) IN THE DIAGNOSIS OF MAJOR PRIMARY IMMUNE DEFICIENCY

Primary Immune Deficiency Type	FCM Findings
Congenital agammaglobulinemia X-linked (XLA)	Absence (or very low numbers) of CD20+ and/or CD19+ B-lymphocytes Absence of intracellular Bruton tyrosine kinase (BTK) in monocytes and platelets
Common variable immunodeficiency (CVID)	Expansion of $CD21^{low}$ B-cells Absence of memory switched B-cells Lack of inducible costimulator (ICOS) up-regulation on T-cells following activation CD19 deficiency (in presence of CD20) B-cell activating factor-receptor (BAFF-R) deficiency
Severe combined immune deficiency (SCID)	Wide range of defects: Adenosine deaminase deficiency: lack of T-, B-, NK-cells Janus kinase 3 deficiency: lack of T- and NK-cells RAG1/2 deficiency: lack of T- and B-cells CD3δ, ε or ζ deficiency: lack of T-cells
Hyper IgM syndromes	Decrease of CD40 and/or CD40 ligand (CD154) expression on activated CD4+ cells
Wiscott Aldrich syndrome (WAS)	Decrease of CD8+ cells and increase of NK-cells Decreased expression of WAS protein
Defects in the interleukin-12/23-Interferon-γ circuit	Aberrant expression of IL-12 receptor β1 and interferon (IFN)-γ receptor1
Toll-like receptor pathway defects	Absence of shedding of CD62L from the surface of granulocytes
Chronic granulomatous disease	Low results of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity assay following granulocyte activation
Leukocyte adhesion deficiency type 1 (LAD1)	Decreased or absent CD11a, CD11b, CD11c, and CD18 on granulocytes
Immune dysregulation, polyendocrinopathy, enteropathy, X-linked inheritance syndrome	Decreased/absent factor forkhead box protein 3 (FOXP3) expression in T-cells
Autoimmune lymphoproliferative syndrome	Elevated levels of CD4-CD8- (double negative) T-cell receptor α/β positive T-cells Low memory B-cells (CD20+CD27+)[en]Increased CD8+CD57+ T-cells
X-linked lymphoproliferative syndrome	Very low numbers of NK T-cells CD3+CD16+CD56+Vα24+Vβ11+ Decreased/absent signaling lymphocyte activation molecule (SLAM)-associated protein (SAP) or X-linked inhibitor of apoptosis (XIAP) protein
Familial hemophagocytic lymphohistiocytosis	Defects in expression of perforin, syntaxin-11 Diminished expression of CD107 on NK-cells

four-color panel includes CD45, CD3, CD4, and CD8. Commercial bead-counting reagents for SPT have resulted in decreased inter-laboratory variability. A single tube model can easily be employed even in countries with limited resources.[200]

However, CD4+ T-cell counts do not fully capture an individual's risk for disease progression. A substantial proportion of patients with more than 350 CD4+ T-cells/μL in blood (the current threshold for treatment initiation) will progress to AIDS within only 3 years. Only a few markers that could identify, early in disease, more HIV+ individuals at risk for rapid disease progression have been reported. For example, in the setting of early HIV disease, the ability of Ki-67 to predict disease progression independently of CD4+ T-cell count or viral load was recently recognized. Similarly, in the setting of chronic infection, CD38 expression is a CD4 count- and viral load-independent predictor of disease outcome (reviewed in Ref. 203). FCM studies have greatly contributed to the understanding of HIV pathogenesis. Coreceptors for the virus have been identified: CCR5 in memory T-cells and CXCR4 in CD4+ T-cells. Loss of CD4+ cells is accompanied by T-cell activation (shown by expression of CD38, HLA-DR, and CD69) and by an increase of senescent CD8+ cells (CD28−) with high cytolytic activity (CD57+, perforin+). Naive and central memory T-cells are progressively depleted (reviewed in Ref. 203).

Analysis of Antigen-Specific T-cells

FCM detection of antigen-specific T-cells became possible by the development of fluorochrome-labeled MHC-peptide complex (so-called tetramers) technology. MHC class I tetramers usually consist of four MHC class I glycoproteins loaded with peptide and labeled with streptavidin bound to a fluorochrome (reviewed in Ref. 204). During incubation with the lymphocytes, the tetramer will bind to CD8+ T-cells that express a T-cell receptor capable of recognizing the specific peptide. MHC class II tetramers are more difficult to produce but have also been developed and applied to study CD4+ cell responses (reviewed in Ref. 205).

At present, standardized FCM methodology has a detection limit of 0.02% specific CD8+ cells in blood, mostly used in vaccine studies. Magnetic bead enrichment using beads coated with antibodies to fluorochrome (mostly PE) has been employed to reach higher sensitivity.

Tetramer technology is also used in functional assays to study proliferation of epitope-specific T-cells or for analysis of T-cells responding to viruses or vaccines. Tetramer-positive T-cell subset analysis is used to determine the quality of the T-cell response and to sort antigen-specific T-cells (reviewed in Ref. 204).

CELLULAR DNA CONTENT AND CELL CYCLE ANALYSIS

FCM methods for measuring DNA content rely on cells being labeled with a fluorochrome that is expected to stain DNA stoichiometrically and the intensity DNA associated fluorescence is obtained. Staining of live cells (so-called supravital staining) is used mainly for cell sorting based on their DNA content. A variety of methods for FCM DNA analysis of fixed cells has been reported, differing in cell permeabilization, choice of fluorochrome, and applicability to different cell populations.[206] In general, precipitating fixatives (alcohols, acetone) are preferred over cross-linking reagents (formaldehyde, glutaraldehyde). The most commonly used fluorochromes are DAPI, PI, and 7-AAD (Table 2.1). Staining with PI required pre-incubation with RNA-se to digest RNA; RNA-se should be free of DNA-se activity. The method of isolating nuclei from paraffin-embedded tissue can be applied to determine DNA ploidy and cell phase in archival material.[207] The results of cellular DNA content are presented in the form of frequency histograms (Fig. 2.10). The DNA analysis software allows estimation

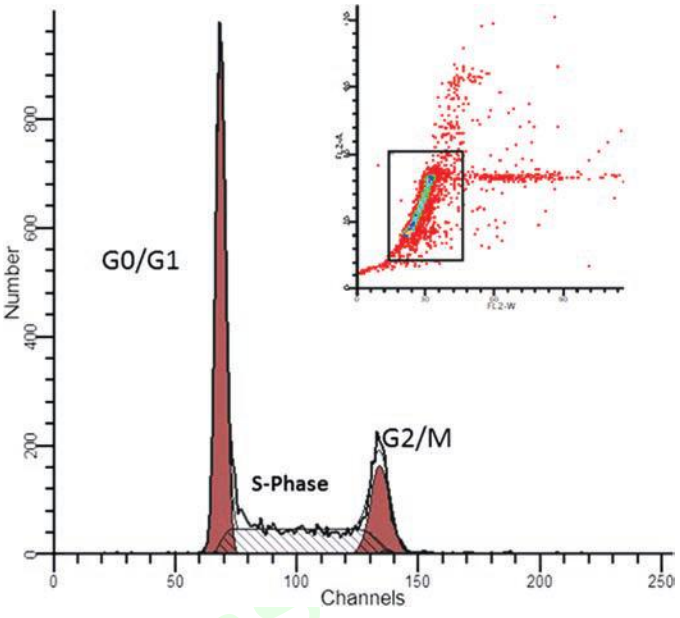

FIGURE 2.10. Schematic presentation of DNA analysis using DNA fluorochrome. Frequency of cells in G0/1, S, and G2/M phases can be determined. Insert shows gating of single cells using FL-W versus FL-A plot.

of the percentage of cells in the G1, S, and G2/M phase of the cell cycle as well as the frequency of apoptotic cells with fractional (sub-G1) DNA content (reviewed in Ref. 208). Before DNA content is analyzed, cell aggregates have to be removed from the analysis window by gating single cells on FL-width versus FL-area plots (Fig. 2.10).

DNA staining can be combined with immunophenotyping by labeling of live cells with a fluorochrome-conjugated MAb and supravital DNA staining or subsequent short fixation in 0.5% to 1% paraformaldehyde in PBS before DNA fluorochrome is applied. During analysis, cell populations of interest can be evaluated separately for DNA content after appropriate gating procedures.[208]

In hematology and oncology, estimation of cell fractions in the proliferation phase and DNA ploidy are frequently assessed. For ploidy assessment, the ratio of peak channel of DNA fluorescence of G0/1 population of the tumor and that of normal cells is established (sc. DNA index, DI). Normal lymphocytes from the same patient are often used as the standard of DI = 1.0.

In hematology, DNA ploidy studies by FCM have determined prognosis in B-ALL and plasma cell myeloma. In ALL, DI $\geq$ 1.16, so-called hyperdiploidy, is of favorable significance, whereas hypodiploidy (DI $>$ 0.9) is related to a worse response to treatment.[209] In myeloma, hyperdiploidy is related to a better response to bortezomib treatment.[210]

Analysis of DNA replication was at first performed using direct incorporation of ^{3}H- or ^{14}C-labeled thymidine, and ^{3}H-uridine incorporation was used for RNA content. Incorporation of 5-bromo-2-deoxyuridine (BrdU) was subsequently applied, based on quenching of Hoechst 33358 fluorescence by BrdU. Distribution of BrdU containing cells through the cell cycle was studied by combining Hoechst 33358 with BrdU-resistant dye such as ethidium bromide or with mithramycin. Recently introduced, the so-called "click chemistry" approach allows measuring DNA synthesis and RNA replication simultaneously, by applying 5-ethyl-2′deoxyuridine as a DNA precursor and 5-ethyluridine as an RNA precursor. These precursors can be detected with fluorochrome-tagged azides by means of a copper(I) catalyzed [3 + 2] cycloaddition reaction (reviewed in Ref. 206).

FUNCTIONAL ASSAYS

Monitoring of Cytokine Profiles

Current FCM technologies allow the simultaneous quantification of multiple cytokines with characterization of cytokine-producing cell subsets. Antibodies to studied cytokines can be combined with lineage markers such as CD4, CD8, CD3, and/or memory/effector phenotype markers such as CCR7, CD57, CD27, or CD45RO.

Intracellular cytokine assays are usually performed after short-term stimulation required for induction of cellular activation and cytokine production. Cytokines can be detected after secretion inhibitors such as monensin or brefeldin are applied, and proteins are retained intracellularly. Intracellular staining is performed after fixation and permeablization (reviewed in Ref. 211). One of the clinical applications includes monitoring of IFN-γ and tumor necrosis factor (TNF)-α producing CD3+ T-cells in aplastic anemia patients under immunosuppressive therapy.[212]

Multiplex cytokine bead arrays are used to quantify soluble plasma cytokines (e.g., Luminex technology). Distinct cytokine profiles were detected allowing differentiation between patients with aplastic anemia and hypoplastic MDS.[213] Very high levels of several cytokines were detected with Luminex methodology in children with anaplastic large cell lymphoma by comparison to other non-Hodgkin lymphoma subtypes.[214]

Protein Phosphorylation

The use of phospho-specific antibodies allows detection of the transient alterations induced by kinases and phosphatases involved in cell signaling. Phosphorylation refers to the addition of a phosphate to one of the amino acid side chains of a protein. Many of the proteins that are phosphorylated upon reception of a signal are protein kinases as well. This organization of kinases produces a phosphorylation cascade, in which one protein kinase is activated by phosphorylation upon reception of a signal; this kinase then phosphorylates the next kinase in the cascade. However, FCM methodology to detect phosphorylation is considered challenging and has not been, as yet, widely introduced for clinical use (reviewed in Ref. 215). Signaling responses have to be determined by comparing the basal level to the activated state of the enzyme. Often, multiple growth factors have to be applied for studies of activation (e.g., SCF and FLT3 for the extracellular signal-regulated kinase [ERK] pathway) and inhibitors are used for appropriate controls (e.g., MEK inhibitor U0126 for the ERK pathway). An appropriate fixation and permeabilization protocol has to be applied, depending on the studied protein. Responses are usually transient and the time-point of measurement is crucial. A high level of consistency in experimental procedures is needed (reviewed in Ref. 215). An example of clinical use is measuring of levels of the phosphorylated signal transducer and activator of transcription (STAT) 5 (P-STAT5) in CML patients. P-STAT5 levels are increased in most untreated CML patients but decrease upon BCR/ABL1 kinase inhibitor treatment.[216]

Apoptosis

Apoptosis (or programmed cell death) plays an essential role in the survival of the organism and is considered to be an imperative component of various processes including normal cell turnover, proper development and functioning of the immune system, multiplication of mutated chromosomes, hormone-dependent atrophy, normal embryonic development, elimination of indisposed cells, and maintenance of cell homeostasis. The importance of apoptosis has prompted development of FCM assays capable of measuring this process. FCM methods employed in apoptosis research include (reviewed in[217]:

- Detection of scatter changes corresponding to cell shrinkage (lower FS and unchanged or increased SC in early phase, and low FS and SC in late phase)
- FCM detection of mitochondrial inner transmembrane potential ($\Delta\pi_m$) loss using lipophilic cationic probes [e.g., Rh123 or $DiOC_6(3)$] that are readily taken up by live cells and accumulate in mitochondria
- FCM detection of caspase activation using fluorochrome-labeled inhibitors of caspases (FLICA) or detection of cleavage of poly ADP ribose polymerase (PARP) using an antibody that recognized 89-kD product of cleavage
- FCM detection of changes in the plasma membrane during apoptosis using fluorochrome-labeled Annexin V that binds to exposed phosphatidylserine on the cell surface
- FCM detection of changes in plasma membrane permeability
- FCM detection of nuclear fragmentation using sub-G0 fraction in DNA analysis or assessment of DNA strand breaks by TdT-mediated dUTP-biotin nick-end labeling (TUNEL)
- Gradual decrease of cyanine SYTO staining in apoptotic cells

Since Apoptosis is a rapid process, knowledge of the time-window when specific markers can be detected is crucial. Moreover, antigen loss often occurs at early stages of apoptosis, causing problems in immunophenotyping apoptotic cells.

CHAPTER 3

CYTOGENETICS

Athena M. Cherry, Charles D. Bangs

INTRODUCTION

Cytogenetics is the study of chromosome structure and function. Chromosome analysis is an integral part of diagnosing hematologic malignancies and is important for determining prognosis (or risk category) and/or treatment. According to the WHO classification of leukemias and lymphomas from 2008,[1] there are several categories of leukemias and lymphomas that are defined by their specific clonal chromosome abnormalities. Chromosome and/or fluorescence in situ hybridization (FISH) analyses are considered "standard of care" for diagnosing and following patients with most hematologic malignancies. Array analyses of these same malignancies, using either array comparative genomic hybridization (CGH) or single nucleotide polymorphism (SNP) array analysis, have been used for identification of smaller, more subtle or complex anomalies not appreciated by chromosome analysis and/or FISH; however, the diagnostic and prognostic value of this technology is just beginning to emerge.

HISTORY

As early as 1890, von Hansemann[2] recognized that mitotic irregularities were associated with the malignant process. He suggested that such nuclear abnormalities could be used as a criterion for diagnosing the malignant state. In 1914, Boveri[3] published his chromosome (or mutation) theory of cancer in his monograph "The Origin of Malignant Tumors." This theory proposed that chromosome aberrations were the cause of the change from normal to malignant growth. He saw cancer as a cellular problem which originated from a single cell with an abnormal chromosome constitution. This single abnormal cell was the founder of a population of cells with the same abnormality (and therefore, clonal, by current definition). Therefore, chromosome abnormalities were seen as the cause of the rapid cellular proliferation observed in malignancies.

By the 1920s, it was widely accepted that the units of heredity in living organisms were chromosomes. In 1923, studying paraffin-embedded preparations of testicular tissue, Painter[4] reported that there were 46 or 48 human chromosomes in the normal karyotype; however, it was popularly believed that there were 48 human chromosomes. With technical advances involving the use of hypotonic solution and mitotic arrest, in 1956 Tjio and Levan[5] determined that the normal diploid number of human chromosomes was actually 46. In 1966, Levan[6] and van Steenis[7] studied published reports of human tumor karyotypes. They found nonrandom karyotypic changes in human tumors. These 40 published cases, which consisted primarily of ascitic forms of gastric, mammary, uterine, and ovarian carcinomas, showed certain chromosomes tended to be increased in number, while others tended to be decreased, in what appeared to be a nonrandom fashion. Nonrandom chromosomal changes are either primary or secondary. Nonrandom primary changes are generally thought to be the cytogenetic changes that are consistently found in a cell population and are believed to be specific for a particular type or subtype of malignancy. Specific nonrandom secondary changes are believed to be related to the progression or the evolution of the tumor.

This is not to say that chromosome alterations are or are not the first step in carcinogenesis. Whether one considers Sandberg's chromosome theory of cancer, in which the key event in oncogenesis involves chromosomal rearrangement,[8] or Knudson's two-hit hypothesis, in which there are at least two mutational events that lead to the malignant state,[9] carcinogenesis is generally thought to be a multistage process, where a number of different barriers must be breached for a malignancy to occur.[10]

Shortly after Tjio and Levan determined the normal diploid number of human chromosomes, a number of constitutional (or germ line) chromosome abnormalities and syndromes were described, beginning with the association of trisomy 21 and Down syndrome by Lejeune in 1959.[11] It should be noted that chromosome abnormalities can be thought of as consisting of two types—constitutional (germ line) or acquired (somatic). Constitutional anomalies typically affect every cell in the body and are congenital, while acquired anomalies affect only the tumor cell population (somatic mutations).

At first, chromosomes were identified only by their size and the placement of their centromere or primary constriction, as they were solid stained. It was not until the advent of chromosome banding in the 1970s that chromosomes could be recognized and identified individually by their banding patterns.

In 1960, Nowell and Hungerford[12] recognized the first chromosome abnormality known to be specific to a particular type of cancer. This was the "Philadelphia" chromosome (or Ph) associated with chronic myelogenous leukemia (CML), so named because of its discovery in that city. The chromosome origin and nature of this minute chromosome was uncertain at the time, as chromosomes were only non-banded and could not be specifically identified (Fig. 3.1). In 1973, after the advent of banding, Rowley[13] and colleagues at the University of Chicago discovered that the Philadelphia chromosome was actually a balanced translocation involving the long arms of chromosomes #9 and #22

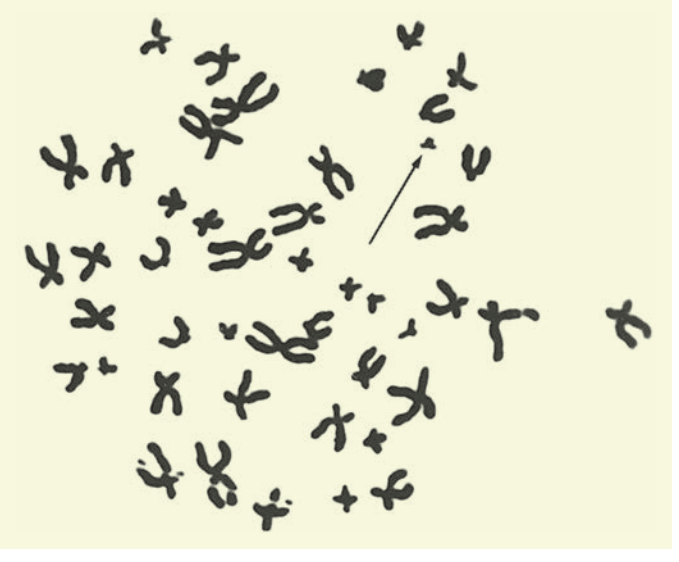

FIGURE 3.1. An unbanded metaphase spread from bone marrow cells of a patient with chronic myelogenous leukemia showing the Ph chromosome.

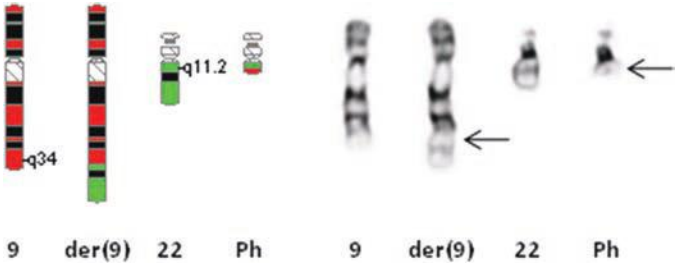

FIGURE 3.2. Illustration of t(9;22) observed in chronic myelogenous leukemia and acute lymphoblastic leukemia. Ideogram of chromosomes #9 and #22 on left with partial karyotype on right. Arrows indicate breakpoints.

[t(9;22)] (Fig. 3.2). The Philadelphia chromosome or a variant rearrangement is seen in nearly all patients with CML. In later studies, it was shown that the translocation involved breakpoints in two genes, *BCR* on chromosome #22 at band 22q11.2 and *ABL1* on chromosome #9 at band 9q34 (Fig. 3.3). These breakpoints were in very specific regions of both genes and the translocated segment of *ABL1* juxtaposed to *BCR* created a functional chimeric fusion protein with increased tyrosine kinase activity. This BCR/ABL1 fusion protein upregulates the growth of these cells and causes them to have a proliferative advantage over the normal cells.[14] Today, inhibitors of tyrosine kinase activity (most notably Gleevec or imatinib) have been used to treat patients with CML and acute lymphoblastic leukemia who have the Ph chromosome. This type of treatment has been very successful in treating these patients.[15] Since then, numerous other chromosome abnormalities have shown associations with specific hematologic disease entities (Table 3.1), some of which have targeted or specific therapy directed toward their fusion protein.

CYTOGENETIC ANALYSIS OF HEMATOLOGIC MALIGNANCIES

Cytogenetic analysis of hematologic malignancies involves at least two, if not three, different approaches. The first is "classic chromosome analysis" (CCA). The second is FISH using DNA probes labeled with fluorochrome(s). Whether FISH is performed on metaphase cells (metaphase chromosomes) or interphase cells (resting, non-dividing nuclei), this technique can be used to ask very specific questions. However, to determine the correct interrogating probe, one must know the question to be answered. The advantage of using interphase FISH is that mitotic cells are not necessary for analysis, as they are for CCA and metaphase FISH. In addition, even formalin-fixed paraffin-embedded tissue can be studied in this fashion. The third approach involves arrays, either CGH arrays, utilizing primarily oligonucleotides spaced throughout the genome, or SNP arrays, with heterozygous SNPs positioned throughout the genome. Both of these array types can be used to determine DNA copy number (one vs. two vs. three); however, loss of heterozygosity (LOH) can only be detected if one uses SNP arrays. In addition, balanced rearrangements (copy neutral), i.e., translocations, inversions, etc., cannot be appreciated by either array method. Malignancies are often made up of both normal and abnormal cells, as well as varying percentages of abnormal clones. This heterogeneity, which can be seen as low levels of mosaicism, typically below 15% to 20%, cannot be detected by array analysis.

CHROMOSOME ANALYSIS

Chromosome analysis can be performed on numerous types of dividing tissue and can help to render diagnoses for constitutional (germ line) chromosome conditions (i.e., trisomy 21), as

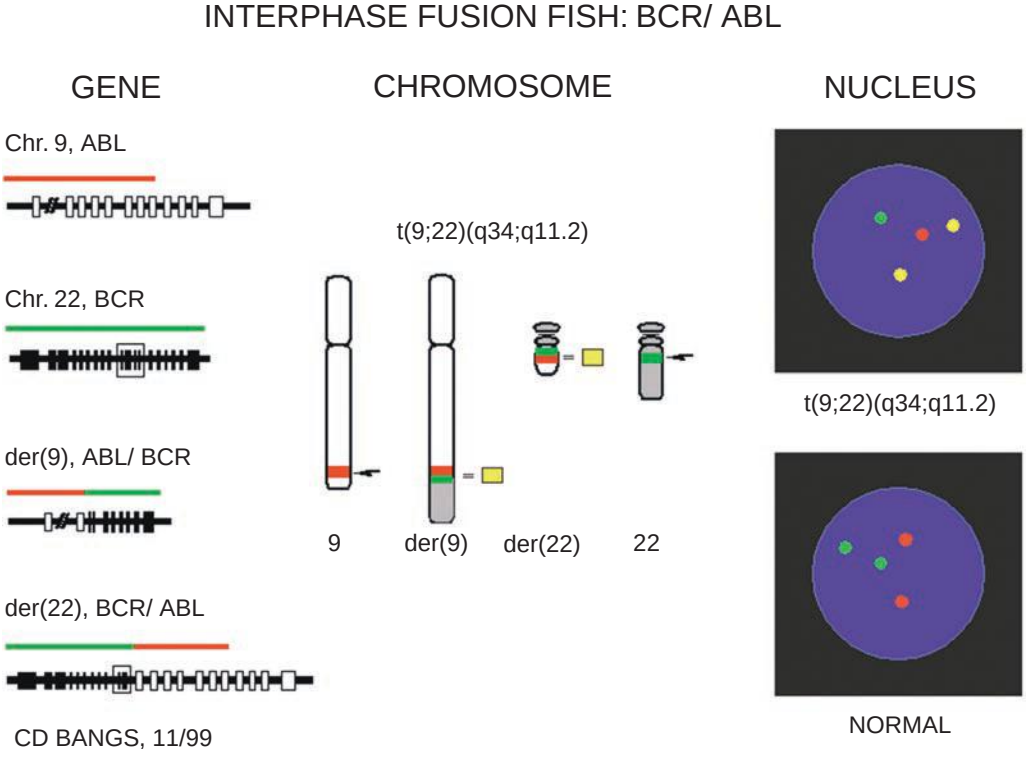

FIGURE 3.3. Fluorescence in situ hybridization illustration of t(9;22) with red-labeled *ABL1* probe spanning the breakpoint at 9q34 and green-labeled *BCR* probe spanning the breakpoint at 22q11.2. At right, nuclei showing abnormal and normal signal pattern with yellow fusions.

ALCL, anaplastic large cell lymphoma; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; APL, acute promyelocytic leukemia; BL, Burkitt lymphoma/B-cell lymphoma; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; DLBCL, diffuse large B-cell lymphoma; FL, follicular lymphoma; MCL, mantle cell lymphoma; MDS, myelodysplastic syndrome; PCM, plasma cell myeloma.

well as acquired (somatic) chromosome abnormalities associated with different types of cancer. Chromosome analysis requires living, dividing cells which are arrested in metaphase by using a substance that inhibits spindle fiber formation during mitosis (e.g., Colcemid, Velban). Typically, leukemias and lymphomas are studied by preparing short-term cultures (direct, 24-, 48-, or 72-hour) grown in suspension. The cells are then "harvested" using a hypotonic solution (sodium chloride or sodium citrate) and fixed using a mixture of methanol and acetic acid. Slides are made by dropping the cell suspension on the slides and drying them. The slides are aged and then banded using trypsin (or pepsin) and Giemsa (or Wright's or Leischman's) stain. This produces the G-banding pattern widely used to recognize and identify chromosomes and their abnormalities (Fig. 3.4). Chromosome analysis is performed by individuals who have been trained to recognize the banding patterns of each individual chromosome pair, chromosomes #1 through #22 and the X and Y sex chromosomes. Banded metaphases are identified and analyzed using a light microscope equipped with high resolution objectives (typically 10× oculars, with 63× or 100× objectives—enlarged up to 1000× their normal size). Images are then acquired using a CCD (charged coupled device) camera, and proprietary software is used to create the karyotype. A karyotype is the chromosomal makeup of a particular cell or individual. The software enables a technologist to create the digital karyotype, but the software/computer cannot completely recognize nor interpret the karyotype; this must be done interactively by the trained technologist. Chromosome analysis of leukemias and lymphomas requires complete analysis of a minimum 20 metaphase cells if possible.[16] This is not a random process. Technologists (or automated imaging systems) scan the slides looking for abnormal metaphases. Often, there are normal metaphases that are part of the milieu. These are typically avoided, if there are abnormal metaphases present. All cells are completely analyzed—matched band-by-band, chromosome-by-chromosome pair, looking for any inconsistencies or abnormalities, be they structural or numerical. Clonal abnormalities are described and documented. Clonal anomalies are defined as two or more cells with the same structural abnormality or same extra chromosome, while loss of a chromosome must be observed in three or more cells in order to be considered clonal.[17] Karyotypes are then created as both an analytical and a documentary tool and the chromosome diagnosis rendered.

Samples for chromosome analysis—fresh bone marrow, bone core biopsy, or peripheral blood—are transported at room temperature in either a sodium heparinized green-topped tube or in transport media with sodium heparin added to prevent clotting. These samples should be received within 24 hours of collection, if possible. Some bone marrow samples are particularly finicky and the abnormal clonal cells are fragile (e.g., acute lymphocytic leukemia). Lymphomas are minced and placed into short-term suspension culture.

CYTOGENETIC NOMENCLATURE

It is important for the hematopathologist to have a basic understanding of cytogenetic nomenclature, as he/she is often asked to incorporate this data into an integrated or comprehensive report including all clinical laboratory analytic data on individuals with hematologic malignancies (i.e., flow cytometry, molecular and cytogenetic analytic data). The International System of Cytogenetic Nomenclature (ISCN)[18] is the accepted method of describing the karyotype of an individual or tumor. There are very specific rules for how this information is presented. This is the internationally accepted cytogenetic language that, using alpha/numeric/symbolic string text allows one laboratory to describe what was observed in the karyotype and another laboratory to understand what that means. Every few years this system of nomenclature is updated. The most recent update was in 2009. ISCN first came into existence in 1978; however, there were several conferences held from 1960 until then to codify the human karyotype, with banded ideograms first introduced in 1971. An ideogram is a scientific representation of the light and dark bands, sub-bands

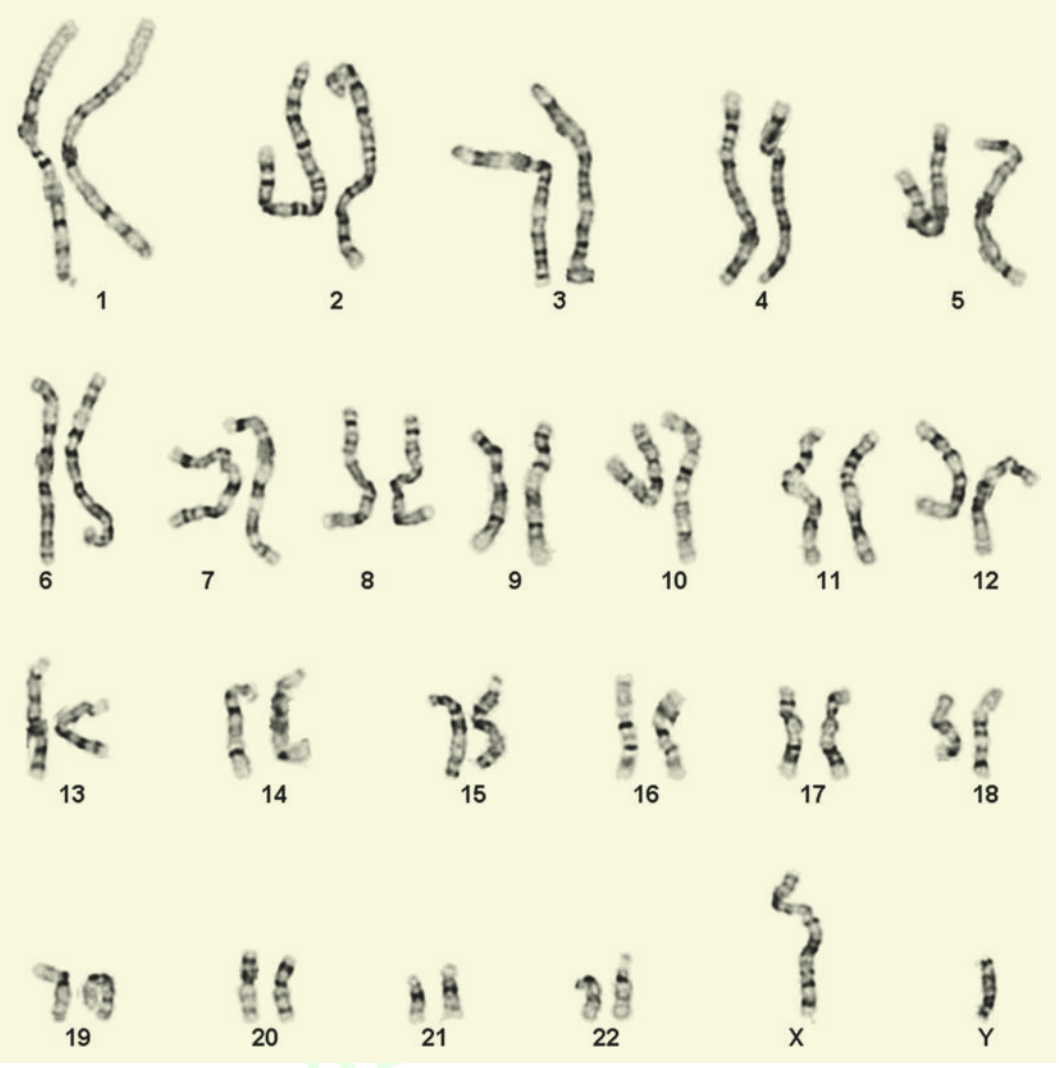

FIGURE 3.4. Normal male G-banded karyotype.

and sub-sub-bands observed by metaphase chromosome analysis. Each chromosome has its own particular set of recognized bands, which allows it to be identified as such (Fig. 3.5). For instance, all human chromosome #1's look very similar to one another, having the same pattern of light and dark bands, with the exception of a known variant region near the centromere. Chromosomes are divided into short arm and long arm by the centromere or primary constriction, which mediates attachment to the spindle fiber apparatus in mitosis. Bands in the short arm are labeled "p," while bands in the long arm are labeled "q." Each chromosome arm has landmark bands which demarcate the regions of the chromosome arm (this is the first number indicated after the p or q designation). These regions are then divided into bands, and possibly sub-bands or sub-sub-bands. Bands are numbered in increasing order starting at the centromere and proceeding toward the end of the chromosome arm (or telomere). The total number of chromosomes observed is stated first, with the sex chromosome designation given following a comma. There are normally no spaces between the numbers, letters, and punctuations that make up the karyotype designation. As an example, a female patient with the Philadelphia chromosome would have a karyotype written as "46,XX,t(9;22)(q34;q11.2)[18]/46,XX[2]," meaning that she has the Ph or t(9;22) in 18 of her metaphases (18 in []), a slash designating a second normal cell line with 46,XX (or normal chromosomes) in two metaphases (2 in []). The breakpoint in chromosome #9 is at band 9q34 (long arm or q arm, region 3, band 4 or band three four, not thirty-four) and the breakpoint in chromosome #22 is at sub-band 22q11.2 (long arm or q arm, region 1, band 1, sub-band .2 or band one one point two, not eleven point two). There are rules as well for describing both interphase and metaphase FISH (Table 3.2).

FLUORESCENCE IN SITU HYBRIDIZATION ANALYSIS

In situ hybridization was first described by Gall and Pardue in 1969,[19] when they hybridized radioactively labeled probes to highly repetitive sequences in mouse and Drosophila. In 1981 Harper and Saunders[20] used a similar technique using tritiated (^{3}H) nucleotides to label probes and autoradiographic methods to map human genes. Also in 1981, Langer et al.[21] introduced biotin-labeled probes for gene mapping purposes, which then could be detected with streptavidin conjugated antibodies which had been fluorescently tagged. In 1988, Pinkel et al.[22] described chromosome painting probes, while Kallioniemi et al. in 1992[23] introduced CGH using metaphase chromosomes as the interrogator.

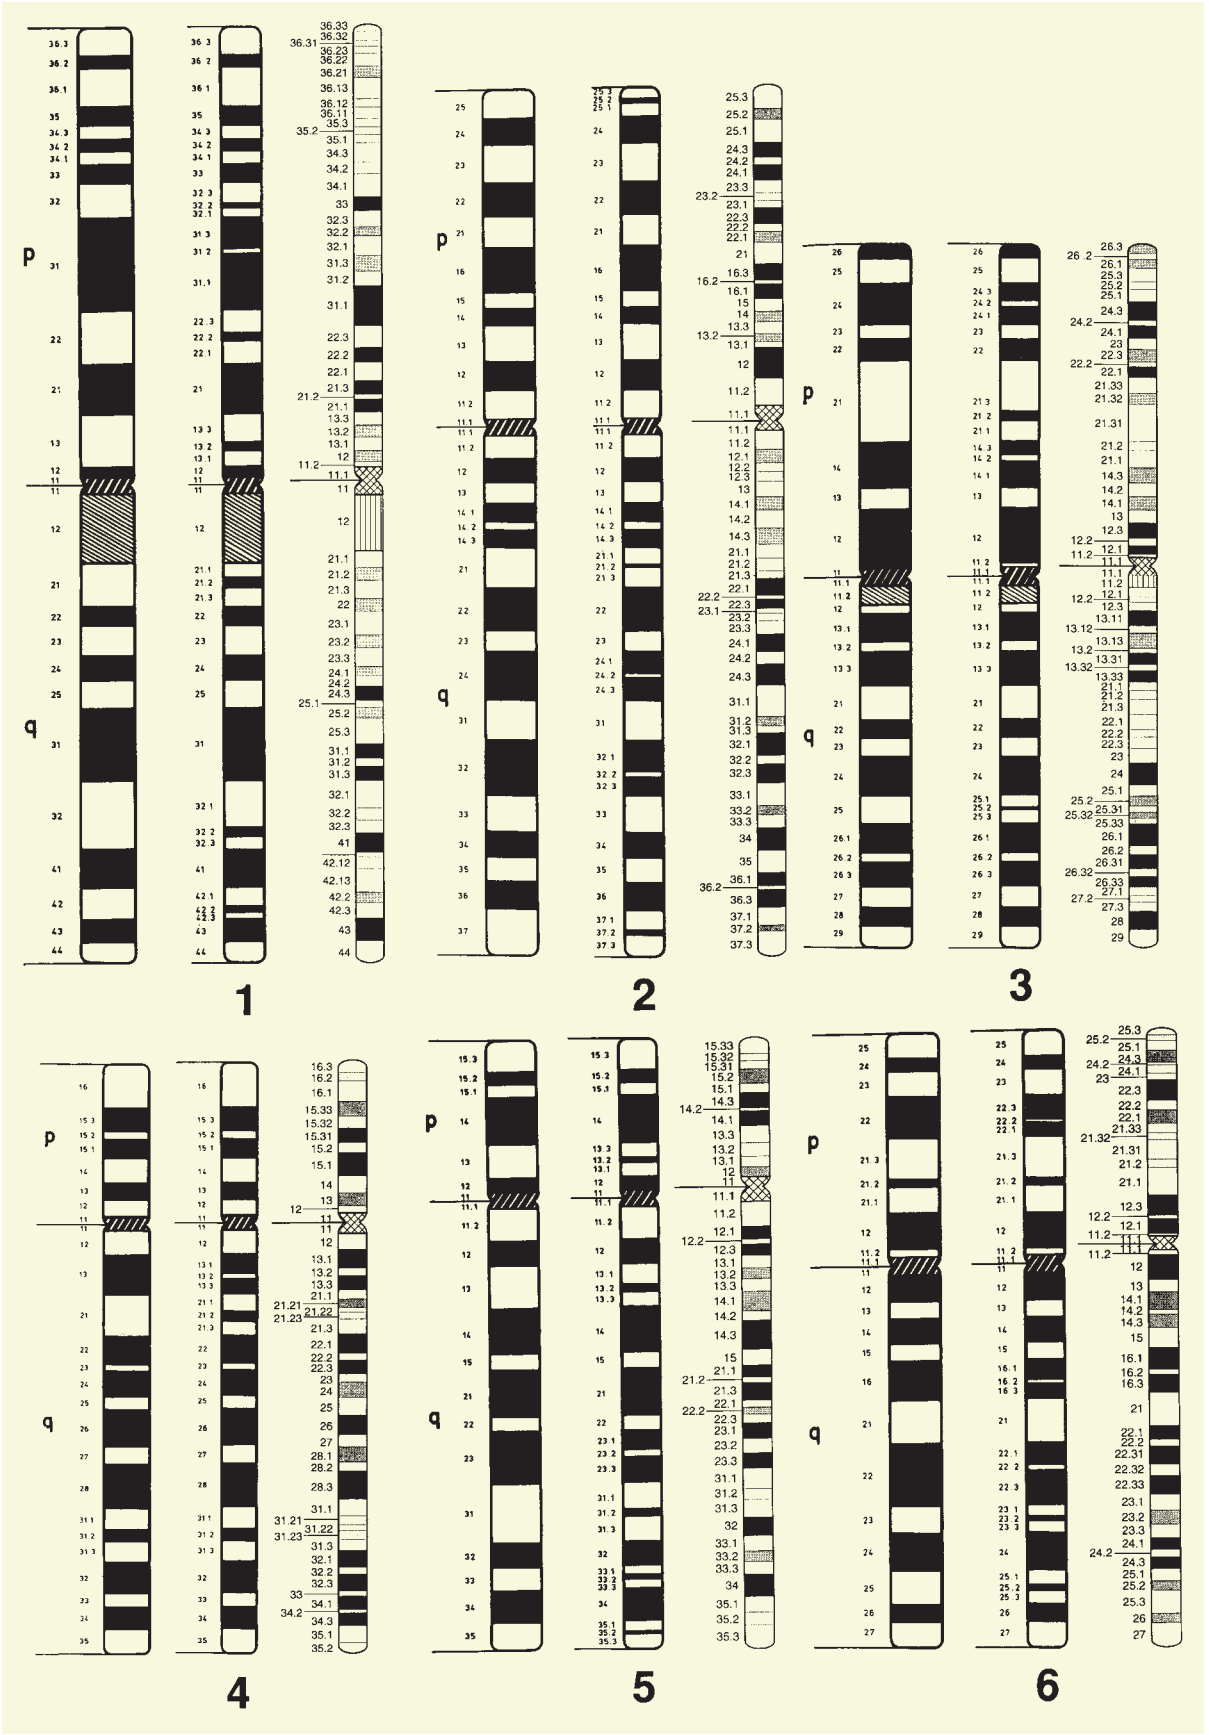

FIGURE 3.5. Ideogram of normal G-banded chromosomes showing banding at 400, 550, and 850 band level of resolution.

TABLE 3.2

FREQUENTLY USED ISCN SYMBOLS AND ABBREVIATED TERMS

Symbol or Term	Interpretation
Add	Additional material of unknown origin
approximate sign (~)	Denotes intervals and boundaries of a chromosome segment or number of chromosomes, fragments, or markers; also used to denote a range of number of copies of a chromosome region
arr	Microarray, array
brackets, angle (<>)	Surround the ploidy level
brackets, square ([])	Surround the number of cells
c	Constitutional anomaly
chr	Chromosome
comma (,)	Separates chromosome number, sex chromosomes, and chromosome abnormalities
con	Connected signals in interphase FISH
cp	Composite karyotype (when karyotype is very heterogeneous)
decimal point (.)	Denotes sub-bands
del	Deletion
der	Derivative chromosome (from a translocation or other rearrangement)
dic	Dicentric chromosome (two centromeres)
dmin	Double minute (amplified material, acentric fragments)
dup	Duplication
hsr	Homogeneously staining region (amplified material within a chromosome)
i	Isochromosome (2 long arms or 2 short arms without the other)
idem	Denotes the stemline karyotype in a subclone
inc	Incomplete karyotype (partially analyzable)
ins	Insertion
inv	Inversion
ish	In situ hybridization
mar	Marker chromosome (unidentified origin)
minus sign (−)	Loss
multiplication sign (×)	Multiple copies
nuc	Nuclear
p	Short arm of a chromosome
parentheses ()	Surround structurally altered chromosomes and breakpoints
period (.)	Separates various techniques
plus sign (+)	Gain
q	Long arm of a chromosome
question mark (?)	Questionable identification of a chromosome, chromosome structure, or breakpoint
r	Ring chromosome
sep	Separated signals (in FISH)
slant line, single (/)	Separates clones
slant line, double (//)	Separates chimeric clones (cross-sex transplant; host//donor)
t	Translocation

In situ hybridization takes advantage of the genetic code, the complementary strands of DNA and their unique, as well as repetitive, sequences. Probes are designed with a particular DNA sequence in mind. These probes are labeled so that they can be detectable, once they have hybridized to the DNA. Target DNA, whether it is in the form of metaphase chromosomes or interphase nuclei, is denatured, as is the DNA probe, using formamide, heat, and salt. The slide/DNA is then re-annealed, so that the DNA probe can hybridize to its complementary target DNA sequence. After hybridization is complete (from a few hours to overnight), the slides are washed and counterstained and the hybridization is visualized. In this manner, questions of loss, gain, or juxtapositioning of target sequences can be answered.

Most DNA probes used for in situ hybridization are directly labeled with fluorochromes and visualized using a fluorescent microscope and the proper filter sets, once the hybridization has taken place. FISH probes can be single copy, unique sequence probes, repetitive probes, or whole chromosome painting probes. Single copy probes can be used to determine copy number (gain or loss) of a single locus or specific chromosome, or can be designed in combination to detect gene rearrangements (either by dual color, dual fusion, or break apart probes, spanning the known breakpoints of critical rearrangements). Single copy probes can also be used to detect amplification of a locus, as in *HER2* (*ERBB2*) amplification in invasive breast carcinoma. Repetitive probes can also be used primarily for chromosome enumeration. These are typically chromosome specific alpha satellite repeats (e.g., DXZ1 and DYZ3 located at the centromeres of the X and Y chromosomes, respectively). There are also chromosome arm specific subtelomeric repeat sequences that are generally within 300 kb of the ends of the chromosomes.

FLUORESCENCE IN SITU HYBRIDIZATION NOMENCLATURE

FISH nomenclature has also been established by the ISCN.[18] FISH can be of either metaphase chromosomes or interphase nuclei. Both have different nomenclature rules. Metaphase FISH is always prefaced by the term "ish," followed by the locus of the DNA probe used or the abnormality observed. The presence, absence, or appearance of the FISH probes is then described. As an example, an individual who has CML and is Ph chromosome positive might have metaphase FISH (using a dual fusion FISH strategy) which would be written:

46,XX,t(9;22)(q34;q11.2).ish
t(9;22)(ABL1+,BCR+;BCR+,ABL1+)[20]

The semicolon separates one chromosome from the other descriptively and shows that while some of *ABL1* has remained at 9q34, some is now translocated to 22q11.2, next to *BCR*, and vice versa. Interphase FISH of this same individual would typically involve scoring 200 interphase nuclei for their signal patterns. This would be described by using the term "nuc ish" followed by the pattern that was observed. This can best be expressed as:

nuc ish(ABL1,BCR)×3(ABL1 con BCR×2)[200]

The above scenario shows that there are three *ABL1* signals and three *BCR* signals; however, two each of these signals are connected ("con") or fused, representing both the *BCR/ABL1* and the *ABL1/BCR* sequence fusions.

Alternatively, if the patient has a normal karyotype and no evidence of the *BCR/ABL1* translocation:

"nuc ish(ABL1,BCR)×2[200]" or "nuc ish(ABL1×2,BCR×2)[200]"

In other words, there are two distinct *ABL1* signals and two distinct *BCR* signals, with no fusion of the two.

It is important to note that while many of the FISH probes used for leukemias, lymphomas, and other solid tumors are FDA approved, all must be validated in the laboratory. Such validation must determine the analytic sensitivity and specificity of each

probe, and establish normal cutoff values or thresholds for determining whether or not a FISH assay is positive or negative for the aberrant signal pattern.

DIAGNOSTIC AND PROGNOSTIC IMPACT OF CHROMOSOME ABNORMALITIES

As stated earlier, the WHO system[1] has classified many leukemias and lymphomas according to their cytogenetic and/or molecular abnormalities. Many of these have not only diagnostic significance, but prognostic significance as well. While this list is by no means exhaustive, it does inform the reader as to the significance of a number of anomalies (Table 3.3). Please refer to online resources The Atlas of Genetics and Cytogenetics in Oncology and Haematology (http://atlasgeneticsoncology.org) and the Mitelman Database of Chromosome Aberrations in Cancer (http://cgap.nci.nih.gov/Chromosomes/Mitelman).

Acute Myeloid Leukemia

According to the WHO 2008,[1] there are certain entities of acute myeloid leukemia (AML) defined by their cytogenetic or molecular abnormalities (recurrent genetic abnormalities). The t(8;21) and the inv(16) and its variants, both core binding factor (CBF) abnormalities, as well as the t(15;17) when observed by either CCA, FISH, or PCR, are considered distinct forms of AML, even if the percent blasts is below 20%. All of these have been associated with a good or favorable risk. The t(9;11)(p22;q23) is an entity with an intermediate risk. While the t(6;9)(p23;q34), inv(3)(q21q26) and its variants, as well as the t(1;22)(p13;q13) are distinct AML entities, all with an associated poor risk, it is unclear if cases with blasts below 20% are actually considered AML, or technically should be classified as myelodysplastic syndrome (or MDS).

Acute Myeloid Leukemia Risk Categories

Slovak et al.,[29] stratified patients with AML into four risk categories. Those in the favorable group had inv(16), t(15;17) or t(8;21), while those in the unfavorable group had monosomy 5/5q deletion, monosomy 7/7q deletion, inv(3), 11q23 (or *MLL*) rearrangements, abnormalities of 17p, 20q or 21q, t(6;9), or complex karyotypes (with 3 or more abnormalities). Those in the intermediate group had a normal karyotype, trisomy 8, trisomy 6, deletion of the 12p, or loss of the Y chromosome. There was also an indeterminant group that contained all other chromosome anomalies. Grimwade et al.[30] proposed a slightly different prognostic classification scheme. Individuals with inv(16), t(15;17) or t(8;21) were in the favorable group, while those in the adverse group included abnormalities of 3q [excluding t(3;5)(q21-25;q31-35)], inv(3), monosomy 5/5q deletion, monosomy 7/7q deletion, t(6;11), t(10;11), 11q23 (or *MLL*) rearrangements [excluding t(9;11) and t(11;19)], t(9;22), monosomy 17/abnormalities of 17p, and complex karyotypes (with 4 or more abnormalities). All others fell into the intermediate group.

More recently, several groups have described the "monosomal karyotype" (or MK) which is believed to have a worse prognosis even when compared to those patients with complex karyotypes (with 3 or more abnormalities).[31,36,37] The concept of a "monosomal karyotype" defined by Breems et al.[31] was defined as a karyotype with loss of at least one chromosome and at least one structural chromosome abnormality or loss of at least two chromosomes. This concept is rather problematic in that most of the MK+ patients also have complex karyotypes, and so are included in the poor prognostic group despite their MK status. Secondly, MK is often a misnomer because many of the karyotypes are not truly monosomic (missing an entire chromosome), as there are often multiple rearrangements and/or marker chromosomes present (a "marker" is a chromosome whose chromosomal origin is unknown or unidentified). Often cytogeneticists designate an abnormality as a marker, even if it is possible to at least partially identify its origin. These markers may contain obvious or cryptic segments of the monosomic chromosome. As CCA is often subjective, two cytogeneticists might describe the same karyotype in different ways. This makes classification of a karyotype as MK problematic. While there might indeed be a difference in outcome for patients with AML that have complex karyotypes (CK) versus those with monosomal karyotypes (MK) per the Breems et al. definition, separating these two entities is not at all straightforward.

TABLE 3.3

PROGNOSTIC RISKS ASSOCIATED WITH CHROMOSOME ABNORMALITIES

Disease	Risk Categories
CML	Poor: additional abnormalities (extra Ph, +8, i(17q), etc.)
CLL	Good: 13q−, normal, +12 Intermediate: 11q− (*ATM* deletion) Poor: 17p− (*TP53* deletion) Dohner et al.[24]
Adult ALL	Favorable: hyperdiploidy with +4 and +10, 9p− Unfavorable: t(9;22), t(4;11), t(8;14), low hypodiploidy/near triploidy, complex (5 or more abnormalities) Moorman et al.[25]
Childhood ALL	Favorable: hyperdiploidy (>50 and <60) with +4, +10 (+17?), t(12;21) Unfavorable: t(9;22), t(v;11q23), 9p−, hypodiploid (<44), t(1;19) Pui et al.[26]; Heerema et al.[27]; Raimondi et al.[28]
AML	Favorable: inv(16), t(8;21), t(15;17) Intermediate: normal, +8, +6, −Y, 12p− Unfavorable: −5/5q−, −7/7q−, inv(3), 11q23 abnormality, abnormal 17p, 20q or 21q, t(6;9), t(9;22), complex (3 or more abnormalities Very poor: monosomal karyotype (MK)* Slovak et al.[29]; Grimwade et al.[30]; *Breems et al.[31]
MDS	High: −7/7q−, complex (3 or more)[en]Intermediate: +8, other anomalies Low: normal, −Y, 5q−, 20q− Greenberg et al.[32]
PCM	Standard: hyperdiploidy (without *TP53* deletion), t(11;14), t(6;14) Intermediate: t(4;14), 13q− or hypodiploidy by chromosome analysis Poor: 17p−, t(14;16), t(14;20), *1q+/1p− Rajkumar[33]; *Klein et al.[34]; *Wu et al.[55]

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; MDS, myelodysplastic syndrome; PCM, plasma cell myeloma.

ARRAY ANALYSIS

Comprehensive analysis of the cancer genome has become a standard research approach to identify new disease loci that may ultimately lead to new therapeutic strategies. One way of studying

the genomes of malignancies is to use array analysis (either array CGH or SNP array, or a combination) to discern copy number changes and/or LOH.

While CCA relies upon metaphase chromosome analysis and the ability to recognize differences in banding patterns visible on metaphase chromosomes by light microscopy, array analysis uses any number of known DNA sequences (SNPs, exons, introns, etc.) and determines their copy number. CCA has a resolution of approximately 5 to 10 Mb (megabase pairs or million base pairs of DNA) even at its highest resolution, while array analysis can detect much smaller anomalies on the order of a 50 to 100 kilobase (kb) pairs (a 1,000 times higher resolution). CCA can detect structural rearrangements, whether balanced (two copies of every gene or DNA sequence, just not in the correct order) or unbalanced (one or three copies versus the normal two); however, array analysis cannot detect balanced rearrangements (i.e., balanced translocations or inversions). Array CGH analysis can detect only copy number changes, often referred to as copy number variants (CNVs). CNVs can be benign, disease-associated or of unknown significance.

There are at least two different types of arrays—CGH arrays, which can be made up of probes that are either BACs (bacterial artificial chromosomes) or oligonucleotides (typically 60 base pairs in length that are synthesized and are specific, unique DNA sequences), or SNP arrays. BAC CGH arrays were the first arrays used clinically for the detection of copy number changes.[38–40] This was seen as a way to do multiple FISH tests simultaneously. These arrays were initially "targeted" arrays which had about 800 probes specific for numerous microdeletion/microduplication syndromes, as well as other Mendelian disorders with associated disease loci. Over the years, because of their reliability and reproducibility, these have been replaced by the more robust oligonucleotide arrays. Oligo arrays typically have anywhere from 44,000 unique sequence probes to over a million. Most clinical laboratories that employ oligo arrays use ones that have between 60,000 and 180,000 probes to detect copy number changes (or CNVs). This detection is performed by labeling patient or tumor DNA and control DNA with different fluorochromes (typically Cy3 and Cy5), denaturing the array DNA as well as the target and control DNAs and hybridizing them together, along with Cot-1 DNA to reduce binding to repetitive sequences. The DNAs will find and hybridize to complementary array probe sequences. After washing, the array is read by a laser which determines the color and intensity of each spot on the array. Using proprietary software, correcting for dye bias and other artifacts, copy number calls are made according to established parameters, typically the $\log_2$ ratios of the intensities of the different fluorochromes. In most cases the imbalanced regions can be detected by as few as three to five consecutive oligonucleotide probes (Fig. 3.6).

SNP arrays were initially used for genome-wide association studies (GWAS) to find associations of particular SNPs with disease; however, it was discovered that they could also be used to determine copy number.[41,42] SNP array analysis is slightly different, in that it utilizes SNPs to determine copy number changes with comparison to expected SNP frequencies, as control DNA is not used. SNPs vary from individual to individual. Individuals have different SNPs, one that is arbitrarily called the "A allele" and the other one the "B allele." It is expected that everyone has two different SNP alleles at various loci (they are AA, AB, or BB). The copy number analysis of SNP array data generally uses two parameters, comparing observed test sample values to expected reference values, the $\log_2$ R intensity ratio and the allelic intensity ratio or "B allele frequency." The latter is used to determine stretches of homozygosity (copy neutral changes where only one SNP allele is detected, presumably from either loss of heterozygosity or identity by descent/relatedness/consanguinity). Most SNP arrays now also include unique sequences, other than the SNPs, as they enhance the ability of the SNP array to detect copy number changes. Most SNP arrays contain about 1 million SNPs and another 1 million unique features. More recently, a few companies have created CGH arrays that include SNPs as well as single copy loci. These are called "oligo + SNP" arrays. While the number of SNPs used is much reduced when compared to SNP arrays, they are sufficient to detect clinically significant LOH, particularly in cancer analysis (Fig. 3.7). Many laboratories have adopted either oligonucleotide arrays or these new oligo + SNP arrays due to their robustness and ease of use, particularly when compared to SNP arrays. While it would seem that the more probes the better, the resolution of both CGH and SNP arrays are very similar.

Array analysis has now become "standard of care" and is considered a first line clinical test in individuals with intellectual disability (ID) and congenital anomalies.[43] While CCA can detect abnormalities in around 5% of individuals with ID and congenital anomalies, array analysis can detect abnormalities in around 15% to 20% of such individuals.

Although many researchers have used array analysis in hematologic malignancies and other tumors, this type of analysis has yet to become "standard of care."

Array analysis can detect smaller, cryptic anomalies, and help to further characterize the karyotype of a tumor better than CCA or FISH; however, there are some problems. Malignancies can often be heterogeneous with multiple clones present in only a few cells. These underrepresented clones may well be missed, if they are in less than 15% of the cells. Arrays cannot detect balanced rearrangements, which are commonly observed in hematologic malignancies. Yet another issue is determining whether CNVs or regions of LOH observed in a tumor are constitutional (and not disease related) or acquired, as often normal control DNA from the patient is unavailable.

Chronic Lymphocytic Leukemia and Array Analysis

In chronic lymphocytic leukemia (CLL), CCA of blood or bone marrow has not been very successful, in part due to the lack of neoplastic B-cells that are actively dividing. Investigators have shown that approximately 80% of patients with B-CLL have clonal chromosome abnormalities that can be detected in non-dividing cells of the blood using interphase FISH employing a number of DNA probes specific for the chromosome abnormalities known to be associated with B-CLL. This group of probes is called a "FISH Panel." Not only are these clonal chromosome abnormalities detectable, they are also of prognostic value. In a study reported by Dohner et al.,[24] it was shown that patients could be placed into different risk categories by their FISH abnormalities alone. They found that those patients with a FISH result that was normal, trisomy 12 or 13q deletion (13q-), had a good prognosis, while those with an *ATM* deletion (11q deletion) were in the intermediate group, and those with a *TP53* deletion (17p deletion) were in the poor prognostic group. Currently, FISH helps to stratify CLL patients. More recently,[44,45] in vitro stimulation with CpG oligonucleotide DSP30 with mitogens has been shown to improve the proliferation of CLL cells and yield metaphases with abnormal karyotypes. These abnormalities are not detected by the standard FISH panel, and when complex, have been shown to impart a worse prognosis.

More recently, array analysis has been performed on CLL patients. Many authors have shown a high concordance with FISH analysis.[46–49] Array analysis has detected several recurrent chromosome abnormalities that are not part of the standard FISH panel for CLL, including 14q32 abnormalities [46,48,50,51] and gains of 2p.[46,50] The clinical significance of these anomalies is unknown. Array analysis has also shown that 13q deletions vary

Data from Dougherty MJ, Wilmoth DM, Tooke LS, et al. Implementation of high resolution single nucleotide polymorphism array analysis as a clinical test for patients with hematologic malignancies. Cancer Genet 2011;204:26–38; Martinelli G, Iacobucci I, Storlazzi CT, et al. IKZF1 (Ikaros) deletions in BCR-ABL1-positive acute lymphoblastic leukemia are associated with short disease-free survival and high rate of cumulative incidence of relapse. A GIMEMA AL WP report. J Clin Oncol 2009;27:5202–5207; Mullighan CG, Su X, Zhang J, et al. Deletion of IKZF1 and prognosis in acute lymphoblastic leukemia. N Engl J Med 2006;360:470–480.

greatly in size, with some being homozygous deletions and others heterozygous deletions of different sizes.[46,47] There is some evidence that the larger 13q deletions (>1.25 Mb) have a worse prognosis than those with the smaller deletions (<1.25 Mb).[50] Overall, array analysis has shown that individuals with a more complex karyotype, either because of overall genomic complexity or clonal diversity, typically have a poorer outcome than those with a simpler karyotype.[49,51–53]

For a good review of abnormalities detected by array analysis of hematologic malignancies, see van der Veken and Buijs[54] (Table 3.4).

CHAPTER 4

MOLECULAR DIAGNOSIS IN HEMATOLOGY

Dan Jones

INTRODUCTION

Molecular diagnostics, including DNA- and RNA-based testing and genomics, play an increasingly important role in diagnosis and monitoring of patients. The tremendous explosion of knowledge about the molecular pathogenesis of both benign and neoplastic hematologic conditions over the last 20 years has now been translated into routine laboratory assays of high complexity. Such clinical molecular diagnostic assays, including advanced DNA sequencing, microarrays, and highly sensitive polymerase chain reaction (PCR) tests, now impact diagnosis, subclassification, minimal residual disease (MRD) monitoring, outcome prediction, and therapy selection. In this chapter, we review the basis of these molecular techniques and discuss their uses in hematology currently and in the future.

AN OVERVIEW OF MOLECULAR BIOLOGY

DNA, the chromosomal material in the cell nucleus, is *transcribed* by polymerases to form RNA species with different functions. These include messenger RNA (mRNA) produced from each of the ~20,000 protein coding genes, microRNAs (mIRs) transcribed from the ~500 regulatory mIR genes, and ribosomal and transfer RNAs that are components of the *ribosome* and the protein biosynthesis machinery. mRNAs are then *translated* into proteins by the ribosome and then typically degraded quickly because of the actions of mIRs and cellular nucleases. The set of mRNAs and mIR genes that get transcribed in any particular cell is regulated by growth factor–responsive *transcription factors*, cell type–specific *enhancer complexes*, and the *epigenetic state* of the DNA surrounding genes as well as their scaffold histone proteins. Epigenetic modulation of DNA and histones occurs commonly through methylation and acetylation and is dynamically regulated during hematopoietic cell development and during the development of leukemias and lymphomas.[1,2]

Acquired (somatic) defects in one or more of these processes underlie the development of hematologic conditions (Table 4.1). In addition, inherited gene defects or normal population variations in these cellular functions lead to predisposition to subsequent development of hematologic conditions.[11,12] With improved understanding of the basic mechanisms underlying disease, therapies which target the type of molecular aberrations in hematologic conditions have increasingly been developed (Table 4.2).

Extraction of Nucleic Acids: The Starting Point for Molecular Assays

Because mutations and alterations in the DNA of disease-causing genes usually lead to detectable aberrations in RNA and protein levels, a variety of analytes are available to diagnose most conditions. DNA is the most stable analyte and can be easily extracted from fresh cells, frozen cells, and formalin-fixed paraffin-embedded (FFPE) tissues. Therefore, DNA is the preferred starting material for most PCR assays and is used for DNA sequencing, for mutation detection by PCR, and for genomic microarrays. DNA is stable at room temperatures for several days, for months to years when refrigerated, and essentially indefinitely when frozen. One exception to the stable preservation of DNA is in decalcified bone marrow trephines where the acid treatment usually fragments the DNA, often making it unsuitable for PCR and microarrays.

DNA can be extracted from cells by a variety of methods, with the first step usually being disruption of the cells using a powerful protease, such as proteinase K, along with a detergent to help solubilize the cell membranes. An RNase enzyme can also be used during this step to degrade the interfering mRNA present. DNA can then be selectively isolated from this mixture using column chromatography, organic extraction of proteins followed by alcohol precipitation, or by the binding of DNA to solid substrates such as glass beads.

RNA is much more labile than DNA and can be quickly degraded in unprocessed blood and bone marrow samples and in FFPE tissues. However, RNA is still the preferred substrate to detect fusion transcripts that occur in hematologic neoplasms (e.g., BCR-ABL1) and when mRNA or mIR expression analysis is needed. Most RNAs begin to degrade within two to three days of blood or bone marrow collection even if the unprocessed sample is refrigerated; RNA must be stored frozen once extracted from cells.

RNA can be isolated from cells using methods similar to those described for DNA extraction above. Care must be taken during extraction to neutralize the RNA-degrading enzymes present in the environment and within the cells themselves. For most molecular assays, RNA is next converted into complementary DNA (cDNA) using reverse transcriptase as the first step in the protocol.

TABLE 4.1

DEFECTS IN THE CELLULAR MOLECULAR MACHINERY UNDERLYING HEMATOLOGIC DISORDERS

Alteration Type	Hematologic Condition(s)	Methods to Detect	References
Large DNA deletions	Thalassemias	Southern blot, genomic assays	3
DNA repeats/ insertions	Inherited cytopenias, drug response in leukemia	Southern blot, genomic arrays, PCR	4,5
DNA point mutations	Acute and chronic leukemias, lymphomas	AS-PCR, DNA sequencing, arrays	6,7
Epigenetic regulation	Bone marrow failure, myelodysplasia	Methylation sequencing, methylation-sensitive PCR, pyrosequencing	8
Ribosomal biogenesis	Diamond Blackfan anemia	Transcript profiling, protein expression	9
Alternate mRNA species	Coagulopathy	Transcript profiling, protein expression	10

AS-PCR, allele-specific PCR; mRNA, messenger RNA; PCR, polymerase chain reaction.

TABLE 4.2

TARGETABLE PATHWAYS ACTIVATED IN HEMATOLYMPHOID TUMORS

Tumor type	Genetic alteration/ mutation	Tumor type(s)	Effect(s)
Myeloid neoplasms (all)	*TET2, IDH1/2,* DNMT3A gene mutations	MPNs, MDS, AML, CMML	Epigenetic regulation of transcription[13]
Myeloproliferative neoplasms	*BCR-ABL1* fusion *JAK2* kinase PM *MPL* receptor PM *PDGFR* kinase fusion *KIT* receptor kinase PM	CML MPNs MPNs HES/MCD MCD	Activation of kinase or ligand-independent signaling or hypersensitivity to lower levels of growth factor[14]
Acute myeloid leukemia	*KIT* receptor PM *FLT3* receptor PM, ITD	CBF-AML AML	Ligand-independent signaling[15]
Lymphoma	*AKT1* & *TCL1* activation *SYK* kinase activation *LCK* kinase fusion/mutation	B-NHL PTCL ALL-T	Hypersensitivity to BCR, TCR, and growth factor signaling[16–18]

MPN, myeloproliferative neoplasm; MDS, myelodysplastic syndrome; AML, acute myeloid leukemia; CMML, chronic myelomonocytic leukemia; CML, chronic myelogenous leukemia; PM, point mutation; ITD, internal tandem duplication; HES, hypereosinophilic syndrome; MCD, mast cell disease; CBF, core binding factor leukemia; B-NHL, B-cell non-Hodgkin's lymphoma; BCR, B-cell receptor; TCR, T-cell receptor; PTCL, peripheral T-cell lymphoma; ALL-T, T-cell acute lymphoblastic leukemia/lymphoma.

Isolation of mIRs often requires modified extraction methods, but they can also be quantified using reverse transcriptase (RT)-PCR and may be more stable than mRNAs.

More recently, clinical assays have begun to assess the cellular epigenetic state through the detection of methylated DNA, which is typically analyzed after the methylated cytosines have been converted following deamination by bisulfite treatment. Abnormalities in protein expression are commonly assessed using immunohistochemistry on fixed tissues, or blotting or immunoassays on fresh samples. A more complete view of the genome can be obtained using conventional karyotyping of chromosomes in fresh samples, or by fluorescence in situ hybridization (FISH) and genomic DNA microarrays on fresh and fixed materials. These techniques are described in more detail in Chapter 3.

Polymerase Chain Reaction: The Indispensable Molecular Technique

From its first application to bacterial genetics in the early 1980s, PCR has been the central technique for amplifying genes so they can be sized to look for pathogenic insertions or deletions; sequenced to look for base pair mutations; and labeled with radioactivity, fluorochromes, or chromogenic moieties to use as probes in blots and reverse microarrays. The PCR technique involves the sequential amplification by repeated cycles of DNA denaturation, reannealing, and polymerase extension of DNA targets using flanking oligonucleotides (Fig. 4.1A). In the initial cycles of the PCR, the target is exponentially amplified before gradually plateauing when the large amount of product present tends to favor reannealing of double-stranded templates rather than primer binding/extension.

To detect the products that have been amplified by PCR, the reaction is typically run out on a solid agarose or polyacrylamide substrate or gel. These PCR amplicons can be detected by a laser using capillary electrophoresis if one of the primers has been labeled with a fluorochrome (Fig. 4.1B), or by slab gel electrophoresis followed by post-staining with a DNA-binding dye (e.g., ethidium bromide) that can be visualized with ultraviolet light (see Fig. 4.2, Step 1). As described above, if RNA is to be analyzed by PCR, it is first converted into cDNA in a technique known as RT-PCR.

If fluorescent probes are added into the reaction, real-time or quantitative PCR (qPCR) can be performed to calculate the amount of an RNA or DNA target present in the initial sample. A common qPCR design is the TaqMan short, gene-specific probe that has a reporter fluorophore at its 5′ end and a quencher molecule at the 3′ end. The probe hybridizes to its target amplicon during the annealing step of each PCR cycle and is then hydrolyzed by the 5′ exonuclease activity of Taq polymerase during DNA extension. When the TaqMan probe is hydrolyzed, the reporter fluorophore is detached from the adjacent quencher molecule and fluoresces in an amount proportional to the degree of PCR product amplification. Thus, as probe is bound to template and its reporter released by the polymerase extension, the detected fluorescence rises exponentially.

In qPCR, the amount of initial target present in a PCR is back-calculated by observing the PCR cycle in which the fluorescence signal first becomes detectable. This threshold cycle (Ct) can then be used for absolute or relative quantitation. For absolute quantitation, the observed Ct is converted to a target copy number by plotting it on a standard curve (log Ct vs. starting copy number) constructed from samples with a known target copy number (Fig. 4.1C). For relative quantitation, target quantities are expressed relative to a co-amplified normalizer control (e.g., a highly expressed housekeeping gene such as *ACTB* [*β-ACTIN*] or *ABL1*). The quantity is then represented as a relative ratio most commonly the delta-Ct calculation: [relative quantity] = $2^{-(\text{Ct of gene target} - \text{Ct of reference gene})}$.

A specialized form of qPCR used to detect single base pair changes in DNA is *allele-specific (AS)-PCR*. This method compares the amplification levels of a PCR probe or primer that recognizes one allele versus the signal from a probe that recognizes only the other allele. This same protocol can also be used to sensitively detect the level of mutated sequences in neoplasms.[19] This method can routinely detect the presence of a mutation down to 0.1% of the template in the sample (Fig. 4.1D).

DNA Sequencing: The Technique Driving the Genomic Revolution

The DNA sequence of genes is built up from combinations of four nucleotides, adenine (A), cytosine (C), guanine (G), and thymine (T), and their epigenetically modified variants, particularly 5-methylcytosine. DNA sequencing to determine the base composition of the genome was first routinely applied in the late 1970s but has remained a difficult and expensive technique until the last several years.

The accurate but costly gold-standard technique for determining DNA base composition, developed by Frederic Sanger, is called the *dideoxy chain termination method.*[20] After an initial PCR step to amplify the gene of interest, this method relies on a second asymmetric PCR step in which stops in the PCR extension are randomly introduced at each position in the product by adding fluorescently labeled chain terminating variants of the A, C, G, and T nucleotides, each terminating nucleotide being labeled with a different color (green, blue, black, and red). This range of DNA molecules each terminated at a different position are then separated by size using electrophoresis and the sequence read by laser detection of the terminally labeled nucleotide (Fig. 4.2).

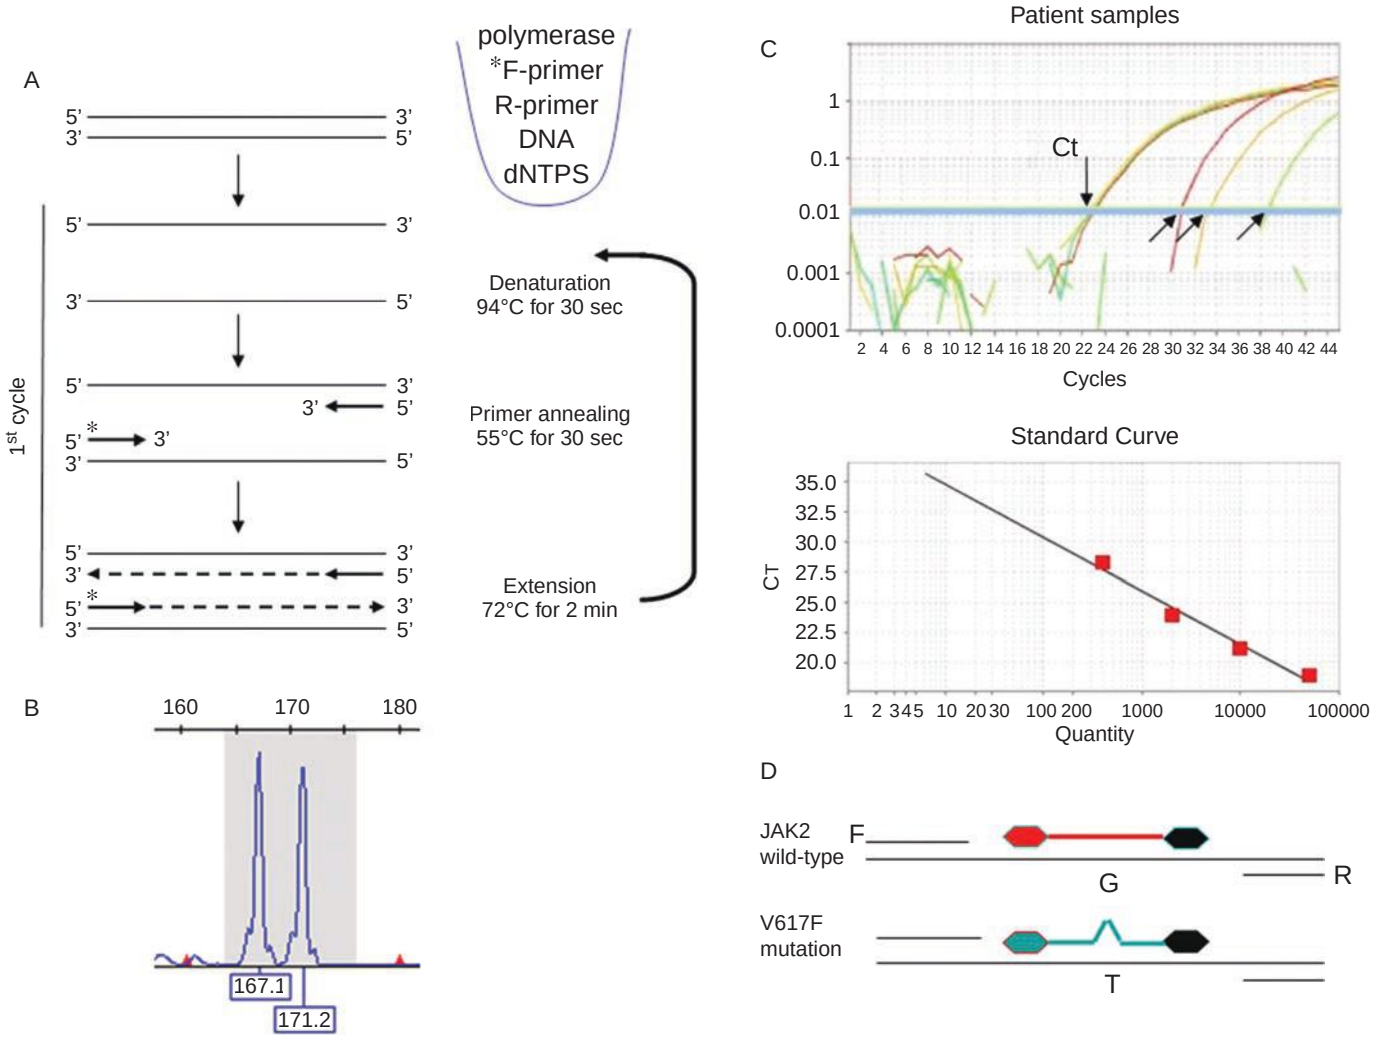

FIGURE 4.1. Polymerase chain reaction (PCR). A. A three-stage conventional PCR, with denaturation, annealing, and extension steps. Components of the typical PCR are illustrated including a DNA template (e.g., target gene), unlabeled nucleotides (dNTPs), a DNA polymerase to copy the templates and forward (F) and reverse (R) DNA primers, one of which is fluorescently labeled (*). **B.** Fluorescent products from the above PCR are then detected by capillary electrophoresis. Shown is a trace with a normally sized 167 base pair *NPM1* gene product and an abnormal copy with a 4 base pair insertion (171b) characteristic of acute myeloid leukemia. **C.** Quantitative PCR using the TaqMan method with four samples showing differing amounts of the target gene as indicated by Cts ranging from 23 to 39 cycles (*arrows*). A graph showing 10-fold dilutions of a reference sample is plotted below, which are used to convert Ct in patient sample into copy number. **D.** Design of a TaqMan qPCR assay for detection of the *JAK2* V617F mutation, with identical F and R primers but two different fluorescent probes; the red one detecting the normal *JAK2* sequence ("G" at that position), and a green probe recognizing the mutated "T" sequence. The black 3′ moiety on the probes represents the quencher dye.

Newer generations of sequencing technologies that are much faster and cheaper to perform are currently replacing the Sanger method and typically use a sequencing-by-synthesis approach. As each nucleotide is added to a growing chain of DNA by the polymerase, its incorporation is detected by release of product or by its chemical or electrochemical properties.[21,22]

Blotting and Array Methods

An alternate method for investigating DNA sequences is solid phase hybridization, in which enzymatically-digested total genomic DNA or RNA from a cell (or specific PCR products) are size-separated using slab gel electrophoresis and then the products are transferred in place from the gel to a nylon or nitrocellulose membrane. This membrane is hybridized with a labeled DNA probe that detects the gene target. The binding of that probe is then visualized using autoradiography or colorimetric detection. In the Southern blot application, prior to electrophoresis genomic DNA is digested with one or more restriction endonucleases that cut(s) within the gene(s) of interest, so that any disruption of the gene (by insertion, deletion, or recombination) is detected by an alternately-sized banding pattern following electrophoresis and probing (Fig. 4.3).

Southern blot is a labor-intensive technique which typically requires several days. For this reason, currently the principal uses of Southern blot in hematology are detecting deletions or amplifications in large genes and their enhancer control regions, such as the globin genes in thalassemia. In these applications, the size of the chromosomal area to be investigated and thus the number of DNA nucleotides to be analyzed are usually too large to be conveniently spanned by PCR and PCR-based DNA sequencing.

A related blotting application is reverse hybridization, in which DNA sequences from a tumor or patient's normal DNA are PCR-amplified and then labeled and hybridized against an array of probes that have been spotted on a membrane or other matrix. These applications are widely used to detect the specific strain of a particular virus present in a sample but in hematology are mostly used for large scale cytogenetic microarray applications that are covered elsewhere in Chapter 3.

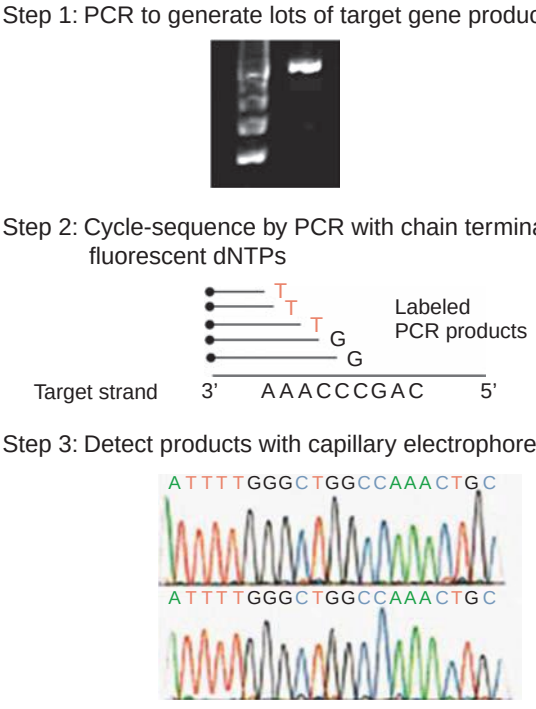

FIGURE 4.2. DNA Sequencing. Steps in the dideoxy chain termination (Sanger) method include: Step 1: Standard polymerase chain reaction (PCR) to produce large amounts of a gene-specific template, detected by slab electrophoresis followed by ethidium bromide staining of the gel. Step 2: Unidirectional (or asymmetric) PCR using the template from the first PCR along with either a forward or reverse primer in a reaction containing normal nucleotides mixed with chain terminating A, C, G, and T bases. Step 3: The range of products from the asymmetric PCR which are terminated at every possible base in the PCR amplicon are then separated by capillary electrophoresis and detected by a laser recognizing the fluorochrome/nucleotide present at the end of products. Base-calling is performed using software which normalizes the peak heights to produce the depicted electropherogram.

MOLECULAR DIAGNOSTIC APPLICATIONS IN HEMATOLOGY

The diagnosis of specific types of lymphoid and myeloid malignancies is discussed elsewhere in this volume, but here we summarize generally how molecular techniques are used to assist in their diagnosis. The current schema for diagnosis of hematologic neoplasms is the World Health Organization (WHO) Classification of Hematologic and Lymphoid Neoplasms.[23] This classification incorporates morphology and immunophenotypic features but also increasingly relies on molecular and cytogenetic testing for definitive diagnosis.

Molecular Diagnostics of Myeloid Neoplasms

Myeloid malignancies can be divided into myeloproliferative neoplasms (MPNs), in which the pathogenetic mutations do not significantly impair cell maturation but instead drive growth, and acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS), in which maturation is impaired (see also Chapter 72).

MPNs show a range of recurrent chromosomal translocations, such as the *BCR-ABL1* fusion in chronic myelogenous leukemia (CML) that can be detected by RT-PCR as well as by FISH.[24] In CML, levels of the *BCR-ABL1* fusion transcript detected by a real-time RT-PCR method are now used to monitor the course of CML therapy with imatinib and other drugs, and to trigger a change in treatment in drug-resistant cases.[25] Given the importance of this test for clinical management, significant progress has been made in standardizing both the PCR protocol[26,27] and the reference materials used to calibrate the *BCR-ABL1* PCR assay.[28] Mutations in the tyrosine kinase *JAK2* are the most commonly detected pathogenetic marker for a group of MPNs that include polycythemia vera, essential thrombocythemia, and primary myelofibrosis.[29] Detection of the most common *JAK2* mutation (V617F) can be done by AS-PCR, providing a highly sensitive method of monitoring disease course in *JAK2*-mutated MPNs (Fig. 4.1D).

In AML and MDS, karyotypic findings along with hematologic parameters remain the principle determinants of diagnostic classification and outcome prediction, as codified in WHO classification and the International Prognostic Scoring System (IPSS) for MDS.[23,30,31,32] Some of the chromosomal translocations that occur in AML, such as the inv(16)/t(16;16) in acute myelomonocytic leukemia and the t(15;17) in acute promyelocytic leukemias, are best monitored by RT-PCR.[33,34] However, characteristic mutations, such as *NPM1* duplications seen in a subset of normal diploid karyotype AML, can be detected by PCR sizing assays (Fig. 4.1B).[35] Other mutations provide important prognostic information in AML, including activating insertions/duplications in the *FLT3* receptor tyrosine kinase (RTK), which can be detected by PCR sizing assays; and mutations in the *KIT* RTK, which can be detected by DNA sequencing (Fig. 4.4A,B). Another set of genes, including *TET2*, *IDH1*, *IHD2*, *KRAS*, *NRAS*, *EZH2*, and *ASXL1*, are mutated in MPNs as well as AML and MDS, making a common molecular panel useful for diagnosis and risk stratification in all myeloid neoplasms.[36,37]

Molecular Diagnostics in Lymphomas and Benign Lymphoid Expansions

The lymphoid neoplasms were the first tumor types to have a standardized diagnostic schema based on lymphocyte maturation stage, beginning in the 1960s. The current standard for diagnosis

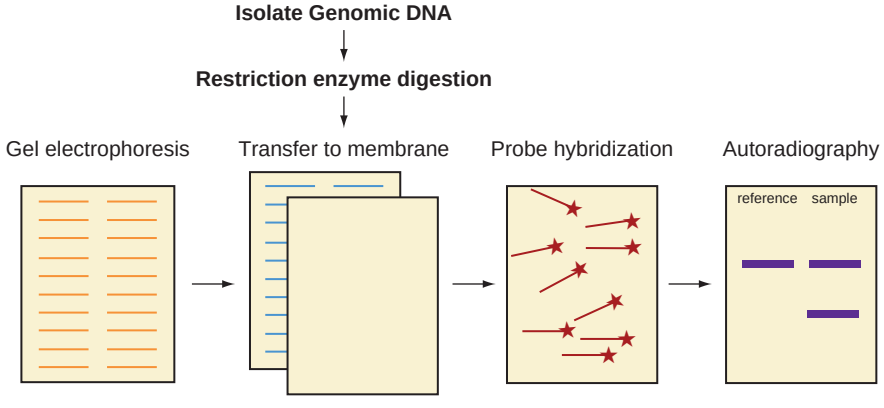

FIGURE 4.3. Blot hybridization. Steps in the Southern blot are illustrated for a reference and patient sample. See text for additional explanation.

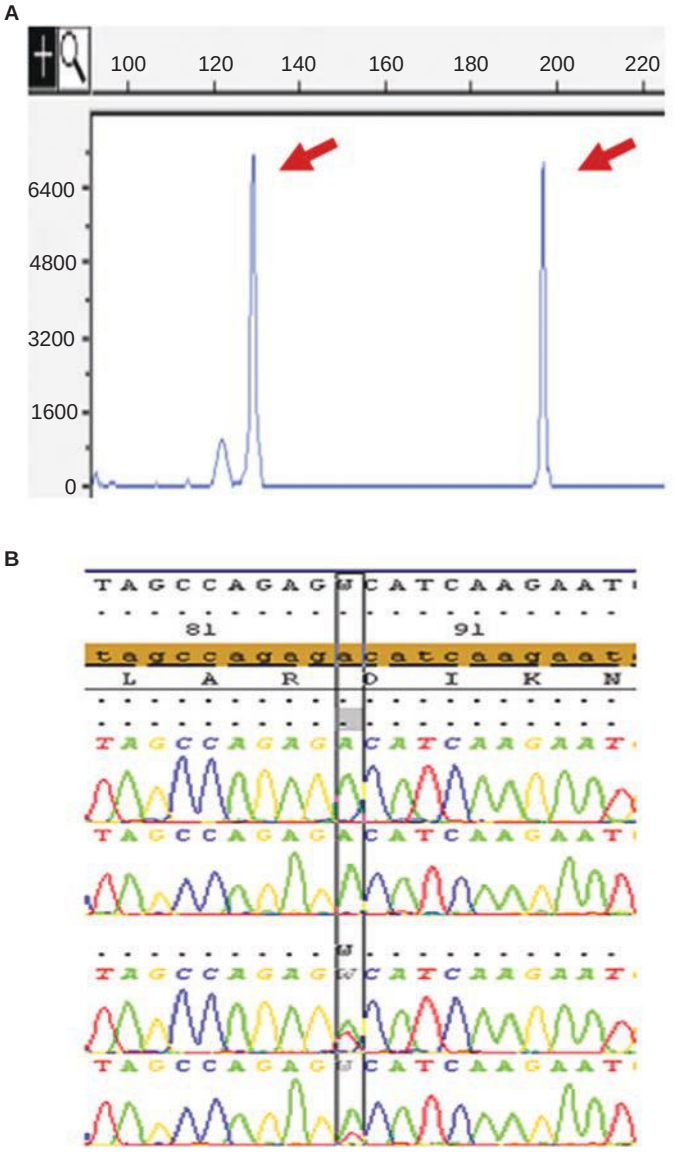

FIGURE 4.4. Detection of mutations in acute myeloid leukemia (AML). A. FLT3 duplication detected by PCR followed by capillary electrophoretic fragment analysis. **B.** *KIT* mutation (D816V) in AML is illustrated by a double peak (boxed) in the lower electropherogram present in both forward and reverse sequences, as opposed to the single wild-type peak noted in the reference unmutated sequence above. The method is dideoxy chain termination DNA sequencing, as in Figure 4.3. Images courtesy of Dr. Zhong Zhang.

in hematopathology, the WHO Classification of Hematologic and Lymphoid Neoplasms,[23] represents an evolution and integration of the previous largely separate efforts in morphology and molecular genetics.

The general principle of classification in the WHO schema and its predecessors is to map neoplasms to the maturation stage of the normal counterpart which they most resemble.[38] Although this simplistic model does not account for all the observed heterogeneity in lymphomas, it has been incredibly successful in placing tumor entities in a comprehensible and easy to remember framework for diagnosis. Therefore, we summarize below how the genetic changes detected by molecular diagnostics correlate with the morphologic groups of both mature and immature B-cell and T-cell neoplasms,[39] with a more detailed review provided in Chapter 87.

Defining Molecular Events in Lymphoid Neoplasms

In acute lymphoid leukemia/lymphoblast lymphoma of B-cell lineage (ALL/LBL), these diagnostic changes include chromosomal fusions that can be detected by RT-PCR, FISH, or by expression microarray.[40] In T-cell lineage ALL/LBL, diagnostic molecular events include mutations in the *NOTCH1* gene[41] and gene activation of HOX regulatory genes through the chromosomal rearrangements that juxtapose the target oncogene next to the T-cell receptor (TCR) enhancer, which selectively drives aberrant expression in the T-cell clone. The gene expression changes induced by oncogene activation can also be detected with RNA expression microarrays.[42]

In mature B-cell lymphomas, chromosomal translocations that juxtapose a variety of different oncogenes next to an immunoglobulin gene (Ig) enhancer (usually) are important initiating events and can be detected by PCR or FISH.[43] In follicular lymphoma, Burkitt lymphoma, marginal zone lymphoma, and mantle cell lymphoma, these Ig-enhancer-driven oncogenes typically include *BCL2*, *MYC*, *MALT1*, and Cyclin D1/*CCND1*, respectively (Table 4.3). Molecular variants of these lymphomas that lack these classical translocations often activate homologous genes, e.g., the activation of Cyclin D3/*CCND3* in variants of mantle cell lymphoma.[44]

In mature T-cell lymphomas, reciprocal chromosomal translocations are much less common, occurring generally only in classical anaplastic large cell lymphoma and T-cell prolymphocytic leukemia. In these two neoplasms, PCR, FISH, or immunohistochemistry to detect the abnormally expressed protein (*ALK* and *TCL1*, respectively) are diagnostic modalities.[45] Recently, other translocations which affect signaling pathways have been identified.[46] However, in other T-cell neoplasms, gene instability resulting in multiple chromosomal alteration and gene mutations, similar to that seen in poor-risk AML, is commonly seen. This finding suggests that genomic arrays may be useful diagnostic tests for these uncommon tumors.[47,48]

Using Polymerase Chain Reaction to Detect B-cell and T-cell Clonality

One of the other key diagnostic issues in hematology is distinguishing benign lymphoid expansions, as seen in autoimmune diseases and

DIAGNOSTIC TESTS USED FOR THE WORKUP OF LYMPHOMA

	Test type
All cases	• Morphologic examination • IHC or flow cytometry panel
Subtyping by FISH, PCR, or IHC	
CLL/SLL	FISH for D13/del13q, del17p13/*TP53*, del11q/*ATM, CEP12*
Mantle cell lymphoma	Cyclin D1 IHC or t(11;14)/*CCND1-IGH@* FISH
Follicular lymphoma	*BCL2/BCL6* IHC or t(14;18)/*IGH-BCL2* FISH
Marginal zone lymphoma	t(18q21;var)/*MALT1* FISH del7q FISH for splenic variants
High-grade B-cell/Burkitt	*MYC; IGH@ BCL2; BCL6* FISH
ALCL	ALK IHC or t(2;5)/*ALK-NPM1*

IHC, immunohistochemistry; FISH, fluorescence in situ hybridization; PCR, polymerase chain reaction; CLL/SLL, chronic lymphocytic leukemia/small lymphocytic lymphoma; ALCL, anaplastic large cell lymphoma; ALK, anaplastic lymphoma kinase.

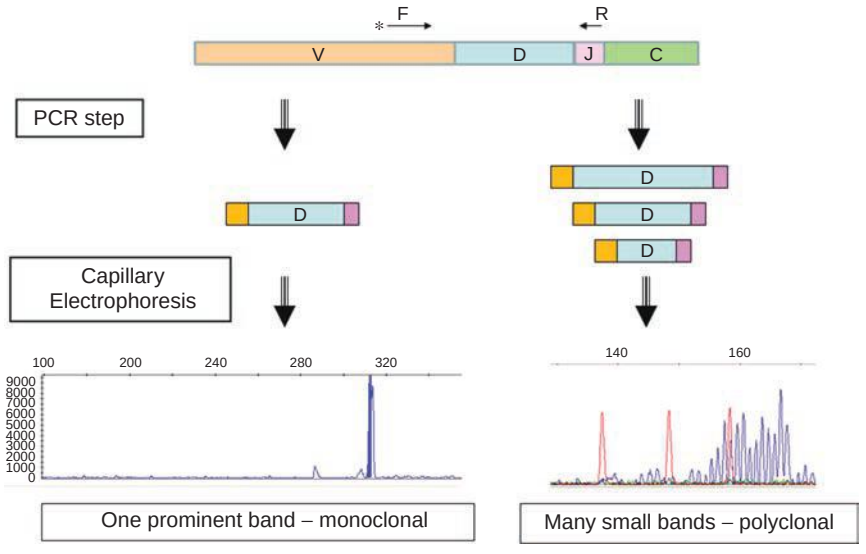

FIGURE 4.5. Principle of B-cell and T-cell clonality assessment by polymerase chain reaction (PCR). (Top) Schematic representation of the immunoglobulin heavy chain (IGH@) gene locus following rearrangement in a B cell; the locations of primers used in IGH@ PCR are indicated by the forward (F) and reverse (R) arrows with one labeled with a fluorochrome (*). The variable region (V) segments are represented in orange, the diversity region (D) segments are represented in blue, and the joining (J) region segments are shown in pink. A unique template-independent sequence is added to the VD and DJ junctions in each individual precursor B cell during IGH@ rearrangement in the bone marrow. A similar process involving the T-cell receptor happens in a precursor T cell in the thymus. **(Middle)** After PCR, a monoclonal B-cell population characteristic of B-cell lymphoma shows a single predominant "clonal" VDJ amplicon of a particular size due to all the B cells being derived from a common precursor cell. Polyclonal/reactive B-cell expansions show VDJ amplicons of varying sizes derived from the range of different B cells in the population. **(Bottom)** The range of VDJ amplicons is visualized by running the IGH@ PCR on capillary electrophoresis. The peaks are detected using the fluorochrome-labeled PCR products run on capillary electrophoresis with the peak height proportional to the amount of PCR products of any particular size. Red peaks represent internal size standards; blue peaks are from the IGH@ PCR.

infections, from clonal proliferations associated with lymphoid leukemias and lymphomas. The core methodology in making this distinction is multiparameter flow cytometry, which can determine even subtle emerging clonal expansions. However, PCR analysis of the B-cell receptor (BCR) and TCR has an important ancillary role, especially when fixed tissue specimens, which cannot be used for flow cytometry, are the only available samples.

B cells arise as precursors in the bone marrow called lymphoblasts or hematogones and then migrate into the peripheral blood as long-lived naive forms, a process that is largely completed in childhood. Further maturation of B cells is dependent on recognition of an appropriate antigen that binds to a specific antibody molecule, also known as the BCR, comprised of immunoglobulin heavy chain (IGH@) and one of two types of immunoglobulin light chain (IGK@ or IGL@). Similarly, precursor T cells arise in the bone marrow and migrate to the thymus early in development, where they rearrange their TCR to produce a unique clonotypic TCR in each precursor T cell and all of its progeny.

The basis of B-cell and T-cell clonality determination by PCR is that since clonal lymphoid expansions arise from a single founder cell, all cells in that expansion will share the same BCR or TCR, which has a particular size following PCR. The structure of the TCR or BCR in a precursor lymphocyte is determined by the process of VDJ recombination that occurs in the DNA during lymphocyte maturation. Due to variation in the size of the diversity (D) region between the variable (V) and joining (J) segments, all cells within a clonal B-cell proliferation will have an identically sized IGH@ gene rearrangement that can be detected by PCR (Fig. 4.5). In contrast, mixed/polyclonal non-neoplastic B-cell expansion will have IGH@ PCR products of varying sizes, giving a normal distribution of PCR products. A similar process occurs in T cells, with PCR for either the TCR-gamma or TCR-beta gene used to determine the presence of a clonal, oligoclonal, or polyclonal T-cell expansion.[49]

Standardized protocols for IGH@, IGK@, TCRG@, TCRB@ PCR have been developed,[50,51] and these can be performed on fresh cells isolated from blood or bone marrow aspirate or from fixed tissue sections. Also, given the exquisite sensitivity of PCR, very small samples (such as minute amounts of cerebrospinal fluid) can be used to detect clonality in limited samples.

Minimal Residual Disease Testing for Leukemias and Lymphomas

One of the principal benefits of real-time PCR is that it is both a highly sensitive and quantitative technique to track residual disease.[27,52,53] If a PCR assay can be designed to selectively amplify an initiating molecular aberration in a leukemia or lymphoma, then a highly sensitive and specific PCR assay can be designed to track disease levels over the treatment course and to monitor for relapse (Table 4.4). The mostly widely used group of these PCR assays are those to detect fusion transcripts in leukemias, including *BCR-ABL1* in CML, *PML-RARA* in acute promyelocytic leukemia, and *MLL* and *ETV6-RUNX1* fusions in lymphoblastic leukemia.[27,54]

Similarly, mutation-specific PCRs that detect only the mutant but not the wild-type base pair changes can be used when specific point mutations characterize the molecular pathogenesis of a tumor, such as *JAK2* mutations in MPNs[55] and *FLT3* and *NPM1* mutations in a subset of AML.[56,57] This PCR MRD approach is limited to those mutations that occur early in the disease course, since mutations occurring later may be present only in subclones that disappear or evolve under treatment. Deep sequencing using

TABLE 4.4

TYPES OF MOLECULAR MONITORING ASSAYS FOR LEUKEMIAS AND LYMPHOMAS

Methodology	Examples	Disease Types (References)
Fusion transcript RT-PCR (RNA)	*BCR-ABL1, PML-RARA, CBFB-MYH11 RUNX1-RUNX1T1 NPM1-ALK, BIRC3-MALT1*	CML, AML ALL/LBL Lymphoma
Translocation detection by PCR of DNA	*IGH@-BCL2*	Follicular lymphoma[52]
Leukemia-associated quantitative mutation detection	*NPM1, FLT3*	AML[56,57]
Leukemia-associated elevated gene expression	*BAALC, WT1*	AML[56]
Clone-specific IGH PCR	IGH@ VDJ/FR3 custom-designed primers	Lymphoblastic leukemia[59]
Surrogate markers	EBV and HHV8 viral load	Virus-associated lymphomas

RT-PCR, reverse transcriptase polymerase chain reaction; CML, chronic myelogenous leukemia; AML, acute myeloid leukemia; ALL/LBL, acute lymphoid leukemia/lymphoblastic lymphoma of B-cell lineage; IGH, immunoglobulin heavy chain; EBV, Epstein-Barr virus; HHV, human herpesvirus.

next-generation platforms shows promise for a more comprehensive approach to the use of mutations for MRD analysis.[58]

Finally, highly complex, leukemia-specific MRD qPCR assays can be designed for B-cell and T-cell neoplasms which rely on designed primers based on the specific TCR or BCR expressed by a patient's tumor.[59] These types of assays, if well-designed, provide the most sensitive methods available for tracking low-levels of residual ALL/LBL, but given their expense have not been widely implemented.

MOLECULAR DIAGNOSIS IN THE NEXT 5 YEARS: THE COMING ASSAYS AND METHODOLOGIES

The above methodologies have evolved relatively slowly, giving practicing hematologists time to integrate these methods into the routine workups. However, the large number of new high-throughput testing methodologies that are likely to be implemented in the next few years, particularly single nucleotide polymorphism arrays and genomic sequencing identifying both germline and somatic mutations, may be more difficult to integrate into routine clinical practice. These methodologies will require integrating complex datasets to derive a treatment plan including:

- interpreting how advanced sequencing panels will be used to relate diagnosis to treatment selection and a molecular monitoring strategy[60];
- integration of acquired and germline polymorphisms into further understanding of bone marrow failure[61];
- combining single cell analysis using flow cytometry with molecular profiles to characterize normal and abnormal stem cells.[62]

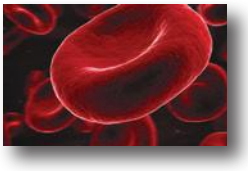
The Normal Hematologic System

SECTION 1 HEMATOPOIESIS



CHAPTER 5

ORIGIN AND DEVELOPMENT OF BLOOD CELLS

Andrew Chow, Paul S. Frenette

BLOOD CELLS

The blood contains several different types of cells. Each of these cell types is quite distinct in appearance, and each has a specific biologic function. *Erythrocytes* are anucleate, biconcave discoid cells filled with hemoglobin, the major protein that binds oxygen. Erythrocytes transport the respiratory gases oxygen and carbon dioxide. *Granulocytes* and *monocytes* are cells that can exit from blood vessels and migrate into many tissues. These two cell types play key roles in inflammation and phagocytosis. *Platelets* are very small, anucleate cells that contain molecules required for hemostasis. In addition, platelets provide hemostasis through their abilities to adhere, aggregate, and provide a surface for coagulation reactions. Lymphocytes mediate highly specific immunity against microorganisms and other sources of foreign macromolecules. B-lymphocytes confer immunity through the production of specific, soluble antibodies, whereas T lymphocytes direct a large variety of immune functions, including killing cells that bear foreign molecules on their surface membranes. Despite these extreme structural and functional differences among the cells of the blood, strong evidence exists that the vast majority of blood cells are the progeny of a single type of cell: the hematopoietic stem cell (HSC). The processes involved in the production of all of the various cells of the blood from the HSCs are collectively called *hematopoiesis*. Hematopoiesis includes HSC self-renewal, HSC commitment to specific lineages, and maturation of lineage-committed progenitors into functional blood cells. Self-renewal may occur by symmetric HSC division, such as expansion of the HSC pool during fetal life or post-HSC transplantation. Other possible fates of HSC divisions include apoptosis or mobilization to the peripheral circulation following stress such as growth factor stimulation or depletion of marrow cells by irradiation or chemotherapy. During normal steady-state conditions, HSCs reside mainly in the marrow cavity, but under certain stress conditions, HSCs can migrate and colonize other organs such as the liver and spleen in a process termed extramedullary hematopoiesis.

Hematopoiesis begins early during embryogenesis and undergoes many changes during fetal and neonatal development. Unlike some organ systems that form in early life and are not continually replaced, turnover and replenishment of the hematopoietic system continue throughout life. Cells of the blood have finite life spans, which vary depending on the cell type. In humans, granulocytes and platelets have life spans of only a few days, whereas some lymphocytes can exist for many months. Cells are replaced as the older cells are removed and the newly formed, mature cells are added. The numbers of the various cell types in the blood are normally kept in relatively constant ranges. In particular, variations in the erythrocyte number are normally minimal, and values 30% above or below the norm for the population have significant health effects. Although the numbers of other blood cell types are not as constant as the number of erythrocytes, the production of other blood cells is also highly regulated. The regulation of hematopoiesis is complex. Some regulatory factors influence overall hematopoiesis by affecting very early progenitor cells: the HSCs and/or their progeny that have not undergone commitment to a single cell lineage. Also, specific regulatory growth factors play key roles in fostering the production of cells of each lineage. Lineage-specific regulation is necessary because of the widely varying life spans and functions of the different mature blood cell types.

This chapter presents an overview of hematopoiesis. Many conclusions presented here are based on experiments carried out in murine systems. All cell lineages that compose blood will be discussed. Some cell types such as dendritic cells and mast cells are derived from the HSCs but are found mostly in tissues rather than blood, where the final steps of differentiation occur. Figure 5.1 is an illustration of the cell types that constitute the hematopoietic spectrum.

ORIGIN OF HEMATOPOIESIS

Sites of Hematopoiesis

During prenatal development, the sites of hematopoiesis change several times in the mouse[1–3] and human[3,4] (Fig. 5.2). Since better characterized in mice (Fig. 5.2A) than humans (Fig. 5.2B), the discussion below will focus on murine developmental hematopoiesis. In humans and other vertebrates, the first hematopoietic cells arise during late gastrulation in the extraembryonic yolk sac (YS) in structures known as blood islands. This initial hematopoiesis is termed *primitive hematopoiesis* and serves a supportive role to rapidly produce erythroid cells, platelets, and macrophages prior to the formation of the circulatory system. Primitive hematopoiesis is transient, occurring on embryonic

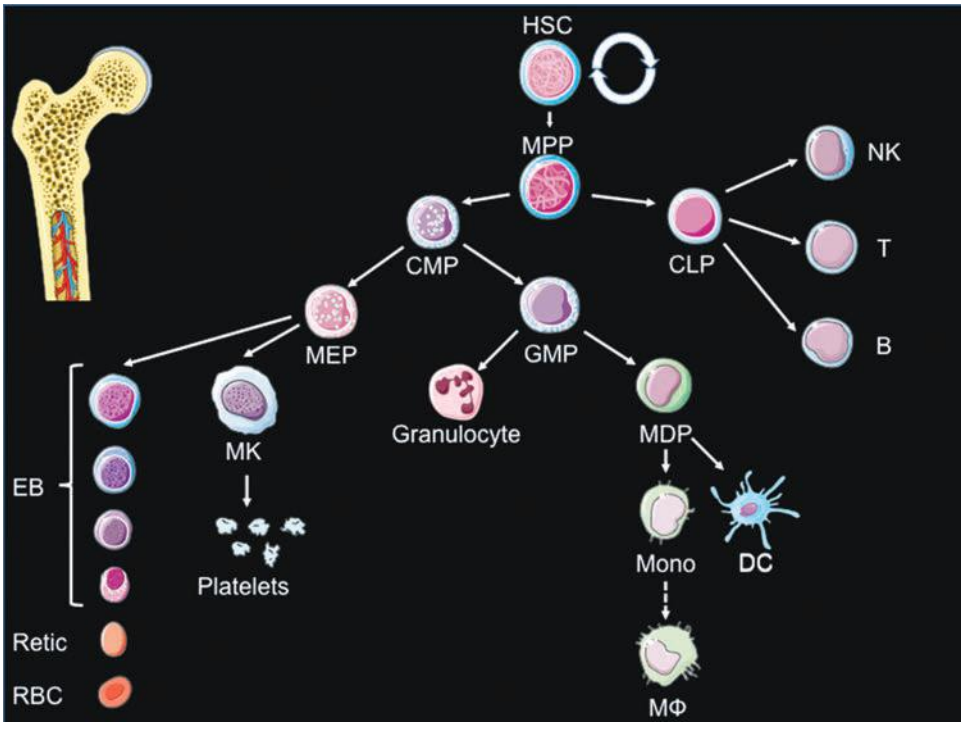


FIGURE 5.1. Cells of the blood and lymphoid organs and their precursors in the bone marrow. days 7.25 (E7.25) through 13 (E13) in mice and day 19 through week 8 in humans. Primitive erythrocytes, which are the first embryonic hematopoietic cells, are large nucleated cells morphologically resembling erythrocytes of phylogenetically lower primitive vertebrate groups, such as birds, amphibians, and fish. These primitive erythrocytes have reduced erythropoietin (EPO) requirements during their development compared to definitive erythroid cells[5] that develop later. Also unlike their definitive counterparts, primitive erythrocytes typically circulate as nucleated cells before enucleating, and additionally express ζ, βH1, and εy globin genes.[6,7] These cells and primitive platelets[8] derive from a primitive bipotent megakaryocyte erythroid progenitor found in the yolk sac in mice (E7.25) and humans.[9,10] Along with maternally derived macrophages (MΦ) that exist, but are declining in numbers, in the yolk sac at E8, two other MΦ progenitors exist in the yolk sac: one with strictly MΦ potential

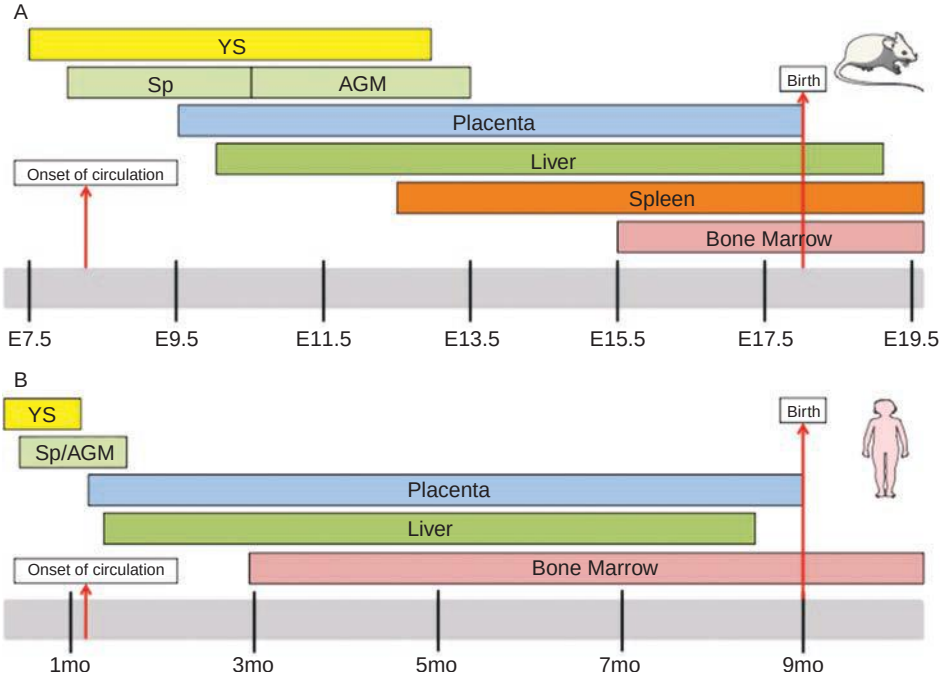

FIGURE 5.2. Sites of hematopoiesis. A: Sites of mouse hematopoietic development. AGM, aorta-gonad-mesonephros; Sp, splanchnopleura; YS, yolk sac. **B:** Sites of human hematopoietic development.

and one with bipotential for MΦ and erythrocytes.[11] Importantly, since circulation does not commence until E8.25, this indicates in situ MΦ development in the yolk sac. Thus, primitive hematopoiesis in the yolk sac provides the developing embryo with three crucial hematopoietic cell types prior to contribution from multipotent stem cells deriving from definitive hematopoiesis (see below).

Since the first hematopoietic cells arise in the extraembryonic yolk sac, it was widely believed in the 1970s that the first HSCs developed in the yolk sac. However, experiments in avian chimeras demonstrated for the first time that although the YS had early contribution, the hematopoietic cells present in the stages closer to birth were exclusively derived from the intraembryonic compartment.[12] Similar avian chimeric experiments subsequently demonstrated that the intraembryonic compartment, rather than the YS, was the exclusive source of B and T cells in the adults.[13] Godin and colleagues subsequently demonstrated in mice that the aortic region of E9 embryos, but not YS precursors, were capable of contributing to B cells in irradiated adult recipients.[14] In the same journal issue, Medvinsky, Dzierzak, and colleagues demonstrated that the E10.5 AGM (aorta-gonad-mesonephros) region had substantially higher and earlier onset of CFU-S activity, an early coarse assay for multipotency, compared to YS cells.[15] Soon afterward, Dzierzak's group demonstrated the ability of E10.5 AGM precursors to provide long-term multilineage reconstitution activity (LTR) in lethally irradiated adult mice.[16] Together, these seminal publications affirmed the intraembryonic contribution to adult mammalian hematopoiesis.

Since the AGM region above was harvested after the establishment of circulation (E8.25), migration of HSCs from a separate undescribed site of origin could not be excluded. To investigate whether HSC development occurred de novo in the AGM, the E8 splanchnopleura (Sp, the future site of the AGM) and the concomitant yolk sac, neither of which have LTR activity, were cultured. While the cultured Sp and YS both produced hematopoietic cells, confirming two independent waves of hematopoietic generation, the YS progenitors were unable to produce lymphoid progeny or have LTR activity.[17,18] Further dissection of the AGM determined that most of the HSC activity is found in hematopoietic intra-aortic clusters found on the ventral wall of the dorsal aorta.[2] HSC activity is also found in the proximal vitelline and umbilical arteries, although these sites have been less characterized. Two reports from the Dzierzak and Mikkola groups established that the placenta represents a previously overlooked major site of hematopoiesis in which HSC emergence parallels that of HSC appearance at E10.5 in the AGM.[19,20] In fact, when LTR HSCs are enumerated, there are 25-fold more LTR HSCs in the placenta than in the AGM.[19] Since the placenta is directly upstream of the fetal liver circulation and since the dramatic expansion of HSC in the FL mirrors that of the placenta, it has been proposed that the placenta is at least a major contributor of LTR HSCs. It has also been proposed that the placenta is a site of de novo HSC emergence independent from the AGM. Indeed, explant and stromal co-culture experiments of mesodermal tissue of the placenta prior to the establishment of circulation demonstrated erythroid and myeloid potential.[21,22] The concept of a de novo generated HSC was bolstered by in vitro culture of E8-9 placenta from *Ncx1*$^{-/-}$ animals, which lack a heartbeat and die by E10.5. Without circulatory contribution, the midgestation site had definitive hematopoietic cells with myelo-erythroid and lymphoid potential.[23] Although LTR HSC cannot be isolated from the placenta of *Ncx1*$^{-/-}$ animals because of developmental retardation and death by E10.5, these experiments show that definitive hematopoiesis emerges in this organ de novo. Whether the AGM, uterine and vitelline arteries, placenta, or a combination of the above are the genuine origin of HSCs, this LTR activity around E10.5 represents the start of definitive hematopoiesis.

Once definitive hematopoiesis begins, lymphocytes, monocytes, granulocytes, and platelets are formed as well as definitive erythrocytes. At E10, hematopoietic cells (both primitive and definitive) colonize the fetal liver (FL). Dramatic expansion of HSCs occurs at this site (daily doubling in absolute numbers of HSC from E12.5 to E14.5).[24] Eventually, LTR HSCs migrate from the fetal liver to the bone marrow via the circulation, and the bone marrow becomes the primary site of hematopoiesis, with a very small reserve of stem cells remaining in the liver. In the late stages of mammalian fetal development, the bone marrow becomes the main site of hematopoiesis. In humans, the bone marrow is the exclusive site of postnatal hematopoiesis under normal circumstances, whereas in the mouse, the spleen is also a hematopoietic organ throughout life.

Cellular Origin of Hematopoiesis

The cellular intermediates through which mesodermal tissue gives rise to hematopoietic tissue in embryonic development is an area of intense investigation. One candidate cellular ancestor is either (a) a mesoderm-derived bipotent hemangioblast capable of giving rise to either vessels and blood cells or (b) a specialized vascular cell type, called hemogenic endothelium, that serves as a precursor for blood cells. A non-mutually exclusive origin points to HSC derivation from mesenchymal tissue below the endothelial layer. Cytologic analyses of the AGM provide evidence for both endothelial-derived and sub-endothelial-derived HSCs through identification of HIACs and subaortic patches (SAPs), respectively.[2] The strict temporal overlap in the appearance at E10.5 and disappearance at E12.5 of HIACs and SAPs suggests that HSCs derived in SAPs can potentially transendothelially migrate to form HIACs prior to release into the bloodstream.[2] Keller and colleagues definitively showed that a bipotential hemangioblast could be found in the posterior region of the primitive streak in vivo.[25] However, until recently, the existence of a bona fide endothelial intermediate had been under debate. Supportive of an endothelial origin of HSCs is the presence of numerous vessel markers on AGM HSCs, including CD31, VE-Cadherin, and Tie-2.[2] Furthermore, AGM HSCs and endothelial cells in the ventral wall of the E10-E11 dorsal aorta both express Ly6A (Sca-1), c-Kit, CD34, Runx1, SCL, and GATA-2.[1] Fate mapping studies elegantly showed that VE-cadherin expressing endothelium contributes to AGM and adult HSCs, while lineage tracing of subendothelial mesenchyme with Myocardin-Cre animals did not result in labeling of HSCs.[26] Subsequently, novel imaging studies of embryonic stem cell-derived mesodermal cells demonstrated a hemogenic endothelial intermediate in the formation of blood cells.[27,28] Morever, when Runx1, an essential gene in definitive hematopoiesis, was specifically deleted in VE-cadherin-expressing cells (endothelial and hematopoietic cells), but not Vav1-expressing cells (only hematopoietic cells), there was a severe disruption in hematopoietic development that was associated with 65% fetal lethality.[29] Finally, Nancy Speck's group recently showed that expression of core binding factor beta (CBFβ) in Ly6a-expressing hemogenic endothelium was sufficient for HSC formation.[30] Together, these observations have supported the concept of blood cell development commencing with mesodermal cells that pass through hemangioblastic and hemogenic endothelial intermediates.

Common Critical Genes in Independent Origins of Hematopoiesis

Gene knockout experiments have provided significant insight into the critical regulators of embryonic hematopoiesis. In both primitive and definitive hematopoiesis, Bmp4, Flk1, Tal1/Scl, Lmo2, Gata2, and Runx1 are all critical for HSC generation.[2] Bmp4 (bone morphogenetic protein 4) is a critical signaling molecule

to specify the dorsal-ventral axis in development. Although the posterior portion of the epiblast in development is fated to give rise to hematopoietic activity, the neurally fated anterior fragment can retain the ability to produce hematopoietic cells by addition of Bmp4.[31] Bmp4 is crucial for hematopoietic development as Bmp4-deficient embryos mostly die around the gastrulation stage, and those that do survive have less yolk sac mesoderm and less lateral plate mesoderm (from which the AGM will develop).[32,33] In definitive hematopoiesis, Bmp-4 is expressed by endothelial cells in the ventral portion of the developing dorsal aorta and the subjacent mesoderm.[2] Using murine ES cells, it was recently shown that Bmp4 is necessary for mesodermal precursor expression of the receptor tyrosine kinase Flk-1 and the bHLH transcription factor Tal-1/SCL.[34]

The initiation of yolk sac hematopoiesis is dependent on the mesoderm and endoderm layers acting in concert, as soluble factors from endoderm substantially bolster the production of endothelial and hematopoietic cells by murine YS mesoderm explants.[35] One of the candidate soluble factor interactions is VEGF derived from endoderm and its receptor Flk1 on the mesoderm.[36,37] Indeed, Flk-1–deficient embryos do not develop vessels or YS blood islands and die in utero between E8.5 and E9.5.[38] To overcome this early developmental mortality, Shalaby and colleagues performed complementation studies with chimeras of *Flk-1*$^{+/-}$ and *Flk1*$^{-/-}$ ES cells and demonstrated convincingly that Flk-1 is also required for the generation of definitive endothelial and hematopoietic cells.[39] It was later shown that Flk-1 signaling appears to not be required intrinsically for endothelial and hematopoietic formation, as *Flk1*$^{-/-}$ ES cells are able to give rise to endothelial and hematopoietic lineages in vitro[40,41]; instead, Flk-1 is likely required for the migration of mesoderm cells from the posterior primitive streak to the yolk sac.[39] In concordance with the importance of the VEGF-Flk-1 signaling axis, VEGF derived from the visceral endoderm (but interestingly, not mesoderm) is sufficient for endothelial and hematopoietic differentiation.[42]

The transcription factor Tal-1/Scl[43–45] and the transcriptional regulator Lmo2[46] are both expressed in the yolk sac mesoderm prior to the onset of primitive hematopoiesis and then subsequently expressed in both endothelial and hematopoietic cells. Gene knockout of both Tal-1/Scl[47,48] and Lmo2[49] results in decreased endothelial cells and abrogates YS blood cell production. These genes are also critical for definitive hematopoiesis, as demonstrated by complementation studies with ES cells chimeras.[50–52] Gata-2–deficient animals have severely impaired primitive hematopoiesis and die at E10.5.[53] Gata2 haploinsufficient embryos have normal yolk sac hematopoiesis,[54] but have a reduction in AGM HSCs, which is consistent with its expression on aortic endothelium[55] and its proposed role in the expansion of hemogenic endothelial progenitors.[55] Runx1 has also been demonstrated to be crucial in definitive hematopoiesis, as Runx1 invalidation abrogates definitive myeloid, lymphoid, and HSC accumulation in the YS, AGM, and fetal liver.[56–58] Runx1 is thought to be crucial cell autonomously, as complementation studies fail to demonstrate hematopoietic contribution by Runx1-null ES cells.[57] While Runx1 was initially thought to be dispensable in murine primitive erythropoiesis, recent studies have recently shown that the morphology and gene expression of erythrocytes are aberrant in Runx1-deficient animals.[59]

HEMATOPOIETIC STEM CELLS

Age of Morphologists

Fascinating accounts of the history of experimental efforts in hematopoiesis are presented in Wintrobe's *Blood, Pure and Eloquent*.[60,61] One milestone in understanding the origins and development of blood cells was the recognition by Neumann and Bizzozero in the mid-nineteenth century that the bone marrow is a site of red blood cell production throughout postnatal life. Another major advance made in the late nineteenth century by Paul Ehrlich, Artur Pappenheim, and others was the application of synthetic dyes and various staining/fixing techniques that led to precise morphologic characterization and classification of blood and marrow cells. A third milestone was the development of the idea of a multipotent stem (ancestral) cell that gives rise to all of the mature blood cell types through extensive proliferation and differentiation. By the use of refined staining methods, Pappenheim observed various transitional cells and organized them into a relational scheme—a tree whose various branches when traced backward converged to a mononuclear cell that had none of the distinct features of the end-stage blood cells or the transitional stages. He proposed the notion that this cell was so morphologically primitive that it could be the common ancestor of all blood cells. Although most morphologists between 1900 and 1940 accepted the idea of ancestral cells in a hematopoietic series leading to progressively more mature types, there was much debate about how many ancestral cell types existed. Many workers believed that lymphocytes had a separate origin from myeloblasts and thus that there were dual or perhaps plural ancestral cells. Reviews of the conflicting concepts of the origin of hematopoietic cells as of the late 1930s are presented in detail in *Handbook of Hematology*.[62]

Advent of Hematopoietic Progenitor Transplantation

In the late 1940s and the 1950s, several new approaches were developed to study hematopoiesis. Among them were radiation exposure followed by grafting of hematopoietic tissue, development of chromosome cytogenetics, and use of radioactive materials. Lorenz et al.[63] showed that mice and guinea pigs can be protected against otherwise lethal whole-body irradiation by injections of bone marrow from other animals of their respective species. Ford et al.[64] used bone marrow from donor mice that had a morphologically identifiable chromosomal marker to show that hematopoiesis in the irradiated recipient mice was reconstituted by cells from the donor marrow—that is, the protected animals were chimeras with respect to their hematopoietic tissues. These experiments did not settle the question about how many types of ancestral cells there were, but experiments generating radiation chimeras have since been used with great power to study the nature of stem cells and their progeny.

Till and McCulloch[65] used radiation/grafting experiments to prove directly the existence of an ancestral cell with multilineage potential. In spleens of mice at 1 week after transplantation, they found growth of macroscopic colonies containing cells of multiple hematopoietic lineages. These colonies were the progeny of individual transplanted cells that were called *colony-forming units spleen* (CFU-S). Because the cells in these spleen colonies could, in turn, be injected into secondary, irradiated mice and give rise to spleen colonies, the CFU-S apparently replicated themselves within the colonies. When the observation time for CFU-S assays was extended from 1 to 2 weeks after transplantation, a series of evanescent colonies was found, and those appearing on later days had greater self-replication and multilineage differentiation capacities.[66,67] Early studies could not demonstrate lymphoid cells in spleen colonies,[68,69] but more recent studies indicate that CFU-S colonies contain lymphoid progenitors as well as myeloid progenitors.[70] Several studies showed that cells with the capacity for long-term hematopoietic reconstitution of irradiated mice can be separated from most CFU-S by size and density.[71] Thus, many CFU-S, although multipotent, do not have long-term repopulating capacity.

Definitive Evidence for a Multipotent Stem Cell

Animal reconstitution experiments with hematopoietic cells that were individually genetically marked have verified the existence of HSCs and demonstrated their capacity for extensive self-renewal.[72,73] In these marking experiments, hematopoietic cells were infected in vitro with a recombinant retrovirus that was able to integrate its DNA (provirus) into a cell but could not replicate and spread to other cells. The one-time, random integration of the provirus into the DNA of an individual cell provides a specific marker for the progeny of that cell that develop in an animal after transplantation. Random integration assures that each provirus has unique flanking sequences of DNA and thus has a high probability of yielding a DNA fragment of a distinguishable size after cutting with a restriction enzyme that does not cut the provirus. Several months after transplantation of the genetically marked cells and establishment of hematopoiesis, it is typically observed that all types of cells in the blood and lymphoid organs contain progeny of an individually marked cell, proving that it was multipotent. Often, these clones of marked cells continue to contribute to all of the hematopoietic lineages in the animal for an extended period. Also, when these primary recipient animals are subsequently used as donors for secondary recipient animals, frequently the same clones of HSCs are apparent in these secondary recipients. This persistence can even be demonstrated in tertiary recipients.[74,75] Thus, clearly many HSCs reproduce themselves (self-renew) over a long period. Long-term reconstitution of the myeloid and lymphoid compartments can be achieved by transplantation of a single murine HSC,[76,77,78] indicating that a single HSC is the smallest repopulating unit. Dick and colleagues recently demonstrated that a single cell transplant of human $CD34^+$ $CD38^-$ $CD45RA^-$ $Thy1^+$ Rho^{lo} $CD49f^+$ cells into immunocompromised mice was able to provide multilineage reconstitution,[79] indicating that the HSC is also the smallest repopulating unit in humans.

It has been noted that not all HSC clones are long lived; some produce progeny for varying periods and then apparently become extinct. Finally, marked clones have been observed to begin contributing to hematopoiesis after some period of post-transplantation latency, indicating that dormancy is possible. Thus, these studies have demonstrated that, after transplantation, some HSCs contribute continuously to hematopoiesis for a long time—in mice, apparently for the whole lifetime of the animal. Other HSCs contribute and then become extinct, and finally, some may remain dormant for some period and then contribute. Additional transplantation studies of marked HSCs in mice[80] have suggested that polyclonal hematopoiesis is more common and that long-term contribution by individual stem cells is more rare than the earlier studies indicated.[74,75] Recent novel technologies combining viral barcoding and high throughput sequencing of HSC confirmed this polyclonal contribution of HSCs.[81] Studies using retroviral insertion site analyses for larger animals, particularly non-human primates, have provided some evidence of polyclonal hematopoiesis.[82,83,84] To what extent these possible behaviors are manifest in normal, nontransplanted mice or larger animals is not clear.

Enrichment of Hematopoietic Stem Cells

The identification of relatively immature HSCs from more committed progenitor cells on the basis of various physical properties, immunophenotypic markers, and functional attributes has greatly advanced the field of hematopoiesis.[85] HSC markers that are expressed from fetal stages through adult life include CD34, CD31 (PECAM1), and Kit, but these markers can also be identified in endothelial cells.[86] In humans, $CD34^+$, $CD38^-$, CD90 $(Thy-1)^+$, $CD45RA^-$ cells that are negative for lineage markers (CD2, CD3, CD4, CD7, CD8, CD10, CD11b, CD14, CD19, CD20, CD56, CD235a) are considered highly enriched for in vivo repopulating HSCs.[87,88] In mice, there is no single consensus panel of HSC markers to identify, enumerate, and sort HSCs. Many markers derive from work by Weissman's lab, which proposes the combination of Sca-1 $(Ly-6A/E)^+$, Kit^+, $Flk2^-$, CD90 $(Thy-1)^+$ and negative for lineage markers (CD3, B220, Mac-1, Gr-1 and Ter119) as a highly purified population enriched for in vivo repopulating HSCs[89,90,91,92] (Table 5.1). Nakauchi's group subsequently showed the enrichment of long-term repopulating activity in the $CD34^{lo}$ fraction.[76] In 2005, Morrison's group developed a novel marker set to identify highly enriched HSCs. They demonstrated that signaling lymphocyte and activation molecule (SLAM) markers were found to be differentially expressed on BM $Lineage^-$ $Sca\text{-}1^+$ $c\text{-}kit^+$ populations such that $CD150^+$ $CD244^-$ $CD48^-$ $CD41^-$ was the population enriched for murine HSC in vivo repopulation capacity.[93] Since the aforementioned phenotypic descriptions involve the use of multiple markers, which are moreover not exclusively expressed on HSC, Mulligan's group proposed the use of endothelial protein C receptor (EPCR, CD201) as a novel "explicit" marker of HSC, since HSCs express high levels of EPCR, while downstream progenitors express only intermediate levels.[94] Importantly, prospective isolation with only EPCR enriched for hematopoietic reconstitution activity. The most immature HSCs with in vivo hematopoietic repopulation potential are detectable within the $CD150^+CD244^-CD48^-$ population. Other studies have pointed to CD105 (endoglin) as an enriching marker for HSCs.[95,96] In addition to immunostaining, HSCs can also be identified by the ability of HSCs to efficiently efflux dyes. The most common methods utilize the dye Hoescht 33342, which when excited at two wavelengths yields a characteristic "side population" on flow cytometry[97] due to dye efflux.

TABLE 5.1

FLOW CYTOMETRIC DEFINITIONS OF HSCs, MPPs, AND SINGLE LINEAGE PROGENITORS

Population	Phenotype	Reference
Hematopoietic stem Cell (HSC)	Lin^- $Sca\text{-}1^+$ Kit^+ $Flk2^-$ $CD34^-$	76, 89

Lin^-, Lineage negative ($Gr1^-$ $CD11b^-$ $CD3^-$ $B220^-$ $Ter119^-$); Sca-1, stem cell antigen 1; Flk2, fms-like kinase 2; CD, cluster of designation.

With the advances in technology, procedures have been developed to enrich greatly the proportion of HSCs in isolated cell populations from mouse, human, and other sources. In mice, with immunophenotyping alone, 50% to 96% of prospectively isolated HSCs have long-term repopulating activity.[98] Isolation of candidate HSCs based on phenotypic markers expressed on the cell surface was first tested in congenic mouse transplantation models and subsequently purified human HSCs were successfully transplanted in a xenogeneic immunodeficient mouse model.[85] The successes in mouse models have led to three human phase I clinical trials that successfully demonstrated sustained hematopoiesis when HSCs purified by immunophenotyping were transplanted into irradiated patients.[99–101]

Hematopoietic Stem Cell Assays

While immunophenotyping is the only feasible option for human HSC therapeutics because of a narrow window for successful transplantation, reliance on surface markers has the major limitation that different clinical scenarios may modulate the expression of utilized markers. For example, the content of long-term repopulating HSCs within the same immunophenotyped Lineage$^-$ Sca-1$^+$ c-kit$^+$ (LSK) Thy1^{lo} fraction can change in aged mice, previously transplanted mice, and mobilized mice.[102] Reliability of CD34 in mice of various age has also been questioned.[103] Use of the CD150$^+$ CD48$^-$ gating scheme, rather than Thy1, with LSK gating retains the fidelity in frequency of long-term repopulating HSCs in aged, transplanted, and mobilized mice.[102] Nonetheless, it still is unknown if the SLAM markers retain fidelity in mutant mice. Moreover, other surface markers can also be modulated by environmental cues. This is illustrated by the Sca-1 upregulation that occurs in inflammatory settings likely secondary to type I interferon exposure,[104,105] which can erroneously lead to conclusions about HSCs based on a population of committed progenitors that artifactually acquired the Sca-1 antigen. Furthermore, not all mouse strains express the prospective HSC antigens, such as Thy1.1 or Sca-1.[106,107] Thus, conclusions drawn about HSCs in mouse or man need to be verified by functional assays in order to demonstrate (a) multipotency and (b) long-term repopulation. There are numerous assays with differing levels of stringency, limitations, and appropriateness to the question being addressed, as recently reviewed.[98]

Long-term In Vitro Assays

In humans and mice, two types of progenitor cells called long-term culture initiating cells (LTC-ICs) and cobblestone area-forming cells (CAFC) can be detected using long-term cell culture assays. Since most committed progenitors have differentiated by 3 weeks in culture, they can be quantified by counting colonies at this time. The various progenitors quantified by in vitro assays are shown in Table 5.2. By 5 weeks or more of long-term culture, more immature progenitors that are dormant during the initial weeks but which possess extensive proliferating capacity continue to proliferate. Counting colonies at these later time points allows quantification of the number of more immature progenitors at the time of culture initiation. One type of long-term culture assay detects early-stage hematopoietic progenitors that are capable of initiating long-term hematopoiesis in culture after seeding them onto irradiated stromal cell monolayers (human[108,109]; mouse[110,111]). These LTC-ICs[108] sustain production of multilineage progenitors for 4 to 6 weeks. In some instances, these cultures have been extended for more than 10 to 12 weeks.[112,113] This continued production of hematopoietic progenitors of multiple lineages in individual cultures is measured after several weeks by harvesting the cultured cells and doing secondary assays for various types of lineage-committed progenitors. Long-term cultures require a supporting stromal monolayer that is commonly generated from bone marrow-derived mesenchymal or fibroblast cells. The stromal layer supports the proliferation and differentiation of seeded hematopoietic progenitor cells, but at later times, it sloughs from the culture dish and fails to sustain continuation of the culture. In CAFC assays, islands or colonies of hematopoietic cells can be recognized morphologically in situ.[110] These cobblestone colonies integrate within the supporting stromal layer, forming clusters of flattened, optically dense, morphologically homogenous–appearing cells tightly adherent with the stromal layer.[114,115] CAFC assays are one-step cultures in contrast to LTC-IC assays, which require plating of fresh hematopoietic cells on established stromal layers. Using limiting dilution and Poisson statistics, the frequency of CAFC or LTC-IC in a test population or following culture can be determined.[109–111,113,116]

Assays of murine bone marrow cells for LTC-ICs and for day 28 CAFCs yield estimates of 1 to 4 LTC-ICs or CAFCs per 10^5 marrow mononuclear cells—a value comparable to that obtained for HSCs in repopulation assays.[117,118] A modification of the mouse LTC-IC assay [119,120] has led to a demonstration that some LTC-ICs form lymphoid as well as myeloid progenitors in vitro. However, LTC-ICs do not necessarily correspond in a 1:1 ratio to hematopoietic repopulating units. For example, several studies have shown that

TABLE 5.2

COLONY-FORMING CAPACITY OF HEMATOPOIETIC PROGENITORS ASSAYED IN VITRO

In Vitro Progenitor Name	Progenitor Stage/ Potential	Factors
CAFC (#)—"cobblestone area-forming cell"	Mouse CAFC (28–40), possible stem cells Mouse CAFC (<28), multilineage	Irradiated BM stromal layer with horse serum and hydrocortisone
LTC-IC—"long-term culture-initiating cell"	Multilineage, possibly stem cells	Irradiated BM stromal layer with horse serum and hydrocortisone
CFU-GEMM—"CFU-granulocyte, erythrocyte, macrophage, megakaryocyte"	Multilineage	Kit ligand, IL-11, GM-CSF, EPO
CFU-GM—"CFU-granulocyte macrophage"	Granulocytes and macrophages	Kit ligand, GM-CSF
CFU-E—"CFU-erythrocyte"	Late stage erythrocyte progenitor	EPO and IGF-1
BFU-E—"burst forming unit-erythrocyte"	Early stage erythrocyte progenitor	EPO, Kit ligand, IGF-1
CFU-G—"CFU-granulocyte"	Granulocytes	G-CSF
CFU-M—"CFU-macrophage"	Macrophages	CSF-1
CFU-Mk—"CFU-megakaryocyte"	Megakaryocytes	TPO, IL-3, Kit ligand
CFU-preB—"CFU-pre-B lymphocytes"	B cells	Kit ligand, IL-7
CFU-DL—"CFU dendritic/ Langerhans cells"	Dendritic cells/ Langerhans cells	GM-CSF, TNF-α

CFU, colony-forming unit; EPO, erythropoietin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IGF-1, insulin-like growth factor-1; IL, interleukin; #, number of days of culture.

ex vivo expansion of hematopoietic cell populations with growth factors in culture leads to a loss of in vivo repopulating cells,[121,122] although measured LTC-ICs do not decrease in parallel. For these shortcomings, the LTC-IC assays is advantageous when an estimate of HSC frequency is required in scenarios in which the test population of HSCs have a defect in homing or engraftment capability, which would result in underestimation of the reduction in HSC activity when used in transplant assays (see below).

In Vivo Hematopoietic Assays

In vivo assays can measure various features of HSCs including homing, survival, proliferation, and differentiation into hematopoietic lineages. Homing and subsequent development of donor-derived blood cells is termed hematopoietic engraftment. To sustain life-long hematopoiesis in the host, transplanted HSCs must self-renew and re-establish an HSC pool. Because in vivo assays can be monitored for a prolonged period for survival, proliferation, and differentiation of transplanted HSCs and, ultimately, the establishment of donor-derived hematopoiesis, they remain the gold standard for measuring the true functional potential of HSC grafts. It is worth noting here again that these assays *confirm* HSC activity and these methods cannot prospectively isolate HSCs. There are broadly three ways to assess long-term repopulating HSC activity in vivo: competitive repopulation assay,[123] limiting dilution assay,[117] and serial transplantation.[124] The nomenclature of these assays is unfortunate since the former two are both actually competitive repopulation assays. Further confusing the matter, limiting dilution assays are frequently called competitive repopulating unit (CRU) assays, while competitive repopulation assays use the unit RU. All three assays rely on availability of a method to discriminate between the test and standard cells (see below). Whereas previous studies utilized retroviral marks to label and track cell lineages, the availability of congenic mice has made the process more convenient. Congenic mice are two strains of mice that are genetically identical with the exception of one gene, which allows discrimination between the two populations. The most commonly utilized congenic mice are CD45.1 and CD45.2 mice, which are both on a C57BL/6 background, and antibodies that specifically recognize the two CD45 markers are widely available.

In the competitive repopulation assay and limiting dilution assay, lethally irradiated animals are typically supplied with a standard, quantified competitor cell population to provide short-term hematopoietic reconstitution. These competitor "support" marrow cells eliminate the chance of potential replicative stress on the small number of HSCs in the test sample following transplantation.[118] Competitive repopulation assays involve transplanting a test population with unknown HSC content (i.e., total BM or a population of cells sorted based on immunophenotypic markers) along with a population of standard, although not definitively known, HSC content (typically 1–2 $\times$ 10^5 total BM cells). The clonal contribution of HSCs is not a linear process and can display stochastic fluctuations in the short term after transplantation. Jordan and colleagues determined that individual oncoretroviral-marked HSCs gave stable contribution to hematopoiesis starting at 6 months post-transplant.[74] The laboratory of Eaves et al. has demonstrated in a congenic system that this stability arises 16 weeks after transplantation, while more committed stem cells gradually lose reconstituting capacity by 16 weeks post-transplant.[125] Thus, Purton and Scadden have suggested 16 weeks and an optimal time-frame of 6 months after transplant to assess donor contribution in transplantation-based HSC assays.[98] The major drawback of the competitive repopulation assay is that it makes a statement regarding the relative number of HSCs, precluding a definitive statement on the actual HSC content of a test sample.

In order to enumerate the actual number of HSCs in a test population, limiting dilution analyses with Poisson statistics is used instead.[117] In this assay, serial dilutions of a test cell population are transplanted into a group of animals. From the known dilutions of test cells given in the transplants and the percentage of mice *without* donor chimerism (defined as <0.1% or <1%, see below) yielded by each test cell dose, one can calculate the number of HSCs in a test sample by using limiting dilution analysis and Poisson statistics.[80,117] A variation of this assay uses limiting dilutions of genotypically distinct donor cells to transplant into stem cell–deficient W/W^v mice that can be used as hosts rather than lethally irradiated mice.[126] A second variation uses, as hosts, mice that have been transplanted previously and thus have a reduced or weakened endogenous stem cell competition capacity. While the limiting dilution assay is the gold standard to enumerate HSCs, it is resource-intensive. In addition to being time- and resource-intensive, other vagaries and considerations must be undertaken when designing limiting dilution experiments. When chimerism studies relied on southern blot detection, a threshold of <5% test-derived cells was considered as a mouse *negative* for engraftment. However, as flow cytometry and congenic markers have allowed for much enhanced sensitivity in detecting fine changes in engraftment, most studies utilize <1% as the threshold. While some investigators propose a <0.1% threshold, it is controversial whether detecting such low levels of chimerism is accurate.[98] Caution should also be taken when enumerating HSC numbers in animals with mutations that affect the proliferation kinetics of progenitors. If progenitors specifically have increased proliferative capacity, they may erroneously indicate enhanced HSC repopulating capacity; and likewise decreased proliferative potential of progenitors might artifactually suggest reduced HSC repopulating activity.

The most stringent functional test (although not necessarily as sensitive or quantitative) is the serial transplantation assay, which involves successive rounds of transplantation, a 16-week engraftment period, and re-transplantation of recipient BM into new recipients. This is the preferred method to demonstrate changes in HSC numbers when there is a perturbation in homing, engraftment, differentiation, or altered progenitor proliferative capacity.[98] Using serially diluted amounts of BM in the primary transplant, the serial transplantation assay can be combined with the limiting dilution assay to add further stringency to this assay. However, this is rarely done because of the enormous resource requirements.

Hematopoietic Stem Cell Studies in Xenograft Models

Humans vary from mice in many aspects, including their body size, life span, and daily demand for hematopoietic cell production.[84,121,127] These differences result in species-specific selective pressures regarding genotoxic stress, tumorigenesis, telomerase activity, and genetic fidelity during proliferation. For example, because of larger body size, proliferative demand on human HSCs is greater than that for mice. The substantially greater life span also places unique selective pressure on human HSCs to not develop deleterious oncogenic mutations.[128] With this said, there are numerous evolutionarily conserved facets of hematopoiesis, and both mouse and human studies are essential and complementary. The need to study human hematopoiesis generated a demand to create xenogenic transplant models into mice. The first humanized mouse models were developed in 1988, as recently reviewed.[128] Murine models that are commonly used are derivatives of the NOD/SCID strain,[129,130] strains deficient in the RAG1 or RAG2 genes necessary for T- and B-cell receptor rearrangements,[131,132] and a fetal ovine system.[133,134] NOD/SCID/β_2-microglobulin^{null} mice support proliferation and differentiation of immature human hematopoietic progenitors.[129,135,136,137] Residual NK cell activity of NOD/SCID mice has been inhibited by administration of monoclonal antibodies against IL-2Rβ[138] or by genetic manipulation to create γc null strains (NSG mice)[139].

NSG mice have 50-fold higher $CD34^+$ cell engraftment compared to NOD/SCID mice. The hematopoietic repopulation ability of transplanted human cells in a sublethally irradiated mouse is quantified as SCID mouse repopulating cells (SRC), the frequency of which can also be determined by limiting dilution analyses.[140] A technical advance in the study of human hematopoiesis in these xenogenic models was the injection of human cells directly into the femurs of NSG mice, leading to more rapid early engraftment of $CD34^+$ cells.[141] Another recent technical advance was the observation that female NSG mice have as much as 11-fold higher chimerism compared to male syngenic NSG mice.[142] One of the most significant recent reports has been the identification of $Thy1^+$ Rho^{lo} $CD49f^+$ as being a marker set to purify human HSCs such that 14% to 28% of single $Thy1^+$ Rho^{lo} $CD49f^+$ cells could give rise to multilineage reconstitution in NSG mice.[79] With the ability to assess the long-term repopulating contribution of single human HSCs for over 8 months and with subsequent serial transplantation studies, the field is moving toward the capability to stringently test human HSC activity.

Hematopoietic Stem Cell Studies in Large Animal Models

Abkowitz et al. have identified important differences between the kinetics and behavior of HSCs in large animals and rodents.[143] The production of blood cells for the whole life span of a mouse is equivalent to the blood cell production of a human in a single day. This limited replication demand due to the relatively short murine life span poses a significant challenge to determine the long-term repopulation activity of human hematopoietic cell populations transplanted into immunodeficient mice. Human cells have been found to persist for several years after transplantation in a pre-immune in utero fetal sheep model.[144] Several large animal models are available for HSC studies, including feline, canine, ovine, and non-human primates,[145] but the genetic and biologic similarities between humans and non-human primates suggest that the non-human primate model is probably the best available model with which to study human hematopoiesis.[84,127] Another advantage of using non-human primates is that their relatively long life span (up to 30 years) compared to rodents (up to 3 years) allows long-term monitoring after transplantation, irradiation, cytokine therapy, chemotherapy, etc. Simultaneous transplantation of genetically marked autologous cells in lethally irradiated non-human primates and immune-deficient mice demonstrated that the reconstituting cells in primates and in mice are distinct, suggesting a lack of overlap between these two cell populations.[146]

Hematopoietic Stem Cells in Culture

Repopulation studies in irradiated mice, as well as experience with bone marrow transplantation in humans, provide strong evidence that HSCs can replicate and expand extensively in vivo (self-renewal). A very significant advance for clinical medicine would be the in vitro expansion of transplantable HSCs. However, mouse HSCs generally decline substantially relative to input numbers over a period of 1 to 4 weeks in culture,[147–149] even though clonal analysis indicates that some HSC clones proliferate.[148] Also, for unknown reasons, repopulating activity is lost with the entrance of cultured HSCs into the active cell cycle.[150] Similarly, homing of actively cycling HSCs is reduced by decreased expression of several molecules on the cell surface.[122,151] Despite this inability to expand transplantable HSCs in vitro, more mature types of progenitors, including those with multilineage or single lineage potential, can be greatly expanded in vitro. Thus, cell expansion technology may be useful to obtain high numbers of hematopoietic progenitor cells that may support patients in the short term after high-dose chemotherapy or marrow transplantation.

In principle, a successful ex vivo expansion strategy must preserve HSC function and permit HSCs to self-renew in order to maintain or expand the number of transplantable HSCs during the culture. Human umbilical cord blood (CB) has been established as an important alternative source of transplantable HSCs instead of bone marrow or peripheral blood stem cells (PBSC) in children especially, because of its decreased GVHD probability.[152] However, the limited number of HSCs present in a single unit of CB poses a significant risk for its use in adult patients, who require greater numbers of input HSCs. Although double cord blood transplants have improved the rate of sustained engraftment, it is still associated with delayed engraftment and elevated engraftment failure when compared to BM or PBSC transplants, indicating the need for more optimal CB expansion protocols.[152]

Early ex vivo culture of human $CD34^+$ CB cells with cytokines for 10 to 14 days demonstrated moderate increases in progenitor cell numbers and safety in patients, but had only modest effects on clinically relevant outcomes, such as time to neutrophil recovery.[153] The ideal culture conditions suitable for such abundant HSC expansion has remained elusive; however, over the last decade, substantial progress has been made to increase the number of phenotypic hematopoietic stem and progenitor cells and more importantly, the number of SCID repopulating units through ex vivo culture. Clinical trials typically involves ex vivo culturing ("manipulating") one cord blood unit and co-infusing with a non-manipulated cord blood unit. Patients co-infused with these mixed units are compared to patients receiving a conventional double cord blood transplant. A few of these modalities currently being tested in clinical trials include Notch ligands, stromal cell-based culture, copper chelators, and prostaglandin E2.[153]

Bernstein's group showed that culture of $CD34^+$ CB cells with immobilized Notch ligand Delta1 combined with fibronectin fragments and the cytokines stem cell factor (SCF), thrombopoietin (TPO), Flt3 ligand (Flt3l), IL-3, and IL-6 resulted in a 222-fold expansion after 17 days of culture and a 16-fold increase in NOD/SCID repopulating units.[154] Importantly, in phase I clinical trials, patients that received a mixed infusion of one conventional CB unit and one ex vivo cultured CB unit demonstrated a pronounced reduction in median time to neutrophil recovery compared to patients receiving the conventional dCBT.[154] In addition, 2 out of 10 patients had persistence of the expanded graft 180 days after transplantation, suggesting the preservation of at least short-term self-renewing cells during ex vivo culture in spite of co-infusion with a non-manipulated unit containing T cells capable of rejecting the expanded unit.[153]

As HSCs develop in vivo in a microenvironment with stromal interactions, Elizabeth J. Shpall and colleagues have pursued HSC expansion by co-culture with mesenchymal stem cells (MSCs) and SCF, TPO, Flt3l, and G-CSF. These culture conditions yield an 8- to 12-fold expansion of $CD34^+$ cells and importantly, resulted in a reduction of median neutrophil recovery to 14 days, compared to 23 for patients receiving conventional DCBT.[152] In spite of these remarkable clinical advances, still, to date, there is no evidence that ex vivo expanded CB cells can contribute to long-term hematopoiesis in human trials.[155]

Use of the copper chelator tetraethylenepentamine (TEPA) with SCF, TPO, Flt3l, and IL-6 resulted in a 159-fold increase in $CD34^+$ cells after 7 weeks of culture and showed improved engraftment in NOD-SCID mice.[156,157] However, early clinical trials reported by Shpall and colleagues have failed to show an improvement in neutrophil recovery,[158] but clinical trials are ongoing.[153] Preclinical data showed that the brief pre-incubation of HSCs[159] with prostaglandin E2 enhances their homing, survival, and proliferation in mice,[160] and clinical trials are ongoing to assess this target in humans.[153] Other promising candidates[153] to enhance the self-renewal of ex vivo cultured HSCs that have yet to reach clinical trials include the aryl hydrocarbon receptor antagonist

SR1 (StemRegenin 1),[161] the endothelial-derived soluble factors Angiopoietin-like 5 (Angptl5), IGFBP2,[162] and pleiotrophin,[163] and the homeobox gene Hoxb4.[164]

Quiescence of Hematopoietic Stem Cells

Compared to downstream CD34$^+$ LSK multipotent progenitors (Fig. 5.2), 90% of which are in cell cycle, <10% of CD34$^-$ CD48$^-$ CD150^{hi} LSK HSCs are cycling.[165] Even within this phenotypically identified HSC pool, the laboratories of Trumpp and Hock have used label-retaining tracking approaches to functionally distinguish the existence of two types of murine HSC: homeostatic (or hematopoietic stress-activated) and dormant HSCs, which represent ~70% and ~30% of the HSC pool, respectively.[105,165] Whereas homeostatic HSCs divide every 28 to 36 days, dormant HSCs divide only every 145 to 193 days, or about 5 times per lifetime.[165,166] This differential cycling has functional consequences for transplantation, as although both homeostatic and dormant HSCs provide long-term repopulation in lethally irradiated recipients, only dormant HSCs provide complete long-term repopulation in secondary transplants.[159,165] Notably, activated HSCs can return to the dormant state.

HEMATOPOIETIC PROGENITOR CELLS

Committed Hematopoietic Progenitor Cells

Committed hematopoietic progenitor cells are progeny of HSCs that have begun to differentiate and can no longer convey long-term reconstitution of all hematopoietic lineages in ablated animals. Figure 5.1 depicts the HSCs and downstream committed progenitors, and notably, only HSCs have the capacity to self-renew, as indicated by the reflexive arrows. This schematic is a working model that is constantly under revision, with numerous nuances that preclude neat boundaries in differentiation potentials of progenitor cells.[167,168] Nonetheless, whichever branching scheme is utilized, each successive stage has a more restricted differentiation potential, and there is a succession of commitment steps. Just as molecular processes determining self-renewal versus commitment decisions for stem cells are not completely understood, neither are the molecular events that lead to subsequent commitment steps. Although phenotypic markers can largely, although not definitively, differentiate cells with stem cell, as opposed to just progenitor cell, potential, the unique contribution of progenitor cells, as opposed to progenitor cells that derive from transferred HSCs, is not well understood. It is known that although a single HSC can yield long-term, multilineage donor contribution, supporting total BM or progenitor cells must be coinfused to allow short-term hematopoiesis; otherwise, survival is not possible. This demonstrates that in clinical transplantation or hematopoietic recovery from myeloablative regimens, progenitor cells are just as critical, if not more critical, than HSCs in the short-term after conditioning.

Multilineage Progenitors

The first committed progenitor without capacity to self-renew is the multipotent progenitor (MPP). Although initially regarded as an HSC assay, the majority of CFU-S colonies cannot provide long-term reconstitution of ablated animals, and what are being quantified are mostly MPPs. Under culture conditions in semisolid medium with adequate supportive growth factors, these progenitor cells can form colonies of multiple cell lineages in vitro.[169,170] Similar multilineage colonies can also be demonstrated in vitro in human hematopoietic cell populations.[171] When the hematopoietic cells reach maturity, the lineage composition of the colonies can be determined by picking out the colonies and spreading the cells on microscope slides, followed by conventional staining or by immunostaining using lineage marker antibodies. Not all multilineage colonies that appear in in vitro or in vivo assays contain all cell lineages. For example, some colonies contain granulocytes, erythrocytes, macrophages, and megakaryocytes (mixed colonies); other colonies contain granulocytes and macrophage (GM colonies); and so forth. Table 5.2 describes a variety of hematopoietic progenitor stages that are defined by in vitro assays.

The observation that colonies with various combinations of lineages occur has been interpreted in several ways (models) to explain how cells are committed to become a particular type of blood cell.[172] The data favor the idea that there are multiple commitment steps and that these steps lead to loss of specific lineage potential in a definite order. The first lineage commitment step separates lymphoid from myeloid potential, then granulocyte/macrophage potential is separated from erythroid/megakaryocyte potential, and so on, until finally, a descendant cell has only one lineage capability. This idea of successive commitment steps is embodied in Figure 5.1. Although this idea is probably generally correct, there are variant models that differ somewhat in their interpretation.[168] Also, it must be remembered that in vitro growth conditions may not be permissive for all possible lineages to appear in a colony. Thus, caution must be exercised in interpreting the exact lineage commitment pathways. For example, multilineage progenitors, CFU-S and in vitro–derived multilineage colonies, had been thought to be incapable of generating lymphoid cells. However, several studies have shown that lymphoid cells are produced by several such progenitors, but that they were not observed previously because growth factor support for colony development was not permissive for descendent lymphoid cells.[70,119,173]

These multipotent progenitors, first described by Morrison and Weissman,[89,174] have been characterized by flow cytometry as Lin$^-$ Sca-1$^+$ c-kit$^+$ Thy1.1$^-$ Flk2$^+$[90] (Table 5.1). Even within this Flk2$^+$ MPP population, there is heterogeneity in multipotency, which can be subdivided based on VCAM1 expression.[175] Recent studies point to improved resolution with the marker set Lin$^-$ Sca-1$^+$ c-kit$^+$ CD150$^-$ CD105$^-$.[96] Recently, in an elegant mouse model utilizing Flk2-Cre animals, fate mapping revealed that all hematopoietic cells in the blood, BM, and spleen arise from a Flk2-expressing cell in the steady state and hematopoietic stress, confirming the hub role of multipotent progenitors.[176]

Single Lineage Progenitors

The descendants of the multilineage colony-forming cells are ultimately restricted to a single lineage potential. The more mature, single lineage–committed progenitor cells are assayed in vitro by their ability to form colonies. These progenitor cells include CFU-G, CFU-M, CFU-E, CFU-MK,[177–179] CFU-preB,[119,180] and CFU-DL[181,182] for colony-forming units granulocyte, macrophage, erythrocyte, megakaryocyte, B-lymphocyte, and dendritic/Langerhans cells, respectively (Table 5.2). In some lineages, it is possible to observe stages of maturity within the lineage-committed progenitors. For example, the single lineage producing burst-forming unit erythroid (BFU-E) is a more immature erythroid progenitor than the CFU-E, forming colonies of many more mature erythroid cells after a longer period of time than the CFU-E.

With the advent of flow cytometry, many of these populations now have phenotypic counterparts (Table 5.1). In fact, flow cytometry allows for a more precise separation of populations and assessment of the progenitor activity, even to the single cell level. The MPP is thought to give rise to the common lymphoid progenitor (CLP)[183] and common myeloid progenitor (CMP),[184] with the former giving rise to B cells, T cells, and NK cells, while the latter spawns the erythroid, megakaryocyte, and myeloid lineages. The CMP subsequently branches off to the megakaryocyte erythroid progenitor (MEP) and granulocyte macrophage progenitor (GMP).

The GMP subdivides into granulocytes and macrophage dendritic cell progenitors (MDP),[185] which produce the respective eponymous lineages. A review of the surface markers for these populations can be found in Table 5.1.

Terminal Phases of Differentiation

Cells in the final stages of hematopoiesis are sufficiently differentiated that they can be identified by morphology using light microscopy with preparations of hematopoietic tissue. These cells are erythroblasts, myelocytes, monocytes, and megakaryocytes, and, because of the vastly amplifying cell divisions that occur by the time the final stages are reached, these cells are by far the most prevalent cells seen in hematopoietic tissues. They are capable of only a few cell divisions, on the order of one to four, yet they are undergoing dramatic specialized changes associated with terminal phases of differentiation/maturation. The erythroblasts rapidly accumulate hemoglobin and begin to assemble a unique membrane skeleton that later maintains the shape and deformation properties of the mature erythrocytes. The nucleus of the erythroblast becomes condensed and is extruded from the cell, leaving an irregular, organelle-containing reticulocyte. Subsequently, over the course of a few days, extensive remodeling occurs within the reticulocyte that eliminates the internal organelles and changes the membrane so that the biconcave erythrocyte is formed. This remodeling process involves extensive, selective proteolysis. In granulocyte progenitors, granules that contain specific proteolytic enzymes are formed in the cytoplasm. The nuclei undergo a condensation process that ultimately results in a multilobular nucleus that is retained in the mature cell. Maturing monocyte precursors undergo similar changes. The terminal-stage megakaryocytes replicate their DNA and undergo several nuclear divisions without cytokinesis; thus, they become polyploid. Dense granules and α-granules form in the cytoplasm, and the cytoplasm becomes highly compartmentalized by demarcation membranes. Platelets form as small portions of the demarcated megakaryocyte cytoplasm separate from the whole cell.

TRAFFICKING OF HEMATOPOIETIC STEM AND PROGENITOR CELLS

Adhesion Molecule Interactions of Hematopoietic Stem Cells and Stroma

Direct molecular interactions between the hematopoietic cells and stromal cells involve ligand-receptor relationships between adhesion molecules on the surfaces of the hematopoietic and stromal cells. There are many cytoadhesion molecules known, and they generally can be classified into several families: sialomucins, selectins, integrins, and members of the immunoglobulin superfamily.[186] Numerous interactions are possible, and there appears in some cases to be redundancy in the systems involved in trafficking within the hematopoietic microenvironment.

Retention and Homing of Hematopoietic Stem Cells

Besides providing a source of growth factors for hematopoietic cells, the stroma of hematopoietic organs directs the trafficking of these cells. This trafficking occurs during embryonic development as the primary organs of hematopoiesis change from the AGM to the fetal liver to the spleen and bone marrow. Also, some HSC/progenitors migrate continuously between bone marrow and blood in normal adult animals.[187] Although not discussed further here, such trafficking to particular tissues is also critical for mature cells, such as monocytes and T lymphocytes, to perform their effector functions with spatial efficiency in order to maximize target tissue effector function (i.e., combating pathogens) while limiting tissue toxicity. Migration is composed of two parts: (1) egress from the source tissue (typically the BM), termed "mobilization," and (2) directed movement towards the target tissue, termed "homing."

With respect to the BM, homing is the process by which circulating HSC/progenitors migrate into the extravascular space within the bone marrow stroma where they selectively interact with specific stromal cells and matrix proteins to initiate and sustain long-term hematopoiesis.[188] Homing occurs not only for HSC/progenitors that are circulating normally, but is also essential for the success of clinical stem cell transplantation. Similar to the receptor-counterreceptor interactions that govern the inflammatory recruitment of mature leukocytes (reviewed in[189,190]), the endothelial progenitor cell interaction for homing is dependent on selectins, integrins, and chemokines.

The selectin family of cytoadhesion molecules are designated E, P, and L. HSC/progenitors have receptors for the selectins, and they can exhibit the rolling phenomenon similar to that of mature leukocytes.[191,192] The initial tethering/rolling of HSC/progenitors is dependent on endothelial P- and E-selectin binding to fucosylated PSGL-1 on HSC/progenitors.[193–196]

Integrins are heterodimeric, transmembrane proteins in which the α and β subunits are joined noncovalently. Both subunits have extracellular and intracellular domains. Eighteen types of α subunits and eight types of β subunits are known, although only a few of the possible heterodimer combinations have been found on hematopoietic or stromal cells and implicated in hematopoiesis. The definitive homing and subsequent retention of HSC/progenitors into the extravascular space is dependent on integrins $\alpha_4\beta_1$,[193,195,197–202] $\alpha_4\beta_7$,[203] $\alpha_5\beta_1$,[200,204,205] and β_6,[206] CD44,[207–209] and also VCAM-1 presumably from the endothelia.[193,195,197,210]

The most critical chemokine receptor in HSC/progenitor homing is CXCR4 binding to CXCL12.[211,212] CXCL12, secreted by bone marrow stroma, is the only known chemokine that elicits directed chemotactic response in HSCs via interactions with CXCR4 on their cell surface.[213,214] Mice lacking SDF-1 or CXCR4 have defective hematopoiesis in fetal bone marrow, due to a decreased ability of HSCs to home from the fetal liver to the marrow cavity.[215,216] Antibodies against CXCR4 block engraftment of severe combined immunodeficiency (SCID) mouse bone marrow by transplanted CD34-enriched HSCs and hematopoietic progenitor cells.[212,217] Once HSC/progenitors are arrested on the endothelia due to selectin/adhesion molecule interactions, stromal-derived CXCL12 can guide HSC/progenitor migration into the BM parenchyma in cooperation with $\alpha_4\beta_1$-, LFA-, CD44-, and Flt3-dependent interactions.[204,207,218]

The adhesion molecules of all families are transmembrane proteins, and many can act as receptors that activate specific intracellular signaling pathways. These adhesion molecules/receptors, in turn, may be regulated by other intracellular signaling pathways.[219–221] Thus, the interactions of hematopoietic cells with stromal cells and matrix can be highly modulated by the adhesion receptors, both in transmitting signals from the microenvironment into the cell and in translating the state of intracellular signaling pathways into changes in the number and affinities of adhesion molecules. Activation of Kit by its ligand (KL) modulates adhesion functions that are mediated by integrins $\alpha_4\beta_1$ (VLA-4) and $\alpha_5\beta_1$ (VLA-5).[202,222,223] Another example is CXCL12 inducing binding of circulating progenitors to the vascular endothelium by activating the integrins VLA-4, VLA-5, and lymphocyte function-associated antigen,[204,224,225] as well as CD44 and hyaluronic acid.[207]

Several of the adhesion molecules on hematopoietic cells specifically bind to sites on particular matrix macromolecules. For example, HSC/progenitors bind to fibronectin, primarily through

interaction with the integrin receptors $\alpha_4\beta_1$ and $\alpha_5\beta_1$.[220,226–229] Another cytoadhesion molecule that interacts with several matrix macromolecules is CD44, which binds with glycosaminoglycans (hyaluronic acid being the major CD44 ligand).[230] The *proteoglycans*, proteins with extensive sulfation such as heparan sulfate and chondroitin sulfate, are extracellular matrix proteins that may contribute to adhesion between the stroma and the hematopoietic progenitor cells.[231–235] The proteoglycans can also concentrate soluble growth factors. For example, granulocyte-macrophage colony-stimulating factor (GM-CSF) binds to heparan sulfate in the marrow matrix.[236,237]

Mobilization of Hematopoietic Stem Cells

Recruitment of circulating HSC/progenitors has been implicated in toll-like receptor-induced myeloid differentiation in tissues[238] and the development of repair-phenotype macrophages after liver injury,[239] but their in vivo steady-state relevance is still unclear. Despite this, their enforced egress to the circulation with pharmacologic agents, such as chemotherapy or hematopoietic growth factor administration, has been utilized in clinical medicine to less invasively procure HSC/progenitors for transplantation, a process termed stem cell mobilization. Mobilized peripheral blood now represents the majority of donor sources for HSC/progenitor transplantations.[240] These mobilized grafts have several advantages over traditional bone marrow grafts for transplantation, including ease of harvesting, higher HSC yields, and faster hematopoietic engraftment following transplantation. Granulocyte colony-stimulating factor (G-CSF) is the most commonly utilized mobilizing agent. Although early observations suggested that the mechanism of G-CSF mobilization depended on the enhanced levels of proteolytic enzymes in the marrow cavity to cleave adhesion factors tethering HSC/progenitors in the BM, unperturbed levels of mobilization in animals deficient of virtually all serine protease activity has cast doubt on this as the primary mechanism.[241] More recent data indicate that reduced production of stem cell retention factors, such as CXCL12, angiopoietin-1, kit ligand, and VCAM-1 in the stroma, rather than increased degradation, mediates mobilization.[242] β-adrenergic signals from sympathetic nerve terminals in the BM are critical for this abrogated stromal production of retention factors.[242,243] Furthermore, there is a circadian time-dependent oscillation in HSC/progenitor trafficking,[244] which indicate optimal times to harvest peripheral blood HSC/progenitors in mobilized mice and humans.[245] Recent data indicate that abrogation of BM macrophage-derived retention signals is another mechanism of G-CSF-induced mobilization.[246–248] The other widely utilized agent for clinical HSC/progenitor mobilization is the CXCR4 antagonist AMD3100. AMD3100 is capable of mobilizing HSCs within hours and synergizes with the mobilizing effects of G-CSF.[249] Since up to 30% of patients are "poor mobilizers" and thus do not mobilize a sufficiently high yield of HSC/progenitors with standard clinical protocols, novel strategies to enhance mobilization efficiency are under active investigation.[250] Among the agents being investigated as adjuncts to G-CSF are GM-CSF, stem cell factor, thrombopoietin, human growth hormone, IL-8 analog, antibodies to VLA-4, retinoic acid receptor-α agonists, and thrombopoietin receptor agonists.[251] Recent preclinical data indicate that abrogation of BM macrophages[246] or antagonism of the epithelial growth factor receptor[252] may be promising strategies to synergize with G-CSF.

LINEAGE COMMITMENT

Branch Points of Hematopoiesis

Multiple lineage relationship models of hematopoiesis have been proposed over the years (reviewed in[168]). Discrepancies among multiple models can be partially explained by the differential predication of the models on differentiation potential versus physiologic production. Whereas certain progenitors may have particular differentiation potentials when cultured in vitro with the appropriate cytokines or in vivo in emergency scenarios, these potentials may not be evident under steady-state physiology. Where possible, assessment of lineage commitment by genetic lineage tracing is the best physiologic method to assess physiologic progenitor-progeny relationships in vivo.

Role of Particular Transcription Factors

Some specific transcription factors exhibit hematopoietic lineage-restricted expression, and some are known to be essential for the complete differentiation of individual lineages. Two examples of transcription factors whose lineage associations are more fully understood are GATA-1, which is essential for terminal erythrocyte and megakaryocyte differentiation, and PU.1, which is essential for B-lymphocyte as well as macrophage development.[253,254] Specific factors not only play a direct role in the expression of lineage-specific genes but, in some cases, appear to antagonize transcription factors important for other lineages; thus, they can repress the expression of genes characteristic of other lineages. For example, GATA-1 can suppress PU.1 activity, and PU.1 can suppress GATA-1 activity by direct protein interactions that block the function of each other.[254] PU.1 and GATA-1 play positive roles in the transcription of their own genes (autoregulatory loops).[255,256] Thus, hypothetically, an excess of GATA-1 over PU.1 could downregulate PU.1 expression at the level of transcription, and excess PU.1 could likewise downregulate GATA-1. In multipotent cells, it is known that there is expression at low levels of sets of genes characteristic of multiple hematopoietic lineages.[257] Thus, commitment appears to occur not only by upregulation of a single lineage program of gene expression but also by the irreversible suppression of competing differentiation programs. Because of observations such as those described above for GATA-1 and PU.1, and because the forced overexpression of particular transcription factors can cause lineage switches in certain in vitro cell systems, some investigators have proposed that the transcription factor profile (stoichiometry relationships) of multipotent cells directs their lineage commitment decisions through cross-antagonism mechanisms.[254,258] How variations in transcription factor stoichiometry occur could be either by extrinsic signals or by stochastic mechanisms. A transcription factor network has been proposed in which combinations of specific lineage-instructive transcription factors at various stages of hematopoietic differentiation from HSCs through the lineage-specific progenitor cells play roles in cell fate decisions.[259]

Role of MicroRNAs

MicroRNAs are 18 to 24 nucleotide noncoding RNAs that bind the 3′ untranslated region of target mRNA, resulting in mRNA degradation or impaired translation efficiency.[260] MicroRNAs rise and fall as cells differentiate along the hematopoietic spectrum, as these microRNAs fine-tune the response to cytokines and transcription factors that are required for lineage commitment and differentiation. Since Chen and colleagues first demonstrated the role of miR-181 in B-lymphoid differentiation in 2004,[261] there has been an explosion of investigations into the role of miRNAs in hematopoiesis, as previously reviewed.[262] Loss of function of all miRNAs can be studied broadly using gene-knockdown models of Dicer, an RNase that is critical for miRNA biosynthesis. For example, conditional knockout of Dicer in the B[263] and T[264] cell compartments impairs development of mature B and T lymphocytes, respectively, indicating a role for miRNAs in lymphocyte differentiation. More precisely, particular hematopoietic populations can be assessed for miRNAs that are expressed and these candidate

miRNAs can be specifically knocked down. This has been used to show that miR-155 inhibits erythropoiesis and megakaryopoiesis[265,266], but is critical in T and B cell function.[267–271] Our knowledge in this area is rapidly evolving. It is already clear, however, that the influence of microRNAs is broad-based, as they play essential roles in the regulation of erythropoiesis,[272] megakaryopoiesis,[273] myelopoiesis,[274] and lymphopoiesis.[275]

Hematopoietic Cytokines

The purification of erythropoietin from the urine of anemic patients in 1977 initiated extensive investigations to find other comparable growth factors for other hematopoietic lineages.[276] Although taken for granted now because most of the discovered hematopoietic cytokines are readily available in recombinant protein form and validated by genetic mouse models, there was substantial controversy in the hematopoietic growth factor field in the 1970s through the 1990s. Most of the early work on these glycoprotein growth factors derived from studies of "conditioned media," which were necessary and greatly stimulatory for hematopoietic cell colony growth. What partially confounded researchers about the discovered colony-stimulating factors (CSFs) was their polyfunctionality.[276] For example, until specialized utilization of different cytoplasmic domains downstream of the same receptor was described, it was unclear how G-CSF could promote the battery of cellular responses for survival, proliferation, differentiation commitment, maturation induction, and functional stimulation.[276,277] Another puzzling aspect of hematopoietic growth factors was the ability of one cytokine to act on many cell types and the ability of multiple cytokines to exert influence on a single cell type. Exemplifying the latter, G-CSF, GM-CSF, IL-3, CSF-1, SCF, and IL-6 all expand granulocytic colonies.[276] This does not necessarily just reflect redundancy, as there is synergistic activity among IL3, G-CSF, GM-CSF, and CSF-1 in myeloid colony formation.[278] Based on certain structural and functional features of the receptors for hematopoietic growth factors, two families of ligands/receptors have been recognized: the cytokine receptor family and the tyrosine kinase receptor family (Table 5.3). Notably, synergy is most prominent when utilizing combinations of cytokines using both sets of receptors. Table 5.3 shows a list of cytokines, their receptors, and expression patterns.

TABLE 5.3

CLASSIFICATION OF HEMATOPOIETIC FACTORS BASED ON THEIR RECEPTOR TYPES

	Receptors consisting of:	Examples
Cytokine type receptors	A single unique peptide chain	EPO, TPO, G-CSF
	Complexes containing gp130*	IL-6, IL-11, IL-12, LIF, OSM
	A ligand-specific common α subunit and/or common gp140 β_c subunits	IL-3, , IL-5, GM-CSF
	A common γ_c subunit and ligand-specific α and/or β subunits	IL-2, IL-4, IL-7, IL-9, IL-15
	Two or more unique subunits	IFN-α, IFN-β, IFN-γ
RTK type receptors	EGF family receptors (type I)	TGF-α
	Insulin family receptors (type II)	IGF-1
	PDGF subfamily with 5 Ig-like domains (type III)	Kit ligand, CSF-1, Flk-2 ligand
	PDGF subfamily with 7 Ig-like domains (type V)	Flk-1 ligand

*gp130 serves as the signal transducer, plus an additional ligand binding unit.
gp, glycoprotein; EPO, erythropoietin; TPO, thrombopoietin; G-CSF, granulocyte colony-stimulating factor; IL, interleukin; LIF, leukemia inhibitory factor; OSM, oncostatin M; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; EGF, epidermal growth factor; TGF, transforming growth factor; IGF, insulin growth factor; PDGF, platelet-derived growth factor; CSF-1, colony-stimulating factor 1 (also known as macrophage colony-stimulating factor, or M-CSF); Flk-2 ligand, fms-like kinase 2 (also known as fms-like tyrosine kinase 3 ligand, or Flt3l).

Factors That Act on Multilineage Progenitors

In vitro cultures of hematopoietic colony-forming cells have continued to be very useful in defining growth factor effects on various lineages of cells.[279–284] Many of the hematopoietic growth factors exhibit positive growth effects on HSCs or progenitors with multilineage potential, or both. These include KL, GM-CSF, G-CSF, CSF-1, IL-3, IL-4, IL-6, IL-11, IL-12, FL, leukemia inhibitory factor, oncostatin M, and TPO.[285–288] In addition, some members of this same group can support differentiation of certain cell types to late stages or even to full maturity. For example, G-CSF, GM-CSF, CSF-1, IL-3, KL, and IL-6 can all support formation of small neutrophilic granulocytic colonies, and CSF-1 and GM-CSF can also support macrophage colonies and mixed granulocyte/macrophage colonies.[285]

Potentiation of hematopoietic cell production in in vitro assays by combinations of growth factors can occur in two basic ways. A combination of growth factors may allow proliferation and differentiation of individual cells that would otherwise die or remain dormant in the presence of a single factor. Second, potentiation can occur by enhanced proliferation in the presence of the combined factors. The latter effect appears to apply to the examples of the combined effect of KL with G-CSF, GM-CSF, IL-3, IL-6, or EPO on expansion of populations of progenitors.[289–291] The numbers of colonies formed in the presence of the combinations are not increased greatly, but there is a large increase in the size of the colonies. The proliferation of HSCs, however, appears to be an example of a requirement of a combination of factors for recruitment of dormant cells into proliferation and differentiation.[172,285,292–294]

When growth factors with effects on multilineage progenitors act alone or in combination, the result of early rounds of proliferation and differentiation is the generation of progeny that become committed individually to form different lineages of mature cells. For some lineages, the resultant single lineage progenitors cannot complete differentiation and maturation without lineage-specific factors; thus, caution must be taken in interpreting negative results. For example, late committed erythroid progenitors (CFU-E) require EPO, or they die. Likewise, appearance of lymphoid cells requires IL-7, and maturation of megakaryocytes and formation of platelets is greatly enhanced by TPO. Thus, the full development of hematopoietic cells from stem cells or early-stage progenitors requires the action of growth factors (alone or in combination) that support the multilineage progenitors and, in addition, growth factors that support terminal differentiation of committed single lineage progenitors.

Granulocyte Growth Factors

Granulocytes are composed of neutrophils, eosinophils, and basophils. Neutrophils are best known for their ability to rapidly arrive and exert effector responses at sites of tissue injury, while basophils and eosinophils are critical in responding to parasitic infections and also promoting allergic reactions. In vitro colony-forming assays have indicated the importance of G-CSF and IL-5 in the support of differentiation of neutrophils[169,269] and eosinophils,[295,296] respectively. This is substantiated by the neutropenia and increased bacterial susceptibility observed in mice deficient in G-CSFR[297] and impaired parasite-induced eosinophilia observed

in IL-5–deficient animals[298] (Table 5.4). Nonetheless, the existence of neutrophils and eosinophils in these animals in the steady state indicates redundancy with other cytokines. GM-CSF has also been implicated in in vitro granulocyte colony formation[177,299]; however, no neutropenia is observed in GM-CSF–deficient animals.[300] Interestingly, mice deficient in G-CSF, GM-CSF, and CSF-1 still have neutrophils, suggesting extensive redundancy/collaboration among the hematopoietic cytokines.[301] G-CSF and GM-CSF not only support differentiation of late-stage progenitors, but also can activate the resulting mature blood cells, stimulating functions such as phagocytosis.[302–304] Importantly, G-CSF (filgrastim) is used clinically to treat patients with neutropenia.

Mast Cell Growth Factors

Mast cell differentiation in vitro is supported by the Kit receptor.[295,305–308] The importance of Kit ligand (also called stem cell factor or SCF)-Kit receptor signaling in mast cell differentiation is validated in vivo by the absence of mast cells in animals deficient in KL (Sl/Sl^{d} mice) or Kit (W/W^{v}) [309] (Table 5.4). KL also activates mature mast cells, causing them to release histamine.[308]

Monocyte/Macrophage Growth Factors

In mice, monocytes in circulation and tissues consist of at least two subtypes: (1) the classical Gr1^{hi} subset (CD14^{+}CD16^{-} in humans, also known as "inflammatory monocytes") and (2) the nonclassical Gr1^{lo} subset (CD14$^{-/lo}$CD16^{+} in humans, also known as "resident monocytes")[310]. Monocytes are critical mediators of inflammation, whether beneficially in combating pathogens or detrimentally in contributing to atherosclerotic plaques and mediating inflammatory disorders. Although monocytes express high levels of the CSF-1R, they are still present in normal numbers in animals with defects in CSF-1 (*Csf1*$^{op/op}$) or deficiency in CSF-1R (*Csf1r*$^{-/-}$) [311] (Table 5.4), indicating that other cytokines contribute or at least can compensate for defective CSF-1R signaling. Monocytes are also present at normal levels in GM-CSF–deficient animals.[300] Mice deficient in G-CSF, GM-CSF, and CSF-1 still have monocytes present, albeit at reduced numbers, again suggesting redundancy among cytokines for differentiation and maintenance of monocytes.[301]

Macrophage differentiation and survival in vitro can be supported by the CSF-1 cytokine.[312] Tissue resident macrophages are severely reduced in *Csf1*$^{op/op}$ or deficiency in *Csf1r*$^{-/-}$ [311] (Table 5.4). Both of these deficient strains develop osteopetrosis because of failure to develop osteoclasts. Although other macrophage populations are normal, lung macrophages are severely reduced in numbers in GM-CSF–deficient animals and develop a characteristic alveolar proteinosis.[300] Importantly, CSF-1 treatment in patients has demonstrated an improved survival benefit in patients with invasive fungal infection in the post-myeloablative setting.[313]

TABLE 5.4

PHENOTYPES CAUSED BY NONFUNCTIONAL MUTATIONS IN GENES FOR HEMATOPOIETIC GROWTH FACTORS OR THEIR RECEPTORS

Factor	Observed Effects
Kit ligand	No functional alleles: Embryonic death associated with no production of fetal hematopoietic cells and other developmental failures. Partially functional allele: Deficiency of hematopoiesis, mast cell deficiency, anemia, and also other defects in pigmentation and in gametogenesis
IL-3	Lack of function does not appear to affect hematopoiesis
GM-CSF	Alveolar proteinosis
CSF-1	Osteopetrosis, alveolar proteinosis, reduced macrophages, normal monocytes
G-CSF	Neutrophil deficiency; approximately 20% of normal numbers; impaired mobilization of neutrophils; demonstrated to be susceptible to some infections
IL-5	Eosinophil deficiency
TPO	Platelet deficiency, approximately 10% of normal numbers
EPO	Embryonic death; failure to produce fetal erythrocytes due to apoptosis of the late progenitors in the fetal liver; production of some embryonic blood cells
Flt3 ligand	Deficiencies in immune system and in myeloid progenitors and CLP; more severe defects in the case of knockout of the ligand than knockout of the receptor (FLT3)
IL-7	Reduced thymic and peripheral lymphoid cellularity, including B- and T-cell development

IL, interleukin; CLP, common lymphoid progenitor; CSF-1, colony-stimulating factor 1; GM-CSF, granulocyte-macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; TPO, thrombopoietin; EPO, erythropoietin; Flt3 ligand, fms-like tyrosine kinase 3 (also known as fms-like kinase 2 ligand, or Flk2 ligand).

Megakaryocyte Growth Factors

In vitro colony assays have been developed for quantifying megakaryocyte progenitor cells, termed *colony-forming units megakaryocyte* (CFU-MK). As in the case of other early committed progenitors, the growth of such colonies is augmented by several of the CSFs with multilineage activity, such as IL-3, IL-6, GM-CSF, KL, and IL-11.[179,314,315] Unlike granulocytes and monocytes, bone marrow production of platelets is regulated by the number of platelets in the blood. Reduction of platelet numbers in rodents by antiplatelet antibodies or by exchange transfusion of platelet-poor blood causes an increase in the number of megakaryocytes in the hematopoietic tissues as well as an increase in their size and ploidy; conversely, platelet transfusion decreases these parameters.[179] However, such manipulations did not affect CFU-MK numbers in the hematopoietic tissues,[316] leading to the speculation that megakaryocyte differentiation and platelet production are controlled by a thrombopoietic factor that is induced by thrombocytopenia.[179,317]

A growth factor has been identified that has some properties of a physiologic regulator of platelet production. This factor, thrombopoietin (TPO), exerts its effect through the activation of a cytokine receptor termed *Mpl*.[318–320] Mpl was identified earlier as the viral oncogene product of the mouse retrovirus, myeloproliferative leukemia virus.[321] Recombinant TPO increases megakaryocyte and platelet numbers in vivo and stimulates CFU-MK growth in vitro.[322,323] Mice bearing homozygous, nonfunctional alleles of *c-mpl* are viable with greatly diminished platelet numbers,[286] indicating that although TPO is not essential for platelet production, it is a strong in vivo regulator of the process. TPO production has been shown to be regulated by blood platelet numbers,[323] and platelet numbers regulate the mRNA for TPO in the marrow and spleen but not in the liver and kidney.[324] It is not yet clear that the modulation of TPO mRNA in these organs is responsible for the regulation of overall TPO protein levels. Several studies indicate that TPO is constitutively synthesized in the liver and that its level in blood is determined by its removal from circulation by binding to c-Mpl receptors on platelets and bone marrow megakaryocytes.[318] Mice lacking TPO have only approximately 10% of the normal number of platelets[286] (Table 5.4). Although early efforts to treat thrombocytopenia with recombinant TPO was complicated by the development of antibodies to endogenous TPO, causing thrombocytopenia, two newly FDA-approved drugs, including a TPO mimetic and TPO-R agonists, offer new hope for treating clinical thrombocytopenia.[325]

Growth Factors for Erythroid Cells

The physiologic regulator of erythrocyte production is erythropoietin (EPO), and this regulation is very precise, keeping the red blood cell mass within very narrow limits.[326] EPO acts on committed erythroid progenitors to support the later phases of erythroid differentiation.[326] The regulation is achieved by EPO's action to modulate apoptosis of these progenitors. The production of EPO is regulated by the O_2 activity in the vicinity of specialized EPO-producing cells in the kidney. These cells are peritubular cells, located in the renal cortex.[327–329] By sensing O_2 activity, they essentially measure the oxygen delivery capacity of the blood, and they adjust EPO production to achieve the number of erythrocytes needed for normal tissue O_2 tension. The liver also contains specialized cells that can produce EPO in an oxygen-dependent manner, although in adult animals, the contribution of the liver to total EPO production is much less than that of the kidney. In specialized kidney and liver cells, the transcription of the EPO gene is controlled by an oxygen-dependent transcription factor, hypoxia-inducible factor (HIF), that interacts with DNA sequences corresponding to the 3′ untranslated sequence of the mRNA and also with sequences in the EPO promoter region.[330] HIF ubiquitination and subsequent proteasomal degradation are dependent upon the hydroxylation of two specific prolines[331–333] and an asparagine of HIF[334,335] by non-heme, iron-containing hydroxylases that use molecular oxygen as a substrate for the reactions. With normoxia, HIF is rapidly hydroxylated and degraded. With hypoxia, HIF is not hydroxylated and degraded, but it does form part of a transcription complex that binds the 3′ enhancer sequence and induces EPO gene transcription. In addition, tissue specificity of expression in the kidney requires specific, *cis*-acting DNA sequences far upstream (between 6 kilobase pairs and 14 kilobase pairs) of the coding sequence.[336,337] EPO is secreted rapidly into the circulation, and it binds in the bone marrow to EPO-receptors on erythroid progenitor cells in the CFU-E through early erythroblast stages. The EPO-EPO-receptor interaction not only triggers signal transduction but leads to endocytosis and degradation of both the EPO and EPO-R.[338] This erythroid progenitor-mediated consumption of EPO appears to be a major determinant of the metabolic fate of EPO both in vitro[339] and in vivo.[340] Loss of function of EPO or the EPO receptor in knockout mice leads to embryonic death at approximately day 13 of gestation due to failure of production of definitive erythrocytes[341,342] (Table 5.4). Also, importantly, recombinant EPO has been used clinically to treat patients with anemia.

KL is also required for erythroid cell development as shown by its requirement for growth of human BFU-E in vitro under serum-free conditions.[343] The Kit receptor is present on multilineage progenitors and on the BFU-E, and it persists on erythroid progenitors up to the proerythroblast stage. KL thus has a stimulatory effect on erythroid progenitors throughout most early stages, including those of the CFU-E and proerythroblast, when EPO stimulation becomes essential for further development. In addition, IGF-1 appears to have a specific role in erythroid development, as it appears necessary for proper erythroid differentiation in serum-free cultures.[344,345] Other multilineage growth factors, such as IL-3 and GM-CSF, have a stimulatory effect on BFU-E growth in vitro, although there does not appear to be a specific requirement for these factors.

Growth Factors for Lymphocytes

Methods for culture of B-lymphocytes and their progenitor cells were originally described by Whitlock and Witte.[346] Subsequently, a colony assay for B-cell progenitors, CFU-preB, was described, in which it was found that IL-7 is a very potent growth stimulatory factor for such progenitors.[180] The role of IL-7 in lymphoid cell development in vivo was demonstrated by generating mice in which the gene for the IL-7 receptor is nonfunctional. Such mice have a profound reduction in thymic and peripheral lymphoid cellularity with defects in B- and T-cell development[347] (Table 5.4). Because of its importance in B-cell growth in vitro, IL-7 has been incorporated into culture media when examining the lineage potential of early multilineage progenitors.[119,120,173] Flt3 ligand and SCF are crucial in lymphoid commitment, as CLPs are severely reduced in deficient animals.[348]

Supportive versus Instructive Signals

There remains controversy over whether cytokines play a stochastic (supportive) or deterministic (instructive) role in determining cell fate, as there are clear examples that accommodate both models. The idea that lineage differentiation is random, and thus that cytokines merely play a role in proliferation or survival of the progeny *after* a differentiation decision has been made, is supported by the persistence of myeloid cells in animals deficient in G-CSF, GM-CSF, and CSF-1.[301] Along the same lines, overexpression of anti-apoptotic proteins can make up for erythroid and T lymphocyte deficiencies caused by the absence of EPO[349] and IL-7R,[350,351] respectively, indicating that these cytokines are not critical for differentiation.

Still, even in the example of anti-apoptotic rescue of IL-7R deficient mice, B cell development is not rescued.[350] In fact, IL-7 receptor signaling upregulates expression of the B cell-specific transcription factor EBF and its target genes; otherwise, B cells become arrested at the pre-proB cell stage, indicating that IL-7 instructs B cell differentiation.[352] Other examples of an instructive role of cytokines on committed progenitors include the demonstration that enforced GM-CSF signaling can redirect lymphoid progenitors to a myeloid fate[353]; that G-CSF upregulates expression of C/EBPα, a critical transcription factor in neutrophil production, in bipotent granulocyte macrophage progenitors[354]; and that G-CSF and CSF-1 differentially instruct common myeloid progenitors to adopt a granulocyte or macrophage fate, respectively.[355] Interestingly, Sieweke and colleagues showed recently that when HSCs deficient in the transcription factor MafB were treated with CSF-1, the myeloid master regulator PU.1 was upregulated, promoting myelomonocytic commitment[356]; thus, CSF-1 could have an instructive role even on HSCs.

HEMATOPOIETIC MICROENVIRONMENTS

Stroma of Hematopoietic Organs

The stroma is composed of non-hematopoietic cells that provide structure and regulate hematopoietic cells in lymphoid tissues. These cells include nerves, endothelial cells, bone, adipocytes, and mesenchymal stem and progenitor cells. The bone marrow houses two major stem cell types: HSCs and non-hematopoietic stem cells that form bone structures.[357,358] These non-hematopoietic stem cells can give rise to mesodermal-derived cells,[359] endothelial cells,[360] or even diverse cell types associated with multiple embryonic germ layers.[284] Among non-hematopoietic stem cells in the bone marrow, mesenchymal stem cells (MSCs) were originally described as undifferentiated cells capable of differentiating in vitro into multiple mesenchymal lineages including bone and cartilage.[357] MSCs are plastic-adherent, fibroblast-like multipotent cells that do not express hematopoietic markers (CD45, CD34, CD14, CD11b, CD79a or CD19, and HLA-DR) but do express other specific surface antigens (CD105, CD73, CD90).[361,362] A relative lack of immunogenicity of MSCs has bolstered its therapeutic use in repair or regeneration of damaged or mutated bone, cartilage, and cardiac tissues.[362] The transplantability of MSC remains

controversial since numerous studies have indicated that following allogeneic, unfractionated whole bone marrow cell transplantation, the bone marrow stroma remains entirely of host origin, while the hematopoietic cells are completely of donor origin.[363] Injured tissue or a constitutive defect in a tissue may provide additional signals for the induction of differentiation of the MSCs present in infused bone marrow cells.[364,365] Horwitz et al.[366] have reported that allogeneic whole bone marrow grafts contain sufficient osteoblast progenitor cells to alter the clinical course of children with osteogenesis imperfecta, a disease caused by mutation of a gene encoding type 1 collagen, the major structural protein of bone. MSCs and HSCs are believed to be derived from two distinct stem cells in the bone marrow; but transplantation of HSCs encoding green fluorescent protein (GFP) have indicated that fibroblasts and myofibroblasts in other organs (lungs, intestine, liver, skin, etc.) may be derived from HSCs.[367] Although these results supporting a common origin of hematopoietic and stromal cells were suggested earlier by other investigators,[368,369] they remain controversial.

The stroma also contains an extracellular matrix that provides a structural network to which hematopoietic progenitors and stromal cells are anchored. This matrix is composed of various fibrous proteins, glycoproteins, and proteoglycans that are produced by the stromal cells.[227] These include collagens (types I, III, IV, V, and VI),[370,371] fibronectin,[372–373,374,375–376] laminin,[377] hemonectin,[234,378,379] tenascin,[380] thrombospondin,[381–385] and proteoglycans.[231–235]

The stroma is functionally important in hematopoiesis through its regulation of hematopoietic progenitor cell proliferation and differentiation, HSC renewal, homing of HSCs to the hematopoietic organs, and egress of mature hematopoietic cells from the bone marrow into the blood. The stroma aids in these functions through the synthesis and secretion of growth factors, direct cell-cell interactions between stromal and hematopoietic cells, and molecular interactions between hematopoietic cells and the extracellular matrix of the hematopoietic organs. One example that illustrates the multiple functions and mechanisms of stromal-hematopoietic interactions was discovered in studies of mice that have mutations in either of two particular genes[386]: the white spotting locus (nonfunctional allele W) and the steel locus (nonfunctional allele Sl). Each of these genes is essential for hematopoiesis. Mouse embryos that are homozygous for null alleles of either of these genes die at an early stage of embryogenesis without forming any blood cells. However, mice have been found and bred that bear mutant alleles of each of the two genes that retain partial function (W^v and Sl^d alleles). Heterozygous mice of the Sl/Sl^d or the W/W^v genotypes are phenotypically similar to one another, with a lack of cutaneous pigment, sterility, and congenital anemia.[386] Reciprocal bone marrow transplantation studies between normal, wild-type mice and heterozygous mice, Sl/Sl^d and W/W^v, revealed that W/W^v mice have defective HSCs but a functional microenvironment that can support transplants of normal HSCs. Conversely, the Sl/Sl^d mice have functional HSCs and can thus serve as donors for marrow transplants, but these mice have a defective microenvironment (stroma) for hematopoiesis; thus, their defect cannot be corrected by the receipt of HSCs from normal donor mice. The mechanism of impaired hematopoiesis caused by mutations in these two genes was understood after the cloning of the genes at the W and Sl loci. The W gene encodes the cell-surface receptor protein Kit (gene designated *c-kit*),[387,388] and the Sl gene encodes the ligand for that receptor, which was discussed in the above section and variably called *steel factor*, *kit ligand*, or *stem cell factor*.[389–391] The Kit protein is a cell-surface receptor on HSCs and hematopoietic progenitor cells, and KL is expressed by stromal cells. KL is produced in two forms because of alternative splicing of the mRNA: a soluble form and an integral membrane form.[392,393] Both the soluble form and the stromal cell membrane–bound form of KL can stimulate HSCs, the former by free ligand-receptor binding and the latter by cell-cell contact. Activation of Kit is essential for the survival and development of immature hematopoietic progenitors. Kit and KL are not only important in hematopoiesis but are also produced in certain other developing tissues, where they have roles in pigmentation and gonadal function. KL is just one of a large number of hematopoietic growth factors produced by stromal cells, some of which also exist in both soluble and membrane-bound forms, including Flt-3 ligand (FL) [284,394,395] and macrophage colony-stimulating factor (colony-stimulating factor-1 [CSF-1]).[396–398]

Hematopoietic Stem Cell Niches in Bone Marrow

The concept of the HSC niche as a microenvironment promoting the maintenance of HSCs was proposed by Schofield in 1978, but the bone marrow niche's role in supporting HSC activity has only recently been identified in experimental animal models.[399] There has been rapid progress in what we have learned about HSC niches. The putative cellular components of the niche to date include endothelial cells, osteoblasts, mesenchymal lineage cells, and very recently, nonmyelinating Schwann cells. A comparison of these candidate cell types can be found in Table 5.5. Whereas osteoblasts were widely implicated as a critical component of the HSC niche,[400–402] a number of observations have called into question the niche activity of osteoblasts: (1) organs with extramedullary hematopoiesis, such as the spleen and liver, do not have osteoblasts; (2) reductions in osteoblasts are not necessarily associated with reductions in HSC[403,404,405]; (3) compared to $nestin^+$ mesenchymal stem cells, sorted osteoblasts from bone have low expression of Cxcl12, Angpt1, Kitl, and Vcam1, four microenvironmental factors implicated in the maintenance and retention of HSC[246]; (4) DT injection in CXCL12-DTR-GFP mice did not reduce osteoblast numbers, suggesting that osteoblasts do not express high levels of Cxcl12[406]; and (5) although homotypic interactions between N-cadherin on osteoblasts and HSCs have been implicated as a critical niche interaction,[402] there have been conflicting data on the effect of N-cadherin loss of function on HSCs.[405,407–409]

The so-called "vascular zone" at the center of the marrow cavity consisting of a thin meshwork of fenestrated sinusoidal vessels has been suggested as the site of a possible vascular niche.[410] The vascular niche was also an early cellular candidate of the HSC niche based on the proximity of $CD150^+$ HSC to sinusoidal endothelial cells in the BM.[93] Although abrogation of VEGFR2 signaling can reduce sinusoidal endothelial cells and impair HSC/progenitor recovery after sublethal irradiation,[411,412] compared to $nestin^+$ MSCs, endothelial cells produce only low levels of niche factors, such as Cxc12, Angpt1, Kitl, and Vcam1.[246] However, Morrison and colleagues recently demonstrated that knockdown of stem cell factor (SCF, kit ligand) on $Tie2^+$ cells reduced HSC content in the BM by 5.2 fold.[413] Endothelial cells were implicated as the Tie2-expressing population, but SCF expression on other $Tie2^+$ stromal populations, including mesenchymal lineage cells, has not been ruled out.

The strongest candidate for the HSC niche cell is a mesenchymal lineage cell type. Three independent groups have described steady-state HSC niche candidate populations with evidence of mesenchymal stem/progenitor cell activity, namely, CXCL12-abundant reticular (CAR) cells,[406] $nestin^+$ cells,[242] and leptin receptor ($LepR^+$) perivascular cells.[413] These cells express high levels of Cxcl12 and other molecules implicated in HSC maintenance (Kitl, Angpt1, and Vcam1), and loss of function studies with these cell types demonstrate reductions in HSCs (Table 5.5).[242,406,413] Furthermore, human $CD146^+$ mesenchymal stromal cells/adventitial reticular cells (ARCs) express angiopoietin and are able to self-renew and form hematopoietic

TABLE 5.5

CANDIDATES FOR CELLULAR IDENTITY OF THE HEMATOPOIETIC STEM AND PROGENITOR CELL NICHE

Cell Type	Phenotype	Frequency in BM	Produce Niche Factors?	Evidence of Functional Niche Activity
Osteoblasts	N-cadherin$^+$ CD45$^-$[402]	NQ	N-cadherin[402]	Increase in LSK and LTC-ICs in Col1-caPRR and PTH-treated mice.[400] Increase in osteoblasts and LSK and CRU in Bmpr1 mutants.[402] Reduction in LSK cells in GCV-treated Col2.3tk mice.[401]
Endothelial cells ("Vascular niche")	VE-Cadherin$^+$ VEGFR2$^+$VEGFR3$^+$[411,412]	NQ	Jagged1, Jagged2[412]	Reduced LSK and CRU in sublethally irradiated mice treated with anti-VE-Cadherin and anti-VEGFR2.[412]
	Tie2$^+$[413]	NQ	Kitl[413]	5.2-fold reduction in LSKCD150$^+$CD48$^-$ CD41$^-$ HSC in Tie2-cre;Scf$^{fl/-}$ mice.[413]
Mesenchymal lineage cells	CD45$^-$Ter119$^-$CXCL12$^+$ Vcam1$^+$ CD44$^+$ CD51$^+$ PDGFRα^+ PDGFRβ^+[406]	0.27%[406]	Cxcl12, Kitl, Vcam1[406]	Reduction in LSKCD34$^-$CD150$^+$CD48$^-$ and competitive repopulation units in DT-treated Cxcl12-DTR-GFP mice.[406]
	CD45$^-$CD31$^-$ Nestin$^+$[242]	0.08%[242]	Cxcl12, Angpt1, Kitl, Vcam1, Il7[242]	Reduction in LSKCD150$^+$CD48$^-$CD41$^-$ cells and LTC-IC after depletion of Nestin+ cells in TAM and DT-treated Nestin-Cre^{ERT2}; iDTR mice.[242]
	LeptinR$^+$[413]	NQ	Cxcl12, Kitl[413]	>5-fold reduction in LSKCD150$^+$CD48$^-$ CD41$^-$ HSC in Lepr-cre;Scf$^{fl/-}$ mice.[413]
Nonmyelinating Schwann cells	GFAP$^+$[416]	0.004%[416]	Cxcl12, Angpt1, Kitl, Tpo[416]	Reduction in LSKCD34$^-$ and competitive repopulation units after surgical lumbar sympathectomy.[416]

NQ, not quantified; Kitl, Kit ligand; Vcam1, vascular cell adhesion molecule 1, Il, Interleukin, TPO, thrombopoietin.

microenvironments in immunocompromised mice.[414] Since all these mesenchymal stromal populations have been anatomically and/or functionally associated with pericytes/mural cells, these cells, which are found in both the endosteum and bone marrow proper, can potentially reconcile the previous findings supporting both an osteoblastic and vascular HSC niche.[415]

Recently, Nakauchi and colleagues have asserted that latent TGFβ-expressing, GFAP$^+$ populations of nonmyelinating Schwann cells are critical for HSC maintenance, as celiac ganglionectomy rapidly led to the degeneration and loss of nonmyelin Schwann cells and reduced HSC content in the BM.[416] Whether this population of cells expresses the appropriate HSC maintenance factors and whether more specific depletion of this population results in the same reduction in HSC content will further elucidate the relative contribution of this niche to HSC maintenance.

Multiple stromal cell populations contribute to HSC maintenance, and future work will further dissect whether there are subsets of niches that are more suitable for HSCs versus hematopoietic progenitors, or among progenitors.

Erythroid Niches in Bone Marrow

Before stromal niches for HSCs were proposed by Schofield in 1978, the first nurse cell in the hematopoietic system was proposed by Bessis in 1958 to be a macrophage promoting red blood cell development in erythroblastic islands.[417,418] Although not yet formally proven to have a role in erythropoiesis in vivo, these macrophage-erythroblast interactions have been shown in vitro to support the proliferation and viability of developing red cells. It is unknown how macrophages maintain erythroblasts, but VCAM-1-VLA-4, CD51-ICAM4, and homotypic interactions between erythrocyte membrane protein (EMP) have been shown to be critical for adhesive interactions in vitro.[418] Future work should elucidate the contribution of these erythroblast island niches in vivo.

B Cell Niches in Bone Marrow

The CXCR4-CXCL12 axis has been implicated in B cell development because chimeric mice reconstituted with CXCR4-deficient fetal liver cells have reduced B cell precursors.[419] As Nagasawa and colleagues pursued CXCL12-expressing niches for B cells in the bone marrow, they discovered that the earliest committed B cell precursors, the pre-proB cells, localized around CAR cells, which did not express IL-7.[420] As they mature to proB cells, they migrate away from CAR cells to IL-7-expressing stromal cells. Then, after peripheral maturation, plasma cells home back to the BM to reside near CAR cells. It is unclear how CAR cells that do not express IL-7 promote B cell development. It is possible that CAR cells retain pre-proB cells and plasma cells so that a third cell type can exert regulation. Indeed, there is evidence that macrophage inhibitory factor (MIF) derived from BM resident dendritic cells is able to promote survival B cells[421] in the bone marrow. Future work will uncover the mesenchymal and hematopoietic contributions to the B cell niche in the bone marrow.

PERSPECTIVES

The hematologic system is a tightly regulated organ system in which a host of different cell types with varied developmental potential and effector capacity work in concert to ensure efficient

oxygen delivery, hemostasis, and immunosurveillance. They are regulated by each other and also by the non-hematopoietic stroma. In spite of all this complexity, most hematopoietic cells originate from HSCs in the bone marrow. This is critical in the context of bone marrow transplantation and other clinical scenarios in which a rebooted hematopoietic system is desired. The following chapters will discuss lineage-specific examples when the hematopoietic system becomes dysregulated.

ACKNOWLEDGMENTS

We would like to acknowledge the contribution of Mark Koury, who wrote a previous version of this chapter, as some parts of this previous version remain in the current version. We are also grateful for his critical reading and helpful suggestions for this updated version. Figures were produced using Servier Medical Art (http://www.servier.com).

CHAPTER 6

THE BIRTH, LIFE, AND DEATH OF RED BLOOD CELLS: ERYTHROPOIESIS, THE MATURE RED BLOOD CELL, AND CELL DESTRUCTION

John G. Quigley, Robert T. Means, Jr., Bertil Glader

ERYTHROPOIESIS

Concept of the Erythron

"There is, unfortunately, no name for this tissue (or organ), and it will save a good deal of paraphrasing and probably some confusion if we make one and call it *erythron*."[1]

The entire process by which red cells are produced in the bone marrow is termed *erythropoiesis*. For descriptive purposes, the process can be divided into various stages, including the commitment of pluripotent stem cell progeny to erythroid differentiation, the erythropoietin (Epo)-independent or early phase of erythropoiesis, and the Epo-dependent or late phase of erythropoiesis. Under normal conditions, erythropoiesis results in a red cell production rate such that the red cell mass in the body remains constant, indicating the presence of regulatory control mechanisms. The control mechanisms regulating the later phases of erythropoiesis are better understood than those regulating the early phases. The hormone Epo is established as the major factor governing red cell production.[2–4] Erythropoiesis involves a great variety and number of cells at different stages of maturation, from stem cell progeny committed to erythroid differentiation to the mature circulating red cell (Fig. 6.1). The whole mass of these erythroid cells has been termed the erythron,[1] a concept that emphasizes the functional unity of the red cells, their morphologically recognizable marrow precursors, and the functionally defined progenitors of these precursors. The concept of erythron as a tissue has thus far contributed significantly to the understanding of the physiology and pathology of erythropoiesis.

ERYTHROID CELLS

Committed Erythroid Progenitors

The processes leading from the undifferentiated hematopoietic stem cell to erythroid commitment are discussed in Chapter 5. Erythroblasts in the bone marrow are generated from proliferating and differentiating earlier, more immature erythroid cells termed erythroid progenitors. These progenitor cells are detectable functionally by their ability to form in vitro erythroid colonies.[5] The development of tissue culture techniques for cloning hematopoietic progenitor cells in semisolid culture media in vitro has led to the recognition and assay in the human and murine bone marrow of at least two erythroid progenitors, the colony-forming unit–erythroid (CFU-E) and the burst-forming unit–erythroid (BFU-E). Under the influence of Epo, these progenitors can grow in semisolid culture media and give rise to colonies of well-hemoglobinized erythroblasts. A two-phase liquid culture system that models human erythroid development has also been described.[6]

Colony-forming Unit–Erythroid

The CFU-E is an erythroid cell closely related to the proerythroblast.[7] Under the influence of low concentrations of Epo, it gives rise (in 2 to 3 days in murine and in 5 to 8 days in human marrow) to colonies of 8 to 32 well-hemoglobinized cells[7–10] (Fig. 6.2). The clonal origin of these colonies has been demonstrated by glucose-6-phosphate dehydrogenase–isoenzyme analysis.[11] Morphologically, CFU-E purified from progenitor cell cultures appear as immature cells with fine nuclear chromatin; a well-defined, large nucleolus; a high nuclear–cytoplasmic ratio; a perinuclear clear zone; and basophilic cytoplasm with pseudopods.[12,13] On electron microscopy, this cell appears as a primitive blast with dispersed nuclear chromatin, a prominent nucleolus, and an agranular cytoplasm containing clumps of mitochondria and frequent pinocytotic vesicles.[12] The number of CFU-E in the human marrow ranges from 50 to 400/10^5 light-density, nonadherent, nucleated cells and varies significantly with the methods used for cell separation and the culture conditions. The majority of CFU-E are in a phase of active DNA synthesis (S phase) as demonstrated by a 70% to 90% killing of cells after short exposure to ^{3}H-thymidine in vitro (^{3}H-thymidine suicide) or after administration of cycle-specific chemotherapeutic agents in vivo.[14–16] The size of the CFU-E compartment in intact animals depends on the levels of circulating Epo. Anemia associated with high Epo levels or the administration of Epo leads to expansion of the CFU-E compartment, whereas transfusion-induced polycythemia leads to low Epo levels and a significant reduction of the CFU-E compartment.[16] From a number of in vitro studies, it has been established that the CFU-E is the most Epo-sensitive cell, carrying the highest density of Epo receptors (EpoR) on its surface, and it is also absolutely dependent on Epo for its survival. In the absence of Epo, CFU-E rapidly undergoes programmed cell death (apoptosis)[12,17,18,19,20] Although the first phase of CFU-E differentiation is Epo-dependent, the later stages are not.[21]

Highly purified CFU-E has been isolated from murine fetal liver cells; this is defined in flow cytometry studies as expressing c-kit, the receptor for the cytokine stem cell factor (SCF), negative for a number of lineage markers (Ter119, B220, Mac-1, CD3, Gr-1, CD32/16, Sca-1, and CD41), and having high cell surface expression of the transferrin receptor (TfR) (CD71) and the heat stable antigen, CD24.[13]

Burst-forming Unit–Erythroid

The BFU-E is an erythroid progenitor that is much more immature than the CFU-E, and more closely related to the multipotent hematopoietic stem cell, as indicated by its cell size, buoyant density, and the relatively low percentage of these cells in active DNA synthesis (0% to 25%).[15,16,22,23] In contrast to CFU-E, BFU-E also has a (limited) capacity for self-renewal and is detectable in

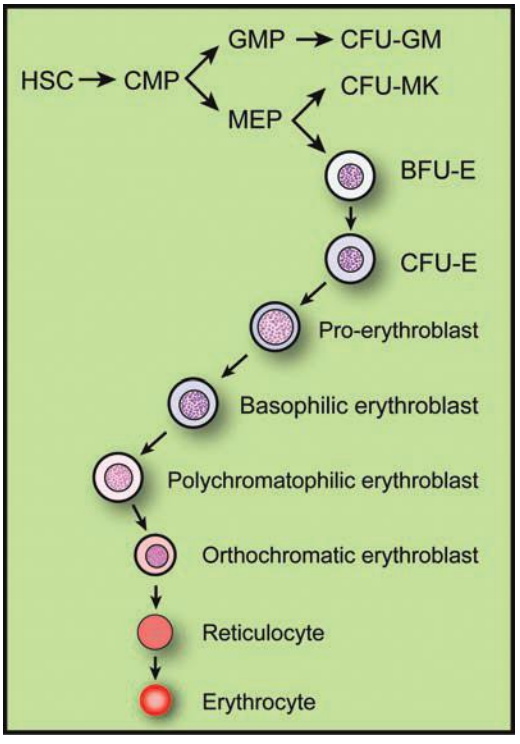

FIGURE 6.1. Schematic representation of the differentiation of erythroid cells from multipotent hematopoietic stem cells. BFU-E, burst-forming unit–erythroid; CFU-E, colony-forming unit–erythroid; CFU-GM, colony-forming unit–granulocyte–monocyte; CFU-MK, colony-forming unit–megakaryocyte; CMP, common myeloid progenitor; GMP, granulocyte–monocyte progenitor; MEP, megakaryocyte/erythroid progenitor.

the peripheral blood at a concentration of 0.02% to 0.05% of light-density mononuclear blood cells.[24,25] BFU-E can be separated from CFU-E by its slower velocity sedimentation at unit gravity.[26] Morphologically, the BFU-E appears as a very immature blast cell with slightly oval, moderately basophilic cytoplasm with occasional pseudopods, very fine nuclear chromatin, and large nucleoli.[13,19] On electron microscopy, the cytoplasm contains polyribosomes and is less abundant than in CFU-E, whereas the nucleus contains small amounts of clumped heterochromatin and prominent nucleoli.[19]

In the presence of Epo and under the influence of other cytokines that act on early hematopoietic cells, such as interleukin-3 (IL-3), IL-6, granulocyte–macrophage colony-stimulating factor (GM-CSF), thrombopoietin (Tpo), and SCF, the BFU-E progenitor gives rise in 5 to 7 days in mice and in 14 to 16 days in humans to clusters of many erythroid colonies (a large "burst") containing a total of 500 to more than 30,000 to 40,000 well-hemoglobinized erythroblasts (Fig. 6.3). Cytokines such as transforming growth factor (TGF) β, tumor necrosis factor (TNF) α, and interferon (IFN) γ, on the other hand, suppress progenitor proliferation. The clonal origin of BFU-E–derived erythroblasts has been demonstrated by characterization of the type of hemoglobin produced by cells in single colonies in co-culture experiments of bone marrow cells from a patient with homozygous hemoglobin C and marrow cells from another patient with homozygous hemoglobin S disease.[27] The BFU-E can be considered as a progenitor of the CFU-E. Indeed, after 6 to 8 days in culture, cells generated from human BFU-E have all the functional characteristics of CFU-E.[12] The concentration of BFU-E in human bone marrow varies from 10 to $50/10^5$ nucleated cells; however, this number fluctuates widely depending on the cell separation methods and culture conditions. From both in vitro and in vivo experiments, it has been established that the early stages of BFU-E proliferation and differentiation are Epo independent.[16,19,23] BFU-E can survive in vitro for 48 to 72 hours in the absence of Epo, but it is absolutely dependent on IL-3 for survival.[19] Only 20% of blood BFU-E expresses a very low density of EpoR detectable by autoradiography.[19] The size of the BFU-E compartment in the marrow of animals remains unaffected by the acute changes in the levels of circulating Epo induced by anemia or transfusional polycythemia.[16] Anemia can induce an increase in the cycling of BFU-E without affecting their numbers,[28] and in vitro Epo can induce BFU-E into DNA synthesis.[29] In humans, chronic administration of Epo is associated with an increase in the concentration and cycling status of marrow BFU-E; however, these changes are also seen in granulocytic–monocytic and megakaryocytic CFUs (CFU-GM, CFU-MK), and multilineage progenitors such as CFU-GEMM, indicating that, at the early progenitor cell level, the marrow responds to Epo as an organ in a non–lineage-specific manner.[30] All these evidences indicate that the early stages of erythropoiesis at the BFU-E level are Epo independent, and Epo dependence develops at a stage between BFU-E and CFU-E.[19] The distinction between early (BFU-E) and late (CFU-E) erythroid progenitors, although valid, is by itself artificial. There is a variety of cells

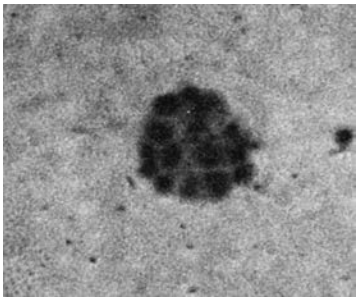

FIGURE 6.2. A day 7 colony-forming unit–erythroid–derived colony of erythroblasts containing 16 cells.

between BFU-E and CFU-E that form a continuum of erythroid progenitors at different stages of differentiation with properties between those of BFU-E and CFU-E. As an example, a subclass of erythroid progenitors termed mature BFU-E has been described in human and murine marrow.[14,15] These cells share properties of both CFU-E and BFU-E. They have a proliferative potential lower than BFU-E but higher than CFU-E, their cycling status is also intermediate between CFU-E and BFU-E, and they do not exhibit IL-3 dependence, but show relative Epo dependence.[14,15,18] Thus, the evidence suggests that during erythroid development, early progenitors of high proliferative potential in a relatively low cycling status with absolute dependence on IL-3 and responsiveness to, but not dependence on, Epo differentiate progressively through various stages into later progenitors of low proliferative potential with a high cycling status that are IL-3 independent and totally Epo dependent.

Increasingly, in place of functional definition of erythroid progenitors, studies, especially in mice but also in humans, allow for prospective identification of progenitors using cell surface markers.[31,32] As noted above, recent work, for example, using murine fetal liver cells as a source of hematopoietic—at the fetal liver stage predominantly erythroid—cells allows isolation of BFU-E and CFU-E progenitors with 94% and 95% purity, respectively: although both these erythroid progenitors express c-kit, BFU-E is distinguished from CFU-E as it has much lower cell surface expression of CD24 and CD71.[13]

Erythroid Precursors

The least mature recognizable erythrocyte precursor cell is known as the proerythroblast (or pronormoblast). The various stages of maturation, in order of increasing maturity, are proerythroblasts, basophilic erythroblasts, polychromatophilic erythroblasts, and orthochromatic erythroblasts. The morphologic characteristics of each stage, as seen with light microscopy after staining with Romanowsky dyes, are widely agreed upon. Cytoplasmic maturation is assessed by the change in staining characteristics, as the deep blue color derived from the high RNA content of immature cells gives way to the red color characteristic of hemoglobin. Nuclear maturation is evaluated by the disappearance of nucleoli and the condensation of chromatin as nuclear activity decreases. In addition, there is a gradual decrease in cell size and EpoR expression and terminally exit from the cell cycle.

Stages of Erythroblastic Differentiation

The proerythroblast is a round or oval cell of moderate to large size (14 to 19 μm diameter; Figs. 6.4A and 6.5A). It possesses a relatively large nucleus, occupying perhaps 80% of the cell, and a rim of basophilic cytoplasm. The nucleus of the youngest cells in this group differs little from that of the myeloblast. Nucleoli are seen and may be prominent. Only small amounts of hemoglobin are present that cannot be detected by Giemsa stain. As compared with that of myeloblasts and lymphoblasts, the cytoplasm is more homogeneous and condensed and may appear granular. A small pale area may be found in the cytoplasm, probably corresponding to the Golgi apparatus.[33] The nuclear chromatin is somewhat coarser than that in myeloblasts or lymphoblasts.

The basophilic erythroblast is similar to the proerythroblast except that nucleoli are no longer visible and the cell is smaller (12 to 17 μm in diameter; Figs. 6.4B and 6.5B). Condensation of chromatin (formation of heterochromatin) begins and, on light microscopy, the chromatin may appear coarse and granular; thus, there is little resemblance to the myeloblast. The nuclear structure may assume a wheel-spoke arrangement. Ribosomes reach their maximum number during this stage, and thus the cytoplasm is deeply basophilic. Cytoplasmic color changes during subsequent stages reflect the increase in acidophilic hemoglobin and the decreasing amount of ribosomal RNA.

The first faint blush of hemoglobin, as indicated by one or more pink areas near the nucleus in dry fixed preparations, introduces the next stage, the polychromatophilic erythroblast (Figs. 6.4C and 6.5C,D). Increasing chromatin condensation is seen and irregular masses of chromatin are formed. Nucleoli are not visible. The nucleus is smaller (7 to 9 μm) as is the cell as a whole (12 to 15 μm).

When the cytoplasm possesses almost its full complement of hemoglobin, the cell is termed an orthochromatic erythroblast (Figs. 6.4D and 6.5E). It is the smallest of the nucleated erythrocyte precursors (8 to 12 μm in diameter). At this stage, the nucleus undergoes pyknotic degeneration, the chromatin becomes greatly condensed, and the nucleus shrinks. It may assume various bizarre forms such as buds, rosettes, and clover leaves prior to extrusion (Fig. 6.6).

After the nucleus is extruded, the cell is known as a reticulocyte. These cells are larger than mature erythrocytes, perhaps 20% greater in volume.[34] They retain certain cytoplasmic organelles, such as ribosomes, mitochondria, and the Golgi complex (Fig. 6.6C,D), and have special staining characteristics. Methyl alcohol or similar fixative agents used in staining cause precipitation of the ribosomal RNA. Such cells may thus appear uniformly blue or gray (diffuse basophilia), or basophilic shades may be intermingled with pink-staining areas (polychromatophilia or polychromasia). Certain supravital staining techniques (see Chapter 1) cause the ribosomal RNA to precipitate or aggregate into a network of strands or clumps termed reticulum; for example, cresyl blue agglutinates the ribosomes. As the reticulocyte matures, the various organelles decrease in number. Usually the mitochondria disappear first and the ribosomes last. "Autophagic vacuoles" (secondary lysosomes) containing degenerated organelles may be seen. The shape of the reticulocyte, as revealed by the scanning electron microscope, differs from that of the mature erythrocyte. Only in the late stages of maturation does the bilaterally indented disc shape of the mature red cell appear.

Flow Cytometric Analysis of Erythroid Precursors

It is now possible to broadly distinguish populations of murine or human erythroid precursors by analyzing patterns of antibodies binding to cell surface antigens. Analyses of murine hematopoietic tissues (bone marrow, spleen,[31] or fetal liver[35]) demonstrate that the TfR (CD71) is expressed at very high levels by the early erythroid precursors, proerythroblasts, and early basophilic erythroblasts (for iron uptake for high-level heme synthesis) and that CD71 expression then decreases with erythroid maturation (and decreasing heme synthesis). On the other hand, Ter-119 (an antibody that recognizes an antigen associated with the predominant mature red cell membrane glycoprotein, glycophorin A) is expressed at intermediate levels in proerythroblasts and subsequently at high levels in more differentiated precursors.[31] Thus, double immunostaining for these antigens (while excluding anucleate red cells) results in four cell populations, $CD71^{high}Ter119^{med}$, $CD71^{high}Ter119^{high}$, $CD71^{med}Ter119^{high}$, and $CD71^{low}Ter119^{high}$ corresponding broadly to proerythroblasts, basophilic, polychromatophilic, and orthochromatic erythroblasts, respectively. Similar immunostaining has also been examined during differentiation of human erythroid precursors; however, TfR expression appears to be more variable. Recent studies of human proerythroblast maturation indicate that the combination of CD36 (a high-affinity scavenger receptor[36]) and CD71 expression can be reliably used to discern basophilic, polychromatophilic, and orthochromatic erythroblasts by flow cytometry.[37]

Proliferation and Maturation of the Erythron

Within the erythron, cellular maturation and proliferation proceed simultaneously. Although BFU-E progenitors have limited self-renewal capacity, CFU-E and the erythrocyte precursors are functionally destined to mature; thus, they are incapable of self-maintenance. In response to acute demands, such as hemorrhage and hemolysis, maintenance of the erythron occurs primarily through the action of Epo promoting both progenitor proliferation (in part through increasing the CFU-E pool by reducing apoptosis[19]) and accelerating terminal maturation. As discussed, a majority of CFU-E progenitors, however, are already in cycle and can undergo at most three to five divisions with maximal Epo stimulation, thus limiting the erythron response. With greater or more chronic demands there appears to be an increase in BFU-E self-renewal divisions to further increase the size of the CFU-E pool.[38] Obviously even greater requirements, for example, during recovery from bone marrow irradiation, necessitate input from the stem cell compartment (see Chapter 5). When severe anemia is present from birth, for example, in patients with thalassemia major, a congenital hemolytic anemia (Chapter 38), there is, in addition to maximal expansion of the various erythroid progenitor and precursor compartments, expansion of the sites of erythropoiesis from the axial bones (vertebra, pelvis, clavicles, ribs, and sternum) to other sites, potentially including the femurs, humeri, skull, spleen, liver, and even thymus.

A scheme of the proliferation of the erythron and its various stages of development is presented in Figure 6.1. It takes approximately 12 to 15 days for a cell at the BFU-E stage to mature into erythroblasts. Within 6 to 8 days, a BFU-E proliferates and differentiates into a CFU-E, which needs another 5 to 7 days to proliferate and develop into basophilic erythroblasts: a period during which the CFU-E undergoes three to five successive divisions. Probably, three to five cell divisions also occur during the maturation of erythroid precursors.[39] Thus, 8 to 32 mature red cells are derived from each proerythroblast. Cell division ceases at the stage of polychromatophilic erythroblasts. Orthochromatic erythroblasts cannot synthesize DNA and, therefore, cannot divide. Two events may decrease the theoretic yield of cells. One of these is the death of erythrocytes before or shortly after release from the marrow (ineffective erythropoiesis) (Chapter 22). The second is a skipped cell division, a phenomenon that may occur with increased Epo stimulation and that results in a large hemoglobin-poor cell (Chapter 22). These events occur only to a limited extent in normal subjects but occur much more frequently under pathologic circumstances.

The biochemical events that occur in stem cell progeny during commitment to erythroid differentiation are incompletely understood. The same holds true for the committed early erythroid progenitor BFU-E. This cell is IL-3 dependent and expresses only small numbers of EpoR.[19] Within 72 hours in culture, these cells become fully dependent on Epo ("mature" BFU-E) and, in its presence, proliferate and differentiate into CFU-E progenitors.[12,19] With Epo stimulation there is selective up-regulation of transcription factors, including GATA1,[40] KLF1 (previously called EKLF[41]), and NFE2.[42] GATA1 interacts with SCL/Tal1 (with LMO2, LDB1, and E2A), or with KLF1 and others in multiprotein complexes that associate with and activate (or, for example, with FOG1 and Gfi-1b and repress) erythroid genes.[38,43,44,45]

At this (CFU-E) stage, a number of differentiation events can be detected. From studies in murine erythroid cells, it has been established that Epo induces an increase in mRNA synthesis and that this is closely followed by the induction of murine globin gene transcription.[46] Other biochemical events associated with terminal erythroid differentiation include increased uptake of calcium and glucose, synthesis of TfRs, increased iron uptake, hemoglobin synthesis, and the appearance of erythrocyte membrane proteins (e.g., bands 3 and 4.1).[47–50] It appears that there is a GATA1-dependent phase of differentiation, controlling EpoR, antiapoptotic genes, and alpha (α–) globin gene expression that is succeeded by a KLF1-dependent phase.[44,51] KLF1 appears to regulate the expression of genes essential for many key aspects of terminal erythroid differentiation including those encoding for major cytoskeletal and cell membrane proteins (ankyrin, band 3, band 4.1, dematin, and glycophorins A and C), iron transport proteins (TfR at the cell membrane and mitoferrin-1 [Mfrn1] in mitochondria[52]), heme synthesis enzymes, α- and beta (β)-globin chains, and α-hemoglobin stabilizing protein (AHSP, which stabilizes α-globin chains and increases their affinity for β-globin chains[41,51,53]). Hemoglobin synthesis continues as the cell matures into a basophilic erythroblast, and, at the polychromatophilic erythroblast stage, enough hemoglobin has accumulated in the cytoplasm to give the cell the mild acidophilic reaction that is detected by Romanowsky stains. Hemoglobin synthesis continues through the orthochromatic stage and persists at a very low rate in the reticulocyte after enucleation. Mature red cells, being devoid of ribosomes, are unable to synthesize hemoglobin.

As previously noted, morphologic evidence of decreasing erythroid precursor nuclear activity (heterochromatin formation) can be seen as early as the basophilic erythroblast stage. By the orthochromatic stage, the nucleus is completely inactive, unable to synthesize either DNA or RNA. The factors leading to cessation of nuclear activity are not fully understood, but it has been suggested that it is related to the intracellular hemoglobin concentration.[54] Hemoglobin is found within the nucleus, possibly gaining entrance through pores in the nuclear membrane.[54–56] After reaching a critical concentration,[54] nuclear hemoglobin may react with nucleohistones, thereby bringing about chromosomal inactivation and nuclear condensation. According to this hypothesis, the number of cell divisions and the ultimate erythrocyte size are related to the rate of hemoglobin synthesis. For example, microcytic cells are produced in iron deficiency because it takes longer to reach the critical hemoglobin concentration and the generation time is unaffected; hence, more cell divisions occur before nuclear inactivation, and the resulting cell is small. In contrast, the macrocytes observed when erythropoiesis is stimulated may be the end results of an Epo-induced acceleration of hemoglobin synthesis, which in turn leads to an earlier onset of nuclear degeneration and a reduced number of cell divisions. Consistent with this hypothesis is the observation that the mean corpuscular hemoglobin concentration is relatively constant in a variety of mammalian species, even though erythrocyte size varies greatly.[57] Recent studies indicate that deacetylation of nucleohistones is critical for formation of heterochromatin and nuclear condensation, and inhibition of deacetylation (by, e.g., HDAC inhibition or ectopic expression of the histone acetyl transferase Gcn5) impedes chromatin condensation and enucleation during terminal erythroid differentiation.[58]

After the nucleus degenerates, it is extruded from the cell.[59] This process, as observed in living erythroblasts by phase contrast microscopy,[60] is completed in 5 to 60 minutes. During the extrusion process, mitochondria and cytoplasmic vesicles accumulate near the nuclear border.[33,61] The role of these structures in nuclear extrusion is not entirely clear, but supravital staining with Janus green B, a mitochondrial toxin, inhibits enucleation.[59] The extruded nucleus carries with it a rim of cytoplasm, including ribosomes, hemoglobin, and occasional mitochondria.

Enucleation is a process similar to cytokinesis during asymmetric cell division and does not seem to depend on either the presence of extracellular matrix proteins or accessory cells.[62] However, the rate of enucleation of murine erythroleukemia (MEL) cells is increased when cultured in fibronectin-coated tissue culture dishes.[63] Among the various cytoskeletal proteins, filamentous actin plays an important role in the process of enucleation, accumulating between the extruding nucleus and the incipient reticulocyte ("cortical actin ring"). Supporting the major role of filamentous actin in the process of enucleation is the fact that low concentrations of cytochalasin D cause complete inhibition of enucleation.[62] A Rac GTPase that activates mDia2, a formin involved in nucleation of actin filaments, is absolutely required for formation of the actin ring and enucleation.[64] Colchicine, which disrupts microtubule formation also impairs enucleation.[65] Interestingly, none of the major erythroid cytoskeletal proteins are found in the region of the plasma membrane that surrounds the extruded nucleus, suggesting degradation at the site of extrusion. Nurse cells are macrophages at the center of an island of erythroblasts that appear to regulate terminal erythropoiesis, supplying developmental signals and iron (and perhaps heme[66]) to adjacent erythroid cells.[67] Erythroblast macrophage protein, expressed on erythroblasts and macrophages, appears to be important for the formation of erythroblast islands and erythroblast enucleation.[68]

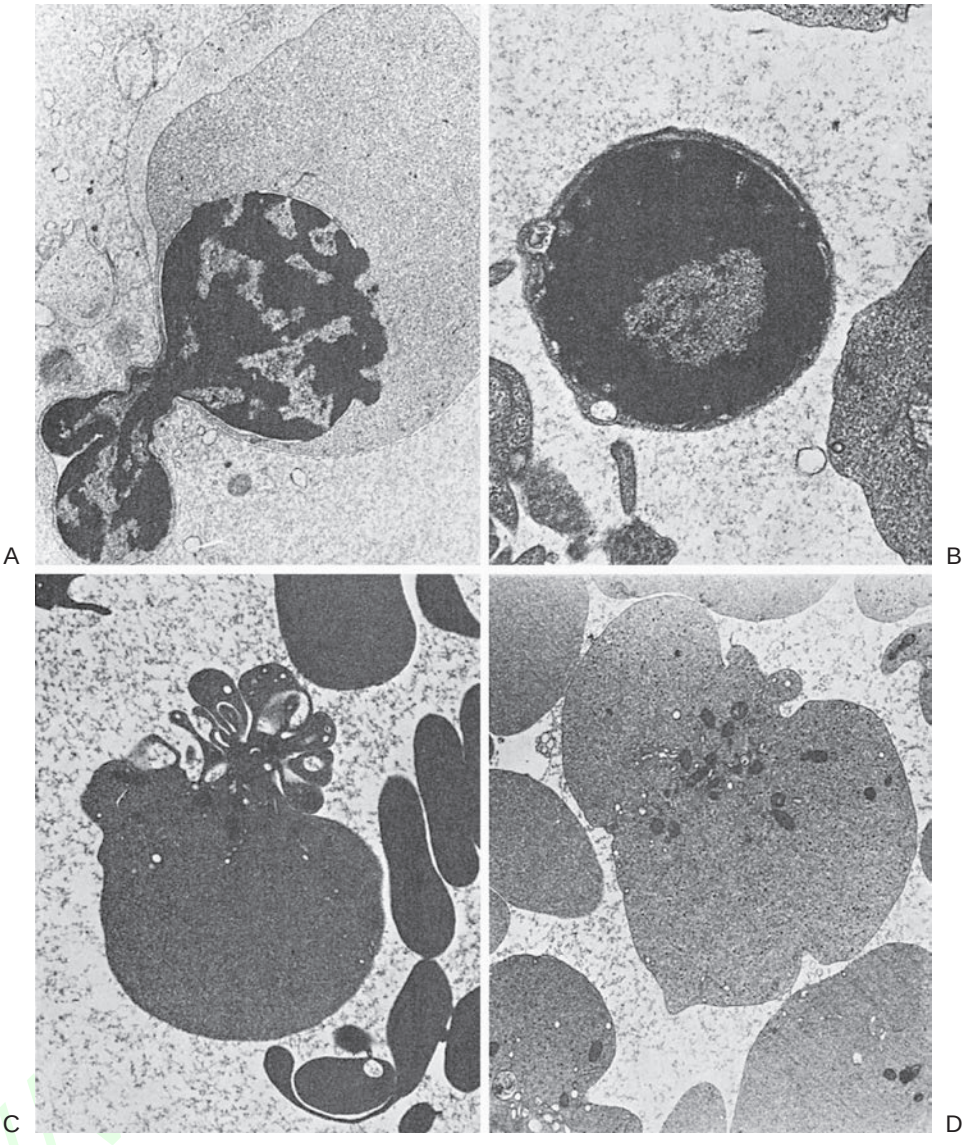

FIGURE 6.6. Formation of reticulocytes. (A) Erythroblast expelling nucleus. **(B)** Erythroblast nucleus after expulsion, with rim of cytoplasm. **(C)** Reticulocyte immediately after expulsion of nucleus. **(D)** Reticulocyte. (Courtesy of Dr. Carl Kjeldsberg.)

However, as with Rac GTPase-deficient cells, EMP-deficient erythroid cells have impaired differentiation which may decrease nuclear condensation and enucleation rates.[68] The importance of microRNAs (miRNA)—small nonprotein–coding RNAs that each down-regulate multiple genes posttranscriptionally—in erythropoiesis is being increasingly recognized.[69] Recent studies suggest a role for miR-191 in erythroid enucleation. miR-191 is normally down-regulated with erythroid differentiation; overexpression, however, represses Mxi1 and Riok3, preventing the physiologic down-regulation of Gcn5 expression, chromatin condensation, and enucleation.[38]

Within the marrow, enucleation may sometimes occur as the erythroblast traverses the endothelial cell that forms the sinus wall.[70] The erythroblast cytoplasm and small organelles (ribosomes and mitochondria) squeeze through endothelial cell cytoplasmic pores 1 to 4 μm in diameter, but the more rigid nucleus cannot conform to this pore size. The nucleus thus becomes caught and "pitted" from the cell. Passage through the endothelial pores is not essential to enucleation, however, because the whole process can be observed in vitro.[60,62] Soon after enucleation, the nucleus is engulfed by an adjacent macrophage. The cell may remain within the marrow as a reticulocyte for several days. After release, the reticulocyte may be sequestered for 1 to 2 days in the spleen.[71] Here, additional maturation may occur, and the composition of the membrane lipids may be altered. As the reticulocyte matures to an adult erythrocyte, it loses its ability to synthesize hemoglobin.[72] RNA appears to be catabolized by a ribonuclease. The resulting oligonucleotides are probably further degraded by phosphodiesterases and phosphatases to pyrimidine nucleotides. A specific pyrimidine 5′-nucleotidase found in reticulocytes dephosphorylates these nucleotides, and the free pyrimidine bases can then leak out of the cell.[73] If the pyrimidine 5′-nucleotidase is lacking because of hereditary deficiency[73] or lead poisoning,[74] RNA degradation is greatly retarded, and basophilic stippling due to retained RNA aggregates becomes prominent.

BIOSYNTHESIS OF HEMOGLOBIN

As hemoglobin accounts for approximately 90% of the dry weight of the mature red cell, the biosynthesis of hemoglobin is intimately related to erythropoiesis. As detailed in the previous section, many of the morphologic criteria used in staging the maturation of erythrocyte precursors are related to hemoglobin production and content. Furthermore, the initial events associated with the differentiation of CFU-E into erythrocyte precursors include the activation of genes relating to hemoglobin synthesis.[46]

Three complex metabolic pathways are required for hemoglobin synthesis, corresponding to the three structural components of hemoglobin: protein (globin), protoporphyrin, and iron. The first two of these are discussed in the pages to follow. Iron metabolism is described in Chapter 23.

Globin Synthesis

Globin Genes and the Structure of Chromatin

Distinct structural genetic loci exist for each of the polypeptide chains in hemoglobin (see also Chapter 34). Thus, there are α, β, γ, δ, and ε genes. In most human populations, the α genetic locus is duplicated, and there are four (two pairs of) identical α genes in normal subjects.[75,76] There are also at least two different pairs of γ genes, one (Gγ) coding for a γ-chain with glycine at position 136 and another (Aγ) coding for a γ-chain with alanine at the same position.[77] In contrast, only single (pairs of) genes code for the β- and δ-chains, respectively.

The α-gene cluster (approximately 30 kb) is located on the short arm of chromosome 16 and also contains the locus encoding for the ζ-chain,[78] while the β-gene cluster (approximately 50 kb) is located on chromosome 11 and includes the genes for the Gγ-, Aγ-, δ-, and ε-globins.[78,79] A schematic representation is shown in Figure 6.7.

The differentiation of erythroid progenitors to erythroblasts is accompanied by the activation of the genes involved in erythroid differentiation, including the globin genes.[46,80] The active genetic regions of DNA (5% to 10% of the genetic material in erythroblasts[78]) make up the open portion, or euchromatin, of nuclear material, whereas unexpressed genes (the majority of genes in the nucleus) are included in the condensed, or heterochromatin, fraction. Chromatin is described as a nucleoprotein that contains, packages, and provides an instructive scaffold for nuclear DNA.[81] Thus modulation of the expression of genes, including the globin genes may be imposed by the chromatin structure, which includes not only strands of DNA, but also histone and nonhistone proteins.

Transcription, Messenger RNA Processing, and Translation

Globin mRNA, like most eukaryotic mRNAs, is synthesized in a precursor form that is two to three times as long as the molecule that ultimately serves as the template for protein synthesis.[75,78,80] These precursor molecules, heterogeneous nuclear RNA, undergo "processing" to be converted into the final mRNA.[82] Posttranscriptional processing includes "capping" at the 5′ end of the molecule, polyadenylation at the 3′ end, and "splicing," which results in removal of so-called intervening sequences or introns. Abnormal splicing of, for example, β-globin mRNA transcripts is a common cause of thalassemia.

The primary structure of mRNA can be divided into four regions: the 5′ untranslated region (which includes the cap), the translated or coding region, the 3′ untranslated region, and the polyadenosine region. The "cap" is characterized by an atypical 5′-triphosphate-5′ linkage with guanosine-5′-triphosphate (GTP) and methylation of adjacent nucleotides. This structure appears to be essential for maximal translational activity and enhances mRNA stability. The cap is followed by an untranslated region ("5-UTR") of 36 nucleotide bases in α-globin mRNA and 53 bases in β-globin mRNA. The difference may explain the observation that β-mRNA is translated more efficiently than α-mRNA.[78,80] Normally, this relatively inefficient translation of the α-chain is compensated for by an increased amount of α-mRNA. The translated sequence begins with an initiator sequence of three bases (AUG) followed by a sequence of triplet codons, each of which corresponds to an amino acid in globin, according to the genetic code. The translated sequence ends with a terminator codon (UAA), which is followed by a noncoding area and a terminal polyadenosine region, of variable length, that affects the stability or half-life of the molecule. The number of adenosine residues appears to decrease as mRNA ages[83]; in older reticulocytes, mRNA may contain little or no polyadenosine. Globin mRNA is quite stable, with a half-life of up to 48 hours, allowing reticulocytes to continue to produce hemoglobin after enucleation.

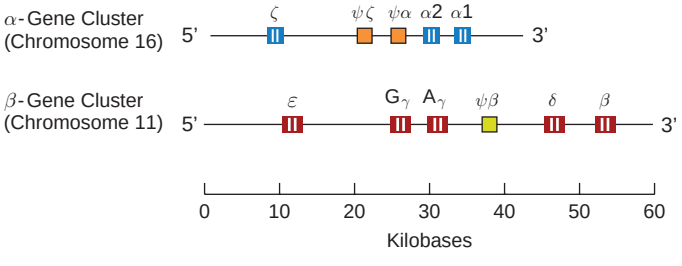

FIGURE 6.7. Organization of the human globin gene clusters on chromosomes 16 and 11. Solid areas within genes represent coding sequences; open areas represent intervening sequences. Each cluster includes pseudogenes ($\Psi\zeta$, $\Psi\alpha$, $\Psi\beta$), which have sequence homology to functional genes but include mutations that prevent their expression.

Regulation of Globin Synthesis

Heme is of particular importance in controlling the rate of globin synthesis.[84,85] It stimulates globin synthesis in intact reticulocytes and cell-free systems, and, in its absence, polyribosomes disaggregate.[86–88] The major effect of heme is exerted on the chain-initiation step in translation. In the absence of heme, an inhibitor of globin synthesis accumulates.[89,90] This inhibitor, heme-regulated eIF2α kinase (HRI), acts by phosphorylating the α-subunit of an initiation factor, eIF-2 that promotes binding of $tRNA^{met}_F$ to ribosomes, to shut down protein synthesis.[91,92] HRI, which has two heme binding sites thus serves as a sensitive intracellular heme "sensor" that closely coordinates heme availability with globin chain production to prevent the accumulation of excessive unfolded globin proteins.[93] Studies of the *hri* knockout mouse verify the importance of this protective mechanism during high-level hemoglobin synthesis. HRI function is especially important in iron (resulting in heme) deficiency: In these circumstances, the continued globin production in $hri^{-/-}$ mice results in cytotoxic globin protein precipitates, causing oxidative stress, and apoptosis of late erythroid precursors.[94] Interestingly, the red cells of iron deficient $hri^{-/-}$ mice are normocytic/hyperchromic rather than microcytic/hypochromic and have globin chain inclusions. HRI also serves to ameliorate the phenotype of β-thalassemia in mice models, minimizing the production and accumulation of α-globin aggregates, erythroid precursor apoptosis, and ineffective erythropoiesis. Recent work indicates that HRI is activated by oxidative stress (e.g., during erythropoiesis in β-thalassemia).[95]

In addition to its effects on globin translation, heme also exerts positive effects on globin transcription, through nuclear binding to the globin transcriptional repressor Bach1 during erythroid differentiation.[96]

Heme Biosynthetic Pathway

Porphyrins are heterocyclic organic rings composed of four pyrrole subunits that are usually linked by methine bridges; their conjugation to diverse divalent metal ions such as Mg^{2+}, Co^{+}, and Fe^{2+} gives rise to the "pigments of life," i.e., chlorophyll, vitamin B12, and heme, respectively. Heme, which is a complex of ferrous iron with the tetrapyrrole protoporphyrin IX, is ubiquitous in aerobic cells and essential for cellular oxidation–reduction reactions. It serves as a critical component of hemoproteins, including cytochromes (for mitochondrial respiratory chain electron transfer and drug metabolism), oxidases (e.g., NADPH oxidase) and peroxidases, and catalases and synthases (e.g., nitric oxide synthase,

NOS), in addition to the oxygen storage and transport molecules, myoglobin and hemoglobin.[97–102,103,104–106] The four pyrrole rings of protoporphyrin IX are designated A, B, C, and D. At the periphery of the tetrapyrrole are eight sites where side chains are located. In heme, the iron atom is inserted "like a gem"[105] into the center of the tetrapyrrole. Note that heme is the ferrous iron complex of protoporphyrin IX; however, the term *heme* is also used in the generic sense in the literature to indicate iron protoporphyrin IX without regard to the oxidation state (valence) of the iron.

Porphyrins, by definition, are cyclicly conjugated tetrapyrroles. As such, they have a number of common properties. They are very stable, essentially flat molecules and the macrocyclic ring itself has little or no affinity for water. All porphyrins are intensely colored and they have an extremely intense absorption band at approximately 400 nm, the so-called Soret band. All porphyrins fluoresce, but fluorescence is characteristically lost when metals are bound to form metalloporphyrins. Exceptions include Mg-porphyrins and Zn-porphyrins, which fluoresce despite their metal content (Chapter 26). Of the known porphyrins, five are of importance in humans: uroporphyrin (two isomers), coproporphyrin (two isomers), and protoporphyrin (one isomer). When porphyrins are fully reduced they are called porphyrinogens. These latter compounds are colorless, do not fluoresce, cannot bind metal ions, and are extremely unstable with regard to oxidation. If uroporphyrinogen or coproporphyrinogen (intermediates in heme biosynthesis) are oxidized to their corresponding porphyrins, they can no longer function as substrates for the heme biosynthetic enzymes and must eventually be excreted in the urine and stool. Uroporphyrinogen and coproporphyrinogen can occur in four isomeric forms. Of these, only two are known to occur naturally in mammalian tissues, namely, the I and III isomer forms. Without exception, all biologically functional tetrapyrroles are derived from uroporphyrinogen III. Uroporphyrinogen I and coproporphyrinogen I are useless by-products of heme synthesis (see Chapter 26). Once formed, most uroporphyrinogen I is enzymatically decarboxylated to coproporphyrinogen I and excreted as the oxidized compound, coproporphyrin I. The difference between the type I and type III isomers is apparent on examination of the D ring. In the type I isomer, the 7 and 8 positions are occupied by acetate and propionate, respectively. In the type III isomer, the order in the D ring is reversed, and propionate and acetate are at positions 7 and 8, respectively. Note that in the case of protoporphyrin IX, the acetate at position 8 has been decarboxylated to form a methyl group (Fig. 6.8).

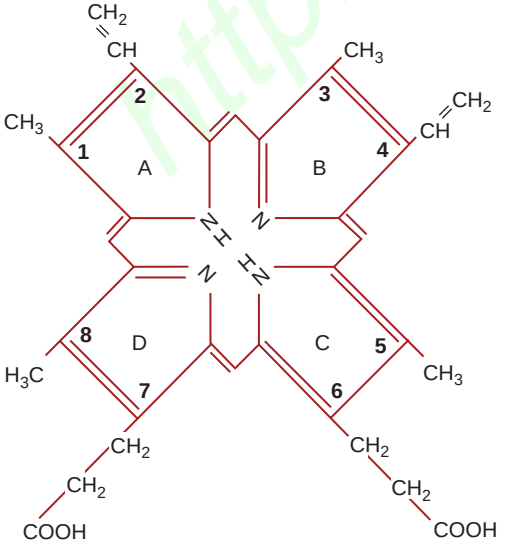

FIGURE 6.8. The chemical structure of protoporphyrin IX.

The first of eight steps in the biosynthesis of heme (Fig. 6.9) is the condensation of glycine and succinyl coenzyme A (CoA) to yield δ-aminolevulinic acid (ALA).[107,108,109] This reaction occurs in the mitochondrial matrix and is highly exergonic and essentially irreversible. The enzyme catalyzing this reaction (ALA synthase) plays a key regulatory role in the biosynthesis of heme. In the cytosol the reduced cyclic tetrapyrrole coproporphyrinogen III is formed from ALA in a series of four enzymatic reactions. Note that the product of step 2 is the monopyrrole porphobilinogen, the primary building block for all natural tetrapyrroles, including hemes, chlorophylls, and the vitamin B_{12} derivatives (cobalamins). How the heme synthesis intermediates are transferred from one cytosolic enzyme to the next in the pathway is at present unknown, but a macrocomplex comprising all four cytosolic enzymes, as has also been proposed for the terminal pathway enzymes, may occur.

Coproporphyrinogen III is then transported back by an unknown mechanism across the outer mitochondrial membrane into the mitochondrial intermembranous space for the three subsequent reactions required to form heme. First, propionic acid side chains at positions 2 and 4 are oxidatively decarboxylated by the enzyme coproporphyrinogen oxidase, forming protoporphyrinogen IX which is then oxidized by protoporphyrinogen IX oxidase to protoporphyrin IX. The enzymes protoporphyrinogen IX oxidase and ferrochelatase (Fech), catalyzing the penultimate and final steps of heme synthesis, are both localized at the mitochondrial inner membrane (protoporphyrinogen IX oxidase is an intermembrane space–facing protein whereas Fech is exposed to the matrix); thus, a channeling of protoporphyrinogen IX and protoporphyrin IX through a enzyme complex formed by protoporphyrinogen IX oxidase and Fech within the inner membrane has been proposed, based on biochemical studies and the crystal structure of the two enzymes.[110,111] The final step, the addition of one atom of Fe^{2+} to protoporphyrin IX by Fech, which results in the formation of protoheme or heme *b*, occurs on the matrix side of the inner membrane, necessitating heme transfer, by as yet unidentified transporters, across both the inner and outer membranes again in order to reach the cytosol.

Biosynthesis of δ-Aminolevulinic Acid

The enzyme responsible for catalyzing the condensation of succinyl CoA and glycine is ALA synthase (ALAS; EC 2.3.1.37). The products of the condensation reaction are ALA, CO_2, and free CoA. ALAS requires pyridoxal 5′-phosphate as a cofactor in the reaction as first suggested by nutritional studies in pigs.[112] There are two forms of the enzyme, one specific for erythroid cells (ALAS2) and the other (ALAS1) present in all other tissues, especially liver. ALAS2 uniquely appears to associate with succinyl CoA synthetase in the mitochondria to promote heme synthesis.[113] The genes encoding for human ALAS have been identified and cloned.[114] The erythroid-specific gene is present on chromosome Xp11, whereas ALAS1 is encoded by a gene on chromosome 3p21.[115,116]

ALAS1 and ALAS2 differ predominantly at their amino terminal ends. The ALAS2 gene has 11 exons and extends over 22 kb. Notably, the mRNA contains a 5′ iron-response element (IRE) in exon 1. IRE are short hairpin structures that allow binding by the iron regulatory proteins 1 and 2 (IRP1 and IRP2) according to the cellular iron status, regulating the expression or stability of mRNAs encoding proteins involved in iron uptake, storage, utilization, or export[117,118] (see Chapter 23). ALAS2 translation begins in exon 2, which encodes the mitochondrial targeting sequence for this nuclear-encoded gene. As also seen with ALAS1 the catalytic domain is encoded by exons 5 to 11. Mutations of ALAS2, especially of exons 5 and 9, are the most common cause of sideroblastic anemias (see Chapter 24). The promoter contains binding sites for GATA1, KLF1, and NF-E2 (although assays suggest the latter may not be functional[119]). However, regions further

FIGURE 6.9. Heme biosynthetic pathway. upstream may also be important for erythroid-specific ALAS2 induction.[120] In addition, analysis of intron 8 indicated the presence of DNAse I hypersensitive sites; the intron appears to contain functional binding sites for GATA1 and Sp1.[121] Of relevance, recent studies identifying *SLC25A38* as another frequent genetic cause of congenital sideroblastic anemias indicate it also affects either ALA synthesis or transport. Studies of yeast deficient in the yeast ortholog suggest the gene encodes a mitochondrial transporter mediating either ALA export into the cytosol or glycine import into the mitochondrial matrix, as ALA levels were low and the heme synthesis impairment was rescued by glycine or ALA supplementation.[122]

Biosynthesis of Porphobilinogen

The monopyrrole porphobilinogen functions as a precursor of the hemes, chlorophylls, and the cobalamins.[123] Because virtually all known forms of life require at least one of these classes

of tetrapyrroles, it follows that porphobilinogen is biologically ubiquitous. Porphobilinogen is formed by the condensation of two molecules of ALA and the loss of two water molecules. The enzyme that catalyzes this reaction is porphobilinogen synthase or ALA dehydratase (EC 4.2.1.24). ALA dehydratase is a soluble enzyme found in the cytosol[98] and abundant in tissues such as bone marrow and liver where heme biosynthesis is active. It is also active in mature circulating erythrocytes, even though these cells are not actively synthesizing heme. Its persistence results from the enzyme's inherent stability.

The mammalian enzyme is an octamer of 31 kDa subunits containing zinc atoms required for stability and activity.[124] The enzyme is inhibited by heavy metals, particularly lead, which displaces the catalytically active zinc ions and thus enzyme activity can serve as an index of environmental pollution by lead.[125,126] Free sulfhydryl groups (–SH) are also essential for activity,[127,128] and these –SH groups seem to be protected by the zinc. Three isoforms of ALA dehydratase have been reported and the gene identified (on chromosome 9q34) and cloned.[129,130] The gene consists of 12 exons, with two promoters generating different transcripts (but encoding the same protein) in erythroid and nonerythroid tissues. The erythroid promoter contains GATA1-binding and CACCC sites.

Biosynthesis of Uroporphyrinogens I and III

Porphobilinogen is a rather unstable, chemically reactive molecule. Within a few hours, a solution of porphobilinogen exposed to air and light develops a deep orange-red color. The color results from the formation of porphobilin, a poorly defined mixture of mono-, di-, and tripyrrolic oxidation products.[98] This phenomenon can be observed in the urine of patients with acute intermittent porphyria, who excrete large quantities of porphobilinogen (see Chapter 30).

If instead porphobilinogen is incubated in solution at an acid pH then nonenzymic condensation or cyclization occurs, forming the tetrapyrrole macrocycle uroporphyrinogen.[98] All four possible isomers of uroporphyrinogen are formed under these conditions. The reaction is often referred to as a "head-to-tail" condensation because of the apparent orientation of the precursor molecules. The penultimate reaction product apparently is an open-chain (linear) tetrapyrrole called hydroxymethylbiliane (HMB). On loss of the amino group attached to ring A, the $-CH_2^+$ can attack the free α-position on the D-ring pyrrole, thus forming the macrocycle.[124]

In vivo at neutral pH, these reactions are catalyzed by the cytosolic enzyme HMB synthase, formerly known as uroporphyrinogen I synthase or porphobilinogen deaminase (EC 2.5.1.61). In the cytosol HMB synthase works in concert with a second enzyme, uroporphyrinogen III synthase[131] (EC 4.2.1.75), to form uroporphyrinogen III, an asymmetric cyclic tetrapyrrole that serves as the common precursor of all known functional tetrapyrroles. Uroporphyrinogen III synthase is a very fast enzyme, outcompeting the uncatalyzed reaction of HMB that results in uroporphyrinogen I (above). HMB synthase is present in humans in two tissue-specific isoenzymes, an erythroid tissue–specific and a shorter nonerythroid form, both of which are products of a single gene located on chromosome 11q23.[98,124,132–134]

The molecular mechanism by which uroporphyrinogen III synthase effects the "turning around" of the D ring has been studied intensively.[98,135,136] The molecular mechanism involved in this reaction has been clarified by nuclear magnetic resonance spectroscopy.[123,135–137] HMB synthase first catalyzes the head-to-tail condensation of four porphobilinogen molecules, yielding the aminomethyl tetrapyrrole. The tetrapyrrole is then deaminated, yielding a macrocycle that has been termed preuroporphyrinogen,[137] which is released from the surface of HMB synthase and serves as the substrate for uroporphyrinogen III synthase.[137] This enzyme opens the bond linking the methylene bridge carbon to the D ring, allowing the D ring to rotate 180° about the carbon–nitrogen bond linking rings A and D. A new carbon–carbon bond is formed linking rings C and D (1,3-sigmatropic shift). The carbon–nitrogen bond then opens, and a new carbon–carbon bond is formed linking rings A and D (1,5-sigmatropic shift) and yielding uroporphyrinogen III.[137]

The gene for uroporphyrinogen III synthase, located on 10q25.3, has alternative promoters in nonerythroid tissues (with transcripts starting in exon 1) and erythroid tissues (transcripts begin in exon 2). As there is no translation initiation site in exon 1, however, identical transcripts are generated. The intron between exons 1 and 2 contains multiple putative GATA1 binding sites. Mutations of the uroporphyrinogen III synthase gene are associated with congenital erythropoietic porphyria (Chapter 26).

Biosynthesis of Coproporphyrinogen III

The formation of coproporphyrinogen III is accomplished by the enzymic decarboxylation of the four acetic acid side chains of uroporphyrinogen III,[99] a reaction catalyzed by the cytosolic enzyme, uroporphyrinogen decarboxylase (EC 4.1.1.37). The decarboxylation proceeds in a clockwise fashion, starting with the acetic acid on the D ring of uroporphyrinogen III and continuing with the successive decarboxylations of the acetic acid residues on rings A, B, and C.[138] The enzyme exists as a dimer and it was proposed that the two catalytic centers interact functionally, perhaps shuttling reaction intermediates between subunits.[139] Recent mutational studies, however, indicate that shuttling is unlikely: Dimerization mediates a more active enzyme than the monomer but without any change in the reaction products.[140]

The gene, located on chromosome 1p34, consists of 10 exons spread over 3 kb. Mutations of the gene encoding uroporphyrinogen decarboxylase are associated with porphyria cutanea tarda (PCT), the most common human porphyria. The structural consequences of some of these mutations have been described.[141] The genetics of the disease are complex, however, with some variants without evidence of gene mutations (sporadic PCT type I; see Chapter 30 for details). A cytosolic competitive inhibitor of the enzyme, porphomethene, has been described in a murine model of PCT as a potential explanation for PCT patients with normal levels of the protein but reduced hepatic enzyme activity.[142]

Biosynthesis of Protoporphyrinogen IX

The formation of protoporphyrinogen IX from coproporphyrinogen III is catalyzed by the enzyme coproporphyrinogen oxidase (EC 1.3.3.3). The exact location of coproporphyrinogen oxidase in the mitochondria is unknown, with studies suggesting it is present in the intermembranous space and/or loosely associated with the inner surface of the outer membrane.[143,144] It may instead form a macrocomplex with protoporphyrinogen IX oxidase and Fech to allow funneling of the substrates from the cytosol into the matrix[111] (reaction products after uroporphyrinogen III being poorly soluble in aqueous solutions). The enzyme, which has a long mitochondrial targeting sequence, functions as a dimer and has an absolute requirement for molecular oxygen.[143,145–147] It sequentially and oxidatively decarboxylates the propionic acid side chains in rings A and B (but not C or D) of coproporphyrinogen III to form vinyl groups.[148] The transporter mediating influx of cytosolic coproporphyrinogen III into the intermembranous space is unknown.

The gene encoding coproporphyrinogen oxidase is located at 3q12, contains seven exons and spans 14 kb. Studies of the murine promoter indicate that SP1, GATA1 binding sites, and a novel transcription factor–binding sequence termed CPRE are important for induction of the enzyme during erythroid

differentiation of MEL cells.[149] Mutations of the gene are associated with hereditary coproporphyria and, more rarely, with erythropoietic harderoporphyria (see Chapter 30).

Biosynthesis of Protoporphyrin IX

The product of the coproporphyrinogen III oxidase reaction is protoporphyrinogen IX. To serve as a substrate for the final enzyme in the pathway (ferrochelatase), protoporphyrinogen IX must first be oxidized to protoporphyrin IX. Although protoporphyrinogen IX is easily oxidized nonenzymatically to protoporphyrin in vitro (or in the cytosol), an enzyme is required to catalyze this reaction in vivo. A membrane-associated, mitochondrial, oxidizing dimeric enzyme—protoporphyrinogen IX oxidase (EC 1.3.3.4)—has been demonstrated in mammalian cells, including rat liver, human fibroblasts, reticulocytes, and leukocytes.[150] The crystal structure of the tobacco plant mitochondrial enzyme has been described.[111] The protein lacks a typical mitochondrial targeting leader sequence and is targeted by just 17 residues in the amino terminus.[145] Flavin adenine dinucleotide (FAD) serves as an essential cofactor and molecular oxygen is utilized to terminally accept the electrons.[144]

The gene is present on chromosome 1q23.3 and consists of 13 exons extending over 4.2 kb. The promoters of the murine and human genes have been characterized[151,152]; both contain SP1 and GATA1 binding sites that may be of importance during erythroid differentiation. Mutations of the gene are associated with variegate porphyria (see Chapter 30).

Biosynthesis of Heme

The insertion of ferrous iron into protoporphyrin IX to form heme is catalyzed by the enzyme ferrochelatase within the mitochondrial matrix. Ferrochelatase (EC 4.99.1.1) is the best characterized of the heme biosynthesis enzymes.[153] The enzyme, which functions as a dimer appears to be tightly bound to or is an integral part of the inner mitochondrial membrane,[154] likely complexed with protoporphyrinogen IX oxidase dimers on the opposite side of the membrane.[144] Insertion of the iron appears to involve distortion of the planar porphyrin by ferrochelatase.[153] No cofactors are required for activity. Although the in vivo substrates are ferrous iron and protoporphyrin, in vitro, the enzyme can also catalyze incorporation of several metals (iron, cobalt, and zinc) into several dicarboxylic porphyrins (protoporphyrin, mesoporphyrin, and deuteroporphyrin).[98]

Studies in cell lines demonstrate that ferrochelatase interacts with Mfrn1, a mitochondrial inner membrane importer of iron up-regulated during erythroid differentiation.[155] In elegant studies it has been shown that Mfrn1 is stabilized by an inner membrane ATP-binding cassette (ABC) transporter known as ABC-me or ABCB10,[156] allowing high-efficiency iron uptake into mitochondria for optimal heme synthesis.[157] Further studies show that ferrochelatase, Mfrn1, and ABCB10 are co-induced during MEL cell erythroid differentiation and that Mfrn1 and ABCB10 interact with ferrochelatase.[155] The gene encoding ABCB10 was originally identified in a screen of mouse genes up-regulated by GATA1 and expression is regulated by heme.[156] The potential substrate of the ABCB10 transporter has not been identified, but heme, which needs to be transferred from the matrix across two mitochondrial membranes into the cytosol, is a candidate.

Apart from its use for heme synthesis, mitochondrial iron is also required for mitochondrial Fe-S cluster biogenesis. Fe-S clusters are modular protein co-factors consisting of iron and sulfur, usually linked by bonds joining the cysteine sulfur atoms of a polypeptide ("scaffold") protein to iron atoms of the cluster. They function, for example, as part of enzyme catalytic centers (e.g., aconitase, succinate dehydrogenase).[158] Ferrochelatase contains a NO-sensitive Fe-S cluster that is attached at the C-terminus.[153] Although the cluster is not required for catalytic function or as a supply of ferrous iron, the enzyme is sensitive to the availability of Fe-S clusters. For example, when Fe-S cluster synthesis is impaired in MEL cells, due to deficiency of the scaffold proteins or iron required for Fe-S cluster biosynthesis, then apo-Fech is rapidly degraded in mitochondria, indicating a direct link between biosynthesis of Fe-S clusters and heme.[159]

The gene encoding ferrochelatase is comprised of 11 exons spread out across 45 kb on chromosome 18q21.3.[160] The promoter region has been examined in detail using in vitro and in vivo studies.[161–163] Sp1, NF-E2, and GATA1 elements have been identified in the promoter region and a fragment of the promoter containing these binding sites allows expression in hematopoietic cells derived from transgenic embryonic mouse cells where a single copy of the reporter construct was inserted. In vivo erythroid specificity is mediated by NF-E2 elements ~300 bp upstream of the transcriptional start site (–275 bp) along with additional erythroid-specific elements that lie between –375 bp and –1,100 bp upstream from the start site.[161] In in vitro assays in K562 cells, the Kruppel-like transcription factor KLF-13 activates the promoters for porphobilinogen deaminase, δ-aminolevulinate synthase, and ferrochelatase genes.[164] Mutations of the ferrochelatase gene are associated with erythropoietic porphyria (see Chapter 26).

Regulation of the Heme Biosynthetic Pathway

δ-Aminolevulinic Acid Synthase

The regulation of a biosynthetic pathway is generally effected at the first enzymatic reaction synthesizing a precursor compound committed to ultimate incorporation into the final product.[165] Frequently, such reactions are strongly exergonic and essentially irreversible. These generalizations hold true for the heme biosynthetic pathway. Control of the pathway is exerted primarily through the enzyme catalyzing the first committed and rate-limiting step, ALA synthase. However, what is also apparent is that the regulation of the ubiquitous enzyme ALAS1 differs markedly from that of the erythroid-specific enzyme ALAS2.[105,107]

Nonerythroid ALAS1 Regulation

About 15% of the daily production of heme is generated in the liver by ALAS1 for cytochromes and enzymes. The amount of ALAS1 is regulated by induction and repression of enzyme synthesis[127] and may increase by a factor as great as 300-fold.[166] The enzyme has a short half-life, allowing a rapid response to changes in the demand for heme and, thus, ALA.[167] The enzyme may be induced by a number of chemicals, drugs, and nonglucocorticoid steroids.[127] Heme plays a critical central role in ALAS1 regulation, repressing transcription,[168] decreasing the half-life of the mRNA, and, through binding to heme regulatory motifs (HRMs) in the 5′ end of the protein, translocation of the enzyme into the mitochondrial matrix.[169] When the amount of intracellular heme is high, ALAS1 synthesis is repressed; when the amount of heme is low, synthesis is induced. Thus, agents that interfere with heme synthesis can induce ALAS1, and agents that induce the synthesis of hemoproteins (e.g., induction of cytochrome p450 enzymes by barbiturates), potentially depleting a putative pool of "free" or "uncommitted" heme, can produce a similar effect.[170,171] Agents that exert these effects on ALAS1 synthesis induction are clinically important, as they may precipitate acute attacks in patients with acute intermittent porphyria and related disorders of porphyrin metabolism (Chapter 26).

Early studies indicated that ALAS1 synthesis is induced during fasting, which can precipitate porphyria attacks, and that nutritional supplements (e.g., glucose loading) may ameliorate

these acute episodes. Handschin et al. recently demonstrated that this occurs because ALAS1 is induced by the concerted actions of peroxisome proliferator-activated receptor γ coactivator 1α (PGC-1α) and the transcription factors FOXO1 and nuclear respiratory factor-1 (NRF-1) on the ALAS1 promoter.[172] PGC-1α, which co-activates nuclear receptors or transcription factors to regulate mitochondrial biogenesis and oxidative phosphorylation, is induced by low glucose levels or glucagon and repressed by high glucose or insulin.[173] Presumably ALAS1-mediated heme synthesis is required for de novo respiratory cytochrome synthesis with mitochondrial biogenesis as a response to decreased cellular ATP levels. In contrast, regulation of ALAS2 in erythroid cells is coordinated with heme synthesis, iron assimilation, and globin synthesis.

Erythroid ALAS2 Regulation

With erythroid differentiation there is coordination of cellular iron assimilation, heme, and globin synthesis to safely allow maximal hemoglobin synthesis within a short timespan without the buildup of individual, potentially cytotoxic components (see below). Regulation of erythroid heme involves the induction of the enzymes of the heme biosynthetic pathway and their regulation once induced,[105,107] regulation of iron uptake and its delivery to ferrochelatase in the mitochondria, and the regulated export of the newly formed heme from the mitochondria to the cytosol to bind to globin chains.

Initial studies suggested that the heme biosynthesis pathway enzymes were sequentially induced with erythroid differentiation (from ALAS2 to ferrochelatase[174]); however, subsequent studies in MEL cells[152] and maturing populations of human erythroblasts[175] indicate early up-regulation of ferrochelatase with ALAS2, with synthesis of mRNAs for the terminal three pathway enzymes up-regulated within 12 hours of erythroid induction of MEL cells with dimethylsulfoxide (DMSO). In contrast to the repressive effects of heme on ALAS1 in hepatocytes, in erythroid cells intracellular heme appears to be necessary for induction of the biosynthetic pathway enzymes, perhaps through up-regulation of the erythroid transcription factor NF-E2,[176] and/or inhibition of the transcriptional repressor Bach1.[96] For example, studies of ALAS2-deficient MEL cells following their "erythroid" induction with DMSO demonstrate a lack of erythroid differentiation (as assessed by a lack of up-regulation of mRNAs for ALA dehydratase, porphobilinogen deaminase, ferrochelatase, and β-globin) that is at least partially reversed by addition of heme to DMSO, in keeping with studies by others of ALAS2-deficient cell lines.[177]

As discussed above, unlike *ALAS1*, there is an IRE in the 5′UTR of the *ALAS2* gene. Therefore depletion of cytosolic iron (believed to exist in a putative labile iron pool) in erythroid precursors should result in binding by IRP1 and IRP2 to the IRE of *ALAS2* transcripts, preventing translation. Thus, it is the supply of iron to the erythroid precursor that ultimately controls heme synthesis. To allow maximal heme synthesis—which requires ~20 mg of iron for the 20 g of erythrocytes generated in adult humans every day—iron is delivered to the bone marrow in the form of ferric-transferrin (Fe-Tf) that is rapidly bound by TfR1 present in large numbers on the cell surface of erythroid precursors (up to 10^6 receptors per cell[178]). In addition, as noted above, the mitochondrial iron importer MFN1 becomes stabilized in a macrocomplex with ferrochelatase and ABCB10 following up-regulation of ABCB10 with erythroid differentiation, thus facilitating the transfer of iron across the mitochondrial inner membrane to ferrochelatase. By necessity, there must also be up-regulation of an unidentified heme transporter to export heme from the mitochondria into the cytosol. As a feedback mechanism "uncommitted" or "free" heme appears to inhibit either Fe-Tf-TfR endocytosis or iron release from Tf to prevent unnecessary iron uptake.[105,179] Like ALAS1, ALAS2 also has HRMs located in the 5′ end of the preALAS2 protein and, in vitro, micromolar quantities of heme inhibit translocation of ALAS2 into isolated mitochondria; however, whether excess uncommitted heme also impedes ALAS2 translocation in erythroid precursors is unknown.[169]

ALAS2 and ferritin transcripts both contain an IRE in their 5′-UTR and their translation is thus susceptible to low cytosolic iron levels; on the other hand, TfR1 contains five IRE modules in its long 3′-UTR and the mRNA should be stabilized (predominantly by IRP2[180]) under the same conditions. However, the standard posttranscriptional regulatory model involving cytosolic iron levels controlling iron transport, utilization, and storage via the IRE/IRP system (see Chapter 23) appears to become uncoupled in differentiating erythroid cells: Here ALAS2 is translated yet ferritin translation blocked, whereas high expression of TfR1 persists despite high Fe-Tf delivery. Recent analyses of mass cultures of erythroid progenitors indicate that, with differentiation, these cells behave as if a "low cytosolic iron level" condition exists.[181] This is in keeping with the "kiss and run" hypothesis of iron delivery proposed by Ponka and co-workers,[182] whereby iron released from Fe-Tf-TfR complexes in the endosome bypasses the cytosol to be delivered to the mitochondria by direct contact between these two organelles. An alternative theory is that MFN1 functions as a highly efficient mitochondrial iron importer driving cytosolic iron transfer across inner mitochondrial membranes for heme or Fe/S synthesis. In addition, it is suggested that the presence of large numbers of ALAS2 transcripts may overwhelm the IRE/IRP system.[181]

Critical Balance between Iron Assimilation, Heme, and Globin Synthesis

In closing this section, note should be made of a number of recently described mechanisms to protect erythroid precursors from the results of any imbalance among iron assimilation, heme, and globin synthesis. Although each component is essential for hemoglobin synthesis, individually they are all potentially cytotoxic and it is therefore crucial that the α- and β-globin chains and heme are produced in the 2:2:4 ratio necessary to form the stable complex of $\alpha_2\beta_2$ and 4 heme molecules that comprise hemoglobin A. The toxicity of free iron is well known, related to its intrinsic ability to generate highly reactive hydroxyl radicals from hydrogen peroxide in the Fenton reaction, whereas "free" or uncommitted heme is lipophilic and toxic to cells, promoting lipid peroxidation and ROS production, resulting in membrane injury and ultimately cell apoptosis.[106,183,184] The cytotoxicity derived from an imbalance in the production of α-globin and β-globin chains is best illustrated by the pathophysiology of β-thalassemia (Chapter 34), where the relative excess in α-globin production and the resultant precipitation of these globin chains triggers oxidative stress and cytotoxicity (first described in the 1960s[185,186]).

These protective systems include the following.

(i) The heme-regulated inhibitor of translation, HRI

As mentioned, HRI, a heme-regulated protein kinase that phosphorylates and inhibits eIF2α and thus general protein translation, serves as a sensor of intracellular heme and is important for coordinating heme and globin production. Studies of the *hri* knockout mouse verify the importance of this protective mechanism during high-level hemoglobin synthesis. HRI function appears to be especially important in iron (resulting in heme) deficiency: In these circumstances, the cessation of globin production seen in control mice presumably does not occur in $hri^{-/-}$ mice, resulting in the observed cytotoxic globin protein precipitates, ROS production and oxidative stress, and apoptosis of late erythroid precursors.[94] Interestingly, the red cells of iron-deficient $hri^{-/-}$ mice are normocytic/hyperchromic (rather than

microcytic/hypochromic, as observed in the iron-deficient control mice), have globin chain inclusions, and a more severe anemia. Similarly, mice with combined HRI and severe ferrochelatase deficiency ($Fech^{m1Pas/m1Pas}$ mice, another model of heme deficiency) have more severe anemia and globin chain inclusions than control $Fech^{m1Pas/m1Pas}$ mice. Notably, these mice have a 30-fold increase in red cell protoporphyrin IX compared with $Fech^{m1Pas/m1Pas}$ mice, emphasizing that HRI-mediated regulation of erythroid precursor protein synthesis also affects heme enzyme biosynthesis and the severity of the porphyria.[172]

HRI also ameliorates the phenotype of β-thalassemia in mice models, minimizing the imbalance in production between α- and β-globins, the accumulation of α-globin aggregates, apoptosis of erythroid precursors, and the resultant ineffective erythropoiesis. Recent work indicates that HRI is also activated by oxidative stress (e.g., during stress erythropoiesis or erythropoiesis in β-thalassemia).[95] HRI, by activating the transcription factor ATf4, induces an antioxidant stress response that seems to be important for erythroid differentiation.

(ii) The feline leukemia virus subgroup C receptor, FLVCR

FLVCR1 is the human ortholog of the feline cell surface receptor for feline leukemia virus subgroup C (FeLV-C). The virus infects all feline hematopoietic cells, impairing feline FLVCR1 function due to binding of the receptor by viral envelope that is continuously synthesized within infected cells. Cats infected with FeLV-C develop a red cell aplasia characterized by a block in erythroid differentiation at the CFU-E/proerythroblast stage. The impairment in differentiation is also observed upon conditional deletion of *flvcr1* in neonatal mice,[187] who develop a severe anemia within 5 weeks of deletion[187] that may be due to erythroid cell apoptosis.[188] FLVCR1 functions as a mammalian cell–surface heme exporter that thus appears to protect differentiating erythroid progenitors from potential heme excesses and subsequent cytotoxicity resulting from any imbalances between heme and globin synthesis.[104,188] As noted, heme synthesis by erythroid ALAS2 is not subject to transcriptional repression by heme and catabolism by heme oxygenases does not normally occur during differentiation of human erythroid progenitors[189] or murine erythroid cell lines.[190] It is hypothesized that heme oxygenase is not induced in order to prevent futile cycles of simultaneous erythroid heme synthesis and catabolism.[188,189] The severity of the anemia in feline and murine models of FLVCR knockdown suggests that excess heme synthesis occurs frequently at the CFU-E/proerythroblast stage (likely prior to initiation of high-level globin synthesis) or that FLVCR has yet another cell function. A recent study suggests another FLVCR isoform functions to export heme from its site of synthesis in the mitochondria into the cytosol[190a]. Of interest, knockdown of murine *flvcr1* is embryonic lethal with the embryos displaying a phenotype similar to that of patients with Diamond-Blackfan anemia (DBA), a congenital red cell aplasia.[191] The most common genetic cause of DBA is haplo-insufficiency of large or small ribosomal protein subunits, impairing erythroid protein (i.e., predominantly globin) synthesis, suggesting DBA is caused by an imbalance of heme and globin synthesis.[192]

(iii) The α-hemoglobin stabilizing protein, AHSP

The gene encoding this small protein (102 aa) is strongly induced by GATA-1 during erythroid differentiation. AHSP primarily binds αHb (i.e., the holoprotein, α-globin–heme), stabilizing it and inhibiting its pro-oxidant properties.[53] It functions as a chaperone, helping newly synthesized apo α-globin chains to fold and promoting the refolding of denatured chains, which may be particularly important in heme deficiency.[193] Studies have shown that AHSP forms a heterodimer with αHb and when βHb is added to these complexes, the AHSP is displaced and tetrameric HbA ($\alpha_2\beta_2$) forms, suggesting that AHSP stabilizes αHb and then passes it to βHb to help form HbA in vivo. Deletion of the gene in mice[194] results in a mild hemolytic anemia with the red cells containing Heinz bodies (eosinophilic inclusions derived from denatured hemoglobin), indicating perhaps that AHSP function is critical only when there is a large imbalance in synthesis between αHb and βHb, such as occurs in β-thalassemia. In subsequent studies, interbreeding of $AHSP^{-/-}$ mice with β-thalassemic mice (like the *Hri* knockout above) was indeed shown to worsen the β-thalassemic phenotype.[195]

Lastly, "protein quality control mechanisms" has been proposed as a name for a number of cellular posttranslational mechanisms that serve to stabilize and aid folding of newly forming proteins (e.g., chaperones such as AHSP), or recognize misfolded proteins or protein aggregates and target them for degradation by the ubiquitin proteosome system or autophagy.[196] These protein quality control mechanisms appear to be particularly important in erythroid precursors during high-level hemoglobin synthesis, and when these systems are overwhelmed—for example, in severe thalassemias—accumulation of unstable insoluble proteins and cytotoxicity occurs.[197]

CONTROL OF ERYTHROPOIESIS

It is evident that a well-balanced mechanism exists that maintains the erythron within "normal" limits and mediates the response to a variety of normal and abnormal situations. In broad outlines, this control system operates in the following manner. Alterations in the concentration of hemoglobin in the blood lead to changes in tissue oxygen tension within the kidney. In response to hypoxia, the kidney secretes a hormone called Epo. This hormone induces differentiation of erythroid progenitor cells, expansion of the erythroid marrow, and increased red cell production. This, in turn, leads to an increase in the size of the erythron and an increase in tissue oxygen levels. The major steps in this process are discussed in greater detail in the sections that follow.

Tissue Oxygen

Tissue oxygen tension depends on the relative rates of oxygen supply and demand. Oxygen supply is a complex function of interacting but semi-independent variables, including (a) blood flow, (b) blood hemoglobin concentration, (c) hemoglobin oxygen saturation, and (d) hemoglobin oxygen affinity. Each of these functions may be altered to compensate for a deficiency in one of the others. For example, in severe anemia, cardiac output and respiratory rate may increase, and hemoglobin oxygen affinity may be reduced through the 2,3-biphosphoglycerate effect. Conversely, in respiratory insufficiency, secondary polycythemia occurs.

Despite cardiovascular and respiratory adjustments, tissue oxygen tension decreases roughly in proportion to the degree of anemia. Conversely, induced polycythemia of moderate degree leads to normal or increased tissue oxygen tension and an increased tolerance to hypoxia. These changes occur despite the increase in blood viscosity that accompanies polycythemia, suggesting that peripheral vascular resistance decreases to compensate for increased viscosity. However, with advanced degrees of polycythemia, the increase in viscosity may be great enough to negate the advantages of increased oxygen-carrying capacity.

Tissue hypoxia is the fundamental stimulus to erythropoiesis, as first suggested by Miescher in 1893. This concept has been amply confirmed.[2] However, hypoxia does not exert its effects by a direct action on the marrow, as Miescher believed, but instead induces a hormone, Epo. The nature of the tissue oxygen receptors (or oxygen sensor) has only recently been understood. These sensors are located within the kidney and Epo production can be induced by renal artery constriction or by hypoxic perfusion of the isolated kidney.

Erythropoietin

Structure of Erythropoietin

Epo is a glycoprotein hormone produced by the kidney, which functions as the major humoral regulator of red cell production. The hormone was originally purified from the urine of patients with aplastic anemia.[198] It has an MW of 34 kDa as determined electrophoretically and contains 30% carbohydrate (11% sialic acid, 11% total hexose, and 8% *N*-acetylglucosamine).[199] The potency of Epo is expressed in units, with one unit defined as the amount of Epo present in one tenth of the International Reference Preparation.[200] This unit was originally defined in starved rats as the amount of Epo that produced the same erythropoietic response (increase in serum Epo level) as treatment with 5 μmol of cobalt.[2] The potency of purified human urinary Epo has been determined to be 70,400 U/mg of protein.[198]

The *Epo* gene has been isolated and cloned[201]; the genomic locus extends over 5.4 kb on chromosome 7q22[202] and contains four introns and five exons, encoding a 193–amino acid polypeptide. The protein includes a 27–amino acid signal peptide, which is cleared during Epo secretion, and a 166–amino acid peptide with an MW of 18.4 kDa.[46] The C-terminal arginine is absent from the recombinant and native proteins, presumably because of posttranslational modification by a carboxypeptidase.[203] Human Epo contains four cysteine residues linked by disulfide bonds, which, when reduced or alkylated, lead to significant loss of activity.[199,204]

Recombinant Epo (rEpo), as synthesized by mammalian cells such as a Chinese hamster ovary cell line, is highly glycosylated, and the carbohydrate structure of the recombinant hormone is similar to but distinct from the glycosylation pattern of native Epo in kidney cells.[203] Glycosylation is absolutely necessary for in vivo activity of Epo, with the bulk of glycosylation occurring at a single site of N-linked carbohydrate. Asialated Epo and nonglycosylated rEpo produced in bacteria have no activity in vivo, which is at least partially attributed to rapid clearance of the hormone by the liver via hepatocyte galactose receptors.[205,206]

Recognition of the importance of glycosylation of Epo to its in vivo activity and half-life led to modifications of the Epo gene/protein to make a more effective pharmaceutical. For example, the gene has been modified by adding a second site of N-linked glycosylation, such that when the gene is expressed in Chinese hamster ovary cells, the amount of carbohydrate attached to the modified protein is almost doubled. This new product, called darbepoetin, has a longer in vivo half-life than rEpo, thus fewer injections per week are required for therapeutic efficacy.[207]

Studies on the amino acid sequences of human and murine Epo have shown a very high degree of conservation of the molecule structure in these two species.[208,209] Analyses of the NMR structure of Epo and the crystal structure of Epo complexed to the extracellular component of the EpoR have been performed.[210] Similar to the structure of hGH and GCSF (Chapter 5), Epo consists topologically of a bundle of α-helices (four in Epo[210]). Two Epo-EpoR binding sites on Epo have been identified, a high-affinity site 1 ($K_d \sim 1$ nM) and low-affinity site 2 ($K_d \sim 1$ μM).[211] The studies are in keeping with the interaction of a single molecule of Epo with EpoR dimers.

Site and Regulation of Erythropoietin Production

More than 50 years ago Jacobson et al. established that the kidney is the major site of Epo production in adult rats.[212] Humans with end-stage renal failure were also found to have low serum Epo concentrations, which were restored to normal following renal transplantation.[213] The cloning of the murine Epo gene has allowed studies on the production of Epo-specific mRNA in anemic mice. Induction of anemia leads, within an hour, to the appearance of Epo-encoding mRNA in the kidney and liver of anemic mice and rats.[213,214] After bleeding, the Epo mRNA in the kidney increases 500 to 1,000 times when compared with Epo mRNA levels in normal kidney, whereas the liver produces only 7% of the total Epo mRNA.[215] These changes in Epo mRNA synthesis are followed by parallel changes in serum Epo concentration, as determined by radioimmunoassay, indicating that Epo production in response to anemia represents de novo synthesis rather than the release of preformed hormone.[214] Murine Epo mRNA is detectable by ribonuclease protection assay at 14 days of gestation in the fetal liver and a week later in the kidneys, which assume a major role in Epo production after birth.[216] In cases of paraneoplastic erythrocytosis, Epo mRNA is detected in the neoplastic cells.[217,218]

Specialized cells producing Epo have been identified in renal and hepatic parenchyma by in situ hybridization techniques, using radioactive probes specific for Epo mRNA.[216,219,220] These rare Epo-producing cells are found in the renal parenchymal interstitium (outside the tubular basement membrane), predominantly in the inner cortex and outer medulla. The bulk of experimental evidence indicates that these are fibroblast-like type I interstitial cells.[221,222] In the liver, Epo mRNA is detected in hepatocytes. The number of interstitial renal Epo-producing cells increases (approximately exponentially) in response to anemia, indicating that increased Epo production is met by an increase in the number of Epo-producing cells; presumably with worsening anemia, increased numbers of these cells become sufficiently hypoxic to trigger Epo synthesis.[62] Notably, there is no detectable storage of the hormone, and increased levels of circulating Epo do not repress further Epo production. Epo and EpoR are also expressed at low levels in other tissues including the spleen, bone marrow, lung, testis, eye, and brain.[223] A possible paracrine function, potentially supporting low-level erythropoiesis, has been ascribed to Epo production within bone marrow hematopoietic progenitors,[224,225] and production of Epo within the CNS appears to protect EpoR-bearing neurons from ischemic damage and apoptosis.[226,227]

The mechanism by which hypoxia leads to Epo synthesis has been determined. A sequence located in a region flanking the 3′ end of the *Epo* gene is oxygen-sensitive and involved in regulation of expression.[227] It has been shown, for example, that this oxygen-sensitive enhancer sequence when fused to a plasmid construct comprising the *Epo* promoter and a reporter gene confers to transfected cells the ability to respond to hypoxia as detected by an increase of the protein encoded by the reporter gene and studies of transgenic mice expressing defined 5′ or 3′ sequences of the human *Epo* gene support these findings.[228] The ligand for this oxygen-sensitive enhancer was identified as a 120 kDa protein termed hypoxia-inducible factor 1 (HIF-1).[228,229] This DNA-binding protein is tightly regulated by intracellular oxygen tension and serves as the physiologic regulator of Epo transcription.[230]

HIFs are heterodimeric helix-loop-helix transcription factors consisting of two subunits, an oxygen-labile protein, HIF-α, and a constitutively expressed β subunit, HIF-β.[231] Note that three genes, HIF1A, HIF2A or EPAS1, and HIF3A, encoding different isoforms of HIF-α are present in the human genome; here HIF-α refers to HIF-1α or HIF-2α. The concentration and transcriptional activity of HIF-α increase in a geometric fashion upon exposure to hypoxia. HIF-α mRNA is constitutively expressed under normoxic conditions, but the protein is rapidly degraded via the ubiquitin proteosome complex following binding by von Hippel-Lindau protein (pVHL). The recognition of HIF-α by pVHL requires prior hydroxylation of specific HIF-α proline residues by prolyl-hydroxylase domain (PHD)-containing proteins.[232–235] These PHDs are oxygen- and iron-dependent enzymes. Under hypoxic conditions, little or no proline hydroxylation takes place; thus, pVHL does not bind to HIF-α, which accumulates in the nucleus, heterodimerizes with HIF-β, and recruits the transcriptional coactivators p300/

CREB-binding protein, with the whole complex then binding to the *Epo* enhancer to positively influence *Epo* promoter activity and gene transcription. The recruitment of p300 to the complex can itself be inhibited by hydroxylation of asparagine-803 in HIF-α, which is catalyzed by asparaginyl-hydroxylase, another oxygen-sensitive enzyme.[236] It seems that these two amino acid hydroxylases, by their dependence on normal intracellular oxygen for their function, act as the oxygen sensor in the Epo-producing interstitial cells in the kidney, and, by regulating the function of HIF-α at two distinct points,[235] ultimately control Epo synthesis and production. Not surprisingly, mutations of this pathway may be associated with an increased red cell mass: Chuvash polycythemia is due to a homozygous mutation of *Vhl* that impairs HIF-1α degradation, resulting in a mild increase in Epo levels[237] whereas mutations of the genes encoding HIF-2α or PHD2 are rarer causes of familial erythrocytosis.[238]

In addition to Epo, a large number of other HIF target genes (e.g., glucose transporters, glycolytic enzymes, and vascular endothelial growth factors) are up-regulated during hypoxia to aid cells adapt to hypoxic conditions.[239] Apart from the indirect effects of hypoxia on erythropoiesis through HIF-mediated renal Epo production, erythroid progenitor cells are also subject to direct cellular effects of hypoxia and HIF production. A recent analysis of early erythroid progenitor genes up-regulated by glucocorticoids (such as cortisol, which is released from the adrenal glands during acute anemic or hypoxic "stress erythropoiesis"[38,240]) found that the promoter regions of many of these erythroid cell genes also contain HIF binding sites. Furthermore, in in vitro studies, HIF synergizes with glucocorticoids to expand erythroid progenitors dramatically, perhaps by increasing BFU-E progenitor self-renewal,[38] a HIF effect previously observed by others during stress erythropoiesis.[241]

Action of Erythropoietin

Erythropoietin Receptors

Epo binds to specific molecules on the cell surface, the EpoR. The expression of both Epo and EpoR is necessary for adult life. Deletion of either of the genes encoding for Epo or EpoR in mice results in the identical phenotype of fetal death at embryonic days E11.5 to E13.5 because of a lack of definitive erythropoiesis in the fetal liver and severe anemia.[242] Arguably, the most important control point of erythropoiesis is the interaction of Epo with the receptor for Epo.[38,243–245] The activation of EpoR generates an intracellular signal in immature erythroid cells that promotes survival of cells that would otherwise undergo apoptosis. Epo also appears to promote erythroblast proliferation and differentiation.

EpoR is expressed on hematopoietic cells that respond to Epo and has been identified on human[12] and murine erythroid cells,[216] on erythroleukemia cell lines,[216] in murine fetal liver tissue rich in erythroid elements, in mouse and rat placenta,[217,246] and on megakaryocytes.[246,247] EpoR expression on erythroid cells is relatively low (approximately 1,000 molecules per cell) and correlates with the cell's responsiveness to and dependence on Epo.[247] EpoR is detectable by autoradiography on human BFU-E; its density increases as BFU-E matures to CFU-E.[19] Erythroid cells at a stage between CFU-E and proerythroblast seem to have the highest density of EpoR, which decreases as the proerythroblast matures and eventually disappears at the stage of orthochromatic erythroblast.[19,246] The receptor is not expressed on reticulocytes or red cells. The presence of EpoR on megakaryocytes[246–248] explains why Epo at physiologic concentrations promotes megakaryocyte differentiation and can thus affect platelet levels. Receptors for Epo are also observed on nonhematopoietic tissues including neurons and cardiac myocytes, endothelial cells, the kidneys, and embryonic muscle. The expression of EpoR in nonerythroid tissues was not believed to be required for normal embryonic development as erythroid tissue-specific EpoR expression (under control of the GATA-1 promoter) in EpoR$^{-/-}$ embryonic stem cells gives rise to apparently normal mice.[249] However, recent studies indicate that EpoR$^{-/-}$ murine embryos develop neural defects,[250] defects in angiogenesis,[251] and cardiac ventricular hypoplasia, which is not a result of generalized hypoxia.[252] In addition, some of the adverse effects observed in patients with certain solid tumors receiving Epo have been ascribed to activation of EpoR expressed on tumor cells.[253]

The MEL EpoR gene encodes a 507–amino acid peptide of 62 kDa with extracellular, single-membrane–spanning and intracellular domains.[254] The EpoR undergoes glycosylation and phosphorylation before being incorporated into the cell membrane as a 70 to 78 kDa protein.[254] Cells transfected with this gene express both high- and low-affinity EpoR.[254] The human gene is located on chromosome 19p13.2, encodes a protein of 508 aa, and is 68 to 72 kDa depending on the degree of glycosylation.[255]

It is now recognized that structurally EpoR is part of a large family of type I cytokine receptors, which includes receptors for IL-2 to IL-7, GM-CSF, and Tpo. Type I cytokine receptors share basic structural features and are characterized by four conserved cysteine residues and a tryptophan-serine-x-serine-tryptophan (WSXSW) motif in the extracellular domain and by conserved box1/box2 regions in the intracytoplasmic domain adjacent to the membrane. Some of these type I cytokine receptors share common subunits and thus are heterodimeric; however, the receptors for Epo, Tpo, and G-CSF consist of homodimers.[256,257] Crystallographic studies confirm that, as is seen with other cytokine receptors, one molecule of Epo simultaneously binds to two EpoR.[258] After binding, both Epo and EpoR are rapidly endocytosed and degraded.[12,216,247,255] Although it is clear that EpoR activation by Epo can lead to formation of EpoR homodimers,[259] evidence also indicates these dimers exist prior to Epo binding, and that binding shifts and stabilizes an active receptor conformation bringing the two EpoR into closer contact.[260,261]

EpoR signaling pathways are outlined in Figure 6.10. Tyrosine phosphorylation of the EpoR[262] is the first observable event after Epo binding. Because EpoR lacks a kinase domain, a tyrosine protein kinase must therefore associate with the receptor. JAK2, a member of the Janus family of cytoplasmic tyrosine kinases, is the primary EpoR-associated kinase and binds to a conserved sequence of amino acids found in cytoplasmic domains of the EpoR[263,264] (and other receptors related in sequence to EpoR). Interestingly, recent studies indicate that the activation of EpoR through binding of Epo initiates a scissorlike rotation of the EpoR dimers, separating the intracellular domains of the two receptor molecules to allow room for the associated Jak2 molecules; in addition there appears to be a self-rotation of each monomer to allow them to orient properly for transphosphorylation of Jak2.[265] Deletion of the JAK2 gene in mice results in fetal death on days 12 to 13 that is associated with a severe anemia mirroring the phenotype after deletion of Epo or EpoR,[266] indicating the importance of Jak2 for Epo signaling.

To summarize current research,[38,243–245] one Epo molecule binds two EpoR molecules, activating JAK2 kinases associated with the juxtamembrane regions (box 1/box 2) of each receptor by physically bringing the inactive (or low-activity) kinases into close proximity during the induced rotational shift in EpoR conformation,[267] such that these kinases cross-phosphorylate each other, gaining full activity. The activated kinases phosphorylate all eight conserved tyrosine residues of the EpoR cytoplasmic tail. The phosphorylated tyrosine (PY) residues then serve as docking sites for up to 20 different signaling molecules or adaptor proteins that may be phosphorylated by JAK2 to become active, and leading to various mitogenic, differentiative, and antiapoptotic responses. The signaling molecules and adaptor proteins contain either Src homology 2 (SH2) or other phosphotyrosine binding domains that mediate recognition of a PY residue in the context of specific

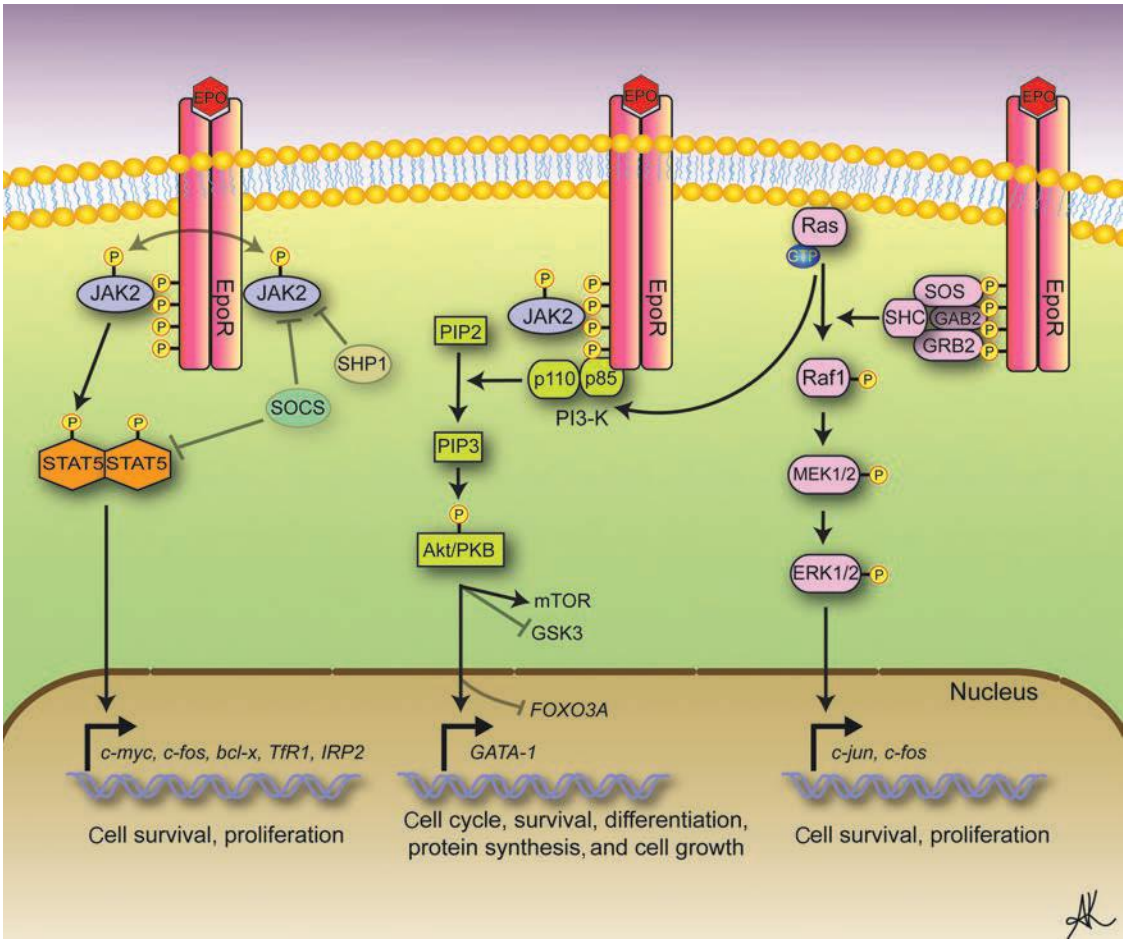

FIGURE 6.10. Overview of the erythropoietin receptor signaling pathways. Conformational changes in EpoR dimers induced by Epo binding facilitate the activation of EpoR-associated Jak2 kinases. Jak2 kinase activation results in phosphorylation of several tyrosines in the EpoR cytoplasmic tail that then serve as docking sites for signaling or adaptor proteins containing phosphotyrosine-binding domains. The signaling proteins become phosphorylated and function in numerous downstream signaling cascades. (1) A major target of Jak2 is Stat5, which is phosphorylated, dimerizes, and travels to the nucleus where it activates genes important for cell survival and proliferation. (2) Binding of the regulatory subunit of PI3-kinase, p85, to EpoR phosphotyrosines results in phosphorylation of membrane lipids and the downstream activation of Akt. This kinase regulates cell-cycle, cell differentiation, and pro-survival pathways and modulates metabolism and protein translation. (3) The ras/raf/MEK/ERK pathway is activated with binding of the SHC/GRB2/SOS complex to EpoR phosphotyrosines. Activation of the downstream kinase ERK1/2 results in phosphorylation of ELK1, a transcription factor important for cell survival and proliferation (via c-jun and c-fos expression). Negative regulatory proteins are necessary to dampen EpoR signaling. SOCS proteins inhibit Jak2 and Stat5 activation whereas phosphatases such as SHP1 and SHIP inhibit other phosphorylation-dependent pathways. Note that other EpoR pathways, such as activation of calcium-dependent isoforms of the PKC family of serine/threonine kinases, are not shown. See text for details.

adjacent (EpoR) amino acids. The major pathways activated by Epo binding to EpoR include the signal transduction activator of transcription 5 (STAT5) pathway, and the phosphatidylinositol-3-kinase (PI3-kinase)/Akt and ras/raf/MAPK (mitogen-activated protein kinase) signaling cascades (Fig. 6.10).

Upon binding to EpoR at PY343 (EpoR numbering here refers to the murine protein), STAT5 is phosphorylated by Jak2,[268] dimerizes, and translocates to the nucleus to mediate gene transcription (e.g., of the mitogenic transcription factor *c-myc*, *Id1*,[10] *TfR1*, and *IRP-2*[269]). Targeted deletions of the eight potential PY residues in EpoR, to dissect the Epo/EpoR/Jak2 signaling axis, have also revealed the importance of pathways downstream of Jak2.[270] Although deletion of all eight residues results (surprisingly) in only mild anemia (the hematocrit in adult mice is reduced by 25% to ~0.37),[271] restoration solely of Epo/EpoR/Jak2/STAT5 signaling (i.e., by deletion of all tyrosines except the *Y343* residue) results in near–wild–type EpoR activities,[272] and in particular, STAT5 signaling restores the erythron capacity for proliferative, stress erythropoiesis responses. The precise role of STAT5 in EpoR signaling in steady-state erythropoiesis, however, is still unclear. STAT5 is expressed from two very similar genes, STAT5a and STAT5b. In animal studies in which both genes were deleted or "knocked out" (STAT5a/b$^{-/-}$ mice), a marked fetal anemia was reported with lesser but significant anemia in newborn and adult animals.[273] More recent studies indicate these knockout STAT5a/b$^{-/-}$ animals contain hypomorphic rather than null STAT5a/b$^{-/-}$ alleles, expressing an N-terminally truncated phosphorylated Stat5 in erythroblasts that appears to retain some biologic STAT5 functions.[274] In addition, Epo weakly activates other STATs in primary erythroid cells, such that STAT3[269] and/or STAT1 activation[274] may also partially compensate for STAT5, resulting in a relatively mild inhibition of murine erythropoiesis.[275]

A potential target of STAT5 is the *Bcl-x* gene, which encodes an antiapoptotic protein, Bcl-x_L, believed to be essential for Epo-dependent survival. Two recent studies of Bcl-x_L–deficient animals confirmed Bcl-x_L expression is required for normal erythropoiesis, but also demonstrate that it promotes the survival of mature erythroid cells that no longer depend on Epo for survival.[276,277] Thus, Bcl-x_L must also be regulated by factors other than Epo-activated STAT5,[274] likely the interplay of GATA-1 and Gf-1B at the *Bcl-x* promoter.[278] Epo/EpoR signaling may promote survival earlier, at the proerythroblast stage, through up-regulation of a

number of other antiapoptotic genes including Pim1, Pim3, Trib3, and Serpina 3g.[255]

The distal end of the EpoR cytoplasmic domain and phosphorylation of Y479 are required for activation of the PI3-kinase/Akt and MAP kinase signaling cascades (Fig. 6.10). Binding of the p85 regulatory subunit of PI3-kinase to EpoR mediates translocation of the kinase from the cytoplasm to phosphorylate lipids at the cell membrane,[279] resulting in modulation of survival, metabolism, and translation through the subsequent effects of Akt (a kinase directly downstream of PI3-kinase) on mTOR, GSK3, FOXO, and GATA-1 transcription factors.[280,281] The central role of PI3 kinase in signaling downstream of the receptor for Epo is suggested by the ability of a constitutively active Akt partially to rescue erythroid development when expressed in JAK2$^{-/-}$ fetal liver cells.[280] With regard to the ras/raf/MAPK cascade, Jak2-initiated phosphorylation of tyrosines at the distal end of EpoR allows a *Shc* adaptor protein to associate with the receptor, which then recruits GRB2 and SOS, resulting in activation of cell membrane–bound Ras and then Raf activation. This signaling cascade gives rise (via MEK) to phosphorylation of ERK1/2 which subsequently phosphorylates up to 60 substrates, promoting erythroid cell-cycle progression and proliferation.[282] In contrast to the two pathways described above, however, knockdown of Ras in erythroid cells has only subtle effects on terminal erythropoiesis.[283] Although Epo may act on progenitor cells to promote survival, drive proliferation, and direct erythroid maturation, it is not clear if some intracellular signaling pathways can distinctly activate only one of these events. Epo-dependent activation of the PI3-kinase pathway appears important for both cell survival and proliferation whereas the MAP kinase pathway appears more important in directing proliferation.[279]

Apart from these three major pathways there are a number of other well-described mediators of responses downstream of Epo/EpoR that likely affect erythropoiesis. These include the inositide-specific phospholipases C (e.g., knockdown of the PLC-γ isoform impedes erythroid development[284]) and the protein kinase C pathways (e.g., inhibition of the PKCα isoform impairs Epo-induced differentiation, whereas PKCε up-regulation protects erythroid cells from TRAIL-induced apoptosis[285,286]). In addition, knockdown of the Src family tyrosine kinase Lyn results in attenuated EpoR signaling and decreased erythroid precursor survival.[270,287,288] The adaptor SH2-containing proteins CrkL (which is phosphorylated by Lyn and indirectly activates Erk1/2[289]), Lnk (which attenuates JAK2 signaling[290]), and Spry1, which appears to down-regulate Erk1/2 and Jak2 activation[291] also appear to be important regulators of EpoR signals. Of interest, recent studies indicate that polymeric IgA (pIgA1–oligomers of IgA joined by their J-chains), produced in small amounts by plasma cells, binds to TfR1 present on the erythroblast cell surface. Binding of pIgA1 or Fe-Tf to TfR1 appears to transmit an intracellular signal that results in activation of erythroblast Akt and ERK1/2, stimulating erythroblast proliferation and differentiation.[292] This pathway may be important to boost erythroid output during stress erythropoiesis as hypoxia increases pIgA1 levels, or during iron deficiency when Fe-Tf levels are low. Recent studies identify over 160 genes that are significantly affected by Epo/EpoR signaling in murine primary bone marrow derived CFU-E-like progenitors,[255] suggesting much remains to be learned.

As is found with other cell signaling cascades there is a need for checks and balances in the form of inhibitory or regulatory factors, to prevent overstimulation of erythroid cells by Epo/EpoR-mediated growth and survival signals. The distal end of EpoR, for example, acts as a negative regulatory domain to which SH2-containing tyrosine protein phosphatases dock (to PY401, 429, 431) to dephosphorylate substrates such as Jak2 and STAT5 and attenuate Epo signaling. For example, a transgenic animal expressing a truncated human receptor Epo developed severe erythrocytosis, mimicking primary familial and congenital polycythemia (PFCP, see Chapter 44) where patients have elevated red cell mass due to mutations in the EpoR gene.[293] A number of kindreds with PFCP due to mutations in this distal regulatory region of EpoR have since been reported.[294] Identified regulatory phosphatases[295] include the SH2-containing tyrosine phosphatases SHP1, SHP2 (PTPN11[32]), and PTP-1B. Other regulatory factors include the control of EpoR trafficking from the ER by Jak2,[296] EpoR internalization upon interaction with Epo,[297] proteasomal degradation of EpoR[298] and signaling adaptor molecules, and the inducible expression of specific inhibitors such as the suppressor of cytokine signaling protein family members SOCS-1, SOCS-3, and CIS-1 (cytokine inducible SH2-containing protein) by STATs. The SOCS family of proteins down-regulates receptor signaling in a negative feedback manner by (a) competing with STAT5 for binding to EpoR phosphotyrosines and (b) binding and inhibiting the Jak2 kinase activation loop, or (c) ubiquitination and proteosomal targeting of Jak2.[299]

The *Epo* gene has been incompletely deleted in 8-week-old mice using a conditional knockout strategy,[300] reducing renal *Epo* gene expression by 95% compared with controls.[301] This animal serves as a model of the Epo/EpoR interactions that likely occur in patients with renal failure, with decreased steady-state erythropoiesis, and a chronic normocytic, normochromic anemia that is moderate (Hct ~75% of control), related to residual Epo production. Remarkably, despite the severe knockdown in Epo expression the animals appear to have normal stress erythropoiesis responses, as they recover normally from acute hypoxic stress (induced by phenylhydrazine-induced hemolysis), indicating the importance of other mechanisms such as glucocorticoids, hypoxia, BMP4, and SCF in supporting murine stress erythropoiesis.[38,240]

Abnormal Epo/EpoR Signaling

In addition to human erythrocytosis related to excessive stimulation of Epo production by HIF or pVHL mutations (see above), a point mutation of the extracytosolic domain of murine EpoR (R129C, a substitution of cysteine for arginine at position 129) that results in constitutive activation of EpoR by homodimerization in the absence of Epo, and erythrocytosis, has been described.[302,303] Murine EpoR may also be activated by interaction with the Friend spleen focus-forming virus (SFFV) envelope glycoprotein, gp55, promoting EpoR dimerization and polycythemia.[276] Deletions of negative regulatory EpoR domains in humans and mouse models, as noted, also increase EpoR signaling and result in erythrocytosis whereas overexpression of a constitutively active mutant of STAT5A, STAT5A1*6, in human cord blood CD34+ cells favors erythroid over myeloid differentiation in vitro.[304]

Building on previous studies,[305,306] constitutive activation of EpoR in patients with the myeloproliferative disease polycythemia vera (PV) was discovered to be due to an activating mutation of Jak2 that encodes a substitution of valine for phenylalanine at position 617 in the protein (^{V617F}Jak2 mutation).[307] The role of JAK2 in PV is discussed in Chapter 82.

Mechanism of Action

Epo is a hormone that promotes erythroid differentiation.[2] The role of Epo during the very early stages of erythropoiesis is still undefined. Cell lines with features of multipotent hematopoietic progenitor cells[308,309] and purified human blood BFU-E[19] express a small number of EpoR, suggesting a possible role for Epo in mediating their survival and differentiation. Although, in vivo, the BFU-E pool is unaffected by acute changes in serum Epo levels, they can respond to the hormone by increasing their cycling, part of the process of erythroid differentiation.[29] Chronic administration of rEpo to humans with end-stage renal disease results in global stimulation of the bone marrow with an increase in the

concentration and cycling of all types of hematopoietic progenitors, but this effect is most likely indirect.[30]

The erythroid cell that is the most sensitive to Epo is a cell between the CFU-E and the proerythroblast,[19,246] and this erythroid cell is considered the primary target of Epo action. These cells express the highest density of EpoR on their cell surface and are absolutely dependent on Epo for survival.[19,47,216] Studies on murine splenic erythroid cells infected with the anemia strain of Friend virus[310] have shown that Epo binding is followed by a series of biochemical events, including increased Ca^{2+} uptake,[49] internalization of Epo,[12] an increase in RNA synthesis,[311] glucose and iron uptake,[247] transcription of the α- and β-globin genes,[46,215] expression of TfR,[48] and eventually increase of hemoglobin synthesis as well as synthesis of membrane bands 3 and 4.1.[47,215] All of these changes result in an increased rate of erythroid differentiation, ending with an increase in the reticulocyte production and an eventual increase in the erythron.

One of the most impressive effects of Epo is the ability of the hormone to maintain the viability of erythroid cells irrespective of any effect on cycling and differentiation.[47,216] It has been shown that Epo retards the cleavage of DNA that occurs normally in CFU-E.[19] In the absence of Epo, DNA cleavage is rapid and proceeds to cell death. The pattern of rapid DNA cleavage is characteristic of cells undergoing caspase-mediated apoptosis.[19] In the presence of Epo, cell death is avoided and the erythroid cells differentiate and form mature red cells. These findings suggest that the hormone promotes erythroid differentiation simply by allowing cell survival. This model also suggests that, under normal conditions—due to their variable sensitivities to Epo—large numbers of generated CFU-E undergo apoptosis, and that high Epo levels cause expansion of the erythroid marrow simply through allowing survival of more CFU-E, resulting in increased red cell production. Similarly, once the red cell mass is restored to normal, the ensuing decrease of Epo levels leads to a rapid turn-off of erythropoiesis by allowing programmed cell death to occur.[19]

The observation that relatively immature erythroid progenitor cells continue to develop in fetal mice in which either the gene encoding for Epo or EpoR is deleted[242] supports the model that Epo acts primarily by promoting survival of more mature erythroid cells and that Epo has no, or a less significant, role in proliferation of erythroid precursors or in directing the erythroid differentiation of immature hematopoietic cells. The abundant erythroid cells (proerythroblasts near the CFU-E stage of erythroid development) from the spleens of either $Epo^{-/-}$ or $EpoR^{-/-}$ mice undergo apoptosis unless they are either cultured in vitro in Epo ($Epo^{-/-}$ mice) or forced (by transfection with EpoR cDNA) to express EpoR ($EpoR^{-/-}$ mice) and then cultured in the presence of Epo. Thus, neither Epo nor receptors for Epo are necessary for the proliferation and differentiation of stem cells and early progenitor cells into relatively mature erythroid cells. Both Epo and the receptors for Epo, however, are absolutely required for erythroid cells to survive the transition from CFU-E/proerythroblasts to mature erythroblasts, suggesting a clear role for Epo in directing the survival of these cells.

Studies of normal murine fetal liver–derived erythroblasts that are transduced with (and thus overexpress) antiapoptotic proteins such as BCL-X_L and Bcl-2 have emphasized the importance of survival factors at this defined stage of erythropoiesis.[312] These erythroblasts require Epo, SCF, and dexamethasone to allow sustained proliferation; however, with removal of these factors (including Epo) there is initiation of what appears to be normal erythroid differentiation with induction of the erythroid transcription factors (GATA1, KLF1, and NFE2), differentiation divisions, size reduction, hemoglobinization, nuclear condensation, and enucleation. These studies would suggest that Epo-induced survival allows cell-autonomous terminal erythroid differentiation. Interestingly, studies also demonstrate that controlled caspase activation is actually necessary for erythroblast maturation.[313] It is hypothesized that caspase-mediated cleavage of proteins such as Lamin B, PARP-1, and Acinus is required for terminal maturation, perhaps for initiation of enucleation.[314] In the absence of Epo there is excessive activation of caspases, resulting in cleavage of GATA1 and maturation arrest or apoptosis. However, Epo induces nuclear migration of a molecular chaperone, the heat shock protein Hsp70, to protect GATA1 from cleavage during caspase activation.[315] Notably, recent studies[316] indicate that abrogation of this protective mechanism may underlie the ineffective erythropoiesis seen in patients with early myelodysplastic syndrome (see Chapter 73).

In addition to erythroid cells, Epo has also been shown to affect megakaryocytes and their progenitors CFU-MK. Epo acts as a colony-stimulating factor for murine CFU-MK,[317] whereas in humans, it potentiates the effect of megakaryocyte colony-stimulating factors present in lymphocyte-conditioned media.[12] It also promotes differentiation of murine megakaryocytes,[318] which express EpoR,[319] and, when injected at high doses into mice, increases platelet production.[320] In patients with renal failure treated with Epo, a minor increase in the platelet count, averaging approximately 30,000/μl, has been noted.[321]

ASSAYS FOR ERYTHROPOIETIN AND LEVELS IN HEALTH AND DISEASE

The presence of Epo in serum, urine, or other body fluids can be detected by bioassays or immunoassays. Historically, Epo was detected by the polycythemic mouse assay in which the serum sample was injected with ^{59}Fe into polycythemic mice and the amount of ^{59}Fe incorporated into newly released red cells was measured.[2,322,323]

Radioimmunoassays for Epo were developed initially by using purified human urinary Epo as antigen and standard[324–328]; these have been replaced by purified human rEpo.[326,327] Using the same principles of immunologic detection of the protein, an enzyme-linked immunosorbent assay was developed, which is commercially available and currently used as the method for determining serum Epo concentrations. The immunoassays have the advantages of being quick, accurate, relatively inexpensive, and capable of quantifying very low Epo levels ordinarily not detectable by bioassays. Normal serum Epo levels, although variable with the type of assay, usually range between 5 and 30 mU/ml. An inverse correlation has been established between the logarithm of serum Epo concentration and the concentration of hemoglobin in the blood[324,327]; however, the magnitude of the increase in the serum Epo concentration in response to anemia is variable among individuals. A disadvantage of the immunoassays is that they detect immunoreactive but not necessarily bioactive hormone. Thus, in renal failure, when serum Epo levels are low or undetectable by bioassays, the immunoassays detect higher levels.[326–328] The utility of Epo assays in clinical practice is discussed in later chapters in relation to specific clinical disorders.

THE MATURE RED BLOOD CELL

Erythrocytes were first described in the 17th century. The Dutch microscopist, Leeuwenhoek, took note of them, as did Malpighi, who mistook them for fat globules "looking like a rosary of red coral." For many years, erythrocytes were not thought to be of any importance. The presence of iron in blood was demonstrated by Lemery in the 17th century, but not until 1851 did Funke isolate hemoglobin in crystalline form. The functional significance of red corpuscles was only appreciated, however, when Hoppe-Seyler demonstrated that hemoglobin has the property of readily taking up and discharging oxygen. This, then, was considered the primary

or even sole function of the red cell (along with CO_2 exchange) until the late 20th century. This section provides a description of RBC membrane structure and function, red cell metabolism, and hemoglobin function. More detailed historic discussion of these erythrocyte features is found in Maxwell Wintrobe's history of hematologic science, *Blood, Pure and Eloquent.*[329]

STRUCTURAL FEATURES OF ERYTHROCYTES

Lacking a nucleus, mitochondria, or ribosomes, the red cell is unable to synthesize new protein, carry out the oxidative reactions associated with mitochondria, or undergo mitosis. More than 95% of the cytoplasmic protein is hemoglobin. The remainder includes those enzymes required for energy production and for the maintenance of hemoglobin in a functional reduced state.

Shape and Dimensions

At rest, the normal human erythrocyte is shaped like a flattened, bilaterally indented sphere, a shape often referred to as a biconcave disc (Fig. 6.11). In fixed, stained blood smears, only the flattened surfaces are observed; hence, on fixed blood films the erythrocyte appears circular, with a diameter of about 7 to 8 μm and an area of central pallor.

Average values for the mean cellular volume in normal subjects range from 80 to 100 fl, depending on the combination of methods used. The variation in cell size can be documented by means of a frequency distribution curve of red cell volumes generated from the output of an electronic cell counter (Fig. 6.12).[330]

Total hemoglobin content and red cell volume vary considerably more than does hemoglobin concentration.[330–332,333] It has been proposed that mature red cell size and hemoglobin content are primarily dependent on erythroid precursor cell size at the last cell division during erythropoiesis.[330] Reticulocytes are 24% to 35% larger than mature red cells, although they have similar total hemoglobin content (and thus a lower hemoglobin concentration).[334]

The disc shape is well suited to erythrocyte function. The ratio of surface to volume approaches the maximum possible value in such a shape,[335] thereby facilitating both gas transfer and deformability as the red cell traverses the microcirculation. When red cell movements within small blood vessels are observed by cinemamicrography,[336] the plane of the biconcave disk is oriented in the direction of flow with the leading edge pointed and the following edge blunted. When deformed in this way, the erythrocyte can pass through a vessel of about 4 μm in maximum diameter. Erythrocyte shape may also vary between large and small vessels and under conditions of high or low shear stress.

Deformability

The erythrocyte is remarkable for its ability to maintain membrane integrity while exhibiting extreme deformability under normal physiologic circumstances.[337] Without undergoing extensive remodeling, the erythrocyte membrane withstands high shear stresses, rapid elongation and folding in the microcirculation, and deformation as the erythrocyte passes through the small fenestrations of the spleen. Cell deformability depends on both the membrane and the cytoplasm; however, the cytoplasm of normal

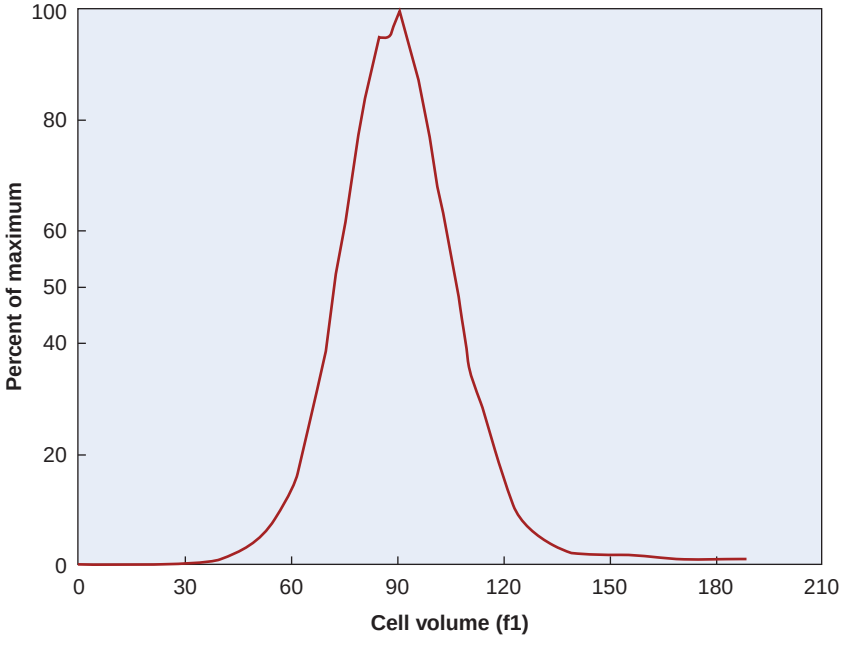

FIGURE 6.12. Frequency distribution curve of erythrocyte volume. The cells are normally distributed about a mean volume of 90 fl. (Modified with permission from Bessman JD, Johnson RK. Erythrocyte volume distribution in normal and abnormal subjects. Blood 1975;46:369.)

erythrocytes at physiologic concentration has very low viscosity.[337] Thus, it is the elasticity and viscosity of the membrane that are most crucial for deformability.

Among the factors that affect membrane deformability and stability are membrane lipid content, lipid distribution, cytoskeletal proteins, and transmembrane proteins.[338] The cytoskeleton, formed by a latticelike network of proteins, undoubtedly contributes to the bending energy necessary for assumption of the biconcave shape, as well as to membrane stability.[339] Abnormalities in cytoskeletal proteins cause a variety of pathologically shaped red cells, including spherocytes and elliptocytes (Chapter 27). In addition, proteins adsorbed to the outer surface of the red cell, especially albumin, may also play a role in both maintaining normal cell shape and effecting changes in that shape under some conditions. Red cells suspended in an isotonic medium tend toward an echinocytic shape until albumin is added, and increasing amounts of albumin move cells toward the discoid shape.[340]

THE ERYTHROCYTE MEMBRANE AND CYTOSKELETON

The central feature of membrane structure is a matrix formed by a double layer of phospholipids. The lipid bilayer hypothesis was first proposed in 1925[341] and refined by Danielli and Davson a decade later.[342–344] Lipid molecules in the bilayer are oriented with the nonpolar groups directed toward one another, forming hydrophobic interactions. The hydrophilic polar head groups are directed outward, where they interact with the aqueous environment on both the cytoplasmic and plasma surfaces.

The best accepted concept of how proteins fit into the lipid membrane structure is the so-called fluid mosaic model.[345,346] Within this "sea of lipids" float globular proteins, some that penetrate the membrane completely and others that penetrate the membrane only partially and may be exposed at only one surface. Some proteins appear to have considerable lateral mobility, but in the red cell, many proteins interact with other membrane components, giving them a degree of immobility. Some proteins traverse the lipid bilayer once, whereas others have multiple membrane-spanning domains. On the cytoplasmic side of the membrane lies a network of structural proteins that form a cytoskeleton. Certain membrane-spanning proteins appear to interact with various cytoskeletal proteins.[347] Some transmembrane proteins also appear to become covalently linked to lipid,[348] whereas the glycosylphosphatidylinositol-anchored class of proteins has no membrane-spanning domain but instead has phospholipid "tails" by which they are attached to the membrane.[349]

Much that is known about red cell membranes is derived from studies of the insoluble portion of the cell remaining after hemolysis induced by osmotic rupture. This material has been called stroma and, if the membrane remains intact after hemolysis, red cell "ghosts." It consists largely of components of the membrane, including the cytoskeleton. Such preparations contain about 52% protein, 40% lipid, and 8% carbohydrate by weight.[350] Most of the carbohydrate is accounted for by the oligosaccharide portion of glycoproteins, but a small fraction (about 7%) is carried by glycolipids.[350,351]

Lipid Composition

Virtually all of the lipids in the mature erythrocyte are found in the membrane[351–355] (Table 6.1). The majority of erythrocyte membrane lipids are phospholipids or unesterified cholesterol, which are present in approximately equimolar quantities. Four classes of compounds account for most of the phospholipid: phosphatidylcholine (lecithin), phosphatidylethanolamine, sphingomyelin, and phosphatidylserine (Table 6.1). Two fatty acid side chains are attached to all of these lipids except sphingomyelin, which has only one. In addition, trace amounts are found of other phospholipids containing only one fatty acid ("lysophospholipids," e.g., lysolecithin). Fatty acids in the membrane are almost evenly divided between saturated and unsaturated fatty acids.[354]

Phospholipids are distributed asymmetrically between the two lipid layers of the membrane.[356,357] Eighty percent or more of the aminophosphatides (phosphatidylethanolamine and phosphatidylserine) lie within the inner (cytoplasmic) monolayer, whereas the choline-containing lipids (phosphatidylcholine and sphingomyelin) are the major components of the outer monolayer (Fig. 6.13). Little or no phosphatidylserine is detectable in the outer lipid layer of normal, nonsenescent red cells. Maintenance of normal asymmetry results in improved mechanical membrane stability under applied shear stress and further appears to supply additional means for cytoskeleton attachment to the lipid bilayer through spectrin–phosphatidylserine interaction.[358]

TABLE 6.1

LIPIDS OF THE NORMAL HUMAN ERYTHROCYTE MEMBRANE

	Molar Concentration[351]		Weight Concentration[350]	
Lipid	**μmol/10^{10} Cells**	**% of Total**	**mg/10^{10} Cells**	**% of Total**
Phospholipids				
Phosphatidylcholine (lecithin)	1.3		1.0	
Phosphatidylethanolamine (cephalin)	1.2		0.9	
Sphingomyelin	1.0		0.8	
Phosphatidylserine	0.6		0.4	
Lysolecithin	0.04			
Others	0.07			
Total phospholipids	4.2	49.5	3.1 (1.7–3.2)[a]	69
Cholesterol	4.0	47.1	1.3 (1.1–1.4)[a]	29
Glycolipids (globoside)	0.21	3.4	0.1	2
Total lipids	8.41	100	4.5 (3.9–5.2)[a]	100

[a]Range in parentheses.

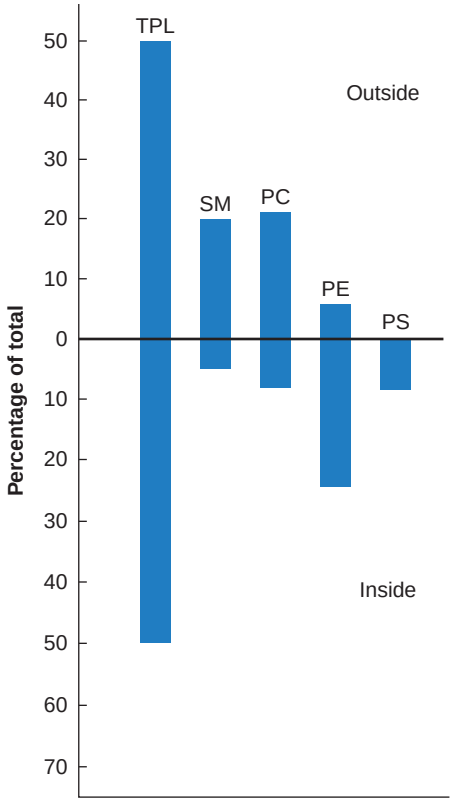

FIGURE 6.13. Distribution of erythrocyte phospholipids between the inner and outer layers of the membrane. PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; SM, sphingomyelin; TPL, total phospholipids. (From Rothman JE, Lenard J. Membrane asymmetry. Science 1977;195:743, with permission. Copyright 1977 by the American Association for the Advancement of Science.)

The lateral mobility of lipids in the outer membrane layer exceeds that of lipids in the inner layer. Although cholesterol is known to restrict lipid lateral mobility,[359] the outer lipid layer likely is relatively enriched in cholesterol.[360] Lipids in the inner layer may be restricted in their mobility because of interactions of phospholipids with cytoskeletal proteins.[358,361,362]

An additional effect on lipid mobility and membrane deformability may come from the fact that the fatty acids found in erythrocyte phospholipids are also not distributed evenly between the two bilayers.[353,357,363,364] Overall, about one half of the fatty acids in the membrane are unsaturated. Unsaturated fatty acids, however, and particularly the polyunsaturated acyl chains with four or more double bonds, are a disproportionately large part of the inner leaflet phospholipids, phosphatidylethanolamine and phosphatidylserine. In contrast, phosphatidylcholine, which is predominantly in the outer lipid layer, contains most of the shorter-chain saturated fatty acids. Sphingomyelin is especially enriched in fatty acids, with a chain length longer than 20. Membranes rich in sphingomyelin are less "fluid" than those with relatively larger amounts of lecithin.[365] An increased ratio of sphingomyelin to lecithin is found in abetalipoproteinemia and probably accounts for the erythrocyte abnormalities associated with that disorder[363] (see Chapter 27).

The neutral lipid of the erythrocyte consists almost entirely of free nonesterified cholesterol.[365] The distribution of cholesterol in the two membrane layers has been difficult to study, at least in part because the translocation rate of cholesterol between the two layers is extremely rapid. Cholesterol has a pronounced effect on membrane fluidity.[366,367] It interacts with phospholipids to form what has been called an "intermediate gel state." Thus, compared with pure phospholipid membranes, membranes containing cholesterol are less fluid, that is, more viscous. Relatively modest increases in membrane cholesterol content decrease membrane deformability.[368] Abnormally high levels of cholesterol lead to distortions in red cell shape; bizarre spicules form ("spur cells"), deformability of the cells is reduced, and they are destroyed in the spleen (Chapter 27).

Lipid Turnover and Acquisition

The mature erythrocyte is unable to synthesize lipids de novo; therefore, any lipid loss must be compensated for by renewal from pathways of interchange with the plasma[364] (Fig. 6.14). Quantitatively, the most important of these pathways is the transfer of cholesterol and phosphatidylcholine (lecithin) from plasma lipoproteins to red cells (pathways 1 and 3). The rates of transfer are functions of the relative plasma and red cell levels of these lipids and are indirectly affected by the activity of the cholesterol-esterifying enzyme in plasma, lecithin-cholesterol acyltransferase (LCAT).[369] This enzyme catalyzes the reaction in which a fatty acid in the 2 position of lecithin is transferred to free cholesterol, forming cholesterol ester and lysolecithin (Fig. 6.14, reaction 1A). Neither of the LCAT reaction products can enter the membrane. In patients with congenital LCAT deficiency, membrane cholesterol and lecithin are increased and the red cells are target-shaped.[370]

The exchange of cholesterol and lecithin between red cells and plasma is also affected by the plasma bile salt concentration.[371] If erythrocytes are incubated in normal plasma to which bile salts have been added, the cells acquire cholesterol, and this change is accompanied by an increase in surface area and the formation of target cells. Although the mechanism of bile salt action is not fully understood, at least two properties appear to be important: Bile salts inhibit the LCAT reaction and, in addition, they bring about a shift in the distribution of free cholesterol between plasma and cell. Phospholipids also may be added to the membrane. One example of this is that albumin-bound lysophospholipid may be transferred to the membrane (Fig. 6.14, pathway 4) and acylated (reactions 5a and 6a) to form a complete phospholipid.[364]

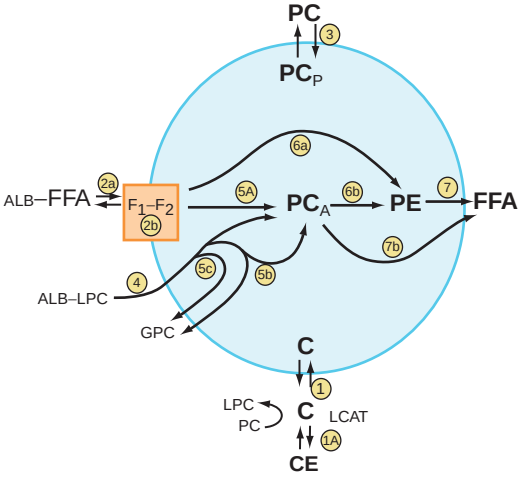

FIGURE 6.14. Pathways of lipid acquisition and turnover in the mature red cell membrane. Reactions and pathways: (*1*) exchange of cholesterol with plasma lipoprotein; (*1A*) the LCAT reaction; (*2a*) transfer of FFA from albumin to membrane; (*2b*) penetration of FFA to a metabolically active site; (*3*) exchange of PC with plasma lipoprotein; (*4*) transfer of LPC from albumin to membrane; (*5A*) LPC + FFA → PC; (*5b*) 2LPC → FFA + GPC; (*5c*) LPC → FFA + GPC; (*6a*) LPE + FFA → PE; (*6b*) PC + LPE → LPC + PE; (*7*) PE → LPE + FFA; (*7b*) PC → LPC + FFA. Alb, albumin; C, cholesterol; CE, cholesterol ester; FFA, free fatty acid; GPC, glycerylphosphoryl choline; LCAT, lecithin-cholesterol acyltransferase; LPC, lysophosphatidyl choline; LPE, lysophosphatidyl ethanolamine; PC, phosphatidyl choline (lecithin); PE, phosphatidyl ethanolamine. Membrane Proteins

Early in the history of membrane biochemistry, erythrocytes were used as a model system for the study of plasma membranes because they lacked organelle and nuclear membranes, making the membranes easy to isolate. Solubilization of membrane proteins can be accomplished by the addition of detergent. Detergent usually is added to red cell ghosts, made relatively hemoglobin-free after hypotonic lysis of red cells.[352] Use of an ionic detergent, most commonly sodium dodecyl sulfate (SDS), accomplishes solubilization of essentially all membrane proteins. Proteins extracted from membranes by detergent solubilization can be separated and analyzed with relatively high resolution by means of electrophoresis in polyacrylamide gels.[372,373] Such gels are stained by protein stains, usually Coomassie Brilliant Blue or by reagents that react with carbohydrate, such as periodic acid-Schiff (PAS).

On Coomassie-stained gels, seven major bands are usually identified, whereas PAS stains four major bands and several minor ones (Fig. 6.15). Originally, the seven major protein bands were referred to by number. As further refinements in SDS-PAGE have produced greater resolution, other bands have been given decimal or alphanumeric designations, such as bands 2.1 and 4.2, sometimes with even further divisions such as in 4.1a and 4.1b. Most of these proteins are no longer identified by this numeric nomenclature because they have been given specific names as their chemical structures and membrane function have been defined. The major PAS-stained bands contain three proteins, two of which form both hetero- and homomultimers. These three proteins have been termed glycophorins, or sialoglycoproteins, with letter designations that vary according to the investigator.[373–376] Glycophorins A and B are proteins that are derived from highly homologous genes and form both homo- and heterodimers. Glycophorins C and D are two proteins produced by a single gene and are structurally unrelated to glycophorins A and B.

With recent advancements in mass spectrometry and the availability of protein databases, the field of proteomics has evolved. The proteome is the entire complement of proteins in a tissue, including all the particular modifications made to a given protein (phosphorylation, glycosylation, acetylation, ubiquitination, etc.). The RBC proteome contains hundreds of membrane and soluble proteins. The significance of erythrocyte protein patterns in normal, aging, and RBC disorders is currently an active area of investigation and should provide important information in the future.[377–378,379]

Historically, as noted above, membrane proteins were first characterized by whether they were stainable by protein-binding or carbohydrate-specific dyes. Now, however, they are classified on the basis of their relationship to the membrane or their functions. One common classification of membrane proteins comprises the categories of integral membrane proteins and peripheral membrane proteins.[345] Integral membrane proteins are most often globular and amphipathic; in their folded, three-dimensional form, they have distinct hydrophobic and hydrophilic domains. Of the major Coomassie-stainable proteins, bands 3, 4.5, and 7 are integral membrane proteins. These proteins have one or more membrane-spanning domains. Band 3 has several extracellular domains, of which some are highly glycosylated. Band 4.5 is the glucose transporter. All other Coomassie-stained bands are situated within the cell, either as part of the cytoskeleton or bound in a more or less loose fashion to the inner leaflet of the membrane. All the PAS-stainable proteins are integral membrane proteins. Integral membrane proteins require detergent for removal from the membrane, whereas peripheral membrane proteins can often be extracted from "ghosts" by manipulation of the pH and ion content of buffers and tend to be soluble in neutral aqueous buffers. Proteins attached by phosphatidylinositol anchors to the outer membrane layer also require detergents or other reagents capable of disrupting the lipid bilayer for solubilization.[349]

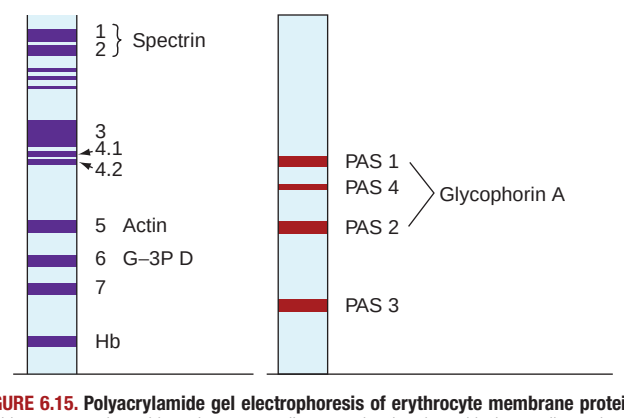

FIGURE 6.15. Polyacrylamide gel electrophoresis of erythrocyte membrane proteins. In this system, polypeptides migrate according to molecular size, with the smaller molecules moving the farthest. Gels were stained with Coomassie Brilliant Blue (*left*) and periodic acid-Schiff (PAS) reaction (*right*). (From Steck TL. The organization of proteins in the human red blood cell membrane. J Cell Biol 1974;62:1, with permission.)

Transmembrane Proteins

The two predominant erythrocyte transmembrane proteins are glycophorin A (GPA) and the anion channel (AE1, formerly known as band 3). AE1 has a number of crucial roles in red cell biology, whereas the importance of GPA is less clear.

Glycophorin A is the principal PAS-stainable glycoprotein of erythrocyte membranes, accounting for approximately 85% of PAS-positive membrane protein. The N terminus of GPA bears the M or N antigen. GPA has also been found to be a binding site for several pathogens, including *Plasmodium falciparum*.[380] Numerous variants of GPA have been described and may cause production of alloantibodies after transfusion. Rarely, some persons lack this protein totally. Although absence of GPA causes no clinically significant hematologic problems, persons with this deficiency may make antibodies that render blood transfusion difficult, given the general unavailability of blood from other GPA-deficient donors.

Glycophorin B, the second most abundant PAS-staining protein, is present on the erythrocyte in one tenth to one third the copy number of GPA.[381] Glycophorin B is highly homologous to GPA and the N terminus of glycophorin B carries the "N" amino acid sequence of GPA and always expresses the N antigen. At amino acid 29, within a region of glycophorin B that is less homologous to GPA, expression of methionine or threonine accounts for the S and s blood group antigens, respectively.

AE1, the erythrocyte anion-channel or anion-exchange protein, is expressed on erythrocytes in about the same copy number as GPA. Human erythroid AE1 cDNA has been cloned.[382,383] The deduced cDNA sequence, as well as confirmatory biochemical analyses, has demonstrated that AE1 most likely traverses the membrane 12 times. It has several extracellular domains, but the fourth is the major bearer of carbohydrate. This domain is heavily glycosylated and bears carbohydrate blood group antigens, including I and i and the antigens of the ABO major blood group system. The function of AE1 relates to $Cl–HCO_3$ exchange and it also interacts with the erythroid cytoskeleton by binding ankyrin. Complete absence of erythroid AE1 is rare in humans and has been associated with severe hemolytic anemia and renal tubular acidosis. However, many different mutations of AE1 have been described in association with hereditary spherocytosis and other RBC membrane disorders associated with hemolysis (Chapter 27).

The *Rh proteins* are also important integral membrane proteins. Although they are present in only 100,000 copies per cell,[381] these proteins are clearly important both to erythrocyte biology as well as to transfusion medicine. The RhD protein is

the most immunodominant determinant of red cells outside the ABO antigens and is thus the only non-ABO determinant routinely taken into account when blood is selected for nonalloimmunized recipients. Absence of all Rh proteins, as in the Rh_{null} syndrome, is associated with multiple erythrocyte defects and mild hemolytic anemia.[384] The proteins that carry the D, C (or c), and E (or e) Rh antigens are highly homologous to one another and traverse the membrane multiple times.[385] Two Rh genes situated very near each other on chromosome 1 encode the proteins that bear Rh antigens; in a normal situation, one gene encodes the D antigen and the other encodes a protein that bears both the E/e and C/c antigens.[386]

Cytoskeletal Proteins

The most abundant of the peripheral proteins are those that make up the so-called spectrin–actin cytoskeletal complex, accounting for about 35% of the membrane protein. The complex includes large α and β spectrin polypeptide chains (bands 1 and 2 on gel electrophoresis, molecular weight about 240 and 225 kDa, respectively) and the smaller actin chain corresponding to band 5. The relationship between the integral and peripheral proteins of the membrane is illustrated in Figure 6.16.

Spectrin proteins are long, rod-shaped molecules that self-associate into a two-dimensional network with the help of other cytoskeletal proteins.[347] The two forms of spectrin are homologous to each other; however, they are encoded by genes on two different chromosomes, chromosome 1 (α spectrin) and chromosome 14 (β spectrin).[387–389] The α and β spectrin molecules form heterodimers by aligning in antiparallel pairs. These heterodimers then form tetramers by head-to-head association.[347] Incorporation of these tetramers into the latticework of the cytoskeleton occurs with the interaction of other peripheral membrane proteins (Fig. 6.16).[347]

Erythrocyte actin, or band 5 as identified in Coomassie-stained gels of erythrocyte membrane proteins (Fig. 6.15), is an abundant erythrocyte protein of about 45 kDa. Like actin in skeletal muscle cells, erythrocyte actin can polymerize into filaments and can activate myosin ATPase activity. Actin filaments associate with spectrin tetramers at the ends containing the carboxy terminus of the α chain and the amino terminus of the β chain. This association, however, is a low-affinity interaction in the absence of other accessory proteins.

In addition to spectrin and actin, other cytoskeletal proteins are important for membrane stability and maintenance of cell shape. Protein 4.1 contains a spectrin-binding domain and is known to promote spectrin–actin interaction. Ankyrin (Protein 2.1) also serves as a mode of attachment of the cytoskeleton to the membrane.[390] Ankyrin binds to both the anion exchanger band 3 and spectrin. As discussed in Chapter 27, deficiencies or abnormalities in these cytoskeletal proteins are associated with abnormal erythrocyte shapes, abnormal membrane stability, and hereditary hemolytic anemias.[391]

Membrane Transport Proteins and Membrane Permeability

In general, the membrane acts as a partial barrier to penetration of all solutes. Nonpolar substances diffuse through the membrane at a rate proportional to their solubility in organic solvents. Polar solutes cross the membrane at specialized sites. The erythrocyte membrane has a number of specialized transport proteins, including the anion transporter (AE1, band 3), several cation transporters, a glucose transporter, and a water channel.

The red blood cell behaves as an osmometer; RBC water always is in osmotic equilibrium. In large part this occurs because erythrocytes have an abundant and highly active water channel protein, aquaporin-1, which contributes as much as 85% of the osmotic water permeability pathway.[392] Aquaporin-1, originally described as CHIP-28 (channel-forming integral protein-28 kDa), occurs as a homotetrameric protein that expresses on its extracellular domain both ABH and Colton blood group antigens and can be inhibited by a variety of mercurial compounds.[393] Red cells that lack aquaporin-1 have only slightly reduced lifespan in vivo.[392]

There are several pathways that regulate water and solute homeostasis, the major determinant being the monovalent cation content. The erythrocyte membrane is only slightly permeable to the major monovalent cations (Na^+ and K^+) whereas it is much more permeable to monovalent anions (Cl^- and HCO_3^-). Cation

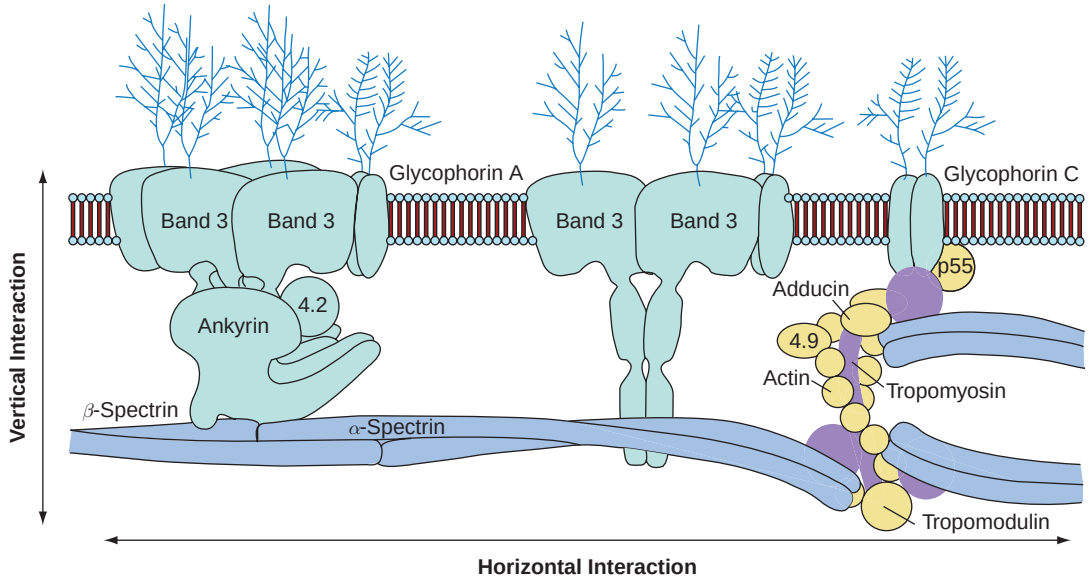

FIGURE 6.16. The erythrocyte membrane. A schematic model of the major proteins of the erythrocyte membrane is shown: α- and β-spectrin, ankyrin, band 3 (the anion exchanger), 4.1 (protein 4.1) and 4.2 (protein 4.2), actin, and glycophorin. Membrane protein–protein and protein–lipid interactions are often divided into two categories: (1) *vertical interactions*, which are perpendicular to the plane of the membrane and involve spectrin–ankyrin–band 3–protein 4.2 interactions and weak interactions between spectrin and the negatively charged lipids of the inner half of the membrane lipid bilayer; and (2) *horizontal interactions*, which are parallel to the plane of the membrane and include interactions between junctional complex proteins and spectrin or other membrane proteins. (Reprinted with permission from Tse WT, Lux SE. Red blood cell membrane disorders. Br J Haematol 1999;104:2.)

concentrations within the erythrocyte are approximately 130 mM K^+ and 8 mM Na^+, whereas the plasma contains approximately 140 mM Na^+ and 4 mM K^+. The steady-state cation concentrations within the erythrocyte are the result of an equilibrium between passive diffusion ("leak") and active transport ("pump"). With respect to sodium, the direction of leak is inward and the direction of pump is outward; in contrast, potassium leaks out and is pumped in. The major cation pump represents a process in which sodium inside the cell is exchanged for potassium on the outside and energy is supplied by ATP. For each molecule of ATP converted to ADP, three sodium ions are pumped out and two potassium ions enter.[394] Active Na^+ and K^+ transport depends on the activity of the membrane protein Na-K ATPase. Anions cross the membrane by one of two pathways. The first represents an exchange reaction in which an internal anion is exchanged for an external anion. This rapid exchange is mediated by the band 3 anion-exchange protein and plays an important role in the chloride–bicarbonate exchanges that occur as the red cell moves between the lungs and tissues (Fig. 6.17).[395] The second anion pathway represents considerably slower ionic diffusion, accounting for net loss or gain of anions in response to excess K^+ loss or Na^+ entry into the cell, respectively. It should be noted that anions are distributed passively across the cell membrane with steady-state concentrations determined by the Donnan equilibrium. Because the total cation content must equal the total anion charge, the presence of negatively charged impermeant intracellular anions (hemoglobin, 2,3-BPG, adenine nucleotides) influences the RBC monovalent anion content, and thereby explains why concentration of intracellular Cl^- and HCO_3^- is less than the intracellular monovalent cation content. Red cells have two additional monovalent transport processes that specifically result in KCl and water loss with a reduction in cell volume. *KCl co-transport* is stimulated by RBC swelling, leading to K^+ and Cl^- exit from the cell, with an obligatory water loss to maintain isotonicity.[396] Of interest, KCl co-transport also is activated by urea.[397] This pathway utilizes KCl co-transporters whose activity is determined by the protein phosphorylation/dephosphorylation state. This KCl transport pathway is particularly important in regulating cell volume, and is most active in reticulocytes. By decreasing the cell volume of reticulocytes the hemoglobin concentration is thereby increased to the levels seen in mature red cells. KCl transport is active in sickle and hemoglobin C disorders, and may account for some of the hydration abnormalities seen in these conditions. The *calcium-activated K^+ channel* was first described many years ago by Gardos.[398] Under conditions where Ca^+ accumulates in red cells, there is a rapid loss of K^+ (and Cl) also causing cellular dehydration. This Gardos effect can be demonstrated in RBC of all ages. The physiologic function of the calcium-activated K^+ channel is not known. It too may be related to some of the RBC hydration changes that are seen in sickle cell anemia.[399]

Glucose and other monosaccharides constitute an important exception to the generalization regarding nonpolar solutes in that the monosaccharides easily cross the membrane barrier, whereas the more lipid-soluble disaccharides do not. The speed of the process depends on molecular structure. Fructose is not transported under physiologic conditions (K_m > 200 mM). Glucose enters the erythrocyte by facilitated diffusion, mediated by a transmembrane protein designated the glucose transporter, encoded by the gene *GLUT1*.[400] The glucose transporter has an asymmetric effect on glucose transit across the membrane: Glucose influx exhibits a higher V_{max} and a lower K_m than does glucose efflux. The transport of glucose into the erythrocyte provides the energy substrate for anaerobic glycolysis; however, the energy requirement of the erythrocyte appears to be relatively low, and the efficiency of glucose transport is relatively high. Therefore, glucose transport is not rate-limiting for glycolysis.[401,402]

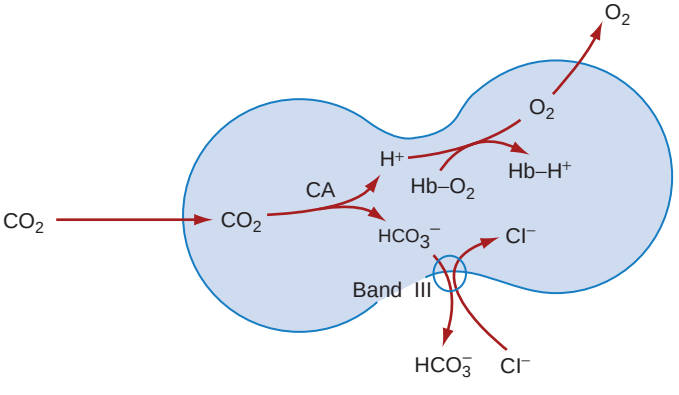

FIGURE 6.17. Role of band 3 in anion and CO_2 transport. The ability of band 3 to accelerate anion transport across the membrane allows rapid equilibration of bicarbonate with the extracellular plasma and concomitant influx of chloride ion. CA, carbonic anhydrase; Hb, hemoglobin. (From Kopito RR, Lodish HF. Structure of the murine anion exchange protein. J Cell Biochem 1985;29:1, with permission.)

Membrane and Membrane-associated Enzymes

At least 50 enzymes are either membrane proteins or are bound to the erythrocyte membrane in some fashion; certain enzymes are both free in the cytoplasm as well as associated with the membrane. Their functions range from facilitating transport of a variety of molecules necessary to the erythrocyte to playing important roles in producing and using energy from glucose metabolism.

Some erythrocyte enzymes are externally oriented and can therefore react with substrates in the red cell environment. A classic example of an externally oriented enzyme is acetylcholinesterase, first of several membrane proteins discovered to be missing from the affected erythrocytes of patients with paroxysmal nocturnal hemoglobinuria (see Chapter 31).[403,404] It belongs to a class of proteins that are attached to the membrane by a phosphatidylinositol-glycan anchor, so that the entire polypeptide portion of the molecule is extracellular.[349] The role of acetylcholinesterase on the red cell remains obscure[405]; however, some other proteins in this class are complement regulatory proteins. It is the absence of these proteins that causes the characteristc hemolysis of paroxysmal nocturnal hemoglobinuria.[404]

Among the enzymes required for the production and use of ATP there are three that form a membrane-bound enzyme complex: Aldolase, glyceraldehyde 3-phosphate dehydrogenase (G3PD), and phosphoglycerate kinase. Together, these three enzymes convert fructose diphosphate to 3-phosphoglycerate with the production of ATP. G3PD is the enzyme present in greatest amount in membrane preparations and is seen as band 6 in polyacrylamide gels. G3PD is also found in the erythrocyte cytoplasm and can be demonstrated to bind to a cytoplasmic segment of band 3.

Enzymes that use and degrade ATP are also found in the membrane, although they are not present in large enough quantities to account for bands seen in Coomassie-stained polyacrylamide gels of membrane proteins. Like protein kinases, ATPases phosphorylate membrane proteins, but instead of forming phosphoserine or phosphothreonine bonds, they form acyl bonds as transient intermediates in the catalytic cycle. Important and well-studied ATPases of the erythrocyte membrane include Na^+-K^+ ATPase, Ca^{2+}-Mg^{2+} ATPase, and Mg^{2+} ATPase. The Na^+-K^+ ATPase is also known as the sodium pump, or sodium–potassium pump.

Protein kinases are enzymes that phosphorylate other proteins in the presence of ATP by forming phosphoserine, or phosphothreonine bonds. Phosphorylation is a major step in the regulation of a variety of target molecules, including structural proteins and enzymes. Both red cell membrane-bound and cytosolic kinases may phosphorylate membrane proteins.[406] In general, phosphorylated structural proteins demonstrate lower-affinity binding

to their target proteins than do unphosphorylated proteins. For example, phosphorylation of protein 4.1 leads to a decreased affinity for spectrin and a decreased ability of 4.1 to promote spectrin–actin association.[347]

HEMOGLOBIN AND ERYTHROCYTE FUNCTION

Hemoglobins are one of the most widespread and specialized hemoproteins existing in nature and have been found in prokaryotes, fungi, plants, and animals. These proteins permit the reversible binding of O_2 to heme while keeping the iron in the 2+ state. They also facilitate the exchange of carbon dioxide between the lungs and the tissues. Studies have also demonstrated the importance of hemoglobin in control of vascular tone mediated by NO. In vertebrates, hemoglobin is the major constituent of the red cell cytoplasm, accounting for about 90% of the dry weight of the mature cell.

In most invertebrates, oxygen-carrying pigment is transported freely in the plasma rather than within cells. This is an inefficient delivery system. Hemoglobin, as a protein free in the plasma, would exert an osmotic pressure about five times greater than that produced by the plasma proteins. By the inclusion of this pigment in corpuscles, the viscosity of the blood can be maintained at a low level, water is not drawn from the tissues by it, and the flow of blood containing such a large amount of protein is made possible. Furthermore, free hemoglobin is not maintained in the circulation and is subject to oxidative denaturation. Attempts to make hemoglobin substitutes have revealed that infusion of free hemoglobin or derivatives causes a significant increase in blood pressure, as a result of the scavenging of NO produced by vascular endothelium.[407,408]

In humans at rest, about 250 ml of oxygen are consumed and 200 ml of carbon dioxide are produced per minute. During exercise, these quantities increase tenfold. If the respiratory gases were carried in physical solution in the plasma, human activity would be restricted to only one fiftieth of that possible in the presence of hemoglobin-containing red cells. Red cell hemoglobin permits the transportation of 100 times more oxygen than could be carried by the plasma alone.

Evolution and Structure of Hemoglobin

Vertebrate hemoglobin is a conjugated protein with a molecular weight near 64.5 kDa. It is a tetramer, consisting of two pairs of similar polypeptide chains called globins, that exhibits a dyad axis of symmetry. Each of the four chains is covalently attached to a heme complex, ferroprotoporphyrin IX, which is a complex of iron and protoporphyrin[409] (Fig. 6.18).

Human hemoglobins share a common ancestry with a simpler, single chain molecule that was similar to myoglobin. The divergence of the invertebrate and vertebrate globin genes occurred >670 million years ago, and the divergence of the α and non–α-globin genes probably descended from a common gene >450 million years ago.[410] Such an evolution would explain the high degree of homology between the α and non-α (ε, γ, β, and δ) chains, as well as the extraordinary similarities among the non-α globins. The non–α-globin gene family is sometimes designated the β-globin gene family. The α and non-α peptide chains most likely arose because of gene duplication, after which time the genes for these individual proteins evolved independently.[411,412] The occurrence of subunit cooperativity (discussed below) brought with it the advantage of increased physiologic effectiveness of the hemoglobin molecule and added a new pressure on further evolution of the hemoglobin chains.[413]

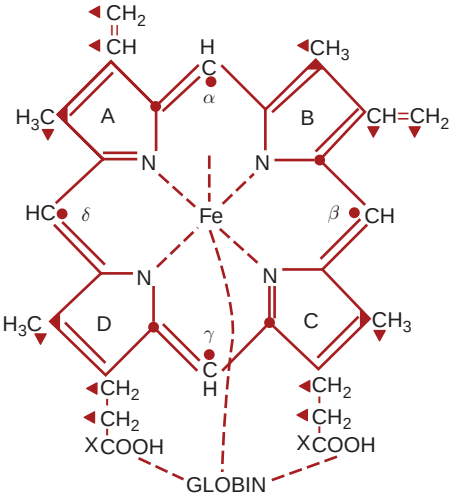

FIGURE 6.18. Chemical structure of heme and its manner of union with globin to form hemoglobin. The carbon atoms derived from the α carbon of glycine are represented by •, those supplied from the methyl carbon of acetate by ▲, and those derived from the carboxyl group of acetate by ×. The unmarked carbons are those derived from either the methyl carbon atom of acetate or from the carboxyl atom. (Prepared by Dr. G. E. Cartwright.)

Ontogeny of Hemoglobins

Erythroid development is divided into three developmental periods: embryonic, fetal, and adult. In each developmental period, the oxygen delivery requirements are different, and erythroid development has evolved to meet these needs. The genes that encode the α-globin gene family are on chromosome 16, whereas the genes that encode the members of the non–α-globin gene family are on chromosome 11.[78,414] These genes are developmentally and coordinately regulated, and through the production of different pairs of globins, different hemoglobins are produced to permit their appropriate expression during different developmental periods. The α-globin gene cluster is capable of producing two types of globins, zeta (ζ) and α. The ζ is an embryonic globin chain produced during the first 8 weeks of fetal development, whereas α is produced during the remainder of the fetal and adult developmental periods.[415] The β-globin gene family members include the embryonic globin ε, the fetal globin γ, and two globins expressed primarily during the adult period, δ and β.

During early embryonic development, the expression of ζ- and ε-globin genes leads to the production and assembly of these globins into the embryonic hemoglobin Gower-1 ($\zeta_2\varepsilon_2$).[416] α and γ globins are also produced at low levels during this period, and this permits the production of two other embryonic hemoglobins, designated Gower-2 ($\alpha_2\varepsilon_2$) and Portland ($\zeta_2\gamma_2$).[417] These embryonic hemoglobins display subunit cooperativity and serve as physiologic oxygen carriers in erythroid cells that were derived from yolk-sac hematopoietic progenitors.[418] Embryonic erythrocytes carrying these hemoglobins have an affinity for oxygen that is similar to fetal blood.

After the 8th week of development, erythropoiesis shifts from the yolk sac to the fetal liver, and the embryonic hemoglobins normally are not detectable in fetal blood.[419] Embryonic hemoglobins are replaced with hemoglobin F ($\alpha_2\gamma_2$), which remains as the predominant hemoglobin until after birth. The γ chains are encoded by pairs of genes located near the normal β-globin gene on chromosome 11. The two γ genes encode nearly identical proteins: Gγ has a glycine at position 136, whereas Aγ has an alanine.[77,420] In addition, many Aγ genes also encode a threonine-for-isoleucine substitution at position 75 of the protein.[421,422] During fetal life, Gγ constitutes about 75% of γ chains, whereas hemoglobin F in adults contains about 60% Aγ chains.[237,423] This has no known physiologic significance.

Red cells containing hemoglobin F have higher oxygen affinity than adult red cells. This permits the fetus to compete effectively for oxygen in the maternal blood. However, hemoglobin lysates from adult and fetal cells have nearly identical oxygen affinity when they are dialyzed against saline or a neutral buffer.[424] This property of fetal hemoglobin is due to amino acid differences in the amino terminus of the γ chains that impair binding of 2,3,-diphosphoglycerate (2,3-DPG, also known as 2,3-bisphosphoglycerate, 2,3-DPG), an allosteric modifier of oxygen binding.[425] Hemoglobin F also has an enhanced alkaline Bohr effect,[426] whereby oxygen affinity is increased as hemoglobin passes through the pulmonary vasculature.

At about 20 weeks of fetal development, the site of erythropoiesis begins to switch from the liver and spleen to the bone marrow, where progenitors show increased expression of adult globins, α and β. Hemoglobin A may constitute 5% of β-family globin expression during this time. Beginning at the 30th week and proceeding to the time of birth, a significant switch from fetal to adult erythropoiesis takes place, such that at the time of birth, fetal hemoglobin constitutes approximately 80% of the total hemoglobin. Over the next 25 to 30 weeks following birth, fetal hemoglobin concentration decreases by approximately 10% every 2 weeks until it reaches its normal adult level of <2% by 30 weeks of age.[427] Neonates with hemoglobinopathies or erythropoietic stress can have a greatly prolonged production of hemoglobin F, sometimes extending into adulthood.[428]

Hemoglobin A, $\alpha_2\beta_2$, is the predominant adult hemoglobin and normally constitutes approximately 96% of the total adult hemoglobin. Hemoglobin A_2 is a minor hemoglobin produced beginning at 35 weeks of gestation but has little physiologic relevance. Hemoglobin A_2 is composed of α globins and the minor adult globin δ. It normally constitutes <3.5% of total adult hemoglobin; however, it is typically increased in β-thalassemias. Clinically, its major importance is its value in diagnosing β-thalassemias.[429]

Modifications of Normal Hemoglobin

Analysis of human red cell hemolysates by cation-exchange chromatography reveals several negatively charged minor hemoglobins that are designated A_{Ia}, A_{Ib}, and A_{Ic}, corresponding to their order of elution. These hemoglobins are formed by the nonenzymic interaction of glucose with the α-amino groups of valine residues at the N terminus of the β chains of hemoglobin (Fig. 6.19).[430]

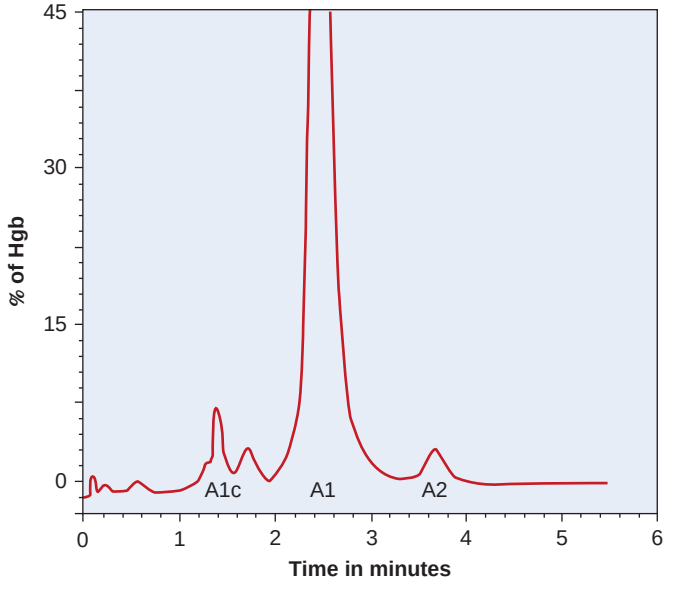

FIGURE 6.19. High-performance liquid chromatography showing modified Hb A variants. (Image provided through the courtesy of the copyright holder, Dr. Edward C. Klatt.)

The best characterized of the acquired variants is hemoglobin A_{Ic}, which constitutes about 3.5% of the hemoglobin in normal subjects and may be increased two- to threefold in individuals with diabetes mellitus. Its level is directly proportional to the time-integrated mean blood glucose concentration over the life of the red cell, typically the preceding 2 to 3 months.[431] In the nonenzymic glycation of hemoglobin A, a molecule of glucose forms a Schiff base with the N terminal of the β chain, then undergoes an Amadori rearrangement to a stable ketamine, 1-amino,1-deoxy fructose.[432,433] Because the glycated (or, as often called, glycosylated) hemoglobins are synthesized throughout the lifespan of the red cell, older cells contain a higher proportion of these modified hemoglobins than younger ones.[434] Preferential destruction of older cells explains the observation that the proportion of hemoglobin A_{Ic} is reduced in hemolytic anemia.[435] Because the rate of synthesis of hemoglobin A_{Ic} depends on the blood glucose level, the concentration of hemoglobin A_{Ic} at any one time is proportional to the average blood sugar over the previous 2 to 3 months.[436] For this reason, the level of hemoglobin A_{Ic} is used widely as a measure of glucose control in diabetic patients, as well as a tool for diagnosis of diabetic states[437]). Clinical laboratories currently use a variety of assays to detect and quantify glycated hemoglobins, most commonly, high-pressure liquid chromatography.[438] Commonly encountered hemoglobin variants, such as Hb S, Hb C, Hb E, and Hb F, can interfere with these assays, and may help explain discordant assay results.

Laboratory Analysis of Hemoglobins

Normal and variant hemoglobins can be detected and quantified by standard clinical laboratory techniques. Standard cellulose acetate electrophoresis performed at alkaline pH or isoelectric focusing (IEF) can detect most of the common variants.[439] Usually, confirmation can be achieved by citrate agar electrophoresis, IEF, or high-performance liquid chromatography (HPLC). The analysis of hemoglobin A_2 and fetal hemoglobin levels deserves special attention because the levels of these components are indicative of common conditions affecting hemoglobin synthesis.

Hemoglobin A_2 normally constitutes <3.5% of the total hemoglobin in adults. In cases of β-thalassemia trait hemoglobin A_2 levels are increased, ranging from 3.6% to 8.0%.[440,441] These subtle increases in hemoglobin A_2 that are characteristic of β-thalassemia trait cannot be quantified accurately by electrophoretic methods. Instead, most laboratories utilize HPLC or ion-exchange-resin microchromatography.[442] It is an error to use hemoglobin electrophoresis as the sole method to rule out β-thalassemia, and most large laboratories add the chromatographic quantification of hemoglobin A_2 as part of their routine hemoglobin analysis. HPLC provides a clear separation of hemoglobins A, F, and A_2 and this technology is commonly used in clinical laboratories.

Hereditary persistence of fetal hemoglobin (HPFH) and δ-β–thalassemia are types of β-thalassemia caused by deletion of δ- and β-globin genes, but distinguished from typical β-thalassemia by more balanced α- and non–α-globin chain synthesis resulting from an increase in γ-globin production. In both of these thalassemias, Hb A_2 levels are reduced as a result of deletion of δ-globin genes.

Elevated levels of hemoglobin F can be caused by thalassemias, disorders of hematopoiesis, or hereditary disorders of globin synthesis such as HPFH and δ-β–thalassemia.[443] Diagnosis requires the precise measurement of hemoglobin F levels, which can be achieved in clinical laboratories by taking advantage of the resistance of hemoglobin F to alkali denaturation.[444] This resistance to alkali denaturation of fetal hemoglobin is due to the greater stability under these conditions of α-γ–globin dimers compared to α-β–globin dimers.[445] In lysates exposed to alkali under controlled conditions, only fetal hemoglobin remains undenatured, and its concentration can be quantified after the other denatured hemoglobins are removed from solution.[446] Routine electrophoretic

procedures do not completely separate hemoglobin F from A, but a more adequate separation can be accomplished at pH 6.0 in agar gel, or more commonly by HPLC at present.[447,448]

In adults, fetal hemoglobin is unevenly distributed in erythrocytes, being restricted to between 0.1% and 7% of total cells.[445] Cells containing fetal hemoglobin are designated F or A/F cells, wherein the hemoglobin F concentration is normally between 14% and 25% of the total hemoglobin.[449] In certain thalassemias and HPFH, the number of F cells is increased. This can be detected by acid treatment of erythrocytes on a glass slide followed by elution of the acid-sensitive hemoglobins (Kleihauer-Betke technique). Counterstaining can identify hemoglobin F–containing cells among a sea of ghosts.[450]

Examination of normal blood by the Kleihauer-Betke method demonstrates both colorless cells and fetal hemoglobin containing (light pink) cells that vary in intensity. By comparison, analysis of cord blood mixed with adult blood demonstrates that true fetal cells in cord blood stain intensely, reflecting the high level of fetal hemoglobin in fetal cells. This assay can be performed on maternal blood to detect fetomaternal hemorrhage or other contamination of the maternal circulation with fetal blood. This can also be tested using flow cytometry with a phycoerythrin-conjugated antiglycophorin antibody to detect fetomaternal hemorrhage.[451]

Structure of Globin

Proteins have at least four levels of structural organization: (a) primary structure, or the linear sequence of amino acids; (b) secondary structure, which describes how the amino acids within segments of the protein are spatially organized (e.g., by folding into an α helix or β-pleated sheet); (c) tertiary structure, which refers to the steric relationships of sequence domains separate from each other when analyzed as part of the linear sequence of the protein; and (d) quaternary structure, or the way in which several polypeptide chains join to form a single molecule.

The exact primary structure of all normal globin chains has been determined based on the DNA sequence of the individual globin genes,[452] and the polypeptide chains in hemoglobin differ from one another in amino acid sequence. The α chain contains 141 amino acids and the non-α chains, 146. The members of the non–α-chain family are more similar than any member of the non-α chain and any member of the α-chain family. The δ chain differs from the β chain in only 10 of the 146 amino acid residues, whereas the γ and β chains differ by 39 amino acids.

In spite of the differences in the primary structure of α and non–α-globin chains, their secondary structures are remarkably similar. Each has eight helical segments designated by the letters A through H.[453] The helices of all the non–α-chain members are of identical length; however, a significant difference exists between the α- and non–α-globin chains in the region of the D helix, which contains seven amino acids in the ε, γ, δ, and β chains, but only two amino acids in the α chain. Because of the size of the D helix in the α-globin chains, many do not assign it a helix designation. The helices make up about 75% of the molecule. Interspersed between them are seven nonhelical segments: NA, AB, CD, EF, FG, GH, and HC. This arrangement is important structurally, because the helices are relatively rigid and linear, whereas the nonhelical segments allow bending.

A given amino acid in a polypeptide chain may be denoted either by its sequential number or by a helical number. In the sequential system, amino acids are numbered from 1 at the N terminus to 141 at the C terminus in the α chain and from 1 to 146 in the β, γ, and δ chains. In the helical system, each amino acid is designated by a letter and a number that indicate the helix and the position in the helix, respectively. The helical system is gradually gaining favor, because it illustrates the homology between chains and has more structural significance. For example, the histidine to which heme attaches is amino acid #87 in the α chain and #92 in the β, γ, and δ chains; the helical designation for this histidine is the same in all the normal chains, F8.

The tertiary and quaternary structures of hemoglobin have been studied by x-ray diffraction techniques, especially by Perutz and co-workers.[453,454] In aqueous solutions and in crystals, the polypeptide chains assume a structure in which the polar amino acids face the molecular surface, where they interact with water, rendering the molecule soluble. The groups directed toward the inner core of the molecule are all nonpolar, and the hydrophobic (van der Waals) bonding that occurs between them makes the structure stable. The resulting, roughly spherical, tertiary structure is similar for all the normal hemoglobin polypeptides (Fig. 6.20) as well as for certain other heme proteins, such as myoglobin.

The heme pocket is the site of many dynamic interactions involving oxygen binding to hemoglobin. Heme is suspended in a nonpolar crevice between the E and F helices (Fig. 6.20), and helices B, G, and H constitute the floor of the pocket. Heme iron forms a covalent bond with the imidazole nitrogen of the "proximal" histidine at F8. In addition, heme forms van der Waals bonds with many other parts of the molecule and in this way makes an important contribution to tertiary structure. If heme is extracted, the central helical regions, C, D, E, and F, unfold with a consequent decrease in solubility.[455] Not surprisingly, some unstable hemoglobins (see Chapter 35) result from amino acid substitutions in the residues that line the heme pocket.[456]

The binding of oxygen to the iron molecule causes the hemoglobin molecule to undergo conformational changes that affect the binding of oxygen to other heme sites.[457] In deoxyhemoglobin, the bond between the imidazole nitrogen of the proximal histidine and iron undergoes considerable strain, displacing iron from the plane of the ring. This strain is conveyed to other parts of the molecule and is in part responsible for the T or tense state of deoxyhemoglobin.[458,459] The addition of two molecules of oxygen, which is bound to the iron atom in the heme ring by end-on geometry, results in the formation of a hydrogen bond between the oxygen atom that is not bound directly to the iron and the imidazole nitrogen of the histidine at E7 (the "distal" histidine).[459] The binding of oxygen to iron changes the electron spin state of iron and relaxes the covalent bond with the proximal histidine, permitting the iron to move into the plane of the ring and relaxing the molecule, contributing to the R or relaxed state.[460] The overall conformational changes to hemoglobin appear to be the greatest after three molecules of O_2 have been added. In general, proteins that undergo an allosteric change from the tense (T) to a relaxed (R) state are better able to interact with substrate in the relaxed state. As a result,

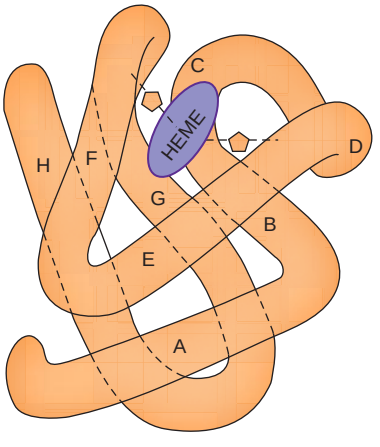

FIGURE 6.20. The tertiary structure of a single globin polypeptide chain. The helical segments, labeled A through H, are relatively linear; bending of the chains occurs between helices. Heme is suspended in a crevice between the E and F helices. (Courtesy of C.A. Finch.)

there are two quaternary structures for hemoglobin: one for the oxygenated form and one for the deoxygenated form.

Assembly of Hemoglobin

In general, there is little posttranscriptional regulation of the synthesis of globins, although factors such as the availability of heme can affect translation of globin mRNA.[461] Aside from several variants, such as hemoglobin Lepore, which are synthesized at a slower rate, the synthesis rate of most normal or mutant globins is the same.[462] Nevertheless, individuals with β-chain variants often express less of the variant hemoglobin than hemoglobin A. This observation has been attributed to an increased rate of catabolism of newly synthesized globin chains resulting from decreased solubility, defective heme binding, or abnormal subunit assembly. The best data indicate that the variations seen in most stable hemoglobin variants result from differences in subunit assembly.[463,464]

Following translation of globin mRNA and globin-chain synthesis, heme associates with globins and α-globin chains pair with members of the β-globin family. In large part this binding is a consequence of the different charges on α globins, which are positively charged (pI = 8.1), and β globins, which are negatively charged (pI = 6.6).[465] The greater the charge difference, the greater is the electrostatic attraction. Positively charged variants, such as β_C and the uncharged β_S, bind to α globin and assemble into α-β dimers at approximately half the rate of β_A during in vitro mixing experiments.[464] Conversely, more negatively charged variants such as $\beta_{\text{N-Baltimore}}$ bind with a greater association rate. This phenomenon has been suggested as an explanation for the ratio of 60:40 seen for hemoglobin A and hemoglobin S in heterozygotes for β_S.

In conditions of α-globin deficiency, this competition is more pronounced and the percentage of the more positively charged variant is further reduced. Patients who are heterozygous for β_S and α-thalassemia carry percentages of hemoglobin S of approximately 35%, 30%, and 25%, corresponding to one-, two-, or three-gene α-thalassemia.[466]

Hemoglobin A_2 is decreased in certain α-thalassemias and sometimes in iron deficiency, which causes an acquired reduction in α-globin synthesis as a result of decreased heme synthesis. Under these conditions, the more positively charged δ globin would be expected to compete less well with the normal β globin. On the contrary, during β-globin deficiency associated with β-thalassemia, δ globin would be expected to compete more effectively for α-globin chains, and the predicted increase in hemoglobin A_2 is observed.[467]

Oxygen Transport

In order to function as the primary medium of exchange of oxygen and carbon dioxide, hemoglobin must fulfill the four requirements first delineated by Barcroft in the 1920s[468]: it must be capable of transporting a large quantity of oxygen, it must be highly soluble, it must take up and release oxygen at "appropriate pressures," and it must also be a good buffer. Normal hemoglobin fulfills these requirements well, although many abnormal variants fail to meet one or more of these conditions.

Each gram of hemoglobin, when fully saturated, binds 1.34 ml of oxygen. The degree of saturation is related to the oxygen tension (pO_2), which normally ranges from 100 mm Hg in arterial blood to about 35 mm Hg in veins. The relation between oxygen tension and hemoglobin oxygen saturation is described by the oxygen dissociation curve of hemoglobin (Fig. 6.21). The characteristics of this curve are related in part to properties of hemoglobin itself and in part to the environment within the erythrocyte, with pH, temperature, and concentration of 2,3-DPG being the most important factors affecting oxygen affinity.

Oxygen affinity of a particular hemoglobin is generally expressed in terms of the oxygen tension at which 50% saturation occurs, the so-called P_{50}. When measured in whole erythrocytes, this value averages about 26 mm Hg in normal nonsmoking males.[469] When oxygen affinity increases, the dissociation curve shifts leftward, and the value for P_{50} is reduced. Conversely, with decreased oxygen affinity, the curve shifts to the right and P_{50} is increased.

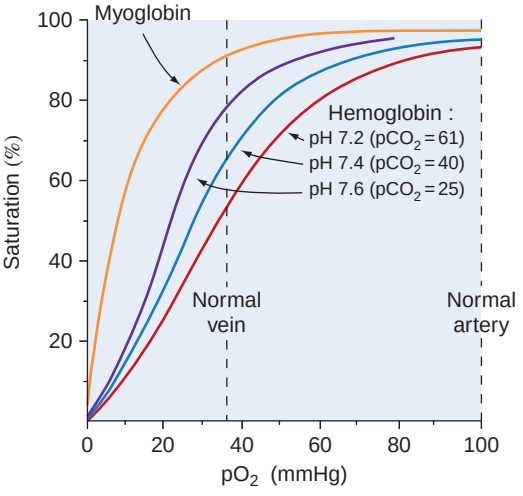

FIGURE 6.21. Oxygen dissociation curve of hemoglobin, at three values for pH, compared with that of myoglobin. pCO_2, partial pressure of carbon dioxide; pO_2, partial pressure of oxygen.

Regulation of Oxygen Affinity

The oxygen dissociation curve of single-subunit heme polypeptides (e.g., myoglobin) is hyperbolic, and oxygen affinity is considerably greater than that of hemoglobin (Fig. 6.21). In contrast, the oxygen curve of hemoglobin is distinctly sigmoidal; the steepest part of its slope occurs at levels of oxygen tension corresponding to those found in tissues. This difference between the hemoglobin and myoglobin curves is the result of interaction between the four heme–polypeptide units of hemoglobin. Although it was called heme–heme interaction in the past, *subunit cooperativity* better describes the process whereby the binding of oxygen by one subunit increases the oxygen affinity of other subunits; no direct interaction among heme moieties is involved. This allosteric property of hemoglobin permits rapid changes in oxygen affinity during the time the red blood cell passes through the capillary bed.

The change in oxygen affinity with pH is known as the Bohr effect.[470–471,472] Hemoglobin oxygen affinity is reduced as the acidity increases (Fig. 6.21). Because the tissues are relatively rich in carbon dioxide, and because red cell carbonic anhydrase readily converts carbon dioxide to carbonic acid, the pH is lower there than in arterial blood; therefore, the Bohr effect facilitates transfer of oxygen to tissues. In the lungs, as oxygen is taken up and carbon dioxide is released, the pH rises and the oxygen-affinity curve shifts to the left. This event, termed the alkaline Bohr effect, increases the oxygen affinity of hemoglobin, helping to maximize oxygen uptake. Thus, the Bohr effect links and enhances the transport of both oxygen and carbon dioxide.

Another important factor affecting the oxygen affinity of hemoglobin is the concentration of 2,3-DPG.[473–476] The molecule can insert into the pocket between β-globin subunits in tetrameric hemoglobin and reduces oxygen affinity. 2,3-DPG is synthesized from glycolytic intermediates by means of a pathway known as the Rapoport-Luebering shunt (Fig. 6.22). In the erythrocyte, 2,3-DPG is the predominant phosphorylated compound, accounting for about two thirds of the red cell phosphorus; in contrast, it is present in only trace amounts in other tissues.

The production of 2,3-DPG depends on the rate of formation of its precursor, 1,3-DPG, and the relative amounts of 1,3-DPG going

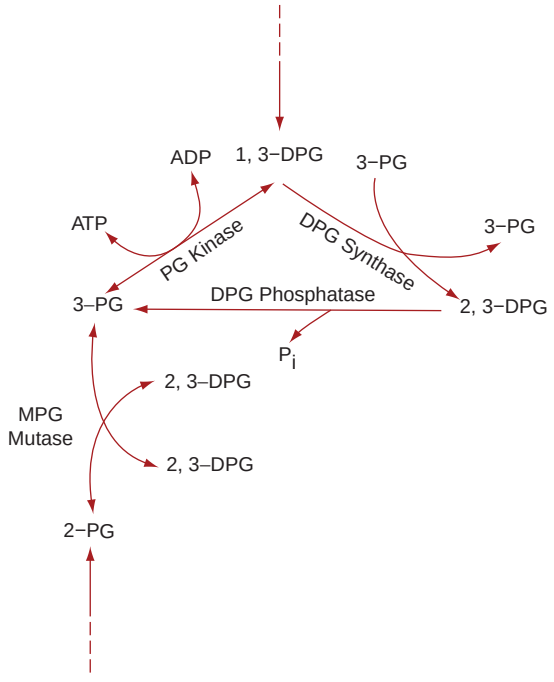

FIGURE 6.22. The synthesis of 2,3-diphosphoglycerate (2,3-DPG) or 3-phosphoglycerate (3-PG) and ATP from 1,3-diphosphoglycerate (1,3-DPG) by the Rapoport-Luebering cycle. (Modified from Keitt AS. Pyruvate kinase deficiency and related disorders of red cell glycolysis. Am J Med 1966;41:762–85 and from Bunn HF, Forget BG. Hemoglobin: molecular, genetic and clinical aspects. Philadelphia, WB Saunders, 1986.)

into the Rapoport-Luebering shunt and into the ATP-forming glycolytic pathway. Actual 2,3-DPG concentration also depends on the rate of hydrolysis of 2,3-DPG. It is the relative concentrations of ATP and ADP that are most directly linked to the rate of 2,3-DPG production. A relative increase in the amount of ADP is associated with an increase in the production of 3-phosphoglycerate and a decrease in 2,3-DPG. Two multifunctional enzymes (BPG mutase and BPG phosphotase/synthase) are important to the synthesis and degradation of 2,3-DPG. Both enzymes are capable of promoting three reactions: the synthesis of 2,3-DPG from 1,3-DPG; the breakdown of 2,3-DPG into 3-PG, water, and phosphorus; and the conversion of 3-PG to 2-PG.[477–479,480]

The most important function of 2,3-DPG is its effect on the oxygen affinity of hemoglobin. In the deoxygenated state, hemoglobin A can bind 2,3-DPG in a molar ratio of 1:1, a reaction that leads to reduced oxygen affinity and improved oxygen delivery to tissues. The increased oxygen affinity of fetal hemoglobin appears to be related to its diminished ability to bind 2,3-BDG. The increased oxygen affinity of stored blood is accounted for by reduced levels of 2,3-DPG.[481] Transfusion of such blood results in an in vivo increase in oxygen affinity that returns toward normal in 7 to 12 hours as the function of the glycolytic pathway is restored. The reduction in 2,3-DPG levels in stored blood can be mitigated by adding inosine or phosphate to the storage solutions.[482] The actual clinical impairment in oxygen delivery resulting from low 2,3-DPG levels remains to be determined.

Changes in 2,3-DPG levels play a significant role in adaptation to hypoxia. In some situations associated with hypoxemia, 2,3-DPG levels in red cells increase, oxygen affinity is reduced, and delivery of oxygen to tissues is facilitated. Such situations include abrupt exposure to high altitude, anoxia resulting from pulmonary or cardiac disease, blood loss, and anemia.[483–485] Increased 2,3-DPG levels also play a role in adaptation to exercise.[482] The compound is not essential to life, however; an individual who lacked the enzymes necessary for 2,3-DPG synthesis was perfectly well except for mild polycythemia (due to increased oxygen affinity). Heme–heme interaction, the Bohr effect, and the effect of 2,3-DPG have been explained on a molecular basis in a model proposed by Perutz.[453] In the completely deoxygenated state, hemoglobin assumes a quaternary structure termed T ("taut" or "tense"). This structure is stabilized by salt bridges involving the carboxy terminals of the peptide chains. The deoxy form is also stabilized by the presence of 2,3-DPG, which joins the β chains.

The tertiary structure of deoxygenated subunits also differs from that of the oxygenated form. In the deoxy form, heme iron is in a high-spin state and, in this form, is displaced slightly from the plane of the porphyrin ring. The penultimate tyrosine is wedged firmly between the F and H helices. When oxygen is added, iron changes to a low-spin state and moves to a position in the plane with the porphyrin ring, a distance of about 0.2 nm, and pulls the attached F helix with it. This movement narrows the space between the F and H helices, expelling the penultimate tyrosine from its pocket. The C-terminal amino acid moves with the tyrosine, thereby breaking the salt bridges with adjacent chains.

Fully oxygenated hemoglobin assumes the R or "relaxed" structure (Fig. 6.23). The exact series of events that bring about this change, along with the change in oxygen affinity that accompanies it, has been difficult to ascertain, in part because of the large number of variables that need to be controlled (e.g., temperature, pH, 2,3-DPG concentration, and hemoglobin concentration) and the extraordinarily large number of thermodynamic measurements that need to be made. Nevertheless, at least some of the molecular events that contribute to this shift in quaternary structure and oxygen affinity have been delineated.[486,487] Hemoglobin appears to exist in a third molecular form, intermediate between the T and R conformations. Achievement of the R conformation occurs when at least one oxygen molecule is bound on each side of the $\alpha_1\beta_2$ interaction; however, significant subunit cooperativity also exists within each $\alpha_1\beta_1$ dimer of the T-state tetramer. Conversion to the R form is also accompanied by expulsion of the 2,3-DPG and disruption of the salt bridges and hydrophobic interactions at the $\alpha_1\beta_2$ contact point (Fig. 6.23). Oxygen affinity then becomes much increased, and oxygen is added to the remaining β chain or chains. Because hemoglobin A has four subunits, it might be expected that the switch from the T state to the R state would occur in four distinct steps. Experimentally, it appears to switch abruptly. This is best explained by the relationship of the four subunits. The α and β chains in the dimers have many more

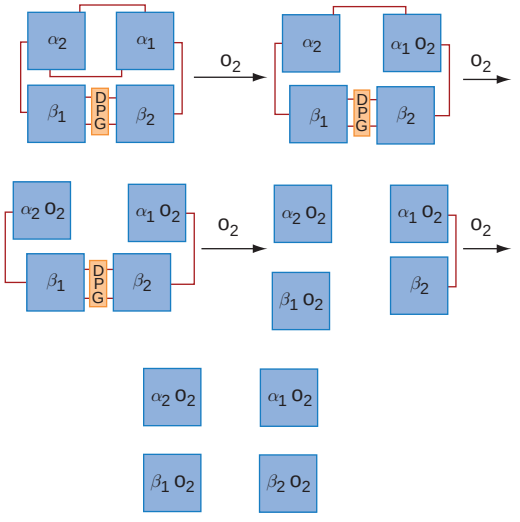

FIGURE 6.23. Diagrammatic representation of the subunit interaction in hemoglobin as oxygen is added. Deoxyhemoglobin (*upper left*), with low oxygen affinity, is in the T (taut) conformation, constrained by salt bridges (*interconnecting lines*) and the 2,3-DPG molecule. As O_2 is added, salt bridges are broken, and eventually the BPG molecule is expelled, resulting in the R (relaxed) configuration with higher oxygen affinity.

contacts than the two dimers with each other, and the dimers can move onto each other. As oxygen is either loaded or unloaded onto the hemoglobin tetramer, tension is created, and the point where the two dimer subunits slide onto each other is determined by the concentration of the allosteric mediaters in the cell, including pH, Cl^- concentration, and 2,3-DPG levels.

The alkaline Bohr effect is explained by rupture of the salt bridges involving the β-chain C-terminal histidine and the α N-terminal valine. When these bridges are broken, the pK of the dissociation of hydrogen ion is reduced. It has also been suggested that about 25% of the alkaline Bohr effect may be accounted for by histidine at α122.[488]

Carbon Dioxide Transport

Transport of carbon dioxide by red cells, unlike that of oxygen, does not occur by direct binding to heme.[489,490,491] In aqueous solutions, carbon dioxide undergoes a pair of reactions:

$$1.\ CO_2 + H_2O \rightarrow H_2CO_3$$

$$2.\ H_2CO_3 \rightarrow H^+ + HCO_3-$$

Carbon dioxide diffuses freely and rapidly into the red cell, where the presence of the enzyme carbonic anhydrase facilitates reaction 1. The H^+ liberated in reaction 2 is accepted by deoxygenated hemoglobin, a process facilitated by the Bohr effect. The bicarbonate formed in this sequence of reactions diffuses freely across the red cell membrane and a portion is exchanged with plasma Cl^-, a phenomenon called the *chloride shift*. The bicarbonate is carried in plasma to the lungs, where ventilation keeps the pCO_2 low, resulting in reversal of these reactions and excretion of CO_2 in the expired air. About 85% of tissue carbon dioxide is processed in this way, and 5% is carried in simple solution.

The remainder of the CO_2 is bound to the N-terminal amino group of each polypeptide chain by a carbamino complex, the result of an attack by the electron-poor carbon atom of CO_2 on the electron-rich terminal amino acids. This nonenzymic process varies directly with pH. Approximately 10% of CO_2 is bound to deoxygenated hemoglobin, forming carbaminohemoglobin (Hb–NH–COO^-).

Earlier, the effect of CO_2 on oxygen affinity was noted and attributed to the Bohr effect. An additional, more direct, effect results from CO_2 binding to hemoglobin. At a given pH, carbaminohemoglobin has a lower affinity for oxygen than has hemoglobin in the absence of CO_2. This is felt to be a result of the stabilization of the T state through additional bonds, especially involving arginine 141.[492]

The carbon dioxide dissociation curve is analogous to the oxygen dissociation curve, in that it depicts the relationship between CO_2 tension (pCO_2) and CO_2 content. It is somewhat more nearly linear than the oxygen curve, especially in the physiologic range (pCO_2 of 40 to 60 mm Hg). Because of the Bohr effect, blood containing deoxyhemoglobin has greater affinity for CO_2 than does oxygenated blood. The shift in the CO_2 dissociation curve related to this phenomenon, known as the Haldane effect, facilitates CO_2 binding in the tissues and release in the lungs (Fig. 6.24).

Carbonic anhydrase (CA) is the second most abundant cytoplasmic protein of the erythrocyte. It is a zinc-containing enzyme for which three separately encoded isoenzymes, CAI, CAII, and CAIII, are recognized. The predominant form in the human erythrocyte is CAI, although CAII is also found. Largely absent from fetal erythrocytes, erythrocyte CAI expression reaches adult levels during the first year of life, in a manner analogous to the expression of adult hemoglobin (hemoglobin A).[493,494] Although carbonic anhydrase clearly facilitates carbon dioxide metabolism, its presence in erythrocytes does not appear to be essential. Carbonic anhydrase expression appears to be under endocrinologic regulation.[495] Hereditary absence of CAI has been reported to occur without hematologic sequelae, and acquired deficiency is often seen with hyperthyroidism.[496,497]

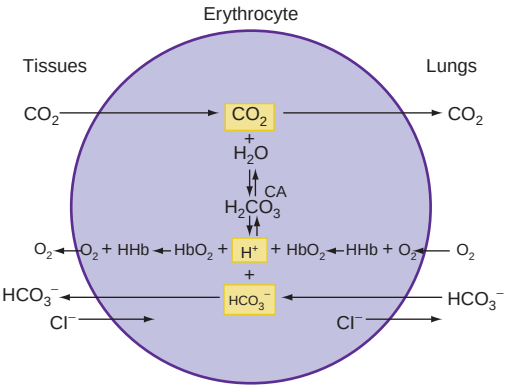

FIGURE 6.24. Interrelations of oxygen and carbon dioxide transport in the erythrocyte. Arrows to the left indicate direction of reactions taking place in the tissues; and those to the right, in the lungs. In the tissue, CO_2 diffuses into the red cell, and its hydration is catalyzed by carbonic anhydrase (CA). Dissociation of the resulting carbonic acid produces bicarbonate and a proton (H^+). The bicarbonate is exchanged for chloride in the plasma. The proton is accepted by oxyhemoglobin (HbO_2), a reaction that, by means of the Bohr effect, facilitates the dissociation of oxygen. These reactions are reversed in the lungs because of the low pCO_2 and high pO_2.

Nitric Oxide: Another Allosteric Effector of Hemoglobin

The discovery of nitric oxide as an important regulator of vascular and smooth muscle tone has provided many insights into our understanding of vascular physiology. Nitric oxide is produced by the vascular endothelium and relaxes muscles surrounding vessels, thereby controlling blood pressure. Subsequently, it was determined that free hemoglobin could act as a scavenger of nitric oxide and inactivate it, explaining the observation that the infusion of free hemoglobin results in significant elevations of blood pressure.[498] This reaction occurs because oxygenated heme iron scavenges nitric oxide in a reaction that yields methemoglobin.

Early studies of the interaction of hemoglobin with NO predicted that a function of hemoglobin was to eliminate or limit the biologic activity of NO and did not predict any functional effect on hemoglobin other than the oxidation of heme iron. This model did not explain how NO could be maintained at observed levels based on its known low levels of production. This was clarified with the discovery of *S*-nitrosohemoglobin (SNO-Hb).[499] When free hemoglobin is incubated with NO or *S*-nitrosothiols, *S*-nitrosothiols (SNOs) rapidly form on the two 93β cysteines of hemoglobin rather than reacting with the oxygenated heme groups as might be expected. The infusion of the SNO-hemoglobin results in no increase in blood pressure.[500]

In the pulmonary circulation, coincident with oxygenation of hemoglobin, nitric oxide is added to hemoglobin, and rather than oxidizing the heme iron, it binds to the iron or forms SNO-Hb through the reactive sulfhydryl groups of cysteine 93β of hemoglobin.[501,502] This function for cysteine 93β may explain why this amino acid is invariant in mammals and birds. Reactivity of nitric oxide with the SH groups of cysteine 93β is controlled by the allosteric transition of hemoglobin and the spin state of heme iron. Thus, oxygen binding and conversion to the R state increase reactivity.[499]

Likewise, loss of oxygen in the peripheral tissues results in transition of hemoglobin to the T state and release of NO. NO is bound to either small thiols or the anion exchanger AE1. The latter is facilitated because hemoglobin can bind to the RBC membrane through specific, high-affinity binding to the amino-terminal cytoplasmic domain of the chloride/bicarbonate anion-exchange protein AE1 (band-3 protein).[503] The amino terminus of AE1 inserts into the cleft usually occupied by 2,3-DPG.[503] NO-mediated vasodilatory activity is released from AE1 by deoxygenation and NO then binds to receptors on the vascular endothelium to induce vasodilation. SNO-Hb is therefore detected

in arterial but not in venous blood. Several reviews have been published on the relationship of nitric oxide and SNO-Hb and the regulation of blood flow.[504,505–506]

Oxidative Denaturation of Hemoglobin: Its Reversibility and Prevention

Oxyhemoglobin in solution gradually undergoes auto-oxidation, becoming methemoglobin ($HbFe^{3+}$). To bind oxygen reversibly, however, the iron in the heme moiety must be maintained in the reduced (ferrous, Fe^{2+}) state, despite exposure to a variety of endogenous and exogenous oxidizing agents. The red cell maintains several metabolic pathways to prevent the action of these oxidizing agents and to reduce hemoglobin iron if it becomes oxidized. Under certain circumstances, these mechanisms fail and hemoglobin becomes nonfunctional. At times, hemolytic anemia supervenes as well. These abnormalities are particularly likely to occur (a) if the red cell is exposed to certain oxidant drugs or toxins, (b) if the intrinsic protective mechanisms of the cell are defective, or (c) if genetic abnormalities of the hemoglobin molecule affect globin stability or the heme crevice (see Chapter 35).

The oxidation of hemoglobin occurs in a stepwise fashion from fully reduced hemoglobin to fully oxidized hemoglobin. Intermediate forms are called *valence hybrids*. In deoxyhemoglobin, the heme iron is in the "high-spin" ferrous state, in which six electrons are in the outer shell, four of which are unpaired. When oxygen is added, one of these electrons is partially transferred to the bound oxygen. Usually, when oxygen is given up, oxyhemoglobin dissociates into partially deoxygenated hemoglobin and molecular oxygen:

$$Hb(O_2)_4 \rightarrow Hb(O_2)_3 + O_2$$

A superoxide anion rather than molecular oxygen may dissociate, however, thus oxidizing the Fe to the ferric state, producing methemoglobin:

$$HbFe^{2+} + O_2 \rightarrow HbFe^{3+}O_2^- \rightarrow HbFe^{3+} + O_2^-$$

This type of dissociation is particularly likely if water gains access to the heme crevice. Methemoglobin formation may also occur in vivo as the result of exposure to superoxide anions:

$$2HbFe^{2+} + O_2 + 2O_2^- + 4H^+ \rightarrow 2HbFe^{3+} + 3O_2 + 2H_2O$$

The formation of methemoglobin may also result from a direct reaction of reduced hemoglobin with the reduction product of the superoxide ion, peroxide:

$$2HbFe^{2+} + 2H_2O_2 \rightarrow 2HbFe^{3+}\cdot H_2O + O_2$$

As a result of these processes, methemoglobin is formed in normal cells at the rate of about 0.5% to 3% per day.[507,508]

Methemoglobin is unable to bind oxygen. It has a distinctive, pH-dependent spectrum (Fig. 6.25), and, in concentrations >10% of the total hemoglobin, imparts to blood a distinctive brownish hue that does not disappear on vigorous shaking in air.[509] When methemoglobin is present in vivo in concentrations >1.5 to 2.0 g/dl, patients appear visibly cyanotic. Methemoglobin combines readily with cyanide to form cyanomethemoglobin, a pigment so stable that it is used in laboratory procedures for quantifying hemoglobin.

As oxidative denaturation continues, methemoglobin is converted to derivatives known as hemichromes.[508,510] Hemichromes also may form directly from hemoglobin without methemoglobin as an intermediate. The hemichromes are low-spin, ferric compounds with a greenish hue and a characteristic spectrum (Fig. 6.25). They are formed when the sixth coordination position of iron becomes covalently attached to a ligand within the globin molecule, a change that requires alteration of tertiary protein structure. Probably the most common internal ligand is the "distal" histidine at E7. The compound so formed has been called a

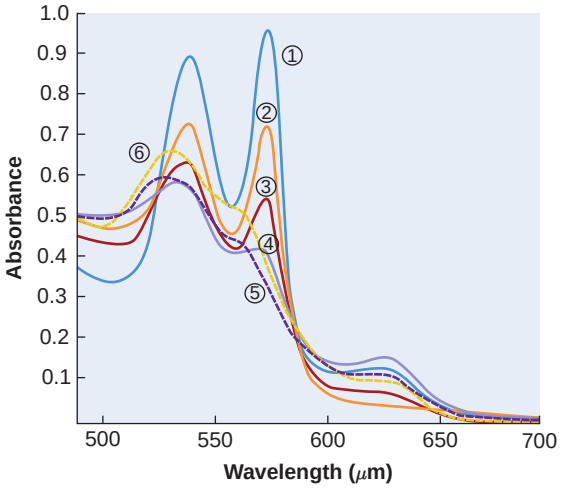

FIGURE 6.25. Change in hemoglobin spectrum as oxyhemoglobin changes to methemoglobin. The numbers 1 through 6 represent curves taken in sequence as oxidation proceeds. Note in particular the disappearance of the band at 575 μm and the appearance of the band at 631 μm.

"reversible" hemichrome, because relatively mild treatment with reducing agents and dialysis under anaerobic conditions converts it to deoxyhemoglobin. It may not be reversible in vivo, however, because it cannot be reduced by methemoglobin reductase.

In contrast, the "irreversible" hemichromes cannot be converted back to normal hemoglobin again in vivo or in vitro, implying that more severe distortions of tertiary protein structure have occurred. In one of the irreversible hemichromes, the histidine imidazole groups are protonated; that is, they participate in hydrogen bonding. The other irreversible hemichrome is characterized by a mercaptide and nitrogenous linkage at the fifth and sixth positions. Presumably, the mercaptide link is provided by a cysteine residue in the globin chain, perhaps at β93.

As these changes occur in the vicinity of the heme group, oxidative changes also occur in other parts of the hemoglobin molecule. Once the cell's supply of glutathione (GSH) is exhausted, the titrateable sulfhydryl groups at β93(F9)Cys are oxidized, often forming a mixed disulfide with glutathione.[511] This change is reversible; however, as further alterations in globin conformation occur, normally protected or "buried" sulfhydryl groups at β112(G14)Cys and α104(G11)Cys become exposed and are oxidized, changes that disrupt the $\alpha_1\beta_2$ contacts. These changes facilitate dissociation of polypeptide chains, first into $\alpha\beta$ dimers and finally into monomers.[512] In some instances, heme may dissociate from globin, particularly in the case of certain unstable hemoglobins.

The end products of these changes are precipitated hemichromes and precipitated hemefree globin. In intact erythrocytes, these precipitates take the form of globular inclusions known as Heinz bodies, which are not visible with ordinary Wright stain but can be seen easily after supravital staining with crystal violet or brilliant cresyl blue. Heinz bodies may become attached to the cell membrane and shorten red cell survival.

Another nonfunctional hemoglobin derivative that is occasionally formed during the oxidative denaturation of hemoglobin is sulfhemoglobin. This is a relatively stable pigment and, once formed, cannot be reconverted to hemoglobin in vivo. Instead, it tends to remain within the cell throughout the cell's life. Sulfhemoglobin is bright green and has a distinctive spectrum characterized by an absorption band at about 618 nm. It is a ferrous compound with one sulfur atom attached to each heme group. The sulfur is probably attached to a β carbon in the porphyrin ring, forming a thiochlorin.[511,513]

Although the exact mode of synthesis of sulfhemoglobin remains to be established, proposed models suggest that methemoglobin is first converted to ferrylhemoglobin in the presence of hydrogen peroxide.[513,514]

$$HbFe^{3+} + H_2O_2 \rightarrow HbFe^{4+}O + H_2O + e^-$$

With the addition of a sulfur-containing compound, such as hydrogen sulfide, the iron in ferrylhemoglobin is reduced and sulfur is incorporated into the porphyrin ring:

$$HbFe^{4+}O + HS^- + 2e^- \rightarrow HbSFe^{2+} + OH^-$$

Although the iron in sulfhemoglobin is reduced, it binds oxygen with an affinity one hundredth that of unmodified hemoglobin.

Known mechanisms for preventing or reversing oxidative denaturation of hemoglobin in the erythrocyte include (a) the methemoglobin reductases, (b) superoxide dismutase, (c) glutathione peroxidase, and (d) catalase.

Methemoglobin Reduction

Most methemoglobin in erythrocytes is reduced through the action of an enzyme, cytochrome b_5 methemoglobin reductase, which acts in the presence of two electron carriers, cytochrome b_5 and NADH. Only a small amount of methemoglobin is reduced by all other pathways of methemoglobin reduction together. These other pathways involve two compounds that cause the nonenzymic reduction of methemoglobin, ascorbic acid and glutathione, as well as a second enzyme, NADPH-flavin reductase. Deficiency of cytochrome b_5 reductase, but not of NADPH-flavin reductase, is associated with methemoglobinemia, confirming that cytochrome b_5 reductase is the most important physiologic means of reducing methemoglobin.[515]

Cytochrome b_5 reductase has been referred to by several other names, including diaphorase I, DPNH dehydrogenase I, NADH dehydrogenase, NADH methemoglobin reductase, and NADH methemoglobin-ferrocyanide reductase. Work in the 1940s established a relationship between the reduction of methemoglobin and the metabolism of lactate to pyruvate, thus implying an important role for NADH.[516] Eventually, two methemoglobin-reducing enzymes were isolated. The NADH-dependent enzyme, which was absent from several patients with methemoglobinemia, has been shown to be a flavoprotein, with one mole of FAD per mole of apo-enzyme. Its molecular weight is approximately 34 kDa. The reduction of methemoglobin by highly purified cytochrome b_5 reductase in the presence of NADH is extremely slow, implying that another factor is most likely required as an electron carrier. In vitro, this role can be filled by dyes or by ferrocyanide. In vivo, cytochrome b_5 acts as the intermediate electron carrier.[517] Erythrocyte cytochrome b_5 greatly accelerates reduction of methemoglobin by cytochrome b_5 reductase and can also serve as a substrate for hepatic microsomal cytochrome b_5 reductase. Congenital methemoglobinemia resulting from a deficiency in cytochrome b_5 has been described (Chapter 35).[518,519] The process by which cytochrome b_5 reductase and cytochrome b_5 reduce methemoglobin in the presence of NADH probably involves three steps. In the first, NADH binds to the FAD-reductase complex and, in the presence of hydrogen ion, the NAD is converted to NAD^+, and the FAD becomes $FADH_2$. In the second step, cytochrome b_5-Fe^{3+} is reduced to cytochrome b_5-Fe^{2+}, and the $FADH_2$ reverts to FAD. Finally, methemoglobin forms a bimolecular complex with reduced cytochrome b_5 through electrostatic interactions between negatively charged groups around the cytochrome heme and positively charged groups around the heme moieties of methemoglobin. The reduction of methemoglobin then takes place as follows:

$$HbFe^{3+}\ Cytb_5Fe^{2+} \rightarrow HbFe^{2+} + Cytb_5Fe^{3+}$$

Of lesser physiologic importance is the enzyme system that depends on NADPH for its activity. It probably accounts for only about 5% of the methemoglobin-reducing activity of normal red cells, and its hereditary deficiency does not lead to methemoglobinemia.[518] The lack of physiologic activity may result from the absence of an intermediate electron carrier analogous to cytochrome b_5. If methylene blue is supplied as the carrier, however, the NADPH-dependent enzyme becomes highly effective in methemoglobin reduction. This property is used in the therapy of methemoglobinemia from various causes.

Enzymes That React with Products of Oxygen Reduction

As molecular oxygen undergoes successive univalent reductions, a variety of reactive species is generated. These species constitute the oxidizing agents most likely to be responsible for the oxidative denaturation of hemoglobin, and they may damage other cellular components as well, especially lipid-containing elements such as the cell membrane.[520,521] A variety of mechanisms has evolved in respiring organisms to deal with these potential toxins, and some are found within the erythrocyte.

Superoxide anions are produced in biologic tissues from several sources, including oxyhemoglobin itself, as well as oxidative reactions catalyzed by flavin enzymes, such as xanthine oxidase.[521] In addition, many drugs and toxins have oxidant activity and appear to generate superoxide.[522] Once superoxide has been generated in aqueous solution, additional toxic products of oxygen may form spontaneously (Fig. 6.26). Thus, superoxide can undergo spontaneous dismutation, yielding peroxide and oxygen:

$$O_2 + O_2 + 2H^+ \rightarrow H_2O_2 + O_2$$

In addition, in the presence of catalytic quantities of transition metals, superoxide and peroxide may react to form the highly reactive hydroxyl radical (OH·):

$$O_2 + H_2O_2 \rightarrow OH\cdot + OH^- + O_2$$

Any of these oxygen derivatives may exert toxic effects on cellular components. As previously noted, superoxide induces

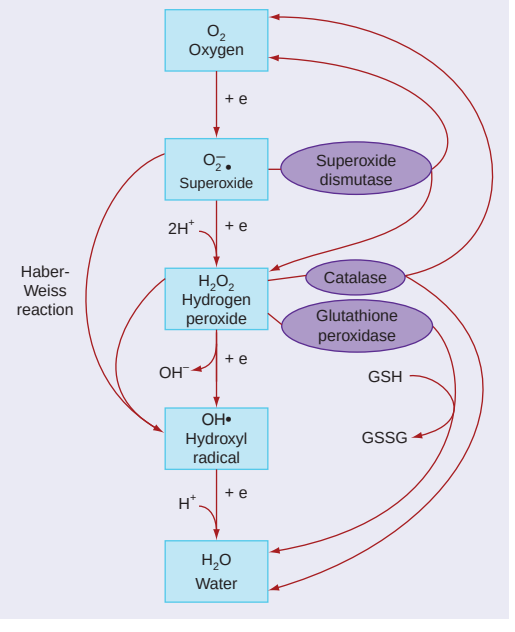

FIGURE 6.26. Steps in the univalent reduction of oxygen and enzymatic pathways affecting the intermediates. The enzymatic pathways, shown on the right, provide the means for processing these intermediates without formation of the highly reactive hydroxyl radical. This potent oxidant can be formed by the reaction shown on the left if superoxide and peroxide concentrations are sufficient and if catalytic quantities of transition metals are present.

methemoglobin formation.[523,524] Hydrogen peroxide is the most stable intermediate in the reduction of oxygen. Although hydrogen peroxide has often been shown to induce the oxidative denaturation of hemoglobin in vitro, whether it does so directly or by giving rise to other products, such as the hydroxyl radical, is not clear.

The hydroxyl radical, one of the most potent redox agents known, may be generated from superoxide and peroxide, as described previously, and from peroxide in the presence of certain metals:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + OH$$

Thus, enzymes that scavenge superoxide and peroxide may be viewed as mechanisms for preventing the accumulation of these intermediates in sufficient quantities to allow the hydroxyl radical to form.[525,526]

The superoxide dismutases are enzymes that catalyze the dismutation of superoxide to oxygen and peroxide. Although this reaction occurs spontaneously, the presence of the enzyme speeds the reaction to a rate as much as 109 times faster than the spontaneous rate.[521] In the erythrocyte, superoxide dismutase is a soluble, copper/zinc enzyme with a molecular weight of about 32 kDa. This enzyme, formerly known as erythrocuprein or hemocuprein, accounts for most of the copper content of the red cell. Once hydrogen peroxide is formed, two enzymes catalyze the decomposition of hydrogen peroxide in erythrocytes. These are glutathione peroxidase and catalase. Glutathione (GSH) peroxidase is a component of the following reaction[413,527]:

$$H_2O_2 + 2GSH \xrightarrow{\text{GSH peroxidase}} 2H_2O + GSSG$$

The enzyme is effective at very low concentrations of peroxide ($K_m = 1 \times 10^{-6}$ M).[527]

Glutathione peroxidase is the major human selenoprotein, which may account for the antioxidant properties of selenium as a micronutrient.[528,529] Human cells grown in the absence of selenium express significantly reduced glutathione peroxidase activity, despite normal glutathione peroxidase mRNA and transcription levels. It had been proposed that a genetic defect in glutathione peroxidase may lead to a drug-sensitive hemolytic anemia.[530] However, it is unlikely that acquired or genetic defects in this enzyme are associated with hemolysis (see Chapter 28).

Catalase, a heme enzyme, decomposes hydrogen peroxide to water and molecular oxygen.[531] It appears to be less important to the red cell than peroxidase, presumably because it is effective only when the peroxide concentration is relatively high.[532] Individuals with hereditary acatalasemia do not develop methemoglobinemia or hemolytic disease.[533,534] Some evidence suggests, however, that erythrocyte catalase may be important in preventing oxidant damage to somatic tissues.[535]

Glutathione Metabolism

Reduced glutathione (GSH) is a tripeptide (γ-glutamyl–cysteinyl–glycine). Two ATP-dependent enzymatic reactions are required for the de novo synthesis of glutathione:

1. Glutamic acid + cysteine → γ-glutamyl-cysteine
2. γ-Glutamyl-cysteine + glycine → GSH

Reaction 1 is catalyzed by glutamyl–cysteine synthetase, reaction 2 by glutathione synthetase. Both reactions can take place in normal erythrocytes.[536] The capacity of normal red cells to synthesize glutathione exceeds the rate of turnover by 150-fold. Deficiencies of both of these glutathione synthetic enzymes have been associated with hemolytic anemia (see Chapter 28).

In the course of reactions that protect hemoglobin from oxidation, GSH is oxidized, forming oxidized glutathione (GSSG), which consists of two GSH molecules joined by a disulfide linkage, and

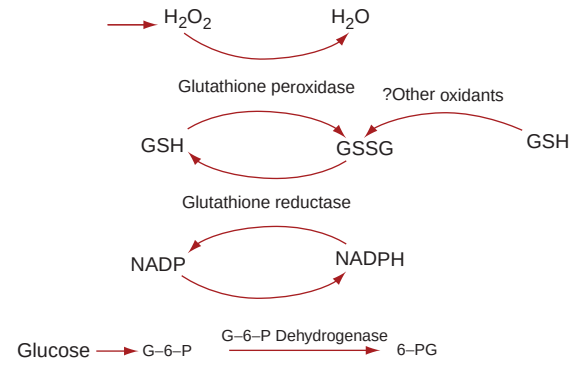

FIGURE 6.27. Glutathione metabolism in the erythrocyte.

mixed disulfides with hemoglobin. GSSG rapidly leaves the erythrocyte.[537] Thus, maintaining a continuous supply of GSH requires a system to reduce the oxidized forms of glutathione. Such a system is provided by glutathione reductase, which catalyzes the reduction of GSSG by NADPH, a product of the pentose phosphate pathway (Fig. 6.27). Glutathione reductase also catalyzes the reduction of hemoglobin–glutathione disulfides, yielding GSH and hemoglobin.[538]

The gene for glutathione reductase maps to chromosome 8. This enzyme is a flavoprotein consisting of two identical peptide chains of 478 amino acids. Because of its flavin component, the activity of glutathione reductase depends on the dietary intake of riboflavin. Erythrocyte glutathione reductase activity may be increased by administration of riboflavin, even in apparently normal subjects.[537]

Energy Metabolism

Lacking a storage compound, the normal erythrocyte must have constant access to glucose if its energy metabolism is to be sustained. As previously discussed, glucose enters the cell by means of a facilitated, carrier-mediated transport mechanism. Insulin or other hormones are not required, and transport is not ordinarily the rate-limiting factor in glucose utilization. Without mitochondria, erythrocytes must depend on two less efficient pathways for production of high-energy compounds, the anaerobic glycolytic (Embden-Meyerhof) pathway and the aerobic pentose phosphate pathway, also known as the hexose monophosphate shunt (Fig. 6.28). Under normal circumstances, about 90% of glucose entering the red cell is metabolized by the anaerobic pathway and 10% by the aerobic pathway.[539] Under conditions of oxidative stress, however, the oxidative pentose pathway may account for up to 90% of glucose consumption.[540]

Three important products are formed by the anaerobic glycolytic pathway: NADH, a co-factor in the methemoglobin reductase reaction; ATP, the major high-energy phosphate nucleotide that powers the cation pump; and 2,3-DPG, a regulator of hemoglobin function (Fig. 6.28). For each molecule of glucose that enters the pathway, two molecules of NADH are generated (Fig. 6.29, reaction 6). The yields of ATP and 2,3-DPG vary depending on the activity of the Rapoport-Luebering shunt (Fig. 6.29, reactions 7b and 7c), a side pathway unique to the red cell. Two molecules of ATP are used in the early steps of glycolysis (Fig. 6.29, reactions 1 and 3), and a maximum of four molecules is produced late in the pathway (two in reaction 7a and two in reaction 10). Thus, at maximum efficiency, a net yield of two molecules of ATP may be expected for each molecule of glucose catabolized. This net yield may be decreased, however, to the extent that 2,3-DPG is formed (Fig. 6.29, reactions 7b and 7c). For this reason, the BPG-forming step is sometimes referred to as an energy clutch.

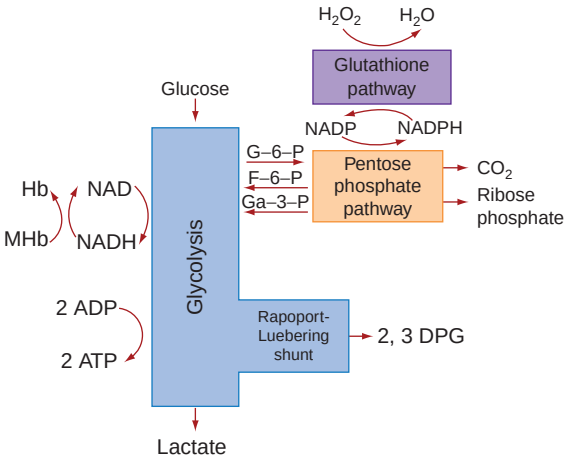

FIGURE 6.28. Energy metabolism in the erythrocyte. Main pathways are shown as boxes; major substrates and products of each are shown outside the boxes. More details of the pathways are given in Figures 6.27 and 6.29. ADP, adenosine diphosphate; ATP, adenosine triphosphate; 2,3-DPG, 2,3-diphosphoglycerate; F-6-P, fructose 6-phosphate; G-6-P, glucose 6-phosphate; Ga-3-P, glyceraldehydes 3-phosphate; Hb, hemoglobin; MHb, methemoglobin; NAD, NADH, nicotinamide adenine dinucleotide; NADP, NADPH, nicotinamide adenine dinucleotide phosphate.

Of the 11 enzymes in the glycolytic pathway, 3 appear to be particularly important in regulation of glycolytic rate. These are hexokinase, phosphofructokinase, and pyruvate kinase (Fig. 6.29). Hexokinase is the least active enzyme in the series and is therefore often rate-limiting. It is inhibited by its product, glucose 6-phosphate, and is stimulated by one of its substrates, Mg-ATP. The activity of phosphofructokinase is greatly affected by intracellular pH. Because the pH optimum of this enzyme is 8.0, the activity of the enzyme and the overall rate of glycolysis tend to increase with increased pH (alkalosis) and decrease with decreased pH (acidosis). Phosphofructokinase may also be activated by the product of the further phosphorylation of fructose 6-phosphate.[541] Pyruvate kinase is strongly inhibited by its product, ATP, and pyruvate kinase activity may therefore be related to the rate at which ATP is used in the cell's metabolic processes.

The importance of glycolysis to the red cell confirmed by the clinical phenotype of the hereditary deficiencies of any of the glycolytic enzymes, which is characterized by decreased red cell survival and consequent hemolytic anemia (Chapter 28).

The most important product of the pentose phosphate pathway in erythrocytes is reduced NADPH. In the red cell, NADPH, serves as a co-factor in the reduction of oxidized glutathione (GSSG), the major reducing agent in the cell and the ultimate source of protection against oxidative attack. The utilization of NADPH is the main stimulus to the utilization of glucose 6-phosphate by the pathway. Redox agents such as methylene blue, cysteine, ascorbate, and others induce up to a 20-fold increase in pentose metabolism, presumably by bringing about oxidation of glutathione.[542,543] This metabolic flexibility allows the red cell to respond to unexpected oxidant challenge. The initial reaction of the pentose phosphate pathway is catalyzed by the enzyme glucose 6-phosphate dehydrogenase (G6PD). Hereditary deficiency of red cell G6PD is one of the most common genetic abnormalities in the world associated with hemolysis (Chapter 28).

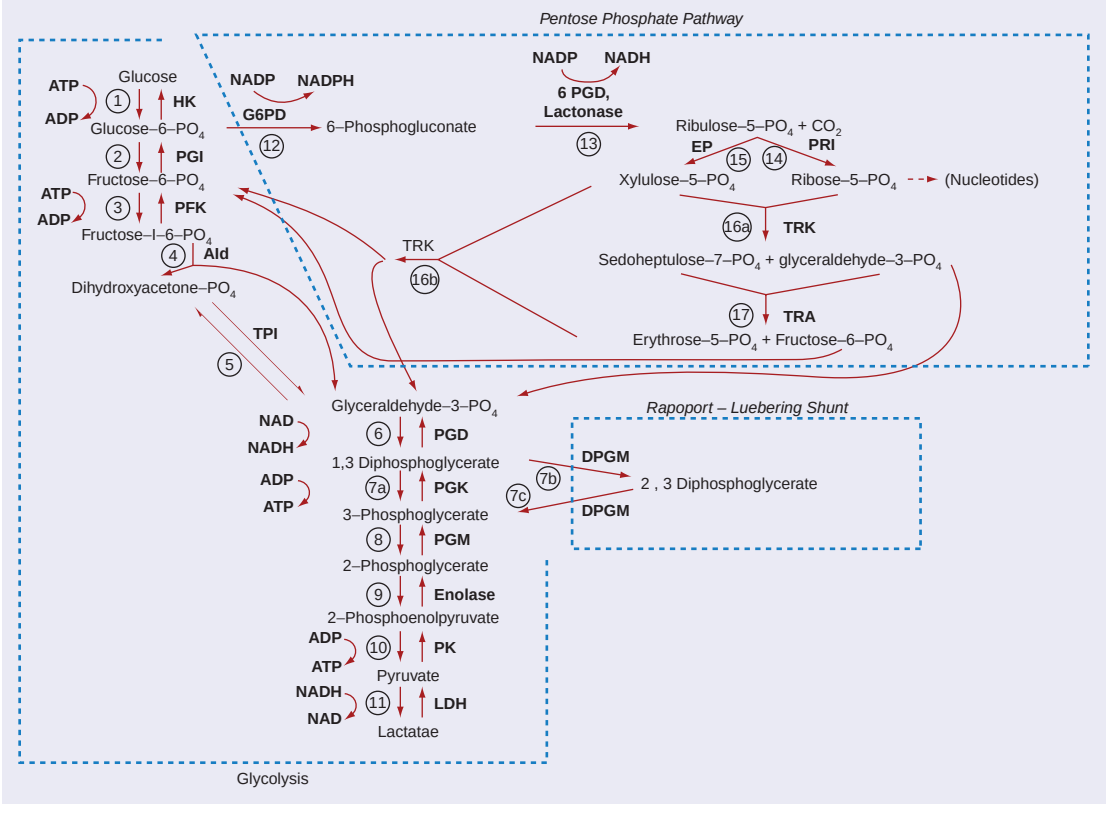

FIGURE 6.29. Energy metabolism in the erythrocyte. Circled numbers represent reactions referred to in the text. Enzymes are designated by abbreviations and are shown in bold to the right or above arrows representing reactions. Cofactors are shown in bold to the left of the arrows or above the enzymes. ADP, adenosine diphosphate; Ald, aldolase; ATP, adenosine triphosphate; DPGM, diphosphoglyceratemutase; Ep, epimerase; G6PD, glucose 6-phosphate dehydrogenase; HK, hexokinase; LDH, lactate dehydrogenase; NAD-NADH, nicotinamide adenine dinucleotide; NADP-NADPH, nicotinamide adenine dinucleotide phosphate; PFK, phosphofructokinase; PGD, phosphoglyceraldehyde dehydrogenase; 6PGD, 6-phosphogluconate dehydrogenase; PGI, phosphoglucose isomerase; PGK, phosphoglycerate kinase; PGM, phosphoglyceromutasetransaldolase; TRK, transketolase.

A second function of the pentose pathway is the conversion of hexoses to pentoses. For the most part, the latter are recycled into the glycolytic pathway; however, D-ribose 5-phosphate may be used for nucleotide synthesis.

CELL DESTRUCTION

Mechanisms and Site of Red Cell Destruction

Each day approximately 1% of the body's red cells (3×10^9 cells/kg) die and are replaced by reticulocytes. Why red blood cells die after 100 to 120 days is not known. Through the years various hypotheses have been proposed to explain normal red cell death. The explanations have included changes in red cell enzymes and energy depletion with age; alterations in calcium balance; changes in membrane surface charge; oxidative injury; development of autologous antibodies to membrane antigens; and changes in membrane phospholipid asymmetry (see Wintrobe 12th edition for discussion of these hypotheses). No one of these changes explains RBC senescence and the mechanism of red cell senescence remains elusive. It may be that human erythrocyte aging and destruction results from a combination of the abnormalities noted above or from some as yet unrecognized phenomenon. Most certainly, emerging studies of RBC proteomics should help clarify the process of red cell death.

Under normal conditions, 80% to 90% of this normal erythrocyte destruction occurs without release of hemoglobin into plasma.[544,545] Thus, most of the destructive process is considered to be *extravascular*, within macrophages of the spleen and, to a lesser extent, the liver and bone marrow. Approximately 10% to 20% of normal destruction is estimated to occur *intravascularly*.

Extravascular Hemolysis

Erythrophagocytosis appears to be the primary mode of extravascular destruction of senescent red cells.[546,547] This is supported by two observations. Heme oxygenases responsible for heme degradation (primarily the inducible enzyme, HO-1) are located in the phagocytic cells of the spleen, liver, and bone marrow (and also in hepatocytes). Second, iron derived from heme degradation is largely stored within the macrophage. Thus, it seems that the processes of red cell destruction and hemoglobin degradation normally occur within these phagocytes. This is also true when red cell destruction is increased in the hemolytic anemias. Likewise, when red cells are damaged in vitro and then reinfused, they are mostly removed from the circulation by macrophages of the spleen and liver.[548]

The relative importance of the spleen and liver in erythrocyte destruction is influenced by the degree of cell damage.[548] Severe red cell damage leads to their destruction in all macrophage-containing organs, but especially in the liver because of its greater blood flow. The spleen, in contrast, preferentially removes minimally damaged erythrocytes.[549] Most senescent red cells are therefore likely destroyed in the spleen; however, after splenectomy, macrophages found in other organs, especially the liver, assume this function, and there is no increase in survival of normal red cells.[550] Recent studies have cleverly attempted to assess splenic sensing and sequestration of spherocytic red cells, as occurs in a number of hemolytic anemias, such as hereditary spherocytosis (Chapter 27). Red cells were first treated with a phospholipid, lysophosphatidylcholine, which causes a dose-dependent decrease in the red cell surface area-to-volume (*S/V*) ratio through cell membrane loss. A decrease in the *S/V* ratio of more than 27% (resulting from a decrease in surface area of more than 18%) leads to rapid and complete sequestration of red cells during passage through freshly isolated human spleens.[551] Notably, the integrity of splenic parenchymal structure, blood flow, and metabolic activity is preserved during the ex vivo perfusion of these intact spleens for up to 6 hours, potentially allowing analysis of human red cell entrapment during physiologic or pathologic conditions.[552]

Intravascular Hemolysis

Analysis of haptoglobin kinetics in humans suggests 10% to 20% of erythrocyte destruction occurs intravascularly.[544,545] Although both osmotic lysis and red cell fragmentation can cause intravascular destruction, it is unlikely that osmotic lysis plays a role in normal red cell destruction. *Fragmentation* is the loss of part of the cell membrane, usually accompanied by a loss of cellular contents, including hemoglobin. This is the characteristic mode of destruction in the "microangiopathic" hemolytic anemias (Chapters 32 and 48). The blood smear reveals small, misshapen, often triangular- or helmet-shaped cells (schistocytes or schizocytes). Fragmentation of red cells is usually due to interactions with injured endothelium, or results from fibrin deposition or increased shear stresses. In response, the cell membrane is capable of limited self-repair. Fragmentation also occurs when reticulocytes are pitted with inclusions, such as residual organelles and hemosiderin granules during passage through the spleen. The enucleation of erythroblasts that normally occurs in the bone marrow may also contribute to hemoglobin release into the circulation, a process that may be increased with ineffective erythropoiesis.

FATE OF INTRAVASCULAR HEMOGLOBIN

Intravascular hemolysis is increased significantly in certain hemolytic anemias (e.g., sickle cell disease, thalassemias, paroxysmal nocturnal hemoglobinuria [Chapters 31 and 34], during infections (e.g., malaria or sepsis due to *Clostridium perfringens*), or trauma. The hemoglobin released into the plasma is pro-oxidant and thus potentially toxic, promoting, for example, the formation of hydroxyl radicals via the Fenton reaction ($H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH\cdot + OH^-$), and oxidative tissue damage.[553] In addition, plasma hemoglobin is a potent scavenger of nitric oxide (NO), mediating its nitrosylation to produce methemoglobin and nitrate. NO serves as an important regulator of smooth muscle tone (of special relevance in small blood vessels), platelet activation and aggregation, and endothelial integrin expression. Intravascular hemolysis may therefore result in smooth muscle dystonias, endothelial dysfunction, and thromboses, problems commonly encountered in sickle cell disease[554,555] and paroxysmal nocturnal hemoglobinuria.[556] Fortunately, there are several physiologic mechanisms to remove free hemoglobin from the circulation (Fig. 6.30).

Haptoglobin

At low rates of release of hemoglobin into the circulation, it is completely bound by haptoglobin (Hp), and, once irreversibly bound to haptoglobin, loses its oxidizing ability.[553,557] Once released from red cells into the plasma, tetrameric hemoglobin rapidly dissociates into $\alpha\beta$ dimers that bind haptoglobin tightly in a noncovalent manner ($K_d \sim 1$ *p*M).[558] Heme-free globin (but not heme) can also be bound by haptoglobin.[559] Binding of hemoglobin by haptoglobin prevents H_2O_2-mediated peroxidative modifications to the hemoglobin molecule,[560] allowing productive interactions of the Hp–Hb complex with the receptor, CD163 (see below). The role of haptoglobin as a hemoglobin-binding protein and as the principal factor affecting the apparent "renal threshold" for hemoglobin was originally described by Laurell and Nyman.[561]

Haptoglobins are a family of α_2-glycoproteins that bind hemoglobin.[562] The tetrameric molecule is comprised of two dimers of an α chain (containing a complement control protein or sushi

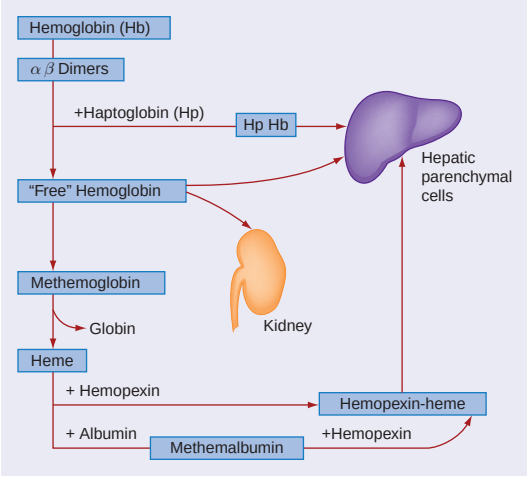

FIGURE 6.30. Pathways for the disposal of hemoglobin in plasma. Hemoglobin freely dissociates into $\alpha\beta$ dimers. These are bound by haptoglobin with subsequent removal of the hemoglobin–haptoglobin complex by hepatic parenchymal cells. Hemoglobin in excess of the haptoglobin-binding capacity circulates as the unbound (free) protein. In this form it is partially removed by hepatic cells, but it may also follow two other pathways; it may be excreted by the kidney or oxidized to methemoglobin, from which heme is easily dissociated. Heme is initially bound to hemopexin, which transports it to the hepatic parenchymal cell. Heme may also be bound nonspecifically by albumin, forming methemalbumin. This complex probably transfers its heme to hemopexin as the latter becomes available.

domain) and β chain (with a serine protease domain) linked in humans by disulfide bonds to form $(\alpha\beta)_2$.[563,564] The gene, located on chromosome 16q22,[565–567] encodes a single polypeptide chain that is cleaved posttranslationally to generate the α and β subunits.[568,569] Transcriptional activity is promoted by IL-1, IL-6, and glucocorticoids as a part of the acute-phase response to systemic inflammation,[570–573] explaining why haptoglobin levels are increased with inflammation.

Human haptoglobin was first described as polymorphic by Smithies et al., who used starch gel electrophoresis to separate the various types. There are two major allelic forms of the *hp* gene (*hp1*, *hp2*) that can therefore give rise to three major phenotypes referred to as Hp1-1, Hp2-1, and Hp2-2. These were distinguished using starch gel or polyacrylamide gel electrophoresis according to their different sizes and band patterns (Hp1-1 = 100 kDa; Hp2-1 = 120 to 220 kDa; Hp2-2 = 160 to 500 kDa).[574] The β chain of Hp contains the binding domain for the $\alpha\beta$ hemoglobin dimer, thus dimeric Hp1-1 binds 2 hemoglobin dimers whereas Hp2-1 and Hp2-2, which are multimeric, may bind several.[575] Differences in the haptoglobin phenotypes observed in different ethnic groups or in association with various diseases (hemochromatosis, diabetes, malaria) have been investigated extensively.[562] For example, in the recent past haptoglobin phenotype analysis was used to study the origin of different populations, and in forensic science; however, these uses have been eclipsed by the development of DNA-sequence–based technologies. Uniquely among mammals is the presence in primates, including humans of an *hpr* gene located 2.2 kb downstream of *hp* on 16q22, and encoding haptoglobin-related protein. Hpr is poorly expressed compared with Hp, with approximately tenfold lower levels in the serum. Hpr, however, does bind hemoglobin and functions in our innate defenses against certain trypanosomal parasites in the bloodstream, forming part of a decoy toxin-containing complex that is taken up by the parasite receptor for haptoglobin–hemoglobin.[576]

Clinical laboratories now measure haptoglobin directly by radial immunodiffusion or immunonephelometric methods, and phenotyping, if performed, employs monoclonal antibodies and immunoblotting.[577,578] Normal haptoglobin concentrations differ substantially with technique; ranges such as 0.5 to 1.6 g/L[579] are representative, but each clinical laboratory normally establishes its own reference values. The concentration is also influenced by age. Haptoglobin levels are very low in newborns, but are measurable by 3 months of age, and increase gradually throughout childhood.[580] Decreased haptoglobin concentrations may be observed with hemolytic anemias, ineffective erythropoiesis, liver disease, and pregnancy or estrogen therapy. Increased concentrations are also seen in diseases where acute-phase proteins are increased, such as infections and malignancies.

Haptoglobin is synthesized in hepatocytes.[581,582] When not bound to hemoglobin, it leaves the plasma with a half-disappearance time of 3.5 to 5 days.[545,583,584] The haptoglobin–hemoglobin (Hp–Hb) complex leaves much more rapidly, with a half-disappearance time of 9 to 30 minutes. In hemolytic anemias characterized by intravascular hemolysis, catabolism of Hp may be so rapid that it essentially disappears from the plasma, a change that is not accompanied by a compensatory increase in haptoglobin synthesis such that it may take 5 to 7 days for serum haptoglobin levels to recover. Hypohaptoglobinemia also occurs in hemolytic states associated with predominantly extravascular hemolysis,[585,586] suggesting some hemoglobin may be regurgitated from macrophages when the rate of phagocytosis of erythrocytes or erythrocyte fragments reaches a maximum.[544]

The Hp–Hb complex is removed from the circulation after high-affinity binding to a receptor (CD163) that is found solely on the cell surface of peripheral blood monocytes (to allow immediate uptake[587]) and tissue macrophages.[588,589] Hp–Hb complexes may also be taken up by hepatocytes by an unidentified mechanism.[584,590] CD163 is a 130 kDa type I transmembrane protein and a member of the scavenger receptor superfamily, which function in binding polyanionic structures such as modified lipoproteins or (bacterial) lipopolysaccharides.[591] In addition to high-affinity binding of Hp–Hb, CD163 is one of five known macrophage cell surface proteins that bind erythroblasts in erythroblastic islands ("nurse cells"[67,592]). After binding to the receptor the Hb–Hp complex is endocytosed into the macrophage. CD163 recycles to the cell membrane whereas the globin moieties of Hp and Hb are degraded within the lysosome, and the heme released into the cytoplasm to be catabolized by HO-1. Subsequently, the iron is transported back to the bone marrow via transferrin, for synthesis of new hemoglobin.

CD163 expression may be stimulated by the effects of glucocorticoids, IL6, and IL10 on a distinct "anti-inflammatory" macrophage population termed "alternatively activated" (or M2-polarized) macrophages[593] that, for example, are important for wound-healing and chronic inflammation (see Chapter 10). Notably, recent studies of chronic leg venous ulcers demonstrate that engulfment of extravasated red blood cells by tissue macrophages and the release of hemoglobin iron activates a "pro-inflammatory" M1 macrophage population that has anomalous high expression of CD163. These M1 macrophages demonstrate enhanced ROS production and TNF-α release, which perpetuates pro-inflammatory M1 activation and impairs wound healing.[594] A soluble form of CD163, sCD163, has also been described. It is present in relatively high concentrations in the plasma (0.7 to 3.9 mg/L) and is derived from ectodomain shedding in response to LPS-mediated activation of Toll-like receptor (TLR) 4, as well as by ligands activating TLR2 and TLR5.[595] Although the function of sCD163 is unclear, levels are markedly elevated when macrophages accumulate, such as in the lysosomal storage disorder, Gauchers disease, or are activated, for example, in the acquired hemophagocytic syndrome[596] (Chapter 61).

CD163 has been recently knocked out in mice to examine the effects on hemoglobin clearance. In control animals hemoglobin was in fact cleared from the circulation faster than the Hb–Hp complex, whereas deletion of CD163 had little or no effect on hepatic Hb–Hp complex uptake, suggesting the presence of another uptake system for Hb–Hp and/or Hb.[597] In contrast,

two acute myeloid leukemia patients treated with gemtuzumab ozogamicin, an immunotoxin to CD33, who later experienced intravascular hemolysis (due to infection) were noted to have high serum free hemoglobin and haptoglobin levels without an increase in bilirubin. Subsequent studies showing that significant numbers of CD163-expressing macrophages (which also express the myeloid marker CD33) were eradicated by gemtuzumab treatment and that sCD163 levels were similarly decreased,[598] lend support for an important role for CD163 in clearance of plasma hemoglobin in humans. These somewhat conflicting results illustrate the significant differences in the haptoglobin genes, haptoglobin expression regulation and haptoglobin and hemoglobin clearance that exist between rodents and humans, differences believed to be due to the evolutionary pressure on primates from prevalent hemolytic diseases such as malaria and trypanosomiasis.

Hemoglobin and the Kidney

The hemoglobin–haptoglobin complex is too large (approximately 150 kDa) to pass into the glomerular filtrate. Thus, the level of circulating haptoglobin is the most important determinant of the apparent renal threshold.[561] When haptoglobin is saturated, free (unbound) hemoglobin circulates briefly in plasma. As discussed, hepatic parenchymal cells are responsible for removal of some of the free hemoglobin from plasma.[584,590] The dissociation of free hemoglobin into $\alpha\beta$ dimers results in a molecular weight of about 32 kDa, which readily passes through the glomerulus.[481] There is a low (<0.6 g/L) renal threshold for free hemoglobin present after haptoglobin saturation related to renal tubular reabsorption through the endocytic receptors megalin and cubilin.[599,600] Once this reabsorption capacity is exceeded, hemoglobin appears in the urine.

Hemoglobinuria, when it is of considerable magnitude, may cause precipitation of heme pigment as casts in the distal tubules, proximal tubule cell necrosis, and acute renal failure. The mechanism is disputed, but several theories have been proposed: (a) hemoglobin or hemoglobin products are directly toxic to proximal tubule cells, (b) precipitation of hemoglobin results in tubular obstruction and renal failure, or (c) direct renal injury by hemoglobin does not occur but instead products of intravascular hemolysis result in systemic or local hypotension (e.g., by scavenging of NO), and these lead to renal failure.[601–604]

Within the tubular epithelial cell, hemoglobin iron is rapidly extracted by heme-induced HO-1, and stored in the cell as ferritin and hemosiderin.[481] Some tubular epithelial iron may be reused for hemoglobin synthesis, but its mobilization for this purpose occurs at a very slow rate. When iron-laden tubular cells are sloughed into the urine, the urine iron concentration increases and both ferritin and hemosiderin may be detected.[604] Clinically, hemosiderinuria is usually detected by Prussian blue staining of the urinary sediment.[605] Detectable hemosiderin usually does not appear in the urine for 48 hours after a specific episode of hemoglobinuria[605] and may persist for more than a week.[601] In chronic intravascular hemolysis, such as occurs in red cell fragmentation associated with abnormal prosthetic heart valves, hemosiderinuria is continuous[606] and can result in iron deficiency.

Animal studies of deletion of Hp (or the Hb–Hp receptor, CD163[597]) confirm that the primary function of Hp is not plasma clearance of hemoglobin (which is equivalent in control animals) but rather the diversion of hemoglobin to hepatic and splenic macrophages and the prevention of renal losses of hemoglobin (and thus iron). With time, Hp-deleted animals accumulate hemoglobin-derived iron in the proximal tubular cells of the kidneys. Notably, the redistribution of iron from the liver to the kidney with deletion of Hp ameliorates the hepatic iron loading observed in a mouse model of hereditary hemochromatosis.[607,608]

Plasma Heme, Hemopexin, and Methemalbumin

Heme

When the buffering capacity of haptoglobin is exceeded, any free hemoglobin present in plasma is readily oxidized to methemoglobin, which then dissociates nonenzymatically into ferriheme (Fe^{3+}) (also known as hemin) and globin.[609] Apart from intravascular hemolysis, plasma heme may also originate from hemoglobin released during normal erythroblast enucleation or derive from the breakdown of hemoproteins such as myoglobin, catalases, cytochromes, and neutrophil myeloperoxidase during tissue damage (e.g., rhabdomyolysis). Heme must be chaperoned within the circulation (and likely within cells[610]) as free heme is lipophilic and toxic to cells, promoting lipid peroxidation and ROS production—the heme-iron is redox-active readily donating or accepting electrons—that can lead to cell membrane injury and apoptosis.[106] In addition, the removal from the circulation and recycling of heme iron prevents iron loss and, importantly, removes a source of readily available iron for invading microorganisms. The heme is immediately taken up by the low-density and high-density lipoproteins, LDL and HDL,[607] and then rapidly transferred to albumin or the heme-binding glycoprotein, hemopexin, ameliorating the strong oxidative and pro-inflammatory effects of free heme. Heme is removed from these proteins primarily by hepatocytes.

Hemopexin

Hemopexin, after haptoglobin, forms the second line of defense against hemoglobin-mediated oxidative damage during intravascular hemolysis or internal hemorrhage.[611] Hemopexin is a 439–amino acid β_1-glycoprotein, consisting of a single polypeptide chain with a molecular weight of about 70 kDa. It binds heme with the highest known affinity of any heme-binding protein ($K_d < 1$ *p*M) and plays an important role in receptor-mediated hepatocyte heme uptake. Hemopexin is mainly synthesized in the liver,[612] but is also expressed in the kidney, eye, and CNS.[103] The human gene encoding hemopexin is located at 11p15.4–p15.5, close to the β-globin gene cluster.[613–615] The crystal structure of the rabbit hemopexin–heme complex has been described.[616] Hemopexin consists of two homologous N- and C-terminal domains (four-bladed β-propeller folding motifs) that resemble two thick discs that abut each other at a 90° angle and are joined by a short linker domain. Heme sits in a pocket formed between the two domains and the linker protein with the heme iron coordinated to a histidine residue in the linker region and another in the C-terminal domain. In addition to heme, hemopexin can also bind other porphyrins and bilirubin, but with less avidity.[617,618]

The half-life of hemopexin in normal subjects is about 7 days,[619] whereas the heme–hemopexin complex is removed from the circulation with a half-disappearance time of 7 to 8 hours.[606] Hemopexin, like haptoglobin, is an acute-phase reactant and plasma levels rise with an inflammatory stimulus.[620] Hemopexin is also an abundant plasma protein in humans, with levels (0.5 to 1.5 mg/ml) similar to that of transferrin (2.0 to 3.6 mg/ml).

Hepatocyte uptake of this complex is by receptor-mediated endocytosis.[621,622] The receptor, LRP/CD91,[623] is a member of the LDL receptor-related protein (LRP) superfamily, also known as CD91. LRP/CD91 is a large protein, 600 kDa, with multiple extracellular domains and binds more than 40 different ligands.[241] This receptor is expressed by a variety of cells and heme–hemopexin complexes are taken up by hepatocytes, macrophages, neurons, fibroblasts, and syncytiotrophoblasts. After endocytosis, the receptor recycles to the cell surface and the heme–hemopexin complex dissociates within the endosome, facilitated by the decrease in pH (and potentially the reduction of ferriheme to ferrous heme), with hemopexin returning to the plasma as an intact

protein.[621,624–626] The heme is discharged into the cytoplasm to undergo catabolism by HO-1. LRP/CD91 is expressed highly by M2-polarized "anti-inflammatory" macrophages that also express CD163 and both receptors are up-regulated by glucocorticoids.[627] Similarities between the heme–hemopexin-LRP/CD91 and the Fe–Tf–TfR endocytic transport systems have also been described.[621] Some studies[623] suggest that when large amounts of heme are released into the circulation, recycling of hemopexin becomes saturated and significant amounts are then degraded in the lysosome. Thus, plasma hemopexin levels may decrease following intravascular hemolysis.[619] The depletion is less pronounced than that of haptoglobin, and low values imply a relatively severe degree of hemolysis.

Like Hp, hemopexin has been deleted in mice. Interestingly, in animals with deletion of Hp or hemopexin the expression of the other protein is up-regulated as a compensatory mechanism,[628] perhaps by heme. Animals with deletion of both genes show no obvious alterations in heme catabolism unless they are subject to acute hemolytic stress when they develop liver inflammation and fibrosis and splenomegaly. Analysis suggests that with acute hemolysis large amounts of hemoglobin and/or heme are deposited in the liver and the splenomegaly appears to be related to red cell congestion.[628] Of note, recent in vitro studies indicate a role for hemopexin in the coordinated extracellular uptake of heme exported by the cell surface transporter FLVCR—in the absence of hemopexin there is a marked decrease of FLVCR-mediated export of cytosolic heme.[629] In addition to the importance of FLVCR for proerythroblast survival[187,188] (see above), in vitro studies of FLVCR-deleted bone marrow-derived macrophages suggest FLVCR may also facilitate some recycling of heme from erythrophagocytic macrophages.[104,187]

Methemalbumin

Each mole of human albumin can bind several moles of heme ($K_d \sim 10^{-6}$) to form methemalbumin.[630] The disappearance of methemalbumin from the circulation is kinetically complex.[631] Heme added to human serum associates primarily with albumin (K_d 5 *n*M, concentration 35 to 55 mg/ml) before being transferred to hemopexin ($K_d < 1$ *p*M, concentration 0.5 to 1.5 mg/ml), presumably because the molar concentration of albumin is much greater than that of hemopexin.[617,632] The heme binding site on albumin can be inhibited in an allosteric or competitive fashion by fatty acids whereas increased heme binding to albumin (e.g., during an acute hemolytic episode) can decrease the protein binding of medications such as warfarin.[607]

EXTRAVASCULAR HEMOGLOBIN DEGRADATION

The Heme Oxygenase System and the Formation of Bilirubin

The heme oxygenases (HO) comprise the major physiologically relevant mechanism of heme catabolism.[633] HO is present in humans in two active isoforms, HO-1 and HO-2, encoded by different genes. HO is a mixed function oxidase [i.e., it utilizes molecular oxygen, generating oxidized products and H_2O (Fig. 6.31). The oxidase catalyzes cleavage of the α-methine bridge of heme—producing iron, CO, and biliverdin IXα—and is the rate-limiting step in the degradation sequence. The concerted activity of NADPH-cytochrome P450 reductase is necessary to supply electrons and activate oxygen. Biliverdin IXα, a physiologic inhibitor of HO function, is rapidly converted to bilirubin IXα by the enzyme biliverdin reductase. HO and NADPH-cytochrome P450 reductase are present in the endoplasmic reticulum, forming a complex with each other and, at least in vitro, with cytosolic biliverdin reductase.[634] Bilirubin IXα is in turn conjugated, once it reaches the liver, by UDP-glucuronyl transferase and eventually excreted into the bile. The daily production of bilirubin in humans is approximately 400 mg, of which approximately 300 mg is derived from the breakdown of hemoglobin,[635] with the remainder derived from catabolism of other hemoproteins, such as cytochromes, catalase, and myoglobin.

Studies in mammals initially focused mostly on the role of HO in heme catabolism during breakdown of hemoglobin. However, it has become widely recognized that HO-mediated degradation of heme has various roles in mammals, including antioxidative and iron reutilization functions.[104]

Antioxidative Function of the Heme Oxygenases

Apart from up-regulation by heme, the inducible heme oxygenase isoform, HO-1, is activated by more stimuli than perhaps any other gene.[633] Expression is induced by various metals (including sodium arsenite, cobalt, and selenium); hypoxia or hyperoxia; environmental chemicals and UV light; hydrogen peroxide and nitric oxide; depletion of intracellular glutathione; and heat shock (another name for HO-1 is HSP32). The enzyme is also induced by hormones, various drugs, fever, starvation, and stress.[636–637,638,639–641] Basic leucine zipper "stress-responsive" transcription factors, including members of the ATf family, c-Fos, c-Jun, and Nrf2, maf family members and Bach-1, all regulate HO-1 expression.[96,642] Biliverdin reductase also regulates HO-1. In addition to catalyzing the reduction of biliverdin to bilirubin, biliverdin reductase has kinase, transcription factor, and intracellular heme transport activities. The transport of heme into the nucleus may increase HO-1 levels as it enables derepression of Bach-1–mediated repression of HO-1 transcription.[96,642,643]

In general, HO-1 expression appears to be rapidly induced in response to an increase in cellular oxidative stress and subsequently repressed again to low levels once the stimulus is removed. In contrast, HO-2, the predominant HO protein expressed in the brain and testis, is constitutively expressed in all cells, with the promoter responding solely to glucocorticoids.[633] Notably, the N-terminus of HO-2 protein contains HRMs,[644] an ancient motif found in proteins in bacteria, yeast, and mammals that binds heme and serves a regulatory function (e.g., in ALAS-2, Bach-1, and HRI; see above and Refs. 169,645,646). In addition, HRM allow protein regulation by the heme-binding gases. For example, HO-2 binds the vasodilator NO with high affinity[163] and, with less affinity, the potential vasodilator (and neurotransmitter) CO, or O_2. In addition, HO-2 interacts with and, through production of CO, stimulates the calcium-sensitive potassium (BK) channels that mediate excitatory responses of the carotid body to hypoxia.[647]

The reason for the reduction of biliverdin IXα to bilirubin has been questioned, as the former is water soluble and thus easily excreted, whereas bilirubin is lipid soluble, toxic to the developing brain and requires conjugation to allow efficient excretion in bile.[648] However, being lipophilic, bilirubin also crosses the placenta from fetus to mother and thus the fetus can utilize the mother's excretory mechanisms. Studies[649–652] indicate that bilirubin at intracellular nanomolar (i.e., physiologic) concentrations is a potent antioxidant that protects cells from up to a 10,000-fold excess of H_2O_2; in so doing, it is itself oxidized to biliverdin IXα, which is then recycled back to form bilirubin.[651] However, some studies suggest it is less important than, for example, other major intracellular antioxidants such as the glutathione system.[653]

Iron Reutilization Function of Heme Oxygenases

Under normal physiologic conditions, approximately 25 mg of iron is consumed daily by erythroblasts for heme biosynthesis. With a daily dietary iron intake of only 1 to 2 mg, the recycling

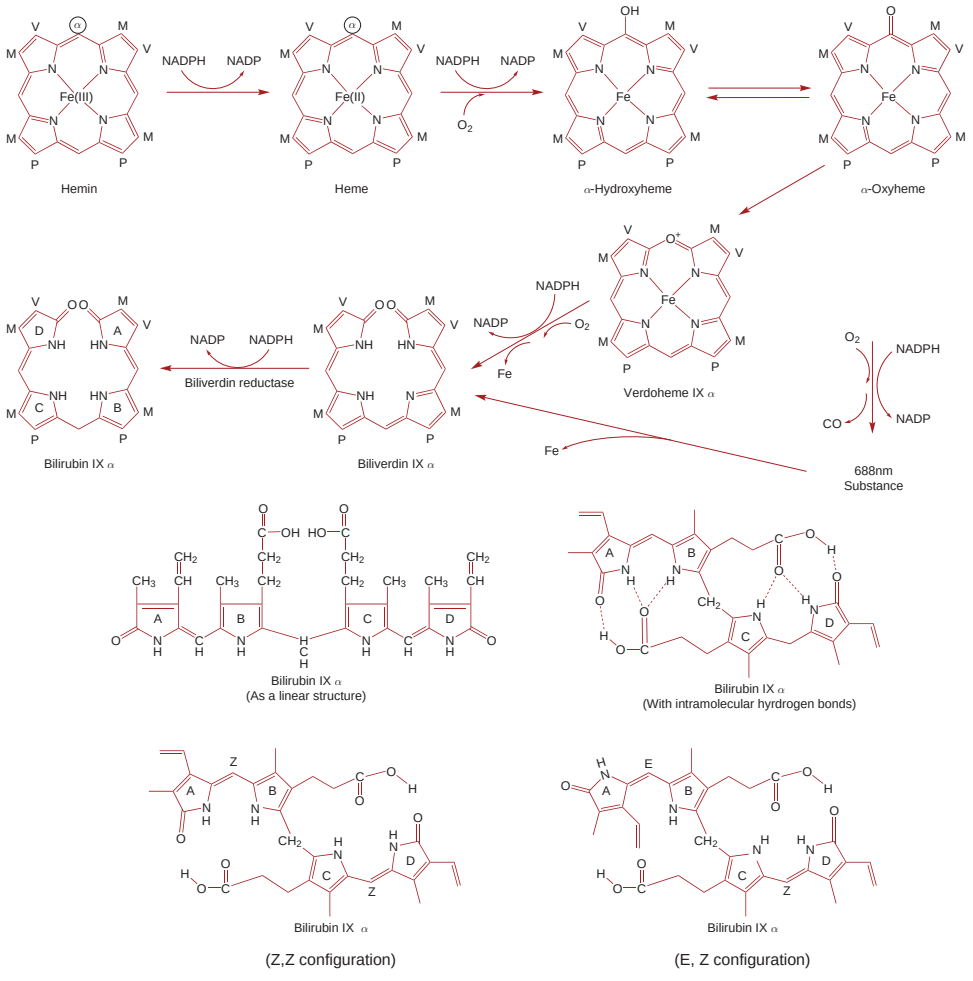

FIGURE 6.31. Formation of bilirubin IXα from heme. The initial reactions are catalyzed by microsomal heme oxygenase and require nicotin–amide adenine dinucleotide phosphate (NADPH) as a co-factor. The reaction has a high specificity for the α-methene bridge, and α-oxyheme is a probable intermediate that is oxidized by molecular oxygen to biliverdin. In mammals, biliverdin is converted to bilirubin by biliverdin reductase. Bottom: alternative methods of representing the structure of bilirubin. The intramolecular hydrogen bonding that occurs with the Z,Z configuration is less extensive in the geometric isomers designated E,Z, and E,E (not shown); hence, the latter are more soluble in water.

of heme-iron from senescent erythrocytes constitutes the main source of iron for erythropoiesis. As mentioned, heme degradation by HO-1 occurs within erythrophagocytic macrophages in the liver, spleen, and bone marrow, releasing iron, which is subsequently exported into the circulation by the sole cell iron exporter ferroportin.[117,654]

A patient with homozygous HO-1 deficiency has been described in detail.[655] The child, who died at age 6 years, had evidence of severe hemolytic anemia with high serum heme levels, low serum bilirubin, absent Hpx but increased haptoglobin, and hypoferremia. Very high von Willebrand factor and thrombomodulin levels with evidence of disseminated intravascular coagulation were observed, suggesting widespread endothelial injury. There was iron overload of the liver (involving both Kuppfer cells and parenchymal cells) and kidney (proximal tubule cells). Asplenia was noted. The child also had hyperlipidemia, and, at autopsy, aortic atheroma were noted. These findings indicate an important role for HO-1–mediated heme breakdown for heme iron reutilization and protection of the vascular endothelium from heme exposure.

Animals with deletion of HO-1 develop hypoferremia, microcytic anemia (hematocrit approximately 0.30), and a similar tissue iron overload phenotype.[652,656] More recently, the murine model of HO-1 deficiency has been re-examined from 6 weeks out to 22 months.[657] The animals develop asplenia over time, due to splenic fibrosis and loss of the red pulp. Notably, there is a marked loss of the (LRP/CD91- and CD163-expressing) erythrophagocytes in the liver, spleen, and bone marrow, due to the toxicity of heme released within macrophages during ingestion of senescent erythrocytes. Thus the high haptoglobin levels observed in the human subject with HO-1 deficiency are explained by the specific loss of erythrophagocytic macrophages expressing the haptoglobin receptor (whereas hemopexin is low as it is also taken up by hepatocytes). Hepatic parenchymal and the proximal renal tubular epithelial cells are the cells regulating iron reutilization from erythrocytes in these mice, likely relying on HO-2 function.[657] In sum, these studies in mice and humans demonstrate the importance of erythrophagocytic macrophage and endothelial cell HO-1 function in ameliorating heme toxicity and the need for the heme oxygenase system for heme iron recycling.

Bilirubin Transport

After release from sites of heme catabolism, bilirubin appears in the plasma. The normal concentration of plasma bilirubin is <1.0 mg/dl. At equilibrium, the concentration is directly related to bilirubin production (mostly from erythropoiesis and red cell destruction) and inversely related to hepatic clearance.[658,659]

The structure of the bilirubin IXα molecule is asymmetric and several isomeric forms exist (Fig. 6.31).[660] In the naturally

occurring configuration, all pyrrole rings are similarly rotated, representing the Z,Z or *trans* configuration. If either outer ring is rotated, then the E,Z or Z,E geometric isomers are formed. Photoisomerization of the Z,Z configuration of bilirubin results in formation of these more soluble photoisomers, which can be excreted without conjugation.[660–662] This is the basis for using phototherapy to prevent neurotoxicity in newborns with hyperbilirubinemia.[660,661,663]

Bilirubin is normally present in plasma in several forms.[664,665] Although unconjugated bilirubin is essentially insoluble in water, it combines reversibly with albumin in neutral or alkaline solution. At normal plasma albumin concentrations, the theoretical bilirubin-binding capacity is approximately 70 mg/dl, of which half is tightly bound. These values are reduced by a decrease in plasma albumin concentration or by the presence of organic anionic substances that compete for albumin-binding sites, such as heme, fatty acids, sulfonamides, and salicylates.[666] When the binding capacity is exceeded, bilirubin readily crosses membranes (e.g., the blood–brain barrier, placental and vascular endothelial or hepatocyte membranes) to diffuse into the tissues, and in jaundiced infants the amount of bilirubin outside the vascular circulation exceeds that within it.[663] The tendency of bilirubin to bind to tissues, such as brain, may be due to complex formation with cell membrane polar groups, such as phosphatidylcholine.[662]

In normal adults, <5% of measurable bilirubin is of the conjugated form,[667,668] but under certain pathologic circumstances, the proportion of conjugated bilirubin is greater. This relatively soluble bilirubin derivative may also bind albumin. Most is less tightly bound than the unconjugated form, but a portion is covalently and irreversibly bound.[669] That portion of esterified bilirubin that is reversibly bound to albumin is ultrafilterable. In contrast to the other forms of bilirubin, this complex enters the glomerular filtrate, is not reabsorbed in the tubules, and is excreted in the urine.

Hepatic Bilirubin Metabolism

Processing of bilirubin by the liver is part of a general mechanism whereby plasma protein-bound, organic anions are metabolized and excreted. Hepatic bilirubin metabolism is divided into three distinct phases: uptake, conjugation, and excretion[635] (Fig. 6.32). All three phases are necessary for bilirubin to be excreted at a normal rate; however, the excretion step is normally the slowest, and therefore the rate-limiting, step.

Within the hepatic sinusoids, the albumin–bilirubin complex dissociates, and bilirubin passes into the hepatocyte where it binds ligandin and is transferred to the ER. How transport into the hepatocyte occurs remains unclear.[663] It may be a dissociation-limited carrier-independent (diffusion) process,[670] or a bidirectional energy-dependent process.[671–673] Bidirectional movement of bilirubin appears to be extensive.[674] In addition, small amounts formed within the hepatocyte from degradation of hepatic hemoproteins reflux into the plasma in the unconjugated form.[675]

Within the hepatocyte, bilirubin is conjugated with glucuronic acid to form bilirubin diglucuronide, which comprises 80% of the bilirubin present in normal bile; the two monoglucuronide isomers make up most of the remainder.[676] Conjugated bilirubins are more water soluble than unconjugated bilirubin, allowing biliary excretion. Little or no unconjugated bilirubin is found in bile, and if conjugation is impaired, bilirubin content is low. The conjugation reaction is catalyzed by uridine diphosphate-glucuronyl transferase (UGT). Hepatocyte UGT exists in several isoforms, catalyzing glucuronidation of various substrates, such as steroid hormones and medications. Bilirubin serves as the substrate for two isoforms (B-UGT 1 and B-UGT 2),[677] but only B-UGT 1 is quantitatively significant in humans.[678] B-UGT activity is also modulated by medications such as phenobarbital, and hormones, such as cortisol and thyroxine.[679]

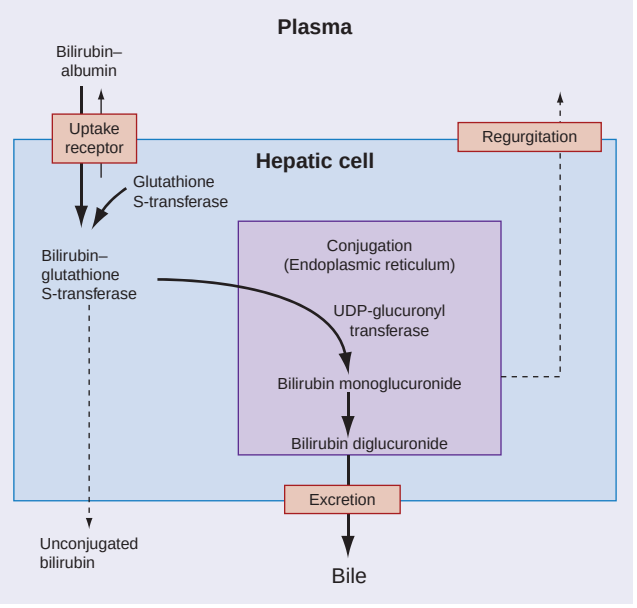

FIGURE 6.32. Normal and abnormal pathways of bilirubin excretion by the hepatic cell. The normal pathways (*solid arrows*) include uptake and conjugation of bilirubin and excretion of the conjugated derivative. Abnormal pathways (*dashed arrows*) include regurgitation of bilirubin glucuronide into plasma and excretion of unconjugated bilirubin into bile.

In hepatocellular disease or biliary obstruction, some conjugated bilirubin may be "regurgitated" into the plasma. In addition, a small portion of conjugated bilirubin within the hepatocyte is deconjugated and may reflux into the plasma.[675] These pathways explain the increase of both bilirubin fractions in cholestatic liver disease. In other clinical situations, hyperbilirubinemia is mainly due to an increase in unconjugated bilirubin. The most common of these is hemolytic disease, where hemoglobin catabolism and thus bilirubin production are increased. However, inherited disorders may also cause unconjugated hyperbilirubinemia because of an impaired capacity for bilirubin conjugation.

The decreased ability to conjugate bilirubin is the common feature of three inherited disorders: in Crigler-Najjar syndrome type I, severe unconjugated hyperbilirubinemia is present from birth and kernicterus is common; in Crigler-Najjar syndrome type II, less severe jaundice occurs; and in Gilbert syndrome, the jaundice is quite mild and often not obvious clinically.[677,680] These disorders are recessively transmitted, and most patients are therefore homozygous for the mutant gene, B-UGT 1, although occasionally heterozygotes have minimal jaundice. In the two Crigler-Najjar syndromes, the mutation frequently involves exon 1, which confers substrate specificity to the enzyme, resulting in a structurally abnormal protein. In Crigler-Najjar syndrome type I, and in the Gunn rat, an animal model of this disease, the enzyme is nonfunctional, whereas in type II, enzyme activity is variably reduced.[678,681–684] In Gilbert syndrome, the mutation in some patients affects the promoter sequence of exon 1.[683,685] Gilbert syndrome is very common, occurring in up to 10% of the population, but the Crigler-Najjar syndromes are rare. In Crigler-Najjar type I, the heme oxygenase inhibitor Sn-protoporphyrin may be effective in reducing bilirubin levels. Early orthotopic liver transplantation is curative.[686] No treatment is usually necessary for the other two disorders.

The degree of hyperbilirubinemia seen in children with chronic hemolytic states is influenced by simultaneous inheritance of the gene for Gilbert disease.[687,688] Infants with hereditary spherocytosis who also have Gilbert syndrome usually require phototherapy for hyperbilirubinemia.[688] The variable hyperbilirubinemia seen in G6PD-deficient neonates may also reflect the presence or absence of the variant form of uridine-diphosphoglucoronylsyl-transferase responsible for Gilbert

syndrome.[687] In infants known to be G6PD deficient, prevention of severe hyperbilirubinemia by administration of a single intramuscular dose of Sn-mesoporphyrin, another inhibitor of heme oxygenase, is highly effective and safe.[173,689]

Excretion of conjugated bilirubin from the hepatic cell into the bile canaliculus proceeds against a 40:1 gradient, when concentration in the bile is compared with that in plasma.[690] Animal studies indicated that bilirubin excretion, normally the rate-limiting step in overall hepatic bilirubin transport, is mediated by an ATP-dependent transport system shared by a variety of organic anions.[684] The Dubin-Johnson syndrome[691,692] is an autosomal recessive disorder characterized by mild conjugated hyperbilirubinemia, and by impaired biliary secretion of non–bile-acid organic anions. Bilirubin uptake and conjugation are normal. The syndrome is due to mutations in the ATP-dependent transporter ABCC2/MRP2, a member of the multidrug resistance protein subfamily that is localized exclusively to the apical membranes of polarized cells including hepatocytes, renal proximal tubules, and intestinal epithelium.[693,694]

Intestinal Bile Pigment Metabolism

Bilirubin diglucuronide is excreted in bile into the duodenum.[695] There is little intestinal absorption of the conjugated form, although unconjugated bilirubin is readily absorbed. Bilirubin diglucuronide probably remains conjugated during its transit through the small intestine. However, with intestinal stasis, and in newborns, increased deconjugation occurs and intestinal absorption occurs. This enterohepatic circulation of bilirubin may contribute to the severity of jaundice associated with the physiologic hyperbilirubinemia of the newborn.[696] When bilirubin diglucuronide reaches the terminal ileum and colon, it is hydrolyzed by bacterial β-glucuronidases. The methine bridges and usually the vinyl groups are then reduced by bacterial flora forming colorless tetrapyrroles called urobilinogens.[696] Because urobilinogen formation is accomplished by bacteria, it does not occur in newborns, and may be affected by administration of antibiotics. The urobilinogens are easily dehydrogenated to form the orange-yellow pigments, urobilins, which contribute to the color of feces. Up to 20% of the urobilinogen formed in the gut is reabsorbed. The reabsorbed fraction is efficiently excreted by the normal liver without being conjugated.[695] A portion of the reabsorbed pigment may be excreted into the urine. Urobilinogen is filtered by the glomerulus, secreted by the renal tubule, and reabsorbed. If the liver's capacity to excrete urobilinogen is impaired, a disproportionate amount appears in the urine.

Alternate Pathways of Heme and Bilirubin Catabolism

Evidence suggests that some heme may be degraded by pathways other than catabolism by the heme oxygenases. On a stoichiometric basis, 35 mg of bilirubin should result from degradation of 1 g of hemoglobin. However, the recovery of fecal urobilinogen is less than expected, suggesting that up to 40% of heme may be degraded by some other pathway.[697] Only minimal amounts of unconjugated bilirubin are excreted in the urine. Excretion of conjugated bilirubin is substantial despite complete biliary obstruction. In rats with biliary fistulas, only 60% to 80% of administered radioactive hemoglobin or heme is recovered as bilirubin; a portion of the remainder is found in nonbilirubin fractions of bile.[698,699] Radioactive bilirubin in patients with prolonged complete biliary obstruction gradually disappears via an unidentified route.[699] Furthermore, in severe inherited defects of bilirubin conjugation, such as those found in infants with the Crigler-Najjar syndrome and the Gunn rat, the alternate pathways appear to be increased.[700] One explanation for these observations is that bilirubin is converted by a series of light-stimulated reactions to a variety of water-soluble derivatives, including hydroxyrubins, bilichrysins, and a dipyrrole.[697] A microsomal P450-dependent mono-oxygenase may contribute to these alternate pathways; in addition, a mitochondrial bilirubin oxygenase has been identified that, in vitro, degrades bilirubin to a variety of products.[701,702]

Laboratory Evaluation of Hemoglobin Catabolism and Bile Pigments

The serum bilirubin concentration is an important marker of the rate of bilirubin production and of hepatobiliary function. Traditionally, it has been measured by the van den Bergh test in which a mixture of sulfanilic acid, hydrochloric acid, and sodium nitrite (diazo reagent) yields a reddish-violet color with a maximum absorption at 450 nm when added to plasma or other solutions containing bilirubin.[703] A direct reaction, in which the color reaches its maximum intensity at once indicates conjugated bilirubin, as is seen in plasma or urine from patients with obstructive jaundice. Detection of the unconjugated bilirubin found in plasma of patients with hemolytic disease requires addition of an accelerator, such as alcohol (indirect reaction).

In situations where bilirubin production may be increased and the bilirubin load is likely high, precise measurements of heme catabolism can be determined by measuring endogenous bilirubin production or generation of carbon monoxide (produced in equimolar amounts during heme breakdown). CO production is estimated by measuring blood carboxyhemoglobin levels; end-tidal CO concentration corrected for ambient CO and pulmonary excretion rates of CO are also measured.[704]

Acknowledgments

The authors gratefully acknowledge the contributions of Drs. Emmanuel Dessypris, Stephen Sawyer, and Marilyn Telen to the chapters covering this content in the previous edition of this textbook. These chapters provided the basis for the current revision.

CHAPTER 7

NEUTROPHILIC LEUKOCYTES

Keith M. Skubitz

Three types of granulocytes are readily identified in peripheral blood smears. Neutrophils are so named because of their neutral staining with Wright stain, whereas eosinophils avidly stain with the dye eosin, and basophils have readily identified large dark-staining granules with Wright stain. Neutrophils play a critical role in host defense by phagocytizing and digesting microorganisms, and inappropriate activation of neutrophils may result in damage to normal host tissues. In the resting uninfected host, the production and elimination of neutrophils are balanced, resulting in a fairly constant concentration of neutrophils in peripheral blood. When an infection occurs, chemotactic agents are generated that result in migration of neutrophils to the site of the infection and activation of neutrophil defensive functions. This effect is often associated with an increased production and release of neutrophils from the bone marrow. This chapter reviews the structure, morphology, production, distribution and kinetics, and functions of neutrophils.

SUBCELLULAR STRUCTURE OF NEUTROPHILS

Mature neutrophils contain several types of granules and other subcellular organelles. Many studies have been performed to identify and characterize the molecular composition of the various subcellular compartments of neutrophils. Two techniques are commonly used for this purpose: immunoelectron microscopy and subcellular fractionation. Most recent subcellular fractionation studies used the technique of nitrogen cavitation to disrupt the neutrophils. In this technique, cells are equilibrated with nitrogen at high pressure and then released into a pressure of 1 atm. The rapid decrease in extracellular pressure results in disruption of the cells by the formation of nitrogen gas within the cell. The disrupted cells are then fractionated by density-gradient centrifugation.[1,2] Many types of subcellular organelles and structures are present in neutrophils, as seen by electron microscopy (EM). Although the granules of neutrophils may be best viewed as a continuous spectrum of granules, possibly resulting from differential production of different granule contents during neutrophil development, studies of neutrophils have operationally defined several types of granules. Four well-defined types of granules in neutrophils are primary granules, secondary granules, tertiary granules, and secretory vesicles, although additional heterogeneity of these fractions may exist. Some of the known constituents of these granules are indicated in Table 7.1.

Azurophilic (Primary) Granules

The azurophilic, or primary, granules are formed during the promyelocytic stage and in general contain many antimicrobial compounds. These granules fuse with phagocytic vesicles, resulting in the delivery of their contents to the ingested organism. Among the azurophilic granule contents is myeloperoxidase (MPO), a protein that catalyzes the production of hypochlorite (OCl^-) from chloride and hydrogen peroxide produced by the oxidative burst. MPO constitutes approximately 5% of the dry weight of the neutrophil[18] and imparts the greenish coloration to pus. The human neutrophil defensins (HNP-1 to -3), a group of cationic proteins that kill a variety of bacteria, fungi, and viruses,[19,20,21] also constitute approximately 5% of total neutrophil protein.[22] Other components of azurophilic granules include lysozyme, which degrades bacterial peptidoglycans,[23] bactericidal permeability-increasing protein, which has antibacterial activity against certain gram-negative bacteria,[24–28] azurocidin, which has antibacterial as well as antifungal activity against *Candida albicans*,[29,30] and the serine proteinases elastase, cathepsin G, proteinase 3, esterase N, and others.[31–34] The granule membrane itself contains a large amount of CD66c[35,36] and CD63 antigens.[37] Heterogeneity among azurophil granules is likely.[3]

Specific (*Secondary*) Granules

Although some specific (also called *secondary*) granules, like azurophilic granules, fuse with phagocytic vesicles, it is believed that these granules are largely for release into the extracellular space. Some of the known contents of these granules are also indicated in Table 7.1 and include apolactoferrin, the major specific granule protein, vitamin B_{12}–binding protein, plasminogen activator, and collagenase. Lysozyme and some gelatinase are also present in specific granules. Release of specific granule contents may modify the inflammatory process. For example, collagenase may degrade collagen, thus augmenting movement through collagen and participating in tissue remodeling. Apolactoferrin, by binding iron, may have an antibacterial effect by preventing bacteria from obtaining necessary iron for growth.[38] Iron binding by apolactoferrin may also modify hydroxyl radical formation and cell adhesion.[39–42] Although the antimicrobial and proinflammatory defensins are stored in azurophil granules, proHNPs produced at more mature stages of differentiation are not cleaved to the antimicrobial form and are stored in specific granules. ProHNPs are constitutively exocytosed, though their function is unclear.[15] Haptoglobin released from specific granules could also inhibit bacterial growth and inflammation.[16] Specific granules also contain a number of membrane-bound molecules that are also expressed on the cell surface. This includes CD11, CD18, CD66a, CD66b, NB-1 (CD177), f-met-leu-phe (FMLP) receptors, C5a receptors, and cytochrome b_{558}. When cells are stimulated, the surface expression of many of these membrane proteins is increased, and some of the upregulated molecules may be derived from specific granules. The importance of the specific granules in neutrophil function is shown in patients who lack specific granules; these patients are susceptible to repeated skin and respiratory infections and have defective neutrophil chemotaxis and adhesion.

Gelatinase (Tertiary) Granules

Gelatinase, or tertiary, granules, which cosediment with specific granules in some subcellular fractionation techniques, were initially identified as gelatinase-containing granules.[43] Like specific granules, tertiary granules also contain many membrane proteins

TABLE 7.1

CONTENTS OF HUMAN NEUTROPHIL GRANULES

Azurophil (Primary) Granules	Specific (Secondary) Granules	Gelatinase (Tertiary) Granules[a]	Secretory Vesicles
Membrane	**Membrane**	**Membrane**	**Membrane**
CD63	CD15 antigens	CD11b	Alkaline phosphatase
CD66c	CD66a	FMLP receptor	Cytochrome b_{558}[b]
CD68	CD66b	Diacylglycerol deacylating enzyme	CD11b
Matrix	Cytochrome b_{558}[b]	Cytochrome b_{558}[b]	u-PA receptor
Lysozyme	FMLP receptor	Laminin receptor	FMLP receptor
Defensins	Fibronectin receptor	**Matrix**	CD10, CD13, CD45
Elastase	G-protein α-subunit	Gelatinase[a]	CD16
Cathepsin G	Laminin receptor	Acetyltransferase	DAF
Proteinase 3	CD11b	Lysozyme	CR1 (CD35)
Esterase N	NB 1 antigen	NRAMP1	**Matrix**
α_1-Antitrypsin	Rap 1, Rap 2	Ficolin-1	Plasma proteins (including tetranectin and albumin)
α-Mannosidase	Thrombospondin receptor		pro–u-PA/u-PA
Azurocidin	Tumor necrosis factor receptor		
Bactericidal permeability-increasing protein	Vitronectin receptor u-PA receptor		
β-Glycerophosphatase	**Matrix**		
β-Glucuronidase	Apolactoferrin		
β-Galactosidase	Lysozyme		
β-Glucosaminidase	β_2-Microglobulin		
α-Fucosidase	Collagenase		
Cathepsin B	Gelatinase[a]		
Cathepsin D	Histaminase		
Acid mucopolysaccharide	Heparinase		
Heparin binding protein	pro–u-PA		
N-Acetyl-β-glucosaminidase	Vitamin B_{12}–binding protein		
Sialidase	Sialidase		
Ubiquitin protein	Protein kinase C inhibitor		
	hCAP-18		
	SGP28		
	PTX3		
	Haptoglobin		
	Prodefensins (proHNPs)		

DAF, decay accelerating factor; FMLP, f-met-leu-phe; u-PA, urokinase-type plasminogen activator.
[a]Gelatinase is present in only a subset of specific granules; most is present in gelatinase granules.
[b]Cytochrome b_{558} is also called b_{245}.
Adapted from references (2) through (17).

that are upregulated to the cell surface with stimulation.[2] The relative contribution of tertiary granules and specific granules to upregulation of membrane proteins is not clear.

Secretory Vesicles

Secretory vesicles, which largely distribute in the plasma membrane fraction using subcellular fractionation techniques, have also been described. Complement receptor (CR)1, recognized by CD35 monoclonal antibodies, has been found exclusively in the light membrane fractions containing secretory vesicles and plasma membranes using subcellular fractionation techniques.[11] The observation that CR1 can be readily upregulated to the neutrophil surface with weak stimulation demonstrates that secretory vesicles provide an intracellular reservoir from which membrane proteins can be recruited to the cell surface. CR3 (HMac-1), recognized by CD11b antibodies and present in both secretory vesicles and specific granules, is also upregulated to the cell surface with weak stimulation. In contrast to CR1, a more marked upregulation of CR3 is observed with more potent stimulation, demonstrating that specific granules can also serve as an intracellular reservoir from which membrane proteins can be upregulated to the cell surface.[11] By EM, the secretory vesicles appear as smooth-surfaced vesicles. A defining feature of secretory vesicles is their rapid and complete translocation to the surface membrane with weak stimulation.[11] These secretory vesicles also contain alkaline phosphatase, cytochrome b_{558}, and FMLP receptors. Secretory vesicles can be upregulated to the cell surface in the absence of extracellular calcium, in contrast to specific and gelatinase granules, which require extracellular calcium for release.[11] The secretory vesicles appear to be formed by a process of endocytosis and contain albumin.

Plasma Membrane

Many constituents of the neutrophil plasma membrane have been defined. These include membrane channels, adhesive proteins, receptors for various ligands, ion pumps, and ectoenzymes. For example, CD11/CD18 and CD62L (L-selectin) are involved in neutrophil adhesion. The FMLP- and C5a-receptors sense stimuli and activate neutrophils, while aminopeptidase N (CD13) can inactivate interleukin (IL)-8, eliminating its chemotactic activity,[44] and neutrophil endopeptidase (CD10) can inactivate the chemotactic peptide FMLP.[45] CD66a, b, c, can activate neutrophils,[46] and some CD45 antibodies, which recognize a transmembrane protein with tyrosine phosphatase activity in its cytoplasmic domain, inhibit neutrophil chemotaxis.[47] Some of the various clusters of differentiation (CD) expressed on neutrophils are shown in Table 7.2. The components of the membrane are not uniformly distributed. Studies have indicated the presence of differentiated domains in the membrane called *rafts*, which are described in the section "Lipid Rafts."

TABLE 7.2

SOME CD ANTIGENS EXPRESSED ON NEUTROPHILS

CD	CD Antigen
CD10	Common acute lymphoid leukemia antigen, neutral endopeptidase
CD11a	Leukocyte factor antigen-1, $\alpha_L\beta_2$
CD11b	Mac-1, $\alpha_M\beta_2$
CD11c	p150, 95, $\alpha_X\beta_2$
CD13	Aminopeptidase N
CD15	Le^x (Ga1β1→4G1cNAc(Fucα1→3) β1→3Ga1β1→4G1cNAc→R)
CD15s	sLe^x
CD16	FcRIII
CDw17	LacCer
CD18	β_2-Integrin
CD24	Glycosyl phosphatidylinositol–linked protein
CD31	Platelet endothelial cell adhesion molecule-1
CD32	FcRII
CD43	Leukosialin, sialophorin
CD44	Pgp-1
CD45	Leukocyte common antigen (a protein tyrosine phosphatase)
CD50	Intercellular adhesion molecule-3
CD53	Tetraspan molecule
CD55	Decay accelerating factor
CD62L	L-Selectin
CD63	Tetraspan family member
CD64	FcRI
CD65	Ga1β1→4G1cNAcβ1→3Ga1β1→G1cNAc(Fucα1→3)→R
CD65s	Sialylated CD65
CD66a	CEACAM1 (Biliary glycoprotein)
CD66b	CEACAM8 (CGM6)
CD66c	CEACAM6 (NCA)
CD66d	CEACAM3 (CGM1)
CD82	Tetraspan family member
CD88	C5a receptor
CD95	Fas, APO-1
CD114	Granulocyte colony-stimulating factor receptor
CD156	ADAM-8 (a disintegrin and metalloprotease domain)
CD157	Bifunctional ectoenzyme (adenosine diphosphate ribosylase)
CD177	NB1, HNA-2a

NOTE: When used to describe the antigen, the term *CD* antigen should be used.

Cytoskeletal Matrix

Like many other cells, neutrophils contain a complex cytoskeleton. Alterations in the distribution of cytoskeletal elements may be important in chemotaxis, phagocytosis, and exocytosis. Many protein components of this cytoskeleton have been identified, including actin, actin-binding protein, α-actinin, gelsolin, profilin, myosin, tubulin, and tropomyosin. Actin accounts for approximately 10% of neutrophil protein.[48] The role of the cytoskeleton in neutrophil function is reviewed in detail elsewhere.[49]

Neutrophil Lipids

Although most studies of neutrophil structure have concentrated on proteins, lipids and carbohydrates also serve important functions. Lipids account for approximately 5% of neutrophils by weight,[50,51] of which approximately 35% is phospholipid.[52] Phosphatidylcholine and phosphatidylethanolamine account for approximately 75% of the phospholipid in intact neutrophils.[52] Subcellular distribution studies reveal that plasma membranes and secretory vesicles contain approximately half the cellular phospholipid. Most of the phosphatidylinositol and phosphatidylcholine are present in plasma membrane and secretory granules, whereas a large part of the phosphatidylethanolamine is found in the specific granules.[52] Among the phospholipids, the phosphoinositides are important as sources of inositol 1,4,5-triphosphate (IP_3) (a signal-transduction molecule that results in calcium release) and diacylglycerol (which activates protein kinase C [PKC]). The occurrence of arachidonic acid in phospholipids, especially phosphatidylcholine, is important as a precursor for the production of leukotrienes, prostaglandins, thromboxanes, and lipoxins.[53,54] Cholesterol and triglycerides constitute most of the nonphospholipid neutrophil lipid. Glycolipids, which include both neutral glycosphingolipids and gangliosides, constitute the remaining neutrophil lipids. The study of glycolipids is complex, and the glycolipid composition of neutrophils is not well understood. Glycolipids are important because their carbohydrate components contain many neutrophil differentiation antigens with a multitude of potential functions. The major neutrophil glycolipid is lactosylceramide (LacCer: Galβ1 → 4Glcβ1 → 1Cer) [55,56,57] and is recognized by CDw17 monoclonal antibodies. Interestingly, the surface expression of LacCer decreases after neutrophil stimulation. More than 75% of neutrophil LacCer is found in intracellular granules.[56,58] It has been hypothesized that most LacCer in the granule membranes is found in the outer leaflet and may contribute to the ability of these membranes to form the highly convex surfaces necessary to form these submicrometer particles.[54] Approximately 75% of the five major glycosphingolipids are located intracellularly.[58] Studies of the subcellular distribution of glycosphingolipids in neutrophils have found no differences among the plasma membrane, primary granules, or secondary granules in the relative amounts of these five glycosphingolipids.[58]

Lipid Rafts

Studies have demonstrated the existence of large noncovalent detergent-resistant complexes in cell extracts that contain important signaling molecules, including protein kinases and many glycosyl phosphatidylinositol–linked membrane proteins capable of transmitting signals.[59–61,62] These complexes have been termed *lipid rafts* or *large detergent-resistant complexes*. It is postulated that these complexes or rafts reflect the existence of specific membrane microdomains that have a particular lipid composition, and that these clusters of molecules may be important in transmembrane signaling by proteins in the complex. There is

evidence that in neutrophils, proteins may enter these rafts when they are translocated to the cell surface. For example, it appears that CD63 and CD11b/CD18 are not present in detergent-resistant complexes when they are intracellular, but they enter such complexes after translocation to the cell surface.[63]

Cytoplasmic Lipid Bodies

Cytoplasmic lipid bodies, non–membrane-bound cytoplasmic inclusions, have been described in neutrophils.[64] In inflammation, the number of cytoplasmic lipid bodies in neutrophils increases.[65] These lipid bodies may provide nonmembrane stores of esterified arachidonate. In addition, some signaling proteins, including phosphatidylinositide-3-kinase, are localized to these lipid bodies,[66] although the exact role of these lipid bodies in cell function is unclear.[66,67]

Cytosol

Although neutrophil cytoplasm contains many components common to all cells, approximately 45% of neutrophil cytosolic protein appears to be attributable to migration inhibitory factor–related proteins (MRPs), MRP-8, and MRP-14.[68] MRP-8 and MRP-14 are members of the S100 family of calcium-binding proteins and form homo- and heterodimers. MRP-14 has been variously called *p14*, *L1 heavy chain*, and *calgranulin b*, and MRP-8 is also known as *p8*, *L1 light chain*, *calgranulin a*, and *cystic fibrosis antigen*.[69–73] Although the role of these proteins in neutrophil function is unclear, the quantity of MRP-8 and MRP-14 associated with neutrophil plasma membranes has been reported to increase after stimulation.[68] MRP-8/MRP-14 are also present in secondary and/or tertiary granules and are released when neutrophils are stimulated.[73] MRP-14 can inhibit macrophage activation.[74] Annexin I or lipocortin I comprises approximately 3% of cytosolic protein.[75] Annexin I is partially regulated by glucocorticoids and appears to be a mediator of the anti-inflammatory effects of glucocorticoids.[75]

One other notable cytoplasmic constituent is glycogen. Because neutrophils are sometimes required to function in hypoxic conditions, as in an abscess, they are very capable of obtaining energy by glycolysis. The presence of large intracellular glycogen stores gives them the additional ability to function in areas of low extracellular glucose.

Nucleus

In the past, it has been felt that neutrophils, as end-stage cells, undergo little RNA or protein synthesis. Subsequently, it was shown that mature neutrophils can synthesize both RNA and protein. This is likely particularly important when neutrophils migrate into sites of inflammation and begin to synthesize proteins and chemokines that may regulate activation and resolution of the innate immune response.[76,77–81,82]

MORPHOLOGY OF NEUTROPHILS AND PRECURSORS

The replenishment of marrow and blood cells from a stem cell compartment is described in Chapter 5. Neither multipotent hematopoietic stem cells nor more committed progenitors are readily identified morphologically by traditional methods.[83–87] Only the more mature forms of each hematopoietic cell series can be reliably distinguished from one another. In the following pages, the cells identifiable as neutrophils and their precursors are described.

Neutrophils follow a pattern of proliferation, differentiation, maturation, and storage in the bone marrow and delivery to the blood. In the first three morphologic stages, the myeloblast, promyelocyte, and myelocyte cells are capable of replication, as shown by their uptake of tritiated thymidine (^{3}H-TdR) and the presence of mitoses; in later stages, cells cannot divide but continue to differentiate. The morphologic boundaries of each cell compartment were defined many years ago and were based on criteria such as cell size, ratio of size of nucleus to cytoplasm, fineness of nuclear chromatin, nuclear shape, the presence or absence of nucleoli, the presence and type of cytoplasmic granules, and the cytoplasmic color of stained cells (Table 7.3).

Because changes in nuclear chromatin and cell size occur during each cell replication cycle, and the formation of granules and other cytoplasmic changes occur gradually during the stages of cell development, morphologic definitions are necessarily arbitrary and do not always conform to significant biochemical or physiologic changes. Classifying a cell in one category or another often is difficult because it is actually in transition between the two. Nevertheless, it is useful to separate the cell lines into morphologic compartments and to define normal limits of cell distribution therein, because gross changes from these patterns indicate disease.

DEVELOPMENT OF NEUTROPHILS AND THEIR PRECURSORS

Neutrophil development is summarized in Figure 7.1.

Cell division is limited to myeloblasts, promyelocytes, and myelocytes, with later developmental stages undergoing differentiation but no further cell division. The myeloblast contains few granules and is derived from more primitive cells as described in Chapter 5. As the cell differentiates to the promyelocyte stage, development of primary or azurophil granule formation becomes evident. This granule contains MPO, an enzyme whose activity is a classic marker of myeloid differentiation. Azurophil granule production ceases at the end of the promyelocyte stage, coincident with the loss of peroxidase activity from the rough endoplasmic reticulum. Secondary granule, or specific granule, formation begins as the neutrophil enters the myelocyte stage. The peroxidase-negative specific granules are smaller (approximately 200-nm diameter) than the azurophil granules (approximately 500-nm diameter) and are near the limit of resolution by light microscopy. The specific granules impart a pinkish ground-glass background color to neutrophils in Wright-stained smears. Because azurophil granule formation ceases in the promyelocyte stage and the subsequent myelocyte form is still capable of cell division, the density of azurophil granules is lower in differentiation stages past the promyelocyte. The result is that mature neutrophils contain approximately two specific granules for every azurophil granule. With maturation, the azurophil granules, which generate reddish-purple staining in the promyelocytes, lose this metachromasia as they leave the myelocyte stage. This alteration in staining properties is thought to be caused by an increase in acid mucosubstances, which complex with basic proteins already present in the azurophil granules.[88] Thus, in the mature neutrophil, the azurophil granules appear as light blue-violet granules on Wright-stained smears. The azurophil granules are readily demonstrated by peroxidase staining with light microscopy.

Data concerning antigenic differences between granulocytes and monocytes and their stages of maturation have largely been developed using monoclonal antibodies. Such monoclonal antibodies have been analyzed in a series of international workshops in which antibodies are grouped into CD. Some of the CD antigens expressed on neutrophils are shown in Table 7.2. Immunogold and enzyme-linked immunologic methods[89] permit simultaneous morphologic and immunologic examination of individual cells.

TABLE 7.3

MORPHOLOGIC CHARACTERISTICS OF LEUKOCYTES (WRIGHT STAIN)

	Nucleus							Cytoplasm			
Type of Cell	Size (μm)	Position	Shape	Color	Chromatin	Nuclear Membrane	Nucleoli	Relative Amount	Color	Perinuclear Clear Zone	Granules
Granulocytes											
Myeloblast	10–18	Eccentric or central	Round or oval	Light reddish purple	Very fine meshwork	Very fine	2–5	Scanty	Blue	None	None
Promyelocyte	12–20	Eccentric or central	Round or oval	Light reddish purple	Very fine meshwork	Fine	2–5	Moderate	Blue	None	Primary (azurophilic, eosinophilic, or baso-phillic)
Myelocyte	12–18	Eccentric	Oval or slightly indented	Reddish purple	Fine but becomes gradually coarser	Indistinct	Rare	Moderate	Bluish pink	None	Primary plus, in neutrophils, secondary or sp
Metamyelocyte	10–18	Central or eccentric	Thick horseshoe or indented	Light purplish blue	Basi- and oxychromatin clearly distin-guished	Present	None	Plentiful	Pink	None	Neutrophilic, eosinophilic, or basophilic
Juvenile or band form	10–16	Central or eccentric	Band shape of uniform thickness	Light purplish blue	Basi- and oxychromatin clearly distin-guished	Present	None	Plentiful	Pink	None	Neutrophilic, eosinophilic, or basophilic
Polymorpho-nuclear neutrophil	10–15	Central or eccentric	2–5 or more dis-tinct lobes	Deep purplish blue	Rather coarse	Present	None	Plentiful	Faint pink	None	Fine, pink, or violet pink

Myeloblast

The word *myeloblast* describes an immature cell, typically found in the bone marrow and not in the blood. This cell can divide and give rise to promyelocytes, which in turn give rise to myelocytes. The neutrophil and macrophage lines share a common stem cell, colony-forming unit granulocyte–monocyte (CFU-GM).[90–93]

The myeloblast (Fig. 7.2) has a large nucleus, is round or slightly oval, and has a small amount of cytoplasm. In preparations treated with Wright stain (Table 7.3), the nuclear membrane is smooth and even in outline and is exceedingly thin, with no condensation of chromatin near its inner surface, as noted in lymphoblasts. The chromatin shows an even, diffuse distribution with no aggregation into larger masses, although some condensation may be noted about the nucleoli. The chromatin may appear in the form of fine strands, thus giving the nucleus a sieve-like appearance; alternatively, it may have the form of fine dust-like granules, producing a uniform stippled effect. Generally, the myeloblast contains two to five pale, sky-blue nucleoli. The cytoplasm is basophilic (blue), and usually, although not invariably, no clear zone is evident about the nucleus. Sometimes, the cytoplasm is reticular, spongy, or foamy. By definition, no granules are present in the cytoplasm. Leukemic myeloblasts that contain no perceptible granules often are identified by special stains that demonstrate the presence of MPO or esterase, thus providing early evidence of differentiation.[94]

EM reveals similar findings.[95,96] The nuclear membrane is thin and indistinct, with minimal or no chromatin condensation. The numerous particles of ribonucleoprotein in the cytoplasm produce deep blue basophilia in stained preparations. Mitochondria are abundant but small, and the endoplasmic reticulum is flat and appears infrequently. The Golgi apparatus is indistinct, and no cytoplasmic granules are present. EM studies of myeloblasts show peroxidase activity in the rough endoplasmic reticulum and Golgi.

Some authors classify what may be slightly more mature cells with several rather large, angular, irregular, and dark-staining azurophilic cytoplasmic granules as myeloblasts. A simpler approach is to include such forms in the promyelocyte stage, thus making the separation between the two cell types clear-cut. The EM classification of myeloid cells, primarily on stages of granule formation, also places cells with beginning granule formation in the promyelocyte category.[87,97]

In wet films, myeloblasts appear immobile, with thin, tenacious borders. In video studies of hanging-drop preparations, myeloblasts manifest a characteristic snail-like movement.[98,99]

Because they are in the process of growth and division, myeloblasts vary in diameter from 10 to 20 μm. In patients with acute leukemia, there may be asynchronous development of the nucleus and cytoplasm; such myeloblasts (sometimes called Rieder cells[100,101]) suggest more rapid maturation on the part of the nucleus than of the cytoplasm (asynchronism of Di Guglielmo). Auer bodies, a marker for acute leukemia, are evident in the cytoplasm of cells that otherwise look like myeloblasts (Fig. 7.3).

Neutrophil Promyelocytes and Myelocytes

The developmental stages in the granulocyte series and some of their morphologic variations are shown in Figure 7.1. In the past, the several stages beyond the myeloblast were differentiated primarily on the basis of the number and type of granules. EM histochemical and biochemical findings demonstrated that the azurophilic or primary granules first appear at the promyelocyte stage and can be identified on fine structural study as characteristic of the neutrophil, eosinophil, or basophil series.[87,95,97,102,103] They do not transform into specific granules but persist throughout the remainder of the maturation sequence and are seen in

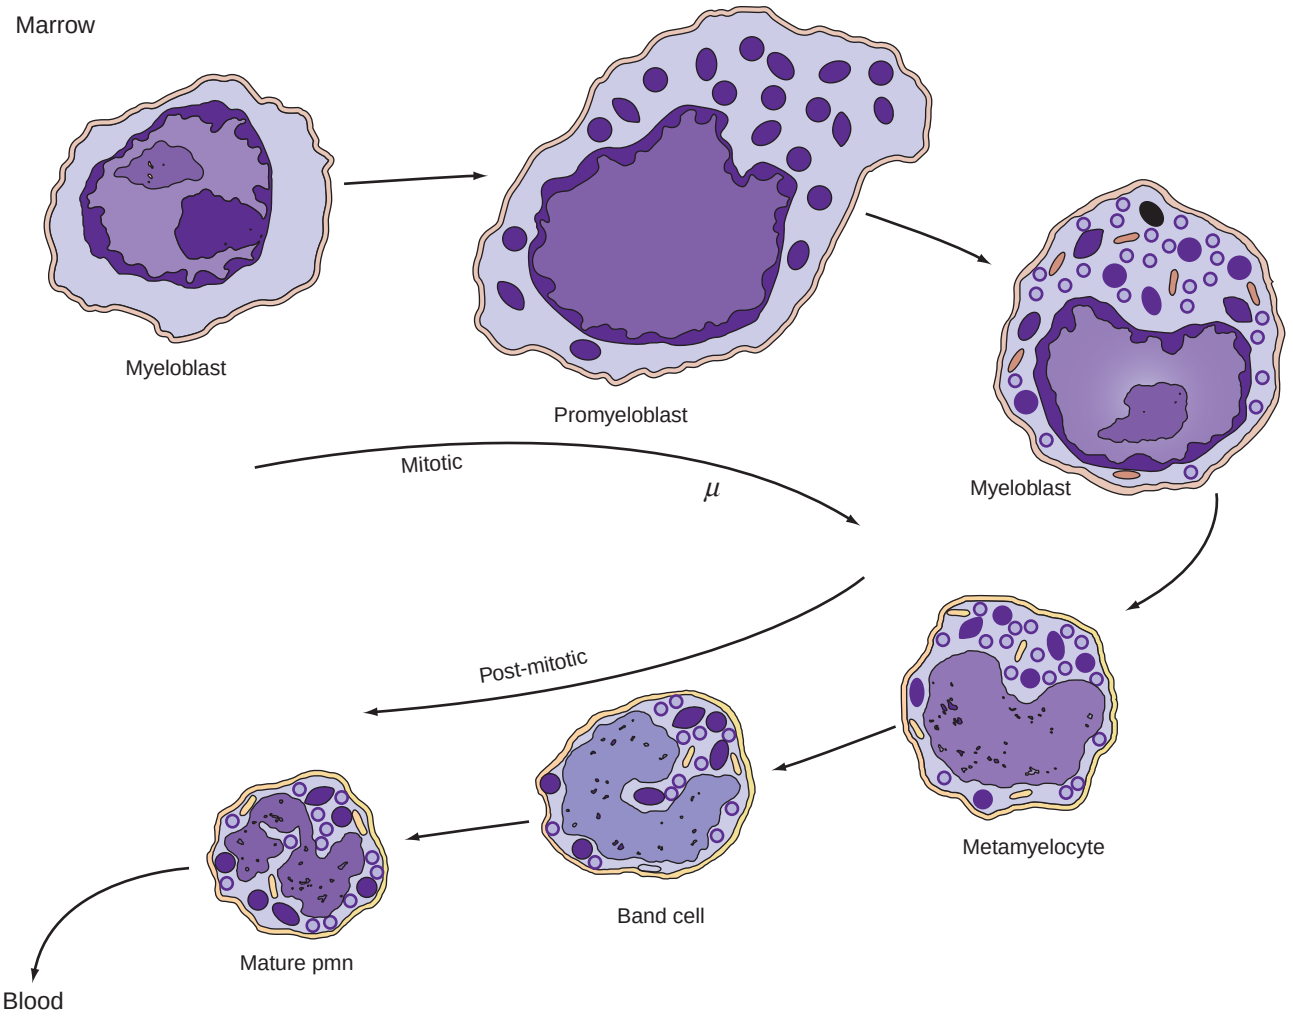

FIGURE 7.1. Appearance of granules during neutrophil maturation. Myeloblasts are undifferentiated cells with a large oval nucleus, large nucleoli, and cytoplasm lacking granules. They originate from a precursor pool of stem cells. Subsequently, there are two stages—the promyelocyte and the myelocyte—each of which produces a distinct type of secretory granule: azurophils (*dark granules*) are produced only during the promyelocyte stage; specific granules (*light granules*) are produced during the myelocyte stage. The metamyelocyte and band forms are nonproliferating stages that develop into the mature polymorphonuclear neutrophil characterized by a multilobulated nucleus and cytoplasm containing primarily glycogen and granules. Both nonspecific azurophilic granules and specific granules persist throughout these later stages. PMN, polymorphonuclear leukocyte. (Modified from Bainton DF, Ullyot JL, Farquhar MG. The development of neutrophilic PMN leukocytes in human bone marrow: origin and content of azurophil and specific granules. J Exp Med 1971;134:907.)

all subsequent stages, including the polymorphonuclear forms (Fig. 7.1).[97,103,104]

The neutrophil promyelocyte is somewhat larger on average than the myeloblast. In both light and EM preparations, it has a round or oval nucleus in which the nuclear chromatin is diffusely distributed, as in the myeloblast; in later stages, slight chromatin condensation is discerned around the nuclear membrane. Nucleoli are present, but as the cell develops, they become less prominent. Compared with the myeloblast, the endoplasmic reticulum in EM preparations is more prominent and takes on a dilated, vesicular appearance. The azurophilic, primary granules appear and accumulate in increasing numbers during this stage, but the specific or secondary granules are not yet present (Fig. 7.4).[87,96,97,102,104] In early promyelocytes, the few granules present may be difficult to see by using light microscopy; they often lie over the nucleus and are evident only on examination at several focal planes.

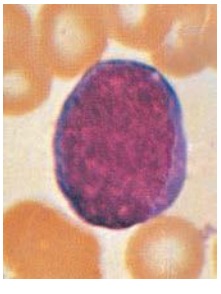

FIGURE 7.2. Myeloblast (×1,000, Wright stain).

Like the myeloblast, the promyelocyte is immobile in flat slide and cover glass preparations; only in the last stage is slight locomotion evident. Even then, the streaming of granules so characteristic of mature granulocytes is lacking.[105] In hanging-drop preparations, however, promyelocytes are actively mobile.

The neutrophilic myelocyte may be defined as the stage in which specific (secondary) granules appear in the cytoplasm and the cell consequently can be identified as belonging to the neutrophilic series when stained and observed to have a pinkish ground-glass background color with the light microscope. As mentioned previously, earlier identification of a cell that will become neutrophilic can be made by EM examination of the azurophilic, or primary, granules.[95] The nucleus of the neutrophilic myelocyte usually is eccentric and round or oval; one side may appear flattened. The nuclear chromatin is somewhat coarse, and nucleoli are small and often not visible, although they are seen clearly with the electron microscope.[102] Primary granules

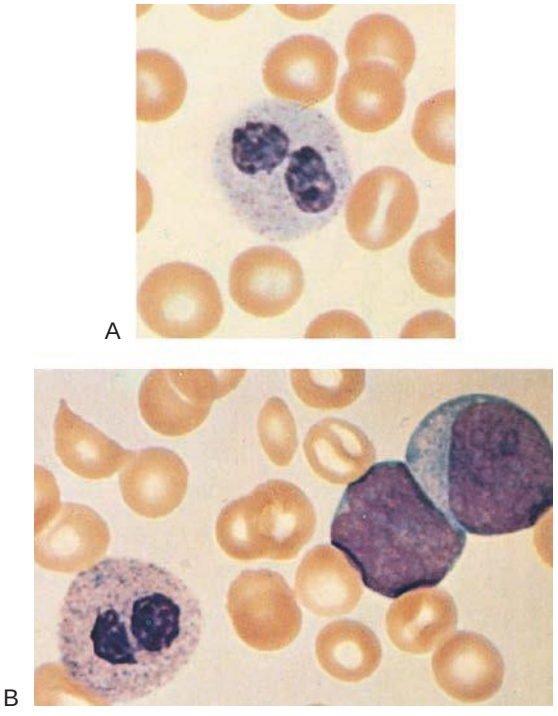

FIGURE 7.3. A, B: Pseudo–Pelger-Huët cells, the latter from the blood of a patient with acute myeloblastic leukemia (×1,000, Wright stain).

persist in myelocytes, but formation of new primary granules is limited to the promyelocyte, and each succeeding cell division leads to a decrease in their number in the daughter population (Fig. 7.1).[97,104,105] The secondary granules of the neutrophil series are smaller than the primary granules; in the rabbit, cat, and human, they are formed in increasing numbers on the convex surface and lateral borders of the somewhat less prominent Golgi apparatus.[97,102,104] The amount of granular endoplasmic reticulum is lower in the myelocyte than in earlier forms, so the cytoplasmic basophilia decreases and disappears. The mitochondria remain small and are few.

Neutrophil Granule Development

It has been suggested that the different neutrophil granules are formed because of temporal differences in gene expression of the granule contents[82,106] and this model fits well with the data. Studies in rabbits, cats, and humans suggest that the primary granules are packaged and released from the inner, concave surface of the Golgi apparatus (Fig. 7.5A)—in contrast to the specific or secondary granules of the myelocyte and later granulocyte stages that appear to be formed and released from the outer, convex surface.[97,102,103,104] Studies of membranes from rabbit azurophil and specific granules, although demonstrating similar ultrastructure, have shown them to be distinct and different in cholesterol–phospholipid ratios and protein components.[107] In the mature neutrophil, a ratio of secondary to primary granules of approximately 9:1 is seen in the rabbit[108] and 2 or 3:1 in humans.[97,109]

The mature primary granules of human neutrophils usually contain central crystalloids when lightly stained.[103] They apparently bind neutral red dye and thus are seen easily as neutral red bodies in supravital preparations.[110] These membrane-bound lysosomes contain enzymes and other substances (Table 7.1).[87,97,111,112] Acid phosphatase activity varies considerably, as reported in different studies and in different species.[102,103,113,114] This may be because of variation in the histochemical assays or to species variations.[87] Peroxidase has been associated with primary granules by histochemical, cytochemical, and biochemical methods and is considered a marker enzyme for primary granules in mammals.[87,115] Sulfated mucosubstance presumably accounts for the azurophilic staining of the primary granules; the uptake of radiosulfate by early-stage neutrophils may be the result of incorporation into this substance.[116,117]

The secondary granules of the neutrophil were once thought to be characterized by their content of alkaline phosphatase and lack of acid phosphatase.[87,97,118] However, subsequent studies demonstrated that alkaline phosphatase is localized in a previously unrecognized organelle, the secretory vesicle (Table 7.1).[119] Lysozyme is present in human neutrophil secondary granules,[120] as well as in primary granules; approximately two thirds of this antibacterial basic protein is in the secondary granule. The standard marker enzymes for specific granules are lactoferrin[115] and B_{12}-binding protein.[121]

A third type of granule, the tertiary granule, also known as the *gelatinase granule* (Table 7.1),[103,122] is synthesized mainly during the band and segmented neutrophil stages.[103,123,124]

Neutrophil Metamyelocytes

The metamyelocyte is characterized by a clearly indented or horseshoe-shaped nucleus without nucleoli, and the nuclear chromatin is moderately dense, with considerable clumping evident along the nuclear membrane. The cytoplasm is filled with primary, secondary, and tertiary[93,116] granules, but the secondary granules predominate. The endoplasmic reticulum is sparse, as are polysomes, thus signifying the virtual completion of protein synthesis.

The boundary between the myelocyte and metamyelocyte compartments is best defined physiologically by the fact that myelocytes synthesize DNA, take up ^{3}H-TdR into their nuclear chromatin, divide, and are actively involved in protein synthesis, as evidenced by the presence of nucleoli, abundant endoplasmic reticulum, and polysomes. Before such techniques became available, differentiation between myelocytes and metamyelocytes was defined mainly in terms of nuclear shape. This characteristic now is recognized as a poor criterion because it has been shown in time-lapse microcinematographic studies of human neutrophils that myelocyte nuclei may assume a markedly indented shape and may subsequently revert to an oval configuration and enter mitosis.[95] Consequently, in classifying cells at this stage, the observer should pay particular attention to evidence in the nucleus and cytoplasm that protein synthesis has decreased or stopped. This determination is made on the basis of the fact that the nuclear chromatin is coarse and clumped and that the cytoplasm is faint pink and is essentially the color of the mature cell in stained preparations. These features are also helpful in differentiating metamyelocytes (Fig. 7.6A,B) from monocytes (Fig. 7.6C) because in monocytes, nuclear chromatin remains fine, and evidence of protein synthesis persists. Amoeboid movement is apparent in metamyelocytes, even in cover glass slide preparations, and it is at this stage that directional migration can regularly be demonstrated.[125]

Band Neutrophils

The band stage is characterized by further condensation of nuclear chromatin and transformation of nuclear shapes into sausage or band configurations that have approximately uniform diameters throughout their length (Fig. 7.1). Subsequently, one or more constrictions begin to develop and progress until the nucleus is divided into two or more lobes connected by filamentous strands of heterochromatin, the polymorphonuclear stage. Some workers require a clearly visible filamentous strand between lobes (Fig. 7.7A,B) before classifying a cell as a polymorphonuclear form; anything less clear-cut, whether because of overlapping of nuclear lobes or incomplete constriction, is classified as a band form.[126,127] Other investigators

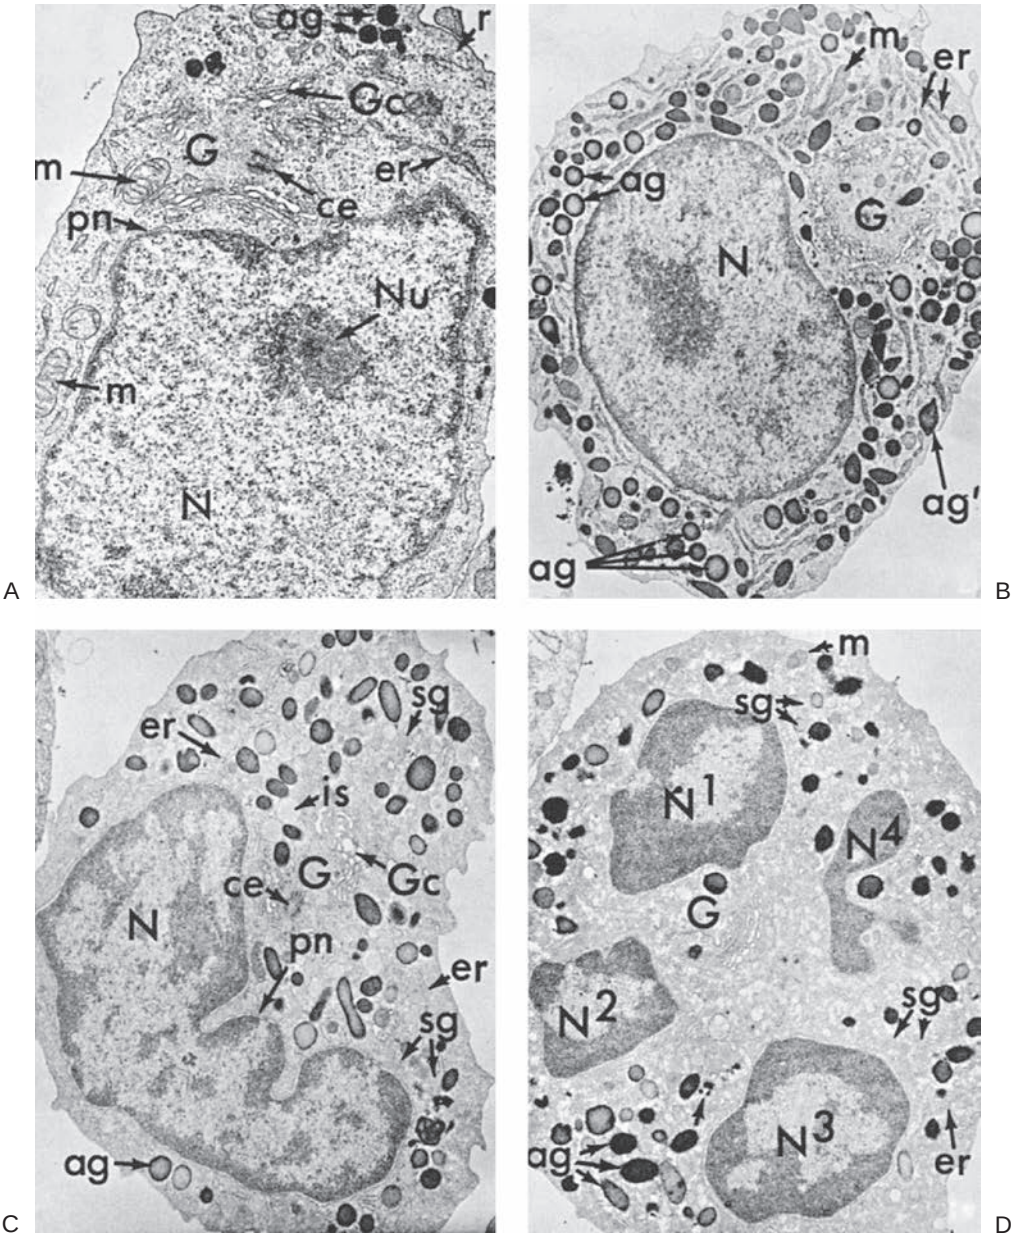

FIGURE 7.4. Early and late promyelocytes, a myelocyte, and a polymorphonuclear neutrophil (PMN) viewed by electron microscopy. (Courtesy of Bainton D, University of California, San Francisco.) **A:** Early neutrophilic promyelocyte (reacted for peroxidase, 10,500). The nucleus (*N*) with its prominent nucleolus (*Nu*) occupies the bulk of this immature cell. The surrounding cytoplasm contains a few azurophil granules (*ag*), a large Golgi complex (*G*), Golgi cisternae (*Gc*), several mitochondria (*m*), scanty rough endoplasmic reticulum (*er*), and many free polysomes (*r*). A centriole (*ce*) is present in the Golgi region. All of the azurophil granules (*ag*) appear dense because they are strongly reactive for peroxidase. The secretory apparatus, i.e., the perinuclear cisterna (*pn*), rough endoplasmic reticulum (*er*), and Golgi cisternae (*Gc*), are also reactive, although less so than the granules. Specimen was fixed in glutaraldehyde for 16 hours at 4°C, incubated in the peroxidase medium of Graham and Karnovsky for 1 hour at 22°C, postfixed in osmium tetroxide, treated in block with uranyl acetate, dehydrated in ethanol, infiltrated with propylene oxide, and embedded in Araldite. Section stained for 1 minute with lead citrate. **B:** Late neutrophilic promyelocyte (reacted for peroxidase, 7,000). This cell is the largest (15 μm) of the neutrophilic series. It has a sizable, slightly indented nucleus (*N*), a prominent Golgi region (*G*), and cytoplasm packed with peroxidase-positive azurophil granules (*ag*). Note the two general shapes of the azurophil granules: spherical (*ag*) and ellipsoid (*ag'*). Most are spherical, with a homogeneous matrix, but a few ellipsoid forms containing crystalloids also are present. Many of the spherical forms (*ag*) have a dense periphery and a lighter core, presumably because of incomplete penetration of substrate into the compact centers of mature granules. Peroxidase reaction product is visible (under higher magnification) in less concentrated form within all compartments of the secretory apparatus (endoplasmic reticulum, perinuclear cisterna, and Golgi cisternae). No reaction product is seen in the cytoplasmic matrix, mitochondria, or nucleus. Specimen was fixed in glutaraldehyde for 10 minutes at 4°C and subsequently processed exactly as was the specimen in **A. C:** Neutrophilic myelocyte (reacted for peroxidase, 9,000). At this stage, the cell is smaller (10 μm) than the promyelocyte, the nucleus is more indented, and the cytoplasm contains two different types of granules: large, peroxidase-positive azurophils (*ag*) and the generally smaller specific granules (*sg*), which do not stain for peroxidase. A number of immature specific granules (*is*), which are larger, less compact, and more irregular in contour than mature granules, are seen in the Golgi region (*G*). Note that peroxidase reaction product is present only in azurophil granules and is not seen in the rough endoplasmic reticulum (*er*), perinuclear cisterna (*pn*), and Golgi cisternae (*Gc*), in keeping with the fact that azurophil production has ceased, and only peroxidase-negative specific granules are produced during the myelocyte stage. **D:** Mature PMN (reacted for peroxidase, 10,500). The cytoplasm is filled with granules; the smaller peroxidase-negative specific granules (*sg*) are more numerous, the azurophils (*ag*) having been reduced in number by cell divisions after the promyelocyte stage. Some small, irregularly shaped azurophil granule variants are also present (*unlabeled arrow*). The nucleus is condensed and lobulated (*N1–N4*), the Golgi region (*G*) is small and lacks forming granules, the endoplasmic reticulum (*er*) is scanty, and mitochondria (*m*) are few. Note that the cytoplasm of this cell has a rather ragged, moth-eaten appearance because the glycogen, which is normally present, has been extracted in this preparation by staining in block with uranyl acetate.

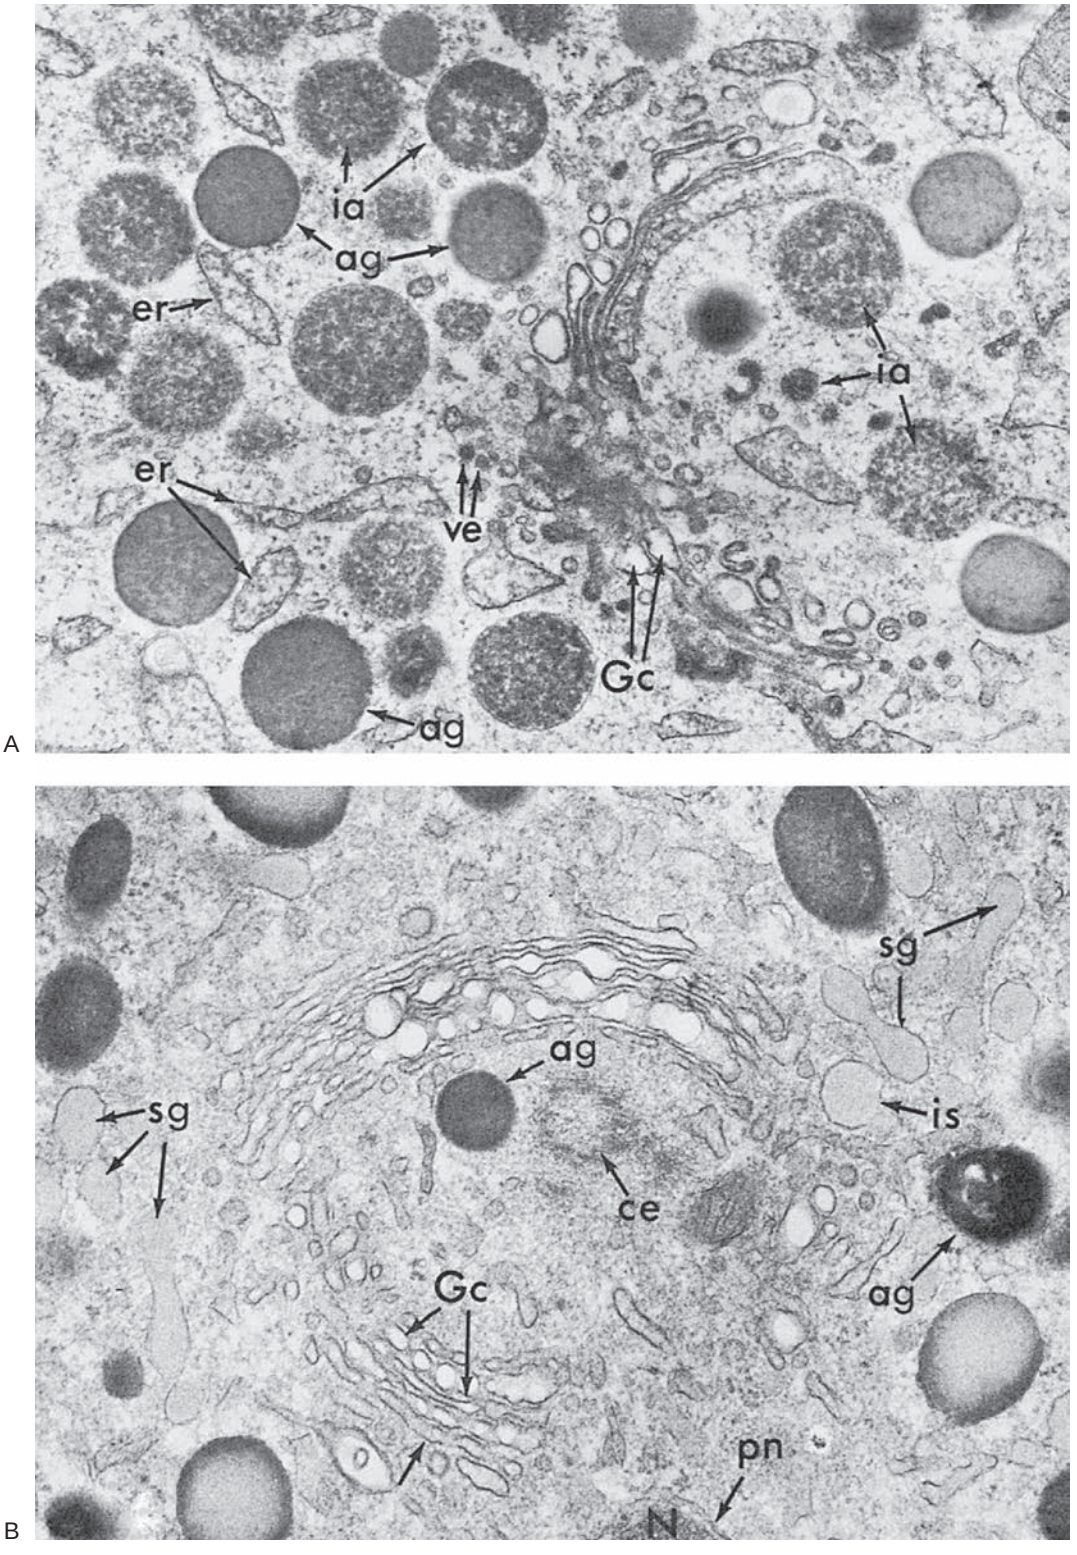

FIGURE 7.5. Granule formation in neutrophil precursors viewed by electron microscopy. (Courtesy of Bainton D, University of California, San Francisco.) **A:** Golgi region of a neutrophilic promyelocyte reacted for peroxidase (×40,000). At this stage, the peroxidase reaction product is present within the rough endoplasmic reticulum (*er*), the clusters of smooth vesicles (*ve*) at the periphery of the Golgi cisternae (*Gc*), in the Golgi cisternae, and in the immature (*ia*) and mature (*ag*) azurophilic granules. The immature granules are larger and less compact than the uniformly dense mature granules. **B:** Golgi region of a neutrophilic myelocyte reacted for peroxidase (×40,000). Peroxidase-reactive material is seen in the primary or azurophilic granules (*ag*) but not in the specific (secondary) granules (*sg*). At this stage (myelocyte), no peroxidase reaction product is seen in the endoplasmic reticulum, Golgi cisternae (*Gc*), or newly formed, immature specific granules (*is*). The stacked Golgi cisternae are oriented around the centriole (*ce*), and the outer cisternae (*unlabeled arrow*) contain material of intermediate density that is similar to the content of the specific granules, suggesting that the specific granules arise from the convex face of the Golgi complex as in the rabbit. pn, perinuclear cisternae.

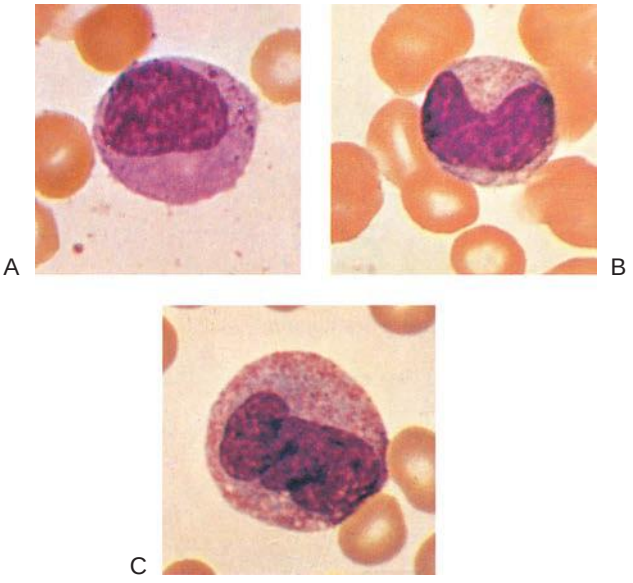

FIGURE 7.6. **A:** Late myelocyte or early metamyelocyte. **B:** Metamyelocyte. **C:** Monocyte (×1,000, Wright stain).

have regarded a constriction greater than one half or two thirds of the nuclear breadth as adequate evidence of lobulation and classify such cells as polymorphonuclear[128,129] or use slightly different criteria.[130] Still others avoid the issue entirely. Because no clear difference has been shown between band and segmented stages other than nuclear shape and a slightly earlier appearance of ^{3}H-TdR in the band forms, the distinction becomes arbitrary. However, a clear and easily recognizable separation is needed if one wishes to count nuclear lobes for diagnostic purposes, as in the early detection of folic acid deficiency[131] or in assessing marrow release of young forms into the blood.[132] For such purposes, we have chosen the clear separation of nuclear lobes as the criterion for inclusion in the polymorphonuclear category.[127] Cells without this complete formation of distinct lobes (usually connected by a filamentous strand) are classified as band forms.

Polymorphonuclear Neutrophils

In the polymorphonuclear stage, the nucleus in Wright-stained preparations is a deep purplish color and contains coarse, condensed chromatin. The lobes are joined by thin filaments of chromatin, although the filaments may not be easily visible if the lobes are partially superimposed. The cytoplasm is faint pink and contains fine, specific granules that sometimes give only a ground-glass appearance. The azurophilic or primary granules have usually lost their dark-staining characteristics by this stage but can be seen with EM. With this technique, the granules exhibit considerable variation in density, presumably a reflection of variation in enzyme content, and they maintain a minimum distance of 100 nm from the cell membrane.[133] Large masses of glycogen become evident for the first time in mature neutrophils; this finding may contribute to their capacity for anaerobic metabolism.

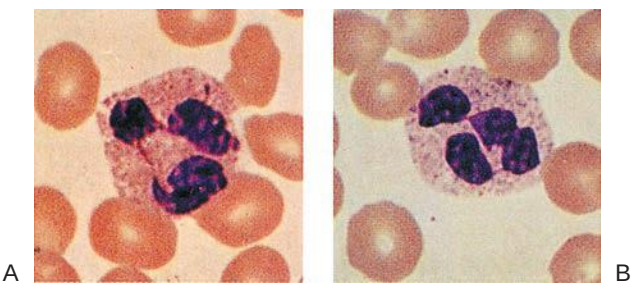

FIGURE 7.7. **A, B:** Polymorphonuclear neutrophils.

The mechanism and purpose of nuclear lobulation are the subject of speculation. Perhaps it enhances cell deformability and movement through vessel walls and into sites of inflammation, or perhaps nuclear segmentation results from nucleolar emptying and has no function.[134] Thus, the mechanism and purpose of nuclear segmentation remain unclear.

It was suggested that granulocytes with three or four lobes are more mature than those with only two.[135] However, the number of lobes a neutrophil develops appears to be determined in the band stage (or earlier), and the time of appearance of neutrophils in the blood after pulse labeling with ^{3}H-TdR is unrelated to the number of nuclear lobes.[136]

In wet films, marked amoeboid activity of polymorphonuclear neutrophils at physiologic temperatures is characteristic.[137] "Senile" polymorphonuclear leukocytes that are no longer motile and fail to take up neutral red stain have been identified in in vitro preparations.[138] They are seen in small numbers in the blood, where their survival time is short.[139]

Pelger-Huët Anomaly

Pelger-Huët anomaly is a benign anomaly of leukocytes and is inherited as a non–sex-linked, dominant trait. It is characterized by distinctive shapes of the nuclei of leukocytes, a reduced number of nuclear segments (best seen in the neutrophils), and coarseness of the chromatin of the nuclei of neutrophils, lymphocytes, and monocytes. The nuclei appear rod-like, dumbbell-shaped, peanut-shaped, and spectacle-like ("pince-nez") with smooth, round, or oval individual lobes (Fig. 7.3), contrasted with the irregular lobes seen in normal neutrophils. Pelger-Huët cells appear to be normal functionally. Pseudo– or acquired Pelger-Huët anomaly may also be seen, in which cells with morphologic changes, such as described above, have been observed occasionally in association with myxedema, acute enteritis, agranulocytosis, multiple myeloma, malaria, leukemoid reactions secondary to metastases to the bone marrow, drug sensitivity, or chronic lymphocytic leukemia. More commonly, pseudo–Pelger-Huët cells are seen in patients with myeloid leukemia or myeloid metaplasia. Pelger-Huët anomaly is discussed further in Chapter 58.

Neutrophil Heterogeneity

Polymorphonuclear neutrophils were first thought to be a homogeneous population of end-stage cells incapable of protein synthesis and of essentially uniform size, granule content, and functional capability. Sabin first suggested potential heterogeneity among neutrophils when she reported that myelocytes were less motile than more mature neutrophils.[138] A range of rates of motility among neutrophils from a single individual has been observed,[140,141] and Harvath and Leonard suggested the existence of two neutrophil populations based on chemotaxis.[142] Subsequently, several monoclonal antibodies were described that recognize subpopulations of neutrophils, including one that appears to recognize the classic NB1 (HNA-2a) neutrophil antigen, and one that recognizes an activation epitope on CD11/CD18.[143–145] Another antibody, 31D8, appears to recognize a neutrophil subset that is more responsive to FMLP as determined by chemotaxis and respiratory burst activity.[143] Neonates have a larger percentage of neutrophils that express low levels of 31D8 antigen.[146] It has been reported that CR2 (CD21), the receptor for C3d, is present on immature neutrophils but not mature blood neutrophils.[147,148] One report found that neutrophils from patients with localized juvenile periodontitis express CD21 (CR2) on their surface, whereas normal neutrophils do not.[149]

Neutrophil heterogeneity has also been demonstrated in the case of olfactomedin 4 expression. Olfactomedin 4 is highly induced in myeloid progenitors by G-CSF. Although olfactomedin 4 mRNA is expressed in all myelocytes and metamyelocytes, only ~25% of neutrophils in peripheral blood contain olfactomedin 4, which is localized to the specific granules.[150]

Some studies of these different populations of polymorphonuclear neutrophils have been interpreted as reflecting maturation or environmental influences,[151] in some cases possibly reflecting intravascular exposure to stimuli.[152,153] The clinical significance of neutrophil subpopulations is unclear.

MACROPOLYCYTES

Macropolycyte is the name applied to giant polymorphonuclear neutrophils with a diameter greater than 16 μm and with 6 to 14 nuclear lobes.[154] Such cells are seen only occasionally in healthy subjects (1.3%), but they are found in approximately 5% of people with infections of various types or with intoxications, usually in association with a neutrophilic leukocytosis and myelocytes in the blood.[154] Macropolycytes are commonly seen in association with folic acid or vitamin B_{12} deficiency, as well as in patients recovering from the pancytopenia that attends treatment with cytotoxic agents, especially hydroxyurea.

Some authors describe cells with hypersegmented nuclei but of a normal size and call them *polycytes*[126] or polylobocytes[129]; similar cells with complex nuclei but without hypersegmentation are called *propolycytes*.[126] The latter forms are seen in approximately 10% of patients recovering from leukocytosis with a marked shift to the left and appear in increasing numbers when anticoagulated blood is allowed to stand in vitro.[126,155]

The mechanism of macropolycyte formation is unknown, but one suggestion is that the skipping of one of the usual cell divisions that occurs during maturation results in a hypersegmented cell.[156]

GENETIC SEX AS INDICATED BY LEUKOCYTES

Only one X chromosome is essential to the normal activity of a cell; the other in the normal XX female remains unextended and thus is visible as a chromatin body. Sex chromatin (Barr) bodies are present in 80% to 90% of the somatic cells of the normal female subject. The sex chromatin body of the neutrophil of females is a small mass, usually adjacent to the nuclear membrane, that stains deeply with hematoxylin and is approximately 0.7 to 1.2 μm in diameter. It takes the form of a drumstick projecting from one of the nuclear lobes of approximately 2% to 3% (extreme range, 1% to 17%) of the segmented neutrophils in the blood.[157] They are well-defined, solid, round projections of chromatin connected to a lobe by a single, fine chromatin strand (Fig. 7.8). They must be distinguished from small clubbed or racket-structured, nonspecific nodules that may be smaller or larger as well as irregular in shape or lacking in chromatin, as well as from small (minor) lobes attached to the rest of the nucleus by two strands. Confirmation of the X chromosome in the drumstick has been provided by *in situ hybridization*.[158] Sessile nodules are equally gender-specific but are more difficult to recognize. Drumsticks are not found in normal male subjects.[159]

The number of chromatin bodies seen in a cell is one less than the number of X chromosomes present. With the increased numbers of X chromosomes found in certain disorders of human development, the number of Barr bodies and drumsticks increases, and isochromosomes formed by duplication of the long arms of the X chromosome give rise to larger drumsticks than are found in the normal female subject.[160] Drumsticks or sessile nodules are seen in chromatin-positive male patients with Klinefelter syndrome and are absent in chromatin-negative female patients with Turner syndrome. Eosinophils and probably basophils also have drumsticks. Drumsticks may be difficult to find in the presence of a marked shift to the left. Double drumsticks[159] or a sessile nodule plus a drumstick in the same neutrophil are rare.[161]

DIFFERENTIAL CELL COUNTING AND NORMAL VALUES FOR LEUKOCYTES

Differential cell counting is the enumeration and classification of the leukocytes seen on the blood smear. The usual procedure is to count at least 100 consecutive leukocytes in an area of good cell distribution. A uniformly thin smear of blood on a cover glass is the best preparation for such examination. Differential cell counting in general is discussed in Chapter 1.

Distributional errors are reduced as more cells are counted. Confidence tables or curves can be used to estimate the probable error of a differential count when various numbers of cells are counted. Clearly, as more cells of a given type are counted and as the total number of cells enumerated increases, the accuracy of the differential count is greater. From the total leukocyte count and the differential count, the absolute concentration of each leukocyte type can be calculated. The accuracy of the result depends on the validity of the total leukocyte count and the differential count. With automatic cell counters, the major component of error now lies in the differential count.

The absolute leukocyte concentration provides a more accurate picture than the differential count because each leukocyte type is a separate cell system with its own functions, control mechanisms, and responses to disease processes; for example, a patient with chronic lymphocytic leukemia whose total leukocyte count is 100 $\times$ 10^9 cells/L, 7% of which are neutrophils and 93% are lymphocytes, does not have granulocytopenia. With a blood neutrophil concentration of 7.0 $\times$ 10^9 cells/L, the problem is lymphocytosis.

Normal values for absolute leukocyte concentrations obtained by using a Coulter counter and differential counts are shown in Table 7.4. Similar values have been reported with the use of other methods.[162] Some variation is evident in values obtained in different population groups and appears to depend on age, sex, pregnancy, time of day, activity level, and other factors.[163] Racial variation has been reported, especially in Ethiopian Jews[164]

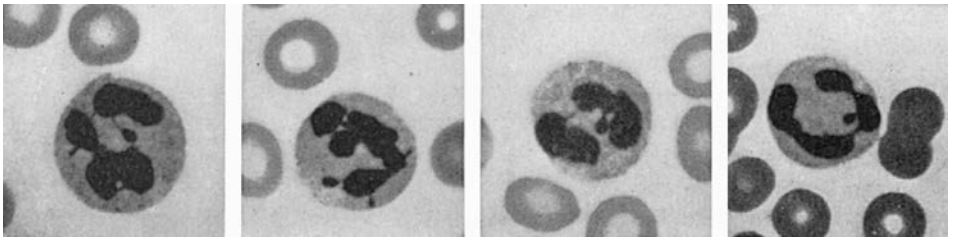

FIGURE 7.8. Granulocytes and sex chromatin patterns. Two cells on the left show the characteristic drumsticks found in the female subjects. The thin strand of chromatin joining the head to a nuclear lobe can be seen clearly. In the two cells on the right, small clubs, such as may be seen in male subjects, should not be confused with drumsticks (Wright stain, ×1,300).

TABLE 7.4

NORMAL BLOOD LEUKOCYTE CONCENTRATIONS (95% CONFIDENCE LIMITS)

Subjects (Age)	Sex	No.	Time of Day (hours)	WBC	Neutrophils	Lymphocytes	Monocytes	Eosinophils	Basophils	WBC Counter	Differential (No. Cells)	Reference

and black Africans, who have significantly lower neutrophil and monocyte counts.[165] Lower counts are less evident in black Americans[127] and in Africans eating a Western diet.[163]

Various systems for differential counting have been used.[166] Arneth, for example, painstakingly recorded and tabulated from left to right the number of neutrophilic leukocytes with 1, 2, 3, etc., lobes and made other subdivisions.[135] The term *shift to the left* is derived from this practice and indicates an increase in the proportion of cells with only one or few lobes, whereas *shift to the right* represents an increase in the proportion of multisegmented forms.

From a clinical viewpoint, it is useful to determine whether young forms of neutrophils (band forms and younger) are increased and whether the proportion of multinucleated forms is increased. An increase of younger forms (band cells, metamyelocytes, and myelocytes) (shift to the left) suggests increased release of young neutrophils from the bone marrow, which is seen in association with acute infections[132] and inflammation. If a shift to the right is suspected, a neutrophil lobe count may be useful. This process involves counting the total number of nuclear lobes in 100 or 200 neutrophils, calculating the average lobe number/neutrophil, and comparing the results with normal values. The chief difficulty associated with this count is clear definition of what constitutes a separate lobe (see "Band Neutrophils" earlier in this chapter). If complete separation of nuclear lobes with or without a connecting filament is the definition used, the normal mean neutrophil lobe count is 2.04, with 95% of normal values falling between 1.66 and 2.42. An increase in mean neutrophil lobe count suggests vitamin B_{12} or folic acid deficiency, congenital hypersegmentation of neutrophils, or renal disease.[131] A ratio of five-lobed to four-lobed polymorphonuclear cells that is greater than 0.17 is said to be associated more regularly with B_{12} deficiency than is an increase in mean nuclear lobe count.[129]

Alterations in the total number of leukocytes and in their relative proportions are significant as measures of the reactions of the body to noxious agents. The reactions of leukocytes in association with certain diseases are discussed later in this book, as is the presence of abnormal inclusions, such as toxic granulation, Döhle bodies, and various inherited abnormalities in leukocyte morphology.

NEUTROPHIL KINETICS

The importance of leukocytes in the defense of the organism is well known. Basic to their roles are cell multiplication, maturation, storage, and delivery to the tissues and sites of infection or cell damage. These processes are called *leukocyte kinetics* and are different for each leukocyte type. To simplify the discussion, each type of leukocyte is considered as a separate system, but these systems constantly interact and complement one another in the defense of the body.

Neutrophil Kinetics in the Adult

In Chapter 5, the process of mitotic cell division, the cell generation cycle, and the origin of neutrophils and other cell types from a multipotent hematopoietic stem cell were discussed. The production, kinetics, and lifespan of the neutrophil have been the subject of a number of reviews.[167–181] A model of these processes in adult humans is shown in Figure 7.9. The neutrophil system appears to be incompletely developed in premature babies and in early neonatal life; this topic is discussed in the section "Neutrophil Kinetics in the Fetus and Newborn" later in the chapter.

Mitotic and Maturation Compartments

Neutrophil production in normal adult humans appears to take place only in the bone marrow. The life cycle of the neutrophil can be divided conveniently into bone marrow, blood, and tissue phases. The assumption is that cells move through the system in an orderly manner as if in a pipeline; this view is supported by the progressive movement of isotopic tracers[117,178,182,183] and azurophilic granules [87,97,104] through the system.

The myeloblast, promyelocyte, and myelocyte are capable of cell division, as judged by direct observation in cultures[95] and by their ability to incorporate ^{3}H-TdR into their nuclear DNA.[183] These forms, therefore, constitute the mitotic compartment (Fig. 7.9). Simultaneously, they undergo differentiation, as evidenced by the appearance of azurophilic and specific granules in their cytoplasm. The more mature forms of the neutrophil series (metamyelocyte, band, and polymorphonuclear neutrophil) are usually considered incapable of cell division (except perhaps in unusual circumstances) [184] and do not incorporate ^{3}H-TdR into their nuclei, but they do exhibit continuing maturational changes and thus constitute the maturation compartment. From the maturation compartment, cells flow into the blood and are distributed in two sites: the circulating blood granulocyte pool (CGP) and the marginal granulocyte pool (MGP). Cells in these two pools are in constant equilibrium. Eventually, the cells move through vessel walls to enter the tissues. The exact nature of the MGP is not clear. In the past, it was felt to represent transient adhesion to, and rolling along the surface of, endothelial cells, primarily in postcapillary venules. However, subsequent studies of a patient with leukocyte adhesion deficiency-2 (LAD-2) demonstrated the presence of a marginating pool,[185] although the MGP in this patient with LAD-2 was reduced. Patients with LAD-2 lack the ligands for the selectins CD62P and CD62E and have a marked decrease in neutrophil rolling in postcapillary venules. Normally, the MGP is approximately equal in size to the CGP. Studies of this patient suggested that approximately 20% of neutrophils are in a selectin-independent MGP and approximately 30% are in a selectin-dependent MGP.[185] Surprisingly, this patient's neutrophils had a shorter than normal half-life in the circulation with an increased turnover rate. The inability of CD18 or CD62L antibodies to shift neutrophils from the MGP to the CGP also suggests that the transient adhesion to endothelial cells manifest as rolling does not account for the MGP.[186,187]

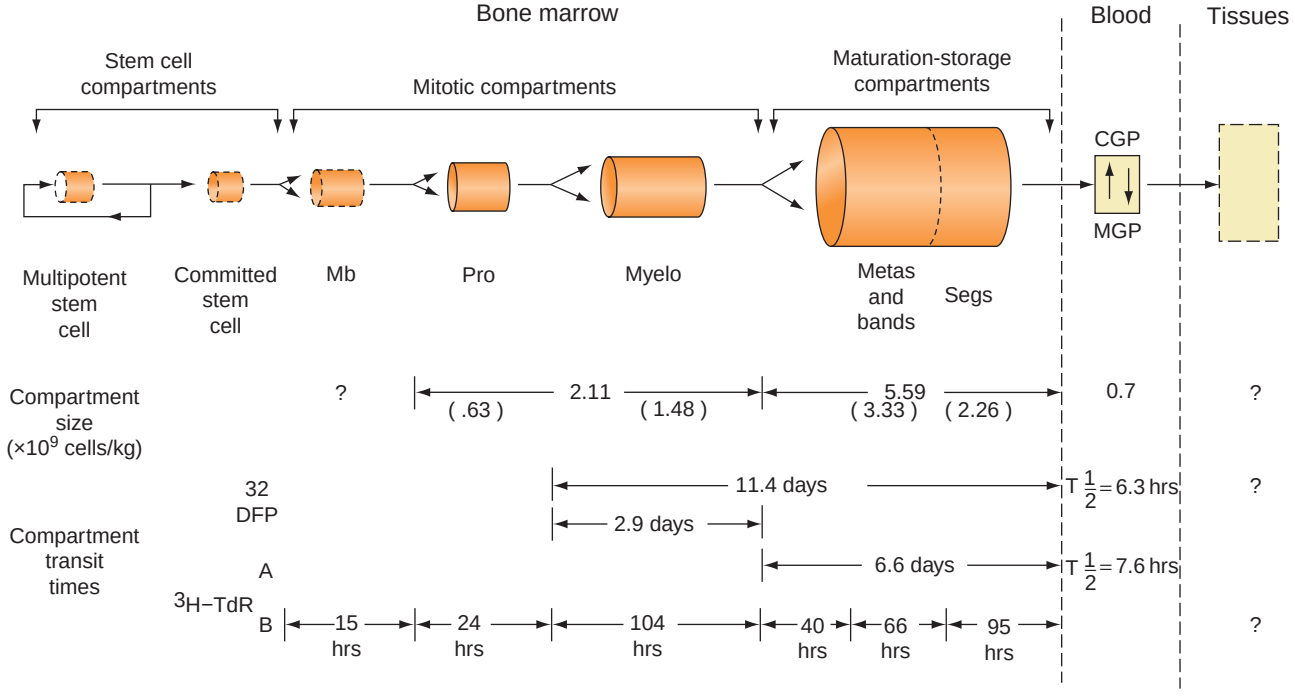

FIGURE 7.9. Model of the production and kinetics of neutrophils in humans. The marrow (555) and blood compartments (147) are drawn to show their relative sizes. In the lower one third of the figure, the compartment transit times as derived from di-isopropylfluorophosphate ($DF^{32}P$) studies (138,147) and from tritiated thymidine (^{3}H-TdR) studies (151,555) are compared. CGP, circulating granulocyte pool; MB, myeloblast; MGP, marginal granulocyte pool; myelo, myelocyte; pro, promyelocyte.

In this model, cell production can be estimated either by assessing the production rate in the mitotic compartment or by measuring cell flow through subsequent stages, such as the blood. Accuracy of these measurements is facilitated if the system is studied in the steady state when compartment sizes are constant and cell flow reflects net production and destruction.[174]

If one assumes a steady state in a scheme such as that shown in Figure 7.5, the flow of cells out of any pool (K_{out}) is equal to the flow of cells into that pool (K_{in}) plus any cells produced in the pool (K_b); thus,

$$K_{out} = K_{in} + K_b$$

Clearly, in pools other than those in the mitotic compartment, K_b is 0, and measurements of cell flow (K_{in} or K_{out}) equal effective cell production, provided no cell death occurs within the pool.

Production in the Mitotic Compartment

Because myeloblasts, promyelocytes, and myelocytes constitute approximately 0.9%, 3.3%, and 12.7% of the marrow cells, respectively, it has been assumed that the system has four or five divisions.[180] From a review of blood neutrophil radioactivity curves obtained after di-isopropylfluorophosphate ($DF^{32}P$) injection into humans, investigators raised the possibility of at least three divisions at the myelocyte stage.[180] Another suggestion generated from marrow differential counts was that only four or five divisions occur in the entire neutrophil proliferation scheme.[180] This supposition agreed with results from experiments in dogs[188] and with data from model studies.[189] In contrast, studies of myeloid islands in the rat thymus provided evidence for seven divisions during granulocytopoiesis: one in the myeloblast stage, two in the promyelocyte stage, three in the myelocyte stage, and a final one in the metamyelocyte stage.[134,190]

Calculations made from mitotic index (MI) data[172,191–193] provide estimates of cell generation time (t_g) and pool turnover time. *MI*[191,192,194] is defined as

$$MI = N_m/N$$

in which MI is the mitotic index for any morphologic cell pool, N_m is the number of mitoses in that pool, and N is the total number of cells in the pool. MI can also be expressed as the ratio of the time spent in mitosis (t_m) to the cell generation time (t_g):

$$MI = t_m/t_g$$

By combining both definitions,

$$MI = N_m/N = t_m/t_g$$

By providing determined values for MI and mitotic time (t_m) in the last equation, the generation time (t_g) for a particular cell pool can be approximated. From t_g and the pool size (N), the birth rate, K_b, can be obtained if all cells in the pool are in cycle, because each mitosis gives rise to one new cell:

$$K_b = N/t_g$$

In effect, the cell birth rate is equal to the number of mitoses occurring per unit time (t), or

$$K_b = N_m/t$$

Although the concept is simple, several problems arise.[193,195] A major problem is that the morphologic boundaries of most cell pools are not clearly delineated in terms of the cell cycle.[195] For example, to calculate cell production in the myelocyte pool, it must be assumed that all myelocytes are destined to divide; that is, no cells are recognized as myelocytes that are not going to divide again. Because the daughter cells of the last myelocyte mitosis almost certainly do not suddenly become metamyelocytes on completion of division, N in the preceding equation will be erroneously large, and thus estimates of t_g will be erroneously long.

If the fraction of nonmitotic cells in the myelocyte population were known, the calculations could be corrected for this error, as has been attempted.[170] A second major problem is the fact that values for the MI have varied considerably.[191,193,196–200] In addition, a considerable diurnal variation exists in the MI in humans, as well as in animals.[193,199–202]

Finally, to calculate the absolute neutrophil production rate (in cells per unit of time), the size of the marrow mitotic compartment must be known. Methods for measuring the sizes of marrow myeloid pools have been developed[203,204–206] (see "Size of Marrow Compartments and Their Morphologic Subdivisions," later in the chapter), but to date no one has measured these sizes and MI in the same animal at the same time and then calculated neutrophil production rate. Nevertheless, values for the MI for each of the neutrophil precursors capable of mitosis have been determined,[193,200] and within the assumptions inherent in such calculations,[195] neutrophil production has been estimated.[176,192]

Similar calculations of neutrophil production can be made from ^{3}H-TdR–labeling index data. After flash labeling with ^{3}H-TdR, autoradiographs of the bone marrow are obtained, and the proportion of nucleated cells that have incorporated the label into their nuclei is determined.[171,177] This labeling index (LI) represents the ratio of labeled cells, $*N$, or cells in DNA synthesis (N_s) to total cells (N) of a defined morphologic type:

$$LI = *N/N = N_s/N$$

The LI can also be defined in terms of DNA synthesis time (t_s) and the cell generation time (t_g), because ^{3}H-TdR is taken into the cell only during the period of DNA synthesis; thus,

$$LI = t_s/t_g$$

By combining both definitions,

$$LI = N_s/N = t_s/t_g$$

and from determined values for LI and t_g, the generation time and turnover of a given cell population can be estimated. As with MI data, birth rate is a function of the population turnover time, which can be approximated from the generation time or time spent in various phases of the cell cycle:

$$K_b = N/t_g = N_s/t_s$$

Some of the same problems arise with the ^{3}H-TdR LI that are encountered in the use of the MI.[195,207] In addition, the use of labeled compounds raises questions of label reuse [208,209] or elution[207] and perturbation of the cell population by the compound[168,188,210–212] or by its radioactivity.[207,213,214]

The LI reported for humans is myeloblast, 0.85; promyelocyte, 0.65; and myelocyte, 0.33.[171] Somewhat different values have been reported in dogs[177] and rats.[200] By using the LI for humans and a value for t_s of 5 hours (based on studies in dogs) and by determining relative compartment sizes for each cell type from the bone marrow differential count, the relative birth rates (K_b) of cells have been calculated.[170,200]

Some authors have found good agreement between neutrophil production as calculated from the MI and the LI,[200] but considerable discrepancy has been reported by other authors.[170] This difference may result from the fact that the MI values obtained were low, the studies were done in different subjects at different times, and too small a value for t_s was used in the calculations.

The turnover time of a labeled compartment and neutrophil production rate also may be estimated by measuring the grain count halving time. The generation time is derived only if each cell in a given class divides and if no label feeds into the compartment from a labeled precursor class or as a result of label reuse.[215] If any of these criteria are not met, the half-time for grain count decrease is longer than the true value, and the estimate of generation time is only a maximal value. Additional disadvantages of this method are that at least several bone marrow samples distributed

throughout several half-times are needed, and that grain counting is extraordinarily tedious and subject to considerable error. Nevertheless, estimates of compartment turnover time have been made with this method by using ^{3}H-TdR and radiosulfate.[122]

After flash labeling with ^{3}H-TdR, the cohort of cells labeled during DNA synthesis may be followed as it subsequently enters mitosis, and the time course of labeled mitoses can be recorded.[215,216] Theoretically, such curves should permit measurement of the post-DNA synthesis gap (G2), mitotic time (t_m), DNA synthesis time (t_s), cell generation time (t_g), and pre-DNA synthesis gap (G1) (see Chapter 5 and Fig. 7.10). In actual practice, biologic variation rounds off the percentage of labeled mitosis curves, and rapid damping of the waves of cells passing through mitosis (Fig. 7.10) renders such measurements less precise than ideal. However, estimates of myeloid DNA synthesis time obtained with this method are approximately 11 to 13 hours in humans[215,216] and are in good agreement with estimates made in gastrointestinal mucosal cells. From the level of the damped plateau reached after a few hours, the ratio of t_s to t_g can be obtained (Fig. 7.10), and the generation time can then be calculated. If the generation time and compartment transit time are presumed to be the same or if the proportion of cells in a compartment that is actively proliferating is known, the neutrophil production rate can be calculated.

Neutrophil Production as Measured by Cell Flow in Other Compartments

Another method for approximating neutrophil production involves following the appearance of ^{3}H-TdR–labeled cells in the metamyelocyte compartment. Because metamyelocytes do not divide or take up ^{3}H-TdR, the appearance of labeled cells in this compartment should reflect the flow of cells into it from the myelocyte compartment; in the steady state, this influx of cells should also reflect the turnover of the metamyelocyte compartment and thus cell production. Approximately 3 hours pass after the injection of ^{3}H-TdR before the label appears in metamyelocytes both in dogs[177] and in humans[215]; this time interval is the minimum time for myelocytes taking up the label to pass through G2 and mitosis and become metamyelocytes. After this lag, the rate of labeled cell inflow into the metamyelocyte compartment is approximately 3% to 5%/hour in both species. In the dog, cell inflow into the metamyelocyte compartment measured in this fashion is less than 50% of that calculated from LI data,[177] suggesting the existence of a major component of ineffective granulocytopoiesis, a myelocyte sink, in the normal animal. However, similar calculations in humans do not confirm the findings of such studies.[170] The resolution of this enigma requires the simultaneous measurement of cell production by using several methods in the same animal at the same time.

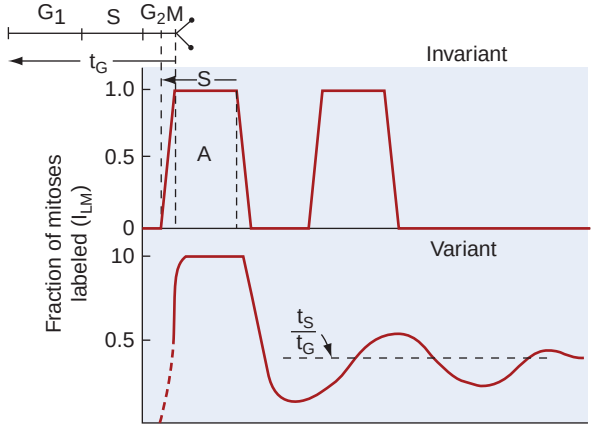

FIGURE 7.10. The percentage of labeled mitoses in the course of cell generation. At the top of the diagram is the theoretical configuration that would be seen if cells flowed through the proliferation cycle with no variation. The effects of moderate variation in time spent in the several cycle phases on the percent labeled mitosis curve are shown at the bottom. G_1 is the pre-DNA synthesis resting phase (*gap*), *S* is the DNA synthetic period, G_2 is the post-DNA synthesis gap, and *M* is mitosis. t_S is the time spent in *S*, and t_G is the duration of the entire generative cycle. (From Cronkite EP, the Brookhaven National Laboratory, and the National Cancer Institute. Kinetics of granulocytopoiesis. Natl Cancer Inst Monogr 30, Human Tumor Cell Kinetics 1969;51.)

Similarly, the marrow production of neutrophils has been estimated from the size of the postmitotic maturation storage compartment and the compartment turnover time.[200,204,217] The compartment size is calculated from the marrow neutrophil-to-erythroid (NE) ratio (determined in marrow sections) and the mean normal marrow normoblast pool size (calculated by multiplying the ratio of subjects' erythroid iron turnover value over the mean normal value for this determination by the mean normal erythroblast population).[204] The compartment transit time is estimated by injecting ^{3}H-TdR and noting the time required for labeled neutrophils to appear in the blood. By this method, marrow neutrophil production in humans has been calculated to be 0.85×10^9 cells/kg/day in the normal steady state.

Neutrophil production also can be approximated by measuring the flow of cells through the blood, the blood granulocyte turnover rate (GTR). DF^{32}P binds irreversibly with a number of esterase enzymes and has been shown to label neutrophils primarily.[218,219] By means of this agent, a subject's own cells can be labeled, and the total blood granulocyte pool (TBGP) and the rate of disappearance of labeled neutrophils from the blood can be determined.[175] Similar measurements can be made by transfusing ^{3}H-TdR–labeled cells from a suitable donor.[204] Because neutrophils leave the blood in a random manner (exponential disappearance curve), the GTR is calculated as follows from the TBGP and the $t_{1/2}$:

$$\text{GTR} = 0.693/t_{1/2}\ \text{TBGP}$$

in which 0.693 is the natural logarithm of 2 and $t_{1/2}$ is the blood neutrophil half-disappearance time.

All of these methods assume that the system is in a steady state during the entire course of the measurements. If neutrophil death in the marrow is not significant, the blood GTR equals total neutrophil production. If neutrophil death in the bone marrow is significant, the blood GTR measures effective neutrophil production, and the difference between this determination and total neutrophil production is ineffective granulocytopoiesis. Measurements of neutrophil production by compartment turnover methods have given values ranging from 62 to 400×10^7 neutrophils/kg/day in humans (Table 7.5) [204,220] and 150 to 560×10^7 neutrophils/kg/day in dogs.[204,217,221]

Of the methods for assessing neutrophil production just described, only the measurement of blood neutrophil turnover rate with DF^{32}P or ^{3}H-TdR can be performed easily enough to be of use in studying groups of patients in a clinical setting, and even this is possible in only a few research centers.

Size of Marrow Compartments and Their Morphologic Subdivisions

In all of the procedures described, with the exception of DF^{32}P and ^{3}H-TdR blood kinetic measurements, the number of marrow myeloid cells under study must be known in order to calculate neutrophil production. In the absence of such data, only calculations of relative cell production are possible.[170] Direct measurements of the volume and cellularity of the marrow (isolation of skeleton and cell counting or bone biopsy and radioactivity measurement) have been made in dogs,[204] rats,[222] mice,[223] and guinea pigs.[224,225]

Several methods for estimating marrow myeloid mass have been devised, but probably the best data are those derived by

TABLE 7.5

BLOOD NEUTROPHIL KINETIC PARAMETERS IN NORMAL HUMANS

	Diisopropylfluorophosphate (Autologous)[a]		Tritiated Thymidine (Isologous)[b]	
Parameter[a]	Mean	95% Limits	Mean	Range
Total blood granulocyte pool (cells × 10^7/kg)	61	27–128	40	30–48
Circulating blood granulocyte pool (cells × 10^7/kg)	31	13–49	22	15–29
Marginated granulocyte pool (cells × 10^7/kg)	29	8–115	17	12–26
Half-life (h)	6.3	4–10	7.6	5.4–9.6
Granulocyte turnover rate (cells × 10^7/kg/d)	160	62–400	87	69–100

[a]Based on data from 71 normal subjects whose own blood was labeled in vitro and reinfused; see reference 240.

using marrow NE ratios and measurement of marrow erythroblast mass by the iron dilution technique as originally suggested by Suit.[226] In early studies,[23,206] marrow erythroblast radioactivity and NE ratios were counted in marrow suspension smears. Corrections were made for incomplete iron localization in the erythron and for an estimated 30% cell destruction that occurred in preparing the marrow suspensions. In later studies,[227] the NE ratios and radioactivity measurements were made on marrow sections in the hope of avoiding the problem of possible cell destruction. Values for marrow erythroid mass were somewhat lower than those reported by Donohue et al.,[205,206] but they agreed with results obtained when no correction for cell destruction was made. By using marrow sections and the ^{59}Fe isotope dilution technique, investigators directly determined the marrow myeloid mass in the dog.[204] In humans, however, direct measurement of the marrow normoblast mass has not been feasible in normal subjects, so marrow normoblast mass was estimated from erythron iron turnover values.[204,228] The mean values obtained in 13 normal subjects are presented in Figure 7.9.

Transit Time Through the Nondividing Maturation Pool

After injection of a pulse label of ^{3}H-TdR or radiophosphate, a delay of several days occurs before labeled segmented neutrophils appear in the blood. This interval represents the minimum time from DNA synthesis in the last myelocyte generative cycle until the cell has matured into a segmented neutrophil (or band form) and is released into the blood. In patients in a normal steady state, this minimum transit time or emergence time was between 96 and 144 hours[229,230]; in patients with infection, it was as short as 48 hours. Emergence time in dogs is 2 to 3 days[231]; in the rat, it is 36 to 42 hours.[136]

The mean value for myelocyte-to-blood transit time after DNA labeling (defined as the time from ^{3}H-TdR or radiophosphate injection to the peak of the blood granulocyte radioactivity curve) was 6 to 9 days in hematologically normal convalescent patients and 7.2 days in eight normal subjects.[203] In contrast, studies in which DF^{32}P was injected intravenously into normal volunteers led to the conclusion that the mean promyelocyte-to-blood transit time was 11.4 days, with a myelocyte compartment transit time of 2.9 days[169,180]—in other words, an 8.5-day myelocyte-to-blood transit time. Results of studies involving the simultaneous use of ^{3}H-TdR and DF^{32}P in the same subjects suggest that the discrepancies reflect differences between normal ambulatory subjects and hematologically normal convalescent patients.[232] In dogs, the average myelocyte-to-blood transit time was 5 days, as measured with both ^{3}H-TdR and DF^{32}P.[232]

Neutrophil Release from Marrow into Blood

After ^{3}H-TdR injection and at the time of first seeing label in band and segmented neutrophils in the bone marrow, some labeled cells are also seen in the blood.[170] Authors have suggested that the release of band or segmented neutrophils from the marrow does not follow a strict pipeline or first-in, first-out sequence.[170,229] However, it is not clear whether these observations reflected variance around a mean transit time[180,231,233] or random release of mature neutrophils from the marrow.[229] Findings in dogs strongly favor the mean transit time concept rather than random release.[231] In fact, because the ratio of band to segmented cells is much higher in marrow than in blood, selective release of segmented cells must occur.

The mechanisms controlling the release of marrow cells into the blood are only partially understood. Endotoxin disturbs the relationship between marrow sinus endothelial cells and the adventitial (reticular) cells.[234–236] Findings of in vitro studies of factors influencing marrow granulocyte migration through membranes demonstrate that pore diameter, morphologic age of cells, and the presence of a chemical attractant may be important in marrow cell release.[237] Thus, immature granulocytes (myeloblasts and promyelocytes) could not penetrate membranes with pores smaller than 8 μm and were not responsive to chemoattractants. Mature granulocytes (band and segmented) could penetrate membranes with pores as small as 1 μm, and egress was accelerated by increasing pore size and by use of a chemoattractant. Myelocytes and metamyelocytes exhibited intermediate activity. Integrins and immunoglobulin (Ig) superfamily members appear to play an important role in the organization of the bone marrow microenvironment, and stem cell factor alters the avidity of $\alpha_4\beta_1$ and $\alpha_5\beta_1$ integrins on hematopoietic cell lines for their ligands.[238] A number of mediators of neutrophil release from the bone marrow have been identified, including tumor necrosis factor (TNF)-α, TNF-β, granulocyte colony-stimulating factor (G-CSF), granulocyte–macrophage colony-stimulating factor (GM-CSF), IL-8, and C5a.[185,239,240]

Kinetics in the Blood

Di-isopropylfluorophosphate Studies

With the development of the DF^{32}P labeling technique, in which neutrophils are labeled in vitro with DF^{32}P and returned to the donor, two pools of neutrophils in the blood have been demonstrated: a CGP and an MGP.[175,241,242] In normal humans, neutrophils in these two pools are in constant equilibrium, and the pools are of approximately equal size (Table 7.5). The CGP is calculated from the blood leukocyte count and the blood volume. The TBGP is measured by the dilution of DF^{32}P-labeled neutrophils after their reinjection.[241] MGP is the difference between the TBGP and the CGP.

Brief exercise or epinephrine injection increases the size of the CGP by approximately 50%, but the TBGP is unchanged; the neutrophilia produced reflects a demargination of cells that lasts only a few minutes.[241] The location of at least some of the marginated cells is thought to be along the walls of small blood vessels, primarily postcapillary venules, in many body tissues, where neutrophils roll along the vessel wall in loose contact with the endothelial cell surface.[243] The distribution of cells in the CGP and MGP can be altered by other means. For example, transient neutropenia was noted 90 minutes after endotoxin injection, but the TBGP was not significantly increased; thus, essentially a shift from CGP to MGP occurred. At the end of 5 hours, the TBGP increased significantly as a result of an outpouring of cells from the bone marrow, and the CGP and MGP were of approximately equal size.[242] The administration of steroids also produced an increase in the size of the TBGP, in part for the same reason but also because of decreased outflow into the tissues.[244] A rapid transient increase in the marginating pool was observed during hemodialysis when cuprophane membranes were used.[245,246] Activation of the complement system by contact with the dialyzer membrane was found to produce inflammatory mediators (C5a being a major contributor) that stimulated an increase in neutrophil margination manifest both by an increase in rolling along small vessel endothelium and by the formation of homotypic aggregates of neutrophils with sludging in small vessels.[247,248,249,250,251] This neutrophil margination was transient, being maximal by approximately 15 minutes and resolving by 1 hour of dialysis.

After the return of DF^{32}P-labeled neutrophils to their donor, the disappearance of labeled cells from the blood follows a single exponential curve with a half-disappearance time (t_2) of approximately 7 hours in most normal subjects.[169,175,203,252–255] This finding implies that neutrophils are destroyed or leave the blood randomly rather than according to their age (senescence), as is the case for erythrocytes and platelets.[175] Support for this theory is found in the fact that ^{3}H-TdR–labeled neutrophils appear in the blood and in saliva almost simultaneously.[139]

Studies involving leukapheresis[256] and other experiments[257] reveal that neutrophils that have crossed the endothelial barrier between blood and tissues probably do not re-enter the circulation, at least not in significant numbers. The number of neutrophils that pass through the blood each day has been estimated at 62 to 400 $\times$ 10^7 cells/kg/day (Table 7.5)—that is, the GTR. In 1964, it was proposed that neutrophils became senescent and developed pyknotic nuclear lobes over time, this process truncating the exponential curve of disappearance of DF^{32}P-labeled neutrophils.[139] Although this concept seemed plausible, no truncation of DF^{32}P curves has been noted. Similar blood kinetic results have been obtained with the use of ^{3}H-TdR and autoradiographic techniques.[258] More recent studies describe the occurrence of apoptosis in neutrophils, and this may be an important mechanism of senescence in some circumstances.

^{51}Cr Studies

Leukocytes can also be labeled in vitro with radiochromate ($^{51}CrO_4$) and then returned to the body.[259–261] Unlike DF^{32}P, which labels primarily granulocytes,[217,219,258] leukocyte types other than neutrophils are heavily labeled by the ^{51}Cr technique.[230,259,261–264] Under some circumstances (such as chronic lymphocytic leukemia), this capacity is advantageous because the distribution and turnover of leukocytes other than neutrophils can be followed.[259,262,264,265] In addition, ^{51}Cr is a γ-emitting isotope, so external counting techniques may detect sites of sequestration or destruction.

Results of studies of the infusion of autologous, radiochromate-labeled leukocytes into hematologically normal subjects are more variable than those using the DF^{32}P method. The proportion of cells recovered in the blood is sometimes less than that associated with DF^{32}P-labeled neutrophils,[261] and complex curves are often noted.[265] Furthermore, there is no general agreement on $t_{1/2}$ values; most investigators report values similar to those obtained with DF^{32}P,[230,259,261,262,266] but values two to three times longer have been described.[267,268] Several factors may explain these differences, but a major one is probably ^{51}Cr labels of multiple cell populations. No significant organ sequestration of labeled leukocytes has been detected in normal subjects.[261]

^{111}In Studies

After the evaluation of a variety of other radioactive agents for labeling leukocytes in vitro,[269] ^{111}In chelated with 8-hydroxyquinoline (oxine) was thought to be promising for evaluating the in vivo localization of abscesses. The ^{111}In-oxine complex labels blood cells effectively (95% uptake in 15 minutes) and exhibits minimal elution (<1% released in 2 hours).[270] This label is nonspecific, however, in that it binds to all cell types; thus, cell separation and purification are necessary before labeling occurs.[271] Nevertheless, the labeling of autologous neutrophils (or leukocyte suspensions containing mostly neutrophils) and their reinjection was sometimes useful in localizing abscesses in humans, although much of the radioactivity initially localizes in the lungs and subsequently appears in the spleen and liver.[270]

Apoptosis

Neutrophils undergo apoptosis in tissue culture (approximately 50% of cells in 24 hours); this process is accompanied by a fall in intracellular pH.[272–274] Apoptosis is manifest by characteristic morphologic changes with nuclear condensation and the formation of pyknotic nuclei. Importantly, the cell remains intact and does not release its potentially toxic contents before it is phagocytosed by macrophages and removed. The addition of G-CSF, GM-CSF, or IL-1 delays but does not prevent this process.[272,275] Macrophages phagocytose senescent (apoptotic) neutrophils (as observed more than a century ago), and this is probably one fate of the short-lived blood neutrophil.[273,274,276–278,279] Interestingly, glucocorticoids inhibit neutrophil apoptosis,[280] but they induce it in susceptible lymphocytes. Fas (CD95) is expressed on neutrophils and is capable of inducing apoptosis as it does in other susceptible cells.[280,281] Neutrophil apoptosis is reversibly inhibited by hypoxia, possibly playing a role in neutrophil survival at sites of inflammation.[282] Neutrophil apoptosis is also delayed in pregnancy, and both estradiol and progesterone can delay neutrophil apoptosis in men and women.[283,284] Neutrophils may also undergo cell death by another mechanism that is caspase-independent, is not associated with DNA laddering, and appears to depend on mitochondria-derived reactive oxygen metabolites.[285] As discussed later, in general diapedesis seems to induce an antiapoptotic state, while phagocytosis seems to promote apoptosis, at least partly by upregulating death receptors, thus providing the conditions for resolution of inflammation and avoidance of tissue damage.[150]

Migration into Tissues and Sites of Destruction

At a local site of tissue damage or infection, adherence of neutrophils to the endothelial cells of the vessel wall and their

subsequent migration into the tissues can be seen within minutes. After initial adherence, neutrophils project microscopically visible pseudopods between or through the endothelial cells and force a passage across the endothelial layer.[286,287] This directed movement, chemotaxis, is induced by the binding of a variety of chemoattractant molecules, such as *n*-formyl peptides (e.g., FMLP), a cleavage product of the fifth component of complement (C5a), leukotriene B_4, and platelet-activating factor, to specific membrane receptors. Further migration is then delayed by the basement membrane and periendothelial cells, and the neutrophils may move parallel to, but beneath, the endothelium until a passage into the surrounding connective tissue is found. Once neutrophils leave the blood, they do not return in significant numbers.[257,288]

The sites into which neutrophils normally disappear are poorly understood. Labeled blood neutrophils are found in saliva,[136] but loss into saliva may reflect subclinical infections, because few if any cells are found in the salivary ducts[289]; the rate at which granulocytes enter the oral cavity has been correlated with the degree of gingivitis.[290] Some cells do penetrate the oral mucosa in healthy subjects, presumably as a result of diapedesis.[289] Loss of leukocytes in the urine also has been demonstrated in normal subjects.[291] Leukocyte loss increases significantly in association with pyelonephritis.[292] In addition, arteriovenous catheterization studies in dogs[293] and in humans[294] provide evidence that suggests leukocytes also are removed in the lungs, liver, and spleen. Significant numbers may be lost into the gastrointestinal tract. No quantitative data concerning the rate of loss through these various organs are available. Interestingly, bone marrow and blood leukocyte counts were essentially the same in germ-free and normal mice, suggesting that loss via subclinical infections at the various body surfaces is not a major factor in neutrophil turnover.[295,296]

Neutrophil Kinetics in the Fetus and Newborn

The fetus exists in a sterile environment and, unlike the adult, does not require antibacterial defenses. However, if the systems ensuring adequate neutrophil production, storage, delivery to tissues, phagocytosis, and bacterial killing are not intact at birth, extrauterine existence is seriously compromised. Maturation of the neutrophil system is not complete in the midgestation fetus, and even the neonate delivered at term has a neutrophil system that in several respects is quantitatively and qualitatively immature. Therefore, one might anticipate that newborns, particularly those delivered prematurely, would be at significant risk for serious bacterial infection, and many studies reveal a strong correlation between prematurity and serious bacterial infection.[297–301] Of all the risk factors for bacterial infection analyzed by the national collaborative study on neonatal infection, premature birth showed the strongest correlation.[302] In addition, babies delivered at term experience a higher incidence of bacterial infection than do older children or adults[303,304] and, when infected, often display poor resolution of infection despite antibiotic therapy.

Newborn infants, particularly if premature, display many other deficiencies in antibacterial defense, such as low levels of IgG antibody, complement components, fibronectin, and lymphokine production,[305] but only maturational differences in neutrophil kinetics are discussed here. Realizing that the neutrophil system of a fetus is underdeveloped and in a state of maturation, a difference in neutrophil pool sizes and kinetics in this group from those in adults can be expected. In addition, rapid somatic growth in the fetus and newborn places added demands, unique to the neonate, on neutrophil production[306]; cells are needed not only for ongoing antibacterial defense, but also for a rapidly increasing body mass.

The investigation of neutrophil kinetics during fetal and neonatal life in humans has been hampered by lack of applicability of the techniques used for such studies in adults. For instance, $DF^{32}P$ and ^{3}H-TdR blood kinetic measurements have not been used in babies because of the radiation exposure and the large volumes of blood required. Nevertheless, the results of clinical studies, coupled with extensive investigation in developing animals, illustrate several developmental differences.

Granulocyte–Macrophage Progenitor Cells

CFU-GM have been isolated from the livers of aborted 5- to 6-week human fetuses.[307] Although early fetal CFU-GM produced colonies of mature neutrophils in vitro, no mature neutrophils could be located in the liver, marrow, or blood of the 5- to 6-week fetuses from which this CFU-GM was obtained.[307] In separate studies, mature neutrophils were not detected in the human fetus until approximately 15 to 16 weeks' gestation,[308–311] at least 10 weeks after the first appearance of CFU-GM.

The concentration of CFU-GM in blood is higher in the fetus and newborn than in adults: 20 to 300 CFU-GM/ml of venous blood in adults and approximately 2,000 CFU-GM/ml in term neonates.[312–319] Even higher venous blood concentrations are found in prematurely delivered infants,[313,318] with the highest values noted in the most premature subjects.[313] The total body pool of CFU-GM has not been measured in human neonates; in rats, the number of CFU-GM/g body weight is small in the fetus ($0.5 \pm 0.1 \times 10^3$ CFU-GM/g) and increases to adult levels ($10.5 \pm 0.2 \times 10^3$/g) at 4 weeks of age.[320]

The proliferative rate of CFU-GM during human gestation, assessed by thymidine suicide, is rapid in the second trimester.[313] Whereas CFU-GM in venous blood of adults displays a thymidine suicide rate ranging from 0 to 7%,[313,321–323] rates of 45% have been observed in term neonates, and rates of 75% were noted in prematurely born neonates.[313] Similarly, in fetal and neonatal rats[225] and mice,[322] the CFU-GM proliferative rate is high and appears to be near maximal at birth, even in the noninfected state.[324,325] Unlike in adult animals, no further increase in CFU-GM number [326] or CFU-GM proliferative rate[324] has been detected during either sublethal or lethal bacterial infection, suggesting that the system operates at capacity. It has been suggested that the inability to accelerate neutrophil production above baseline might handicap neonates by limiting their neutrophil supply during a bacterial infection.

Neutrophil Storage Pool

In the fetus, as in the adult, mature neutrophils are stored within the skeletal marrow but also are found in the liver and spleen.[326] Techniques that measure the size of the neutrophil storage pool, such as radioisotopic iron labeling, with subsequent liver, spleen, and bone marrow biopsy, have not been applied to normal human neonates. In fetal and neonatal animals, however, the liver and spleen, as well as the long bones, can be removed, and the neutrophils within them can be quantified. Such studies in rats show that the neutrophil storage pool is considerably smaller in prematurely delivered animals (1.0 to 1.3×10^6 cells/g body weight) than in term (1.3 to 2.5×10^6 cells/g) and adult animals (4.5 to 7.5×10^6/g).[327]

During experimental bacterial sepsis in neonatal dogs and rats, the size of the neutrophil storage pool has been serially quantified. Experiments performed with a variety of organisms[326,328–334] demonstrate depletion of the storage pool and neutropenia before death. Similarly, in human neonates with lethal bacterial sepsis, neutropenia and depletion of the neutrophil storage pool, as assessed by bone marrow aspiration, are nearly universal findings.[310,332,335,336]

Release from Storage Pool into Blood

Within 1 hour of inoculating adult animals with as few as 10^4 type III group B streptococci/g body weight, an accelerated rate of egress of neutrophils from the storage pool into the blood can

be detected.[335] In contrast, when newborn animals were given the same or a larger inoculum of 10^6 organisms/g, a 4-hour delay occurred before this acceleration in neutrophil storage pool release was observed.[335] This delay between bacterial inoculation and accelerated release of marrow neutrophils may be a significant physiologic disadvantage, which permits prolific initial bacterial multiplication. In other studies, this delay in release of marrow neutrophils was completely corrected by prior administration of type-specific antibody directed toward the organism with which the animal was inoculated.[329,335]

Alterations in Migration into Tissues and Sites of Destruction in Neonates

In many studies, investigators have demonstrated defective neutrophil chemotaxis in neonates. In early investigations, Eitzman and Smith, using the Rebuck skin window technique, demonstrated that a preponderance of eosinophils, not neutrophils, was attracted to the abraded dermis of neonates.[337] Using the same technique, Bullock et al. demonstrated that neutrophils in neonates remained at the site of abrasion longer than they did in adults.[338]

Using the Boyden chamber method, neutrophils from newborns were found to be less responsive than adult neutrophils in chemotaxis.[339] In addition, factors generated from neonatal serum attracted neutrophils less well than did factors from adult serum. Diminished chemotaxis of cord blood neutrophils was also demonstrated, with reduction to approximately 80% of levels observed with adult neutrophils.[340–342] Using a different in vitro technique for quantification of neutrophil movement (agarose gel), newborn neutrophil chemotaxis was found to be reduced to approximately 20% to 27% of that seen with adult neutrophils.[343] In prematurely delivered neonates, neutrophil chemotaxis was even more defective,[344] and the defect persists for a considerable time after birth.

A further reduction in chemotaxis of neutrophils from ill neonates compared to healthy neonates[345] and decreased chemotaxis in preterm neonates with bacterial sepsis followed by a return to normal neonatal values (approx. 20% of adult values) with resolution of the infection[346] have been reported.

Neutrophil migration has also been investigated in vivo in neonatal and adult animals. One technique involved surgical implantation of a sterile polyvinyl sponge disc, standardized for body weight, into rats. At various intervals, the sponges were removed, and neutrophils that had migrated into them were chemically quantified. Concurrent with sponge removal, the long bones (and the liver and spleen in neonates) were also removed, and the size of the total body neutrophil storage pool was determined.[331] By comparison with control animals, only approximately 9% of the neutrophils released from the storage pool in neonates could be accounted for in the sponge. In contrast, approximately 60% of the neutrophils released from the marrow in adults migrated to the sponge, indicating more efficient neutrophil migration in the adult. Another study found that the accumulation of neutrophils in the peritoneal cavity of rats after intraperitoneal inoculation with various chemical attractants was impaired in neonates.[347]

The mechanism responsible for deficient neutrophil chemotaxis in neonates is only partly known. By measuring the pressure needed to aspirate neutrophils into a glass pipet, Miller determined that the neonatal neutrophil was more rigid and less deformable than the adult neutrophil, a characteristic that may be detrimental to movement of neutrophils through tissues.[348] In addition, neutrophils from human neonates irreversibly aggregated after activation by C5a, whereas after exposure to the same stimulus, adult neutrophils aggregated and then deaggregated.[247,248,249,250,351] Irreversible aggregation of neonatal neutrophils has also been seen in response to activation by FMLP.[350] If irreversible neutrophil aggregation occurs in vivo in neonates, then independent neutrophil mobility would probably be impaired. A deficiency in the redistribution of cell-surface adhesion sites, factors related to impaired migration, and impairment of neutrophil adhesiveness has also been reported[351,352] and would impair neutrophil function in vivo. Response to complement-derived peptides was also impaired, as shown in the response of cord blood neutrophils to endotoxin-activated serum.[353] Concanavalin A capping,[354] phytohemagglutinin-induced aggregation,[355] and C5a-induced chemotaxis,[330] as well as FMLP-induced membrane potential change,[356] are reduced in the neonatal neutrophil. No difference in calcium uptake in FMLP-stimulated neutrophils was noted between human neonates and adults, but reduction in calcium uptake by resting neonatal neutrophils was significant.[357] Diminished orientation of neonatal neutrophils after exposure to a chemotactic gradient was noted, and a significant decrease both in the number of microtubules/cell and in the assembly of microtubules was observed.[358]

PHYSIOLOGIC VARIATION IN LEUKOCYTES

By the age of 4 to 8 years, the blood differential cell count approaches that seen in the adult. Normal values are presented in Table 7.4. Metamyelocytes or myelocytes are not often seen on routine examination of the blood smear, but a few such cells can be found in normal blood after a careful search or, more readily, by examination of buffy coat smears (3.6/3,000 granulocytes) [359]; atypical mononuclear forms and megakaryocyte fragments containing nuclei are also seen in such smears. Whether a significant difference exists in leukocyte concentration between the sexes or with advancing years has been debated.[360–363] Racial variations were reported in black Africans, with lower neutrophil and monocyte counts and higher eosinophil counts; however, these differences were less evident in Africans eating a Western diet[364] or in black Americans.[127,163]

Although leukocyte concentration is maintained within definite limits in normal humans, fluctuations occur during a single day and from day to day. The suggestion that a characteristic hourly rhythm occurs has not been confirmed,[365,366] nor has the occurrence of a digestive leukocytosis been established.[367] Light influences the diurnal variation of neutrophils.[202,368] Under conditions of complete physical and mental relaxation, a basal level of 5.0 to 7.0 $\times$ 10^9 cells/L is usual.[369] Ordinary activity may be associated with a moderate increase, and a somewhat higher level is common in the afternoon. Under all these conditions, however, the leukocyte count tends to remain within the normal range (Table 7.4).

Conclusive demonstration of the effects of climate or season on the leukocyte count is lacking. Some authors claim that meteorologically conditioned fluctuations occur.[370] Heat and intense solar radiation are said to cause leukocytosis.[371] Prolonged residence in Antarctica has been reported to cause leukopenia.[372] Artificially induced heat, sunlight, and ultraviolet light have been reported to cause lymphocytosis.[373] Acute anoxia, both anoxic and anemic, causes neutrophilic leukocytosis[374] that does not develop in adrenodemedullated rats. In the first few days after a subject has arrived at a high altitude, some leukocytosis, accompanied by lymphopenia and eosinopenia, has been observed, followed quickly by slight lymphocytosis and eosinophilia.[375]

Marked leukocytosis occurs regularly with strenuous exercise. Counts as high as 22.0 $\times$ 10^9/L have been recorded for a runner after an 11-second 100-yard dash, and 35.0 $\times$ 10^9/L has been recorded after completing a quarter-mile run in less than 1 minute.[369] The increment of cells usually consists of segmented neutrophils, but lymphocytosis may be prominent as well. Such leukocytosis recedes to normal in less than 1 hour and, in the neutrophil series, is related to a shift of cells from marginal sites

(MGP) to the circulation (CGP) (shift leukocytosis).[240,241] This leukocytosis occurs in the absence of the spleen, suggesting that the spleen is not a major site of cell margination. Leukocyte counts >20.0 × 10^9/L, mainly neutrophils, are regularly recorded for runners who complete a 26-mile marathon in 2.5 to 3.0 hours; whether a shift to the left, suggesting mobilization of marrow neutrophils, occurs in this circumstance is debatable.[369] Postmarathon leukocytosis subsides slowly over a number of hours and probably reflects a redistribution of granulocytes in the blood, combined with mobilization of cells from the marrow with an increase in TBGP size. The magnitude of the leukocytosis associated with exercise appears to depend primarily on the intensity of the activity rather than on its duration.[376]

Convulsive seizures, from whatever cause, are associated with an increase in leukocyte count similar to that noted after violent exercise. Electrically induced convulsions are followed by a reduction in eosinophil and lymphocyte number and an increase in neutrophil number, findings consistent with the effects of adrenal hormone secretion.[377] Epinephrine injection produces leukocytosis, the nature and duration of which appear to vary with the mode of administration. Intramuscular injection causes leukocytosis in two phases.[378,379] In the first phase, maximal at 17 minutes, the number of neutrophils, lymphocytes, and eosinophils increases and then returns toward normal over several hours. This pattern almost certainly represents a shift leukocytosis. In the second phase, the number of neutrophils rises again at approximately 4 hours, although the number of lymphocytes and eosinophils remains at or below preinjection levels[379]; this phase may reflect an adrenal steroid effect and consists of an absolute neutrophilia. After intravenous injection, leukocytosis peaking at 5 to 10 minutes and of total duration of less than 20 minutes occurs and has been shown to be purely shift neutrophilia.[241,242] The leukocytosis that follows subcutaneous injection is more variable.

During attacks of paroxysmal tachycardia, leukocytosis with cell counts of 13.0 to 22.0 × 10^9 cells/L has been reported.[380] Pain, nausea and vomiting, and anxiety may cause leukocytosis in the absence of infection.[381] The paucity of band forms and metamyelocytes indicates that the neutrophilia results from the redistribution of the cells between the marginal and circulating pools.

Ether anesthesia produces leukocytosis, probably because of emotional and reflex reactions, as well as struggling during the stage of excitement. Narcosis with barbital compounds usually reduces the leukocyte count.

During the ovulatory period, eosinopenia and a slight rise in the number of leukocytes, as well as increased 17-hydroxycorticosteroid levels, have been reported.[382,383] Slight leukocytosis occurs during pregnancy, and neutrophilia increases as term approaches.[161,382] The onset of labor is accompanied by neutrophilic leukocytosis, which sometimes is pronounced (34.0 × 10^9/L). This state continues for 1 day after delivery, receding to normal only after 4 or 5 days. These changes are accompanied by a reduction in the number of circulating eosinophils.[382]

Many of the physiologic variations in leukocytes that have been described can be explained as manifestations of stimulation of the adrenal cortex. The administration of cortisone or hydrocortisone results in increased blood levels of 17-hydroxycorticosteroids that peak at 1 hour[384] and are associated with neutrophilia.[385] Eosinopenia and lymphopenia follow, become maximal at 4 to 8 hours, and are proportional to the quantity of hormone administered. Neutrophilia was less constant than the depression in eosinophil and lymphocyte numbers but is probably caused by a steroid hormone–mediated decreased efflux of neutrophils from the blood and increased cell release from the bone marrow.[242,244] Just as exercise can raise the circulating neutrophil count, intense exercise has also been reported to induce neutrophil activation as determined by studies of cell-surface antigen expression.[386] In contrast, ultraviolet B radiation, at doses similar to those naturally received, inhibits neutrophil phagocytosis and adhesion, although the practical significance of these observations is unknown.[387]

CONTROL MECHANISMS REGULATING NEUTROPHIL PRODUCTION

It is evident that a true steady state of neutrophil kinetics exists only for brief periods. Shifts of cells between marginal and circulating sites may occur without changes in blood neutrophil turnover,[242] but any change in TBGP size must result from changes in cell inflow or egress. Studies involving leukapheresis have shown that a normal animal replenishes a depleted TBGP by mobilizing cells from the marrow granulocyte reserves.[24] This increase in neutrophil concentration and TBGP size, like that seen with most bacterial infections or after endotoxin or steroid administration, must be triggered by some signal, and some means of stimulating cell production must be available to replenish depleted marrow reserves, whatever the etiology.

The nature of these control mechanisms is complex, but several control points exist: recruitment of pluripotent stem cells and their induction into committed stem cells, stimulation (and perhaps inhibition) of stem cell and myeloid proliferative cell growth, and selective release of cells from the marrow.

Blood cell development is discussed in Chapter 5 and is only briefly discussed here. Pluripotent stem cells are mostly in the G_0 state and must be induced into actively proliferating committed stem cells. Hematopoietic cell growth and development are usually restricted to certain tissues (e.g., bone marrow in adult humans and bone marrow and spleen in mice). Because cell differentiation is influenced by organ microenvironment (e.g., erythropoiesis is favored in mouse spleen, but granulocytopoiesis is favored in the bone marrow), the concept of local control of pluripotent stem cell induction was developed (the hematopoietic microenvironment).[388] The importance of the hematopoietic microenvironment is exemplified by the anemia of Steel mice, which results from a defective hematopoietic microenvironment.[388] The defect in Steel mice involves the granulocyte system as well as erythropoiesis[389] and results from a diminished ability of organ stroma in the bone marrow and spleen to induce committed stem cells from pluripotent stem cells.[390] The demonstration that the Steel (Sl) gene product, deficient in Steel mice, is a growth factor (stem cell factor or stem cell colony-stimulating factor) that binds to a receptor coded by the c-kit proto-oncogene (or white-spotting locus, W) has provided a molecular basis for understanding the hematopoietic abnormalities in mice with genetic defects in the Steel or W genes.[238,391]

As judged from suspension cultures, at least three cell types (giant fat cells, epithelial cells, and phagocytic mononuclear cells) provide the microenvironment needed for multipotent stem cell proliferation.[392] Presumably, these stromal cells produce sufficient concentrations of hematopoietic cell growth factors locally to promote multipotent stem cell proliferation and renewal when required.[393]

Growth Factors

A large number of growth factors or colony-stimulating factors have been identified that regulate neutrophil production in the bone marrow, as described in Chapter 5. Two of these, G-CSF and GM-CSF, are in clinical use. Exogenous administration of G-CSF expands the granulocyte mitotic pool and also decreases the bone marrow transit time of the postmitotic cells without changing the blood neutrophil half-life.[394] These factors not only speed the recovery of neutrophil counts after chemotherapy and may decrease associated infectious complications,[395–399] but also have effects on mature neutrophils. For example, G-CSF transiently increases CD11b expression[396,400,401] and the affinity of CD62L (L-selectin) for its ligand and then causes CD62L surface expression to decrease.[402] G-CSF also primes neutrophils for subsequent superoxide production in response to FMLP.[403–406] Intravenous administration of G-CSF can result in an immediate transient neutropenia[407,408] similar to the transient increase in the MGP

seen with hemodialysis. Evidence of neutrophil degranulation in vivo after administration of G-CSF has also been observed.[409] A number of other cytokines among this class can also activate or prime neutrophils, including TNF-α, IL-6, IL-1, and IL-8.[410–413]

In addition to locally produced stimulators of colony-forming unit stem cell proliferation,[414] inhibitors of proliferation have also been described.[415,416] Lactoferrin (present in the secondary or specific neutrophil granule) binds to specific receptors on some monocyte-macrophages and suppresses release of GM-CSF (and other cytokines), thus inhibiting colony formation. Transferrin also exhibits colony-suppression activity, possibly through inhibition of GM-CSF production by T lymphocytes.[417] Soluble forms of receptors for cytokines may also regulate the response of bone marrow progenitors to growth factors.[418] Neural mechanisms controlling hematopoietic cell proliferation and release have also been suggested.[419]

Another control point in the system is the selective release of granulocytes from the marrow. In studies of perfused rat hind limbs, the release of neutrophils from the marrow into the blood[420] increased with an increase in perfusion flow rate or with a low leukocyte content of the perfusate.[421] Serum or plasma from animals or humans made neutropenic by endotoxin, vinblastine, or nitrogen mustard also induced neutrophilia.[422–425] The activity was present during the period of neutropenia and rising neutrophil concentration—but not before or after this period. This neutrophilia-inducing activity was qualitatively dissimilar from that noted after endotoxin, epinephrine, or cortisone administration and acted by causing release of marrow cells. The results of these studies suggest that an endogenously produced humoral factor causes neutrophil release from the marrow.[422] Several factors that stimulate neutrophil release from the bone marrow have been identified, including G-CSF, GM-CSF, C5a, TNF-α, TNF-β, IL-8, and, possibly, a cleavage product of the third component of complement.[185,239,240] Studies in rabbits have found that IL-8 induces neutrophil release from the bone marrow without altering the transit time through the mitotic and postmitotic marrow pools.[240]

Thus, evidence exists that several factors, including cell nuclear and cytoplasmic deformability, cell motility, affinity of cell adhesion molecules for ligands, blood flow, and others are important in the control of marrow cell release.[238,426–428]

NEUTROPHIL FUNCTION

The major role of neutrophils is to protect the host against infectious agents. To accomplish this task, the neutrophil must first sense infection, migrate to the site of the infecting organism, and then destroy the infectious agents. Although neutrophils can sense a stimulus in suspension, they can migrate only when in contact with a surface. Thus, although in some cases neutrophils in blood may respond to a stimulus by adhering to other blood cells or foreign bodies, such as bacteria or biomaterials, the usual first step of the neutrophil after sensing an inflammatory stimulus is to adhere more strongly to the blood vessel wall. Usually, this occurs in a postcapillary venule. After adhesion to the endothelial surface, the neutrophil follows a gradient of chemotactic factors to the site of infection and interacts with the organisms. Finally, when the neutrophil reaches the infecting organism, it must destroy it. This destruction is generally accomplished by phagocytosis of the agent followed by release of granules into the phagocytic vesicle, followed by killing of the organism. The mechanisms by which these phenomena occur are very complex and not completely understood.

History

An important role of pus in infections has been long recognized. White, creamy pus, due to the presence of many neutrophils, suggested a better outcome than thin watery pus, and was known as "good and laudible pus" (pus bonum et laudable).[429,430] Antibacterial properties of blood were described by the British surgeon John Hunter in ~1761 during the Seven Years' War. He observed that the cellular (buffy coat) component of blood could retard the "spoilage" of blood[431]; we now would recognize these effects as reflecting the antibacterial properties of leukocytes. In these classic studies, Hunter observed that when blood was allowed to stand, a "buff colored" layer was visible on top of the red cells. He noted that blood from patients with infected wounds had a thicker "buff colored inflammatory crust" than observed in blood from healthy subjects, which we now understand reflects the neutrophilia associated with infection. With time, he noted that blood would "spoil," as determined by the development of an odor typical of spoiled food. Hunter found that the addition of the "buff colored inflammatory crust" to a blood sample would delay the time to "spoilage," now understood to reflect the antibacterial abilities of neutrophils.

The response to infection by neutrophils in the microvasculature was elegantly described in *An American Text-Book of Surgery* in 1892.[279] This description remains instructive and is summarized here. At one time, the inflammatory cells at sites of infection were thought to be caused by proliferation of connective tissue cells. After the observations of von Recklinghausen that many of these cells were capable of locomotion (and called "amoeboid cells from their resemblance to the amoeba"), and the work of Addison, who suggested that leukocytes in blood could extravasate to tissues,[429,432] Cohnheim identified the cells in the inflamed tissue as leukocytes.[279] Microscopic examination of a frog's mesentery or tongue reveals "an arteriole with its rapid pulsating current of blood, and nearby a small vein in which the blood flows with a more steady movement. The red blood corpuscles occupy the axis of the blood vessel, and the few white corpuscles which are seen float in the more sluggish stream of plasma which occupies the borders of the lumen and appears as a transparent layer" (Fig. 7.11). Induction of inflammation by the application of a caustic agent leads to hyperemia. "The rapidity of the flow of blood is greatly increased and a greater amount of blood is observed in the part. The lumen of the artery is greater

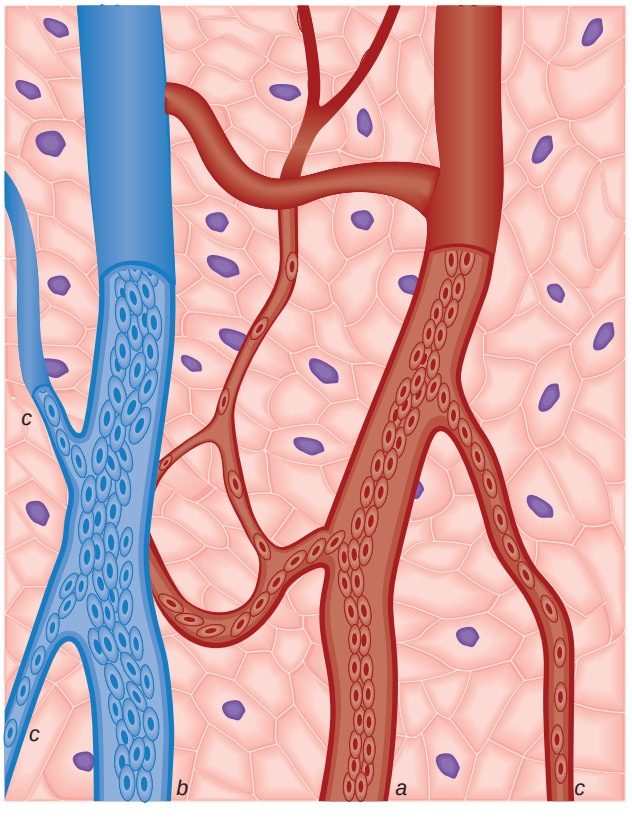

FIGURE 7.11. Diagram of normal vessels and bloodstream: *a*, artery; *b*, vein; *c*, capillary. (Adapted from Keen WW, White JW, eds. An American textbook of surgery. Philadelphia, PA: WB Saunders, 1892:14.)

than before, and the column of red corpuscles is much broader, and fills a comparatively greater portion of the lumen of the vessel. The capillaries are now quite distinctly seen, and are crowded with blood corpuscles" (Fig. 7.12). This is followed by

> a slowing of the current, which soon becomes much more sluggish than in the normal state. This is first noticed in the capillaries, and soon after in the veins. The pulsation, however, continues in the arteries. As a result of this diminution of speed the column of blood corpuscles becomes broader and almost completely fills the interior of the vessels. In the veins a great accumulation of white corpuscles takes place on the interior of the walls. . . . Finally, they are so greatly increased in numbers that the entire wall of the vessel appears to be lined with leukocytes. The white corpuscles also accumulate in the capillaries, but not to the same extent (Fig. 7.13).

The margination of the neutrophils is shown schematically in Figure 7.14 (platelets or "blood plaques" are also shown).

> Beginning concurrently with the slowing of the blood stream, is the emigration of the leukocytes from the interior of the veins. Many leukocytes, by a change of shape, send out little prolongations of protoplasm into the substance of the wall, and slight protuberances are soon seen projecting from its outer surface. These enlarge, and we now see the corpuscles presenting an hour-glass appearance. The portions within the vessel soon follow those without, and the leukocytes escape from all contact with the vessel. Many corpuscles appear to follow one another through the same point in the wall (Fig. 7.15).

Migration takes place to a limited extent also from the capillary vessels, but no such process is observed in the walls of the arteries. These same actions of neutrophils, as well as the formation of neutrophil-neutrophil aggregates with infections in rabbit ear veins, were videotaped by W.B. Wood in the 1960s. Using fluorescein-labeled neutrophils, Hammerschmidt et al. later demonstrated that injection of C5a reproduced the increase in neutrophil margination and aggregation in rat mesentery.[433]

Early views of neutrophil function at the site of inflammation included a role in the repair process. Later, their ability to phagocytose was recognized. Metchnikoff advanced the theory known as phagocytosis,

> Here according to this theory, the cells of the inflamed part, by virtue of their ability to consume foreign substances, attack and destroy the invading bacteria (Fig. 7.16). These cells are called phagocytes (from the Greek "to eat" and "cell"). If they are able to destroy the bacteria, the system is protected from the invading organisms. The leukocytes are called micro-phagocytes (or microphages), and the larger cells developed from the fixed connective tissue cells are called the macro-phagocytes (or macrophages).[279]

Chemotactic Factor Receptors

The initial step of the neutrophil response to infection is the detection of an appropriate signal. The interaction of bacteria with blood components, especially antibodies and the complement system, results in the formation of various chemotactic factors. In some instances, the bacteria directly release factors that are chemotactic for neutrophils. The interaction of bacteria or their products with other host cells may also result in the formation of chemotactic factors. Neutrophils express specific receptors on their cell surface for a variety of chemotactic factors. These receptors include those for *n*-formylated peptides such as *n*-formyl-met-leu-phe (FMLP), C5a, leukotriene B_4, and platelet-activating factor. The initial activation of the neutrophil occurs when soluble chemotactic factors bind their receptors on the neutrophil surface. As with the interaction of antibodies and haptens, the association kinetics for these receptor–ligand interactions are very rapid. Typically, sufficient receptor–ligand interaction to initiate neutrophil activation occurs within seconds.

Signaling

Many chemotactic factor receptors appear to be coupled to guanine nucleotide-binding proteins (G proteins).[434] The role of G proteins in neutrophil signal transduction is supported by a variety of studies, including classic studies using pertussis toxin. Pertussis toxin adenosine diphosphate ribosylates certain G proteins and inhibits neutrophil responses to a number of stimuli, including FMLP. In contrast, some neutrophil responses, such as phorbol ester–induced secretion, are not inhibited by pertussis toxin. Although the details of signal transduction in neutrophils are not fully elucidated, it appears that the G proteins associated with chemotactic factor receptors are important in receptor activation of phospholipase C, which then hydrolyzes phosphatidylinositol bisphosphate (PIP_2), resulting in the generation of two second messengers, IP_3 and 1,2-diacylglycerol (DAG). Experiments suggest that IP_3 binds to specific receptors on intracellular membranes, resulting in the release of calcium from intracellular stores, which is rapidly augmented by an influx of extracellular calcium. Thus, shortly after receptor–ligand binding, the intracellular calcium rapidly rises from a resting level of approximately 0.1 mmol/L to approximately 1 mmol/L.[435–437] This rise in free intracellular calcium is transient and returns to baseline in approximately 1 to 3 minutes.

It appears that the initial rise in intracellular calcium caused by the release of intracellular calcium stores plays a critical part in the alteration of membrane permeability to allow the influx of extracellular calcium. To some extent, variations in intracellular calcium transients may direct specific cellular functions, in that specific granule release occurs at very low (submicromolar) free calcium concentrations, whereas in studies using permeabilized cells, higher (micromolar) levels of free calcium result in release of both specific and azurophil granules.[438–440] Although the extracellular calcium influx is critical for many neutrophil responses, it is not critical for all, as degranulation is not blocked by ethyleneglycol-bis(2-aminoethyl) tetra-acetic acid.[441] Similarly, phagocytosis of particles opsonized with C3bi can occur without apparent intracellular calcium transients.[442]

Protein phosphorylation is an important mechanism of the regulation of protein function, and a number of studies suggest its role in neutrophil activation. Phorbol myristate acetate, which activates a number of neutrophil functions, binds to PKC and results in its activation. Although phorbol myristate acetate is not present in neutrophils, DAG, released when phospholipase C hydrolyses PIP_2, also binds and activates PKC. Because calcium is also important in PKC activation and IP_3 increases intracellular calcium, the hydrolysis of PIP_2 to IP_3 and DAG may contribute to PKC activation via both DAG and IP_3. Interestingly, the specific granules have been reported to contain a PKC inhibitor, thus providing a possible mechanism to downregulate PKC-mediated responses.[443]

Although this model explains many observations, it has become clear that signal transduction in neutrophils is far more complex, with both Ca^{2+} and PKC-independent pathways. Tyrosine phosphorylation has been found to play a critical role in signal transduction from various chemotactic factor receptors. Multiple neutrophil proteins are rapidly phosphorylated after activation, including Src family kinases; the Lyn kinase is activated by chemotaxins, increasing its ability to phosphorylate substrates. Serine and threonine kinases also appear to be involved in signaling, and some are activated by FMLP. In addition, phosphatidylinositol 3-kinase is also activated by chemotaxins. Phosphatidylinositol 3-kinase catalyzes the phosphorylation of PIP_2 to PIP_3. Phosphatidylinositol 3-kinase binds some phosphotyrosine residues via the SH2 domain on one of its subunits. Protein tyrosine phosphatases probably also play a role, as the transmembrane protein phosphatase CD45 has been implicated as a regulator of neutrophil function.[47,444] Chemotactic factors have also been found to activate phospholipase A_2 and phospholipase D. Finally, the importance of low-molecular-weight guanosine triphosphatases (LMWG) is also being recognized. Knowledge of signal transduction is rapidly advancing, and the reader is referred to the current literature.

Physiologic soluble inhibitors of neutrophil function have also been identified. For example, adenosine inhibits neutrophil aggregation, adhesion, chemotaxis, and superoxide production.[445–448] These inhibitory effects appear to act via A_2 receptors without preventing the transient rise in intracellular Ca^{2+}.[445–447]

Neutrophil Priming

"Priming" is an important concept in neutrophil signaling. Signaling in neutrophils is complex and can be initiated by many different stimuli that may share downstream signaling pathways. When neutrophils are exposed to an appropriate low level of a stimulus, they can be primed to a condition such that they display a much more prominent response to a second stimulus than they would if they had not been primed.[448–451,452] Neutrophils can

be primed by one stimulus for a response to a different agonist. Priming occurs at doses that do not result in a rise in cytoplasmic free calcium, but still cause protein tyrosine phosphorylation of signaling molecules. After priming, neutrophils exhibit a more prominent respiratory burst or secretory response to a given stimulus than would occur if priming had not occurred. This phenomenon may be involved in many physiologic neutrophil responses in vivo. Neutrophil priming can be reversible, with the cells still capable of being reprimed.[453]

The mechanism of priming is gradually becoming better understood. In resting neutrophils, the various components of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase are sequestered within the cell. Following neutrophil stimulation, cytoplasmic components of the NADPH oxidase translocate to the phagosome membrane and assemble to form the active oxidase. This activation process in not "all-or-none." Some stimuli can prime neutrophils, resulting in a state in which agents that normally do not activate neutrophils can stimulate oxidase activity, and in which the oxidase response to suboptimal concentrations of agents that do stimulate the oxidase results in a greater than expected oxidase response. For example, TNF-α does not stimulate neutrophil NADPH oxidase activity, while FMLP does. However, when neutrophils are pretreated with TNF-α, these primed neutrophils respond to suboptimal concentrations of FMLP with increased oxidase activity. The mechanism of neutrophil priming appears to be the result of a conformational change in p47phox.[454,455] TNF-α priming results in phosphorylation of ser354 in p47phox, which then binds the peptidyl prolyl cis–trans isomerase Pin1, resulting in conformational changes in p47phox that result in phosphorylation of other serine residues. This leads to other conformational changes exposing cryptic SH3 sites that can then bind p22phox, resulting in oxidase assembly, making the oxidase more responsive to stimuli.[454,455]

Desensitization

After previous exposure to a stimulus, neutrophils react less to subsequent stimulation by the same stimulus.[456–458] This phenomenon has been termed *desensitization*. In some cases, the desensitization appears to be specific to the original stimulus, but in other cases desensitization to different stimuli is also observed (cross-desensitization).[456–459]

Such desensitization has been observed in patients undergoing hemodialysis, in which exposure of blood to a cuprophane dialyzer membrane results in the generation of C5a and possibly other factors, which causes a transient neutropenia due to pulmonary leukostasis, as described in Chapter 58.[247,248] Although C5a generation persists throughout dialysis, the neutropenia is transient.[249] In contrast to neutrophils obtained at the start of dialysis, neutrophils obtained after 2 hours of dialysis (after the leukostasis has resolved) do not aggregate in response to plasma leaving the dialyzer membrane, demonstrating desensitization in vivo.[249] A patient with cytomegalovirus infection, whose serum induced granulocyte aggregation (presumably due to C5a), did not experience neutropenia during dialysis, and his neutrophils did not aggregate in response to serum leaving the dialyzer, in contrast to control cells, also demonstrating in vivo desensitization.[249] Similar desensitization was demonstrated in rabbits using the chemotactic peptide FMLP, wherein continuous intravenous infusion of FMLP reproduced a transient neutropenia due to pulmonary sequestration.[460] It is likely that neutrophil desensitization may also occur in other pathologic states, including infection, trauma, and multiorgan failure syndrome, and may contribute to neutrophil dysfunction, although the clinical significance of this phenomenon is unclear.

Neutrophil function can also be regulated by the neuroendocrine axis. For example, glucocorticoids can regulate neutrophil function, at least partly through annexin I or lipocortin I.[75] The phenomenon of desensitization has also been implicated as the mechanism by which glucocorticoids inhibit neutrophil function. It appears that the glucocorticoid-regulated protein annexin 1 (lipocortin 1) can bind a formyl-peptide receptor, induce calcium transients, and desensitize neutrophils to subsequent stimulation by other agents.[461,462] Two formyl-peptide receptors are expressed in neutrophils, the classical FPR and the related receptor FPRL-1/AXL. Annexin 1 appears to bind to FRPL-1/AXL, whereas some peptides derived from annexin 1 may bind both receptors.[461,462] Opiates have been reported to alter many immune functions, including neutrophil functions such as the respiratory burst, in many species.[463] MRP-14, a prominent component of neutrophils, can inhibit the function of activated macrophages and, possibly by this mechanism, can decrease inflammatory pain.[74]

Neutrophil–Endothelial Adhesion

Both neutrophils and endothelial cells express a variety of adhesive molecules on their cell surface, and the expression and activity of these molecules in many cases can be regulated by stimuli. Some of the known adhesion molecules of neutrophils and endothelial cells are indicated in Table 7.6. Approximately one half of the circulating neutrophils exist in the so-called marginating pool, some of which can be seen microscopically to be rolling along the endothelial surface, maintaining a loose intermittent contact with endothelial cells. The importance of hemodynamic forces, especially of red cells, in directing leukocytes outward from the flowing blood toward the endothelium was described many years ago and subsequently confirmed.[279,464–466] An attractive model of neutrophil–endothelial cell adhesion has been proposed by Springer, which accounts well for the known data.[106,467] In this model, selectin molecules on the cell surface are responsible for neutrophil rolling along the vessel wall. This loose adhesion brings the neutrophil in close proximity to the endothelial cell, where chemoattractants can be released or displayed on the cell surface. The interaction of these chemoattractants with neutrophil receptors results in signal transmission and the activation of integrin molecules. These integrins can then bind their ligands on the endothelial cell surface, resulting in a marked increase in adhesion to the endothelial cell and cessation of rolling. After this, the cells sense further chemoattractant gradients and migrate into the tissue where the neutrophils produce compounds that attract other inflammatory cells such as monocytes, lymphocytes, and other neutrophils, as well as promote wound healing. Subsequently they undergo changes promoting apoptosis and resolution of inflammation.[106]

Selectins

Three selectins have been identified that each have an N-terminal domain that is homologous to Ca^{2+}-dependent lectins (Fig. 7.17). L-selectin (CD62L) is expressed on the neutrophil surface. The main ligand for L-selectin is the glycoprotein known as *Gly-CAM-1* (glycosylation-dependent cell adhesion molecule-1). Endothelial cells express both E-selectin (CD62E, endothelial-leukocyte adhesion molecule-1) and P-selectin (CD62P, granule membrane protein-140). E-selectin and P-selectin both recognize $Lewis^x$-related sialylated carbohydrates, mostly on PSGL-1 (P-selectin ligand 1), and also L-selectin. Both PSGL-1 and L-selectin are localized on the tips of neutrophil microvilli, organized by the ERM proteins ezrin, radixin, and moesin that connect to the actin cytoskeleton.[106] Expression of E-selectin on the endothelial cell surface can be induced with stimuli such as IL-1 and TNF but requires protein synthesis. In contrast, P-selectin (CD62P) is found in both the Weibel-Palade granules of endothelial cells and the platelet α-granule. Thus, stimulation of endothelial cells with the appropriate stimulus, such as thrombin or histamine, can result in a rapid mobilization of CD62P (P-selectin) to the endothelial cell surface.

TABLE 7.6

NEUTROPHIL–ENDOTHELIAL CELL ADHESION PROTEINS

Neutrophil Integrin		Ligand
$\alpha_L\beta_2$	Leukocyte function antigen-1, CD11a/CD18	ICAM-1 (CD54), CAM-2 (CD102) ICAM-3 (CD50)
$\alpha_M\beta_2$	HMac-1, CD11b/CD18	ICAM-1, iC3b, fibrinogen, factor X
$\alpha_X\beta_2$	p150,95,CD11c/CD18	? iC3b, fibrinogen
Neutrophil Selectins		**Ligand**
L-selectin	CD62L, leukocyte adhesion molecule-1, Mel-14	Sialylated carbohydrates related to sLe^x (CD15s) and sLe^a on Gly-CAM-1
Endothelial Selectins		**Ligand**
E-selectin	CD62E, ELAM-1	Sialylated carbohydrates
P-selectin	CD62P, granule membrane protein-140, platelet activation–dependent granule-external membrane protein	Sialylated carbohydrates including PSGL-1 on neutrophils
Endothelial Ig Family		**Ligand**
CD54	ICAM-1	CD11a/CD18, CD11b/CD18
CD102	ICAM-2	CD11a/CD18
CD31	PECAM-1	NB1/CD177, CD31
Neutrophil Ig Family		**Ligand**
CD31	PECAM-1	CD31
CD50	ICAM-3	CD11a/CD18
CD66a	CEACAM1 (Biliary glycoprotein)	CD66a, CD66c, CD66e
CD66b	CEACAM8 (CGM6)	CD66c
CD66c	CEACAM6 (NCA 50/90)	CD66a, CD66b, CD66c, CD66e
Neutrophil Leukocyte Antigen-6 superfamily		**Ligand**
CD177	NB1	CD31 (PECAM-1)

ELAM, endothelial-leukocyte adhesion molecule; ICAM, intercellular adhesion molecule; Ig, immunoglobulin; PECAM, platelet–endothelial cell adhesion molecule; PSGL, P-selectin glycoprotein ligand.

Integrins

Integrins are noncovalently associated heterodimers of α and β subunits, each of which has characteristic structural motifs (Figs. 7.18 and 7.19). The major integrins of neutrophils are the β_2 integrins made up of $\alpha_L\beta_2$ (leukocyte function antigen-1, CD11a/CD18), $\alpha_m\beta_2$ (HMac-1, CD11b/CD18), and $\alpha_x\beta_2$ (p150,95, CD11c/CD18).

Intercellular adhesion molecule (ICAM)-1 (CD54) expressed on the endothelial cell surface is a ligand for both CD11a/CD18 and CD11b/CD18. Other Ig superfamily members are probably also involved in neutrophil–endothelial cell adhesion, including platelet endothelial cell adhesion molecule-1 (CD31), ICAM-3 (CD50) (expressed on the neutrophil but not the endothelial cell), and the CD66 family of neutrophil-activation antigens.

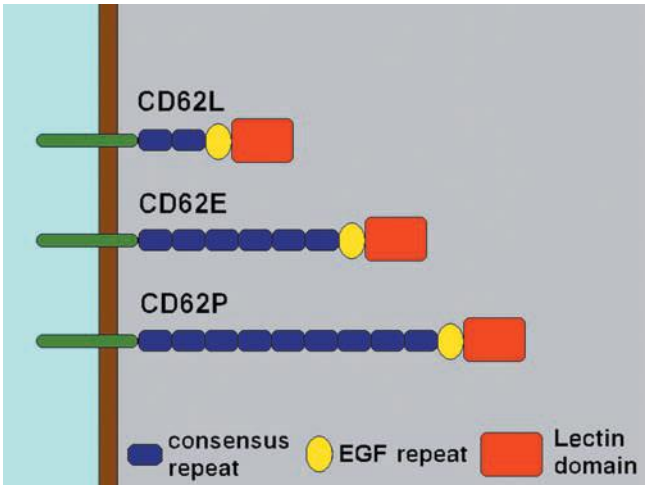

FIGURE 7.17. Schematic of selectin structure. The selectins are attached to the cell via a transmembrane domain with an extracellular domain consisting of a series of short consensus repeats (*blue*) that form a stalk-like structure linked by an epidermal growth factor–like domain (*yellow*) to a carbohydrate-binding C-type lectin domain (*red*). CD62L contains a membrane-proximal site that is cleaved by a protease after neutrophil activation, resulting in shedding of the extracellular domain. EGF, epidermal growth factor. (From Skubitz A, with permission.)

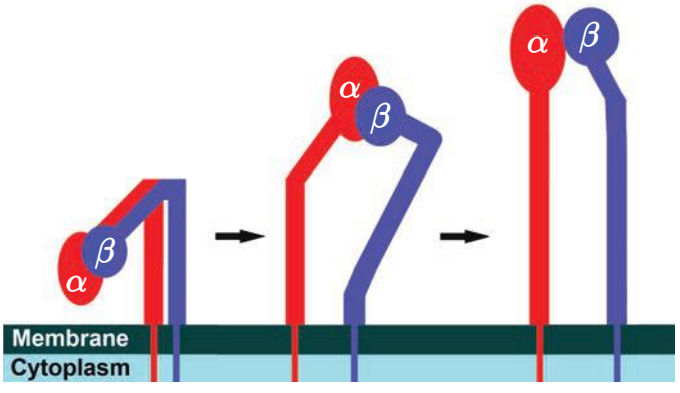

FIGURE 7.18. Schematic of an α,β_2 integrin dimer, showing the inactive, low-affinity state (*left*) and the active, high-affinity state (*right*). Integrins are heterodimers of α and β subunits with a globular "head" region and two "legs." The head of the α subunit contains EF hand repeats that are divalent metal-binding sites, and a "β propeller" domain with an I domain that contains a binding site for Mg^{2+} and Mn^{2+}. The β subunit contains an I-like domain. In the low-affinity, inactive state with no ligand bound, the integrin is either bent toward the membrane with a closed headpiece facing toward the membrane, or extended with a closed headpiece. With activation, the integrin straightens and rotates the head region outward and the headpiece opens, with an associated change to higher ligand affinity. This change in structure is associated with a separation of the α and β subunits. (From Skubitz A, with permission.)

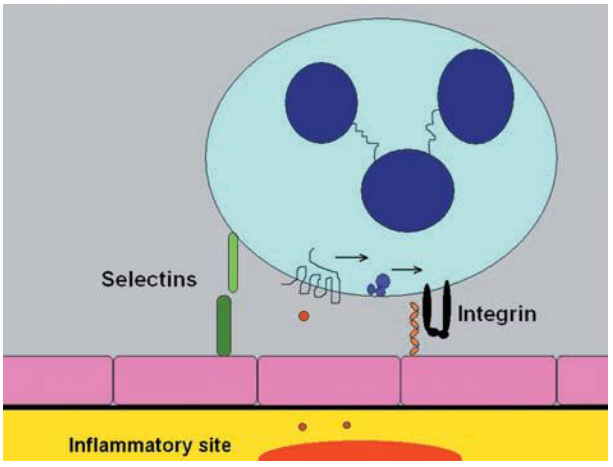

FIGURE 7.19. Neutrophil adhesion to inflamed endothelium follows three sequential steps. First, selectin molecules (*green*) that recognize carbohydrate ligands bind their ligand and result in tethering and rolling along the vascular wall, bringing the neutrophil in close proximity to the endothelial cell surface. Chemotactic agents (*red balls*) released from the site of inflammation (*red*) and bound to or released from the endothelial cell surface interact with specific receptors that span the neutrophil membrane seven times and transduce activation signals via G proteins (*purple*) that activate integrins (*black*). These integrins then bind their ligands (immunoglobulin superfamily members, *orange*) on the endothelial cell surface, resulting in arrest of the neutrophil and subsequent transmigration across the endothelial surface and subsequent chemotaxis to the site of chemoattractant production. (From Skubitz L, with permission.)

Sequence of Neutrophil–Endothelial Cell Adhesion

In the Springer model, selectins are responsible for the initial rolling of the neutrophil along the endothelial cell. The association and disassociation constants of selectins for their ligands are very high, and stimulation of neutrophils can result in a rapid increase in L-selectin affinity for its ligand, resulting in tethering of a flowing cell and rolling within a millisecond.[467,468] This increase in affinity is transient, and, in fact, by 5 minutes after stimulation, much of the CD62L is shed from the neutrophil surface. The close interaction of the neutrophil with the endothelial cell surface, mediated by the selectins, allows the neutrophils to sense chemoattractants released from or displayed on the endothelial surface. These chemoattractants bind to specific receptors on the neutrophil surface, many of which span the membrane seven times, are coupled with G proteins, and result in transduction of signals that activate integrin-adhesive activity (Fig. 7.19). Some of the known chemoattractants for neutrophils are listed in Table 7.7. Many tissue-derived chemotactic factors form a protein family termed *chemokines*. These proteins have four conserved cysteines that form two disulfide bonds. The chemokine family is composed of CXC and CC chemokines. The CXC chemokines have their first two cysteines separated by a single amino acid and stimulate neutrophils, whereas the CC chemokines do not. Among the classically described chemoattractants are the *n*-formyl peptides. These chemoattractants were initially identified by studies of the observation that supernatants of bacterial cultures were chemotactic for neutrophils. Subsequent studies identified a number of *n*-formyl peptides with chemotactic activity, and it was hypothesized that the presence of such a receptor would provide a preimmune receptor for the neutrophil to sense bacterial infections, because bacterial protein synthesis begins with *n*-formyl methionine, whereas mammalian protein synthesis does not. Interestingly, mammalian mitochondria do synthesize *n*-formyl methionyl peptides, and these may in some cases also result in neutrophil activation. Another classic chemoattractant is C5a, a cleavage fragment of the fifth component of complement.

TABLE 7.7

NEUTROPHIL CHEMOATTRACTANTS

Chemoattractant
C5a
N-Formyl peptides
Platelet-activating factor (PAF)
Neutrophil-activating peptide (NAP)-2
IL-8 (NAP-1)
Leukotriene B_4 (LTB4)
Epithelial cell-derived neutrophil attractant (ENA)-78
Growth-related oncogene (GRO)-α, GRO-β, GRO-γ
Macrophage inflammatory protein (MIP)-1, MIP-2
Platelet factor (PF)-4

Integrins form a family of adhesive molecules whose affinity for ligand can be rapidly regulated. Stimulation of neutrophils with *n*-formyl peptides or C5a results in rapid upregulation of CD11b/CD18 expression on the neutrophil surface. This increase in expression is caused by fusion of secretory vesicles with the cell membrane. With strong stimulation, it is possible that secondary/tertiary granule fusion contributes as well. However, mere translocation to the cell surface with an increase in cell-surface expression of CD11/CD18 is not sufficient for an increase in adhesiveness. Similarly, studies of cytoplasts have demonstrated that alterations in β_2 integrin–mediated cell adhesion can be manifest without a change in surface expression of CD11b/CD18. Data suggest that alterations in CD11b/CD18-mediated cell adhesiveness are the result of a conformational change of the integrin, causing an alteration in ligand binding.[145,469] Studies have shown that, after activation of neutrophils by chemoattractants, approximately 10% of the surface CD11b/CD18 molecules express an activation epitope recognized by a monoclonal antibody.[145] Cell-surface integrins are in equilibrium between three conformational states. The bent conformation has a closed headpiece, while two extended conformations have either a closed or open headpiece. The extended open conformation has a much higher affinity for ligand and mediates integrin adhesion.[470,471]

As shown in Table 7.7, several Ig superfamily members are expressed on endothelial cells and are ligands for leukocyte integrins. Mac-1 (CD11b/CD18) binds to a specific site in the third Ig domain of ICAM-1. Leukocyte function antigen-1 (CD11a/CD18) binds to the N-terminal domains of both ICAM-1 and ICAM-2. Thus, the model for neutrophil adhesion and transmigration through vessel walls can be depicted as in Figures 7.19 and 7.20. The initial rolling of neutrophils along the vessel wall is mediated by selectins (L-selectin, E-selectin, and P-selectin), and their expression and affinity for ligand can be regulated by inflammatory stimuli. At sites of inflammation, leukocyte rolling along the vessel wall is increased, and cells may become more closely apposed to the vessel wall, allowing better interaction with chemoattractants released from or presented on the surface of the endothelial cells. Interactions of these chemoattractants with the neutrophil then result in activation of integrin affinity for its ligand, with a resultant firm adhesion of the neutrophil to the endothelial cell surface. Subsequent migration of the neutrophil through the endothelial cell proceeds along the gradient of the chemotactic agent. Extravasation via transcellular (through the endothelial cells) has been demonstrated, and the endothelial cell may play a role in this process.[472] The relative contribution of transcellular and intercellular extravasation is unclear, and may depend on the particular tissue and stimuli involved. The presence of multiple adhesion molecules and ligands on both the neutrophil and the endothelial cell, which may vary among endothelial cells in different environments, coupled with the array of chemoattractant agents that may be released locally, provides potentially high

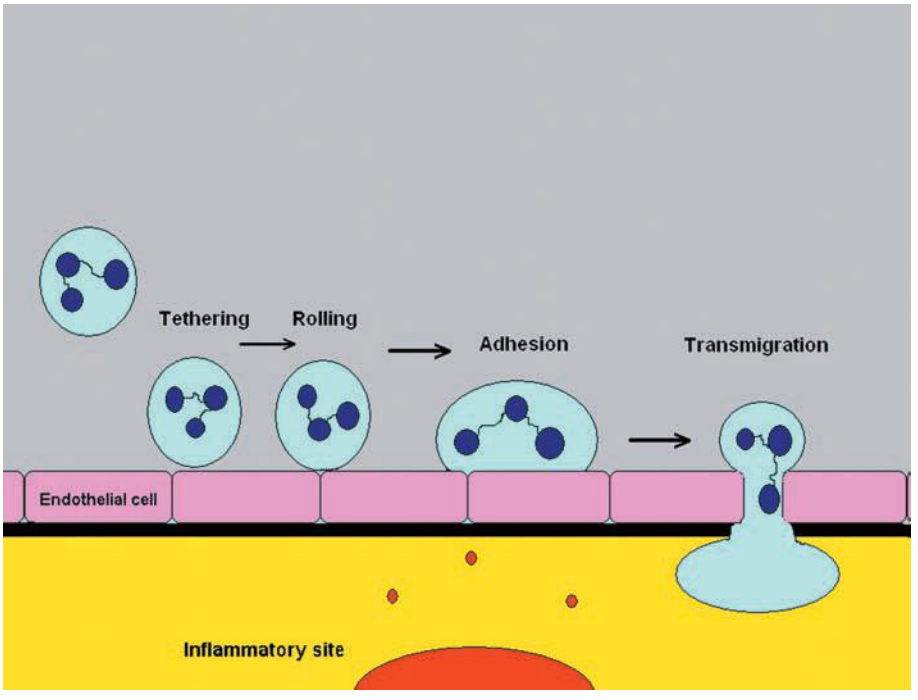

FIGURE 7.20. Neutrophil adhesion to the vascular wall at a site of inflammation. Sequential interactions of neutrophils with selectins result in rolling along the vascular wall, followed by sensing chemoattractants (*red balls*), which activate integrins to cause increased adhesion to the endothelial cells, followed by transmigration through the endothelial cells and basement membrane, followed by chemotaxis to the site of inflammation. (From Skubitz L, with permission.)

specificity for localizing the interaction of a particular type of cell within a particular endothelial environment, based on the large number of combinatorial adhesive molecule–ligand pair combinations available.[467]

This model is supported by elegant studies demonstrating that at physiologic shear stress, neutrophils form rolling adhesions on phospholipid bilayers containing P-selectin but not on those containing ICAM-1. Chemoattractants result in integrin-mediated adhesion to bilayers containing ICAM-1 under static conditions but not under shear conditions. In contrast, neutrophils rolling on bilayers containing both P-selectin and ICAM-1 respond to chemoattractants by spreading and becoming firmly adherent via an integrin–ICAM-1 interaction. Chemoattractants do not increase adhesion or rolling on bilayers containing P-selectin alone.[467]

Feedback systems also exist that can inhibit neutrophil rolling and adhesion to endothelial cells (Fig. 7.21). The pentraxin PTX3 is stored in specific granules. While PTX3 can bind pathogens and activate complement, it can also inhibit neutrophil recruitment to inflammatory sites. It appears that neutrophils can release PTX3 from specific granules, and that the PTX3 can then bind P-selectin (CD62P) on endothelial cells. The binding of PTX3 to CD62P inhibits CD62P binding to PSGL-1 on neutrophils, thus inhibiting rolling.[473] Endothelial cells can release the glycoprotein Del-1, which can bind CD11a/CD18 on neutrophils. Del-1 binding to CD11a/CD18 inhibits CD11a/CD18 binding to ICAM-1, inhibiting neutrophil adhesion.[474,475] CD11/CD18 complexes can also be shed by neutrophils, and may further regulate neutrophil function in inflammation.[476,477]

Neutrophil Aggregation

The increase in polymorphonuclear neutrophil adhesion after stimulation is manifest not only by increased adhesion to endothelial cells, but also by neutrophil–neutrophil and neutrophil–platelet adhesion. Although the in vivo formation of neutrophil aggregates was clearly visualized by W.B. Wood in a rabbit ear model of inflammation in the 1960s, the possibility of neutrophil homotypic aggregation was considered novel when it was formally demonstrated by Craddock et al.[247,248] Craddock's observations stemmed from earlier descriptions of the phenomenon of hemodialysis neutropenia.[245,246] The initiation of hemodialysis, using cuprophane membranes, is followed by a rapid fall in the circulating neutrophil count caused by a transient sequestration of neutrophils in the lung, with a return to the circulation by 1 hour.[245,246] Craddock demonstrated that neutrophils undergo homotypic aggregation in response to plasma that had been

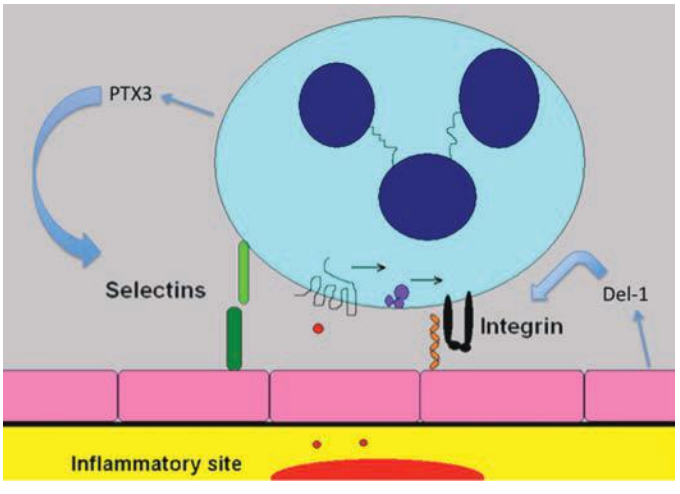

FIGURE 7.21. Feedback mechanisms inhibit neutrophil recruitment to inflammatory sites. Neutrophils can release PTX3 from specific granules, and the PTX3 can then bind P-selectin (CD62P) on endothelial cells. The binding of PTX3 to CD62P inhibits CD62P binding to PSGL-1 on neutrophils, thus inhibiting rolling. Endothelial cells can release the glycoprotein Del-1, which can bind CD11a/CD18 on neutrophils. Del-1 binding to CD11a/CD18 inhibits CD11a/CD18 binding to ICAM-1, inhibiting neutrophil adhesion. (From Skubitz L, with permission.)

exposed to cuprophane, largely because of generation of C5a by complement activation.[247,248,250,251] Aggregation was also induced by other neutrophil stimuli. Further studies demonstrated that the transient nature of hemodialysis neutropenia was caused by desensitization of neutrophils to the continued infusion of stimulus from the hemodialysis machine, thus demonstrating in vivo the phenomenon of desensitization.[249] This phenomenon, in some clinical situations (e.g., viral infections), may result in neutrophil dysfunction as described later in this book. Subsequent studies have suggested that neutrophil aggregation and sludging, with resultant organ damage or dysfunction, may play a role in a variety of pathologic processes, including adult respiratory distress syndrome and reperfusion injury.

Chemotaxis

The work of von Recklinghausen and Conheim described amoeba-like movement of leukocytes more than a century ago.[279] The neutrophil moves on a surface through a gradient of chemotactic agent by advancing a projection called a *lamellipodium* or *pseudopodium*. Chemotaxis begins with the protrusion of a pseudopodium or lamellipodium at the front of the cell. This occurs where the submembranous actin filament network (the cortex) becomes less filamentous. As the cell moves, the pseudopodium ruffles rapidly. Part of the pseudopodium adheres to the underlying surface, and the contents of the cell move forward into the pseudopodium, making the pseudopodium less prominent. This cycle is then repeated with the protrusion of another pseudopodium. Chemotaxis occurs by repetitions of this process, although often the process is so well coordinated as to appear as a continuous gliding motion. The mechanism of these cell movements appears to involve alterations in the polymerization state of actin, regulated by several proteins, including actin-binding protein, gelsolin, and others, as well as adenosine triphosphate–dependent contraction of the actin network mediated by myosin.[49,478] Local contraction of the cytoskeleton could move intracellular components forward into an area where the cortical gel has weakened because of shortening of actin filaments beneath the surface of the advancing pseudopodium. Characteristic contraction waves have been observed in human leukocytes and likened to those seen in amoebae and earthworms (Fig. 7.22).[479] In leukocytes, the contraction wave appears to originate in the superficial layer of the submembranous organelle-excluding region called the *cortex*, producing a concave area, and the anterior part of the cell stretches or is propelled forward as a pseudopodium.[479] How localized changes in the state of actin assembly are established and maintained at a single site in neutrophils during chemotaxis is unclear. Data suggest that a change in plasma membrane tension is the main factor limiting the spread of the leading front and suppressing the development of secondary fronts.[480] While integrin-mediated adhesion plays an important role in migration on a two-dimensional surface, and in crossing tissue barriers such as the endothelium, integrins do not appear important in interstitial migration. In studies of migration in three-dimensional environments, elimination of all integrin heterodimers in mouse leukocytes did not affect migration. Thus, the migration in this system was shown to be due solely to the force of changes in the actin network.[478]

Interestingly, mice that express no gelsolin can breed in captivity and have a prolonged bleeding time and abnormal neutrophil chemotaxis.[49] Thus, gelsolin is important in neutrophil chemotaxis, but other proteins can compensate to some extent in its absence. The increase in free calcium that alters the cytoskeleton by activating gelsolin, and thereby decreasing filamentous actin with a resultant decrease in viscosity, may play a role in locomotion; in addition, the transient dissolution of the submembranous cytoskeletal network may allow closer contact of intracellular granules with the plasma membrane, facilitating granule fusion and release. Some granule release occurs with chemotaxis.

Although the mobility of neutrophils and their concentration in inflammatory lesions were appreciated in early experiments, the development of a two-compartment chamber separated by a leukocyte-permeable membrane has permitted quantitation of chemotaxis in vitro and facilitated the investigation of chemotactic factors.[481,482] Such studies revealed that neutrophils show directional migration under the influence of chemotactic agents, but a concentration gradient is needed for migration to occur. Even in the absence of a gradient, however, in the presence of a chemotactic factor, random migration is enhanced, and localization, or trapping, of the phagocytes occurs.

Phagocytosis

Metchnikoff played an important role in describing the phenomenon of phagocytosis (Figs. 7.16 and 7.23). When a neutrophil meets a particle, it envelops it with pseudopodia, which fuse around it, forming a phagosome that rapidly fuses with azurophilic and specific granules. *Endocytosis* is the process by which material is taken into a cell enclosed within pieces of plasma membrane and, therefore, never occurs free within the cytoplasm of the cell.[483] Endocytosis is further divided into pinocytosis (drinking by cells) and phagocytosis (eating by cells). Phagocytosis is usually visible by light microscopy, whereas pinocytosis is not, involving ingestion of small particles, such as macromolecules. Both processes proceed through invagination

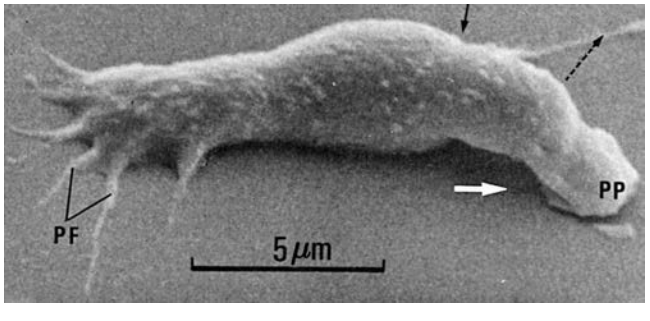

FIGURE 7.22. Scanning electron micrograph of a moving neutrophil. The contraction wave is observed as a concave (*black solid arrow*) and a convex (*black dashed arrow*) area. The advancing pseudopodium (*PP*) is seen being pushed out in the direction of movement (*white arrow*). Pseudoflagellae (*PF*) are seen in the rear of the cell. (From Senda N, Tamura H, Shibata N, Yoshitake J, Konko K, Tanaka K. The mechanism of the movement of leucocytes. Exp Cell Res 1975;91:393, with permission.)

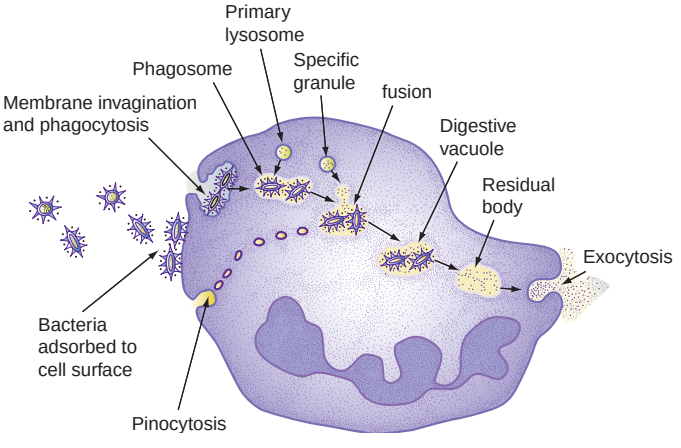

FIGURE 7.23. Diagram of endocytosis; both phagocytosis of immunoglobulin-coated bacteria and pinocytosis are shown. The fusion of a primary lysosome and a specific granule with the phagosome to form the digestive vacuole, the subsequent degradation of the bacteria leading to the formation of a residual body, and the expulsion of indigestible components are also depicted.

of the cell membrane and the formation of vesicles or vacuoles (phagosomes).

Neutrophils and macrophages are motile and thus are free to migrate into sites of inflammation. Once they are in the area of inflammation, they come in contact with the foreign material, engulf it, and subject it to the microbicidal and digestive enzymes they contain. This sequence was appreciated by Metchnikoff in the 1880s,[484] when he observed the migration of phagocytes into areas of tissue damage in sponges and lower animals. How phagocytes distinguish foreign particles and damaged autologous cells from normal self-components is complex, but this capacity is critical to effective phagocytic function.

Granule Release

Neutrophils contain four well-defined types of intracellular granules: azurophilic, specific, and gelatinase granules; and secretory vesicles. The azurophilic granules contain many antibacterial compounds, and it appears that the fusion of these granules with phagocytic vesicles is important in bacterial killing. Azurophilic granules also contain compounds, such as elastase, that may alter locomotion by hydrolyzing certain extracellular matrix components. The specific granules are more readily released from the cell, suggesting an important function in the extracellular milieu. For example, specific granules contain products that activate the complement cascade.[485] Collagenase may be important in hydrolyzing extracellular matrix proteins and facilitating locomotion. Apolactoferrin, which binds iron, may exert an antibacterial effect by depriving bacteria of iron, altering hydroxyl radical formation, and altering cell adhesion.[39,40] The tertiary granules contain gelatinase in addition to other components, and, like collagenase, this enzyme may play a role in extracellular matrix remodeling during locomotion. Finally, both tertiary granules and the secretory vesicles contain membrane proteins that can be rapidly upregulated to the cell surface and may play a role in alterations of the functional use of these surface proteins after stimulation. Membrane components of secondary granules are also upregulated during granule release and may play a role in regulating the expression of these membrane proteins on the cell surface. The specific granules are more readily released than the azurophilic granules, and their secretion, therefore, must be regulated somewhat differently.

Bacterial Killing and Digestion

Bacterial killing by neutrophils can be ascribed to two general and often synergistic mechanisms: oxidative and nonoxidative. Bacterial killing in the phagosome is augmented by the generation of superoxide. Activated neutrophils produce superoxide via a multicomponent NADPH–dependent oxidase that is activated by neutrophil stimulation. In resting cells, the oxidase components are found in both the plasma membrane and intracellular stores. After stimulation, intracellular components are translocated to the plasma membrane and activated, producing superoxide. Subsequent reactions result in the formation of H_2O_2 and hypochlorous acid (HOCl), which increase bacterial killing. Small amounts of other species (such as singlet oxygen and hydroxyl radical) may also form but are probably of little import in bacterial killing.

Bacterial killing decreases under anaerobic conditions, whereas phagocytosis does not, so the respiratory burst is important to bactericidal activity. Furthermore, because chronic granulomatous disease is one of the most severe clinical disorders characterized by a defect in bacterial killing, and the defect in this disorder is an inability to develop all of the reactions associated with the respiratory burst, the oxygen-dependent mechanisms appear to be of major importance in bacterial killing.[486,487] However, other bactericidal mechanisms that do not require oxygen also operate within phagocytes (Table 7.7).

Oxygen-dependent Antimicrobial Systems

Neutrophil activation is accompanied by a prominent increase in O_2 use called the *oxidative burst* or *respiratory burst*, described by Baldridge and Gerard in 1933.[488] In 1964, Rossi and Zatti suggested that the respiratory burst is due to an NADPH oxidase[489]; and in 1973, Babior et al. reported the production of superoxide by the NADPH oxidase.[490] The respiratory burst or oxidative burst is a series of metabolic events that takes place when phagocytes are appropriately stimulated, resulting in an increase in oxygen consumption, the production of superoxide (O_2^-), the production of H_2O_2, and an increase in glucose oxidation via the hexose monophosphate shunt.[486,491,492] Most of the oxidative burst is caused by activation of an NADPH oxidase that catalyzes the one-electron reduction of oxygen to superoxide, using the electron donor NADPH[486,493]:

$$2O_2 + NADPH \rightarrow 2O_2^- + NADP^+ + H^+$$

Activation of the hexose monophosphate shunt occurs because of the increased $NADP^+$ produced.

The NADPH oxidase exists in a latent state consisting of both membrane and cytosolic components in distinct subcellular compartments. Activation involves multiple steps, including assembly at the membrane of two membrane-bound components ($gp91^{phox}$ and $p22^{phox}$), three cytosolic components ($p40^{phox}$, $p47^{phox}$, and $p67^{phox}$) (the term *phox* indicates that the protein is a component of the phagocyte oxidase), and a low-molecular-weight G protein (rac1 or rac2) to form the membrane-bound oxidase complex[492,494,495] (Figs. 7.24 and 7.25). The activated oxidase is readily detected by nitroblue tetrazolium or cytochrome reduction or the production of chemiluminescence; several mechanisms by which this series of oxygen-dependent reactions may kill bacteria have been postulated (Table 7.8). When stimulated by phagocytosis, reactive oxygen metabolites are found localized at the phagosome, and not on parts of the plasma membrane that are not involved in phagocytosis.[495] Although O_2^- has some antibacterial activity, most O_2^- is rapidly converted to H_2O_2 by dismutation, either spontaneously or catalytically by superoxide dismutase:

$$2O_2^- + 2H^+ \rightarrow O_2 + H_2O_2$$

Of the microbicidal oxidants generated by the respiratory burst, O_2^- and H_2O_2 are not potent microbicides; rather, they function as starting materials to generate more potent oxidizing radicals, such as oxidized halogens and oxidizing radicals.[495]

Myeloperoxidase-mediated Oxygen-dependent Bacterial Killing with Oxidized Halogens

The antibacterial effect of OCl^- was demonstrated by Koch in 1881, and chlorine-based disinfectants have been widely used since, though their use was suggested even earlier in the 19th century by both Alcock and Semmelweis.[496] MPO is present in high concentration in the azurophilic or primary granules of neutrophils and is released into the phagosome during granule-phagosome fusion. MPO, together with H_2O_2 generated during phagocytosis[497,498] and an oxidizable cofactor such as halide (e.g., Cl^- or Br^-), forms oxidized halogens that are potent antimicrobials effective against bacteria, fungi, viruses, mycoplasma, and tumor cells[487]:

$$Cl^- + H_2O_2 \rightarrow H_2O + OCl^-$$

The combination of MPO, halide, and H_2O_2 is efficient in killing bacteria at H_2O_2 concentrations as low as 10 μm, whereas H_2O_2 in the absence of MPO requires 0.5 mmol/L or greater levels to produce similar killing.[486] Thus, H_2O_2 alone is a weak antimicrobial. Several mechanisms that have been proposed to explain bacterial killing by this system include halogenation of the bacterial cell

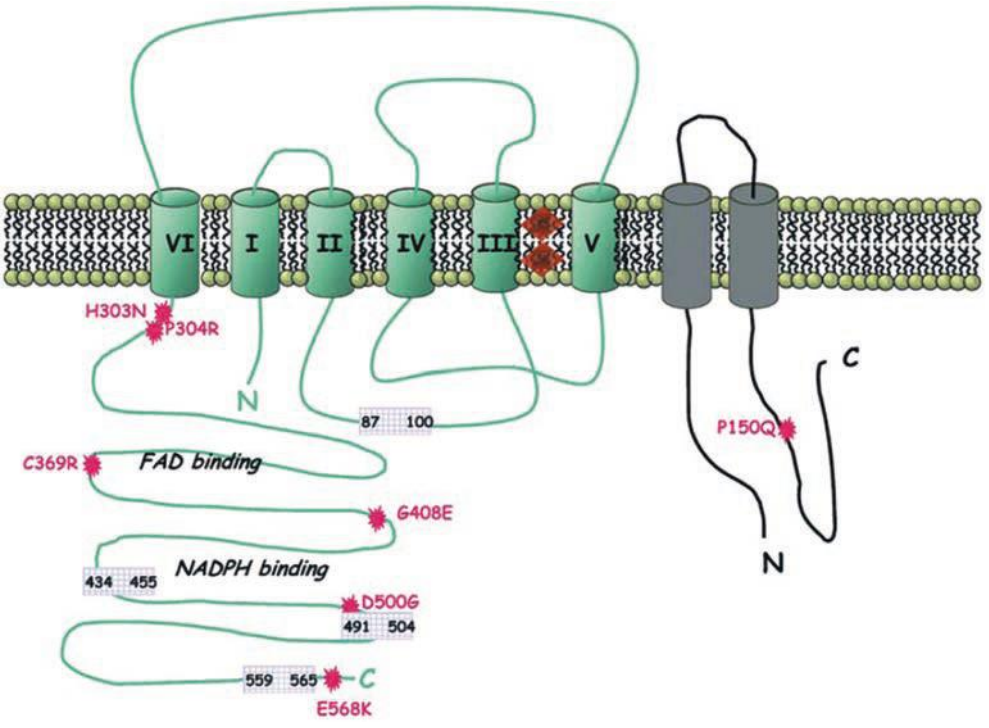

FIGURE 7.24. Model of flavocytochrome b558. Both gp91^{phox} and p22^{phox} are shown, with the aligned bis-hemes and the sites for FAD and NADPH binding on gp91^{phox} indicated. The seven specific mutations identified in patients with chronic granulomatous disease and associated with defective oxidase assembly are indicated in red bursts. Regions in the cytoplasmic loops of gp91^{phox} that have been implicated in mediating oxidase assembly by studies using synthetic peptides or specific monoclonal antibodies are indicated in partially filled rectangles. FAD, flavin adenine dinucleotide; NADPH, nicotinamide adenine dinucleotide phosphate. (Nauseef WM. From Histochem Cell Biol 2004;122:277–291, with permission.)

wall, oxidation of various bacterial components, the decarboxylation of bacterial wall amino acids,[486,487] and the generation of long-lived chloramines that have antimicrobial activity[486,499]:

$$OCl^- + RNH_3 \rightarrow OH^- + RNH_2Cl$$

There is some evidence that reactive nitrogen intermediates may also be produced.[500,501]

Regardless of the mechanisms of killing, the fact that azide inhibition of MPO greatly decreases the microbicidal activity of normal leukocytes provides strong evidence for the importance of this system.[497] In patients with MPO deficiency (which is often quantitative rather than qualitative), the activity of other antimicrobial systems is increased, thus partially compensating for the MPO deficiency.[497] This finding may explain the increased susceptibility to infection in only approximately 20% of MPO-deficient patients.[502]

Myeloperoxidase-independent (but Oxygen Radical–dependent) Bacterial Killing

This antimicrobial system is important because cells with no detectable MPO activity retain antibacterial actions that require oxygen; in fact, bacterial killing in MPO-deficient cells is associated with greater oxygen consumption than in normal cells.[487]

Hydrogen Peroxide

As mentioned, H_2O_2 at high concentrations (>0.5 mmol/L) has antimicrobial activity in the absence of MPO.[503] Some organisms are more sensitive than others to H_2O_2, and this sensitivity may depend in part on their ability to degrade it (i.e., catalase or peroxidase content). Certain substances such as iodide or ascorbic acid may enhance the bactericidal action of H_2O_2 or render organisms more sensitive to still other killing mechanisms, such as lysozyme.[487]

Superoxide Anion

After the discovery that O_2^- was generated in phagocytes, some authors postulated that O_2^- itself might be microbicidal. The microbicidal activity of O_2^- appears to be weak, however, when compared to that of the H_2O_2 formed from it, especially if MPO is present. Superoxide by itself has minimal bactericidal activity.[486,487]

Hydroxyl Radicals

Human neutrophils and monocytes generate OH· radicals, which have a very short half-life in vivo (~10^{-9} seconds), but the role of this highly reactive compound in microbial killing is unclear.[486,487]

FIGURE 7.25. Oxidase assembly. Two models for the organization of the cytosolic oxidase complex in resting phagocytes are shown. **A:** In the first model, $p40^{phox}$ provides the organizing central structure, interacting via its PC motif with the PB1 region of $p67^{phox}$, and via its SH3 domain with the PRR of $p47^{phox}$. **B:** In the second model, $p67^{phox}$ is at the center of the complex, bound to $p40^{phox}$ in the same fashion as in **A** but associated via its C-terminal SH3 domain with the PRR of $p47^{phox}$. **C:** In the activated phagocyte, the cytosolic components associate at the phagosomal or plasma membrane via several contact points (*bidirectional arrows*). With stimulation of the cell, RacGDP dissociates from RhoGDI, undergoes guanine nucleotide exchange, and the RacGTP associates with the membrane via its C-terminal prenyl group and associates directly with $gp91^{phox}$ (*1*). $p47^{phox}$, released from its autoinhibited conformation by multiple phosphorylations in the polybasic region, associates via its N-terminal SH3 domain with the PRR of $p22^{phox}$ (*2*) and via its PX domain with the phophoinositides in the target membrane (*3*). The TPRs of $p67^{phox}$ associate with RacGTP (4), while its activation domain binds directly to $pg91^{phox}$ (*5*) and its PRR associates with the C-terminal SH3 domain of $p47^{phox}$ (*6*). FAD, flavin adenine dinucleotide; NADPH, nicotinamide adenine dinucleotide phosphate. (Nauseef WM. From Histochem Cell Biol 2004;122:277–291, with permission.)

$OH\cdot$ production from H_2O_2 and superoxide is catalyzed by iron in the Haber-Weiss reaction:

$$H_2O_2 + O_2^- \rightarrow OH\cdot + OH^- + O_2$$

$OH\cdot$ could also be produced from a reaction between ozone and H_2O_2.[494]

Singlet Oxygen

Singlet oxygen ($^1O_2$) is a highly reactive form of oxygen that is capable of attacking compounds containing double bonds. However, significant amounts of singlet oxygen are unlikely to form, so its role in bacterial killing is probably not significant.[502]

Nitric Oxide

Nitric oxide may interact with neutrophil-derived oxidants to yield other relevant oxidant species, though its role in neutrophil function is unclear.[496] Nitric oxide can react with superoxide to produce reactive nitrogen intermediates that can react with a variety of biologic targets. Though the clinical significance of neutrophil-derived reactive nitrogen intermediates is unclear, MPO potentiates NO-mediated nitrosation.[504] Nitric oxide reacts with superoxide to form the potent oxidant peroxynitrate ($ONOO^-$). Nitrite (NO_2^-), a major end product of nitric oxide metabolism, has been found to interact with HOCl or MPO, or both, to form nitrylchloride (NO_2Cl) and thus promotes tyrosine nitration.[505,506] Activated neutrophils can convert NO_2^- to NO_2Cl and $NO_2\cdot$ through an MPO-dependent pathway and inactivate endothelial angiotensin-converting enzyme.[505] Thus, neutrophil conversion of NO_2^- to nitrating and chlorinating species may play important physiologic roles. Nitric oxide synthase has been found in primary granules of resting neutrophils,[507] and nitric oxide production by neutrophils has been observed.[506] The expression of the NOS2 isoform can be induced in neutrophils by endotoxin, whereas NOS1 is present in the resting state.[508,509]

Oxygen-independent Antimicrobial Systems

Because an anaerobic environment does not abolish antimicrobial activity, other mechanisms must be operative, and several have been identified, including the effects of acid, lysozyme, lactoferrin, defensins, cationic proteins, and neutral proteases. The delivery of the wide array of antibacterial compounds to the phagosome by fusion with azurophilic and specific granules generally results in bacterial killing caused by the direct actions of the granule contents. In addition, these effects are potentiated by the acidification of the phagosome, caused partly by the granule contents themselves, as well as by active translocation of H^+ ions into the phagosome by ion pumps. The effectiveness of these mechanisms in the absence of superoxide production is demonstrated by both bacterial killing in anaerobic environments and killing by cells from patients with chronic granulomatous disease, in which catalase-positive organisms have an advantage over catalase-negative species. Nonoxidative killing is of obvious importance in hypoxic environments such as an abscess.

Acid

After particle ingestion, the intraphagosomal pH has been reported to decrease to between 3.0 and 6.5.[510–512] Some organisms, such as pneumococci, are sensitive to an acid pH, whereas others tolerate acid environments without damage. In addition, the acid environment may enhance the effect of lysosomal hydrolytic enzymes, most of which have optimal activity at acid pH.

Lysozyme

Lysozyme, a low-molecular-weight (14,500-dalton) basic protein, is present in both primary and secondary neutrophil granules and is capable of hydrolyzing the cell wall of certain bacteria. Most organisms are resistant to the direct action of lysozyme,[487] although they may become sensitive to its action after exposure to antibody and complement or to H_2O_2 and ascorbic acid.[487] Usually, bacterial death appears to precede the action of lysozyme, so its action may be mostly digestive. The leukocytes of Guernsey and Hereford cattle contain no lysozyme but kill organisms normally.[513]

Lactoferrin

Lactoferrin is a microbiostatic protein (molecular weight 77,000 daltons) that is found in the specific granules of rabbit heterophils[514] and in human neutrophils[515] as well as in many secretions (e.g., milk and mucus) and exudates.[516] It inhibits bacterial growth by binding the essential nutrient iron (two atoms per molecule); and, in contrast to transferrin, this property is maintained at the low pH values encountered in exudates. A synergistic relationship between lactoferrin and other antimicrobial systems may exist, and lactoferrin may be bactericidal for some organisms.[517]

Defensins

Prominent among the cationic neutrophil granule proteins are the defensins. These small microbicidal peptides kill a variety of bacteria, fungi, and viruses.[19–21] Defensins appear to exert their effects by forming voltage-dependent ion channels. They are present in very high concentration compared to other stored antibacterial peptides (about. 5% of total neutrophil weight).

Bactericidal Permeability-increasing Protein

Bactericidal permeability-increasing protein has antibacterial activity against certain gram-negative bacteria.[24–28] It also has the property of neutralizing the toxic effects of endotoxin.

Ficolin-1

Ficolins are soluble molecules that form part of the innate immune system. They can act as pattern recognition molecules, and recognize carbohydrates on microorganisms and damaged cells. As part of the innate immune system, ficolins can bind a serine protease and activate the complement system via the lectin pathway. Ficolin-1 has been shown to be present in both gelatinase granules, and also a readily exocytosable gelatinase-poor granule.[17] Ficolin-1 becomes associated with the surface membrane following stimulated release.

Other Granule Proteins

Leukocyte granules from humans, rabbits, guinea pigs, and chickens contain several other basic proteins that migrate toward the cathode on electrophoresis in agarose and exhibit antimicrobial activity.[24,515] These proteins differ from species to species,[24,515] and their relative importance as antimicrobial agents probably also varies. For example, because chicken leukocytes lack MPO, the cationic proteins presumably are of greatest importance in that species. In rabbit heterophils[518] and in chicken[519] and human[19–21] polymorphs, the cationic proteins are located in the primary granules and are delivered into the phagosome, where they coat the bacteria and are presumed to kill them.[23,515] Other antibacterial granule components include azurocidin[29,30] and the serine proteinases elastase, cathepsin G, and proteinase 3.[31–34,520]

Digestion

Digestion of bacteria is demonstrated both by changes in the morphologic appearance of organisms after phagocytosis and by the release of labeled fragments of bacteria into the surrounding

medium.[520,521] Digestion is thought to result from the action of the acid hydrolytic enzymes released into the phagosome from the primary lysosome. Metabolic blocking agents, such as iodoacetate, cyanide, and arsenite, which inhibit glycolysis and respiration, have no effect on digestion once the bacteria are within the cell.[522] Some bacteria ingested by neutrophils (e.g., certain pneumococci) may be killed and digested slowly, the undigested material remaining as myelin or residual bodies.

Unsuccessful Ingestion, Killing, or Digestion

Phagocytosis and bacterial killing are not always completed successfully. Some organisms (e.g., certain virulent staphylococci) may survive and multiply within neutrophils and appear to kill them, thus overcoming the defense mechanism.[523] Still other materials ingested by neutrophils, such as the uric acid crystals of gout or the hydroxyapatite crystals of pseudogout, may cause a breakdown of the phagosome wall and release the hydrolytic enzymes into the cell sap.[524] This action may be fatal to the cell, which then lyses and releases its enzymes into the surrounding tissues, where they cause tissue damage and secondary inflammation. In certain streptococcal and other infections, bacterial exotoxins (e.g., streptolysin) are released and damage the phagosomal membrane, thus killing the cell in a similar manner[525]; the infecting organism is freed in the process. Also, certain vitamins (vitamin A) and drugs, when incorporated into phagosomal membranes, render the membranes fragile and readily susceptible to rupture, thereby leading to inflammation.[525]

Secretory Functions of the Neutrophil

While the contents of the neutrophil can be released passively as a result of cell lysis, a variety of substances probably are actively secreted by leukocytes in vitro. Most of these substances have been shown to originate from the granule (including secretory vesicle) fraction. Specific granule contents (lactoferrin, B_{12}-binding protein, or both) are released before primary granule contents, and tertiary granules and secretory vesicles are secreted even more rapidly and completely, providing evidence for a differential secretion of granule contents.[526] Because some of these substances are present in plasma normally and the concentration increases in patients with diseases involving the neutrophil system,[527–529] some authors suggest that neutrophils may serve a secretory function as well as a phagocytic role in vivo.[530,531]

Two modes of enzyme release or exocytosis are (a) release into phagocytic vacuoles (including release outside the cell during phagocytosis but before the phagosome is sealed off from the exterior of the cell, or release during attempted phagocytosis that cannot be completed because of particle size) [531]; and (b) granule content release that is not associated with phagocytosis—that is, true secretion.[526]

Among the well-studied released granule proteins are the B_{12}-binding proteins or transcobalamins. Granulocytes contain and actively release B_{12}-binding protein.[530,532] It appears that transcobalamin III is derived from granulocytes; it is unsaturated with B_{12}.[533] Markedly elevated transcobalamin I levels are seen in cases of chronic myelocytic leukemia and myeloid metaplasia; low values occur in patients with chronic leukopenia and aplastic anemia,[534] and good correlation with blood granulocyte pool size has been reported.[527]

Lysozyme is present in primary, secondary, and tertiary granules and is also present in monocytes, serum, and tears and other secretions.[529,536] Increased concentrations in serum and urine are found in association with monocytic and myeloblastic leukemias.[528,535] Although it was proposed that serum lysozyme may provide a measure of GTR,[536] lysozyme is present in several cell types, and the GTR does not correlate with serum lysozyme levels in neutropenic patients. In addition, the plasma kinetics of lysozyme do not mirror the kinetics of other neutrophil granule proteins or short-term alterations in the number of circulating neutrophils (in contrast to the kinetics of lactoferrin and gelatinase).[529]

Stimulated neutrophils also synthesize and release a variety of cytokines that may regulate the inflammatory response. For example, neutrophils stimulated with lipopolysaccharides synthesize IL-1, TNF-α, and IL-1 receptor antagonist,[79] whereas GM-CSF induces synthesis of TNF-α and IL-6.[80,81] Neutrophil gene expression has two major peaks, one during marrow development when much of the granule content is synthesized, and one when the neutrophil leaves the circulation and enters tissues. On entering the tissue, neutrophils begin to synthesize proteins and cytokines, including ones that might attract monocytes, lymphocytes, and other neutrophils, and assist wound healing.[82] In general, diapedesis seems to induce an antiapoptotic state, while phagocytosis seems to promote apoptosis, at least partly by upregulating death receptors, thus providing the conditions for resolution of inflammation and avoidance of tissue damage.[82]

Some granule proteins originally viewed as primarily antimicrobial agents may have other effects as well. For example, neutrophil serine proteases also appear to play a regulatory role in granulopoiesis by antagonizing growth factor effects.[537–539] Mutations in neutrophil elastase result in many cases of cyclic and severe congenital neutropenia.[539] The defensins (HNP-1 to -3) also can regulate lipoprotein metabolism by stimulating the binding of lipoprotein(a) and low-density lipoprotein to vascular cells, and can regulate smooth muscle cell contraction.[540]

Inflammasomes

IL-1β, a member of the IL-1β family of cytokines, is involved in many inflammatory responses. Toll-like (TLR) binding to pathogen-associated molecular patterns (PAMPs) results in transcription of the IL-1β precursor pro-IL-1β. Pro-IL-1β is processed by a multi-molecular complex termed the inflammasome, which converts pro-caspase-1 to its active form, which then cleaves pro-IL-1β to IL-1β. Inflammasomes are present in both neutrophils and macrophages. In neutrophils, LPS activates the caspase-1 inflammasome, resulting in IL-1β production.[541] Studies also suggest that other neutrophil proteases, including elastase, proteinase 3, and cathepsin G, can also process pro-IL-1β to its active form.[542] The inflammasome may be an important component of the regulation of gene expression in neutrophils when they extravasate into the tissue at sites of inflammation.

Neutrophil Extracellular Traps (NETs)

Studies have observed that under some conditions neutrophils can extrude DNA, histones, and granule contents to form structures termed NETs.[543] Although studies have also reported that microbes can be trapped in these NETs and killed, at present there is some controversy as to their physiologic role.[544]

Other Effects of Oxygen Metabolites

Reactive oxygen metabolites may also contribute to the physiologic effects of activated neutrophils by activating latent enzyme activities of granule proteases such as collagenase.[545] The significance of this process for bacterial killing is unclear but is relevant to other pathophysiologic processes.

Superoxide produced by neutrophils may also stimulate fibroblast proliferation and wound healing, as well as lymphocyte proliferation[546,547]; and also may regulate gene expression and the function of some enzymes, including protein kinases.[548]

Neutrophil Antigens

Neutrophil antigens have been identified by the use of both monoclonal antibodies and patient sera using classic blood-banking

techniques. Some neutrophil antigens defined by monoclonal antibodies are shown in Table 7.2. Neutrophil antigens relevant to blood banking and immune neutropenia are discussed more fully in Chapters 21 and 22. The first clinically relevant neutrophil antigens were described by Lalezari et al. and termed NA1 and its allele NA2, and a second antigen termed NB1. The NA1 and NA2 alleles were found to be present on the glycosyl phosphatidylinositol–linked receptor FcγRIIIB.[549,550] The NB1 antigen (HNA-2a) [551] is present on an N-glycosylated, glycosyl phosphatidylinositol–linked 58- to 64-kDa protein that is present in secondary granules as well as the cell surface.[552–554] The NB1 antigen is also known as CD177, and is upregulated on the cell surface with stimulation. NB1/CD177 also functions as a binding partner for PECAM-1 (CD31) on endothelial cells. Interestingly, the ability of CD177-positive neutrophils to migrate through endothelial cell monolayers correlates with a specific endothelial cell PECAM-1 polymorphism in a region that is the putative binding site of CD177.[555] Thus, CD177/PECAM-1 binding appears to affect neutrophil transmigration across the endothelial lining.

Subsequently, a new nomenclature was established.[556,557] In this system the antigens are termed HNA, for human neutrophil antigen, with the protein/antigen denoted by an integer, and the epitope by a letter. In this system NA1 became HNA-1a, NA2 became HNA-1b, and NB1 became HNA-2a (Table 7.9). Most clinically relevant allo- and autoantibodies appear to react with the HNA-1 and HNA-2 systems. Transfusion-related acute lung injury (TRALI) is a major cause of transfusion-related mortality, and is often due to antibodies against HNA-3a. The HNA-3a antigen results from a nucleotide polymorphism in the choline transporter-like protein-2 gene (SLC44A2).[558,559] Some differences in neutrophil function have been reported based on HNA phenotype. For example, neutrophils that are homozygous for HNA-1b have a lower affinity for IgG3, and phagocytose targets opsonized with IgG1 and IgG3 at a lower rate than neutrophils homozygous for HNA-1a.[560–562] HNA-1a is typically expressed on about 45% to 65% of circulatory neutrophils,[556,563] but on about 90% of circulating neutrophils in healthy people receiving G-CSF for several days.[564]

Infections That Exhibit Tropism for Neutrophils

Human granulocytic anaplasmosis (previously known as human granulocytic ehrlichiosis) is a tick-borne zoonosis caused by *Anaplasma phagocytophilum*.[565–569] *Anaplasma phagocytophilum* is an obligate gram-negative intracellular bacterium that targets and replicates in neutrophils and their progenitors, and is related to rickettsia. *Anaplasma phagocytophilum* may target neutrophils via α-(1,3) fucosylated PSGL-1, although it may also use other targets, and replicates in vacuoles that do not fuse with lysosomes, forming microcolonies that appear as morulae.[569] Human granulocytic anaplasmosis is an acute febrile illness accompanied by severe myalgias and headaches, usually occurring within 2 weeks of contact with ixodid ticks. Common laboratory findings include leukopenia, thrombocytopenia, and increased transaminases. Although most patients respond promptly to doxycycline, death has been reported to occur in approximately 5% of reported cases, and complications such as pneumonia, renal failure, and central nervous system damage have been reported. Characteristic intracytoplasmic inclusions in neutrophils (morulae) are not always seen or recognized. Human granulocytic anaplasmosis is closely related to the veterinary pathogen ***Anaplasma phagocytophilum*** that infect granulocytes in cattle.

Francisella tularensis, a gram-negative bacterium that causes tularemia, can evade intracellular killing when ingested by neutrophils, in part by disrupting the respiratory burst.[570] In neutrophils infected with live *F. tularensis,* the NADPH oxidase assembly was disrupted and the cells did not generate reactive oxygen species. At the same time, *F. tularensis* also impaired neutrophil activation by heterologous stimuli. Later in infection, the bacteria can escape the phagosome, and persist in the neutrophil cytosol for at least 12 hours.[570]

TABLE 7.9

NEUTROPHIL ANTIGENS

Antigen System	Antigen Name	Old Name	Molecule
HNA-1	HNA-1a	NA1	FCRgammalllb
	HNA-1b	NA2	FCRgammalllb
	HNA-1c	SH	FCRgammalllb
HNA-2	HNA-2a	NB1	CD117
HNA-3	HNA-3a	5b	SLC44A2
HNA-4	HNA-4a	Mart	CD11b
HNA-5	HNA-5a	Ond	CD11a

CHAPTER 8

THE HUMAN EOSINOPHIL

Paige Lacy, Darryl J. Adamko, Redwan Moqbel

INTRODUCTION

The eosinophil was first described for its characteristic intracytoplasmic granules exhibiting a high affinity for the negatively charged dye, eosin. Although rare in healthy individuals, the eosinophil is prominent in peripheral blood and tissue in association with various disease conditions including allergy,[1,2,3] inflammatory responses against metazoan helminthic parasites,[4,5] and certain skin and malignant conditions. The eosinophil has received special attention for its potential pathophysiologic role in the manifestation of allergic diseases such as asthma, rhinitis, eczema, eosinophilic esophagitis, and Crohn's disease. Disorders of the respiratory tract, particularly allergic asthma and rhinitis, exhibit a strong correlation with the number as well as activation status of infiltrating tissue eosinophils. Similarly, many disorders of the gastrointestinal system exhibit prominent eosinophilic inflammation in the mucosa. The presence of eosinophils in the airway and gut mucosa has been associated with both allergic (IgE-dependent) and nonallergic (IgE-independent) manifestations of disease. Although clinically these conditions have been characterized as either allergic or nonallergic, it appears that the mechanisms underlying recruitment and activation of eosinophils in both types of disease are similar. Despite some difficulties in defining the exact immunologic role of the eosinophil in disease, there is evidence that the eosinophil remains a major effector cell in many types of allergic and nonallergic inflammation.

Eosinophils are mobile, terminally differentiated granulocytes that arise principally from the bone marrow.[6] They are approximately 8 μm in diameter and their nuclei are usually bilobed, although three or more lobes are also often observed. The eosinophil is characterized by large crystalloid granules, also known as secondary or specific granules, as shown in light microscopy by their bright red staining properties with acidic dyes such as eosin (Fig. 8.1). As apparent in electron micrographs, the crystalloid granules contain electron-dense crystalline cores surrounded by an electron-lucent granule matrix (Fig. 8.2). Eosinophils contain up to four other "granule" types: primary granules, small granules, lipid bodies, and small secretory vesicles. Crystalloid granules are membrane-bound and contain a number of highly cationic basic proteins. The latter have been implicated in the tissue damage observed in asthma and other similar allergic conditions. Allergen and parasite-induced eosinophilia have been shown to be T-cell–dependent and are mediated by soluble factors (cytokines) released from sensitized lymphocytes.[7] Recent advances in human eosinophil research have also indicated that eosinophil infiltration into the tissue in allergic-type responses and asthma is regulated by a series of biologic events which includes a complex interplay between immunologic and inflammatory mechanisms including cytokines and chemokines.[1,3]

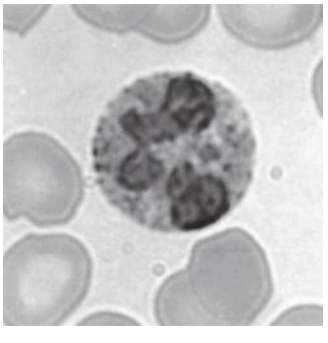

FIGURE 8.1. Photomicrograph of a peripheral blood eosinophil stained with May-Grünwald-Giemsa.

EOSINOPHIL MEDIATORS

The eosinophil is considered to be both a factory and a store for a large array of mediators that are released upon activation and are thought to be important in various inflammatory reactions associated with this cell (Fig. 8.3).

Eosinophil Granule Proteins

Eosinophils contain at least five different populations of phospholipid bilayer membrane-bound granules.

a. Crystalloid granules: these specialized and unique granules measure between 0.5 and 0.8 μm in diameter, contain crystalline electron-dense cores (internum) surrounded by an electron-lucent matrix, and can take up acidic dyes avidly due to their cationic nature.[8,9] They are mainly present in mature eosinophils, although coreless granules have been observed in immature eosinophils. These granules contain the bulk of highly charged cationic proteins present in eosinophils, including major basic protein (MBP), eosinophil peroxidase (EPO), eosinophil cationic protein (ECP), and eosinophil-derived neurotoxin (EDN). There are approximately 200 crystalloid granules in each cell. The core is predominantly comprised of crystallized MBP (Fig. 8.4).
b. Primary granules: these coreless granules are enriched with Charcot-Leyden crystal protein (CLC) and are present mainly in immature eosinophils, although mature eosinophils have been found to contain primary granules as well. Some authors refer to immature crystalloid granules as primary granules in eosinophil promyelocytes. These measure between 0.1 and 0.5 mm in diameter and are less abundant than crystalloid granules.
c. Small granules: these granules are free of cores, are less than 0.1 μm in diameter, and contain acid phosphatase, arylsulfatase B, catalase, and cytochrome b_{558}.
d. Lipid bodies: there are around five lipid bodies per mature eosinophil, the number of which increase in certain eosinophilic disorders, especially in idiopathic hypereosinophilia. Lipid bodies are enriched in arachidonic acid esterified into glycerophospholipids.
e. Secretory vesicles: eosinophils are densely packed with small secretory vesicles in their cytoplasm. These vesicles appear as dumbbell-shaped structures in cross-sections, and contain albumin, suggesting an endocytotic origin. These structures are also known as microgranules or tubulovesicular structures.

Eosinophil MBP (13.8 kDa) is an arginine-rich 117 amino acid protein that constitutes a significant proportion of total cell protein in human eosinophils (5 to 10 pg/cell). MBP was originally named for its abundance in guinea pig eosinophils, which contain as many as 250 pg/cell, making up 50% of the total cellular protein.[10] The high calculated pI point of MBP (11.4) cannot be measured accurately due to the extremely basic nature of the protein.[11] MBP is initially translated as pro-MBP (23 to 25 kDa)

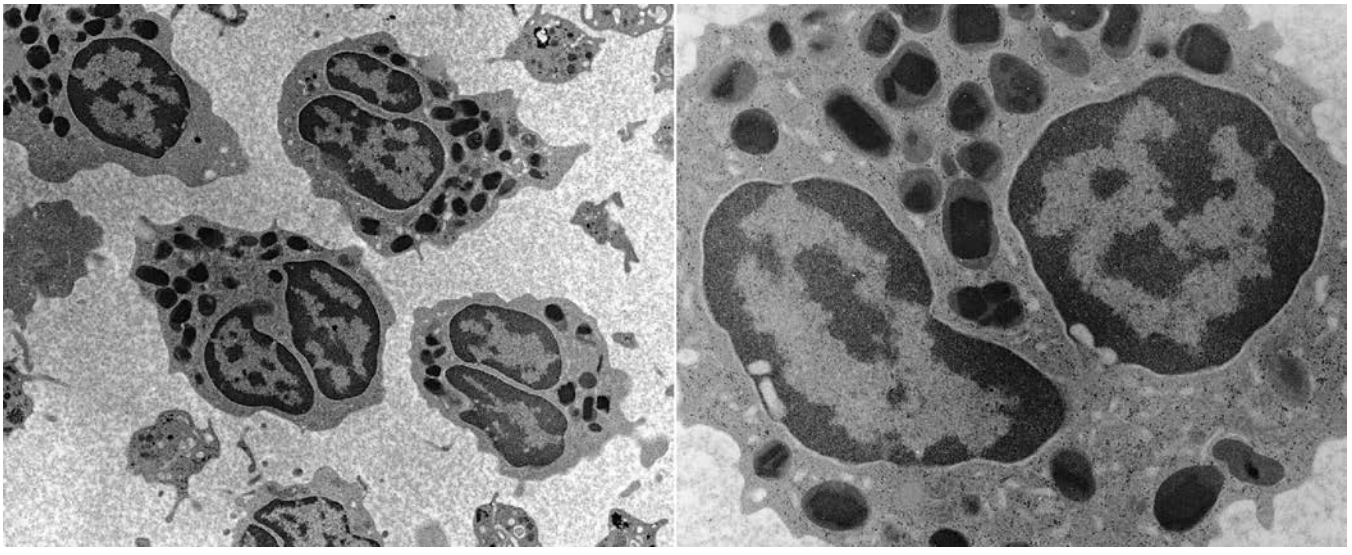

FIGURE 8.2. Electron photomicrographs of peripheral blood eosinophils from buffy-coat. Original magnification 7,655× and 22,000×. Courtesy of Dr. G.E. Quinonez, Department of Pathology, University of Manitoba.

with a calculated pI of 6 to 6.2 in maturing eosinophils.[12,13] The synthesis of MBP is initiated during the promyelocytic stage of eosinophil development, characterized by the presence of message encoding this protein, in a neutral prepro-form which is later processed to form pro-MBP that is subsequently transported to the immature crystalloid granule and cleaved to form MBP.[12,13] The pro-segment of pro-MBP is postulated to protect the cell from cytotoxic effects of MBP during trafficking of pro-MBP from the Golgi apparatus to the crystalloid granule. Mature MBP undergoes condensation from the periphery of immature crystalloid granules to the internum, where it develops a crystalline core as its concentration is increased.[13,14] Once eosinophils have reached full maturity, MBP is no longer synthesized and messenger RNA encoding MBP disappears from the cell.[13,15]

MBP has been shown to exert cytotoxic effects on helminthic parasites and certain bacteria.[8] It is also cytotoxic to human cells and especially airway tissues, including bronchial epithelial cells and pneumocytes, by disruption of cell membrane lipid bilayers.[16] Such disruption leads to cell permeabilization and lysis, and leakage of cell contents to the extracellular milieu. Thus, MBP may be at least partly responsible for tissue damage and neural dysfunction associated with eosinophil infiltration into the bronchial mucosa in asthma.[9,17,18] Indeed, airway sections from patients with status asthmaticus exhibit intense MBP-specific immunofluorescence, suggesting that infiltrated eosinophils were fully activated, undergoing extracellular secretion of their contents of MBP.[19] MBP acts on other inflammatory cells, including neutrophils and eosinophils, to induce degranulation and lipid mediator release.[20,21] Parasympathetic ganglia in the airways of patients dying of asthma exhibit eosinophil infiltration, and MBP is an allosteric antagonist for the M2 muscarinic receptor. Loss of M2 receptor function results in airway hyperreactivity.[18] A homolog of MBP has been recently discovered, MBP2, with a calculated pI of 8.7, that possesses similar activities to MBP in cell killing as well as neutrophil and basophil stimulation, but with reduced potency.[22]

Other eosinophil basic proteins, including EPO, ECP, and EDN, reside in the matrix compartment of the crystalloid granule. EPO is a highly basic (pI of 10.9) heme-containing protein composed of two subunits, a heavy chain of 50 to 57 kDa and a light chain of 11 to 15 kDa. EPO is a haloperoxidase with 68% sequence identity to neutrophil and monocyte-expressed myeloperoxidase, suggesting that a peroxidase multigene family may have developed through gene duplication.[11,23] Eosinophils store approximately 15 pg/cell of EPO, which is important in catalyzing the peroxidative oxidation of halides and pseudohalides, leading to the formation of bactericidal hypohalous acids in reaction with hydrogen peroxide generated during respiratory burst.[24,25,26]

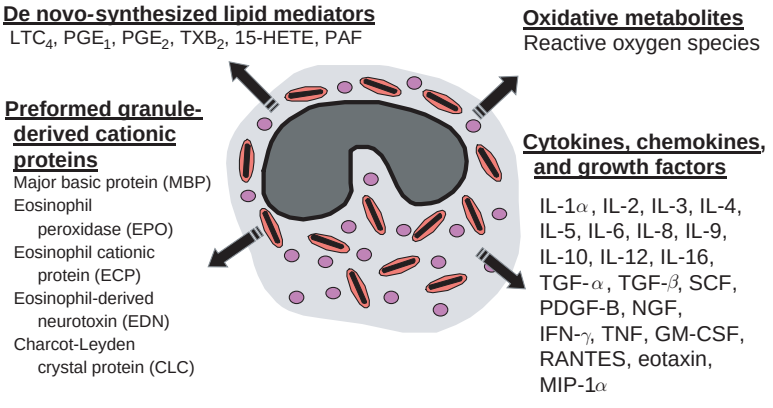

FIGURE 8.3. Mediators released by activated eosinophils. De novo-synthesized lipid mediators and oxidative metabolites are elaborated directly from the cell membrane or lipid bodies following enzyme activation, while granule-derived cationic proteins and cytokines, chemokines, and growth factors are released following granule–plasma membrane fusion during degranulation. GM-CSF, granulocytemacrophage colony-stimulating factor; IFN, interferon; IL, interleukin; MIP, macrophage inhibitory protein; NGF, nerve growth factor; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; PGE_2, prostaglandin E_2; SCF, stem cell factor; TGF, transforming growth factor; TNF, tumor necrosis factor; TXB_2, thromboxane B_2.

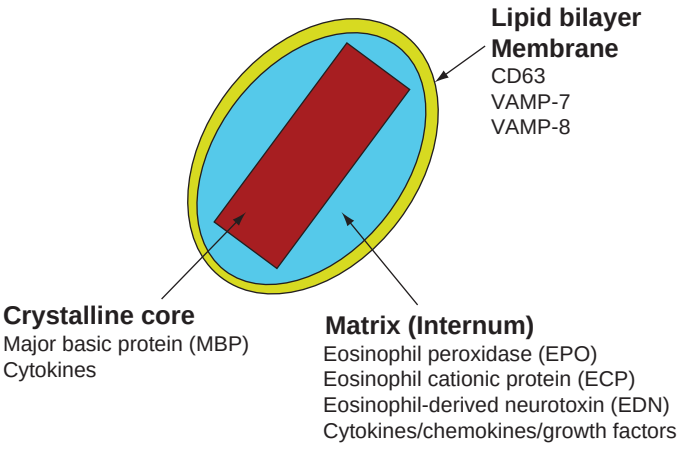

FIGURE 8.4. Structure of the eosinophil crystalloid granule. This membrane-bound organelle is a major site of storage of eosinophil cationic granule proteins as well as a number of cytokines, chemokines, and growth factors.

Unlike myeloperoxidase, EPO preferentially uses bromide over chloride in its enzyme activity, generating hypobromous acid.[27] EPO in the presence of H_2O_2 and halide (usually bromide) kills a variety of microorganisms, but also inflicts collateral damage on host tissue such as mast cells, and possesses antitumor activity. Binding of EPO to bacterial and parasitic pathogens also enhances their killing by phagocytic cells.

The molecular mass of ECP is 15 kDa, with around 15 pg/cell expressed in human eosinophils. The pI of ECP (10.8) is similar to that of MBP due to a similar arginine-rich sequence. ECP, also known as RNase-3, possesses intrinsic ribonuclease (RNase) activity and is a member of a subfamily of RNase A multigenes, with homology to pancreatic RNase. It is also antiviral, bactericidal, promotes degranulation of mast cells, and is toxic to helminthic parasites.[28–31] The mechanism of action of ECP is thought to involve the formation of pores or channels in the target membrane, which is apparently not dependent on its reversible RNase activity.[32] ECP is also neurotoxic as derived from its ability to elicit the Gordon phenomenon, involving the destruction of nerve cells.[33,34]

EDN, another member of the RNase A multigene family of 18.5 kDa with approximately a hundredfold higher RNase activity than ECP, is less basic than MBP or ECP with a pI of 8.9 due to a relatively smaller number of arginine residues in its sequence. ECP and EDN share a remarkable sequence homology of 67% at the amino acid level for the pre-form of both proteins, suggesting that evolutionarily, these proteins are derived from the same gene.[35,36] Eosinophils express approximately 10 pg/cell of EDN, but there is marked variation between individuals. EDN also induces the Gordon phenomenon.[33,34] Similar to ECP, EDN also has significant toxicity against viruses, bacteria, and helminths.[31,37] Messenger RNA encoding EPO, ECP, and EDN has been detected in mature eosinophils, suggesting that eosinophils have the capacity to continue to synthesize these proteins.[15]

The gene family expressing ECP and EDN has among the highest rates of mutation in the primate genome, ranking with those of immunoglobulins, T-cell receptors, and major histocompatibility complex (MHC) classes.[36] These genes effectively comprise a superfamily of RNases expressed in the mammalian genome. Such an extreme rate of mutation suggests that the evolutionary constraints acting on the ECP/EDN superfamily have promoted the acquisition of a specialized antiviral activity. This may be inferred from the high mutation rates of other genes commonly associated with host protection against viral infection. Whether ECP or EDN possess any antiviral activity has yet to be demonstrated, although some studies have indicated that EDN may be a potent antiviral factor in respiratory infections.[31]

The CLC protein (17.4 kDa) is produced in eosinophils at very high levels (accounting for 10% of the total cellular protein) although its functional role is still obscure. CLC is a hydrophobic protein with lysophospholipase activity and bears a strong sequence homology to the carbohydrate-binding galectin family of proteins. For this reason, CLC protein has been designated galectin-10.[38] CLC is released in large quantities in the tissues in eosinophilic disorders, resulting in the formation of distinct, needle-shaped structures which are colorless and measure 20 to 40 μm in length and 2 to 4 μm across. CLC crystals are abundant in the sputum and feces of patients with severe respiratory and gastrointestinal eosinophilia, which were first observed by Charcot and Robin in 1853.

A list of these and other granule proteins synthesized and stored in eosinophils is presented in Table 8.1 and published elsewhere.[1,2,39–41]

Eosinophil-derived Cytokines, Chemokines, and Growth Factors

Human eosinophils have been shown to produce at least 30 different cytokines, chemokines, and growth factors (Table 8.2) with the potential to regulate various immune responses. These cytokines have been identified in eosinophils by detecting mRNA and/or protein using RT-PCR, in situ hybridization, and immunocytochemical staining.[42,43,44,45] In addition, picogram amounts of cytokines, chemokines, and growth factors were measured in supernatants of stimulated eosinophils.[43,46] These cytokines are likely to act in an autocrine, paracrine, or juxtacrine manner, thereby regulating local inflammatory events. Studies have demonstrated that the production of eosinophil-activating cytokines (e.g., IL-3 and GM-CSF) by eosinophils may be important in prolonging the survival of these cells by a putative autocrine loop.[43,47] For instance, adherence of highly purified eosinophils to the extracellular matrix protein, fibronectin, resulted in prolongation of survival of these cells in the absence of exogenous cytokines.[47] Fibronectin-induced eosinophil survival was inhibitable by antibodies against fibronectin and VLA-4 and up-regulated by picogram amounts of IL-3 and GM-CSF derived from eosinophils.[47] Observations on eosinophil cytokine release have been mainly studied in vitro, but a few have been confirmed in vivo.[48–51] A recent study demonstrated that eosinophils elaborate APRIL (a proliferation-inducing ligand) and IL-6 which were essential for maintaining plasma cells in the bone marrow.[52]

A major distinction in cytokine production between eosinophils and T-cells is that the former store their cytokines intracellularly as pre-formed mediators, and the latter produce and release cytokines only following activation. Although many eosinophil-derived cytokines are elaborated at lower concentrations than other leukocytes, eosinophils possess the ability to release these cytokines immediately (within minutes) following stimulation. Stored cytokines include IL-2, IL-4, IL-5, IL-6, IL-10, IL-13, IL-16, GM-CSF, TNFα, CC chemokine ligand 11 (CCL11)/eotaxin, IL-8, CCL5/RANTES, NGF, and TGFα.[45] Studies using immunogold electron microscopic analysis or confocal laser scanning microscopy coupled with double immunofluorescence labeling have indicated that several of these cytokines are found in close association with either the crystalline core or matrix of the crystalloid-specific granules of the cell (Table 8.2).[44,53,54–56,57,58] For example, CCL5/RANTES was found to be associated predominantly with the matrix compartment of the crystalloid granule in eosinophils (Fig. 8.5).

TABLE 8.1

CONTENT OF HUMAN EOSINOPHIL GRANULES AND SECRETORY VESICLES

Crystalloid Granules	Primary Granules	Small Granules	Lipid Bodies	Secretory Vesicles
Core				
Catalase				
Cathepsin D				
Enoyl-CoA-hydrolase				
β-Glucuronidase				
Major basic protein				
Matrix				
Acid phosphatase	Charcot-Leyden crystal protein (galectin-10)	Acid phosphatase	Arachidonic acid	Plasma proteins [Albumin]
Acyl-CoA oxidase		Arylsulfatase B (active)	Cyclooxygenase	
Arylsulfatase B (inactive)		Catalase	Eosinophil peroxidase	
Acid β-glycerophosphatase		Elastase	Esterase	
Bactericidal/permeability-increasing protein		Eosinophil cationic protein	5-Lipoxygenase	
Catalase			15-Lipoxygenase	
Cathepsin D			LTC_4 synthase	
Collagenase				
Elastase				
Enoyl-CoA-hydrolase (also in core)				
Eosinophil cationic protein				
Eosinophil-derived neurotoxin				
Eosinophil peroxidase				
Flavin adenine dinucleotide (FAD)				
β-Glucuronidase				
β-Hexosaminidase				
3-Ketoacyl-CoA thiolase				
Lysozyme				
Major basic protein				
Phospholipase A_2 (Type II)				
Nonspecific esterases				
Membrane				
CD63		VAMP-7		Cytochrome b_{558} [p22*phox*]
V-type H^+-ATPase		VAMP-8		VAMP-2
VAMP-7				VAMP-7
VAMP-8				VAMP-8

Developing eosinophils possess the ability to express cytokine message and protein at early stages of maturation. Eosinophils generated from semi-solid culture of cord blood-derived $CD34^+$ cells in the presence of IL-3 and IL-5 were shown to express IL-5 and GM-CSF mRNA after 10 days of culture.[59] Freshly purified $CD34^+$ cells expressed IL-4 and CCL5/RANTES mRNA, but not IL-4 and CCL5/RANTES protein. On day 23 of culture, IL-4 and CCL5/RANTES localized to the matrix of MBP^+ crystalloid granules as determined by immunofluorescence.[60] In addition, IL-6 protein expression was found in cells after day 16 of culture.[14]

Another site of storage of cytokines and chemokines is within the small secretory vesicle. At least two such proteins were shown to be associated with these vesicles, namely CCL5/RANTES and TGFα immunolabeling.[44,61] These organelles belong to the same group of secretory vesicles identified by electron microscopy analysis as tubulovesicular structures. CCL5/RANTES-positive vesicles are highly sensitive to stimulation by IFNγ and are rapidly mobilized (within 10 minutes of stimulation) to secrete CCL5/RANTES extracellularly.[44,62] Crystalloid granules, which also contain CCL5/RANTES within their matrix compartment, were found to release this chemokine more slowly in response to IFNγ (1 hour), whereas the majority of MBP remained associated with the core of these granules. These observations suggest that eosinophils have the ability to "shuttle" CCL5/RANTES from the crystalloid granules to the cell exterior, and may provide an important in vitro model for eosinophil piecemeal degranulation.

Eosinophil Degranulation

Degranulation is defined as the exocytotic fusion of granules with the plasma membrane during receptor-mediated secretion. During exocytosis, the outer leaflet of the lipid bilayer membrane surrounding the granule encounters the inner leaflet of the plasma membrane,

TABLE 8.2

CYTOKINES, CHEMOKINES, AND GROWTH FACTORS PRODUCED BY HUMAN EOSINOPHILS

Cytokine	Products	Stored Protein in Resting Cells (per 10^6 cells)	Intracellular Site of Storage
Interleukins			
Interleukin-1α	mRNA, protein	–	–
Interleukin-2	mRNA, protein	6 ± 2 pg	Crystalloid granules (core)
Interleukin-3	mRNA, protein	–	–
Interleukin-4	mRNA, protein	~75 ± 20 pg	Crystalloid granules (core)
Interleukin-5	mRNA, protein	–	Crystalloid granules (core/matrix?)
Interleukin-6	mRNA, protein	25 ± 6 pg	Crystalloid granules (matrix)
Interleukin-9	mRNA, protein	–	–
Interleukin-10	mRNA, protein	~25 pg	–
Interleukin-11	mRNA	–	–
Interleukin-12	mRNA, protein	–	–
Interleukin-13	mRNA, protein	–	–
Interleukin-16	mRNA, protein	1.6 ± 0.8 ng	–
Leukemia inhibitory factor (LIF)	mRNA, protein	–	–
Interferons and Others			
Interferon-γ (IFNγ)	mRNA, protein	–	–
APRIL (a proliferation-inducing ligand)	Protein	–	–
Granulocyte/macrophage colony-stimulating factor (GM-CSF)	mRNA, protein	15.1 ± 0.3 pg	Crystalloid granules (core)
Tumor necrosis factor (TNF)	mRNA, protein	–	Crystalloid granules (matrix)
Chemokines			
Eotaxin	mRNA, protein	19 ± 4 pg	Crystalloid granules
Interleukin-8	mRNA, protein	140 pg	Cytoplasmic
Macrophage inflammatory protein-1α (MIP-1α)	mRNA, protein	–	–
Monocyte chemoattractant protein-1 (MCP-1)	Protein	–	–
MCP-3	mRNA	–	–
MCP-4	mRNA	–	–
RANTES	mRNA, protein	72 ± 15 pg	Crystalloid granules (matrix) and small secretory vesicles
Growth Factors			
Heparin-binding epidermal growth factor-like binding protein (HB-EGF-LBP)	mRNA, protein	–	–
Nerve growth factor (NGF)	mRNA, protein	4 ± 2 pg	–
Platelet-derived growth factor, B chain (PDGF-B)	mRNA	–	–
Stem cell factor (SCF)	mRNA, protein	–	Membrane, cytoplasm
Transforming growth factor-α (TGFα)	mRNA, protein	22 ± 6 pg	Crystalloid granules (matrix) and small secretory vesicles
Transforming growth factor-β1 (TGF-β1)	mRNA, protein	–	–

a process known as "docking." The docking step is hypothesized to be regulated by intracellular membrane-associated proteins that act as receptors directing the specificity of granule targeting. After docking, the granule and plasma membrane fuse together and form a reversible structure called the fusion pore, which is also thought to be regulated by similar, or the same, membrane-associated proteins regulating granule docking. Depending on the intensity of the stimulus, the fusion pore may either retreat, leading to re-separation of the granule from the plasma membrane, or it may expand and allow complete integration of the granule membrane into the plasma membrane as a continuous sheet. The inner leaflet of the granule membrane becomes outwardly exposed, and the granule contents are subsequently expelled to the exterior of the cell.[63]

There are four main forms of eosinophil granule release, which have been observed in vitro and in vivo (Fig. 8.6). The first is the classical sequential release of single crystalloid granules, which was the original hypothesis suggested for a predominant route of degranulation in eosinophils. This type of release is typically seen in vitro and can be elegantly demonstrated electrophysiologically using patch-clamp procedures that measure changes in membrane capacitance, which are directly proportional to increases in the surface area of the cell membrane. During the

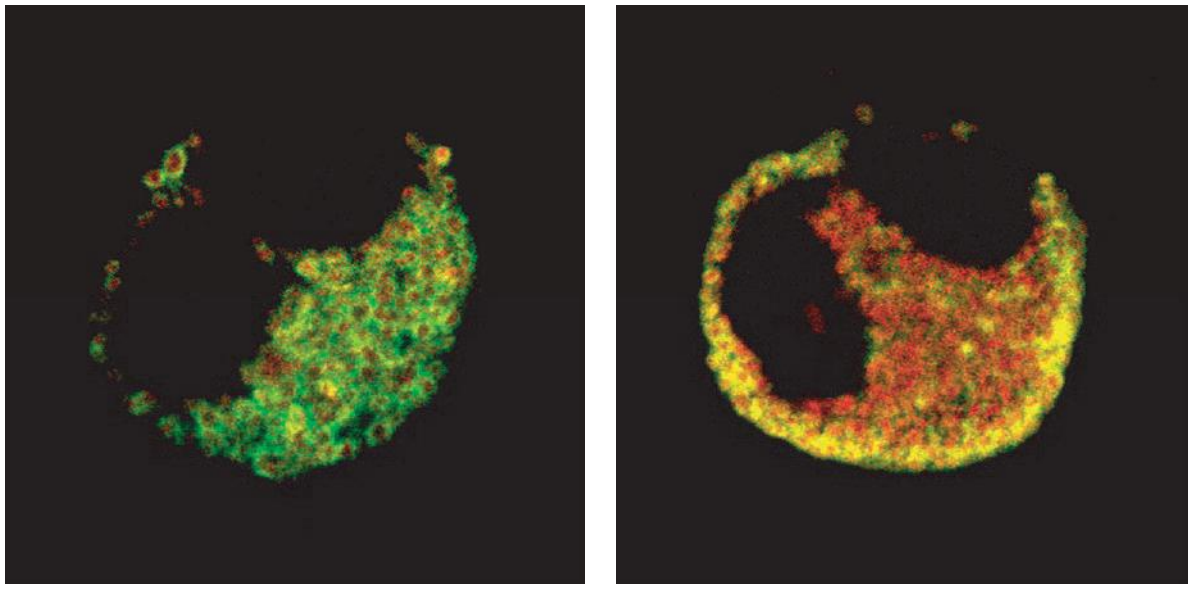

FIGURE 8.5. Translocation of the chemokine CCL5/RANTES in human eosinophils activated by interferon-γ in vitro. Immunoreactivities for CCL5/RANTES (green fluorescence) and eosinophil major basic protein (red fluorescence) are shown in control **(A)** and IFN-γ-stimulated (10 min, 500 U/ml) **(B)** cells. The yellow color in **(B)** resulted from co-localization of green and red immunofluorescence stains. Note that immunoreactivity for MBP remained associated with the cores of the crystalloid granules in both cells, whereas the green label for CCL5/RANTES translocated toward the cell membrane. CCL5/RANTES was proposed to be released from eosinophils by piecemeal degranulation. Experimental conditions described in Lacy et al. (1999) Blood 94:23–32.

sequential release of individual crystalloid granules, a stepwise increment in capacitance may be observed as their membranes fuse with that of the cell membrane.[64,65,66] The second mode of granule release is compound exocytosis, also demonstrated by patch-clamp analysis in which sudden, very large increments in whole-cell capacitance occur resulting from individual granules fusing with the cell membrane.[67] Ultrastructural studies of guinea pig eosinophils have also demonstrated evidence for compound exocytosis [68] similar to that observed in rat eosinophils adhering to the outer surface of opsonized parasitic larvae.[67,69] Additional evidence for compound exocytosis was suggested in eosinophils stimulated with a cocktail of IL-3, IL-5, and GM-CSF, which were observed to fuse their granules following activation as determined by immunofluorescence for CD63, a marker for crystalloid granules.[70]

The third manner in which eosinophils degranulate is by piecemeal degranulation (PMD). PMD was first characterized by Dvorak and colleagues for the appearance of numerous small vesicles in the cytoplasm coupled with the apparent loss of crystalloid granule core and matrix components, creating a "mottled" appearance in the crystalloid granules by electron microscopy analysis.[71] This was thought to be due to small vesicles budding off from the larger secondary granules and moving to the plasma membrane for fusion, thereby causing gradual emptying of the crystalloid granules to the outside of the cell. PMD was the most commonly observed pattern of degranulation seen in situ in biopsy samples from the upper airways of allergic individuals,[72] and is likely to be physiologically the most important mechanism for eosinophil mediator release in allergic disease. An in vitro model for PMD has been established using IFNγ-stimulated eosinophils, in which a piecemeal manner of CCL5/RANTES release was observed.[44,62] More recent studies have demonstrated that PMD occurs through the formation of tubular structures budding off from crystalloid granules.[73,74] Vesicles associated with PMD are also necessary for the transportation of MBP[75] and eosinophil-derived IL-4.[73,76]

Airway tissue eosinophils in allergic subjects also appear necrotic, which is a fourth pattern of granule release, also termed "cytolysis".[77] This type of release has been previously observed to occur following in vitro stimulation of human eosinophils with the calcium ionophore A23187,[78] and appears to be a physiologically relevant event in granule release.

Eosinophil degranulation may be induced by immobilized or soluble stimuli. Degranulation responses to immobilized stimuli have been extensively characterized in eosinophils in view of their role in helminth infections. When incubated with opsonized helminths, eosinophils degranulate onto the surface of the parasite.[69,79] A similar phenomenon occurs when eosinophils are incubated with Sepharose beads coated with antibodies, specifically IgG, IgA, and secretory IgA (sIgA), with sIgA being the most potent inducer of degranulation.[80] Cross-linking of immunoglobulin receptors on eosinophils has been shown to be highly effective at inducing respiratory burst and EDN degranulation in eosinophils, with a hierarchy of effectiveness in degranulation demonstrated to be on the order of secretory IgA (sIgA) = IgA > IgG >> IgE.[80] Eosinophil cytokines such as IL-3, IL-5, and GM-CSF were demonstrated to enhance this process.[81]

Eosinophils express a range of receptors for immunoglobulins that may contribute to chemotactic and activation responses in

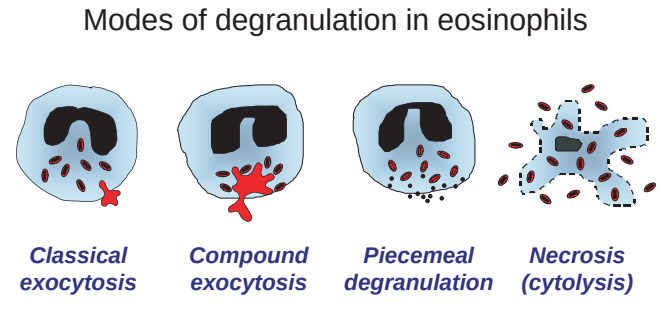

FIGURE 8.6. Four putative physiologic modes of eosinophil degranulation. The most commonly observed forms of degranulation in allergic disease are piecemeal degranulation and necrosis (cytolysis). Parasitic and fungal diseases typically exhibit eosinophils undergoing compound exocytosis.

tissues. These include receptors for IgA, IgD, IgE, IgG, and IgM, which may possess up to three chains (α, β, and γ). Human eosinophils express FcαR, which is enhanced in allergic individuals,[82] as well as FcγRII (CD32), but not FcγRI (CD64) or FcγRIII (CD16). Mucosal tissues are enriched in sIgA, potentially as a mechanism against invasive pathogens. IgA, particularly the secretory isoform, is an important mucosal antibody involved in supporting the body's first line of defense. Thus, the sensitivity of the eosinophil to IgA is in agreement with its proposed role in protection against invasive organisms in mucosal tissues. Taken together, these findings along with eosinophil localization in mucosal tissues suggest an important role for sIgA and IgG in mediating the effector functions of eosinophils in vivo.

Some controversy has surrounded the existence of the high-affinity receptor for IgE (FcεRI) on eosinophils. Studies have shown that the α subunit of FcεRI in eosinophils is expressed intracellularly rather than on the cell surface in resting cells, which may be mobilized to the surface and released during activation.[83,84] Interestingly, although mouse FcεRI contains α, β, and γ subunits, the human homologue lacks the β subunit, suggesting that this subunit is redundant in signaling in cells expressing FcεRI. Eosinophils express an IgE-binding protein, galectin-3 (Mac-2/ε binding protein), as well as the low-affinity FcεRII (CD23), which may have contributed to apparent high-affinity binding for IgE in earlier studies.

Degranulation from eosinophils may also be induced by a range of soluble stimuli. Cytokines and chemokines induce eosinophil degranulation, with IL-5 and GM-CSF having a more potent effect than CCL3/MIP-1α or CCL5/RANTES.[85,86,87] Eosinophil granule proteins (MBP and EPO) themselves can cause degranulation, suggesting that eosinophil granule proteins may promote degranulation in an autocrine manner.[21] Many other soluble stimuli can also induce degranulation, including complement fragments C3a and C5a, f-Met-Leu-Phe, PAF, and naturally occurring peptides such as substance P and melittin.[88,89] In addition, artificial stimuli potently evoke degranulation such as calcium ionophore (A23187) and phorbol myristate acetate (PMA).[78,90] In particular, PAF is a potent secretagogue for eosinophils, inducing the release of granule proteins, reactive oxygen species, and lipid mediators.[89,91,92] Furthermore, PAF activates at least two distinct effector pathways in eosinophils, one of which is independent of known PAF receptors.[91,93] Eosinophils also respond by degranulation to endogenous molecules released by stressed or damaged tissues. These include uric acid, ATP, high mobility group box (HMGB)-1 protein, and the S100 family of calcium-binding proteins.[94–96] Recently, eosinophils have been shown to express a newly discovered seven-transmembrane receptor, the chemoattractant receptor–homologous molecule expressed on Th2 cells (CRTh2),[97] which responds to prostaglandin D_2, a major prostanoid released by mast cells. PGD_2 induces morphologic changes, chemokinesis, and degranulation in eosinophils through CRTh2.

A role for eosinophils and their degranulation in the maintenance of innate immunity has been shown by their expression of Toll-like receptors (TLRs), which serve a role in recognition of conserved motifs in pathogens.[98] Eosinophils express the lipopolysaccharide (LPS)-binding receptor, TLR4, together with CD14,[99,100] and respond to LPS stimulation. Furthermore, eosinophils constitutively express TLR1, TLR7, TLR9, and TLR10 mRNAs, and are activated by the TLR7 ligand.[101] This may represent an important mechanism for eosinophil-mediated host defense against viral and bacterial infections.

Proteolytic enzymes also have the capacity to induce eosinophil degranulation. These are produced by microbes and are also present in various allergens, including house dust mites, fungi, and cockroaches. These enzymes interact with a family of G protein-coupled protease-activated receptors (PARs), and eosinophils constitutively transcribe mRNA for PAR2 and PAR3, but not PAR1 or PAR4.[102] Exposure of eosinophils to trypsin, a potent serine protease that serves as an agonist for PAR2, induces respiratory burst and degranulation in eosinophils. Eosinophils also degranulate in response to cysteine proteases such as those from cockroaches and *Der f 1* from mite allergens.[103,104] Finally, eosinophils can degranulate in response to aspartate proteases produced by the fungus *Alternaria alternata*.[105] These findings suggest that eosinophils are able to recognize and respond to proteases in the environment, and that this results in the release of proinflammatory mediators.

Eosinophils also undergo degranulation upon stimulation of a β_2 integrin, Mac-1 (CD11b/CD18, $\alpha M\beta 2$). This molecule has multiple roles in eosinophils; it is not only important in eosinophil adhesion and recruitment but also for activation of eosinophil effector functions. Integrins and especially Mac-1, play a crucial role in eosinophil activation by immobilized stimuli such as IgG.[106] Degranulation responses induced by soluble stimuli are potently enhanced by adhesion of eosinophils through integrins. Moreover, Mac-1 can directly recognize fungal molecules such as β-glucan, and eosinophils react by degranulation to fungi through this mechanism.[107] Thus, integrins play a major role in recognition of external pathogens and in eosinophil effector functions.

The mechanisms associated with classical exocytosis, compound exocytosis, and PMD, but not cytolysis, are thought to require specific intracellular membrane-associated proteins acting as receptors for granule docking and fusion. These proteins include a family of molecules known as SNAREs (an acronym for *SNA*P *re*ceptors). The paradigm associated with the SNARE molecule function predicts that these proteins are essential for exocytosis. SNAREs were originally described in neuronal tissues and were found to group themselves into two distinct locations, the granule-associated SNAREs (the so-called vesicular SNAREs or v-SNAREs) and the plasma membrane-associated SNAREs (target SNAREs or t-SNAREs).[108] In order for a functional SNARE complex to form, allowing the granule to dock with the plasma membrane, one v-SNARE binds to two t-SNARE molecules. In neuronal cells, a commonly observed v-SNARE is vesicle-associated membrane protein (VAMP)-1 or its isoform VAMP-2. In these cells, the t-SNAREs associating with VAMP-2 that were originally described were the synaptosome-associated protein of 25 kDa (SNAP-25) and syntaxin-1A. These three molecules form a stable detergent-resistant four-helix coiled-coil bundle, which may be regulated by protein phosphorylation.

Nonneuronal cells also express SNAREs, although some isoforms have been identified with high sequence homology to the neuronal SNAREs. At least three SNAP-25 and 16 syntaxin isoforms have been characterized based on detection of homologous SNARE motif messenger RNA sequences. Interestingly, most nonneuronal secretory cells appear to require SNAP-23 and syntaxin-3, syntaxin-4, or syntaxin-6 [109–111] for control of exocytosis. Eosinophils have been shown to express the v-SNARE, VAMP-2, in their small secretory vesicles containing CCL5/RANTES, but not their crystalloid granules.[112] Crystalloid granules express mainly VAMP-7 and VAMP-8, the former being important in regulation of crystalloid granule secretion during degranulation responses from permeabilized eosinophils.[113] The t-SNARE isoforms syntaxin-4 and SNAP-23 are expressed in the cell membrane of eosinophils, and these have the potential to act as cognate membrane binding partners for VAMP-2 and VAMP-7 degranulation.[114] The SNARE molecules VAMP-2, SNAP-23, and syntaxin-4 identified in eosinophils are proposed to regulate docking and fusion of CCL5/RANTES-containing small secretory vesicles during piecemeal degranulation (Fig. 8.7).

A fascinating study has identified a hitherto unrecognized functional capacity for eosinophil granules that have been cytolytically released extracellularly (cell-free), a phenomenon known to occur in vivo.[115] Isolated eosinophil granules were shown to respond to specific cytokine and chemokine stimuli via cognate receptors expressed on granule membranes, in

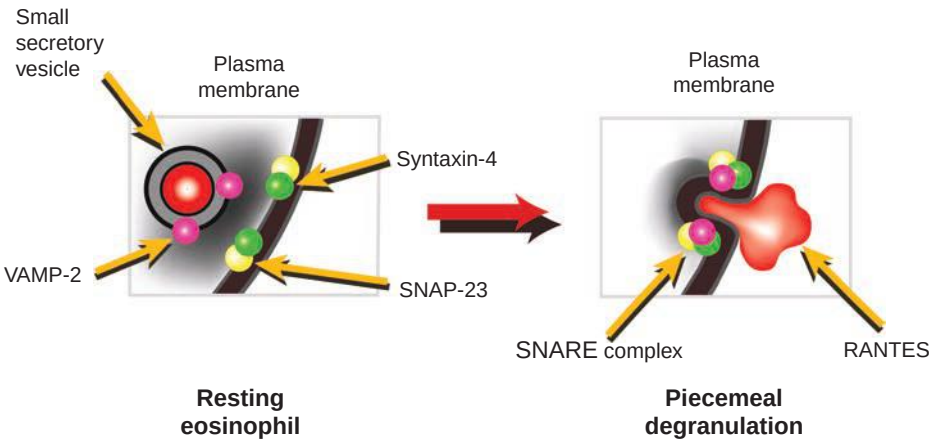

FIGURE 8.7. Schematic model for molecular regulation of granule–plasma membrane fusion proposed to occur in piecemeal degranulation in eosinophils. In this model, the v-SNARE VAMP-2 is expressed on small secretory vesicles that store CCL5/RANTES as a preformed mediator, and t-SNAREs, SNAP-23, and syntaxin-4 reside on the inside of the plasma membrane. Following cell activation, v- and t-SNAREs bind together to form a SNARE complex, resulting in fusion and release of vesicular contents including CCL5/RANTES. (See Lacy P, Logan MR, Bablitz B, Moqbel R. Fusion protein vesicle-associated membrane protein 2 is implicated in IFN-g-induced piecemeal degranulation in human eosinophils from atopic individuals. J Allergy Clin Immunol 2001;107:671–678 and Logan MR, Lacy P, Bablitz B, Moqbel R. Expression of eosinophil target SNAREs as potential cognate receptors for vesicle-associated membrane protein-2 in exocytosis. J Allergy Clin Immunol 2002;109:299–306.

vitro.[116] These cytokine and chemokine receptors were found expressed on the granule membrane, in the same orientation as those on plasma membranes. Stimulating cell-free granule receptors resulted in activation of intragranular signaling pathways, which in turn, elicited secretion of cytokines and cationic proteins from within granules.[116] This study has identified a novel postcytolytic capacity of intracellular organelles to function autonomously outside the eosinophil as ligand-responsive secretion competent structures for regulated secretion of eosinophil granule proteins. Such observations have implications for the notion that tissue-discharged, intact eosinophil granules may continue to contribute to eosinophil-mediated inflammation and immunomodulation.

Mechanisms associated with granule release in eosinophils are critical for effector function of eosinophils. In the absence of degranulation and mediator secretion, the eosinophil is a relatively inert cell, and does not affect surrounding tissues, as seen in cases of idiopathic pulmonary eosinophilia and eosinophilic pneumonia. In these conditions, eosinophil numbers are increased in the capillaries and tissues of the lung, but no cellular or structural damage is evident, likely because of the lack of eosinophil degranulation. In contrast, asthmatic patients show profound eosinophil activation in the airways combined with significant tissue destruction, suggesting that, in addition to eosinophilic infiltration, their undergoing degranulation may contribute to mucosal damage in the airways and related symptoms of asthma. Thus, degranulation is a key event in eosinophil-mediated tissue damage.

Membrane-derived Mediators

Eosinophils produce a wide variety of lipid-derived mediators, which have profound biologic activity. The more important products are eicosanoids, which include leukotrienes (especially LTC_4), prostaglandins (particularly PGE_2), thromboxane, and lipoxins (especially LXA_4) as well as PAF. The main substrate for these mediators is arachidonic acid (AA), which is specifically liberated from membrane phospholipids possessing this fatty acid at the *sn*-2 position by phospholipase A_2 (PLA_2) during receptor stimulation. Of the nine known families of PLA_2, two families are expressed in eosinophils, the type IIA and type IV enzymes, which are commonly known as secretory and cytosolic PLA_2, respectively.[117,118] These enzymes are distinguished by their distribution, size, and sensitivity to Ca^{2+}, where granule-stored $sPLA_2$ (13 to 15 kDa) requires millimolar amounts of Ca^{2+} for activity and cytosolically localized $cPLA_2$ (85 kDa) is catalytically active in the presence of micromolar amounts of Ca^{2+}. Interestingly, eosinophils express twenty- to a hundredfold higher levels of secretory PLA_2 in their granules than other circulating leukocytes, suggesting a functional role in inflammatory processes involving eosinophil degranulation.

Eosinophils are a rich source of LTC_4 (5S-hydroxy-6R, S-glutathionyl-7,9,-*trans*-11,14-*cis*-eicosatetraenoic acid).[119,120] Stimulation with the calcium ionophore A23187 generates up to 40 ng/10^6 cells of LTC_4 from normal density eosinophils, whereas light density eosinophils elaborate 70 ng/10^6 cells. Eosinophils produce negligible amounts (6 ng/10^6 cells) of LTB_4 (5S-12R-dihydroxy-6,14-*cis*-8,10-*trans*-eicosatetraenoic acid) compared with up to 200 ng/10^6 cells from neutrophils. LTC_4 generation by human eosinophils was also observed after stimulation with both opsonized zymosan and via an FcγRII-dependent mechanism using Sepharose beads coated with IgG.[121] Release was maximal at 45 minutes, greater in hypodense eosinophils than normal density eosinophils and was enhanced by fMLF (see *Eosinophil Heterogeneity* below for a description of hypodense eosinophils). The production of LTC_4 is critically dependent upon the activation of 5-lipoxygenase, an enzyme that resides in the euchromatin region of the nucleus which translocates to the nuclear membrane upon cell activation, where it activates an 18 kDa protein called FLAP.[122] The substrate for 5-lipoxygenase is AA, which may be released from membrane phospholipids by PLA_2. The first product of this enzyme is an intermediary compound, 5-HPETE, which is transformed into the unstable epoxide LTA_4. At this point, human eosinophils predominantly generate LTC_4 through the action of LTC_4 synthetase.[119,120] Eosinophils are particularly rich in LTC_4 synthetase, and account for 70% of all LTC_4 synthetase-positive cells in the airway mucosa of normal and asthmatic individuals.[123] LTC_4 is generated intracellularly in human eosinophils stimulated with the calcium ionophore A23187. LTC_4 is later exported from the cell in a regulated manner.[124]

The production of 15-HETE, a lipid mediator generated via the 15-lipoxygenase pathway, occurs in activated eosinophils. The product 15-HETE has proinflammatory actions and can modulate the chemotactic effects of LTB_4 on neutrophils.[125] The enzyme 15-lipoxygenase may be distinguished from 5-lipoxygenase in that it can modify a larger pool of fatty acid substrates than the latter enzyme, and will oxygenate fatty acids that are esterified in phospholipids. Substrates include arachidonic acid, linoleic acid, polyenoic acids, and more complex lipids, such as lipoproteins. Eosinophils are the major cellular source of elevated 15-HETE in asthmatic airways, and are capable of generating 100 to 300 times more 15-HETE than neutrophils, endothelial cells, and fibroblasts.[126] Eosinophils also account for 85% of cells positive for 15-lipoxygenase in the airway submucosa of normal and asthmatic subjects.[127,128]

Eosinophils generate large amounts of PAF after stimulation with either calcium ionophore, opsonized zymosan, or IgG-coated Sepharose beads.[129–132] PAF (1-*O*-alkyl-2-acetyl-*sn*-glycerol-3-phosphocholine) is a potent phospholipid mediator, which causes leukocyte activation. For instance, eosinophils elaborated 25 ng/10^6 cells of PAF after stimulation with calcium ionophore and up to 2 ng/10^6 cells after IgG stimulation. Much of the PAF remained cell-associated, possibly acting as an intracellular messenger, or alternatively binding to PAF receptors on eosinophils thus acting as an autocrine agent. Interestingly, stimulation of eosinophils with fMLF did not augment PAF release and hypodense eosinophils from patients with a marked eosinophilia released less PAF than normal eosinophils. [^{3}H]PAF added to hypodense eosinophils was more rapidly incorporated into the phospholipid pool than [^{3}H]PAF with normal density cells.[131] This suggested that hypodense eosinophils were metabolizing the exogenous PAF at a greater rate than normodense cells and may explain why stimulation with fMLF did not result in an increased amount of PAF generation. As with leukotriene synthesis, eosinophil-derived release of PAF was maximal at 45 minutes. Regulated PAF production is controlled by the release of biologically inactive lyso-PAF from membrane phospholipids by PLA_2, which is later acetylated to form PAF by an acetyltransferase.[130]

The cyclooxygenase pathway is prominent in eosinophils as well, and eosinophils are capable of producing PGE_1 and PGE_2, and thromboxane B_2 from cyclooxygenase acting on free AA. In studies with guinea pig eosinophils, thromboxane B_2 and PGE_2 were shown to be generated following PAF or A23187 stimulation.[133,134]

Many of the enzymes associated with membrane-derived mediator release from eosinophils, including cyclooxygenase and 5-lipoxygenase, are found stored in association with lipid bodies (see Table 8.1).[135,136,137]

Respiratory Burst

Eosinophils undergo respiratory burst concurrently with the release of other mediators during cell activation. The immune function of respiratory burst is to mediate killing of invasive pathogenic microorganisms; it also has the undesired effect of collateral tissue damage when dysregulated. Respiratory burst is defined as the increase in cell metabolism (measured by the elevated activity of the hexose monophosphate shunt) and oxygen consumption, coupled with the inducible release of reactive oxygen species (ROS) in response to specific stimuli. Many stimuli are capable of inducing respiratory burst in eosinophils, including LTB_4, PAF, fMLF, C5a, opsonized particles, and CCL5/RANTES.[39] The principal product of respiratory burst is superoxide ($O_2^{-\bullet}$), a potent oxidant with a highly reactive electron in its outer valence, possessing relatively weak intrinsic microbicidal activity and a very brief half-life. The function of $O_2^{-\bullet}$ is thought to reside in its ability to dismutate rapidly into more reactive ROS, including hydrogen peroxide (H_2O_2), the hydroxyl radical ($OH^{-\bullet}$), and formation of hypohalous acids (HOBr) upon reaction with EPO produced following eosinophil degranulation. The formation of ROS subsequent to $O_2^{-\bullet}$ generation is dependent upon the presence of a number of catalysts, such as superoxide dismutase (SOD), which accelerates the formation of H_2O_2, and the ferrous ion, which induces $OH^{-\bullet}$ production from H_2O_2. $O_2^{-\bullet}$, is also able to react with nitric oxide (NO) produced from nitric oxide synthase enzymes (e.g., iNOS, eNOS) to form the highly reactive peroxynitrite (ONOO-), which alters cell functions and is cytotoxic.

The regulated burst of $O_2^{-\bullet}$ production is mediated through the activation of a membrane-associated enzyme complex, the NADPH oxidase. This enzyme complex is crucial for maintenance of host defense as it is a key mechanism in the destruction of ROS-sensitive organisms. In addition, overactivation of the NADPH oxidase is likely to be cytotoxic to tissues, and has been implicated in the pathogenesis of many eosinophil-related disorders including allergic asthma.[138] Interestingly, eosinophils possess the ability to generate up to tenfold more superoxide than other phagocytes, including neutrophils, in which the mechanisms associated with NADPH oxidase activation have been studied in greater detail.[139] The ability of eosinophils to release more $O_2^{-\bullet}$ is thought to be the result of higher levels of expression of the protein components that make up the NADPH oxidase complex.[140–142,143,144] In addition, preferential assembly of NADPH oxidase occurs at the cell membrane in eosinophils, eliciting a predominantly extracellular form of $O_2^{-\bullet}$ release.[145] This is in contrast to neutrophils, which show predominantly intracellular NADPH oxidase assembly during respiratory burst stimulation and bacterial infection.[145,146]

NADPH oxidase is a complex of at least 6 proteins consisting of phagocytic oxidase (*phox*) subunits, of which two (p22*phox* and gp91*phox*) reside in the membrane as part of the cytochrome b_{558} protein, and the remaining proteins (p40*phox*, p47*phox*, p67*phox*, and Rac1 or Rac2) are cytosolic in resting cells.[139] The minimal components of the NADPH oxidase complex were determined using cell-free assays,[147] although several other proteins, such as p40*phox* and Rap1a, also translocate to the membrane-associated oxidase complex during activation, and may be involved in "fine-tuning" the activity of the oxidase.[148] Under normal nonstimulated conditions, the phagocytic oxidases p40*phox*, p47*phox*, and p67*phox* are complexed in the cytosol, whereas Rac1 or Rac2 are bound to the cytosolic guanine dissociation inhibitor RhoGDI (Fig. 8.8). Binding between p47*phox* and p67*phox* occurs through the C-terminal SH3 domain of p67*phox* and a proline-rich region (PRR) in p47*phox*. The p67*phox* protein also contains a C-terminal Bem1p (PB1) motif that allows a high-affinity interaction with a C-terminal *phox* and Cdc motif in p40*phox*.[149,150] An SH3 domain also exists in p40*phox* that is capable of interacting with the PRR

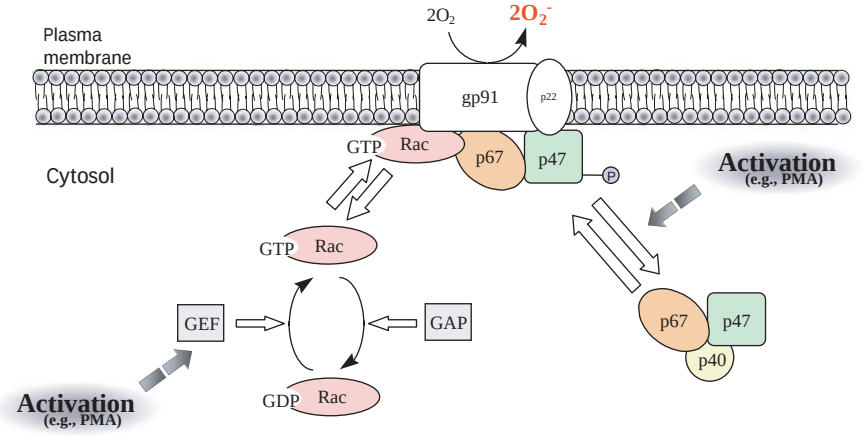

FIGURE 8.8. Assembly and activation of the NADPH oxidase complex during respiratory burst. This complex is essential for the inducible release of superoxide for microbicidal reactions and is also present in neutrophils. During cell activation, the GTPase Rac, normally bound to GDP in the resting cell, is activated by a guanine exchange factor (GEF) to bind to GTP. This results in translocation of Rac-GTP to the cell membrane, where other cytosolic proteins p67*phox* and p47*phox* have also translocated, to bind to the two subunits of cytochrome b_{558} (gp91*phox* and p22*phox*). Following the assembly of the oxidase, electrons are transferred from NADPH in the cytosol via flavin adenine dinucleotide (a co-factor) to oxygen molecules to form the highly reactive oxygen intermediate, superoxide. Assembly of this complex is reversed by GTPase-activating protein (GAP), which hydrolyzes GTP on Rac to GDP, and by the dissociation of the *phox* subunits.

domain in p47*phox*, although in vitro binding studies indicate that the affinity of this interaction is lower than that of p40*phox* for p67*phox*.[151,152]

During activation by cell surface receptors engaged by opsonized microbes or inflammatory mediators, p47*phox* is phosphorylated by cellular kinases on multiple serine residues, unmasking tandem SH3 domains to allow binding to p22*phox* in the membrane. Concurrently, p67*phox* and p40*phox*, which are still complexed to p47*phox*, translocate to the cell membrane, and the "activation domain" in p67*phox* promotes electron transfer between NADPH and flavin adenine dinucleotide.[153] Superoxide generation from NADPH oxidase also requires concurrent activation and membrane translocation of Rac1 or Rac2, which binds to tetratricopeptide repeat motifs in the N-terminus of p67*phox* and cytochrome b_{558} to induce additional conformational changes necessary for efficient electron transport to O_2.[154] The function of p40*phox* is still uncertain, although a recent study suggests that it may have a role in activating superoxide production during IgG-mediated phagocytosis.[150]

Rac1 and Rac2 are monomeric guanine triphosphatases (GTPases), which exhibit 92% homology in their amino acid sequence, and are functionally interchangeable in their ability to activate NADPH oxidase, although they differ in their tissue distribution. Another potential modulator of the oxidase is the monomeric GTPase Rap1a, although its precise role is unknown. Rac1 is ubiquitously expressed throughout the body, whereas neutrophils, eosinophils, and other blood cells predominantly express Rac2, which is mainly expressed in hemopoietic tissues.[145,155–157] Activation of the respiratory burst in eosinophils leads to translocation of Rac to NADPH complexes predominantly at the cell membrane, in contrast to neutrophils which form NADPH complexes mainly at intracellular sites.[145] These patterns of NADPH oxidase complex formation align with the concept that eosinophils undergo "frustrated phagocytosis" upon encountering large extracellular organisms such as helminthic parasites, whereas neutrophils preferentially phagocytose smaller microbes for intracellular killing. Eosinophils are partially dependent on Rac2 for the activation of respiratory burst responses, based on findings with $Rac2^{-/-}$ mouse eosinophils, inferring that Rac1 may also be required for NADPH oxidase activation in these cells.[158]

The pathway leading from receptor stimulation to activation of the oxidase is still poorly understood. Many studies on NADPH oxidase activation use phorbol esters, such as phorbol myristate acetate (PMA), as highly potent artificial stimuli to activate respiratory burst in eosinophils. Phorbol esters are classically known for their ability to activate protein kinase C (PKC) directly.[159–161] The use of pharmacologic inhibitors of PKC in respiratory burst has generated paradoxical results, in that PKC inhibitors only partially inhibit agonist-induced H_2O_2 release in guinea pig eosinophils.[160,162] However, there is a species difference in sensitivity to PMA, as in human eosinophils, where PKC inhibitors actually augment the rate of oxygen consumption in response to opsonized particles.[163] These findings suggest that PKC is not critical for agonist-induced respiratory burst in eosinophils, although stimulation of PKC appears to be able to induce superoxide release on its own.

Taken together, eosinophils generate substantial amounts of $O_2^{-\bullet}$ as part of their role in host defense, and the mechanisms associated with the release of this toxic mediator are under investigation. The release of $O_2^{-\bullet}$ from eosinophils is likely to be a crucial component of the pathophysiologic processes underlying eosinophilic inflammation in mucosal tissues.

Eosinophils as Immunoregulatory Cells

The consistent association of eosinophils with a specific pattern of immune response common to helminth infection and atopy suggests that eosinophils may be either a bystander cell or an active component of a complex immune disease. To determine the involvement of eosinophil-derived factors in modulating the immune response, the expression and bioactivity of cytokines released from eosinophils have been explored for their potential physiologic effects in immune regulation. Studies have shown that a striking diversity of cytokines and chemokines, including IL-2, IL-4, IL-12, IL-16, GM-CSF, CCL5/RANTES, and TGFβ, are derived from eosinophils and are capable of exerting bioactive effects.[41,45] For example, IL-2 and IFNγ from CD28-stimulated eosinophils were shown to stimulate proliferation in an IL-2-dependent cell line and MHC Class II expression on Colo 205 cells, respectively.[164] The release of IL-4 from eosinophils is important in driving the initiation of a Th2-type response in *Schistosoma mansoni* infection in mice.[165] Eosinophil-derived IL-4 also plays an immunoregulatory role in pulmonary cryptococcosis, as determined in 4get mice (IL-4-IRES-eGFP mice, with eGFP+ IL-4 expressing cells) treated with *Cryptococcus neoformans*, contributing to a susceptibility to Th2-dependent allergic responses during bronchopulmonary mycosis.[166] Secretion of the cytokines APRIL and IL-6 from eosinophils has been shown to be critical for the maintenance of plasma cells in the bone marrow.[52] These studies have demonstrated that eosinophil-derived cytokines and chemokines have the ability to regulate a range of immune and inflammatory responses.

Generally speaking, eosinophils produce significantly smaller amounts of cytokines than T-cells, B-cells, and other cells. However, in eosinophilic inflammation, eosinophils outnumber T-cells in the tissues by as much as a hundredfold. As such, the magnitude of the presence of eosinophils may be a determining factor in regulating immune responses at a local level. The release of eosinophil cytokines often takes place within a much shorter period than cytokines released by T-cells (which may be several hours), as eosinophil-derived cytokines are stored as pre-formed mediators in crystalloid granules and may be secreted in response to stimuli in a matter of minutes. The production of cytokines by eosinophils is postulated to contribute to an immunoregulatory role by these cells, and may promote an allergic phenotype by influencing the production of Th2 cytokines by T-cells.

Allergy is often characterized by a significant polarization of the immune response toward enhanced production of Th2 cytokines and a dramatic increase in allergen-specific and total immunoglobulin E (IgE) levels. Allergic disease is initiated by the generation of allergen-specific $CD4^+$ cells that produce the Th2 cytokines IL-4, IL-5, IL-9, and IL-13. These cytokines are crucial for the maturation, proliferation, survival, and activation of mast cells, basophils, and eosinophils, important effector cells. Th2 cytokines also regulate IgE synthesis by B-cells and mucus production by epithelial cells. In contrast, Th1 cells are characterized by the production of the Th1 cytokines IL-2 and IFN-γ. The immunologic responses of eosinophils are dependent on an array of cytokines and chemokines that may traditionally be associated with Th1 or Th2 responses. Eosinophils synthesize many of these cytokines and chemokines to which they can also respond. Based on their ability to synthesize, store, and release both Th1 and Th2 cytokines and chemokines, and significant evidence indicating the bioactivity of their released cytokines, eosinophils have been implicated as active components of allergic disease, rather than as bystander cells.

Classically, the Th1 response has been modeled as an immune response that exerts inhibitory effects on Th2 responses. It is therefore paradoxical that eosinophils, as a cell type marking Th2-type responses to allergic diseases or helminthic infections, synthesize and store both Th1 and Th2 cytokines (see Table 8.2). For example, binding of CD28 on human eosinophils induced the release of bioactive IL-2 and IFN-γ,[164] both of which are Th1 cytokines, and IL-13, a Th2 cytokine.[167] Because Th1 and Th2 responses are mutually inhibitory, it has been very difficult to dissect the specific roles of eosinophil-derived cytokines in the

initiation and effector phases of the allergic immune response. The role of eosinophil-derived Th1 or Th2 cytokines may therefore depend on the timing of eosinophil infiltration into sites of allergic inflammation. Indeed, recent studies using a mouse model of *Nippostrongylus brasiliensis* infection have shown that although eosinophils may be crucial for secondary Th2 polarized immune response against this parasite, the primary response does not require eosinophil-derived IL-4 or IL-13.[168] However, in the context of viral infections, IFNγ-mediated stimulation of eosinophils leads to the production of CCL5/RANTES that may serve to recruit further immune cells and limit the spread of viruses.[169]

Experimental models that induced eosinophilia in the absence of tissue infiltration of eosinophils have exquisitely demonstrated the importance of the timing and location of chemokine release in recruitment of eosinophils. For example, CCL11/eotaxin gene-knockout ($Eo^{-/-}$) mice showed decreased tissue eosinophils during the early (but not late) phase of allergic inflammation.[170] Moreover, $Eo^{-/-}$ mice also showed a significant defect in clearing the larvae of *Trichinella spiralis* from skeletal muscles compared to wild-type animals in spite of similar levels of blood eosinophilia.[171] Thus, the presence of eosinophils in allergic disease results from a carefully orchestrated process that involves cytokines and chemokines controlling the maturation and recruitment of eosinophils to the site of allergen exposure.

The implications of eosinophil cytokine production are extensive, such as in the case of IL-4, where this cytokine may be released from eosinophils to direct Th2 cell differentiation in local lymph nodes. In support of this possibility, eosinophils have been shown to traffic to paratracheal draining lymph nodes (in a mouse model of asthma), where they were demonstrated to function as antigen-presenting cells expressing MHC Class II and co-stimulatory CD80 and CD86 to stimulate $CD4^+$ T cells.[172,173] In humans, eosinophils can be induced to express MHC class II and co-stimulatory molecules following cytokine stimulation and transmigration through endothelial monolayers.[174–177] Moreover, human eosinophils constitutively express a Notch ligand, Jagged1, suggesting that they have the capacity to polarize naïve $CD4^+$ T cells.[178]

During intimate cell–cell contact, the production of IL-4 and IL-13 is not required in abundance to effect important immunoregulatory events, such as enhanced switching of T-cells to Th2 phenotype and increased IgE synthesis, both of which are hallmarks of allergic disorders.[179,180] Mouse eosinophils can process and present antigens to T-cells.[181,182] Under such conditions, antigen-loaded eosinophils, acting as antigen-presenting cells, were found to preferentially initiate the generation of a Th2 response to ovalbumin in an experimental mouse model.[183,184] Furthermore, antigen-pulsed eosinophils were sufficient for expansion of Th2 cells in draining lymph nodes.[184]

Earlier studies suggested that eosinophil recruitment into sites of inflammation was the result of IL-5 and CCL11/eotaxin generation from the adaptive immune response.[1] However, numerous studies in mouse models have shown that the influx of eosinophils into sites of inflammation precedes that of lymphocytes, and that it can occur in mice with a deficient adaptive immune system.[165,168,185–187] These studies suggest that eosinophils may regulate the adaptive Th2 immune response in allergic inflammation. A major role for eosinophils in the localized recruitment of effector T-cells into the lungs of allergen-sensitized and -challenged mice has been demonstrated, whereby lung eosinophils elicit the expression of CCL17/thymus- and activation-regulated chemokine (TARC) and CCL22/ macrophage-derived chemokine (MDC).[188] These studies have supported the notion that eosinophils can participate in the generation of allergic immune response through the secretion of a wide diversity of immunomodulatory cytokines, either directly or indirectly through other tissues.

Eosinophils also engage in the maintenance of immune homeostasis by being involved in major histocompatibility complex (MHC) class I-restricted thymocyte deletion in the thymus.[189] In the thymus, eosinophils express MHC class I and co-stimulatory molecules CD86 and CD30L, and are also positive for CD11b/CD11c, CD25, and CD69, with decreased expression of CD62L, suggestive of an activated phenotype. These eosinophils are anatomically localized within specific compartments of the thymus coinciding with negative selection of double-positive thymocytes. Thus, eosinophils may be associated with MHC class I-restricted thymocyte deletion as part of the maintenance of immune function in early life.

Indeed, abundant numbers of eosinophils were detected in human thymus tissue in infants ranging between the ages of 2 weeks to 12 years undergoing open-heart surgery for congenital cardiac disease. Eosinophils constituted 2% of total thymic cell count post-natally; the counts were shown to be highest during the early stages of life and declined with age.[190] Confirming what was shown previously for peripheral blood eosinophils,[191] thymic eosinophils were shown to express constitutively biologically active IDO as suggested by the detection of copious kynurenine catabolites deriving from tryptophan breakdown in eosinophil/IDO-rich thymic tissue.[190] The study also showed that thymic eosinophil numbers, IDO expression, and tryptophan catabolites correlated with mRNA expression for Th2, but not Th1 markers. A fascinating observation was the detection of numerous eosinophils within unique thymic Hassall's corpuscles. The latter were suggested to play a major role in regulatory T-cell (Treg) differentiation via the epithelial lining of these corpuscles.[190,192] The lining of Hassall's corpuscles synthesizes and releases thymic stromal lymphopoietin (TSLP) that instructs resident thymic dendritic cells to effect the conversion of self-reactive T-cells into $CD4^+CD25^+Foxp3^+$ cells.[193] Indeed, in the mouse, inflammatory Th2-type responses to TSLP were shown to be eosinophil-dependent.[194] Together, these observations imply an immune regulating and/or modulating role for eosinophils in the thymus. This has potential relevance for the development of early-in-life immune response patterns especially in regard to polarization of the immature immune system. These observations may have significant relevance for the role of the eosinophil in health and disease.

Eosinophils are also likely to play a role in long-term maintenance of bone marrow plasma cells, inasmuch as plasma cell numbers were decreased in the bone marrow of eosinophil-deficient mice; a defect that was reversed by eosinophil reconstitution.[52] Eosinophils supported the survival of plasma cells by secretion of APRIL and IL-6.

Apart from these, other eosinophil-derived immunoregulatory factors have been recently recognized. Based on initial data showing that its inhibition resulted in an immune-mediated abortion in mice,[195] studies in the last 5 years have shown that indoleamine 2,3 dioxygenase (IDO), the rate-limiting enzyme in the oxidative catabolism of tryptophan, may play a central role in immune regulation.[196] Subsequent studies have associated tryptophan catabolism with mechanisms of tumor escape from T-cells,[197] dysfunctional tolerance in autoimmune diabetes mellitus in NOD mice,[198] and protective negative regulation of trinitrozobenzene-induced (Th1) model of colitis in the mouse.[199] According to this mechanism, a discrete population of dendritic cells (DCs) that express functional IDO in lymphoid tissues is able to inhibit T-cell proliferation and induce T-cell apoptosis.[200] The presence of this minority population of inhibitory DCs in lymphoid tissue can override the activating properties of other DCs and, therefore, act as a strong negative feedback mechanism on immune activation.[201] Further studies have shown that regulatory T-cells (Tregs) that constitutively express cytotoxic T-lymphocyte antigen-4 (CTLA-4), the so-called central Tregs, down-regulate the immune response using this mechanism.[202,203]

Human eosinophils constitutively express the enzyme IDO,[191] in contrast to DCs where IDO is inducible. Furthermore, co-culture of IDO-expressing eosinophils with T-lymphocytes

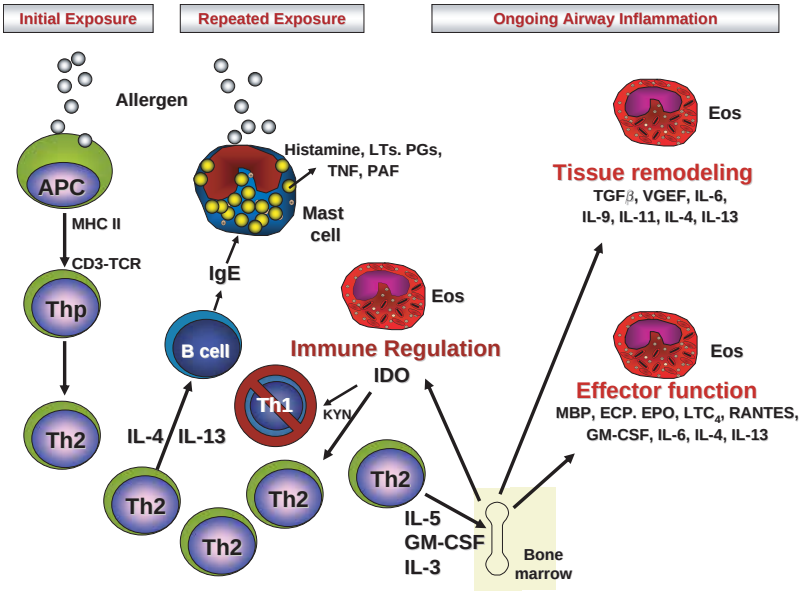

FIGURE 8.9. A proposed scheme addressing an immunoregulatory role that the eosinophil may play in asthma and allergy. Eosinophils have the capacity to exert powerful effector functions against mucosal tissues that may contribute to airway hyperresponsiveness. One way that eosinophils may regulate immune cells is through indoleamine 2,3 dioxygenase (IDO), a rate-limiting enzyme in the metabolism of the amino acid tryptophan. Eosinophils constitutively express IDO, and when stimulated by IFNγ, eosinophils lower the level of extracellular tryptophan and catalyze the production of kynurenines (KYN). KYN have been shown to target Th1 cells to reduce their proliferation by apoptosis, and in this manner allow the proliferation of Th2 cells. APC, antigen-presenting cell; ECP, eosinophil cationic protein; EPO, eosinophil peroxidase; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; LT, leukotriene; MBP, major basic protein; MHC, major histocompatibility complex; PAF, platelet-activating factor; PG, prostaglandin; TCR, T-cell receptor; TGF, transforming growth factor; TNF, tumor necrosis factor; VGEF, vascular endothelial growth factor.

selectively inhibited the proliferation of Th1 cells while having no effect on Th2 cells. Immunostaining of histologic sections of human lymphoid tissues and those from ovalbumin-sensitized and -challenged mice also showed the presence of IDO-expressing eosinophils. Similarly, a study investigating the expression of IDO in tumor biopsies from 25 cases of non-small–cell lung cancer showed that eosinophils were the only IDO-expressing cells in these tissues, and concluded that eosinophil-derived IDO may play a significant role in the escape of non-small–cell lung cancer from immune surveillance.[204] In this study, the presence of IDO-expressing tumor-infiltrating eosinophils was strongly correlated with poor survival. When these findings are juxtaposed with previous studies investigating the prognostic value of tumor-associated tissue eosinophilia, it becomes apparent that eosinophil-derived IDO may be a major immunoregulatory mechanism in several eosinophil-associated conditions[205,206] (Fig. 8.9).

Another immunomodulatory molecule generated by the eosinophil is one of its granule proteins, EDN. In addition to its RNase activity and antiviral properties, EDN is a chemoattractant for dendritic cells,[207] and can induce maturation and activation of dendritic cells.[208] In addition, EDN has the capacity to act as an alarmin by enhancing Th2 responses through a Toll-like receptor 2 (TLR2)-dependent mechanism.[209]

The recognition of the capacity of the eosinophil to synthesize and release cytokines, and produce other immunomodulatory molecules, introduced a paradigm shift in understanding the potential of the eosinophil as an effector cell in allergic inflammation and other eosinophil-associated conditions. However, the full capacity of the eosinophil to elaborate cytokines, the precise microenvironment requirements for such synthesis, the intracellular pattern of production and storage, including the timing of its immunomodulatory function during immune responses, remain the subject of intensive investigation.

EOSINOPHIL DIFFERENTIATION

Peripheral blood and tissue eosinophils are derived by hemopoiesis from $CD34^+$ myelocytic progenitors found in the bone marrow and in inflamed tissues. Eosinophils make up approximately 3% of the bone marrow from healthy individuals, of which 37% is fully differentiated, and the remainder is promyelocytes/myelocytes and metamyelocytes.[6,210] The appearance of newly matured cells in the blood occurs approximately 2.5 days from the time of the last mitotic division.[6] The turnover of eosinophils is approximately 2.2×10^8 cells/kg/day, and the bone marrow possesses the largest end-differentiated eosinophil reservoir in the healthy body (9 to 14×10^8 cells/kg).[211] Progenitors differentiate upon exposure to a network of cytokines and chemokines to become committed to the eosinophil/basophil (Eo/B) lineage.[212] Transcription factors regulate the production of eosinophils in the bone marrow, involving at least three classes: GATA-1 (a zinc finger family member), PU.1, and C/EBP members (CCAAT/enhancer-binding protein family).[213] The fate of distinct lineages is regulated by PU.1, in which low levels induce lymphocytic cells and high levels promote myeloid differentiation.[214] Eosinophil lineage differentiation is synergistically induced by GATA-1 and PU.1.[215] However, GATA-1 is likely the most important transcription factor for eosinophil differentiation, as mice lacking GATA-1 have a specific deficiency in eosinophils.[216]

Eosinophils are more closely related to basophils than neutrophils and monocytes due to lineage differentiation at this stage.[217] In addition, eosinophils retain elements of expression of basophil/mast cell-specific high-affinity Fcε receptor (α subunit),[218] whereas basophils continue expression of low concentrations of eosinophil major basic protein (MBP).[219] Cytokines and chemokines are generated under appropriate stimulation from T-cells in the bone marrow. The three key cytokines that are critical for stimulation of bone marrow production of eosinophils are interleukin-3 (IL-3), IL-5, and granulocyte/macrophage colony-stimulating factor (GM-CSF).[220,221] These three cytokines are also produced by $CD4^+$ and $CD8^+$ T-lymphocytes from peripheral blood as well as inflamed tissues.[222] In bone marrow samples, committed eosinophil precursors can be recognized by their expression of the IL-5 receptor (IL-5R) and the C–C chemokine receptor, CCR3, in addition to CD34.[223] It is now well recognized that IL-5 is a key cytokine in terminal differentiation of eosinophils,[224] and expression of the IL-5R on the progenitor cell is one of the first signs of commitment to the eosinophil lineage. The expression of IL-5R is almost exclusively limited to eosinophil progenitors and mature peripheral blood eosinophils, with some expression on basophils but not neutrophils or monocytes. This selectivity in receptor distribution indicates that IL-5 acts primarily as an eosinophilopoietic cytokine. This has resulted in several groups proposing that inhibition of IL-5 with anti-IL-5 antibody therapy will result in the complete loss of eosinophils from the body, thus preventing the manifestation of allergic symptoms. The obligatory role of IL-5 in the differentiation of the eosinophil

has been confirmed by numerous studies on transgenic mice in which overexpression of the gene for IL-5 caused marked eosinophilia and increased numbers of eosinophil precursors in their bone marrow.[225,226] Interestingly, eosinophil differentiation in this transgenic model appeared to be completely independent of IL-3 and GM-CSF, suggesting that IL-5 alone may be sufficient to generate an eosinophilia from stem cell precursors. Gene deletion of IL-5 results in depletion of eosinophils from the circulation, as IL-5 gene-deficient mice exhibit a complete ablation of peripheral blood eosinophils.[227,228] However, although IL-5 gene-deficient mice exhibit almost no eosinophils in their blood, a small pool of apparently IL-5-independent eosinophils persist in the mucosal tissues of these animals.[229]

Additional eosinophilopoietic factors may assist in inducing the differentiation of Eo/B progenitors in the bone marrow, including IL-4, IL-6, IL-11, IL-12, SCF, and others.[39] C–C chemokines, named for their adjacent cysteine residues in the C-terminus amino acid sequence as distinct from the CXC chemokines, include CCL11/eotaxin and CCL5/RANTES, which have also been shown to be important in the development of eosinophils.[230] CCL11/eotaxin facilitates the efflux of fully mature eosinophils into the peripheral circulation and promotes the recruitment of eosinophils to target tissues. Overall, at the level of the bone marrow, the early development of Eo/B progenitors is driven by IL-3 and GM-CSF, among other factors, whereas at later stages, IL-5 regulates the terminal differentiation of eosinophils.

The half-life of eosinophils in the circulation is approximately 18 hours with a mean blood transit time of 26 hours,[231] although this is extended in eosinophilic conditions, possibly due to the elevation of systemic eosinophil-activating cytokines that promote eosinophil survival. Based on a study of 740 medical students, the normal range of blood eosinophils was shown to be between 0 and 0.5×10^9/L, with counts ranging from 0.015 to 0.65×10^9/L.[232] Circulating eosinophil counts exhibit diurnal variation in humans, in which the lowest and highest levels are seen in the morning and evening, respectively, often exhibiting more than 40% variation within a day.[233,234] Mild eosinophilia is generally considered to be 0.5 to 1.5×10^9/L, moderate eosinophilia as 1.5 to 5.0×10^9/L, and marked eosinophilia greater than 5.0×10^9/L. Allergy is commonly associated with eosinophilia in the mild range, whereas parasitic infestation is often characterized by a marked eosinophilia.

Eosinophils are predominantly tissue cells, and their major target organs for homing in the healthy individual is the gastrointestinal tract (outside of the esophagus), mammary gland, uterus, thymus, and bone marrow. The gastrointestinal tract is the predominant site of homing for tissue eosinophils in healthy humans.[235] In states of disease, eosinophils appear in the lungs, esophagus, skin, and brain (e.g., during strokes). Once they enter target tissues, eosinophils do not return to the blood circulation. Eosinophil numbers can remain high in tissues even when peripheral numbers are low, suggesting that their survival is enhanced upon extravasation. Curiously, pathogen-free laboratory animals have no eosinophils in their blood, and tissue eosinophils are scarce, suggesting that the appearance of eosinophils may be environment- or disease-related.[210]

Eosinophil Production and Survival in Peripheral Tissue

Eosinophil development and maturation may also occur in situ in peripheral (extramedullary) sites outside of the bone marrow. In this case, Eo/B precursors are released into the bloodstream directly from the bone marrow to circulate to sites where they specifically transmigrate in response to locally produced cytokines and chemokines. This may provide an alternative mechanism for the persistence or accumulation of tissue eosinophils. Like neutrophils, eosinophils are end-stage cells, which, in culture, rapidly undergo cell death by either apoptosis or necrosis. However, eosinophil-active cytokines, such as IL-3, IL-5, and GM-CSF, as well as interferon-γ (IFNγ), prolong eosinophil survival in culture for up to 2 weeks.[236,237,238] They also enhance receptor expression and cell function, including cytotoxicity against metazoan targets, and mediator release. Cytokines derived from eosinophils may lead to autocrine prolongation of eosinophil maturation and survival in tissues.[45] Local tissue types such as endothelial cells, fibroblasts, and epithelial cells may also contribute to the production of IL-5 and GM-CSF for in situ eosinophil maturation and differentiation in airway or gut mucosa.

Extracellular matrix proteins have been shown to modulate eosinophil responses to soluble physiologic stimuli.[239] Eosinophils were shown to adhere specifically to fibronectin[47] an abundant extracellular matrix protein. Moreover, VLA-4, a known receptor for fibronectin,[240] is involved in mediating eosinophil/fibronectin interactions.[47] Similarly, VLA-6 expressed on eosinophils interacts with the connective tissue protein laminin. These receptors function to enhance eosinophil responses and are likely to promote the activation of tissue eosinophils by cytokines and other signaling molecules.

The eosinophil-specific cytokine, IL-5, delays eosinophil apoptosis and promotes eosinophil priming and activation.[241] IL-5 production by airway $CD4^+$ T-cells may be directly stimulated by eosinophils in a paracrine manner to enhance survival of tissue eosinophils.[242] Eosinophil progenitors in nasal explants from atopic patients have been shown to survive and develop into fully mature eosinophils ex vivo using similar mechanisms.[243] Allergen challenge of these explants, as well as lung explants of brown Norway rats, was shown to evoke a rapid (6 hours) accumulation of MBP-positive cells after allergen challenge.[244] This was shown to be dependent on IL-5 production within the explant, a key cytokine in eosinophil survival.

The IL-5R consists of two subunits, an α subunit of 60 to 80 kDa, and a common β_c subunit of between 120 and 140 kDa, which is shared with IL-3R and GM-CSFR. IL-5 interacts with its α subunit specifically but at a lower affinity than the β_c subunit.[245] IL-5 stimulation through the β_c subunit leads to phosphorylation of the tyrosine kinases, Jak2, Lyn, and Syk. Jak2 signals through the nuclear translocation factor STAT1, but Lyn and Syk signal through the mitogenic Ras-Raf1-MEK-ERK pathway (Fig. 8.10). Tyrosine phosphorylation enhances the expression of the antiapoptotic protein Bcl-x_L in eosinophils, and decreases translocation of the proapoptotic signaling molecule Bax, resulting in decreased activation of apoptotic signaling through the caspase family.[246,247] GM-CSF prolongs the survival of eosinophils bound to tissue sites via α4 integrin for up to 2 weeks,[47] and has also been shown to inhibit eosinophil apoptosis similarly to IL-5. Thus, the growth, maturation, and prolongation of survival of eosinophils in extramedullary tissues may occur in sites other than the bone marrow.

EOSINOPHIL HETEROGENEITY

Human peripheral blood eosinophils exhibit marked heterogeneity based on their physical, morphologic, and functional properties. There are three different populations of eosinophils that can be characterized based on their intrinsic buoyant density and responsiveness to stimuli. These are the normodense, hypodense, and primed eosinophils, which can be described in both normal and eosinophilic subjects. Each of these populations responds differently to stimuli, which may be related to their stage of maturation. In addition, they may derive from distinct pools of eosinophils that are genetically regulated. The majority of blood eosinophils (>90%) from normal individuals are normodense, which separate out from other leukocytes in the lower interfaces of Percoll or metrizamide discontinuous density gradients. Hypodense eosinophils can be seen in a proportion of

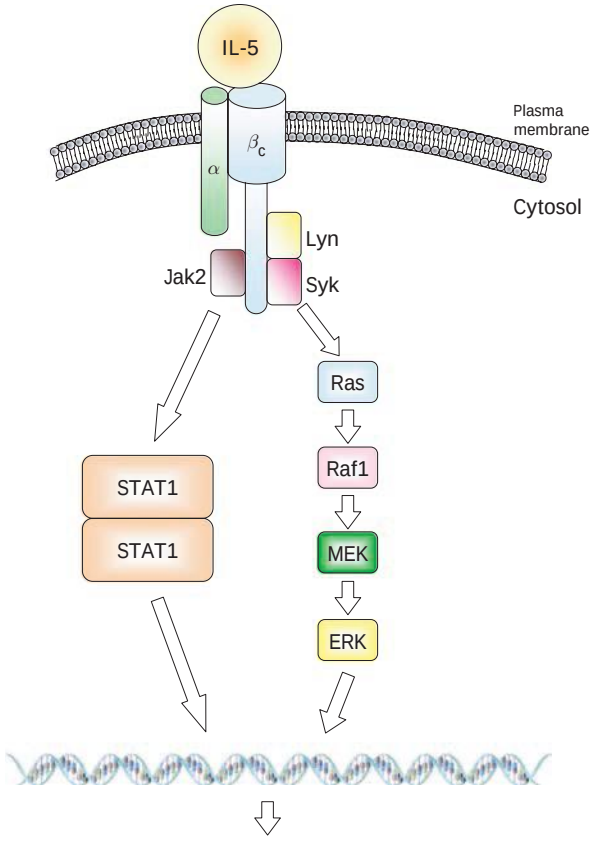

FIGURE 8.10. Signaling pathway leading from binding of IL-5 to its receptor in the membrane to transcriptional activation in the cell nucleus via the Ras-Raf1-MEK-ERK pathway. The β subunit of the receptor is also able to activate the Jak2-STAT1 pathway. Transcriptional activation is proposed to generate antiapoptotic effects in eosinophils.

eosinophils from individuals with a raised eosinophil count that exhibit lower density (<1.085 g/ml) than eosinophils from normal subjects, resulting in a spread of eosinophil populations in the gradient, with contaminating mononuclear cell bands.[237,248] Morphologically, hypodense eosinophils appear vacuolated, contain more lipid bodies, express less MBP, and possess smaller-size crystalloid granules that appear to be slightly more lucent and take up less cell volume, although these are of equal numbers to normodense eosinophils.[249] They also exhibit a greater cell volume than normodense eosinophils.[250] The mechanism for this heterogeneity is not clear. The presence of low density (or hypodense) eosinophils appears to be a nonspecific phenomenon that occurs in any eosinophilic condition including parasitosis, asthma, allergic rhinitis, idiopathic hypereosinophilic syndrome, and certain malignancies. It was originally thought that the numbers of hypodense cells correlated with the degree of eosinophilia, although this has not been consistently observed.[248,251–254] Thus, the mechanisms governing the production of hypodense eosinophils are likely to be distinct from those that control eosinopoiesis.

Functionally, hypodense eosinophils appear to be more activated, because they exhibit elevated oxygen consumption,[248] increased cytotoxicity toward helminthic targets,[251] and release more LTC_4 after physiologic stimulation.[121] Activation of eosinophils, in vitro, with inflammatory mediators such as platelet activating factor (PAF), as well as long-term culture with cytokines (e.g., IL-3, IL-5, and GM-CSF), has been associated with a decrease in eosinophil density.[236,255] Two possible explanations may account for the enhanced responsiveness of hypodense eosinophils. The first is that hypodense eosinophils frequently co-migrate to the same density as neutrophils in metrizamide or Percoll gradients, thus making it difficult to separate these two cell types. Neutrophils could, therefore, enhance the responsiveness of eosinophils through cell–cell interaction. For example, total LTC_4 produced by a mixture of eosinophils and neutrophils was found to be greater than the amount produced by either cell type alone.[256] However, other studies assessing the possibility of neutrophils enhancing eosinophil responsiveness have been negative.[257,258] Secondly, hypodense eosinophils have been shown to express a greater number of receptors for IgG, IgE, CD44, complement, and the p55 subunit of the IL-2 receptor when compared with normodense cells,[248,259,260,261] which may explain their enhanced responsiveness to stimuli. However, the surface expression of numerous other receptors does not differ between normodense and hypodense eosinophils, with some populations (e.g., CD18) even showing decreased expression in hypodense cells.[262] Furthermore, normodense eosinophils from patients with an eosinophilia have enhanced effector function compared with eosinophils from normal individuals. It is possible, therefore, that the formation of low-density eosinophils results from the migration of normodense eosinophils from the bone marrow to the circulation, whereupon they become activated by elevated systemic factors. Another scenario may be that the association between hypodensity and activation is coincidental, with the less dense cells being immature. This heterogeneity in eosinophils has not received significant attention in recent years, likely due to changes in purification techniques for eosinophils. Although early studies generated eosinophils purified by density gradients, using Percoll, for example, by far the most common approach in modern studies is negative selection by immunomagnetic bead separation.[263] Immunomagnetic separation of eosinophils has the advantage of greatly enhancing the purity of eosinophils, but reveals little regarding hypodense subpopulations.

EOSINOPHIL TISSUE ACCUMULATION

Eosinophils migrate to the gastrointestinal tract during their normal development,[235,264,265] and possibly in response to environmental factors as part of a role in innate defense against parasites. The mechanisms involved in the selective tissue recruitment of eosinophils across the vascular endothelium and into tissues in allergic reactions occur sequentially in four well-defined steps. These include (1) the *tethering* of the eosinophil to the lumenal surface of the vascular endothelium during normal transport through the blood vessel, (2) *rolling* of the eosinophil along the lumenal surface of the activated endothelium in a reversible manner, (3) firm *adhesion* of the eosinophil to endothelial cells, and (4) *transmigration* of the eosinophil through the endothelium into target tissues (Fig. 8.11). A further, less understood, step in eosinophil trafficking in the tissues is the in situ differentiation of circulating committed Eo/B precursors. Most migration through endothelium occurs at post-capillary venules.

Each of these steps is controlled by a complex network of chemotactic factors and adhesion molecules, which collectively direct the movement of the eosinophil into the tissues. For eosinophils, L-selectin and α4 integrin are thought to be important in tethering and rolling, and α4 and β2 (CD18) integrins mediate firm adhesion. The transmigration step is primarily regulated by β2 integrins as well as C–C chemokines such as CCL11/eotaxin. Cytokines and chemokines are elaborated by surrounding tissues to modulate the transmigration of eosinophils into tissues. Many of these mechanisms appear to be controlled at the level of the T-cell response to antigen (allergen)-presenting cells, and the subsequent release of cytokines and chemokines which in turn regulate the activity of eosinophils.

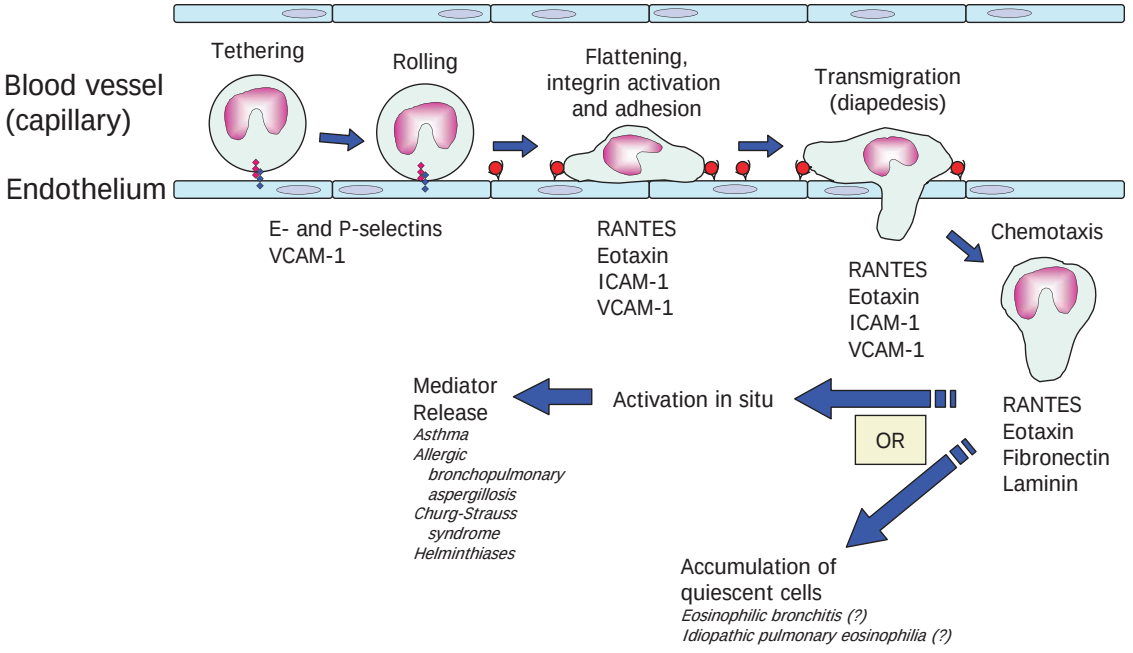

FIGURE 8.11. Eosinophil tethering, rolling, adhesion, transmigration, and chemotaxis in response to inflammatory signals in tissues. During chemotaxis, eosinophils may either become activated in response to local inflammation and release mediators, as in asthma and other related conditions, or they accumulate in tissues in the apparent absence of mediator release.

Tethering and Rolling

Our knowledge of the mechanisms involved in eosinophil interactions with the endothelium extends primarily from in vitro assays of leukocyte adhesion to cultured human umbilical vein endothelial cells (HUVEC) both in stable and under flow conditions. Antibodies specific for adhesion molecules have been applied in this system and have identified critical regulatory molecules required for adhesion and transmigration of eosinophils. Tethering and rolling of eosinophils on HUVEC cells under flow conditions are regulated by L-selectin (CD62L) expressed on the eosinophil surface interacting with E- and P-selectins (CD62E and CD62P) on endothelial cells.[266] Selectins are characterized by a lectin-binding domain, which is involved in the initial anchoring of inflammatory cells to the venular endothelium. This interaction is enhanced after the release of inflammatory mediators from these cells as well as neighboring tissues. Once tethered, eosinophils roll until they become stimulated by a chemoattractant stimulus (indicating local inflammation), which induces activation of $\alpha 4$ integrin receptors on the leukocyte. In addition, rolling appears to facilitate the subsequent adherence and transmigration of eosinophils into tissues. Eosinophils also express PSGL-1 and the integrins $\alpha 4\beta 1$ (VLA-4) and $\alpha 4\beta 7$, which are involved in cell rolling.[266] Eosinophil integrins bind to target sites in the endothelium, primarily ICAM-1 (CD54) and VCAM-1 (CD106), through their Mac-1 (a $\beta 2$ integrin, also known as CR3 or CD11b/CD18) and VLA-4 ($\alpha 4\beta 1$ integrin) receptors, respectively. The constitutive expression of VLA-4 ($\alpha 4\beta 1$ integrin) is limited to a small number of leukocytes, including eosinophils, monocytes, basophils, and T-cells, suggesting that regulated expression of its ligand, VCAM-1, on endothelial cells may be important in selective recruitment of these cells.[267]

Adhesion

The firm adhesion of eosinophils involves the interaction of $\alpha 4$ and $\beta 2$ integrins with the endothelial layer. Specifically, eosinophils adhere to TNFα-, IL-1β-, and LPS-activated HUVECs through CR3/ICAM-1 and VLA-4/VCAM-1 interactions.[267,268,269,270,271] Other adhesion molecules that may contribute to this process are LFA-1, VLA-6 ($\alpha 4\beta 1$), $\alpha 4\beta 7$ integrin, p150,95, and CD11d. Eosinophils exhibit differential binding properties through VCAM-1 and ICAM-1, which are dependent on their activation status. Freshly prepared unstimulated eosinophils preferentially bind to endothelial VCAM-1 via VLA-4 ($\alpha 4\beta 1$) rather than $\beta 2$ to ICAM-1.[230,272] Once activated, eosinophil preference for VCAM-1 shifts to that of endothelial ICAM-1 via $\beta 2$ integrins.[230,273–275] During extravasation (diapedesis) into tissues, the eosinophil becomes progressively more activated upon contact with extracellular matrix proteins and other stimulated cells. Tissue eosinophils from an antigen challenge model express increased CD11, CD69, and ICAM-1.[276] Eosinophil binding in tissues switches to ICAM-1 and the CS-1 region of tissue fibronectin.[170,266,273] The change in the activation status is also confirmed by the changes in the expression of cell surface molecules seen as the eosinophil goes through tissue. Eosinophils recovered from bronchoalveolar lavage (BAL) express increased ICAM-1, Mac-1, CD69, and decreased L-selectin, suggesting an activated state.[247]

Cytokines such as IL-4 and IL-13 have been shown to up-regulate eosinophil adhesion, primarily through up-regulation of VCAM-1 on endothelial cells.[277,278] The effects of IL-4 and IL-13 are mediated through Jak3 and the nuclear transcription factor STAT-6.[279,280] Interestingly, a decrease in tissue eosinophilia has been observed in allergen-challenged STAT-6$^{-/-}$ mice, in spite of high levels of VCAM-1 expression.[280] This difference was thought to be due to decreased expression of CCR3 in eosinophils, which is directly controlled by STAT-6.[281] Results from STAT-6$^{-/-}$ mice would suggest that IL-4 and IL-13 also have a role in the induction of CCR3 on eosinophils and T-cells. These findings underline the importance of cytokine and chemokine cross-talk in the generation of blood eosinophilia and tissue diapedesis.

The switch to ICAM-1-mediated adhesion and transmigration may be associated with facilitation of eosinophil entrance into the tissue. Increased $\beta 1$ expression (VCAM-associated) has been shown to slow eosinophil migration compared with ICAM-1/$\beta 2$.[282] It is important to note that anti-VLA-4 antibodies may not prevent eosinophil migration into tissue if ICAM-1 or P-selectin sites are the first targets for activated eosinophils.[266]

IL-5 also up-regulates eosinophil, but not neutrophil, adhesion to unstimulated endothelium, offering a selective pathway of eosinophil adhesion.[64] IL-5 has been shown to activate transendothelial migration of eosinophils through ICAM-1 via decreased $\beta 1$ and increased $\beta 2$ integrin expression.[283] Similarly, stimulation of eosinophil CCR3 with a chemokine such as CCL11/eotaxin, which can be released from endothelial cells, also increases $\beta 2$ integrin expression, resulting in preferential binding to ICAM-1.[284] Thus, numerous cytokines and chemokines have been shown to enhance eosinophil adhesion to endothelium.

Complement proteins are also important in eosinophilic trafficking in tissues. Complement-mediated inflammation, as seen with parasite infection, is associated with the release of C3a and C5a. C3a increases binding of eosinophil to endothelium but does not increase migration; however, C5a increases both adhesion and migration.[285] VCAM-1 and ICAM-1 are involved in complement-mediated binding and migration of eosinophils, as this process is blocked by the application of anti-$\alpha 4$ and $\beta 2$ antibodies. These findings illustrate the importance of adhesion molecules VCAM-1 and ICAM-1 in the complement-mediated pathway of anaphylaxis and host defense.

Other more general inflammatory cytokines, such as IL-1 and TNFα, are also released by inflamed tissues and have significant effects on eosinophil migration.[266] Message encoding both IL-1 and TNFα is increased in the airways of symptomatic as opposed to nonsymptomatic asthmatics,[286] and IL-1 is increased in tissues from sites of cutaneous allergy.[287] Antibodies to IL-1 have been shown to decrease the expression of VCAM-1 and ICAM-1 in endothelial cells.[288] Mice deficient in IL-1 expression (IL-$1^{-/-}$) have decreased eosinophil rolling, adhesion, and transmigration.[289] TNFα has also been shown to increase expression of endothelial ICAM-1, VCAM-1, P-selectin, and E-selectin, causing increased eosinophil rolling and adhesion.[290,291,292] In addition, $TNF^{-/-}$ mice show decreased eosinophil adhesion and migration into tissue, similar to IL-$1^{-/-}$ mice.[293] These factors may have important roles in allergic asthma where preferential accumulation of eosinophils is a feature of atopic (IgE-dependent) inflammatory conditions.

Transmigration and Chemotaxis

Once eosinophils adhere to vascular endothelium, they commence diapedesis whereby they emerge out of the capillaries and traverse the adjacent connective tissue en route to the focus of the inflammatory response. Eosinophils move through the endothelium by extending lamellipodia in the form of a uropod, thus leading to lamellar motion.[266] For cells to move, there must be increased binding forward via the uropod and release of binding to the rear. Changes in the binding affinity for adhesion molecules and extracellular matrix proteins are thought to contribute to cell movement on a substratum. A gradient in binding affinity of eosinophil VLA-4 to fibronectin has been demonstrated,[294] where increased adherence at the leading edge of the cell is followed by de-adherence at the rear of the cell, allowing the cell to move on. Cytokines and chemokines also influence the binding of eosinophils to tissue surfaces, such as GM-CSF which increases the binding affinity of VLA-4 to VCAM-1 or CS-1,[295] and CCL11/eotaxin which stimulates the reverse reaction.[284] CCL11/eotaxin induces cytoskeletal changes via mitogen-activated protein kinases (MAPK),[266] Rho guanosine triphosphatases (GTPases), and Rho kinase.[296,297] Eosinophil chemotaxis may be inhibited by CXCL9 (monokine induced by interferon γ, Mig), a factor that inhibits eotaxin-induced chemotaxis.[298,299] Other chemokines or chemotactic factors, such as CCL5/RANTES, CCL7/monocyte chemoattractant protein-3 (MCP-3) and C5a, may also alter $\beta 1$ integrin affinity in eosinophils.[273,300] The balance of these factors determines the rate of eosinophil migration.

Although cytokines (e.g., IL-3, IL-5, and GM-CSF) are essential for the development and proliferation of eosinophils, they are likely to play an immunomodulatory role in priming eosinophils for better chemotactic responses to target tissue sites. The most potent eosinophil chemoattractants include PAF, LTD_4, C5a, IL-2, and C–C chemokines such as CCL11/eotaxin and CCL5/RANTES (regulated upon activation, normal T-cell expressed and secreted).[86,301] C–C chemokines appear to be essential for inducing the specific migration of eosinophils to inflamed sites. Several distinct families of chemokines have been identified, and the CCR3-binding family in particular plays a crucial role in generating tissue eosinophilia due the nearly exclusive expression of CCR3 in eosinophils.[230] This family of chemokines consists of CCL11/eotaxin (1, 2, and 3), CCL5/RANTES, CCL7, CCL8, CCL12 (MCP-2, 3, and 5), and CCL3/macrophage inhibitory protein (MIP)-1α. Chemokines binding CCR3 may be selective for granulocytes such as eosinophils and basophils, as neutrophils do not express this receptor. CCL11/eotaxin is the only chemokine with potent chemoattractant effects on eosinophils, making it a key ligand for the CCR3 family.[301,302] CCR3 chemokines are produced by endothelial cells, epithelial cells, parasympathetic nerves, T-cells, macrophages, fibroblasts, and eosinophils, among other tissue sources.[45,303,304]

Basal expression of CCL11/eotaxin in the gut is elevated compared with other tissues in the normal animal.[305] During allergen-induced eosinophilia, CCL11/eotaxin expression is further increased within tissues.[306] Some synergism exists between IL-5 and CCL11/eotaxin, as IL-5 stimulation enhances the eosinophil response to CCL11/eotaxin both in vitro and in vivo.[307,308] In order to define the specific role of CCL11/eotaxin in inflammation, CCL11/eotaxin gene-knockout ($Eo^{-/-}$) mice have been deployed.[235,309] These mice produce IL-5 normally, and thus continue to develop blood eosinophilia similar to their wild-type heterozygotes. However, $Eo^{-/-}$ mice do not develop tissue eosinophilia. Thus, the primary role of CCR3 appears to be involved in the homing of circulating eosinophils to target tissues expressing CCL11/eotaxin.

Additional chemokines of the CCR3 family have been shown to exert important effects in situations where CCL11/eotaxin may not be necessarily essential to the response.[266,310] Each chemokine appears to have a unique role in the timing and location of tissue eosinophilia. Peripheral blood levels and cultured mononuclear cells from patients with allergic dermatitis produce increased levels of CCL5/RANTES, CCL2/MCP-1, and CCL3/MIP-1α compared with nonallergic controls.[311] Similarly to CCL11/eotaxin, IL-5-stimulated eosinophils have an increased affinity for CCL5/RANTES. However, unlike CCL11/eotaxin, CCL5/RANTES was specifically associated with exacerbations of eosinophilic bronchitis, thought to be provoked by viral infection. Infections with respiratory syncytial virus (RSV) leading to eosinophilia have been correlated with increased CCL5/RANTES, CCL2/MCP-1, and CCL3/MIP-1α expression.[312,313] Children with asthma have large increases in eosinophil-associated MBP, CCL5/RANTES, and CCL3/MIP-1α in their nasal secretions during naturally acquired viral infections.[314] Therefore, the apparently broader range of effects of CCL5/RANTES, CCL3/MIP-1α, and CCL/2MCP-1 may also increase the range of eosinophil activity in disease, even though all of these bind specifically to CCR3 on eosinophils.

Other factors are also produced in mucosal tissues, which are moderately or strongly chemotactic for eosinophils. These include bacterial products (e.g., endotoxin and the tripeptide f-Met-Leu-Phe [fMLF]), the anaphylatoxin complement factor, C5a, opsonized particles (which exert their effect via complement [CR1, CR3] and FcγRII receptors), and other cytokines (IL-4, CXCL8/IL-8, and possibly IL-13). In addition, the lipid-derived mediators, leukotriene B_4 (LTB_4) and PAF, which are elevated in allergic responses and induce eosinophil respiratory burst and degranulation at higher doses,[39,239,315,316] are also eosinophilotactic. Eosinophil cytokines IL-3, IL-5, and GM-CSF are able to enhance the chemotactic ability of each of these factors. Although PAF antagonists are not sufficient at preventing eosinophilic inflammation in allergy,

treatment of allergic individuals with leukotriene modifiers has been effective at reducing eosinophil numbers and inhibiting eosinophil activation.[317]

EOSINOPHILS AND ALLERGIC DISEASE

The association between eosinophils and allergic disease has been known for many years. Eosinophils are a feature of allergic and nonallergic asthma,[265] and large numbers of eosinophils and eosinophil granule products are found in and around the bronchi in asthma patients.[19,318–322] The gastrointestinal tract is a natural homing site for eosinophils, however, excessive eosinophilia and active secretion in various compartments of the gut result in disease states such as eosinophilic esophagitis, gastroesophageal reflux disease (GERD), or inflammatory bowel disease (IBD).[264] Patients with atopic dermatitis also show strong evidence of eosinophil presence and mediator release.[323–325]

Eosinophils and Asthma

There is a strong correlation between the presence of bronchial hyperresponsiveness (a cardinal clinical feature of asthma) and eosinophilia, particularly activated eosinophils.[233,319,326] Challenge of the airways with inhaled allergen induces local airway inflammation characterized by influx of both eosinophils and neutrophils. In the late phase of the response, eosinophils are a predominant feature.[326–328] A transient peripheral blood eosinophilia may also occur following these challenges.[326] Challenges with low molecular weight occupational compounds such as toluene diisocyanate have also been associated with eosinophilia.[329] Even nonatopic asthma, which appears to lack an IgE-mediated immune response, shows similar increases in airway eosinophils.[329,330]

Eosinophils in the airways may be assessed using bronchial biopsy, bronchoalveolar lavage (BAL), or induced sputum. The use of fiberoptic bronchoscopy with biopsy is considered the gold standard for acquiring the best appreciation of eosinophil involvement in asthma.[331,332] A consistent finding in asthmatic airways is the presence of increased numbers of activated eosinophils or their release products, which correlate broadly with the severity of disease as reflected in symptoms, bronchial hyperreactivity, and lung function.[330,333] Segmental allergen challenge of human subjects' bronchi induces increased eosinophils in the airways,[327,328] that were positive for the early activation marker CD69 [334] and show up-regulation of integrins.[335] Even in mild disease, there may be a significant increase in numbers of eosinophils in the airways of patients, and these are CD69-positive.[330,336]

Eosinophil granule proteins are significantly associated with the incidence of allergy and allergic asthma. As mentioned previously, MBP is found in large amounts in the lung tissues of patients with status asthmaticus, suggesting widespread eosinophil recruitment and degranulation.[19] The analysis of BAL samples from patients with asthma demonstrated that high concentrations of MBP correlate with the severity of bronchial hyperreactivity.[8] Intratracheal instillation of MBP and EPO in a primate model provoked bronchoconstriction, and MBP enhanced airway responsiveness to inhaled methacholine.[8] These physiologic effects of MBP are likely mediated by its cationic properties, inasmuch as treatment with polyanionic peptides such as polyglutamic acid reverse the effects of MBP.[337,338] These studies suggest that eosinophil degranulation is a major feature of allergic asthma. However, whether degranulation from eosinophils is simply the result of eosinophil infiltration, or if it plays an important role in allergic disease, is yet to be determined.

Sputum analysis offers a noninvasive technique showing correlation of eosinophil numbers with clinical outcomes.[339–341] Increases in sputum eosinophils correlate with the degree of airway responsiveness, asthma symptom scores, and asthma exacerbations.[330,342,343] Monitoring eosinophilic inflammation using induced sputum samples has been suggested as an important adjunct to the clinical management of asthma beyond relying on lung function and symptoms alone.[344] Conversely, a lack of eosinophils in sputum analysis appears to correlate with a lack of response to inhaled corticosteroids.[345]

The Eosinophil Controversy

Early studies on eosinophil function in the immune response suggested that eosinophils played an immunoprotective role in allergy. For example, eosinophils produce histaminase, which was thought to act by down-regulating mast-cell–mediated early phase responses to allergen.[346] However, reports emerging in the latter part of the 20th century suggested that eosinophils had a destructive role in allergic and asthmatic airways, based on the discovery of intensely stained deposits of eosinophil MBP in the airways of individuals who died from fatal asthma.[19] More recent studies then cast this concept back into doubt, including animal models of asthma (IL-5 gene knockouts and anti-IL-5–treated mice) and clinical trials using anti-IL-5, IL-12, and IFNγ.

Mouse Models of Airway Hyperresponsiveness

The roles of IL-5 and eosinophilia in mouse models became a concern. Depending on the protocol used for sensitization and challenge, it appeared that airway hyperresponsiveness could persist in mice in spite of treatment with an antibody to IL-5 and depletion of blood eosinophils. Animal models of asthma have utilized IL-5$^{-/-}$ mice to determine the contribution of eosinophils to the pathogenesis of airway inflammation induced by allergens. One report showed that airway hyperresponsiveness was not affected in allergen-sensitized and challenged IL-5$^{-/-}$ mice, although blood eosinophil numbers were significantly diminished.[347] Studies using anti-IL-5 injections in mice generated similar observations.[228,348] In contrast, using another allergen challenge model, increased blood and tissue IL-5 levels were evident in wild-type mice.[349] These levels correlated with both blood and tissue eosinophilia and airway hyperresponsiveness. In the same study, IL-5$^{-/-}$ mice did not mount a blood or tissue eosinophil response after allergen challenge, nor did they develop airway hyperresponsiveness.[349] Restoring IL-5 expression in these animals via vaccinia virus encoding IL-5 reconstituted blood and tissue eosinophilia with an associated development of airway hyperresponsiveness. In an inducible model of T-cell–specific transgenic expression of IL-5, mice produced severe skin lesions, gastrointestinal dysfunction, splenic enlargement, and airway hyperresponsiveness similar to symptoms associated with human eosinophilic disorders,[350] supporting a crucial role for the eosinophil in tissue damage associated with allergy.

It appeared that airway hyperresponsiveness could develop during allergen challenge even though blood eosinophilia was lost. The answer to this dilemma may be in the persistence of tissue eosinophils even during IL-5 depletion. Although IL-5 is important in the differentiation and proliferation of eosinophils in the bone marrow, once they arrive in peripheral mucosal tissues, they may to switch to an IL-5–independent mechanism of activation, and possibly recruitment, due to the strong down-regulatory effects of IL-5 on eosinophil IL-5 receptor expression.

The possibility of persistence of IL-5-independent tissue eosinophils has been implicated in results from Eo$^{-/-}$ mice. Despite developing blood eosinophilia, Eo$^{-/-}$ mice show reduced but not abolished tissue eosinophilia [242] with its associated eosinophil-mediated tissue damage following allergen challenge.[351] However, in IL-5 transgenic mice treated with recombinant CCL11/eotaxin-2, both IL-5 and CCL/eotaxin-2 cooperatively

promote eosinophil accumulation in the blood and tissues, leading to increased IL-13 production and enhanced airway hyperresponsiveness during allergen challenge.[229] Neither IL-5 nor CCL11/eotaxin on its own was able to induce these events. These studies indicate that there are distinct roles for eotaxin and IL-5 in eosinophil maturation, proliferation, and homing to target tissues. Thus, although IL-5 is critical for the maturation and proliferation of eosinophils in the bone marrow, eotaxin may be equally essential in a cooperative manner for movement and maintenance of eosinophilia in the tissues. Therefore, a key event in eosinophil-mediated inflammation leading to airway hyperresponsiveness may lie in the persistence of activated eosinophils in the tissue.

Studies in an eosinophil-knockout mouse, generated by linking the diphtheria toxin promoter to the gene expressing eosinophil peroxidase (the so-called "PHIL" mouse), indicate a key role for eosinophils in establishing airway hyperresponsiveness in an acute model of allergic inflammation.[352] In the PHIL mice, eosinophils were depleted in both blood and tissue compartments, and Th2-type airway inflammation and an asthmalike pathology was attenuated upon sensitization and challenge with ovalbumin. These responses were restored by reconstitution of eosinophils[353] or a combination of eosinophils and antigen-specific T-cells.[188] Another study showed that GATA-1 promoter disruption in mice (generating the Δdbl-GATA lineage), which also leads to the ablation of eosinophils, had no effect on airway hyperresponsiveness to methacholine challenge in either acute or chronic models of allergic inflammation, but showed reduced mucus production and airway remodeling.[216,354] In general, these studies show supportive data for a role for eosinophils in mediating Th2-type inflammatory responses, at least in the mouse model, but with some conflicting details. For example, the Δdbl-GATA mice did not show any significant differences in airway hyperresponsiveness following allergen sensitization and challenge, whereas PHIL mice exhibited a profound reduction in airway resistance upon challenge with methacholine.

Indeed, the appropriateness of the mouse as an animal model for investigating airway hyperresponsiveness has been brought into question. A major limitation of mouse models is that mouse eosinophils seem to be markedly deficient in their ability to undergo respiratory burst[158,355] and degranulate in vivo or in vitro in response to any known eosinophil-specific agonists. As mentioned earlier, eosinophil degranulation appears to be a vital component of the symptoms associated with allergic airway disease, and the use of mice may be counterproductive in providing clues relating to a better understanding of the role of the eosinophil in airway hyperresponsiveness.

In conclusion, these findings have important implications for the treatment of asthmatic patients with antieosinophil therapies, such that more specific and targeted treatments may be needed to block either the recruitment or activation of eosinophils at sites of inflammation.

Antieosinophil Strategies in Human Asthma

Although eosinophils are closely associated with the clinical presentation of asthma and other atopic diseases, the evidence that this reflects a direct cause-and-effect relationship is still a subject of debate. The discovery of interleukin-5 in the 1980s as the most crucial cytokine in the regulation of growth and terminal differentiation of the eosinophil[224,356] led to major pharmaceutical investments aimed at antagonizing IL-5 with a view to blocking the eosinophil influx into the tissue and presumably inhibiting its associated inflammatory sequelae. Animal models, particularly simian, pointed optimistically to such a possibility.[357] However, clinical trials with a humanized anti-IL-5 monoclonal antibody, mepolizumab, concluded that targeting the eosinophil is far more complex than blocking its differentiation at the level of the bone marrow and blood.[358,359,360] As expected, a single intravenous injection of anti-IL-5 induced a profound reduction in peripheral blood eosinophils in patients for up to 16 weeks. However, in spite of the loss of eosinophils from the circulation, bronchial hyperresponsiveness to histamine persisted in these patients for up to 6 weeks after treatment. Based on these findings, the authors questioned the role of the eosinophil in the late-phase asthmatic response and bronchial hyperresponsiveness.

However, the study design and patient selection criteria may have been deficient in determining the success of mepolizumab in these reports.[361] Moreover, the measurement of eosinophils in sputum or airway fluids alone may not reflect the complete contribution of airway tissue eosinophils. Mepolizumab only depleted ~50% of bronchial tissue eosinophils in spite of its ability to eradicate blood and BAL fluid eosinophils.[362] Airway tissue eosinophils may be less dependent on IL-5 for their survival. The development and maturation of eosinophils can occur in situ in peripheral sites of inflammation. Eosinophil progenitors are released into the circulation to reach such tissue sites.[220] Eosinophils can release GM-CSF in an autocrine fashion,[42,47] a cytokine which is stored in association with eosinophil granules,[55] and can enhance tissue eosinophil maturation and prolong their survival in tissues. Autocrine GM-CSF stimulation of eosinophils bound to fibronectin, via $\alpha 4$ integrin, promoted eosinophil survival for 2 weeks.[47] Additionally, GM-CSF appears to have a strong role in inhibiting eosinophil apoptosis at the tissue level. Other eosinophil-derived and stored cytokines (e.g., IL-4 [56] and IL-13 [167,363]) and chemokines (e.g., RANTES[44,364]) may further amplify the inflammatory milieu. Eosinophils may enhance their own survival by directly stimulating $CD4^+$ T-cells within tissue to produce IL-5.[242] Nasal explants from atopic patients were shown to survive ex vivo using similar mechanisms to promote extramedullary eosinophil maturation and survival.[241,243] Lee et al. demonstrated that eosinophils, when instilled into the trachea of IL-5 knockout mice, not only survive in the absence of IL-5, but in concert with $CD4^+$ T-cells, migrate back into lung, and reconstitute the asthma phenotype of wild-type antigen-challenged animals.[365] Overall, although IL-5 is essential in the maturation and differentiation of eosinophils in the bone marrow,[212] the recruitment to tissues and function within tissues may be IL-5-independent.

The position of eosinophils in the airways may also play a role. Patients with eosinophilic bronchitis have increased sputum and tissue eosinophils, but do not develop asthma.[366] From histopathologic samples of patients with asthma, eosinophils can be found clustered around vagal nerve ganglia in the lung.[18] As well, positive staining for extracellular eosinophil MBP has been detected in the vicinity of these nerves.[18] In guinea pig models of antigen sensitization followed by challenge[367] and antigen sensitization followed by virus infection,[17] the release of MBP from eosinophils has been shown to cause M2 receptor dysfunction and hyperreactivity. This may be related to the increased number of eosinophils found in closer proximity to the parasympathetic nerves of sensitized guinea pigs compared to nonsensitized animals.[368]

In summary, despite uncertainty surrounding the specific role of eosinophils in asthma, significant correlations between numbers of activated airway eosinophils (and their released products) and disease severity have been provided in a large body of literature.[9,360,369–371] More recently, targeting IL-5 has shown favorable results improving health outcomes in a subgroup of patients with eosinophilic asthma.[372,373] Further studies will be essential for determining the precise role of the eosinophil in asthma.

Eosinophilic Esophagitis

Eosinophils are also associated with the pathogenesis of gastrointestinal disorders such as eosinophilic esophagitis (EE). Often patients undergoing biopsy for diagnosis of gastroesophageal reflux disease (GERD) have increased numbers of intraepithelial eosinophils,[374,375] which appear to clear with effective antireflux

therapy.[376] The condition of EE is described as a distinct clinical entity, although the feature of esophageal dysfunction is shared with GERD. The pathogenesis of EE has an allergic basis, and EE has been called asthma of the esophagus. Patients with EE present with increased gastroesophageal reflux, and also exhibit choking or food impaction. The clinical symptoms of EE respond well to antiasthma therapy such as systemic corticosteroids,[377] topical corticosteroids,[378–381] and montelukast.[382,383] Despite therapy, EE appears to be chronic illness with the potential for relapses.[384] Similar to asthma, a key stimulus for developing exacerbations of EE symptoms is not always food allergen, but inhaled aeroallergen.[385,386] The mechanism of this surprising observation is not known, but may relate back to the shared embryonic origin of the gastrointestinal and respiratory tracts.

THE EFFECTOR ROLE OF THE EOSINOPHIL IN WORM INFECTIONS

There is a strong relationship between parasitic infection and eosinophilia. Infection with helminths is the most common cause of moderate to marked eosinophilia. Studies in the late 1970s demonstrated that eosinophils had the capacity to kill parasitic targets and led to the concept that eosinophils were immunoprotective.[5,138]

As in allergic inflammation, the precise role of eosinophils in the immunopathologic changes associated with helminth infections remains ill-understood and rather controversial. Increases in the number of tissue and peripheral blood eosinophils, together with elevations in the levels of total and parasitic-specific IgE and mastocytosis, have been considered for a long time to be hallmarks of infection with parasitic worms,[4] especially during their tissue migratory phases. Much has been published about the inimical role this cell may play in protection against helminths, but there is equally important evidence to suggest that their presence may be a reflection of their participation in the pathology of the disease rather than immunity to the parasitic metazoa.[387] The original observation of Basten and Beeson[7] that helminth-associated eosinophilia is T-cell–dependent was an important turning point in our current understanding of eosinophil-mediated inflammation in worm infections. The identification and subsequent cloning of GM-CSF, IL-3, and particularly IL-5 helped to explain the T-cell control of eosinophilic response both in terms of eosinophilopoiesis and differentiation as well as priming and activation of the mature cell. The question, however, remains as to why there is a selective increase of eosinophils and what their function is, both locally, and systematically, in infected subjects.

In Vitro and Mouse Parasitic Helminth Studies

Much has been published on the helminthicidal effects of human, primate, and rodent eosinophils against metazoan targets coated with either IgG, IgA, IgE, and/or complement components. In this context, a number of parasitic targets have been studied including schistosomula of *Schistosoma mansoni*, newborn larvae of *Trichinella spiralis*, larvae of *Nippostrongylus brasiliensis, Fasciola hepatica*, and others.[8,388]

Eosinophils adhere readily to appropriately coated larvae and undergo exocytosis which results in the deposition of the basic and cytotoxic granule-associated proteins. On their own, these pre-formed products of eosinophils (including MBP, ECP, and EPO) have potent helminthicidal properties at low molar concentrations.[8] The exogenous addition of a number of chemotactic agents, such as LTB_4, PAF, fMLF,[389,390] and cytokines such as GM-CSF, IL-3 TNF-α," and IL-5 [391] to eosinophil preparations enhances their cytotoxic capacity against parasitic larvae. In addition to killing worm larvae, eosinophils that adhere to schistosomula via IgG, IgE, or complement, generate substantial amounts of membrane phospholipid-derived mediators, especially LTC_4.[392] More recent studies have shown that in IL-$5^{-/-}$ mice, skin implants containing parasites failed to eliminate larval forms of the organisms.[393] The mechanism underlying larval expulsion was shown to be dependent on eosinophils as well as IgM, and the results suggested that the function of eosinophil granule proteins might be associated with disrupting parasitic larvae to allow processing by antigen-presenting cells, including the eosinophil itself. A recent study using the eosinophil-less PHIL mice demonstrated that infection of these mice with *Schistosoma mansoni* had no effect on traditional measures of disease in this model.[394] However, these findings should be taken with caution as there are many differences in eosinophil functions between mice and humans, and specifically, mouse eosinophils are not as readily activated as their human counterparts.[355]

Helminthiases in Humans and Nonhuman Primates

The precise regulatory and functional roles of eosinophils in human helminthiases during the well-documented inflammatory reaction require urgent and extensive attention. In general, no clear evidence exists of direct contract between eosinophils and adult worms, although accumulation of eosinophils around helminthic parasites has been described. Eosinophil-rich granulomas surrounding dead fragments of skin-invading larvae of the skin-invading nematode *Strongyloides ratti* have been described in hyperimmune rats following challenge.[395] Eosinophils were also found in close contact with the surface tegument of schistosomula of *S. haematobium* in the cutaneous tissue of immune monkeys, associated with the presence of a large number of dead larvae in eosinophil-rich sites.[389] Similar observations were made in other host–parasite systems.[8] Using appropriate antibodies, eosinophil-derived toxic proteins such as MBP have been identified on filarial worm targets in vivo[390] and levels of blood ECP is elevated in patients with filariasis which may suggest the activation and degranulation of eosinophils.[391]

CONCLUSIONS

The eosinophil is an enigmatic and fascinating cell that has intrigued biomedical scientists for more than a century. The precise function of this cell in allergic inflammation and asthma remains a matter of debate and requires further study in appropriately designed research projects. However, it is important to recognize that no single cell type, whether the eosinophil, T-cell, mast cell, neutrophil, or other lung cell, is on its own responsible for all aspects of the immunopathology and clinical sequelae of airway inflammation in asthma and related diseases. In recognition of this fact, the attention currently focused on the eosinophil is warranted and timely. This relates partially to the overwhelming evidence in favor of a potential effector role of the eosinophil in parasitic helminthic and allergic diseases, including asthma. Although the mechanisms of eosinophilia in association with allergic disease are not yet fully understood, they seem likely to be controlled at the level of the T-cell response to antigen and the subsequent elaboration of cytokines that exert both direct and indirect effect on these inflammatory cells. The profile of cytokines generated in allergic reactions, such as the allergen-induced late-phase response in the skin, nose, and lung, appears to conform to a Th2 profile, because mRNA expression of IL-4 and IL-5, but not IFNγ or IL-2, is expressed or up-regulated during these reactions. The release of IL-5 by Th2-type T-cells following stimulation with allergen may, therefore, be responsible for the eosinophilia of allergic disease. Thus, a complex network of T-cells, eosinophils, and other inflammatory cells as well as their cytokine products may participate in a cascade of events that leads to specific

accumulation of eosinophils in sites of allergic inflammation and asthma. Whether tissue damage, a feature of these disease conditions, is the consequence of the activation and exocytosis of these infiltrating cytotoxic cells and the release of their highly basic protein products, is yet to be demonstrated unequivocally.

CHAPTER 9

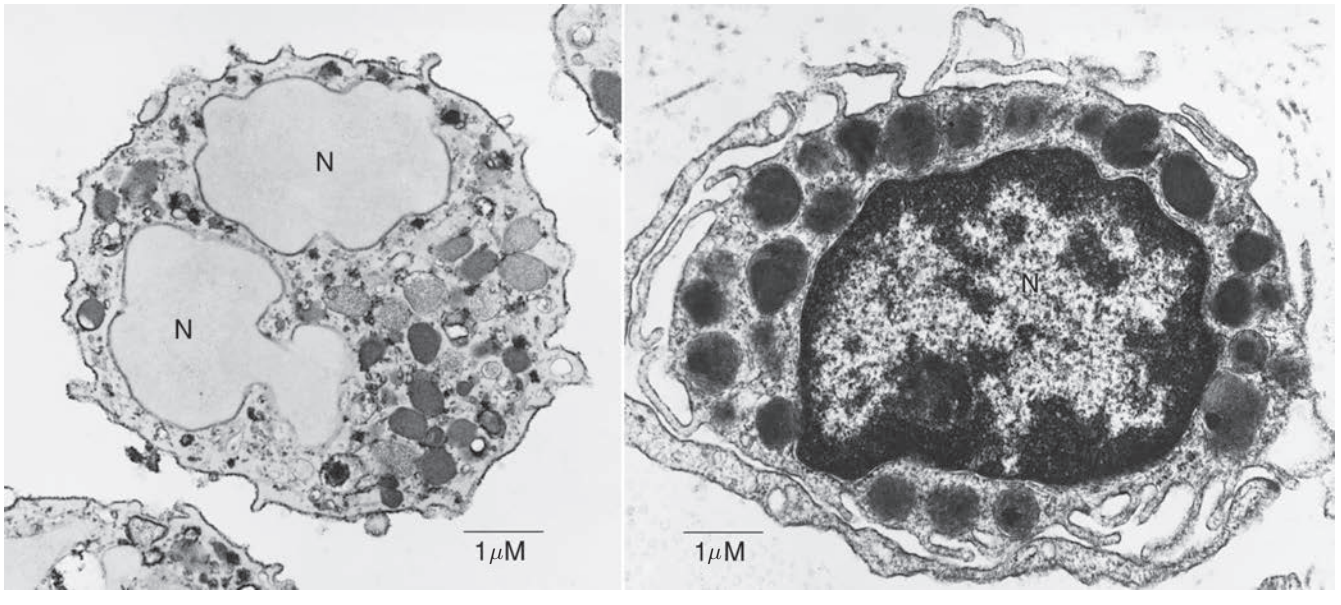
MAST CELLS AND BASOPHILS: ONTOGENY, CHARACTERISTICS, AND FUNCTIONAL DIVERSITY

A. Dean Befus, Kelly M. McNagny, Judah A. Denburg

INTRODUCTION

In 1965, Selye[1] reviewed the literature on two populations of basophilic leukocytes, namely mast cells and basophils. These cells have many similarities, but they also exhibit several intriguing differences. Recent contributions to the literature documenting advances made in our understanding of these cells, their development, contents, biosynthetic activities, activation, and functions in physiology and pathophysiology[2,3,4,5,6,7] are helping us begin to understand the nature of their relationship in ontogeny and immunity,[2] and factors that govern their elicitation and contributions to a wide variety of inflammatory disorders, including allergic inflammation. Mast cells and basophils contain electron-dense cytoplasmic granules and stain metachromatically with selected basic dyes. They produce numerous inflammatory mediators, many—such as histamine—that are common to both cells, and others that are cell-specific. Both cells express a tetrameric isoform of the high-affinity receptor for immunoglobulin E (IgE) and are best known for their ability to release a plethora of factors and inflammatory mediators in response to receptor cross-linking. When the tetrameric high-affinity IgE receptor is cross-linked by sensitizing allergen or by anti-IgE antibodies, mast cells and basophils can be activated, mediator synthesis and secretion are induced, and gene expression altered, with consequences on many immune and inflammatory events.

Classical ontogenic and ultrastructural descriptions for mast cells and basophils are shown in Figure 9.1 A,B; however, new information and emerging technologies have greatly expanded our understanding of the roles of basophils and mast cells in both innate and acquired immunity,[2,4,8,9,10,11,12,13] notably including: (a) a burgeoning literature and controversy on basophil involvement as antigen-presenting cells in Th2 immune responses[2,8,9,10,11,12,13]; (b) new insights into the role of gut microbiota and thymic stromal lymphopoietin (TSLP) in basophil hemopoiesis and in mast cell localization and function[14,15]; (c) expression of the hemopoietic antigen, CD34, on mast cells involved in a variety of inflammatory reactions[16,17,18]; (d) novel roles for mast cells in tissue remodeling, angiogenesis, and tumor growth[19,20,21,22]; and (e) the capacity of mast cells to be derived from a compartment of multipotential hemopoietic progenitors, distinct from the myeloid lineage.[23,24,25] In many ways the original statement by Ehrlich in 1879[1] that basophils are "blood mast



A B

FIGURE 9.1. A. Basophils are "cells with the kinetics and natural history of granulocytes that mature in bone marrow, circulate in the blood, and retain certain characteristic ultrastructural features, even after migrating into the tissues during inflammatory or immunologic processes. The ultrastructure of mature basophils varies according to species but generally includes electron-dense cytoplasmic granules, prominent aggregates of cytoplasmic glycogen, and short, blunt, irregularly distributed plasma membrane processes. There is no convincing evidence that mature basophils, whether in the circulation or in the tissues, retain mitotic capability, or that basophils metamorphose into mast cells upon entering the tissues." (Galli SJ, Dvorak AM, Dvorak HF. Prog Allergy 1984;34:1–141). As shown in Figure 9.1A, human basophils are round and have irregular, short surface projections, cytoplasmic secretory granules, and aggregates of cytoplasmic glycogen. N, nucleus; bar, 1 μm. (Reproduced with permission from the authors and Blackwell Science Ltd., Dvorak AM, Warner JA, Fox P, et al. Recovery of human basophils after FMLP-stimulated secretion. Clin Exp Allergy 1996; 26:281–294.) **B.** Mast cells "ordinarily mature outside of the bone marrow or circulation, generally in the connective tissues or serous cavities. Cells in this lineage(s), wherever distributed, apparently retain at least limited or latent proliferative capacity…(I)mmature and mature granules of mast cells and basophils differ distinctively in ultrastructure. Mast cells also differ from basophils in lacking electron-dense aggregates of cytoplasmic glycogen, and in having a plasma membrane surface with uniformly distributed, thin, elongate folds and processes. Mast cell nuclei may appear bilobed in an individual photomicrograph, but they generally lack the pattern of peripherally condensed nuclear chromatin characteristic of basophils and other granulocytes." (Galli SJ, Dvorak AM, Dvorak HF. Prog Allergy. Basophils and mast cells: morphologic insights into their biology, secretory patterns, and function. 1984;34:1–141). A human skin mast cell is shown with monolobed nucleus with partially condensed chromatin, numerous cytoplasmic granules containing crystalline structures and regularly distributed, narrow, thin surface projections. Bar, 1 μm. (Reproduced with permission from the author and Springer-Verlag. Dvorak AM. Human mast cells. In: Beck F, Hild W, Kriz W, et al., eds. Advances in anatomy, embryology and cell biology. Leicester: Springer-Verlag, 1989;114:1–107.)

cells," and the corollary, that mast cells are "tissue basophils," although imprecise from a strictly developmental standpoint, is still of some value in thinking about the nature of these two cell types. The striking inverse relationship between the numbers of circulating basophils and the numbers of tissue mast cells has been used for decades to infer similarities in function.[1]

This chapter provides an overview of the developmental biology of these two cell types, comparing and contrasting basophil and mast cell physiology, phenotype, activation, and function; lineage commitment and differentiation; and roles in innate and acquired immunity. Anticipated increases in the understanding of basophil and mast cell function will lead to effective new diagnostic and therapeutic strategies for the betterment of those suffering from allergic and other related diseases.

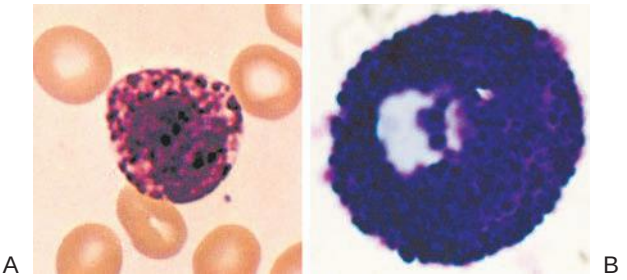


FIGURE 9.2. A. Human peripheral blood basophil stained with Wright's. (From Lee, Bithell, Foerster, et al., eds. Wintrobe's clinical hematology, 9th ed. Philadelphia, PA: Lea & Febiger, 1993.) **B.** Rat peritoneal mast cell stained with May-Grünwald-Giemsa.

GENERAL MORPHOLOGY, MEDIATOR SECRETION, AND RECOVERY

Morphology

Histochemical staining of blood smears or cytocentrifuge preparations of enriched basophils or mast cells with Wright or May-Grünwald-Giemsa stain show many similarities in these cell types (Fig. 9.2 A,B). The cytoplasm of the cells generally stains pink, the nucleus is purplish or blue, and the cytoplasmic granules are dark blue to purple or even blackish. Basophils in peripheral blood or tissues range in size from 10 to 15 µm, whereas mast cells in tissue sites may appear irregular in shape and up to 20 µm in a long dimension. Ultrastructural analyses demonstrate many similarities between mast cells and basophils, but also identify some distinct differences (Fig. 9.1A,B).[26] In the blood, basophils are round, whereas in the tissues they can acquire various shapes. Mast cells can appear to be round, oval, or elongate-spindle shaped in the tissues. The surface of basophils exhibits blunt processes of variable shape and size, whereas mast cells often possess long fingerlike processes that extend from the surface. The nucleus of mast cells can be round or lobed, whereas that of the basophil is generally multilobed. Nucleoli are often not apparent or are absent from normal mast cells and basophils. Basophils have an abundance of condensed chromatin positioned at the periphery of the nucleus, whereas mast cells have little condensed chromatin, possibly reflecting their capacity for continued proliferation. The cytoplasm of normal mature mast cells has few mitochondria and a relatively inconspicuous Golgi apparatus; and ribosomes, rough endoplasmic reticulum, and aggregates of glycogen are rare. In normal basophils, mitochondria and aggregates of glycogen are more abundant than in mast cells, but as with mast cells, Golgi apparatus, ribosomes, and rough endoplasmic reticulum are rare in normal basophils. The most prominent cytoplasmic elements in both cell types are the membrane-bound, electron-dense granules.

Basophils generally possess fewer granules than mast cells and the granules exhibit a more homogeneous ultrastructural morphology than those of mast cells. Basophil granules are often homogeneously electron-dense, although dense particles may be interspersed with membrane aggregates and whorls. Charcot-Leyden crystals can be formed in basophils as well. Mast cell granules may be homogeneously electron-dense or may exhibit electron-dense particles, membrane or complex scroll-like patterns, highly organized crystalline structures, or combinations of these. The relationship of these different granule patterns to the tissue site, phase in development, or mediator content is not clear. Interestingly, Dvorak has reported that mast cell granules, in addition to storing mediators, are also sites of RNA metabolism and protein synthesis activity. Mast cells produce 30 to 100 nm extracellular membrane vesicles of endocytic origin, called exosomes, that possess mRNA, microRNAs, proteins, and lipids, and have been shown to transfer these components to other cells and influence their functions.[27] Moreover, the composition and cell-to-cell communication functions of exosomes are influenced by activation of mast cells.[28] Basophils have not been shown to produce exosomes, but they do contain numerous electron-lucent vesicles of 50 to 70 nm that often have contents similar to granules. These may be associated with a form of mediator exocytosis (see below).

Mast cells and basophils also contain rounded, non-membrane–bound, electron-dense structures called lipid bodies, a rich store of arachidonic acid. Lipid bodies increase in number during cell activation, and are thought to be derived from membrane catabolism and the rapid synthesis of lipid mediators such as the cyclooxygenase and lipoxygenase derivatives of arachidonic acid.[29]

Mediator Secretion

Mast cells and basophils undergo distinct patterns of granule mediator secretion or synthesis, depending on the stimuli involved in their activation.[26,30] *Degranulation* or *regulated exocytosis,* whereby granules or their contents are released, occurs following stimulation through the IgE receptor or numerous other receptors, such as those for fragments of the complement cascade. This degranulation can be extensive, involving the majority of the granules, or it can be more restricted. The numbers of granules involved appear to correlate with the proportion of the total cellular histamine that is released. The granules rapidly exhibit signs of swelling, then demonstrate membrane fusion with adjacent granules; interconnecting chains and channels form that ultimately fuse with the plasma membrane, creating pores or larger openings and subsequently granule contents or larger granule structures can be seen outside the cell. Prominent cytoplasmic microtubules can be seen close to the granules, and actin complexes appear outside the cell in association with granules or their contents. The process is generally similar for basophils. Electron-dense granules appear to evolve into electron-lucent vacuoles, many of which communicate with other vacuoles and the cell surface through pores within 5 to 10 minutes of activation. Apparently intact granules can be seen outside the cell. This degranulation does not lead to prominent cell death, and cells can recover and degranulate again.[26,31]

Another form of secretion of stored mediators is *piecemeal degranulation*, involving production of small vesicles arising from granules that shuttle selected granule components to the extracellular milieu.[30] Piecemeal degranulation also occurs in both mast cells and basophils, as well as in eosinophils,[26,32] and is the most prevalent morphologic expression of mast cell and basophil secretion in nonallergic inflammatory conditions in human biopsy material. It is postulated that intragranular vesiculotubular networks fuse with the plasma membrane, and discharge their granule contents to the extracellular space. This form of mediator secretion appears to be associated with secretion of selected mediators, rather than the entire contents of the granules. It has been reported in communications between mast cells and neurons

in the brain,[33] in psychosocial stress,[34] and in acute gastritis,[35] and may be a component of responses to Toll-like receptor (TLR) activation.[4] In inflammatory reactions in which mast cell and basophil infiltration occurs, such as in cutaneous delayed hypersensitivity, piecemeal degranulation can occur. As with anaphylactic degranulation, piecemeal secretion is associated with the ability of mast cells to recharge their granules and function again.

Cytokines and chemokines are also secreted by mechanisms independent of degranulation, as are arachidonic acid metabolites, prostaglandins, and leukotrienes. Newly synthesized cytokines and chemokines can be secreted by a process called *constitutive exocytosis*. The pathways of secretion of arachidonic acid metabolites as well as those for exosome release are poorly known.

Recovery after Activation

Dvorak[26] summarized the evidence for the ability of mast cells and basophils to recover and regranulate following activation. During this process, mast cells and basophils appear to conserve membranes and other components and to resynthesize granule and other components, such as rough endoplasmic reticulum, Golgi, and microtubules. This recovery generally occurs within 1 to 2 days; whether death occurs by necrosis or apoptosis as a critical feature of mast cell or basophil activation in vivo needs to be more carefully evaluated.

ONTOGENY AND DEVELOPMENTAL BIOLOGY OF MAST CELLS AND BASOPHILS

The tissue mast cell and the blood basophil are not normally derived directly from a common progenitor, but share their origins from a $CD34^+$ hemopoietic stem cell regulated closely by various marrow and tissue stromal factors (Fig. 9.3A, B). A unique role is played by CD34 itself—which can be found on some mast cell subpopulations, and is involved in mast cell migration as well as tissue inflammatory responses—in these processes.[18,36]

Recent evidence suggests that mast cells are derived from a separate, nonmyeloid lineage-committed progenitor,[23] and that, for the most part, basophils and mast cells have distinct ontogenic derivations and markers,[23] although evidence from leukemic cell lines raises the possibility of some lineage pathway commonalities.[37–39,40] Phylogenetically, there appears to be an inverse relationship between the presence of basophils and mast cells, as well as supporting evidence for a "common origin" by analysis of the evolution of a mast cell progenitor from an ancestral leukocyte involved in innate immunity.[1,2,41] Major advances in understanding human basophil and mast cell growth and differentiation have come from rodent models,[14,42,43,44] which have recently included an appreciation of the pivotal roles played by epithelial factors such as TSLP, IL-33, IL-25, and receptors such as the TLRs [45,46] in basophil, eosinophil, and mast cell differentiation.

Identification of the mast-cell hemopoietin and ligand, stem cell factor (SCF), and its receptor, *c-kit* (CD117), has provided a wealth of insight into the functional role of mast cells in a variety of processes. Mutations in either the ligand ("Steel" locus) or its receptor ("W" locus) render mice largely mast-cell–deficient, facilitating evaluation of the role of mast cells in a variety of animal models.[47,48] Mast cells have thus been revealed to be key players not only in allergic inflammation but also in angiogenesis and tumor growth, tissue remodeling, graft tolerance, and some autoimmune diseases.[19,20,21,22,49,50,51,52] However, inasmuch as mutations of the SCF/c-kit loci also affect other hematopoietic lineages and gut function, these studies must be interpreted with caution; novel studies with more selective mutations have suggested that some of the functions previously ascribed to mast cells might be artifacts of the "W" strains.[53,54] Nonetheless, advances in isolation and analysis of mast cell and basophil populations[3,9,10,11] have provided novel insights into their functions and transcriptional regulation of their hemopoietic development.

Mast Cell Growth and Differentiation

Rodent and human mast cells can be grown in vitro from lineage-committed, unipotent, or multipotent progenitors. Although

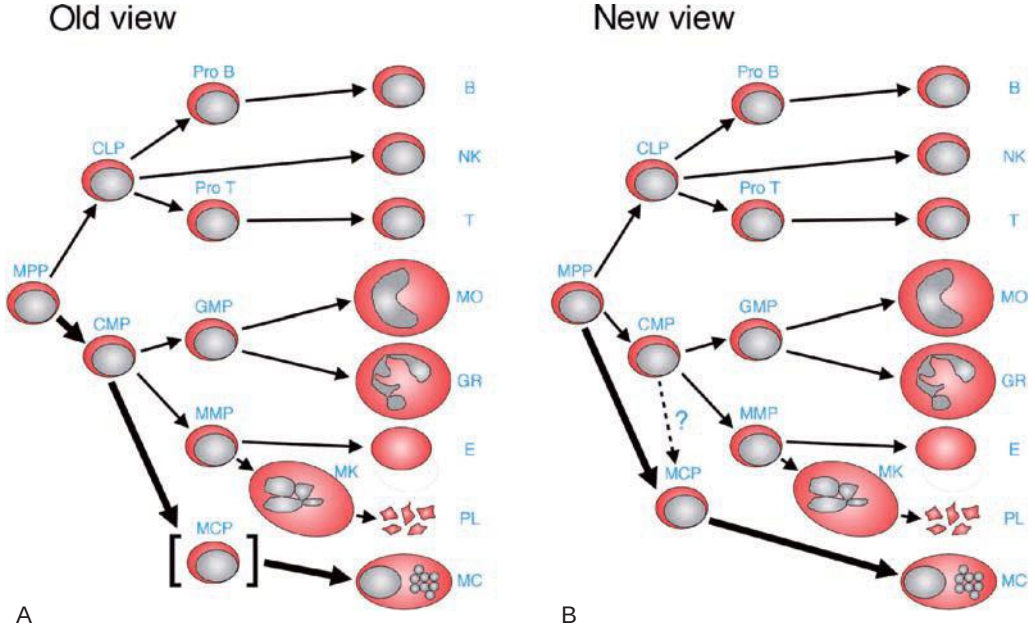

FIGURE 9.3. Change of lineage model of hematopoiesis. A. In the old view, the presence of mast cell committed progenitors (MCP) was not clear, but mast cells were considered to be the progeny of common myeloid progenitors (CMP) without convincing evidence. Therefore, MCP is put in brackets. **B.** In the new view proposed by Chen et al.[23] the presence of MCP is clear, and MCP is directly derived from multipotential progenitors (MPP). The thick line shows the main differentiation route from MPP to mast cell. CLP, common lymphoid progenitor; GMP, granulocyte/macrophage progenitor; Pro B, progenitor B cell; Pro T, progenitor T cell; B, B cell; NK, natural killer cell; T, T cell; MO, monocyte/macrophage; GR, granulocyte; E, erythrocyte; PL, platelet; MC, mast cell. (Reproduced with permission, Proc Natl Acad Sci U S A 2005;102:11129–11130 © 2005 National Academy of Sciences, U.S.A[74]).

interleukin-3 (IL-3) is known to contribute to murine mast cell and to both human and rodent basophil development,[55,56,57] it is SCF or *c-kit* ligand[58] which uniquely drives human mast cell differentiation, and not other cytokines that may help promote mast cell development in rodents, such as IL-3, IL-4, IL-9, IL-10,[59] and nerve growth factor (NGF).[60] SCF is produced by murine and human fibroblasts, epithelial cells, endothelial cells, and tumor cell lines,[61] and must bind to *c-kit* to effect differentiation. Mutations in *c-kit* can result in mast cell deficiency in vivo and in vitro ("loss-of-function") or, alternately, in autonomous mast cell growth ("gain of function"), generally leading to autophosphorylation.[62] The latter mutations, especially the D-816-V–associated mastocytosis (which can be transferred with similar consequences to the mouse[62]) have formed the basis of newly designed tyrosine kinase inhibitors in some proliferative mast cell and hypereosinophilic disorders.

Recently, it has been shown that both Th1 and Th2 cytokines (interferon-g [IFN-g], IL-4, and IL-5), the latter induced in rodents via TSLP and IL-25 or IL-33 acting in concert, induce a distinct population of multipotent mucosal progenitors ("nuocytes")[14,42,43,44,63] and thus may exert differential modulatory effects on SCF-dependent mast cell numbers in vitro and in vivo.[64] Table 9.1 lists cytokines, growth factors, transcription factors, and signaling molecules that regulate primate/human and rodent mast cell differentiation.[51,65,66,67,68]

Mast Cell and Basophil Progenitors

In humans and in rodents, mast cell differentiation proceeds from an immature $CD34^+$, $CD38^+$, $CD13^+$, c-kit^+, $Fc\varepsilon RI^-$, $Fc\gamma RII/III^+$ cell, or, as recently shown, from a previously uncharacterized immature cell in mouse marrow.[23,24,25] More specifically, a multipotent hemopoietic progenitor of both mucosal and serosal mast cell phenotypes can be identified, and is characterized as Lin^-c-kit^+Sca-1−Ly6$c^-$$Fc\varepsilon RI^-CD27^{-\beta}7^+$T1/$ST2^+$[69] (Fig. 9.4).

Mast cell differentiation, heterogeneity, abundance, and functional responses are also regulated in vitro and in vivo in rodents by CD34 itself and through the actions of several transcriptional and nucleosomal regulators such as PU.1, GATA factors, C/EBP factors, and MITF, as well as through M-Ras, and RabGEF1 type signaling molecules.[39,66,68,70,71,72] Phenotypical alterations of mast cell populations can be governed by the tissue milieu, and they also exhibit switching and "trans-differentiation," [1,73] reflecting stochastic processes in progenitor differentiation. Primitive cord blood $CD34^+$ c-kit^+ progenitors may respond quite differently to hemopoietic cytokines than more mature $Fc\varepsilon RI^+$, c-kit^+ cells.[23,74] Thus, tissue-dependent stages of progenitor commitment and of growth and differentiation signals may ultimately predict differences in mast cell phenotype in vivo.[75] Mast cell progenitors can be identified in blood, bone marrow, and various other tissues, especially in relation to mast-cell–inducing stimuli, such as viruses or nematodes.[69]

Leukemic or other self-sustaining cell lines with basophilic or mast cell phenotype have also been used to study progenitors and immunophenotypic markers of lineage commitment.[76] Although these findings may represent aberrant pathways activated during malignant transformation, the recent identification of a novel antigenic marker of mast cells, basophils, and their progenitors,[77] and the presence in peripheral blood of basophilic cells that express mast cell proteases[78] have revived earlier postulates[79] that these cell types share some lineage characteristics under conditions of aberrant cell growth,[37,38] although rodent eosinophil lineage-committed progenitors may not express basophil/mast cell-related proteases.[80]

New and exciting information has emerged on the role of gut microbiota in regulating a TSLP-induced, IgE-dependent Th2 response, involving basophil progenitors in rodents, and in humans with hyper-IgE syndrome.[12] Profound decreases in gut flora lead to a B-cell driven overproduction of IgE with binding to its high-affinity receptor, and thus to increased marrow basophilopoiesis, with Th2 skewed inflammatory responses. Previous work on normal, atopic, or leukemic/mastocytotic human blood or marrow had identified pure or mixed basophil colonies in semisolid cultures,[79,81,82] thus defining a basophil progenitor (termed "CFU-baso" or "CFU-baso/eo").[81,83] The phenotype and lineage commitment of the basophil progenitor, including recent controversial notions of possible lineage pathway commonalities with mast cells and/or megakaryocytes,[84,85] are depicted in Figure 9.4.

TABLE 9.1

CYTOKINES AND OTHER FACTORS INVOLVED IN BASOPHIL AND MAST CELL GROWTH AND DIFFERENTIATION

Cytokine	Effect
GM-CSF	Basophil growth and differentiation; promotes in vivo basophilia and increases in circulating CFU-baso/eo (primates); basophil activation/survival; down-regulates human mast cell differentiation.
IL-3	Human basophil growth and differentiation; basophil activation/survival; promotes in vivo basophilia (in primates); mast cell differentiating activity in rodents.
IL-5	Primarily eosinophil, but also basophil growth and differentiation; basophil and eosinophil activation/survival.
TSLP/IL-33/IL-25	Co-factors in rodent nuocyte (multipotent mucosal progenitor) differentiation and tissue basophilic responses.
IL-4/IL-13	Produced by basophils with minimal activity on differentiation.
IL-9/IL-10/THPO	Co-factors in rodent mast cell phenotype switching.
TGF-β/IFN-α	Negative regulators of basophil differentiation.
SCF	Primary mast cell growth factors in mouse and rat; little known effect on basophil differentiation.
NGF	Induces mast cell hyperplasia (rodents), human mast cell line (HMC-1), and basophil–eosinophil differentiation in vitro.
RA	A mutation in the RA receptor allows for expression of basophil differentiation; may concurrently down-regulate human mast cell differentiation.
v-erb	Associated with the development of lethal mastocytosis in the rodent.
$Fc\gamma RIIB$	Down-regulates mast cell growth.
Stat5	An essential regulator in vivo of mast cell development.
IL-6/TNF/IFN-γ	May play a role in regulating phenotypic direction and lineage commitment of human basophils and mast cell subtypes.

GM-CSF, granulocyte–macrophage colony stimulating factor; INF, interferon; IL-, interleukin-; NGF, nerve growth factor; RA, retinoic acid; SCF, stem cell factor; TSLP, thymic stromal lymphopoietin; TNF, tumor necrosis factor.

Basophil Differentiation-inducing Cytokines

IL-3 is the main cytokine involved in human basophil growth and differentiation,[86] with some evidence for a co-factor role for TSLP. Granulocyte–macrophage colony stimulating factor (GM-CSF),[79,81,82,87] IL-4,[88] IL-5,[83,88] and SCF[89] may also play roles. A mutation in the retinoic acid (RA) receptor permits basophil differentiation; studies on basophil crisis in chronic myeloid leukemia and the in vitro suppressive effects of RA on basophil–eosinophil differentiation support this notion.[90] Cytokines and other factors that modulate basophil or mast cell differentiation are listed in Table 9.1.

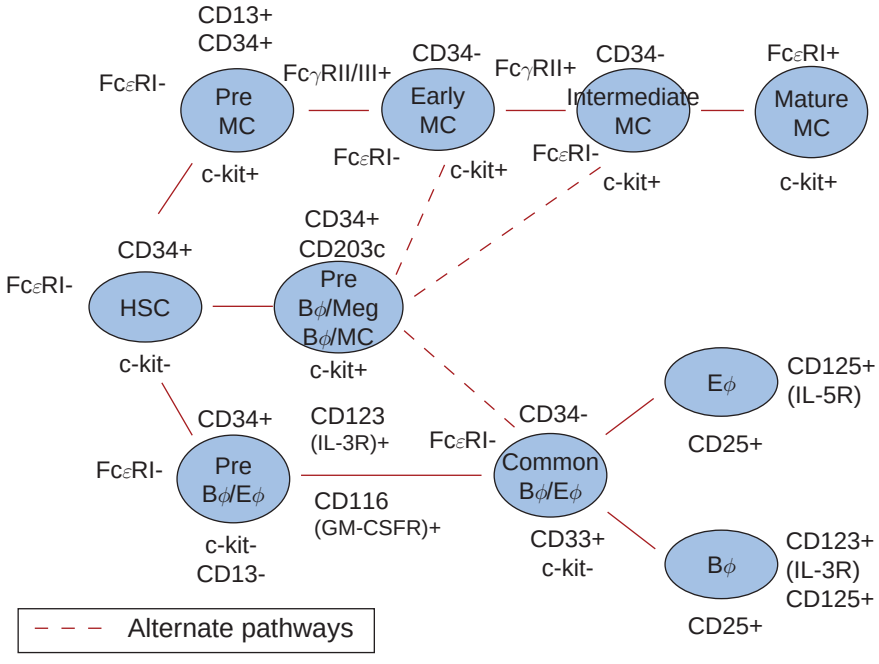

FIGURE 9.4. Mast cell and basophil ontogeny. An orderly sequence of differentiation is depicted, beginning with a primitive CD34$^+$, FcεRI$^-$, c-kit$^-$ hemopoietic stem cell (HSC), and proceeding through various stages of commitment to either mast cell or basophil/eosinophil lineages. In reality, the differentiation process is stochastic, and multiple cytokines binding to their receptors permit specific, end-stage differentiation to proceed. For more detailed phenotypic analyses of basophil and mast cell progenitors, see Wang et al. [37]

Clinical Relevance of Basophil and Mast Cell Differentiation

Allergic Diseases

The relationship to disease activity, severity, and response to therapy of fluctuations in numbers of human basophil–eosinophil, basophil–mast, or mast cell progenitors—including CD34$^+$ cell subpopulations—in the blood and bone marrow of patients with a variety of allergic disorders, including allergic rhinitis, nasal polyposis, asthma, atopic dermatitis, and drug allergies, has been extensively documented.[59,91] Indeed, therapies targeting basophil–eosinophil progenitors with anti-IL-5 monoclonal antibodies have had some efficacy in causing maturation arrest of these shared lineages, accompanied by some clinical benefits, in patients with eosinophilic bronchitis and asthma[92,93]; targeting of basophil or mast cell progenitors in these and some hematologic disorders may likewise prove to be effective treatments. For example, the IL-3R is expressed at high levels by basophil progenitors and subsets of dendritic cells; therefore, development of high-affinity monoclonal antibodies to this receptor would be predicted to dampen allergic disease.

It has been noted that up-regulated CD34 expression correlates closely with the development of allergic disease.[94] Although it is best known for its expression by early multipotent hematopoietic progenitors, CD34 is more selectively expressed by monopotent lineages associated with allergic disease (mast cell, eosinophil, and dendritic cell precursors[95]); recent data suggest that CD34 enhances their capacity for migration to peripheral tissues.[96] Therefore, therapeutic antibodies targeting CD34 as an enhancer of migration may also prove to be an effective approach. Finally, because IgE binding to FceRI leads to basophilopoiesis and increased susceptibility to allergic disease,[12] blocking antibodies directed to IgE, IgE-producing B-cells, or the IgE receptor on basophils would also be predicted to be helpful therapeutically via a number of mechanisms. Given that deletion of the encoding genes for these receptors (IL-3R, CD34, and FceRI) in mice has no apparent deleterious effects on development, therapies targeting these molecules would be predicted to be well tolerated.[97,98,99]

Malignancies

In transient leukemias occurring in Down syndrome (trisomy 21), in various hematologic malignancies, as well as in megakaryoblastic leukemia, there is basophilic differentiation (which may also include mast cell proliferation) from leukemic cell progenitors. This could involve aberrant stimulation of basophil or mast cell progenitors by certain transcription factors that also regulate erythroid and megakaryocytic lineages, including GATA-1 to GATA-3.[100,101] Embryonic stem cells or CD34$^+$ progenitors transfected with GATA genes express varying degrees of erythroid/megakaryocytic and basophil/mast cell commitment,[100] whereas mice with mutations in the eosinophil-specific promoter of the GATA-1 gene completely lack eosinophils. Factors such as Gab-2, certain adaptor proteins,[102] signaling molecules, Lyn, and SHP-1, or the flt3 ligand for this tyrosine kinase receptor, also can play important roles in basophil and mast cell differentiation.

Other hemopoietic malignancies also exhibit dysregulation of basophil and mast cell lineages, including chronic myeloid leukemia (CML), other myeloproliferative disorders and mast cell proliferative diseases (mastocytosis of various subtypes, urticaria pigmentosa, and mast cell leukemia). In the latter disorders, proliferation of mast cells occurs mainly in tissues, with immature or mature mast cells rarely circulating in blood (the aforementioned leukemia). However, higher numbers of both basophil and mast cell progenitors and changes in their regulatory factors can be documented[79,103,104,105] in both mast cell disorders and leukemias. These observations underscore the capacity of hemopoietic malignancies to blur the normal differences that exist between basophil and mast cell lineages. The previously mentioned "gain of function" mutations in both juxtamembrane and intracellular domains of *c-kit* provide an explanation for many adult mast cell proliferative diseases, although such mutations are rarely found in the pediatric form of limited, skin-associated mastocytosis (urticaria pigmentosa). The biologic significance of increased numbers of mast cells in various hemopoietic and lymphatic malignancies, as well as in refractory anemias, may be related to acquisition in the leukemic clone of concomitant *c-kit* mutations.

Basophilia or basophil crisis heralding terminal blast crisis in CML is well known[103] and the fusion protein bcr-abl may be

involved in basophil/mast cell lineage expression during this phase (see above). Hyperhistaminemia in CML and myeloproliferative disorders is related to increased numbers of basophils (and, possibly, mast cells) [90]; indeed, blood basophilia and increases in basophil progenitors are poor prognostic indicators in CML.[90,103] Such phenomena may relate to specific chromosomal abnormalities in forms of leukemia associated with basophilia or eosinophilia, for example, inversion of chromosome 16 (inv 16) associated with atypical eosinophils with mixed granulation; t(6;9) chromosomal translocation associated with basophilia and leukemia; trisomy 21; and several translocations associated with increased numbers of basophils in acute promyelocytic and other leukemias, such as t(15;17), del(5)(q31q35), and t(9;14).[106,107] However, the precise relationship between specific chromosomal aberrations and basophil or mast cell differentiation in vivo is not clear. Recently and importantly, increases in blood basophils, presumably on the basis of increased basophilopoiesis, have been described in human hyper-IgE syndrome, associated with a DOCK8$^-$ polymorphism,[108] paralleling the rodent model.[12]

Apart from *c-kit*/SCF, whether other cytokines are involved in malignant basophil or mast cell proliferation in vivo is not known; for example, dysregulated cytokine genes such as those encoding IL-3, IL-4, IL-5, and GM-CSF in 5q-leukemias may play a role in phenotypic expression of leukemic cells. Detailed therapeutic approaches for hematologically based basophil and mast cell disorders is beyond the scope of this chapter, and is dealt with elsewhere in this book.

CHARACTERISTICS OF MAST CELLS AND BASOPHILS

Surface Phenotype and Activation

A wealth of information is available about the surface phenotype of mast cells and basophils (Table 9.2), including identification of receptors for immunoglobulins, complement components, cytokines and chemokines, arachidonic acid metabolites, e.g., CRTH2 (chemoattractant receptor-homologous molecule expressed on T-helper class 2 cells, also known as D prostanoid receptor 2 [DP2]), CD200, vitamin D, and ligands for TLR; as well as integrins and other molecules with or without CD nomenclature.[4,5,109,110–112,113,114,115,116] However, one must be cautious in making generalizations about surface receptor expression and mast cell/basophil phenotype given the heterogeneity of mast cells from various tissue sites and species, and the in vivo relevance of various mast cell and basophil-like cell lines.

One prominent difference between mast cells and basophils is that mature mast cells can express CD117 or *c-kit* (Table 9.2), whereas basophils do not. Another potentially important difference lies in expression of Fc receptors that provide key pathways for activation and modulation of function (Table 9.2 and 9.3). Although both mast cells and basophils express high-affinity receptors for IgE,[117,118] mast cells can express the FcγR CD16, CD32, and CD64,[119,120] but to date the only receptors for IgG that have been identified on basophils are FcγRIIA and B (CD32). Further investigation of Fcγ receptors on human mast cells and basophils will be important, because different receptors such as FcγRIIA and B and FcγRIII, can play distinct roles in mediator secretion and phagocytosis or endocytosis.[120] Mice deficient in FcγRIIB are highly sensitive to IgG-triggered mast cell degranulation through FcγRIII, and exhibit enhanced passive cutaneous anaphylaxis and elevated immunoglobulin levels in response to antigen stimulation.[121] FcγRIIB down-regulates FcεRI signaling and is important in the regulation of mast cell and basophil activities.[122,123] Interestingly, it has recently been shown that basophils and mast cells express a protease-sensitive, IL-3- or IL-4-inducible receptor for IgD that is distinct from receptors for

TABLE 9.2

EXPRESSION OF SELECTED SURFACE MARKERS ON HUMAN MAST CELLS AND BASOPHILS

Marker	Mast Cells	Basophils
Fc Receptors	FcεRI ($\alpha\beta\gamma2$); FcγRI, IIA, IIB, III (CD64, 32, 16)	FcεRI ($\alpha\beta\gamma2$); FcγRIIA, IIB
Integrins	CD11c/18 ($\alpha X\beta_2$)	
B_2 family		CD11a/18 ($\alpha L\beta_2$) CD11b/18 ($\alpha M\beta_2$) CD11c/18
	CD49c/CD29 (α_3B_1)	
B_1 family	CD49d/CD29 (α_4B_1) CD49e/CD29 (α_5B_1)	CD49d/CD29 CD49e/CD29
Selectins	N/A	L, P, and E (CD62L, CD162, CD15s)
Chemokine receptors	CCR1,3,4,5,7 CXCR1,2,3,4,6	CCR1,2,3,7 CXCR2,4
Cytokine receptors	c-kit (CD117) IL-3Rα (CD123) IFNγR IL-1R, IL-10R IL-33R (ST2)	IL-2R (CD25) IL-3R2 (CD123) IL-3/5/GMRβ IL-18Rβ IL-33R
Cysteinyl leukotriene receptors	cysLT1,2	cysLT1,2
Prostaglandin receptors	$CRTH_2$ EP1-3	$CRTH_2$
Toll-like receptors	TLR2,3,4,6,9	TLR1,2,4,6,9
Other	CD200R3 Vitamin D receptor	CD200R3 2D7 antigen

TABLE 9.3

SELECTED MEDIATORS OF HUMAN MAST CELLS AND BASOPHILS[a]

	Cell Type	
Marker	**Mast Cells**	**Basophils**
Histamine	+	+
Platelet-activating factor (PAF)	+	+
Nitric oxide	+	NK[b]
Proteoglycans	Heparin, chondroitin sulfates	Chondroitin sulfates
Arachidonic acid metabolites	LTB_4, LTC_4, PGD_2, PGF_2, thromboxane A_2	LTB_4, LTC_4
Proteinases	Tryptase, chymase, carboxypeptidase A, cathepsin G-like	
Cytokines/ chemokines/ growth factors	IL-1,2,3,4,5,6,8,10,11,13,16 TNF, LT, NGF, TGF-β, GM-CSF, RANTES (CCL5), MCP1 (CCL2), I-309 (CCL1), MIP1α (CCL3), 1β (CCL4), lymphotactin (XCL1), FGF, PDGFAB, VEGF, BDNF	IL-4, IL-13, MIP-1α (CCL3)

[a]Mediators selected from more comprehensive lists published by others and recent updates (e.g., [4,5,131,132,149]).
[b]NK, not known.

IgG, IgE, and IgA.[124] Activation of basophils via this IgD receptor has no effect on histamine secretion, but can induce release of antimicrobial peptides, IL-4, and B-cell activating factor.[5,124]

A number of other stimuli, including anaphylatoxins C3a and C5a, certain lectins, and the bacterial product formyl methionyl leucyl phenylalanine (fMLP) activate basophils and/or mast cells. Interestingly, polycationic substances such as compound 48/80 and numerous basic polypeptides including a spectrum of neuropeptides activate human skin mast cells, but not human mast cells from other sites, or human basophils.[125] Presently, the working model to explain these observations[125] is that human skin and rat peritoneal mast cells possess a binding site for these polycationic secretagogues, including neuropeptides such as substance P, which leads to activation of G_i-like G-protein and cell activation. This binding site appears to be distinct from the tachykinin NK1 receptor that has been associated with in vivo mast cell activation.[126] Neurogenic vasodilatation produced by an axonal reflex in human skin appears to involve mast cell activation by neuropeptides released from primary afferent nerves.[125] Mast cell-dependent neurogenic inflammation has been described in the respiratory and gastrointestinal tracts [e.g.,[127]], and appears to be important in at least some inflammatory and infectious diseases. More recently, the relationship between mast cells and nerves has been emphasized in the intestine as a component of the gut–brain axis,[128] as well as in pain hypersensitivity [129] and hypoxia–ischemia injury in the immature brain.[130] Further work on bidirectional communications between mast cells and the nervous system will be enlightening.

Recently there has been great interest in activation of basophils and mast cells by several interleukins, chemokines, and other factors (Table 9.4).[24,131,132] The significance of these pathways of basophil and mast cell activation in vivo in health or disease is becoming increasingly clear, particularly in chronic allergic and parasitic diseases, and in relation to commensal bacteria and particularly the gut microbiome.[3,9,10,11,12,14,42,43,44,133,134] The CC chemokines appear to be important in basophil activation; however, there is less information for mast cells. SCF appears to be a specific stimulus for mast cells, acting through the receptor CD117.[135] Redegeld et al. have made the intriguing observation that highly purified immunoglobulin light chain can sensitize mast cells for antigen-specific activation, providing a molecular mechanism for earlier observations of antigen-specific, but non-antibody–mediated mast cell activation. Additional research on the role of such stimuli for mast cells and/or basophils will shed light on the pathogenesis of inflammatory disorders such as inflammatory bowel disease, rheumatoid arthritis, and allergic airway diseases.[136,137]

Another intriguing difference between mast cells and basophils lies in their expression of selected integrin molecules (Table 9.2). Human basophils, but not mast cells, express CD11a/18, CD11b/18, and CD11c/18, which have as their complementary ligands, ICAM-1/2, C3bi, and fibrinogen, respectively. The latter are expressed on endothelial cells and appear to be involved in the migration of basophils into the tissues during inflammation. By contrast, mature mast cells and basophils express a repertoire of adhesion molecules designed to interact with the extracellular matrix components, which play significant roles in cell recruitment and activation. In particular, rodent basophils are readily distinguished from mast cells based on their selective expression of the collagen receptor, CD49b/29.[138]

Recent focus on mast cells in innate immunity, including their expression of TLR and other molecules[4,131,139,140] has markedly influenced our view of these cells. Basophils express a partially overlapping, but distinct, repertoire of these types of receptors,[5] and thus must have roles in innate immunity distinct from mast cells. Similarly, although some exciting clues have been uncovered (e.g., ultraviolet B irradiation- and vitamin D receptor-dependent production of inflammation-depressing IL-10 by cutaneous mast cells[141]), much remains to be learned about the functions of many other surface molecules on mast cells and basophils, including the vitamin D receptor, CD200R,[142,143] and receptors for IL-33[144,145] and TSLP[146,147] (see Table 9.2).

TABLE 9.4

FACTORS THAT ACTIVATE MEDIATOR SECRETION FROM HUMAN BASOPHILS AND MAST CELLS

Stimulation	Mast Cells	Basophils
FcεR and FcγR cross-linkage	+	+
Compound 48/80	SMC only	−
Basic polypeptides[a] (includes several neuropeptides)	SMC only	−
Anaphylatoxins (C3a C5a)	+	+
fMLP	−	+
Lectins (e.g., Concanavalin A)	+	+
Interleukins/chemokines (CC)/ histamine releasing factors (HRF)	MIP-1α (CCL3) IL-1 SCF Ig light chain	MCP1(CCL-2), MCP2(CCL-8), MCP3(CCL-7), MIP-1α(CCL3), RANTES(CCL5), IL-8(CXCL8), HrHRF CTAPIII/NAP-2
TLR ligands	TLR2,3,4	TLR2
IL-33 increases cytokine production and secretion without degranulation.[145]		
TSLP stimulates Th2 cytokine production in mast cells.[15,147]		
CD200R binds CD200 and thereby inhibits mast cell degranulation and cytokine secretion.[143]		

SMC, human skin mast cells.

[a]Includes ACTH, mellitin, substance P, vasoactive intestinal polypeptide, neurotensin, bradykinin, etc.

Mediators

Mast cells and basophils are storehouses of inflammatory mediators that can be released by IgE receptor activation and other stimuli and also synthesize several other mediators upon activation (Table 9.3 and 9.4). Mediators such as histamine, platelet-activating factor (PAF), arachidonic acid metabolites, and several proteinases have been extensively studied and are important in the pathogenesis of inflammatory diseases and tissue injury and repair (e.g.,[4,5,8,132,148]). A major distinction between the two cell types lies in the proteinases that are abundant in mast cells from humans and other species,[149,150] but are not major markers of basophils. These proteinases include tryptases, chymases, carboxypeptidase A3, and dipeptidylpeptidase 1 (cathepsin C).[149] Indeed, proteinases are used as markers of human mast cell heterogeneity, with two major populations separated on their serine proteinase content, namely, those with tryptase only (MC_T) and those with both tryptase and chymase (MC_{TC}). A limited number of MC_C are also found. Recent work on proteinase-based mast cell heterogeneity in mice has established that even for one previously recognized phenotype, mucosal mast cells, there can be tissue-specific differences in proteinase expression, e.g., intestine versus airways.[150] Human basophils can express low levels of tryptases, but little or no chymase.[151] In the mouse, mast cell proteinase 8 (MCP8) and MCP11 have been shown to be more abundant in basophils than mast cells; indeed, MCP8 has been targeted in two

strains of engineered mice to constitutively deplete basophils, or to deplete basophils in a conditional manner (e.g., diphtheria toxin-mediated[7]). Since initial observations in the 1980s, research on cytokine and chemokine production by mast cells and basophils has expanded rapidly (Table 9.3).[132,152,153,154,155] Given that there is literature on cytokine expression in cells from in vivo sites, the relevance of many studies utilizing long-term in vitro cell lines must be viewed cautiously. Moreover, although expression of mRNA may be detected by sensitive methodologies, the actual quantities of the encoding proteins secreted by mast cells and/or basophils may range from small to relatively large; how this relates to levels produced by other cell types must be carefully evaluated. For example, basophils produce relatively large quantities of IL-4 and IL-13 (hundreds of picograms per 10^6 cells) and are therefore considered to be important in vivo sources of these cytokines in selected settings. Mast-cell–derived chemotactic factors can be important components of host defenses induced by viruses as well as by cancer.[154,155] Furthermore, the cytokine repertoire of mast cells includes a broad spectrum, representing those associated with both Th1 and Th2 phenotypes; it is likely, therefore, that in a given population of mast cells, cytokines are differentially expressed in individual cells or at different times, or that individual mast cells express several functionally distinct cytokines. In the latter case, control mechanisms may regulate production, secretion, and functions of individual cytokines. Most recent work suggests that cell type-specific regulation of cytokine expression can be under epigenetic control at the level of structural modifications in the DNA.[156]

Inhibition of Basophil and Mast Cell Activation

Several antiallergic and anti-inflammatory drugs inhibit the release of histamine and other mediators, including cytokines and chemokines and arachidonic acid metabolites from human basophils and/or mast cells (Table 9.5).[157,158] Although many of these drugs are valuable in the treatment of allergies and other inflammatory diseases, their mechanisms of action are diverse: none is mast cell- or basophil-specific, and the precise targets in vivo can be difficult to define. Furthermore, given the heterogeneity of mast cells at different tissue sites, and perhaps even at different times during the evolution of an inflammatory insult (e.g., initial injury, repair, chronic, or remodeling phases), agents may vary in the nature or extent of their modulatory effects on basophils and mast cells during the course of an inflammatory response or disease.

There are several promising advances in drug development targeting mast cells and basophils and their roles in allergic and other inflammatory processes. One such development has been with humanized monoclonal antibodies. For example, humanized monoclonal antibodies to IgE reduce IgE levels and decrease the density of high-affinity IgE receptors on mast cells and basophils, thus limiting sensitivity to allergens. Anti-IgE has been reported to be effective and safe in treatment of allergic asthma, rhinitis and peanut allergy,[159] and its use in other conditions is under investigation. Moreover, from this pioneering approach with humanized monoclonal antibodies, numerous other potential therapeutic targets are being explored, including, for example: IL-4, IL-5, IL-9, IL-13, and CCR3.[160,161] Other promising targets for development of drugs that would inhibit mast cell and basophil function include: Syk kinase[162,163]; the prostaglandin D2 receptor, CRTH2 [164,165]; c-kit[166]; and several inhibitory molecules expressed by mast cells and basophils that have in common immunoreceptor tyrosine-based inhibitory motifs (ITIM), such as FcγRIIB, leukocyte Ig-like receptor B4 (LILRB4), sialic acid-binding immunoglobulin-like lectin 8 (Siglec-8), CD200R; and mast cell function associated antigen (MAFA).[167,168,169,170] Other classes of compounds, such as the plant flavonoids have a variety of anti-inflammatory activities including the inhibition of mast cell and basophil functions (e.g., [171,172]).

Given their potency, and the plethora of functions of mast cell and basophil cytokines and chemokines, it is not surprising that these cells are a focus of study to modulate allergic and other inflammatory events. Furthermore, the postulate that distinct profiles of cytokines (Th1 and Th2) orchestrate these responses has stimulated studies of cytokine regulation of mast cell and basophil functions. As predicted by the Th1/Th2 paradigm, the Th1-associated cytokine IFN-γ and related IFN-α/β, inhibit mast cell degranulation and tumor necrosis factor (TNF) secretion.[4] IFN-γ has no effect on basophil cytokine secretion, but IFN-α inhibits IL-4 and IL-13 secretion from human basophils, but has no effect on histamine of LTC4 secretion.[173] Interestingly, the effects of IFN-γ on mast cell mediator secretion are dependent on exogenous or endogenous nitric oxide.[4,174] TGF-β_1 also inhibits histamine and TNF production by rat mast cells.[175] Furthermore, IL-10, often associated with Th2 responses, inhibits TNF and IL-6 production by mast cells.[176] but enhances their antigen-induced secretion of histamine.[177] This information, taken together with evidence that other mediators such as histamine and arachidonic acid metabolites[178–181] modulate mediator secretion, suggests that several basophil and mast cell mediators may have autocrine-regulatory roles in inflammation.

TABLE 9.5

INHIBITION OF MEDIATOR SECRETION FROM MAST CELLS AND BASOPHILS

Existing Drugs
β_2 Adrenergic agonists
Methylxanthines (nonselective phosphodiesterase inhibitors)
Antihistamines (H1–H4)
Sulfasalazine (or metabolites)
Corticosteroids
Cyclosporine A/Fk506
Ketotifen
Monoclonal antibodies (e.g., anti-IgE)
Sodium cromoglycate/nedocromil sodium (inhibit mast cells but not basophils)
Drugs in Development
Flavonoids (e.g., Quercetin)
Syk kinase inhibitors
Monoclonal antibodies to several biologic targets
Agonism of immunoreceptor tyrosine-based, inhibitory motifs (e.g., FcγRIIB, $LILRB_4$, MAFA; see text)

BASOPHIL AND MAST CELL FUNCTIONS

Inflammatory Injury and Host Defenses

Investigations of the functions of basophils and mast cells have focused on their roles in allergic and other inflammatory disorders because of the highly visible symptoms of IgE-mediated allergic reactions, including life-threatening anaphylaxis. In turn, a great deal has been learned about some aspects of these cells, notably about their activation, inflammatory mediators, and regulation. Numerous drugs are available that inhibit many of their functions, and a wealth of novel approaches are emerging that will exploit numerous pathways to regulate allergic and other inflammatory responses. Nevertheless, several challenges remain, including perhaps the most obvious question: why do both basophils and mast cells exist, and what functions distinguish them?

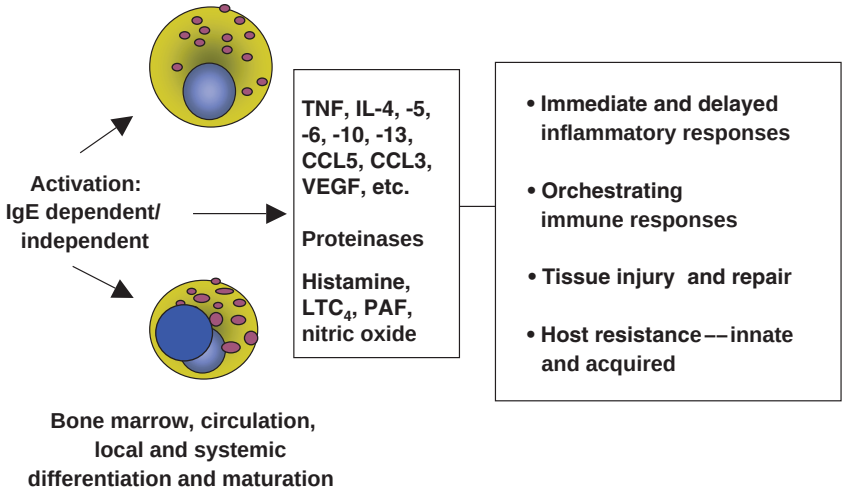

FIGURE 9.5. Summary of the activation of mast cells and basophils, the mediators they produce, and the spectrum of their actions in host defenses and tissue injury.

Basophils and mast cells are central players in allergic inflammation as they express high-affinity receptors for IgE and produce several mediators in common, each with potential to initiate inflammatory cascades and complex cellular and molecular networks involved in injury and repair (Fig. 9.5). In early phases of allergic responses, the pool of circulating mature basophils and the large tissue repository of mast cells are important. However, basophils and mast cells are not restricted to these sites, because under certain circumstances a large influx of basophils can occur into local tissues (e.g., cutaneous basophilic hypersensitivity[182], asthma[183]), and the numbers of mast cell progenitors in the circulation and in selected tissues can be increased.[184,185]

The roles of basophils and mast cells in allergic inflammation differ with regard to some of the stimuli that are important for cell activation. Some mast cell populations respond to a number of basic secretagogues, including several neuropeptides, and given the close anatomical association between mast cells and nerves[186] and abundant evidence for their functional interdependence, it is likely that mast-cell–dependent neurogenic pathways are important. There is much less evidence to suggest that neurogenic inflammation is a major pathway in basophil-mediated reactions. It is intriguing that IgE receptors have recently been discovered on neurons,[187,188] and although the clinical significance of this observation is currently unknown, the implications are considerable. For example, depending upon the distribution of IgE receptors on neurons in the CNS as well as peripherally, allergens could communicate directly with the nervous system and impact sensory pathways, central processing or efferent responses, as well as cognition and behavior. Such pathways might help explain associations between stress and depression and allergy.[189]

Since the first reports of the role of mast cells in innate antimicrobial immunity,[190,191] there has been great interest in expression and function of TLRs on mast cells[131,132] and basophils.[139,140] The signaling pathways employed by such receptors to induce mast cell and basophil activation and mediator secretion will be particularly enlightening with regard to selectivity of mediator secretion and cell functions.[192] There is increasing evidence that the profiles of mediators produced by these pathways differ from those following IgE-mediated activation; knowledge of such differences will help elucidate the distinct roles of these two cell types in host defenses and inflammatory diseases (e.g.,[193]).

The role of mast cells and basophils in the development and expression of adaptive immunity has also been an exciting area of new knowledge, albeit with some controversy.[3,5,11,193] Both mast cells and basophils can enter draining lymph nodes[194,195] and mast cells are well known to induce dendritic cell traffic to lymph nodes and dendritic cell priming.[196,197] Indeed, mast cell activators and even synthetic mast cell granules are adjuvants of primary immune responses.[198,199] Initial studies suggested that basophils could act as dendritic cells, especially in responses to protease-containing allergens eliciting a Th2 response, but this has been challenged.[3,9,11] As outlined above, the use of W mutant mice that are naturally deficient in mast cells has been a powerful tool to study mast cell functions, but recent work in two additional strains of mice engineered to be mast-cell–deficient (independent of mutations in *kit*) have raised some questions about the conclusions from earlier studies with W mutant mice regarding these functions.[200] Mast cells are confirmed to be critical components in contact sensitivity reactions,[201] but their roles in at least some autoimmune responses have been questioned.[53] With new and powerful tools and models, the next few years promise to provide more clarity about the precise roles of mast cells and basophils in immunity.

The spectrums of mediators produced by mast cells and basophils have similarities and differences. Several mediators are common (histamine, LTC4, PAF, and others, etc.), whereas the cytokine and proteinase profiles of the two cells types are distinct. Although the differences in proteinase content likely hold clues to the functional distinctions among the cell types and among mast cell subpopulations, knowledge of substrate specificities of mast cell proteinases is limited, and thus the functional significance remains to be fully clarified.[149,202,203] It is intriguing that inhibitors of mast-cell–specific tryptase have promising effects in models of allergic asthma.[149] Furthermore, another function associated with mast cell tryptase-heparin complexes is the inhibition of the production of fibrin and clots through fibrinogen degradation at sites of inflammation.[204] Knockout of mast cell proteinases has rapidly expanded our knowledge of some of the functions of these abundant and diverse enzymes. For example, mouse MCP4 has an anti-inflammatory effect in allergic asthma,[205,206] but is pro-inflammatory in models of bullous pemphigoid.[207] Mouse MCP4 and mast cell carboxypeptidase A3 are important in degradation of several animal toxins, e.g., snake, Gila monster and scorpion venom.[208] Basophil-derived MCP11 induces microvascular leakage in mice, independent of mast cells.[209] In the future, drugs designed to selectively activate or inhibit specific mast cell or basophil enzyme-substrate interactions will be of therapeutic value and also help distinguish between the roles of mast cells and basophils in allergic and other inflammatory cascades, such as between the early- and late-phase asthmatic responses to allergen.

Containment of Injury, Initiation of Repair, Remodeling, and Normal Function

Following initial insult and injury, the inflammatory response elaborates mediators and pathways that minimize the extent of

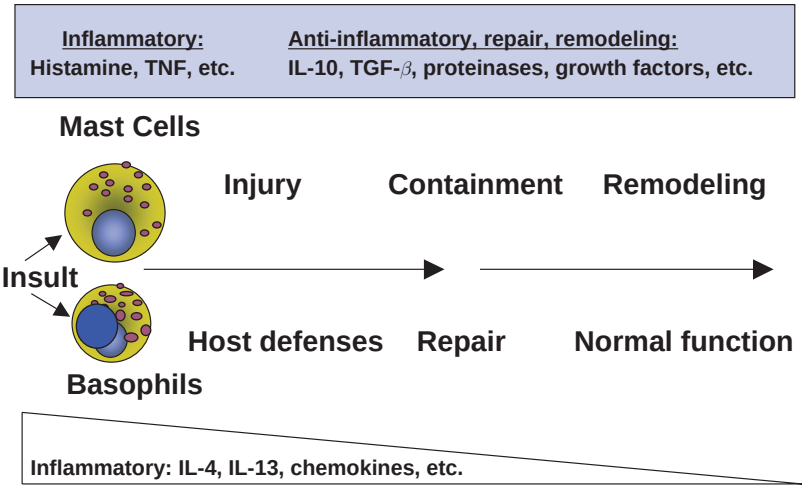

FIGURE 9.6. Model of activities of mast cells and basophils in the sequential responses of tissue injury, containment, repair, and remodeling.

the tissue damage and begin repair processes. In addition to early activation, mast cell and basophil mediators are involved in these phases of the response (Fig. 9.6). Histamine, arachidonic acid metabolites, and several cytokines, particularly, IL-1, IL-6, IL-10, TNF, and TGF-β, have several effects on endothelial, epithelial, mesenchymal, and inflammatory cells. Such effects include influences on epithelial integrity and function, regulation of blood flow and vascular permeability, tissue edema, fibroblast proliferation, and biochemical phenotype, and others. The relationship between mast cell activation and fibroblasts and angiogenesis,[19,20,21,22] in models of tissue repair and remodeling,[51] has been studied,[210,211] and it is obvious that the pathways involved are multifactorial. As experimental models are developed to address these questions, we will begin to understand the role of mast cells and basophils in this "containment and repair phase" of inflammatory injury.

Once the site of injury is contained and repair processes have begun, mast cells and perhaps basophils are likely to be involved in the remodeling of the tissues, and the return to normal function. The numerous proteinases of mast cells have distinct substrate specificities, and restructuring of the connective tissue, extracellular matrix in the local environment is very likely to be among their functions. Cytokines such as TGF-β, IL-1, and IL-6 that influence the activities of fibroblasts are likely to be important candidates for this remodeling phase in the responses to injury. Given the life span and normal distribution of mast cells and basophils, an attractive hypothesis is that basophils play a particularly important role in the injury phase, but their importance in the latter phases (containment and remodeling) is minimal. By contrast, mast cells are undoubtedly important in the injury phase, but also in the containment and remodeling phases. Given the plasticity of mast cell phenotypes, it may be that there is a general pattern of expression of functionally linked clusters of mast cell genes that, in a carefully orchestrated manner, facilitate the evolving roles of local mast cell populations in the three phases of injury, containment, and repair/remodeling.

Dynamic Equilibrium and Homeostasis

In addition to the evolving mast cell phenotype in the above sequence, some subsets of mast cells are involved in normal tissue homeostasis, such as neurogenic and endocrine responses.[212,213,214] While these aspects of mast cell function are not well understood, there is a diverse literature on mast cell involvement in such processes as sexual behavior, implantation, parturition, neuroendocrine signaling, the hypothalamic-pituitary-adrenal axis, gastric acid secretion, bone metabolism, and myelopoiesis. Furthermore, given the prominent anatomical association between mast cells and the vasculature, and the effects of mast cell products on blood flow, permeability, and leukocyte adhesion and diapedesis in inflammation,[215] it is widely held that one normal physiologic role of mast cells is in the dynamic regulation of tissue perfusion and the chemical and cellular composition of extravascular spaces. To date, little direct evidence exists that basophils exhibit similar functions within tissues; rather, the basophil appears to be mostly involved in a rapid, circulating response with potential for recruitment to sites of injury.

CHAPTER 10

MONOCYTES, MACROPHAGES, AND DENDRITIC CELLS

Matthew Collin, Derralynn A. Hughes, Annette Plüddemann, Siamon Gordon

INTRODUCTION

Monocytes, macrophages, and dendritic cells (DCs) constitute a group of myeloid cells which share common hematopoietic origins and express related functions in host homeostasis and innate and acquired immunity. They develop in hematopoietic organs, enter the circulation, and are widely distributed throughout almost all tissues. They express a variable capacity for migration, phagocytosis, antigen presentation, and secretion.

Study of this family of cells, initially known as the reticuloendothelial system (RES), and later as the mononuclear phagocyte system (MPS), is undergoing rapid change, with recent emphasis on cellular heterogeneity and differentiation, compounded by complex modulation of their phenotype within tissues. As a result of their specialized functions, the fields of macrophage and DC immunobiology have diverged to a great extent. Our goal in this chapter is to re-integrate these divisions, to emphasize their related properties and variations on a common theme. While much remains unknown concerning their life history and properties in situ, there is a considerable body of detail now available from studies in cell culture and in experimental animals, especially in the mouse, which may not necessarily reflect their behavior in humans. In this chapter, we summarize their cellular and molecular properties and emphasize studies in humans, drawing attention where possible to clinically relevant functions and pathogenic mechanisms. While primarily aimed at hematologists, this chapter highlights the major populations present in the

A BRIEF HISTORY[1,2–4,5,6,7]

The award of the Nobel Prize in 1908 to Elie Metchnikoff, shared with Paul Ehrlich, established the macrophage as a specialized phagocyte, distinct from the microphage (neutrophil) and an important part of the inflammatory cellular response to foreign bodies and infection. There was still considerable confusion between monocytes and lymphocytes, based on morphology and histology alone. Electron microscopy in the 1950s (such as the work of Marchesi and Florey) characterized the ultrastructure of monocytes, their diapedesis and the pleomorphic appearance of macrophages in tissues. The precursor–product studies of Ebert and Florey and the migration studies of Volkman and Gowans helped to clarify the distinctions between these mononuclear cells. Recent reviews by Cavaillon[2,3] cover the origins, the first half of the 20th century, and the emergence of the RES in detail. During this time the importance of mycobacterial infection of monocytes and macrophages was a popular research topic: for example, in the significant work of Florence Sabin.

In the 1960s Zanvil Cohn and James Hirsch turned from their studies on granulocytes and defined the endocytic and cellular properties in culture of mouse macrophages that had been isolated from the peritoneal cavity. Together with Ralph van Furth and a group of investigators, they established the classification of macrophage-related cells as members of the MPS. A series of influential international Leiden conferences reviewed and published progress of research in the field from the late 1960s to the early 1990s.

During the 1950s and 1960s George Mackaness described the antigen-dependent but nonspecific activation of macrophages by cell-mediated protective immune responses to intracellular pathogens such as BCG and *Listeria monocytogenes*. This association of macrophages with T lymphocytes had profound implications for acquired immunity. The search for accessory cells responsible for antigen specific activation of T helper lymphocytes led to the discovery of DC, by Ralph Steinman and Zanvil Cohn[8] in 1973. The unique role of DCs in antigen presentation, later shown by others to depend on the Major Histocompatibility Antigen complex, forms a bridge between innate and adaptive immunity and was recognized by part of the Nobel Prize for Medicine and Physiology in 2011.

Macrophages and DCs are both considered to be components of the MPS, although significant debate remains concerning their exact relationship and derivation in the steady state and inflammation. Derivatives of macrophages and DCs form an abundant component of the organized structures known as granulomata, as shown by Walter Spector. Although they are a prominent feature of important chronic infectious diseases such as tuberculosis the nature of their interactions with T lymphocytes and their precise functions are still unclear.

Other milestones of macrophage research include the discovery and exploitation of growth factors for macrophages and other hematopoietic cells, notably by Donald Metcalf; the identification of cytokines such as tumor necrosis factor (TNF) by Anthony Cerami and Lloyd Old, that play an important role and provide a therapeutic target in diseases such as rheumatoid arthritis; and the recognition by Russell Ross of the central role of monocytes that adhere to the walls of large arteries and give rise to lipid-laden macrophages in atherosclerosis. In addition, Marcel Bessis recognized the hematopoietic importance of macrophages in erythroblastic islands, although the full implications of his discovery remain to be explored.

The DC field has gained increasing momentum since the 1970s. The discovery of toll-like receptors (TLRs), C-type lectins, and other pathogen-associated molecular pattern recognition systems were key events in understanding how DCs and macrophages distinguish self from nonself. The contributions of Jules Hoffman and Bruce Beutler to this area were also recognized in the 2011 Nobel Prize. Another important breakthrough was the isolation of distinct precursors of DCs and macrophages through the work of several groups including Frederic Geissmann, Marcus Manz, Ken Shortman, Miriam Merad, and Michel Nussenzweig. More recently, the genetic control and specialized functions of distinct DC subsets have been documented in both mouse and humans. Unique pathways of ontogeny have also been described for special members of the MPS including osteoclasts, epidermal Langerhans cells, and microglia of the brain.

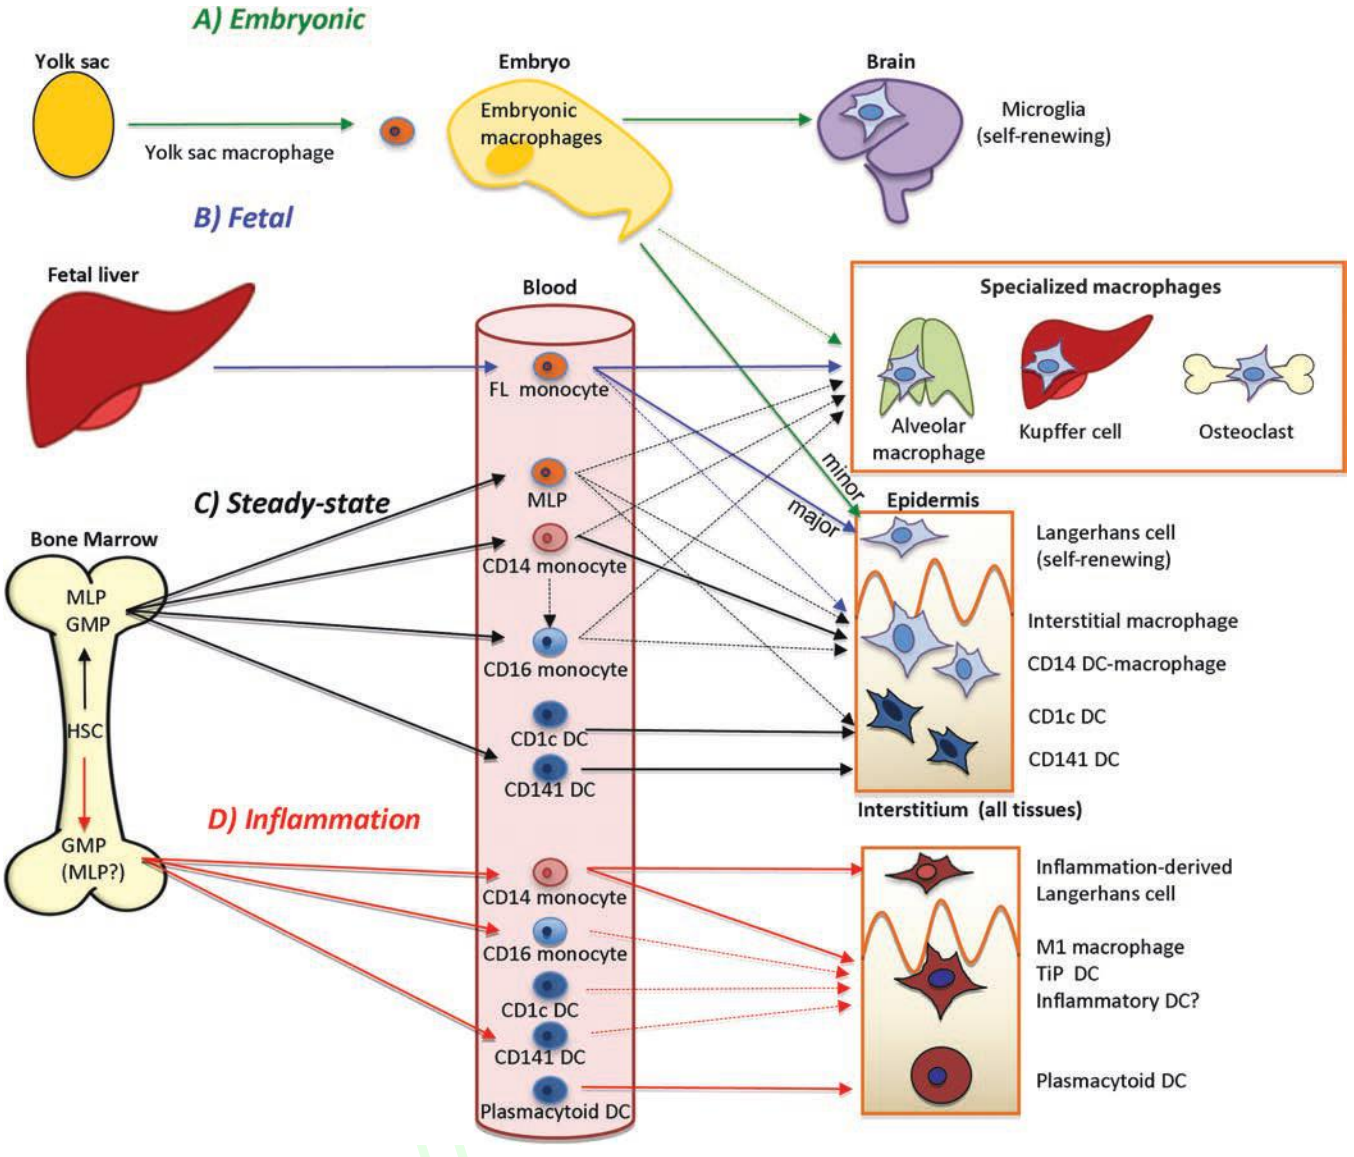

FIGURE 10.1. Summary of the main pathways of monocyte, macrophage, and dendritic cell (DC) development in human tissue during embryogenesis, fetal development, adult steady state, and inflammation. **A:** Embryonic. Yolk sac macrophages are the first hematopoietic cells to appear. Studies in mice indicate that these cells migrate through the mesoderm prior to vasculogenesis, proliferating and colonizing all the tissues of the embryo. Lineage tracing indicates that 100% of microglia arise from the yolk sac, becoming isolated in the developing brain by closure of the blood–brain barrier. They are maintained in adult life by local proliferation. **B:** Fetal. In models derived from lineage tracing in mice, hematopoiesis in the liver gives rise to the first monocytes, which circulate widely and dilute the contribution of yolk sac macrophages in almost all tissue sites. Residual yolk sac contribution of approximately 10% is detectable in the Langerhans cells of the epidermis; the other 90% are fetal liver–derived and become locally self-renewing in adult life. Tissue macrophages and specialized populations of macrophages: alveolar, Kupffer, and osteoclasts, may also derive from fetal liver monocytes, at least initially. **C:** Adult steady-state hematopoiesis, arising from multi-lymphoid progenitors (MLP) capable of differentiating into monocytes, DCs, lymphoid cells, and granulocyte-macrophage progenitors (GMP), contributes a wide variety of cells with macrophage and DC potential into the blood. These include circulating CD34+ MLP, classical CD14+ and nonclassical CD16+ monocytes, CD1c+ myeloid DCs, CD141+ myeloid DCs, and plasmacytoid DCs. The contribution of these steady state blood components to macrophage homeostasis in a wide range of tissues, in addition to those illustrated, has not been rigorously defined. CD34+ precursors and both subsets of monocytes potentially contribute to tissue macrophages in interstitial and specialized sites. CD14+ monocytes and CD16+ monocytes are closely related to CD14+ interstitial DCs, while CD1c+ and CD141+ blood DCs both have phenotypically similar interstitial DC counterparts. CD34+ precursors also have the potential to form tissue DCs. Plasmacytoid DCs do not migrate into the tissues in the steady state. **D:** Inflammation. Upregulation of myelopoiesis under conditions of stress is likely to involve expansion of GMP production of monocytes, myeloid DCs, and plasmacytoid DCs. Multiple inflammatory signals potentially recruit all peripheral blood populations to the tissues. Classical CD14+ monocytes are the most significant component giving rise to inflammatory activated "M1" macrophages and TNF/i-NOS–producing DCs (Tip-DCs) in a range of tissues. This may include the CNS (pathway not shown for simplicity here). Langerhans cells are also replaced by inflammatory classical monocytes in desquamating epidermal inflammation. Myeloid DCs may be directly recruited to give inflammatory DCs, and infiltration with plasmacytoid DCs is well documented.

tissues, both normally and in a range of inflammatory, infectious, metabolic, and neoplastic diseases.

In the following section, we summarize general and specialized features of monocytes, macrophages, and DCs, collectively termed mononuclear phagocytes (MPs). Figure 10.1 illustrates a comprehensive overview of human MP differentiation and distribution, to be discussed in detail in subsequent sections.

FUNCTIONAL PROPERTIES

Cellular Morphology[9,10]

Aspects of mononuclear cell differentiation and morphology in situ and ex vivo are illustrated in Figures 10.1 through 10.4 and summarized in Table 10.1.

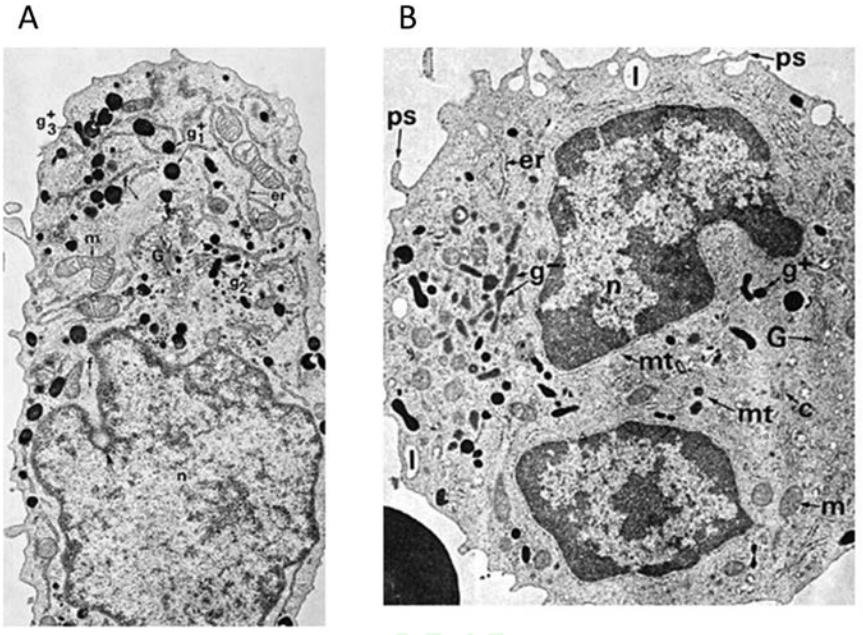

FIGURE 10.2. Ultrastructure of promonocyte and monocyte. **A:** Electron micrograph of a promonocyte from human bone marrow stained for peroxidase. The nucleus (n), situated at one end of the cell, exhibits an irregular outline and deep indentation. The cytoplasm contains a number of cytoplasmic organelles. Peroxidase reactivity is demonstrable throughout the rough endoplasmic reticulum (er), Golgi complex (G), and all cytoplasmic granules (g^+_1, g^+_2, g^+_3). Apparently, all granules mature from the earliest forms, which are spherical and dense (g^+_1), with a homogenous matrix, to more condensed and elongated forms (g^+_2), and then to dumbbell forms (g^+_3). The Golgi complex (G) is composed of several stacks of cisternae and occupies a large area adjacent to the nucleus. Bundles of filaments (f) are prominent in the cytoplasm and are believed to be useful in characterizing the cell as a monocyte form. Several mitochondria (m) are also seen ×18,000. **B:** Electron micrograph of a normal human monocyte examined for peroxidase. In the nucleus (n), the chromatin is more condensed than in earlier forms, is mainly peripheral in distribution, and is interrupted at the nuclear pores. The voluminous cytoplasm (c) contains a full complement of organelles associated with protein synthesis and export of secretory granules. Peroxidase is present in only some of the granules (g^+), but others (g:), as well as the endoplasmic reticulum (er) and Golgi complex (G), now lack the reaction product. At this stage, the two kinds of granules are approximately equal in number and similar in size and shape, ranging from 90 to 450 nm in length and from spherical or rodlike to dumbbell in shape. Microtubules (mt) radiate from the cell center, where a centriole can be seen adjacent to the Golgi complex (G). The moderately abundant endoplasmic reticulum has a more peripheral distribution than in the promonocyte, and modest numbers of mitochondria (m) are present. Numerous pseudopodia (ps) extend from the cell surface. The peripheral lacunae (l) represent a tangential section through surface irregularities ×16,200. From Nicholls BA, Bainton DF: Differentiation of human monocytes in bone marrow and blood. Sequential formation of two granule populations. Lab Invest 1973;29:27–40, with permission.

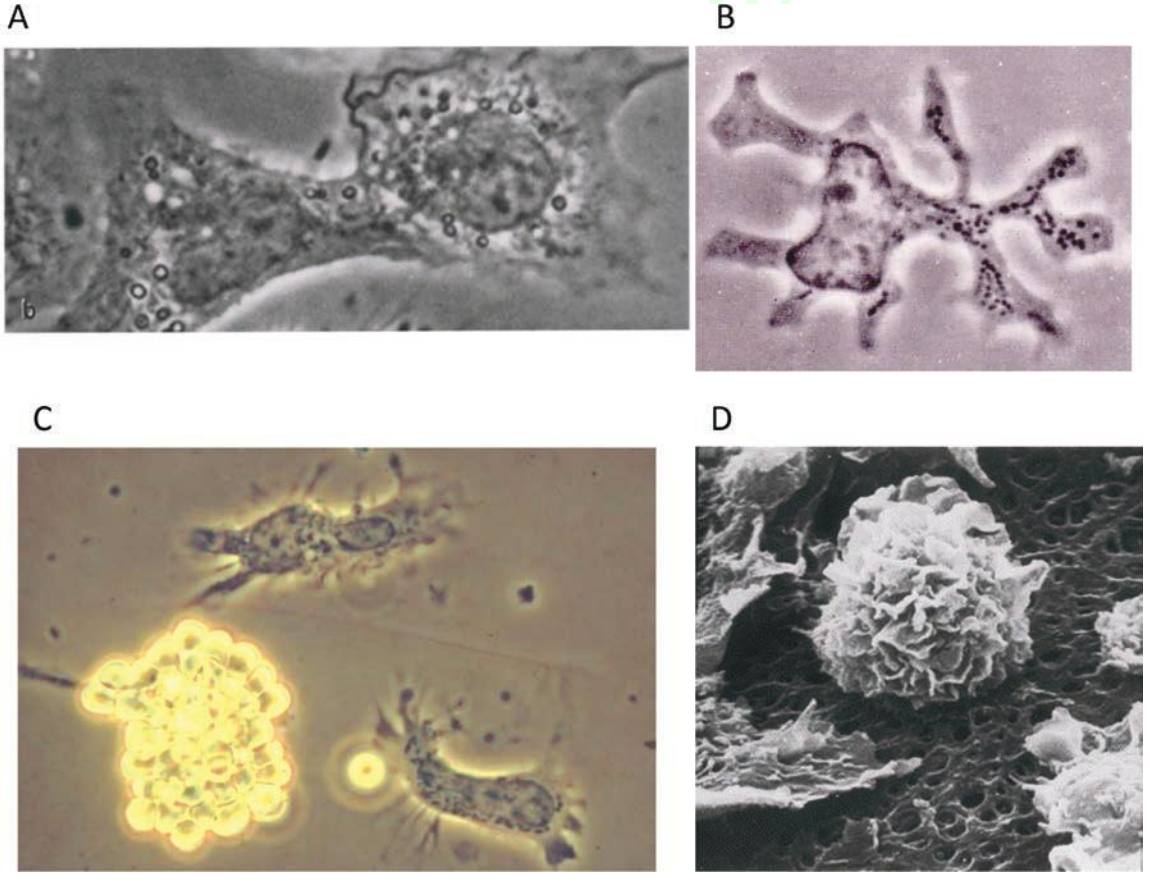

FIGURE 10.3. Morphology of mouse mononuclear phagocytes. **A:** Mouse peritoneal macrophages in culture on cover glasses undergo cell fusion shortly after addition of UV-irradiated Sendai virus. Note cytoplasmic bridge formation in nascent homokaryon. Phase contrast microscopy reveals characteristic nuclear morphology, rudimentary nucleoli, and extensive phase-lucent and phase-dense vesicles. Plasma membrane shows spreading of organelle-poor cell periphery with ruffling. From Gordon S, Cohn Z. Macrophage-melanocyte heterokaryons. I. Preparation and properties. J Exp Med 1970:131:981–1003, with permission. **B,C:** Phase contrast micrograph of dendritic cell isolated by Steinman and Cohn from mouse spleen. **B:** Note extensive dendrites, euchromatin nucleus, and mitochondria-rich cytoplasm, a feature of their high motility. **C:** Note lack of resetting of DCs with antibody-coated sheep erythrocytes, compared with macrophages in the same preparation, one of the features which allowed separation and their distinction. From Steinman RM, Cohn ZA. Identification of a novel cell type in peripheral lymphoid organs of mice. I. Morphology, quantitation, tissue distribution. J Exp Med 1973:1142–1162, with permission. **D:** Scanning electron microscopy of human alveolar macrophages cultured on cellulose membrane in a biphasic cell culture system. Note characteristic rounded appearance with extensive ruffles. From Wallaert B, Fahy O, Tsicopoulos A, Gosset P, Tonnel AB. Experimental systems for mechanistic studies of toxicant induced lung inflammation. Toxicol Lett 2000;112–113:157–163, with permission.

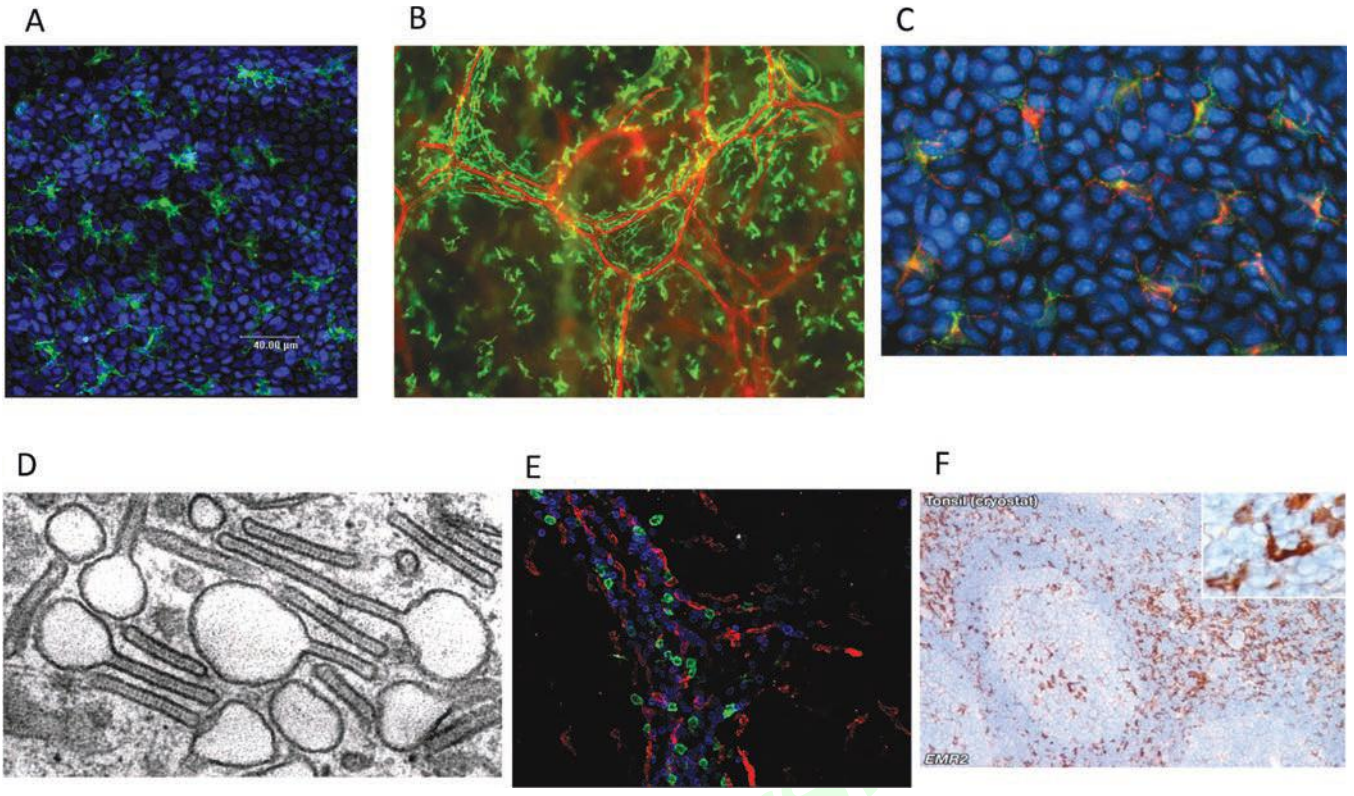

FIGURE 10.4. Mononuclear phagocytes in human skin and thymus. **A:** Epidermis: CD1a+ Langerhans cells. **B:** Dermis/interstitium Lyve-1+ macrophages and CD31+ endothelium. **C:** Epidermis: Langerhans cells express langerin and MHCII, which co-localize. **D:** Electron micrograph of Birbeck granules. **E:** Dermis: Triple labeling shows CD11c (DCs, green), XIIIa (macrophages, red) and CD3 (T cells, blue). **F:** Thymic macrophages and DCs express EMR2. Photomicrograph D from Romani N, Clausen BE, Stoitzner P. Langerhans cells and more: langerin expressing cell subsets in the skin. Immunol Rev 2010;234(1):120–141, with permission. TABLE 10.1

SELECTED PROPERTIES OF HUMAN MONONUCLEAR PHAGOCYTES

Properties	Functions
A. Monocytes	
Low level in blood (~1–4%)	
Subpopulations:	
Classical (~90%) $CD14^{hi}$ $CD16^{var}$	Phagocytosis, secretion, inflammation
Nonclassical (~10%) $CD14^{mod/dim}$ $CD16^{hi}$	Patrolling, intravascular
Migration/adhesion:	Recruitment by inflammation, infection, immune stimulation
$CCR2^{+}$ (classical)	
CX_3CR_1, variable	
$CD11b^{+}$	
$CD11c^{+}$	
LFA-1 (nonclassical)	
Recognition, endocytosis, phagocytosis:	Clearance
Opsonic receptors, e.g., FcR, CR	Humoral immunity
Nonopsonic receptors, e.g., TLR, CD36, Lectins	Innate immunity, homeostasis
Cytosolic sensors	Inflammasome activation
Biosynthesis: varied secretion:	Link to acquired immunity
Myeloperoxidase (MPO), Lysozyme	Antimicrobial
Respiratory burst (RB)	Microbial killing
Cytokines	Cell activation, regulation
Leukotrienes	Inflammation
Tissue factor	Procoagulant

(*Continued*)

Properties	Functions
Differentiation/modulation:	
Precursor for macrophages and DCs	Inflammation, T cell activation
B. Macrophages	
Widely distributed: Lymphohemopoietic tissues as resident and recruited populations	Local and systemic homeostasis Trophic functions—inflammation and repair
Variable life span	
Heterogeneous phenotype	
Sessile (mainly)	
Endocytosis and phagocytosis:	Clearance, digestion, host defense
Opsonic (Fc, CR)	Humoral immunity
Nonopsonic recognition (SR, Lectins)	Defense and homeostasis
CD163, CD71, folate receptors	Uptake hemoglobin–haptoglobin, transferrin, B12
Sensing (TLR, cytosolic)	Innate immunity
Regulatory receptors, e.g., TREMs, EMR2, GPCR	Potentiate responses
Biosynthesis and secretion:	Trophic and cytocidal
Pro- and anti-inflammatory cytokines	Inflammation, repair
E.g., IL-1, TNF, IL-6, IL-12, IL-18, IL-10, TGF-β	Innate immunity
Neutral proteinases, enzymes	Tissue catabolism
Low-molecular-weight mediators: RB, nitric oxide, prostanoids	Defense and inflammation
Modulation:	
Classical (M1) and alternative activation (M2)	Regulation of cellular immunity
Immune interactions:	Activation/suppression of primed T cells
Expression of MHCII and costimulatory molecules	Adaptive immune regulation
C. Myeloid Dendritic cells (mDC)	
Minor population in blood, lymph tissues	Sentinel cells
Short to medium-lived	Bridge innate to adaptive immunity or tolerance
Subsets described, varied antigen markers	
Motile	Migration
Chemokine receptors, e.g., CCR7	
Transient adhesion	
Endocytosis and phagocytosis	Antigen capture
Two-stage maturation/activation:	Induced by LPS, other ligands, e.g., TLR
Loss endocytosis, macropinocytosis, phagocytosis	Processing, direct and cross-presentation to naive lymphocytes
Intracellular MHCII redistributed to surface	
Limited digestion, capture peptides DM	
Specialized endosomal compartment (multivesicular bodies, Birbeck granules)	
CD1d expression	Lipid antigen presentation
Cytosolic sensors	Nucleic acid recognition
Costimulatory molecules	Activation and inhibition of APC functions
TLR, PRR-dependent cytokine production, e.g., IL-12, IL-18	Activation, regulation of tissue activation
D. Plasmacytoid Dendritic Cells (pDCs)	
Minor, blood, tissue	
Short-lived, labile	
Mixed phenotype markers, e.g., CD123 (IL-3R); TLR3, 7, 9; Siglec H (mouse), RLR, helicases	
Biosynthesis, secretion:	
Type I interferon+	Antiviral responses

IL-1, interleukin-1; MPO, Myeloperoxidase; RLRs, RIG-I-like receptor; PRRs, pattern recognition receptors; TGF-β, tumor growth factor-β; TNF, tumor necrosis factor; TLR, Toll-like receptors; LFA-1, Lymphocyte function-associated antigen 1; APC, antigen presenting cell; MHCII, major histocompatibility complex Class II.

Monocytes are rounded cells, 10 to 15 μm in size, with oval, kidney-shaped, or indented nuclei, a rim of heterochromatin, and mostly euchromatic nucleoplasm. Their cytoplasm is relatively abundant, compared with nonactivated lymphocytes, containing myeloperoxidase+ and rudimentary lysozyme+ granules, nonspecific esterases, and lysosomes. Scanning electron microscopy reveals extensive surface folds. They adhere readily to native and artificial substrates by a range of adhesion receptors, flattening out and spreading in characteristic fried egg or stellate shape with fine plasma membrane processes. They respond slowly to chemotactic gradients in vitro, compared with neutrophils.

Macrophages are larger, rounded (e.g., in alveolar space, peritoneal cavity), or stellate, with two or more processes, sticky and sluggish though motile, and with extensive, dynamic plasma membrane processes and filopodia. Podosomes have been observed. The cytoplasm of cultured cells has a well-developed centrosome, with an organized cytoskeleton, and is rich in synthetic organelles and endocytic vesicles, often containing debris and residues of phagocytosis in abundant lysosomes. They lose their peroxidase granules as monocytes mature in culture. Macrophages love lining up along surface irregularities on culture substrata and usually keep their distance from one another in culture; inflammatory stimuli cause aggregation. Occasional binucleate cells arise by failure of cytokinesis; macrophage fusion can be observed "spontaneously," especially on selected substrates, or after exposure to serum lipids or cytokines such as interleukin (IL)-4.

DCs in the blood are smaller than monocytes and may be found in the "lymphoid" gates on flow cytometry analyses. In the tissues, they are smaller than macrophages and less extensively arborized with multiple short processes. During migration through the afferent lymph they mature into "veiled cells" with extensive macropinocytic processes. In lymph nodes they are highly motile and transit rapidly between T cells until a cognate antigen interaction is detected by the T cell. In vitro they are lightly or nonadherent compared with monocytes or macrophages, a property that was exploited in their original isolation from mouse spleen.

Chemotaxis, Migration, and Adhesion

See Figures 10.5 and 10.6A. Selected antigen markers and receptors are listed in Tables 10.2 and 10.3.[11,12,13,14–22,23,24,25]

Chemotaxis of MPs to inflammatory sites is stimulated by factors such as complement component C5a, *N*-formylated oligopeptides, fragments of fibronectin, elastin, and collagen; and by secreted proteins called chemokines. Stimulation by chemotactic factors results in increased integrin affinity and therefore binding to the endothelium at the same time as formation of lamellipodia and actin polymerization, resulting in cell movement. Chemokines are divided into subclasses on the basis of the spacing of the N-terminal cysteine residues. CCL#, CXCL#, CL#, and CX3CL# refer to four families of chemokine ligands, in which # denotes the identifying number, C denotes a cysteine, and X denotes a noncysteine amino acid. CC chemokines are responsible for attracting monocytes and lymphocytes, directing traffic of leukocytes under steady state conditions; whereas inflammatory chemokines are expressed by circulating leukocytes and other cells only upon activation. In the mouse two subsets, classical (Ly6C+ analogous to human $CD14^{++}CD16^{-}$) and nonclassical monocytes ($Ly6C^{lo,\ human}$ $CD14^{dim}CD16^{+}$) express different chemokine receptors, especially CCR1, CCR2, and CX3CR1 (fractalkine receptor). Under conditions of inflammation, monocytes are recruited to tissues by CCL2 (MCP-1), CCL3 (MIP1a), and CCL5 (RANTES) acting through CCR1, CCR2, and CCR5. These inflammatory monocytes are able to differentiate into macrophages or DCs that appear to play important roles in the initiation of immune responses. The signals that drive steady state recruitment have not been solved but are independent of CCR1, CCR2, and CCR5.

Monocytes and macrophages adhere to other cell types, including lymphocytes and vascular endothelial cells, and to extracellular matrix components, e.g., fibronectin and laminin, using specific cell surface adhesion receptors. Inflammatory macrophages and DCs originate from the migration and differentiation of circulating monocytes into virtually all tissues, contributing to

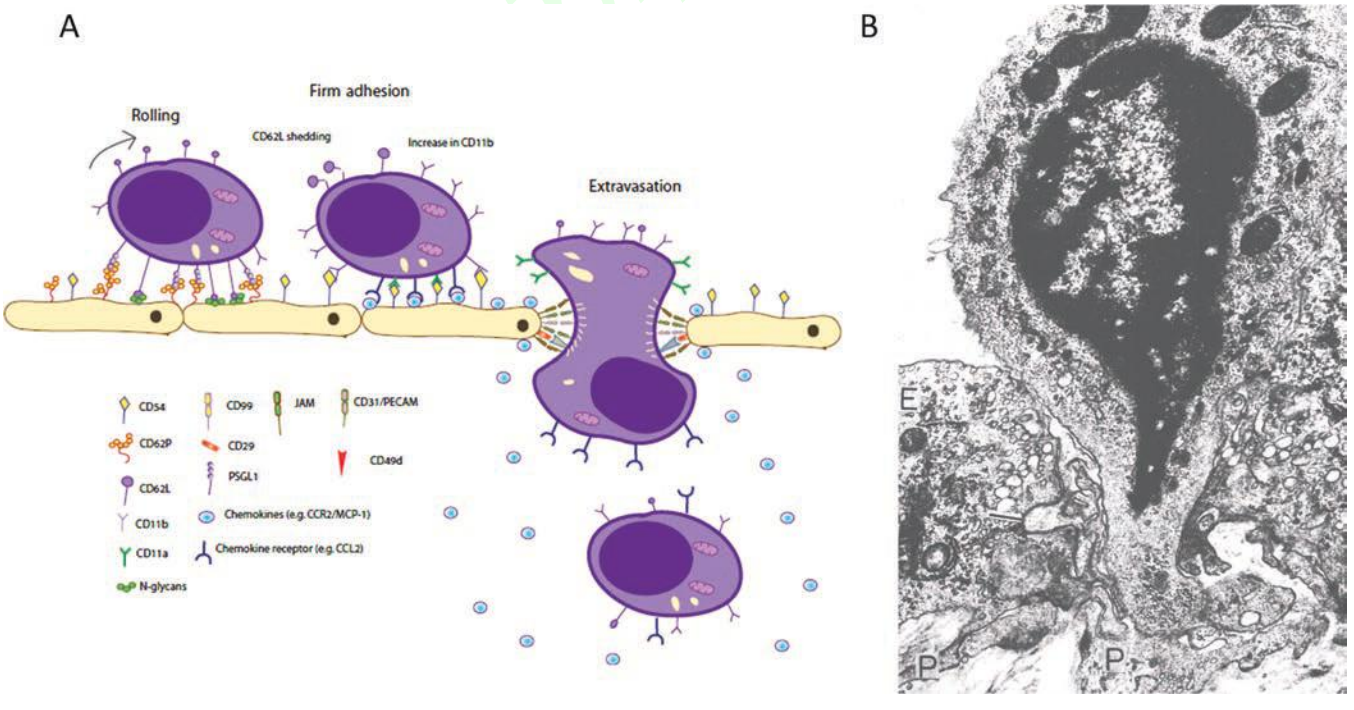

FIGURE 10.5. (A) Recruitment. Stages of monocyte adherence to endothelium and diapedesis, induced by inflammatory stimuli. The model is mainly based on the recruitment of neutrophils, with which it shares many features, although monocyte- specific chemokines, receptors, and adhesion ligands exist, especially in constitutive and noninfectious, metabolic forms of inflammation. Figure provided by S. Yona. **(B)** Monocyte diapedesis. Electron micrograph from collection of H. Florey.

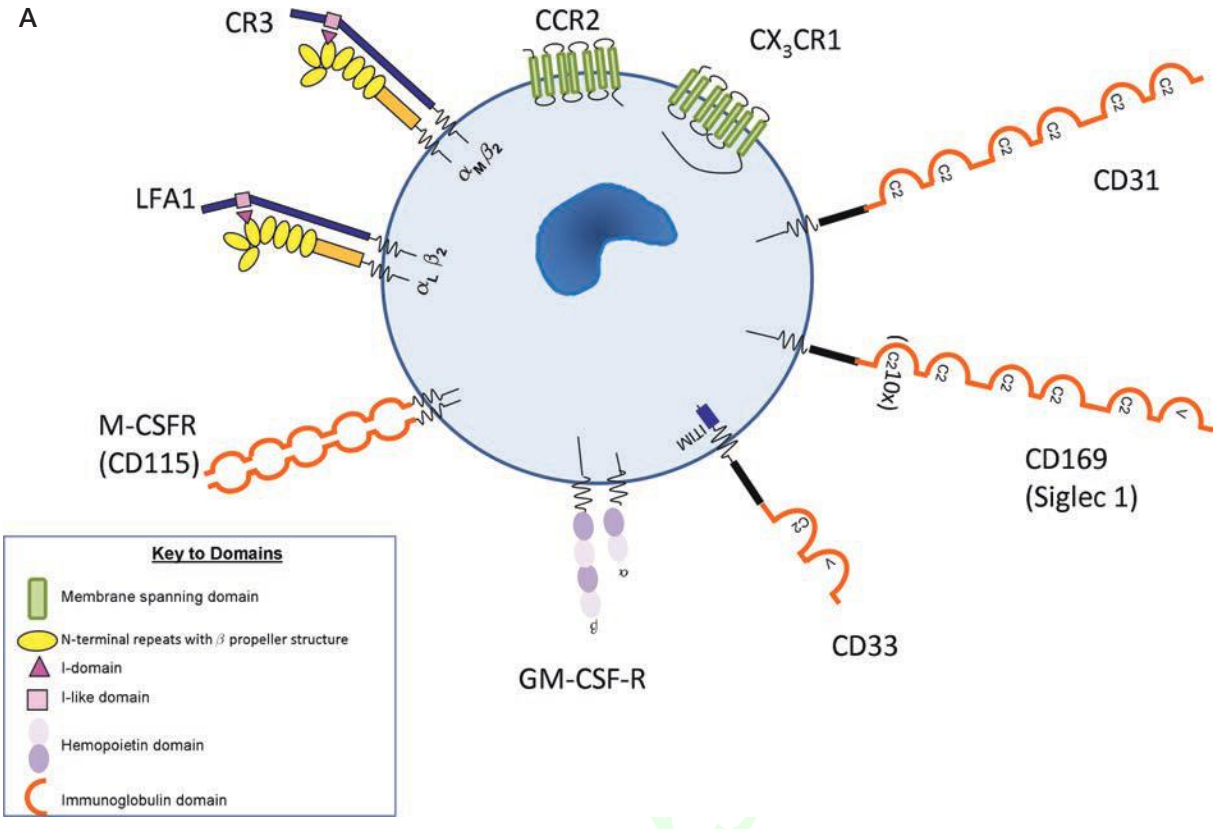

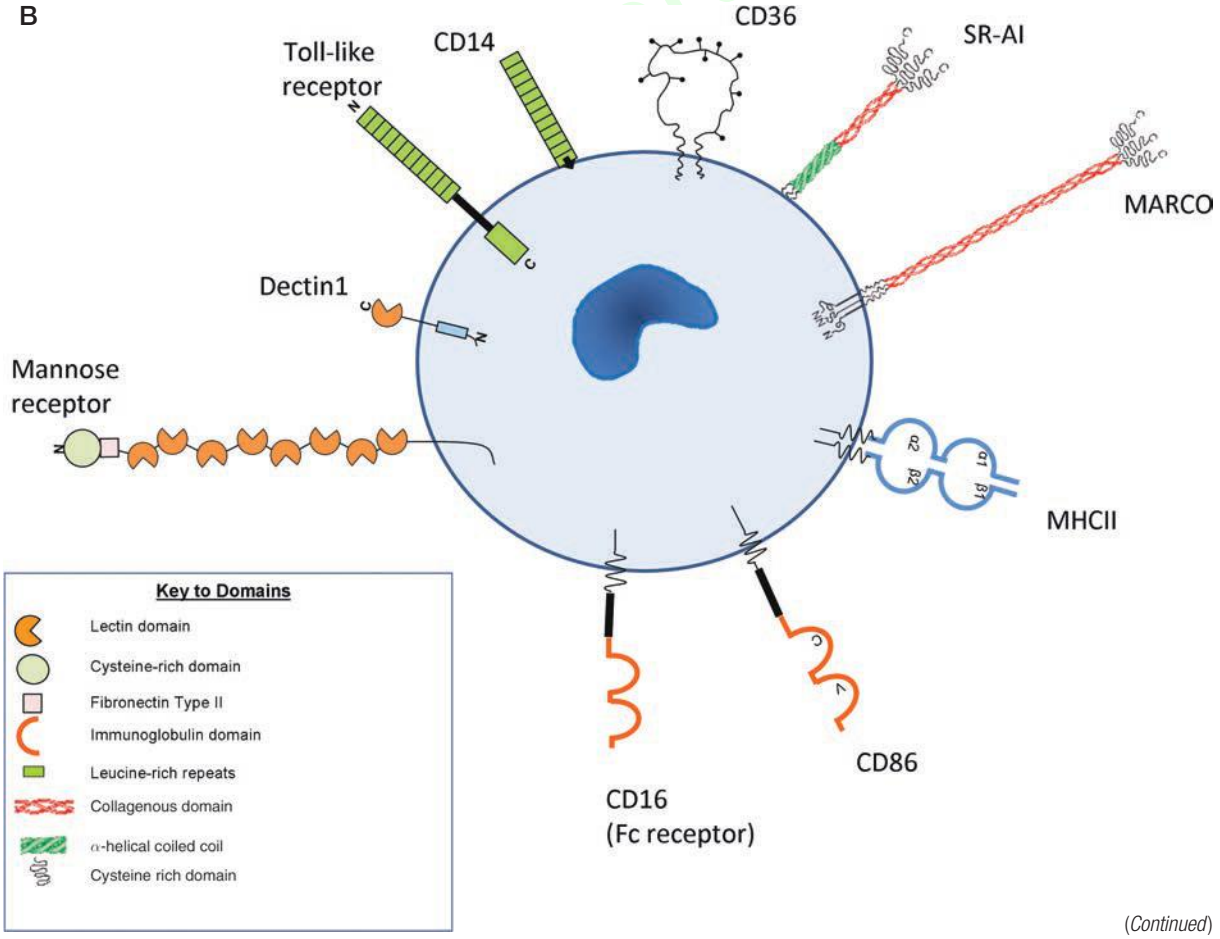

(*Continued*)

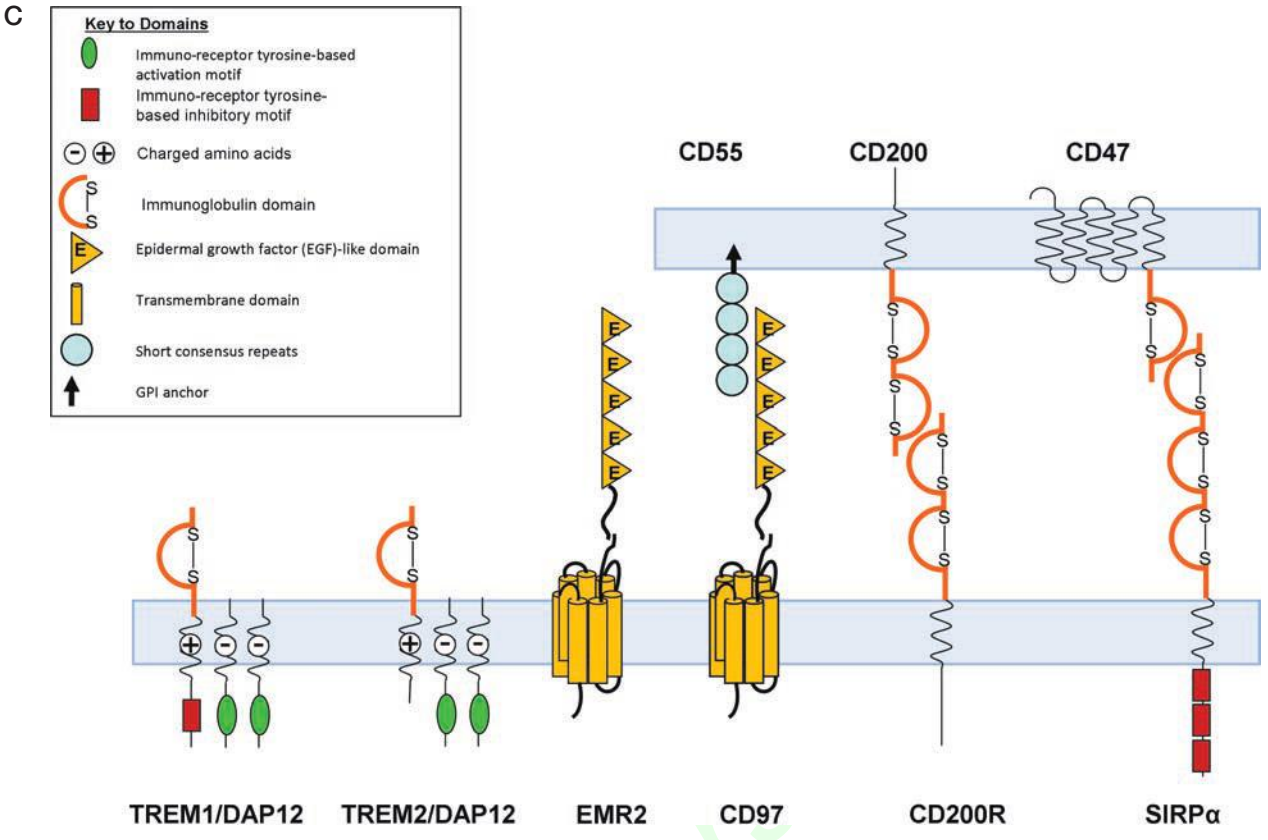

FIGURE 10.6. Selected macrophage plasma membrane receptors. **(C)** Potentiation and negative regulation.

the pathophysiology of many human diseases including atherogenesis and other inflammatory diseases. The origin of steady state tissue macrophages and DCs is much less certain, as discussed below. It is likely that blood monocytes and blood DCs contribute, but circulating hematopoietic progenitor cells may also give rise to tissue leukocytes.

Three families of cell surface glycoproteins mediate most cell adhesion: integrins, immunoglobulin-related molecules, and selectins. Integrins are large heterodimeric glycoproteins classified in subfamilies according to the common beta subunit; beta 1 (CD49/cd29) or VLA, beta 2 (CD11/CD18), beta 3 (cytoadhesion), and beta 7 are the most relevant. Integrins recognize Ig-related molecules such as intercellular adhesion molecule-1 (ICAM-1), ICAM-2, and vascular cell adhesion molecule (VCAM). Selectins (L-selectin, E-selectin, and P-selectin) recognize oligosaccharides, e.g., Sialyl Le^x. CD44 and CD36 are structurally unrelated but important adhesion molecules which bind to hyaluronic acid and thrombospondin. Macrophage entry into tissues is a multistep process involving both adhesion and transendothelial migration. The process involves monocyte tethering and rolling on the surface of activated endothelial cells mediated mainly by activated selectins; firm adhesion is mediated by VCAM-1 and ICAM-1 on the endothelium, binding to $\beta 1$ and $\beta 2$ integrins expressed on leukocytes. Subsequently, monocytes transmigrate the endothelium.

The dynamic complexity of adhesion receptor utilization in chronic inflammatory processes such as atherosclerosis is exemplified by the following studies. Analysis of integrin, immunoglobulin-related, and selectin expression on blood monocytes, in vitro differentiated macrophages, and alveolar macrophages reveals monocyte expression of $\beta 1$ (CD29), $\alpha 4$, $\alpha 5$, $\alpha 6$, $\beta 2$ (CD18), CD11a, CD11b, and CD11c subunits, but not αV (CD51). Some expression of CD41b (IIb) and CD61 ($\beta 3$) has been detected. The Ig-related molecules CD54 (ICAM-1), ICAM-2, and CD58 (LFA-3) are expressed, as well as L-selectin and the carbohydrate ligands Le^x (CD15) and sialyl Le^x. CD44 and CD36 are strongly positive. Alveolar macrophages exhibit lower expression of $\alpha 4$, $\alpha 6$, $\beta 2$, CD11a, CD11b, L-selectin, Le^x, and sialyl Le^x. ICAM-2 and CD36 are absent, whereas expression of $\alpha 3$, but not of CD11c, is higher. Similar results were obtained with in vitro differentiated macrophages. The profile of adhesion receptors expressed as monocytes differentiate into macrophages varies according to tissue location and the disease state. For example, endothelium overlying human atherosclerotic lesions and fatty streaks expresses high levels of E- and P-selectins, ICAM-1, and VCAM-1. Selectin deficiency reduces atherosclerosis, and genetic mutation of ICAM-1 or VCAM-1 reduces atherosclerosis in mice. Oxidized LDL leads to endothelial dysfunction, leading to expression of adhesion molecules and recruitment of monocytes into the subendothelial space. Ox-LDL is taken up by macrophages via scavenger receptors such as SR-A1, SR-A2, and LOX-1, which are themselves implicated in local macrophage adhesion. CD36, a multifunctional membrane receptor present on MPs and other cells, functions as a scavenger receptor for oxidized phospholipids. On macrophages, CD36 interaction with oxidized LDL triggers a pro-inflammatory and pro-atherogenic response involving activation of src-family kinases, MAP kinases, and Vav family guanine nucleotide exchange factors and results in ligand internalization, foam cell formation, and inhibition of migration.

Macrophage adhesion molecules also have an important role in homotypic cell fusion, forming osteoclasts and multinucleated giant cells associated with chronic inflammation. Progress has recently been made in identifying molecules involved in macrophage fusion. Signaling processes mediated by DAP12 and STAT6 induce a fusion-competent status. Chemotaxis through CCL2, cell-cell adhesion mediated by E-cadherin, exposure of phosphatidylserine, lipid recognition by CD36, purinergic receptors, and cytoskeletal rearrangement dependent on RAC1 are prerequisites for successful macrophage fusion.

TABLE 10.2

SELECTED ANTIGEN MARKERS EXPRESSED BY HUMAN MONONUCLEAR PHAGOCYTES

	Antigen	Ligand/Comment
Monocytes:	CD14	LPS, TLR
	$CD16^{+/-}$	FcRγ
	CD115	CSF-1
	CD45	Leukocyte common, phosphatase
	CD11b	Complement receptor
	$CD11c^{+/-}$	Complement receptor
	CD11a	LFA-1—patrolling monocytes
	CD163	Haptoglobin–hemoglobin complex
	CD36	OxLDL
	$SLAN^{+/-}$	6-SulfoLacNAc
	CX_3CR_1	Fractalkine
	MHCII	Peptides
	CD4	
Macrophages	CD115	CSF-1
	CD68	Endosomal pan-macrophage, DC osteoclasts
	CD312 (EMR2)	Myeloid adhesion GPCR (also monocytes, DCs, neutrophils)
	CD169	Siglec-1 (sialoadhesin), macrophage subsets, e.g., marginal zone, subcapsular sinus
	CD206	MMR, alternative activation
	fXIIIa	
mDCs:	CD115	CSF-1, IL-34
	CD116	GM-CSF
	CD135	Flt-3L
	CD11c	Not unique to DCs
	CD1a, c (BDCA-1), d	Major subset
	$MHCII^{hi}$	
	CD83, 80, 86	Costimulatory molecules
	CD205 (Dec205)	Lectin-like
	CD206	MMR
	CD209 (DC-SIGN)	Interstitial DCs, not unique
	CD141 (BDCA-3, thrombomodulin)	Minor subset—cross presenting (widely expressed)
	Langerin	Mannosylated and sulfated glycans
	CD103 ($\alpha_E\beta_7$ Integrin)	Gut DCs tolerogenic
pDCs:	CD123 (IL-3R)	
	CD303 (BDCA-2)	Type II C-type lectin
	CD304 (Neuropilin-1; BDCA-4)	
	(Siglec H–member mouse CD33 family)	
	CD2	Lymphoid antigen
	CD7	Lymphoid antigen

CSF-1, colony stimulating factor-1; GM-CSF, granulocyte-macrophage colony stimulating factor-1; TLR, Toll-like receptors; LPS, lipopolysaccharide; MMR, macrophage mannose receptor; OxLDL, oxidized low-density lipoprotein; BDCA, blood dendritic cell antigen.

TABLE 10.3

SELECTED PLASMA MEMBRANE PATTERN RECOGNITION RECEPTORS (PRRs) EXPRESSED BY HUMAN MONONUCLEAR PHAGOCYTES

Receptor	Ligand	Comment
FcR	Immunoglobulins	Phagocytosis, ADCC
CD11b/18	Complement, other	Phagocytosis, myeloid adhesion
CD163	Haptoglobin–hemoglobin complex	
CD14	LPS	TLR complex
TLR (various)	Microbial, endogenous	
Siglec-1 (CD169)	Sialylated glycoconjugates	Subset macrophages
DC-SIGN (CD209)	Mannose, fucose, GlcNAc	
Dectin-1 CLEC-1	β-glucan	Fungal infection
Dectin-2	High mannose	Th17 activation
Langerin	Mannosyl and sulfated glycans	Abundant in Birbeck granules
Mincle	C-type lectin-like	Binds mycobacterial cord factor
CLEC-9A (DNGR-1)	Actin	Cross-presentation
TAM (Tyro3, Axl, MER)	Gas6, ProtS	Apoptotic cell uptake
SR-A	Polyanions, ApoA1, LPS, LTA *Neisseria* proteins	Endocytosis, adhesion
MARCO	LPS, *Neisseria* proteins	Innate immunity, phagocytosis, adhesion
CD36	OxLDL, phosphatidylserine	Adhesion, apoptotic cell clearance, fusion of macrophages
TIM(1–4)	Phosphatidylserine	Apoptotic cell uptake
CD300a	Phosphatidylserine	Apoptotic cell uptake
EMR2	Chondroitin sulfate B	Adhesion GPCR
CD97	CD55	Adhesion GPCR

TLR, toll-like receptor; ADCC, antibody-dependent cell-mediated cytotoxicity; GPCR, G protein-coupled receptor; LPS, lipopolysaccharide; DC-SIGN, dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin; OxLDL, oxidized low-density lipoprotein; LTA, lipoteichoic acid; TIM, T-cell immunoglobulin mucin; EMR2, epidermal growth factor-like module-containing mucin-like hormone receptor 2.

The regulation of DC function is intimately linked to migration. At sites of antigen contact, myeloid or "classical" DCs are found in immature forms with high expression of pattern recognition receptors (PRRs) and endocytic activity, but low surface expression of MHC and costimulatory molecules. Migration and maturation are believed to occur in the steady state, but are massively increased by local inflammatory stimuli mediated by TLR agonists, cytokines, and other danger signals. DC migration from tissue sites to afferent lymphatics is integrin-independent and driven by chemokine gradients of CCL19 and CCL21 acting through CCR7. Recent studies show that these chemokines decorate the endothelium of afferent lymphatics. The passive drainage of fluid through afferent lymphatics may also play a part in the migration of DCs towards lymph nodes. Within the node, similar chemokine gradients position DCs in the T cell areas, where they upregulate antigen-bearing MHC molecules and costimulatory antigens. Antigen uptake declines and morphological changes ensue, including the extension of dendrites. Myeloid and plasmacytoid DCs also enter the lymph nodes directly from the bloodstream, where they undergo a parallel process of maturation. In the later stages of immune activation, monocyte-derived DCs also reach the lymph nodes by direct recruitment from the blood or via inflamed tissues.

Recognition: Plasma Membrane Antigen Markers, Sensors, and Regulators

See Figures 10.6 through 10.12 and Tables 10.1 through 10.3.[26,27–32,33,34,35,36,37]

Monocytes and macrophages express a range of opsonic and nonopsonic plasma membrane and endosomal receptors to recognize foreign and modified self-ligands. These include activatory (ITAM cytoplasmic motif) and inhibitory (ITIM motif) Fc receptors, receptors for complement-derived ligands, TLRs, lectins, and scavenger receptors, as well as receptors for other humoral ligands, for example, collectins and pentraxins. Monocytes also express CD14, a GPI-linked receptor for LPS, which is downregulated upon cell maturation in culture. Resting monocytes do not express class A scavenger receptor I/II, which is upregulated on macrophages during maturation, but do express MARCO,

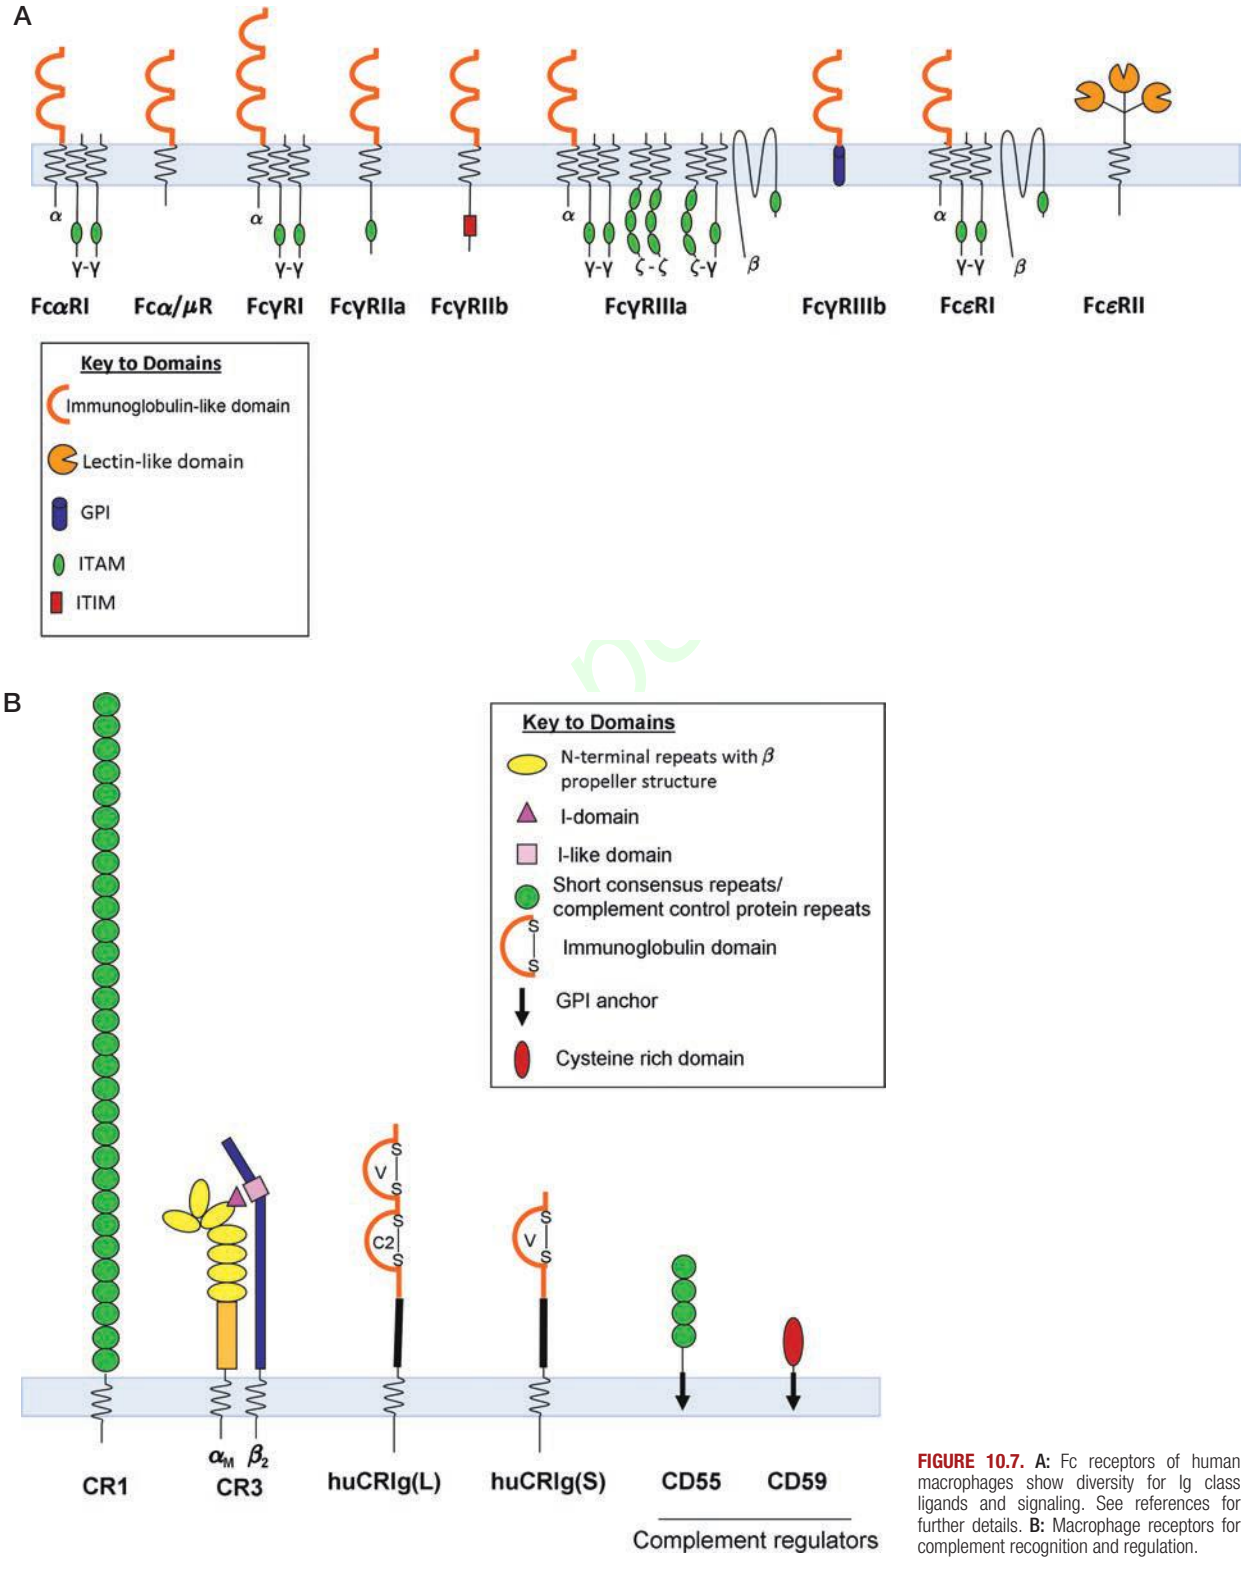

FIGURE 10.7. A: Fc receptors of human macrophages show diversity for Ig class ligands and signaling. See references for further details. **B:** Macrophage receptors for complement recognition and regulation.

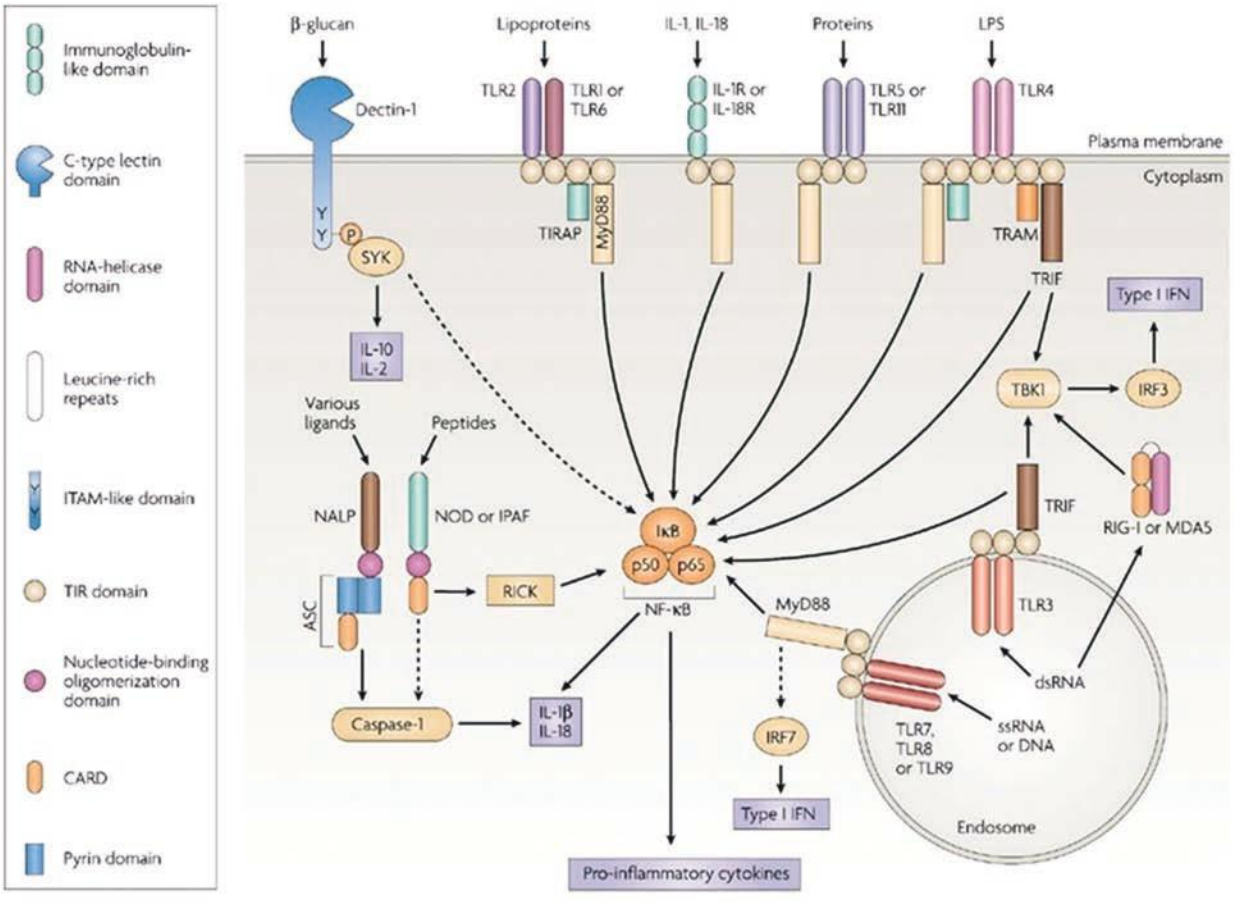

FIGURE 10.8. Cooperation of Toll-like receptor signals and Dectin-1 (with cytosolic inflammasome activation and type I interferon) in innate immune defense. From Trinichieri G, Sher A. Cooperation of Toll-like receptor signals in innate immune defense. Nat Immunol Rev 2007;7:179–190, with permission.

a related SR, and CD36, another promiscuous adhesion molecule also present on platelets and endothelial cells. The lectins include Dectin-1, the receptor for fungal β-glucan, expressed by monocytes, macrophages, neutrophils, and DCs; the mannose receptor, a multilectin with distinct carbohydrate recognition domains for GlcNac, mannosyl, and fucosyl ligands on microbes and selected host molecules; and a cysteine-rich domain which recognizes endogenous sulfated sugars. Other mannose binding lectins include DC-SIGN and Dectin-2; galectin is a receptor for galactosyl recognition. Additional plasma membrane receptors include CD163, an SR-like molecule that recognizes haptoglobin–hemoglobin complexes, and which is induced by glucocorticoids. Additional SR, not shown, are present on endothelial cells, which also express SR-A. Apart from the scavenger receptors, several other receptors can recognize apoptotic cells, e.g., the Tyro3, Axl, and Mer (TAM) receptors, which recognize Gas 6 and Protein S ligands. Several TIM molecules and CD300A bind phosphatidyl serine, another ligand for apoptotic cell recognition.

In common with monocytes and macrophages, DCs are equipped with an array of PRRs, which can detect evolutionary-conserved pathogen-associated molecular patterns (PAMPs), including proteins, lipids, carbohydrates, and nucleic acids. The PRRs encompass families of membrane-bound TLRs and C-type lectin receptors (CLRs), such as Langerin, MMR, DC-205, DC-LAMP, DC-SIGN, Dectin-1, and DCIR. The PRRs also include cytosolic NOD-like receptors (NLRs), RIG-I-like receptors (RLRs), and helicase nucleic acid receptors, as discussed further below. Human DCs are equipped with multiple CD1 antigens for the recognition of bacterial lipid antigens (notably CD1a and CD1c) and a range of receptors for complement (CD11b and CD11c) and coagulation proteins (CD141: thrombomodulin).

The SIGLEC family of leukocyte plasma membrane molecules interacts with sialylated glycoconjugates, and members are variably expressed on myeloid cells of different species, including macrophages and plasmacytoid DCs. Siglec-1 (sialoadhesin, CD169) has been implicated in binding of hematopoietic cells, including lymphocytes.

The murine macrophage plasma membrane antigen marker F4/80 is part of a small family of seven transmembrane adhesion GPCR which includes CD97 and EMR2, more broadly expressed on myeloid cells. EMR2 is a useful immunocytochemical marker for human tissue macrophages, as well as neutrophils, in which it potentiates a range of cellular functions. The TREM family also modulates myeloid cell responses; TREM-2, for example, associates with DAP-12 as one of several signaling partners. Counter-receptors include the negative receptor pair CD200/CD200R.

Genetic polymorphisms have been described for a range of the above surface molecules; for example, TLR mediating pro-inflammatory signaling and Fc receptors, which mediate important functions such as phagocytosis, antibody-dependent cytotoxicity, and immunomodulation.

Cytosolic Recognition and Inflammasome Activation

See Figures 10.8 and 10.9.[38,39,40,41]

This topic has benefited enormously from the study of auto-inflammatory syndromes associated with rare genetic

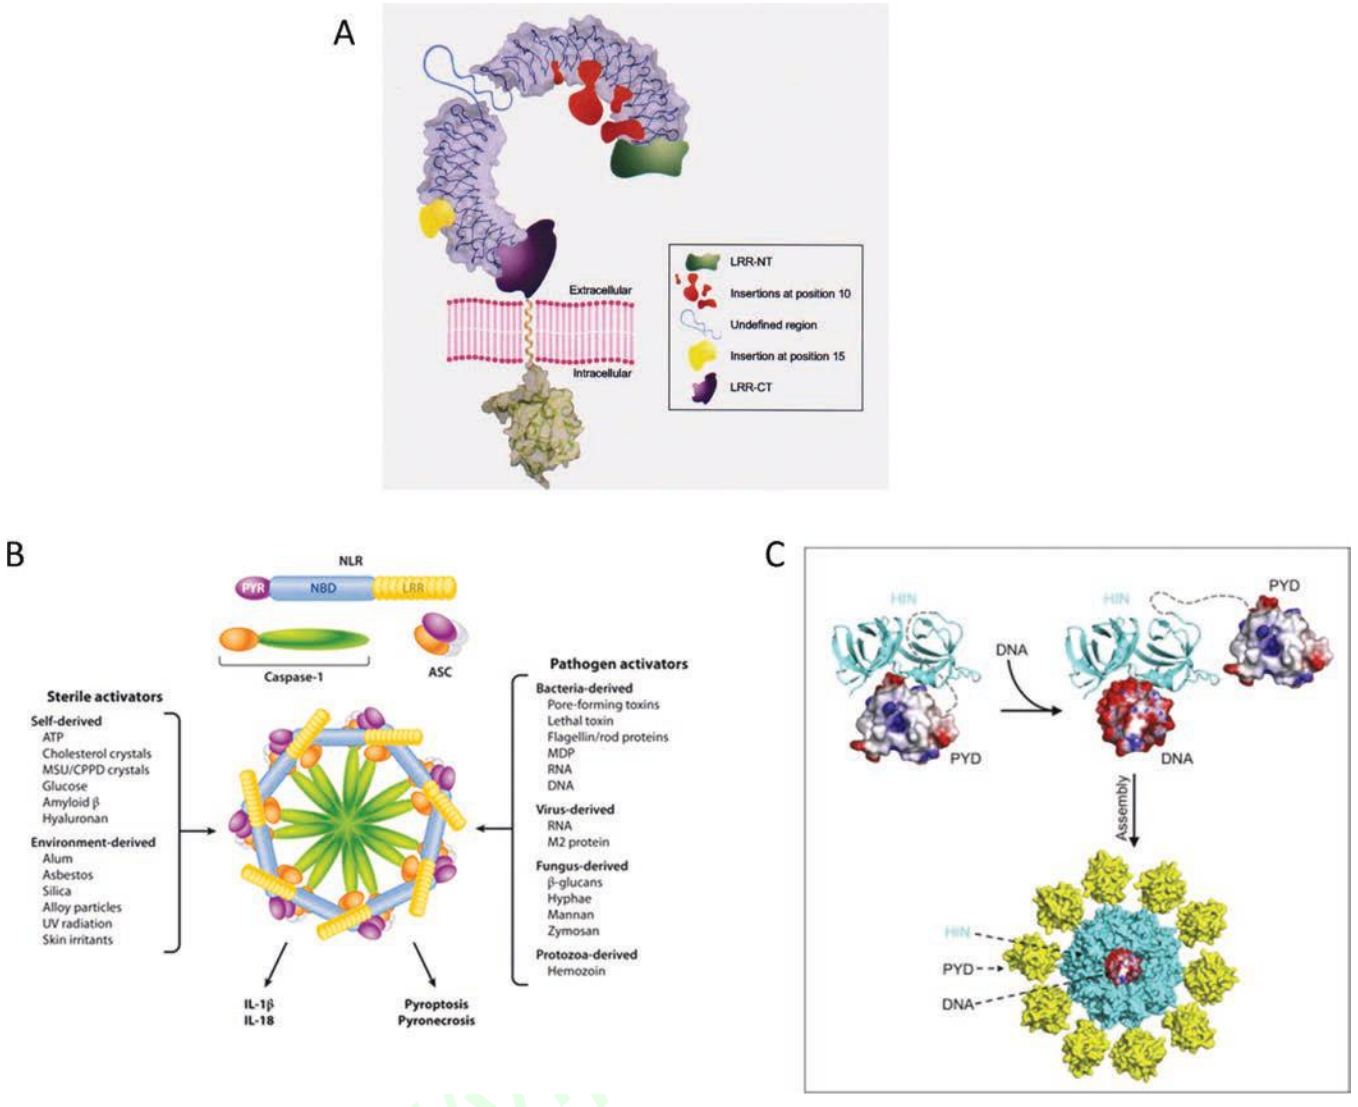

FIGURE 10.9. Models of inflammasome structure. A: A Toll-like receptor (TLR). TLRs are integral membrane glycoproteins with an N-terminal ectodomain and a single transmembrane domain. The ectodomain of a TLR7, TLR8, and TLR9 family member is depicted, with the leucine-rich repeat (LRR) solenoid shown with a gray molecular surface, and the N- and C-terminal flanking regions shown in green and purple, respectively. An undefined region present in TLR7, TLR8, and TLR9, but not in the other TLRs, is shown as a light blue string. Insertions within LRRs at position 10 are indicated in red and might contribute to the formation of the pathogen-associated molecular pattern (PAMP) binding site. An insert at position 15 is indicated in yellow. Also shown is a cartoon of the transmembrane domain (presumed to be a single α-helix), followed by a molecular surface representation of the TLR1 Toll–IL-1 and IL-18 receptor (TIR) domain. From Bell JY, Mullen GE, Leifer CA, Mazzoni A, Davies DR, Segal DM. Leucine-rich repeats and pathogen recognition in Toll-like receptors. Trends Immunol 2003;24:528–533, with permission. **B:** Activators of the inflammasome. Sterile activators include host- and environment-derived molecules, and pathogen-associated activators include PAMPs derived from bacteria, viruses, fungi, and protozoa. Assembly of the NLRs, ASC, and caspase-1 leads to the formation of a pentad- or heptamer structure: the inflammasome. Activation of the inflammasome leads to maturation and secretion of IL-1β and IL-18, as well as inflammatory cell death, by either pyroptosis or pyronecrosis. ASC, apoptosis-associated speck-like protein containing a caspase recruitment domain; CPPD, calcium pyrophosphate dihydrate; MDP, muramyl dipeptide; MSU, monosodium urate; NLR, nucleotide-binding domain, leucine-rich repeat containing; PAMP, pathogen-associated molecular patterns. From Davis BK, Wen H, Ting JP. The inflammasome NLRs in immunity, inflammation, and associated diseases. Annu Rev Immunol 2011;29:707–735. **C:** Electrostatic attraction underlies innate dsDNA recognition by the HIN domains. Both oligonucleotide/oligosaccharide binding folds and the linker between them engage the dsDNA backbone. An autoinhibited state of AIM2 is activated by DNA that liberates the PYD domain. DNA serves as an oligomerization platform for the inflammasome assembly. From Jin T, Perry A, Jiang J, et al. Structures of the HIN domain: DNA complexes reveal ligand binding and activation mechanisms of the AIM2 inflammasome and IFI16 receptor. Immunity 2012;36(4):561–571, with permission.

disorders, and their dramatic amelioration by IL-1 antagonists. Inflammasomes are protein complex platforms which are required for the activation of inflammatory caspases and the maturation of their pro-inflammatory cytokines including IL-1β and IL-18. They are constructed around several proteins, including NLRP3, NLRC4, AIM2, and NLRP6, and recognize inflammatory signals arising from receptors for PAMPs, damage-associated molecules (DAMPs), and sterile particulates, such as uric acid crystals. Recognition of immune signals by one of several families of receptors results in direct activation of caspase-1 and caspase-5, secretion of potent pro-inflammatory cytokines, and a form of cell death called pyroptosis. PRRs of innate immune cells can be classified into phagocytic and sensor PRRs and, in addition to the plasma membrane receptors described above, include intracellular TLRs, retinoic acid–inducible gene I–like receptors (RLRs), and nucleotide-binding oligomerization domain-like receptors (NLRs). Inflammasome-mediated processes are important during microbial infections and also in regulating both metabolic processes and mucosal immune responses. For example, the NLRP3 inflammasome has

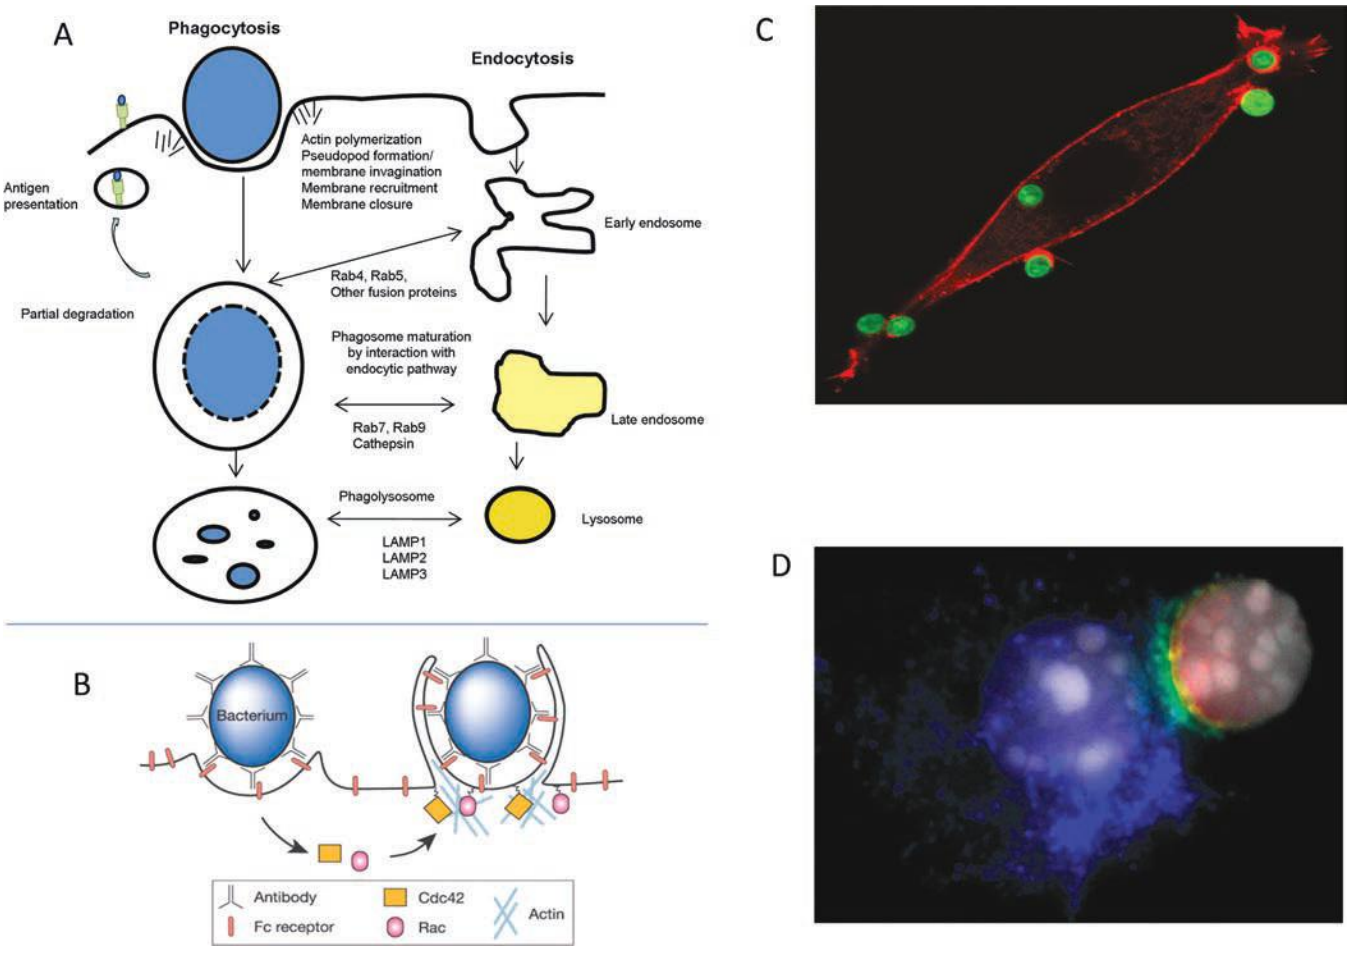

FIGURE 10.10. A: Phagocytosis and endocytosis pathways. Particulates are taken up by actin-dependent sequential maturation processes, involving membrane fusion and fission, which intersect with the endocytic pathway at several stages. Cytosolic small guanosine triphosphatases (rabs) determine organelle-specific interactions. Membrane is recycled to the plasma membrane, with processed antigen. Progressive acidification and delivery of lysosomal hydrolases result in terminal degradation. Compartment membranes express marker proteins such as LAMP1; the pan-macrophage CD68 antigen is associated with late endosomes and lysosomes. **B:** Schematic representation of FcR-mediated uptake of a bacterium by a zipper-like mechanism, initiating actin assembly. Modified from Conner SD, Schmid SL. Regulated portals of entry into the cell. Nature 2003;422(6927):37–44. **C:** Dectin-1 transfected fibroblast taking up unopsonized zymosan (yeast wall particle) through β-glucan recognition, to initiate a phagocytic cup. (Courtesy of G. Brown.) **D:** Uptake of *Pneumocystis carinii* via Dectin-1. Contact zone resembles phagocytic synapse described by Goodridge et al.[30]

been demonstrated to be involved in antibacterial, viral, fungal, and parasitic immune responses. On infection with influenza A, endosomal TLR7 recognizes viral RNA and induces transcription of the NLRP3 inflammasome components. Selected bacteria have been shown to allow the cytoplasmic entry of flagellin, the NLRC4 ligand, leading to activation of the NLRC4 pathway. Some inflammasome activators are exogenous particles, e.g., silica and asbestos, whose uptake by pulmonary macrophages activates NLRP3 inflammasome-dependent caspase activation, cytokine, and cellular reactive oxygen species release, contributing to silicosis or asbestosis. Inflammasomes have also been implicated in metabolic pathologies with activation of caspase-1 by NLRP3 in adipose tissue, resulting in inhibition of insulin signaling, expression of TNF-α, and induction of CD4 T helper cells. However, a protective role for activated inflammasomes in age-related macular degeneration has also been proposed, since lack of NLRP3 or IL-18 exacerbates choroidal neovascularization.

Intracellular detection of nucleic acids by DCs is very sophisticated. TLR3, TLR7, and TLR9 cooperate with a large family of helicases, RLRs, and DNA sensors in the recognition of single- and double-stranded nucleic acids. Ligation of these receptors leads to rapid phenotypic maturation, activation of antigen-presenting capacity, and cytokine release; plasmacytoid DCs, for example, release abundant type 1 interferon in response to viral infection.

Endocytosis and Phagocytosis

See Figures 10.10 and 10.11.[42–46,47–48]

Monocytes and macrophages are able to internalize and ingest soluble and particulate ligands, including apoptotic cells and micro-organisms, with variable efficiency. Surface molecules which mediate receptor-mediated endocytosis, apart from those listed above, include transferrin (CD71) and folate receptors. Macrophages are able to internalize the equivalent of their surface in 20 minutes; and a series of fusions and fissions, assisted by small GTP-ases, result in membrane retrieval, receptor recycling to the cell surface, or cargo delivery from endosomes to lysosomes for digestion. Phagosome formation and fusion result in formation of phagolysosomes. Fc receptor-mediated uptake depends on circumferential engagement of the target ligands by pseudopodia, a zipper-like process, and ingestion depends on the actin cytoskeleton. Complement-mediated uptake proceeds by a distinct "sinking" mechanism. Underwood and colleagues have described formation of a phagocytic synapse in the uptake of yeast particles

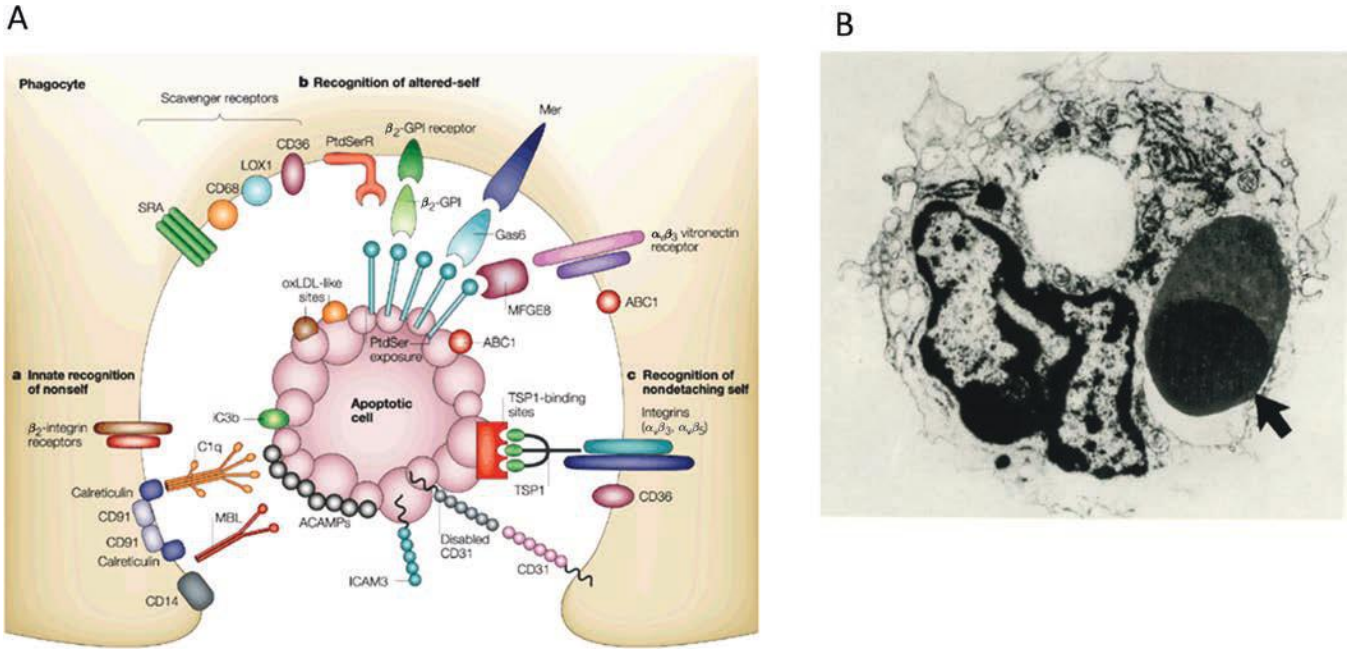

FIGURE 10.11. A: Phagocytic receptors for apoptotic cell phagocytosis. Macrophages and immature myeloid dendritic cells (mDCs) express multiple receptors for direct or opsonic binding, e.g., mannose binding lectin (MBL) or milk fat globulin (mFGE8). Phosphatidylserine (PS) exposed on the outer surface of the apoptotic cell can be recognized by a range of receptors, including TIM4, TIM1 and CD300A (not shown). Discrimination of nonself and altered-self may involve combinations of different phagocyte receptors. Apoptotic cell uptake results in an antiinflammatory response (e.g., release of transforming growth factor-β and prostaglandin E2), but has also been implicated in cross-presentation by DCs. From Savill J, Dransfield I, Gregory C, Haslett C. A blast from the past: clearance of apoptotic cells regulates immune responses. Nat Rev Immunol 2002;2:965–975, with permission. **B:** Thymic macrophage with apoptotic thymocyte in phagocytic vacuole. The vast majority of thymocytes never leave the thymus, undergo apoptosis, and are rapidly removed by macrophages (×4,500).

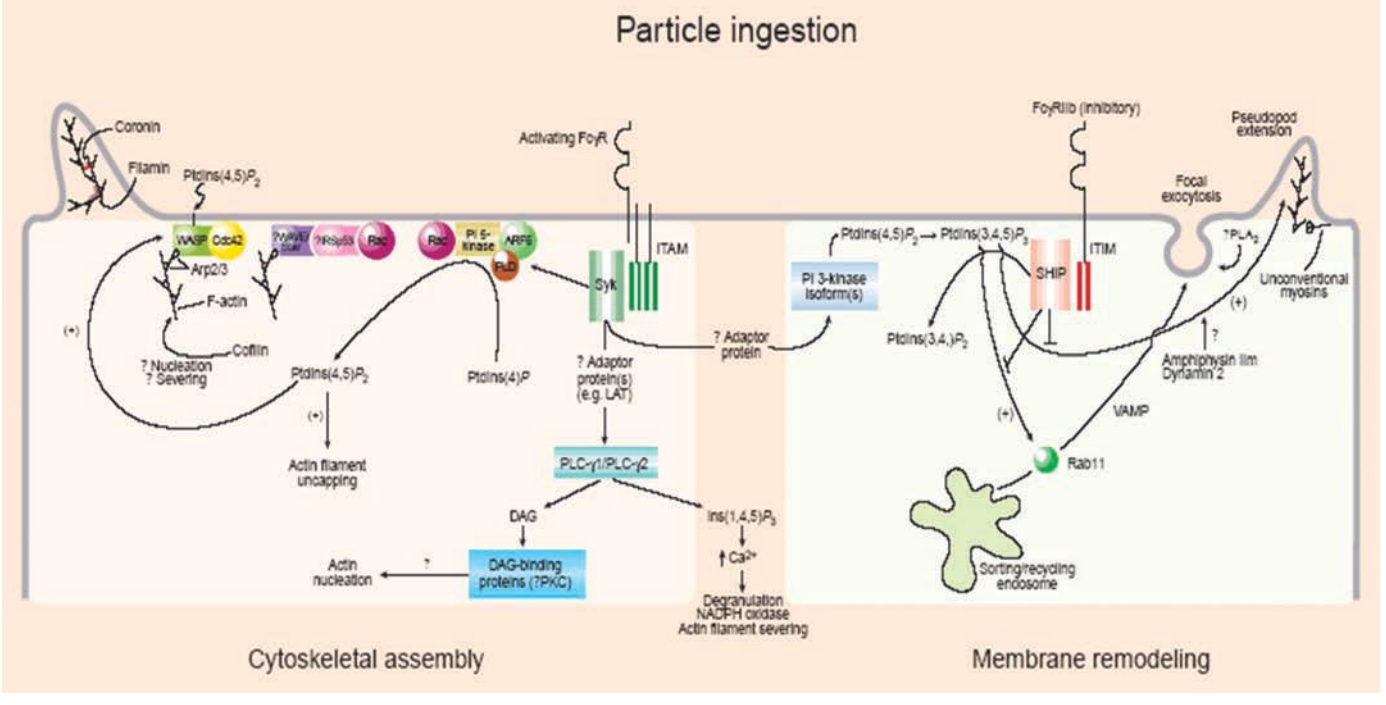

FIGURE 10.12. Plasma membrane remodeling, cytoskeletal assembly, and cytoplasmic signaling associated with Fc receptor-mediated particle ingestion. From Greenberg S. Diversity in phagocytic signalling. J Cell Sci 2001;114(Pt 6):1039–1040, with permission.[44]

by Dectin-1, which has a hemi-ITAM in its cytoplasmic domain, by a syk- and CARD9-dependent pathway. Uptake is associated with acidification, to promote digestion of all macromolecules.

Endocytosis by DCs follows special pathways that preserve antigens for presentation on MHC molecules. Most DCs are competent to present externally acquired antigen to maturing MHC class II dimers in the late endosomes. A complex pathway involving invariant chain and HLA-DM maintains MHC class II in an open configuration for peptide binding. A subset of DCs is competent at cross-presenting externally acquired antigen to Class I MHC. These

DCs are characterized by high expression of CD141 in humans and CD8 in mice. They also possess a unique chemokine receptor XCR1 and lectin CLEC9A (DNGR-1) with actin as ligand; and they express a high level of TLR3. Specialized biochemical machinery allows these cells to transfer exogenous antigen to the endogenously loaded MHC class I presentation pathway.

Autophagy is an analogous process by which macrophages and DCs surround damaged cytoplasmic organelles with membrane for delivery to lysosomes, especially after microbial infection. Several components involved in this process have been identified and some have been implicated in genetic predisposition to inflammatory bowel disease. This is also thought to be a key process in antigen presentation of cytosolic antigens to MHC class I.

Signaling and Gene Expression

See Figures 10.8, 10.9, and 10.12.[49–52]

A range of signaling pathways have been characterized in myeloid cells following on receptor ligation and collaboration, which differ depending on the cell type involved. These include sequential phosphorylation/dephosphorylation by kinases and phosphatases, the assembly and disassembly of protein complexes, and redistribution of molecules including phosphoinositides and lipid metabolites from cytoplasm to the plasma membrane as well as to the nucleus. The adaptor proteins for TLR-signaling include MyD-88, TRIF, and TIRAP/MAL. Signaling pathways that are particularly well characterized include MAP kinase activation, classical and alternative NFkB activation, and GPCR activation, e.g., by leukotrienes. Actin assembly and disassembly play a prominent role in cell migration and phagocytosis, as well as secretion. Gene expression depends on dynamic changes in chromatin conformation, binding and release of transcription complexes, and epigenetic modifications of DNA as well as histones by methylation and acetylation. Recent studies have begun to compare transcription by monocytes, macrophages, and DCs in considerable detail, including microRNA analysis. Translational modifications include glycosylation, prenylation and other lipid modifications, and ubiquitination, which determine protein turnover and export, as well as biosynthetic quality control. Current high throughput sequencing and microarray and proteomic analysis is set to transform our knowledge of cell functions and differences as well as of similarities among monocytes, macrophages, and DCs. We include a few recent references of useful resources in a fast-moving field.

Antigen Presentation

See Figure 10.13.[6,53]

The capacity of macrophages and DCs to present antigens to T cells was first recognized in classical experiments describing the requirement for "accessory" cells in order to generate lymphocyte proliferation and antibody production in response to antigens in vitro. Accessory cell function is now known to encompass antigen uptake, processing, and presentation as peptide bound to MHC molecules. Both macrophages and DCs are able to perform this function, but DCs are superior. Indeed, DCs were first described in the mouse spleen by Steinman and colleagues and differentiated from macrophages by their lack of adherence, characteristic morphology, and ability to stimulate the proliferation of naive T cells with approximately 100-fold greater potency than macrophages.

The ability to take up, process, and present antigens, to migrate through tissues, and to prime naive T cell responses are defining DC characteristics. Immature DCs bear Fc receptors, C-type lectin-like receptors, scavenger receptors, and complement receptors.[54] Antigen is acquired and directed to endosomal compartments containing MHC, rather than being degraded in lysosomes.

In vivo depletion models have confirmed that efficient T cell priming is dependent upon DCs, but not macrophages.

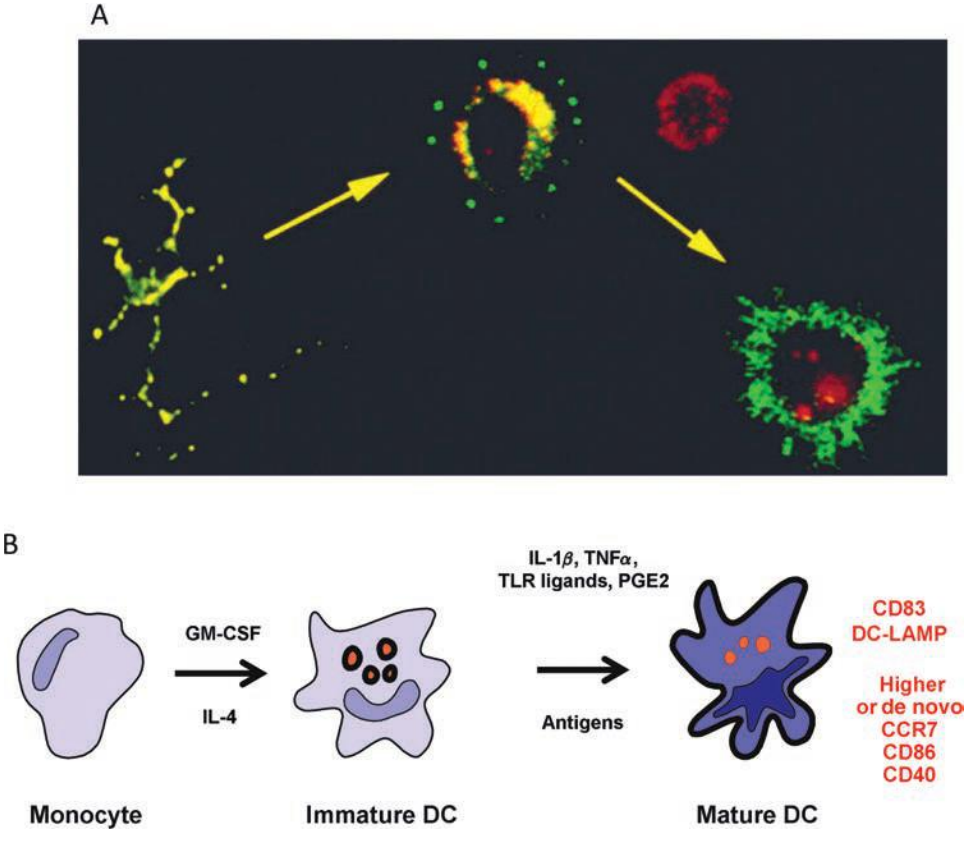

FIGURE 10.13. Maturation/activation of dendritic cells (DCs) leads to acquisition of APC function. A: DC maturation ex vivo. Langerhans cells upon explantation from mouse skin undergo "spontaneous" maturation with redistribution of MHCII from an intracellular compartment to the cell surface. (Courtesy of Ira Mellman and Ralph Steinman.) **B:** One of the first systems to produce large numbers of human dendritic cells from blood monocytes; the added cytokines and other maturation stimuli influence the function of the DCs. Based on studies by Lanzavecchia, Sallusto, Romani, Schuler, Bhardwaj, and their colleagues.

The superior ability of DCs in T cell priming is linked to high expression of MHC (signal 1), costimulatory molecules (signal 2), secretion of polarizing factors (signal 3), and imprinting instructions (signal 4).

MP function is often described as bridging innate and adaptive immunity. Antigen presentation frequently involves recruitment of NK cells and other innate lymphocytes to amplify and polarize immunity. Thus the invariant MHC molecules CD1a, CD1c, and CD1d are prominent markers of human DCs and have a critical function in presenting lipoproteins to innate lymphocytes. A number of complex and phylogenetically ancient soluble molecules also enhance cooperation between innate and adaptive immunity; these include pentraxins, high mobility group proteins, and heat shock proteins.

Secretion

See Figures 10.14 and 10.15.[55–57,58]

Macrophages are highly active secretory cells, producing a great variety of molecules when stimulated, some of which are listed in Table 10.4. These include enzymes such as lysozyme; neutral proteinases (urokinase, collagenase, and elastase); and inhibitors such as alpha1-antitrypsin, complement proteins, a range of cytokines (IL-1β, TNF-α, IL-6, type 1 interferon, IL10, IL-12 family, and transforming growth factor-β [TGF-β]), growth factors (e.g., CSF-1 and GM-CSF), and chemokines. Low molecular products include reactive oxygen species, reactive nitrogen species and arachidonate metabolites. Secretion can be induced by TLR, Fc receptor, or Dectin-1 stimulation. The secretory mechanism of IL-1β release depends on inflammasome and caspase activation. Jenny Stow has studied the secretory pathway of TNF and other cytokines.[58a] Macrophage activation by innate, cytokine, and phagocytic stimuli profoundly influences their secretory activity, as discussed further below.

The lysozyme secretory pathway has not been defined. In culture it is secreted constitutively by monocyte-derived macrophages; in vivo it is markedly upregulated by granuloma formation, as in BCG infection and sarcoidosis; extraordinary levels enter the blood and urine in monocytic leukemia.

Many other questions remain, relating to the control of secretion by macrophage populations in situ. Degranulation is less of a feature than in granulocytes. Many plasma membrane glycoproteins such as CD163 and TNF receptors are shed into the circulation by proteolytic cleavage, but the biological significance is unclear in many cases. CD14 may be an exception, since it can be incorporated into the membrane of other cells. Macrophage products may provide biomarkers for underlying chronic inflammatory and storage disorders, such as plasma chitotriosidase in Gaucher's disease, and angiotensin converting enzyme in sarcoidosis.

Macrophage secretion, though considerably lower than other sources such as hepatocytes, may be significant within a confined local environment. Thus macrophage neutral proteinases, peptidases, and their inhibitors are able to contribute to inflammation and repair, and activate and regulate the plasma cascades of complement, coagulation, fibrinolysis, and the generation of kinins. Finally, macrophages release important products of digestion, including salvaged iron in various forms, as well as acid hydrolases after phagocytosis under particular circumstances.

DC secretion is important for the polarization and imprinting of T cells, following TCR ligation (signal 1) and costimulation (signal 2). Polarizing signals (signal 3) include IL-12 for the initiation of TH1 responses, IL-4 for generation of TH2 cells, and IL-23 for TH-17 cells. Mature DCs also provide homing instructions to activated T cells in order to navigate the T cells to the tissue from which the DCs originated. The exact mechanism of this "signal 4" is not clear, but upregulation of skin-targeting receptors CLA and CCR10 or gut targeting receptors $\alpha 4\beta 7$ and CCR9 endows T cells with specific tissue homing properties. It has been shown that DCs possess the enzymes to metabolize sunlight-induced vitamin D3 into the active form 1,25-dihydroxyvitamin D3, which induces CCR10 on T cells and concomitantly suppresses gut-homing receptors $\alpha 4\beta 7$ and CCR9.

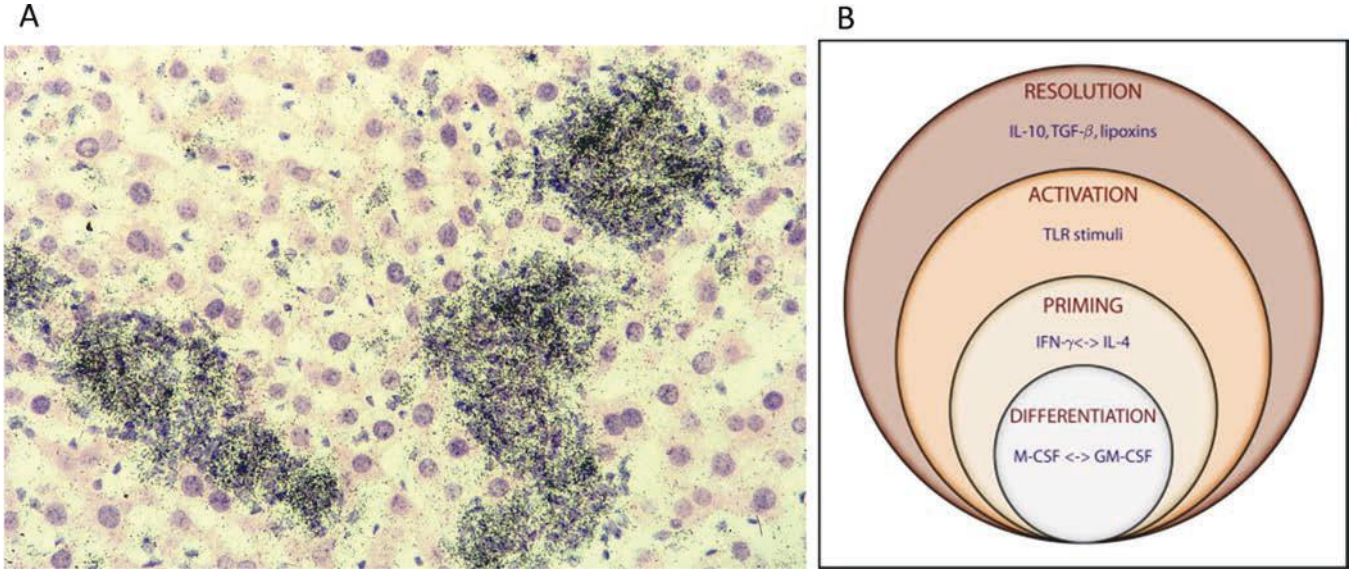

FIGURE 10.14. A: BCG-induced granulomata in mouse liver. In situ hybridization reveals intense lysozyme mRNA expression in macrophage-rich granulomata. Sinusoids display weaker expression by trafficking monocytes and activated Kupffer cells. (Courtesy of S. Keshav.) **B:** Paradigm of macrophage activation. The development into fully activated macrophages can be divided into successive stages. During a first phase the recruited monocytes mature into macrophages. The balance of macrophage-colony stimulating factor (M-CSF), granulocyte-macrophage–colony stimulating factor (GM-CSF), retinoic acids, and lipoproteins determine substantial differences in the phenotype of the mature macrophage. During recruitment, monocytes are exposed to cytokines, inducing a second phase of priming. During the third phase of activation, macrophages reach a mature functional phenotype in response to toll-like receptor (TLR) and opsonic stimuli. The final phase of deactivation and/or resolution allows clearance of debris and expression of general repair functions, regulated by interleukin-10 (IL-10), tumor necrosis factor-β (TGF-β), and antiinflammatory mediators such as nucleotides, lipoxins, and glucocorticoids.[68]

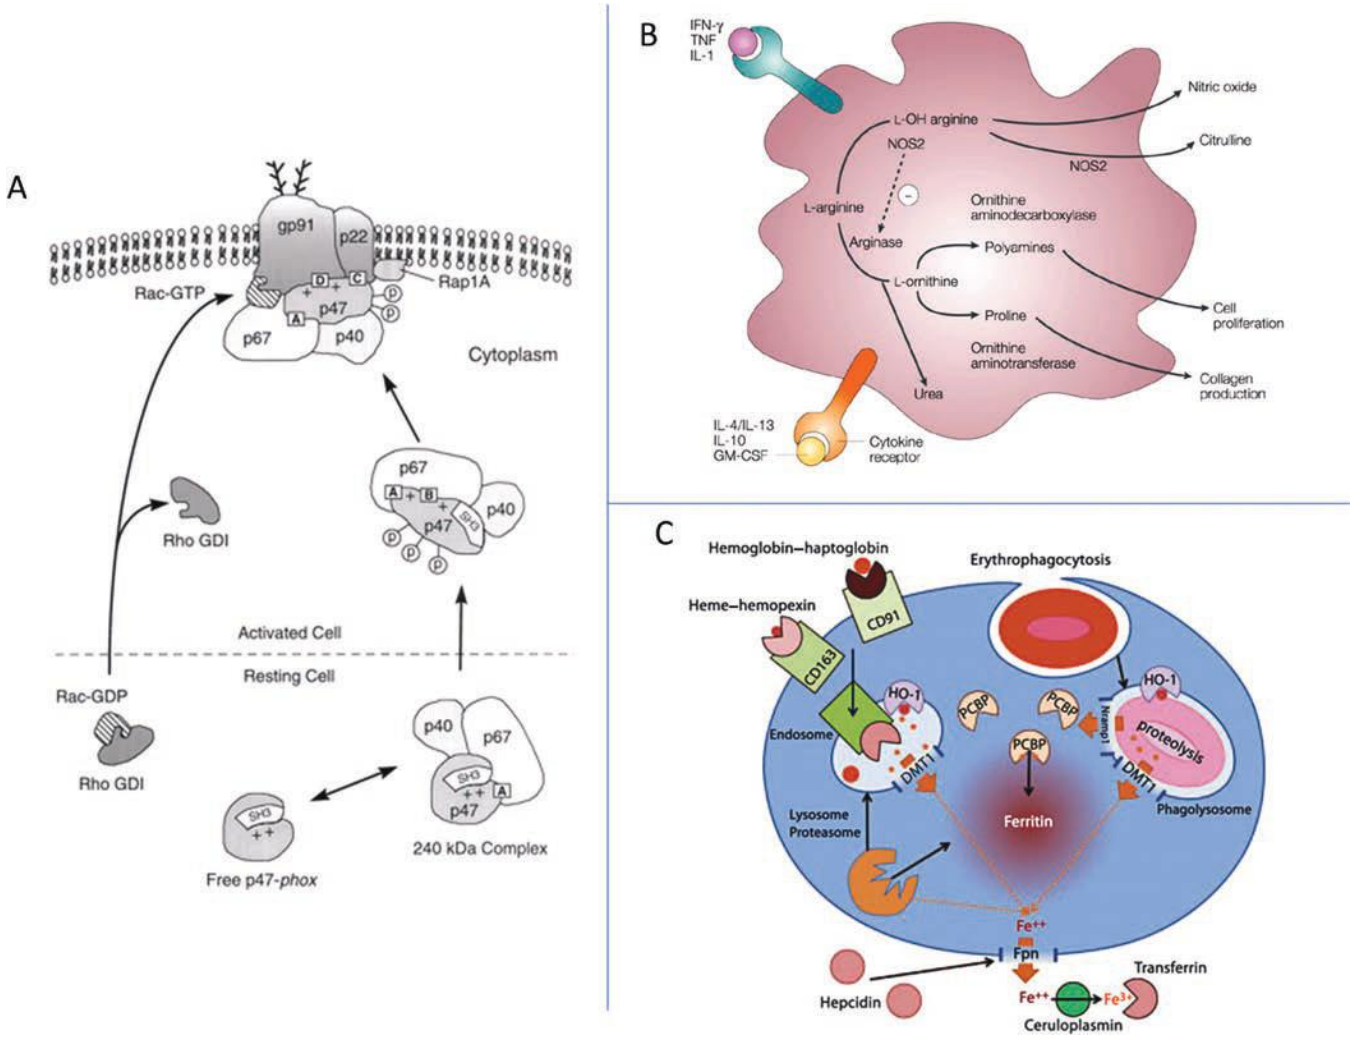

FIGURE 10.15. A: Schematic representation of NADPH oxidase activation and assembly. Following stimulation of resting phagocytes, cytoplasmic subunits form a complex at the plasma membrane which converts oxygen to highly reactive oxygen radicals, the respiratory burst. From De Leo FR, Ulman KV, Davis AR, Jutila KL, Quinn MT. Assembly of the human neutrophil NADPH oxidase involves binding of p67phox and flavocytochrome b to a common functional domain in p47phox. J Biol Chem 1996;271:17013–17020, with permission.[55] **B:** The role of nitrogen metabolism in macrophage function. Interferon-γ (IFNγ) enhances the activity of nitric oxide synthase 2 (NOS2) to generate nitric oxide, and inhibits arginase. IL-4 and IL-13 promote arginine-dependent formation of L-ornithine and ultimately fibroblast proliferation and collagen production. From Gordon S. Alternative activation of macrophages. Nat Rev Immunol Jan 2003;3(1):23–35, with permission.[133] **C:** Flow of iron in macrophages. Macrophages take up iron through erythrophagocytosis of damaged or senescent erythrocytes. Macrophages can also scavenge heme and hemoglobin, usually complexed with hemopexin and haptoglobin, and endocytosed by CD163 and CD91 for proteolysis to release heme. Heme is degraded by HO-1 to release iron, which is exported to the cytoplasm by DMT1 and possibly by Nramp1. Cytoplasmic chaperones of the poly(rC)-binding protein (PCBP) family deliver iron for storage in ferritin. Alternatively, iron may also be delivered by an unknown carrier to ferroportin (Fpn) for export. When demand for iron is high, ferritin is degraded by lysosomes or proteasomes, and the released ferrous iron is exported through ferroportin. Iron export is controlled by extracellular hepcidin through its ability to induce endocytosis and proteolysis of ferroportin. The ferroxidase ceruloplasmin oxidizes iron to its ferric form and facilitates iron export and loading onto the carrier protein transferrin. From Ganz T. Macrophages and systemic iron homeostasis. J Innate Immun 2012;4(5–6):446–453, with permission.[125]

Antimicrobial Activity

See Figure 10.15.[55,58]

The respiratory burst of human neutrophils and activated monocytes/macrophages has been well studied as a result of the inborn errors that give rise to chronic granulomatous disease (Fig. 10.15A). The components which assemble to form the NADPH oxidase include a novel cytochrome, and the various targets of mutation have been defined. The burst of oxygen consumption gives rise to superoxide anions, singlet oxygen, hydroxyl radicals, and hydrogen peroxide, which, in combination with myeloperoxidase and halides (the Klebanoff reaction), gives rise to enhanced oxidative power. The role of ion channels in the initial alkalinization associated with the respiratory burst remains controversial. Glutathione and other intracellular reducing mechanisms provide protection against injury.

The role of the inducible nitric oxidase in humans is unresolved; in mice the NADPH oxidase and i-NOS together account for almost all the microbicidal activity of myeloid leukocytes. In mouse macrophages the metabolism of arginine is strongly regulated by the Th1/2 cytokines.

The cationic antimicrobial peptides such as cathelicidins are produced by various cells, including neutrophils and some but not all monocytes and tissue macrophages; by contrast, lysozyme requires additional damage to the microbial wall, e.g., by complement, for microbicidal lysis. Although neutrophil extracellular traps (NETS) are now established as antimicrobial mechanisms of neutrophils, this has not been documented in activated human monocytes/macrophages, a likely counterpart.

A role has been proposed for potent neutral proteinases such as elastase in microbial killing, as well as degradation.

TABLE 10.4

SELECTED SECRETION PRODUCTS OF MACROPHAGES

Proteins	Product	Comment
Enzymes	Lysozyme	Bulk product
	Urokinase type plasminogen activator	Regulated by inflammation
	Collagenase	Regulated by inflammation
	Elastase	Regulated by inflammation
	Metalloproteinases	Also inhibitors
	Complement	All components and regulators
	Arginase	Alternative activation
	Angiotensin converting enzyme	Induced glucocorticoids, granulomas
	Chitotriosidase	Gaucher's disease, lysosomal storage
	Acid hydrolases	All classes (mainly intracellular)
Inhibitors	TIMP	
Chemokines	Many C-C, C-X-C, CX_3C-, e.g., MCP, Rantes, IL-8	Initiates acute and chronic recruitment of myeloid and lymphoid cells
Cytokines	IL-1β, TNF-a	Pro and anti-inflammatory, also antagonists, e.g. IL-1Ra
	IL-6, IL-10, IL-12, IL-17, IL-18, IL-23	Pro and anti-inflammatory, also antagonists, e.g. IL-1Ra
	Type I interferon	Autocrine and paracrine amplification
Apolipoproteins	Apolipoprotein E	Local source, bone marrow origin after adoptive transfer
Growth/differentiation factors	TGF-β	Also other family members (activins), fibrosis
	M-CSF	Myeloid growth and differentiation
	GM-CSF	
	FGF	Fibrosis
	PDGF	Repair
	VEGF	Angiogenesis
Opsonins	Fibronectin, Pentraxin (PTX3)	Also uncharacterized receptor on MØ
Soluble receptors	Mannose receptor	Soluble mannose receptor
Cationic peptides	Defensins	Subpopulations and species variation
Lipids	Procoagulant	Initiation clotting
	Arachidonate metabolites:	Pro- and anti-inflammatory mediators
	Prostaglandins	
	Leukotrienes	
	Thromboxanes	
	Resolvins and maresins	
Metabolites	Reactive oxygen intermediates	
	Reactive nitrogen intermediates	
	Heme breakdown (bile pigments)	
	Iron, B12 binding protein	
	Vit. D metabolites	

GM-CSF, granulocyte-macrophage–colony stimulating factor; IL, interleukin; M-CSF, macrophage-colony stimulating factor; TNF-α, tumor necrosis factor-α; TIMP, tissue inhibitor of metalloproteinase; MCP, monocyte chemoattractant protein-1; FGF, fibroblast growth factor; PDGF, platelet-derived growth factor; VEGF, vascular endothelial growth factor.

Inflammation and Repair[59–61]

Monocytes and macrophages play central roles in the generation and resolution of inflammatory responses. The function of DCs is less obvious, although steady state populations may be required to maintain tolerance in the periphery.

Upon stimulation, monocytes and macrophages are able to initiate, amplify, regulate, and terminate inflammation and repair. This depends on their integrated recognition of microbes and modified host components, uptake, signaling by NFkB and other pathways, altered gene expression, and secretion of a host of mediators, including pro- and antithrombotic agents. Apart from the products listed above, they generate both pro- and anti-inflammatory prostaglandins, thromboxanes, and leukotrienes; recent studies by Serhan and colleagues have described potent resolvins and maresins, implicated in resolution and repair. They orchestrate granulocyte and lymphocyte recruitment, contribute to coagulation and thrombolysis, modulate endothelial cells, and regulate angiogenesis. Macrophage-derived urokinase plays an important role in fibrinolysis, through the generation of plasmin; the UPA receptor and PA inhibitor-1 help to localize and regulate plasmin generation. Interactions with neutrophils are particularly important in acute inflammation and with T and B lymphocytes and their products in chronic inflammation. Poor degradation of particulates within macrophage lysosomes is a driver of chronicity, through altered and persistent protein synthesis and secretion of host degrading enzymes, and through pathologic fibrosis. Once local defenses are breached, the systemic consequences include metabolic and endocrine effects, as well as fever and anorexia via the nervous system. The balance between activation and inhibition of macrophage activation is influenced by a range of amplifying and negative regulators.

Monocyte Subsets

See Figure 10.16.[62–66]

Monocytes may be divided into two or more subsets based on the expression of phenotypic properties and differentiation potential. The major "classical" subset in humans expresses high CD14 and variable CD16 and comprises 90% of circulating monocytes.

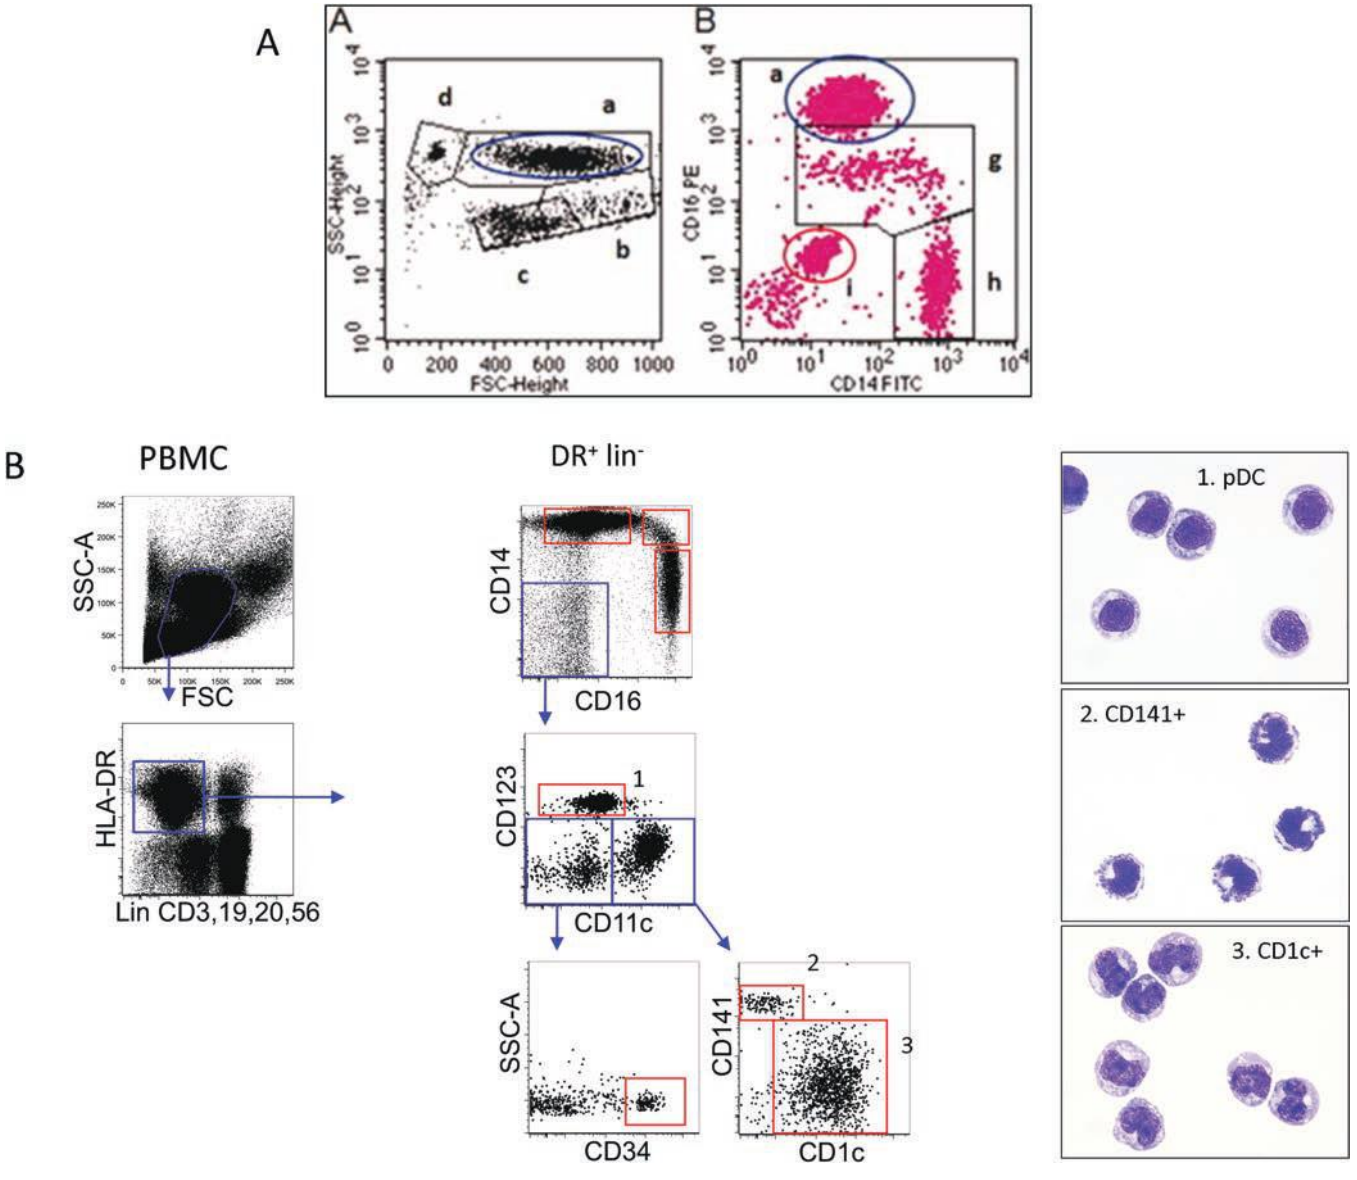

FIGURE 10.16. FACS analysis of human blood leukocytes to distinguish monocytes from granulocytes. A: Stained cells were analyzed with scatter gates around monocytes and granulocytes (a and b in A). The CD14 and CD16 histogram (B) demonstrates CD16-positive neutrophils (a) and CD16-negative eosinophils (i). A representative example is shown: (a) granulocytes, (b) monocytes, (c) lymphocytes, (d) beads, (g) $CD14^{+}CD16^{+}$ monocytes, (h) $CD14^{+}CD16^{-}$ monocytes, and (i) eosinophilic granulocytes. From Heimbeck I, Hofer TP, Eder C, et al. Standardized single-platform assay for human monocyte subpopulations: Lower CD14+CD16++ monocytes in females. Cytometry A 2010;77:823–830, with permission.[64] **B:** Schema for isolating human blood DCs from gradient purified PBMC (peripheral blood mononuclear cells). SSC, side scatter; FSC, forward scatter; Lin, lineage. $HLA\text{-}DR^{+}$ lin^{-} contains all monocyte and DC subsets and includes CD34+ progenitors. Gate 1 plasmacytoid DCs; Gate 2 CD141+ myeloid DCs; Gate 3 CD1c+ myeloid DCs; CD34+ progenitors are found in the $CD11c^{-}$ $CD123^{-}$ gate. Note the basophilic cytoplasm and perinuclear lucency of plasmacytoid DCs (1), the more activated membrane appearance of CD141+ DCs (2), and the heterochromatin with prominent nucleoli of CD1c+ DCs (3).

The remaining 10% express high CD16 and moderate CD14 and are known as "nonclassical." This is a useful basis to approach monocyte heterogeneity; but casual inspection of the CD14 vs. CD16 flow cytometry plot shows that it is difficult to draw distinct boundaries between the two subsets, and some authorities recognize a third CD14+CD16+ population known as "intermediate" at the knee of the population. Confusion still arises over whether the CD14+CD16+ double positive cells are closer to the classical or nonclassical group.

Classical and nonclassical monocytes differ in a number of important properties (see Table 10.1). Most notably, the classical monocyte expresses CCR2 and is rapidly recruited in a CCR2-dependent fashion to sites of inflammation in animal models. Although this seems straightforward, it is apparent that CCR2 signaling is actually required for monocytes to leave the BM and the precise role of this chemokine receptor in recruitment from blood to tissue therefore remains unsolved. The nonclassical cell bears CX3CR1 and is found in contact with the endothelium, where it is said to perform a "patrolling" function. Deletion of the ligand CX3CL1 (fractalkine) in mice reduces the survival of nonclassical monocytes and their recruitment to the spleen during bacterial sepsis. This function is not exclusive, as classical monocytes also show dependence upon CX3CR1 signaling. Monocytes also express CCR1 and CCR5. Recruitment through these molecules may result in a more chronic inflammatory phenotype and is implicated in atherosclerosis, rheumatoid arthritis, and multiple sclerosis.

Historically, there has been confusion over the status of the nonclassical monocyte, and in many publications it is referred to as the CD16+ "dendritic cell." The two terms are synonymous and

there is only a single discrete population of myeloid cells bearing CD16 in the mononuclear compartment of human blood. Inclusion of CD16+ monocytes in the DC lineage reflects a number of properties of these cells, including higher expression of MHC class II and costimulatory molecules CD80 and CD86. A subset of CD16+ monocytes also expresses SLAN (6-sulfoLacNAc). Gene expression analysis indicates that SLAN+ and SLAN− monocytes are equivalent, but a case has been made for a specialized role of "SLAN-DC" in host defense.

Automated blood counters most likely recognize the classical CD14+ monocyte with its larger size and granularity and may enumerate the smaller nonclassical populations as lymphocytes. Clinical hematology pays little heed to the separation of monocyte subsets, in spite of a wealth of information indicating differential modulation of one or the other in disease states.

Macrophage Activation, Regulation, and the M1 M2 Paradigm

See Figure 10.14.[67,68,69,70,71,72,72a]

The concept of macrophage activation became an important issue following the studies by George Mackaness and colleagues, who demonstrated enhanced antimicrobial resistance of mice, associated with altered macrophage effector functions, after infection by BCG and *Listeria monocytogenes*. Subsequently, this effect of cell-mediated immunity to intracellular bacteria was shown to be due to interferon-γ (IFNγ), released by activated CD4 T helper 1 cells and by NK cells. Microbial constituents such as LPS further enhance macrophage inflammatory and antimicrobial activities, but since these TLR ligands are also able to induce distinct changes in macrophages directly, in the absence of IFNγ, we have chosen to term this innate activation. The scavenger receptor MARCO is a marker of innate activation of macrophages.

Studies by many groups have catalogued IFNγ-induced changes in macrophage gene expression, induction of MHC II and costimulatory molecules, and secretion of pro-inflammatory cytokines such as TNF-α and of reactive oxygen and nitrogen metabolites. We prefer the term classical activation, also widely known as M1 polarization, to describe the cellular program evoked by the priming stimulus (IFNγ) with or without a secondary microbial ligand. The role of IFNγ, IL12, their receptors, and STAT 1 in classical activation, initially discovered in mouse studies, has been confirmed in inborn errors in humans by Casanova, Holland, Gallin, and others. Recent studies by Udalova and colleagues have drawn attention to the role of INF-regulatory proteins 4, 5 in regulating macrophage activation.

The concept of alternative (M2) activation arose from studies of mouse peritoneal macrophages treated with IL-4, which induced distinct activation activities such as upregulation of mannose receptors, in contrast to IFNγ, a selective downregulator. Other markers in the mouse include induction of Arginase1, instead of i-NOS, as part of a distinctive gene signature. This was shown to be due to TH2-derived cytokines, IL-4 or IL-13, acting through their specific surface receptors, and signaling and transcription factors, mainly STAT6. DNA-specific demethylation has been shown to play a critical role in alternative activation. These cytokines derive from innate and acquired sources, especially during parasitic and allergic inflammation, and also regulate the cellular response to TH1 stimuli. Currently, we are defining the effects of TH-2 cytokines on human macrophages, and testing their relevance to disease in human tissues. Recent studies have demonstrated unexpected homeostatic functions of IL-4 in thermoregulation and metabolism. IL-13 has been implicated in fibrosis.

Other types of M2 activation include Fc receptor-stimulated alteration of IL10/IL12 ratios, to induce a distinct form of regulatory macrophages, described in mice by David Mosser and colleagues. IL-10 is primarily a negative counter of M1 activation and its potential to produce inflammatory injury in tissue. Additional anti-inflammatory mediators in macrophages include TGF-β, prostaglandin E, induced, for example, by macrophage uptake of apoptotic cells; surface CD200–CD200 receptor and SIRP alpha-CD47 interactions; and cytoplasmic inhibitors such as the SOCS proteins. Glucocorticosteroids are potent inhibitors of macrophage activation.

Microarray and proteomic studies, in vitro and ex vivo, are helping to define the remarkable plasticity of macrophage phenotype, which needs further study in situ, at the level of cell populations and individual cells. Pathogens are able to manipulate macrophage activation mechanisms for their own benefit, in a dynamic interplay with infected and neighboring host cells.

Dendritic Cell Functional Subsets[73]

In recent years it has become clear that different subsets of DCs are equipped with functional specializations that influence their interactions with antigen and other immune cells. Human and mouse DCs fall into two principal categories, myeloid or "classical" (in mice) and plasmacytoid. These terms originally arose from morphology and surface markers: blood myeloid DCs have a pale-staining monocytoid morphology and also bear CD11c, in common with monocytes; plasmacytoid DCs are more basophilic, reflecting their secretory capacity, and may express a number of lymphoid markers including CD2 and CD7. All human DCs and monocyte subsets express CD4, but none express CD8, unlike the mouse. Myeloid DCs consist of at least one major subset, marked by CD1c and a minor subset expressing CD141 (BDCA-3; thrombomodulin).

Plasmacytoid DCs (pDCs) are found in several mammalian species and perform unique antiviral functions through the expression of PRRs for viral nucleic acids (TLR3, TLR7 and TLR9, RLRS, and HELICASES) and the capacity to synthesize large quantities of IFNα rapidly when challenged. Depletion of pDCs in animal models does not attenuate initial responses to viral infection as much as might be anticipated by their kinetics of response, but rather limits the formation of robust antiviral memory. Human blood pDCs are labile and do not survive well ex vivo.

Myeloid DCs (mDCs) are an important component of human blood, although conspicuously absent from the mouse. The properties of CD1c+ mDCs are similar to the so-called classical or conventional DCs isolated from mouse spleen in that they phagocytose external antigens, mature through expression of CD83 and costimulatory molecules CD80 and CD86, and are capable of priming naive CD4+ T cells to proliferate.

CD1c+ myeloid DCs are also found in epithelial tissues including skin, gut, liver, and lung. In the tissues they usually express CD1a, CD205 (DEC205), and CD206 (macrophage mannose receptor), but do not bear CD14 or DC-SIGN (DC209). It seems likely from comparison of gene expression profiles that blood CD1c+ DCs give rise to analogous cells in the tissues. In the steady state, these cells are distinct from monocytes, but differentiation of monocytes in the presence of GM-CSF and IL-4 leads to rapid expression of CD1a and myeloid DC-like features.

Myeloid DCs with similar surface phenotype constitute the bulk of DCs found in the T cell areas of lymph nodes (interdigitating cells), but it has been difficult to dissect in humans whether these cells are predominantly derived by migration from the tissues or recruitment from the blood.

CD141+ marks a specialized DC subset that has superior cross-presenting capacity and potential to interact with CD8+ T cells. Recent comparative transcriptomic and functional analyses have shown that these DCs are related to the CD8+ DCs of mouse lymphoid tissue. They are present at very low frequency—approximately 0.1% of mononuclear cells—but their potency in cross-presentation assays suggests they may play a key role in

immunity to viral infection, tumors, and extracellular pathogens. In some analyses, as discussed above, CD16+ nonclassical monocytes are considered to be a subset of myeloid DCs.

The specialization of each DC subset is determined by functional adaptations at many levels. A particular repertoire of PRRs focuses interactions with certain pathogens; thus TLR2/4 is prominent on myeloid DCs, TLR3 is found highly expressed on cross-presenting DCs, and pDCs have abundant TLR7/9. Characteristic C-type lectins are also displayed by DCs with different functions, most notably langerin on the epidermal Langerhans cell, DC-SIGN on interstitial DCs, and CLEC9A on cross-presenting myeloid DCs. Antigen processing and presentation pathways are adapted to drive MHCI or MHC II-restricted responses in the context of the appropriate polarizing cytokines. For example, cross-presenting DCs that are specialized for interaction with viruses have abundant nucleic acid receptors, cross-presenting capacity, and biased stimulation of TH1 and CD8 responses.

DISTRIBUTION OF MONONUCLEAR PHAGOCYTES

In the following section we describe the distribution of MPs in different tissue compartments of the adult, emphasizing humans where possible, but drawing on information obtained in the mouse with the antigen F4/80 marker, as appropriate. Macrophage and DC generation and turnover depend on growth factors and transcriptional regulators and will be described in detail below, except for osteoclasts, discussed in this section.

Blood[74,75]

MPs are found in almost all tissues. The human blood mononuclear cell compartment has been almost exhaustively investigated and is the most readily accessible and clinically relevant tissue.

A recommended FACS analysis of human blood leukocytes to distinguish monocytes from granulocytes is illustrated in Figure 10.16A. A schema for classifying blood monocytes and DCs is shown in Figure 10.16B. All monocytes and DCs express MHC class II HLA-DR molecules. B cells, activated T cells, and NK cells also bear MHC class II antigens, so the most useful starting point is to identify HLA-DR$^+$ lineage cells. Lineage markers are a cocktail of antibodies that usually include a minimum of CD19/20 (B cells), CD3 (T cells), and CD56 (NK cells). Circulating hematopoietic progenitors also express HLA-DR and may be excluded by adding CD34 to the lineage cocktail.

HLA-DR$^+$ lineage cells defined in this way comprise approximately 10% of all peripheral blood mononuclear cells. Ninety percent of these cells are monocytes and approximately 10% DCs. Monocytes comprise a major fraction of classical CD14+ cells (90%) and a minor CD16+ nonclassical fraction as discussed previously.

The DCs of human blood comprise 10% of HLA-DR$^+$ lineage cells and 2% to 3% of total mononuclear cells. Plasmacytoid DCs are the major component and myeloid DCs a smaller component comprising 30% to 40% of blood DCs. A common way to separate these two groups is by differential expression of CD123 (IL-3R) and CD11c (alpha X integrin), respectively. Plasmacytoid DCs are also marked by CD303 (a C-type lectin) and CD304 (neuropilin-1), antigens also known as BDCA-2 and BDCA-4. Human myeloid DCs are mainly CD1c+ while a small fraction (10% to 20%) expresses CD141. CD1c+ is an invariant class I molecule identified by BDCA-1 antibody and is a reliable marker of tissue and lymphoid DCs in many sites. CD141 (thrombomodulin) is more widely expressed and finds utility only in identifying DCs within the hierarchy of markers already described.

Bone Marrow (See Figs. 10.1, 10.17 and 10.18)[76–80]

Both developing monocytes and mature macrophages supporting hematopoiesis are found within the bone marrow microenvironment in normal bone marrow. Macrophages are large cells with a large amount of cytoplasm and small nuclei, and are often surrounded by plasma cells, lymphocytes, or maturing erythroid cells. Their cytoplasm is often ruffled and vacuolated and contains phagocytosed debris. Hematopoietic stem cells are found in specific areas near osteoblast-lineage cells at the endosteum. Macrophages are important components of the hematopoietic stem cell niche and interact with both osteoblasts and mesenchymal stem cells to retain hematopoietic stem cells within the bone marrow. G-CSF mobilization depletes endosteal macrophages that support osteoblast function, resulting in reduced endosteal osteoblasts, as well as suppression of bone formation and factors required for stem cell retention and renewal with consequent mobilization of stem cells into peripheral blood.

The appearance of hematopoietic cell clusters in bone marrow has been known for many years. Studies by Paul Crocker and colleagues in the mouse identified F4/80+ mature stromal macrophages at the center of such clusters with differentiating hematopoietic cells. They described the presence of a novel sialic acid–recognition macrophage adhesion receptor, sialoadhesin (Siglec-1, CD169), which was concentrated at the sites of contact with developing granulocytes (Fig. 10.18). Similar stromal macrophages were found within hematopoietic clusters in human bone marrow (Fig. 10.17). The function of CD169 or other divalent cation-dependent stromal macrophage adhesion molecules is not understood, but specific depletion of CD169+ macrophages as opposed to monocytes is sufficient to induce progenitor egress in the mouse.

Lymphoid Organs (See Fig. 10.19)[81]

Macrophages and DCs form important components of lymphoid tissue. Macrophages play carefully choreographed roles in the induction of immune responses. In the subcapsular spaces of lymph nodes, CD169+ macrophages are positioned to capture antigen from afferent lymph and transport it to B cells in the follicles. This function is one of many examples of monocyte and macrophages providing direct help to B cells through presentation of intact antigen and elaboration of maturation and class-switching factors including BAFF and APRIL. Surrounding the follicles, a capsule of marginal zone macrophages is specialized to engulf apoptotic B cells that fail to receive survival stimuli and achieve maturation in the germinal centers. Macrophages also occupy the medulla and splenic red pulp. Here they provide niches for plasma cells. In the spleen the sinus-lining macrophages play a key role in the uptake of senescent red cells.

DCs are classically found as “interdigitating cells” of the perifollicular T cell regions and splenic white pulp. Lineage tracing studies now show that these are a mixture of migratory myeloid DCs arriving from the periphery and blood-derived cells recruited directly to the node. During inflammation their number increases manyfold and is augmented by plasmacytoid DCs and monocyte-derived inflammatory DCs. Live cell imaging shows dynamic and complex interactions between DCs and T cells in these regions.

Follicular DCs are a unique population of antigen-storing cells that are mesenchymal in origin and do not express typical leukocyte markers, but are rich in complement and Fc receptors. They have a complex arborizing structure and are found scattered in the germinal centers where they attract B cells by CXCL13 signaling. Their function has been linked to the preservation of opsonized intact antigen and promotion of B cell memory responses.

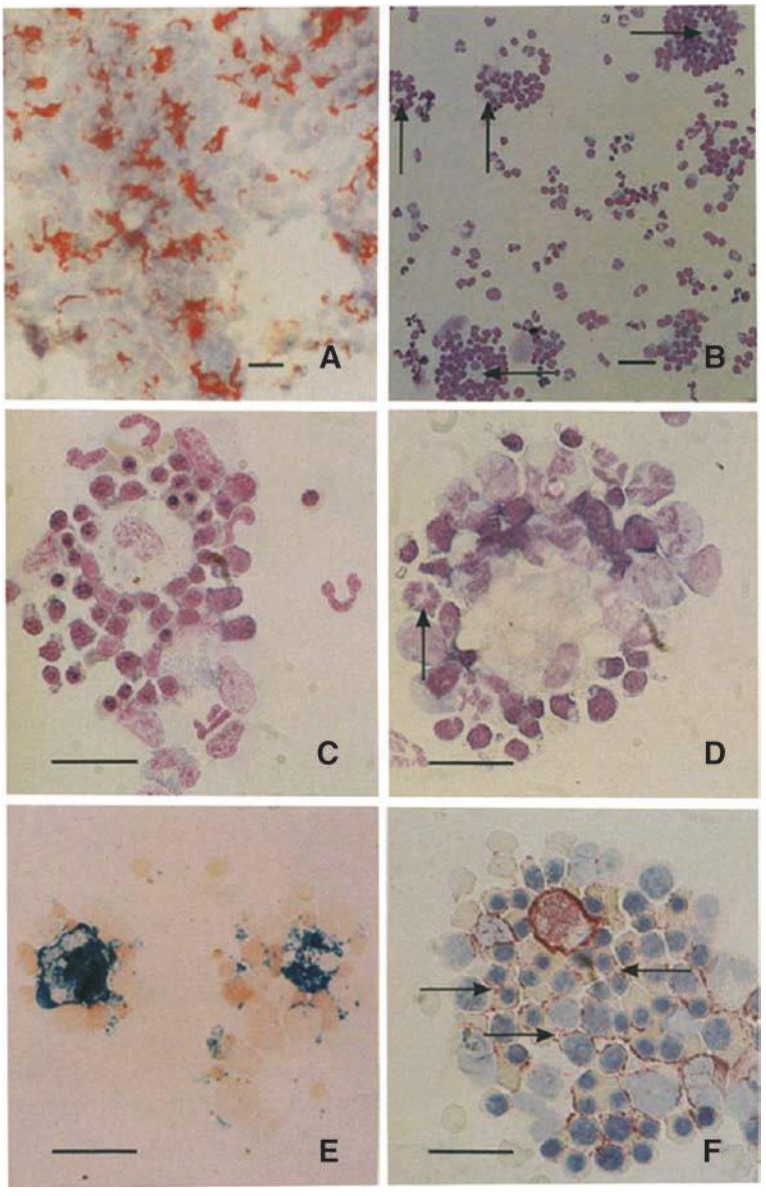

FIGURE 10.17. A: Stromal macrophages in human marrow associate with developing hematopoietic cells in islands/clusters. Immunocytochemical staining with antimacrophage monoclonal antibody Y-1/82A of marrow section reveals a network of arborizing stromal macrophages uniformly distributed throughout the marrow interstitium (alkaline phosphatase–anti-alkaline phosphatase [APAAP] stain; hematoxylin counterstain). **B:** Marrow cells depleted of red cells and other single cells are enriched for cell clusters, most of which are erythroid clusters with a central stromal macrophage (*arrows*; Giemsa). **C:** Isolated erythroid cluster with intermediate and late normoblasts surrounding a central stromal macrophage (Giemsa). **D:** Isolated mixed cluster with both myeloid and erythroid cells attached to a central stromal macrophage. A dividing cell (*arrow*) is seen (Giemsa). **E:** Isolated erythroid clusters from a pathologic marrow sample show intense staining for hemosiderin of stromal macrophages with cellular processes extending between attached erythroblasts (Perl acid ferrocyanide reaction; counterstain neutral red). **F:** Immunocytochemical stain with antibody Y1/82A of isolated erythroid cluster. Both the stromal macrophage cell body and processes (*arrows*) between attached erythroblasts are visible (APAAP stain; hematoxylin counterstain). Bar = 50 μm. From Lee SH, Crocker PR, Westaby S, et al. Isolation and immunocytochemical characterization of human bone marrow stromal macrophages in hemopoietic clusters. J Exp Med 1988;168:1193–1198, with permission.[79]

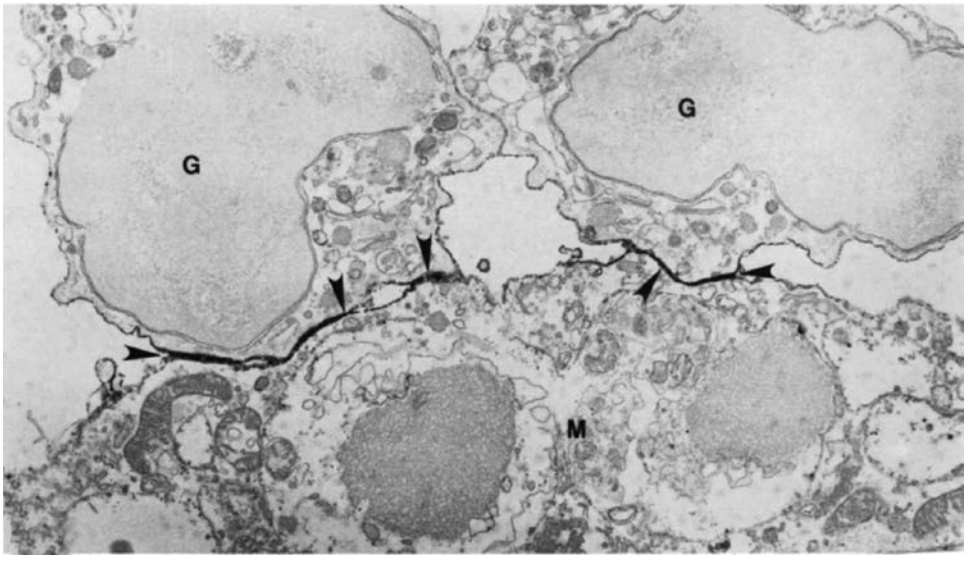

FIGURE 10.18. Ultrastructural localization of CD169 (siglec-1, sialoadhesin) in mouse macrophage-hematopoietic cell clusters. Immunoelectronmicroscopy with monoclonal antibody to CD169 shows concentration of CD169 at contacts between macrophages (M) and developing granulocytic cells (G). CD169 was diffusely localized at the contact zones between macrophages and erythroblasts (not shown). (See Crocker PR, Werb Z, Gordon S, Bainton DF. Ultrastructural localization of a macrophage-restricted sialic acid binding hemagglutinin, SER, in macrophage-hematopoietic cell clusters. Blood 1990;76(6):1131–1138, for further details.)

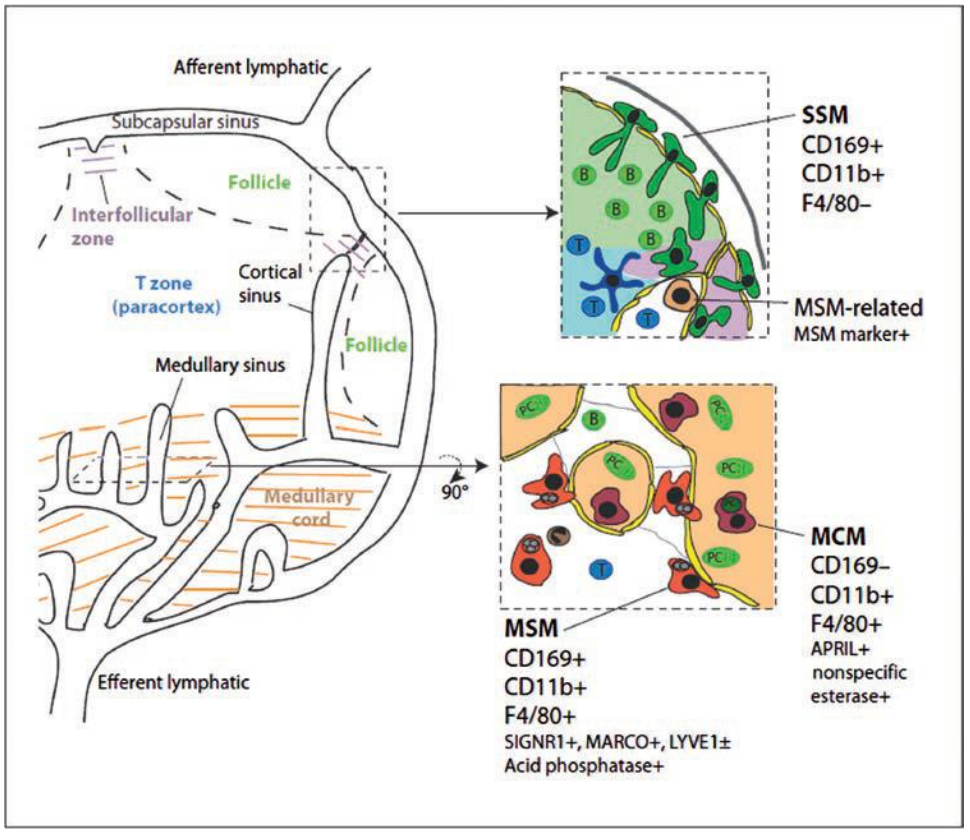

FIGURE 10.19. Schematic of mouse lymph node showing major zones and lymphatic sinuses with macrophage subsets (subcapsular sinus [SCS] macrophages [SSM], medullary sinus macrophages [MSM], and medullary cord macrophages [MCM]). Boxed regions are enlarged on the right. Upper box: SCS and interfollicular region with follicle shown in green shading, T zone in blue, and interfollicular region in purple. Lower box: medullary region in cross-section showing medullary cords in light brown. Sinuses are shown in white and sinus-lining lymphatic endothelial cells are yellow. Their CD169, CD11b, and F4/80 phenotype is summarized. A DC is shown in dark blue (upper) and a polymorphonuclear cell in brown (lower). Reticular fibers within medullary sinuses are in gray. B, B cell; PC, plasma cell; T, T cell. From Gray EE, Cyster JG. Lymph node macrophages. J Innate Immun 2012;4(5–6):424–436, with permission.

DCs and macrophages are also found in the thymus. DCs are critical in the positive selection of T cells in the cortex while macrophages in the medulla remove apoptotic debris resulting from negative selection to remove autoreactive T cells.

Spleen (See Fig. 10.20)[82,83,84,85]

In the mouse, histological examination of the spleen reveals a marginal zone (MZ) between the hematopoietic red pulp (RP) and lymphoid white pulp (WP), constituting an interface between the circulation and resident lymphoid tissue. The white pulp contains CD68+F4/80− cells, macrophages as well as DCs, which can be induced to migrate into the white pulp in response to antigenic stimulation. The MZ contains an inner CD169+ F4/80− metallophilic population and an outer population of phagocytic MARCO+ SIGNR-1+ macrophages. A subset of metallophilic macrophages also expresses ligands for the cysteine-rich N-terminus of the mannose receptor (CD206), which itself functions as a receptor for sulfated sugars, targeting captured glycoconjugates to the marginal zone. The MARCO scavenger receptor and SIGNR1 lectin (counterpart of human DC-SIGN) are important in the clearance of apoptotic cells and avoidance of immunization by autoantigens. Depletion of MZM leads to enhanced phagocytosis of apoptotic cells by RP macrophages, an inflammatory response, and in mice, acceleration of autoimmune disease and increased susceptibility to certain pathogens including *Listeria monocytogenes*.

Red pulp macrophages are strongly F4/80+ CD206+ and are involved in clearance of senescent erythrocytes and granulocytes and in iron turnover. They have also been implicated in a tolerogenic function. The red pulp can also serve as reservoir for mobilization of monocytes to peripheral sites of injury, and contributes to hematopoiesis in the normal mouse.

Humans lack the characteristic features of MZ found in rodents; studies by Steiniger, Crocker, and colleagues have identified an interfollicular region with CD169+ cells which may fulfill a parallel function. Martinez-Pomares and colleagues found that CD68+ macrophages in the red pulp of human spleen are distinct from MR+ cells, which are present in venous sinuses, and co-express ligands for the MR cysteine-rich domain, as well as the Lyve-1 antigen.

Given these striking species differences, it is difficult at present to attribute particular immunological functions to specialized macrophages and DCs in human spleen, comparable to the role attributed to CD169+ MZ cells in specific interactions with lymphocytes, including CD8+ T cells.

Nonlymphoid (Interstitial) Tissues

Analysis of the leukocyte content of human tissues and lymphoid organs has been a preoccupation of pathology for more than a century but only recently have modern multiparameter tools and functional studies been applied to elucidate the complexity of resident and inflammatory cells in these sites. Interstitial tissues such as the dermis are rich in leukocytes, blood vessels, and lymphatics. Most tissues contain a macrophage or histiocyte component, myeloid DCs, predominantly CD4+ effector memory lymphocytes,

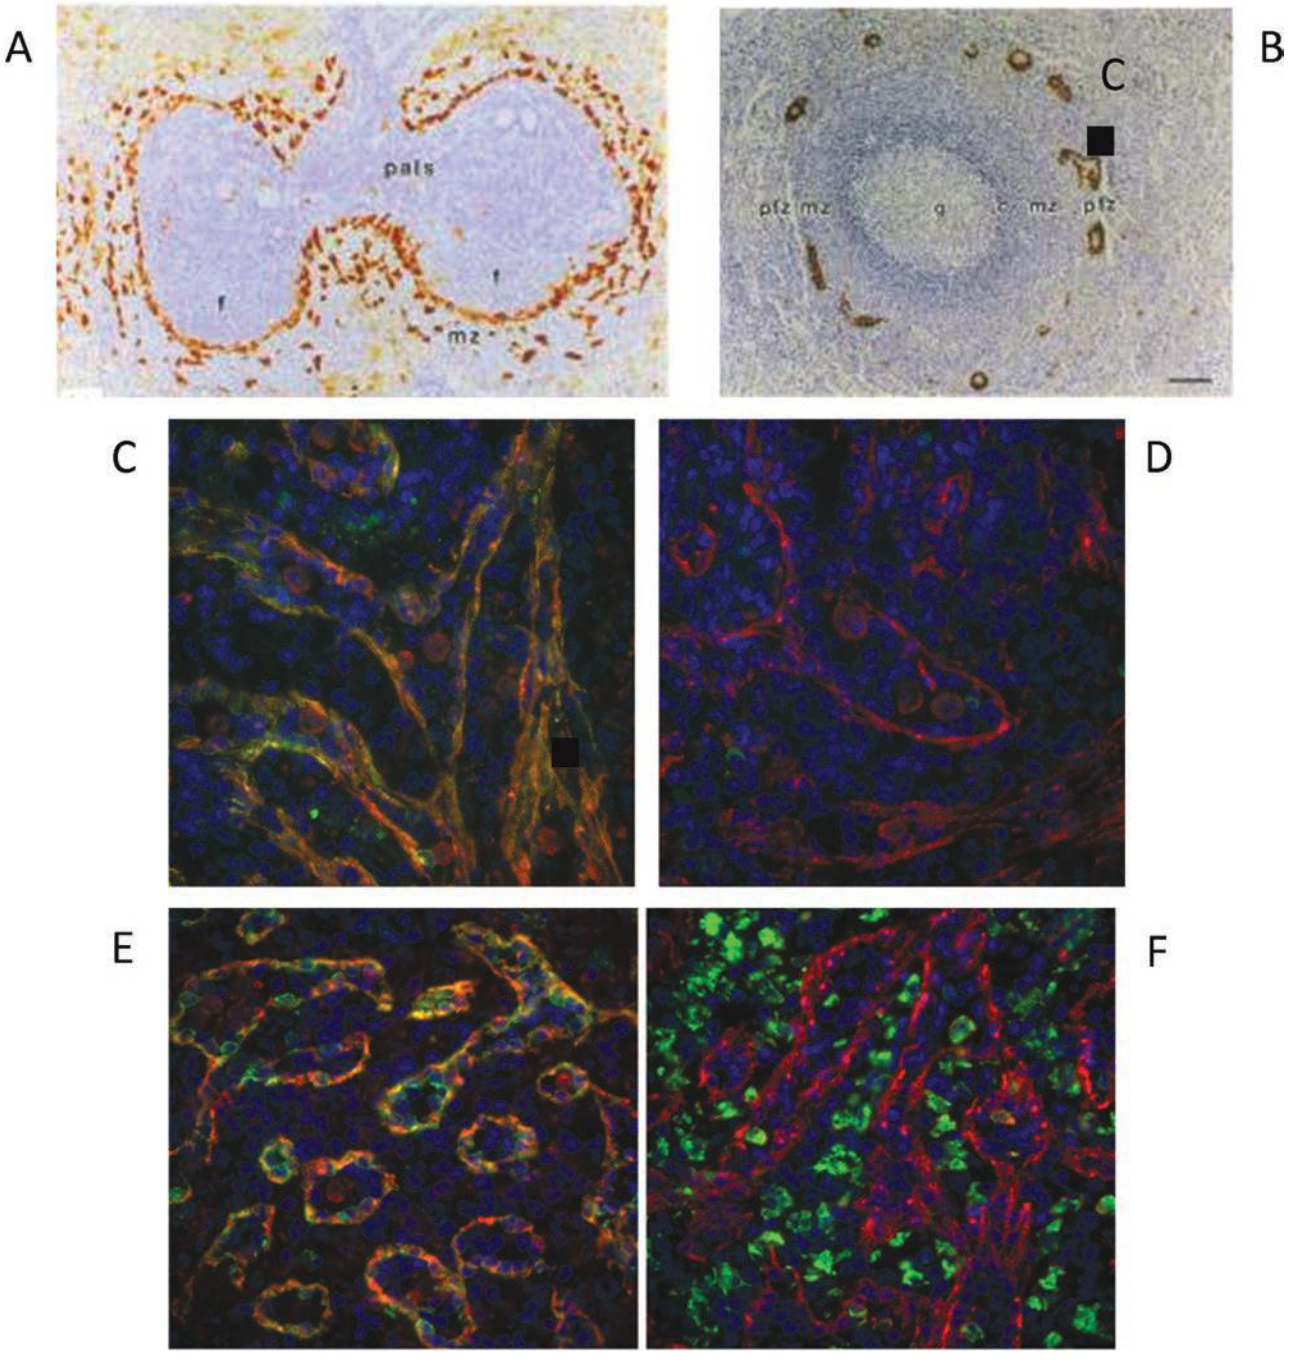

FIGURE 10.20. Species and antigen expression differences of splenic macrophages. A, B: Human and rat spleens differ markedly in marginal zone structure. **A:** Rat spleen demonstrates CD169 antigen on marginal metallophilic macrophages (monoclonal antibody ED3). **B:** $CD169^+$ macrophages form sheaths around capillaries in the perifollicular region of the human spleen. From Steiniger B, Barth P, Herbst B, Hartnell A, Crocker PR. The species-specific structure of microanatomical compartments in the human spleen: strongly sialoadhesin-positive macrophages occur in the perifollicular zone, but not in the marginal zone. Immunology 1997;92(2):307–316, with permission. **C–F:** Mannose receptor and cysteine-rich domain ligands in the human spleen do not co-localize with CD68+ macrophages. From Martinez-Pomares L, Hanitsch LG, Stillion R, Keshav S, Gordon S. Expression of mannose receptor and ligands for its cysteine-rich domain in venous sinuses of human spleen. Lab Invest Oct 2005;85(10):1238–1249, with permission. **C, D:** MR- and CR ligands co-localize in venous sinuses of splenic red pulp. Fluorescent labeling of CR ligands (in green) and MR (in red) in the presence or absence of SO4-4-GalNAc demonstrates that there is a perfect co-localization of the MR and ligands for the CR in venous sinuses. **E, F:** MR is present in Lyve-1+ cells lining venous sinuses in human spleen. MR-specific fluorescent labeling in human spleen (in red) does not co-localize with CD68-specific labeling (in green, [*right*]), but co-localizes with Lyve-1-specific labeling (in green, [*left*]).

and mast cells. Plasmacytoid DCs, NK cells, and B cells are not usually found in uninflamed tissue.

Tissue macrophages and DCs were originally recognized as histiocytes—literally "tissue cells." Early studies with intravital dyes and carbon particles, combined with light and electron microscopy, revealed the presence of phagocytic histiocytes in all tissues of the body, typically underlying the basement membranes of epithelia, even in the absence of inflammation.

The distinction between macrophages and DCs arrived much later. Quite accurately, as it has since emerged, macrophages were said to be "fixed" in the tissues and had little propensity to migrate to draining lymph nodes. Common evidence of this is seen

in the survival of tattoo pigment in resident human dermal macrophages with little evidence of diffusion over the course of many decades. Dermal macrophages also have a half-life of more than 1 year after hematopoietic stem cell transplantation, in contrast to DCs, which are replaced within weeks. This property can also be recapitulated in vitro by their inability to leave explanted tissue fragments, in contrast with DCs and resident T cells. Interstitial macrophages in the dermis are laden with melanin and are also known as melanophages. Macrophages are scattered throughout the interstitium, while DCs are found mainly in the perivascular sheaths and close to the basement membrane of epithelia.

Human tissue macrophages and DCs both express CD45 leukocyte antigen, HLA-DR, CD68, EMR2, and CD11b. The best markers for macrophages are FXIIIa, LYVE-1, and CD163; they also express CD14 and DC-SIGN at low level. The major population of tissue DCs are CD1c+ myeloid DCs analogous to the CD1c+ DCs found in human blood. These express higher amounts of HLA-DR and are specifically identified by CD11c and CD1c.[86] In addition, fascin and CD1a have been used but are less reliable markers. A previous erroneous assignment of FXIIIa as a DC marker has led to significant confusion in the field. FXIIIa positive "dermal dendrocytes" are elongated branching cells that are now known to be macrophages. They often expanded in chronic inflammatory conditions by the recruitment of monocyte-derived cells. In addition to resident interstitial macrophages and CD1c+ DCs, there exists a minor population of CD14+ cells that have previously been described as "interstitial DCs." These are mobile and migrate in vitro, but gene expression analysis links them to monocytes and macrophages rather than the DC lineage. In common with macrophages they express CD14, DC-SIGN, and FXIIIa. Plasmacytoid DCs are not found in resting tissues, and CD141+ myeloid DCs can be isolated by flow cytometry but are rare and difficult to observe in situ.[87] In the gut there is evidence for an additional CD103+ DC involved in tolerance in both mice and humans. Although research studies clearly delineate the difference between macrophages and DCs, routine diagnostic immunopathology does not differentiate between these cells.

Specialized Populations of Mononuclear Phagocytes[43]

Kupffer Cells

Kupffer cells are abundant sinus-lining macrophages of the liver, sharing clearance functions with endothelial cells. Macrophage cytokines such as IL-6 play an important role in induction of acute phase proteins, such as C reactive protein, serum amyloid protein (SAP), complement, and fibrinogen, in humans. The resident Kupffer cells become tolerant to LPS delivered by the portal system and may represent an entry site to pathogens; the host depends on newly recruited monocytes to mount an effective antimicrobial response.

Gastrointestinal Macrophages and Dendritic Cells[31,87,88]

The gut contains an abundant population of macrophages in the body. The lamina propria is rich in macrophages and DCs throughout the intestine; the microbial flora, especially in the colon, may be sampled, captured, and transported into lymph and the portal circulation. Macrophages and DCs take up and digest apoptotic epithelial cells, contributing to tolerance of food antigens. They also contribute to epithelial integrity and barrier functions, in part dependent on TLR-dependent responses to symbionts. The macrophage phenotype in the small intestine is downregulated by TGF-β and IL-10, interacting with a range of innate and adaptive T lymphocytes. Peyer's patches contain M cells, specialized for antigen uptake. In mice and humans, a specialized population of CD103+ gut DCs is thought to play a role in tolerance.

The peritoneal cavity of the mouse provides an accessible source of resident, inflammatory, and immunologically activated macrophages for experimentation; much of our knowledge of macrophage immunobiology derives from studies on peritoneal macrophages.

Alveolar Macrophages (See Fig. 10.3D)[89,90]

Alveolar macrophages from humans accumulate inhaled particles and pollutants and often contain poorly degradable cigarette residues. The cells express a range of phagocytic receptors, take up and metabolize surfactant molecules, and secrete abundant lysozyme, among other products. Alveolar macrophages often suppress inflammation and immune responses. Within the lung interstitium, a full complement of macrophages, myeloid DCs, and monocyte-derived cells are found similar to other interstitial tissue sites. These are anatomically and phenotypically distinct from alveolar macrophages.

Microglia[31,91,92]

In the mouse, microglia derive from yolk sac macrophages during development, removing apoptotic neurons as they enter the neutrophil; they adapt within days to their neuroparenchymal environment. Their arborized morphology varies in different regions of the brain. Their functions in the absence of inflammation or degeneration remain mysterious. Microglia differ in their phenotype from the perivascular, meningeal, and choroidal macrophages. The response of microglia to excitotoxin injury, amyloid deposits, inflammation, and infection includes striking changes in morphology, recruitment of blood monocytes, and local proliferation. The blood–brain barrier controls entry of other resting and activated white blood cells and of soluble molecules from the systemic circulation.

Langerhans Cells (See Figs. 10.4 and 10.13A)[86,92–97,98,99]

The Langerhans cell of human epidermis furnished a critical paradigm of MP biology. Originally described as a nerve cell by Paul Langerhans in 1868, a series of studies by Stingl and others in the 1970s confirmed its leukocyte origin and expression of MHC class II molecules. Subsequent studies developed a specific antigen marker, the C-type lectin Langerin, a component of Birbeck granules. The study of skin explants then revealed the striking property of this DC to round up and migrate out of the epidermis where it became a potent immunostimulatory cell akin to the "veiled cells" of afferent lymph. In this way it was conceived that resident myeloid-derived cells would function as sentinels of the immune system by capturing and transporting exogenous antigen to lymph nodes, where they would differentiate into antigen-presenting cells. This concept remains a cornerstone of DC biology. Paradoxically, the role of LCs in immunity remains a subject of debate. Mice lacking LCs have very few defects in immunity, although recent evidence points towards a role in maintaining TH17-directed resistance to *Candida*.

The dermis contains heterogeneous populations of macrophages and DCs and may represent an important source of APCs draining to regional lymph nodes.

Osteoclasts (See Fig. 10.21)[100,101,102,103]

Early studies by Loutit, for example, demonstrated that osteoclasts derived from circulating monocytes; many subsequent studies established that in vitro culture in CSF-1 and RANK

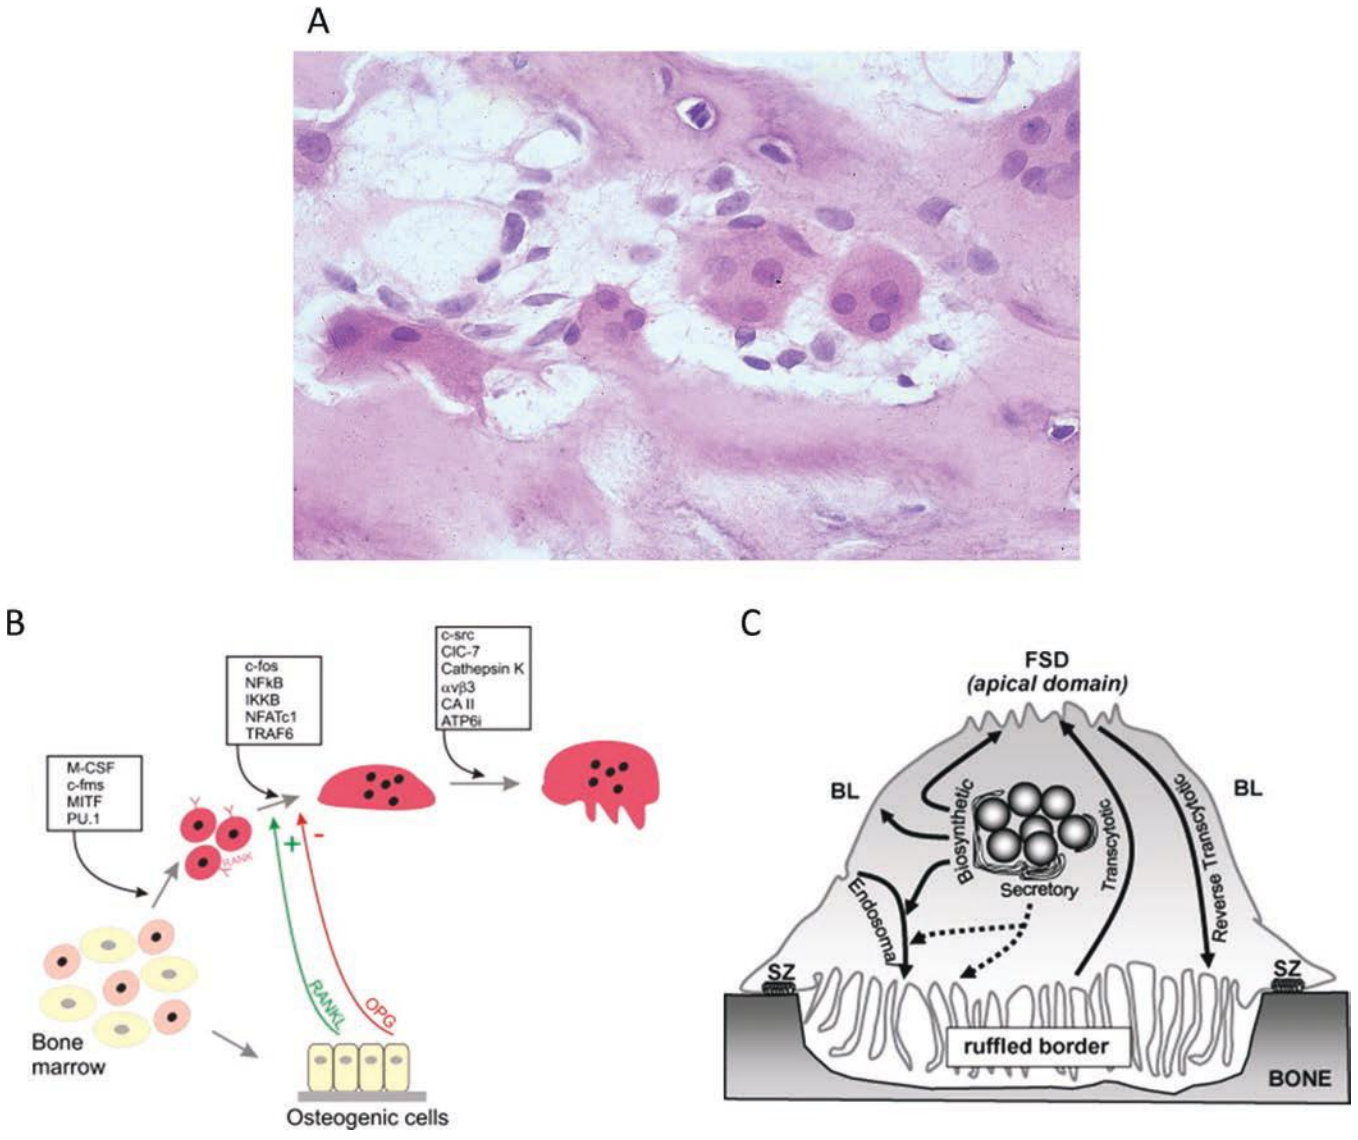

FIGURE 10.21. Morphology, differentiation, and function of osteoclasts. **A:** Light micrograph to illustrate appearance of osteoclasts in situ. **B:** Osteoclasts differentiate from myeloid stem cells via macrophage-colony-forming units (CFU-M). The exact point at which definitive commitment into osteoclasts along the differentiation pathway occurs is currently unknown. The mononuclear precursors fuse to form terminally differentiated multinuclear osteoclasts. From Vaananen HK, Laitala-Leinonen T. Osteoclast lineage and function. Arch Biochem Biophys 2008;473(2):132–138, with permission. **C:** Vesicular trafficking pathways in osteoclasts. The ruffled border is formed as a consequence of trafficking of vesicles in the endosomal pathway and therefore has characteristics of a late endosomal membrane. A distinct biosynthetic pathway may also contribute to the formation of the ruffled border. Degradation products from the resorption process are removed from the resorption lacuna by a transcytotic pathway and released at the FSD, which exhibits characteristics of an apical membrane. Recently, a reverse pathway from the FSD to the ruffled border has been identified. BL, basolateral domain; FSD, functional secretory domain; SZ, sealing zone. From Coxon FP, Taylor A. Vesicular trafficking in osteoclasts. Semin Cell Dev Biol 2008;19(5):424–433, with permission.

ligand could generate multinucleated osteoclasts able to resorb living bone. Fusion with mononuclear precursors occurs throughout life, and survival of osteoclasts is believed to be dependent upon continued replenishment by fusion. They share many properties with, but differ from, multinucleated macrophage giant cells present in granulomata, e.g., in tuberculosis and schistosomiasis.

One of the three principal cell types present in bone, osteoclasts are giant multinucleated cells arising from the monocyte-macrophage-DC common progenitor. (Bone also contains mononucleated macrophages which lack the special features of osteoclasts.) Osteoblasts, on the other hand, are of mesenchymal origin, having the function of bone formation; and osteocytes arise from mature osteoblasts that, having once deposited the bone matrix, remain trapped in it, becoming quiescent cells. Osteoclasts are unique bone-resorbing cells. In histological sections, they appear attached to the bone matrix, in small depressions caused by bone resorption, "Howslip's lacunae." They are derived from the fusion of mononuclear cells, resulting in polykarya containing 4 to 50 nuclei up to 100 micrometers in diameter which can resorb large areas of tissue using an extracellular lysosomal compartment. Proteolytic enzymes required to digest the organic components of the bone tissue are secreted from a specialized ruffled border segregated from the extracellular fluid by an adhesion area.

In 1981 Marks and Walker demonstrated the peripheral blood origin of osteoclasts in a parabiosis experiment connecting normal and osteopetrotic mice. Subsequent in vitro work

has shown that multinuclear osteoclasts can be derived from differentiation of CFU-M in culture. Osteoclasts in turn promote mobilization of hematopoietic progenitors from the bone marrow by degrading endosteal components. The antigenic phenotype of human fetal osteoclasts has been compared with that of human tissue macrophages and macrophage-derived giant cells. Osteoclasts express a subset of macrophage-associated antigens including CD13, CD15A, CD44, CD45, CD54 (ICAM-1), CD71 (transferrin receptor), and CD68. Antigens expressed on macrophages and macrophage polykaryons, but not on osteoclasts, include CD1 a,b,c, CD18, CD14, CD31, CD36, CD37, CD39, and CD43 antigens; and less strong expression of CD16 (FcRIII), CD25 (IL-2 receptor), CD32 (FcRII), CD35 (C3b receptor), and HLA-DR by macrophage giant cells. The presence of some macrophage-associated antigens on osteoclasts is consistent with their common origin; however, the differences in antigenic phenotype suggest that their pathways of development and differentiation are not identical.

Macrophage-colony stimulating factor (CSF-1) promotes the differentiation of a common CSF-1 receptor expressing progenitor into populations of monocytes, macrophages, DCs, and bone-resorbing osteoclasts. Mutations of the *Csf-1* locus in the osteopetrotic mouse (*op/op*) results in the loss of osteoclast differentiation. However, while mononuclear macrophages are generated in the presence of M-CSF alone, culture with M-CSF plus RANKL (receptor activator of nuclear factor kappa B ligand) is required for cell-cell fusion and generation of multinuclear osteoclasts using various adhesion molecules, such as E-cadherin. RANKL, also known as TNF ligand superfamily member 11, TNF-related activation-induced cytokine (TRANCE), osteoprotegerin ligand, and osteoclast differentiation factor, is a protein that in humans is encoded by the *TNFSF11* gene and found in both a membrane-bound form expressed on preosteoblastic/stromal cells and a soluble form. RANKL mRNA is most highly expressed in bone and bone marrow, but also found in lymphoid tissues including lymph node, thymus, spleen, fetal liver, and Peyer's patches; whereas RANK mRNA is highly expressed by bone marrow-derived osteoclast progenitors and by mature osteoclasts in vivo. OPG, osteoprotogerin, is a soluble, decoy receptor belonging to the TNF receptor superfamily which inhibits osteoclast differentiation and activity by binding to RANKL.

RANKL stimulation regulates osteoclastogenesis positively through NFATc1 and AP1TRAF6 (TNF receptor activated factor 6), which is recruited by binding of RANKL and activates MAP kinases and IκB, leading to the nuclear translocation of transcription factors such as c-fo, c-jun, ATF2 (activating transcription factor 2), and nuclear factor-kappaB (NF-kappaB), that drive the expression of osteoclast-specific genes. Deficiency of RANKL in mice results in the abrogation of bone resorption, which leads to lack of bone marrow and the absence of tooth eruption. In bone marrow macrophage cultures, RANKL treatment results in production and secretion of sphingosine 1 phosphate, a factor which has a dual role in triggering a negative loop in osteoclasts in response to RANKL, and stimulating migration and survival of osteoblasts.

The transcription factor PU.1 drives the expression of the *c-fms* gene, encoding the tyrosine kinase receptor of M-CSF as well as of the receptor RANK. PU.1 is essential for the initial commitment to osteoclast differentiation. PU.1-deficient mice are characterized by the absence of osteoclasts and macrophages, and PU.1 expression increases as marrow macrophages differentiate into osteoclasts. PU.1 also interacts with another transcription factor that distinguishes osteoclast and macrophage differentiation, Mitf-E (microphthalmia-associated transcription factor-E). This is a basic-loop-helix-leucine zipper which occurs in two forms, Mitf-A and Mitf-E. Mitf-A is expressed in macrophages and osteoclasts at similar levels, whereas Mitf-E increases during osteoclast differentiation by increasing transcription of ctsk and acp5, encoding cathepsin k and tartrate resistant acid phosphatase.

Cell fusion is controlled via the regulator DC-STAMP, which itself was originally isolated by a cDNA subtractive screen between osteoclasts and macrophages. In DC-STAMP–deficient mice the expression of osteoclast differentiation markers is normal; however, the multinucleation of osteoclasts is completely absent. Bcl6 has been demonstrated to bind directly to the *DC-STAMP* promoter, becoming dissociated upon RANKL stimulation. Lack of Bcl6 results in increased osteoclast differentiation and osteopenia.

Bone cell development does not occur in isolation. Many of the molecules involved in osteoclastogenesis are also immune system regulators and there is considerable bone-immune system interaction. RANKL has a function in the immune system, where it is expressed by T helper cells and is thought to be involved in DC maturation. It was shown to be a DC survival factor and is involved in the regulation of T cell-dependent immune response. A subset of T lymphocytes, named osteoclastogenic TH cells, which are able to induce osteoclast differentiation through IL-17, have also been identified. Other studies have demonstrated a positive relationship between bone density and fat mass, possibly through the adipokine leptin, which is produced by adipocytes increasing osteoblast proliferation and differentiation, inhibiting osteoclast differentiation.

Adipose Tissue

Figure 10.22 illustrates some of the transcription factors associated with macrophage specialization in different tissue environments such as adipose tissue, and in different functions, including infection.

The co-localization of macrophages and adipocytes has attracted interest in adipokine functions and metabolic regulation. Bone marrow–derived mesenchymal stem cells differentiate to the osteogenic and adipogenic lineages. As bone volume decreases with age, osteoporosis is accompanied by an increase in adipose tissue, implying a relationship between the adipogenic process and bone loss.

Genitourinary Tract

The mouse kidney contains interstitial macrophages associated with the tubular epithelium and the juxta-glomerular complex, perhaps part of erythropoietin and renin homeostasis. The glomerular tuft does not contain F4/80+ macrophages, which line Bowman's capsule. Mesangial cells are F4/80−, but express mannose receptors. The bladder has a population of macrophages which penetrate its transitional epithelium. The ovary and testis contain prominent macrophage populations which fluctuate with the reproductive cycle, e.g., during follicular atresia, and the removal of apoptotic sperm. The uterus contains specialized Hofbauer macrophages, and the placenta and umbilical cord provide specialized fetal progenitors and macrophage populations.

Endocrine Organs

F4/80+ macrophages are present in the anterior and posterior pituitary, thyroid, adrenal, and pancreas; they may play an unrecognized role in hormone homeostasis.

Cardiovascular Systems[104]

Healthy large blood vessels and the normal heart do contain interstitial macrophages, but the accumulation of lipid serves to

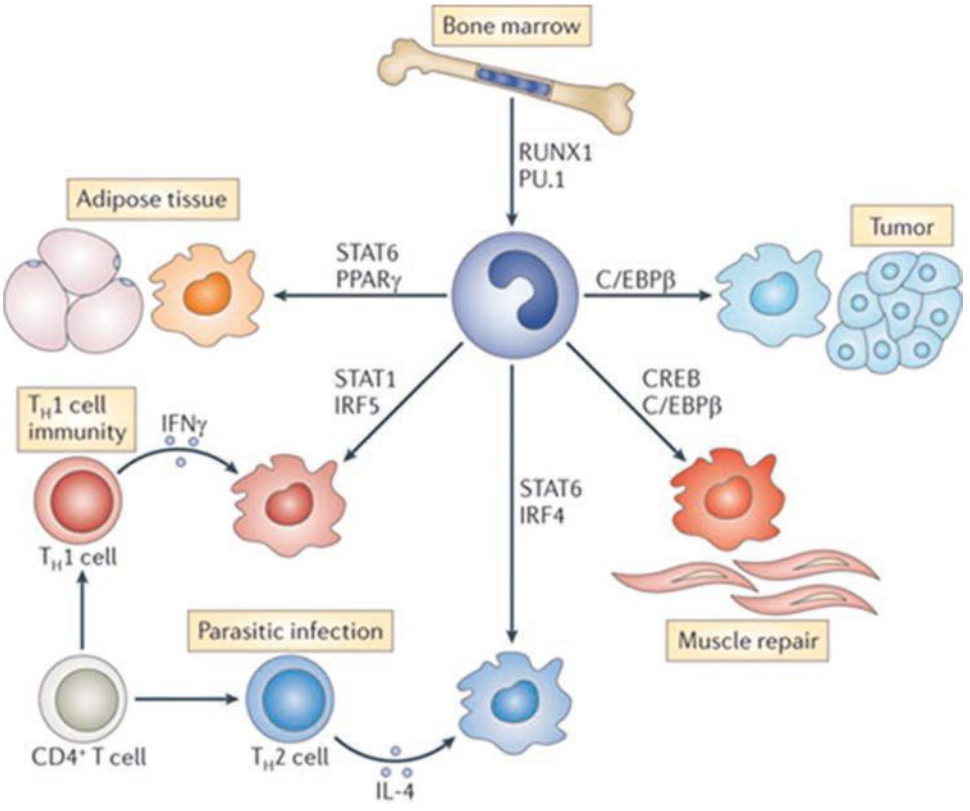

FIGURE 10.22. Transcription factors associated with different polarized populations of macrophages. recruit monocytes to the intima, atheromatous plaque formation, thrombosis, and vascular occlusion.

Muscle and Connective Tissue

Macrophages are present throughout these tissues. In muscle they play a part in the hematopoietic and metabolic response to exercise, as well as to tissue injury and repair (Fig. 10.22), catabolism, and wasting syndromes.

DEVELOPMENT AND RENEWAL

(See Fig. 10.1.)

Yolk Sac Macrophages[105,106]

The earliest hematopoietic cells are yolk sac macrophages. It has recently been demonstrated in mice by lineage tracing studies that these colonize the ectodermal and mesodermal tissues late in embryogenesis, prior to the onset of definitive hematopoiesis in the fetal liver. A striking finding is that 100% of microglia and 10% of Langerhans cells remain derived from this early wave of primitive macrophage invasion. Yolk sac does not appear to contribute to other macrophage populations in interstitial tissues; rather these and the bulk of Langerhans cells arise from a second wave of immigration by fetal liver monocytes. Once seeded in the tissues, it is likely that these cells are postmitotic and renewed by blood-borne precursors at an extremely slow rate.

Renewal of Steady-state Macrophages in the Adult[21,91,107–111]

Conventional wisdom suggests that tissue macrophages are replaced by circulating monocytes, although it appears that

MACROPHAGE DEVELOPMENT IN THE MOUSE[31]

Our knowledge of the origin, differentiation, and tissue distribution of macrophage lineage cell types depends on experimental studies in the mouse using genetic and immunological methods. The monoclonal antibody F4/80 was used to detect a sensitive and fixation-stable plasma membrane antigen present in many mature macrophages. This made it possible to identify F4/80- progenitors by their ability to give rise to F4/80+ progeny by day 4. The first F4/80+ macrophages in the mouse embryo were detected in the yolk sac at day 8 to 9, together with nucleated erythroid cells. Fetal liver showed increasing numbers of F4/80+ monocytes and stellate macrophages in clusters with erythroblasts undergoing definitive erythropoiesis; the clusters reached a peak at day 12 to 14, declining by day 15 as hematopoiesis moved to the spleen and then the bone marrow by day 17/18 before birth. By a week after birth, the stellate macrophages appeared to remain as isolated early Kupffer cells, no longer in clusters with erythroid cells and no longer containing the remnants of phagocytosed erythroid nuclei. Maturation after birth included the appearance of CD169+ metallophilic macrophages in the developing marginal zone of the spleen between 2 and 4 weeks. This antigen, also known as sialoadhesin or siglec-1, closely related to, if not identical with, MOMA-1, recognizes sialylated ligands on erythroid and myeloid cells.

Further studies documented expression of F4/80 in a wide range of tissues in adult mice, normally and in a range of disease models. Subsequent studies with F4/80 knockout mice identified a role for the antigen in peripheral tolerance in the anterior chamber of the eye. The human counterpart, EMR1, has not been suitable for immunocytochemical detection of macrophages or DCs, but the EMR2 antigen, expressed by monocytes, macrophages, DCs, and neutrophils, provides a promising alternative.

this dogma arose through extrapolation of models of inflammatory monocyte recruitment. Several attempts have been made to dissect which monocyte subset is more likely to give rise to tissue macrophages, but the rate of renewal is sufficiently slow that adoptive transfer and parabiosis experiments (experimental joining of the circulation of two animals) produce only very subtle signals in the tissues. These findings are in keeping with the very slow renewal of tissue macrophages following hematopoietic stem cell transplantation in humans. A small pool of monocytes may be mobile enough to traffic in and out of tissues as evidenced by the minor population of CD14+ cells present in human interstitial sites, but these appear to equilibrate only very slowly with tissue macrophages, if indeed they serve any precursor function at all. Lineage tracing experiments now indicate that tissue macrophages may arise through intermediates that do not express lysozyme, thus excluding the majority of monocytes. These findings resonate with the observation in humans that tissue macrophages are retained for many years after the generation of blood monocytes has failed because of genetic disorders of hematopoiesis. Current efforts to understand this paradox are focusing on circulating hematopoietic progenitors that occupy most tissue sites and potentially contribute directly to tissue macrophage homeostasis.

Local Proliferation[73,107,108,111]

One general distinction between monocytes and macrophages and cells of the DC lineage in the steady state is that monocytes and macrophages are generally nondividing cells, while blood and tissue DCs include small proportions of cells in S/M/G2 by DNA content analysis and Ki-67 staining. In mice, and probably also in humans, Langerhans cells and microglia undergo sufficient proliferation to maintain numbers independently of blood-borne precursors in the steady state. Following hematopoietic stem cell transplantation, this is sufficient to enable recipient LCs to survive independently of the donor bone marrow. However, observations in humans suggest that LCs are more labile and become donor-derived by 3 months. A postmortem study of human microglia suggested that recipient microglia persist several years after hematopoietic transplantation.

It should be noted that the observation of cycling cells is not sufficient to conclude that a population is self-renewing, however; and DC populations, although completing a small number of cell divisions in situ, appear to be rapidly replenished by bone marrow–derived precursors in human transplantation, parabiosis, and adoptive transfer models. Historical studies in which the appearance of pulsed tritiated thymidine was presented as evidence of relatively rapid renewal of tissue macrophages from the bone marrow should be interpreted with caution in the light of local proliferation, more precise definitions of phenotypes, and experimental systems with fewer variables.

Monocyte and Dendritic Cell Hematopoiesis[112,113,114,115]

In contrast with macrophage populations which appear largely static, monocytes and DCs are continually produced by the bone marrow. Inflammatory monocytes have an estimated half-life of several days; nonclassical monocytes and DCs are likely to live a little longer, although this has not been accurately measured in humans. According to conventional models, monocytes arise from hematopoietic stem cells via common myeloid and granulocyte-macrophage progenitors. In the mouse, further stages of differentiation have been mapped by clonogenic assays and adoptive transfer. GMP are said to lose granulocyte potential, giving rise to monocytes and DCs via a macrophage-dendritic progenitor (MDP). The MDP has the potential to give rise to monocytes and to a common DC progenitor (CDP). Plasmacytoid DCs arise directly from CDPs, while a committed "pre-DC" forms the classical and cross-presenting myeloid DCs. No such intermediates have been found in humans. It has been shown that GMPs can form macrophages and DCs but many studies have also found that committed lymphoid progenitors retain monocyte and DC potential. Indeed, state of the art transcriptomic mapping of human hematopoiesis, while confirming the proximity of monocytes to granulocytes, places the DC lineage adrift between myeloid and lymphoid signatures. A full discussion of the hematopoietic hierarchy is beyond the scope of this chapter, but these studies raise questions about the classical split between myeloid and lymphoid hematopoiesis, somewhat confounding the myeloid-biased model of murine DC differentiation. One significant problem in understanding the differences between human monocyte and DC hematopoiesis is that the factors that control steady state DC differentiation are poorly understood, and many assays claiming to show in vitro differentiation of DCs may simply be examining inflammatory monocyte-derived DCs. At the time of writing, it has been possible to generate cells resembling 14+ monocytes, pDCs, and CD141+ DCs in vitro, but not CD16+ monocytes or CD1c+ myeloid DCs.

Regulation by Soluble Factors[46,92,116]

A number of soluble mediators play a part in monocyte and DC differentiation, although many have been verified only in mouse models or human in vitro studies. Standard colony forming assays in which erythroid, granulocyte, and macrophage colonies may be detected by morphology contain SCF, IL-3, GM-CSF, G-CSF, and Epo. M-CSF, FLT-3L, and TPO have all been added to enhance the production of monocytes or DCs, but their effects are pleiotropic and have not been resolved in detail. M-CSF, FLT-3L, and TPO are all steady state cytokines present in normal plasma and widely produced by stromal tissues. Receptors for M-CSF (CD115) and FLT-3L (CD135) are present on monocytes and circulating DCs and may play a role in enhancing both the generation and functional capacity of mature cells. In mice, osteoclast generation, Langerhans cell differentiation, and the formation of microglia are all dependent upon signaling through the M-CSF receptor, while DC generation is critically dependent upon FLT-3. Recently, IL-34, an alternate ligand for CD115, has emerged as a critical cytokine in the differentiation of microglia and LC. All monocytes and DCs express receptors for GM-CSF (CD116). Quantities of this cytokine are much more limited in the steady state, and although lymphoid DCs develop normally in GM-CSF deficient mice, recent experiments show that nonlymphoid tissue DCs are depleted. Production by epithelial surfaces appears to be important, since antibodies to GM-CSF in humans cause dysfunction of alveolar macrophages, leading to pulmonary alveolar proteinosis (PAP). There is considerable interest in the use of growth factors to augment production or activity of monocytes and DCs, particularly in the field of vaccination and cancer therapy. Clinical trials of GM-CSF and FLT-3L have been performed. One of the difficulties in the interpretation of results is that the expansion of immature precursors may have immunosuppressive effects by inducing populations with properties similar to those attributed to myeloid suppressor cells. GM-CSF as a local adjuvant may have more promise; and the only FDA-licensed DC therapy "Provenge" uses a GM-CSF conjugated immunogen.

Regulation by Transcription Factors[4,71,117,118,119]

Recent work in mice and also humans has defined the transcription factors associated with macrophage, monocyte, and DC differentiation. Macrophage development requires PU.1 and Myb and is interrupted by defects of Ikaros and GFI1. DCs are dependent upon PU.1, IRF2, IRF4, and IRF8, and a recently described zDC. Ikaros and GFI1 deletion probably also affect DC development. Many of these transcription factors control the development

of monocytes, but this is not always reported. Specific factors are required for the development of pDC (E2-2) and CD8+ cross-presenting DCs (Batf3, Id2). Analysis of genetic defects in human DC deficiency was recently reported. Ikaros and IRF8 mutations prevent the formation of monocytes and DCs. GATA-2 mutation interrupts mononuclear cell development, leading to a late-onset loss of DCs.

Trafficking of Blood-borne Precursors to Quiescent Tissues[62,87]

It has recently been recognized that nonlymphoid tissues contain myeloid DC populations and CD14+ monocyte-like cells similar to those found in peripheral blood. The tissue counterparts of CD1c+ DCs, CD141+ DCs, and classical CD14+ monocytes appear more mature than their blood relatives, implying that each blood subset gives rise to a corresponding tissue cell. In the mouse a few selected DC populations are monocyte-derived in the steady state, notably the CD11b+ CX3CR1+ resident mononuclear cell of mouse lamina propria, which is derived from a classical monocyte. The role of patrolling nonclassical monocytes in steady state tissue homeostasis remains unclear. Although these cells are anatomically apposed to the endothelium and more mature in phenotype than classical monocytes, they do not appear to contribute quantitatively to homeostasis in the tissues.

Inflammatory Recruitment[67,74,104]

Both classical and nonclassical monocytes are recruited during inflammation. In mouse in vivo models, nonclassical cells are recruited more quickly, but classical monocytes are quantitatively more important. Classical monocytes can differentiate into inflammatory TiP DC/M1 macrophages in the tissues and replace microglia and Langerhans cells after an inflammatory insult. A great variety of infection models in mice have confirmed the role of CCR2 and classical monocytes in the response to and resolution of infection. These include mycobacteria, *Listeria*, *Toxoplasma*, *Cryptococcus*, *Aspergillus*, and influenza. Classical monocytes are clearly implicated in the sterile inflammation of atherosclerosis and in the response of humans to myocardial infarction. Granulomata provide an intriguing opportunity to examine this by intravital microscopy, as shown by Germain and colleagues. Earlier studies showed that mycobacterial granulomata depend on TNF-α and the type 3 complement receptor, CD11b/CD18. The presence of multinucleated giant cells, products of macrophage fusion, in tuberculous (Langhans giant cells) and schistosome egg granulomata has long attracted attention of pathologists. Their formation by IL-4, for example, depends on surface glycoproteins such as CD36 and DAP12, and of lipids of microbial and host origin. Notably, granulomata are produced by persistent, poorly degraded pathogens and foreign bodies, rather than viruses, which can also induce syncytia. It would be useful to compare epithelioid and giant cell phenotypes in different organs such as the liver (BCG), lung (schistosome eggs), and intestine (Crohn's disease), as well as by the same causal agent in different tissues, e.g., tuberculosis.

In the mouse, local macrophage proliferation has been reported during infection with helminths stimulating Th2-type responses. It remains to be determined how significant this is quantitatively and whether these mechanisms occur in humans under similar conditions.

Monocyte-derived Macrophages and Dendritic Cells[46]

A great deal of human research has focused on the generation of DC and macrophage-like cells from peripheral blood monocytes. The major drawback of these models is that they recreate inflammatory conditions and probably bear little or no relationship to the origin and differentiation of steady state macrophages and DCs, which are really distinct cells with very different provenances. However, the true value of studying monocyte-derived cells is now being put into context by many emerging in vivo studies of inflammatory monocyte-derived macrophages and DCs which play important roles in immunity.

A vast array of different antigen-presenting cells may be derived from monocytes in vitro, and it is clear that macrophages form in the presence of M-CSF, IL-10, and serum, while a potent DC can be derived using IFNα or GM-CSF. The addition of TFG-β causes monocyte-derived DCs to express langerin and resemble a Langerhans cell. It is likely that in vitro phenotypes bear some relationship to cells present in different inflammatory contexts, although experimental data to support this are hard to find.

MONONUCLEAR PHAGOCYTES IN MEDICINE

Transplantation[120]

Allogeneic organ and stem cell transplantation is an important modality of clinical therapy that generates a unique immunological problem because of differences between donor and recipient major or minor histocompatibility antigens. Allograft rejection and graft-versus-host disease are mediated by T cells primed to recognize histocompatibility antigens. DCs are likely to play an important role in the initiation of alloreactive T cell responses. Tissue macrophages may also exacerbate or modulate this process, and recruited inflammatory monocytes contribute to effector responses and immunopathology.

Allograft Rejection

Solid organs including the heart, kidney, and liver contain tissue macrophages and DCs that contribute to the sensitization of recipient T cells and the activation of rejection mechanisms. Broadly speaking, the density of antigen-presenting cells within a tissue correlates with the strength of rejection reactions and is in the order skin > lung/gut > liver > heart/kidney. Conditioning a transplanted organ to deplete donor DCs results in enhanced allograft survival, and methods to optimize this may present therapeutic opportunities. More recent allograft experiments using inducible depletion of DCs or antibodies have confirmed this finding.

Graft-versus-Host Disease

Conversely to solid organs in which donor DCs and macrophages may trigger rejection, the dominant immune response in hematopoietic stem cell transplantation is between donor T cells and recipient antigen-presenting cells. The role of recipient BM-derived cells was first demonstrated by the blood-lymph filtering experiments of Sprent and colleagues. Attenuation of recipient antigen-presenting capacity has since been shown to ameliorate GVHD, suggesting that recipient DCs are essential for the initiation of GVHD, at least in models dependent upon alloreactive CD8+ T cells recognizing directly presented minor histocompatibility antigen. Many studies have confirmed this finding and shown that donor DCs serve mainly to augment continuing GVHD responses. Support for potential therapeutic targeting of DCs was provided by a demonstration that anti-CD83 antibodies could delay GVHD in a xeno-transplant model. However, more recent experiments have shown that complete ablation of recipient DCs in inducible depletion models fails to prevent GVHD. Another interesting manipulation was the expansion of recipient

monocytes by M-CSF injection, resulting in less GVHD. Expansion of myeloid suppressor cells or tolerogenic DCs has been mooted as the explanation.

In human bone marrow transplantation, it was noted that alemtuzumab (anti-CD52) might attenuate GVHD not only by depleting donor T cells, but also by removing recipient APC including monocytes and blood DCs but not their tissue counterparts or Langerhans cells. Several studies have shown those recipient DCs are rapidly lost after transplantation. Recipient Langerhans cells survive for a month or so but are eventually replaced even in the absence of GVHD and are unlikely to constitute a reservoir of persistent recipient histocompatibility antigen. Interstitial tissue macrophages are the most long-lived antigen-presenting cells in humans and may promote chronic GVHD responses. In haplo-identical transplantation, ablation of recipient DCs by donor NKs has been suggested to play a role in the relatively low risk of GVHD experienced by these patients. Depletion or modulation of cutaneous DCs by UV light has also been suggested as a useful form of localized prophylactic therapy for GVHD. The mechanisms underlying chronic GVHD are more obscure. From a simple perspective, the delayed onset of chronic GVHD suggests a greater dependence on donor-derived APC and indirect rather than direct routes of antigen presentation. The difference between acute and chronic GVHD might be explained by a transition from CD8-mediated pathology to a CD4-dominated response to tissue-specific antigens.

Efferent Pathway

Recruitment of inflammatory monocytes also plays a role in the effector phase of organ rejection and GVHD. Injection of iron nanoparticles has been used as a means to demonstrate infiltration of rejecting organs by inflammatory monocytes. A high density of macrophages in GHVD biopsies has also been shown to correlate with poor outcome. Selective ablation of monocytes by inducible genetic systems or administration of M-CSFR antibodies attenuates both processes and offers the potential of a new means of controlling allograft rejection in humans. Further work is required to dissect the pathways of differentiation and the precise roles of recruited monocytes infiltrating during organ rejection or GVHD.

Macrophages and Dendritic Cells in Hematopoietic Disorders

Disorders of Production: Monocyte and Dendritic Cell Deficiency[107,109,117]

While specific defects of lymphocyte development, granulocyte differentiation, and function are well known, primary disorders involving loss of monocytes, DCs, and macrophages have been described only relatively recently. GATA-2 mutation causes a syndrome known as DC, monocyte, B, and NK lymphocyte (DCML) deficiency. This is characterized by a failure of mononuclear cell development, resulting in immunodeficiency to intracellular pathogens, viruses, and tumors, and evolves to myelodysplasia and leukemia. It has also been described as "monoMAC" to reflect the link between monocytopenia and *Mycobacterium avium* infection. IRF8 mutation, CXCR4 mutation, E2-2 mutation, and several other genes have also been shown to lead to deficiency of DCs and monocytes. Although these affect very small numbers of patients, they provide fascinating insights into the genetic regulation of DC and monocyte development.

Histiocytoses[121,122]

The histiocytoses are a group of disorders characterized by the accumulation of abnormal DCs or macrophages. A recent Histiocyte Society classification attempts to correlate each disorder with the transformation of a normal physiological counterpart: Langerhans cell, DC, or macrophage.

Langerhans cell histiocytosis (LCH) is the most prevalent and best characterized. LCH cells are CD1a+, Langerin+, and S100+. Their characterization as abnormal LCs was initially suggested by the demonstration of Birbeck granules under EM. Although LCH is "epidermotropic" in the skin, it occurs in many other organs where LCs are not normally found and therefore represents a significant dysregulation of LC homeostasis. In the steady state, epidermal LCs are self-renewing, but LCH cells probably derive from classical monocytes, along a pathway described for inflammatory generation of LCs. Gene expression profiling confirms that LCH cells are much more immature compared with epidermal LCs, and recent genetic analysis has strikingly revealed that approximately two-thirds of cases harbor mutated BRAF (V600E).

The other histiocytoses, Erdheim Chester disease (ECD), juvenile xanthogranuloma (JXG), and Rosai-Dorfman disease/sinus histiocytosis with massive lymphadenopathy (RDD/SHML), are much rarer. These are classically described as more macrophage-like and express CD68 and CD14; JXG is also typically Factor XIIIA+. Although at the cellular level LCH appears quite distinct from any of these macrophage-like disorders, a firm link between LCH and ECD has recently been established by the finding that two-thirds of ECD cases also have mutated BRAF. This unexpected observation suggests that LCH and ECD are two facets of the same pathology, as had been suggested by the occasional finding of both in the same patient. However, neither the precursor cell nor the mechanisms that control its differentiation are established. In the same publication it was demonstrated that JXG and RDD do not share mutated BRAF and should perhaps be considered distinct.

Another distinct entity is hemophagocytic lymphohistiocytosis (HLH, or "hemophagocytic syndrome"). This extreme inflammatory disorder shows a spectrum of activity, from a familial neonatal presentation to an apparently sporadic secondary disorder occurring in adulthood. Nearly all cases of HLH are now thought to derive from a defect in NK- or CD8-mediated cytotoxicity. In the familial cases, very clear defects in cytotoxicity mechanisms have been found, including mutations in perforin. Sporadic, late occurrences are often perceived as "secondary" to uncontrolled viral infection with EBV, but are likely to represent a manifestation of more subtle, possibly polygenic, variations in cytolytic mechanisms. In all cases, the inability to control viral replication leads to uncontrolled immune activation with a cytokine storm, massive elevation of ferritin and sCD25, and widespread macrophage activation, leading to phagocytic destruction of the hematopoietic tissue.

Disorders of Destruction

In spite of its importance, the recognition and destruction mechanisms of normal senescent erythrocytes remain unclear, with complement, lectins, and possibly antibody-dependent Fc receptors all implicated. Apoptotic cell recognition and clearance have been described above.

Splenic macrophages play a prominent role in immune destructive processes, including immune thrombocytopenic purpura (ITP) and autoimmune hemolytic anaemia (AIHA), using Fc receptor and complement-mediated uptake of opsonized platelets and red cells. In other autoimmune disorders, phagocytosis of apoptotic cells and antigen presentation by DCs and macrophages may be critical in initiating T cell–mediated cytotoxicity. M2 macrophages are particularly efficient at scavenging self-tissues following injury through receptors like the MR and scavenger receptor A, and may contribute to autoimmune disease.

Lysosomal Storage Diseases[123,124]

Lysosomal storage disorders (LSDs) are a heterogeneous group of diseases arising from genetic deficiency of a catabolic lysosomal enzyme. Disorders are classified according to the accumulated substrate and consequent phenotype. Sphingolipid accumulation in macrophages involved in the digestion of effete hematological cells occurs in patients with Gaucher disease (β-glucocerebrosidase deficiency), the most common LSD. The accumulation of glucosylceramide and its deacetylated form glucosylsphingosine leads to intracellular lipid accumulation and the formation of foamy macrophages known as Gaucher cells. Patients with genotypes conferring very low residual glucocerebrosidase activity confer neuronopathic disease, in which microglia are also affected.

Gaucher cells accumulate in sheets and have voluminous cytoplasm. Boven et al. demonstrated that Gaucher cells expressed common macrophage markers including CD68, CD14, and HLA-class II, and have a phenotype of M2 macrophages (CD163, IL-1RA, and CCL-18). Other lysosomal storage disorders exhibiting foamy macrophages are Fabry disease, GM1 gangliosidosis, and Wolman/cholesterol ester storage disorder. In Niemann-Pick A and B the macrophages have a distinctly blue appearance and are described as sea blue histiocytes. Macrophages with identical appearances to Gaucher cells by light microscopy (pseudo-Gaucher cells) have been demonstrated in the bone marrow trephines of patients with other disorders with high cellular turnover, including multiple myeloma, Hodgkin lymphoma, NHL, chronic myeloid leukemia (CML), myelodysplastic and common B-ALL, and nonmalignant hematological conditions, including thalassemia and sickle cell disease.

Hemochromatosis, Macrophages, and Iron[57,125,126,127]

Bone marrow and "reticuloendothelial" macrophages in the liver and spleen are responsible for the majority of iron storage outside the red cell mass or "erythron." Iron is acquired by uptake of transferrin through receptor-mediated endocytosis of the transferrin receptor (CD71). Iron-laden macrophages can be easily observed in conditions of iron overload such as genetic hemochromatosis and multiple transfusions. These appear brown with "hemosiderin" in unstained sections and blue with Perl's stain, a specific preparation for visualizing iron. In health, most iron is stored as intracellular ferritin, but this may be released into the circulation during acute phase responses. The highest ferritin levels (>10,000) are seen in HLH, where there is widespread extreme macrophage activation.

Osteoclast Disorders[128–130]

Disorders of osteoclast function or number illustrate their pivotal role in bone mineralization. Compromise of osteoclast function results in osteoporosis, whereas in the Paget disease–like disorders, osteoclast overactivity results in abnormal bone remodeling brought about by waves of bone resorption and reformation. A number of genes relevant to the various clinical patterns of osteopetrosis have been identified. Loss-of-function mutations explain about 70% of cases. Mutant *TCIRG1, CLCN7, OSTM1,* and *PLEKHM1*, which are involved in the trafficking of acidic vesicles in osteoclasts, are found in autosomal recessive osteopetrosis. Mutations in the *OSTM1* gene results in a severe form of autosomal recessive osteopetrosis, whereas an intermediate form is caused by a mutation in *PLEKHM1*. Gain-of-function mutation in *LRP5* results in autosomal dominant osteopetrosis type I; autosomal dominant osteopetrosis type II is caused by loss-of-function mutations in *CLCN7*. The etiology of failure of osteoclast formation in vivo (osteoclast-poor osteopetrosis), is unknown, but may be related to mutations in the osteoclast growth factors M-CSF and RANKL, or their receptors.

Paget's disease occurs in a number of forms and severities. Juvenile Paget's disease is caused by loss-of-function mutations in the gene for OPG (*TNFRSF11B),* resulting in undetectable OPG and elevation of RANKL. It can be treated by reconstituting OPG. Classic Paget's disease of bone (PDB) is associated with mutations in *SQSTM1* (p62). p62 functions as a scaffold protein with multiple domains to integrate kinase-activated and ubiquitin-mediated signaling pathways with the IL receptor and TNF receptor family members, especially RANK. The severe Paget-like disorders, early-onset PDB, familial expansile osteolysis, and expansile skeletal hyperphosphatasia, are all associated with mutations in the signal peptide region of the RANK gene, *TNFRSF11A*. The clinical symptoms in these diseases are similar, and all include early tooth loss and deafness; however, there is significant interindividual variation, suggesting environmental and epigenetic involvement.

Infection[26,36]

Monocytes, macrophages, and DCs play an important role in all infectious processes as part of the recognition of pathogens, hematopoietic, and immunological responses; mobilization and delivery of mononuclear and myeloid cells to local sites of infection; destruction or otherwise of invading microbes; and the orchestration of systemic reactions of the host, such as fever, and cardiovascular and metabolic responses. We have learned much from the study of model systems in transgenic mice, detailed observation of the natural history of infectious disease in humans, and the experiments of nature, the inborn errors of metabolism and their resistance or susceptibility to infection. In turn, the great variety of microbiome commensal and pathogenic organisms and their invasion and evasion strategies have taught us a great deal about the cellular and molecular properties of these myeloid cells and their interactions with other elements of the hematopoietic system. Here we can only illustrate this rich field by bringing out a few principles and raising questions relevant to hematology.

MPs play a role in the initiation and subsequent reactions to acute as well as chronic infection by bacteria, viruses, fungi, protozoa, and multicellular parasites. Apart from their well-established role in intracellular pathogen entry, killing, and persistence, e.g., tuberculosis, they contribute to the host's innate and adaptive immune response to extracellular bacteria, e.g., streptococci, and to facultative intracellular organisms such as *Listeria* and *Neisseria meningitidis*. Microbes exploit MP receptors' usage, and cytokine dysregulation is a common feature of infection. Macrophages play a devastating role in the inflammatory storm of acute sepsis, as well as the lethal complications of antiretroviral treatment after mixed infection by HIV-1 and tuberculosis, the immune reconstitution inflammatory syndrome. MPs express plasma membrane and cytosolic inhibitors as well as amplifiers, to regulate inflammation and tissue injury: for example, the TREM family of myeloid enhancers of proinflammatory responses, and the CD200/CD200R pair, a downregulator of TLR, NLR, and inflammasome activation. Focal macrophage-rich destructive inflammatory lesions are characteristic of granulomata, by known or unidentified microbes, e.g., Crohn's disease. Malaria results in diffuse intravascular pathology and hematological dyscrasia, as monocytes and sinus-lining macrophages ingest parasitized erythrocytes, and accumulate pigment residues. Polarization of macrophages by TH1 and TH2 cytokines has been outlined above. Depending on the outcome of host-pathogen interaction, macrophages contribute to latency and immunosuppression.

Granulomatous Disorders

These include a range of infectious and autoimmune conditions of genetic origin, such as CGD (NADPH oxidase), Blau syndrome (NOD), or the combination of genetic predisposition and poorly

characterized environmental factors (Crohn's disease). Here we restrict our discussion to granuloma annulare and sarcoidosis.

Granuloma Annulare

This is a relatively common benign inflammatory condition of the dermis and subcutaneous tissue of unknown etiology. Histological analysis of dermal papules and annular plaques reveals foci of palisaded granulomatous inflammation around "necrobiotic" collagen. Fifty percent of patients have IgM and C3 in vessels. It may be associated with diabetes, HIV, EBV, or lymphoma.

Sarcoidosis

Sarcoidosis is an idiopathic granulomatous disease in which collections of chronic inflammatory cells form nodules in multiple organs, most commonly lungs or lymph nodes. Sarcoidosis may be asymptomatic or chronic or may progress to life-threatening organ fibrosis. The pathogenesis involves exposure to an undescribed antigen in a host with genetic susceptibility, resulting in nonnecrotizing granulomatous inflammation. There is a prominent Th1 cell–mediated immune response characterized by IFNγ and TNF-α with increased macrophage and CD4 helper T cell activation, but suppression of responses to other antigenic challenges. Patients with sarcoidosis exhibit increased risk for malignancy, including lung cancer and lymphoma.

Tumor-associated Macrophages[68,131,132,133]

Interactions with trophic and immunosuppressive host cells promote the emergence and perhaps metastasis of neoplastic disease. Some cancers attract macrophages through CSF-1, and stimulate their local growth and angiogenic properties, in part through alternative activation of macrophage. IL-6 plays a direct role in the establishment of myelomas; macrophage-derived growth factors may also contribute to asbestos-induced mesothelioma. In addition, tumors evoke the recruitment of myeloid-derived suppressor cells and immature granulocytes and monocytes, which downregulate antitumor T cell responses.

Macrophages have been found to be more abundant in the bone marrow of patients with multiple myeloma, a malignant proliferation of plasma cells, than in healthy controls. Macrophage contact upregulates antiapoptotic proteins, and prevents chemotherapy-induced death in plasma cells. Higher numbers of infiltrating tumor-associated macrophages (TAMs) are associated with tumor invasion, lymph node metastasis, and advanced disease in colorectal cancer. Poor prognosis is conferred by the presence of large numbers of TAMs in other cancers such as sinonasal melanoma, and predicts an inferior outcome to hormonal therapy in prostate cancer.

Metabolic Disease

Atherosclerosis is now well recognized as a modified form of inflammation in which monocytes and macrophages are major drivers of plaque formation and thrombosis. As circulating cells they interact with platelets and adhere to endothelium or exposed vessel wall constituents. They take up and accumulate lipids through their scavenger receptors, become foam cells, and either remain in the intima, or migrate to the media to interact with smooth muscle. A characteristic feature is death in situ, although cells can also emigrate from the vessel wall, as shown in experimental models. Metalloproteinases are involved in vulnerable plaque rupture, and pro- and anticoagulant balance contributes to local thrombosis and embolism. Of course, monocytes are part of the host response to infarcts, leading to repair and fibrosis; depletion of monocyte recruitment via anti-MCP-1 antibody has been achieved experimentally.

Recent attention to the role of macrophages in obesity has grown; they associate with adipocytes, and cytokines from both cell types have been implicated in cell activation and lipolysis. The role of macrophages in diabetes has been somewhat neglected; they are present in the pancreas in early stages of beta cell damage, and both DCs and macrophages have been implicated in autoimmune recruitment and activation, resulting in islet inflammation and beta cell destruction. Macrophages are also involved in the complications of diabetes resulting from hyperglycemia and the generation and clearance of advanced glycosylation end (AGE) products, via AGE receptors.

CONCLUSION[124]

We have compared the properties of three monocyte-derived sublineages, macrophages, DCs, and osteoclasts, which express many genes in common, although specialization of function is also clear. Further studies are required to identify osteoclast progenitors in yolk sac, fetal liver, bone marrow, and blood, comparable to what has been done with DCs, to establish branch points during differentiation, as well as common precursors. Comprehensive ex vivo and in vitro microarray, RNA sequencing, and proteomic analysis will help, but there are many variables of maturation, modulation, and culture, as well as species, that make such comparisons difficult. RNA-mediated silencing of transcription factors will assist this analysis, in mouse and human deficiency syndromes. The recent application of induced pluripotent stem cell (IPS) technology to Gaucher disease is a stunning illustration of how immortal macrophages and other differentiated cell types can be generated from fibroblasts or monocyte-derived macrophages from individual patients.

Even within each sublineage, modulation within cell populations among individual cells needs to be defined, not only for a few selected cytokines but also for a much larger group of stimuli, including activation, deactivation, and regulation. In particular, the roles of local tissue microenvironments, perhaps due to stromal cell heterogeneity, as well as hormones and microbial constituents, need clarification.

The application of FACS and immunocytochemistry to cells in situ, ex vivo, and in vitro needs to be extended; suitable antibodies are needed for further tissue analysis, especially in humans. Monocytic mononuclear cell populations may contain minor populations of distinct precursors and unrelated lineages. To deal with genetic variation among humans, it will be helpful to study individual subjects sequentially during different stages of a disease.

Disease-specific biomarkers and signatures for blood monocytes, sera, or other body fluids could provide considerable diagnostic and prognostic value.

With regard to the role of MPs in hematology, it is important to remember that apart from the fact that they are themselves part of the hematopoietic system, these cells play a still poorly understood role in trophic functions for other hematopoietic and nonhematopoietic cells; hence the importance of considering their contribution to all disease processes. Improved noninvasive tests, and standardization of more complex assays of their function, are urgently required. Improved imaging methods, based on NMR and PET, for example, with antibodies, iron oxide tracers, and particles, should provide fresh insight into bone marrow, spleen, and lymph node function in health and disease.

ACKNOWLEDGMENTS

SG would like to thank the Stellenbosch Institute for Advanced Study (STIAS) for a visiting fellowship in November 2012, during which this chapter was completed.

CHAPTER 11

LYMPHOCYTES AND LYMPHATIC ORGANS

Frixos Paraskevas

LYMPHOCYTES: HISTORICAL PERSPECTIVE

In the early part of the 20th century, the main debate about the nature and function of the lymphocyte centered around its relationship to cells of the connective tissue and cells of inflammatory exudate. Lymphocytes were considered capable of transforming into granulocytes, monocytes, macrophages, fibroblasts, and other cells. Although Marschalko,[1] Downey,[2] Maximow,[3] and Bloom[4] believed that lymphocytes gave rise to plasma cells, the scientific evidence for these assumptions was lacking; and Rich (1936) suggested that "The complete ignorance of the function of this cell is one of the most humiliating and disgraceful gaps in all medical knowledge."[5] The first conclusive evidence that antibodies are formed in the lymph nodes (LNs) was presented in 1935 by McMaster and Hudack,[6] but it took another decade to prove that lymphoid cells in LNs were the cells that contained antibody.[7,8] This discovery tipped the balance in favor of the lymphocytic theory of antibody production.[9]

In parallel with these studies, the classic work of Fagraeus brought strong indirect evidence of the relationship of plasma cells to antibody production.[10] The demonstration with immunofluorescence techniques by Coons et al. of the presence of antibodies in plasma cells is a landmark in the long debate on the origin of antibodies and the function of plasma cells.[11,12] The question whether plasma cells arise from lymphocytes was answered later by the elegant ultrastructural studies of Harris et al., who by means of electron microscopy demonstrated the gradual change of a lymphocyte to an antibody-forming plasma cell.[13,14,15]

Lymphocytes are a heterogeneous population of cells which differ greatly in terms of origin, life span, preferred areas of settlement within the lymphoid organs, surface structure, molecular markers, and function.[16]

Certain morphologic characteristics, such as size, granularity, and nucleocytoplasmic ratio, distinguish a variety of lymphocyte populations, but provide no clues to identification of their lineage and function. A precise and quantitative method used in clinical laboratories is based on detection of certain glycoproteins displayed on the membrane of lymphocytes known as markers. Two discoveries have helped in the dissemination of routine application of lymphocyte marker analysis in clinical medicine, the development of monoclonal antibodies and the invention of flow cytometry.

LYMPHOCYTES

Light Microscopy

Most blood lymphocytes are small (10 μm or smaller) but larger forms are common (Fig. 11.1A). Some of the large lymphocytes are known as large granular lymphocytes and contain azurophilic granules in their cytoplasm (Fig. 11.1B).[17,18] The dimensions of the cells vary according to the method of preparation. In blood smears stained with Romanovsky dyes, the nucleus is deep purple-blue, usually round or slightly indented, composed of dense aggregates of chromatin. Nucleoli are not visible in Giemsa stained smears with ordinary techniques, although a nucleolus may be seen in wet smears and histologic sections. The cytoplasm forms a narrow rim in small lymphocytes, but it may be abundant in larger cells. The cytoplasm is moderately basophilic and usually is devoid of granules, but larger cells may contain several bright reddish-violet (azurophilic) granules that differ from the granules of myeloid cells because they are not positive in oxidase or peroxidase reactions. By phase contrast microscopy, a well-defined centrosome can be observed adjacent to the nucleus and because it is somewhat rigid, it may cause an indentation in the nucleus. Transitional forms between lymphocytes and plasma cells are often seen in the blood of patients with viral infections (Fig. 11.1C–E). These cells are variously known as lymphocytoid plasma cells or plasmacytoid lymphocytes and represent morphologic stages of differentiation of antigenically stimulated lymphocytes.

Flow Cytometry

Flow cytometry, invented in the 1960s, has been used for diagnosis, staging, and evaluation of patients with hematologic malignancies and has contributed to identification and characterization

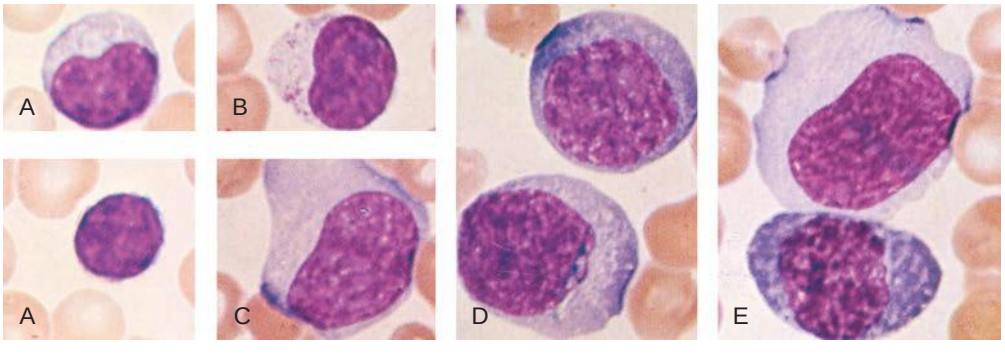

FIGURE 11.1. Morphologic heterogeneity of human peripheral blood lymphocytes. A: Giemsa-stained blood smears: Small and large lymphocytes. **B:** Large granular lymphocyte with azurophilic granules. **C:** Atypical lymphocyte. **D:** Lymphocytes resembling plasma cells (plasmacytoid) from the blood of a patient with viral pneumonia. **E:** One atypical lymphocyte and one plasmacytoid lymphocyte from peripheral blood.

of cell populations. With the advent of one- and two-color flow cytometers, two major lymphocyte lineages were identified, comprising the humoral arm (B cell) and the cellular arm (T cell) of immunity. The characterization of the cells on the basis of their phenotype provided a more reliable platform than morphology for accurate diagnosis and evaluation of residual disease. The new technology, using 12- to 18-color analysis of the patient's blood or other body fluids, brought an unprecedented resolution, which identified multiple subpopulations of T cells, i.e., follicular helper T cells, Th-17 cells and regulatory T cells. Flow cytometry helped our understanding of certain functions of the immune system such as cell cycle analysis, immune deficiencies, the nature of leukemia/lymphoma, and detection of apoptosis induced by various concentrations of gamma secretase inhibitor, *N*-(3,5-Difluorophenacetyl)-**1**-Alanyl-Sphenylglycine T-butyl ester (DAPT), and signaling by Notch 1, recognized as the cell fate signaling molecule.

Electron Microscopy

The small lymphocyte is 6 to 9 μm in size, with a smooth bilaminar cytoplasmic membrane that contains only a few microvilli, except in the area of the uropod in motile cells (Fig. 11.2).[19] The scanty cytoplasm of small lymphocytes shows a remarkable absence of organelles. The Golgi apparatus is small, usually found near the nuclear notch, and one or two centrioles are often seen. No organized endoplasmic reticulum is observed, although careful scrutiny may reveal one or two profiles. Many ribosomes are evident, occasionally in clusters, and typical mitochondria are common, but lysosomes containing enzymes characteristic of these organelles are sparse. Dense bodies of unknown significance may also be seen occasionally. The cytoskeleton consists of occasional microtubules in the cytoplasm and microfilaments adjacent to the cell membrane. The nucleus is enveloped by a membrane consisting of two layers which fuse at the site of nuclear pores, while abundant dense heterochromatin forms aggregates close to the membrane, but less often in the center of the body of the nucleus. These aggregates are separated by interchromatinic spaces which contain smaller bits of chromatin aggregates, particles resembling ribosomes, fibrils, and usually a nucleolus.

The medium lymphocyte is larger (6 to 8 μm) because of an increase in the amount of cytoplasm and a Golgi apparatus which is more developed than in the small lymphocyte. The cytoplasm contains numerous polyribosomes and a few strands of endoplasmic reticulum parallel to the nuclear membrane. Lymphoblasts are usually larger cells (8 to 12 μm) with scarce cisternae of endoplasmic reticulum, a nucleus with loose chromatin, and a giant nucleolus that has a reticulated appearance and occupies as much as one third of the nuclear area. Lymphocytes carry the normal diploid number of 44 autosomes and two sex chromosomes.

Scanning Electron Microscopy

By scanning electron microscopy, the human peripheral blood lymphocytes can be seen to be of two broad categories on the basis of their cell surface [20]; one population has a fairly smooth surface, whereas the other is covered by numerous microvilli (described as "hairy") (Fig. 11.3). The smooth cells correspond to thymus-derived, or T lymphocytes, whereas the one with the microvilli is bone marrow–derived or B lymphocyte. The surface features of the lymphocyte depend on the functional state of the cells as well as the methods used for preparation of the cells.[21] All lymphocytes develop villi if they are stimulated by mitogens or after crossing the high endothelial cells of LN venules, but recover their smooth surface when they reach their respective home microenvironment. Therefore the smooth cell surface is likely associated with resting lymphocytes, whereas microvilli appear following environmental stimuli that interact with cell-surface receptors and may help lymphocytes to interact with target substrates.

B cells with characteristic thin cytoplasmatic projections, i.e., hairy, are positive for tartrate-resistant acid phosphatase (TRAP), and by immunophenotyping they are shown to be positive for CD-103, CD-25, and CD-11c.

Malignancy of this B cell subpopulation has a typical clonal pattern and is known as hairy cell leukemia (HCL), an indolent B cell lymphoproliferative disease, characterized by splenomegaly and pancytopenia.[22]

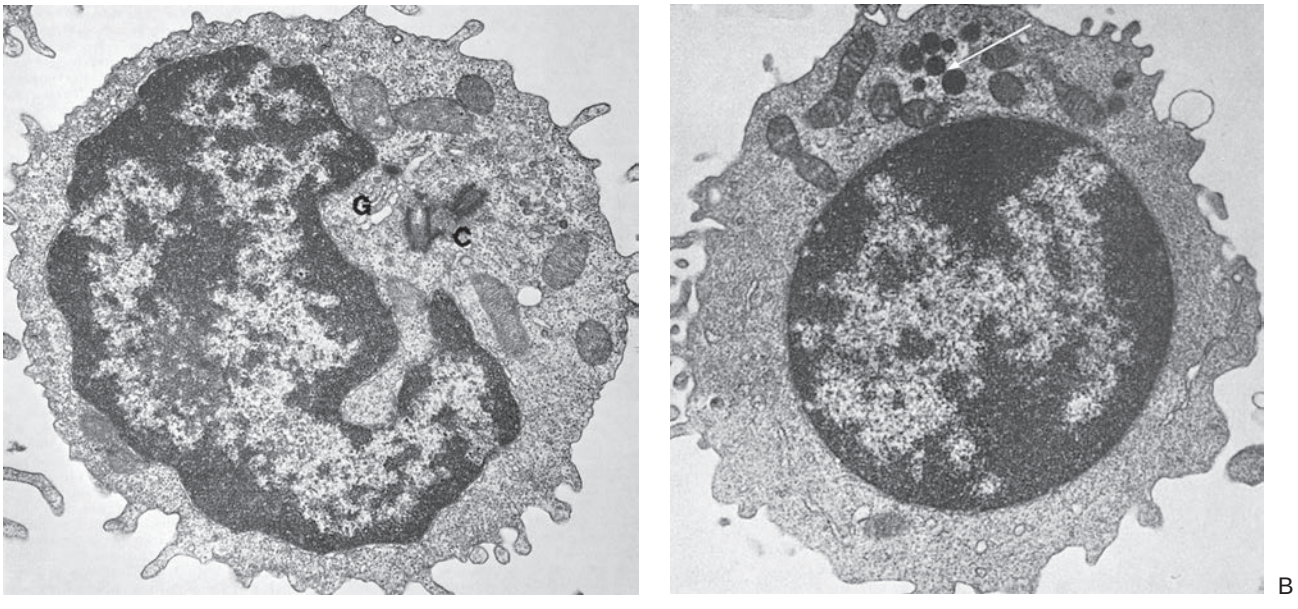

FIGURE 11.2. Ultrastructure of normal peripheral blood lymphocytes. A: A typical resting lymphocyte. The nucleus contains primarily heterochromatin in aggregates along the nuclear membrane. The nucleolus in lymphocytes is usually small. In the cytoplasm, the ribosomes are dispersed, but occasionally, a few short strands of rough endoplasmic reticulum are visible. The mitochondria are well developed, and the centrioles (*C*), longitudinally sectioned in this illustration, show evidence that the cell is ready to enter mitosis on triggering. The Golgi apparatus (*G*) is small (×24,000). **B:** This lymphocyte contains granules (*arrow*) and is likely to correspond to the large granular lymphocyte variety. The cytoplasm is abundant and filled with ribosomes with a few strands of endoplasmic reticulum (×12,000). (From Zucker-Franklin D, Greaves MF, Grossi CF. Atlas of blood cells, 2nd ed. Philadelphia, PA: Lea & Febiger, 1988, with permission.)

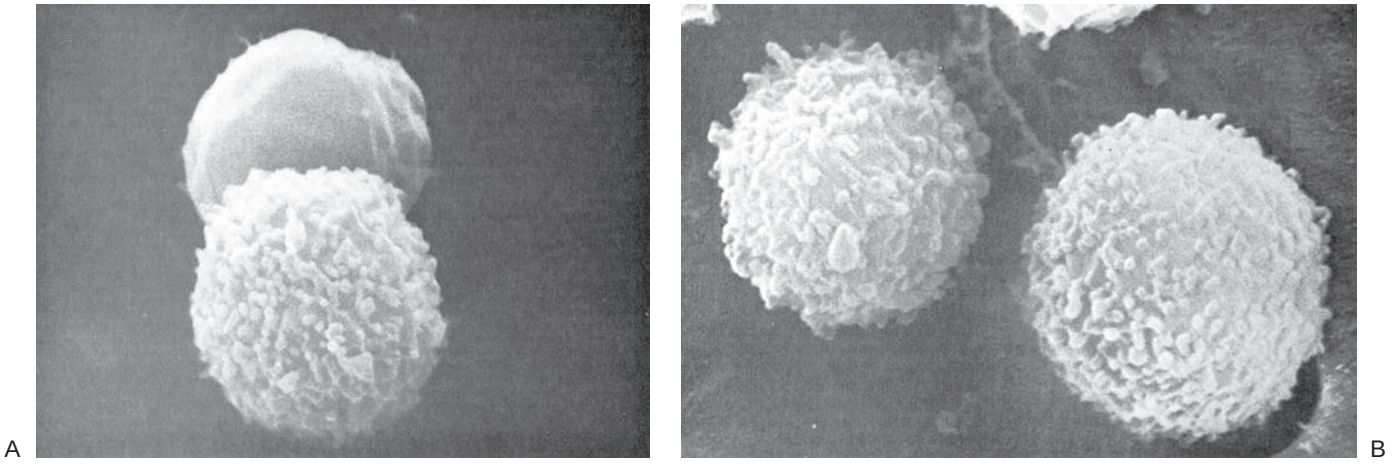

FIGURE 11.3. Heterogeneity of human lymphocytes by scanning electron microscope. A: A smooth and villous lymphocyte thought to correspond to that of T and B lymphocytes, respectively. The appearance of the lymphocytes, however, depends on the method of preparation; both lymphocytes are smooth when they rest in their microenvironments (×14,500). **B:** Two villous cells in a preparation depleted of T cells (×14,500). (From Zucker-Franclin D, Greaves MF, Grossi CF. Atlas of blood cells, 2nd ed. Philadelphia, PA: Lea and Feibiger 1988, with permission).

Lymphocyte Locomotion

The motile lymphocyte may extend cytoplasmic projections, 12.5 to 200 nm wide and up to 0.8 μm in length, and moves with an average speed of 20 μm/minute. Its motility increases with the state of activation; thus lymphoblasts demonstrate greater locomotion compared to small lymphocytes. Locomotion is enhanced by stimuli inducing blast transformation, and the trailing edge of the mobile lymphocyte, the "uropod," is associated not only with locomotion, but with a variety of interactions with lymphocytes, macrophages, and other cells.[23] (Fig. 11.4)

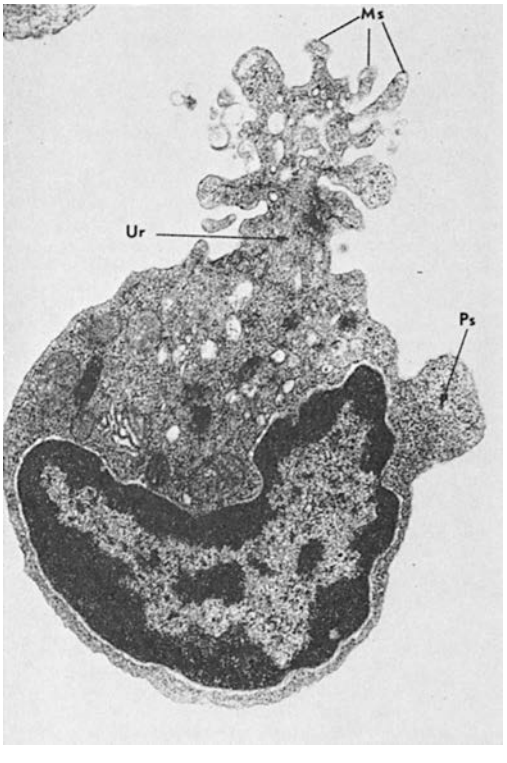

FIGURE 11.4. Lymphocyte locomotion. The lymphocyte assumes the characteristic hand-mirror configuration. The nucleus occupies the front, and part of the cytoplasm forms a tail or uropod (*Ur*), which displays an elaborate pattern of microspikes (*Ms*). A small pseudopod (*Ps*) on the side contains only ribosomes. (From Rosenstreich DI, Shevach E, Green I, et al. The uropod-bearing lymphocyte of the guinea pig. Evidence for thymic origin. J Exp Med 1972;135:1037, with permission.)

The T lymphocytes adhere to macrophages, forming clusters or rosettes, and their mobility is regulated by their lamellipodia and filopodia.[24] A stable cluster forms only when macrophages and lymphocytes are exposed to antigen and the T lymphocytes within the clusters are stimulated into proliferative activity. In general, the uropod formation is a morphologic expression of lymphocyte activation as measured by DNA synthesis. The locomotion of lymphocytes is strikingly different from that of other cells, since they move forward in a steady manner, maintaining a hand mirror shape, whereas myeloblasts express a wriggling worm-like locomotion, and the cells of the monocytic series change shape and direction continuously. Locomotion of the lymphocytes is an important function regulated by the Krupel-like transcription factors which regulate other important functions, such as trafficking and differentiation.[25] Although the uropod is characteristic of T lymphocytes, the B lymphocytes also form uropods after stimulation with anti-immunoglobulin antibodies[26] and the formation by surface immunoglobulin (Ig) of caps, which eventually are endocytosed. The uropod therefore serves not only in cell mobility but also as a site for endocytosis of foreign substances, and ultrastructurally contains practically all cytoplasmic organelles, including the Golgi apparatus, mitochondria, microfilaments, and microtubules. It has been shown that an important protein in T cell motility, known as Kidins-220, is expressed in high concentration in the T cell uropod associated with intercellular adhesion molecule-3 (ICAM-3).[27] The enzyme kinase-D, which interacts with Kidin-220, regulates the motility and migration of the T cell, essential for its response to foreign antigens.

PLASMA CELLS

Plasma cells are the progeny of lymphocytes and morphologically are easily distinguished from other cell types (Fig. 11.5) by their spherical or ellipsoid shape and their size, which ranges from 5 to 30 μm. The cytoplasm is abundant and basophilic, usually deep blue, and may have a granular character. There is a well-defined perinuclear clear zone that contains the Golgi apparatus. The nucleus is small in relation to the cell size, round or oval, eccentrically placed, and contains dense masses of chromatin.

By electron microscopy, the plasma cell membrane and the nucleus appear to be similar to those of the lymphocyte, but their cytoplasm is characterized by a well-developed rough endoplasmic reticulum (Fig. 11.6A) that fills most of the cytoplasmic space, except for a clear area in the perinuclear zone which

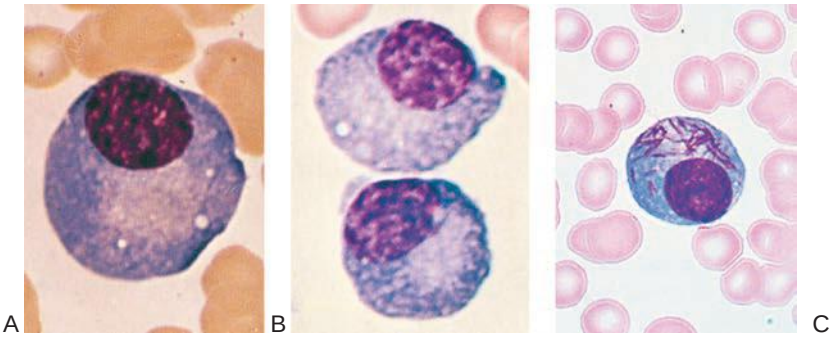

FIGURE 11.5. Plasma cells. A: Normal plasma cell. **B:** Plasmacytes with vacuoles from the bone marrow of a patient with infection and arthritis. **C:** Needle type of inclusions in plasma cell. (C used with permission of the American Society of Hematology Slide Bank, 3rd ed., 1990.)

contains the Golgi apparatus. The endoplasmic reticulum consists of lamellae arranged in a variety of patterns but usually as parallel convolutions. Their inner surfaces are smooth and form the walls of spaces (cisternae) that are filled with amorphous products of varying density. The outer aspects of the lamellae are rough because of attached ribosomes, and a few mitochondria may be seen.

The morphology of plasma cells shown by electron microscopy as described above is the most typical, but intermediate forms exist which resemble small lymphocytes,[14] with a scant amount of cytoplasm and an unusually well-developed rough endoplasmic reticulum (Fig. 11.6B). Such intermediate cells (Fig. 11.1C–E) are common in the blood of patients with plasma cell dyscrasias or immunologic diseases characterized by hypergammaglobulinemia. Similar cells have been observed in the blood of patients with viral infections (Turk cells),[19] including infectious mononucleosis, as well as in the blood of apparently healthy individuals. Alternatively, immature plasma cells may have an appearance more akin to that of phytohemagglutinin (PHA)-transformed lymphocytes, with large and leptochromatic nuclei and cytoplasm containing a simple endoplasmic reticulum, but many ribosomes and polyribosomes, demonstrating that it is often difficult to draw sharp cytologic dividing lines. Other plasma cells may contain vacuoles or needle-type inclusions in the cytoplasm (Fig. 11.5C).

PRIMARY LYMPHOID ORGANS

The cells of the immune system originate in the primary lymphoid organs, which in humans are the bone marrow and the thymus, and during their life span settle in the secondary lymphoid organs, i.e., spleen, LNs, and Peyer patches (PPs) of the gut and the Waldeyer ring (tonsils and adenoids). This division provides the anatomic basis for the two fundamental stages of lymphocyte differentiation, i.e., the antigen-independent stage in primary lymphoid organs and the antigen-dependent stage in the secondary.

The primary lymphoid organs develop first in ontogeny, while the secondary organs provide the proper microenvironment for antigen-dependent differentiation of lymphocytes from immature precursors. Immunocompetent lymphocytes are released from the primary organs and home to specific areas of the secondary lymphoid organs.

The secondary lymphoid organs provide an optimal microenvironment for attracting antigen-specific lymphocytes directing the terminal stages of lymphocyte differentiation activated by antigens.

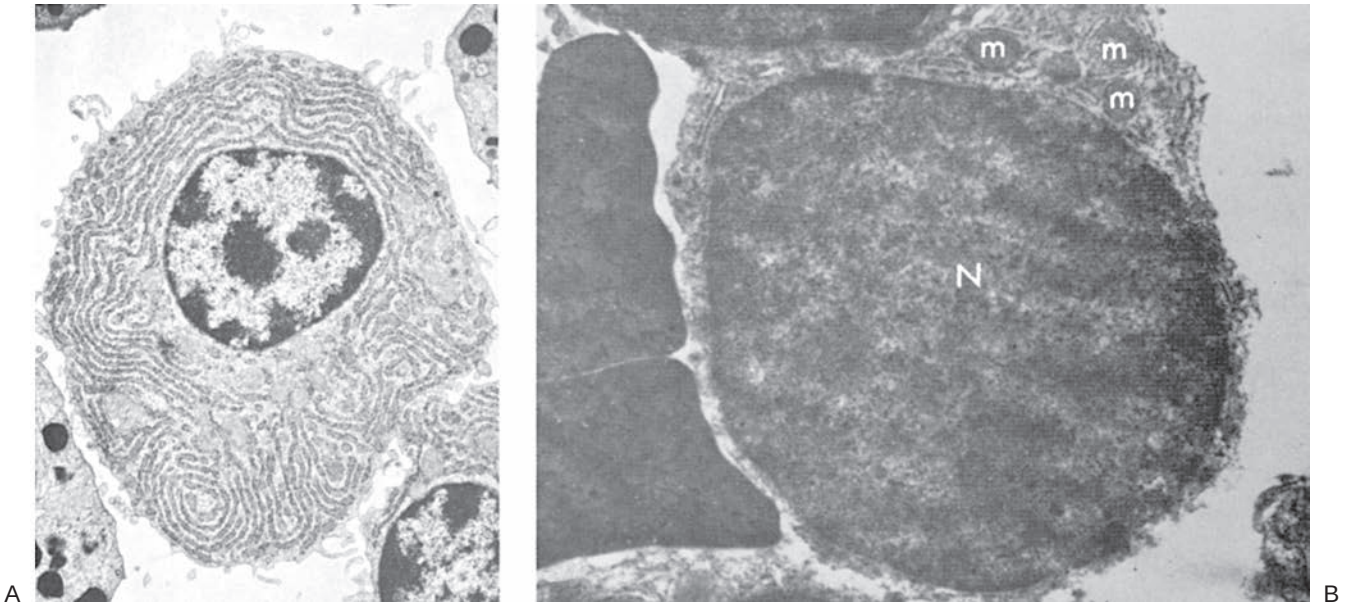

FIGURE 11.6. Electron micrographs of a plasma cell and an intermediate form. N, nucleus. (From Maldonado JE, Kyle RA, Brown AL, et al. "Intermediate" cell types and mixed cell proliferation in multiple myeloma: electron microscopic observations. Blood 1966;27:212–226, with permission.)

Bone Marrow

A detailed account of the histologic features and function of bone marrow is given in Chapter 5. Here we concentrate on the contribution of bone marrow in lymphopoiesis as a "primary lymphoid organ." The bone marrow occupies the medullary cavities of bones throughout the skeleton. It is the major hematopoietic organ in humans and supports differentiation of all blood cells,[28] although in some cases this differentiation is not always complete. T lymphocytes and monocytes, for example, reach their final stages of maturation in locations outside the bone marrow.

The bone marrow is divided into an extravascular compartment, which is the site of hematopoiesis, and a vascular compartment, composed of wide venous blood vessels known as sinuses. These vessels receive blood from the nutrient artery and the periosteal capillary network. The sinuses are radially disposed in the bone marrow and eventually open into larger, centrally located sinuses that exit through the same foramina used by the nutrient arteries. The walls of the venous sinuses consist of an endothelial layer, a basement membrane, and the adventitia. The endothelial cells are flat, with tapering ends, and contain the usual organelles and therefore are endowed with endocytic activity.

The adventitial cells have broad sheet-like processes that form a reticulum, the interstices of which are occupied by the hematopoietic cells. Under certain circumstances, the adventitial cells become swollen because of an increased fat content, and the gross appearance of the marrow turns from red to yellow. In conditions of increased demand on the hematopoietic process, the fatty adventitial cells decrease in size, allowing an expansion of the hematopoietic compartment. The adventitial cells are related to the reticular cells found in the splenic cords and are therefore called adventitial reticular cells.

The hematopoietic compartment displays specific cellular arrangements of hematopoietic cells. Megakaryocytes lie close to the adventitial cells and deliver platelets directly into the sinuses through apertures in the sinus walls. Erythrocytes are produced near the sinuses, forming erythroblastic islets, while granulocytopoiesis takes place at a distance from the sinus wall in a diffuse pattern or sometimes in distinct clusters or sheets.

Available evidence obtained through labeling techniques suggests that new lymphocytes are formed at the periphery of the bone marrow and move toward the center in a centripetal fashion.

The lymphocyte progenitors are enriched with a prolymphocyte population which contains progenitors for B cells and natural killer (NK) cells, which are $CD122^+$ and under defined culture conditions can mature toward B or NK lineage. The B cells are generated from hematopoietic stem cells (HSCs), which migrate from the subendosteal region toward the center of the cavity.

These stem cells differentiate toward several cell lines as a result of signals received from bone marrow–adherent cells that create microenvironments known as niches that support hematopoiesis. The bone marrow stromal cells can be identified by their phenotype, i.e., CD105, CD90, CD184, and class MHC II.[29] HSCs interact with the osteoblasts of the bone, which may contribute to the creation of the hematopoietic niche[30] and support the development of hematopoietic colonies as a result of secretion of a variety of cytokines.[31]

The development of an in vitro culture system[32] facilitated the identification of the growth and differentiation factors necessary for B cell lymphopoiesis, while animal studies defined five stages of B cell differentiation downstream from the common lymphocyte progenitor (CLP) cell: (a) pre-pro–B cell, (b) pro-B cell, (c) pre-B cell, (d) immature B cell and (e) mature B cell. The CLP is the first cell which is irreversibly committed to B or T cell differentiation, but the terminal stages of B cell differentiation, within bone marrow niches, require the availability of certain growth and differentiation factors such as Ikaros,[33] which acts as a factor of lineage competency and facilitates both myeloid and lymphoid development programs.[34]

Immediately after commitment to the B lineage, precursors become dependent on SDF1 chemokine and its receptor CXCR4, as shown with the earliest identifiable B cell precursor populations in the bone marrow, where their development in *CXCL12 (SDF1)*$^{-/-}$, but not in *IL7*$^{-/-}$, embryos is severely disrupted.[35]

The SDF-1 and its receptor are the first example of a chemokine and its receptor responsible for specific biologic activities of the B cell precursors in the earliest B lineage stages.[35] Other important molecules for the function of B cells are the early B cell factor (EBF) and the FLT3 ligand, essential at the pre-pro–B and pro-B stages and the chemokine ligand CXCL12 (known as stromal cell–derived factor-1, SDF1).[36]

The B cell growth after pro-B cell is regulated by interleukin-7 (IL7) (which is essential for the development of B cells.[37] The chemokine CXCL12, which binds to its receptor CXCR4 of stromal cell, guides and retains B cells to appropriate secondary lymphoid organs.[38] Newly synthesized lymphocytes are discharged into the circulation and have been found singly or in small groups near the sinusoidal walls. Some of them are in transit through the wall of the sinus, which suggests that B lymphocytes are not stored in the bone marrow except for brief periods of time before they are released into the circulation. Histologically, no lymphoid follicles are distinguishable in normal bone marrow, which resembles the red pulp of the spleen with vascular sinuses and reticular meshwork formed by the adventitial cells or the cordal reticular cells, respectively. The bone marrow circulation, however, is closed while the circulation of the red pulp is partially open, and there is no endothelial continuity between the arteries and the veins.

Thymus

Ontogeny and Histology

The thymus is a lymphoepithelial organ situated in the superior mediastinum[39,40] which consists of two lobes that are divided into lobules forming the basic anatomic units of the thymus. The thymus is covered by a fibrous capsule from which fibrous bands (trabeculae) penetrate the parenchyma, dividing it into lobules. Histologically, the lobules have two distinct regions (Fig. 11.7), (1) a peripheral region named the cortex which is divided into the outermost or subcapsular cortex, and the inner or deep cortex, and (2) a central region named the medulla. In hematoxylin-eosin–stained sections, the cortex appears dark blue to purple because of the predominance of lymphocytes (80% to 85%), whereas the medulla appears eosinophilic because of the predominance of the epithelial cells. These anatomic divisions correspond to functionally distinct microenvironments that support specific phases of thymocyte differentiation. The subcapsular or superficial cortex contains large, actively dividing blasts with many mitotic figures, while the deep cortex is composed principally of nondividing small thymocytes.

The medulla contains predominantly medium-sized thymocytes. The relationships between the thymocytes in each compartment and the mechanisms underlying thymocyte differentiation are discussed in detail in Chapter 13.

The embryologic origin of the thymus has been under dispute for more than 30 years[41]. According to one view, the thymic primordium arises from the third pharyngeal pouch (endoderm) as well as the pharyngeal crest (ectoderm) [42]; while another study supported exclusively an endodermal origin,[43] which alone contributes to the formation of the thymus.[44]

The pharyngeal pouches are transient embryonic structures and their formation requires the paired box gene 1 (*PAX 1)* and 9 (*PAX 9*) as well as the fibroblastic growth factor-8 (*FGF8*). They develop in an anterior to posterior sequence and are separated from each other by pharyngeal arches. Each endodermal primordium contains precursors for one thymic lobe and one parathyroid gland. It is surrounded by a capsule of mesenchymal cells derived from cells of the neural crest, which supports the growth

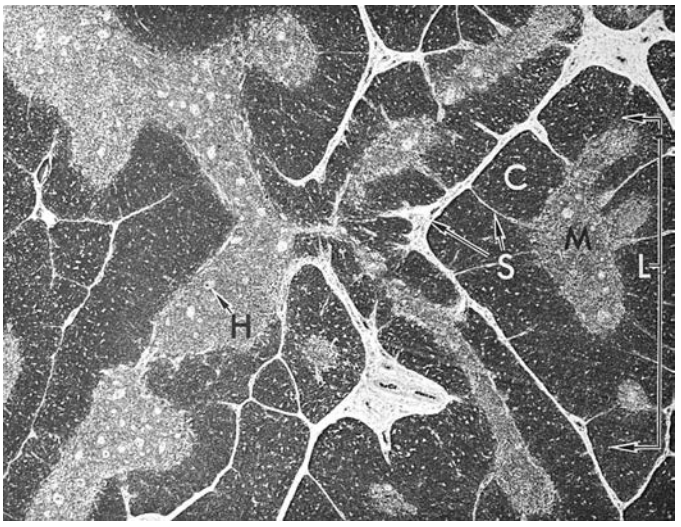

FIGURE 11.7. Histology of thymus shows lobules (*L*) consisting of cortex (*C*) and medulla (*M*). H, Hassall corpuscles; S, septa (trabeculae).

and development of the primordium, and under their guidance it separates into a thymus and pharynx.

The development of the thymus proceeds through several stages: (a) positioning, i.e., determination of the place where the organ rudiment will develop; (b) growth and patterning, i.e., generation of distinct regions in the growing rudiment; and (c) differentiation, i.e., separation of distinct cell types that have been developed. The function of the homeobox A3 (*HOXA3)* is necessary to identify the third pouch, which forms the thymus and may control the position of the mitral rudiment.[44] Mice lacking *Hoxa3* are athymic and have no parathyroids, since the third pouch endoderm cannot differentiate appropriately. The expression of *PAX1* in all pharyngeal pouches requires two other genes such as the eyes absent gene *(EYA1*) and the sine oculus-related homeobox1 homologue (*SIX1).*[45] Functional evidence that the endoderm alone forms a fully functional thymus was obtained through ectopic transplantation of isolated endoderm tissue grafted under the kidney capsule.[46] Normally, the structures of the original tubular epithelium, one on each side, descend into the anterior superior mediastinum where they fuse, forming the mature organ with two lobes. At this stage, the thymus is triangular, with the base resting on the pericardium and the apex pointing toward the neck.

Once the anlage is formed, the function of the *WHN* (winged helix nude; now known as *FOXN1*) gene is required for the completion of thymic structure and function.[47,48] The nude locus gene encodes the FOXN1 transcription factor, of the forked/winged/helix family. It contains a DNA-binding domain and a strongly acidic transcriptional activation domain, which is functionally indispensable. Mutations affect the DNA-binding domain or the C-terminal transcriptional activation domain and are associated with athymia and hairlessness because the gene regulates the keratinization of hair.

The neural crest contributes to the formation of several glands, including the perivascular mesenchyme of the thymus.[49] The neural crest cells migrate into the thymus early in development, surrounding the epithelial rudiments and are closely associated with the developing thymocytes. They form the connective tissue capsule and trabecular septa that penetrate the parenchyma, dividing it into lobules, and likely provide extracellular matrix into the cortex and medulla, such as hyaluronan, collagen, and fibronectin, which may be important for the presentation of growth factors to the thymocytes. Hyaluronan is the ligand of CD44, and their interactions are important in the early stages of human thymus development.[50] The undifferentiated epithelial cells are large, with dispersed chromatin, short, blunt cytoplasmic processes, and sparse tonofilaments. As the cell matures, the amount of cytoplasm decreases and long dendritic processes form, which permit tight junctions between adjacent cells and the formation of the epithelial framework, within the interstices of which T-lymphocyte differentiation takes place.

Migrating lymphoid progenitors initiate a symbiotic relationship with the epithelial cells and contribute to the organization of the thymic microenvironments. Whereas prothymocytes (i.e., immature T cells) regulate induction of the cortical microenvironment,[51] the mature thymocytes, i.e., T cell receptors (TCR)+ organize thymic medullary epithelial cells.[52] E-cadherin plays an important role at this stage because it mediates interactions that shape the cortical and medullary thymic microenvironments which are architecturally distinct.[53]

Heterotypic interactions important for thymocyte proliferation occur between epithelial cells, which express the E-cadherin, and the double-negative T lymphocytes, which express the ligand of E-cadherin, i.e., CD103 or $\alpha_E\beta_7$ integrin.[54]

The thymic anlage is permeated by blood vessels, which also contribute to a well-organized medullary epithelial compartment, even in the absence of $CD3^+$ mature thymocytes (i.e., in *Rag2*$^{-/-}$mice). Medullary epithelial cells arranged as cuffs around vessels of intermediate size affect the development of the thymic microenvironment.[55]

Addition of keratinocyte growth factor, a member of the fibroblast growth factor family secreted from mesenchymal cells, results in the expansion of the medullary epithelial compartment in the *Rag2*$^{-/-}$mice.[56] These data emphasize the fact that the growth and maintenance of a functional thymic microenvironment is a highly complex process and is maintained by stimuli from all structural components. The *RELB* gene encodes a subunit of the nuclear factor-κB complex, critical for the coordination of several aspects in the development and organization of medullary epithelial cells and dendritic cells.

Overexpression of CD40L on thymocytes disrupts the thymic architecture and the epithelial differentiation, with loss of cortical epithelial cells, expansion of the medullary compartment, and infiltration of the capsule with a mixture of $CD3^+$ cells, B cells, and macrophages.[57] These findings point out that regulation of normal development of the thymus is a highly complex process, delicately regulated by multiple cellular interactions and soluble factors released as a result of these interactions.

The medullary epithelium expresses several molecules, considered tissue specific such as parathyroid hormone, thyroglobulin, insulin, and respiratory epithelium. This may represent a "promiscuous" gene expression or a "mosaic" of epithelial differentiation,[58] which may be the basis for the establishment of self-tolerance. This view is supported by the demonstration that the *AIRE* gene, which is defective in autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED), is expressed by medullary thymic epithelial cells (TECs).[59]

AIRE (auto immune regulator) is a DNA-binding nuclear protein with a putative DNA-binding domain named SAND (**S**p100, **A**ire-1, **N**ucP41/75, **D**EAF-1) and four LXXLL nuclear receptor–binding motifs. The structure of AIRE suggests that its function is that of a transcription regulator[60,61] which interacts with CREB-binding protein (CBP), a property that mediates its transcriptional regulation property.[62] It also contains a proline-rich region, known to be expressed by several transcription factors which mediate interactions with SH3 domains.

The LXXLL motif binds coactivators to nuclear receptors and activates transcription of target genes by nuclear receptors. AIRE plays a vital role in preventing autoimmunity; and mutations in this molecule cause a recessive inherited disease known as APECED or autoimmune polyendocrinopathy syndrome type-1 (APS-1). APECED at the beginning is presented as mucocutaneous candidiasis early in childhood with eventual destruction of endocrine organs and the appearance of Addison disease, hypoparathyroidism, and type I diabetes.[63] AIRE is expressed in medullary

epithelial cells, testes, and cells of dendritic lineage.[64] It has been suggested that AIRE may induce transcription of genes specific to other tissues that are promiscuously expressed in the TECs.[65]

It promotes the expression by TECs of self antigens from other tissues facilitating the removal of thymocytes with self-reactive T cell receptors.[66,67]

Recently, a second thymus has been identified in the neck of mice with typical cortical and medullary structures.[68] The cervical thymus is structurally the same as the thoracic thymus, consisting of cortex and medulla and containing double-positive ($CD4^+/CD8^+$) and single-positive ($CD4^+/CD8^-$ and $CD4^-/CD8^+$) thymocytes expressing TCR/CD3 complexes. The cervical thymus is fully functional, because it could supply T cells to athymic (nude) mice, correcting their immune deficiency.

This unexpected discovery poses a number of questions for experimental work done with thymectomized animals over the past 45 years.[69] Perhaps the cervical thymus is too small to be relevant and its cellularity is only 1/500th of the thoracic thymus.[70]

Work done with thymectomized animals suggest that the role of the thymus in autoimmune disease may have to be reconsidered.[71]

Nonlymphoid Cells

Thymic Epithelial Cells

The thymic rudiment is populated by epithelial cells which are distinguished anatomically as cortical and medullary. Lack of *Hoxa3* has an impact on the early phases of thymic organogenesis from the third pharyngeal pouch.[72] *Foxn1* is expressed in epithelial progenitors of cortical and medullary compartments and regulates the differentiation of TECs during embryonic and adult life. In *Pax9* null mice, the thymic anlage develops as an ectopic polyp-like structure, and expression of the Foxn1, a marker of thymic epithelium, is markedly reduced. Expression, however, of the *Tcrb* genes is readily detectable in the mutant thymus, but the TCR gamma chain is not detectable.[73] The forkhead transcription factor Foxn1 is indispensable for TEC development and function, acting as a master regulator of the epithelial programs of the thymus.[74]

Overexpression of *Foxn1* attenuates the decline of thymocyte numbers and frequency of early thymic progenitors, and histologic studies reveal that structural alterations associated with thymic involution are diminished in aged *Foxn1* transgenic mice.[75]

Deletion of *Pax*1 results in thymic hypoplasia as a result of defective organogenesis of the thymus, while *Pax9* causes marked thymic hypoplasia because of defective cellular migration to thymic rudiments. In *Pax*9 null mice the thymic anlage develops as an ectopic polyp-like structure in the larynx, expresses *Whn/Foxn1*, the markers of thymic epithelium, but fails to perform the normal caudo-ventral movement to the upper mediastinum, and the TCR-γ chain is not detectable.[73] Loss of *Foxn1* function, on the other hand, results in a more complex phenotype known collectively as the "nude" mouse.

The "nude" mouse has been an important "experiment" of nature that has provided important insights of the function of the thymus.

Abnormal thymic development is associated with defective keratinization, as seen in the nude mouse,[76] and although the early stages of development proceed normally, including normal mediastinal migration, the subsequent rudiment of the thymus does not develop as a result of failure of its colonization by lymphoid progenitors.[77]

It is generally accepted that organogenesis of the thymus is completed in two distinct steps. During the first stage, endodermal elements of the third pharyngeal pouch migrate to the mediastinum and form the thymic rudiment. In the second stage the Foxn1 transcription factor drives differentiation of multipotential progenitors to the thymic cell lineage. In the absence of *Foxn1* function, the cells of the rudiment resemble respiratory epithelium in their phenotype and organizational features.[74] As shown in nude mice, T cell development and selection require expression of the forkhead transcription factor *Foxn1* regulated by Wnt glycoproteins secreted by epithelial cells and thymocytes. In the absence of their function, epithelial cell morphogenesis is defective and lymphoid precursors are not attracted to the thymic primordium. The Wnt molecules therefore provide regulatory signals critical for thymic function.[78]

The glycoproteins Wnt bind to glycosaminoglycans of the extracellular matrix, cell-surface receptors of the Frizzled (Fz) family, and members of receptors related to low density-lipoprotein receptors. Through regulation of *Foxn1* function the Wnt proteins contribute importantly in the development of TECs.

The epithelial cells in the cortex and medulla have a common progenitor as shown by clonal analysis,[79] and these progenitors still exist in the thymus after birth.[80]

Ultrastructurally, the epithelial cells are highly heterogeneous, probably reflecting their divergent origins (see Chapter 13). In the past, the epithelial cells have been referred to by a variety of designations, such as reticular, syncytial, epithelioid, and squamoid (Fig. 11.8). The characteristic features that distinguish them from other cells in the thymic parenchyma are the presence of tonofilaments and desmosomes. The tonofilaments are filamentous structures approximately 3.0 nm in diameter and 0.1 to 3.0 μm in length which often form bundles and are located close to the nucleus. Desmosomes are detected at the junctions of the dendritic processes of adjacent epithelial cells. Their oval nuclei have evenly distributed chromatin and prominent nucleoli. The epithelial cells joined by desmosomes form a continuous meshwork that surrounds the trabeculae, the blood vessels and the inner surface of the capsule. Between the epithelial sheath and the supporting scaffolding of the trabeculae and blood vessels there forms a kind of a continuous basement membrane or meshwork, which is distinct from the basement membrane of the capillaries and separates the epithelial meshwork from the cavernous spaces filled with thymocytes.

The cortical epithelial cells do not have secretory granules and probably do not participate in the secretion of thymic hormones. Such interactions are regulated by products of genes of the major histocompatibility complex. Indeed, the presence on epithelial cells of class I and II molecules in mice and humans has been demonstrated.

The distribution of class II antigens is typically dendritic in the cortex, but is confluent in the medulla. MHC II levels, as well as the percentages and cycling status of TEC populations expressing MHC II, were not static during postnatal development, suggesting

FIGURE 11.8. Ultrastructure of the thymus. An epithelial dendritic cell at center (*E*) extends long cytoplasmic processes (*arrows*). Note the intimate contact between the epithelial cell and the surrounding thymocytes (×4,400). (From Bloodworth JMB Jr, Hiratsuka H, Hickey RC, Wu J. Ultrastructure of the human thymus, thymic tumors, and myasthenia gravis. Pathol Annu 1975;10:329, with permission.)

quantitative flexibility in presenting signals to the developing thymocytes.[81]

The class II antigens are of higher density than the class I antigens in cortical epithelial cells, but they are of the same high density in the medullary epithelium. Using immunohistochemical techniques and electron microscopy, investigators have shown that these molecules are of epithelial origin because they are located on cells containing desmosomes and tonofilaments.

The thymocyte–epithelial cell interaction in the outer cortex results in the formation of lymphoepithelial complexes known as nurse cells (TNC) (Fig. 11.9). TNCs are located within the corticomedullary junction to express cytokeratins five and eight (K5 and K8) and the transcription factor Trp-63. The phenotype suggests that the TNCs play an important role in thymocyte selection and may also be involved in the maintenance of thymic epithelia.[82] They are composed of large clusters of lymphocytes surrounded by cell membrane and appear to reside within the cell body of an epithelial cell. Their significance in T cell differentiation is discussed in Chapter 13.

The epithelial cells of the medulla do not have long dendritic processes and are known as epithelioid or spatulate epithelial cells. They are more pleomorphic and contain dark granular inclusions that may have secretory functions. Another variety of epithelial cells, known as squamoid, is found exclusively in the medulla. These cells probably give rise to Hassall corpuscles and contain dense bundles of tonofilaments and masses of keratohyalin.

The Hassall corpuscles, first described more than 150 years ago,[83] are solid or cystic, and their origin is highly disputed. Hammar suggested that Hassall corpuscles arise as solid structures through the tight apposition of as many as 20 to 50 epithelial cells in a concentric fashion, but degenerative changes in the centrally located cells produce the cystic forms. The cavity of the cystic forms of these corpuscles is lined by epithelial cells with villous projections, and sometimes it is filled with debris and degenerated cells. In some solid corpuscles, keratinization is prominent and is similar to that of the skin.

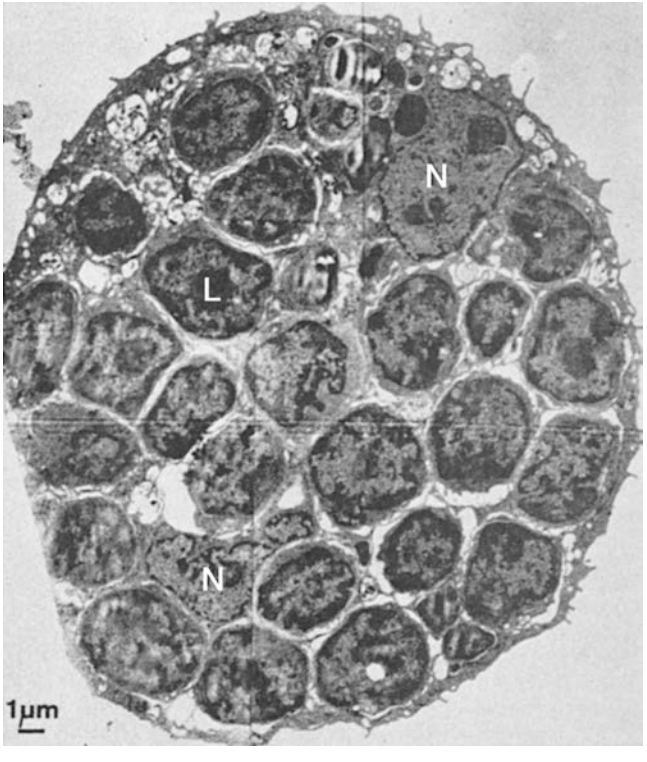

FIGURE 11.9. A typical large nurse cell containing many thymocytes (*L*) and two epithelial nuclei (*N*). Between the internalized thymocytes are cytoplasmic vesicles and tonofilaments. Some nurse cells contain thymocytes in mitosis. (From Wekerle H, Ketelsen UP, Ernst M. Thymic nurse cells. Lymphoepithelial cell complexes in murine thymuses: morphologic and serologic characterization. J Exp Med 1980;151:925, with permission.)

Monoclonal antibodies specific for high-molecular-weight keratins that react with terminally differentiated epithelial cells of the skin also bind to Hassall corpuscles.[39,84] Epithelial cells of the deep cortex are phenotypically different from those in the medulla, which undergo terminal keratinocyte differentiation. Hassall corpuscles are not the epithelial cell graveyard as previously thought, but contribute actively to important immunoregulatory functions. They secrete thymic stromal lymphopoietin (TSLP), which regulates $CD4^+$ T cell homeostasis through activation of thymic dendritic cells (TDCs) (see below) and induces proliferation and differentiation of $CD4^+/CD25^+/Foxp3^+$ regulatory T cells from $CD4^+/CD25^-$ thymocytes.[85]

Macrophages

Macrophages are found throughout the thymus: among thymocytes, in capsular and septal connective tissues, and in the perivascular space. Some macrophages are surrounded by thymocytes and form rosette-like structures. Thymic macrophages direct thymocyte maturation, but appear to be involved also in the disposal of many thymocytes dying within the thymus. Macrophages are more prominent in involuted thymuses after stress or steroid hormone treatment, rendering the histologic picture of a starry sky.

Lymphocyte phagocytosis is found in the germinal center (GC), a site that also is characterized by high proliferative activity.

Interdigitating Dendritic Cells

A third population of nonlymphoid cells in the corticomedullary junction is known as interdigitating dendritic cells or thymic dendritic cells (TDCs). They contain an irregularly shaped nucleus and clear cytoplasm, but they lack the Birbeck granules characteristic of Langerhans cells (LCs) and their phenotype and origin apparently varies.

Specialized dendritic cells (DCs) within the thymus are crucial for deletion of autoreactive T cells. The question of whether these cells arise from intrathymic precursors with T cell potential has been hotly debated, and the regulatory pathways as well as the signals that direct their development remain unclear.[86] Some are $CD8a^+$-derived from a common precursor with T cells and therefore are lymphoid-related and the granulocyte-macrophage colony-stimulating factor is not required for their development (in contrast to the myeloid DCs), and they need functional Ikaros transcription factors for their maturation.[87] In humans, pluripotent stem cells, which leave the bone marrow to migrate to the thymus, have the potential to develop into T cells and DCs.[88] The question whether these cells arise from intrathymic precursors with T cell potential has been hotly debated, and the regulatory pathways and signals that direct their development remain unclear.[89]

Other thymic DCs express the CD116/CD8 phenotype (i.e., the Langerhans cells in other tissues) and originate from DC precursors.[90] Their differentiation is driven by factors produced by TECs as well as Hassall corpuscles.[91] Another pathway of TDC differentiation is from double-negative thymocytes (i.e., $CD4^-/CD8^-$) stimulated, in the presence of IL7, by IL18 produced by TECs.[92]

Thymic stromal cells produce the IL7-like lymphopoietin, TSLP, that acts through appropriate receptors on dendritic cells carrying self-peptide–MHC complexes inducing expansion of $CD4^+$ T cells. TSLP is also produced by epithelial cells in tonsillar crypts and other mucosal tissues, and thus may exert a homeostatic mechanism on $CD4^+$ T cells, through dendritic cell activation not only within the thymus, but in other mucosal lymphoid tissues as well.

Myoid Cells

Myoid cells are striated muscle cells seen in many lower vertebrates and are found in the medulla of the thymus. Their origin has not been documented but it is believed to originate from mesenchymal or epithelial cells to which they are attached by desmosomes.

They contain muscle proteins, including myosin, desmin, acetylcholine receptors, and numerous intracytoplasmic filaments arranged in haphazard fashion.

Their presence in human fetal thymuses has been documented and plays a role in T cell differentiation, maturation, and protection of thymocytes from apoptosis.[93]

Lymphoid Cells

Lymphoid cells constitute 80% to 85% of the cortical and 15% of the medullary cells. The outer cortex lymphocytes are large blast cells with dark blue cytoplasm that proliferate actively. They are the immediate descendants of bone marrow–derived prothymocytes, which enter the thymus and migrate to the subcapsular cortex. As they mature, they move into the deeper cortex, which is occupied by small nondividing thymocytes. The medullary thymocytes are of medium size and are considered emigrant cells, although this fact has not been proven conclusively. The recruitment, migration, and differentiation of lymphocytes and the relationship between subcapsular, deep cortical, and medullary thymocytes are discussed in Chapter 13.

Thymic Vasculature

The thymic anlage initially is avascular and is penetrated by vessels at approximately 12 to 14 weeks of gestation. The thymic arteries are branches of the inferior thyroid, internal mammary, and pericardial phrenic arteries; they enter the thymus and pass down to the medulla, branching into arterioles which penetrate into the deep cortex.

Capillaries that arise from the arterioles run toward the subcapsular cortex, where they anastomose and turn inward toward the medulla, eventually forming venules.[94] The vessels are ensheathed with epithelial cells and connective tissue that is continuous with the capsule.

Histologically, a number of layers can be distinguished from the lumen of the blood vessels outward which constitute the blood-thymus barrier: (a) endothelium; (b) vascular basement membrane; (c) mesenchymal perivascular connective tissue space occupied by collagen fibers; (d) fibroblasts, macrophages, and other cells; (e) epithelial basement membrane; and (f) epithelial cell syncytium. The mesenchymal interstitial space is probably formed in the early stages of development when the TECs envelop the blood vessels; it is considered extraparenchymal. The tightness of the barrier has been tested with particulate and protein tracers. It is tight in the cortex, mainly because of the impermeability of the endothelial junctions. Traces of protein transported by plasmalemmal vesicles of the endothelial cells which are released on the parenchymal front are removed rapidly by macrophages along the interstitial spaces of the vessels and are prevented from coming into contact with the thymocytes. This barrier, however, is incomplete in the medulla, especially along the site of thymocyte migration through the wall of venules.[95] The fact that antigens are detected in the thymus indicates that the "barrier" has leaks, although experimental tracers have never reached the cortical parenchyma. This arrangement of the vasculature and the epithelial sheaths separates the thymus into the intraparenchymal compartment, composed of the lymphoepithelial complex and the extraparenchymal compartment composed of the blood vessels and the surrounding interstitial space.

Involution

Beginning at puberty, the thymus undergoes a gradual process of involution, characterized by loss of the cortical lymphocytes and atrophy of epithelial cells and their replacement by fat originating from mesenchymal cells present in the connective tissues along the vasculature and capsule. More than 50% of the thymus is replaced by adipose tissue by the age of 40 to 45 years, but the fat is still contained in the extraparenchymal compartment, separated from the remaining lymphoepithelial complex by the epithelial basement membrane and the sheet of epithelial cells. The age-related involution may be influenced by stress and other factors.

Thymic involution starting at puberty has been associated with use of sex hormones. This hypothesis, however, has been challenged, since morphometric studies have shown that thymic involution actually starts early in life,[96] as the potential of intrathymic progenitors to maintain the level of mature thymocytes starts to decrease at that time.[97]

With a rise of sex hormone concentration there is a decline in the production of growth hormone and many of its effects in the periphery are mediated by insulin growth factor-I induction.[98] A slow rate of thymic activity is maintained throughout life with complete but slow renewal of T cells,[99] but the changes of the thymic tissue are quantitative rather than qualitative. At the molecular level thymic involution is linked with the expression of JAGGED-1 protein in T cells[100] together with Delta protein. The gene of this protein is a member of the Delta/Serrate/Lag2 (DSL) genes which regulate Notch signaling implicated in regulation of T cell activation and differentiation. Expression of JAGGED-1 on T cells interferes with Notch signaling and induces premature involution as a result of apoptosis of TECs. In contrast to chronic involution which is a result of aging, the thymus undergoes acute involution as a result of stress, which is mediated by adrenal corticosteroids. Injections of glucocorticoids eliminate as much as 75% of the thymocytes within 2 to 3 days, affecting both the cortex and the medulla, but the effects are more pronounced in the cortex. Most of the cortical thymocytes are cortisone sensitive, whereas the medullary thymocytes are cortisone resistant. As a result of acute stress the lymphocytes undergo pyknotic changes, fragmentation of the nuclei, and eventually a decrease in size; subsequently they are phagocytosed by macrophages.

Recovery takes place within 8 to 10 days and is marked by an early increase in mitotic activity in the subcapsular cortex.

Pathology of Human Thymus

Myasthenia Gravis

In some of the patients with myasthenia gravis, the thymus shows an increase in the number of medullary epithelial cells containing thymic hormones and development of follicles with GCs composed of B cells and many plasma cells,[101] i.e., histologic changes which are typical of reactive peripheral lymphoid organs. These follicles are located outside the epithelial basement membrane, predominantly in the medulla, and are surrounded by many Hassall corpuscles; but the cause of these histopathologic lesions is unknown. Antibodies against the acetylcholine receptor, in the neuromuscular junction, play an important role in the pathogenesis of myasthenia gravis; and it is intriguing that this receptor, or a structurally similar antigen, has been detected on thymic cells.[102] Patients with myasthenia gravis have circulating antibodiesreacting in culture with the striations of myoid cells from animal and human thymuses, as well as muscle cells expressing acetylcholine receptors.[103] These are the "myasthenogenic" factors in the blood of the patients, which in mice induce many characteristic features of the disease, i.e., reduced amplitudes of the miniature endplate potentials and a reduction of the number of acetylcholine receptors available for binding of bungarotoxin

up to 38% to 54%. Approximately 10% to 15% of patients with myasthenia gravis have thymomas, but these histologic changes are not characteristic of myasthenia gravis, since they have been observed in patients with other diseases such as endocrinopathies, i.e., Addison disease and thyrotoxicosis; and autoimmune diseases, such as systemic lupus erythematosus.

Similar lesions have been identified in thymuses from patients with multiple sclerosis, supporting a well-documented fact that the thymus and the brain share some antigens such as the Thy-1 antigen (CD90).

Dysplasia. The thymus of patients with severe combined immunodeficiency disease is characterized by scant lymphocytes with reduced numbers of epithelial cells.

Thymomas. Tumors of the thymus are epithelial, lymphocytic, or consist of a mixture of both cellular elements; while others are mixtures of ductal and glandular structures mixed with epithelial cells. These cases are thought to imitate the early ontogenetic stages of the thymic anlage and support the view of the double origin of the thymic epithelium. Thymic lymphomas that appear as mediastinal masses are associated with acute T cell leukemia in children who bear the phenotype of cortical thymocytes in the early stages of their development. The diagnosis of primary thymic epithelial tumors has been controversial, because of the difficulties in their histopathologic classification and prognostication of their clinical behavior. A new histologic classification has recently been proposed by the World Health Organization (WHO),[104] which provides an improved platform over pre-existing classifications for clinical practice in relation to assessment and treatment of the patients.

SECONDARY LYMPHOID ORGANS

Lymph Nodes

Ontogeny

The fundamental concepts of lymphoid organ neogenesis were generated approximately 100 years ago, and the ontogeny of the secondary lymphoid organs, i.e., lymph nodes (LN), Peyer patches (PP), and spleen is highly complex (reviewed in Refs. 105–107). The evolution of their development generated structures, the lymphoid organs of the immune system, to fit their function, i.e., as defenders of the integrity of "self." This of course requires enhancement of their "sensitivity of antigen recognition" in order to facilitate activation and differentiation of antigen-specific cells, to be followed by the activation and deployment of the defence mechanisms of the body. The LN and PP develop from the budding of a group of cells from large vessels of lymph sacs which are penetrated by connective tissue and lymphatic vessels interconnecting with other vessels forming a network; this is regulated by the *PROX1* gene which is expressed on lymphatic endothelial cells and is required for budding and sprouting of the lymphatic endothelium[108]. The budding occurs in one spot in the anterior cardinal veins of the neck and generates a lymph sac, which gives rise to the lymphatics of the neck, thorax, heart, lungs, and forelegs regulated by the *PROX1* gene.[109] After the development of the lymphatics, circulating $CD45^+$ $CD4^+$ $CD3^-$ hematopoietic progenitor cells from the liver provide the signals for the induction of LNs and PPs. Lymphotoxin (LT) is essential for the formation of LNs and PPs, as shown in mice rendered deficient in LT by gene targeting,[110] and in the white pulp of the spleen normal segregation of B and T cells does not occur. Both phenotypes of T cells, i.e., $CD4^+CD8^-$ and $CD4^-CD8^+$ are present in a normal ratio.

Lymphocytes positive for immunoglobulin-M are present in increased numbers in both the spleen and peripheral blood. These findings suggest that LT is essential in the normal development of peripheral lymphoid organs.[111] Lymphocytes positive for immunoglobulin M are present in increased numbers in both the spleen and peripheral blood. The membrane-bound LT forms heterotrimers, i.e., LT-1-2, which bind to the LT receptor (LT-R). The LT-1-2 triggers expression of kinase NIK, which induces the nuclear transcription factor k-B and initiates an alternative pathway for its activation, which plays a pivotal role in innate and adaptive immunity.[112] The interaction of LT 1-2 with its receptor LTR constitutes a major pathway in the development of the architecture and the function of the secondary lymphoid organs [113] for adaptive immune responses. These findings document the crucial roles of LT- and LT-R in building and maintaining the architecture of lymphoid organs and ensuring the function of the immune response against invading pathogens.

Chronic inflammation, autoimmunity, or cancer may interfere with the development of secondary lymphoid organs; and the maintenance of their microarchitecture depends on interactions of cells of hematopoietic and nonhematopoietic origin, as well as the chemokines CXCR5 and CCR7.[114,115]

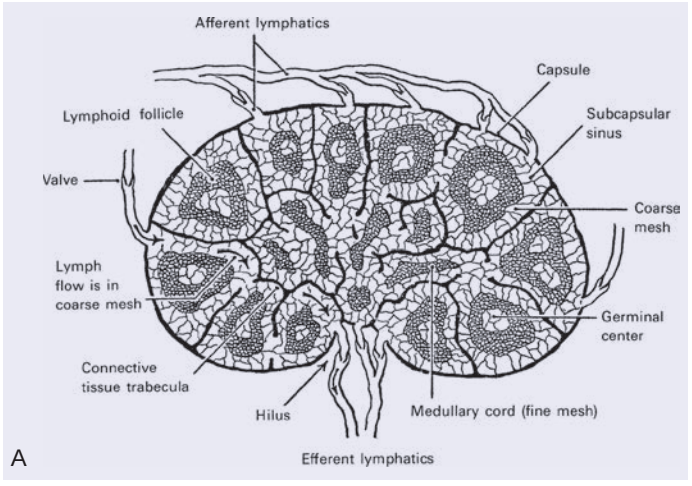
The chemokines CCL12 and CCL19, which bind to chemokine receptor CCR7, and the CXCL13, which binds to receptor CXCR5, are important for the colonization of lymphoid organs by T and B lymphocytes and antigen-presenting cells.[114] The enzyme IKK kinase limits gene activation in inflammatory responses, and downregulates signaling by the transcription factor NF-κB. Upon completion of the connective tissue skeleton the first cells which colonize the LN in mice express the $CD4^+CD3^-$ phenotype, and after stimulation with IL-2, differentiate to NK cells, or, depending on the combination of cytokines, will give rise to antigen-presenting cells. The precursors of these cells are $CD45^+/CD4^+/CD3^-$ and IL7 R^+ residing in the liver.[116]

Their development requires the function of the *RORC* gene[117] as well as the *Id2* gene, which regulates LN and PP development in mice.[118] Development of LNs depends also on signaling from TNFSF11, known also as RANKL or TRANCE,[119] a member of the TNF family of cytokines. This protein is involved in the development of secondary lymphoid organs and regulation of homeostasis of the immune system. Mice deficient in Trance lack LNs (although the PPs are normal), and the development of the bone marrow is defective because of the absence of osteoclasts.

Another genetic defect of the development of the primary lymphoid organs is alymphoplasia, (aly/aly),[120] and mice with this defect have a mutation in nuclear factor-kappa B inducing kinase *Nik*, now known as *Map3k14*. The *Map3k14* mutation causes disruption of the architecture of the thymus, affecting the TECs[121] and aly/aly mice show decreased numbers of $CD25^+$ $CD4^+$ T cells in the spleen.[122] Mutation of the alymphoplasia, ("aly" or *Map3k14*) gene results in the complete absence of LNs and PPs and well-defined lymphoid follicles in the spleen. Development of lymphoid follicles rich in B cells requires the function of the B-lymphocyte chemoattractant BLC (CXCL13) and its receptor CXCR5, which stimulate homing of B lymphocytes to the follicles. BLC induces upregulation of lymphotoxin alpha-1 beta-2, which promotes follicular DC development and BLC expression, establishing a positive feedback loop.

Histology

The LNs are ovoid structures ranging in size from a few millimeters to more than a centimeter. They are particularly common at the base of extremities, in the retroperitoneum, the mediastinum, and along blood vessels. A fibrous capsule surrounds the LN, and trabeculae penetrate the parenchyma, forming a supporting meshwork, while blood vessels enter and leave the LN through the hilum. Histologically, two regions can be distinguished, a peripheral cortex and a central medulla. The cortex is subdivided into the superficial cortex, located immediately beneath the capsule, and the deep cortex or paracortex, which is located toward the center of the node (Fig. 11.10). The function of the LN is best understood by considering the reticulum and the cellular compartment.



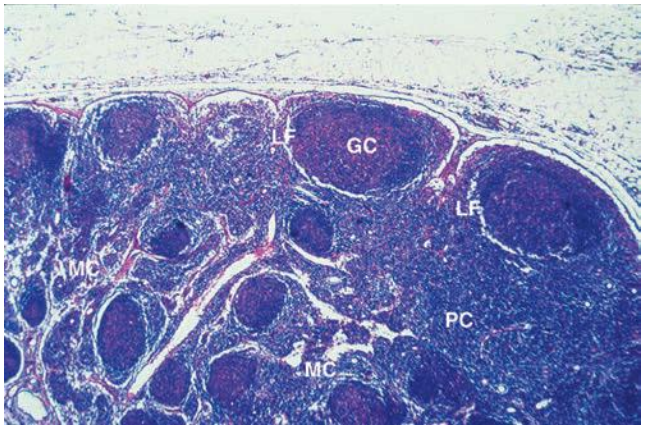


FIGURE 11.10. Lymph node. A: Drawing of a lymph node. **B:** Cross section of a normal lymph node. GC, germinal centers; LF, lymphocytic follicles; MC, medullary cords; PC, paracortical lymphoid areas.

FIGURE 11.11. Ultrastructure of a lymph node. The area in the center and to the right is occupied by dense lymphoid tissue with many lymphoid cells. It is separated from the sinus (*upper area, left, and below*) by flat endothelial cells lining the sinus (*s*), bulky reticular cells (*R*) bordering the dense lymphoid tissue, and collagenous fibers (*c*) between the two cellular layers. *Arrows* indicate collagenous fibers traversing the dense lymphoid tissue. Cap, blood capillary. (From Clark SL Jr. The reticulum of lymph nodes in mice studied with the electron microscope. Am J Anat 1962;110:217, with permission.)

Reticulum

The basic framework of the LN is composed of trabeculae made of bundles of collagen and a few elastic fibers.[123,124] This fibrous reticulum is argyrophilic when silver impregnation techniques are applied, forming a closely knit sponge-like framework, with the fibers branching frequently and anastomosing freely with each other. The fibers surround the sinuses and penetrate the dense lymphatic tissue and are ensheathed by two kinds of cells (Fig. 11.11). On the side bordering the dense lymphoid tissue, the fibrous reticulum is covered by thin elongated cells that have been identified as fibroblasts or fibroblastic reticulum cells. They have large nuclei and endoplasmic reticulum in their cytoplasm. Cytoplasmic processes join similar processes of adjacent cells forming a continuous cellular sheath (cellular reticulum), which separates the fibrous reticulum from the dense lymphoid tissue. On the side bordering the sinuses, which are lined by littoral or endothelial cells, the fibrous reticulum is lined by flat endothelial cells with multiple vesicles and fibers which cross the sinuses and divide the lumen into smaller interconnecting compartments (Fig. 11.12).

The fibrous trabeculae provide mechanical support for the sinuses and slow the flow of the lymph, enhancing the opportunities for phagocytosis by macrophages which are present along their course as well as covering the sinus wall. The sinuses which follow the fibrous trabeculae originate from a foramen on the inner wall of the subcapsular sinus where afferent lymphatics terminate. Viewed from this perspective, the reticulum divides the LN into two distinct spaces. One consists of conventional vascular channels, with a rapid flow, facilitating lymphocyte traffic. The other space is lined with fibroblasts, the flow is slow, and the lumen is tightly packed with lymphocytes and other cells.

Cellular interactions of the immune responses take place in this compartment and both communicate through pores in the inner wall of the subcapsular sinus.

Cellular Compartments

The most abundant cells in the LN are the lymphocytes, arranged in clusters known as follicles which occupy the region beneath the capsule known as the cortex. A follicle composed of uniform small lymphocytes is known as the primary follicle and one containing pale, lightly stained, blast-like cells with a euchromatic nucleus in its center is the secondary follicle. The central zone of the secondary follicle is called the germinal center (GC) and is the hallmark of antigenic stimulation. In the secondary follicles, the lymphocytes surrounding the GC constitute the mantle or crescent. The name germinal center was given by Flemming in 1884 because he considered them as "breeding grounds for the generation of lymphocytes."[125] Later Hellman called them "reaction centers," and considered them important in the induction of immunity.[126] In the areas between the follicles the lymphocytes are distributed diffusely (the diffuse cortex), and the region which separates the cortex from the medulla is known as the deep cortex or paracortex, occupied predominantly by tightly packed T lymphocytes. The histologic arrangement of lymphocytes in the LN corresponds to distinct functions performed by separate classes of lymphocytes (Fig. 11.13). The follicles are occupied by B lymphocytes and are sites of intense activity during antibody responses (Chapters 12 and 14).

A: Subcapsular sinus (*SS*) traversed by trabeculae (*arrows*) stretches between the capsule (*Cs*) and the parenchyma (*LP*) (×600). **B:** Medullary sinus (*MS*) with medullary cord (*MC*) and a meshwork of trabeculae (*asterisk*). (×1,900). **C:** Lymphoid parenchyma and the meshwork of trabeculae (*arrows*) separating intercommunicating cavernous spaces normally occupied by lymphocytes (*Ly*). (*left,* ×1,100; *right,* ×1,600). BV, blood vessel. (From Luk SC, Nopajarooysri C, and Simon GT. The architecture of the normal lymph node and hemolymph node. A scanning and transmission electron microscopic study. Lab Invest 1973;29:258, with permission.)

The GC is occupied by two types of lymphoid cells, the centroblasts (noncleaved), which are large activated B lymphocytes, and the centrocytes (cleaved), which are small lymphocytes originating from centroblasts. The centroblasts are located at the bottom of the GC (dark zone), while the centrocytes are located at the upper part (apical zone). The role of the GC in the maturation of the antibody response is discussed in Chapter 12.

The GCs contain a subpopulation of centroblasts which express a phenotype characteristic of Burkitt cells[127] and a subset of $CD4^+$ $CD45RO^+$ $CD57^+$ T cells[128] which belong to the Th-2 subset, important for the initiation of T–B cell interactions in antibody formation. A large number of B lymphocytes die by apoptosis, and are subsequently disposed of by phagocytic macrophages known as tingible body macrophages.

The mantle of the follicle is composed of small lymphocytes that morphologically appear identical, but phenotypically and functionally are heterogeneous. A small number of lymphocytes, not yet antigenically stimulated, are immunologically competent and express both IgM and IgD; and a third population are long-lived memory B cells, which are recirculating and express IgG or IgA. B lymphocytes of the mantle are $CD5^+$ and their relationship to $CD5^+$–B cells is discussed in Chapter 12.

The paracortex and diffuse cortex constitute the T cell compartment of the LN, which undergoes histologic changes during cell-mediated immunity. Sometimes the paracortex contains nodules formed after an immune response, consisting of interdigitating DCs and T cells.[129] The B cells in these clusters are selected in an antigen dependent, MHC restricted fashion and become responsive to soluble, polyclonal helper factors. Cross sections of paracortex stained with special stains show a set of concentric rings, which form barriers or walls separating vascular spaces in between, where the lymph flows (Fig. 11.14). This structure constitutes the paracortical cord,[130] with its center in the high endothelial venule (HEV) (see description later in this section). In the medulla, the cells are arranged in cords (medullary cords) composed of lymphocytes, macrophages, and plasma cells.

Lymphocytes exit the HEV through an interendothelial route and emerge into the perivenular channels (PVCs), which is the space between the abluminal side of the endothelium and the surrounding pericytes. The channels are bounded by pericytes or fibroblastic reticular cells (FRCs), which circumscribe the HEV with at least two layers of overlapping cells. The flow of lymphocytes through the PVCs is rate limiting because the PVC around the HEV is extremely narrow, and lymphocytes must distend the channel to pass through it. As they emerge from the PVCs, the lymphocytes enter a space packed densely with cells known as the corridor. The corridors accommodate two lymphocytes side by side and their walls consist of reticular fibers enclosed by FRCs, which leave narrow spaces surrounding the fibers named the conduit. The corridors allow cellular interactions between slowly

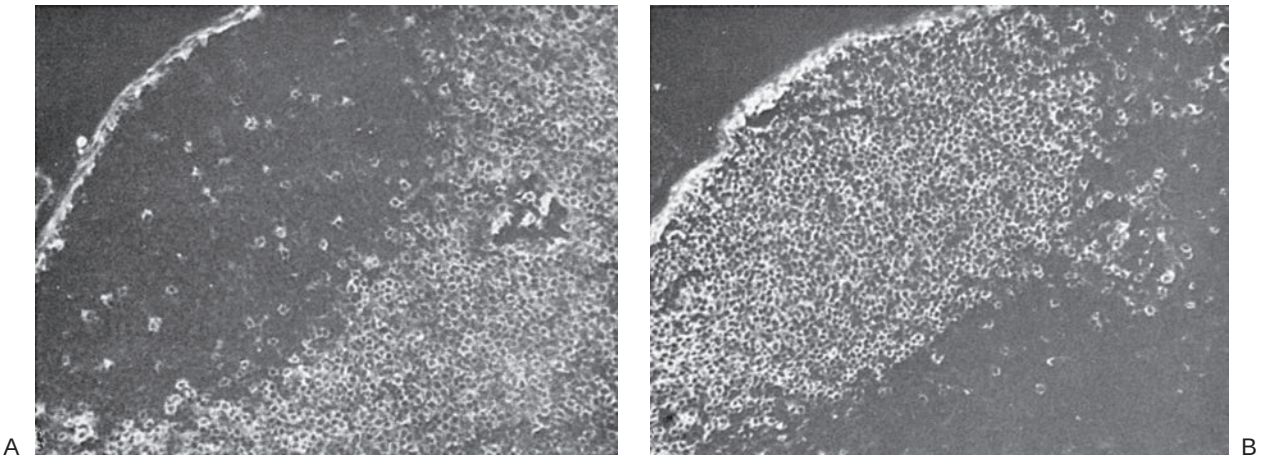

FIGURE 11.13. B– and T cell–dependent areas of the lymph node. A frozen section of a mouse lymph node was examined by immunofluorescence with an anti-immunoglobulin antiserum **(A)** or an antiserum to T cells **(B). A:** Only the follicle fluoresces (B cell–dependent area). **B:** The paracortex fluoresces brightly (T cell–dependent area), whereas the follicle remains dark except for a few scattered fluorescent T cells. These are $CD4^+$ helper T cells, which migrate to the germinal center because they express the chemokine receptor CXCR5 and are attracted to its ligand, BCA-1 chemokine released from cells in the follicle (see Lymphocyte Homing and Recirculation). (From Weissman IL, Weiryke R, Butcher EC, et al. The lymphoid system. Its normal architecture and the potential for understanding the system through the study of lymphoproliferative diseases. Hum Pathol 1978;9:25–45 with permission.)

moving T cells that sample antigens presented by stationary DCs, "shaking hands much like the receiving line at a wedding."[131] The conduit, on the other hand, is a specialized system where fluid carries soluble factors important for the immune functions of the lymphocytes. The corridor space, where flow is slow, is separated from the sinuses, where flow is fast, by the reticular fibers and the endothelium of the sinuses.

Dendritic Cells

The functions of lymphocytes are predicated by their interactions with other cells, such as macrophages and dendritic cells (DCs). Macrophages are found in large numbers in the walls of the sinuses and in the dense lymphoid regions. They remove by phagocytosis within minutes foreign substances which are found in the phagolysosomes of medullary macrophages. Macrophages therefore contribute in an important way to the filtering functions of LNs, since as they capture and destroy infectious agents and foreign material by phagocytosis, they process it for presentation to the T lymphocytes. Antigen presentation is also mediated by the nonphagocytic dendritic cells,[132] a name which vividly describes their morphology, i.e., long arborizing cytoplasmic processes or dendrites (from the Greek dendron which means "tree"), extending for long distances from the cell body.

Within the LN there are two distinct populations of DCs: one resides in the follicles, known as a follicular DC (FDC), and the second in the paracortex, known as interdigitating DC (IDC). Their origins, functions, and cellular associations are distinct, i.e., while FDCs are autochthonous, the IDCs are immigrants arriving from remote parts of the body using the routes of the lymphatic vessels. The FDCs of the follicles have an irregularly shaped nucleus with long, beaded cytoplasmic processes. They are not phagocytic, but retain the captured antigen for prolonged periods, in the form of immune complexes. FDCs therefore function as the arbiters of life or death for emerging centrocytes, based, respectively, on the high or low affinity of their receptor for antigen (see Chapters 12 and 14). They also have been implicated in the generation of memory lymphocytes and the maintenance of antibody production. Two types of FDCs have been described, one with filiform and one with beaded dendrites.[133] The FDCs through adhesion molecules expressed on their surface, i.e., the intercellular adhesion molecule-1 (ICAM1) (CD54) and the vascular cell adhesion molecule-1 (VCAM1) (CD106), interact with their respective "ligands," LFA1 (CD11a/CD18 or L2 integrin) and VLA4 (CD49d)

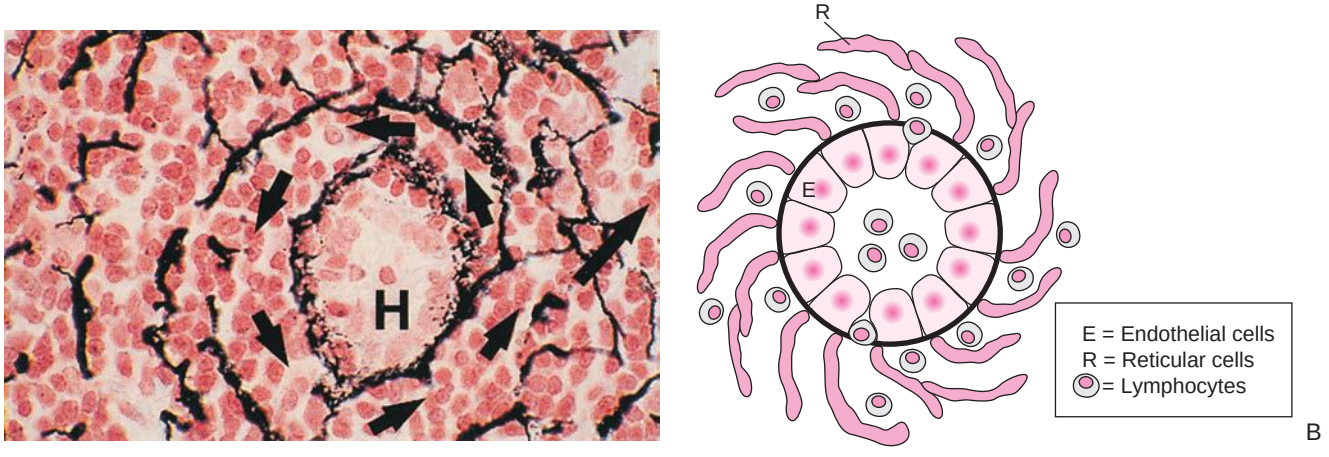

FIGURE 11.14. Cross section of a paracortical cord showing the corridor, outlined by reticular fibers stained by Gomoristain. A: The corridor encircles the high endothelial venule in the center (*H*). **B:** The drawing represents an "idealized" cross section of panel A. (Courtesy of Drs. Gretz, Anderson, and Shaw. From Gretz JE, Anderson AO, Shaw S. Cords, channels, corridors, and conduits: critical architectural elements facilitating cell interactions in the lymph node cortex. Immunol Rev 1997;156:11–24, with permission.)

on the surface of the B cells.[134] The FDC network is disrupted in angioimmunoblastic lymphadenopathy, acquired immunodeficiency syndrome, and Hodgkin lymphoma[135]; and as a result, lack of appropriate handling of foreign antigens is reflected in the clinical consequences for these patients. Electron microscopic studies of the primary follicles detected reticulum cells with little or no evidence of phagocytic activity making contact with neighboring cells by very tight adhesions or desmosomes.[136] These "reticulum cells" are stellate in shape, have long cytoplasmic processes and are probably of mesenchymal origin. The FDC of the germinal center probably originates from the reticulum cells of the primary follicle and is not ensheathed by collagenous fibers like the fibroblastic reticulum cell.

The Interstitial Dendritic Cells (IDC) are located in the paracortex and extend numerous cytoplasmic processes that surround T cells. They are not phagocytic, but carry antigen from the periphery for presentation to T cells in the paracortex of the LNs. Tight junctions between IDC and T lymphocyte have been detected by electron microscopy and become particularly prominent after stimulation with antigens that elicit strong cell-mediated immunity. Their cytoplasm is electron lucent and contains lysosome-like vesicles and tubular structures extending to the periphery of the cell. The IDCs are surrounded by clusters of T cells around the endothelial venules of the paracortical nodules. Antigen-specific T lymphocytes around the B cell follicles, form prominent nodules, known as "composite nodules," and are detected in dermatopathic lymphadenitis, a condition characterized by large numbers of DCs migrating from the areas of inflamed skin. Similar changes are also seen in regional LNs, draining areas of T cell lymphomas involving the skin.

In ontogeny the dendritic cell system develops slowly, and as a result during neonatal life the body depends primarily on innate immunity.[137] The traffic of DCs is regulated by cytokines, i.e., IL1, TNF-α, and chemokines; and regardless of their origin, immature DCs express the chemokine receptor-6 (CCR6), which binds the chemokine macrophage inflammatory protein MIP -3 alpha (CCL20). The CCR6, which is constitutively expressed by keratinocytes, is also the only known receptor for MIP-3 a, a CC chemokine chemotactic for lymphocytes and dendritic cells. The CCR6 is expressed on memory T cells and on B cells, and therefore chemotaxis by MIP-3 alpha is limited to these cells. The defensins are a group of vertebrate antimicrobial peptides (AMPs) with microbicidal and immune regulatory functions. In spite of their conservation across the vertebrate lineage ranging from bony fish to human, the evolutionary origin of these molecules remains unsolved The defensins produced by mucosal membranes after microbial infection bind also to CCR6 and thus attract DCs to submucosal areas.

In response to antigenic stimulation at the initiation of the immune response, vascular growth is necessary in the draining lymph nodes and is reflected in the growth of the endothelial cells of the venules, growth which is concomitantly associated with increased cell entry into the LN. The $CD11c^+$ DCs optimize the microenvironment of the draining lymph node by increasing the levels of vascular endothelial growth factor (VEGF) which induces endothelial cell proliferation.[138,139] Maintenance of lymphatic vessels, as well as the growth and maturation of new vessels, is regulated by the function of tyrosine kinases, which thus may be used as an attractive target for inhibition of lymphangiogenesis in cancers.[140] The cellularity of the lymph nodes and the maintenance of a functional HEV status in adult mice relies largely on lymphotoxin-beta (LT-beta) receptor signaling, which may be reduced by a blockade of the receptor in adult mice.[141] Another factor which influences the cellularity of the lymph node is the movement of small lymphocytes across the postcapillary venules. This movement modifies the structure of the endothelium, evidenced by intravenously injected small thymocytes which trigger migration of small numbers of lymphocytes.[142] The CD40–CD40 ligand may also play a role for their emigration.

Detached DCs downregulate CCR6 and upregulate chemokine receptor CCR7, known to regulate homing as well as retention of T cells, which allows the now mobile DCs to move toward the lymphatic vessels in response to its ligand SLC.

The barrier to their migration, imposed by the basement membrane of the skin (collagen IV), is brought down by the matrix metalloproteinase-9, released by DCs with specificity to collagen IV. DCs cross the abluminal side of the lymphatic vessels, probably with the involvement of P-glycoprotein, and eventually enter LNs. In the lymphatic vessels, they are known as veiled cells because of their morphology (i.e., large lamellipodia veils), which like sails propel them forward. DCs are divided into different subsets based on their biologic functions, with plasmacytoid DCs (pDCs) and conventional DCs (cDCs) being two major populations. They both derive from bone marrow precursors of myeloid- or lymphoid-origin and enter the LN from the afferent lymphatic vessel into the subcapsular sinus to reach the T cell areas. The CCL21 is the ligand for CCR7 cells and regulates homing to, as well as retention of, T cells in the LNs. The CCL21 binds to the surface of DCs via its heparin-binding domain, which explains why T cells leave LNs more rapidly in the absence of DCs.

These data suggest that DCs attracted by SLC and MIP-3α (or ELC), both of them ligands of the CCR7 receptor, regulate T cell homeostasis in LNs.[143] In the T cell areas, they are known as IDCs, as their elaborate long cytoplasmic processes interdigitate between T cells. IDCs present to T cells the antigens they have captured in the periphery, initiating an immune response (see Chapter 14). The lymphatic vascular system plays an important role in the regulation of tissue fluid homeostasis, immune surveillance, and growth and maturation of new vessels, as well as maintenance of existing lymphatic vessels, the functions of which are regulated by tyrosine kinases.

Growth factors of the vascular endothelial cell family (VEGF) control lymphangiogenesis and activate VEGF-specific receptors, of which VEGFR3 (FLT4), VEGFC, and VEGFD have been implicated in the regulation of lymphatic development.

Both are processed after synthesis and form mature dimers of the VEGF domain. Both bind with high affinity to VEGFR2 and VEGFR3 expressed on endothelial cells. The VEGFR3 is a receptor tyrosine kinase with seven extracellular Ig-like domains and a cytoplasmic tyrosine kinase domain.[140] The growth of the endothelial cells of the high endothelial venules is regulated by VEGF, secreted by $CD11c^+$ dendritic cells,[139] and optimizes the microenvironment for the immune response. VEGF binds to VEGF receptors on endothelial cells, triggering the tyrosine kinase pathway leading to angiogenesis. Lymph node endothelial cell proliferation is dependent on VEGF, and DCs are associated with increased lymph node VEGF levels. DC-induced endothelial cell proliferation and increased VEGF levels are mediated by DC-induced recruitment of blood-borne cells. Vascular growth in the draining lymph node includes the growth of endothelial cells in the high endothelial venules associated with increased entry of cells into the lymph node. Existing evidence suggests that the endothelial cell in the draining lymph node is induced by DCs as part of a program that optimizes the microenvironment for the ensuing immune response.

The importance of the lymphatic vessels in fluid and cellular homeostasis provides opportunities for developing inhibitors to target tyrosine kinases and thus affect lymphatic vessel functions or even lymphangiogenesis in the chemotherapy of malignancies. Afferent lymphatics pierce the capsule and empty into a subcapsular sinus, which gives rise to cortical sinuses and often runs along the trabeculae through the cortex to the medulla. At this point they become medullary sinuses which eventually become the efferent lymphatic vessels that leave the LN at the hilum. The artery enters the LN at the hilum, gives rise to arterioles that reach the cortex along the trabeculae and finally split into a rich network of capillaries. The capillaries empty into venules that

extend from the cortex to the medullary cords and eventually exit from the hilum as veins. The venules which give rise to capillaries possess unique endothelial cells that are tall and cuboidal and therefore contrast with the endothelial linings of other venules that usually are low or flat. The HEVs (Figs. 11.15 and 11.16) are the sites of lymphocyte crossing from the blood into the lymphatic circulation and homing to the paracortex, which results in marked reduction of the cellularity of the lymph node.

Lymphotoxin signaling, which controls the expression of GleNAc-6-0 sulfotransferase-1 and -2, binds to the lymphotoxin-B receptor and generates signals required for the homeostatic control of HEV differentiation and function.[141] The LT, through its LT receptor, plays crucial roles in building and maintaining the architecture of lymphoid organs and ensures an adapted immune response against invading pathogens. Induction of inhibitors, such as antagonist antibodies or decoy receptors, may be used in chronic inflammation, autoimmunity, cell death, or cancer, i.e., disorders that occur when the LT/LTR system malfunctions. Two types of high endothelial cells are distinguished, one having abundant cytoplasm, and their luminal surface is covered by a coat of filamentous and granular material 1.5 nm in thickness. By electron microscopy, on the basis of the content of their polyribosomes, one cell is lighter and one darker and intensely pyroninophilic. Their cytoplasm contains numerous microtubules which radiate from the centriole and multiple dense bodies which probably are related to lysosomes and function as storage sites for glycoproteins used for the formation of the cellular coat. A striking morphologic feature of these cells is their large Golgi complex with many vesicles which are associated with actively secreting cells not seen in endothelial cells. Indeed, these cells secrete chemokines, which direct the transendothelial migration of lymphocytes in HEVs (see section Lymphocyte Homing and Recirculation). Their bulky nucleus protrudes into the lumen and contains a well-developed reticulated nucleolus, both characteristics of a metabolically highly active cell. Acid hydrolase activity and nonspecific esterases that are not present in other endothelia have been detected in these cells, as well as a peculiar ability to switch to anaerobic metabolism.

The metabolic activity of the endothelial cells is influenced by the number of circulating T lymphocytes. In congenitally athymic mice or in normal mice following neonatal thymectomy or chronic thoracic duct drainage, i.e., conditions with no lymphocyte migration through the HEV wall, the endothelium is flat and has lost its pyroninophilia,[142] but infusion of lymphocytes reconstitutes the normal morphologic appearance of the HEV. Some evidence also has implicated the dendritic cells as playing a regulatory role in determining the morphology and metabolic activity of the endothelial cells.[143]

The HEVs are surrounded by layers of sheaths that derive from cytoplasmic plates of reticular cells linked to the fibrous reticulum of the LN. These sheaths may regulate the passage of lymphocytes to the LN while limiting fluid leakage and providing vascular support (Fig. 11.14B). When Marchesi and Gowans[144] originally identified the HEVs as the site for lymphocyte migration, they thought that lymphocytes cross the HEV wall by penetrating the cytoplasm of the high endothelial cells. This crossing is now recognized as an artifact because all lymphocytes that appeared on electron microscopic sections to be surrounded by endothelial cells were in fact outside of these cells when evaluated with tracer studies. Thus the lymphocytes migrate across the HEV wall by insinuating themselves between endothelial cells.[145,146] The interactions of lymphocytes and the HEV during homing and recirculation are described in the section Transendothelial Migration.

Morphologic Changes during the Immune Response

Antigens enter the LN via the afferent lymphatics, which empty into the subcapsular sinus, percolating through the parenchyma. They are deposited in two areas of the LN, the medulla[147] and the cortex, and are associated with the membranes of FDCs.[148]

Antibody facilitates follicular localization since intense proliferative activity is observed in the center of the follicles after immunization and large pyroninophilic cells are seen in the GCs of draining LNs within 72 hours.[149] These cells have been given various names, such as immunoblasts, a term introduced

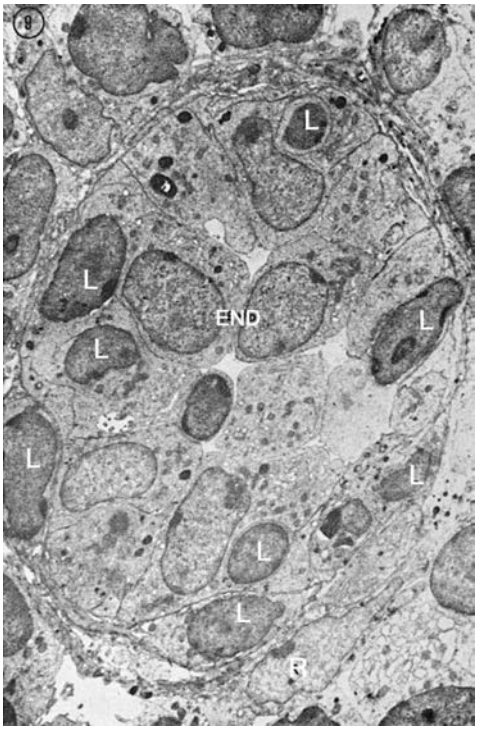

FIGURE 11.15. A postcapillary venule is practically occluded by tall endothelial cells *(End)*. Some lymphocytes (*L*) are crossing the wall of the high endothelial venule and enter the lymph node. The wall is surrounded by reticular cells (*R*) (×4,500). (From Clark SJL Jr. The reticulum of lymph nodes in mice studied with the electron microscope. Am J Anat 1962;110:217, with permission.)

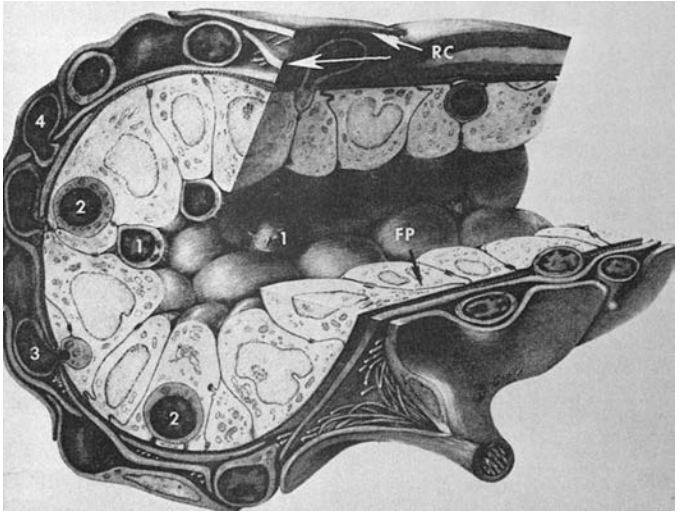

FIGURE 11.16. Lymphocytes crossing the high endothelial venule (HEV). Lymphocyte migration is shown in successive stages (*1–4*). After attachment to the luminal surface of an endothelial cell (*1*), the lymphocytes insinuate between endothelial cells (*2*) and cross the basement membrane (*3*) and a sheath of reticular cells (*RC*) surrounding the HEV (*4*). The endothelial cells are attached to the neighboring cells by junctional complexes and to the perivascular sheaths by foot processes (*FP*). (From Anderson AO, Anderson ND. Lymphocyte emigration from high endothelial venules in rat lymph nodes. Immunology 1976;31:455, with permission.)

originally by Dameshek,[150] or germinoblasts. In order to avoid confusion with gonadal cells, however, they were renamed centroblasts. The blast is a large cell (larger than 10 μm) and has a nucleus with loose chromatin and a giant reticulated nucleolus that may occupy as much as one half of the nuclear area. The Golgi apparatus is moderately developed and contains many free polyribosomes but only few cisternae of endoplasmic reticulum. As the endoplasmic reticulum becomes more abundant, these cells are known as plasmablasts.[151] At this stage their nucleus possesses clumps of heterochromatin and a moderate-sized nucleolus. Free polyribosomes are still present and the cisternae of the endoplasmic reticulum do not fill the cytoplasm entirely.

By day five there is an increase of the number of tingible body macrophages, i.e., macrophages which contain engulfed apoptotic nuclei (Korper of Flemming) and have phagocytosed nuclear debris of lymphocytes (the graveyard theory).[152] Because of their intense basophilic cytoplasm, the immunoblasts (or centroblasts) demarcate a histologic area known as the dark zone (also known as the basal or lower zone because it is located in the area of the GC that is toward the interior of the LN).[153] As they become more mature (immunocytes, centrocytes), they occupy the light zone, also called the upper zone because it is located above the dark zone toward the capsule. Further differentiation gives rise to plasma cells, which are detected in small numbers in the GCs. Kinetic studies with H-3 thymidine, which allows studies of lymphocyte turnover, provid evidence of the origin of mature lymphocytes (centrocytes) from GC immature cells centroblasts) which then disseminate beyond the GC confines.[154]

The formation of GCs depends on T lymphocyte function[155]; The GCs become the home of B cell blasts which display a unique phenotype characterized by lack of membrane IgD.

The role therefore of T lymphocyte in the life of the B lymphocyte stretches from the early stages of building the GCs to helping later in antibody formation by mature B cells. The significance of the GC reaction is discussed in Chapter 14. Antigenic stimulation drives the differentiation of B cells into plasma cells,[156] seen in the medullary cords by day 3 or 4 after immunization, as well as the proliferative activity reflected in the increase of pyroninophilic blast cells in the paracortex.

Lymph Node Functions

The LNs are dynamic structures, with their cells being constantly on the move, and their functions may be considered in two broad categories: as efficient mechanical filters due to an exquisite arrangement of a reticular meshwork, and as masters of phagocytosis with macrophages strategically located in the sinuses. Failure of filtration and phagocytic functions by the LN results in loss of control of infectious agents and spread of the disease.

The immune function of the LNs is carried out by lymphocytes, which activate humoral and cell-mediated immunity, following complex interactions between dendritic cells or macrophages, as antigen-presenting cells and T or B cells. To this effect LNs provide a suitable microenvironment, that includes the HEV, which controls lymphocyte homing and recirculation, stromal cells, and distinct domains occupied by IDC and FDC in the cortex. The LNs therefore are important sites for activation of the effector mechanisms of immunity, i.e., humoral and cell-mediated immune responses. The effector cells of both responses are exported to remote sites for effective control of the infection.

Spleen

The orphan homeobox gene-11 *HOX11*, now known as *TLX1*, regulates expression of the spleen,[157] as shown in *Tlx1* mice, which lack the spleen while other secondary lymphoid organs develop normally. Although the spleen is considered a secondary lymphoid organ, it serves several other functions unrelated to the immune system and affects all blood cells throughout their life span.[158]

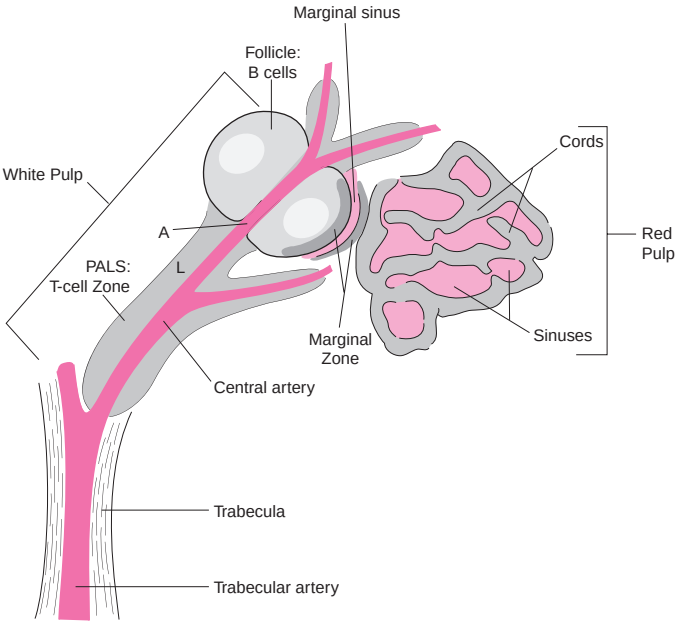

FIGURE 11.17. Drawing of the splenic structure and circulation. PALS, periarteriolar lymphatic sheath.

It provides the microenvironment for the final differentiation of reticulocytes, platelets, and monocytes, and is the reservoir for erythrocytes and granulocytes and removes aged or deformed red blood cells. The spleen of human adults has a unique reservoir of multilineage adult stem cells, that express the developmental transcription factor *TLX1*. In contrast to hematopoietic stem cells, *TLX1* spleen stem cells hold potentially broader therapeutic applications because they are less lineage restricted.

The spleen is covered by a connective tissue capsule which is several millimeters thick,[159] and in humans it contains only a few muscle cells and is not capable of marked contractions. The internal surface of the capsule is the point of origin of an extensive network of trabeculae that divides the organ into communicating compartments, with a sponge-like appearance and spaces containing the parenchyma, or pulp tissue. The capsule is indented on the medial surface where the blood vessels, lymphatics, and nerves enter and leave. Histologic studies show two kinds of parenchyma: one is stained dark blue to purple because of the predominance of small lymphocytes (the white pulp), and the second is red because of the predominance of blood-filled sinuses (the red pulp) (Figs. 11.17 and 11.18).

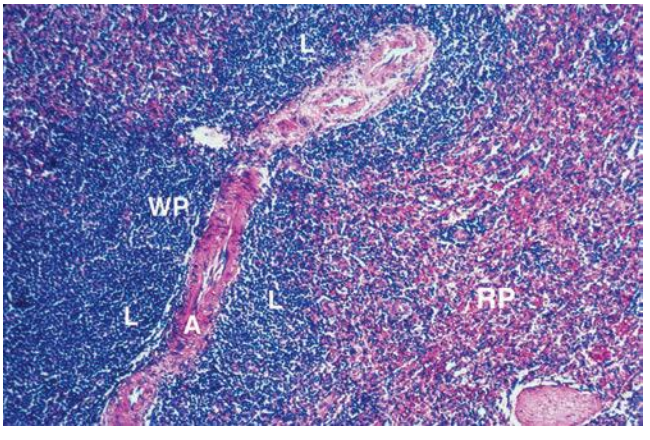

FIGURE 11.18. Section of the spleen. White pulp (*WP*): Lymphocytes (*L*) packed around an arteriole (*A*). Red pulp (*RP*) surrounds the white pulp and consists mainly of sinuses, the cords, and cordal spaces.

White Pulp

The white pulp is the main lymphatic tissue of the spleen and surrounds the blood vessels (Figs. 11.19 and 11.20); it is composed of the supporting reticulum, the free cells, and the blood vessels. The splenic artery branches into trabecular arteries (central arteries), muscular vessels that can alter blood flow by their contraction and relaxation, which follow the trabeculae and periodically give off branches (Fig. 11.20). The reticulum is a scaffolding made of reticular fibers secreted from spindle shaped reticular cells, with conspicuous microfilaments in their cytoplasm, a prominent endoplasmic reticulum, and a nucleus which contains finely dispersed chromatin. It provides support for free cells and blood vessels, runs circumferentially around the central artery, and becomes particularly pronounced in the periphery of the white pulp, where the reticular cells extend concentric sheets of membranes[160,161] (Fig. 11.19A). The central artery gives off secondary branches that radiate through the white pulp with different destinations, some terminating before they reach the edges of the white pulp, while others terminate in the marginal zone (MZ) or extend even further into the red pulp. In the human spleen, some branches curve back from the red pulp to form a delicate network around lymphatic follicles located at the periphery of the white pulp.

The predominant cell type of the white pulp is the lymphocyte, which occupies the interstices of the sponge-like meshwork of the reticulum, forming two histologically distinct arrangements. The central artery is surrounded by tightly packed lymphocytes which follow the artery, becoming eventually a diffuse thin sheath as the artery divides into small arterioles known as the periarteriolar lymphatic sheath (PALS) (Figs. 11.18 and 11.19A). The PALS is divided into the central and peripheral areas, the former consisting of tightly packed T lymphocytes and interdigitating cells, seen in the T dependent area, or paracortex of the LN. The PALS in the human spleen is not continuous, and at intervals the arteriole runs across a follicle but subsequently re-enters the T cell region,[162] where T lymphocytes usually are found in intimate contact with the interdigitating cells. The periphery of the PALS lacks the interdigitating cells and contains B and T lymphocyte collections known as follicles and blast-like cells in the germinal center (GC) of the secondary follicle.

Small lymphocytes surrounding the GCs constitute the mantle zone which separates the MZ from the GC, which histologically is divided into a dark zone, occupied by large pyroninophilic blasts with high mitotic activity, and a light zone with more mature cells.

The light zone, which faces the MZ, has an abundance of characteristic FDCs that are present also in the nodules of the LN.

They are large with unusually shaped nuclei, poor in heterochromatin, and their cytoplasmic extensions are thin sheets rather than dendrites. The FDCs are not phagocytic but retain foreign substances on their membranes for long periods. No FDC

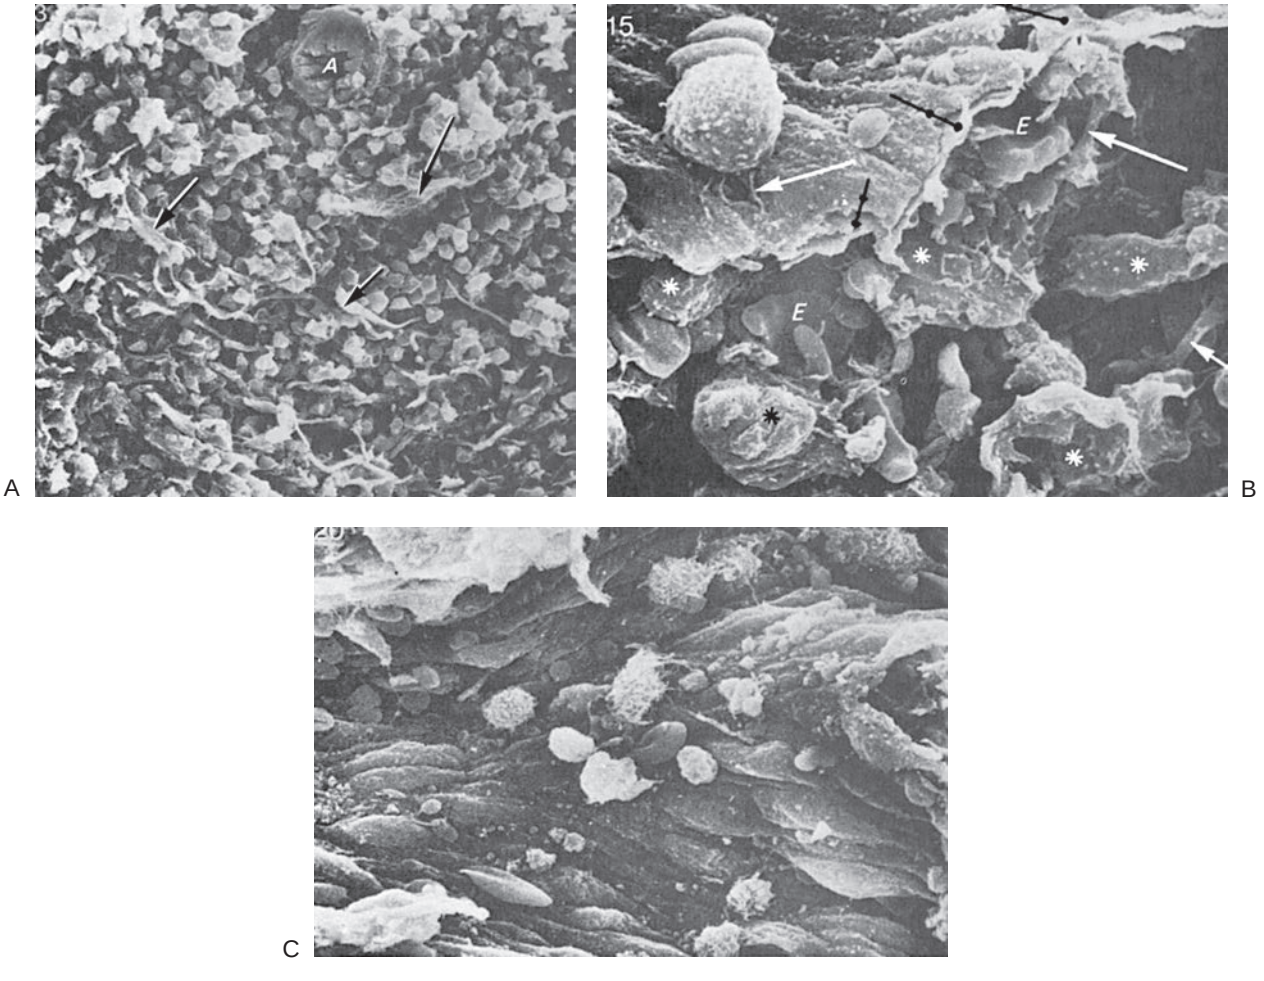

FIGURE 11.19. Ultrastructure of the spleen by scanning electron microscopy. A: Periarteriolar lymphatic sheath with a central artery (*A*). Tightly packed lymphocytes lie between fibers and reticular cells (*arrows*) that run circumferentially around the artery. **B:** Lumen of a sinus at upper left has elongated endothelial lining cells. The cord below contains bulky reticular cells (*asterisks*) and fibers (*white arrows*). Some erythrocytes (*E*) are visible in the cordal spaces. The large cell in the lumen of the sinus is probably a macrophage with several thin cytoplasmic strands (*arrow*). The beaded black lines at the cut edge of the sinus identify its adventitial layer (terminal bead) and its endothelial layer (subterminal bead). **C:** Lumen of a sinus that bifurcates to the right. The elongated endothelial cells are in close apposition without any visible gaps. (From Weiss L. A scanning electron microscopic study of the spleen. Blood 1974;43:665, with permission.)

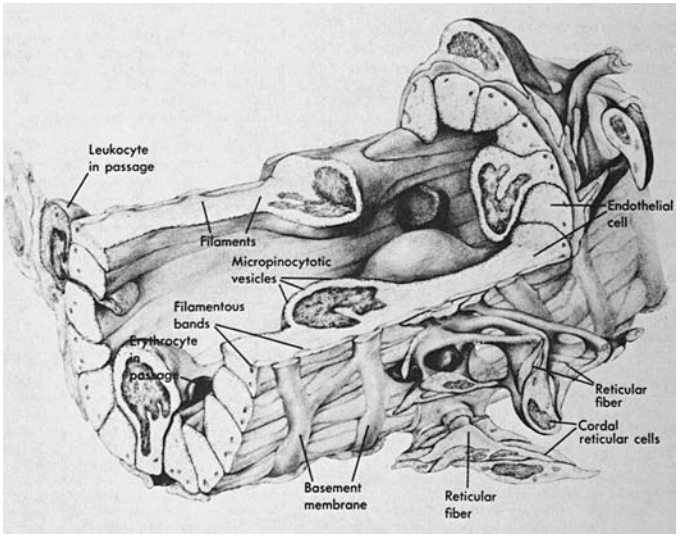

FIGURE 11.20. A human splenic sinus. The elongated lining cells run parallel to the axis of the sinus. The vessel is supported by cordal reticular cells and fibers and a fenestrated basement membrane consisting of heavy fibrous strands running circumferentially and lighter longitudinal strands. Thus, the circular bands, like the hoops of a barrel, hold the endothelial cells (staves of the barrel) tightly. (From Weiss L. The spleen. In: Weiss L, ed. Cell and tissue biology. Baltimore, MD: Urban and Schwarzenberg, 1988, with permission.)

is located in the central section of PALS, and their presence in the mantle of the nodules, facing the MZ, places them in a strategic location to capture foreign substances entering the spleen. Foreign antigens are localized first in the MZ and then cross the marginal sinus to lodge in the mantle of the nodules, forming a crescentic cap. The nodules of the peripheral section of PALS constitute the B-dependent regions of the spleen. The segregation of the two major lymphocyte populations within distinct settlements of the secondary lymphoid organs seems to be determined by the nature of their underlying neighbors.

Marginal Zone

MZ is the part of the parenchyma that lies between the white pulp and red pulp (Figs. 11.17 and 11.18). This area of the spleen comes in contact with large quantities of circulating blood as many arterial vessels terminate in this region and some of them, with funnel-shaped orifices, empty their contents into the interstices of the MZ, which, unlike the red pulp, has no sinuses. In rodents a marginal sinus separates the MZ from the white pulp, but the human spleen lacks a marginal sinus. Some authors suggest that the marginal sinus may be functionally equivalent to the postcapillary venule, which in rodents is the site at which lymphocytes enter the splenic parenchyma.

The lymphocytes entering the marginal sinus have multiple microvilli with which they establish contacts with reticular cells as they find their way toward their microenvironments, and once they reach their destination the microvilli disappear. The marginal sinus does not have the tall endothelial cells that direct traffic in the LNs and some authors speculate that this function is performed by splenic macrophages located in the marginal sinus. These cells have distinct phagocytic and morphologic properties which distinguish them from macrophages in other locations of the spleen, including the ability to bind lymphocytes.[163]

Marginal Zone Lymphocytes: Functions and Lymphomas

In the human spleen, the MZ contains clusters of B cells and macrophages in the vicinity of the periphery of the white pulp. These cells differ from naive B cells in morphology, phenotype, and genotype, i.e., they are large with pale cytoplasm and an irregular nucleus; they express IgD–, CD5–, CD10–, and CD23–; and they have mutated their Ig-V genes.[164,165] On the basis of their VH gene rearrangements, the MZ B cells are heterogeneous memory cells; and in terms of response to antigens they are divided into three categories: one B cell responds to T cell–dependent antigens and two respond to T cell–independent antigens such as lipopolysaccharide (type-1)[166] or bacterial capsular polysaccharides (type-2).[164] The B cells originate from precursors in the bone marrow and settle in the lymphoid organs, where they mature, giving rise to two morphologically and functionally distinct subsets: (a) follicular B cells and (b) MZ B cells.[167] The follicular B cells are small in size, express low levels of IgM but high levels of IgD, and recirculate; while the B cells of the MZ of the spleen are of medium size, with high expression of IgM and low IgD.

On the basis of cell-surface markers, maturation of B cells in the periphery proceeds through three transitional stages. The MZ B cells arise from an intermediate $CD23^{+}$ stage[168] and respond rapidly to certain antigens brought by blood.[167] Activation of B cells is triggered by the signaling molecule Notch 2, which preferentially is expressed at the mature stage.[169] Notch 2 is preferentially expressed in mature B cells and is indispensable for marginal zone B lineage development, migration,[170] and localization in the marginal zone.[171] An intriguing concept for the development of MZ B cells suggests that their development depends on signal strength from self antigens[172] and is independent of exogenous antigens.[173]

Some B cells in lymph nodes have a similar phenotype and morphology as the MZ B cells and are known as nodal-MZ B cells or monocytoid B cells. The splenic MZ B cells and nodal B cells rearrange the same VH-3 family of genes, suggesting that both of these B cell populations are closely related.[174] There is other evidence, however, that the monocytoid B cells are distinct from the MZ B cells on the basis of their phenotype, i.e., lack of IgM and IgD expression from most of them, and polyclonal Ig gene rearrangements with lack of somatic mutations.[175] However, the occurrence of hypermutation in the MZ B cells has been challenged, because the activation-induced cytidine deaminase (AID) (see Chapter 14), the enzyme that is essential for somatic hypermutation and class-switch recombination, is not detected in MZ B cells.[176] The splenic MZ B cell subpopulation may mutate their Ig genes as a result of recognition of self-lipids presented by the CD1 of NK T cells.[177,178] Another intriguing finding which may shed some light on the origin and nature of the MZ B cells is that the BCR of the MZ B cells is "polyreactive",[178] but these results from experimental animals may not necessarily apply to humans.[179] The CD27 B cells of human spleens are detected in the periphery of the follicles corresponding to the mantle, but these cells are not present exclusively in the spleen, and most likely CD27 expression is associated with memory B cells.[180]

B-cell neoplasms with cells strikingly similar in morphologic, phenotypic, and cytogenetic characteristics have been detected in different anatomic locations, i.e., spleen, lymph nodes, and extranodal locations.[181,182] Variations detected by mutational analysis are considered as evidence that these lymphomas originate from different subsets of marginal cells.[183] More recent studies of MZ B cell lymphomas utilizing complementary DNA microarray analysis identified the expression of three genes which may distinguish splenic MZ lymphoma, *FOXK2*, *SETX*, and *CD40*.[184] Furthermore, the evidence that mucosal-associated lymphomas preferentially disseminate to the spleen is considered evidence of the relationship of these cells to the splenic MZ cell.[185]

Red Pulp

As seen in histologic sections the red pulp consists of sinuses and cords,[186,187] which are composed of a meshwork of reticular fibers and cells. The reticular cells are large, extend membranous processes into the interstices (Figs. 11.17, 11.18, and 11.19),

and contact those of adjacent cells, forming cavernous spaces. The large reticular cell sheets have microfilaments that endow them with the capacity to retract and extend, and thus determine the available space and regulate blood flow. These cordal spaces receive blood directly from the arterial vessels, as the central artery gives off many branches which terminate in slender, straight, nonanastomosing arterioles that enter the cords of the red pulp but not the sinuses. Some of the arterioles divide into arterial capillaries which are enveloped by a sheath of phagocytic cells. These sheaths were called ellipsoids, but now are called periarterial macrophage sheaths, which in the human spleen is not well developed. The periarterial macrophage sheath functions as a major source of phagocytic cells and also may regulate blood flow. The cords represent a unique vascular space, with regulation by the cordal reticular cells of its flow, which removes old or damaged red cells.

The red pulp sinuses are tortuous vascular channels 35 to 40 μm in diameter, lined with an endothelium consisting of elongated tapered cells arranged with their long axes parallel to that of the vessel (Fig. 11.19B,C).

The endothelial cells have three distinctive morphologic features: (a) micropinocytotic vesicles, (b) loosely organized cytoplasmic filaments, and (c) tightly organized filaments along the basal side, which provide the cell with rigidity and contractility. Slit-like gaps between the endothelial cells allow the passage of blood cells from the cordal spaces into the lumen; but the slits never exceed 0.2 to 0.5 μm in width, which cannot be enlarged since the intra-endothelial filaments run parallel to the slits and restrict their opening.[188] Although normal red blood cells are flexible and capable of passing through the slits, the presence of rigid inclusions, such as Heinz bodies, interferes with their passage.

The basement membrane is not continuous, but consists of a network of reticular fibers that resemble a roll of chicken wire. Fibers running circumferentially (annular fibers) are thick and are joined by thinner fibers that run longitudinally (Fig. 11.20). The network is connected to the reticulum of the cords and some reticular cells are in close contact with the wall of the sinuses. Through the fenestrations of this network blood cells pass from the cords to the sinuses. Adventitial cells cover the sinus wall from the cordal side and contribute to blood flow regulation by covering or exposing the interendothelial slits.

The short description of the splenic circulation emphasizes its complexity as well as its importance and explains the fact that it has been the subject of debate for a long time. It is believed that the circulation is closed, with endothelial continuity from the arteries to the sinuses and veins. Others believe that the circulation is open, i.e., the arteries empty their blood into the MZ and red pulp cords, and the blood percolates through the cavernous spaces of the cords and finally crosses the wall of the sinuses through the interendothelial slits.

According to this view, although the circulation is anatomically open, it is functionally closed. This issue has not been resolved, but it is likely that both types of pathways exist. In keeping with this last hypothesis is the finding that the largest amount of blood passes through the spleen as rapidly as it does through other organs, but a smaller portion of blood has a considerably slower rate of flow.

Morphologic Changes of the Immune Response

Within 24 hours of antigenic stimulation, an accumulation of polymorphonuclear leukocytes is detected in the red pulp,[151] and large pyroninophilic blast cells are first seen 3 to 4 days later in the PALS, which then migrate toward the periphery.

Proplasmacytes, which is the next stage of maturation, have an abundant endoplasmic reticulum and a few remaining free ribosomes, findings that differentiate this stage of development from mature plasma cells. They eventually reach the cords of the red pulp and are found even within the sinuses. When viewed by electron microscopy, the most immature blasts, known as immunoblasts or plasmablasts, have a large nucleus, a prominent nucleolus, and an increase in the number of ribosomes; but no organized endoplasmic reticulum is evident and they mature to plasma cells in GCs which are well developed by the end of the first week.

Immunologic Functions of the Spleen

The two most important immunologic functions of the spleen are phagocytosis and the development of the effector mechanisms of humoral and cell-mediated immunity.[189]

The labyrinthine structure of the spleen is ideal for the effective removal of invading microorganisms by phagocytes that come to reside in the spaces of the reticulum.

Phagocytosis is facilitated by opsonization, i.e., coating of bacteria with complement, antibody, or both. Although the phagocytic function of the spleen is well recognized, its contribution to humoral or cell-mediated immunity in humans has generated considerable controversy.[190,191] Originally it was reported that children who had splenectomy for congenital hemolytic anemia acquired an increased incidence of overwhelming fatal infections, but not all subsequent studies yielded results that confirmed these findings.

Splenectomy for hematologic disorders apparently has far more serious consequences than splenectomy for trauma. The incidence of overwhelming sepsis in the former cases is 24.8% compared to a 1.45% incidence for the latter group.[192] In humans, the loss of the spleen compromises the immune system and its ability to form antibody,[193] and postsplenectomy antibody synthesis by peripheral blood lymphocytes is impaired.[194]

Against the evidence cited above of the importance of the spleen for defense against infections, *Hox11 -/-* mice without spleen have no major defect in antiviral immunity except for some delay in antibody response by 1 to 2 days.[195]

LYMPHOCYTE HOMING AND RECIRCULATION

Homing to Secondary Lymphoid Organs

Migration of leukocytes across the vascular endothelium is a complex multistep process which involves different types of endothelia for different leukocytes, as well as a variety of adhesion molecules. When B and T lymphocytes complete their maturation in the bone marrow and thymus respectively (primary lymphoid organs), they are still naive, i.e., they have not yet encountered antigenic stimulation. The migration patterns of naive lymphocytes differ from those of the activated (or memory) lymphocytes. Naive lymphocytes enter the secondary lymphoid organs (homing) and settle in specific (T-dependent or T-independent) compartments.

Subsequently they use the blood and lymphatic circulation as traffic routes and migrate between secondary lymphoid organs without any specific preference (recirculation).

Antigen-activated or memory lymphocytes migrate specifically to sites where they have encountered antigen. Thus memory T lymphocytes tend to accumulate in extranodal tissues where they have previously been antigenically stimulated. These lymphoid accumulations are sometimes called tertiary lymphoid tissues and are associated with epithelial surfaces such as the gut, respiratory tree, and sites of inflammation in the skin and synovium. In some of these accumulations, however, there are also small numbers of naive lymphocytes.

Homing of lymphocytes to the spleen takes place through blood sinusoids in the MZ, but in regional LNs antigen triggers accumulation of antigen-specific memory T lymphocytes by two fundamentally distinct routes of entry.[196]

The first is by crossing the HEV, primarily followed by the naive lymphocytes; the second is by crossing flat endothelium, a

route followed by the activated T lymphocytes. HEVs are abundant in the T cell–dependent areas of the LN and are used as entry sites for both T and B lymphocytes.[197,198,199,200] HEVs are found in lymph nodes and other extranodal locations, such as PPs, tonsils, adenoids of the pharynx, appendix, and lymphocyte aggregates of the stomach and small intestine. The best HEV marker currently available is a carbohydrate epitope recognized by the monoclonal antibody MECA-79.[201]

Crossing HEVs by lymphocytes involves interaction of leukocytes with endothelia in three steps (a) tethering and rolling, (b) integrin activation and arrest or tight adhesion, and (c) transendothelial migration (Fig. 11.21).

Tethering and Rolling

Blood flow "rolls" the lymphocyte over the endothelial cells, establishing loose and transient contacts with them. This tethering and rolling over the vascular endothelium in the HEV, is mediated by L-selectin (CD62L), previously known as LECAM-1 (Leukocyte-Endothelial Cell Adhesion Molecule 1), LAM-1, SELL, or MEL14. It is expressed on lymphocytes and interacts with its counter-receptor on HEV cells. In order for L-selectin to mediate primary adhesion (i.e., rolling), it must be located on the tips of the microvilli[202,203] of HEV in peripheral LNs. Homing of naive lymphocytes to secondary lymphoid organs or the PPs of the gut requires L-selectin interaction with integrin, but it is not required for activated T lymphocytes which lack expression of L-selectin.[204] The L-selectin is important for lymphocyte adhesion to HEV as shown in gene knockout mice and with antibodies which block lymphocyte migration to LN by 99%.[205]

Rolling by L-selectin requires its linkage to cytoskeletal proteins such as actinin, vinculin, and talin through its carboxy terminal eleven amino acids.[206] This enables leukocytes to reduce speed and sense chemoattractants which activate firm adhesion.

At higher shear the average lifetime of rolling tethers is much longer as a result of the elongation of the microvillus tethers

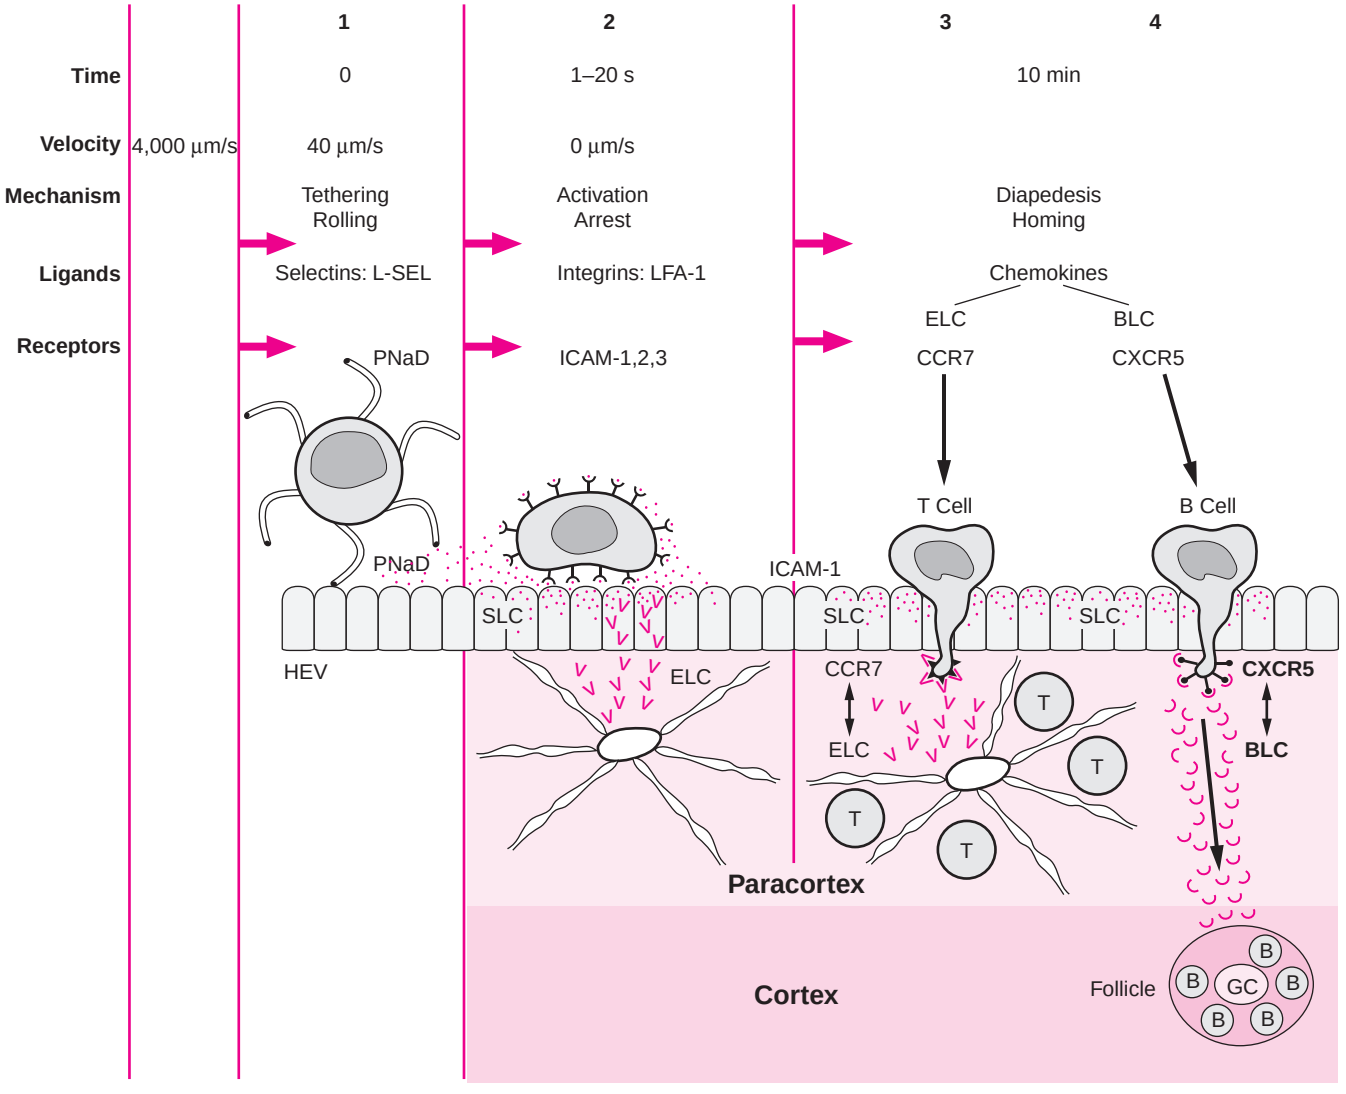

FIGURE 11.21. Homing of T and B lymphocytes to peripheral lymph nodes. 1. Rolling: Lymphocytes entering the high endothelial venule (*HEV*) slow down as a result of interaction of the L-selectin (*L-SEL*) (lymphocytes) with its ligand, the peripheral node addressin (*PNad*) on endothelial cells. **2. Arrest:** Secondary lymphoid tissue chemokine (*SLC*), constitutively produced by HEV cells, activates integrin $\alpha_L\beta_2$ (CD11a/CD18) and tightly adheres lymphocyte to the endothelial surface. **3. Diapedesis:** SLC (produced by HEV cells) and Epstein-Barr virus–induced molecule-1 ligand chemokine (*ELC*) (produced by dendritic cells and trancytosed to the surface) act on appropriate receptors (CCR7) and attract T (stronger) and B (weaker) cells that insinuate themselves through the endothelial cells. **4. Home settling:** Entering the node, T cells settle in the paracortex (ELC production), while B cells and a few antigenically experienced $CD4^+$ T cells move on, being attracted by another chemokine, B-lymphocyte chemoattractant (BLC) (or BCA-1), acting on both of them, expressing the receptor CXCR5 to settle in the follicles. Gc, germinal center; ICAM, intercellular adhesion molecule; INT, integrin.

which stabilize leukocyte rolling over a wide range of shear forces.[207] For efficient rolling the ligand for L-selectin needs to carry three critical structural elements: sialic acid, fucose, and sulfate. Monoclonal antibodies specific for sialyl- 6-sulfate of Lewis X oligosaccharide inhibit almost completely the binding of L-selectin to human HEVs. Examination of the adhesion requirements of the three selectin members has clearly shown that the L-selectin prefers carbohydrate 6-sulfation to tyrosine sulfation, which is the preference of the E-selectin.[208]

Molecules carrying L-selectin–binding saccharides are known as vascular addressins, but some of them are secreted proteins and do not participate in lymphocyte trafficking, like the glycosylation cell adhesion molecule-1 (GlyCAM-1). The lymphocyte trafficking is basically a physiologic multimolecular adhesion cascade, which involves lymphocyte endothelial recognition mediated by the alpha-4 integrins as a "bridge" between selectin and beta-2 integrin, although it may involve only preactivated alpha-4 integrins. At the present time the nature of the macromolecule which carries the epitope detected by the monoclonal antibody MECA79, known as peripheral node addressin (PNad), which defines an HEV-specific carbohydrate epitope, remains elusive.[209,210] Biochemical and genetic evidence implies that, for the synthesis of sulfated glycan moieties, sulfation precedes sialylation, which is followed by 1,3 fucosylation, required for an L-selectin ligand. With targeted deletion of the FucT-VII locus, which encodes an 1,3 fucosyltransferase expressed in HEVs, there is an 80% to 90% reduction of short-term lymphocyte homing. However, some other work suggests that although sulfate on the epitope is required for L-selectin binding, neither sialic acid[211] nor fucose[212] are directly involved in the binding. Sulfate groups are required for optimal L-selectin binding, because if the sialyl Lewis-X (i.e., "sialyl-"-2-3–galactopyranosyl-1-4–*N* acetylglucosamine-"-1-3-fuco-pyranosyl") is modified with sulfate, it generates a critically important L-selectin recognition determinant.

The most important sulfate modification is known as "sialyl 6-sulfo Lewis X," i.e., sialyl Lewis X with sulfation of GlcNAc on the sixth position.[211] Sulfation is catalyzed by a member of the GlcNAc-6-0-sulfotransferases (Glc-N-Ac-6-STs) family, which has five members.[213,214] L-selectin–mediated leukocyte rolling is extremely fast and jerky in nature.[215] This is probably due to endothelial chemokines juxtaposed to endothelial L-selectin ligands.[216] Rolling leukocyte is of a jerky nature probably as a result of detachment of the cell from its binding site followed by binding to another ligand downstream. The endothelial chemokines CCR7 and CXCK5 are G-protein–coupled receptors (GPCRs), or SLC/ELC and BCA-1, respectively. It is hypothesized that clusters of GPCR around L-selectin prevent the association of multiple L-selectin molecules necessary for stabilization of L-selectin contacts.

The sulfated/sialylated-O-linked oligosaccharides recognized by L-selectin are displayed on sialomucin core proteins. One of them is endomucin, which is expressed on HEVs of the lymph nodes but also on endothelial cells of other vessels. One of the sialomucins is endomucin, which is decorated with carbohydrate chains reactive with L-selectin, and its isoform-a is expressed on PNad of HEVs. Appropriately modified by glycotransferases and sulfotransferases, it can function as a ligand for L-selectin.[217,218]

The P-selectin glycoprotein ligand-1 (PSGL-1), a mucin-like glycoprotein detected on various leukocytes, is a ligand for P-selectin, but it also binds to L-selectin and E-selectin.

PSGL-1 is a heavily glycosylated sialomucin expressed on most leukocytes and has dual function, as a selectin ligand for leukocytes rolling on vascular selectins expressed in inflammation, and as a facilitator of resting T cells homing into lymphoid organs.[218]

Flow cytometric analyses show that the endothelial cells from the cremaster muscle bound L-selectin in a PSGL-1–independent manner. These results provide evidence for the existence of an L-selectin ligand distinct from PSGL-1 in inflammation and indicate that such a ligand is expressed on endothelial cells, promoting neutrophil rolling in vivo.

The enzymes fucosyltransferase (FucT)-IV and FucT-VII confer the L-selectin binding activity.[219]

Integrin Activation and Lymphocyte Arrest

In preparation for transendothelial migration, lymphocytes need to adhere firmly to the endothelial cells. Arrest is achieved by activation of LFA-1 (L-2) integrin, which interacts with ICAM1 or ICAM2. On resting lymphocytes the LFA-1 exists in an inactive form; but within less than a second, it is activated by chemokines constitutively expressed on lymphoid tissues ("lymphoid chemokines").[220–222] These are the secondary lymphoid tissue chemokine (SLC) or CCL21,[223,224] and the Epstein-Barr virus–induced molecule-1 ligand chemokine, ELC, or CCL19, also called MIP-3.[225]

SLC induces arrest of naive T cells to ICAM-1 [226] with sixfold higher efficiency for naive than for memory T cells.[227] The arrest is pertussis toxin–sensitive, implying that the signaling mechanism is mediated through G-proteins. The ELC shares the same binding specificity with SLC, but its role is less obvious. ELC transcripts are restricted to nonendothelial cells in the perivascular area of the paracortex,[228] and is brought to the luminal surface of the HEV by transcytosis, where it is able to participate in LFA-1 activation and arrest of the lymphocytes through the same receptor CCR7 as the SLC.[229] Integrin activation and affinity is regulated by conformational changes of their extracellular domains[230] and these changes occur through extension of the genu, followed by separation of the stalks that lead to the high-affinity conformation (see details of integrin structure and activation in Chapter 14).

Transendothelial Migration

SLC induces strong chemotaxis for T cells and to a lesser extent for B cells[223] and their entry to the secondary lymphoid organs, which requires the expression of CCR7, its high-affinity receptor, as shown in mice with *Plt* mutation (paucity of LN T cells).

These mice lack SLC lymphocytes which cannot enter through HEVs, and as result the structure of the paracortical areas is severely disorganized. The *Slc* gene in mice is located on chromosome-4,[231] which corresponds to human chromosome 9p13 where *CCL21* (*SLC*) is located. Furthermore, T cells lacking the SLC receptor (CCR7) have a markedly reduced ability to enter LNs and PPs. In CCR7-deficient mice the homing of B cells into secondary lymphoid organs is not disturbed, and the arrest of B cells on HEVs takes place in the absence of SLC, indicating that other chemotactic activities regulate entry of B cells into secondary LNs. Lymphocyte entry into LNs may also be mediated by 1 (CXCL12) which is recognized by the CXCR4 receptor expressed on resting T and B cells.

However, this interaction is not important for T cells as CXCR4-deficient mice have normal T cell areas. The redundancy of the mechanisms for B cell homing explains the normal B cell homing in plt mice, as well as on CXCL12- and CXCR4-deficient mice.

Transgenic mice that do not produce SLC in the normal anatomic locations but have SLC expression directed to the pancreas under the control of the insulin promoter II have collections of $CD4^+$ and $CD8^+$ cells near the center of the islets and only a few scattered B cells surrounding them.[232] In older mice, these clusters in the islets develop stromal reticulum, seen in LNs and vascular endothelium with morphology of HEVs. B cells as follicular-like clusters without GCs merge with the T cell areas, which demonstrates the important role of SLC in LN neogenesis.

Once naive lymphocytes have crossed the HEV, chemokines direct the lymphocytes to their compartmental homing, i.e., T lymphocytes to the paracortex and B lymphocytes to the follicles.

SLC is expressed not only on HEVs, but also by stromal cells within the T cell areas of LNs, spleen, and PPs. A second ligand for CCR7 is ELC, which is also expressed in T cell areas and is made by macrophages and the DCs of the paracortex. In vitro, the SLC and ELC attract T cells effectively and B cells weakly. In conclusion, SLC and ELC chemokines bind to their receptor CCR7 and stimulate the T cells' crossing of the HEV, while B cells cross the HEV by more than one chemokine/receptor system (Fig. 11.21).

Once inside the LN, T cells are attracted to the follicles by chemokine CXCL13 (BLC, BCA-1, B cell–attracting chemokine-1), which binds to the receptor CXCR5 (or BLR-1, Burkitt lymphoma receptor-1). The CXCR5 is expressed by mature as well as by activated B cells and in addition by $CD4^+$-activated T cells. Antigen-activated $CD4^+$ T cells downregulate CCR7 and upregulate CXCR5; and this $CD4^+$ T cell subset, in contrast to naive T cells that stay in the paracortex, travel with B cells to the follicles. This explains the results of fluorescent antibody, which detects small numbers of scattered T cells within the GC (Fig. 11.13A), which induce strong antibody responses in culture with B cells.[233] CXCR5-deficient mice show defective follicular localization of B cells. BLC is expressed constitutively by FDC in lymphoid follicles of LNs and other secondary lymphoid organs, and in BLC-deficient mice there are severe defects in the development of secondary lymphoid organs. Histologically, B cells are not organized in follicles but form a ring around the T cell areas.[234] The importance of BLC for the organization of B cells into follicles was shown by the ectopic expression of BLC in pancreatic islets, where B lymphocytes but not T cells accumulate in these sites.[235] The organization of primary follicles requires an FDC network , which is strongly dependent on LT-1 and LT-2 and TNF expressed on B cells.[236]

In conclusion, for proper formation of follicles and localization of B lymphocytes, two ligand-receptor systems are mandatory: TNF and the LT-1 and LT-2 ligand and their receptor LTR, as well as the BLC ligand and its receptor CXCR5.

Signaling for Lymphocyte Homing

Cells receive a multitude of stimuli which may be chemical (such as cytokines and growth factors) or physical (such as mechanical stresses or adhesion to extracellular matrix or other cells). These stimuli influence their function by affecting intracellular signaling pathways, and often involve cell-surface receptors or other molecules that function through activation of the Rho family of small GTPases. Rho GTPases control multiple cellular processes, including actin and microtubule dynamics, gene expression, cell cycle and polarity, and membrane transport; and they bind to numerous downstream effectors diverting signaling pathways appropriately.

The integrin activation pathway involves intracellular signaling mediated by the Ras homologous A protein (Rho-A), which is a guanosine triphosphate–binding protein.[237,238] Rho-A activation depends on the cytoplasmic tail of ICAM1, but the exact mechanism of activation remains unknown. Activation of Ras stimulates a cascade of activations initiated with the phosphorylation of the mitogen-activated protein kinase and phospholipase-C, which in turn activates protein kinase-C and mobilizes $Ca2^+$ from intracellular sources.

Activation of PI-3 kinase by chemokine stimulation activates in turn phospholipase D and initiates actin rearrangements and vesicular trafficking.[239,240,241] There are several PI-3 kinase isoforms and cytokines which affect cell migration by altering the isoform of activated PI-3 kinase, which in cooperation with DOCK2 activates homing of T and B lymphocytes.[242]

DOCK2 is a hematopoietic cell-specific protein of the CDM family and is indispensable for lymphocyte chemotaxis. *Dock2*-deficient mice (*Dock2*$^{-/-}$) exhibit migration defects of T and B lymphocytes but not of monocytes, and response to chemokines results in several abnormalities including T lymphocytopenia, atrophy of lymphoid follicles, and loss of marginal-zone B cells. DOCK-2 is a member of the CDM protein family, which regulates cell motility and cytokine production in mammalian hematopoietic cells through the activation of *Rac* and plays a pivotal role in the modulation of the immune system.[243] It is also expressed in lymphoma cells such as follicular lymphoma and diffuse large B cell lymphoma. DOCK2 is the mammalian homologue of the CED-5 protein family in *Caenorhabditis elegans* and activates *Rac* which in turn regulates actin cytoskeleton and therefore cell mobility. DOCK2 mediates migration of lymphocytes, independently of PI-3 kinase; and its intracellular signals result in reorganization of the cytoskeleton, causing cells to send out pseudopodia and move along the chemoattractant gradient. Transendothelial migration occurs rapidly, and within minutes lymphocytes reach the basement membrane and move toward the cell–cell junctions. Adhesive contacts with the endothelium are modulated so that the cell is not immobilized, but this may result from a decrease of activation signals.

Dendritic Cell Migration

The traffic of DCs is regulated by cytokines (IL1, TNF-α), chemokines, and defensins; but regardless of their origin, immature DCs express the chemokine receptor-6 (CCR6), which binds the chemokine MIP-3 (CCL20). The ligand for CCR6 (i.e., MIP-3) is constitutively expressed by keratinocytes and provides homing signals for the positioning of LC to the suprabasal layer of epidermis.[244]

In mucosal surfaces, such as in the intestinal mucosa, the CCR6 functions as a mucosa-specific regulator of humoral immunity and lymphocyte homeostasis and attracts immature DCs to submucosal areas.[245] CCR6 binds a family of antimicrobial peptides known as defensins, which constitute one of the first lines of host defense. For example, the human beta-defensins (hBD), such as hBD-2 and -3 have anti-HIV activity.

The defensins are detected throughout evolution, in fungi and flowering plants as well as in invertebrates and vertebrates. They are cysteine-rich, cationic peptides with the ability to kill a broad range of microorganisms including bacteria, yeast, and viruses, and thus they are a strong component of the arsenal in innate immunity.

The antigen-presenting cell required for induction of primary immune responses in skin are the LCs. Following activation by a foreign antigen, their level of MHC class II antigen and their accessory cell activity are increased; they migrate to regional lymph nodes, where they stimulate T cells. One of the earliest manifestations of LC activation is the accumulation of increased amounts of IL-1-beta mRNA within 15 minutes after exposure to antigens such as contact allergens in vivo. LCs are connected physically with keratinocytes through homotypic interactions mediated by E-cadherin, which is downregulated by inflammatory or allergic stimuli and results in "maturation" and detachment of LCs.[246] The migration of antigen-bearing LCs, from the skin to draining lymph nodes is mediated by TNF-α and CD40–CD40 ligand interactions critical for Ag presentation to T cells in eliciting an immune response.[247] Their interaction is mediated by the ligand of 6C-kine, known also as Exodus-2/6 C-kine secondary lymphoid tissue chemokine/T cell activator protein-4. Another potent stimulator of T cell migration is the macrophage inflammatory protein MIP-3, which binds to the CC chemokine receptor-7 (CCR7). These chemokines are expressed in lymphoid organs and the 6-Ckine has been localized to high endothelial venules and lymphatic endothelium. It is therefore likely that they may play an important role in the homing of dendritic cells to lymphoid tissues.[248]

The barrier to their migration, imposed by the basement membrane of the skin (collagen IV), is brought down by the matrix metalloproteinase-9, released by LCs with specificity for collagen IV.[249] LCs cross the abluminal side of the lymphatic vessels,

probably with the involvement of P-glycoprotein, and eventually enter LNs. In the lymphatic vessels they are known as veiled cells on the basis of their morphology (i.e., large lamellipodia veils), which like sails propel them forward. Attracted by SLC and MIP-3 (or ELC), both of them ligands of the CCR7 receptor, they enter the LN from the afferent lymphatic vessel into the subcapsular sinus to reach the T cell areas.[250] In the T cell areas, they are known as IDCs, as their elaborate long cytoplasmic processes interdigitate between T cells. IDCs present to T cell antigens they have captured in the periphery, initiating an immune response (see Chapter 14).

Special Homing Pathways

Homing to the Skin

Memory lymphocytes tend to return to the type of tissue where they have encountered the antigen.[251] Lymphocytes that entered the afferent lymphatics from the skin have a distinct phenotype and express a marker called cutaneous lymphocyte-associated antigen (CLA),[252] which binds to E-selectin.[253,254] E-selectin is induced on dermal endothelial cells in the delayed type of hypersensitivity and in chronically inflamed skin.

Other molecules also mediate strong adhesion of memory T cells to skin, such as VLA(Very Late Antigen-4, or CDw49d) interacting with VCAM1, and the integrin alpha-3 beta-11 with the extracellular matrix component epiligrin, an interaction which may be involved in cutaneous inflammation.[255] T lymphocytes may penetrate the epidermis using E-cadherin, a member of a group of single-pass transmembrane proteins which mediate specific cell–cell interactions with their extracellular regions, while the intracellular region is associated with the actin cytoskeleton.[256]

Homing to the Gut

Lymphoid cells in the gut are found in three areas: (a) well-organized collections known as Peyer patches, which are secondary lymphoid organs; (b) in the lamina propria underlying the intestinal epithelium; and (c) interspersed between epithelial cells (after penetration of the basement membrane) known as intraepithelial lymphocytes (IEL).

Naive lymphocytes home to PPs, whereas memory cells home to extralymphoid sites, i.e., the intestinal lamina propria, because of variation in the expression of highly specialized homing receptors. Expression of the ligand of L-selectin and MADCAM1 (mucosal addressin cellular adhesion molecule-1) is weak in the HEV of the PPs; and therefore neither set of these molecules alone is capable of mediating tethering and rolling to initiate integrin activation, but their cooperation allows naive lymphocytes to enter the PPs. The endothelium of the lamina propria, on the other hand, is negative for the ligand of L-selectin but strong for MADCAM1 expression; and as a result naive lymphocytes are unable to use the L-selectin pathway, and since the expression of $\alpha_E\beta_7$ is weak, they cannot use this pathway either in order to initiate rolling. This is the reason that naive lymphocytes are blocked from normally infiltrating the lamina propria.

On the other hand, memory lymphocytes, although they lack L-selectin and cannot use this set of molecules to enter PPs, have a strong expression of $\alpha_E\beta_7$ and are able to initiate rolling to enter the lamina propria. One may assume that this an expression of the wisdom of nature to allow only memory, i.e., activated lymphocytes, already well-equipped for defense, to enter areas with infectious foci. Some of the lymphocytes are able to penetrate the basement membrane of the intestinal epithelium and settle between enterocytes to become IELs. The IELs interact with the intestinal epithelium through an integrin known as the human mucosal lymphocyte molecule, now shown to be the $\alpha_E\beta_7$ integrin.[257,258]

The $\alpha_E\beta_7$ integrin is expressed in approximately 2% to 6% of blood T cells, a memory subset which is negative for CLA-1 and L-selectin[259] and is induced by transforming growth factor-β.[260] The same cytokine is also known to trigger a class switch of IgM^+ B cells to IgA, which is the predominant Ig class produced by the gut lymphocytes. It is of interest that MADCAM1, a gut mucosal addressin, contains an IgA-like domain.[261]

Homing to Inflammatory Sites

Lymphocytes are known to accumulate in sites of chronic inflammation and tissues with active autoimmune mechanisms. The phenotype of these lymphocytes indicates that they are activated, and therefore antigenically stimulated.[251] Cytokines produced from macrophages, such as interferon-γ and TNF-α, regulate lymphocyte traffic to inflammatory sites. Accumulation of lymphocytes at chronic inflammation sites involves several adhesion molecules such as LFA-1 and α-4 integrins, as well as E-selectin and VCAM1. Chemoattractants such as MIP-1β enhance binding of $CD8^+$ T cells,[262] whereas RANTES selectively attracts memory T cells.[263] The MPC-1 is a major lymphocyte chemoattractant (in addition to its strong activity on monocytes),[216] which explains the mixed composition of cellular infiltrates, rich in lymphocytes and monocytes, in sites of chronic and autoimmune inflammatory reactions. MCP-1 is present in abundance in areas of antigenic challenge and autoimmune diseases.[264] The data suggest that -C-C chemokines provide the triggering signal for the integrin-dependent tight adhesion of lymphocytes to endothelia for emigration to inflammatory sites.

Homing to Other Sites

In bone marrow transplantation the hemopoietic progenitors use the "$\alpha 4\beta 1$–V CAM1 to home to bone marrow,[265] as well as interactions involving P-selectin with PSGL-1, the P-selectin ligand.[266] Lymphocyte homing to tonsils is mediated by L-selectin and CD34,[267] whereas the attachment of lymphocytes to brain microvasculature is mediated by the sulfoglucuronosyl paragloboside, a ligand for L-selectin.[268] Integrin adhesion receptors mediate cell–cell and cell–extracellular matrix interactions, which control cell morphology, migration, differentiation, and tissue integrity.

Integrin heterodimers, such as $\alpha 4\beta 1$ and $\alpha 5\beta 1$ are considered to generate distinct signal transduction mechanisms.

The Significance of Lymphocyte Homing and Recirculation

It is estimated that as many as 5×10^6 lymphocytes/second leave the blood and cross HEVs in the body. The process of rolling and sticking to the HEV takes 1 to 20 seconds and the transendothelial passage approximately 10 minutes.[269] From in situ microscopic observations of PPs, the velocity of the lymphocyte before contact with the HEV is approximately 4,000 μm/second, and rolling effectively reduces this to approximately 40 μm/second.[206] Thus, rolling increases the chances for firm adhesion, but at the same time the cell may escape if proper triggering for activation of integrin mechanisms fails to be initiated. Triggering mechanisms involve G-protein–linked chemoattractant receptors and their ligands, and they can bring about integrin activation within 1 to 3 seconds after contact for tight adhesion. Homing and recirculation are not random, but the result of active interactions determined by the phenotypes of the HEV cells and the lymphocytes. Homing to specific microenvironments of the secondary lymphoid organs is developmentally acquired, carried out under the guidance of chemokines,[270] and influenced by the cellular composition of the microenvironments (i.e., IDCs vs. FDCs).

Chemokines mediate entry of lymphocytes into lymphatic tissues, and sphingosine 1-phosphate (S1P) promotes localization of

lymphocytes to the vasculature. Both signals are sensed through G protein-coupled receptors (GPCRs).

When lymphocytes are antigenically stimulated, the pattern of migration is modified and antigen-specific lymphocytes are directed to particular tissues so that they may influence more effectively various aspects of the immune response. This ultimately is the significance of lymphocyte recirculation reflected in the difference between naive and antigenically experienced lymphocytes. Immune responses within various microenvironments[271,272] are all under the control of the chemokines. Knowledge of the mechanisms of chemokine regulation will allow the development of therapeutic strategies to control inflammatory diseases.[273]

CHAPTER 12

B LYMPHOCYTES

Frixos Paraskevas

ONTOGENY

Pluripotential stem cells give rise to all hematopoietic lineages, undergoing asymmetric division, i.e., one daughter cell follows a pathway of differentiation, whereas the other remains as a self-renewing stem cell. Depending on their interaction with the appropriate stromal cells, as well as growth and differentiation factors, stem cells differentiate into various lineages including B and T lymphocytes. Their differentiation is guided by the type of stromal elements to which they are exposed; i.e., in the thymic microenvironment they develop as T cells, whereas in contact with bone marrow–derived stromal cells they develop as B lymphocytes or myeloid cells. Multiple checkpoints ensure proper differentiation of precursor to mature B lymphocytes, and several have been found disrupted in patients with primary immunodeficiency. The differentiation of the B cell involves critical processes divided into two periods; the first from stem cell to immature Ig-M^+ B cell is antigen-independent, while the second period from immature B cell to plasma cell is antigen-dependent. The first period is subdivided into two stages: from stem cell to progenitor B (pro-B) cell and from pro-B cell to immature Ig^+ B cell. Differentiation has been studied in animals and humans with cells obtained from different stages of development (embryonic as well as adult) and with cells from patients with lymphoproliferative disorders, which are considered "frozen windows" of normal differentiation. This approach, however, is not accepted universally because evidence from acute leukemias suggests the existence of some degree of asynchronous maturation with phenotypes not found normally.[1]

STEM CELL TO PROGENITOR B CELL

See Figure 12.1

Transcriptional Regulation

Hematopoiesis is coordinated by several genes that orchestrate multiple cell interactions which release growth and differentiation factors.[2] More than eight specific cell lineages have been identified which differentiate from pluripotent stem cells, guided through a well-defined hierarchical sequence to mature functional cells.[3]

During fetal life lymphopoiesis takes place in the yolk sac and liver and after birth in the bone marrow.[4] "Master" genes regulate differentiation of lineages through transcription factors which activate target genes, progressively narrowing their differentiation potential to specific lineages,[3] and which coordinate the various stages of lymphocytic development.[5,6,7,8] A common progenitor gives rise to separate myeloid and lymphoid progenitors, and the latter to lymphocytic lineages B, T, natural killer (NK), and dendritic cells (DC).

Normal development of lymphopoiesis depends on the Ikaros family of transcription factors, which regulate lymphocytic development. The Ikaros gene (*IKZF1*) encodes a zinc finger protein (ZFP), which is a transcription factor expressed by B and T cells at different stages of differentiation (except plasma cells).[9]

A long-standing goal of molecular biology has been the construction of DNA-binding proteins for the control of gene expression by using the classical Cys2-His2 design of a ZFP, ideally suited for such purposes; and it was adopted for discriminating genes with closely related DNA sequences.[10] The classical ZFs are one of the most common protein domains in higher eukaryotes widely used in zinc finger nucleases (ZFN) and are currently used in human clinical trials with an aim of therapeutic gene editing. ZFPs are nucleases designed to cut at specific DNA sequences and are becoming powerful tools in gene targeting to replace a gene within a genome by homologous recombination (HR), or to permanently modify plant and mammalian genomes, including the human genome. They were developed and used in Drosophila, rats, and zebra fish to generate modified organisms with gene-targeted mutations and/or deletions.

This brief review emphasizes the point that Ikaros is a master regulator of gene expression and chromatin remodeling, and its biologic roles include regulation of the development and function of the immune system and overall even the hematopoietic differentiation.

The *Ikaros*$^{-/-}$ mice have a complete block of B-cell differentiation, with lack of pro-B and precursor B (pre-B) cells in fetal liver and bone marrow. The *Ikaros* gene generates eight protein isoforms by alternative splicing and some of them bind, through the N-terminal ZFP motif, to DNA sequences which contain GGGA core motifs. This family of DNA-binding proteins, restricted to lymphocytes, are highly conserved in humans and mice and regulate the expression of other genes. They are localized in the nucleus of most primitive hematopoietic stem cell subsets, particularly at two stages: (a) long-term self-renewing stem cells and (b) multipotent progenitors, which are not self-renewing, but able to differentiate into lymphoid-committed progenitors.[11] The isoforms detected in hematopoietic stem cells differ from those detected in lymphoid progenitors, but all of them share two C-terminal zinc fingers that mediate their self-association, forming multiple heteromeric complexes. Other members of the Ikaros family (i.e., Aiolos and Helios) encode transcription factors that form multimeric complexes with Ikaros.[12]

The *Ikaros* gene is required not only for the early stages of lymphocytic differentiation but also for late stages, especially in T-cell maturation. It exerts multiple regulatory functions by recruiting repressor complexes, or what are known as chromatin remodeling machines, an unconventional function of transcription factors. *IKAROS* is also needed for the maintenance of B cells by regulating BCR signaling, and importantly overall it acts as a master regulator of hematopoietic differentiation and as a tumor suppressor in acute lymphoblastic leukemia (ALL), especially forms of the disease associated with poor prognosis.[13]

The transcription factor PU.1 acts at the pluripotent level of myeloid-lymphoid progenitors, and its expression maintains the hematopoietic progenitor pool by supporting the generation of the earliest lymphoid and myeloid progenitors.[14]

It regulates early B-cell development by activating the *IL7Rα* gene, rendering B-cell progenitors responsive to appropriate differentiation signals, and thus promoting differentiation to the pro-B-cell stage . Among the three main B-cell populations, B-1, B-2 (follicular), and marginal zone B cells, PU.1 directs differentiation toward the B-2 subpopulation[15] and enhances the activity of other transcription factors, i.e., the interferon (IFN)-regulatory factor. The B-1 and B-2 B cells which are involved in innate and adaptive immune responses, respectively, arise from distinct progenitors.[16]

The *TCF3* (previously E2A) gene is important for lymphocytic differentiation encoding two proteins, E12 and E47 of the basic helix–loop–helix family by differential splicing. The proteins encoded by *TCF3* bind uniquely to the DNA of B cells as homodimers[17] and are essential for the coordination of Ig gene

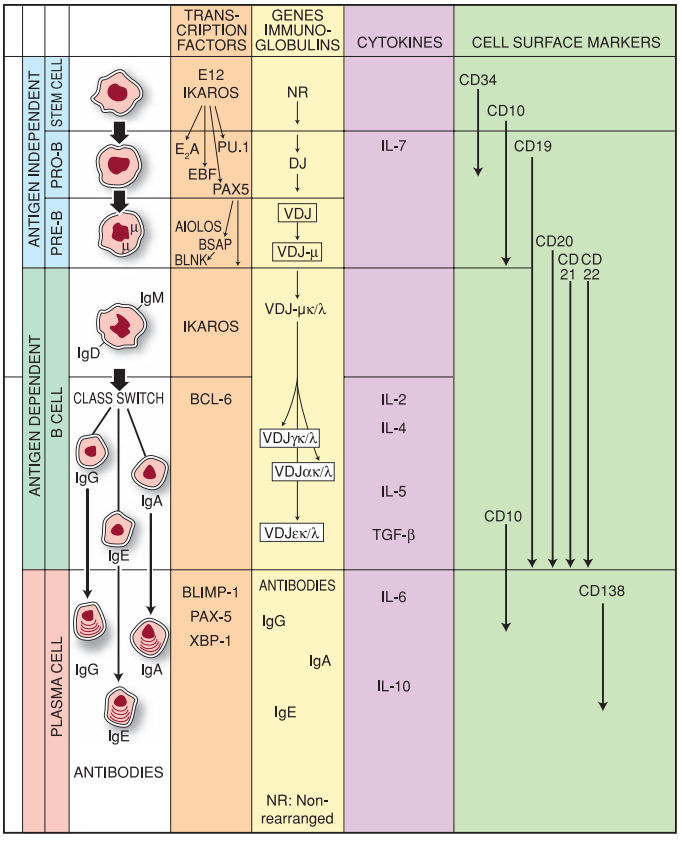

FIGURE 12.1. B-cell differentiation. The first stage of B-cell development takes place in the bone marrow. Normal development of lymphopoiesis depends on the Ikaros family of transcription factors, which form multimeric complexes with other members, i.e., Aiolos and Helios. These complexes are known as chromatin remodeling machines, and their targets induce a second wave of transcription factors, i.e., PU.1, E2A, EBF, PAX5, etc. Their targets are a third set of genes, forming BSAP that acts on the adaptor protein BLNK (SLP-65). Targets of BSAP are the genes for CD-19, V-preB, and λ5, i.e., markers distinctly of the B-cell lineage. BLNK regulates the transition from pro-B to pre-B, whereas PAX5 is needed for V(D)J recombination. This stage of development is independent of exposure to antigen and is followed by an antigen-dependent stage that unravels in the peripheral lymphoid organs. Antigen receptors, i.e., Igs, expressed on their surface interact with antigen and helper T cells, and trigger B-cell differentiation (plasma cells) and antibody secretion. Class switching generates distinct classes of antibodies suitable to dispose antigens in the various microenvironments, i.e., inside the body as well as on body surfaces.

rearrangements;[18] therefore in their absence B-cell differentiation is blocked before entrance into the pro-B-cell stage. The basic region mediates DNA binding, whereas the HLH domain is required for protein dimerization. The E12 targets the genes of the early B-cell factor (*EBF*)[19] and the *Pax5*,[20] directing differentiation along B lineage while it blocks myeloid differentiation.

The *Pax5* is exclusively expressed in the stage between pro-B cell and mature B cell.[20] The B-cell–specific activator protein, BSAP/ PAX5, is a paired domain DNA-binding protein expressed in the developing nervous system, testis, and in all B-lineage cells, except terminally differentiated plasma cells. BSAP regulates transcription of several genes expressed in B cells and also the activity of the 3′-*IgH* enhancer and targets the genes of *CD19*, VPREB1, the gene transcribing for the lambda light chain, and several intronic sites of the *C4B* gene. The *Pax5* gene regulates the V(D)J Ig heavy-chain gene rearrangements after the first DJ-H rearrangement,[21] which generates the pro-B-cell population. Mice deficient for *Pax5* have a pre-B-1 cell population which do not express CD19 or Ig-α and to a lesser extent Ig-β, V-preB, and lambda-5. These cells proliferate normally in vitro on stromal cells in the presence of interleukin IL7 and carry out D-J rearrangements of both IgH chain alleles. Removal of IL7 from the cultures inhibits differentiation to surface Igm expressing B cells. Transplantation of *Pax5*-deficient pre-B I clones into *Rag*-deficient hosts leads to full reconstitution of the thymus with D(H)J(H) rearrangements and normal positive and negative selection of $CD4^{-}CD8^{-}$ and $CD4^{+}CD8^{+}$ thymocytes and the development of normal, mature $CD4^{+}$ and $CD8^{+}$ T-cell compartments in the peripheral lymphoid tissues.

The target for BSAP is the adaptor protein B-cell linker protein (BLNK) which is linked with surface IgM by CMTM7, a tetra-spanning membrane protein, co-localized with clathrin and sIgM on the plasma membrane. The linking of sIgM with BLNK, a pivotal adaptor protein in the signal transduction, results in its recruitment to the vicinity of the tyrosine kinase Syk and initiation of signal transduction. This culminates in MAP kinase activation as well as other downstream signaling proteins, i.e., PLC-γ_2, Bruton tyrosine kinase (Btk), etc.[22] The BSAP regulation of *BLNK* gene expression controls also the pro-B to pre-B transition and mediates the constitutive signaling of the pre-B cell receptor (pre-BCR) in cell proliferation, growth factor responsiveness, and V(D)J recombination. BSAP diverts differentiation of a common myeloid/lymphoid progenitor to lymphocytic differentiation as a result of its ability to suppress the response of the progenitor cell to myeloid growth factors,[23] and represses genes inappropriately expressed at the pro-B-cell stage.[24]

Essential for early B-lymphocyte development is the EBF which regulates the expression of Ig-α (mb-1) and Ig-β (B-29) coreceptors. Isolated human EBF factor binds to Ig-α and Ig-β promoters, and EBF-deficient mice lack Ig-α and Ig-β transcripts in pro-B cells.[25,26] EBF activates transcription of B-cell–specific genes and initiates necessary events such as gene activation of other transcriptional regulators (i.e., *Pax5*) that direct the early stages of B-cell lymphopoiesis.[27] Mutations of *E2A* or *EBF* arrest B-cell development at a stage earlier than that of PAX5, because recombinase expression is blocked and expression of pre-BCR, λ5, and V-preB genes is inhibited.[27] The three transcription factors PAX5, TCF3 (E2A), and EBF form a cross-regulatory network with the *TCF3* gene being the most potent B-cell regulator, essential for expression of PAX5 and EBF, which in turn is needed for expression of E47. Collectively, the targets of *IKZF1* are the genes of the transcription factors TCF3 (E2A), PU.1, EBF, and PAX5, all of which regulate stages of B-cell differentiation before the expression of Ig genes. It has been shown however, that the *TCF3* gene plays a central role for some aspects in subsequent stages of B-cell lymphopoiesis.[28] TCF3 (E2A) proteins are required for the interleukin IL7–dependent expansion of pro–B cells and their progression to the pre-B-cell stage and even later, for the regulation of rearrangements of the *IgK* gene and heavy-chain isotype switching.[29,30,31] *TCF3* encodes proteins that enhance hypermutation by recruiting AID to the Ig loci[29] and is essential in promoting pre-B- and B-cell survival.[30]

CELL INTERACTIONS IN EARLY B-CELL DEVELOPMENT

Study of B-cell differentiation has become feasible with the development of long-term bone marrow culture techniques. This approach has helped to define the cells that are essential for the development of B cells and the factors that support B-cell growth and differentiation. The bone marrow stroma makes a critical contribution to hematopoietic differentiation and the term stroma is used in a collective sense to include a variety of cells, such as adventitial reticular cells, adipocytes, fibroblasts, and endothelial cells of the sinuses.[32] The stroma includes also the extracellular matrix, composed of various fibrous proteins, glycoproteins, and heparan sulfate, effective in binding cytokines.

Granulocyte-macrophage colony-stimulating factor can bind to marrow stromal glycosaminoglycans and be presented to

hematopoietic stem cells. Stroma cells have been isolated from adult bone marrow[33] or fetal bone marrow after removal of adherent cells (i.e., macrophages, endothelial cells). Stroma cells have the morphology of an adventitial/reticular/fibroblast cell, which expresses several adhesion molecules. They support, in cultures, differentiation of fetal bone marrow cells ($CD34^+$, $CD19^-$)[34] toward B-cell lineage, i.e., with loss of CD34 and acquisition of CD19 and the V-pre-B protein.

Several adhesion molecules have been implicated in the mediation of interactions between B-cell progenitors and stroma cells. Critical among them are vascular cell adhesion molecule-1 (VCAM1) on stroma cells and very late antigen-4 (VLA-4) on B-cell progenitors.[33,35] The CD34 is expressed not only on stem cells,[36] but also on stroma cell precursors[37] and endothelial cells,[38] and thus mediates interactions with its counterreceptor, L-selectin expressed on progenitor cells. Among cytokines with a wide range of functions is IL7, which acts in an early stage of common lymphoid progenitors (CLP, B/T/NK), mediates growth and differentiation of lymphocytes in the bone marrow, and plays a critical role in B-cell development.[39] IL7 maintains B-cell differentiation programs open; and although in the absence of IL7 the differentiation of T/NK proceeds normally, B-cell differentiation is arrested since IL7 modulates EBF expression, which activates target genes that are specific for B-cell differentiation programs.[40]

In mice lacking IL-7R the recombination process comes to a halt, because normally it is the IL-7R which targets V_H segments to the recombinase complex; and furthermore, aberration in the expression of *Pax5,* a gene with pivotal importance in B-cell development and regulation, is associated with B-cell malignancies.[41] Even though the block from IL7 deficiency is after the pro-B cell stage, these cells have certain abnormalities, such as failure to upregulate terminal deoxynucleotidyl transferase (TdT) and the high-affinity IL-7R chain.[42] The net result of IL7 deficiency is lack of expression of the μ-chain and the pre-BCR, events that normally promote the advancement from pro-B-cell to pre-B-cell stage. Stimulation of proliferation and expression of the μ-chain follows distinct signaling pathways, because the Y449F mutation in the cytoplasmic region of the l7rα chain, which abrogates proliferation induced by IL7, does not block μ-chain expression.[43] In the absence of IL7, the thymic stroma lymphopoietin (TSLP) (see Chapter 11) assumes a host of functions, i.e., regulation of the development of IgM^+ B cells from IgM^- precursors, the promotion of B-cell and Th-2 differentiation of naive $CD4^+$ T cells, and the activation of NK T cells, basophils, and other innate immune cells at the initial stage of inflammation.

TSLP affects B cell maturation and activation and may also influence differentiation and development of T regulatory T (Treg) cells.[44] Human X-linked severe immunodeficiency results from mutations of the γ chain, a common subunit for several cytokine receptors (i.e., IL2, IL4, IL7, IL9, and IL15). The patients lack T and NK cells but have normal or even elevated B cells,[45] and normal numbers of B cells are detected in patients with mutations of the IL7Rα chain.[46] The IL7 exerts changes in gene expression, which effect differentiation of pro-B cells to pre-B cells, especially in concert with other growth factors of stromal cells.[47] It synergizes with FMS-like tyrosine kinase 3 ligand (*FLT3LG*) and induces strong expansion of fetal B cells in vitro.[48] IL7R has been detected on human B-cell progenitors, with a pro-B-cell phenotype, which lack expression of CD19 and clonogenic capacity,[49] are $CD34^+$, have messenger RNAs (mRNAs) for CD79B*, RAG1, PAX5,* and are TdT^+. The IL7R-α^-/$CD19^-$/$CD34^+$ cells do not differentiate in short-term cultures into pro-B cells, therefore the expression of IL7R-α defines an entry into a stage characterized by upregulation of multiple B-lymphoid–associated markers. Single adult human $CD34^+$ $CD38^-$ $CD7^-$ cells cultured over a murine fetal liver adherent cell line supplied with IL7, FLT3LG, and IL3 differentiate into B cells, NK cells, myeloid cells, and DC.[50]

B-lineage development therefore is based on a complex, interconnected network of genetic programs which provide lineage commitment and specification.[8,51]

The CXCR4 chemokine receptor is detected in $CD34^+$ hematopoietic progenitors[52] committed to B-cell development,[53] and its ligand is the stromal cell–derived factor-1 (SDF1 or PBSF, now known as CXCL12).[54] The CXCL12 chemokine orchestrates rapid revascularization of injured, ischaemic, and regenerating tissues via the CXC chemokine receptors CXCR4 and CXCR7. The CXCL12 induces intracellular actin polymerization in lymphocytes, a process that is thought to be a prerequisite for cell motility. Expression of CXCR4 on $CD34^+$ BM cells is one of the phenotypic alterations for committed lymphoid progenitors and allows discrimination of lymphoid progenitors from myeloid progenitors. Since $CD34^+CXCR4^+$ cells are differentiated from $CD34^+CXCR4^-$ cells, multipotential progenitors located in the BM are likely to be negative for CXCR4 expression.

CXCR4 is also known as fusin and acts as a coreceptor for human immunodeficiency virus (HIV) which infects host cells, but CXCL12 blocks the entry of HIV to T cells.[53] The $CD34^+$ $CXCR4^-$ bone marrow cells generate myeloid and lymphoid progenitors, while the $CD34^+$, $CXCR4^+$ cells, although they give rise to B cells and T cells, lack the potential for myeloid, erythroid, megakaryocytic, and mixed colony-forming progenitors. CXCR4 therefore defines B-lineage committed progenitors more accurately than other commonly used markers and is expressed earlier than IL7R or TdT.

PRO-B CELL TO IG^+ B CELL

The early development of B cell differentiation is divided into two stages, the pro-B and the pre-B cells. In pro-B cells the first rearrangement involves the D_H to J_H segments of the immunoglobulin heavy chain (*IGH@*). With the completion of this step, the V_H to DH-JH rearrangement begins and if it is productive, an H chain is formed which binds a surrogate light chain (SLC) forming the pre-BCR. Further signaling by the pre-BCR stimulates proliferation followed by light chain rearrangement. *IGK@* light chain rearrangement begins before the rearrangement of the *IGL@* light-chain genes. These epigenetic changes regulate the transition to the B cell stage, characterized by rearrangements of the light-chain genes with the kappa light chain preceding the rearrangement of the lambda chain gene.

Molecular definition of the stages of early B-cell development identified cells with μH chains in the cytoplasm without L chains and no mature IgM molecules on the cell surface,[55] followed by phenotypic markers or Ig gene rearrangement.[56] Single-cell polymerase chain reaction analysis and Ig gene rearrangements allowed a more precise identification of B-lineage commitment and definition of the stages which characterize the transition from stem cells to pro-B-cell stage and B-cell development (Fig. 12.1). The pro-B cell stage in B cell development is followed by the pre-B cell, which may be divided into pre-B-I and pre-B-II stages.

Clones of pre-B I cells carry characteristic D(H)J(H) rearrangements on both *IGH@* chain alleles. However removal of IL7 from the tissue cultures does not induce B-cell differentiation in B cells expressing surface IgM.

When the Ig gene rearrangements reach their final stage, IgM is expressed on the cell surface and differentiation reaches the end of the immature B lymphocyte stage. Three sets of genes regulate the transition from the pro-B-cell to the pre-B-cell stage, with expression of the complete Ig molecule on the surface of the B cell. One set includes *RAG1* and *RAG2* genes, and a third gene encodes the SLC which is composed of the proteins from the *VPREB1* and λ5 genes.

The proteins from two other genes, CD79A (mb1, *PSMBS*; IGB) and CD79B (*CD79B; IGB*) *CD79B; IGB*, form the coreceptor. These

genes support the expression of IgM on the surface of the B cell, the BCR repertoire, and allelic exclusion (i.e., expression of only one of the two alleles). The rearrangements of the Ig genes start with the joining of a D to J_H segment in the pro-B cells, which proliferate in contact with stromal elements and express the SLC linked to a gp30 protein, sometimes referred to as the surrogate heavy chain of the pro-B-cell complex.[57–59] SLC expression is required to establish immunoglobulin heavy chain allelic exclusion during early B-cell development and is easily detected on mouse pro-B cells but difficult to detect on human pro-B cells.[58,59] The SLC consists of two noncovalently associated proteins, VPREB1 and λ5 (Fig. 12.2), encoded by genes located on chromosome 22, where the λ-chain genes are also located.[60,61] The VPREB1 and λ5 proteins have several unusual features that distinguish them from conventional light chains. The VPREB1 protein is composed of 102 amino acids with homology to a conventional V domain and both have atypical sequences which target them to the endoplasmic reticulum (ER).[62]

However, whereas the conventional V domain has a total of nine beta strands, including a sequence encoded by a J segment, the VPREB1 has no sequence similar to the J segment and is shorter by one strand, the β7 strand, and its C-terminal portion has no homology to any other known protein. The N-terminal end of the λ5 protein is unique, with only marginal sequence homologies to conventional domains. The C-terminal end of the λ5 protein has an Ig-like fold, homologous to the conventional λ-chain C domain. This is followed by a sequence with marginal homology to the Ig structures and an extra β-strand that is homologous to the J region of the conventional Vλ domains. Unique regions and Ig-like domains of the VPREB1 and lambda-5 proteins control the folding and assembly of SLC,[62] which associates with the μ-chain to form the pre-BCR. The C-1 domain of the μ-H chain in the pre-BCR is protected from improper folding by the hsp-70 protein BiP, which retains the μ-H chain in the ER.[63] The protection from improper folding of CH-1 is taken over by the C-λ5 protein at a later stage as long as the CH-1 is associated with the VPREB1 as SLC.[64] SLC escorts the μ-H chain to the surface of the cell, although not all μ-H chains can pair with the SLC, since some V segments have

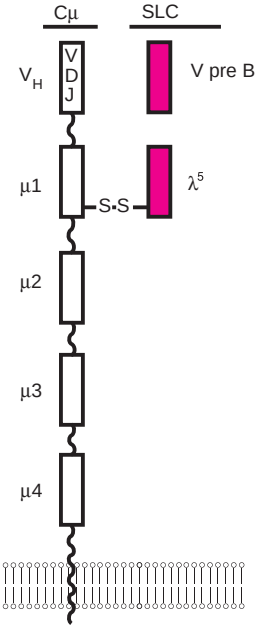

FIGURE 12.2. The structure of the pre-B-cell receptor. The pre-B-cell receptor is composed of the μ chain and a surrogate light chain that consists of two components, the λ5 and the V-preB. The μ chain is linked by disulfide bond to the λ5 component, whereas the V-preB is noncovalently attached. It is not yet clear whether the surrogate light chain can be expressed on the surface without the μ chain.

structural features that prevent their association. At this point, the *RAG1, RAG2,* and *DNTT* (*TDT*)*TdT* genes are turned off, securing allelic exclusion and thus preventing further rearrangements at the other allele.[65] The *λ-5* chain of the pre-BCR represents the C domain of the conventional L chain of BCR, and has 85% homology with the C-λ domain, while the VPREB1 is the equivalent to the VL domain.[66] The SLC is linked by a disulfide bond to the μ_H chain through the Cμ-1, i.e., the first constant domain,[67] and its role in the formation of the pre-BCR is dual. The C domain of λ-5 protein interacts with Cμ-1 and the VPREB1 (and part of λ5) with the V_H domain of the μ_H chain.[68] This last interaction is likely to be the first step in the selection of the B-cell repertoire[67] as the pre-BCR induces asymmetric divisions of pre-B cells.[69] In contact with pre-BCR ligands on stromal cells, i.e., heparin sulfate[70] or galectin-1,[71] the SLC mediates receptor aggregation, signaling, and internalization, as well as transition from pro-B cells to pre-B cells.[72] Pre-B-cell signals induce proliferative activity of pre-B cells, allelic exclusion of the heavy-chain locus, and activation of the light-chain loci preparing for V(D)J recombination.[73]

Productive rearrangement of the L chain completes induction of the IgM molecule expressed on the B cell surface, and marks the transition to the immature B-cell stage. The strong proliferative capacity of the pre-B cells was analyzed in *Pax5*$^{-/-}$ mice, which showed that the pre-B cell has an extensive renewal capacity, multipotency, and the ability to reconstitute recipient animals with lymphoid and myeloid lineages.[74]

Signaling is transmitted by the CD79A/CD79B partners of the pre-BCR, which is linked to several protein tyrosine kinases, i.e., Bruton's tyrosine kinase [BTK], SYK, ITK, BLNK, and phosphoinositide 3-kinase (PI-3K).[75] Ligand binding causes aggregation of the pre-BCR, resulting in endocytosis of pre-BCR, loss of cell surface expression, and accumulation of pre-BCR within membrane lipid microdomains.

The pre-BCR signaling achieves two important outcomes for subsequent differentiation of the B cell: activation of MAP kinases, which block apoptosis usually triggered by the engagement of CD24;[76] and downregulation of RAG1/RAG2 expression to turn V(D)J recombination off, so that allelic exclusion is accomplished.[77] The RAG1/RAG2 proteins are still expressed on active proliferating cells of the pre-BI stage, but are silenced during the pre-BII stage. Because the cell has achieved its objectives (i.e., survival and allelic exclusion), it reactivates the V(D)J recombination machinery to allow rearrangements of the conventional κ/λ chains, to be able to form the complete IgM molecule and thus enter the immature B-cell stage.

Existing epigenetic mechanisms prioritize expression of single heavy and light chain alleles (allelic exclusion) in order to maintain monoallelic expression of both genes in a single B cell,[78] maintaining at the same time single specificity of the B cell receptor. At a later stage of B cell development, additional mechanisms contribute to prioritizing expression of single IGH@ and IGL@ alleles to help maintain the monoallelic expression of Ig.

The nontranscribed allele is in close association with heterochromatin, and the transcription factor IKZF1 initiates the silencing of transcription of the lambda-5 gene through a direct effect on the promoter.[79] Individual B lymphocytes normally express immunoglobulin (Ig) proteins derived from single Ig heavy chain (H) and light chain (L) alleles. At later stages of B cell development, additional mechanisms may contribute in prioritizing expression of single IGH@ and IGL@ alleles. The importance of pre-BCR signaling for progression from pro-B-cell to pre-B-cell stages and beyond is emphasized by the fact that deficiencies of any component of the pre-BCR or downstream signaling molecules blocks developmental progression of B cells at the pro-B or pre-B stage.[80] Targeting the genes for VPREB1,[81] λ5,[82] or exons of the μ-chain blocks B-cell differentiation at the pro-B to pre-B-cell stage.[83] In mice with λ5-deficiency the expression of VPREB1 is normal, which excludes an essential role for pro-B and pre-B

cell receptors in VPREB1 regulation.[84] Similarly, in a patient with agammaglobulinemia, mutations in both λ5/*IGLL1* genes were associated with agammaglobulinemia and reduced numbers of B cells.[85]

The SLC is not detected on the surface or in the cytoplasm of a subpopulation of self-reactive cells found in germinal centers[86] and circulation.[87] B cells having a VPREB1 sequence in their BCR and RAG mRNA have also been described in normal human tonsils and the joints of patients with rheumatoid arthritis.[88,89] The pre-B cell signaling that terminates pre-B cell expansion and induces Ig L-chain rearrangement is transmitted by Bruton's tyrosine kinase and the BLNK (Src homology-2 domain), which contains a leukocyte-specific phosphoprotein of 65 kD.[90] The V-region of a pre-B receptor and λ5 proteins of the pre-BCR are invariant, but each contains unique evolutionarily conserved non-Ig sequences (unique regions or URs) attached to the Ig sequences.[91] The URs interrupt the SLC complex and may be considered equivalent to the CDR3 of the Ig L chain which participates in antigen binding.[92] The transcription factors that are most active and are specifically upregulated at this stage are TCF3, EBF1, PAX5, and IRF4.[93] The pre-BCR not only switches on the Ig genes, it appears to select preferentially those that provide μH chains of a higher quality, i.e., with a higher potential to assemble with Ig L chains.[94]

In conclusion, the pre-BCR plays a major role in the expansion of pre-B cells, allelic exclusion, repertoire selection, activation of V(D)J recombination, and developmental progression to IgM^+ B cells.[73] Multiple checkpoints ensure proper differentiation of precursor and mature B lymphocytes. Many of these checkpoints have been found disrupted in patients with primary immunodeficiency; and it still remains unclear how B cells are affected, as 11 critical processes in B cell differentiation have been identified.

IMMUNOGLOBULIN GENES

Among the early successes of investigations in recombinant DNA, was the characterization of the Ig genes. There are three loci for the heavy chains and two for the light chains (κ, λ). The gene for the human heavy chain is located on chromosome-14,[95] the C(κ) gene on chromosome-2,[96] and the C-λ on chromosome-22.[97,98] Separate genes encode the V and C domains of the Ig molecule. The human heavy-chain genes are not completely linked and the Cμ gene is the closest to the Vdj segments.

At the 3′ end of the H chain locus, there are two copies of a γ-γ-ε-α unit (Fig. 12.3). One of the duplicated ε-sequences is a pseudogene (ψε) in which the CH1 and CH2 domains have been deleted. The genome contains a third closely homologous ε-related sequence, a "processed" pseudogene found on chromosome-9. These kinds of pseudogenes probably are products of a reverse transcription from RNA and then are inserted at locations in the genome that are unrelated to the original locus. A γ-related pseudogene lacking the switch region is present between the two γ-ε-α duplications. The recombination events occur in a region on the 5′ side of the C_H coding sequences.

This region contains repetitive DNA sequences and has been known as the switch region (S) sequence. Within the switch regions occur the recombination breakpoints during isotype switch (see Chapter 14). Usually the stimuli for switch recombination, like IL4 and CD40, promote transcription across the S regions to produce switch junctions, one retained in the chromosome while the other is found in a circular DNA (see Chapter 14).

V_H–D–J_H GENES

The heavy chain of the IgM molecule is encoded by four sets of DNA: variable (V_H), diversity (D), joining (J_H), and the constant (C-μ) genes.

A V_H gene encodes the first 95 or 96 amino acids of a V domain but the exact number of V_H genes is not known; it is estimated, however, to be 100 to 200. Of the available V_H genes only a portion are functional, and an even smaller portion is available for rearrangement.[99,100] The V_H genes constitute seven families based on their homology at the DNA level and are known as V_HI to V_HVII. Most V_H genes are polymorphic, but the degree of variation is usually small.[101] The V_H segment encodes the hydrophobic leader sequence, the three framework regions, and the two complementarity-determining regions (CDR).

The name D gene, or segment, was proposed to indicate the diversity of an antibody at positions after amino acid 99 to the beginning of the J segment,[102] which spans the third CDR. The D segments are located in chromosome band 14q32, with the major locus between V_H and J_H loci and several D segments interspersed within the V_H segments, sandwiched between signal sequences (see later).The CDR-3 is encoded by the 3′ end of the V_H segment, the D gene segment, and the D-J_H junctional area. There are approximately 30 D segments grouped in seven families, and each one spans approximately 70 kb, with a promoter on its 5′ end that allows initiation of transcription when Ig genes at the pre-B-cell stage start rearrangements. The first rearrangement produces a DJ_H complex, which together with the μ gene, encodes a protein known as Dμ protein. There are six functional J_H genes and three pseudogenes, each J_H gene encoding the 3′ end of CDR-3 and the fourth framework region.

V (D) J RECOMBINATION: FORMATION OF THE CODING AND SIGNAL JOINTS

Next to the V, D, and J genes are conserved sequences of seven nucleotides (heptamers), which are attached to the 3′ side of the V segments, the 5′ side of the J segments, and on both sides of the D segments (Fig. 12.4). The heptamer is followed by 12 or 23 nonconserved base pairs (bp) (spacers), followed by another sequence of 9 bp (nonamers), which may diverge from the consensus sequence. This noncoding sequence is known as the recombination signal sequence (RSS).

Recombination signal sequences for V(D)J joining consist of a conserved heptamer (CACAGTG) and a nonamer (ACAAAAACC) separated by a spacer of a constant length of 12 or 23 bp. The presence of three consecutive A residues in the nonamer is necessary for efficient recombination, and the nucleotides flanking the A-rich core should be other than A residues, so that the border of the A-stretch is precisely defined. This may be important when the recombinase measures the distance between the heptamer and the nonamer to satisfy the 12/23-bp spacer rule.[103]

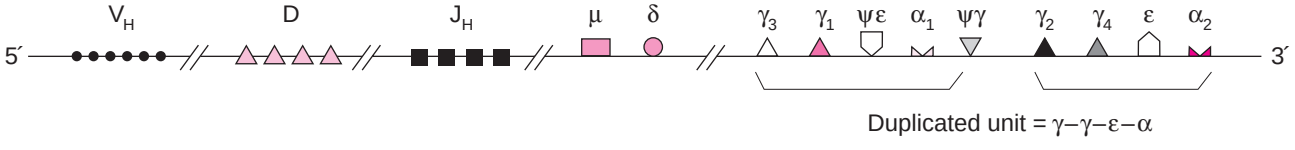

FIGURE 12.3. Human immunoglobulin heavy-chain gene locus. The heavy-chain gene locus contains the μ and δ genes close to the J_H genes, whereas the remaining heavy-chain genes are farther downstream in two clusters from duplications. See text.

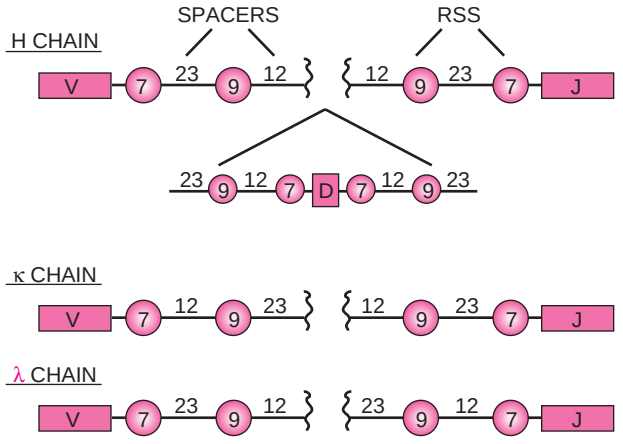

FIGURE 12.4. Recombination signal sequences (RSS) and heptamer/nonamer spacing sequences. The coding sequences of the immunoglobulin genes are flanked by a 7-nucleotide sequence (heptamer), which is followed by either 12 or 23 nucleotides, which in turn are followed by a 9-nucleotide sequence (nonamer) and again by a 23- or 12-nucleotide spacer. This order allows rearrangements only between a segment in which the 7/9 sequences are separated by a 12-mer spacer and another segment in which they are separated by a 23-mer spacer. This is known as the 12/23 rule.

The 12-bp spacer corresponds to one turn of the DNA α-helix, whereas the 23-bp spacer corresponds to two turns. This way, the recombining segments are juxtaposed on the same side of the DNA helix, so that they can be recognized by the enzymes of the recombination machinery.[104,105] Joining of the various segments is limited between an RSS with a 12-bp spacer and one with 23 bp[106] (the 12/23 rule). Recombination follows strictly the 12/23 rule of spacers, which prevents inappropriate recombination, i.e., a V_H segment joining directly to a J_H segment, as both of them have a 23-bp spacer between their heptamers and nonamers.[106] The pattern of the RSS at each locus is uniform. For example, in the Ig locus, all V_k segments have next to their heptamers a 12-bp spacer, whereas all J_k segments have a 23-bp spacer. This prevents accidental joining of two V_k or J_k segments. The RSS sequences are the only ones that are required for recombination, whereas the coding sequences (V, D, or J) can be replaced by other DNA while the joining still occurs if the 12/23 rule is satisfied. During recombination, two new structures are formed: the joining of the coding sequences (coding joint), which is imprecise, and the joining of the RSS (signal joint), which is precise.

The V(D)J recombination (Fig. 12.5) is mediated by two enzymes known as RAG proteins,[107] the RAG1 and RAG2, which are not related to other proteins. Their expression normally is limited to immature B and T cells, even after the expression of surface antigen receptor, until the receptor is cross-linked. Deficiency of RAG proteins in mice[108,109] or humans[110] results in SCID. The RAG2 is divided into an N-terminal (core) domain and a C-terminal (non-core) domain. The core domain is necessary and sufficient for carrying out the V(D)J recombination. The C terminus of RAG2 contains a PHD finger motif, usually present in chromatin-associated proteins. The PHD (Plant Homeodomain) is encoded by many genes, including *RAG2*, and recognizes or "reads" the gene status of expression for histone H-3, lysine-4, and DNA damage, i.e., histone modifications, and as a result is known as a chromatin reader. The PHD finger of *RAG2* modulates V(D)J recombination,[111] and mutations of *RAG2* at this site result in immunodeficiencies. Tetramers of the RAG1/RAG2 proteins initiate the V(D)J recombination, which proceeds in three steps.[112,113,114,115] The RAG1 binds to the nonamer, which acts as an anchoring platform, while the heptamer stabilizes the complex in the presence of RAG2. The recognition by RAG proteins of the RSS is assisted by sequence-nonspecific DNA-binding proteins, HMG1/2 (high-motility group), which enhance binding and cleavage. In the RAG1/RAG2 complex, the RAG2 C terminus probably interacts directly with histones and stabilizes the RAG1/RAG2 complex.[116] This interaction, which requires Mg^{2+}, may bring the recombinase to specific signal sequences which may be required for the postcleavage phase of the recombination. HMGB proteins bind to DNA through two DNA-binding domains known as HMG-box-A and -B.[117] Each consists of 80 amino acids interacting with the minor groove of the DNA. Box-A bends distorted DNA structures, whereas box-B bends severely linear DNA sequences. Mutations in HMGB proteins block synaptic complex formation, or possibly recognize distorted DNA structures induced initially by RAG1/RAG2 binding. Their binding stabilizes the formation of the synaptic complex and thus promotes the DNA cleavage.[118] The recognition by RAG proteins of the RSS is assisted by sequence-nonspecific DNA-binding proteins, HMG ½, which enhance binding and cleavage. During the first step of V(D)J recombination, the RSSs are recognized by the recombinase and are brought in juxtaposition, forming the synaptic complex, which is composed of a dimer of RAG-2 and at least a trimer of RAG1.[119] In the second step the recombinase nicks the phosphoester bond between the last nucleotide of the coding sequence and the first nucleotide of the RSS (Fig. 12.5, Panel 1). The precise mechanism of the hydrolysis of the phosphate ester bond is not known. The nicking reaction requires the physiologic divalent cation Mg^{2+}. The cleavage leaves blunt phosphorylated signal ends and hairpin sealed coding ends (Fig. 12.5, Panels 2 and 3), which are formed between the 3′-OH of the coding sequence (top strand) and the central phosphorus atom of the phosphate group between the coding sequence and the RSS of the opposite strand (the lower strand in Fig. 12.5). Formation of the hairpin requires significant bending of one or both DNA strands (Fig. 12.5, Panel 4). In the third step, the hairpin must be nicked open, so that the two coding ends form the coding joint. Opening of the hairpin may be done by a DNA repair complex[120] or by RAG proteins themselves.[121] Because the nicking may not be exactly in the center of the hairpin, the opening creates an overhang in one strand formed by the nucleotides from the other strand (Fig. 12.5, Panels 5 and 6). These are known as P-nucleotides, which are coming from the opposite or complementary end of the hairpin or palindrome (from the Greek *palindromicos*, meaning successive movement forward and backward, like the piston of an engine). As a result, they have an inverse complementary relationship with the adjacent coding end. Most of the coding ends detected in normal lymphoid precursors have 3′ overhangs.[122] TdT adds nucleotides known as N-nucleotides (nongermline) to the strand with the missing nucleotides (Fig. 12.5, Panels 7 and 8). Disruption of TdT drastically lowers junctional insertions. In fetal and neonatal periods, the N insertions are low or absent as a result of the developmental regulation of TdT. The alterations in the coding joint as a result of P- and N-nucleotides are the basis for junctional diversity (Fig. 12.5, Panel 9).

The RAG proteins continue to be bound to the signal and coding ends in a four-end complex, known as a cleaved signal complex, at least while the coding ends are still processed. The RSSs are highly conserved among vertebrates, from sharks to humans. The three heptamer nucleotides closest to the recombination site are the most important, whereas mutations at other heptamer positions still allow recombination. Variations in the position of RSS may influence the use of gene segments *IGK@* vs. *IGL@*.

The RSS joint is assumed to be lost by being converted to reactive, broken DNA, disposed of in the next cell division (deletional recombination). However, the existence of inverted segments of DNA in these loci indicates that sometimes signal joints are retained in the chromosome (invertional recombination), a mechanism that restores chromosomal integrity. The fate of the signal joint has taken an unexpected direction as a result of findings indicating that the RAG proteins perform genetic transposition

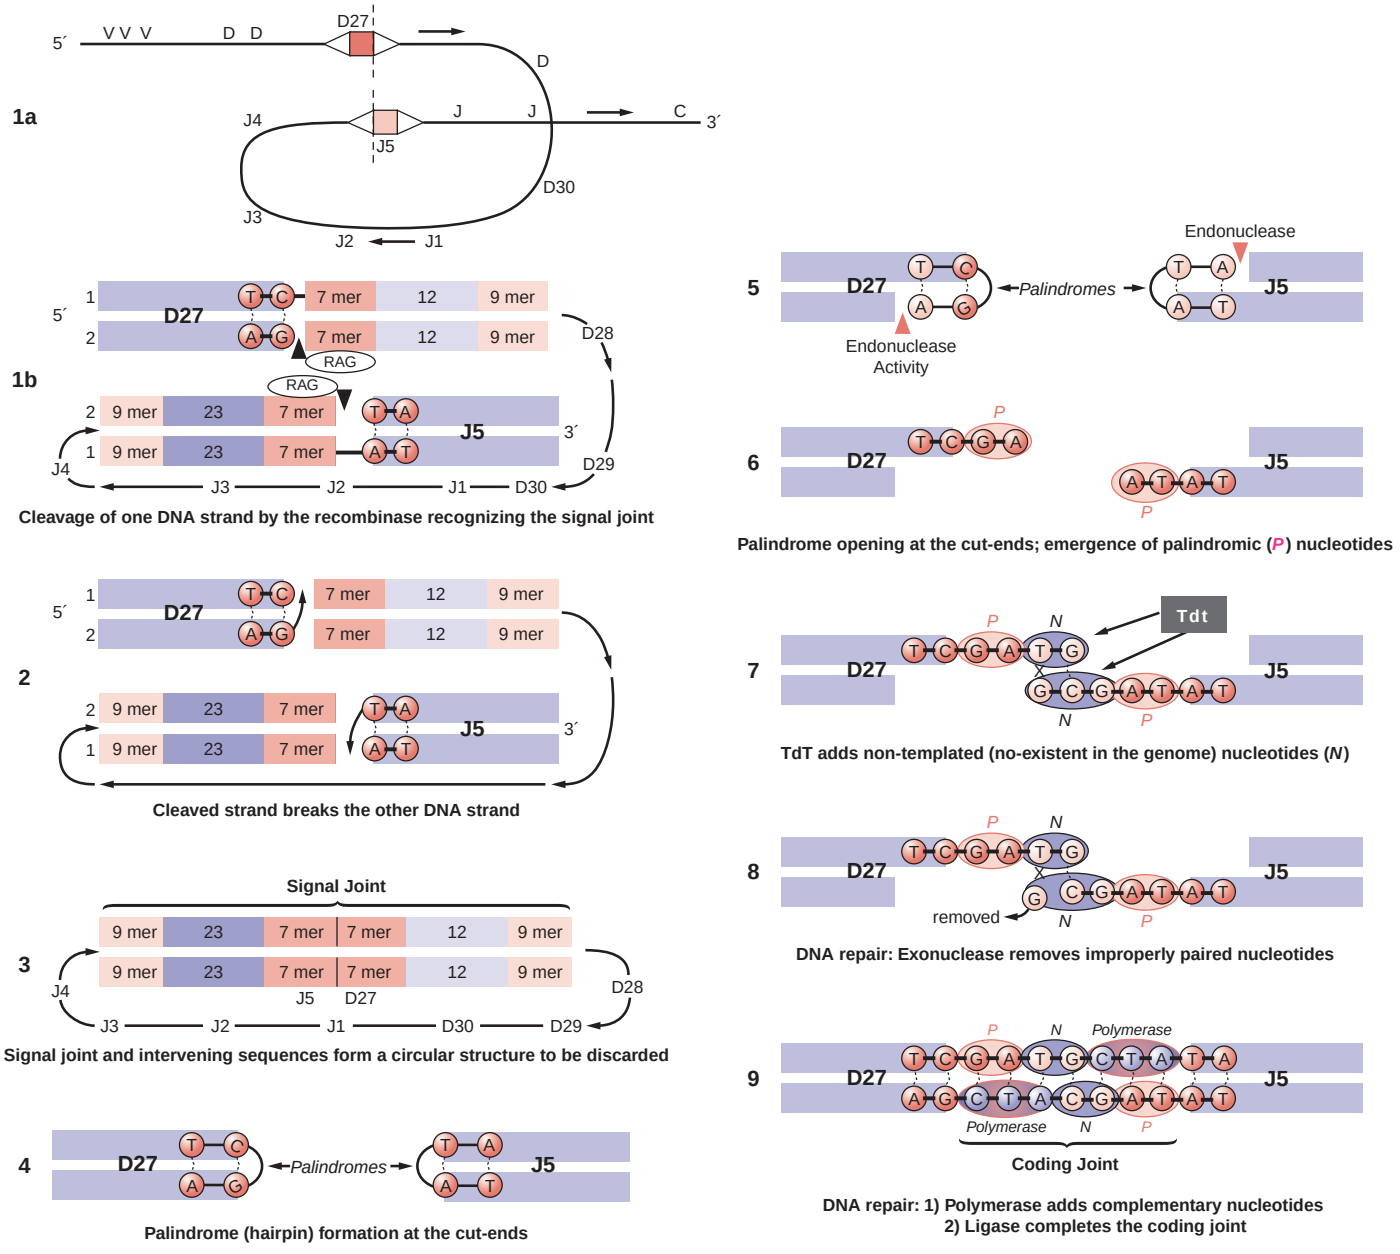

FIGURE 12.5. V(D)J recombination. Shown in this figure is the recombination of two hypothetical segments, D27 and J5. The recombination begins with recombination-activating gene-1 (RAG-1) and RAG-2 recognizing the heptamers and monomers (see text) **(Panel 1)**. They cut out one strand at the junction between the heptamer and the coding sequence. The other strand is severed by a nucleophile attack from the cut end **(Panel 2)**. The two blunt ends of the heptamers form the signal joint **(Panel 3)**, while a hairpin seals the cut coding ends **(Panel 4)**. The hairpin is nicked open either by the RAG proteins or by a ubiquitous DNA double-strand repair complex **(Panels 5 and 6)**. The opening is usually asymmetric and creates overhangs, with the nucleotides at the end of the overhang being complementary because they derive from the complementary opposite strand. These are known as palindromic *(P)* nucleotides **(Panels 5 and 6)** (from the Greek *palindromicos*, meaning moving forward and backward in succession). The double DNA strand breaks of the coding joint receive nucleotides from the function of TdT (nongermline nucleotides) known as *N-nucleotides* **(Panel 7)**. Improperly paired nucleotides are removed **(Panel 8)**, and the coding joint is completed with the addition of missing nucleotides **(Panel 9)**. The P- and N-nucleotides added to the coding joint constitute the junctional diversity.

(i.e., act as transposases).[123,124] The name given to the enzyme indicates its function, i.e., transposing or inserting pieces of DNA in a new location. The transposase MuA of the bacteriophage Mu is the best characterized in this class of enzymes, consisting of a tetramer in which two of the subunits nick the two ends of the Mu genome, while the other two catalyze the transfer of the ends into the target DNA. These reactions are important in the transmission of drug resistance among bacteria and the integration of retroviruses, such as HIV and others, into the genome. In fact the active site of MuA exhibits a striking similarity to the HIV integrase. It is interesting that the RAG1/2 act as tetramers in V(D)J recombination and resemble the HIV integrase responsible for inserting DNA copies of the viral genome into the cellular chromosomes. There are also similarities between the mechanisms of transposition and V(D)J recombination, suggesting that the RAG proteins may be members of the retroviral integrase superfamily.[125] Hairpins during V(D)J recombination are the targets of the RAG-mediated transposition. Notable differences, however, exist in the nick-cleavage mechanisms between the two.[126] Transposition of RSS in various positions, targeted to DNA, results in branched molecules.[127,128] The high Mg^{2+} concentration prevailing in mammals, however, results in removal of transposed DNA by disintegration. No transposition in vivo has been reported as yet, probably because it is suppressed by GTP

and the C terminus of the RAG2 protein.[129,130] Active transposition events are detrimental to the host because of the mutagenic potential of genomic rearrangements.

As a result of these recent insights into the nature of V(D)J recombination and the function of RAG1/2, the question of the fate of the signal joint becomes very important. Signal joints have been found to be cleaved quite efficiently.[128] In vitro experiments showed that transposition is targeted not to a particular DNA sequence, but to structural features, such as hairpins, inverted repeats, supercoiling of DNA forming cruciform structures, and generally distorted DNA structures.[131,132] In vitro experiments demonstrating transposition were performed with only the core part of RAG1/2; it is conceivable that other parts of the molecule exert an inhibitory effect on this potential function of RAG1/2. Although the in vitro experimental evidence suggests that there is a bias toward transposition, there is no evidence that this occurs in vivo, as it severely compromises genomic stability in the lymphocytes. On the other hand, lymphoid malignancies are associated with chromosomal translocations, many of which involve the Ig or T-cell receptor (TCR) loci and potentially may be mediated by the V(D)J recombinase.[133]

DNA REPAIR MECHANISMS

Cleavage of DNA is always potentially dangerous, and although the recombinase function is essential for the integrity and normal function of the immune system, it is, at the same time, perilous. The V(D)J recombination, as well as class switch recombination, are necessary processes, but they demand double-strand DNA breakage. As vital as these two processes are for survival, the DNA double-strand break (DSB) is a threat to survival and it does occur in viral infections and malignancies. If genetic integrity is to be maintained, the DNA breaks need to be repaired.[134] Although nature has developed a highly complex repair mechanism, it is, however, efficient. Double-strand breaks generate an alarm mechanism, based on the transduction of signals from the sensors to the transducers and eventually to the effectors for the DNA repair job. An important sensor is the MRN complex, consisting of a nuclease (Mre-11) and the chromosome protein (RAD50), which maintain chromosomal structure and protein NBN.[135,136,137] RAD50 and NBN are recruited rapidly to DSB sites for processing broken ends. MRN transduces the early signals to a kinase, the main transducer, known as ATM (ataxia telangiectasia mutated), which rapidly phosphorylates various substrates needed in the repair pathway. ATM belongs to a family of proteins known as PI-3-K–like protein kinases (PIKK), with five members, while an additional protein is the catalytic subunit of the DNA-PK kinase. Four of the PIKKs are involved in the DNA damage response: DNA-PK, ATM, ATR, and SMG1. ATM is the first to be recruited to DSBs, where it is activated by MRN, probably as a result of changes in chromatin configuration; it then phosphorylates and activates several DNA repair and cell cycle checkpoint proteins, i.e., the histone λH2AX and NBN, required for recruiting other ATM targets.

ATM initiates a pathway that activates NF-κB (associated with cellular survival), as well as phosphorylates BID, which plays an anti-apoptotic role.

The DNA-PK (DNA-dependent protein kinase) complex consists of a catalytic subunit (DNA-Pkcs) and a DNA-binding complex called Ku, which binds altered DNA structures such as double-strand breaks, nicks, or hairpin loops. Recombination of broken DNA strands occurs either between strands that have long stretches of homology (HR) or between DNA strand breaks, without relying on the presence of considerable homology between them. This recombination is known as nonhomologous end joining (NHEJ).[138] Mutations in this system result in the accumulation of V(D)J-specific double-strand breaks, indicating a defective repair mechanism, which causes SCID. A new gene has been added to those already known that regulate double-strand DNA break repairs. It was named *ARTEMIS* (now known as *DCLRE1C*),[139] after the Greek goddess who was the protector of small children and animals.[140] It belongs to the superfamily of metallo-β-lactamase enzymes and is now called DNA cross-link repair K (DCLRE1C).[141] It is involved in the nonhomologous end joining pathway, a DNA repair process used by eukaryotic cells,[142,143] as well as in the repair of broken DNA ends from the V(D)J recombinase activity.

The repair requires that the hairpin in the coding joint is opened by the DNA-PK–DCLRE1C protein complex.[141,144] In such a complex, DCLRE1C acquires endonuclease activity, which it does not possess by itself.[144] *DCLRE1C* has been shown to be mutated in patients with SCID, expressing radiosensitivity.[138] Patients with hypomorphic mutations in *DCLRE1C* have not only immunodeficiency, but also a predisposition to lymphoma.[144]

RAG1 AND RAG2 PROTEINS

The evolutionary origin of the RAG proteins has been controversial. Up to now it was accepted that the *RAG* genes originated from a horizontal gene transfer of a transposon, i.e., a mobile DNA element, and therefore are related to transposases, as discussed earlier.

Recently, however, two genes in sea urchins (Echinodermata) were detected that bear structural similarities to the RAG proteins.[145] Echinodermata are an earlier evolutionary stage of chordates, to which vertebrates and humans belong. It is therefore possible that RAG proteins may have arisen very early in evolution and acquired their present-day function early in vertebrate evolution.

Both RAG proteins are required for V(D)J recombination, because lack of function of either one leads to SCID.[146,147] A region that retains the recombinase activity is known as the core and has been used for studies in vitro. For RAG1, the core is located in the sequence 384–1,008 from a total of 1,040 amino acids, and for RAG2 in amino acids 1 to 383 of a total of 527. The core of RAG2 contains six repeats, each consisting of an antiparallel β-sheet, formed by four β-strands. The repeats are arranged in a circular formation like blades of a propeller,[147] a structure that is known to mediate protein–protein interactions. The C-terminal quarter of RAG2 consists of a plant homeodomain fold, which is found in proteins with chromatin-binding properties.[148]

Mutational analysis of the RAG proteins has provided some clues about structure–function relations. The catalytic properties of the proteins have similarities with members of the retroviral integrase superfamily[132] and require divalent metal ions for their function—a requirement that is characteristic of some nucleases, the functions of which depend on acidic amino acids. Indeed, in RAG1, several acidic amino acids are critical for both nicking and hairpin formation, without affecting the DNA binding.[149] For RAG1, the N terminus is important for activity,[149] and the binding of RAG1 directly to DNA is supported by basic residues of RAG2.[151] Deletion of the C-terminal region of RAG2 results in a reduction of the number of B and T cells.[152] The plant homeodomain of RAG2 regulates differential access to sites of recombination, and although it is dispensable for D/J_H recombination, it is essential for the V_H/DJ_H step.[153]

SOMATIC HYPERMUTATION

The primary importance of somatic hypermutation (SHM) is related to affinity maturation, i.e., the increase of the affinity of antibodies following repeated antigenic stimulations.[154] However, a wider scope of hypermutation is to provide a better defense

against hypermutating microorganisms. Many pathogens such as *Trypanosoma, Neisseria*, influenza virus, and HIV evade the immune system by variations of the antigens of their coat (antigenic variation). Accordingly, SHM is the adaptation of the B cell in response to hypermutating microorganisms.[155] SHM introduces mutations in the V gene at the rate of about 10^3 mutations/base pair/cell division, i.e., 10^6-fold higher than spontaneous mutations of somatic cells. At this rate genomic integrity can be maintained only if the SHM specifically targets the Ig genes. However, it has been suggested that SHM is not a mechanism specific for the Ig genes but it may occur in other genes. Perhaps the apparent preference for the Ig genes may be due to their higher density of certain hot spots,[156] and SHM appears to target preferentially certain hot spots, such as the short DNA motif DGYW.

HUMAN HEAVY- AND LIGHT-CHAIN GENE LOCI

The heavy and light chains of the Ig molecule are assembled from a large collection of preexisting gene segments by the lymphoid-specific RAG1 and RAG2 proteins. The RAG proteins cooperate to make double-strand breaks at specific recognition sequences (recombination signal sequences) or RSS.[157] The recombination takes place between one RSS with 12-bp spacer (12-signal) and one with a 23-bp spacer (23-signal) and this arrangement is called the 12/23 rule. In the presence of the metal ion $Mn2^+$, a single signal sequence supports double-strand cleavage, whereas $Mg\text{-}2^+$ requires two signal sequences.[157] The two light-chain isotypes, κ (kappa) and λ (lambda), comprise approximately 60% and 40% of all igs, respectively, and consist of a V domain and a C domain of approximately 107 residues each in length. The V domain is encoded by the V and J segments, the former encoding the first 95 to 96 residues and the latter encoding the remaining 12 to 13. There is a single C-κ gene, and several C-λ genes. The κ locus contains approximately seventy-six V-κ segments grouped into six families, and five J-κ segments, but no d segments. The λ-locus contains 10 families of V-λ segments, a high number of pseudogenes, and several C-λ genes, each preceded by a single J-λ segment.

One of the consequences of the imprecision of the V(D)G recombination is a change in the reading frame at the junction between the two gene segments, causing the segments to join out of phase, so that the triplet reading frame for translation is not preserved. In this case the rearrangement results in V(D)J combinations with numerous stop codons which interrupt the translation. Recombination may be nonproductive or productive; when the junction lies within a codon, the resulting amino acid is encoded by nucleotides from both gene segments involved. It is estimated that only one in three recombination attempts are productive, but the imprecision in the joints between variable gene segments increases their diversity by at least 100-fold. Difference in mRNA stability allows pro-B cells to distinguish between productive and nonproductive Ig gene rearrangements.

The Ig gene rearrangements follow a certain sequence of the various loci and use only some of the available gene segments (allelic exclusion), which indicates that there are regulatory mechanisms underlying the process of rearrangement. For the IgG molecule the *IGH@* gene is rearranged first and forms a complete V gene from three individual segment clusters, i.e., V, D, and J. One of the D segments joins a JH segment forming the D-JH complex and in the next step, which is regulated by the Dμ protein, the V segment joins the complex. A D-J_H rearrangement has also been found sometimes in T cells. The Dμ protein, which lacks a V_H segment, is encoded by the D-J_H complex and the constant gene of the μ–heavy chain and may be expressed on the membrane of the cell with an SLC. Expression of Dμ protein prevents further V_H-to-DJ_H rearrangement, or the rearrangements are diverted to another pathway such as κ-chain rearrangements, which are accelerated. Completion of the μ-chain inhibits further rearrangements by the opposite allele (known as allelic exclusion).[158] Completion of the μ-chain rearrangement is followed by rearrangements of the *IGK@* gene, and if both κ alleles fail to rearrange productively, the *IGL@* gene is rearranged (Fig. 12.6). However, this hierarchical order of Ig gene rearrangements has been challenged, because examination of B cells at different stages of early development shows that the heavy and light-chain genes rearrange independently.[159] At the end of its early developmental stage, the B cell emerges with the expression on its surface of a unique antigen receptor consisting of IgM accompanied by two accessory molecules, CD79A and CD79B.[160]

REGULATION OF V(D)J RECOMBINATION

Initiation of rearrangements by the recombinase requires that the gene must be accessible, i.e., the locus must be able to act as a template for the recombinase. In cells competent for rearrangement it was found that J_K and V_H genes have already been transcribed, but these RNAs, named germline or sterile transcripts, are incapable of encoding the protein. Several possibilities may exist to explain this finding, and since inactive genes are not accessible to the recombinase, it is possible that the altered structure of the chromatin allows the recombinase to recognize the RSS. Alternately, the enhancers may establish altered chromatin regions where both the recombinase and the transcription machinery have access; this is known as the accessibility hypothesis.[104,161] Enhancers and promoters function as accessibility control elements (ACEs), which regulate V(D)J recombination. Enhancers maintain an open chromatin state in multiple embryonic tissues independent of their activity level. Regions of nonprotein coding genomic DNA bind protein transcription factors (TFs) and thus direct the expression of target genes. The enhancer of the IgM heavy chain (Eμ) is located within the intron between the J_H segments and the Cμ gene and is associated with matrix attachment regions (MAR), which improve production of the protein by recombination.[162] Transcriptional regulation by enhancers is fundamental to the evolutionary diversity of metazoans as well as their embryonic development. The regulation of a gene is an exceedingly complex process controlled by interacting proximal and distal DNA elements usually placed in a cis configuration, proximal to the basal promoter where the general transcription machinery assembles. A promoter is always located in close proximity to the 5′-end of a gene and is necessary, but not sufficient, for its transcription, while enhancers or silencers are distant elements.

Enhancers are thought to be composed of binding sites for transcription factors (TF), which upon recruitment to the enhancer loop over the promoter and activate the transcription of the target gene. There are three additional enhancers within the Ig heavy-chain locus, and one of them (DQ52) competes more efficiently in conferring accessibility to the JH region. Interaction between DQ52 and Eμ is likely responsible for ordered rearrangement, i.e., D to J_H followed by V_H-to-DJ_H complex.[163] The κ–light chain intronic enhancer is active only in mature B cells and plasmacytomas, and its stage restriction is dictated by a single motif that binds the transcription of nuclear factor-κB (NF-κB), which recognizes a 10-bp motif. The NF-κB consists of two subunits and the DNA-binding function is mediated by the smaller one. The enhancers for the Ig transcription lie in the vicinity of the C-α gene and κ locus. The enhancer between the Jκ and Cκ genes becomes transcriptionally active in the transition from the pre-B to B-cell stage.[164] The matrix attachment regions are regions rich in AT

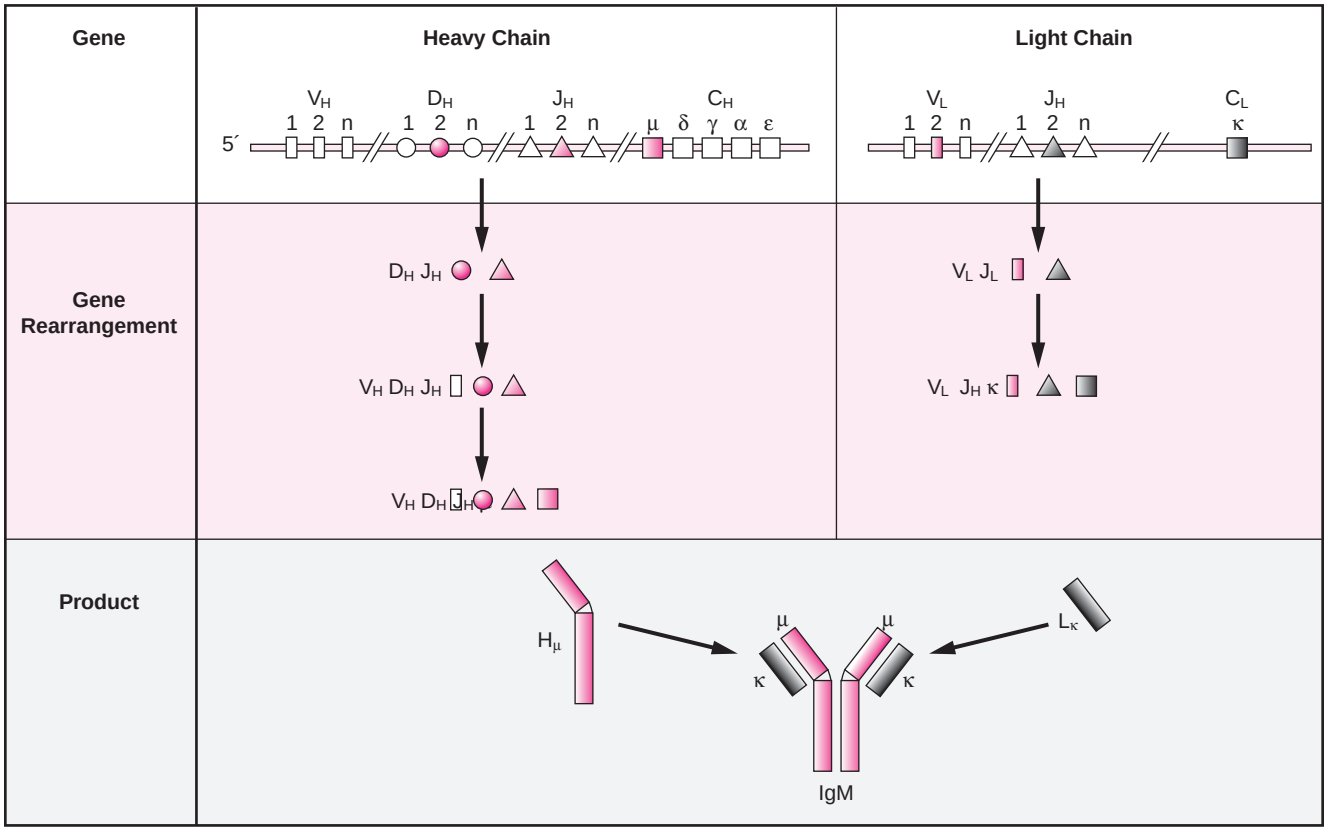

FIGURE 12.6. Heavy-chain immunoglobulin (Ig) M and kappa light-chain rearrangement. With the completion of the V(D)J recombination of the μ chain and the formation of a complete μH chain, the LK chain rearranges, and, if successful, it forms the complete IgMK molecule. If both κ alleles rearrange unsuccessfully, the λ gene rearranges. If successful, an IgMλ molecule is formed. If both λ genes cannot rearrange successfully, the cell dies by apoptosis.

and demarcate regions of chromatin that undergo base unpairing and other regions that mediate binding of topoisomerase II. This regional division of chromatin may also be regulated from a distance by trans-acting factors, which bind to specific motifs within the enhancer or promoter. Despite the promiscuity and redundancy of regulatory sequences, transcription is still specific for tissue lineage and even stage of development. Several transcription factors and other signals lead to changes in expression levels, yet no clear model exists to explain the complexity of transcriptional regulation. The clear result is that disruption of the TCF3 and EBF1 transcription factors results in blocking of B-cell development at a stage before Ig heavy-chain gene rearrangements.

BCR V GENE REPERTOIRE

Certain aspects of the study of the Ig V gene repertoire and the Ig gene rearrangement have found wide applications in clinical medicine.[165] The total number of V genes defines the available repertoire. However, not all genes are equally functional, and as a result, the repertoire which is usually expressed is biased, because some of the V genes are expressed with a significantly higher frequency than would be expected if all had an equal chance for rearrangement. This biased expression affects all V, D, and J gene segments; thus the J_H4 segment (one of the existing six), on the basis of equal opportunity among all five segments, should be detected in 17% of B cells, yet it is found in 32% of B clones from fetal liver and in 42% of pre-B-cell ALL. The bias of the expressed repertoire shows striking association with certain diseases. For example, the V_H4-21, a member of the V_H4 family, is found in cold agglutinins.[166] Preferential expression of certain V_H segments is also detected in ALL clones. In ALL the frequency of N-nucleotide additions differs in children less than 3 years of age (12.5%) compared with children greater than 3 years old (89%).[167] Because in fetal B lymphocytes the frequency of N-nucleotide additions is low, it is suggested that the transforming event in the younger age group probably occurred during fetal life.

In chronic lymphocytic leukemia (CLL), the use of V genes is also restricted, and the same is true in non-Hodgkin lymphomas. It is interesting that in certain cases of follicular lymphoma, the V genes not only have undergone somatic mutations, but also continue to do so during the course of the disease, suggesting that the malignant clone is responsive to an antigen.[168,169] Somatic mutations, as expected, have also been detected in multiple myeloma, because the malignancy derives from an advanced stage of differentiation of B cells.[170] This brief summary emphasizes the fact that defects in V(D)J recombination[171] are associated with human diseases such as loss of RAG1/RAG2 function, which results in SCID. In certain autosomal recessive diseases, hypersensitivity to DNA-damaging agents results in chromosomal breaks and rearrangements, with an increased incidence for development of leukemia and other malignancies. They have been classified as DNA repair disorders and include AT, Fanconi anemia, xeroderma pigmentosum, and Bloom syndrome (see later). Genomic instability is most often linked to DNA repair deficiencies, which suggests that evaluation of deficiencies in repair mechanisms in pluripotent human stem cells should be a necessary step prior to their clinical and research use. The DNA repair pathways and repair capacities in pluripotent cells are more heterogeneous than those of differentiated cell lines. In mice the SCID mutation, an autosomal recessive mutation, results in the absence of B and T cells as a result of impairment of the V(D)J recombination. Both lymphoid and nonlymphoid SCID cells are hypersensitive to killing by ionizing radiation because of a DNA double-strand base-repair

defect. It is rather important that a human gene on chromosome 8q11 has been identified that restores V(D)J recombination, double-strand base repairs, and normal resistance to irradiation in SCID cells.[172,173] V(D)J recombination is necessary for immune diversity and survival, but this objective can be achieved only through DSBs which threaten genomic stability. The complexity of the recombinase function is matched by complex DNA repair machinery. Disorders related to V(D)J recombination may be considered in two categories: those related to the first step (cleavage) and those related to the second step (cleavage repair).[174]

THE MUTATION IN SEVERE COMBINED IMMUNODEFICIENCY

Two fundamental processes operate in V(D)J recombination, i.e., double-strand breaks during the gene rearrangements, followed by DNA repair. The SCID mutation in mice[175] is associated with lack of mature lymphocytes and agammaglobulinemia. SCID T cells have long P-nucleotide sequences and accumulate hairpins at the *TRD@* coding ends. In addition to the lack of rearrangements, there is an inability to repair damage from irradiation. In mice the SCID mutation is located on chromosome 16, and since human chromosome 8 can complement mouse SCID defects, it has been assumed that the SCID defect for humans should be in chromosome 8, although human chromosome 8 is not associated with any known immunodeficiency or DNA repair diseases. The gene, however, for the DNA polymerase-8, is in chromosome 8p11-12. Mutated *RAG* genes have been detected in nine patients from seven families.[176] Recombination activity was undetectable with mutations in the *RAG* core domains, and in four patients there was a complete B-cell differentiation arrest between the pre-BI and pre-BII stages.

V(D)J RECOMBINATION: DNA CLEAVAGE

Two types of *RAG1* and *RAG2* gene inactivations have been identified in mice. The first type results in the inactivation of the recombinase so that V(D)J recombinations cannot be initiated,[108,109] and as result the mice have no mature T and B lymphocytes, although there is an increase of immature lymphocytes in the lymphoid organs. The second type of mutation consists of a single conservative amino acid substitution in both proteins. It does not affect the initiation of V(D)J recombination, but severely impairs the coding and signal joint formation.[177,178] The mutant enzymes are defective in hairpin opening in vitro and the formation of the coding joint in vivo. This evidence indicates that the RAG proteins, in addition to their cleavage function, are important for the formation of the joints; therefore, they must remain associated with the postcleavage complex to achieve opening of the hairpin.

In severe combined immune deficiency (SCID), approximately 20% of the patients lack both T and B lymphocytes, but have normal NK cell counts;[179] some of these patients have *RAG1* or *RAG2* gene mutations,[110] while others have increased radiosensitivity of their bone marrow cells and fibroblasts (RS-SCID).[180] The *RAG2* structure consists of two globular domains separated by a hinge of approximately 60 amino acids. The largest domain which is enzymatically active has 350 residues and includes the previously described core region of *RAG2*. This domain forms a β-propeller with six blades arranged in a circle from a center. The β-propellers are made of 4 to 10 β-sheet units (blades) circularly arranged around a central tunnel, and have probably evolved by duplication and fusion of a rudimentary repetitive unit. The beta-propeller fold is phylogenetically widespread and able to support a variety of functions such as catalysis, ligand binding and transport, regulation, and protein binding. Interestingly, it appears that the beta-propeller topology is also compatible with strikingly diverse sequences. Amongst this diversity there are three large groups of proteins with related sequences and very important cellular and intercellular regulatory functions. The WD-40 repeat proteins have a variety of functions, such as signal transduction, transcription regulation, cell cycle control, autophagy, and apoptosis. The YWTD proteins and the Kelch repeats interact directly with the actin-binding protein LASP1 in membrane ruffles at the tips of pseudopodia, where both proteins are necessary for pseudopodial elongation. A common characteristic among the proteins of these families is the internal repeats of 40 to 45 residues. The β-propellers are widely utilized in nature as recognition modules, and the well-conserved β-propeller fold exhibits a high degree of functional diversity, which is probably accomplished through variations in the surface properties of the proteins.[181] The β-propeller fold shows a high degree of functional diversity, probably accomplished through variations in the surface properties of the proteins. It is present in some integrins and other proteins which are known to mediate protein–protein interactions. Six out of seven mutations so far described in RAG2 in humans are clustered on one side of the propeller. This side is involved in interactions between *RAG1* and *RAG2* which are critical for functional activity. Two of these mutants (C41W and M285R) reduce the interaction between *RAG1* and *RAG2* in vitro but no DNA-binding activity of the complex was detected.[182] This is consistent with the hypothesis that *RAG2* stabilizes the *RAG1/RAG2* complex.[183]

OMENN SYNDROME

Omenn syndrome (OS) is an inherited disorder characterized by absence of circulating B cells, infiltration of the skin and intestine with activated oligoclonal T lymphocytes (HLA-D^+), eosinophilia, and elevated serum IgE.[184]

The immunologic hallmark of OS is the expansion and activation of an oligoclonal population of autoreactive T cells. These cells should be controlled rapidly by immunosuppressive agents.[185] The patient has diffuse erythroderma, lymphadenopathy, hepatosplenomegaly, protracted diarrhea, and failure to thrive. The T cells are activated, secrete Th-2 types of cytokines,[186] and express oligoclonal expansion of TRB@ chains with VDJ junction similarities, suggesting a common antigenic specificity with possible autoimmune proliferation and a critical defect in the development of lymphocytes.[187] The hallmarks of OS are expansion and activation of an oligoclonal population of autoreactive T cells, skin erythroderma, and elevated IgE in the absence of circulating B cells.[188] The syndrome expresses clinical symptoms and signs which define an inflammatory condition associated with various genetic defects.[188] The patients have activated oligoclonal T cells, and it appears that genes other than those directly involved in V(D)J recombination may play a role in the pathogenesis of OS. Omenn-like features are associated with mutations of genes involved in the maturation steps of lymphoid cells and not those directly regulating V(D)J recombination.[188]

OS is characterized by a cellular infiltrate of the skin, gut, liver, and spleen and a resemblance to graft-versus-host–like disease. The V(D)J recombination process is impaired but not abolished and leads to the generation of a few T cells which expand in the periphery and infiltrate target organs such as skin and gut, resulting in severe erythroderma and colitis, supporting the evidence that Omenn is an inflammatory condition.

Inherited mutations in *RAG1* and *RAG2* genes have been reported[189,190] in a series of 20 patients with OS, and were shown to result in partial V(D)J recombinase activity.[191] Because similar mutations have been detected in patients with T/B SCID, it has been suggested that an additional factor exists in OS to account for the different clinical picture, such as an autoantigen or an external antigen that drives T-cell activation. In a 5-week-old girl with

Omenn-like SCID, the *RAG1* gene had a mutation with deletion of nucleotide (631 del-T),[190] and as a result the N-terminal region of RAG1 protein was deleted by a premature stop codon. The patient had a high number of T cells with almost a polyclonal TCR gene rearrangement, but there were no B cells and hardly detectable Ig gene rearrangements. The truncated RAG1 protein apparently could still support TCR, but not Ig gene rearrangements. This suggests that the N terminus of RAG1 is specifically involved in Ig V(D)J rearrangements. Another case of OS was reported with a mutation in the *DCLRE1C* (*ARTEMIS*) gene,[192] a mutated maternal allele, and as a result the DCLRE1C protein was not functional as endonuclease, lacking the hairpin opening activity in a V(D)J recombination assay. In a cohort of nine patients with OS, only two of the nine had *RAG* mutations,[193] but the cause of OS in seven other patients remains unknown.

All patients, however, expressed restricted TCR-V and B cell repertoire, which might have occurred in response to infections. Missense mutations in *RAG1* (p.Arg474Cys and p.Leu506 Phe) result in reduced *RAG* activity with idiopathic $CD4^+$ T lymphocytopenia (ICL) and reduction of T and B cells, but no evidence of autoimmunity or infections. It is therefore likely that *RAG* mutations are associated with conditions such as severe immune defects or even an almost normal condition.

V(D)J RECOMBINATION: DNA REPAIR

A double-strand break (DSB) is one of the most significant of DNA lesions which threatens cell integrity, but the cells have developed an exquisite repair machinery to maintain genomic stability. Immune diversity, which is a function vital for the survival of an organism, has to cross the dangerous path of DSBs.[194] The body uses the nonhomologous machinery to repair the damage caused by the recombinase,[195] and the major mechanism for repair in mammalian cells is nonhomologous end joining. Five proteins operate in nonhomologous end joining; three of them form the DNA-PK complex (KU70/XRCC6, KU80/XRCC5, PRKDC), the XRCC4, and the DNA ligase IV.[196] The Ku protein is an autoantigen that induces autoantibodies in patients with scleroderma, polymyositis, or systemic lupus erythematosus. Two proteins, the XRCC6 (KU70) and XRCC5 (KU80), form a stable heterodimer, which binds DNA ends regardless of sequence composition. The heterodimer forms a complex with a third component, the DNA-PK complex, which phosphorylates many DNA-binding proteins, including transcription factors c-Jun and p53. However, the most efficiently phosphorylated substrates are those close to DSBs, including the Ku components of the DNA-PK complex, which appears to regulate the nonhomologous end joining process which is the main function of the DNA-PK complex. Mice that are defective in Ku proteins have SCID,[197,198] and in general the defects in the DSB repair machinery are associated with immune deficiencies.[199]

ATAXIA TELANGIECTASIA

AT is an autosomal recessive disorder characterized by immunodeficiency, progressive cerebellar ataxia, oculocutaneous telangiectasias, clinical radiosensitivity, chromosomal instability, and elevated risk for development of lymphoid malignancies. AT is due to deficiency of a protein kinase that mediates repair to double-strand breaks generated during metabolic processes or from DNA-damaging agents.[137] One of the hallmarks of AT is the generation of aberrant rearrangements during V(D)J recombination, such as translocations, large chromosomal deletions, and inversions. A protein kinase known as ATM mediates repairs of DSB by phosphorylating and activating several repair proteins.[135,137]

Immunodeficiency affects both T and B cells and there is a decrease of serum IgA. The AT cells display γ-irradiation sensitivity, a cell cycle checkpoint control (i.e., inability to arrest at the G_1-S and S-phase checkpoints), and a G_2-M arrest. AT cells have also a DNA repair defect,[200] i.e., they can rejoin DNA at the DSB efficiently. The defect is localized on a protein member of the PI-3K family of kinases with serine-threonine protein kinase activity,[201] which phosphorylates a number of proteins involved in the mechanisms of damage repair (i.e., p53 and CHK).[202,203]

NIJMEGEN BREAKAGE SYNDROME

Nijmegen breakage syndrome is a rare autosomal disorder with clinical features overlapping with those of AT. The patients have defective humoral and cellular immunity, radiosensitivity, chromosomal instability, and predisposition to cancer.[203]

The patients have recurrent bacterial sinopulmonary infections, hypogammaglobulinemia, and impaired antibody responses to antigens. The cells from the patients have defects at some checkpoints of the cell cycle.[204] The defective protein is NBN (nibrin or NBS1), which shows homology with the protein Xrs-2, involved in DNA repair response in yeast.

BLOOM SYNDROME

Bloom syndrome (BS) is a rare autosomal recessive disorder with immunodeficiency, genomic instability, and predisposition to cancer. It presents with a variable clinical picture including respiratory infections, chronic lung disease, and low IgM levels. Affected individuals show sun sensitivity on the face and infertility.[205] BS is caused by mutations in the *BLM* gene, located in chromosome 15 at 15q26.1, which encodes the BLM protein,[206] a member of the helicase subfamily. It displays ATP- and Mg^{2+}-dependent 3′-5′-DNA helicase activity. It is a member of the BASC (BRCA-1–associated genome surveillance complex) family, which includes *ATM* and *NBN*, which are defective in Nijmegen syndrome.

DEFECTS OF LIGASES

There are multiple DNA ligases in higher organisms and a point mutational change in DNA ligase-1, which does not abolish the activity of the enzyme. It was found in an individual who experienced recurrent sinopulmonary infections leading to bronchiectasis.[207] The patients display pancytopenia and microcephaly and the V(D)J recombination shows mildly impaired fidelity, which may result in oncogenesis.[174] In bacterial and viral infections a severe form has been reported with a SCID presentation, evolving into an Epstein-Barr virus (EBV)–induced lymphoma.[207]

XERODERMA PIGMENTOSUM

Xeroderma pigmentosum is a rare disorder associated with sun sensitivity, high risk of cutaneous malignancy in sun-exposed areas, and immunodeficiency in some patients.[208] Some aspects of immunosuppression associated with xeroderma pigmentosum are due to defects in the DNA repair machinery. The patients have impaired NK cell cytotoxicity.

GENETIC DEFECTS OF B-CELL DEVELOPMENT

Signaling during B-Cell Development

After the V_H-to-DJ_H rearrangement of the *IGH@* gene, the cytoplasmic μ-chain pairs with the SLC and traffics to the cell surface in association with the signal-transducing chains CD79A and

CD79B to form the pre-B-cell complex. Signaling for the transition from pre-B cells to Ig^+ B cells requires the immunoreceptor tyrosine-based activation motif (ITAM) of the cytoplasmic domains of the CD79A and CD79B chains, because inactivation of ITAMs by mutation blocks the transition to the Ig^+ B-cell stage.[209] Deficiency of CD79B chain by gene targeting abolishes formation of the CD79A-CD79B dimer and blocks assembly of the SLC. As a result, the differentiation of B cells is arrested at the pro-B-cell stage.[210]

Interactions of pro-B and pre-B cells with stromal elements are necessary for progression through the early stages of B-cell development, but a ligand for the pre-BCR has not yet been identified and it is conceivable that the receptor may be signaling constitutively. It is apparent that the presence of ITAM motifs and the concentration of signaling molecules around them are the critical factors in determining progression through the early stages of B-cell development. Pro-B cells are able to become pre-B cells in the absence of the μ-H chain as long as the CD79A/CD79B chains are aggregated and thus can recruit sufficient numbers of signaling molecules around their ITAMs.[211] Furthermore, signaling by other molecules unrelated to pre-BCR, such as EBV latent protein-2A (LMP-2A), can drive pro-B- to pre-B-cell transition. LMP-2A protein with ITAM motifs in its cytoplasmic region, spanning the membrane twelve times, possesses constitutively its own signaling activity in nontransformed cells.[212] Phosphorylation of these motifs recruits SYK and SRC kinases and thus bypasses the normal checkpoints of B-cell development. Of all the signaling molecules assembled around the cytoplasmic tail of the pre-BCR complex, the CD79A and CD79B chains' ITAMs act as docking sites for SYK kinase and trigger its activation, which is important for the transition from pro-B- to pre-B cell.[213] An important signaling function is provided by the adaptor protein BLNK, which acts as a scaffolding to link BTK (and other molecules) to downstream signaling molecules. In $Blnk^{-/-}$ mice the transition from the pro-B- to the pre-B-cell stage is blocked,[214] and a similar defect has been detected in a patient with deficiency of *BLNK*, which blocks B-cell development.[215] SYK kinase deficiency is more effective than BLNK deficiency in arresting B-cell development.

Signaling Defects

Failure of B-cell development may result from defects in signaling through the pre-BCR. These experiments of nature have helped in delineating the molecular mechanisms of early B-cell development.[80] Immune deficiencies resulting from arrest of B-cell development are usually associated clinically with recurrent bacterial infections, laboratory findings of markedly reduced numbers of B cells, and hypogammaglobulinemia. Of all the patients, 85% have mutations in *BTK*, whereas the remaining 15% constitute a heterogeneous group with defects of various signaling molecules.

Defects of λ-5 Genes

The SLC is formed from two components: the BPREB1 and the lambda 5 (λ5). In humans there is one *VPREB1* gene and three immunoglobulin lambda-like (lambda 5) genes (*IGLL1*, *IGLL3P* and *IGLL2P*).[216] A boy with mutations in both alleles of the λ-5 genes expressed recurrent infections, hypogammaglobulinemia, and lack of B cells at an early age. The patient had three base-pair changes in a single allele and alterations within exon-3. Changes in codons 131 and 140 were silent, whereas that in codon 142 resulted in the replacement of proline, which in this place is highly conserved, by leucine (P142L).[85] The boy at 9 years of age had 0.1% $CD19^+$ cells in the blood, but these cells were of the mature phenotype. In contrast to this patient, mice that are deficient in λ-5 have a leaky block at the pro-B-cell stage and still maintain 10 to 20% of the B cells.

Defects of *CD79A*

While screening several patients with defects of B-cell development, one 2-year-old girl was identified with an A-to-G substitution in the splice-acceptor site preceding exon 3 of Igα,[217] resulting in CD79A transcripts that were aberrant, because most of them had no exon 3. The patient showed failure to thrive, had diarrhea in the first month of life, and, later, had bronchitis and neutropenia. She had severe hypogammaglobulinemia and absent B cells. The block of B-cell development was at the pro-B-cell stage.

Defects of the μ Heavy Chain

Defects in μH have been associated with agammaglobulinemia in individuals from two families. The defects consist of a large deletion of a 75- to 100-kb segment, including D, JH, and μ genes, or a base-pair substitution in the alternative splice site, with inhibition of the synthesis of the membrane form of Ig.[218] Mutations of the μ-H chain with agammaglobulinemia should be distinguished from X-linked agammaglobulinemia, because the disease from μ-H mutations can occur in females. Another report described a female patient with a cytosine insertion at the beginning of the CH-1 exon of the μ gene, which resulted in premature codon and absence of the μ-H chain.[219]

Defects of B-cell Linker Protein

The gene for human *BLNK* is located on the long arm of chromosome 10 at 10q23.22. The BLNK is an adapter protein which, after phosphorylation by SYK, recruits several signaling molecules (i.e., PLCG2, VAV1, CBL, and BTK). A 20-year-old man with absent B cells and hypogammaglobulinemia was found to have two base-pair alterations: One of them did not change the amino acid (proline), but the second which was an A-to-T substitution, affected the position of the splice-donor site for intron-1, approximately 20 bp downstream from the first alteration. The second defect resulted in a marked decrease of the *BLNK* transcripts and BLNK protein.[215] The patient had recurrent infections, undetectable serum Ig, and at the age of 20 years less than 0.01% of $CD19^+$ cells in the blood. Mice with *Blnk* deficiency have only a leaky block of B-cell differentiation at the pro-B-cell stage; and in humans, mutations of λ-5 or *BLNK* cause a profound block of B-cell differentiation.

BRUTON AGAMMAGLOBULINEMIA

In 1952 Bruton described a male child with hypogammaglobulinemia and early onset of bacterial infections,[220] later found to be inherited in an X-linked pattern that became known as X-linked agammaglobulinemia.[221] The constellation of findings consisted of very low serum Ig levels (i.e., for IgG approximately 10% of the normal control), no antibody production after immunization, markedly decreased B cells (0.3% of normal levels), and no germinal centers.[222] The genetic defect was located in the midportion of the long arm of the X chromosome (i.e., Xq22).[223] There are several variants of the disease in relation to immunologic function and clinical heterogeneity.[224] The product of this gene was identified as an SRC protein tyrosine kinase (PTK) that was called Bruton tyrosine kinase or BTK,[225,226] and more than 400 mutations have been characterized to date.[227] *BTK* is essential to BCR signaling and the BTK protein and the mRNA are significantly overexpressed in CLL compared with normal B cells. Although *BTK* is not always constitutively active in CLL cells, BCR or CD40 signaling is accompanied by effective activation of this pathway.

BTK is a member of the BTK-Tec family of PTKs, which includes *BTK, TEC*, *ITK*, *TXK*, and *BMX*.[228] In the C-terminal end the *BTK* contains the catalytic SH-2 domain, and next to it lies the SH-2 domain, which associates with phosphorylated tyrosines

in other signaling molecules. The SH-2 is followed by one SH-3 domain, which binds proline-rich sequences in protein–protein interactions, and next is a T-ec homology (T-H) domain, which contains the Zn^{2+}-binding BTK motif and a proline-rich stretch. At the N terminus is the pleckstrin homology (PH) domain, which binds with high-affinity phosphatidylinositol-3,4,5-triphosphate (PIP_3) and is responsible for the translocation of BTK to the membrane. BTK occupies a central position in BCR signaling and regulation of lineage development and is linked to multiple downstream signaling pathways through BLNK (also known as SH2 domain–containing leukocyte protein [SLP-65). BLNK functions as a scaffolding protein and binds to the SH2 domain of BTK.[229] It connects Syk to BTK and links BTK to downstream signaling molecules, like PLCG2, a linkage essential for Ca^{2+} signals.[230] BTK also associates with Wiskott-Aldrich syndrome protein via the SH_3 domain; this is the reason that in XLA patients with defective BTK, the collagen-induced tyrosine phosphorylation of Wiskott-Aldrich syndrome protein in platelets is reduced.[231] Different regions of BTK are critical for its activation and signal transduction, that is, the PH domain binds to Ca^{2+}-dependent (α, β-I, β-II) and Ca^{2+}-independent isoforms of protein kinase C (PKC) (ε and ζ), to $I\text{-}P_3$,[232] and to heterotrimeric G proteins.[233] Sequential phosphorylations of regulatory tyrosines by the BRC-associated Src kinases activate BTK, such as the phosphorylation of Tyr551 in the kinase domain or Tyr 223 in the SH-3 domain.[234,235]

In SRC kinases, negative regulation is mediated by the Tyr-527 in their C-terminal region, but BTK has no equivalent residue, and it is likely that such a function is mediated by the recently identified inhibitor of BTK (I-BTK). I-BTK binds to the PH domain and downregulates Btk function, such as Ca^{2+} mobilization and NF-κ B activation.[236]

BTK is a bidirectional regulator with the capacity to deliver survival or apoptotic signals, depending on the expression of surface receptors and the stage of the cell differentiation.[237,238] The molecular mechanism of *BTK* function in XLA is still not quite clear. Mutations of *BTK* gene, i.e., deletions, insertions, or substitutions,[239] produce variable degrees of immunodeficiency, whether in the kinase domain[226] or in other domains.

Evidence from the bone marrow of XLA patients shows that there is an expansion of pro-B cells, whereas the numbers of more mature B cells are negligible.[240] Based on the expression of VPREB1, the pre-BI cells are SLC-positive, and a number of them are large in size and cycling, whereas the pre-BII cells are SLC-negative. It appears that BTK blocks normal B-cell maturation at a point just before that stage (i.e., it interferes with the transition of pro-B cells to pre-BI stage).[240] Some patients express an inactive form of BTK and have a more severe form of XLA than those expressing no BTK molecule.[241]

EARLY STAGES OF B-CELL DEVELOPMENT

The study of phenotypes of B-cell precursors in normal adult bone marrow is hampered by the relative paucity of these cells. Therefore, some investigators have resorted to the study of leukemias, under the assumption that they accurately reflect normal B-cell development. Because aberrant phenotypes in acute leukemias have been identified, suggesting asynchronous antigen expression, the validity of the results from such an approach has been challenged.[1,242] Studies which used normal adult bone marrow[243] or fetal bone marrow and fetal liver[244,245] as a source of B-cell precursors in cultures or after injection in SCID mice have shown that B lymphocytes derive from cells expressing high levels of CD34.[246,247]

The development of B cells can be separated into three stages according to phenotype: (a) pre-B cells (which includes pro-B cells and pre-B cells), (b) immature B cells, and (c) mature B cells (Fig. 12.1). Markers defining the first stage are CD19; occasionally some other promiscuous markers, such as CD2 or CD7, are detected, but probably the best marker is the SLC, a hallmark of a B cell, which may be detected by a monoclonal antibody. Entrance into the immature B-cell stage is defined by the expression on the surface of the cell of IgM, with antisera not only for μ chains but also for κ or λ light chains. This indicates that the μ chain is associated with a light chain and not with the SLC, and therefore the Ig gene rearrangements are complete. The immature B-cell stage is characterized by expression of only IgM without IgD. Functionally, this is important because the former phenotype defines a cell that is vulnerable to tolerogenic stimuli, indicative of its immaturity. At this stage the cell expresses other markers, such as CD10 at high density. The mature B-cell stage is simply identified by coexpression of IgD as well as other markers such as CD20, CD21, and CD22.

Another useful phenotypic marker for precursors of B cells is the nuclear enzyme TdT,[248] which is a DNA polymerase catalyzing the elongation of polynucleotide chains without template,[249] and which adds *N*-nucleotides at the DNA cleavage site during V(D)J recombination. CD24 is also expressed at a very early stage and at a higher density compared to mature sIg^+ B lymphocyte.[250] The expression of the CD2 has been detected on biphenotypic ALL cells and also on their normal counterparts in human fetal hematopoietic tissues,[251,252] but whether they represent common T- and B-lineage progenitors remains to be seen. Pre-B cells have been detected during fetal life, first in the liver (by 8 weeks) and later in the bone marrow (by 12 weeks).[253,254] In the liver they are mixed among other myeloid cells next to liver parenchyma in extrasinusoidal areas.[255] The small pre-B cell, the immediate precursor of the immature B cells, starts to express sIgM by the end of the first trimester, and in adults the pre-B cells are present in the bone marrow, where they constitute 0% to 7% of the nucleated cells but rarely are noted in the peripheral lymphoid organs.

During the last phase of pre-B cell development, expression of CD34 and TdT disappears, CD10 is downregulated, and the cell expresses first CD22 and later CD20. Before its appearance on the cell surface, the CD22 is detected in the cytoplasm very early during development. It is identical to the surface CD22 and is B-lineage–restricted.[256] The receptors for Fc are not present on pre-B cells, but receptors for C3b have been detected in some large pre-B cells and in approximately 40% of the small pre-B cells.[257]

MATURE B LYMPHOCYTES

The expression of sIgM is the hallmark of B lymphocytes, which early in life are mostly $CD5^+$ and settle in the primary lymphoid follicles. By 13 weeks most of the B cells are IgM^+IgD^+, but later IgG or IgA are added. This phenotype of fetal B cells persists until birth and is converted to the adult phenotype during the first few months of life. By 10 weeks of age practically all B cells in the spleen are IgM^+IgD^+, whereas in the bone marrow only 30% to 40% coexpress the two isotypes. Maturation of B lymphocytes is associated with a change in the density of the two isotypes from $IgM^{high}IgD+^-$ eventually to $IGM^{low}IgD^{high}$. New markers appear on B lymphocytes with the expression of IgM (Fig. 12.1), such as the CD21 which is present in more than 90% of the cells, as well as the C3d/EBV receptor. Activation triggers loss of CD21 and CD22, while CD23 is expressed and is upregulated by IL4.[258] The EBV nuclear antigen-2 (EBNA-2)[259] is downregulated by interferon-γ. Expression of CD24 decreases with B-cell maturation and in combination with the expression of CD45, it can be used to identify the mature stage of B cells, and it is useful in B-cell neoplasias.[260] CD45 expression varies with B-cell maturation and is low in the most immature precursors in the bone marrow. It is upregulated as normal B-cell differentiation progresses and then declines at the terminal stages of differentiation as plasma cells become negative for CD45.[261]

Probably the most important application of the B cell phenotype is in B-cell malignancies such as leukemias and lymphomas, which arise in distinct stages of differentiation. An attempt to incorporate the immunophenotype into the traditional morphologic features resulted in the revised classification of well-defined disease entities[262] by the World Health Organization.[263]

SURFACE IMMUNOGLOBULIN

Surface Ig on the surface of B lymphocytes serves as the receptor for antigen and is identified most commonly with the use of fluorochrome-conjugated anti-Ig antisera. The first Ig to appear on B lymphocytes is IgM, which is composed of only one subunit, in contrast to the secreted pentameric form of membrane IgM (mIgM), containing two H and two L chains. The second isotype to appear is IgD, which is present either as a complete four-chain molecule or as a half-molecule. IgD is present in the serum in very low concentrations and it is not known to have a role in humoral responses, by tuning finely the BCR for its binding with the antigen.[264] The ratio of secreted Ig to mIg increases with maturation from resting B cells to plasma cells. The transmembrane and secreted forms are encoded by the same gene. There are two polyadenylation sites for transcription termination; one is 3′ to the last exon of the constant chain and the second is 3′ to the second transmembrane exon (Fig. 12.7). Termination at the first site results in loss of the transmembrane exons and production of the secreted form, whereas polyadenylation at the second site produces the membrane form of Ig.

Each B lymphocyte contains on the average 50,000 to 100,000 molecules of Ig, although the density of sIg varies among individual B cells.[265] The mIg is distributed on the surface in small clusters, including the microvilli[266,267]; in human B lymphocytes the clusters are separated from each other by a few thousand angstroms of bare membrane, indicating restriction in the free distribution of mIg. In the mouse the clusters are interconnected by strands composed of a few molecules forming a lacy continuous network. When examined at 4°C in the fluorescent microscope with fluorescein-conjugated anti-Ig antibodies, the mIg appears distributed as a ring, and the increase in temperature to 37°C prompts the formation of clusters (patching) that move rapidly toward one pole of the cell, forming a cap[268] (Figs. 12.8 and 12.9). Shortly after the formation of the cap, changes in cell shape occur accompanied by cell movement. The cell pushes out a projection located opposite to the cap, which corresponds to the membrane ruffles noted on scanning electron microscopic analysis[269] (Fig. 12.10).

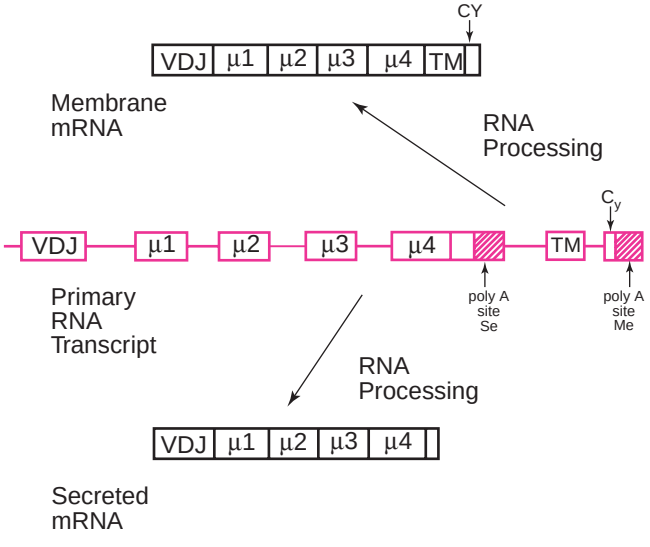

FIGURE 12.7. Expression of membrane versus secreted immunoglobulin (Ig) depends on alternative processing of the primary RNA transcript. There are two polyadenylation (poly A) sites, one for secreted (Se) and one for membrane (Me) forms. Cμ1–Cμ4 are the exons of IgM. Cy, cytoplasmic region; mRNA, messenger RNA; TM, transmembrane region.

After the formation of the cap, a constriction under the cap encircles the cell and the cell takes the shape of a hand mirror, with the cap occupying the area of the uropod with numerous microvilli. A dense band of microfilaments is collected under the constriction which separates the cell body from the uropod, and the area opposite the cap contains the cell organelles and the nucleus.[270]

The majority of human B lymphocytes cannot form a cap because the Ig clusters on the surface of the cell are widely separated from each other. Capping requires energy provided by the respiratory chain and glycolysis and is not affected by cell motility, which is complete in many B cells before any amoeboid movement is noticed.[270]

Colchicine, which disrupts microtubules, has no effect on capping and only a slight effect is noted with cytochalasin B, which disrupts the microfilaments; but the combination of these drugs inhibits mIg capping. Calcium, which plays an important role in contractile systems, is also involved in mIg capping.[270,271] The fate of the complexes in the cap has been studied morphologically using autoradiography, electron microscopy, and measurements of radioactivity. The bulk of the complexes is internalized (endocytosed) in the presence of adequate antibody. Endocytosed material is catabolized within the lysosomes, and small fragments are released into the culture medium. With the completion of endocytosis, the B lymphocyte remains free of mIg until it is resynthesized to the original level in 24 hours.

BCR COMPLEX: STRUCTURE AND SIGNALING

The surface Ig (sIg) of the B lymphocyte, or BCR, forms a complex with several components assembled into two structurally and functionally distinct modules: an antigen-recognition module (sIg) and a signal-transducer module which is the heterodimer of the CD79A/CD79B polypeptide chains (Fig. 12.11).[272,273,274]

The BCR is an antigen-specific receptor which transmits signals regulating activation, growth, and differentiation. Since the cytoplasmic tails of both heavy chains of mIgM consist of three amino acids, the mIgM is not suitable for signal transduction; as a result this function is undertaken by two other proteins, associated with the mIgM BCR: CD79A with a 61-residue cytoplasmic tail and the CD79B with a 48-residue tail. The cytoplasmic domain of the CD79A and CD79B proteins initiate their internalization by a signal from the first cytoplasmic tyrosine residue, Y-176 of the CD79A and Y-195 of CD79B. The genes encoding these proteins are also known as mb-1 and B-29, respectively. The transmembrane region of Cμ is a highly conserved portion of the Ig molecule between species and isotypes and provides the site which binds the CD79A/CD79B heterodimer. The conserved amino acids are not all hydrophobic, but contain several hydrophilic residues; and its amphipathic nature indicates that mIg forms complexes with other proteins. These proteins carry in their cytoplasmic tails a sequence motif of six conserved and precisely distributed amino acids (tyrosines and negatively charged amino acids) over a sequence of 26 residues.

The motif named immunoreceptor tyrosine-based activation motif, or ITAM,[275] is found in γ, δ, ε, ζ, and η chains of CD3 and Fc receptors. The ITAMs are sequences in multiple receptor chains, and in TCR they mediate signal transduction following phosphorylation of the two tyrosines in the ITAM, which activates the SRC family kinase Lyn, but not SYK. In mice the B-lymphocyte accessory molecule Cd79a (I-α), which is encoded by the B cell–specific gene *Cd79a* (mb-1), Cd79b (Ig-β) and the

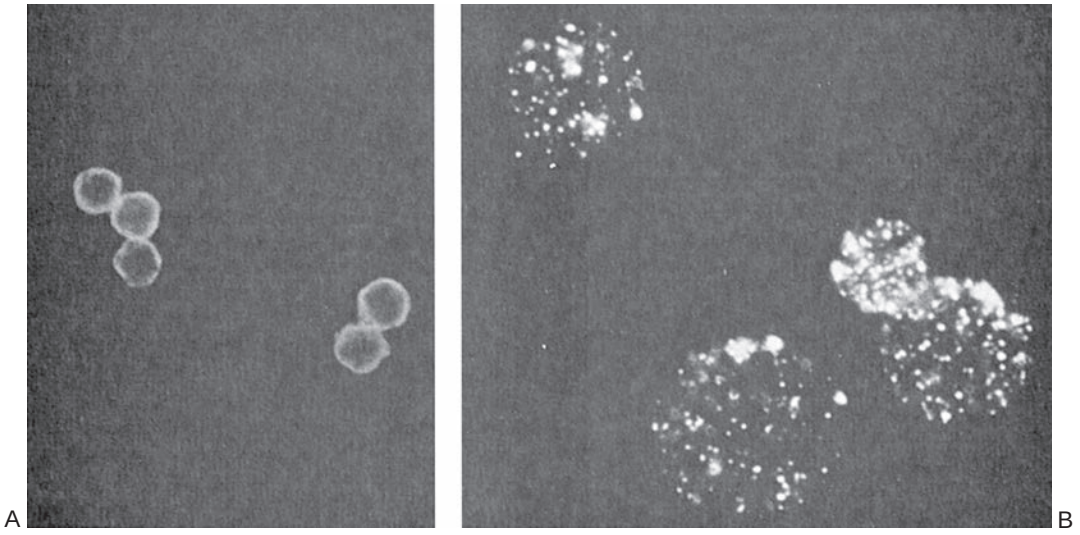

FIGURE 12.8. Demonstration of surface immunoglobulin (Ig) by immunofluorescence on B lymphocytes. Viable normal B lymphocytes treated with anti-IgM antiserum at 4°C present a staining pattern of a uniform ring around the periphery of the cell **(A)** or discrete patches uniformly dispersed over the cell surface **(B)**. (From Zucker-Franklin D, Greaves MF, Grossi CF. Atlas of blood cells, 2nd ed. Philadelphia, PA: Lea & Febiger, 1988, with permission.)

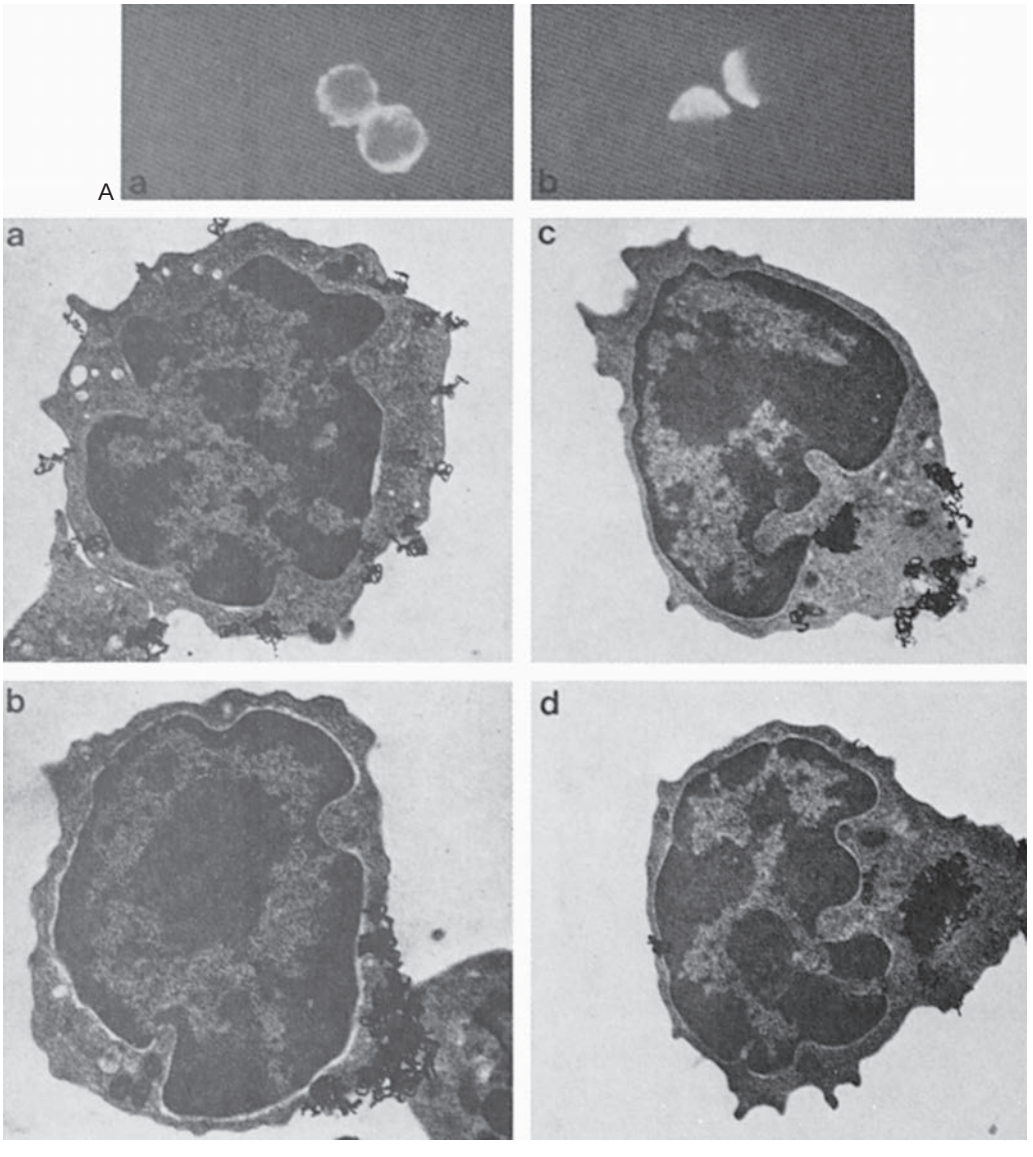

FIGURE 12.9. Redistribution of surface immunoglobulin (Ig). A: Mouse B lymphocytes treated with fluorescein-conjugated anti-mouse Ig antibody. **a:** Surface Ig is uniformly distributed around the cell (ring pattern). This pattern is seen only if the cell is kept at 0°C. **b:** Warming the cell to room temperature causes redistribution of the Ig so that it occupies only one pole (cap pattern). (From Taylor RB, Duffus WP, Raff MC, de Petris S. Redistribution and pinocytosis of lymphocyte surface immunoglobulin molecules induced by anti-immunoglobulin antibody. FIGURE 12.11. The B-cell receptor (BCR). The surface immunoglobulin (Ig) (two heavy and two light chains) constitutes the antigen-specific component of BCR, which is associated noncovalently with a heterodimer consisting of two chains, Igα and Igβ. This heterodimer constitutes the signal transduction component. The Igα chain associates with the H chains through ionic interactions. ITAM, immunoreceptor tyrosine-based activation motif; mIgM, membrane immunoglobulin M.

membrane-bound immunoglobulin (mIg) form the B-cell receptor (BCR). Cd79a and Cd79b form a heterodimer which, upon antigen binding and receptor clustering, initiates and controls BCR intracellular signaling, ultimately triggering an effector response. The signaling capacity of Cd79a is contained within its immunoreceptor tyrosine-based activation motif (ITAM), which is also a key component for intracellular signaling initiation in other immune cell-specific receptors and is required in Syk-dependent integrin signaling. Following the binding of the ligand by the BCR, the ITAMs transmit activation signals initiating proliferation and differentiation of the B cell. However, the ITAMs also transmit what have been called tonic signals, which have a role in B cell development and survival;[276] but the molecular mechanism for their induction is not known. The *CD79A* and *CD79B* genes are active only in the B lineage and are expressed before the assembly of the V gene. In cells from multiple myeloma, however, only the *CD79B* is expressed and that prevents expression of Ig in plasma cells. The expression of surface Ig requires the complete assembly of the Ig with the CD79A/CD79B heterodimers, which explains the lack of detection of mIg on plasma cells;[277] and indeed, the transfection of plasma cells with the *CD79A* gene results in expression of sIg.[278] A patch of polar amino acids within the transmembrane region of Cμ signals the retention of IgM within the ER until the CD79A/CD79B heterodimer associates with IgM for transportation to the cell surface.

The functional B-cell receptor is a complex consisting of IgM with one CD79A/CD79B heterodimer on each side.[279] New

evidence, however, indicates that each IgM molecule is associated with only one CD79A/CD79B heterodimer (Fig. 12.11).[280] If this model is correct, the question remains whether both chains are linked to IgM, or whether only CD79A binds to both heavy chains and CD79A-BCR forms oligomers with additional molecules of the same isotype.

B-CELL RECEPTOR AND LIPID RAFTS

Ligand binding changes the orientation of the BCR molecules so that their ITAMs become more accessible to phosphorylation, which causes signal spreading restricted to BCRs of the same isotype.[280] Lipid rafts are dynamic assemblies of proteins and lipids that float freely within the liquid-disordered bilayer of cellular membranes, but can also cluster to form larger, ordered platforms which regulate membrane function in eukaryotic cells.[281] These early events of BCR reorganization provide a mechanism for detecting low concentrations of antigens, thus increasing the threshold of activation. Cross-linking of BCR by multivalent antigen leads to a series of morphologic and molecular events that are interrelated, i.e., BCR aggregation and its loading to lipid rafts, signaling, and finally internalization and antigen presentation.

In the resting state the BCR floats on the cell membrane as monomer, but at the time of signal spreading it forms oligomers which are carried on specialized membrane microdomains referred to as lipid rafts. Lipid rafts are estimated to represent 30% to 40% of the cell surface in lymphocytes and have a role in B-cell activation as platforms for BCR signaling and might also act in antigen trafficking. Lipid rafts are an important component of B-cell signaling, since they facilitate the regulation of the BCR during B cell development by B-cell coreceptors.[282] Their size varies from submicroscopic dimensions which contain only a few hundred phospholipid molecules and four to ten protein molecules. Cross-linking of the BCR with antigen enhances its transfer to lipid rafts,[281,282,283,284] while the pre-BCR which is constitutively located on lipid rafts generates a calcium signal.[75] Lipid rafts are also preferential sites of formation of prion proteins and β-amyloid associated with Alzheimer's disease.[285]

The mechanism of their action is not clear, but it is believed that they act as molecular sorting machines, coordinating signal transduction pathways. It is rather intriguing that they serve as portals of entry for various pathogens and toxins, such as HIV-1. In this case the raft microdomains mediate the mechanisms of the fusion of HIV-1 with the host cell. Lipid rafts are enriched in cholesterol and glycosphingolipids with saturated fatty acid side chains consisting of GM-1 gangliosides, and are resistant to solubilization in nonionic detergents at low temperatures. Most proteins are excluded from the lipid rafts, except proteins modified by saturated fatty acids such as acylated Src kinases and the α-subunits of trimeric G proteins. They facilitate BCR signaling by co-localizing signaling molecules, i.e., LYN, FYN, and BLK, members of the SCR family of kinases, but also by excluding molecules that inhibit BCR signaling such as CD22. Furthermore, in anergic or tolerized B cells, the BCR is unable to enter lipid rafts, indicating that inclusion of BCR within these microdomains is an absolute requirement for initiation of signaling.[286] Similarly, localization of BCR within the rafts occurs only in mature, but not immature, B cells.[287] The translocation of the BCR into lipid rafts is independent of any signaling initiated by the receptor and does not require actin cytoskeleton polymerization or the CD79A/CD79B complex.[288] Lipid rafts facilitate not only activation but also apoptosis, because cross-linking of CD24, a glycosylphosphatidylinositol-anchored protein that is downregulated during B-cell differentiation, induces apoptosis via a lipid raft signaling system.[289] CD24 cross-linking brings some BCR within the lipid rafts, activating LYN kinase. EZR (EZRIN) is a member of the ezrin–radixin–moesin (ERM) family, is dephosphorylated by BCR, and is detached from the actin as well as from lipid rafts, resulting in greater coalescence of lipid rafts and more effective B-cell activation.[290] B cells are not only antibody-producing cells, but in addition are antigen-processing and -presenting cells. For this function they interact with antigen-specific T cells to receive T cell help.[291] Antigen captured by B cells induces BCR cross-linking, translocation into lipid rafts, where it is phosphorylated, promoting BCR internalization mediated by clathrin associated with the rafts. This is followed by BCR cross-linking, antigen internalization, which is diverted to the endocytic pathway for further processing and presentation to T cells.[284]

The B cell antigen receptor and the T cell receptor have no inherent kinase activity and, like other multichain immune recognition receptors (MIRRs), they are associated with members of the SRC family kinases to initiate signaling spatially organized by the lipid rafts and regulated by clathrin.

The CD21/CD19 complex coreceptor markedly enhances BCR activation, stabilizes the residence of BCR within the rafts, and thus prolongs B-cell activation.[292] In contrast, the FCGR2, which inhibits B-cell activation, destabilizes BCR-raft association.[293] After translocation of BCR (or other immune receptors) onto lipid rafts, the rafts appear to form clusters, i.e., clustered rafts,[281] which increases the range of their diameters from hundreds of nanometers to micrometers. Clustering results from cross-linking of receptors located on separate rafts and eventually from the linking of rafts with linker proteins. In addition, cytosolic proteins that have been associated with the cytoplasmic domains of receptors residing on a raft may also contribute to the bridging of individual lipid rafts to form larger conglomerates. Cytoskeletal components are also linked to activated receptors and their reorganization bridges clustered rafts.

Continuation of raft clustering eventually leads to the formation of the synapse, a highly ordered membrane structure in which immune receptors, signaling molecules, and cell adhesion molecules are clustered.[294] Synapse formation is a highly organized structure with a cluster of immune receptors in the center ringed by adhesion molecules and several signaling molecules and cytoskeletal components on the cytoplasmic side.

The formation of a synapse was first described in T cells, but it has now been detected on B cells,[295] suggesting that this is a unique mechanism associated with foreign antigen capturing for processing and handling by the immune system to secure a cellular response. When DC capture the antigen, they trigger the formation of the synapse on B cells and during the close encounter between B cell and DC around the synapse, the B cell samples and gathers antigen for internalization and processing. Internalization of the antigen and signaling are two interrelated and inseparable events mediated by lipid rafts.[282,296] B cells with deficiency of expression of the SRC kinases, which normally initiate B-cell signaling, fail to internalize the receptor, and as a result, targeting of antigen to MHC-II peptide-loading compartment is also disrupted.[297] Internalization of BCR occurs when clathrin, which is associated with the rafts, is phosphorylated on its tyrosine after BCR cross-linking.[293] When lipid rafts are disrupted by the expression of LMP2A protein of the EBV or by reagents that sequester cholesterol, the internalization of the antigen does not occur.[298,299]

Expression of LMP2A therefore not only inhibits BCR function, but generates a ligand-independent cellular activation signal, which provides a molecular switch for different EBV life cycle stages and thus contributes to EBV-associated lymphoproliferative disorders.

B-CELL RECEPTOR SIGNALING

The most important structural elements of signaling molecules for the initiation of B-cell activation and differentiation are the ITAM motifs of the CD79A/CD79B heterodimer and the PTKs associated with the complex (Fig. 12.12). The ITAM is characterized by a sequence of 26 amino acids, D/E-X_7-D/E-X_2-YXXL/I-X_6(7)-YXXL/I, with six of them being conserved (X = any amino acid). Critical for signaling are the two tyrosines (Y), and one or both of them are phosphorylated when the BCR is engaged by antigen. Some evidence suggests that activation of B cells may be triggered not only by the tyrosine-based activation motif (ITAM), but by a critical non-ITAM tyrosine 204 residue that is conserved in evolution.[300]

BCR signaling is a highly complex process,[213, 301, 302] but for the sake of understanding, we divide the interactions somewhat arbitrarily into three major pathways: (a) initial interactions, (b) phosphoinositide pathways, and (c) the ras pathway.

INITIATION PATHWAY

BCR has no intrinsic protein tyrosine kinase (PTK) activity but uses several distinct families of cytoplasmic PTKs. Three distinct types of PTKs are activated on BCR engagement: (a) the SRC-PTKs (LYN, BLK, and FYN), (b) SYK, and (c) BTK.[301] Activation of LYN is one of the earliest events in BCR-induced signaling, which is constitutively acylated and, as a result, localizes in the cell membrane. It is responsible for the initial phosphorylation of the ITAMs of CD79A and CD79B. The kinase activity of LYN is regulated by phosphorylation of a carboxy-terminal regulatory tyrosine by the kinase CSK[303] and dephosphorylation by the phosphatase CD45.[304] LYN has one SH-3 domain on its N terminus, followed by one SH-2 domain and the kinase domain in the C terminus. SH-2 domains bind phosphorylated tyrosines, whereas the SH-3 domains bind proline-rich sequences. BCR engagement triggers dephosphorylation of Tyr-508 by the CD45 phosphatase, whereas Ty394 within the catalytic domain is rapidly phosphorylated. SYK kinase is recruited to the phosphorylated ITAMs of CD79A and CD79B, and is phosphorylated by LYN or by an autophosphorylation mechanism.[305]

Activation of SYK is a critical event in BCR signaling and for recruitment of BLNK, or SLP-65, a linker protein with a major scaffolding function connecting several downstream signaling molecules.[306] BLNK assembles macromolecular complexes that include PLCG2, VAV, BTK, and additional linker proteins GRB2 and NCK1.[307,308]

Phosphorylation of five tyrosine residues of BLNK is required for coordination of the assembly of multimolecular complexes. BTK belongs to the TEC family of kinases and differs in several aspects from the SRC kinases (i.e., it is not myristoylated, does not contain a negative regulatory phosphorylation site in the C terminus, and has a pleckstrin homology domain [PH] in the N terminus). BTK function is regulated by phosphorylation of the Tyr551, which is essential for BTK participation in signal transduction.[234] BTK also interacts with phosphatidylinositol-3,4,5-tri-phosphate (PIP3), an interaction required for recruitment of BTK to the cell membrane.[309] Because PIP3 is generated from activated PI3 kinase, BTK is targeted to the membrane after PI3 kinase activation, where it could be phosphorylated by LYN or SYK.

GENERATION OF PHOSPHOINOSITIDES

Hydrolysis of inositol-containing phospholipids is mediated by the lipid metabolizing enzymes PLCG2 and PIK3CA. There are several pathways leading to activation of PLCG2 in B cells.[310] BLNK associated with PLCG2 (which is the main isoform in B cells) brings it to an appropriate position for activation by SYK kinase. On the other hand, BTK also contributes to PLCG2 activation because B cells from XLA patients show a profound reduction of IP3 production on BCR engagement.[311] PIP_3, the product of PIK3CA activation, binds to the PH domain of PLCG2, thus providing another pathway for PLCG2 activation. PLCG2 activation leads to hydrolysis of phospholipids, generating IP_3 and DAG (diacylglycerol). IP_3 binds to appropriate receptors on the ER, leading to Ca^{2+} release from internal stores.

PIK3CA is activated by at least two pathways and a prominent substrate for tyrosine phosphorylation is the product of the oncogene *CBL*. BCR engagement phosphorylates p12-CBL, which is then associated with the 85-kDa component of PIK3CA.[312] A second pathway is through the CD19/CD21 coreceptor complex.[313,314] BCR stimulation phosphorylates the two YXXM motifs of CD19, which then bind the SH-2 domain of the p85 regulatory subunit of PIK3CA. Enhanced phosphorylation occurs when the CD19/CD21 complex binds C3d fragments. Furthermore, the proline-rich region of the p85 subunit binds to SH-3 domains of LYN and FYN, further enhancing PIK3CA activation.

Ca^{2+} binds to calmodulin and promotes calmodulin-dependent protein kinase activation and calcineurin, a serine-threonine–specific protein phosphatase. Calcineurin directly dephosphorylates the NFAT family of transcription factors.[315,316] DAG1, (diacylglycerol), one of the two second messengers produced by *PLCG2* gene activation, activates cPKC. One target of PKC on B cells is *MARCKS*, (Myristoylated Alanine–Rich C- Kinase Substrate) that regulates actin reorganization. Elevation Ca^{2+} also activates a number of other transcription factors, such as NF-κB and ATF2. Phosphoinositides generated by PIK3CA bind to AKT1(PKB) kinase, an evolutionarily conserved kinase across species.[317] AKT1 is the product of an oncogene transduced by the acute transforming retrovirus (Akt8). The viral and cellular oncogenes encode a serine-threonine protein kinase consisting of a C-terminal kinase domain and an N-terminal PH domain. Mutations of the PH domain block AKT1 activation by growth factors or phosphoinositides. AKT1 activation is also mediated by the serine/threonine kinase PDK1 (Pyruvate Dehydrogenase Kinase 1), which is stimulated by PIP_3 and phosphorylates AKT1 on Thr308. AKT1 inhibits glycogen synthase kinase 3 (GSK3), which destabilizes MYC and cyclin D, both required for cell cycle progression. A combination of various AKT1 activation effects plays a role for its transforming and oncogenic potential. Some of its multiple effects include transcriptional regulation of gene expression, inhibition of apoptosis, cell cycle regulation, insulin-induced metabolic signals, endocytosis, etc.

THE RAS PATHWAY

BCR cross-linking leads to an increase of the guanosine triphosphate (GTP)–bound ras and its accumulation in the membrane under BCR. RAS is a guanine nucleotide–binding protein, which cycles between a guanosine diphosphate (GDP)–bound (inactive) and a GTP-bound (active) state. The proteins of the RAS family are proto-oncogenes, which, on mutation, accumulate in the GTP-bound state in human tumors. On activation of B lymphocytes, Ras is rapidly converted to the GTP-bound state. The cycle between GDP and GTP binding is controlled by guanine nucleotide exchange factors (GEFs) that promote the transition from a GDP- to a GTP-bound state. This is reversed by guanosine triphosphatase (GTPase)–activating proteins, which stimulate GTPase activity of Ras and result in hydrolysis of GTP to GDP. The balance between GEFs and GTPase-activating proteins regulates RAS activity.[318] The most likely pathway of ras activation is through the adapter protein SHC1, which is phosphorylated after

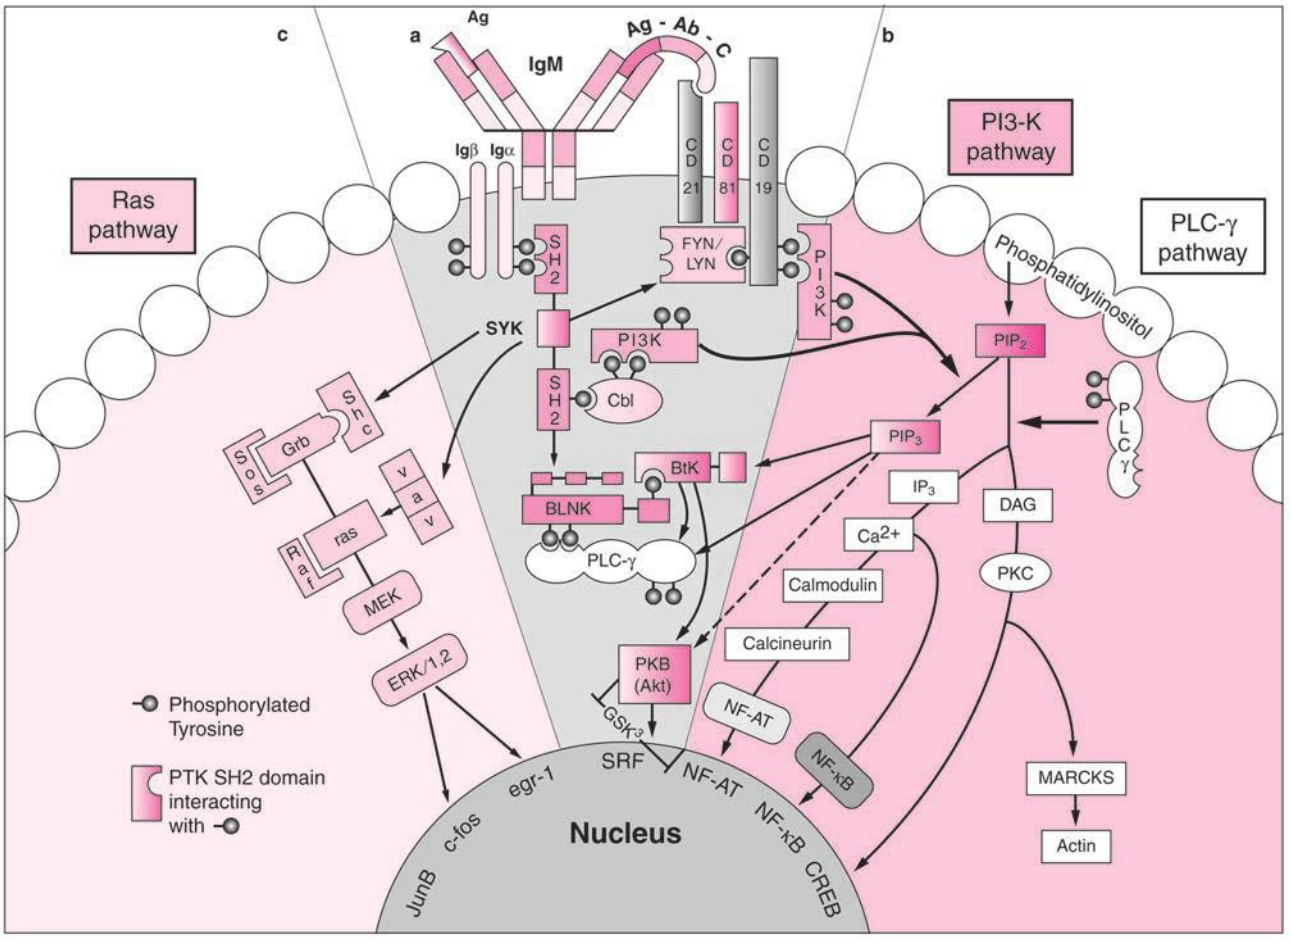

FIGURE 12.12. B-cell activation. Signal transduction initiated by the engagement of the B-cell receptor (BCR) is a highly complex process. For better understanding, it is divided arbitrarily into three main signaling pathways: (a) initiation: with the assembly by adapter proteins such as BLNK (B-cell linker protein), Cbl, and others of signaling protein tyrosine kinase (PTK) complexes such as Src (Lyn, Fyn), Syk, and Btk; (b) inositol phosphatides generation by the activation of PI3K and PLC-γ; (c) the ras/Erk pathway assembled by adapter proteins Grb, Shc, and Sos. These pathways carry the signals downstream to other signaling molecules Akt, calcineurin, and Erk/1,2, and to activation of transcription factors nuclear factor-AT (Nfat), NF-κB, Creb, c-fos, etc.

BCR engagement. SHC1 binds to a second adapter protein GRB2, which in turn binds to SOS, a nucleotide exchange factor.

This multimolecular complex is associated with the membrane.[319,320] A guanine nucleotide exchanger protein, VAV, which is a GEF in the Rho family of GTPases, is recruited to the phosphorylated Tyr-341 and Tyr-345 of SYK through its SH-2 domain and is subsequently phosphorylated.[321] These RAS-like proteins are molecular switches that are active in the GTP-bound state and can promote site-specific actin polymerization to create alterations in plasma membrane structures such as filopodia and lamellipodia. VAV has a Dbl homology domain, which has the GEF activity, a PH domain (binds phosphoinositides), an SH-2 domain, and two SH-3 domains. The PH domain of VAV uses PIP_3 for recruitment to the cell membrane. VAV may also be recruited to the membrane by binding to Tyr-391 of CD19. A negative regulator of the RAS pathway is CBL, which competes for the binding to SOS. CBL (*C*asitas *b*-lineage *l*ymphoma) is the cellular homolog of v-Cbl, part of the transforming gene of the Cas-NS1 retrovirus, a murine virus, capable of causing pre-B-cell lymphomas. It contains a proline-rich region (residues 481 to 688), a leucine zipper motif (residues 855 to the C terminus), and multiple potential SH-2–binding motifs. It binds to PTKs such as FYN, ZAP70, and BTK, to the adapter molecule GRB2, and to PI-3K.[322] In B-cell signaling, CBL binds to BLNK through its SH-2 domain and inhibits association of PLCG2 phosphorylation.[323]

Binding of SOS and CBL to GRB2 is mutually exclusive, because the proline-rich domains of these proteins compete for the same SH-3 domain of GRB2. A group of signal transduction pathways is characterized by successive phosphorylations of serine/threonine kinases. This group consists of a mitogen-activated protein kinase (MAPK), a MAPK kinase (MAPKK), and a MAPKK kinase (MAPKKK). RAS-GTP phosphorylates RAF1, which is the MAPKKK of this cascade. RAF1 phosphorylates and activates MAP2K1 (MEK1) and MAP2K2 (MEK2), which in turn phosphorylates MAPK3 (ERK1) and MAPK1 (ERK2). Phosphorylated ERKs form dimers and are translocated to the nucleus, where they phosphorylate transcription factors c-fos and JUN members of the ETS family.

ADAPTER MOLECULES: PLASTICITY AND DIVERSITY OF SIGNALING

Adapter proteins possess domains that mediate protein–protein or protein–lipid interactions, but they have no enzymatic activity. Two groups of adapter proteins can be identified: transmembrane adapter proteins and cytosolic adapter proteins (CAPs). In general, adapter proteins assemble multimolecular signaling complexes and direct their formation to specific cellular locations.[324–327] At the initial stages of B-cell activation, LYN, SYK, and

BTK kinases are activated. A transmembrane adapter protein, PAG (*p*hosphoprotein *a*ssociated with *g*lycosphingolipid-enriched microdomains), links Lyn to the kinase that phosphorylates the C-terminal tyrosine for LYN activation. The CAP adapter protein BLNK (or SLP-65, *S*H-2 containing *L*inker *P*rotein of 65 kDa) connects BTK to SYK and brings PLCG2 on the lipid rafts. There are inhibitors for adapter proteins, such as I-BTK, which binds to the pleckstrin domain of BTK and negatively regulates its activation. BLNK, which connects several important molecules to BCR for the initial stage of signaling, is indispensable for LMP2A (latent membrane protein), a constitutively activated EBV protein in infected B cells. LMP2A signaling can substitute for the signaling of BCR and maintains survival of EBV-infected B cells, leading to infectious mononucleosis or Burkitt lymphoma. The CAP BLNK is clearly required for the translocation of PLCG2 from the cytosol to the plasma membrane and its subsequent activation. BLNK (SLP-65) is essential in pre-B-cell development and, with BTK, induces cell proliferation.

B-CELL SIGNALING BY ACCESSORY STRUCTURES

Many other cell surface molecules participate in B-cell signaling. The coreceptor complex CD19/CD21 activates the CD19-associated PTKs, which induce phosphorylation of tyrosine residues on CD19 motifs.[328] These then become potential SH2-binding sites for PI3 kinase, which generates phosphoinositides. Recruitment of PI3K to CD19 requires phosphorylation of Tyr484 and Tyr515. Activation of PI3K generates PIP-3, which functions to localize BTK to the plasma membrane, where it is phosphorylated and activated by SRC and SYK kinases. BCR activation of BTK is dependent on CD19 expression, whereas activation of LYN and SYK is not.[329] PLC activation generates DAG, which activates PKC and 1,4,5-triphosphate, which increases cellular Ca^{2+}. CD22 is associated with BCR, which on engagement phosphorylates some of the six tyrosines of CD22. This in turn leads to recruitment of PTPN6 (SHP-1) via its SH-2 domain to CD22.[330] CD22 contains ITAMs and four immunoreceptor tyrosine-based inhibition motifs (ITIMs) in the cytoplasmic region. PI3K and PLCG1 associate with CD22 through the YXXM motif recognized by the N-terminal SH-2 domain of the p85 subunit of PI3K, whereas the protein tyrosine phosphatase PTPN6 (SHP-1) binds to ITIMs. As a result of multiple ITIMs, CD22 is probably a negative regulator of B cell activation. (For more details, see CD22 in Appendix A.)

INTERLEUKIN-4

Although several cytokines act on B cells, the action of IL4 was first demonstrated on B lymphocytes, and on these cells IL4 evokes the strongest reactions. IL4 binds to a transmembrane receptor and results in cross-linking with another protein termed common gamma chain (γc), which is shared by other cytokines.[331,332,333] Mutations in the γc chain results in X-linked SCID, an inherited disease with profound suppression of cell-mediated and humoral immunity.[334,335] IL4 binding induces phosphorylation of a substrate of 170 kDa designated as 4P*S*, which is unique because no other cytokine except IL13 binding phosphorylates a similar substrate. However, insulin and insulin growth factor-1 result also in 4PS phosphorylation. 4PS is structurally similar to insulin receptor substrate-1 (IRS-1). The gene for 4PS has been cloned and is called *IRS2*. IRS1/2 contains more than 20 potential tyrosine phosphorylation sites and 30 potential threonine/serine phosphorylation sites. The tyrosine phosphorylation sites bind with high affinity to cellular proteins possessing SH-2 domains and thus act as docking sites for several signal-transducing proteins such as PI3 kinase and growth factor receptor-bound protein-2 (GRB2). Mutational analysis has mapped a region of the IL4R between amino acids 437 and 557, which is important for IRS1 phosphorylation and therefore signal transduction.[336] This region contains a single tyrosine, is shared by the IL4 receptor (IL4R) and the insulin receptor, and is known as the I4R motif.

Although the insulin receptor and IL4R have many similarities, they have an important difference. The insulin receptor is a receptor tyrosine kinase, whereas the IL4R and γc are not, but are associated with nonreceptor PTKs. Association of IL4R and γc activates kinases associated with IL4R, which then phosphorylates the tyrosine in the I4R motif. This allows 4PS to bind to the IL4R and to be phosphorylated by the kinases associated with the IL4R. The phosphorylated motif I4R interacts with the PTB domain of IRS1/2. PTB domains are found in adapter proteins, such as SHC, and bind phosphopeptides.

IRS1/2 becomes phosphorylated as a result of interaction with the IL4Rα receptor and binds to the p85 subunit of PI3K, which as an adapter links IRS1/2 to the catalytic subunit p110. PI3K is activated as a result of conformational changes, acts on phosphatidylinositol of the cell membrane, and transfers phosphate groups from adenosine triphosphate to the D_3 position of inositol-generating PIP_3 and phosphatidylinositol 3,4-biphosphate. The phosphoinositides act on downstream kinases (i.e., PKC and AKT1) that make important contributions to cell survival. Activation of the IRS1/2 signaling proteins is associated with activation of the RAS/MAPK pathway (see "The RAS Pathway"). IL4R is also associated with the Janus kinases (or JAKs).[337,338] The α chain binds to JAK1, whereas the γc chain binds to JAK3. The receptors bind to these kinases through their membrane-proximal domains, which are known as box 1 and box 2 motifs and have some similarity among cytokine receptors.

The sequence of residues 557 and 657 of the α-chain (known as the gene-regulation domain) is critical for expression of IL4–responsive genes. It contains three conserved Tyr residues (Y575, Y603, and Y631), which can potentially be phosphorylated and thus be able to associate with SH-2 domains. IL4 utilizes the STAT6 member of the transcription factor family known as STATs (*s*ignal *t*ransducers and *a*ctivators of *t*ranscription). IL4–responsive genes include class II HLA, *CD23*, germline Igε and γ-1 chains, and IL4Rα chains.

Engagement of IL4R results in the activation of JAK1 and JAK3, which phosphorylate tyrosines of the cytoplasmic region of the receptor. STAT6 binds through its SH-2 domains to the phosphorylated tyrosines and becomes itself phosphorylated at its C terminus by the activated JAK kinases. The phosphorylated STAT6 dimerizes and binds to promoters of the IL4–responsive genes.[339] (For more on IL4 see Chapter 14.)

INTERLEUKIN-5

The α chain of IL5R is a type-I membrane protein of 415 amino acids, its extracellular region comprising three sets of fibronectin type III domains, whereas the intracellular domain does not contain sequences of tyrosine kinase but shows homology with a part of the actin-binding domain of β-spectrin.[340] It also has a region rich in prolines conserved among receptors of other cytokines (e.g., IL3, granulocyte-macrophage colony-stimulating factor receptor or CD116; see Appendix A).

A second β-chain is important for signal transduction but it does not contribute to IL5 binding. A membrane-proximal region contains a conserved box-1/box-2 motif that is responsible for the interaction with JAK2, and the distal domain is responsible for the activation of the RAS-related pathways. IL5 signaling increases BTK activity.

INTERLEUKIN-6

IL6 is a pleiotropic cytokine that, among many other functions, is involved in terminal differentiation of B cells.[341,342] The extracellular region of the IL6R consists of one constant region domain of the Ig superfamily and two fibronectin type III domains, which have four conserved cysteine residues and a motif containing two tryptophans and two serines. This motif is located in a groove between the two fibronectin domains. The intracellular domain is short and is not involved in signal transduction. Associated with the IL-6R is a protein known as gp130, which dimerizes when IL6 binds to the IL6R. The gp130 protein is shared by other cytokine receptors and initiates signal transduction. Homodimerization of gp130 induces activation of JAK kinases, which are associated with the membrane-proximal region of gp130, also known as box-1. This leads into phosphorylation of a tyrosine in the distal part of gp130 (box-3), resulting in binding through an SH-2 domain of the transcription factor STAT3, previously known as acute phase response factor or APRF. JAK kinases activate STAT3 by phosphorylation.

Another nuclear target for gp130 signaling is the transcription factor NF-IL6 with a leucine zipper motif. This factor is inducible in hepatocytes and monocytes by IL6 and other cytokines and mediates the expression of IL6–inducible genes. NF-IL6 has a consensus sequence for MAP kinase, suggesting that it is activated through this pathway, which is RAS-dependent. (For further details, see Chapter 14.)

CD 40

CD40 is a member of the tumor necrosis factor receptor family, which interacts with its ligand, CD154, expressed on T cells. (See "CD40 and CD40 Ligand [CD154]"; Appendix A.) Signal transduction by CD40 is mediated by certain proteins that bind to its cytoplasmic region and are known as TRAFs (tumor necrosis factor receptor activation factor) (see Appendix A: CDs). Engagement of CD40 by its ligand activates the SRC kinases LYN and FYN and BTK. Signaling follows the RAS pathway via the nucleotide exchanging factor SOS, leading to MAPK8 (JNK) and MAPK1 (ERK) activation. The functional outcome of CD40 depends on the state of activation of B cells and the intensity of stimulation. On naive B cells it induces proliferation and Ig production, but on memory cells it induces apoptosis. CD40 activation induces homotypic adhesion of B cells mediated by CD54 (intercellular adhesion molecule-1)–CD11/CD18 (ITGB2 or LFA-1), or CD23–CD21. The functional outcomes depend on the type of TRAFs that are associated with CD40. For example, trimers of TRAF2 mediate apoptosis, whereas trimers of TRAF6 or TRAF5 mediate proliferation.[343] Germinal-center formation and Ig class switch are hallmarks of T-cell–dependent responses, and TRAF6 plays a role in class switch (see Chapter 14).

POLYCLONAL ACTIVATION

Certain substances can activate B lymphocytes independently of their antigenic specificity. The response to these substances involves all B-cell clones, and for this reason these substances became known as polyclonal B-cell activators (PBAs).

PBAs are primarily microbial cell constituents such as lipopolysaccharide (LPS), purified protein derivative, staphylococcal protein A, streptolysin O, pneumococcal polysaccharide III, a water-soluble antigen from *Nocardia*, EBV, dextrans, etc.

PBAs can be categorized on the basis of their effect on B lymphocytes; some promote only B-cell proliferation, whereas others in addition stimulate Ig secretion.

LPS has been used experimentally as PBA for several years, but only recently was its receptor shown to be the CD14 molecule.[344] LPS binding to CD14 is enhanced in the presence of a plasma protein, LPS-binding protein.[345] CD14 is expressed primarily on monocytes and granulocytes. Its structure, function, and role in human disease have been reviewed.[346]

MORPHOLOGIC CHANGES ASSOCIATED WITH B-CELL DIFFERENTIATION

Plasma Cell

Elegant studies of morphologic differentiation in immunized animals at the ultrastructural level were performed by Harris et al., who isolated individual cells involved in antibody synthesis[347] (Fig. 12.13). These authors showed that antibody production is detected while the cell still retains a lymphocytic morphology and contains no ER. These cells can be differentiated from inactive lymphocytes by the abundance of free polyribosomes and a large nucleolus. A spectrum of cells that actively secrete antibody can be ranked according to the size and development of the ER.[348,349,350–352]

During early differentiation, the ER is scarce and unorganized. Later, the lamellae increase in length and become parallel, until they fill the entire cytoplasm and give rise to its onion-skin appearance. The Golgi apparatus increases concomitantly. No dividing line exists that distinguishes the cells that make IgM from those that make IgG antibody, although a preponderance of IgM producers with lymphocytic morphology and of IgG producers with plasmacytic morphology is noted.[348]

The name plasma cell was first used by Waldeyer in 1875.[353] His description, however, included several types of cells; and in 1881 Unna[354] redefined the cells as he observed them in a case of lupus, emphasizing the characteristic basophilia of the cytoplasm (granuloplasm). In a subsequent report[355] containing pictures of methyl green- and pyronin-stained cells, several cells are identified easily as characteristic plasma cells. In 1895, Marschalko took issue with Unna's description and emphasized that the appearance of the nucleus with its characteristic arrangement of angular chromatin blocks and its eccentric position within the cell are to be used as stringent criteria for the identification of plasma cells.[356] The characteristic nuclear morphology was given the name radkern by Pappenheim. Early analytic reviews of plasma cells were provided by Downey[357] and later by Michels.[358] In those early years, whether the plasma cell was a normal constituent of tissues was the subject of considerable debate. Its origin was disputed, but several prominent investigators believed that it originated from lymphocytes.

The modern period of plasma cell study originated in 1937 with the clinical observations of Bing and Plum, who noted the close association of hyperglobulinemia and the presence of plasma cells.[359] Subsequent studies in hyperimmunized rabbits were carried out by Bjornboe and Gormsen,[360] who demonstrated that antibody production correlated with massive plasma cell proliferation in the spleen. In his doctoral thesis, Fagraeus[361] left little doubt about the importance of plasma cells in antibody formation. Differences among animals in their capacity to produce antibody could be related to differences in the number of plasma cells, particularly immature plasma cells. Fagraeus thought that mature plasma cells had "passed the stage of their greatest functional intensity."

Indisputable evidence in favor of antibody production by plasma cells was provided by Coons, who introduced the powerful technique of immunofluorescence to immunology.[362,363] Plasma cells containing antibody were detected in the red pulp of the spleen, the medullary cords of the lymph nodes, and the focal granulomata of immunized animals.

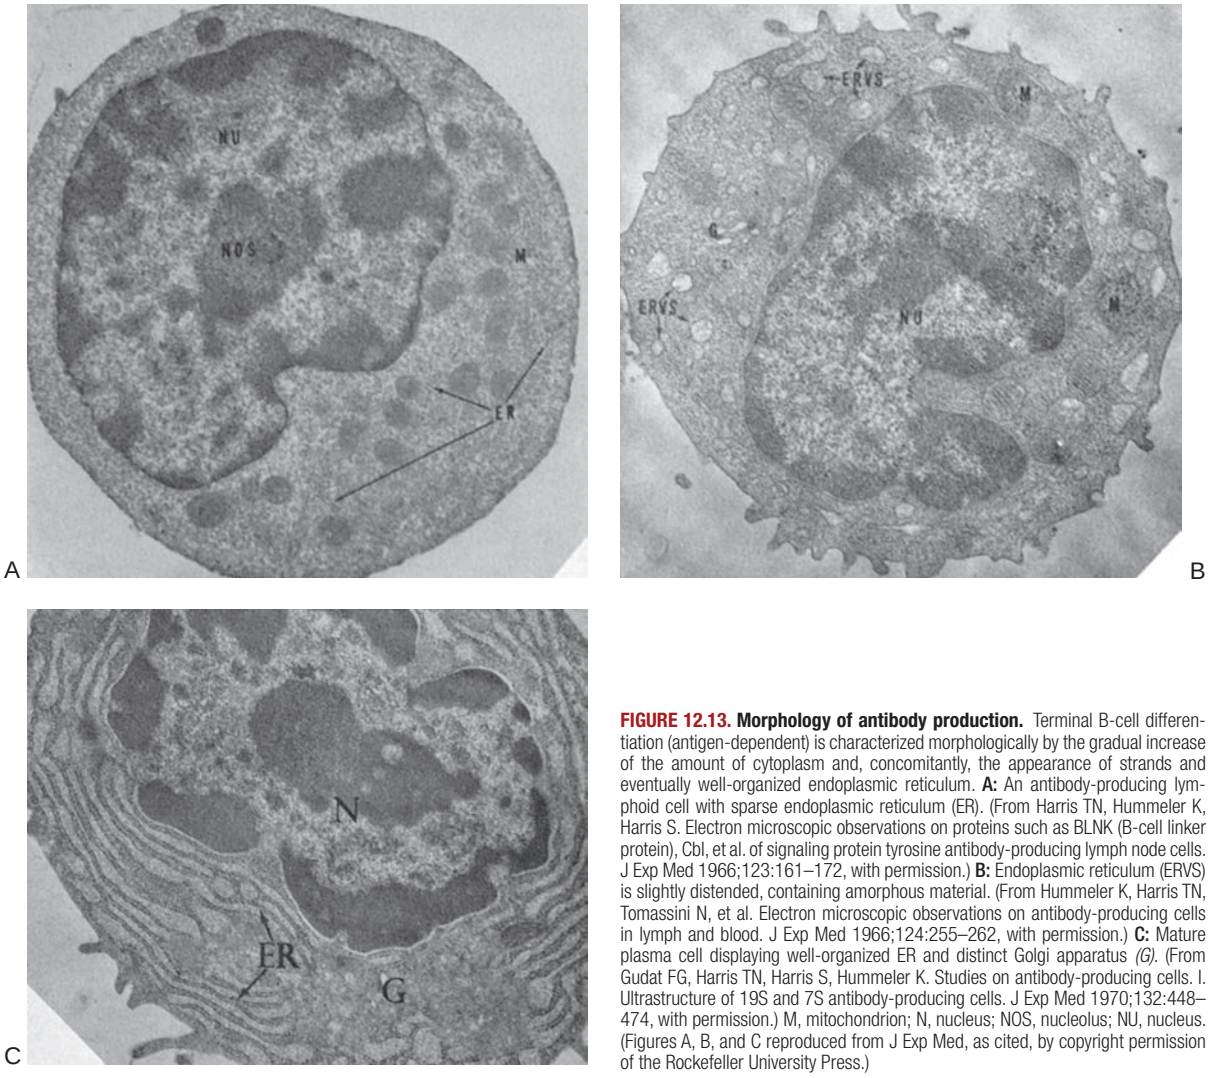

FIGURE 12.13. Morphology of antibody production. Terminal B-cell differentiation (antigen-dependent) is characterized morphologically by the gradual increase of the amount of cytoplasm and, concomitantly, the appearance of strands and eventually well-organized endoplasmic reticulum. **A:** An antibody-producing lymphoid cell with sparse endoplasmic reticulum (ER). (From Harris TN, Hummeler K, Harris S. Electron microscopic observations on proteins such as BLNK (B-cell linker protein), Cbl, et al. of signaling protein tyrosine antibody-producing lymph node cells. J Exp Med 1966;123:161–172, with permission.) **B:** Endoplasmic reticulum (ERVS) is slightly distended, containing amorphous material. (From Hummeler K, Harris TN, Tomassini N, et al. Electron microscopic observations on antibody-producing cells in lymph and blood. J Exp Med 1966;124:255–262, with permission.) **C:** Mature plasma cell displaying well-organized ER and distinct Golgi apparatus *(G).* (From Gudat FG, Harris TN, Harris S, Hummeler K. Studies on antibody-producing cells. I. Ultrastructure of 19S and 7S antibody-producing cells. J Exp Med 1970;132:448–474, with permission.) M, mitochondrion; N, nucleus; NOS, nucleolus; NU, nucleus. (Figures A, B, and C reproduced from J Exp Med, as cited, by copyright permission of the Rockefeller University Press.)

Excellent detailed descriptions of the morphology and ultrastructure of plasma cells have been published.[364,365] The plasma cell is round or oval, with an eccentrically located nucleus and chromatin arranged in pyramidal blocks against the nuclear membrane, giving the characteristic "cartwheel" appearance (Fig. 12.14). The cytoplasm is intensely basophilic because of the high content of ribonucleoprotein. Certain plasma cells stain red to violaceous rather than blue, and are known as flaming plasma cells, a name coined by Undritz. This coloration is attributed to the accumulation within the ER cisternae of Ig with a high carbohydrate content. Electron microscopic studies revealed that the nucleus is surrounded by a double membrane. The outer membrane is covered with ribonucleoprotein particles and is continuous with the cytoplasmic ER. The Golgi is well developed and consists of vesicles and tubules. The centrosome lies next to the nucleus, surrounded by the Golgi apparatus. Several microtubules radiate from the centriole. Many prominent mitochondria are scattered between the ER lamellae. A striking ultrastructural feature of the plasma cell is the rich and well-organized ER. It consists of membranes studded on one side with ribosomal particles and arranged in parallel arrays. In the mature plasma cell, the ER fills the entire cytoplasm. The cisternae are sometimes distended with granular or homogeneous material, giving rise to cytoplasmic inclusions known as Russell bodies.[366] The Russell bodies are composed of Ig,[366,367] although sometimes Ig cannot be demonstrated,[368] and it was suggested that these inclusions are

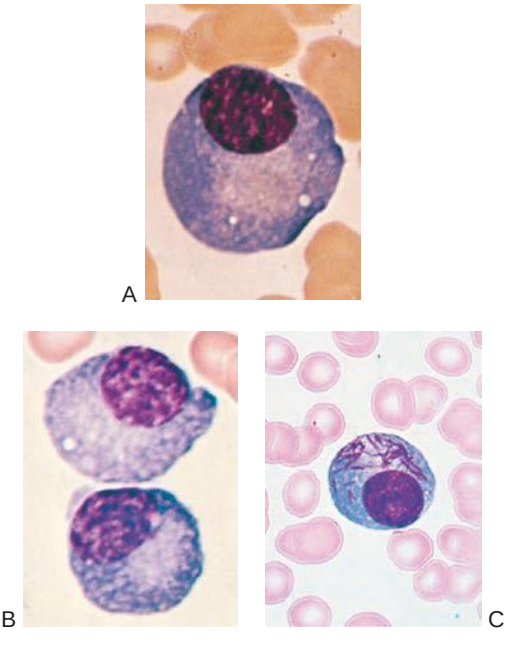

FIGURE 12.14. Plasma cells. A: Normal. **B, C:** Plasmacytes with vacuoles from the bone marrow of a patient with infection and arthritis.

not made from Ig aggregates. Alternatively, the Ig is condensed to such a degree that it cannot be penetrated by the dyes. Russell bodies sometimes are detected within the nucleus (intranuclear inclusions). Under certain circumstances, the plasma cell contains large quantities of a homogeneous material that distends the cell and stains gray or sometimes red as in the flaming cells. These cells, called thesaurocytes,[369] reveal, under electron microscopic analysis, dilation of the ER cisternae[370] (Fig. 12.15). The flaming cell likely represents an early stage of the thesaurocyte in terms of storage of synthesized Ig.[371,372] Two lines of evidence suggest that these forms are the result of disturbances in the secretion of Ig. In nonsecretory myelomas, the cells often are similar to thesaurocytes,[373] or flaming plasma cells.[374] Mott cells, which are considered plasma cells with multiple Russell bodies, may also result from a complete or partial block in the secretion of Ig, causing localized distention of ER cisternae.[375]

The most immature plasma cell is the plasmablast, with a nucleus which has evenly dispersed chromatin and a large nucleolus. The ER is sparse and the cytoplasm is filled with clusters of polyribosomes. As the cell matures the chromatin forms clumps and the ER becomes more abundant and well organized. As the lymphocytes mature into plasma cells, they pass through intermediate stages, which are seen in the blood of patients with plasma cell dyscrasias or immunologic diseases characterized by hypergammaglobulinemia. Similar cells sometimes are encountered in the blood of patients with viral infections (Turk cells), including infectious mononucleosis. The intermediate forms have blue cytoplasm with abundant ER, but not as much as the mature plasma cells. Some intermediate forms resemble the less mature transformed lymphocytes with simple ER and many ribosomes and polyribosomes.

By the time the lymphocyte evolves into plasma cells, certain surface molecules such as the BCR, the major histocompatibility complex class II, CD19, and CD20 are downregulated; while other molecules such as syndecan-1 (CD138) and CD38 are expressed on the surface of plasma cells. The differentiation of lymphocyte to plasma cells requires the transcription factor PRDM1 (BLMP1), which is a transcriptional repressor.[376] PRDM1 represses *MYC* transcription, which explains the cessation of the cell cycle in plasma cells, and also represses *PAX5*, which is required for lineage commitment of B-cell development and for isotype switching in germinal centers. Downregulation of PAX5 is necessary for the development of antibody-producing cells, because it represses XBP1, J-chain, and Ig heavy-chain gene transcription.[377] PRDM1 promotes plasmacytic differentiation by extinguishing the expression of genes that are important for BCR signaling, germinal-center function, and proliferation, but allowing the expression of XBP1 (X-box binding protein). XBP1 is the only transcription factor required specifically for terminal differentiation of B lymphocytes to plasma cells.[378] XBP1 is a basic region leucine zipper protein essential for the growth of hepatocytes and has been implicated in the proliferation of malignant plasma cells.[379]

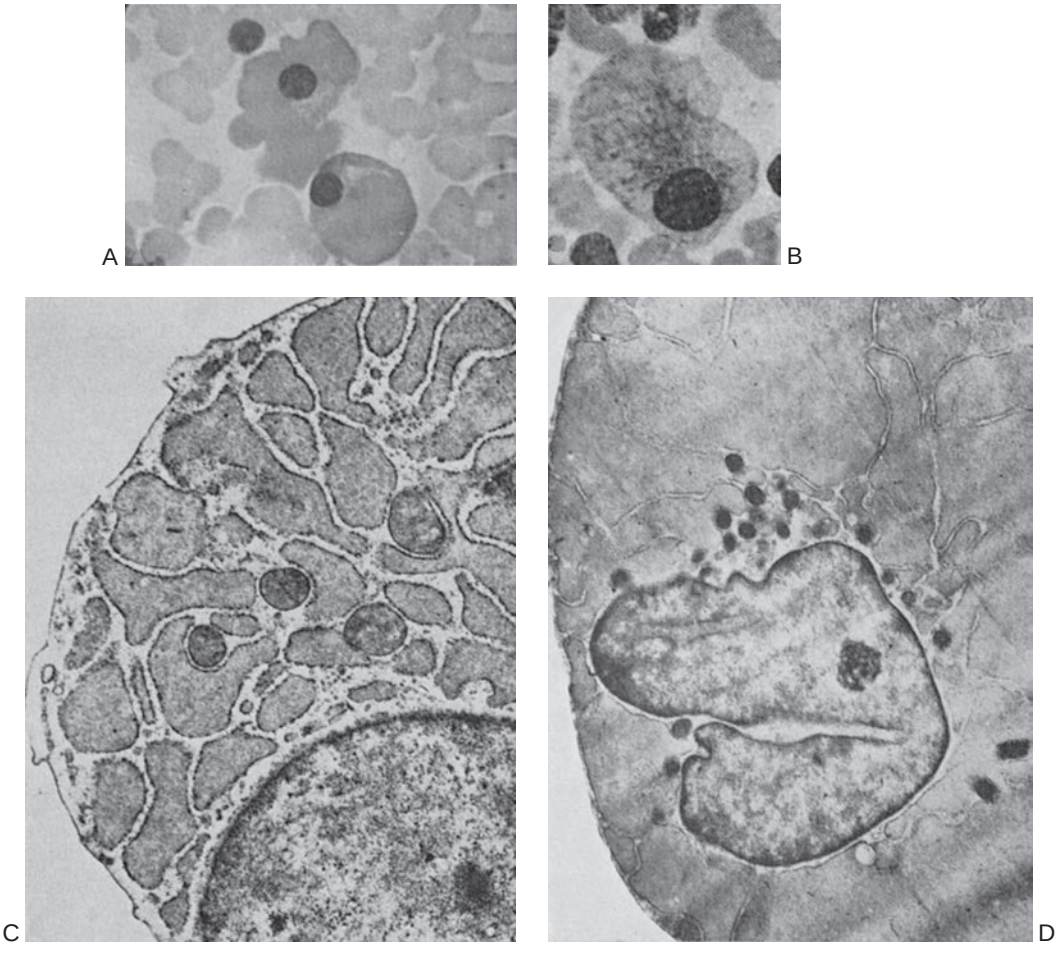

FIGURE 12.15. Unusual forms of plasma cells. Under certain circumstances related to immunoglobulin (Ig) secretion, the cisternae of endoplasmic reticulum are distended as a result of the accumulation of Ig. Plasma cells with accumulation of a homogeneous material that sometimes stains pink or red on Giemsa preparations (thesaurocytes). **A, B:** Giemsa stain of bone marrow from two patients with IgA myeloma. **C, D:** Ultrastructure of thesaurocytes with different degrees of distention of the cisternae of the endoplasmic reticulum. (From Bessis M, Breton-Gorius J, Binet JL. Étude comparée du plasmacytome et du syndrome de Waldenstrom. Nouv Rev Fr Hematol 1963;3:159, with permission.)

A small subpopulation of germinal-center cells in the light zone express PRDM1, which functions upstream from XBP1.[380] These cells have survived the selection and are probably destined to become plasma cells. PRDM1, a germinal-center–restricted transcriptional repressor, inhibits *BCL6,* required for germinal-center function. A negative feedback loop operates in the germinal centers between PRDM1 and *BCL6*, the expression of which blocks PRDM1 expression and plasma cell differentiation irreversibly (see also Chapter 14).

MOLECULAR AND ULTRASTRUCTURAL ASPECTS OF IMMUNOGLOBULIN BIOSYNTHESIS

Heavy and light chains are synthesized separately, the H chain on large 270S to 300S polyribosomes composed of 16 to 20 subunits, and the L chains on smaller 190S to 200S polyribosomes composed of 7 to 8 subunits. The size of these polysomes is such as to suggest synthesis of each chain as a single unit. Under normal conditions the L chains may be synthesized in slight excess. After completion of separate synthesis of H and L chains, intramolecular folding and assembly of the individual chains begins on nascent proteins and continues into the cisternae of the ER. Depending on the Ig class, the assembly begins with the formation of the H-L half-molecules, two of which then combine to form a complete Ig monomer. Alternatively, two H chains combine to form H2, followed by H2L, suggesting that the final H2-L2 structure may be reached by several pathways.[381] Assembly of H chains is restricted between chains of the same class, so that dimers between different H chain isotypes are not formed in cells expressing both. In most instances, polymeric Ig, such as IgM and IgA (9S, 11S, 13S), are assembled intracellularly from their constituent subunits.

The attachment of core oligosaccharides to the *N*-glycosylation acceptor site begins on the ribosome, but glycosylation is completed in the Golgi apparatus, where the polypeptides are transported from the ER.[382] The Golgi apparatus is also the site of final processing of the carbohydrate,[383] and where the molecule is attached to membrane and then packaged into vesicles for secretion or incorporation into the plasma membrane.[383] This mechanism of secretion is a form of reverse pinocytosis. Disruption of the traffic of the vesicles containing Ig inhibits Ig secretion.

The carbohydrate moiety may facilitate the secretion of Ig by the cell, although this effect depends on the Ig class and the amount of Ig synthesized. For some classes, such as IgM, Ig secretion is blocked when glycosylation is inhibited. H chains that have not bound to L chains form complexes with an H chain–binding protein (BiP).[384,385] BiP prevents transportation of H chains to the Golgi complex until they become associated with the L chains that displace BiP. The presence of such complexes provides an explanation for the lack of secretion of μ chains in pre-B cells when L chains are not available. In contrast to the normal situation, free H chains are secreted in certain lymphomas (H chain disease).[386,387] In these disorders, the H chains have a large deletion involving the CH-1 domain,[388] which explains how these mutant chains can be secreted, i.e., complexes with BiP can be formed only through the CH-1 domain.[389,390] Although the synthesis of L chains and H chains takes only 30 and 60 seconds, respectively, the addition of carbohydrates and the process of secretion take at least another 30 minutes. An adult synthesizes approximately 2.3 g of Ig daily,[391] and most Ig-synthesizing cells contain one type of H chain and one type of L chain,[392] but a few cells (usually <1%) contain more than one type of H chain, usually μ and γ.

Antibody first appears in the perinuclear cisternae[393] and eventually is detected in the rest of the ER[394,395] (Fig. 12.16). Activation of the ER cisternae is gradual, because not all of them within the same cell contain antibody at any one moment. Antibody is found in association with the ribosomes of ER and is not detected outside the ER cisternae. In most immature blasts with a sparse or nonexistent ER, antibody is present in the cytoplasm, synthesized on polyribosomal clusters. Not only the intracellular distribution but also the rate of synthesis increases with time; and Ig, in some cases, distends the cisternae, forming large spheric masses reminiscent of Russell bodies. Not all plasma cells contain antibody during the primary response. In the first 2 to 3 days after immunization, most of the plasma cells contain Ig that has no antibody activity.[396] Antibody-containing plasma cells appear later in the response and throughout plasmacytic differentiation, the Golgi apparatus always contains antibody.

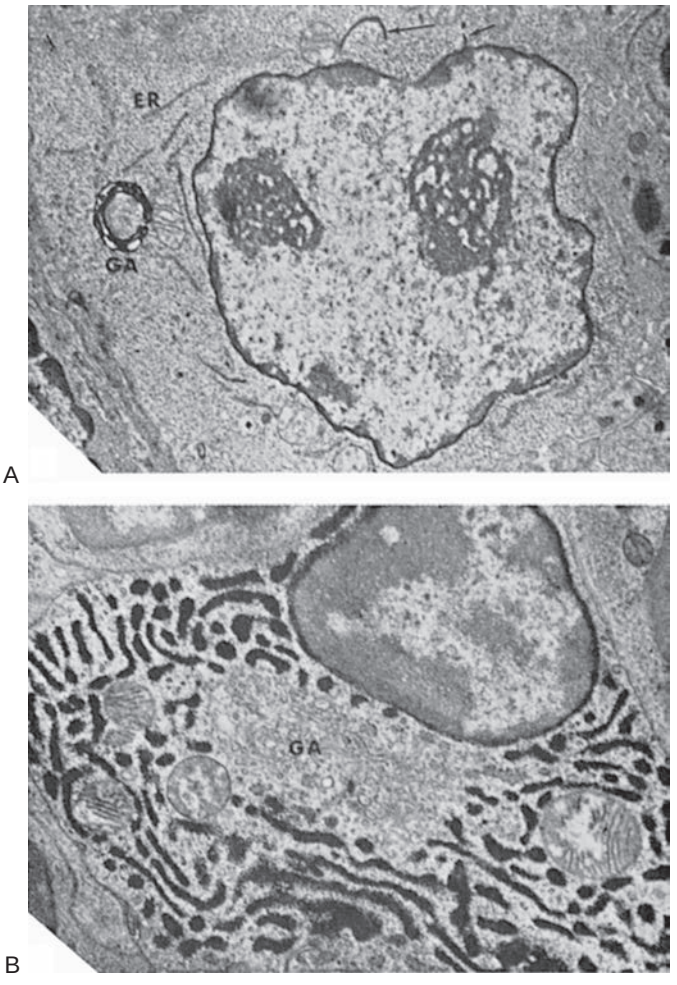

FIGURE 12.16. Ultrastructural localization of antibody. A: An immature plasma cell demonstrates antibody primarily in the perinuclear area. Antibody is also detected in the few strands of endoplasmic reticulum (*ER, arrows*) and the Golgi (*GA*) apparatus. **B:** Plasma cell with well-developed endoplasmic reticulum filled with antibody. Both cells were isolated from rabbits immunized with peroxidase. For the intracellular localization of the antiperoxidase antibody, the cells were treated with peroxidase before incubation with diaminobenzidine. (From Leduc EH, Avrameas S, Bouteille M. Ultrastructural localization of antibody in differentiating plasma cells. J Exp Med 1968;127:109–118. Reproduced by copyright permission of the Rockefeller University Press.)

B-CELL ACTIVATION AND DIFFERENTIATION

Malignancies arise from one cell; therefore they are monoclonal and inherit a unique Ig rearrangement.[106] The new technology of gene profiling enables identification of the genes that are activated

and very likely it is characteristic of each stage in the life of the B cell. This technology has already been applied on normal B cells to characterize their genetic profile in various functional states. Gene profiling inspects activation and gene transcription of hundreds or thousands of genes, providing a global genomic view.[397] In contrast to gene sequencing (structural genomics), gene profiling is considered a new field of functional genomics.

Serial analysis of gene expression (SAGE) uses gene-specific 14-bp sequence tags for enumeration of genes expressed in a cell.[398] In the new methods, DNA fragments from individual genes are placed on a solid support in an ordered array. Total cellular mRNA isolated from cells is used to generate, by reverse transcription, cDNA probes tagged by radioactivity or fluorescence. The cDNA probes are then applied to the arrays for hybridization with the DNA on the array. The hybridization results are quantitated by phosphor imagers for radioactive probes, or by scanning confocal microscopy for fluorescent probes. In one commonly used microarray system, oligonucleotides are produced by in situ synthesis in a technique called photolithography and are hybridized by fluorescent cDNA probes.[399,400] In another technique, PCR products from cDNA clones are spotted onto coated glass slides.[401] In this technique, two cDNA probes from different samples, labeled with different fluorochromes (usually Cy3 or Cy5), are applied on the microarray simultaneously for hybridization. The expression for each gene is evaluated by the ratio of the fluorescence, and interpretation of the data uses algorithms. Various analytical tools are available, but no single tool is better than others. Their use may well depend on the experimental design and the questions asked.[402,403]

One approach uses hierarchical clustering,[404] and this algorithm begins by clustering pairs of genes with the most similar patterns of expression, eventually building larger and larger clusters. Clustering may be unsupervised (i.e., the arrangement of gene expression follows predefined parameters built into the algorithm). In supervised clustering, the investigator introduces other parameters such as clinical data. Several algorithms have been designed for data analysis, and more than one may be necessary for the analysis.

Three B-cell functional states were evaluated in an experimental model: naive B cells, B cells activated in vitro by a foreign antigen (hen egg lysozyme, HEL), and B cells tolerant against self. In this case B cells were obtained from transgenic mice (i.e., expressing HEL from birth); therefore, the B cells have developed tolerance against HEL as for any other natural self-antigen.[405,406] The results show that the naive or resting state is maintained by several inhibitory genes, whereas activation is associated with loss of expression of some of the inhibitory genes rather than the induction of genes that regulate entry into the cell cycle. B cells tolerant to "self" are characterized by increasing expression of more inhibitory genes at the same time that they maintain the expression of the basal inhibitory gene profile.

Some other data reveal that the gene profile of in vitro activated B cells differs from that of germinal-center B cells, where they are activated by T cells.[397] Germinal-center B cells differ from naive B cells in the expression of hundreds of genes.[407] The function of signaling molecules has been studied by inactivation of the appropriate gene, but repercussions from changes in the expression of other genes cannot be heard. An attempt was made to provide an answer to this question from the effect of reduction of the function of PI3K or BTK to other genes. Reduced function of PI3K or BTK significantly affected 5% of BCR-dependent gene expression.[408] The data also suggested that PI3K acts through BTK in regulating genes that are critical for determining entry into the cell cycle. By hierarchical clustering it has been possible to identify groups of genes that are characteristic of a lineage or a specific stage of differentiation or proliferation (i.e., germinal-center B cells), and each group of genes defines a signature of a cell type or of a function, etc.

Plasma cells, which represent the end stage of B-cell differentiation, were found to have 1,476 known genes, which were differently expressed compared to B cells.[409] A number of factors characteristic of terminal differentiation (i.e., related to RNA polymerase I) were downregulated, while a number of transcription factors were maintained (e.g., AP-1, NFAT, and NF-κB). Two genes specific for factors associated with neuronal cell positioning, reeling and neuropilin-1, were unexpectedly expressed and their role in plasma cell life remains to be determined.

B-CELL MALIGNANCIES

A large body of data has already been collected in the short period since this technology was developed for large-scale application, and the findings in B-cell malignancies hold a number of unexpected results.[410] Diffuse large B-cell lymphomas (DLBCLs) have been shown to have two different gene profiles.[410] In one group of patients, the cells had a germinal-center gene profile, whereas in the second group, the lymphoma cells showed a profile of mitogenically activated B cells, and these two groups differ in several genes. DLBCL with the germinal-center B-cell profile has retained the hypermutation machinery, but the second group resembling mitogenically activated B cells has not.[411] The germinal-center B-like DLBCL also resembles closely follicular lymphoma.[412] On the basis of sharing some gene expressions with a small population of germinal-center B cells, as well as with plasma cells, it has been suggested that the activated B-like DLBCL may arise from a cell in its transition to becoming a plasma cell.

Another important finding is the possibility that B-CLL, which phenotypically has been separated into two groups on the basis of CD38 expression, may actually be one genomic disease with two variants.[413] A small number of <30 genes may, however, be able to distinguish cases with IgV-mutated versus -unmutated profiles.[414] Furthermore, the gene profiles have indicated that in the majority of cases, the cells are related to memory B cells rather than naive B cells or B cells of any other category. This may not be unexpected, because the somatic hypermutation machinery is active in CLL and could play a role in intraclonal diversification development.[415] Microarray gene profiling has been used to identify B-CLL cases with cells resistant to apoptosis after DNA damage. Thirteen of 16 genes were found that were specific for resistant B-CLL cells.[416] A study of mantle cell lymphoma also detected resistance to apoptosis gene profiling. The *FADD* (Fas-Associated Death Domain) gene, a key gene associated with Fas-mediated apoptosis, was downregulated 10-fold in this lymphoma.[417]

In multiple myeloma, the profiling suggests a classification into four subgroups.[418,419] Group 1 patients (MM1) have a gene profile similar to MGUS (Monoclonal Gammopathy of Unknown Significance), whereas the patients in the MM4 group have poor prognosis, with a gene profile similar to myeloma cell lines. Numerous unexplained genes with unknown function have been detected, so that only 10% of all these genes have matched entries in the database Expressed Sequence Tags.[420]

The origin of Hodgkin and Reed-Sternberg (HRS) cells has remained elusive, and recently, strong evidence has been presented that in most cases with this disease, the cell is of B-lineage origin and only rarely originates from a T cell.[421] Identification of gene profiling demonstrated that the HRS cell expresses a distinct gene profile regardless of its B- or T-cell derivation. The gene profile is similar to that of EBV-transformed B cells or cell lines from large cell lymphomas, with features of in vitro–activated B cells.[422] Among the genes specifically identified in HRS are a cluster of genes for transcription factors (i.e., *GATA3*, *MSC/ABF-1*, *NR2F1/EAR-3*, and *NFE2L3/NRF3*). Downregulation of several genes that are active in B cells was identified. Several of these genes are positively regulated by the transcription factor

PAX5 (see "Stem Cell to Progenitor B [Pro-B] Cell"). However, the *PAX5* gene is still expressed in HRS cells, and therefore the loss of B-cell–specific gene expression remains unknown.[423]

BTK mutations influence the expression of other genes in EBV-transformed cell lines and, in the absence of functional *BTK*, 11 genes were identified that were induced more than 1.9-fold.[424] Microarray gene profiling has been applied to develop a molecular predictor of survival after chemotherapy for DLBCL. The study used 17 genes to construct a predictor of overall survival.[425] Four gene groups were identified and clustered within individual signatures. The proliferation signature was the best predictor for adverse outcome. Signatures identifying good prognosis were the lymph node signature, encoding extracellular matrix, and the connective tissue growth factor, which promotes fibrosis and synthesis of extracellular matrix. Some of these genes are linked to histologic or other lymph node reactions, known already for their favorable prognosis. For example, the lymph node signature is associated with expression of genes that are also expressed in macrophages and NK cells, presumed to indicate a cellular antitumor response. The other favorable signature is the major histocompatibility complex class II gene expression.

B-CELL SUBPOPULATIONS

A subpopulation of B cells can be detected on the basis of expression of the CD5 antigen ordinarily present on T cells. The CD5 antigen (formerly T1 or Leu1) is a 67,000-dalton gp detected on all normal T cells,[426,427] on a small subpopulation of normal B cells,[428] and on all cells from patients with CLL.[429–431] The CD5 B cells possess unique properties, i.e., they are phenotypically identical to $CD5^-$ B cells,[432] but they are larger; in mice they have 10 times more mIgM with λ chains, which is expressed only rarely in mice. The $CD5^+$ B cells are present in high numbers in fetal and neonatal life (50% of all IgM^+ B cells), but they progressively diminish in number after birth and are present in small numbers in secondary lymphoid organs in adult life.[433–435] At birth most of the B cells in cord blood are $CD5^+$,[434] but they constitute less than 10% to 30% of B cells in adult spleen, lymph nodes, and peripheral blood. Their proliferative capacity is high and as a result, they give rise spontaneously to cell lines that demonstrate *MYC* amplification.[436] Presently there are two views regarding the origin of the $CD5^+$ subpopulation. According to one of them, the $CD5^+$ cells (also known as B1a) belong to a lineage of B cells distinct from the conventional B lymphocytes ($CD5^-$).[437–439]

The $CD5^+$ (B-1) cells develop early in ontogeny and, in the adult, predominate in peritoneal and pleural cavities and are self-replenished; that is, they do not arise from undifferentiated progenitors. Progenitors of $CD5^+$ cells are present in fetal liver and omentum but not adult bone marrow, whereas conventional B-cell progenitors are present in fetal liver and adult bone marrow. According to the second hypothesis, the B-1 cells derive from conventional B cells,[440,441] based on in vitro evidence of stimulation of conventional B cells with anti-IgM antibodies and IL6, which generated the B-1 phenotype.[442]

B-1 cells may have different antibody repertoires (e.g., have few N-region insertions in their rearranged V genes), and the V_H repertoire is biased toward V gene families proximal to J_H, whereas in adult B cells it is more randomized.

Perhaps the most controversial aspect is the production of autoantibodies. In NZB mice (New Zealand Black), a strain well-known for autoimmune phenomena, the $CD5^+$ B cells are increased in number and spontaneously secrete IgM autoantibodies.[443] Increased numbers of $CD5^+$ B cells are found in patients with rheumatoid arthritis,[444,445] Sjögren syndrome,[446] and progressive systemic sclerosis,[447] but not in patients with systemic lupus erythematosus.[447] Numbers of $CD5^+$ B cells are also increased after bone marrow transplantation.[448] In 95% of patients with B-cell CLL, the leukemic cells express the CD5 antigen,[429,430,449] which is also detected on cells from other B-cell lymphomas, the $CD5^+$ B cells from normal subjects,[450,451] or from patients with CLL.[452] The $CD5^+$ B-cell subpopulation may therefore play an important role in the development of B-cell repertoire related to natural immunity, which develops in the absence of an encounter with exogenous antigens. Certain V genes are selectively expressed in $CD5^+$ B cells, and those are not changed by somatic hypermutations normally observed in $CD5^-$ B cells responding to exogenous antigens. The marginal zone B lymphocytes share many phenotypic characteristics with B-1 cells and, like them, develop in response to T-independent type-2 antigens. The B-2 repertoire is selected by self-antigen and therefore tends to be autoreactive. Selection into the B-1a population is favored during fetal life because TdT is not expressed during this period; therefore, the repertoire is limited in its specificity range. This dangerous repertoire is kept under control by the CD5-mediated negative signaling, thus preventing inappropriate activation. On the other hand, this repertoire is useful because the B-1 cell specificities are directed against several pathogens and are important in mucosal immunity.[453]

CHAPTER 13

T LYMPHOCYTES AND NATURAL KILLER CELLS

Frixos Paraskevas

MORPHOLOGY

The T lymphocyte under routine staining procedures (Giemsa or Wright) is 5 to 8 μm in diameter, with a high nucleocytoplasmic ratio. The nucleus is purple with densely packed chromatin, and the cytoplasm forms a narrow light-blue rim.

By transmission electron microscopy, the nucleus shows shallow indentations with dense heterochromatin along the nuclear membrane and euchromatin occupying most of the remaining nuclear surface. One or two nucleoli are visible (Fig. 13.1). The cytoplasm shows a few organelles, such as mitochondria and a small Golgi apparatus. By scanning electron microscopy, the surface of the T lymphocytes is either smooth or shows short microvilli, depending on the method of preparation as well as the state of activation.[1,2]

Some T lymphocytes present in normal subjects are characterized by a highly indented nucleus and are known as cerebriform mononuclear cells.[3] These cells are not detected in T-lymphocyte–depleted fractions and constitute approximately 3% to 4% of the unfractionated T lymphocytes. They possess scanty cytoplasm, and the degree of their nuclear indentation is expressed as a nuclear contour index (nuclear perimeter/area).[4] Their structural similarity to the cells present in cutaneous T-cell lymphomas suggests that they represent the normal equivalent of Sézary cells, which are derived from T lymphocytes.

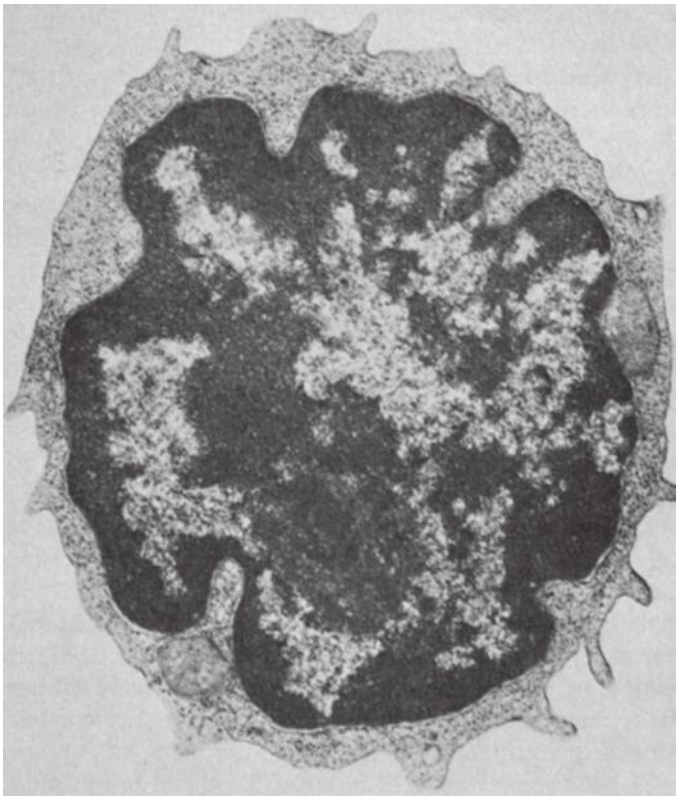

FIGURE 13.1. Ultrastructure of T-cells. The normal T-cell has a small rim of cytoplasm with only a few organelles. Nucleus shows dense heterochromatin. (From Zucker-Franklin D, Greaves MF, Grossi CE. Atlas of blood cells, 2nded. Philadelphia: Lea & Febiger, 1988, with permission.)

ONTOGENY OF THYMIC MICROENVIRONMENT

The thymic anlage develops from epithelial structures of the third branchial complex (Fig. 13.2). Neural crest cells (Hoxa3-positive) invade the epithelial cluster to form the thymic rudiment. Several studies support the view that the cortical and medullary epithelia originate from a common precursor, and, in the early stages, the epithelium co-expresses markers that are later segregated to the cortical or medullary compartments. After completion of thymic organogenesis, the cortical epithelia are cytokeratin-8$^+$, whereas medullary epithelia are cytokeratin-5$^+$,[5] except for a small subpopulation in the corticomedullary junction, which is cytokeratin 5$^+$/8$^+$.[5] Furthermore, neoplastic human thymomas often express both cortical and medullary epithelial markers.[6]

The best evidence of the origin of thymic epithelia from a common progenitor is the identification by monoclonal antibodies of a cell that generates in vivo the thymic microenvironment.[7,8] The monoclonal antibody MTS24 detects a glycoprotein with mucinlike characteristics and a peptide backbone.[7] The antigen is detected during the early embryonic stages in the anterior

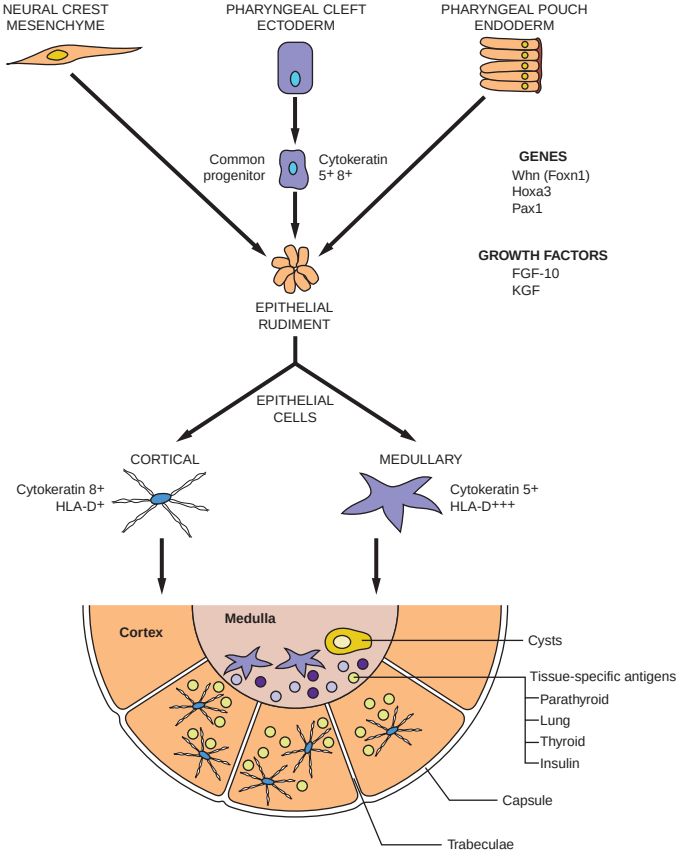

FIGURE 13.2. Morphogenesis of thymus. Elements from the third pharyngeal cleft form the epithelial rudiment, joined by mesenchymal cells from the neural crest. The common epithelial progenitor differentiates into cortical and medullary epithelium under the influence of the mesenchyme. The presence of endodermal cysts and tissue-specific "antigens" and "organoids" suggests some contribution from the endoderm. FGF, fibroblast growth factor; KGF, keratinocyte growth factor.

endodermal epithelium, the pharyngeal endoderm, and a portion of intermediate mesoderm, which develops the urogenital epithelium. The MTS24$^+$ cells are positive for major histocompatibility complex (MHC) class II and express cytokeratin-5 and cytokeratin-8, which are markers of the medullary and cortical epithelium, respectively. Highly purified MTS24 cells, inserted under the kidney capsule, are able to develop into a complete thymus and, furthermore, provide the complete milieu necessary for T-cell development.

Because primordial epithelial cells normally need the cooperation of mesenchymal cells for thymus organogenesis,[9] it is conceivable that, in the case of the ectopically placed MTS24 cells, this is provided by comparable cellular elements from the kidney capsule. The MTS24 antibody completely blocks T-cell development in fetal thymic organ cultures, supporting the conclusion that the molecule recognized by the MTS24 antibody regulates normal epithelial function. During this early stage in the development of the thymus, the cell interactions are regulated by a number of transcription factors, such as *HOXA3* and *PAX1* which are part of cluster A on chromosome 7 and encode a DNA-binding transcription factor which may regulate gene expression, morphogenesis, and differentiation.[10,11] An important step in our understanding of the genetic control of thymic development came from the study of the "nude" mouse and the cloning of the gene that confers the nude phenotype, designated *Whn*, for *W*inged *h n*,[12] more recently renamed *Foxn1*. The *Foxn1* gene encodes a transcription factor with a DNA-binding domain of the forkhead/winged helix class. The defect responsible for the nude phenotype is a single base pair deletion in the third exon of the *Foxn1* gene. It results in hair loss, the arrest of the thymic epithelial cell expansion, and inability to attract the hematopoietic precursors into the epithelial rudiment.[13,14] Formation of the epithelial primordium is not affected by the loss of *Whn* function, but subsequent differentiation of the primitive epithelial precursors into subcapsular, cortical, and medullary epithelial cells is arrested[15] and the epithelial rudiment becomes cystic.

In normal development, the epithelial rudiment is invaded by mesenchymal cells from the neural crest,[16] which stimulate epithelial progenitor differentiation into cortical and medullary subpopulations.[8,17,18,19] These mesenchymal–epithelial interactions are mediated by growth factors and their receptors, such as the fibroblast growth factor 10 (FGF10) and its specific receptor, FGFR2IIIb, on thymic epithelial cells. Deficiency of either the factor or the receptor results in severe thymic hypoplasia.[20,21] When immature lymphoid cells begin to arrive in the thymic rudiment, another wave of cellular interactions takes place between the developing lymphoid cells and the stromal epithelial cells. This second stage of thymic development establishes thymic microenvironments conducive to thymocyte differentiation and repertoire selection. Further differentiation and maturation are under the regulation of interactions with thymocytes. Experiments in animals and experiments of nature in humans (disease processes) have clearly shown the symbiotic relationship between epithelial cells and lymphocytes. Prothymocytes regulate differentiation of cortical epithelial cells,[22] whereas mature thymocytes organize the medullary microenvironment.[23,24,25]

The epithelial cells in the cortex and medulla differ by ultrastructure, by immunophenotype, and by functional characteristics. Ultrastructurally, three subsets have been detected on the basis of cytoplasmic processes, secretory organelles, and desmosome connections.[26] Type I cells, located in the cortex, have stellate cytoplasmic processes and make contact with their neighbors, forming a syncytium. Type II cells are found in the medulla, are voluminous with many secretory intracellular vesicles, and have short cytoplasmic processes. Type III cells are rare, may contain vacuoles (pseudocysts), and are located in the medulla.

Six clusters of thymic epithelial staining (CTES) have been identified: type 1 epithelium (CTES II)[27] produces thymic hormones, type II (pale), type III (CTES III) of intermediate electron lucency, and type IV (dark with oval nuclei) are in the cortex proper. These cells extend fine cytoplasmic processes, establishing contacts with neighboring cells, and are connected by desmosomes forming a syncytium, the interstices of which are filled with thymocytes. Some tend to engulf up to 20 to 40 thymocytes in a lymphoepithelial cluster, known as nurse cells, detected in human thymus[28,29] (Chapter 11, Fig. 11.9). The internalized thymocytes are located within caveolae lined by plasma membranes. The lack of penetration by certain dyes indicates that the nurse cells are not an artifact, are completely sealed from the rest of the thymus, and may play a role in T-cell selection. Their formation is not dependent on interactions of T-cell receptors (TCRs) with MHC because they are present in knockout mice deprived of TCR-$\alpha\beta$.[30]

A better understanding of the thymocyte–epithelial cell interdependence for survival came from experiments with a variety of TCR-transgenic mice.[31] The final organization of the cortical and medullary epithelium depends on interactions of the TCR on the thymocytes with ligands on stromal cells. Thymocytes expressing a transgenic TCR that triggers strong positive selection, resulting only in maturation of CD4$^+$/CD8$^-$ T-cells, lose the normal reticular pattern of cortical epithelial cells, and the epithelium in the medulla forms small scattered groups of cells surrounded by macrophages and dendritic cells.[32]

Several other transgenic models demonstrated that maintenance of a balance among positive selection (PS), negative selection (NS), and nonselection is necessary to preserve normal compartmentalization and architectural integrity of the thymic epithelia.[33,34] It is the diversity of signals emanating from these physiologic processes within the thymus during thymocyte maturation that are critical for the maintenance of epithelial organization. These signals are generated from the endogenously rearranged TCRs, which regulate positive and NS. In addition to thymocytes, the thymic vasculature is also an important epithelial organizer.[35] In *Rag2*$^{-/-}$ mice, the medullary epithelium forms cuffs around intermediate-sized vessels, particularly the post-capillary venules. This anatomic arrangement may have important functional implications. The medullary epithelial cells have been linked to NS and tolerance induction[36–38] and are therefore strategically located around the post-capillary venules, where the concentration of autoantigens would be high. The possible functional importance of this peculiar anatomic arrangement of the medullary epithelium is also suggested from the detection of several molecules and structures considered to be tissue-specific within the medulla (i.e., parathyroid hormone, thyroglobulin, insulin, and even organized epithelial "organoids" with ultrastructural features of respiratory epithelium and thyroid follicles).[39] The ectopic location of these molecules and structures is supported by the detection of the expression of the appropriate genes.[39] It has also been postulated that, because these "ectopic" tissues within the medulla have their origin from primordial endoderm, the precursors of the epithelial cells in the medulla also may arise from pharyngeal endoderm. Further support of this view comes from the histologic appearance of medulla in athymic mice, in which further differentiation of these cells fails and the epithelium remains in the primordial condition of endodermal cysts.

Whereas epithelial development depends on FGF, its functional integrity is maintained by other growth factors contributed by the mesenchyme. The keratinocyte growth factor (KGF), a member of the FGF family, is a paracrine growth factor produced by mesenchymal cells. It acts on epithelial cells that express a splice variant of FGF (i.e., FGFR2IIIb). In fetal thymic organ cultures, exogenous KGF expands the medullary epithelium, and in *Rag*$^{-/-}$ animals deprived of thymocytes, which normally produce KGF, the administration of KGF restores the normal medullary epithelial architecture.[40]

The architectural integrity of the thymus is maintained throughout life, but eventually it atrophies with age.[41] Changes

in signals between epithelial cells and thymocytes may determine thymic involution.[42] *Stat3* has been identified as an important signaling molecule between epithelial and mesenchymal cells in the thymic microenvironment.[43] *Stat3* gene disruption in mice results in severe thymic atrophy and enhanced susceptibility of the thymus to environmental stress, such as glucocorticoids or γ-irradiation.

The extracellular matrix (ECM) is an important component of thymic stroma after the cells and certain interactions between differentiating thymocytes and thymic epithelial cells are mediated by ECM proteins that influence intrathymic migration events and thymocyte differentiation.[44] The ECM consists primarily of fibers of collagens, reticulin, glycosaminoglycans, and glycoproteins, including laminin and fibronectin.

Heterotrimeric laminin molecules consist of at least 15 naturally occurring isoforms, which are formed by five α, three β, and three γ subunits. In the human thymus, laminin with α_2-chains (LN-2/4) or α_5-chains (LN-10/11) are detected in the subcapsular epithelium and blood vessels.[45] The $CD4^-/CD8^-$ (double negative) thymocytes are located in the subcapsular area by strong attachment to LN-10/11 through their $\alpha_6\beta_1$ integrin. The $CD4^+/CD8^+$ (double positive) thymocytes, however, lose their capacity to adhere to LN-10/11 and move down to the cortex.

The interactions between thymocytes and stroma facilitate intrathymic migration and regulate positioning of the developing thymocytes to appropriate microenvironments during differentiation. The ECM proteins support the growth of thymocytes and epithelial cells and facilitate cell–cell interaction, especially migration of thymocytes in and out of nurse cells. Receptors for ECM proteins are highest in the double-negative precursors but gradually decrease with maturation.

T-CELL PROGENITORS

The T-cell progenitors in fetal life derive from the liver, whereas in adult life, they come from the bone marrow. The difference in stem cell origin has implications in subsequent lymphoid development, apparently as a result of precommitment or restriction of developmental options at the level of stem cell.[46] Human thymus becomes fully differentiated by approximately the 15th week of gestation (i.e., approximately 7 to 8 weeks after colonization of the thymic rudiment). These early migrants contribute to the development of the thymic microenvironment.

Cells with the $CD34^+/CD38^{weak}/CD90^+$ phenotype contain T-cell progenitors when they grow in fetal thymic organ cultures. In human adult bone marrow, $CD34^+/CD38^-/HLA\text{-}DR^+$ stem cells have the potential to differentiate toward lymphoid and myeloid lineages.[47] These cells are $CD45RA^+$, lack Thy1 (CD90) antigen, and may represent an intermediate oligopotent stem cell with T-cell–reconstituting ability.[48] By phenotype, there are three subpopulations in the bone marrow, which can differentiate to T-cells in the thymus: $CD34^+/CD2^+$, $CD34^+/CD7^+$, and $CD34^+/CD2^+/CD7^+$ and all three are negative for CD3/CD4/CD8.[49] The thymus is populated by hematopoietic multipotent progenitors from the bone marrow.[50]

Experiments with transgenic mice have shown that disruption of the zinc finger protein Zbtb1, resulted in a $T(-)B^+NK^-$ SCID phenotype.[51] In knockout mice for Zbtb1 protein differentiation of common lymphoid progenitors is inhibited and it is associated with expanded populations of bone marrow hematopoietic stem cells and multipotent and early lymphoid lineages[51] corresponding to a common lymphoid progenitor subset.[52] The most primitive thymocytes are Lin^-, $c\text{-}Kit^{high}$, $L\text{-}selectin^+$, TdT^+, and $RAG1^-$, a phenotype similar to progenitor population in the bone marrow which sustains the adult thymus.[53]

Recruitment involves the chemokines CCL21 (or SLC, secondary lymphoid tissue chemokine) and CCL25 produced by the fetal thymus, which attract $CD4^-/CD8^-/CD25^-/CD44^+$ thymocytes.[54] At the site of entry P-selection of the thymic vascular endothelium binds arrests precursors expressing the P-selectin ligand (rolling). Chemokine CCL25 from endothelial cells activates precursors through the CCR9 receptor, and intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1(VCAM-1) of the endothelial cells bind the cells firmly through the integrins $\alpha_L\beta_2$ and $\alpha_4\beta_1$, respectively.[55] The multipotent T-cell progenitors entering the thymus trigger Notch activation, which is critical for T-cell development (see below) for later stages of TCR-dependent selection within the thymus as well as during peripheral T-cell differentiation.[55] There is some overlap of regulatory programs between those required for T-cell specification and those needed for stem cell maintenance or self-renewal, such as Notch pathway, *GATA3*, *IKZF1* (*IKAROS*), and *SPI1 (PU.1)*.[56] The genes that need to be turned on for a successful entrance in the early stage of T-cell development include *RAG*1 and *RAG*2 and *CD3G* and *CD3E* of the pre-TCR and TCR. Although certain options of differentiation are eliminated relatively early after T-cell lineage commitment, others such as differentiation into dendritic cells and natural killer (NK) cells remain through some stages of the T-cell development. The B-cell potential is lost early within the thymus probably as a result of Notch signaling. Additional factors, such as *GATA3* (T-cell–specific among the hematopoietic cells), *TCF3* (*E2A*), shared with B lineage and even non-T–cell–specific such as *RUNX1* and *IKZF1* are also used in T-cell development.

NOTCH AND T-CELL COMMITMENT

Signaling through the Notch receptor is a key factor for T-cell commitment.[57–60] Notch plays a pivotal role in determining T-/B-lineage choice, and signaling through Notch drives commitment of lymphoid precursors to T lineage.[61–63] Notch belongs to a family of conserved proteins that function as cell-surface receptors and direct regulators of gene transcription.[64] It was first isolated as a gene involved in chromosomal translocations with the *TRB@* gene in a subset of cases of human T-cell acute lymphoblastic leukemia. The extracellular domain of Notch contains a variable number of tandem epidermal growth-factor–like repeats and three Lin/Notch repeats, which function for ligand binding and Notch activation.[65] The intracellular region contains six Cdc10/ankyrin repeats characteristic of protein–protein interactions and essential for signal transduction. The Notch protein initially is synthesized as a single-polypeptide chain, but, as a result of proteolytic processing, it is split into two parts. The extracellular region is separated and forms a noncovalent heterodimer with the remaining portion consisting of the transmembrane and the cytoplasmic regions.

Ligands for Notch are Delta, Serrate, and several other molecules corresponding to these two classes. In general, those homologous to Delta are referred to as Delta, and those homologous to Serrate are called Serrate or Jagged.[65] These ligands are transmembrane proteins with an extracellular domain with a variable number of epidermal growth-factor–like repeats and the unique domain for this family, the DSL (Delta/Serrate Lag-2) domain, which mediates binding to Notch and activation. Which of the two groups of ligands is important for lineage commitment remains controversial.[66] In cells of the immune system, there are two Notch receptors, NOTCH1 and NOTCH2, and four signals.[67] The pleiotropic signaling by Notch regulates differentiation, proliferation, and cell death, but it is not yet clear which function most precisely determines cell fate and ultimately directs T-cell commitment.[68] With Notch inactivation, the double-negative T-cells diminish in the thymus, whereas B-cell precursors increase, probably from a more efficient production of B-cells within the thymus.[69] On the other hand, transgenic expression of Notch in the bone marrow permits the accumulation of $CD4^+/CD8^+$ T-cells. The NOTCH1 functional role seems to

be in developmental specification, driving T-cell precursors at the expense of B-cell precursors and perhaps directing the choice of a common precursor between these two fates. Notch is also needed for later stages for *TRB@* gene rearrangements, PS, and CD4/CD8 lineage choices.[56]

PHENOTYPIC DIFFERENTIATION

The first migrants from the bone marrow to the thymus settle in the corticomedullary junction and are large dividing cells expressing $CD34^+/CD45RA^+$, $CD2^+$, and $CD7^+$, with the TCR genes in the germline configuration (Fig. 13.3). The new immigrants potentially are able to differentiate to other lineages, such as NK-cells, dendritic cells, and monocytes. The $CD34^+$ cells then co-express other markers such as CD38 and CD71 (transferrin receptor) associated with proliferating cells, and a portion of them are $CD10^+$. They are subdivided into three categories, double negative-1 (DN-1), DN-2, and DN-3, depending on the expression of CD44 and CD25.[70,71] Recruitment involves interactions between P-selectin expressed by thymic endothelium and P-selectin glycoprotein ligand-1 detected on the bone marrow progenitor cells.[72] Upon arrival they migrate to the subcapsular cortex (DN-3 cells), where they acquire expression of CD1A and CD4 and CD8, and as a result become double positive (DP). In the cortex they are submitted to PS (vide infra) and those considered

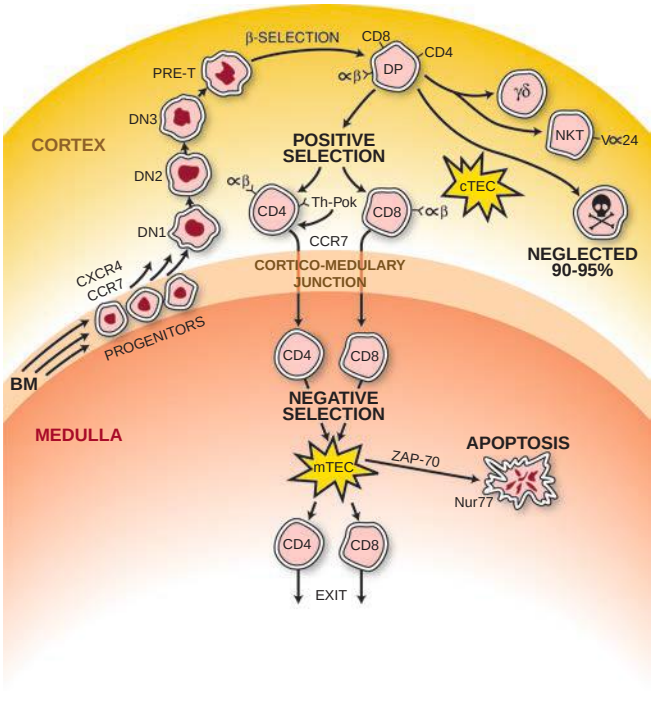

FIGURE 13.3. The first migrants from the bone marrow arrive and settle in the corticomedullary junction. They lack expression of CD4 and CD8 and are known as double negatives (DN). These new immigrants begin to move to the outer cortex and, depending on certain markers, are distinguished in three stages: DN1, DN2, and DN3. The migration is supported through interactions between P-selectin (thymic epithelium) and its ligand (progenitor cells). In the outer cortex they become double positive (DP) (i.e., $CD4^+/CD8^+$), and at the DN3 stage, undergo gene rearrangements with expression of the T-cell receptor (TCR)-β gene (β selection). Signals provided by the CCR-7 chemokine receptor guide the positively selected thymocytes that have already separated into the CD4 or CD8 lineages back to the medulla. A final screening for the "affinity" of their TCR binding to autoantigens takes place in the medulla (NS). It is triggered by contacts of their TCR with tissue-restricted self-antigens (TRAs) on medullary thymic endothelial cells (mTECs). Promiscuous gene expression (pGE), for autoantigens, regulated by the AIRE gene (see text for details), controls central tolerance. The thymic medullary epithelium ultimately allows survival of the "useful," and it ignores the "useless" and "destroys" the harmful[128]. Exit of mature T-cells from the thymus is regulated by the G-protein–coupled receptor sphingosine-1-phosphate receptor 1 (S1P-1) as well as the very late antigen (VLA-) and lymphotoxin-β receptor.

"useful" return back to the medulla, and they are separated into two distinct phenotypes, $CD4^+$ and $CD8^+$ single-positive (SP) cells. These migrations across the thymic parenchyma are mediated by several chemokine receptors, CXCR4, CCR7, and CCR9. Adherence of thymocytes to epithelial cells is also mediated by CD2 and the lymphocyte function molecule-3 (LFA3, CD58), ICAM, and LFA1. The SP thymocytes are submitted to another screening in the medulla. Those with high-affinity TCR against self-antigens are deleted (NS). After this checkpoint, the surviving thymocytes exit the thymus for the secondary lymphoid organs. Emigration of thymocytes requires the sphingosine-1-phosphate receptor 1 (S1P-1).

In the process of differentiation, CD34 is progressively lost, whereas the intensity of CD7 decreases. Myeloid and NK-cells have been detected in various in vitro systems arising from thymocytes,[73,74] and the thymic microenvironment is able to support myeloid differentiation.

Evidence of direct cellular communication between various thymic cells was provided by the demonstration of the existence of gap junctions formed by connexin 43 between two epithelial cells or between epithelial cells and thymocytes.[75]

Of the cytokines that have been implicated in T-cell differentiation, interleukin-7 (IL7) is essential.[76] It is produced constitutively by epithelial cells, and it induces proliferation of DN thymocytes[77] or maintains their viability.[78] $CD34^+$ thymocytes cultured with IL7 start to express CD8 and CD4 but remain CD3 and TCR negative, indicating that other stimuli from stromal cells are essential for generating $CD3^+/CD4^+/CD8^+$ cells. IL7 also induces *Tcrb* gene rearrangements.[79] Mice genetically deficient in IL7 receptor have a profound reduction of T and B lymphocytes, and thymocyte development is blocked at a very early stage before the induction of CD25 and *Tcrb* gene rearrangements.[80] IL7 regulation is tightly coordinated during T-cell maturation within the thymus for thymocyte survival, as IL7 is essential for post-selection expansion of positively selected thymocytes.[81]

Other cytokines, such as IL1, IL2, and IL4, have also been shown to play some role in thymocyte differentiation.[76] The thymus is continuously colonized by hematopoietic progenitors that have the genes for the *Tcr* in germline configuration. Approximately 100 to 1,000 such progenitors enter the thymus daily, and it takes approximately 3 weeks to undergo complete differentiation to mature functional and self-tolerant T-cells.

The biologic processes within the thymus are highly complex, but for a better understanding, we divide them, somewhat arbitrarily, into three areas: (a) lineage determination i.e., TCR-$\alpha\beta$ versus TCR-$\gamma\delta$, (b) separation of the two main T-cell subsets, i.e., CD4 versus CD8, and (c) selection for survival of those cells with a TCR able to recognize foreign antigens, i.e., PS and elimination of those possessing autoreactive configurations, i.e., NS. Understanding of these events will be facilitated by a prior description of the genes encoding the *Tcrs*.

T-CELL RECEPTOR GENES

Knowledge of the structure and patterns of expression of the various TCR genes is essential to our understanding of antigen recognition by T-cells. The *TCR* gene, "a needle in the haystack," was isolated by the technique of subtractive hybridization.[82] Four human and murine *TCR* genes have been identified: α (*TRA@, Tcra*),[83] β (*TRB@, Tcrb*),[84] γ (*TRG@, Tcrg*), and δ (*TRD@, Tcrd*)[85,86] (Fig. 13.4).

The *TRA@* gene is located on chromosome 14 (bands q11-12),[87] as is the immunoglobulin (Ig) gene (band q32). Rearrangement involving the region of the chromosome containing *TRA@* has been detected in patients with T-cell malignancies.[88,89] The *TRD@* gene is located on chromosome 14 within the *TRA@* gene.[90] The *TRB@* and *TRG@* genes are located on chromosome 7.[91,92] Translocations and inversions of chromosomes 14 and 7 are

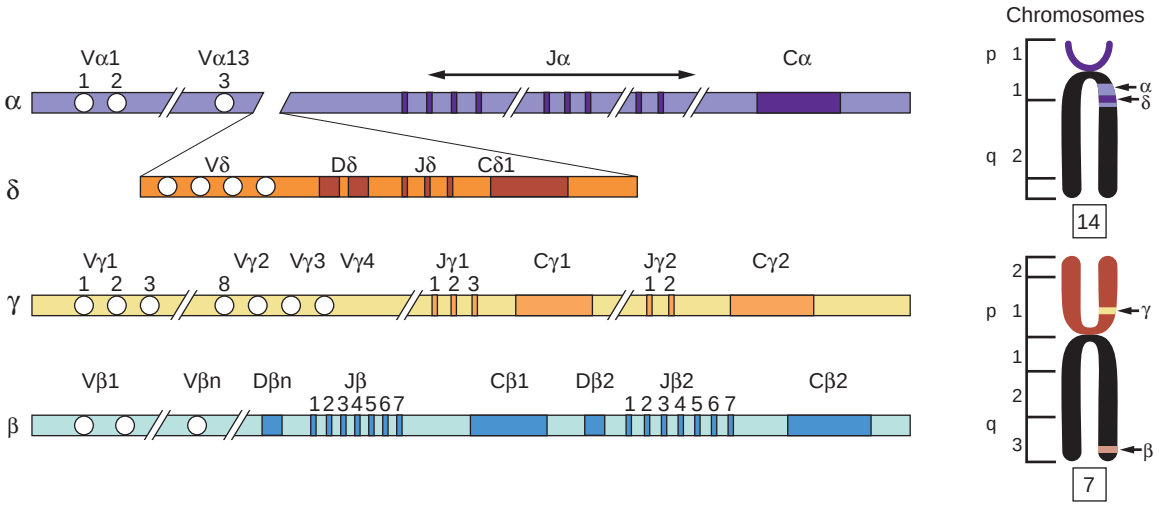

FIGURE 13.4. Organization of the genes for human T-cell receptor chains (see text for details). (Adapted from Kronenberg M, Siu G, Hood LE, et al. The molecular genetics of the T-cell antigen receptor and T-cell antigen recognition. Annu Rev Immunol 1986;4:529–591; and Raulet DH. The structure, function, and molecular genetics of the γ/δ T-cell receptor. Annu Rev Immunol 1989;7:175–207.)

often seen in association with ataxia telangiectasia, probably involving fragile sites that normally are used during the *TCR* gene rearrangements.

All *TCR* genes display an overall organization similar to that of the Ig genes. They are composed of variable (V) and constant (C) genes. The V gene is made of three segments (V, J, and D) in the *TRB*@ and *TRD*@ genes, but only two segments (V and J) in the *TRA*@ and *TRG*@ genes.[86] Each V gene family is divided into subfamilies like the Ig V genes, on the basis of sequence similarity (more than 75%). In humans, the *TCR* gene group consists of one *C-α* gene,[93] two C-*β* genes,[94] two *C-γ* genes, and one C-δ gene. With the exception of the *C-γ* gene, which is composed of three exons, all of the genes have four exons. The *TRD*@ locus is located between the *C-α* and *J-α* gene segments. Diversity of the *TCR* genes is generated through rearrangements, with each of the V and J segments and the D segment, in the case of *TRB*@ and *TRD*@ genes, forming the complete V gene. The *TCR* genes, however, contain a large number of J segments as compared to the *Ig* genes.

Associated with the *C-α* gene are approximately 50 *Vα* and 61 *Jα* segments that spread over 100 kb of DNA. The *β*-chain (*TRB*@) gene complex is located on chromosome six, spans 600 kb[95] and incorporates 57 *V-β* segments. Each of the two *C-β* genes possesses a set of *J-β* segments and one *D-β* segment. The *V-β* segments are all located upstream from the two clusters of *C-β* genes. During rearrangements, when a *V-β* segment forms a VDJ complex, the transcript is committed to using the same *C-β* segment genes. The *TRG*@ gene locus contains two *C-γ* genes, each associated with its own set of *J-γ* segments. There are approximately 14 *V-γ* segments, all located upstream separately from the two *Cγ*–J*γ* clusters. The *C-δ* gene complex lies between the V and J segments of the *TRA*@ gene complex and contains eight *V-δ*, three *D-δ*, and three *J-δ* segments. The *TCR* gene segments, as are the Ig gene segments, are flanked by heptamer-spacer–nonamer sequences, which serve as recognition sites for the recombinase, the enzyme that initiates V(D)J recombination which is regulated by the *RAG1* and *RAG2* genes for both T- and B-cells. The RAG1/RAG2 proteins act in a lineage-specific manner; i.e., *Ig* genes are assembled only in B-cells and *TCR* genes only in T-cells. The recombinations are also developmentally regulated. For T-cells the *β* genes are recombined before *TRA*@ genes and for B-cells the *IGH*@ gene is recombined before *IGL*@. These differences are explained by differential accessibility of V genes during development. Accessibility for V(D)J recombination is usually accompanied by germline transcription at antigen receptor loci.[96]

Two mutually exclusive T-cell lineages have been identified on the basis of TCR: *αβ* and *γδ*.

Transcription increases the recombination of J (*α*) segments located within several kilobases of a promoter and prevents the activation of downstream promoters.[97] The mechanism of V(D)J recombination has been described in detail in Chapter 12.

The mechanisms generating diversity are combinatorial associations of different V, D, and *J* segments and combinatorial pairing of TCR protein. However in contrast to the Ig genes, fewer *V* segments are available to the *TCR* genes. The diversity of the *TCR* is mainly junctional, i.e., a result of additions of nucleotides at the DNA cleavage site. Additions that depend on the template are known as P nucleotides, whereas random additions are called N nucleotides, added by terminal deoxynucleotidyl transferase (TdT) (see Chapter 12). TdT is not expressed during fetal life and in TdT knockout mice, the T-cell repertoire is of fetal type (i.e., less diverse). TdT is expressed only in immature lymphocytes and is responsible for the transition from fetal to adult repertoire by contributing significantly to the lymphocyte antigen receptor repertoire. A striking difference between Ig and TCR is the lack of somatic hypermutations, which is very important in generating high-affinity antibodies in the germinal centers (Chapter 11). Assembly of *V* segments of *TRB*@, *TRG*@, and *TRD*@ genes occurs during the DN stage. If the *β*-chain rearranges successfully, it forms a heterodimer with the pre-T*α* (PTA) chain and differentiates along the T-*αβ* lineage entering the DP phenotype stage.

TCR gene rearrangements occur in two discrete stages of thymocyte development: first during the DN stage with the *TRD*@ gene rearranging first, followed by the *TRG*@ and *TRB*@ genes and the *TRA*@ gene rearranging during the DP stage. During the *TRB*@ gene rearrangement, a *D-β* segment joins a *J-β* segment and as with the *IGH*@ gene rearrangement, a *V-β* joins the *Dβ*-J*β* complex. If the rearrangement is not productive the cell may have one more chance at rearranging a second *C-β* cluster inasmuch as there are two *C-β* segments each with its own *D* and *J* segments.

PRE-T–CELL RECEPTOR AND T-CELL-*αβ*, T-CELL-*γδ* LINEAGES

The decision in choosing a TCR-*γδ* versus a TCR-*αβ* lineage is made by any one of three proposed models. According to one mechanism each lineage starts from a separate precursor

(stochastic or independent pathway), and a second model proposes that there is a common precursor for both lineages (instructive pathway). The third model (competitive pathway) postulates that rearrangements for the genes of the lineages start concurrently and those finishing successfully first determine the fate of the cell. Some evidence appears to support a variant of the stochastic model.[96] It is agreed that the *TRD@* gene rearrangement occurs in thymocytes that can adopt either one of the γδ or αβ fates, but activation of the *TRA@* gene rearrangement during the DP stage seals the fate of the T-cell for the αβ lineage.

Determination of lineage is regulated by transcription factors that act on promoters and enhancers and make appropriate genes accessible to the recombinase.[97,98] Another regulatory mechanism involves the pre-TCR. At this stage of T-cell development, the TCR-β chain forms a heterodimer with the PTAchain and the complex is referred to as pre-TCR.[99] The PTA is a 33-kd type I transmembrane protein of the Ig superfamily, with a single Ig-like domain. Two cysteines form the intrachain disulfide bond, whereas a third cysteine just above the transmembrane region forms the disulfide bridge with the TCR-β chain.[100] The human PTA gene is located on the short arm of chromosome 6, in the vicinity of the HLA locus. The PTA chain is not essential for CD3 expression, but has a major role in TCR-αβ versus TCR-γδ commitment. It generates large numbers of $CD4^+/CD8^+$ T-cells with productive TCR-β rearrangements and directs these cells to the TCR-αβ lineage.[101] At the DN-3 stage, thymocytes undergo extensive DNA rearrangements at the *TRB@*, *TRG@*, and *TRD@* gene loci and make a choice for selection, between the TCR-αβ and TCR-γ receptors. Expression of the TCR-β chain in combination with the pre-TCR–α chain results in a process known as β selection, which leads to rearrangements of the *TRA@* genes and formation of the complete TCR-αβ. If the *TRD@* or *TRG@* genes are rearranged, the cells follow the TCR-γδ lineage (γδ selection).[102–104]

The selection for TCR-β is initiated at a stage phenotypically characterized by expression of $CD4^+/CD8\alpha^+\beta^-$.[105] The productive V-β gene rearrangement in one allele prevents rearrangements of the second allele, a process called allelic exclusion that is regulated by the pre-TCR. Signaling by the pre-TCR requires the CD-3 chains γ, ε, ζ, and η, and the LCK kinase,[106] which is associated with the CD3-ε and -γ chains and is indispensable for the pre-TCR function. Other functions mediated by pre-TCR signaling are cell survival and phenotypic changes. Pre-TCR promotes thymocyte survival, whereas signaling by TCR induces apoptosis.[107,108] Because pre-TCR is expressed on DN T-cells, the antiapoptotic function of pre-TCR is crucial for their survival and differentiation of DN T-cells into the DP stage when the TCR is needed for positive or NS.

Both receptors follow initially similar signaling pathways, such as tyrosine phosphorylation and so forth, but in the apoptotic pathway, they diverge at the level of Fas ligand (FasL) induction, which requires induction of Nur-77 and transcription factors from the nuclear factor of activated T-cells (NFAT). These factors can be induced only by the TCR-αβ but not by the pre-TCR. The PTA possesses a palmitoyl moiety that spontaneously targets the PTA chain to the cell membrane (lipid rafts).[109] This may offset the requirements for a ligand because the pre-TCR from such a location is able to signal constitutively. Signaling through pre-TCR results in expression of certain transcription factors required for the differentiation of precursors to αβ T-cells, i.e., β selection (see above). Some of these factors are the E-proteins of the basic helix-loop-helix transcription activators required for expression of CD4, TCR-α and TCR-β chains and so forth.[110]

CD4/CD8 LINEAGE COMMITMENT

The DP thymocyte ($CD4^+/CD8^+$) differentiates into two phenotypically and functionally distinct lineages of αβ T-cells: $CD4^+$ and $CD8^+$. The TCR of the $CD4^+$ cells interacts with peptides bound to class II MHC molecules, whereas the TCR of the $CD8^+$ cells recognizes peptide–class I MHC complexes. The CD4 and CD8 proteins are not clonally distributed and are known as coreceptors because they recognize the same ligands as the TCR.[111] The mechanism by which the separation of the lineages from DP thymocytes is achieved remains unresolved.[112,113]

According to one theory, known as *instructive*, thymocytes carrying an MHC class I restricted TCR differentiate to $CD8^+$ lineage, whereas engagement of TCR with class II MHC induces commitment to CD4. An alternative model, known as stochastic (or selective), accepts that the DP thymocytes are already committed randomly to a lineage; they make a choice that is unrelated to the MHC specificity of their TCR. Data collected from a variety of approaches do not agree with any particular mechanism in lineage commitment. The instructive model proposes that the CD4 or CD8 transduces differentiation-specific signals, but no lineage-specific signals have ever been identified.

It is also possible that the cytoplasmic region of CD4 directs CD4 lineage commitment. A chimeric construct, for example, made of the cytoplasmic region of CD4 and the extracellular and transmembrane region of CD8a supported the development of cells with the $CD4^+/CD8a^-$ phenotype but with a class I restricted TCR.[114] CD4 is preferentially associated with its cytoplasmic tail with the tyrosine kinase LCK. Therefore, CD4 is likely to deliver stronger signals than the coengagement of TCR and CD8.[115,116]

The strength of signal model suggests that strong signals dictated by the frequency of the available ligand induce CD4 differentiation, whereas weak signals induce CD8. Another aspect of signaling that was evaluated was the duration of signals as an important parameter. When the interaction is limited to a few hours, the cells become $CD8^+$, but exposure for longer periods of time results in $CD4^+$ lineage commitment.[117] Accordingly, TCR of a DP thymocyte initiates down-regulation of CD8 and produces a $CD4^+/CD8^-$ intermediate cell. At this stage, the duration of signaling determines the final outcome. That is, short signaling produces $CD8^+$ T-cells, whereas persistence of signaling in the $CD4^+/CD8^-$ intermediate cell causes $CD4^+$ differentiation.[118] Variation of LCK function seems to be the single most important parameter in CD4/CD8 lineage decision. Constitutively active LCK promotes CD4 differentiation, even in the presence of class I MHC-restricted TCR. When, on the other hand, LCK is catalytically inactive, all thymocytes including those with class II MHC-restricted TCR, become $CD8^+$.[119,120] In the absence of LCK, cross-linking of CD3 induces CD8 differentiation.[121] The LCK-dependent regulation of lineage commitment is not only phenotypic, but also functional, because the class II MHC-restricted $CD8^+$ cells behave as killer cells, whereas the class I restricted $CD4^+$ cells up-regulate CD40 ligand, a function characteristic of helper T-cells.[119] Signaling initiating from LCK is channelled through the Ras–Erk pathway.[122]

The various experimental approaches used in these studies make it clear that the signals required for CD4 differentiation are promiscuous, which is believed to indicate that CD-4 differentiation is a default pathway.[123] The multiplicity of the models entertained and the ambiguity of some of the results are also a testimony that the precise mechanism of T-cell lineage commitment remains still elusive and certainly complex.[113,124]

More recently a new transcription factor Th-POK (T-helper–inducing POK factor) was found to be necessary and sufficient for CD4 lineage commitment and absence of Th-POK results in the development of $CD8^+$ T-cells.[125] The existence of this factor was suspected as a result of studies of the spontaneous recessive mutant mouse with helper deficient cells (i.e., $CD4^+$ T-cells).[126] Th-POK belongs to the POK family of transcription factors characterized by two motifs, a regulatory POZ/BTB domain (for interaction with other transcription factors) and a Zn finger DNA-binding domain.

In summary, LCK is a key regulator, but other signals originating from the TCR in the absence of a coreceptor or in the

absence of a significant recruitment of LCK provide sufficient SRC activity for a response. Such signals depend on the nature of the peptides involved in positive versus NS, which is linked to lineage selection.[121] Although the prevailing opinion accepts that lineage commitment and the selection of thymocytes with useful TCRs are linked, some of the models proposed point to the opposite.[127] The latest view that CD4/CD8 lineage commitment is transcriptionally regulated will put an end to this question hotly debated for a long time.

POSITIVE AND NEGATIVE SELECTION

The random nature of rearrangements of TCR genes generates specificities directed not only against foreign antigens, but also against self-antigens. Self-reactive T-cells are harmful if they have the opportunity of exiting the thymus. Mechanisms have therefore been developed that allow the thymus to "select the useful, neglect the useless and destroy the harmful."[128] The time for selection appears to begin at the DP stage when the TCR is expressed at low levels.[129–132] The TCR of the thymocytes recognizes self-peptides presented by the MHC molecules. It has been widely accepted that the options for each DP thymocyte are determined by some fine qualities and properties of the TCR and MHC–peptide (pMHC) ligand interaction. If the affinity of interaction is "weak," the cell is positively selected, whereas a T-cell with high affinity is negatively selected.[133]

Cells with TCRs that cannot bind with sufficient avidity are neglected and die by apoptosis, whereas in the positively selected cell the expression of RAG, which encodes the proteins regulating V(D)J recombination and the *PTCRA* (pre-T–cell receptor) gene are turned off and expression of CD4 and CD8 are partially down-regulated. At this stage the cell moves from the cortex to the medulla, one of the coreceptors is re-expressed and the cell lineage is defined.[122,134] Signaling by LCK regulates positive and NS and in its absence the selection mechanisms are compromised.[135] LCK interacts with the coreceptors CD4 and CD8 through two cysteines in the cytoplasmic region of each co-receptor and two cysteines in LCK.[136]

The binding of TCR to the ligand induces phosphorylation of the three immunoreceptor tyrosine-based activation motifs (ITAMs) of the ζ-chain and the single ITAM in each of the CD3 ε-, δ-, and γ-chains. The ζ-chain is constitutively associated in thymocytes with the ZAP70 kinase, suggesting that a low level of activation takes place continuously.[137] The fate of the immature thymocyte depends on the type of APC that it encounters in the various histologic compartments of the thymus. The cortical thymic epithelial cells usually mediate PS,[138,139] and the medullary hematopoietic cells mediate NS,[140] although under certain circumstances they may also contribute to PS.[141] Interactions among thymocytes may also support PS if the selecting thymocyte carries MHC class II molecules.[142] In this case the α-chain of the TCR, and particularly the highly diverse CDR3 loop of the α-chain, plays an important regulatory role.[143] Signals provided by the CCR7 chemokine receptor[144] guide the positively selected thymocyte to the medulla. The CCR7 signals provide guidance for the selected thymocyte through the corticomedullary maze, in preparation of the central tolerance in the medulla prior to their exit to the periphery.[144] An important selective force in these cellular interactions is the strength of the interaction, which determines the outcome. Strong interactions lead to deletion, whereas intermediate strength induces PS. This may explain the increase of PS following blocking of CD28/B7 interactions.[145] Removal of strong self-reactive cells is the sole purpose of the NS. Such clones potentially may initiate autoimmunity if they exit to the periphery. An estimated 2,000 to 3,000 tissue-specific antigens are expressed in human or murine medullary thymic endothelial cells (mTECs),[146,147] i.e., 5% to 10% of the known mouse genes, in addition to their normal tissue expression. About 500 of these genes may be *AIRE* (autoimmune regulator) -dependent. Using hen egg lysozyme as reporter for the insulin promoter, it was shown that the expression of the antigen in the thymic stroma is necessary and sufficient for deletion.[148]

Expression of tissue-restricted self-antigens (TRAs) by mTECs is the result of promiscuous gene expression (pGE) by the mTECs.[146] Some of the genes are expressed by both mTECs and cortical thymic endothelial cells (cTECs; pool 1), whereas others are expressed only by mTECs (pool 2), and finally others are expressed only in the more mature mTECs (i.e., strongly positive for MHC class II; pool 3). Depending on the stage of differentiation of mTECs, two models have been proposed for pGE: (a) in the developmental, or progressive restriction model, pGE is detected in immature and perhaps pluripotent progenitor cells and (b) in the terminal differentiation model, pGE is mutated in mTECs of a mature phenotype.[149] The pGE is regulated by *AIRE,* the gene mutated in the rare autoimmune disorder known as autoimmune polyglandular syndrome type 1 (APS-1).[150]

AIRE has a nuclear localization signal and several potential DNA-binding and protein interaction domains. In cooperation with transcription factor CREB-binding protein it transactivates the transcription of other genes, although it is still a mystery how as a single molecule it controls the transcription of such an array of genes.

The pGE has been conserved across species barriers during evolution as a study recently with human pure populations of thymic cTECs and mTECs has shown.[151] The *AIRE* gene showed the highest enrichment in mTECs and the promiscuously overexpressed genes are those remarkably well conserved among species. A set of 443 genes have been detected overexpressed in mTECs (comparable to 555 in mouse). This is an underestimate as most were detected by polymerase chain reaction. These genes show no preference for any chromosome. Another interesting aspect is the finding of clustering of nonhomologous genes. This clustering has been suggested to result from the juxtaposition during evolution of genes involved in the formation of a particular tissue. Because the promiscuously expressed genes do not all share such a function, the clustering is the result of epigenetic mechanisms of regulation. They become accessible to mTECs as a result of belonging to the same "gene neighborhood." pGE not only is sufficient for self-tolerance, but also likely has been essential for survival of the species inasmuch as infertility as a result of gonad-specific autoimmunity is highly prevalent in APS-1[152] and in $Aire^{-/-}$ mice.[153] In addition to genetic control, self-tolerance may also be regulated by epigenetic mechanisms. The lymphotoxin β receptor (LTβR) directs the three-dimensional organization of mTECs,[154] and TRAF6, a cytoplasmic adaptor molecule, which does not bind to LTβR, was still shown to direct mTEC development.[155,156]

Self-tolerance is mediated primarily by NS or clonal deletion,[157] but some of the self-reactive T-cells are submitted to nondeletional central tolerance and give rise to immunosuppressive $CD4^+$ T-cells, also known as natural regulatory T-cells (T reg) cells.[158] T reg cells are T-cells with medium to high affinity for self-antigens. However, they escape NS and are positively selected by a subset of dendritic cells that have been educated by a thymic stromal lymphopoietin produced by Hassall corpuscles.[159] Other evidence, on the other hand, indicates that $CD4^+$ T reg cells are positively selected by thymic epithelial cells expressing self-antigens but not by bone-marrow–derived dendritic cells.[160] ZAP70 is indispensable for positive and NS because both processes are abrogated in ZAP70-deficient mice.[161]

The SRC-like adaptor protein (SLAP) down-regulates the TCR expression during the DP stage of development and rescues T-cell development in the absence of ZAP70. Overall, SLAP acts as a

negative regulator and probably "marks" activated receptors for retention and degradation.[162] The main downstream signaling pathway for PS is the Ras/map kinase (MAPK) cascade.[163] TCR signaling alone is not sufficient to induce selection for survival or death.[164] CD2 expression exerts a strong influence on the TCR repertoire. In the absence of CD2, the thymocytes with high affinity for peptide MHC escape NS.[165] CD2 also influences pre-TCR function in the usage of Vα genes, which is substantially altered in CD2-deficient mice.

The costimulatory interaction of CD40/CD40L is a master regulator of NS, usually acting in the regulation of the ligands of other costimulatory molecules, such as CD80 and CD86.[166] CD40 may also induce other co-stimuli required for thymocyte deletion, such as CD54 (ICAM-1), FASL, or tumor necrosis factor (TNF).[167–169] These molecules could regulate NS separately or in combination with CD5 and CD28. The CD28 costimulatory molecule engaged with TCR signals thymocytes to undergo apoptosis or maturation, depending on the intensity of costimulation.[170]

Stimulation of maturation of DP thymocytes follows activation of the extracellular signal-regulated kinase ERK/MAPK pathway and up-regulation of the antiapoptotic protein BCL2. Apoptosis is triggered with the expression of the Nur77 family of transcription factors and occurs only if TCR engagement is accompanied by costimulation. Ca^{2+} fluxes in mature T lymphocytes regulate proliferation, differentiation, and survival. Some of the functions of Ca^{2+} are mediated by the Ca^{2+}-dependent phosphatase calcineurin. The function of calcineurin is disrupted by cyclosporin A and FK506. Both of these substances form complexes with cellular proteins, termed immunophilins, that bind and sequester calcineurin. Cyclosporin A and FK-506 block the initial steps of PS.[171,172] On the other hand, intracellular chelators reduce deletion,[173] which suggests that interference of Ca^{2+} fluxes and function exerts several effects on the selection process.

All signaling pathways end up targeting regulation of transcription factors, and various studies have examined the roles of NFAT and nuclear factor-κB (NF-κB), but only members of the Nur-77 family have been clearly shown to be involved in the process of selection, with a major role in apoptosis of massive numbers of thymocytes.[174] It has been estimated that 90% to 95% of thymocytes die inside the thymus, and the appearance of very large numbers of dead cells on histologic sections is the reason that histopathologists called the thymus the "graveyard" of T-cells. The timing of positive versus NS has been difficult to define. NS was believed to occur relatively late because the TCR affinity increases with time, and it is the high affinity of TCR that triggers NS.

THE CELLS AND MOLECULES IN THE SELECTION OF THYMOCYTES

Hematopoietic components of the thymic stroma are radiosensitive, whereas the epithelial components are radioresistant. These differences allowed the construction of chimeric thymuses (i.e., thymuses composed of epithelial and hematopoietic elements with a different MHC background). These experiments indicated that the thymic cortical epithelium is responsible for PS.[175] The hematopoietic stromal cells, on the other hand, are potent inducers of NS. The cortical epithelial cells have weak MHC expression and the developing DP thymocytes at that stage have low TCR expression; as a result, the interactions are only of low avidity, required by positive. Similarly, the hematopoietic cells in the corticomedullary junction express MHC molecules at higher density, and the T-cells have up-regulated their TCRs. As a result, the interactions in this anatomic location are appropriate for NS. The concentration of the peptide may also play a role in the selection process. thymocyte bearing a TCR specific for class-I–peptide complex is positively selected if the peptide it carries is in a low concentration and is killed if the peptide concentration is high.[176] However, the weak interactions required for PS and the strong interactions operating in NS can also be provided by the half-life of the pMHC complex (i.e., short half-life for positive and long half-life for NS).

The original question of affinity versus concentration was better answered with manipulation of the pMHC. PS is driven by peptides with varying affinities; however, by increasing the concentration of the peptide, even low-affinity ligands can positively select.[177] It has been argued that the recognition of self-peptides in PS must be relatively degenerate. In other words, a single pMHC can trigger the PS of multiple thymocytes;[178] therefore, the peptide recognition during PS is cross-reactive.[179] This apparent degeneracy of the peptide binding to TCR is the result of a significant contribution to the binding by the MHC molecule.[180]

Other parameters of a pMHC complex, such as the conformation[181] and the concentration[182] of the peptide, contribute to the repertoire selection. Despite the evidence that each pMHC complex selects more than one TCR, the large diversity of the fully developed T-cell repertoire depends on a large number of pMHCs[183] as well as on the quantity and quality of the stromal cells.[184] Peptide diversity during the selection seems to have a greater effect on negative than on PS. In thymus organ cultures, testing with a diverse array of peptides, the addition of 1% of dendritic cells reduced the number of $CD4^+$ T-cells selected by 80% compared to that of the controls in the absence of dendritic cells. Thus, the quantity and quality of the selecting stromal cells have a significant impact on the selected repertoire by multiple peptides.[184] At the end of the selection process, mature T lymphocytes exit the thymus and home to the secondary lymphoid organs (see Chapter 11). There are two types of TCR-$\alpha\beta$ T-cells, the $CD4^+$ (T helper cell) and the $CD8^+$ (cytotoxic T-cell) and one TCR-$\gamma\delta$ cell.

THE α/β T-CELL RECEPTOR COMPLEX

The TCR complex is composed of two components: one is unique in each T-cell and is involved in antigen recognition (ligand binding) and the second component is the same in all T-cells and is involved in signal transduction leading to T-cell activation.[185–187]

THE MAJOR HISTOCOMPATIBILITY COMPLEX–PEPTIDE COMPLEX

The $\alpha\beta$ receptor is formed by two chains, α and β (Fig. 13.5), each consisting of a constant domain, C-α and C-β, and a variable domain, V-α and V-β. The V-α domain is encoded by two gene segments, V-α and J-α, and is homologous to the V domain of the Ig heavy chain (*IGH@*). The V-β domain is formed by three polypeptides, V-β, D, and J-β. The constant domains correspond to the Ig C domains, but there are certain differences. The C-α–C-β interface is highly polar, whereas that of CL–CH1 is hydrophobic. C-β has a large loop, which extends out to the side of the domain. It has been proposed that it may interact with the coreceptors. The C-α domain has several structural deviations from the C-type Ig domain.

The V domains are very similar to the V domains of an antibody molecule. They contribute to the formation of the TCR-combining site, which is made up of hypervariable loops or complementarity-determining regions CDR 1, 2, and 3 from the α- and β-chains and another loop termed HV-4, which exhibits some hypervariability. The CDR1 and CDR2 are formed by the V segments, which are less polymorphic in the TCR than in *IGH@* because fewer V segments are available for TCR, whereas the CDR3 is polymorphic as

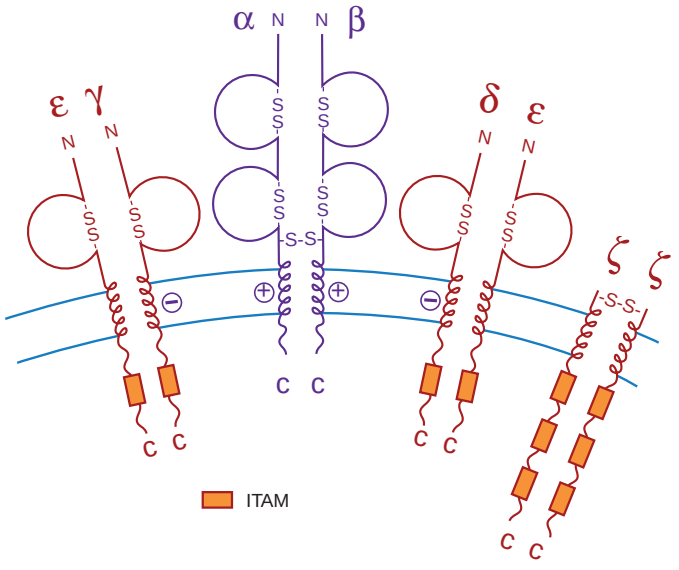

FIGURE 13.5. T-cell receptor complex. The T-cell receptor complex consists of two components: ligand binding (antigen recognition) and signal transduction. The antigen recognition component consists of two polypeptide chains, α and β. Because of their short intracytoplasmic tails, they cannot link themselves to the signal transduction cascade. The signal transduction component consists of the CD3 proteins γ, δ, and ε, members of the immunoglobulin superfamily, and two other proteins forming either a homodimer (two ζ proteins) or a heterodimer (ζ-η). The γ-, δ-, and ε-chains have one immunoreceptor tyrosine-based activation motif each, and the ζ-chain has three. See text for details.

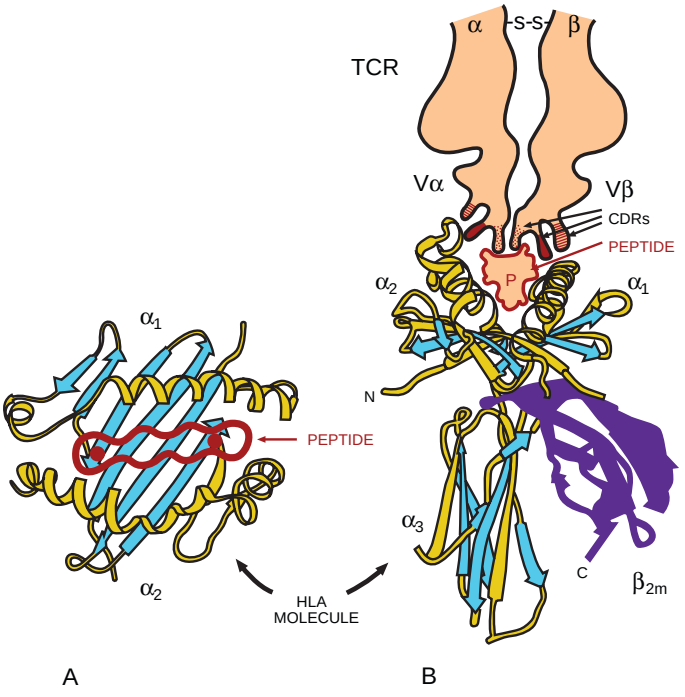

FIGURE 13.6. T-cell receptor (TCR) interaction with HLA/peptide complex. Crystallographic studies of the HLA class I molecule have shown that the two variable domains (α1 and α2) form a groove that binds the peptide that is released as a result of antigen processing. The peptide groove is formed by the helices of the α1 and α2 domains **(A).** Binding of the peptide is mediated through anchor amino acids near both ends of the peptide (in **A**). The TCR binds to both the major histocompatibility complex molecule and the peptide. The complementarity-determining region (CDR) 3 of both the α- and β-chains interacts with amino acids of the peptide, whereas the CDR1 and CDR2 interact with the major histocompatibility complex molecule **(B).**

a result of the larger number of J segments available for β-chain contributing to CDR3.

The loops of V-β that form the expected antigen-binding site of the TCR are similarly placed as in the *IGH@* V region. The chains are linked by a disulfide bond, and the heterodimer is anchored to the cell membrane by the transmembrane region, ending in the cytoplasm by a short (three- to five-amino acid) cytoplasmic tail. Crystallization of the TCR shows that it resembles the Fab fragment of the Ig molecule.[187] However, the TCR-$\alpha\beta$ is extensively glycosylated with up to seven N-linked sites distributed between the α- and β-chains. The combining site is usually flat, similar to antiprotein antibodies and consistent with the TCR's function of binding to the generally flat, undulating surface of the pMHC.[188] The diversity of the CDR3 is much higher, implying that the function of CD-3 is in peptide discrimination, whereas CDR1 and 2 interact with more conserved structural elements of the MHC. The TCR contains many more J segments and thus are able to increase V-Jα and V-D-Jβ junctional diversity in the CDR3.[189] The residues of the TCR that contact the pMHC are always in the apices of the CDR (i.e., for CDR1α, residues 27 to 30; for CDR2α, residues 50 to 52; for CDR1β residues 27 to 30; and for CDR2β residues 52 and 53).

The TCR interacts with peptides bound to MHC molecules (Fig. 13.6). The aminoterminal domains, α_1 and α_2 of the MHC class I heavy chain, form the binding site for the peptide. The site consists of a floor of eight strands of antiparallel β-pleated sheets, which support two α helices, one contributed by the α_1 domain and the other by the α_2 domain aligned in an antiparallel orientation. The floor of the groove is supported by two Ig domains from below; one is the α_3 domain of the heavy chain and the other the β_2-microglobulin. This arrangement forms a groove, on the floor of which lies the peptide from an antigen to be presented to the TCR. Some of the residues of the peptide are exposed above the groove and interact directly with the TCR, whereas others point to the floor of the groove. Depressions in the floor of the groove, known as pockets A through F, interact with some side chains of the bound peptide.[190]

For HLA-B27, the side chain of the C-terminal of the bound peptide sits deep in the F pocket, whereas the N-terminal forms strong hydrogen bonds with the hydroxyl groups of conserved amino acids at the end of the groove.[191] (For details of interaction with the pMHC, see Chapter 14.) For crystallization of TCR-pMHC, the peptide was attached covalently through a linker to the amino terminus of the β-chain of an MHC class II molecule[192] or covalently connected to the amino terminus of the β-chain of the TCR[193] and thus tethered to the MHC groove. Such approaches provided stable complexes of HLA-DR1 and HLA-DR4 that permitted their crystallization. Several TCR-pMHCs have been analyzed to clarify the contributions of Vα for the buried surface area (i.e., the interface between TCR and the pMHC). The contribution of Vα is on the average 57% and that of the Vβ 43%.[194] The orientation of the TCR over the pMHC is diagonal rather than orthogonal.[195] It is more likely that the TCR turns around the MHC molecule by approximately 35° and varies also in its roll in a range of 19° (range 30°).[196] As shown by x-ray crystallography, with 2.5 angstrom resolution, of a complex of human $\alpha\beta$-TCR bound to a complex of HLA-A2/HTLV-1 Tax peptide, (HTLV = human T-cell leukemia virus), the initiation of T-cell signaling is favored by a diagonal binding position of the TCR with the supramolecular assembly. This form of interaction of the TCR with its target is in striking contrast to antibody molecules, which use different binding positions even with the same antigen. The diagonal approach of the TCR, to the MHC/peptide complex, evolved to facilitate the initiation of T-cell signaling, inasmuch as the same MHC-bound antigen can be recognized by different TCRs. Unlike antibody molecules, which bind even to the same antigen by many different binding geometries, the TCRs interact with the MHC/peptide complex with a diagonal binding mode. The diagonal binding

geometry has implications for the mechanism of initiation of T-cell signaling, because it places the TCR in a orientation that facilitates the positioning of the CDR1 and CDR2 loops over the α_1/α_2 helices of MHC class I, and the α_1/β_1 helices for class II molecules. The Vα domain is critical in setting up these orientations facilitating the read-out of the peptide sequence. Thus the CDR1 and CDR2 interactions of Vα are conservative[186] and provide the basic affinity of the TCR. The CDR3 loop is primarily positioned for contact of the peptide in the peptide-binding groove whereas the Vβ interaction is more variable in the C-terminal half of the peptide. The contribution of the individual CDR loops to the interaction varies. CDR1β and CDR2β actually contribute little or nothing to the interaction whereas the CDR3 loops are centrally located and usually dominate the interactions.[194] The contribution of the peptide to the interactions with the TCR varies and usually, two to five side chains of the peptide make direct contact with the TCR. These contact points, known as hot spots, are peptide residues that bulge out of the groove which is more prominent and sometimes profound as in MHC class I.[197] In the interactions of MHC class II with the TCR, the contributions of the peptide side chains are more uniformly dispersed and the peptides are slightly deeper in the MHC binding groove.[197] No single contact dominates the TCR–pMHC interactions, as is often observed in the antigen–antibody interactions. A small number of amino acids dominate the energy landscape in antigen–antibody interaction, as shown by somatic mutations that result in higher-affinity binding.[198] Based on these considerations, it appears likely that the CDR1 and CDR2 loops interacting with the helices of the MHC are responsible for PS, and the CDR3 loops probably play a more important role in NS. As an extension of these considerations in delineating the roles of V-region loops of the TCR, the CDR1 and CDR2 loops provide the basic affinity in the interaction, whereas the CDR3 provides the specificity.[194] The residues of the peptide that protrude highest from the groove provide the basis for discrimination of peptide and for altering affinity or half-life of the TCR–pMHC interaction.

An important point that came out of these crystallographic studies is the role of the water that fills the TCR–pMHC interfaces. This water provides additional complementarity by filling the cavities in the interface, and some of these molecules mediate contact between TCR and pMHC.[199] Overall, the consistent feature of TCR–pMHC interaction is that the peptide contributes a smaller portion of the binding interface (21% to 34%) and a smaller proportion of contacts (26% to 47%) than the MHC. The central positions of the peptide play the critical role and those define the peptides as agonists, partial agonists, and antagonists.[200] The binding of TCR to the pMHC results in T-cell activation and usually there is a broad correlation among affinity, half-life, and the functional outcomes.[201] Mutational analysis of the role of the centrally located residues indicates that in some systems, the biologic activity increases,[202] yet in others, the peptide is converted from an agonist to an antagonist;[203] nevertheless the affinities of the pMHC for TCR change only marginally.

Contacts on certain hot spots are very sensitive in changing the functional read-out but are not based on changes in the affinity of binding or half-life differences in the TCR–pMHC complexes. It has been argued that affinities usually have been measured in isolated TCR–pMHC complexes, and true affinity measurements may require the presence of coreceptors and signaling components and need to be measured with cellular assays.[203]

Because changes in the TCR–pMHC complementarity interface are important for triggering biologic reactions, the conformational changes that have been observed in the TCR-complex crystal structures have been considered for initiation of signaling, but their role is not clear.[204] Conformational changes contribute to an increase in the binding of a number of other peptides (i.e., an expansion of the repertoire).[205]

PEPTIDE–MAJOR HISTOCOMPATIBILITY COMPLEX INTERACTION: THE CORECEPTORS

The TCR is not alone in its interaction with the pMHC but is associated with coreceptors (i.e., CD4, CD8, and the CD3 chains). The monomorphic CD3 γ-, δ-, ε-, and ζ-chains, together with the $\alpha\beta$ heterodimer form the TCR complex. The CD4 or CD8 act as assistants to the TCRs in the helper or cytotoxic function of the cells, respectively. Therefore they have been known as coreceptors.[111] In the current model, the CD4 binds to the same MHC II as the TCR of the $CD4^+$ T-cell and similarly the CD8 binds to the same MHC I as the TCR of the $CD8^+$ T-cell. The binding of the coreceptors occurs with another site of the MHC molecule than that involved in the TCR binding. The TCR binds to the pMHC surface at an angle of 45° to 80° relative to the axis of the two α-helices of MHC,[206] which excludes the possibility for direct association of the coreceptors with the TCR that binds the same pMHC. One possibility is that the coreceptors could be linked with TCR in the cytoplasm through signaling molecules (i.e., ZAP70 and LCK).[207] Another possibility is that the coreceptor associated with a TCR binds to a different pMHC to which a second TCR binds forming a pseudodimer.[208]

The CD8 acts as a dimer that includes either two α-chains or one α- and one β-chain, whereas CD4 is a monomer with four Ig-like domains. Both CD8 chains consist of an Ig-like V domain and a long mucinlike stalk. The Ig-like domain binds to the α3 domain of MHC,[209] forming also some hydrogen bonds with the α_2 domain and the β_2M-chain, away from the peptide interface. In CD4, only the fourth Ig-like domain binds directly to pMHC. The ternary complex (TCR-pMHC-CD4/CD8) within the T-cell–APC interface of the immunologic synapse (IS) has a V shape[210] (Fig. 13.7). Although the CD8α stalk is longer than the CD8β chain, even in its full extension, it reaches only 50 to 60 Å, which is not long enough to traverse the distance of approximately 100 Å to the TCR–pMHC complex. As a result, the TCR–pMHC has to tilt for the CD-8 to reach the MHC. The stalk of the CD8 chains is heavily glycosylated and changes in glycosylation (which occur after T-cell activation) result in a decrease of binding to MHC.[211] The coreceptors enhance TCR signaling by strengthening the stability of the TCR–pMHC complex.[212] The V-shaped ternary complex accepts that the coreceptors bind to the same pMHC as the TCR,[210] whereas the CD-3 components probably lie inside the "open angel" of the V-shaped structure (Fig. 13.7). Such an arrangement makes possible the association of signaling molecules, such as ZAP-70, LCK, and SRC kinases, with CD4 and CD8. With this topologic model, direct interaction of the coreceptors with TCR is not likely as was previously indicated.[213]

The CD2 binds to CD58 (LFA-3) in humans based on electrostatic complementarity, with the CD2 surface heavily populated by basic residues, whereas the CD58 is acidic. The interactions span approximately 134 Å, very similar to that of TCR–pMHC. Therefore, the CD2/CD58 interaction in the contact zone between T-cell and the APC, would facilitate the scanning of pMHC by TCR and lower the threshold for TCR triggering in vitro and T-cell activation in vivo.[214]

CD28 and CTLA4 (CD152) are type I membrane proteins consisting of one moderately to heavily glycosylated V Ig-like domain and are expressed as disulfide-linked homodimers. Their counterreceptors B7-1 (CD80) and B7-2 (CD86) consist of two Ig-like domains, a membrane-proximal C-2 type, and a membrane-distal V-type. B7-2 binds C-28 more effectively than CTLA4 and as a result, enhances costimulatory effects when CD28 and CTLA4 are co-expressed. In contrast, B7-1 binds preferentially CTLA4, and its inhibitory effect would not be affected in the presence of CD28. Delayed expression of B7-1 on APCs appears to be timed to enhance the inhibitory function of

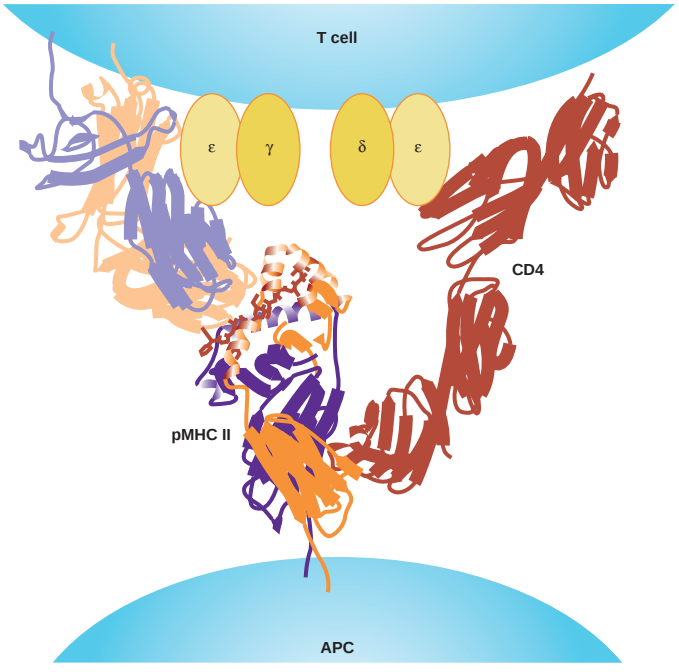

FIGURE 13.7. T-cell receptor (TCR) major histocompatibility complex (MHC) coreceptor interaction. The CD4 and CD8 are coreceptors of the TCR (i.e., "assistants" in the interaction of TCR with peptide–MHC complex [pMHC]). In this function, the N-terminal domain of CD4 (D1) makes contact with the $\alpha 2$ and $\beta 2$ domains of MHC II. In the CD8, the CD8α subunit of the CD8$\alpha\beta$ heterodimer contributes the binding energy, interacting with both the $\alpha 2$ and $\alpha 3$ domains of pMHC I, and CD8β binds only to $\alpha 3$. Therefore, both coreceptors recognize different sites of MHC from the TCR. The length of each receptor is not long enough to reach the MHC binding site, traversing alongside the TCR–MHC complex. It is proposed that TCR–MHC has to tilt for the coreceptor to reach the MHC, forming a V-shaped ternary complex. The CD3 components of the TCR (γ, δ, ε) probably are located inside the V-shaped structure. APC, T-cell–antigen presenting cell. (Courtesy of Dr. G. F. Gao.)

CTLA4. The CTLA4 periodic arrays of crystal lattices enhance the avidity of interaction, whereas the CD28/B7-2 interaction does not have this potential. As a result, during an immune response the CD28/B7-2–activating complexes are 10,000-fold less stable than the inhibitory complexes formed later by CTLA4/B7-1.[215]

THE T-CELL RECEPTOR: SIGNAL TRANSDUCTION COMPONENT

The TCR-$\alpha\beta$ is accompanied by five other polypeptide chains, collectively known as CD3 proteins: γ, δ, ε, ζ, and η. They form disulfide-linked heterodimers, such as $\gamma\delta$, $\varepsilon\delta$, $\zeta\eta$, or a homodimer $\zeta\zeta$[216] (Fig. 13.5). The γ, δ, and ε proteins show a significant degree of similarity to one another and consist of an Ig-like domain similar to a C domain, with an intrachain disulfide bond. The extracellular region of the ζ-chain is only nine amino acids long and contains the only cysteine of the molecule, which forms the disulfide bond with another ζ chain or with an η-chain. In the transmembrane region, the γ, δ, and ε proteins have a negatively charged amino acid complementary to a positively charged amino acid of the transmembrane region of the TCR-$\alpha\beta$ chains. The cytoplasmic regions of γ-, δ-, and ε-chains are long, ranging from 40 to 80 amino acids, whereas that of the ζ-chain is longer with 113 amino acids. The η-chain is a splice variant of the ζ-chain and like a heterodimer with the ζ-chain, exists only in a small number of T-cells. The CD3 proteins have a dual mission in the function of the TCR: escort the receptor to the cell membrane and mediate the signals generated by the TCR–pMHC complex. The complex is assembled in the endoplasmic reticulum, transported to the Golgi apparatus, and then transferred to the plasma membrane. The numbers of the ζ-chain are the rate limiting of the synthesis of the other chains because, although it is synthesized at only 10% of the level of the other chains, it regulates the degradation of a vast majority of the newly synthesized α, β, or CD3 components within 4 hours of their synthesis. The remaining nondegraded chains are long lived and form the complete TCR–CD3 complexes with a limiting role by the ζ-chain. The TCR–CD3 complex lacking the ζ-chain, migrates through the endoplasmic reticulum and Golgi apparatus intact and it is then transported to the lysosomes, where it is degraded. A lysosome-targeting motif has been identified in the δ- and γ-chains and consists of a dileucine-based motif (DKQTLL) and tyrosine-based motif[217] in the carboxy terminal region. In the completed complex the TCR α-chain pairs with CD3 δ- and ε-chains, and the TCR β-chain pairs with CD3 γ and ε. The ζ-chain joins the TCR and the CD3 chains in the last stage of the assembly. The topology of the TCR–CD3 complex is shown in Figure 13.5. Two TCR $\alpha\beta$ heterodimers are associated with one each of $\gamma\varepsilon$ and $\delta\varepsilon$ heterodimers and one $\zeta\zeta$ homodimer. The signal transduction function of the CD3 proteins is based on the presence of one ITAM in each of the γ, δ, and ε proteins and three in the ζ-chain. An ITAM consists of two YXXY/L sequences separated by six to eight amino acids and in the one-letter code for amino acids: Y = tyrosine, X = any amino acid, and L = leucine).[218]

Phosphorylation of the tyrosines turns the ITAM motifs into docking sites for protein tyrosine kinases, which bind to the ITAM through their SH2 domain (see below). An important protein tyrosine kinase in T-cell activation is the ZAP70, which is recruited to the ITAM motifs of the ζ-chain. The multiplicity of ITAM motifs in the cytoplasmic tails of the CD3 proteins results in signal amplification and increases the sensitivity of the TCR to ligand stimulation. Triplication of a single ITAM motif significantly enhances Ca^{2+} mobilization, association with ZAP70 and transcriptional activity in the NFAT complex involved in *IL2* gene regulation.[219] Cross-linking of a single isolated ITAM results in approximately threefold induction in NFAT-regulated activity and cross-linking of a triplicated motif results in an approximately eightfold increase in NFAT-regulated activity (i.e., comparable to intact ζ-chain).

CORECEPTORS TO T-CELL RECEPTOR: CD4 AND C-8 CD4

CD4 is the characteristic marker of $\alpha\beta$ T-cells with helper activity and cytokine secretion. The molecule consists of four Ig-like domains, (D-1 to D-4), with domains D-1 and D-3 similar to a V domain and D-2 and D-4 similar to C domains (C-2 type), but with patches of sequences similar to the V domain. In D-1 and D-3 domains, the nine β strands form two β sheets, linked by a disulfide bond. The domains are linearly arranged, forming a rod with limited flexibility.[220] The binding of CD4 to MHC II molecules and to HIVgp120-envelop protein was studied by mutational analysis. The binding is mediated by a sequence within the D1 domain of two β strands, C′C″, that form a ridge (residues 35 to 46).[221] Phe-43 within this sequence is critical for binding to gp120, as well as for CD4 coreceptor function[222] because it provides the major binding energy, whereas the surrounding charged amino acids facilitate specificity.[223] Crystal structure of the D1/D2 domains from CD4 complexed with class II molecule shows that the CD4 N-terminal V domain is directed and reaching into the two membrane-proximal domains of the MHC II molecule.[224] Both TCR and CD4 are tilted rather than vertically oriented, forming a V-shaped CD4-pMHCII-TCR ternary complex (Fig. 13.7).

In this complex, the antigen-binding groove of pMHC II is no longer parallel to the cell surface but makes an approximately

45° angle with the membrane. However, despite the V shape of the ternary complex, the membrane-proximal domains of each of the components are all roughly vertical, including domain 4 of CD4 and the α_2 and β_2 domains of pMHC II as well as the C-β domain of TCR. Only the C-α domain of TCR hangs almost parallel above the membrane with its lengthy stalk bridging the space.

The extracellular fragment of CD4 crystallizes as a dimer associated via the D-4 domains.[225] The CD4 dimers are associated with superdimers or dimers of dimers of the MHC II molecules[227] and each CD4 molecule of the CD4 dimer interacts with one dimer of MHC II. X-ray crystallography of several MHC class II molecules revealed a structure described as a dimer of heterodimers, or a superdimer. This discovery led to the hypothesis that the MHC class II molecule may interact with the TCR and CD4 as an α/β-2 superdimer, potentially providing more stable and stimulatory interactions than can be provided by the simple $\alpha\beta$ heterodimer alone and indeed oligomers of CD4 have been extracted from isolated lymphocytes.[226] Amino acid substitutions in the faces of the MHC II molecules that participate in the formation of the superdimers block activation of $CD4^+$ T-cells, implying that superdimer formation is a prerequisite for T-cell activation.[227] Stable binding of the T-cell to MHC II requires oligomerization of CD4, facilitated by the D3/D4 domains. Existing evidence suggests that CD4, once it binds to one MHC II molecule, forms tetramers or even larger oligomers and cross-linked lattices[228] a process influenced not only by MHC II but also by the TCR.

When CD4 and TCR co-localize for interaction with the same pMHC II molecule, the CD4 brings $p56^{lck}$, associated with its short cytoplasmic tail to the site of immune recognition. This may constitute one of the main contributions of CD4 to TCR signaling.[229]

CD8

The CD8 consists of an Ig-like ectodomain, a membrane-proximal stalk (or hinge) region, a transmembrane region, and a cytoplasmic region. The Ig-like domain is involved in the binding to MHC, as shown by crystallographic evidence[230] and mutational analysis.[231] The CDR loops of the A and B strands of the CD8$\alpha\alpha$ molecule contact the α_2, α_3, and β_2-M domains of MHC I.[232] The β-subunit of the CD8 interacts only with the α_3 domain, whereas the α-subunit interacts with the α_2 and α_3 domains.[233] In these interactions, the α_3 domain is shifted for better accommodation of the CD8 binding.[209] Multiple contacts between the coreceptor and MHC I promote the functional contributions of the coreceptor to T-cell activation.[195] CD8 enhances cytotoxic T lymphocyte (CTL) activation by promoting the stability of interaction between the APC and the T-cell.[234]

The α-chain of the CD8 is associated with the $p56^{lck}$, which is brought closer to the ZAP70 kinase associated with the TCR, a role that has also been assigned to the CD4 coreceptor. The contributions therefore of both coreceptors in ligand recognition and enhancement of TCR signaling are multiple and involve facilitation of TCR clustering, stabilization of the TCR–pMHC complex, and promotion of signaling by bringing together signaling molecules attached separately on the cytoplasmic tails of the TCR and coreceptors.[235] The availability of pMHC tetramers has encouraged studies on the function of CD4 and CD8 coreceptors in TCR binding to pMHC. The CD4 is critical for signal transduction with pMHC tetramers,[236–238] but the CD8 coreceptor also contributes to the initial phase of interaction (binding), the duration of interaction (stability), and the delivery of signal transduction.[239,240] The final result of CD8 function depends on an epitope of the CD8 involved in the interactions, which are more pronounced with low-affinity ligands. Blockade of CD8-β may affect TCR–C-8 rather than CD8–MHC interaction. The CD8β is more efficient than CD8-α for association with the TCR.[241]

An important function of the coreceptors in TCR-mediated activation is the demonstration that CD4 and CD8 associate with LAT (linker for activation of T-cells), a 36- to 38-kD membrane-associated adaptor protein, that plays a central role in TCR signaling.[242,243] As a result of LAT association with surface coreceptors and coengagement of the TCR with the coreceptors, LAT is phosphorylated and recruits downstream signaling molecules.[244] In conclusion, the contribution of the coreceptors in TCR signaling results from (a) the physical approximation of the LCK, which is associated with the coreceptors; (b) phosphorylation of the ITAMs of the CD3 chains of TCR; (c) recruitment of ZAP70; and (d) phosphorylation of LAT, also associated with the coreceptors. Individual TCR molecules are probably associated with either LCK or with LAT.[244]

T-CELL RECEPTOR AND T-CELL ACTIVATION

Topology of Immune Recognition

The $\alpha\beta$-TCR recognizes short peptides (i.e., eight to ten residues long) for class I–restricted TCRs or 13 to 25 amino acids for class II restricted TCRs. However, approximately only nine amino acids contact the TCR. The peptide is held by the MHC molecule embedded in a groove formed by the α_1-α_2 domains of MHC I or by the α_1-β_1 domains of the MHC II (see Chapter 14). Interaction of TCRs initiates signal transduction leading to transcription of genes encoding cytokines in $CD4^+$ T-cells or assembling and mobilizing the lytic machinery in $CD8^+$ T-cells for killing cells infected by viruses, transformed to a malignant state, or being "strangers," such as in transplanted tissues. The crystal structure of $\alpha\beta$-TCR has been solved and, for several of them in complex with their cognate pMHC ligand.[193,195,196,245–247] The data support the docking model of the TCR ligand interaction, in which the TCR approaches the peptide held on an MHC platform. In this model, the Vα domain of the TCR is closest to the N-terminal residues of the peptide, whereas the Vβ domain of the TCR is closest to the C-terminal end of the peptide. In this orientation, the TCR Vβ domain contacts the MHC I α_1 domain, whereas the TCR Vα domain interacts with the α_2 of MHC I. The TCR orientation relative to the long axis of the MHC platform varies between 45° and 80° (i.e., the angle formed between a line passing through the centers of the Vα and Vβ domains of the TCR and a second line defined by the peptide on the MHC platform).[248] The peptides in all MHC I structures have their N- and C-termini anchored into two fixed pockets approximately 20 Å apart in the MHC I platform. Longer peptides usually bulge in the center. In MHC II, the peptides assume an extended conformation, and the middle portion is smooth and concaves away from the TCR. Residues 1 and 5 of the peptide (p-1, p-5) in MHC II point toward the TCR and are critical in TCR recognition. The coreceptors bind to the same pMHC ligand as the TCR, but the binding of the coreceptor is independent of the TCR binding and is severalfold weaker.[229,249]

The TCR, the pMHC, and the coreceptor form a ternary complex that assumes a V shape with the pMHC II at the apex and the TCR and CD4 as the two arms.

Overall, the data from crystallized complexes of TCR with pMHC suggest that TCR docking on the MHC platform involves residues that are conserved within the CDR1 and CDR2 of the TCR and provide a basal level of stabilizing energy in the formation of the complex.[250] Variations within the CDR3α and CDR3β loops affect the way the TCRs footprint on the pMHC surface.

Lipid Rafts and the Immunologic Synapse

A model for T-cell activation proposes that a naive or resting T-cell needs to cross several stages to achieve full activation.[251] During the first stage, which lasts a few seconds, contacts need to be established by adhesion molecules that overcome charge repulsions between cells. In the next stage, active cytoskeletal

rearrangements bring together accessory molecules and the TCR and concomitantly exclude unligated molecules, such as CD45 (a protein tyrosine phosphatase) as well as CD43. CD43 is a highly glycosylated protein with strong repulsive forces forming a thick glycocalyx "cloud" approximately 45 nm thick around the cells. The distance spanned between the TCR and the MHC-Ag complex is a mere 15 nm; in order for the TCR to sample the complex, it is mandatory that the area of contact between TCR and MHC is clear from interfering tall molecules, such as CD43 and CD45. This process takes minutes. On the other hand, the fundamental signaling units consisting of several molecules, are "loaded" on a lipid raft that is sustained by the cytoskeleton, a process that takes hours. Lipid rafts in evolution are conserved structures that gather receptors involved in signaling in various cell types.[252–255] The lipid rafts are cholesterol-dependent microdomains, resistant to solubilization in nonionic detergents at low temperatures.[256] The lipids contained within the cellular plasma membrane include glycerophospholipids, glycosphingolipids, and sterols. Rafts consist of sphingolipids and cholesterol, which can move through the more liquid-disordered phase of the membrane containing glycerophospholipids.[257] Because of their consistency, lipid rafts have also been referred to as glycosphingo-lipid–enriched membrane microdomains or GEMs. Lipid rafts are anchored by filamentous actin and actin polymerization causes their coalescence.

Phosphatidylinositol-4,5 biphosphate (PIP2) activates proteins involved in actin–membrane interactions, such as binding of the ezrin-radixin–moesin family to CD44, a protein broadly expressed on detergent-resistant membranes. Detergent-resistant membranes are presumed to be isolated rafts. PIP2 activates actin nucleation and polymerization of raft domains. Raft size is poorly understood because they cannot be visualized by light microscopy without clustering.[258] In resting T-cells, the TCR and GM1 are homogeneously distributed. Cross-linking, however, produces large enough aggregates to be visualized using epifluorescence microscopy. Fluorescence resonance energy transfer is sensitive to distances on the order of a few nanometers. Because fluorescence resonance energy transfer was detected between glycosylphosphatidylinositol (GPI)-anchored transferrin receptors interacting with natural ligands, it was concluded that rafts exist but that they are smaller than 70 nm in diameter.[258] Others could not find microdomains enriched in GPI-anchored proteins or GM1. Some MHC II molecules loaded with a select set of peptides are detected on microdomains made up of tetraspan proteins, such as CD9, CD63, CD81, or CD82.[256] These tetraspan microdomains are recognized by CDw78 antibody (mAb FN1), which originally was believed to recognize an epitope of HLA–class II molecules.

A central feature of lipid rafts is that they allow for the lateral segregation of proteins within the plasma membrane. This provides a mechanism for compartmentalization of signaling components within the membrane, concentrating certain components in lipid rafts and excluding others (Fig. 13.8). Proteins with GPI linkage, such as CD14, CD16, CD48, and CD58, are associated with the outer leaflet of lipid rafts. Cytoplasmic proteins, on the other hand, associate with the inner leaflet of lipid rafts through acylation. Most of the SRC signaling proteins are acylated and raft associated. The vast majority of transmembrane proteins are excluded from rafts constitutively and cannot be induced to partition into rafts on cross-linking.

Some proteins important in T-cell activation, such as LAT, CD4, and CD8, reside on rafts. Other proteins reside constitutively outside the rafts but, when activated, become translocated to rafts. The multichain immune recognition receptor family is an example.[259,260] Translocation into rafts after ligand binding appears to be immediate, occurring within seconds of engagement of the receptors, and is selective. For example, CD45, α_4 integrin, and IL1 receptor are excluded from rafts and do not translocate into rafts, even on cross-linking.[261,262] The transmembrane domains of the receptors appear to have a significant influence on translocation, as exchange or mutation of the transmembrane regions

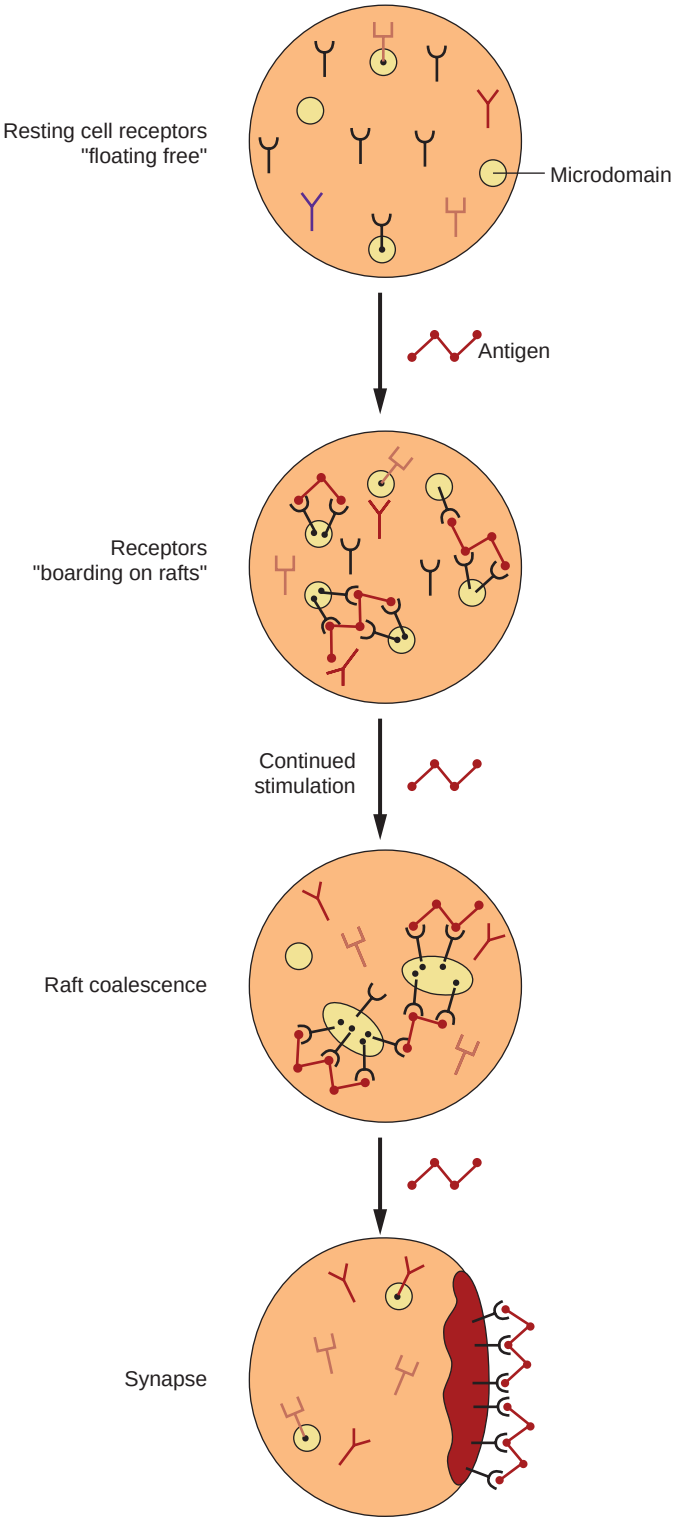

FIGURE 13.8. Rafts: elementary units of the immunologic synapse? In the resting state, the multichain immune recognition receptors (MIRR; i.e., T-cell receptor, B-cell receptor, etc.) "float" free on the lipid membrane, or transiently, some may get on board on certain membrane "microdomains," also known as "lipid rafts." Interaction with a multivalent ligand aggregates several receptors that accumulate within the rafts, forming multimolecular clusters. On prolonged exposure to the ligand, the MIRR clusters result in raft coalescence with the formation of a large aggregate, the immunologic synapse. Cytoskeletal reorganization from multichain immune recognition receptor and chemokine signaling promotes immunologic synapse formation. (Adapted from a model proposed by Dykstra M, Cherukuri A, Sohn HW et al. Location is everything: lipid rafts and immune cell signaling. Annu Rev Immunol 2003;21:457–481.)

alters the translocation properties of the receptors. Translocation of the receptor into the lipid rafts does not need actin reorganization. However, stable residency into the rafts depends on interaction with actin cytoskeleton. The constitutive presence of receptors in rafts may be related to their role in cell survival. For example, the pre-TCR is constitutively associated with rafts and, with its signaling, instructs lineage commitment. TCR/CD28 is excluded from rafts in immature thymocytes and signaling leads to apoptosis.[253]

In addition to their role in signaling, lipid rafts serve as platforms for B-cell receptors (BCRs) to transport bound antigen for processing and presentation. The internalization of BCRs with captured antigen is initiated from rafts.

Retention of receptors in rafts is a mechanism for augmentation of cell activation. The CD19/CD21 complex is excluded from rafts, but its colligation with BCRs by antigen–antibody–complement complexes causes translocation of BCR and CD19/CD21 complex into rafts, where the complex prolongs the retention of BCR within the rafts.[263]

T-cell activation causes rearrangement of the actin cytoskeleton and polarization of the cell toward the site of activation, such as the APC. This polarization is reflected by re-orientation of the microtubule-organizing center (MTOC) toward the APC.[264,265] The TCR is clustered together with associated molecules (CD4, CD8, CD2, CD28, etc.), a process known as *capping*. Capping depends on actin reorganization regulated by phosphoinositides, which activate Vav (a guanosine diphosphate–guanosine triphosphate [GTP] exchange factor) and the Wiskott-Aldrich syndrome protein (WASP). In patients with Wiskott-Aldrich syndrome, WASP is lacking or markedly reduced, and they have defects in actin polymerization, capping, and antigen-induced proliferative responses.[266] WASP regulates the Arp2/3 complex, which mediates actin branching and polymerization.

PIP3 is a strong activator of Vav, which is targeted to detergent-resistant membranes after TCR activation. In Vav-deficient mice, the capping is severely disrupted, and T-cell proliferation is reduced. Raft aggregation is disrupted by the negative regulator of T-cell activation, Cblb (Casitas B-cell lymphoma-b), which is a molecular adaptor and part of the ubiquitin ligation machinery involved in the degradation of phosphorylated proteins. Cblb inhibits TCR clustering and sustained tyrosine phosphorylation. In *Cblb*-deficient mice, TCR/CD3 stimulation alone can activate receptor clustering without the need for CD28 costimulation.[267]

Immunologic Synapse

The TCR interactions with pMHC take place in an intercellular junction between the T-cell and the APC. In this junction, signal 1 (TCR) and signal 2 (costimulation) are processed. This interface reveals a dramatic reorganization of signaling components, forming what is called the IS, a term borrowed from Sherrington's turn-of-the-century definition of the interconnections of neurons as synapses (from the Greek *synapsis*, meaning joining, linking, connecting).[268] The IS relays information across the cell junction in both directions[269] organized into two major compartments. The central supramolecular activation cluster (cSMAC), enriched in TCRs and CD28 and the peripheral supramolecular activation cluster (pSMAC), which contains the LFA1 molecule and talin[270] (Fig. 13.9). On the side of the APC, correspondingly, the cSMAC contains the pMHC and CD80 (ligand for CD28) and the pSMAC contains the ICAM-1 (counterreceptor for LFA1) and CD58, ligand for CD2. The IS develops over a period of minutes after interactions of the T-cell and the APC. Formation of the synapse depends on an intact cytoskeleton.[271] T-cell activation is accompanied by a dynamic reorganization of cortical actin with increase of filamentous actin. These cytoskeletal changes are accompanied by progressive morphologic changes of the T-cells, which first become round, followed by spreading of the cell.[272] In the absence of antigen, the T-cell maintains its motility, continues to crawl around the APC and may even leave for another partner. Some receptors on the APC may convey a "danger signal" for the T-cell to pay particular attention and explore the APC in search of antigen.[273]

In the first stage, the contact is antigen-independent and is mediated by CD28 on the T-cell and CD80/CD-86 on the APC, which are more abundant ($>10^4$) than the pMHC (approximately 100 to 200). The CD28 affinity for CD80 is at least two orders of magnitude above that determined for the TCR–pMHC interaction. These interactions of CD28 preceding the TCR encounters are actually contrary to the original definition of the costimulatory function of CD28, believed to parallel or even follow TCR signaling.

The second stage of IS formation is antigen-dependent and the T-cell extends large cytoplasmic, pulsatile protrusions toward the APC.[274,275] Tyrosine phosphorylated Vav-1 and tyrosine phosphorylated LCP2 (SLP76) assemble with the p21-activated kinase (PAK1) via the adaptor protein NCK1.[276–278]

The T-cell–APC complex is stabilized in the third stage, which is regulated by increases of intracellular Ca^{2+}. By the end of the third phase, SMAC is in place with all the receptors and the signaling molecules, held together with clusters of GEMs (lipid rafts) on the surface and an elaborate cytoskeleton scaffolding underneath.

The kinetics of the IS from its early beginnings are coordinated and organized by the cytoskeleton.[271] The TCR–pMHC can only interact at a distance of 15 nm, which is significantly below the thick glycocalyces of the two cells that separate their membranes by a 50-to 100-nm distance. Adhesion molecules, such as L-selectin, located on the tip of microvilli, may very well initiate the T-cell–APC interaction, until LFA1, lying on flat surfaces of the membrane, is released from its inhibitory state by activating signals delivered by chemokines. These signals also result in the formation of myosin II thick filaments, which disrupt and pull the thick network of polymerized actin away. In this clearing, new actin polymerization pushes forward new filopodia and lamellipodia (i.e., the cell becomes motile). Now that the T-cell is polarized, the long interfering molecules of the glycocalyx, such as CD43 and CD45, are pulled to the rear end, or uropod, of the cell.

In the meantime, activated high-affinity LFA1 released from inhibition stabilizes the contact area between the cells, moving laterally and forming strong bonds with ICAM-1 across the cell junction.[279] In the membrane clearing created and stabilized by LFA1 adhesion, the TCRs sample MHC on the APC surface for complementary peptides. It has been noted that paradoxically, a large cluster of TCRs has been pulled to the rear of the cell, but through the mediation of myosin II is brought to the front, reinforcing the frontal cluster.[280] Nascent IS is further stabilized by TCR links with the cytoskeleton. These links are mediated by some of the components of CD3 (i.e., ζ-chain), which, through its phosphorylated ITAMs, induces actin polymerization.

If pMHCs are present on the APC surface, the T-cell stops moving.[275,281] The central area of T-cell closest to the APC includes the bulk of the TCRs, which are surrounded by integrins farther away.[270,282]

The final arrangement defines the mature IS or the bull's eye[270] (i.e., the cSMAC, a central area 1 to 3 μm in diameter that contains TCR, CD28, and C-2), surrounded by pSMAC, an adhesion ring that contains the LFA1 and talin. Formation of mature IS with APCs (instead of artificial lipid bilayers) shows that the TCR signaling precedes the completion of the mature IS.[283] Bull's eye IS also has been observed with $CD8^+$ T-cells during recognition and killing of target cells.[284] Granule secretion occurs after the MTOC polarization in cSMAC, where membrane fusion occurs. Cellular functions between T-cells and the target cells have been demonstrated by transmission and scanning electron microscopy several years ago. These junctions are followed by disruption and blebbing of the target cell membrane.[285]

Synapses with dendritic cells are formed even in the absence of antigen or MHC.[286,287] Encounters with dendritic cells are relatively short as compared to B-cells.[288] This may be due to chemokine secretion by dendritic cells, which stimulate T-cell

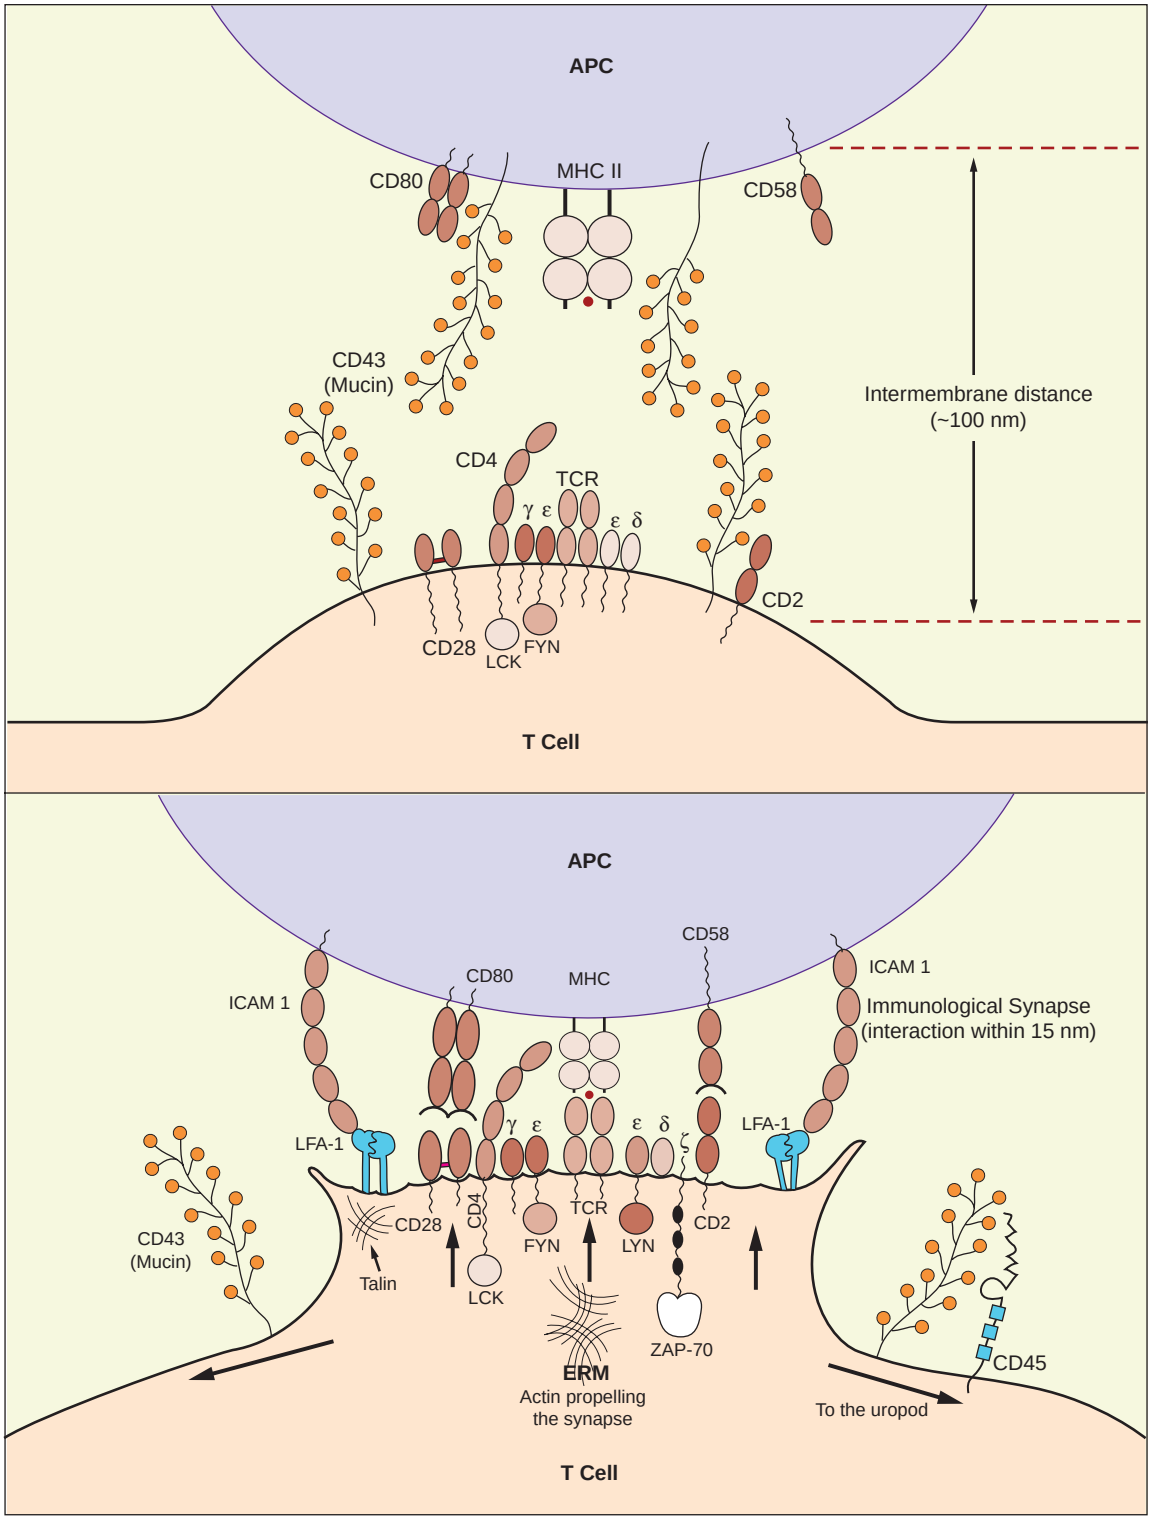

FIGURE 13.9. The structure of the immunologic synapse. The immunologic synapse is formed between T-cell and an antigen-presenting cell (APC; in the case of the $CD4^+$ T-cell) or with a target cell (in the case of the CD81 T-cell). Immunologic synapse formation is a multistep process. A thick glycocalyx on both cells, made predominantly from the mucin molecule CD43, comes in conflict with the approaching T-cell and APC. This distance (50 to 100 nm) is too long for the T-cell receptor (TCR) peptide–major histocompatibility complex (MHC), which interacts at 15 nm. The integrin lymphocyte function molecule (LFA)-1 and its counterreceptor, intercellular adhesion molecule (ICAM), which interact at 40 nm, may bring the cells for an initial contact. More important, chemokine signaling that activates heterotrimeric G proteins activates myosin II, and the cortical cytoskeleton collapses, disanchoring CD43 by the ERM (ezrin/radixin/moesin) adaptor proteins. With loss of the cell rigidity, a new F-actin network creates a pseudopod that propels the leading edge of the T-cell toward the APC. This approach at an intercellular distance of 15 nm prevents CD43 re-entry in the central area of T-cell–APC contact. Concomitantly, talin (a large cytoskeletal protein with attachment to integrins) maintains LFA-1 immobilized in a ring around the central part of the synapse. Although LFA-1/ICAM-1 interacts initially at a distance of 40 nm (extended LFA-1 form), after activation it assumes a bent form (high affinity) that brings the cell membranes closer ("ratchet"-like effect). Multiple other adhesion molecules of low affinity, such as between CD2 and CD58, contribute to the alignment of the two cell surfaces at a 15-nm distance, allowing the TCR to sample the small numbers of peptide–MHC ("proofreading"). The final mature immunologic synapse ("bull's eye") consists of a central supramolecular activation cluster and the peripheral integrin-rich zone. (From Dustin ML, Cooper JA. The immunological synapse and the actin cytoskeleton: molecular hardware for T cell signaling. Nat Immunol 2000;1:23–29; and Delon J, Stelon S, Germain RN, et al. Imaging of T-cell interactions with antigen-presenting cells in culture and in intact lymphoid tissue. Immunol Rev 2002;189:51–63.)

migration. There also seem to be other differences between dendritic cells and B-cells, such as the length of time of the encounter, which is short for dendritic cells but longer for B-cells. The role of the dendritic cell in the formation of IS is active with full involvement of its cytoskeleton, whereas the B-cell remains passive and the T-cell makes the major contribution.[289] The functional consequences of the formation of a mature IS are believed to be primarily related to polarized secretion[290,291] and signaling.[292] IS may help to retain secreted substances close to the targeted cell. Although this is true for the synapses formed by killer lymphocytes such as the $CD8^+$ cytotoxic T-cell or the NK-cell, it may not apply to the $CD4^+$ T-cell, which uses the APC to pull the trigger for its activation. In this case, the IS concentrates crucial molecules, such as CD28, that provide costimulatory signals and enhance TCR-mediated signaling.[293,294]

T-cell Receptor Signaling

Two models have been proposed for sustained T-cell signaling: (a) serial engagement (migration), when the T-cell migrates from one APC to the next and thus renews its signaling capacity;[288] and (b) signaling based on formation of IS. Both models achieve similar results but require different molecular mechanisms. The mature IS forms a specialized mode of signaling and enables T-cells to remain responsive to antigen while still with the initial APC. For a better understanding of the complexities of signaling, we organize it into three phases: (a) initiation, (b) generation of phosphoinositides, and (c) the Ras pathway (Fig. 13.10, Table 13.1).

Initiation Phase of Signaling

Signaling is initiated by activation of LCK, which is regulated by two tyrosines: Tyr 394 in the activation loop and Tyr 505 in the C-terminus. LCK is kept inactive or "closed" by two intramolecular bonds: One is between Tyr 505, which is phosphorylated by the C-terminal SRC, Csk, and binds to the SH2 domain of LCK; a second bond is formed between the SH3 domain of LCK and a sequence connecting the SH2 and the kinase domains. For activation of LCK, the Tyr 505 needs to be dephosphorylated by CD45, a protein tyrosine phosphatase,[295] whereas Tyr 394 is autophosphorylated and activates the kinase domain. The large-size CD45 isoforms are excluded from the IS,[296,297] but some move back to cSMAC adjacent to the TCRs.[298] LCK, recruited by CD4, is maintained in the activated state by CD28[294] and phosphorylates the ITAMs of the ζ-chain of TCR in a sequential and ordered manner, establishing thresholds of T-cell activation.[299] This mechanism determines whether a sufficient number of tyrosines are phosphorylated for full activation and supports the kinetic proofreading model of T-cell activation, which examines the relationship between kinetics of TCR–ligand interaction and intensities of T-cell activation.[300–303]

ZAP70 is recruited to the phosphorylated ITAMs of the ζ-chain and in turn activates the adaptor protein LAT, which then is localized in the rafts. LAT has a short extracellular and long intracellular region and possesses a central position in T-cell activation because it assembles other adaptor molecules and signaling proteins.

There are two groups of adaptor proteins: transmembrane adaptor proteins and cytosolic adaptor proteins.[304] LAT (a transmembrane adaptor protein) is located in the rafts and is phosphorylated by ZAP70. As a result, it recruits PLCG1, phosphoinositide 3-kinase (PI3-K), IL-2–inducible T-cell kinase (ITK), adaptor proteins GRB2 and GADS (GRAP2), and, indirectly, Vav and LCP2 (SLP76).[242,305,306] LCP2 is a cytosolic adaptor protein that has three protein-binding motifs and plays an essential role in signaling pathways required for IL2 secretion.[307] It is expressed on thymocytes, T-cells, mast cells, NK-cells, and platelets. Through Gads, it binds indirectly to LAT after TCR ligation. So LAT and LCP2 function as mutually dependent intermolecular scaffolds, together recruiting crucial signaling regulators to sites of raft aggregation. In mice deficient in LCP2 (or LAT), thymocyte development is arrested at the stage at which the TCR β-chain is coupled to the pre-Tα–chain. LCP2 recruits ITK to lipid rafts and allows for optimal phosphorylation of PLCG1, which also associates with ZAP70.

Phosphoinositide Metabolism

Phosphoinositides are produced by the action of PLCG1 and PI3-K. PLCG1 binds to LAT and is activated as a result of phosphorylation of multiple tyrosines by ZAP70. PLCG1 hydrolyzes inositol phospholipids generating diacylglycerol and inositol (1,4,5)-triphosphate (IP_3).

Diacylglycerol contributes to activation of protein kinase C (PKC), whereas IP_3 increases Ca^{2+} released from intracellular sources. There are multiple isoforms of PKC serine kinases, which are regulated by Ca^{2+}, diacylglycerol, phospholipids, the classic PKC (α, β, γ), and the novel PKC (δ, ε, η, and θ).[308] PKC-θ is recruited to the plasma membrane and is the only isoform detected in cSMAC together with TCR.[309] The PKC-θ targets are activation of the NF-κB, production of IL2, regulation of integrin function, and control of the cytoskeleton through association with Vav. Both Ca^{2+} and PKC synergize in the increase in transcriptional activity of NFAT. Ca^{2+} acts through calcineurin, a calmodulin-dependent phosphatase that contributes to induction or function of NFAT.

The PI3-K produces phosphatidylinositol 3,4,5-triphosphate (PI-3,4,5-P_3), which acts as a second messenger. It binds to proteins that contain a pleckstrin homology domain and recruits them to the inner leaflet of the cell membrane.[310] PI3-K overall is involved in survival and cytoskeletal signaling processes and is essential for adhesion signals. Important targets for PI3-K products are the GTPases, Rac and Rho, stimulated by GEF (guanine nucleotide exchange) proteins promoting transition from the inactive guanosine-diphosphate–bound state to the active GTP-bound conformation. Rac and Rho regulate several functions in the life of the T-cell, and during T-cell activation, they regulate cytoskeletal rearrangements. The PI-3,4,5-P_2 product of PI3-K is converted to PI-3,4-P_2 by the phosphatidylinositol-5 phosphatase (SHIP). This product binds to the pleckstrin homology domain of the protein kinase B or AKT.

AKT moves to the nucleus, where it acts on several substrates regulating cell survival, NF-κB activation, metabolism, and energy generation.[311] It also regulates transcription factors (i.e., NFAT and the Forkhead family), promoting cell survival and progression through the cell cycle. All signals from PI3-K products are eventually terminated by the inositol phosphatase SHIP.

The Ras Pathway

The adaptor protein GRB2 is a bifunctional molecule having an SH2 domain with which it binds to phosphorylated tyrosines of LAT, whereas its SH3 domain binds other proteins that have proline-rich sequences. These proteins are cytosolic, but through association with LAT, they are translocated to the membrane.[305] GRB2 functions in many cells and associates with a large number of proteins.[312] In T-cells it is associated with the proline-rich domain of SOS, the mammalian homolog of the Drosophila "son of Sevenless" protein, which is a critical activator of the small G protein RAS.[313] The GRB2-SOS binding is also mediated by another small linker protein, SHC, and CBL binding to GRB2 inhibits activation.

The Ras pathway activates Erk kinase and MAPK. MAPK pathway may induce integrin activation, and, in reverse, the integrin may induce the MAPK pathway through PI3-K. There are other bidirectional signaling pathways that, in general, send signals to the nucleus and activate membrane molecules by a feedback pathway.

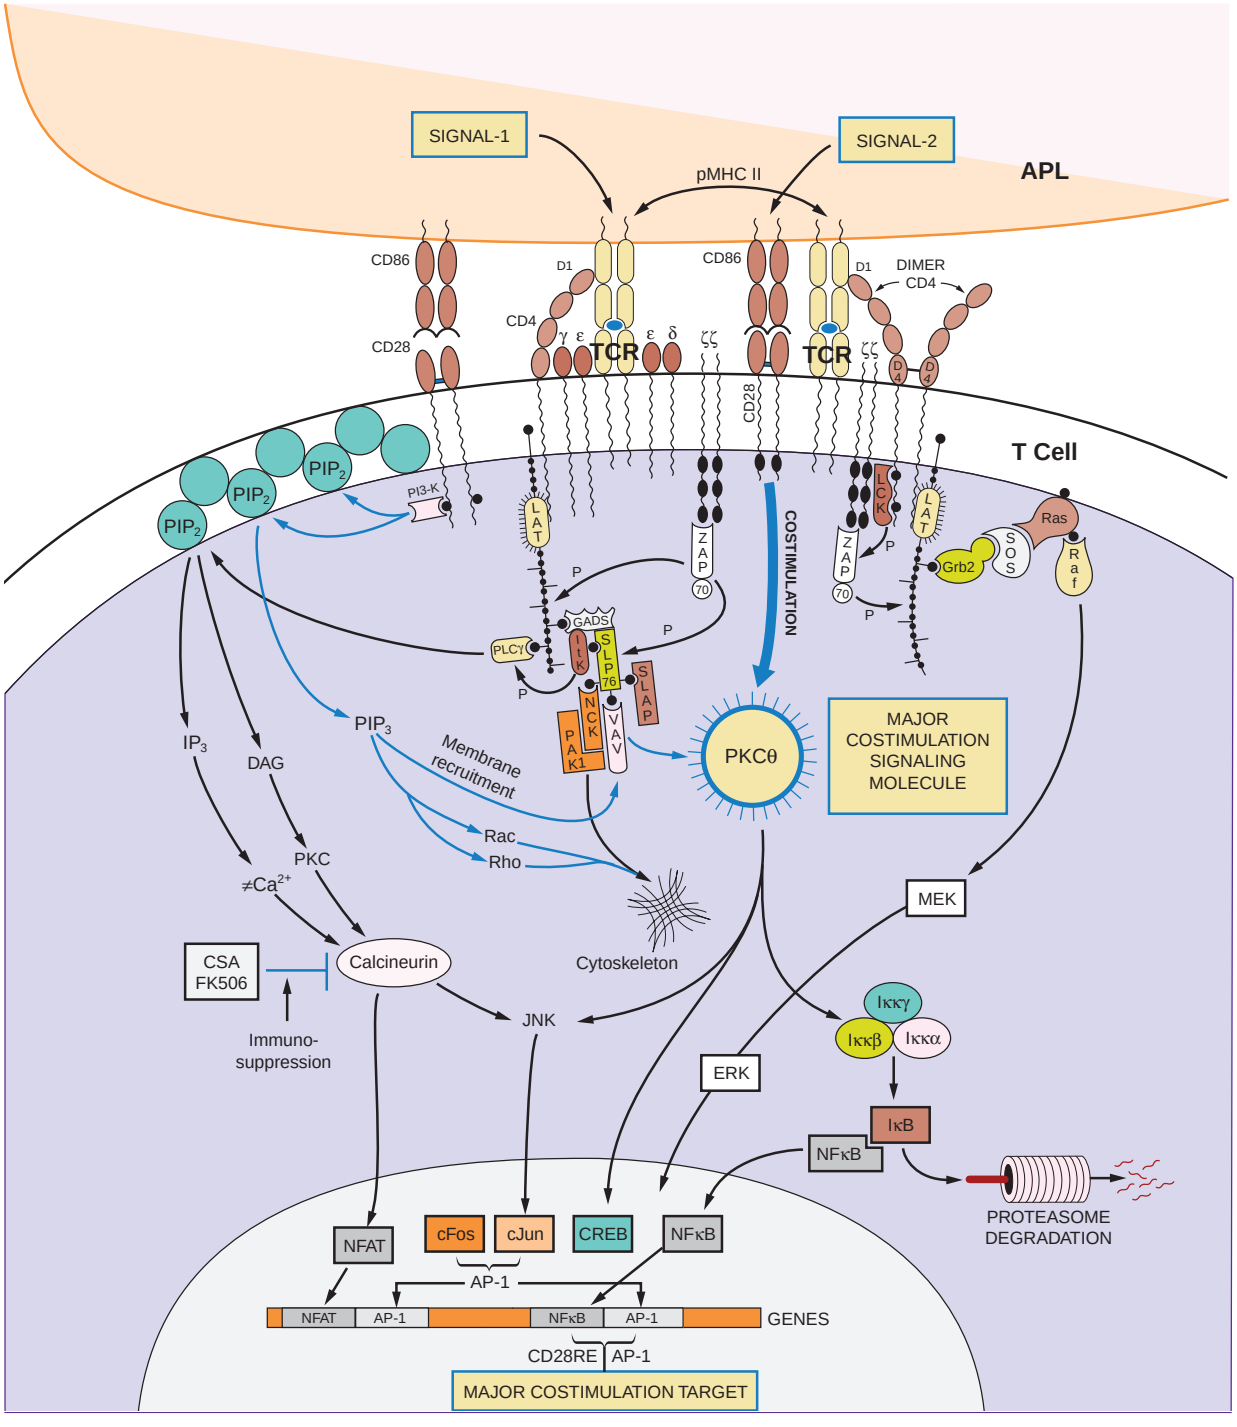

FIGURE 13.10. T-cell activation. T-cells are activated by two signals: signal 1 is delivered by the T-cell receptor (TCR) interacting with peptide–major histocompatibility complex (pMHC), and signal 2, or costimulatory signal, by CD28 interacting with CD80/CD86. A number of adaptor proteins (i.e., proteins acting as scaffolding) assemble a supramolecular signaling complex. Foremost among them are LAT (linker for activated T-cells) and SLP-76 (SH_2-domain–containing leukocyte-specific phosphoprotein of 76 kD). LAT expression is limited to T-cells, natural killer (NK) cells, platelets, and mast cells and is not expressed on B-cells or monocytes. LAT is a membrane adaptor protein as compared to SLP-76, which is cytoplasmic. Engagement of TCR activates Lck, which is associated with the coreceptor (CD4 or CD8). Lck phosphorylates ZAP-70 (ζ-chain–associated protein). ZAP-70 in turn phosphorylates LAT, which at this point makes the transition between proximal and downstream signaling events initiated by TCR. LAT is also associated with the coreceptor, competing in the binding with Lck. LAT and Lck are linked to individual coreceptors, rather than both of them being linked to the same molecule. LAT as an adaptor protein is a scaffolding that is associated with several downstream molecules: phospholipase (PLC)-γ generates phosphoinositides and increases Ca^{2+}, which activate protein kinase C (PKC) and calcineurin, respectively. Another cluster is formed with Gads (Grb-related protein), SLP-76, Vav, and so forth that regulates the cytoskeleton together with the PIP_3 product of phosphoinositide-3-kinase (PI3-K). The other signaling pathway linked to LAT is through the Ras activation, linking to the activation of MAPK/ERK kinase (MEK) and extracellular signal-regulated kinase (ERK). A central position in T-cell signaling is occupied by the novel PKC isoform, PKCθ, which is selectively expressed in T lymphocytes and is recruited to the immunologic synapse. It induces essential activation signals for interleukin-2 synthesis in cooperation with calcineurin. It is a master inducer of NFκB activation and its translocation to the nucleus. PI3-K associated with CD28 generates PIP_3 that recruits Vav and PKCθ to the membrane. APC, antigen-presenting cell; DAG, diacylglycerol; SLPP, serum lipophosphoprotein. T-cell Activation and the Cytoskeleton

The cytoskeleton plays an important role in IS formation and T-cell activation. T-cells polarize toward their target, focusing the signaling on the secretory apparatus at the APC or target cell. Cytochalasin, which disrupts the cytoskeleton assembly, blocks T-cell activation. Actin dynamics are controlled by a biphasic model at the IS. TCR engagement initiates actin solubilization through changes in the phosphorylation of ezrin, radixin, and moesin that allow certain molecules to move away from the points of contact with APC.[314] With the formation of new actin filaments, LFA-1 is anchored and stabilizes the adhesion between T-cell and APC.[315] Polarization of the MTOC requires TCR and involves members of the Rho family of GTPases CDC42, ATK1 (RAC), and RHO.

Disruption of the Rho family members disrupts the proliferation, differentiation, migration, and effector functions and even survival of T-cells.[272,316] CDC42, as with all members of the Rho family of GTPases, functions as a binary switch regulated by nucleotide binding. When CDC42 binds GTP, it is converted from the inactive to the active form and binds effector molecules with high affinity. One of its important substrates is the *WASP* gene. Mutations are responsible for the clinical manifestations of Wiskott-Aldrich syndrome (i.e., thrombocytopenia, eczema, and recurrent infections). T-cells from Wiskott-Aldrich syndrome patients lack microvilli and have an abnormal cell shape. Mutants with inactive CDC42 prevent efficient conjugation of T-cells with APC. In contrast, T-cells with constitutively active CDC42 mutants form extensive filopodia rich in F-actin, which interfere with the formation of IS because CDC42 accumulates in the T-cell–APC contact area. Activation of WASP is achieved by a complex formed by LCP2 (SLP76) adaptor protein, VAV, and NCK (phosphorylated by ZAP70). In this trimolecular complex, LCP2 binds VAV, which converts CDC42-guanosine diphosphate to the GTP form. CDC42-GTP binds to the GTPase binding domain of WASP. At the same time, the NCK binds by its SH3 domain to the polyproline sequence of WASP. These interactions release WASP from its autoinhibitory state and enable it to activate the Arp2/3 complex for actin-branching polymerization.[317–320] Other studies suggest that WASP may not be the critical or even the sole regulator of actin polymerization, but other molecules, such as its homolog WASP, are involved. However, mice with a WASP deficient in the VCA domain have defects in T-cell development.[321]

A significant contribution to the T-cell interaction with the APC is made by the ERM cytoskeletal proteins (i.e., ezrin-radixin-moesin).[322] These proteins act as linkers between cortical actin and plasma membrane, connecting the F-actin to cytoplasmic tails of several transmembrane proteins (i.e., ICAMs, CD43, FAS, etc.). In the resting T-cell, the plasma membrane is rigid because of the thick actin network kept by phosphorylated moesin. With TCR engagement, moesin is dephosphorylated, the actin network "thaws," and the proteins linked to the cytoskeleton are freed to move. The tall ones, CD43, are "squeezed" out of the narrow junction between the T-cell and APC.[323] At the same time, new F-actin networks create pseudopod extensions for contact with the APC. Moesin in the back of the cell is rephosphorylated and keeps the excluded molecules actively out of the IS. CD43 and other molecules that are excluded from the uropod form a cluster called the distal pole complex. This cluster may not be simply a negative contributor to T-cell activation by collecting tall molecules interfering in the formation of the IS, but it has its own signaling mechanism in some aspects of T-cell activation, such as cytokine secretion.[324]

Regulation of T-cell Activation: Costimulation and Inhibition

T-cell activation depends on signals delivered by the TCR engaged with pMHC. However, additional signaling is needed, and this function is known as costimulation. Costimulatory signals are delivered to the T-cell through the CD-28 molecule reacting with ligands (counterreceptors) on APCs (i.e., CD80 [B7-1] and CD86 [B7-2]). These receptors do not act independently but modify the responses mediated by TCR. The CD28 consists of one Ig-like domain of V-type, whereas the two ligands contain two Ig domains, one V-type and one C-type. CD28 is constitutively expressed on T-cells (all $CD4^+$ and approximately 50% of $CD8^+$).

Another receptor, the CTLA4 (CD152), shares approximately 30% identity with CD28; it is not detected in naive T-cells but is induced after T-cell activation.

Both CD28 and CTLA4 share the same ligands. In costimulation, the critical event is up-regulation of the B7 molecules on the surface of the APCs.[325] The major role of CD28 function is to stimulate cell cycle progression and prevent apoptosis. It also enhances production of various cytokines, such as IL1, IL2, IL4, IL5, and interferon (IFN)-γ, and plays a fundamental role in Th1-Th2 differentiation. CD28/B7 interactions also play a critical role in B-cell stimulation. The importance of CD28/B7 interaction was established in transplantation. The importance of the CD28/B7 costimulation pathway was established with studies in transplantation in mice in which blockade of the pathway by CTLA4-Ig prolonged cardiac graft survival and prevented development of vascular lesions associated with chronic rejection.[326] Another costimulatory receptor homologous to CD28 and CTLA4, termed ICOS (inducible costimulator), is a disulfide-linked homodimer.[327] ICOS lacks the extracellular motif present in CD28, which is implicated in binding with the B7 molecules. It is an inducible molecule expressed in activated, but not resting, T-cells. ICOS augments T-cell proliferative responses and cytokine secretion, particularly IL10.[328] The ligand for ICOS (ICOS-L or B7h) is a B7-like molecule expressed constitutively on B-cells and macrophages. Costimulation by ICOS promotes germinal center reaction and isotype switching. ICOS and CD28 regulate Th2 responses, but whereas CD28 is critical in the priming stage to induce Th-2 differentiation, ICOS plays a role in regulating Th2 effector functions.[329] Activation of the ICOS pathway of costimulation initiates acute and chronic graft rejection, which indicates that the ICOS costimulatory pathway also regulates Th1 responses.[330]

CD4 T-CELL DIFFERENTIATION

Activated naive CD4$^+$ helper T-cells (Th), in response to signals from TCR engagement with pMHC, proliferate and differentiate into cytokine-secreting effector cells, which have been distinguished into two major categories.[331] Th1 cells produce primarily IFN-γ, IL2, and TNF-β, whereas Th2 cells secrete IL4, IL5, IL6, IL10, and IL13. Both types of cells produce IL3, TNF-α, and granulocyte-macrophage colony-stimulating factor. Once the initial stimulus from TCR is received, the cells proliferate in response to the autocrine growth factor IL2. At this stage, they are called pT helper cells (pTh) because they have not yet differentiated enough to secrete cytokines. Both Th1 and Th2 cells derive from a single precursor, and several factors regulate their differentiation.[332–334] The Th1 cells induce predominantly inflammatory immune reactions and control intracellular bacterial infections (cellular immunity). They are also associated with some autoimmune diseases. The Th2 cells provide defense against extracellular pathogens, regulating the humoral antibody-mediated immune response. They are also the mediators of allergic reactions.

Th1 versus Th2 differentiation takes place in two stages. During the first stage, the activation signals delivered by TCR pre-condition the naive T-cell for one or the other pathway of differentiation. In the second stage, final development of effector cells is dependent on IL12 or IL4 (Fig. 13.11).

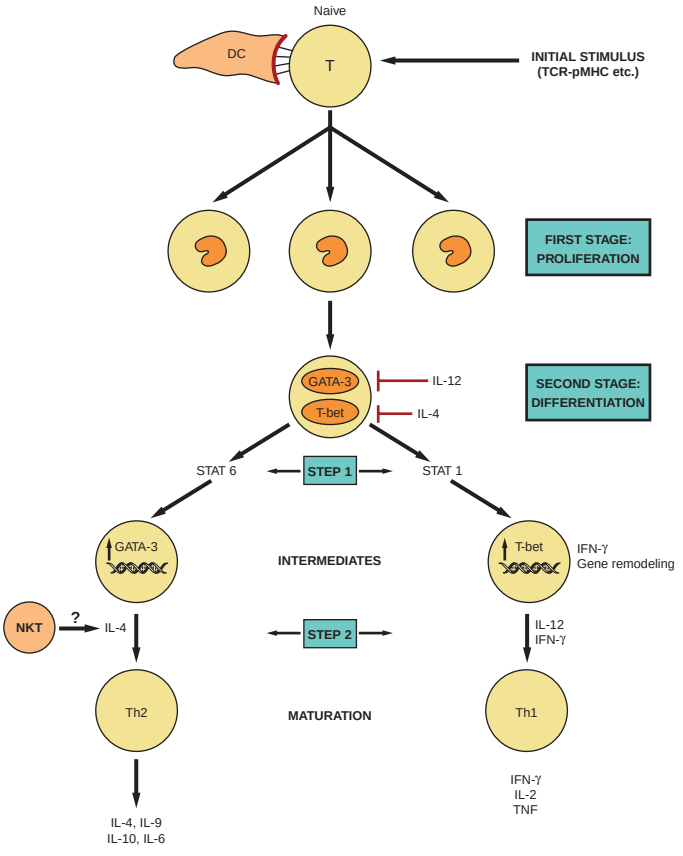

FIGURE 13.11. CD4$^+$ T-cell differentiation. After their differentiation in the thymus into the two main lineages, CD4$^+$ and CD8$^+$, the CD4$^+$ or Th cells differentiate further in the peripheral lymphatic organs into effector cells with distinct patterns of cytokine secretion. The initial stimulus is delivered by the T-cell receptor (TCR) and results in the proliferation of the naive T-cell. These activated T-cells (pTh) have only a limited potential of interleukin (IL)-2 secretion, and they acquire the propensity to respond to additional signals for further differentiation. Primary stimuli via the TCR (dose of antigen, intensity and duration of TCR triggering) influence downstream signaling (Ca^{2+}, protein kinase C, map kinase, etc.) that regulates transcription factor expression. Expression of GATA-3 leads to Th2, whereas T-bet leads to Th1 differentiation. In the second stage, exposure to cytokines (i.e., IL-4 or IL-12/interferon [IFN]-γ) drives the final steps of differentiation to the Th1 or Th2 pattern of cytokine secretion. NKT, natural killer T-cell; TNF, tumor necrosis factor. (Adapted from Noble A. Review article: molecular signals and genetic reprogramming in peripheral T-cell differentiation. Immunology 2000;101:289–299; Murphy KM, Reiner SL. The lineage decisions of helper T cells. Nat Rev Immunol 2002;2:933–944; and Diehl S, Rincón M. The two faces of IL-6 on Th1/Th2 differentiation. Mol Immunol 2002;39:531–536.)

Transcriptional Regulation

In the early stages of Th cell differentiation, TCR stimulation activates a number of downstream signaling pathways. Differential signaling of MAPKs, PKC, and calcineurin pre-conditions Th cells toward one or the other pathway in the absence of cytokines from the environment.[335] A number of parameters related to antigenic stimulation and costimulation influence the final outcome. Low doses of antigen or low affinity of binding favor Th2 development, whereas large doses of antigen or high affinity of binding support predominantly Th1 differentiation. Costimulatory signals modulate the outcome. CD28 ligation favors Th2 development, perhaps by enhancing IL4 production[336] or by direct activation of signal transducer and activator of transcription 6 (STAT6).[337]

The CD40/CD40L interactions selectively induce Th1 cells, but this is the result of the production of IL12 from APCs.[338] During the early stage of Th activation, key genetic and epigenetic events take place that lead to accessibility and activation of specific genes. Expression of certain transcription factors is critical in the early regulation of differentiation.[339,340]

Th1 Regulation

The most prominent factor for Th1 differentiation is IL12. In naive T-cells, the IL12 receptor is not functional but is induced by IFN-α/β. Binding of IL12 to its receptor induces phosphorylation of Janus kinases JAK2 and TYK2, which phosphorylate STAT4. STAT4 translocates to the nucleus and activates target genes. The GTPase RAC2, which is selectively expressed on Th1 cells, activates the IFN-γ promoter via NF-κB and MAPK.[341] During the early Th1 polarizing signaling, the key transcription factor for Th1 development is T-bet (for box expressed in T-cells) induced in naive T-cells.[342,343] T-bet transactivates IFN-γ promoter, induces chromatin remodeling of the gene that encodes INF-γ,[344] and induces expression of the β_2 subunit of the IL12 receptor.[343] The importance of T-bet in Th1 differentiation is underscored by the susceptibility of T-bet knockout mice to challenge with Leishmania major[345] and their predisposition to allergic disease.

Th2 Regulation

The key transcription factor for Th2 differentiation is GATA3,[339] induced in the early stages of Th2 signaling. GATA refers to a family of transcription factors, important regulators of T-cell development. STAT6 activation enhances expression of GATA3. GATA3 induces expression of another Th2-specific factor, MAF. MAF is a basic region/leucine-zipper transcription factor that binds to and transactivates the IL4 promoter.[346,347]

Epigenetic Modification of Cytokine Genes

Detailed description of these early events is beyond the scope of this brief review. The reader is referred to reviews of the topic.[339,348] Transcriptionally inactive gene loci have a condensed chromatin with DNA tightly packed around the nucleosomes. For gene transcription, "open" chromatin is associated with acetylated histones and hypomethylation of DNA. Accessibility of IL4 and IFN-γ genes is initiated promptly after TCR and CD28 activation, but for sustained transcription, STAT6 or STAT4 signaling, and induction, GATA3 and T-bet are required. Within the first few days of Th1 and Th2 differentiation, signs of accessibility of the cytokine gene loci are observed in Th-activated cells. These signs are hypersensitivity to DNAase I and DNA demethylation.

Maturation of Th1/Th2 Cells

The IL12 and IL4 play a major role in the maturation of Th1 and Th2 cells, respectively. IL12 and IL18 act synergistically to produce IFN-γ from terminally differentiating Th1 cells. IL23 is composed of the p40 subunit of IL12 paired with the IL23 α-chain related to one of the chains of IL12. It binds to IL12 β-chain but interacts with its own IL23R. It activates STAT4 and may act during the induction of Th1 and the production of IFN-γ in cooperation with IL18. The IL27 is produced by APCs and induces proliferation of naive T-cells. It acts together with IL12 in promoting IFN-γ production and is the ligand for the T-cell cytokine receptor in the early development of Th1 cells.[349] Th2 maturation is promoted by IL21, which is produced from Th2 cells, and specifically inhibits IFN-γ production and decreases responsiveness of T-cells to IL12, thus amplifying Th2 development.[350]

IL6 produced by several types of cells, especially APCs, activates transcription by NFAT, leading to production of IL4, which promotes Th2 differentiation. However IL6 also inhibits Th1 development because it up-regulates the **s**uppression of cytokine **s**ignaling (SOCS)-1. SOCS, also known as STAT-induced STAT inhibitor, belongs to a family of regulators of cytokine production. SOCS1 inhibits IFN-γ production and the development of Th1 cells. Thus, IL6 plays a dual role in Th1/Th2 differentiation through induction of IL4 and SOCS1.[351] IL10 has also been reported to promote Th2 differentiation, but its main effect is in suppressing Th1 cells.

Another cytokine with double regulatory function is IL18. IL18 is produced from macrophages and synergizes with IL12 for IFN-γ production from NK-cells and T-cells. In collaboration with IL2, it promotes Th1 differentiation in activated T-cells.[352] Overproduction of both cytokines induces severe inflammatory disorders. In addition to its function as a Th1 inducer and as a proinflammatory cytokine, under certain experimental conditions, IL18 stimulates Th2 cell differentiation, increase of IgE, and allergic manifestations.[353] The role of dendritic cells in humans is not clear as the production of cytokines varies depending on signals received from T-cells.

CD8 T-CELL DIFFERENTIATION

$CD8^+$ T-cells produce primarily type 1 cytokines because $CD8^+$ T-cells have no requirement for STAT4 signaling via IL12 to develop into Tc1 effectors. The Tc1/Tc2 regulation is mediated by transforming growth factor (TGF)-β with IL4 promoting Tc1 development and cytotoxicity in the presence of TGF-β.[354] There is some kind of cross-regulation between $CD4^+$ and $CD8^+$ T-cells. $CD8^+$ T-cells produce relatively high levels of IFN-γ and as a result, enhance Th1 immunity. On the other hand, Th2-cell–derived IL4 stimulates development of Tc2 cells in allergic states.

GENOMIC VIEW OF TYPE 1 AND TYPE 2 DIFFERENTIATION

Application of the new technology of gene expression by gene microarrays on polarized type 1 and type 2 CD4 and CD8 T-cells identified similarities in the broad pattern of gene expression in both CD4 and CD8 T-cells for type 1 and type 2 polarization, but differences were also identified between the two lineages.[355] Large numbers of apoptosis-related genes were expressed, particularly in Th1 cells, which correlates with the propensity of these cells to undergo activation-induced cell death.[356] A large number of cytokine and growth factor genes are preferentially expressed by either type Th1 or type Th2 cells. Th2 cells resemble Tc2 cells in their cytokine gene profile. Differences are also noted in genes involved in synthesis of cell migration molecules, such as CCR1, CXCR4, and β_7 integrin in Th2 cells and α_4 integrin in Th1 cells. This is something that should be expected because the two Th populations home to different locations.[357]

THE TH1—TH2 PARADIGM

T lymphocytes constitute a diversified population. Of the two $CD4^+$ T-cells, the Th2 activates the B-cells for antibody production and the second, $CD4^+$ the Th1, activates macrophages for cell-mediated immunity. The first provides defense against extracellular and helminthic infections. The second acts against intracellular bacterial infections, fungi, and protozoa (Fig. 13.12).

Th1 cells coordinate the activation of macrophages and constitute the most important cellular defense mechanism against intracellular pathogens. Macrophage activation is mediated by IFN-γ, the principal cytokine produced by Th1 cells. Macrophages activated by IFN-γ rapidly kill susceptible intracellular bacteria. They produce TNF-α, which synergizes with IFN-γ. IFN-γ has been used successfully as adjunct to chemotherapy in the treatment of leprosy, tuberculosis, and atypical mycobacteriosis. In induction of Th1 immunity, IL12 is rapidly produced by infected macrophages, which activates NK-cells and stimulates production of IFN-γ, which subsequently induces Th1 differentiation. However, overproduction of IL12, by a positive feedback mechanism triggered by IFN-γ, results in inflammatory responses.[358] IL12 production is inhibited by IL10.

There is compelling evidence that the Th1 cells have an essential role in protection from mycobacterial infection. Mice deficient in IL4, a major Th2 cytokine, have a normal response to *Mycobacterium tuberculosis*, whereas increased production of IL4

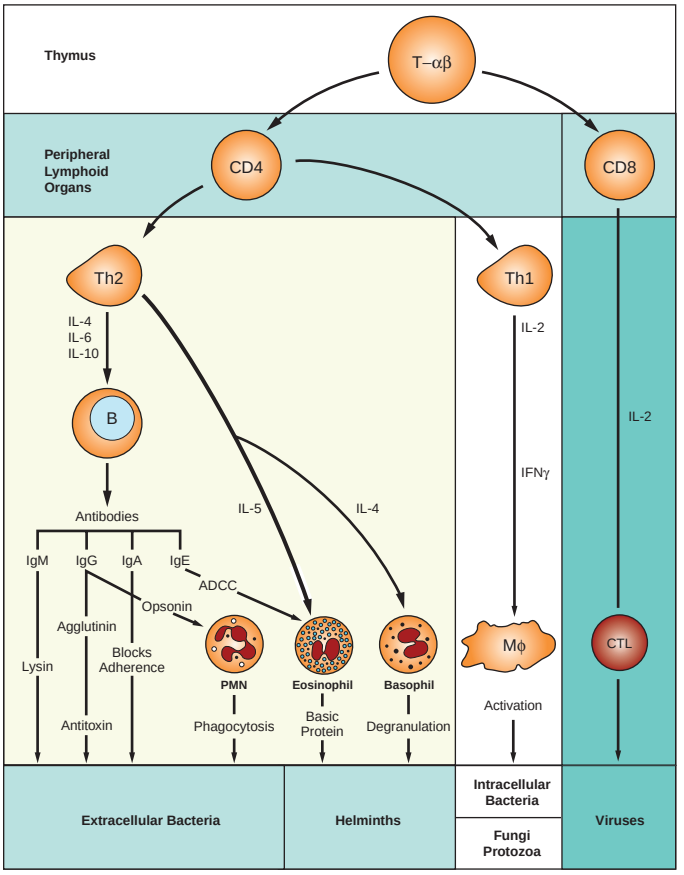

FIGURE 13.12. Th1 and Th2 cells and effector mechanisms against pathogens. See text for details. ADCC, antibody-dependent cell-mediated cytotoxicity; CTL, cytotoxic T lymphocyte; IFN, interferon; Ig, immunoglobulin; IL, interleukin; PMN, polymorphonuclear cells.

correlates with disease progression.[359] Mice infected acutely with *M. tuberculosis* are protected by adoptive transfer of Th1 cells with a tenfold reduction in bacterial counts, whereas recipients of Th2 cells suffer from weight loss and lung fibrosis.[360]

Leishmanial disease currently affects some 12 million people in 88 countries. The annual incidence is approximately 2 million new cases. Experimental studies have clearly documented that Th1 response is associated with restriction of the disease and cure, whereas a Th2 response is associated with progressive systemic disease. Balb/c mice are susceptible to *Leishmania* infection because they are unable to generate a Th1 response, whereas C57Bl/6 mice are resistant to the infection as a result of strong Th1 response. In Balb/c mice, the draining lymph nodes show elevated transcripts for IL4 but not for IFN-γ.[361]

The most critical unifying effect able to induce resistance has been the successful attenuation of IL4 expression in the draining lymph node of infected susceptible animals during the first 24 hours of infection. The extent of IL12 responsiveness is also a critical determinant for the development of a curative immune response because it induces a Th1 response.[362]

Another example of the importance of a balanced Th1/Th2 response is related to the allergic inflammation.[363] The pathophysiologic mechanisms of asthma seem to be based on dysregulation of the Th1/Th2 balanced response with a preponderance of Th2 cytokines. Asthma affects 8% to 10% of the population in the United States and is the leading cause of hospitalization among children younger than 15 years of age, causing an exorbitant financial burden on society. Th2-dominant responses stimulate antibody-mediated responses, activate mast cells and elicit tissue eosinophilia (i.e., the predominant response in the asthmatic airway).[364] IL13 is one of the Th2 cytokines, and overexpression of IL13 in transgenic mice induces an inflammatory response with an infiltrate rich in eosinophils and macrophages. Furthermore, it causes airway fibrosis, mucous metaplasia, and airway hyperresponsiveness.[365] It is likely that asthma is the result of a dysregulated mucosal immune system and pathologic T-cell response in genetically susceptible individuals.[366]

CD8$^+$ T LYMPHOCYTES

The CD8$^+$ T lymphocyte is one of the two professional cytotoxic lymphocytes, the other being the NK-cell. The CD8$^+$ T lymphocytes, also known as CTLs, differ from NK-cells in the basic mechanism of target recognition. CTL expresses an $\alpha\beta$-TCR, recognizing processed peptides presented by MHC class I molecules (pMHC), whereas the NK-cell cytotoxicity is regulated by the C-lectin type of NK-cell receptors (CD94) or members of the killer cell Ig-like receptors (KIRs), which recognize class I HLA allotypes rather than pMHC.[367]

Two fundamentally different groups of methods of evaluation of target cell lysis have been developed: one evaluates disruption of cell membrane and release of tracers incorporated into the target, and the other evaluates DNA fragmentation resulting from apoptotic nuclear damage. In the first category, the most widely used method has been the release of radioactive chromium, ^{51}Cr, preloaded into the target.[368] More sensitive techniques using fluorescent impermanent dyes have been developed. DNA fragments released from the nuclei are harvested, and a "ladder" pattern is identified.[369] Direct comparisons of the cytotoxic potency of different cell populations cannot be made by these methods because the target cell death is not linearly related to the cytotoxic input. Usually, the number of cytotoxic cells required to achieve a given level of target cell lysis is expressed in lytic units, which are inversely related to the effector cell number.

Activation of Cytotoxic T Lymphocytes

For the CTL to become an active effector, the precursor cell must be stimulated by antigen to undergo proliferation and differentiation.[370] The activation or priming results from the interaction of the naive CD8$^+$ T-cell with professional APCs. Granules are not always visible before activation, but the killing machinery (i.e., perforin, granzymes, and FasL) is delivered immediately upon priming.[371,372] The granule by electron microscopy is 0.5 to 1.0 μm in diameter and is heterogeneous in its structure.[373] The core is homogeneous and sometimes it is surrounded by double membranes containing the perforin enclosed by a thin membrane.[374] Multiple small vesicles surround the core toward the periphery of the granule. Depending on the preponderance of these two components, granules have been distinguished as type I (dominated by the cores) or type II (with dominant multivesicular component but no cores), and other granules in terms of content are intermediate between types I and II. The granules are similar to late endosomes and have the properties of two usually separate organelles: those of the secretory type and those of the lysosomes.[375] Similarities with lysosomes include the acidic pH, the mannose-6-phosphate receptor (MPR), and the lysosomal marker, lysosome-associated membrane protein. Endocytic components carrying CD3/TCR, CD8, and MHC molecules reach the perforin-containing granule and are displayed in the outer leaflet of the membrane.

GRANULE CONTENTS

Perforin (Cytolysin)

Perforin is a 65- to 75-kD glycoprotein with patchy homology to C9 complement component. It is synthesized as an inactive precursor, which is cleaved to yield a 60-kD active form.[376] The protein consists of two regions: one has homology to complement proteins (C_6 to C_9), and the other is a C-2 domain related to Ca^{2+}-binding proteins.[377] The C-terminal portion is cleaved by proteolytic enzymes activating the C-2 domains for phospholipid binding.[378] The N terminal is involved in interaction with the membrane and polymerization. However, the central portion contains four membrane-spanning domains, potentially capable of forming amphipathic α helices of β sheets. At the carboxy terminal, a short peptide (propiece with a bulky glycan attached) is removed, and the remaining perforin monomer undergoes conformational changes in the presence of Ca^{2+}, inserting itself in the membrane. Interaction with other perforin monomers forms the polyperforin pores.[379–381] At least three to four monomers are needed to form a functional channel, whereas 10 to 20 aggregated monomers are needed to produce a pore visible by electron microscopy.

Granulysin

Granulysin is a member of the saposin[382,383] family of lipid-binding proteins, related functionally to defensins and other bacterial peptides, but is structurally different. It is active against Gram-positive and Gram-negative bacteria, fungi, and parasites. It disrupts artificial liposomes, damages mitochondria, and activates caspase 9 to induce apoptosis. It probably plays an important role in innate and acquired antimicrobial defenses. It kills extracellular *M. tuberculosis* and decreases their viability inside the cell.[384]

Granzymes

Granzymes are serine proteases of the chymotrypsin family.[385,386] The crystal structure of granzyme B has been solved, and its structural similarity with chymotrypsin has been verified.[387] On the basis of the gene structure, proteolytic specificity, and biologic function, these enzymes are divided into three subfamilies. They are produced as proenzymes, with an acidic inactivating peptide. During their transport through the endoplasmic reticulum and Golgi apparatus, they are processed so that they are targeted to the secretory pathway. The activation peptide is removed by dipeptidyl peptidase I (DPPI), and a sequence motif interacts with

proteoglycan in the granule to maintain proper conformation for activation. Granzyme B has a unique specificity among mammalian serine proteases in that it requires aspartic acid as P1 amino acid (i.e., the cleavage leaves a carboxy-terminal aspartic acid). Granzymes are highly positively charged proteins at neutral pH and form complexes with proteoglycans in the granule and extracellularly with polyanionic components.

Calreticulin

Calreticulin is a Ca^{2+} storage protein and carries a sequence that retains it in the endoplasmic reticulum. It co-localizes with perforin and is released together with perforin, which binds to the P-domain of calreticulin. Calreticulin functions as a chaperone protein for perforin and protects the CTL during biogenesis of the granules.[388] Fragments of individual calreticulin domains used in lytic assays showed that the Ca^{2+}-binding C-domain, which does not bind perforin, has the strongest capacity for inhibitory activity.[389] Lysis, however, is independent of calreticulin's ability to sequester Ca^{2+}. It is suggested that calreticulin stabilizes membranes and thus prevents polyperforin pore formation.

Other Components

Chondroitin sulfate proteoglycans are negatively charged and are exocytosed during target lysis. They probably regulate delivery of the positively charged granzymes.[390] The multivesicular domain of the granule is rich in MPR, which is normally absent in mature lysosomes but present in early endosomes.

The DPPI (cathepsin C) is a lysosomal cysteine protease responsible for post-translational processing in the generation of activated myeloid and lymphoid granule serine proteases.

TARGET CELL LYSIS

Secretory Synapse

As we have seen with the CD4 T lymphocyte, recognition of the antigenic determinants by TCR is associated with the formation of the IS. In the synapse, the SMAC is organized by TCR and adhesion molecules. CTL also forms a synapse with the target cells, and within the synapse, there is a defined secretory domain.[391] LFA-1 and talin form an outer ring of adhesion proteins with a distinct secretory domain in the center and separate from the cluster of the TCR and signaling molecules.[392] Electron microscopy shows granules at the point of degranulation. The CTL acquires the hand-mirror configuration during its movement, with the nucleus leading in the front and cytoplasmic organelles trailing behind. The Golgi is apposed tightly to the membrane at the point of contact and the organelles appear to be "streaming" toward the contact site. Confocal microscopy shows that the granules initially cluster behind the MTOC and then go around the MTOC to reach the secretory domain. Intimate interdigitations are visible over a large area, but a thin extracellular space separates the two cells that are held together by gap junctions[393] (Fig. 13.13). Gap junctions exist normally between cells in various tissues and probably serve the function of cellular communication. The nucleus moves away and the granules take up position next to the area of adherence with the target. Confocal microscopy identifies regions of the secretory synapse where granules are secreted between LCK and talin or CD11a (Fig. 13.9). The granules stream around the nucleus along microtubules and accumulate behind the MTOC and the Golgi apparatus. Then they move around the Golgi and reach the synapse, where secretion occurs between the adhesion ring and the signaling domain. They fuse with the membrane within 4 minutes after contact with the target.[394]

This fusion marks the beginning of the Ca^{2+}-dependent second stage characterized by striking intracellular changes. The most remarkable of these changes is the re-orientation of the MTOC, which, together with the Golgi, takes a position facing the area of contact with the target.[395–397] The Ca^{2+} requirements for lysis may also be due to the Ca^{2+} dependency of the MTOC re-orientation that is a prerequisite for CTL killing.[398] Granules attach to and then move along microtubules toward the MTOC and finally are secreted at the MTOC. Disruption of microtubules by certain drugs severely impairs killing.[397]

For the last stage of granule secretion, a GTP-binding protein, RAB27A, is critical for moving the granules from the MTOC to the synapse.[399] In a rare autosomal recessive disease known as Griscelli syndrome, RAB27A is defective. These patients have albinism because melanocytes require RAB27A to secrete melanosomes. WASP, which activates the Arp2/3 complex for actin polymerization, is also required for cytotoxicity.[399]

Lymphocyte-mediated killing can be confined to two pathways: the perforin-granzyme–mediated and the Fas-mediated pathways.[400] Independent of the importance of the contribution of each pathway in target cell lysis, the fact is that lysis absolutely requires exocytosis of granules and their contents. Exocytosis requires signaling from PI3-K and ERK. The importance of exocytosis is emphasized by markedly decreased cytotoxicity of CTLs and NK-cells in Griscelli syndrome (a rare autosomal recessive disorder characterized by partial albinism and the ashen mouse). The ashen mice have a profound decrease of cytotoxicity, even though they have normal FASL expression and FASL cytotoxicity.[401] Patients with Griscelli syndrome and the ashen mouse have a loss of function mutation in the *RAB27A* gene that abrogates the expression of RAB27A GTPase (one of approximately 50 GTPases). RAB27A affects the functions of the dense granules of platelets, melanosomes of melanocytes, and secretory lysosomes of CTLs. In platelets, RAB27A regulates secretion only of the dense granules. Increase of Ca^{2+} is critical for cytotoxicity, which results from extracellular sources, because it does not occur if extracellular Ca^{2+} is removed.[402]

The Role of Perforin

Perforin was the name given to a protein within the granules that perforates the cell membrane and opens pores, which originally were believed to be the cause of lysis and cell death. The C-terminal domain of perforin is the Ca^{2+}-binding site that initiates the insertion of the molecule into cell membrane.[378] The insertion is mediated by exposure of several aspartate residues after cleavage of the C-terminus to yield a 60-kD active form. These residues are presumed to become approximated in three dimensions and bind Ca^{2+}, and the molecule becomes highly reactive for lipids from exposure of amphipathic domains. Some data suggest that perforin actually is inserted into the lipid bilayer with the help of a receptor. NK-cells release a lysolipid, the platelet-activating factor, which binds to its receptor and forms a bridge between the platelet-activating factor receptor and perforin.[403]

At 37°C, perforin inserts into the membrane, and approximately 20 perforin monomers form a tubular structure (16 nm wide) with a torus in the upper ring,[404] similar to that formed by the C9 component of complement (Fig. 13.14). Purified perforin causes cell lysis but not the DNA fragmentation and condensation associated with apoptosis, which is a hallmark of target cell lysis by CTLs.[405] Furthermore, nuclear changes occur before cell membrane damage.[406] Targeting cell death requires the combined action of perforin and granule-associated granzymes. However, mice deficient in perforin suffer more serious consequences of lack of or diminished cytolytic functions[407] as compared to mice deficient in granzymes A and B.[408] It has been assumed that granzymes enter passively through perforin pores (Fig. 13.15). Large pores that allow passive diffusion of the granzymes are formed only with large concentrations of perforin. The pore size formed by small concentrations of perforin does not permit diffusion of

proteins larger than 8 kD. However, even under these conditions, granzymes (32 to 65 kD) have access to the cytosol, although evidently not by direct diffusion through perforin pores. A lysin from *Listeria monocytogenes* also permits granzyme access to cytosol even in the absence of any measurable plasma membrane damage.[409]

The entrance of granzyme B into the cell at low perforin concentrations is suggested to occur, probably as a result of endocytosis ("facilitated access" hypothesis). Perforin endocytosed together with granzyme disrupts the endocytic pathway and releases granzyme for delivery to the nucleus. Support for this interpretation comes from the observation that brefeldin, which interferes with redistribution of proteins out of the endosomal system, inhibited perforin-induced release of granzyme B, blocked its translocation to the nucleus, and inhibited cell death.[409] Granzyme B is therefore able to enter into the interior of the cell autonomously in the absence of perforin. However, apoptotic death does not occur unless perforin is added.[410] Granzyme binds to MPR, when it is trafficking within the cell at the time of synthesis but also on the surface of the target cell.[411] However, MPR is not critical for transportation of granzyme B within the target cell because cells lacking MPR are still subject to apoptosis by granzyme B, which enters the cell by constitutive fluid-phase micropinocytosis[412,413] or some other, probably specific, receptor.

Endocytosis follows the binding to the receptor, and the granzyme B is detected first within Rab5-positive endocytic vesicles and subsequently in Rab5-negative, novel endocytic compartments that are not identifiable by any of the known endocytic markers.[414] The granzyme B is released to the cytoplasm by a second signal provided by perforin or replication deficient adenovirus (Ad2). From the cytoplasm, the granzyme B reaches the nucleus, initiating the apoptotic pathway. The localization in the nucleus occurs before the nuclear events of apoptosis, suggesting that nuclear translocation of the granzyme B transmits an apoptotic signal that is communicated to the nucleus.[415]

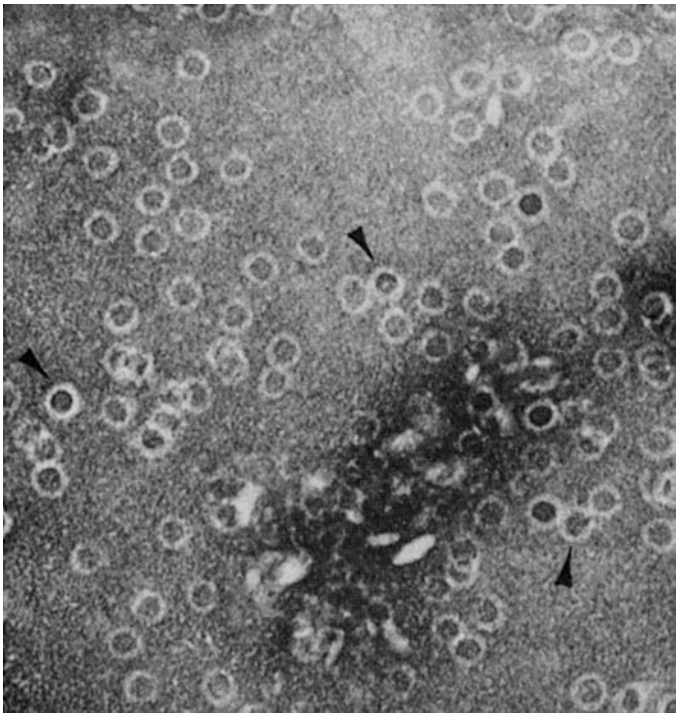

FIGURE 13.14. Lesions (*arrows*) inflicted on its target by cytotoxic T lymphocytes. Cytotoxic T lymphocytes form punched-out lesions on the membrane of the target similar to those formed by complement. (From Dennert G, Podack ER. Cytolysis by H-2-specific T killer cells. Assembly of tubular complexes on target membranes. J Exp Med 1983;157:1483–1495, with permission.)

The Role of Granzymes

Independent of the role played by each of the constituents of the granules, it is absolutely clear that *exocytosis* is crucial for target cell death. In T-cells, the granules are synthesized when the cells receive activation signals, whereas in NK-cells, the granules are preformed. At least four granzymes are present ubiquitously in human cytotoxic cells (i.e., A, G, H, and K). After their synthesis, the granzymes undergo post-translational modifications and as a result assume an active conformation. First, the signal peptide is removed and subsequently, a short propeptide which for granzymes A and B is DPPI a cysteine aminopeptidase that can activate several serine proteases.[416] Subsequently they are glycosylated and then sorted by MPR in the Golgi apparatus on the way to the granules.[417] Granzyme B is a serine protease originally defined as an *aspase* because it cleaves aspartic acid in the P1 position and is the only granzyme with the preference for proteolytic cleavage of aspartate residues. In this respect, it has a specificity similar to caspases and has an extended substrate specificity with nine amino acids making contact with the substrate. The first substrate of biologic significance of granzyme B was found to be a member of the caspase family.[418] Cleavage of target cell caspases[419] results in the activation of the cellular apoptotic cascade (Fig. 13.16).

Granzyme B activates apoptosis by two distinct pathways: i.e., by directly cleaving its substrates, caspase 3 or caspase 8,[420] or by a caspase-independent pathway through mitochondria. Mitochondrial factors enhance extramitochondrial caspase activation and play a central role in the execution of apoptosis, involving disruption of electron transport, energy metabolism, production of reactive oxygen radicals, and the release of apoptotic proteins, such as cytochrome-c.[421,422]

BCL2 can rescue cells from granzyme-B–mediated cell death, specifically blocking the pathways that operate directly through mitochondrial perturbations. BCL2 suppresses the mitochondrial pathway because it prevents loss of mitochondrial membrane depolarization and inhibits the release of cytochrome c and apoptosis-inducing factor into the cytosol.[423] The mitochondrial apoptotic pathway is triggered by direct cleavage of BID (BH-3 interacting domain)[424]; it results in translocation of BID to mitochondria, where it interacts with its receptors, BAX (BCL2 –associated X protein) and BAK (BCL2-antagonist killer) triggering cytochrome-c release. Cytochrome c then activates apoptosome, which in turn activates caspase 9 and ultimately caspase 3.[425] BCL2 apparently blocks granzyme-B–induced apoptosis by acting at an upstream point of the granzyme B pathway, i.e., blocking the translocation of the granzyme to the nucleus.[426]

Granzyme A

Granzyme A is a tryptase and induces caspase-independent cell death. It concentrates in the nucleus of the targeted cells and degrades histone H1 into small fragments.[427] Histone H1 plays

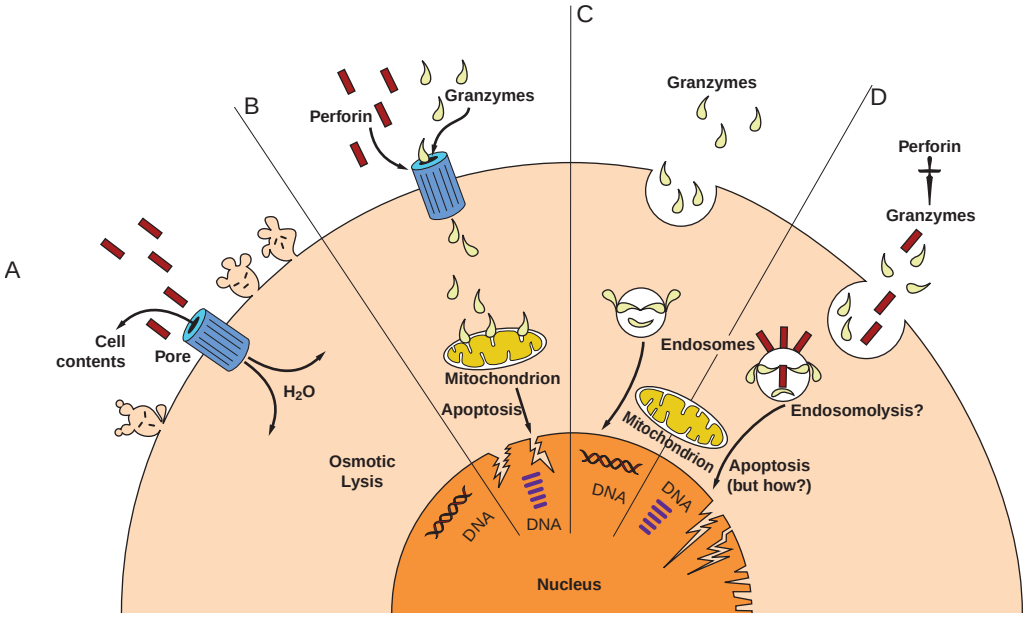

FIGURE 13.15. What is the role of perforin in cell lysis? The perforin lesion used to be considered the cause of cell death by osmotic lysis (as with complement) **(A).** When the granzymes were implicated in the cause of cell death by the apoptotic pathway, it was believed that the pores of perforin allow the entrance of the granzymes into the cell **(B).** Granzymes, however, can still enter the cell without perforin, but by themselves, they cannot cause cell death **(C).** Because granzymes enter the cell by endocytosis and are within endocytic vesicles, it is argued that perforin is needed to release them in the cytosol by punching holes in the vesicles (endosomolytic mechanism; **D).** At this point, it is known that cytotoxic T lymphocytes kill their targets, and for this function, they need at least two of the contents of the granules: the granzymes and the perforin. The exact mechanism, however, is still strongly debated.

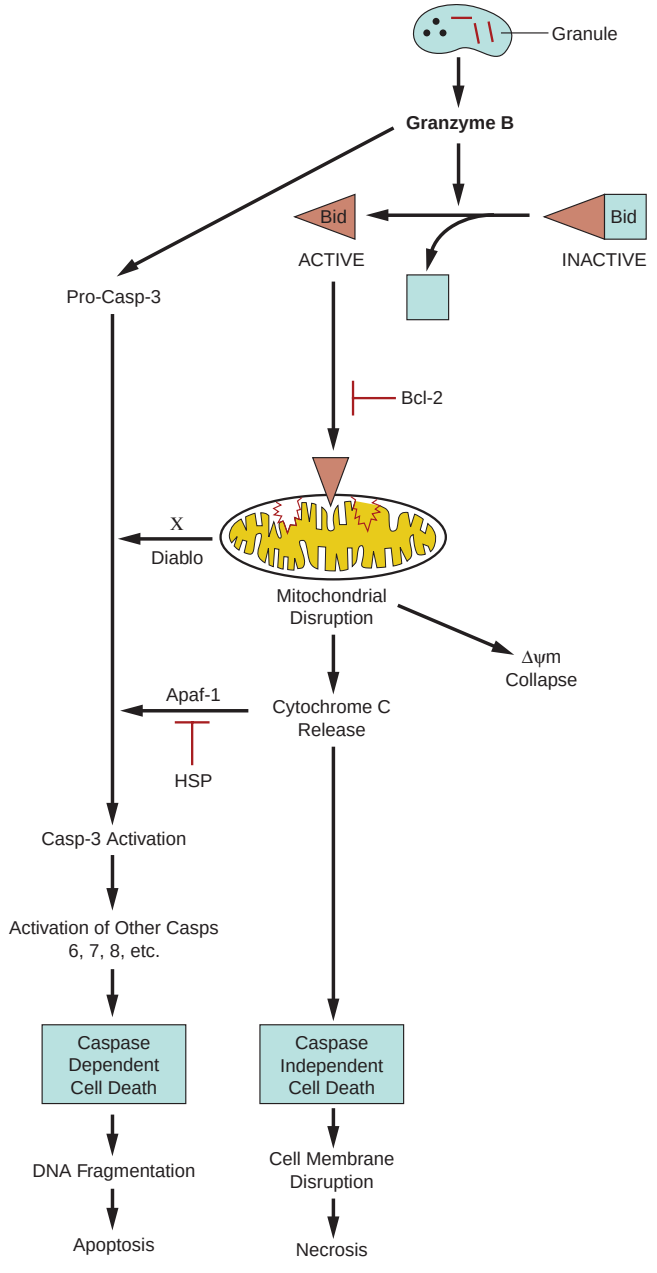

FIGURE 13.16. Cytotoxic T-lymphocyte killing of target cells. The cytotoxic T-lymphocyte killing of its targets is mediated by both the granzyme(s) (Gr), especially GrB, and the perforin, and because both of them share the same intracellular residence (i.e., the granule), the killing mechanism is known as the *granule exocytosis mechanism*. GrB activates caspase (Casp)-3, either directly or, most likely, in vivo by cleavage of the proapoptotic member of the Bcl2 family, Bid. The active Bid acts on the mitochondrion and causes opening of the permeability transition (PT) pore of the inner mitochondrial membrane that causes (or is the result of) the collapse of the $\Delta\Psi$m (mitochondrial transmembrane potential). $\Delta\Psi$m normally results from the asymmetric distribution of protons and other ions on both sides of the inner mitochondrial membrane. It is essential for normal mitochondrial function. $\Delta\Psi$m disruption occurs before cells exhibit nuclear DNA fragmentation or aberrant exposure of phosphatidyl serine on the outer cell membrane; therefore, it constitutes probably the earliest common event of the apoptotic cascade. Mitochondrial disruption activates a factor not yet well identified (X) and contributes to amplification of activation of Casp-3 and other Casps subsequently (Casp-6, -7, -8, -9, -10). The factor X may be Diablo (direct inhibitor of apoptosis protein–binding protein), which facilitates processing of Casps through inhibition of inhibitor of apoptosis proteins. The Bid pathway of Casp-3 activation provides a greater lethal threshold of amplification of activation of Casps than the direct GrB activation. In addition to the Casp-dependent pathway (apoptosis), disruption of mitochondria by GrB-activated Bid leads to cell death by necrosis. HSP, heat-shock protein. (From Kroemer G, Zamzami N, Snesin SA, et al. Mitochondrial control of apoptosis. Immunol Today 1997;18: 44–51; Heibein JA, Barry M, Molyca B, et al. Granzyme B-induced loss of mitochondrial inner membrane potential [Delta Psi m] and cytochrome c release are caspase independent. J Immunol 1999;163:4683–4693; Sutton VR, Davis JE, Cancilla M, et al. Initiation of apoptosis by granzyme B requires direct cleavage of bid, but not direct granzyme B-mediated caspase activation. J Exp Med 2000;192:1403–1413; and Barry M, Bleackley RC. Cytotoxic T lymphocytes: all roads lead to death. Nat Rev Immunol 2002;2:401–409.)

a critical role in chromatin hypercondensation, which protects genomic DNA from endonuclease digestion. Histone digestion provides a mechanism for unfolding compacted chromatin and facilitating endogenous DNAase access to DNA during T-cell granule-mediated apoptosis. Another target for granzyme A is protein HMG2 (high-mobility group protein 2). HMG2 is a nonhistone protein that binds to the internucleosomal linker region of DNA and to core histones and is involved in critical steps in DNA replication and transcription. It binds preferentially to distorted DNA and unwinds damaged DNA for its repair. It facilitates the assembly of higher-order nucleoprotein structures by bending and looping DNA or by stabilizing underwound DNA. However, the HMG2 is cleaved by granzyme A and thus opens up chromatin and blocks the de novo transcription required for cellular repair responses. Opening up chromatin probably contributes to the observed synergy of granzyme A with granzyme B in the induction of oligonucleosomal DNA fragmentation during CTL lysis.[428] Both granzyme A and B directly cleave lamin B,[429] a member of the lamin family of proteins that maintain the integrity of the nuclear envelope.

Granzyme A bound to proteoglycans, has been detected in the blood of patients with viral diseases and rheumatoid arthritis.[430] In complexes with proteoglycans, it is protected against inactivation by protease inhibitors such as α_2-macroglobulin and others. However, its role in the blood in these conditions remains unknown. The entry of granzyme A into the nucleus requires the signal from perforin and once inside the nucleus, it binds to insoluble factors because it does not leak out even after the nuclear membrane is permeabilized.[431]

Death Receptor Pathway

Cytotoxic lymphocytes use two pathways for killing their targets: the exocytosis pathway (perforin–granzyme) and a death receptor pathway. Although there are multiple receptors on the cell surface that can initiate an apoptotic cascade, they converge at one point downstream to a common final pathway. The point of confluence is the adaptor molecule FADD (fas-associated death domain). These alternate apoptotic pathways may be considered as the FADD pathway.[432] The pathways that converge to FADD are initiated by FAS (CD95), physiologically the most important receptor in the family of TNF receptors. FADD binds and recruits caspase-8, which stands at the apex of the cascade of all caspases[433] and forms the DISC (death-inducing signaling complex).[434] Caspase-8 may target the mitochondria through BID or caspase 3, depending on the cell type.[435,436]

In the FADD pathway, the FASL is not stored even in activated cells, and as a result, it requires the induction of a new ligand after TCR stimulation, which requires 1 to 2 hours after stimulation. The half-life of the ligand is long (2 to 3 hours), and the CTL can kill innocent bystanders (as long as they express the appropriate receptor, FAS) without the need for TCR signaling.[437] In this respect, the FADD pathway is much more promiscuous than the perforin pathway. The death receptor pathway is important for $CD4^+$ Th1 cells.[438]

Membrane Morphology of Target Cell Lysis

In the early stages of cell death induced by CTL, plasma membrane components are translocated to intracellular membrane structures, including nuclear envelope and mitochondria. Membrane-bound perforin and the granzymes are internalized at the same time, and it is postulated that, subsequently, perforin releases the granzymes to the cytosol by an endosomolytic action for activation of the caspase pathway (Figs. 13.15 and 13.16). In the early stage, the target does not undergo extensive permeabilization during perforin-dependent CTL lysis.

The first detectable change in the target-cell–surface morphology consists of the formation of small dilatations of the surface

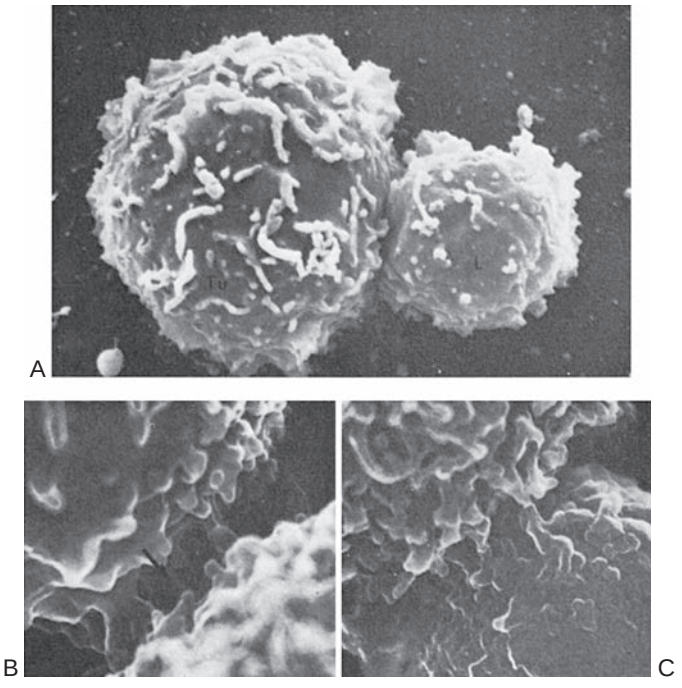

FIGURE 13.17. Cytotoxic T-lymphocyte–target cell interaction. A–C: Scanning electron microscopy of the formation of the killer cell synapses. Intimate contact is established between the microvilli of the two cells. Compare with the electron microscopic view in Figure 13.13. (B and C from Kalina M, Berke G. Contact regions of cytotoxic T lymphocyte-target cell conjugates. Cell Immunol 1976;25:41–51; and A from Grimm E, Price Z, Bonavida B. Studies on the induction and expression of T cell-mediated immunity. VIII. Effector-target junctions and target cell membrane disruption during cytolysis. Cell Immunol 1979;46:77–99, with permission.)

microvilli, forming small vesicles that eventually expand into large blebs even before ^{51}Cr release can be detected. Some of the detached vesicles attach to neighboring CTLs, suggesting that they carry some target-specific antigens on their surface (Fig. 13.17).

THE FUNCTION OF CYTOTOXIC T LYMPHOCYTES

Deficiencies of Granule Contents

Virus-specific cytotoxic CD8$^+$ T-cells (CTL) are induced during viral infections (Fig. 13.12) and lyse infected cells during the eclipse phase, i.e., before infectious virus is generated. They kill virus-infected cells before new viral antigens can be detected on the surface of infected cells with antibodies.[439] Fas deficiency has no effect on the role of viral clearance, but elimination of both Fas and perforin leads to uncontrolled infection.[440] Normal mice easily survive a high inoculum (10^6 PFU) of the ectromelia virus, a murine-specific poxvirus. However, perforin-deficient mice succumb with a dose as small as 10 PFU.

Perforin deficiency in mice is associated with increased susceptibility to a variety of infections by viruses, protozoa, (plasmodium, *Trypanosoma cruzi)* and bacteria (i.e., mycobacteria, salmonella, chlamydia, listeria, etc.).[441] Defense involves not only cytolytic mechanisms but also cytokines (i.e., IFN-γ, TNF, etc.), as well as microbicidal molecules. In the experimental model of lymphocytic choriomeningitis virus infection in mice, a nonlytic viral infection, perforin-dependent cytotoxicity is crucial in the control of the acute stage.[442] During the chronic stage of this infection, perforin down-regulates CD8$^+$ T-cell expansion and prevents immunopathology.[443] In perforin-deficient mice, however, the lack of this immunoregulatory control results in expansion of CD8$^+$-activated T-cells, with approximately 50% of the animals dying within 2 to 4 weeks as a result of the immunopathologic damage from uncontrollable CD8$^+$ proliferation and activation. Infusion of normal CD8$^+$ T-cells fully reverses pathology and the associated mortality. This example clearly differentiates between defense and immunopathology, which normally is averted from an "exocytosis"-mediated mechanism of regulation of CD8$^+$ cytolytic cells.

In another model involving the *lpr/lpr* mice, which are deficient in the Fas receptor, deficiency of perforin markedly accelerates the spontaneous lymphoproliferative disease, which normally occurs at a slower pace in these mice. This evidence also supports the notion that perforin plays a role in immune regulation, prevention of immunopathology, and autoimmunity. Recently a homozygous loss of function defect in the human perforin gene has been detected that is associated with several clinical manifestations, mainly due to uncontrolled T-cell and macrophage activation with overproduction of inflammatory cytokines. The syndrome is known as familial hemophagocytic lymphohistiocytosis (FHL).[444] The disease is mapped in chromosome 10q21-22 (i.e., the location of the perforin gene). Overall, the incidence of the mutation is approximately 20% in all FHL patients. For the development of FHL syndrome, a viral infection or a defect of an additional pathway that controls lymphocyte homeostasis is required. Perforin-deficient mice, for reasons unknown at the present time, do not develop symptomatology similar to human FHL. Mice deficient in granzyme B lose the ability to induce DNA fragmentation, even though perforin causes membrane damage. Deficiency of both granzymes A and B causes susceptibility to ectromelia infection,[445] although cytotoxic lymphocytes with the same deficiency and inability to cause DNA fragmentation are still able to exert a potent antitumor effect.[446]

DPPI, also known as cathepsin (CTSC), is a lysosomal cysteine protease expressed in most tissues, and in CTLs, it is found in the secretory compartment. It belongs to the papain superfamily of proteases and shares similarities to lysosomal cysteine proteases cathepsins B, H, and L. Granzymes A and B become enzymatically active only after cleavage of the N-terminal dipeptide by DPPI and are stored in the lysosomal granules in the active form along with perforin. DPPI knockout mice resemble the perforin-deficient mice: Both fail to cause apoptosis. DPPI deficiency results in failure to activate the granzymes, whereas perforin deficiency fails to deliver the granzymes into target cells.[447,448] Deficiency of DPPI has been detected in humans with Papillon-Lefèvre syndrome, which is characterized by keratosis palmoplantaris with periodontopathia.[449] There is premature tooth loss due to periodontal disease and thickening of the skin.

Graft versus Host and Graft versus Leukemia Reactions

Lymphocyte cytotoxicity has been implicated in graft versus host disease after allogeneic bone marrow transplantation, with contribution to the pathogenesis by both the perforin and Fas pathways.[450–452] It is agreed that cytotoxic lymphocytes contribute to the development of the disease, but there is no agreement about the underlying mechanism. The graft versus leukemia effect, however, seems to be mediated predominantly by the perforin pathway.

Granzyme Inhibitors

An important characteristic of the function of cytotoxic cells is that they successfully avoid the damaging effect of the lethal weapons they deliver to kill their targets. As a matter of fact, the CTLs, after a successful hit, disengage and are directed against another target.

Some recent observations provided a molecular explanation for their protection from "suicide." The effector cells contain a potent inhibitor of granzyme B, known as proteinase inhibitor 9.[453,454] The inhibitor is a serpin, is found in both the cytoplasm and the nucleus, and forms tight complexes with granzyme B but does not inhibit most of the caspases. Serpins are a large family of intracellular and extracellular protease inhibitors. Many viruses encode serpins that block caspases, the enzymes of apoptosis. Inhibitors of granzyme B can be encoded by several viruses. Best described is the poxvirus-encoded cytokine response modifier A (Crm A). Overexpression of Crm A in target cells inhibits CTL-mediated killing, but predominantly through a Fas-mediated pathway. Crm A inhibits granzyme B and several caspases. With several of the steps of CTL cytotoxicity now understood, therapeutic interventions are possible for several of the steps of lymphocyte cytotoxicity in a number of human conditions.

Apoptosis

Despite the wealth of information on the mechanism of this important pathway, there are several areas that are not well understood. Perforin has an indispensable role in the delivery of granzyme B, but certainly not simply as a pore-forming molecule. Granzymes, on the other hand, induce the nuclear changes affecting the DNA (i.e., by apoptosis), but even if they enter the cell in the absence of perforin, they cannot be translocated to the nucleus without perforin.[455] The mechanism of granzyme delivery by perforin is not clear. It has been postulated that intracellular delivery of granzymes is through an endosomolytic mechanism.[456] Translocation of a fluorescent probe from the target cell membrane to interior membranes, including the nuclear envelope and mitochondria, is supportive of this prediction.[457]

The relationship of the roles of perforin and granzymes in cytotoxicity was examined in the *gld/gld* (*Fasl/Fasl*) mice, which have a FasL deficiency and therefore cannot have Fas-mediated cytotoxicity. The additional deficiency of granzyme B in *gld/gld* mice (i.e., mice with the phenotype GrB *gld/gld)* leads to CTLs with residual cytotoxicity, which can only be perforin-dependent. This can be concluded also from the fact that perforin$^{-/-}$ *gld/gld* CTLs have no residual cytotoxicity.[458] It is reasonable to conclude that the cytotoxicity, which is independent of granzyme B, is normally partially accounted for by a Fas pathway and partially by a second perforin-dependent mechanism. Finally, inhibitors of caspases block the Fas death pathway, but in CTL granule exocytosis, the target cell lysis is not detectably blocked, although the accompanying apoptotic nuclear damage is efficiently blocked. Thus, caspase inhibitors prevent the hallmark phenotype of apoptosis without affecting cell death, as evidenced by lysis.[459] At this point, not all the roads used by the CTL that may lead to cell death have been fully explored.

Regulatory T-cells

T reg cells constitute about 5% to 10% of the peripheral CD4$^+$ T-cells and express the characteristic phenotype CD4$^+$/CD25$^+$ (the α-chain of the IL2 receptor). They are also CTLA4$^+$ (costimulatory molecule cytotoxic T-lymphocyte antigen-4) and GITR$^+$ (glucocorticoidinduced TNF receptor family-related protein).[158] Differentiation of CD4$^+$ T reg cells is mediated by interactions of CD4$^+$ thymocytes with stromal cells. Some thymocytes acquire MHC II molecules,[460] which are derived from APCs.[461] T reg cells are enriched in autoreactive cells,[462] but are resistant to deletion by NS, as compared to conventional CD4$^+$ thymocytes.[463] The TCRs of T reg cells are of relatively high affinity for autoantigens, and this may facilitate their reactivation in the periphery by self-antigens. However, their affinity is still below the level required to trigger NS. These fundamental differences between the TCRs of T reg cells and the other thymocytes, in terms of specificity (MHC II vs. peripheral tissue antigens), affinity, and the nature of the selecting cell, provides an additional mechanism of protection against autoimmunity (i.e., active peripheral suppression in addition to central tolerance). Selection of T reg cells is mediated by the bone-marrow–derived APCs and not the epithelial cells.[464] It has been suggested that the TCR affinities of T reg cells are just below the deletion level, permitting them to follow a unique differentiative pathway with regulatory function.[465] The development and function of natural T reg cells depends on the transcription factor FOXP3, which encodes a new member of the forkhead/winged helix family of transcription factors.[466] Mutations of the human gene *FOXP3* is the cause of the IPEX syndrome (immune dysregulation polyendocrinopathy enteropathy and X-linked syndrome),[467] an X-linked immunodeficiency syndrome associated with autoimmunity involving multiple endocrine organs, inflammatory bowel disease, and atopic dermatitis. TGF-β maintains a central role in the generation and function of T reg cells.[468] CD4$^+$/CD25$^+$ T reg cells may arise from CD4$^+$/CD25$^-$ T-cells following stimulation of TCR and costimulation with TGF-β.[469] Once they exit the thymus, the T reg cells depend for their survival, preservation, and function on dendritic cells, which present them with autoantigens.[470] The continuous exposure to self-antigens will maintain the T reg cells in a state of activation.

A portion of T reg cells arising in the thymus are "anergic," i.e., in a state of partial or total unresponsiveness.[471] Anergy may follow TCR stimulation without subsequent costimulation. Anergic T-cells are unable to produce IL2 and induce a proliferative response. Naturally arising anergic T-cells upon stimulation suppress effector T-cells but are prone to apoptosis, probably as a result of a continuous antigenic stimulation from self-antigens. Anergic T-cells exert their suppressor function by targeting APCs. The APC brings the anergic-suppressive cell into proximity with the target T-cell, forming a tricellular complex and setting the stage for a T–T-cell interaction.[472] T–T-cell interaction is the foundation for induction and spreading of the anergic state, otherwise known as infectious tolerance.

$\gamma\delta$ T-CELLS

Commitment to $\gamma\delta$ T-cell lineage takes place in the thymus as discussed earlier in this chapter. (See "T-Cell-$\alpha\beta$ versus T-Cell-$\gamma\delta$"and "The Pre-T–cell Receptor.")

Rearrangements of the human γ and δ genes appear to occur in a developmentally ordered fashion.[473] Initially the $\gamma\delta$ TCR repertoire is small inasmuch as it involves rearrangements of a small number of V segments and as a result the junctional diversity is limited.

In human embryos between 8.5 and15.0 weeks of gestation, the most common V fragments are Vδ2 joined to Dδ3 and Vγ1–8 or Vγ9 with Jγ1. These cells are referred to as the Vδ2 cells. Rearrangements after birth at approximately 4 to 6 months of age involve the joining of other $\gamma\delta$ segments such as Vδ1 to Dδ1 and Dδ2 and the Vγ1 family with the Jγ2 cluster. Postnatally in the thymus, the Vδ2 subset represents 15% and the Vδ1 85% of the $\gamma\delta$ cells, and these proportions remain relatively constant throughout adult life.

It has, however, been questioned whether two distinct subsets of $\gamma\delta$ T-cell subsets exist, or one V9V2 T-cell population exerts multiple effector functions.[474] Although intrinsic or genetic factors generate $\gamma\delta$ T-cell subsets, extrinsic or environmental factors act further to shape and select specific clones. An enormous selective pressure is exerted on the development of $\gamma\delta$ T-cells throughout life to produce populations of cells that express antigen receptors that are encoded by specific gene segments. The predominance in adult human blood of the Vδ2 to Vγ9 population is explained by such antigen-mediated expansion. These expansions create oligoclonal populations due to selection pressures from environmental microbes and certain edible plants. In contrast to the Vγ2/Vδ2

(Vγ2 is the same as Vγ9) T-cells which are a major circulating population, the Vδ1 cells account for the vast majority of the γδ T-cells in tissues such as intestine and spleen.[475]

γδ T-cell Receptor: Structure and Antigen Recognition

Antigen recognition by the γδ TCR resembles recognition by antibodies.[476] The V and C domains are organized into "Ig folds" (i.e., approximately seven β strands packed face to face in two antiparallel β sheets, constrained by intradomain disulfide bonding). The V regions are subdivided into framework and hypervariable regions, which have three CDRs. The orientations of Vγ and Vδ are similar to the relative orientations between the V domains in the Fab Ig fragment or the αβ TCR. However, the CDR3 of Vδ is diverse in length and composition (8 to 21 amino acids), a range similar only to the IGH@ (3 to 25). Furthermore the CDR3 loops of the γδ TCR protrude above the rest of the molecule creating clefts between them; these strikingly distinguish them from the equivalent loops of the αβ TCR, which are flat and bind to pMHC, and from the antibodies that bind large proteins.[477]

The γδ TCR exists as a complex with the CD3 polypeptide chains and recognizes antigens with a wide distribution, by a mechanism fundamentally different from that of αβ TCRs; i.e., antigen is not processed and there is no MHC restriction.[476–479] Examples of nonprotein substances are pyrophosphates and alkyl-amines found in bacteria, plant, or animal cells,[480–482] and bacterial and mammalian homologs of heat-shock protein 60 kD (HSP-60).[483] Human peripheral blood Vγ2Vδ2 cells are present in large numbers in lepromatous lesions reactive with monoalkyl compounds of mycobacterial cell walls. The most potent compound is monoethylphosphate, which stimulates cytotoxic activity of these cells and the phosphate group is very important in their recognition by the γδ TCR. Alkyl-amines, derived from plant food products or from bacteria also stimulate $V\gamma9V\delta2^+$ T-cells[482] and the aminobiphosphonates that inhibit osteoclastic bone resorption, particularly in cancer patients, can also stimulate Vγ9Vδ2 cells.[484] The $V\gamma9^+$ T-cells respond to superantigens, such as staphylococcal enterotoxin A.[485] Some mucosal γδ T-cells interact with MHC-encoded proteins, MICA and MICB,[486] through the NKG2D C-type lectin receptor.[487] MICA and MICB class I molecules identify stressed cells and have a very restricted pattern of expression, primarily limited to intestine. MICA and MICB do not present peptides because the peptide-binding groove is of limited size.[488] These molecules may function in innate immunity as important targets for $V\delta1^+$ cells for elimination of stressed cells.[475] Some $V\delta1^+$ cells recognize the nonpolymorphic CD1C member of the CD1 family of molecules, expressed on APCs, that presents lipid and glycolipid foreign antigens to T-cells.[489] These γδ cells activated in response to CD1C produce IFN-γ and direct αβ T-cells to Th1 differentiation. Furthermore they are cytotoxic, express granulysin, and they could lyse infected dendritic cells via the perforin pathway and kill released bacteria by granulysin. Therefore their role is significant in host defense before antigen-specific T-cells have differentiated.[490]

Direct recognition of CD1C may represent a bridge between innate and adaptive immunity in a similar fashion to recognition of CD1D by murine and human NK^+ αβ T-cells,[491] which polarize T-cells to a Th2 phenotype. The CD1C-restricted γδ T-cells promote the maturation of myeloid-derived dendritic cells, which are able to present antigens to $CD4^+$ T-cells. This function of γδ T-cells is important because they stimulate rapid accumulation of mature dendritic cells,[492] early during microbial invasion; at the same time they secrete IL12 to drive T-cell polarization to the Th1 type.

γδ T-cell Function

The recognition of antigens by the γδ TCR is more akin to that of antibodies and does not need antigen processing and presentation. The Vδ1 and Vδ2 cells are believed to represent separate lineages with different developmental pathways and tissue distribution.[493] Most of the γδ T-cells with intraepithelial localization are Vδ1, whereas the Vδ2, about 5% of all T-cells, are detected in the peripheral blood. The Vγ9/Vδ2 T-cells release proinflammatory chemokines[494] and provide protection against mycobacteria by directly killing infected macrophages[495] as well as extracellular bacteria by granulysin and perforin.[496]

Persistent chronic disease correlates with a decline or disappearance of mycobacteria-reactive γδ T-cells.[497] This contributes to the prevention of chronic inflammatory disease by directly killing activated macrophages.[498] This function of γδ T-cells may be facilitated by the expression of CCR5, the receptor for the chemokine RANTES (MIP-Iα) produced by macrophages.[499] The evidence of a role of γδ cells against cancer is still circumstantial.[500] Their mucosal localization plays an immunoregulatory role in IL10-mediated low-dose oral tolerance induction, but not in the induction of systemic tolerance.[501] In nonobese diabetic mice with spontaneous insulitis and diabetes, administration of insulin intranasally induces IL10 secreting suppressor γδ T-cells.[502]

In patients with rheumatoid arthritis[503] or in collagen-induced arthritis, γδ T-cells accumulate in the synovium, their role depending on the stage of the disease.[504] The γδ T-cells in defense, immune regulation, and surveillance, are critical in their role as a "sentinel" between innate and adaptive immunity.[505]

A population of TCR-γδ cells resides within the intestinal epithelium and these intraepithelial lymphocytes may have an extrathymic origin (bone marrow),[506] express a CD8αα homodimer[507] and are important in maintaining self-tolerance.[508] These TCR-γδ lymphocytes are "educated" by thymic stroma and are dendritic in morphology.[509]

NATURAL KILLER CELLS: MORPHOLOGY, CYTOCHEMISTRY, AND SURFACE MARKERS

NK cells originally described on a functional basis according to their capability of killing certain tumor cells in the absence of prior stimulation are of hematopoietic origin. They are a discrete population of cytolytic lymphocytes implicated in several activities in vivo, such as activity against tumor cells, resistance to viral infections, and regulation of hematopoiesis.[510,511] NK-cells are a heterogeneous population with respect to phenotype and target specificity. Although the majority of the $CD\text{-}56^+$ NK-cells are $CD\text{-}3^+$, small numbers of $CD\text{-}45^+$ cells have been detected and large granular lymphocyte (LGL) leukemias with the same phenotype have been reported.[512] LGLs are large cells with pale blue cytoplasm and a high cytoplasmic-to-nuclear ratio with azurophilic granules. These cells constitute 2% to 6% of the peripheral white cells and approximately 10% to 15% of the peripheral blood lymphocytes. They are larger than the typical lymphocytes (10 to 12 μm) with a larger amount of cytoplasm that contains peroxidase-negative granules (Fig. 13.18). The α-naphthyl acetate esterase distribution is diffuse, similar to that found in monocytes, and is different from the dotlike pattern of T lymphocytes. LGLs do not adhere to surfaces and have no phagocytic activity. Ultrastructurally, they are heterogeneous in terms of size and the density of the granule matrix.[513] The granules are located next to the Golgi apparatus, which also contains several smooth membranes and coated vesicles. The granules have an electron-dense center surrounded by a layer of lesser opacity. Like the granules of CTL, the NK-cell granules contain perforin and granzymes, both important for their cytotoxic function[514] and may be present in various forms, such as smooth or coated, depending on the stage of cell activation. LGLs are phenotypically and functionally heterogeneous (i.e., $CD56^+/CD3^-/CD8^-$) and 80% to 90% of them

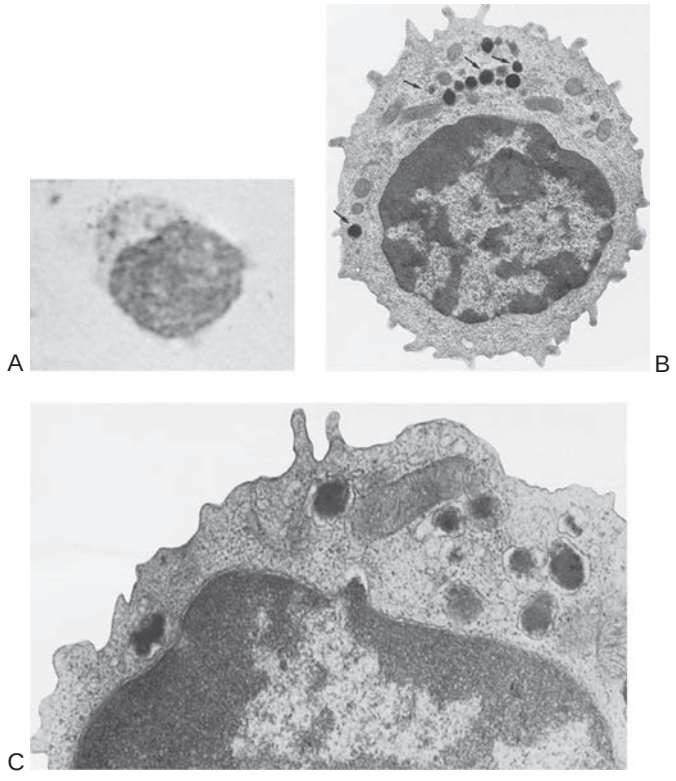

FIGURE 13.18. Natural killer cell morphology and ultrastructure. A: Natural killer cell is characterized by large amounts of pale blue cytoplasm and the presence of azurophilic granules. **B:** By electron microscopy, the granules in the cytoplasm appear heterogeneous in terms of size and density (*arrows*). A few scattered mitochondria are present. **C:** The granule consists of an electron-dense center that contains the perforin and may be enclosed by a thin membrane. Surrounding the core is a layer of lesser opacity containing the granzymes. The granules of the cytotoxic cells are probably derived from two separate organelles—those of secretory granules and those of lysosomes—and are sometimes called *granulosomes.* (From Zucker-Franklin D, Greaves MF, Grossi CE. Atlas of blood cells, 2nded. Philadelphia: Lea & Febiger, 1988, with permission.)

are CD16$^+$ and others CD57$^+$/CD3$^+$/CD8$^+$/TCR-$\alpha\beta^+$. Both populations are cytolytic, but the CD57$^+$ cells are T (or NK-like) cells that are non-MHC restricted. The CD56$^+$ population is sometimes known as *NK*-LGL, whereas the CD57$^+$ population is known as T-LGL and both are CD2$^+$ and CD7$^+$. The separation of the two cell types is not absolute, and we often detect an intermediate cell population that is CD56$^+$/CD57$^+$. The relationship of these cells to those expressing only one of the two markers is not known. Clonal diseases have been described from both the NK-LGL and T-LGL lineages with distinct clinical syndromes.

Ontogeny of Natural Killer Cells

Phenotypic Studies

The presence on NK-cells of some markers (CD2, CD7) characteristic of T-cells raised the question of common ontogenetic origins between these two lymphocytes. However, interference with T-cell development, as in athymic or severe combined immunodeficiency (SCID) mice[515] or in mice with targeted disruptions of RAG, has no impact on NK-cell development. It is conceivable that the two lineages derive from a common progenitor with separation of their developmental pathways.

Some evidence for a common T/NK precursor has been obtained[516,517] and relates to expression of cytoplasmic CD3γ, δ, and ε. Cytoplasmic expression of CD3γ, δ, and ε proteins has been detected in fetal NK-cells,[518] and overexpression of CD3ε blocks T/NK-cell development without affecting other hematopoietic lineages.[519] Based on the expression of CD56 progenitors of NK-cells have been identified in the thymus within the triple-negative (TN) thymocyte population[74] and a common T/NK-cell precursor was detected among the CD-34$^+$ TN population.[520] The common progenitor has a CD45/CD5 phenotype and becomes an NK-committed cell with loss of the capacity for T-cell differentiation with the expression of CD56. The common precursor is present among TN thymocytes that are CD34$^+$ and become CD34$^-$ as the cell is committed to NK lineage. NK-cell differentiation requires a combination of stem cell factor, IL7, and IL2 in the presence of a stromal feeder layer. Precursors of NK-cells, that can differentiate into DP (CD4$^+$/CD8$^+$) thymocytes, have also been identified in fetal thymuses of mice[521] if they remain in contact with the thymic stroma, or into NK-cells if they are removed from the thymic microenvironment. This again supports the notion that the thymus is not essential for NK-cell development. The common T- and NK-cell progenitor in fetal mouse thymus is CD117$^+$/CD44$^+$/CD25$^-$/NK1.1$^+$ and shows commitment to NK lineage with loss of CD117 expression.[522] The overall scheme of differentiation in fetal mouse thymus suggests that multipotent precursors entering the thymus first lose B-lymphoid potential as they up-regulate NK1.1 and commit to a T/NK lineage. Then CD25 is up-regulated, CD117 is down-regulated, and cells commit to T- and NK-cell lineages, respectively.

Bone marrow is also an important location of NK-cell progenitors which are CD34$^+$/CD7$^+$ and differentiate to mature NK-cells either in the presence[523] or absence of stromal cells.[524–526] The progenitors express CD34 and CD7 and cytokines such as stem cell factor, IL2, and IL7 are essential, for their differentiation.

Cytolytic activity against NK-cell targets is detected at the time of CD56 expression. Mature NK-cells can be stimulated by IL2 for further enhancement of cytotoxic activity, increase of cytotoxic granule content, expression of adhesion molecules, and acquisition of properties attributed to lymphokine-activated killer cells. Other cytokines, such as IL7 and IL12, have similar effects, albeit to a lesser degree than IL2. The common lymphocyte precursor in the bone marrow with the CD-34$^+$/CD-10$^+$/CD-45RA$^+$ phenotype is able to develop into NK-cells in vitro.[527] Uncommitted hematopoietic progenitors are CD-34$^+$/CD-38$^-$, but up-regulation of CD38 indicates enrichment of cells committed to a particular hematopoietic lineage. CD34$^+$/CD38^{2+} progenitors in fetal thymus develop into T-cells, but CD34$^+$/CD382$^+$ progenitors in fetal liver have no T-cell precursor activity. This population has no *TRD@* rearrangements and no pre-TCR–α chain expression and develops in vitro into NK-cells through an intermediate stage of CD3$^-$/NKRP-1$^+$/CD34$^-$/CD56$^-$.[528,529] A similar NKRD-1$^+$/CD56$^-$ population has been detected in cord blood and develops into mature CD56$^+$ NK-cells in the presence of IL12.[530]

Natural Killer Cell Functional Studies

The cytokine environment regulates NK-cell maturation for the two distinct human NK-cell populations, one producing IFN-γ and the second IL13. IL-4 regulates the size of the IL13 population primarily by inducing their proliferation, whereas IL12 has minimal effects on the proliferation of IFN-γ+ NK-cells. Cells with the CD161$^+$ (NKR-P1)/CD56$^-$ phenotype produce IL13 but not IFN-γ and have no perforin-mediated cytotoxicity.[531] CD161 is encoded by the NK-gene complex including CD69 and CD94. The CD161$^+$CD56$^-$ cells produce IL13 and differentiate to phenotypically mature IFN-γ– producing cells in the presence of IL12 and feeder cells. As cells mature they pass through an intermediate stage of IL13$^+$/IFN-γ+ NK-cells and eventually acquire the mature irreversible phenotype IFN-γ+/IL13$^-$ CD56$^+$.[532] The molecular defect of X-linked SCID conclusively demonstrated that cytokines are critical for T- and NK-cell development.[533,534] These X-SCID patients present with a severe block of T- and NK-cell development, whereas normal or even elevated numbers of B-cells are

present. The cause of the disease is the lack of the common γc-chain shared by several interleukin receptors (i.e., IL2, IL4, IL7, IL9, and IL15). The most important among these interleukins is IL7, which promotes development of human thymocytes (and, in the mouse, B lymphocytes also). Deficiency of Jak3, a tyrosine kinase associated with the γc-chain, also blocks NK-cell development.[535] Other data suggest a critical role for IL15.[536,537] Of the transcription factors, the Ikaros family is required for transcriptional regulation of NK-cell development.[538,539]

Natural Killer Cell Receptors

NK-cells are one of the important cellular components of innate immunity, with the mission to defend the body immediately against pathogens or in the early stages of tumor development. As a consequence, the recognition molecules or receptors of the NK-cells are displayed on the cell surface without the need of assembly, i.e., rearrangements from multiple DNA segments after the antigenic encounter.[540–545] Another important difference from other receptors such as BCRs or TCRs is that NK receptors do not directly recognize pathogens or their products but the quantitative change of MHC molecules induced as a result of the infection. In humans, three distinct families of genes have been defined that encode for receptors of HLA class I molecules. One family belongs to the Ig superfamily and is composed of KIRs. The second family is structurally Ig-like, named Ig-like transcripts (ILTs). ILTs are expressed mainly on B, T, and myeloid cells, but some members are also present on NK-cells. They are also called LIRs for leukocyte Ig-like receptors. The third family consists of C-type lectin receptors. C-type lectins are a superfamily with homologous modular carbohydrate recognition domains (CRDs) that bind carbohydrates in a Ca^{2+}-dependent manner.[546] The proteins of this family of NK receptors form group V outside of a total of seven groups. The C-type lectin receptors, however, have structural differences from the other (more than 200) members of the superfamily, and it has been proposed that it be renamed as a new family of C-type lectin-like NK-receptor domains.[547] The human lectin-like receptor gene complex is on chromosome 12p13.1 and the genes for the Ig-like receptors are in chromosome 19g13.4.

The Leukocyte Immunoglobulin-like Receptors

NK cells express Ig-like receptors, known as "KIRs", shown to be involved in regulation of adaptive cytotoxic T-cell responses.

The KIRs have two or three Ig-like domains and hence are designated KIR2D or KIR3D receptors, respectively[548] (Fig. 13.19 and Table 13.2). The cytoplasmic domains of the KIRs can be either long (L) or short (S), corresponding to their function, either inhibitory or activating, respectively. The inhibitory receptors contain one or two immunoreceptor tyrosine-based inhibitory motifs, or ITIMs (I/V/L/S)-X-Y-XX-(L/V) (where X denotes any amino acid).[549] When tyrosine (Y) is phosphorylated, it recruits and activates SHP-1 phosphatase, leading to inhibition of signaling. Activating receptors do not signal directly but must associate noncovalently (via a salt bridge linking the transmembrane regions) with other signaling adaptor molecules that have ITAMs in their cytoplasmic domain (consensus sequence, -Y-X-X-L-X_{6-8}-YXXL/I).[550] NK-cells express three ITAM-bearing transmembrane proteins: ζ, FcεRIγ, and DAP12. The first two are present as homodimers or heterodimers, whereas DAP12 is exclusively a disulfide homodimer. (The KIRs in the CD designation are known CD158a-m and CD158z. See Table 13.2 and Appendix A for details.)

A fundamental difference between recognition by KIRs and TCRs is that the KIRs recognize more than one MHC allele. They do this by recognizing conserved residues within the polymorphic regions of MHC, whereas TCR recognizes the polymorphic residues. In addition, KIRs display a precise specificity for a particular MHC allotype. This is achieved by variations in single amino acids of KIR molecules.[551]

The ligands for KIRs are alleles of all three MHC class I molecules, HLA-A, HLA-B, and HLA-C, which can confer protection from lysis by NK-cells. Generally, KIR3D receptors recognize HLA-A and -B, whereas KIR2D receptors recognize HLA-C alleles. A number of techniques have been used to study the binding and specificity of the receptors. No other molecule is necessary for binding except the HLA alleles.[552–554] Crystal structures of some KIR receptors with their ligands have been solved. The KIR2DL2 in complex with HLA-Cw3 and peptide shows that KIR binds in nearly orthogonal orientation across the α1 and α2 helices of HLA-Cw3. It contacts positions 7 and 8 of the peptide, but most contacts are between the KIR and conserved HLA-C residues.[555]

Allotypic specificity is determined by the interaction between Lys44 of KIR2DL2 and Asn80 of the HLA-Cw3. In general, the peptides play a minimal role in the interaction, a point that strikingly distinguishes TCR–MHC from the KIR–MHC interactions.[556] LIR-1 is a member of the LIR family (LIR-1 to LIR-8) expressed on monocytes, B-cells, dendritic cells, and some NK-cells. LIRs have two to four extracellular Ig-like domains and ITIMs in the cytoplasmic region; therefore, engagement with MHC molecules protects target cells from lysis. The first amino terminal domain of LIR-1 binds to the nonpolymorphic α3 domain of MHC I, an interaction that is more similar to that of CD4 with the MHC II than to that of KIRs. LIR-1 also recognizes the human cytomegalovirus protein UL-18, which has a structure similar to MHC I and associates even with β_2-microglobulin and host peptides. LIR-1 binds to this human cytomegalovirus protein with an affinity that is more than 1,000-fold higher than the host MHC I. This mechanism illustrates an example of viral subversion of host defenses and protection of infected cells from lysis[557] because the binding of LIR-1 to UL-18 sends an inhibitory signal.

C-type Lectin-like Receptors

The members of the C-type lectin-like receptor family are either homodimers (the large murine family Ly-49A-W, CD69, and NKR-P1) or heterodimers, which consist of an invariant chain CD94 and a second subunit from the NKG2 family members A, B, C, and E.[558] The function of the heterodimeric proteins depends on the cytoplasmic regions of the variant chains (i.e., whether long [NKG2A,B] or short [NKG2C,E], corresponding to inhibitory or activating functions, respectively). The inhibitory subunits have one pair of ITIMs in the cytoplasmic region, whereas the activating subunits associate with the ITAM-containing adaptor molecule DAP12. The NKG2D (KLRK1) protein forms a homodimer (does not pair with CD94) and is an activating receptor. Each subunit is composed of an extracellular C-type lectin-like domain known also as an NK-receptor domain or NKD. The NKD, however, binds proteins and not carbohydrates, which are the ligands for the classical C-type lectins, and furthermore, their structure differs from the classical C-type lectins.[559] C-type lectin-like NK-receptor domains include other important molecules of innate immunity, macrophage mannose receptor, collectins (i.e., pulmonary surfactants), and so forth. The ligands for CD94/NKG2 proteins are the nonclassical HLA-E molecule, which binds peptides from the leader sequence of the HLA-A, -B, -C, and -G molecules.[560,561] Expression of HLA-E depends on the presence of the signal peptides, thus providing a safe strategy for NK-cells to monitor the presence of polymorphic HLA molecules[562] because absence of HLA-E would indicate absence of some of the HLA-A, -B, or -C. HLA-E is also capable of binding the signal sequence of heat-shock protein HSP60. HSP60 is present in all living cellular organisms[563] and serves as a mitochondrial chaperone. HSP60 levels are increased in response to stress stimuli (i.e., temperature increase, nutrient deprivation, exposure to toxic chemicals, inflammation, etc.). HSP60 protects these cells from harmful stimuli, but at the

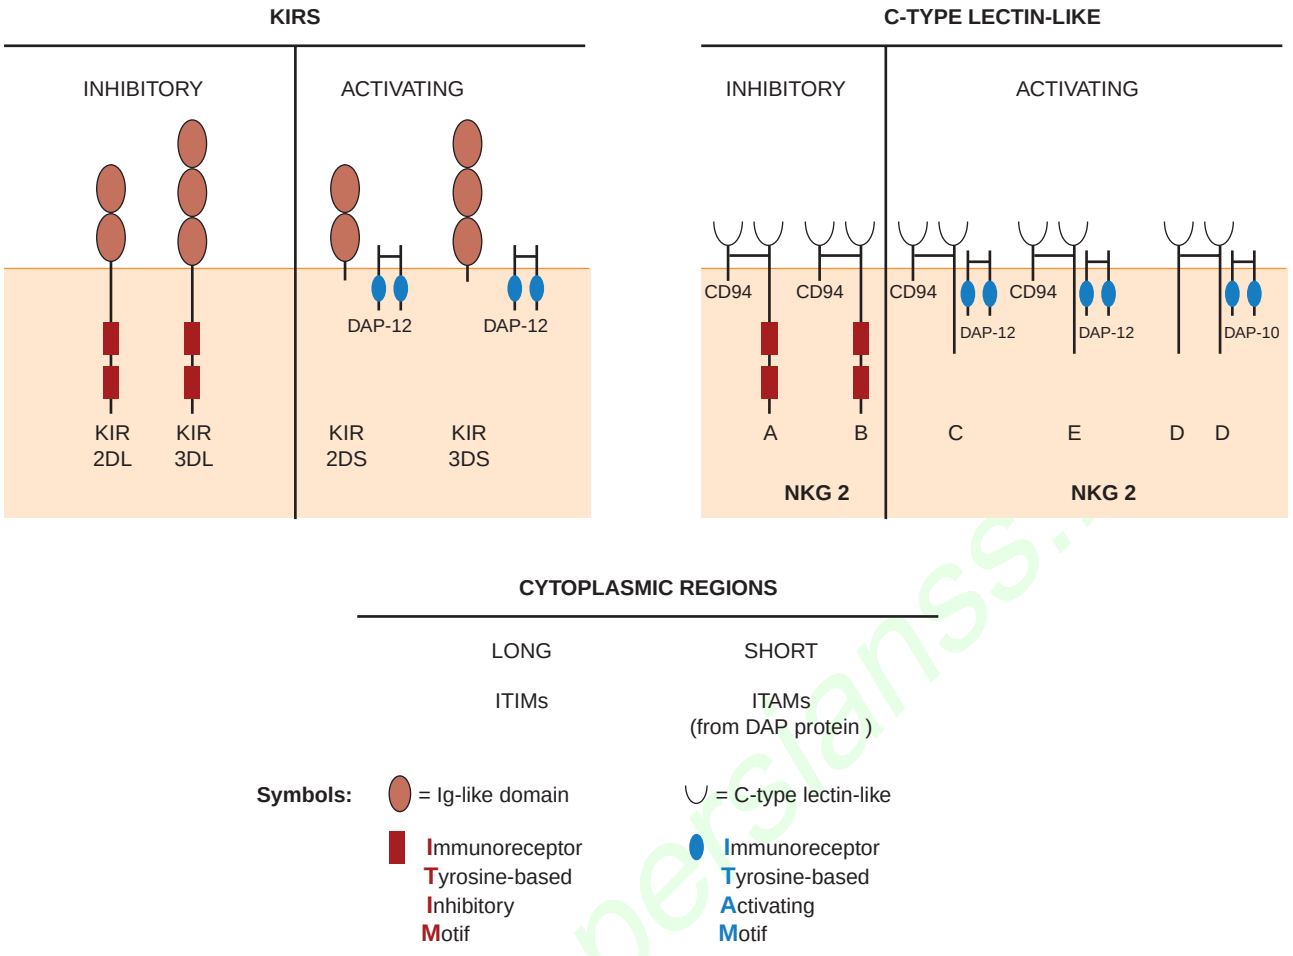

FIGURE 13.19. Natural killer (NK) cell receptors. The NK-cell receptors in humans structurally belong to two different families: one family has immunoglobulin (Ig) domains in the extracellular region and are known as *killer Ig receptors* (KIRs) and the other family has a C-type lectin-like domain. The C-type lectin domain recognizes oligosaccharides (and sometimes polypeptides), but the binding is directly mediated by Ca^{2+}, hence the term *C-type lectin*. However, the NK-cell receptors with the C-type fold lack the Ca^{2+}-ligating elements and thus have been termed *C-type lectin-like*. (See Kogelberg H, Feizi T. New structural insights into lectin-type proteins of the immune system. Curr Opin Struct Biol 2001;11:635–643.) The NK-cell receptors in both families are functionally divided into *inhibitory and activating*. The labyrinthine jargon of the NK-cell receptors becomes simpler with the acquaintance of some rules: The inhibitory KIRs have either two or three Ig domains in the extracellular region (i.e., 2D or 3D) and a long or short cytoplasmic tail (i.e., 2DL or 2DS and 3DL or 3DS). Those with long cytoplasmic tails are inhibitory, whereas those with short tails are activating. Thus, the receptor KIR 2DL is an inhibitory receptor with two Ig domains, whereas the receptor KIR 3DS is an activating receptor with three Ig domains. (See more details in text and in Table 13.2.)

same time, the HLA-E/HSP60 peptide is not recognized by the inhibitory receptor, CD94/NKG2A, and these cells are eliminated by NK-cell activation.[564]

In humans the ligands for the NKG2D receptor are the MHC class I-related molecules MICA and MICB, which are up-regulated in virally infected cells and many tumors.[565,566] They are minimally expressed in normal tissues but up-regulated in stressed cells.[567] MICA is composed of two structural domains: one in the form of a platform formed by $\alpha 1/\alpha 2$ and the second in the form of a C-type Ig-like α_3 domain.[568] The NKG2D receptor binds orthogonally to the MICA platform in a way similar to the docking of TCR on pMHC (see above).[569] For signaling, it uses the adaptor protein DAP10, which has no ITAMs but contains the sequence YINM and propagates signaling through PI3-kinase and is thus less susceptible to the SHP-1–coupled receptors. The NKG2D receptor in mice (Kirk1) may associate with another adaptor protein, DAP12 (also known as KARAP), which recruits protein tyrosine kinases.[570] Through DAP12, it can activate ZAP70 or SYK protein kinases through the ITAM of DAP12 and the p85 subunit of PI3-K. Thus depending on the availability of the adaptor partners, NKG2D may mediate costimulation in T-cells and/or activation in NK-cells.[570] Furthermore, the functional outcomes of NKG2D stimulation depend on ligand density, cytokines, or the presence of inhibitory ligands.[571] Another family of ligands for NKG2D contains proteins that bind the UL16 cytomegalovirus protein, known as UL16-binding proteins (ULBP).[572,573] The ULBP possess α_1 and α_2 domains but differ from MIC and MHC I in lacking the α_3 domain, and they are GPI-anchored proteins without β_2M protein. Binding to the NKG2D receptor has been demonstrated by blocking of ULBP binding by anti-NKG2D antibodies.[574] The presence on NK-cells of receptors that recognize infected or abnormal (malignant) cells provides a new platform for developing strategies for immunotherapy of malignancy.[575]

The major breakthrough in the regulation of NK-cell function came with the formulation of the "missing self" hypothesis[576,577] (Fig. 13.20). This hypothesis states that NK-cells can recognize and selectively lyse targets that fail to express self–MHC I antigens. The validity of the hypothesis has been demonstrated in multiple in vivo and in vitro systems as summarized.[576] The basic premise is that when appropriate MHC I molecules are expressed, lysis of the target is inhibited, but when the target is deficient in MHC I expression, the target is lysed. Specific inhibitory receptors engaged with normal MHC I molecules prevent activating receptors to kill the target. Cells that have lost a normal MHC I expression ("missing self"; i.e., tumors or infected cells) are unable to deliver an inhibitory signal to NK-cells and

TABLE 13.2

NATURAL KILLER CELL RECEPTORS AND CD DESIGNATION

A	KIRs	B	LIRs/ILTs
CD158a	KIR2DL1	CD85a	LIR3 (ILT5)

become susceptible to lysis. Cells susceptible to lysis by NK-cells as a result of deficiency of MHC I molecules could be protected by transfection of MHC I alleles. This experiment provided formal demonstration of the validity of the missing self hypothesis. However, NK-cells under persistent stimulatory signals, below the level of full activation, become hyporesponsive or "anergic" (i.e., chronic stimulation induces loss or responsiveness to NK-cells [disarming model]).[578,579] Another possibility (arming model) assumes that MHC class I inhibitory receptors induce functional maturation and in their absence the NK-cells remain immature (i.e., hyporesponsive).

The effector functions of the NK-cell receptors are controlled by the transmembrane and cytoplasmic regions. The inhibitory receptors have ITIMs in their cytoplasmic tails and recruit SHP-1 phosphatase. Activating receptors have a short cytoplasmic region, but for signaling, they borrow the function of ITAMs by associating with adaptor molecules such as DAP12 (TYROBP). Association is mediated by a positively charged residue of the receptor and an oppositely charged (i.e., aspartate) residue of the adaptor.[580] Further research into the regulation of NK-cell function by the NK receptors is expected to expose new initiatives for investigating tumor immunosurveillance[581,582] and autoimmunity.[583] In hematology specifically, the manipulation of receptor–ligand interactions may help in allogeneic bone marrow transplantation to prevent leukemia relapse and graft versus host disease.[584–586]

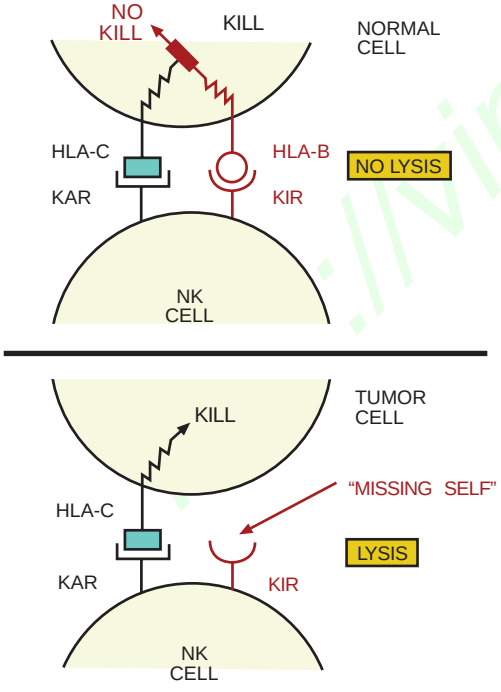

FIGURE 13.20. Natural killer (NK) cell cytotoxicity: the missing self. NK-cell cytotoxicity is a delicate balance between activating receptors and inhibitory receptors. Both (whether of the immunoglobulin SF or C-type lectin) have HLA class I specificity, although some receptors recognize nonmajor histocompatibility complex molecules. The presence of activating receptors against normal cells causes no problem as long as the NK-cells possess at least one inhibitory receptor, the signal of which is always dominant. However, with alterations of the structure of a class I molecule or complete loss of the molecule, the binding of the inhibitory receptor is abolished and the activating signal remains unopposed. This is the essence of the missing self hypothesis. KAR, killer-activating receptor; KIR, killer Ig receptor. (From Kärre K. How to recognize a foreign submarine. Immunol Rev 1997;155:5–9.)

Cytotoxicity of Natural Killer Cells

Two major mechanisms are used by NK-cells to kill target cells and both require contact with their targets. One pathway involves proteins released from granules by the process of exocytosis such as perforin (see section "Cytotoxic T Lymphocytes") or serine proteases, the granzymes with various substrate specificities. The other pathway involves engagement of death receptors (e.g., FAS/CD95) on target cells, with their cognate ligands (FASL) on NK-cells.[587] Engagement of the NK-cell with its targets is mediated by the NK-cell receptors (see above).

Natural Resistance

NK-cells are one of the main effectors of innate immunity. Their role against viral infections has been well documented.[588] NK-cells selectively lyse virally infected cells but spare noninfected cells. The mechanism of natural resistance against viral infections may involve direct lysis of the infected cells or production of TNF-α, which stimulates NK-cell activity. A patient with selective deficiency of NK-cells has been described who had life-threatening viral infections.[589] NK-cells also play a role against certain intracellular parasites, such as *Toxoplasma gondii*. Production of TNF-α and IL12 activates NK-cells for production of IFN-γ, which is important for macrophage activation in the defense against intracellular parasites.[590]

Regulation of Adaptive Immunity

NK-cells enhance responses of B- and T-cells during the early stages of an immune response. As a result of stimulation by IL12, produced by macrophages in response to infectious agents, NK-cells produce large amounts of IFN-γ.[591] IFN-γ acts on macrophages and enhances their antigen-presenting function by increasing expression of class II antigens. IFN-γ is important in directing T-cell differentiation to Th1 cytokine responses. Induction of predominantly Th1 responses leads to enhancement of cell-mediated immunity. Finally IFN-γ activates macrophages enhancing their microbicidal function.

Natural Killer Cells: Malignancies and Bone Marrow Transplantation

NK-cells provide surveillance against tumor cells and virus-infected cells.[565] In patients with X-linked lymphoproliferative disease[592] or deficient NK activity,[592] there is a high incidence

of cancer.[593] Nude mice are T-cell deficient, but have normal NK activity, and no increased susceptibility for development to malignancies. There is a positive correlation between NK-cell activity and survival time without metastasis in patients with solid tumors.[594] Decrease of NK-cell activity has been detected in patients with malignant lymphoma, in patients before relapse of leukemia, and also in women with breast cancer and metastasis to regional lymph nodes. Acceptance of organ grafts in the F1 progeny of inbred strains of mice results from the fact that the F1 animals express co-dominantly the class I antigens from both parents, and therefore, the F1 T-cells recognize them as self but reject bone marrow stem cells from either parent.[595,596] This is known as hybrid resistance mediated by NK-cells but not T-cells.

After bone marrow transplantation the NK-cells engraft during the first few weeks.[597,598] In one third of the patients after autologous or allogeneic bone marrow transplantation, a minor NK subpopulation ($CD56^+/CD16^-$) was markedly expanded (up to 40% of peripheral blood lymphocytes).[599] NK activity helps the acceptance of the graft by controlling viral infections, eliminating leukemic cells, or stimulating hematopoiesis.[593]

Regulation of Hematopoiesis

Existing evidence suggests that NK-cells exert both inhibitory and stimulatory effects on hemopoietic progenitors. These effects are mediated predominantly by the release of cytokines from NK-cells rather than by cytotoxicity.

Strong evidence exists that an increase in the number of LGLs is associated with anemia or granulocytopenia. NK-cells inhibit in vitro granulocytopoiesis in the granulocyte-macrophage colony-forming cell assay.[600] NK-cells also exert a promoting effect on hematopoiesis, however, and the net effect may actually depend on the stage of maturation of the progenitor cells.[601]

In some patients with neutropenia, there is an increase of NK-like cells in the bone marrow but not in the peripheral blood. These cells can be identified only by immunophenotyping.[602]

Decidual Natural Killer Cells

A unique subset of $CD56^{bright}$ NK-cells accumulates in the maternal decidua in direct contact with fetal trophoblasts.[603] These NK-cells are not derived from peripheral blood and produce IL8 and interferon-inducible protein-10 chemokines. They secrete a variety of angiogenic factors, induce vascular growth in the decidua, and possess low or even inefficient cytotoxic abilities and overall orchestrate developmental processes in the fetal–maternal interface.

Natural Killer Cell Proliferations

Artificially five to seven times the normal number (250 to 450/μl), is believed to represent a lymphoproliferative disease of LGL if it persists for longer than 3 months.[604] Some of the most common clinical presentations are fever, infections, neutropenia, anemia, and thrombocytopenia. Mortality was associated with moderately elevated counts of LGLs (2,000 to 3,000/μl) and very high counts (more than 7,000 μl), which indicates that LGL proliferations are, in general highly heterogeneous.

Cytogenetic abnormalities have been detected, and in LGL cases that are $CD57^+$ (and therefore express TCRs), rearrangements of *TRB@* genes are detected in most of the cases.[605] Because these cases are also associated with widespread involvement of several organs, such as the spleen, liver, and bone marrow, the term LGL leukemia has been proposed. The predominant phenotype of the LGL is $CD57^+$ ($HNK\text{-}1^+$)/$CD3^+$ and these patients often have rheumatoid arthritis, neutropenia, and splenomegaly, a combination resembling Felty syndrome. Anemia and thrombocytopenia are not uncommon, and serologically, rheumatoid factor, antinuclear antibodies, hypergammaglobulinemia, and immune complexes are detectable.

Two major subtypes have been distinguished in terms of clinical presentation and the phenotype of the cells.[606–608] The LGLs in type A, also known as T-LGLs, are $CD57^+/CD3^+/CD8^+/CD2^+$, and those in type B, also known as NK-LGLs, are $CD56^+/CD3^+/CD8^+/CD2^+$. Patients with T-LGL ($CD57^+$) often may have neutropenia (84%), rheumatoid arthritis, and autoantibodies. However, these clinical and serologic findings in patients with T-LGL could not be confirmed in other studies.[609] NK-LGL leukemias are observed in younger patients and run an aggressive course.[610] The most characteristic clinical presentation is hepatosplenomegaly and involvement of the gastrointestinal system with ascites. The course of the disease is acute, and often the patients die within 1 to 2 months after diagnosis.

NATURAL KILLER T-CELLS

Natural killer T-(NKT) cells have been identified as a novel lymphocyte lineage, which, in humans expresses the cell-surface marker CD161 (NKR-PIA) structurally related to several other proteins encoded by the NK-gene complex, including CD94, NKG2, and CD69.[611] Because α-glycosphingolipids are not detected in mammals, the α-Gal-Cer probably mimics self-antigens that are recognized by NKT-cells.

The NKT-cells express an invariant Vα-14 receptor (Vα-14i TCP), which is used only by the NKT-cells but not by T-cells. The expression of an invariant TCR suggests that the selection is mediated by a monomorphic rather than polymorphic MHC molecule.[612] The NKT-cells are selected from DP $CD4^+/CD8^+$ thymocytes expressing CD1D.[613] Their thymic $CD4^+CD8^+$ Vα14i precursors, recognize endogenous CD1D-associated glycolipids on other $CD4^+CD8^+$ thymocytes and are selected to undergo a maturation program involving sequential expression of CD44 and NK-related markers such as NK1.1.[614] After their selection, the Vα14i precursors are exported and acquire the NKT phenotype in the periphery.[615] They migrate to the liver and from there to sites of inflammation responding to stimuli, i.e., chemokines and glycolipids. They have a surface phenotype characteristic of recently activated or memory T-cells, even when the cells are obtained from cord blood,[616] consistent with the postulated autoreactivity of the NKT-cells.

Inhibitory receptors prevent unchecked autoreactivity for CD1D DCs.[617] The NKT-cells expressing Vα24 in their TCR play a critical role in immune responses, inhibition of tumor development, and protection from autoimmune disease development.[618,619] These cells have cytolytic function and rapidly induce cytokines after stimulation and activate other cells (i.e., NK-cells, T-cells, B-cells, and macrophages).

In humans the $CD4^+$ Vα24i cells preferably produce IL-4, which is believed to regulate Th1/Th2 differentiation,[620,621] but the Th1 versus Th2 polarization is more complex and depends on additional factors such as the number of antigenic stimulations with a shift to Th2 after multiple challenges.[622,623] Th2 cytokine prevents the development of type I diabetes in mice with genetic predisposition,[624] as well as allergic encephalomyelitis in another strain susceptible to the development of this disease.[625] In experimental autoimmune diseases that develop spontaneously, there is a direct correlation between the development of the disease and the decline of Vα-14 cells.[626]

Selective reduction of Vα24 cells has also been shown in patients with systemic sclerosis,[627] systemic lupus erythematosus, rheumatoid arthritis,[628] and type I diabetes.[629] Stimulation of NKT-cells by α-Gal-Cer in animals triggers secretion of large amounts of cytokines (IFN-γ, IL4, Il2, IL5, etc.).[630] The fact remains, however, that NKT-cells promote Th2 responses and suppress Th1-dominant autoimmunity.[631]

Others have found that NKT-cells are not critical in the IL12-mediated rejection of tumors,[632] and it appears that the conflicting results in the literature about the role of NKT in tumor responses are due to complex factors, including the types of tumors and their microenvironment, and functionally different subsets of NKT-cells.[633] NKT-cells have been implicated in protective immunity against several pathogens, i.e., mycobacteria[634] and malaria parasites.[635] In conclusion, NKT-cells are phenotypically and functionally heterogeneous, endowed with cytolytic and cytokine secretion functions and regulation of several functions of the immune response that are related to host defenses against infections, autoimmunity, and tumor immunity.

They have been called "nonconformist" and "unconventional" because they are suited to get involved in such a great variety of homeostatic disequilibrium conditions of the host.

Th17 CD4$^+$ Cells

Effector CD4$^+$ T-cells develop in response to cytokines elicited from cells activated during an immune response. as in the development of Th1 and Th2. Another CD4 T-cell lineage known as Th17, represents an additional CD4$^+$ T-cell effector cell, characterized by a distinct profile of effector cytokines such as IL17, IL17F, and IL6.[636] In the absence of IFN-γ and IL4, IL23 induces naive precursors to differentiate to Th17 cells.[637] TGF-β is critical for up-regulation of the IL23 receptor, thus conferring responsiveness to IL23.[638] IL6 probably is also needed in cooperation with TGF-β for Th17 cell development from naive T-cells.[639] Others, however, have shown that TGF-β alone is a critical factor for differentiation of IL17-producing effector cells.[640] The role of IL23 may be important for stabilizing the Th17 phenotype in chronic inflammation[641] and control of certain pathogen-induced diseases not covered by Th1 and Th2.[642]

CHAPTER 14

EFFECTOR MECHANISMS IN IMMUNITY

Frixos Paraskevas

MAJOR HISTOCOMPATIBILITY COMPLEX

The function of the immune system is under genetic control[1] and molecular genetic studies have helped to elucidate the mechanism of gene regulation of immune functions.[2] The genes that regulate immune functions are found in the chromosomal region of the major histocompatibility complex (MHC) involved in defining histocompatibility for transplantation, and these antigens have been given specific names in different species, i.e., human leukocyte antigens (HLAs) in humans and histocompatibility-2 or *H2* in the mouse.

The HLA complex extends approximately over 4,000 kilobases (kb) on the short arm of chromosome 6, i.e., 6p21-3, whereas the *H2* complex is located on chromosome 17 and occupies a segment that is halfway between the centromere and the telomere. Approximately 180 genes have been located within the HLA region and the number grows constantly with the increase in sensitivity and sophistication of techniques of molecular biology.

The complex is divided into three regions: (a) the class I region occupies the most distal (telomeric) end of the short arm of the chromosome and spans approximately 1.8 megabases (Mb); (b) the class II region (approximately 1 Mb) occupies the most centromeric end of the chromosome; and (c) the class III region is between the other two regions[2] (Fig. 14.1).

Class I Region
