18. Proteomics: Applications and Advances

Vernon E. Coyne

Proteomics provides a snapshot of gene expression in a particular cell, tissue, or organ at the time of sampling. Since the proteome is the link between the genotype and phenotype of an organism, characterization of the proteome provides information regarding the adaptability and physiology of an organism in relation to its environment. Proteomics is proving invaluable as a tool in marine biotechnology, where it has been employed to identify and characterize unique bioactive gene products, characterize the function and regulation of metabolic processes, elucidate marine biodiversity, and identify biomarkers of pollution and disease. Aquaculture of commercially important marine fish and shellfish has benefitted through a proteomics approach to address issues relating to disease, larviculture, and animal production in order to improve the profitability and sustainability of the industry. This chapter describes a wide variety of studies that illustrate the application of proteomics in marine biotechnology. The rapid improvements in proteomics technology expected over the next few years are guaranteed to result in dramatic advances in our understanding and use of the valuable resources provided by the marine environment.

18.1 Omics

In 1998, the nematode *Caenorhabditis elegans* was the first multicellular organism to have its genome sequenced [18.1]. Since then, the *omics era* has essentially transformed molecular biology in terms of the vast volumes of data generated in our quest to better understand the cellular processes responsible for the evolutionary success and survival of living organisms. Omics is a collective term for genomics, transcriptomics and proteomics, which focus on the three basic levels of genetic expression in the cell, and is inclusive of additional technologies such as metabolomics, metagenomics, epigenomics, lipidomics, etc.

While genomics characterizes all the genes of a particular organism in an attempt to elucidate their function and regulation, transcriptomics and proteomics provide a more dynamic approach to studying gene expression and regulation at the cellular level. Whereas transcriptomics allows messenger ribonucleic acid (mRNA) levels to be assessed as a measure of gene expression, proteomics provides more detail since it detects the products of alternative mRNA splicing and post-translational modification of proteins [18.2, 3]. In addition to providing a *qualitative snap shot* of gene expression in a particular cell, tissue or organism, proteomics

can quantify protein expression at a particular time point. Thus, the proteome is the link between genotypic and phenotypic variation, and consequently, reflects the adaptability and physiology of an organism in relation to its environment [18.4].

While it is not the purpose of this chapter to provide an in-depth explanation and evaluation of the techniques used in proteomics, a general overview of the tools used in proteomic studies will be advantageous.

18.2 Overview of Proteomics Techniques

Polyacrylamide gel electrophoresis (PAGE) is the most common and simplest technique used in proteomic research [18.5]. A protein extract is suspended in a sample buffer incorporating the anionic detergent sodium dodecyl sulphate (SDS), which linearizes and binds to proteins, causing them to become negatively charged. Since there is an even distribution of charge per unit mass, the proteins are separated by approximate size during electrophoresis through a polyacrylamide gel. The technique can be improved by expanding protein fractionation by PAGE to two dimensions (2D-PAGE). The technique involves fractionation of a protein mixture according to the isoelectric point (pI) of each protein (first dimension) by electrophoresis through an immobilized pH gradient (IPG), followed by separation according to size by standard SDS-PAGE where the electric current is applied in a direction that is perpendicular to the first dimension [18.6].

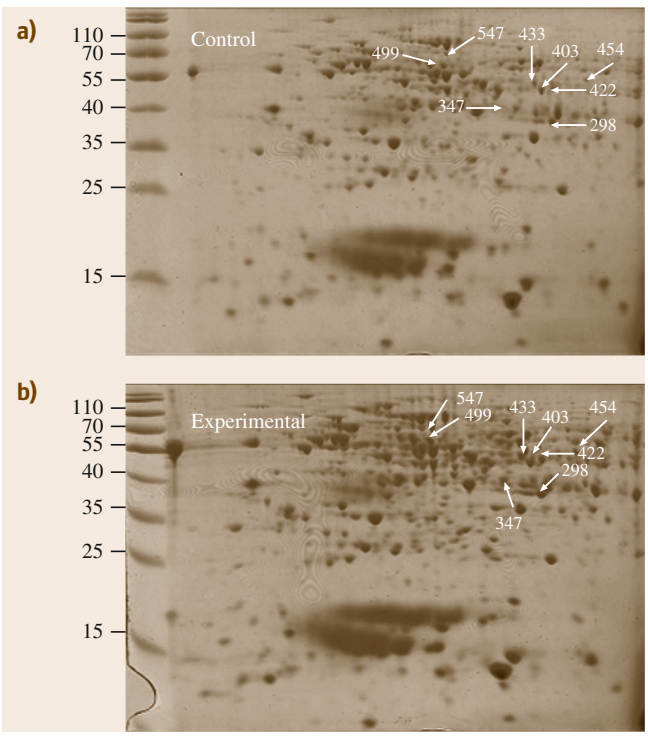

Fig. 18.1a,b Two-dimensional polyacrylamide gel electrophoresis was used to detect changes in the abundance of cellular proteins isolated from the red seaweed *Gracilaria gracilis* cultured in either nitrogen-replete (control) **(a)** or nitrogen-limited (experimental) **(b)** media for 6 h. Nitrogen-responsive proteins identified by tandem mass spectrometry (MS/MS) analysis are indicated by *arrows*. The levels of these proteins had increased in the nitrogen-limited samples relative to the control. A pre-stained molecular weight marker (Fermentas) on the *left side* of each gel image represents approximate molecular weights in kDa to enable estimation of the size of each protein spot (photograph by R.K. Naidoo)

Two-dimensional electrophoresis can routinely detect approximately 2000 proteins, which is an order of magnitude greater than what is possible with 1D-PAGE. Consequently, 2D-PAGE has been extensively employed in numerous proteomic studies in conjunction with mass spectroscopy (MS) [18.2, 6]. In addition to providing a qualitative analysis of the proteome in a particular sample, 2D-PAGE can also quantitate the relative expression of proteins sampled from organisms or cells exposed to different treatments through the use of various image analysis software packages (Fig. 18.1). Two-dimensional difference in-gel electrophoresis (2D-DIGE) is a refinement of 2D-PAGE. Since proteomics studies typically analyze multiple protein samples from various treatments, 2D-DIGE involves differentially labeling the proteins in various treatment groups with fluorescent cyanine dyes (Cy-Dyes) and then mixing equal quantities of the labeled proteins prior to fractionation by standard 2D-PAGE on the same gel, thus eliminating inter-gel variation [18.2, 3, 6]. Detection of proteins fractionated by 2D-PAGE is accomplished by staining with either colloidal Coomassie blue or silver nitrate, which detect 10 and 0.5 ng of protein per spot, respectively [18.7]. The sensitivity of protein spot detection following 2D-DIGE is a function of the method employed to

label the proteins with the fluorescent CyDyes, ranging from 1 to < 0.1 ng protein per spot with minimal or saturation labeling, respectively [18.8]. Once differentially expressed protein spots have been identified, either manual spot picking or a robotic spot picker is used to obtain samples of the spots for identification by MS.

MS is widely used for the identification and quantitation of proteins in biological samples [18.9, 10]. The majority of protocols involve trypsin digestion of the protein in each of the sampled spots to generate peptides with a mass range that is more conducive to MS, since they can be effectively ionized by electrospray [18.4, 9]. The resulting peptide mixture is fractionated by reverse phase liquid chromatography and analyzed by tandem mass spectrometry (MS/MS) [18.10]. Briefly, MS/MS involves ionization of the peptides followed by separation of the peptide ions according to their mass to charge ratio and further fragmentation for sequence analysis [18.2].

Data obtained by MS/MS includes information concerning the peptide masses, fragment ion masses, and intensities, which is transformed into a peak list that is searched against a protein database of in silico-digested proteins using open-source or proprietary software packages [18.2]. If insufficient sequence data is available regarding the organism under investigation, de novo peptide sequences can be used to interrogate protein sequence databases. Besides identification of the proteins present in a particular biological sample, MS can also be used to quantitate the proteins present in individual samples. Isobaric tags for relative and absolute quantification (iTRAQ) is a widely used chemical labeling technique that allows quantitative comparison of protein samples from up to eight treatments simultaneously [18.11, 12]. Since the eight isobaric mass tags result in different mass spectra following peptide fragmentation, iTRAQ allows simultaneous identification and quantitation of the peptides in the eight samples [18.2].

18.3 Proteomics and Marine Biotechnology

The marine environment covers 70% of the Earth's surface and is inhabited by a broad diversity of organisms [18.13, 14]. The latter reflects the fact that life originated in the sea approximately 3.8 million years ago and has adapted to the wide range of habitats that comprise the marine environment, many of which are considered extreme [18.14].

Given the extent of the marine environment and the biodiversity it contains, marine biotechnology promises to deliver a vast array of commercially important products that include novel bioactive compounds, enzymes, and biopolymers. In addition, technology has been developed that has allowed aquaculture of a number of fish and shellfish species to provide an increasingly important source of protein for human consumption.

Indeed, marine aquaculture production is increasing steadily, achieving a 20% growth in production from 2004 (16.7 mt) to 2009 (20.1 mt), while wild fisheries harvest decreased by almost 5% from 83.8 to 79.9 mt over the same period [18.15]. Despite the many potential benefits that may be derived from marine organisms, the health of the marine environment is being damaged enormously due to rapidly elevating levels of anthropogenic pollution, over-fishing, and the effects of climate change. In fact, a significant proportion of the world's population lives within 75 mi of an ocean coast and the number is expected to continue to increase together with a substantial impact on the marine environment [18.16].

In order for us to derive the benefits that the marine environment offers humanity through marine biotechnology and mitigate the damage done to the marine environment, it is necessary for us to utilize modern technologies to better understand the functioning of the organisms that inhabit the marine environment in terms of their ecology and biology. As discussed earlier, the omics era is generating new insights into the molecular biology of living organisms at a rate never before achieved. Proteomics provides a unique opportunity to characterize the phenotype of marine organisms, which dynamically responds to changing environmental conditions and associated stresses. Indeed, proteomics has a range of applications in marine biotechnology, such as identification of unique bioactive gene products, characterization of the function and regulation of metabolic processes, determination of biodiversity, and identification of biomarkers of pollution and disease. The following sections of this chapter will discuss many areas of marine biotechnology which have been investigated using a proteomic approach.

18.4 Aquaculture

In order to continue to meet the worldwide demand for seafood, it is estimated that fish production will have to increase sevenfold by 2020 and that this will need to be accomplished through aquaculture [18.13]. Although production levels of farmed shellfish and fish are steadily increasing, the industry faces many challenges that must be met in order to be sustainable. Some of the issues that the industry faces include improved larviculture, prevention and treatment of disease, feed quality and increased growth rates, nutritional quality of the product, etc. Perhaps the greatest threat to the future growth of aquaculture is the escalating rate of climate change that will have a significant impact on aquaculture in the same way that it will affect terrestrial farming [18.17, 18].

18.4.1 Disease

Aquaculture of fish and shellfish is subject to the same constant threat of infectious disease as farmed terrestrial animals and plants [18.19–23]. For example, even though Scotland generates 97% of farmed Atlantic salmon (*Salmosalar*) in the United Kingdom, it is estimated that a third of production is lost due to disease [18.24]. Similarly, although 2.7 million metric tons of the white leg shrimp *Penaeus vannamei* was produced in 2010, with a value of US$ 11.3 billion [18.25], the cumulative loss in global production since the emergence of white spot disease in the early 1990s is estimated at nearly US$ 15 billion [18.26]. Although it is difficult to find definitive figures, it is estimated that the global loss of aquacultured animals to disease amounts to approximately several billion US$ per annum [18.27]. Marine organisms are subject to infection by viruses, bacteria, and parasites, many of which are uncharacterized and thus designated as *emerging diseases* [18.28]. Consequently, the means to either prevent or mitigate disease in aquacultured marine organisms is currently quite limited. Antibiotics are no longer an acceptable treatment against bacterial pathogens due to the potential of resistance arising in target bacteria, as well as the fact that antibiotic residues in seafood destined for human consumption are not acceptable [18.27]. Consequently, the development of vaccines for treatment and disease prevention is receiving a great deal of attention [18.29, 30], while probiotics are being investigated as an alternative to antibiotics [18.21, 31].

Proteomics has been employed in a number of studies investigating disease in aquacultured marine animals. It has become increasingly evident that stress is intimately linked to the onset of disease in aquacultured organisms [18.17, 32–34]. Hypoxic conditions in shrimp ponds has been shown to lead to stunted growth rates and an increased susceptibility to infectious disease [18.35]. Consequently, the proteome of the hepatopancreas of adult Chinese shrimp *Fenneropenaeus chinensis* was characterized to obtain a better understanding of the hypoxia stress response in this commercially important crustacean.

Two-dimensional electrophoresis identified 67 protein spots that were differentially expressed in response to anoxic conditions [18.35]; 51 of these spots were identified as 33 proteins by LC-ESI-MS/MS (LC: liquid chromatography; ESI: electrospray ionization), including preamylase, arginine kinase, phosphopyruvate hydratase, citrate synthase, adenosine triphosphate (ATP) synthase alpha subunit, chymotrypsin B1, chitinase, ferritin, C-type lectin receptors, transketolase, formylglutathione hydrolase, formyltetrahydrofolate dehydrogenase, aldehyde dehydrogenase, glutathione peroxidase, cytosolic manganese superoxide dismutase, protein disulphide isomerase, β-actin, oncoprotein 23 nm, and crustacyanin-C1. Many of the proteins could be classified into functional groups such as energy production, immunity, chaperones, and antioxidants, thus providing insight into the type of metabolic processes and stress response systems evoked in response to hypoxia [18.35].

The effect of hypoxia on humoral immunity in the Eurasian perch *Perca fluviatilis*, currently undergoing domestication for aquaculture, was investigated by exposing captive fish from two generations (F1 and F5) to either single or multiple 4 h hypoxic episodes over a period of 46 days and examining the serum proteome using 2D-DIGE [18.36]. C3 complement proteins were found to be up-regulated following a single exposure to hypoxia, while exposure to multiple hypoxic events resulted in up-regulation of transferrin and differential expression (some up and others down-regulated) of a number of C3 complement proteins. The study concluded that the serum proteome responded to single and multiple hypoxic events in the same way and that repeated exposure resulted in acclimation to the stress, suggesting that *Perca fluviatilis* can adapt to hypoxic conditions that may arise during aquaculture [18.36].

In another study conducted to identify biomarkers of chronic stress, the liver proteome from gilthead sea bream (*Sparus aurata*, L.) that had been stressed by repetitive handling or stocked at high density was compared to that of control fish using comparative proteomics [18.37]. Approximately 299 differentially expressed proteins were detected by 2D-PAGE, with 235 spots differentially expressed in response to handling stress, 223 spots regulated in response to overcrowding, and 70 spots that responded to both treatments. LC-MS/MS analysis allowed identification of 12 differentially expressed proteins: fatty acid binding protein and haemoglobin were up-regulated, while calmodulin, triose-phosphate isomerase, β-tubulin, glutamine synthetase, pyruvate dehydrogenase, heat shock cognate protein 70, glyceraldehyde 3-phosphate dehydrogenase, α-enolase, voltage-dependent anion channel 1, and cofilin were all down-regulated [18.37]. The proteins could be assigned to key functional groups, reflecting their role in lipid transport, antioxidation, chaperoning, Ca^{2+} signaling, lipid oxidation, ammonia metabolism, cytoskeleton, and carbohydrate metabolism. *Alves* et al. [18.37] list fatty acid binding protein, calmodulin, pyruvate dehydrogenase, heat shock cognate protein 70, and voltage-dependent anion channel 1 as the most promising molecular markers identified in their study since their role in the stress response is better understood. However, the authors caution that additional proteomic studies need to be conducted using different tissues in order to ensure that biomarkers used to monitor chronic stress in farmed fish are robust. Furthermore, expression of these potential biomarkers during activities that affect metabolism, such as feeding and exercise, needs to be assessed to ensure their specificity with regard to chronic stress.

Although *Moraxella* sp. colonizing the internal organs of farmed fish has not been directly associated with disease, farmers have reported slow growth rates, poor feed conversion, and decreased weight gain in sea cage-farmed fish [18.38]. A proteomic investigation of kidney samples obtained from cage-farmed *Sparus aurata* that were positive or negative for *Moraxella* sp. showed that several mitochondrial enzymes were significantly up-regulated in the *Moraxella* sp. infected kidneys, reflecting what has been reported in lipopolysaccharide (LPS) challenge experiments [18.38]. A number of nonmitochondrial proteins were found to be up-regulated, including peroxiredoxins, *S*-adenosyl-homocysteine hydrolase, antiquitin, warm acclimation-related protein 65, transferrin, glutathione *S*-transferase, carbonic anhydrase, and Cu/Zn superoxide dismutase, many of which function in oxidative stress, infection, inflammation, or apoptosis. The study suggested that metabolic alterations do occur in *Moraxella* sp. infected fish and identified various proteins that could potentially be used as biomarkers of *Moraxella* sp. infection in farmed fish.

The protozoan parasite *Marteilia sydneyi* is responsible for QX disease in Sydney rock oysters (*Saccostrea glomerata*), which can result in up to 95% mortality [18.39]. A proteomic approach to identify markers of QX disease resistance among Sydney rock oysters was undertaken by developing proteome maps of total haemolymph proteins from the fifth generation of a QX resistant oyster line derived from successive generations of selective breeding in which parental broodstock had survived disease outbreaks (QXR5), and comparing these to proteome maps from uninfected and infected wild-type oysters. Six proteins, found to be uniquely associated with resistance, were characterized by ESIMS/MS, which showed that two proteins were homologous to cavortin from the Pacific oyster *Crassostrea agigas* and domin in from the Eastern oyster *Crassostrea avirginica* [18.39]. Although the remaining four proteins could not be identified due to the absence of homologous sequences in the National Center for Biotechnology Information (NCBI) database, the two superoxide dismutase-like molecules are being investigated further as potential markers for selective breeding of QX disease-resistant oysters.

As previously mentioned, probiotic treatment of aquacultured animals is being developed as an alternative to antibiotics (Fig. 18.2). In a study aimed at investigating the effects of probiotic treatment on lar-

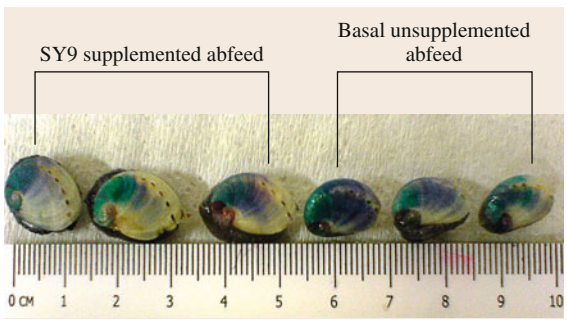

Fig. 18.2 Juvenile South African abalone *Haliotis midae* ($\approx$ 7.5 mm shell length) fed a diet supplemented with the probiotic bacterium *Vibrio midae* SY9 for 60 days had a 55% increased growth rate (shell length) in comparison to abalone that had been fed an unsupplemented diet (Coyne, unpublished)

val Atlantic cod (*Gadus morhua*), 2D-PAGE and MS were used to identify changes in the expression of larval proteins [18.40]. Interestingly, the study found that the five identified cod larval proteins that were downregulated in the probiotic-treated larvae function in the immune system of the fish, while two of the four upregulated proteins identified in the probiotic-treated larvae were α-actins from skeletal muscle. *Sveinsdóttir* et al. [18.40] concluded that probiotic treatment may have decreased the effect of environmental stress on the larvae, resulting in increased growth and development as indicated by decreased expression of immune system proteins and increased α-actin expression, respectively.

Proteomics has also proved to be invaluable for investigating the virulence response of bacterial pathogens of marine organisms. Although members of the genus *Vibrio* are ubiquitous in the ocean, a number of species are pathogenic to sea urchins, oysters, abalone, and fish, and thus are a major threat to aquaculture operations farming these animals. *Vibrio splendidus* is known to infect and cause disease in fish and shellfish, and is responsible for major mortalities of farmed animals [18.41]. The virulence mechanism of this bacterium towards marine invertebrates is poorly characterized due to the absence of molluscan cell lines, making it necessary to employ an ex vivo approach to investigate *Vibrio splendidus* virulence. Consequently, *Binesse* et al. [18.42] conducted a study of the extracellular products (ECPs) of the oyster pathogen *Vibrio splendidus* LGP32 which induce a strong cytopathic effect in infected oysters. Since the ECPs of a *Δvsm* strain, a metalloprotease deletion mutant of LGP32, were significantly less toxic, a proteomic analysis of the ECPs of both LGP32 and the *Δvsm* mutant was performed to identify additional cytotoxic proteins [18.42]. One of the differentially expressed proteins (VSA1062), found to have 41% identity to the *Bacillus thuringiensis* virulence factor immune inhibitor A precursor (InHA), was identified as a metalloprotease. The observation that the cytotoxicity of the ECPs of a *Δvsm*-1062 double mutant was similar to that of the *Δvsm* mutant even though metalloprotease activity could not be detected in the *Δvsm*-1062 mutant, led *Binesse* et al. [18.42] to discard the hypothesis that the VSA1062 metalloprotease compensated for the loss of VSM activity in the *Δvsm* mutant. Instead, they proposed that VSA1062 plays a role in bacterial resistance to the oyster immune response in a similar manner to InHA which functions in antibacterial peptide resistance.

In another study, the cellular and extracellular protein profiles of two *Vibrio anguillarum* strains, *Vibrio anguillarum* MN and 3010, were compared by 2D-PAGE and MALDI-TOF/TOF analysis since *Vibrio anguillarum* MN is 50-fold more virulent than 3010 towards the Japanese flounder *Paralichthys olivaceus* [18.43]. Two of the nine spots found to be differentially expressed between the two strains were identified as the outer membrane protein OmpU and the metalloprotease PrtV, both of which were highly upregulated in *Vibrio anguillarum* MN. Since OmpU increases the bacterium's resistance to bile [18.44], allowing it to colonize the fish digestive system, while PrtV from closely related *Vibrio cholera* is cytotoxic and can degrade extracellular matrix components such as fibronectin, fibrinogen, and plasminogen [18.45], *Zhao* et al. [18.43] concluded that these proteins most likely participate in the virulence response of *V. anguillarum*.

18.4.2 Reproduction

Aquaculture of commercially important marine animals relies on breeding healthy, fast-growing, high-quality animals. Consequently, a great deal of research and development has been invested in larviculture and hatchery design. As the aquaculture industry expands, there is a growing reliance on hatchery-produced seed for restocking farms. Many hatcheries maintain broodstock animals that are artificially induced to spawn in relation to a schedule based on the routine of the farm. Up to now, broodstock animals have either been obtained from the wild and cared for under optimal conditions or from what are perceived as being fast-growing animals produced on the farm and retained for breeding. However, it is becoming increasingly evident that a more directed approach to selecting broodstock for seed production is required in order to ensure production of robust, fast-growing spat.

Some studies have been published that employed a proteomics approach to address various challenges associated with breeding marine animals for commercial production. For example, it is necessary to determine that the gonads of broodstock animals have reached the appropriate developmental stage in order to induce spawning. The most common approach to this is visual inspection, which is acceptable for gastropods such as abalone, but inappropriate for bivalves such as oysters. *Li* et al. [18.46] employed surface enhanced laser desorption/ionization (SELDI) technology (ProteinChip Array System, Ciphergen Biosystems, Fremont, CA, USA) to obtain haemolymph protein profiles

during reproductive development of the Eastern oyster *Crassostrea virginica*. SELDI-TOF-MS combines array technology, which allows high resolution separation of proteins from complex mixtures on a chip, and mass spectrometry [18.47]. SELDI-TOF-MS is more sensitive than traditional MS and allows rapid sample throughput [18.46, 47]. The study identified 62 peptides associated with oyster reproduction and, consequently, was able to categorize individual broodstock animals into one of five groups: undifferentiated, female developing, female ripe, male developing, and male ripe with an accuracy of 98.8% [18.46].

Besides ensuring that broodstock animals are ripe for spawning, the quality of the eggs produced is also important in terms of ensuring that viable progeny are consistently produced in the hatchery. *Corporeau* et al. [18.48] employed a proteomic approach to identify abundant proteins linked to oocyte quality in the Pacific oyster *Crassostrea gigas*, rather than measuring oocyte diameter or total lipid content. Ten proteins were found to be up-regulated in low quality oocytes, which included vitellogenin-breakdown products and metabolic enzymes, while six up-regulated proteins from high quality oocytes included the chaperone heat-shock cognate protein 70 (HSC70) and cell-cycle control proteins [18.48]. The authors of the study postulated that increased levels of HSC70 may ensure improved protein folding in two-cell embryos and enhanced protection of oocytes and early embryos directly exposed to environmental stresses such as oxidative stress and temperature fluctuations. Likewise, up-regulation of the putative cell-cycle control protein 14-3-3 ε may be important in oocyte cell-cycle control and enhanced protection of embryos, while proliferative cell nuclear antigen (PCNA) has been associated with processivity of deoxyribonucleic acid (DNA) synthesis during early development [18.48].

18.4.3 Animal Production

To ensure that an aquaculture enterprise remains profitable, it is important that the growth rate of the animals is optimized so that the time they spend on the farm is minimized in order to keep production costs relatively low and reduce the risk of loss to stress and disease. Maslinic acid (MA, 2α,3β-dihydroxyolean-12-en-28-oic acid) has been found to improve the growth rate of rainbow trout by increasing hepatic protein-turnover rates, elevating the hyperplasia level and augmenting liver glycogen content [18.49]. Indeed, *Fernández-Navarro* et al. [18.50] found that trout fed a diet supplemented with 250 mg MA per kg feed for 225 days exhibited a 29% increase in weight in comparison to control animals.

Since *Sparus aurata* is an economically valuable marine species for fish farming, the effect of MA supplementation on the liver proteome of this fish was tested under farm conditions [18.49]. Two-dimensional electrophoresis of total protein samples from the experimental and control groups showed that 49 protein spots were differentially regulated in fish fed the MA-supplemented diet for 210 days. MALDI-TOF/TOF analysis allowed unambiguous identification of 19 different proteins that play a role in metabolism of glucose (phosphoglucomutase 1, phosphoglucose isomerase, and *S*-adenosyl methionine-dependent methyltransferase class 1), lipids (17β-hydroxysteroid dehydrogenase type 4 (HSDH4)), amino acids (fumarylacetoacetate hydrolase, 4-hydroxy-phenylpyruvic dioxygenase, methylmalonate-semialdehyde dehydrogenase), and purines (urate oxidase), as well as detoxification and metabolism of xenobiotics (aldehyde dehydrogenase), oxidative stress (catalase and 6-phosphogluconate dehydrogenase), immune system (lysozyme chain A), protein synthesis (elongation factor 2 of eukaryotic protein synthesis), protein folding (Hsp60, 58 kDa glucose-regulated protein), signalling (kinase suppressor of Ras1 (KSR1)), and cytoskeleton formation (cytokeratin E7, intermediate filament proteins, KERII).

Fernández-Navarro et al. [18.50] proposed a signaling mechanism to explain how MA affected the liver of gilthead sea bream at the molecular and cellular level. The interaction between MA and its receptors, modulated by increased HDSH4, inhibits KSR1 expression and consequently activates the signal-transduction pathway mediated by Ras. This affects cellular functions such as glucose and other metabolism, detoxification and xenobiotic metabolism, oxidative stress, amino acid catabolism, nonspecific immune system, purine catabolism, protein synthesis and folding, and cytoskeleton proteins, leading to stimulation of growth, protein-turnover rates, total content of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and proteins, nicotinamide adenine dinucleotide phosphate (NADPH)-production systems, and antioxidant defence.

A similar approach was used to assess the effect of the glutamine precursor α-ketoglutarate (AKG), used as a dietary supplement, on the pituitary proteome of gilt-head sea bream [18.51]. The rationale for the study was based on the fact that pituitary hor-

mones regulate metabolism and somatic growth, which in turn, require a sufficient nutrient supply. Thus the aim of the study was to determine whether a feedback loop exists between nutritional status and pituitary hormone synthesis and secretion, since there is very little information available regarding the effect of dietary supplementation with AKG on the fish endocrine system. *Ibarz* et al. [18.51] found that AKG supplementation resulted in up-regulation of proteins such as fructose-bis-phosphate aldolase, glyceraldehyde-phosphate dehydrogenase and malate dehydrogenase that function in glucose metabolism. Proteins responsible for protein folding, such as two heat shock protein isoforms, cyclophylin and chaperonin, were also up-regulated, as well as cofilin and Vat-protein, which are involved in regeneration of neural function. On the other hand, an unusual apolipoprotein-A-1 and the hormone somatolactin were down-regulated in fish fed the AKG-supplemented diet. These observations led the authors to suggest that an endocrine/metabolic regulatory loop is, indeed, activated by AKG supplementation [18.51].

Since the muscle tissue of the fish is the portion that is consumed, it is important to safeguard the quality of farmed fish muscle tissue. Muscle quality is based on its composition, which is a function of the number and integrity of muscular fiber [18.52]. Since muscle tissue is central to many aspects of fish aquaculture, such as physiology, growth, food safety, seafood authentication and quality, traceability, and shelf-life, *Addis* et al. [18.52] conducted a study of the muscle proteome of *Sparus aurata* in which fish from four offshore floating cages and two re-population lagoons, located at remote sites from each other, were sampled on a two-monthly basis over a period of 22 months in order to investigate muscle proteome variability in relation to fish size and environmental conditions. Although the expression pattern of the muscle proteome was found to be relatively stable, the study revealed significant variation in the abundance of parvalbumins, troponins, and warm temperature acclimation-related protein 65 isoforms (Wap65) in relation to fish length and water temperature [18.52]. The authors also noted that structural proteins were more abundant in longer wild fish, while shorter farmed fish had an abundance of proteins involved in glycolysis. However, the muscle proteome was found to be comparable in wild and farmed fish of the same size, indicating that cage farming does generate high-quality fish for commercial production [18.52].

Similarly, since sea urchin gonads are a high-value seafood product, farmed sea urchins must be provided a quality diet to ensure gonad quality and quantity. Consequently, *Sewell* et al. [18.53] employed a proteomic approach to define the proteome of mature ovaries of the New Zealand sea urchin *Evechinus chloroticus*. The study successfully identified 138 proteins, of which only 12 were linked to ovarian reproductive function, and established a foundation for quantification of changes in expression of the ovary proteome which could be correlated with gonad quality and diet formulation [18.53].

18.5 Environment

As mentioned previously, the world's oceans occupy two-thirds of the earth's surface and harbor a vast diversity of microbes, plants, and animals. The marine environment plays an important role in regulating the earth's climate and in turn, the ocean's currents and temperatures are significantly influenced by climate [18.18]. Climate change is not only a serious threat to terrestrial environments, but is also impacting the marine environment and its inhabitants. Carbon dioxide emissions are directly responsible for ocean acidification and increased water temperatures, which in turn, leads to oxygen limitation [18.17, 54]. In addition, the large proportion of the human population living in close proximity to the coast has had a detrimental impact on the marine environment due to over-exploitation of biological resources and significant microbial and chemical contamination of coastal and near-shore regions [18.18, 55].

18.5.1 Climate Change

Ocean acidification (OA) affects marine organisms by disrupting acid–base regulation, respiration, energy turnover, and metabolism, as well as reducing growth rates, reproductive success, calcification, and sensory mechanisms [18.17]. Since climate change is responsible for increased temperatures and hypercapnia (elevated CO_2 levels), the negative effects on marine biota are likely to be interactive and cumulative [18.56].

Most marine invertebrates have a biphasic life cycle, where the fitness of the pelagic larval stage is responsible for the success of the benthic adult stage in that they must locate a suitable substrate for attachment and subsequent metamorphosis to the adult form, while simultaneously dealing with the cumulative effects of environmental stress imposed by climate change. Consequently, larvae that undergo settlement and metamorphosis may exhibit a more detectable proteome response to environmental stressors compared to the adult form due to their rapid development, greater susceptibility, and the complex developmental reprogramming that occurs in the proteome during the larval–juvenile transition [18.57]. Since barnacles are model organisms used in studies of larval development in intertidal benthic invertebrates, *Wong* et al. [18.54] investigated the effect of OA on protein expression in metamorphosing larvae of the economically and ecologically important barnacle *Balanus amphitrite*, which were cultured from nauplius to the cyprid stage under current and projected CO_2 concentrations for the year 2100. Two-dimensional polyacrylamide gel electrophoresis revealed proteins that were differentially up or down-regulated in response to OA which could be placed in three major functional groups: energy-metabolism, respiration, and molecular chaperones, possibly reflecting the strategy employed by the barnacle larvae to tolerate OA stress.

In a study investigating the effect of OA on *C. virginica*, the proteomes of mantle tissue samples obtained from animals exposed to normal ($\approx$39 Pa pCO_2) and hypercapnic ($\approx$357 Pa pCO_2) conditions were analyzed for changes induced by elevated CO_2 [18.58]. Proteomic analysis revealed 54 of the 456 proteins (12%) detected by 2D-PAGE were differentially expressed in response to hypercapnic conditions; 17 of the proteins responding to elevated CO_2 were identified and found to either be associated with the cytoskeleton or the oxidative stress response. *Tomanek* et al. [18.58] suggest that the mantel cytoskeleton is a major target of oxidative stress caused by elevated CO_2 levels which increase reactive oxygen species (ROS) either indirectly by lowering the pH of the organism and/or directly by interactions between CO_2 and other ROS to form more free radicals.

One consequence of climate change will be altered distribution patterns of fish and shellfish as a function of increased water temperatures [18.18, 55]. The Mediterranean blue mussel *Mytilus galloprovincialis* is an invasive species along the southern Californian coast, which has displaced the more heat-sensitive native species *Mytilus trossulus* [18.59]. *Tomanek* and *Zuzow* [18.59] investigated changes in the proteome of gill tissue sampled from the two congeners in response to acute heat stress (exposure to 24, 28, and 32 °C for 1 h, followed by a 24 h recovery at 13 °C) in order to detect responses common to both species as well as differences that account for the greater heat tolerance of the invasive mussel. The study found that the expression of proteins involved in molecular chaperoning, proteolysis, energy metabolism, oxidative damage, cytoskeleton, and deacetylation reflected a common heat stress response in both mussels, but also showed a lower sensitivity to high-temperature damage in the warm-adapted Mediterranean mussel, which may explain its increased range in warmer waters. For example, increased expression of a number of molecular chaperones occurred at a lower temperature in the cold-adapted *Mytilus trossulus*, which also seemed to be incapable of responding to heat-induced oxidative stress beyond 28 °C when nicotinamide adenine dinucleotide phosphate (NADPH)-producing pathways were found to be down-regulated in order to decrease the production of ROS via the electron transport chain [18.59].

The *Tomanek* and *Zuzow* study [18.59] was the first comparative investigation which identified systems-level differences in the proteome's response to acute thermal stress in a pair of congeners whose biogeographic ranges are in flux. In a follow-up study that investigated temperature acclimation (7, 13, and 19 °C for 4 weeks) in the two mussel species, warm acclimation was found to affect proteins that comprise the cytoskeleton and function in energy metabolism, which is consistent with increased filtration and respiration rates associated with increased culinary activity [18.60]. Increased levels of molecular chaperones were detected in *Mytilus trossulus* at 19 °C that were not evident in *Mytilus galloprovincialis*, reflecting differences in the long-term upper thermal limits of the congeners and suggesting that 19 °C is close to the chronic thermal limit of *Mytilus trossulus*. Although their data indicate that *Mytilus trossulus* may have a competitive advantage at colder temperatures, *Fields* et al. [18.60] suggest that their study shows why *Mytilus galloprovincialis* displaced *Mytilus trossulus* in southern California and indicates that climate change could increase this competitive advantage.

18.5.2 Pollution

Coastal and near-shore regions receive a steady influx of anthropogenic pollutants, which accumulate in

sediments and are a constant threat to the health of marine organisms [18.61]. Pollutants accumulating in coastal and near-shore zones affect marine animals by altering metabolic and developmental processes and, consequently, disrupting reproduction, modifying behavior, and decreasing disease resistance [18.55, 62]. Biomonitoring of marine pollution has been extensively used as a means of determining the extent of pollution. The rationale is that xenobiotic pollutants are biomagnified and accumulate in marine organisms, especially filter feeding invertebrates, in direct correlation to the concentration in which they occur in the environment [18.63]. Thus, pollutants can be quantified in tissue samples from key marine animals, referred to as sentinel organisms, living in the monitored environment [18.64, 65]. Bivalves are favored as sentinel organisms, since they are sessile filter feeders capable of accumulating high levels of xenobiotics, and consequently, they provide temporal and spatial information regarding the extent of contamination [18.64]. Since many biological and abiotic factors have been found to affect xenobiotic bioaccumulation, biomonitoring programs now include the use of biomarkers, such as metallothioneins, cytochrome P450, glutathione transferase, and heat-shock proteins, which specifically respond to xenobiotics encountered by sentinel organisms [18.63–66]. Even so, effective use of biomolecules as a means of monitoring marine pollution has its limitations, since their activity, which fluctuates naturally in response to biotic and abiotic factors, is governed by the route of chemical exposure (dietary or waterborne), the extent of bioaccumulation of the xenobiotic and detoxification mechanisms of the sentinel organism [18.64–66]. Consequently, *environmental proteomics* or *ecotoxicoproteomics* is increasingly becoming the biomonitoring tool of choice [18.63, 66].

The advantage of using proteomics for biomonitoring is that it provides information regarding the response of the entire proteome to the pollutant, thus identifying groups of proteins that respond strongly and specifically to particular pollutants [18.64]. In addition to establishing a protein expression signature (PES) specific to a particular xenobiotic, proteomics provides additional information that may elucidate the molecular processes and pathways that detoxify and catabolize particular pollutants [18.63, 65–67].

Ecotoxicoproteomics is already proving invaluable as a biomonitoring tool. *Liu* et al. [18.63] used a proteomic approach to investigate the effect of cadmium (Cd) on bioaccumulation of other heavy metals in four bivalves: the scallop *Chlamys nobilis*, the clam *Ruditapes philippinarum*, the mussel *Perna viridis*, and the oyster *Saccostrea cucullata*. Cd, which pollutes the marine environment through activities such as mining, mineral ore refining, electro-plating and fertilizers, is highly toxic to marine organisms as it results in oxidative damage by ROS and disrupts physiological processes involved with essential metal ions such as Ca^{2+} [18.66]. Although they found that exposure to cadmium influenced the bioaccumulation of other trace metals, Cd had little effect on the bivalve proteomes, and the identified proteins were insufficient to explain the observed disruption of trace element metabolism. Nevertheless, the PES could distinguish between clams and mussels that had accumulated different concentrations of Cd, and even though a PES for oysters and scallops was not obtained, the strong up-regulation of galectin in Cd-exposed oysters suggests that this protein has potential as a novel biomarker in environmental monitoring [18.63].

In another study, *Leung* et al. [18.66] investigated the proteomic response in hepatopancreas and adductor muscle tissue sampled from the green lipped mussel *Perna viridis* after a two-week exposure to Cd and hydrogen peroxide (H_2O_2), a persistent ROS linked to anthropogenic pollution such as dissolved organic matter and sewage disposal. Cd and H_2O_2 resulted in two unique sets of tissue-specific PESs and revealed that the former xenobiotic was responsible for endoplasmic reticulum and oxidative stress in the hepatopancreas and disrupted Ca^{2+} homeostasis in adductor muscle [18.66].

A study investigating changes in the proteome of the hepatopancreas of the blue mussel *Mytilus edulis* sampled from four sites in the vicinity of Gothenburg harbor, Sweden, generated a PES composed of 13 proteins that allowed the pollution-free site (Fjällbacka) to be distinguished from the 3 polluted sites [18.65]. Principal component analysis (PCA) and hierarchical clustering validated the discriminatory power of the PES and provided a spatial gradient from the polluted source.

Not only has proteomics proved invaluable for the discovery ofbiomarkers for monitoring environmental pollution, the technology has also been successfully used to investigate the effects of environmental pollutants on marine organisms, both in terms of their health and the health of seafood consumers. Mercury is a heavy metal pollutant that poses a danger worldwide as a consequence of its neurotoxic effect on fish and human brain tissue [18.68]. A report recently released by the Biodiversity Research Institute's Center

for Mercury Research stated that commercially important seafood such as lobster, tuna, and swordfish have muscle mercury concentrations (0.22–0.95 ppm, wet weight (ww)) that exceed the consumption guideline of one meal per month [18.69]. Since information regarding the molecular mechanisms of mercury neurotoxicity in fish is scarce, *Berg* et al. [18.68] conducted a proteomic study of Atlantic cod (*Gadus morhua*) brain tissue from fish exposed to methylmercury (MeHg) for 2 weeks after being injected intraperitoneally with MeHg at a concentration of 0.5 or 2 mg/kg. Although many of the proteins that were significantly expressed in response to MeHg had already been shown to respond to MeHg in mammals, confirming the validity of the data, the study also identified a number of proteins that have critically important, nervous system-specific functions that had never been associated with MeHg. These proteins included pyridoxal kinase (essential for the synthesis of several neurotransmitters), G protein (coupled to neurotransmitter receptors), nicotinamide phosphoribosyl-transferase (protects against axonal degeneration), dihydropyrimidinase-like 5 (axon guidance and regeneration), septin (dendrite development), phosphatidylethanolamine binding protein (precursor for hippocampal cholinergic neurostimulating peptide) and protein phosphatase 1 (control of brain recovery by synaptic plasticity) [18.68]. Not only has the data obtained from this study proved invaluable in confirming the involvement of a number of molecular processes associated with MeHg exposure and toxicity, but it also identified proteins that had not been investigated in the context of MeHg accumulation, which may prove invaluable as biomarkers of MeHg contaminated fish.

Endocrine disrupting compounds (EDC) are a diverse group of anthropogenic chemicals that are occurring in ever increasing concentrations in the marine environment. EDCs, thought to be responsible for the significant decline in many populations of aquatic species in a number of geographical locations worldwide [18.70], can be defined as [18.71]:

> *an exogenous substance or mixture that alters the function(s) of the endocrine system and consequently causes adverse health effects in an intact organism or its progeny or (sub)populations.*

EDCs interfere with hormonal function by binding to cytoplasmic oestrogen receptors and consequently, have been shown to affect sexual development, growth, osmoregulation, stress, and immune responses in fish [18.70, 72, 73]. Although the concentrations of nonylphenol mixtures (NPs) and bisphenol A (BPA) detected in polluted environments are much lower (<10 µg/L) than the median effective concentrations (EC_{50}) of these compounds for marine invertebrates such as adult *Mytilus edulis* and the adult cnidarian *Hydra vulgaris* (30 mg NPs/L [18.74] and 6.9 mg BPA/L [18.75], respectively), environmental concentrations of EDCs have been reported to affect the more susceptible larval stages of marine organisms [18.76]. Indeed, many invertebrate larvae settle on benthic diatoms that have been shown to biomagnify EDCs to levels greater than those in the environment, making them more likely to be harmful to the larval stage of marine organisms [18.77].

Since not much information is available regarding the effect of EDCs on marine invertebrate larvae, and since many of the life cycles of these animals include larval settlement and ingestion of benthic diatoms, *Liu* et al. [18.76] used a proteomic approach to investigate the effect of NPs and BPA on larval *Haliotis diversicolor supertexta* (a commercially important abalone from Taiwan). The study showed that toxicity of the EDCs towards the abalone larvae increased due to EDC accumulation by the diatom *Navicula incerta* that was used as a settlement substrate in the experimental setup. Larval proteins affected by EDC exposure function in ATP synthesis (down-regulated), the stress and defence response (up-regulated), metabolism, signal transduction (up-regulated), cytoskeleton (mostly down-regulated), and cilia formation (down-regulated) [18.76]. Consequently, Liu et al. [18.76] suggested that inhibition of ATP synthesis, actin, β-tubulin, and cilia formation protein could explain the malformations observed during embryogenesis and consequent failure of metamorphosis in *Haliotis diversicolor supertexta* larvae settled on *Navicula incerta* exposed to EDCs.

18.5.3 Population Proteomics

Marine fish populations are under severe pressure due to over-exploitation in conjunction with the effects of climate change and pollution, and consequently, it is becoming increasingly important that fish populations be accurately defined and characterized if wild fisheries and fish biodiversity are to be sustained and protected. Indeed, a United Nations report states that more than two-thirds of the world's fisheries have been overfished or fully harvested, and more than one third is in a state of decline due to lost habitats, increasing pollution levels, and climate change [18.78]. Although traditional population studies of marine fish have been conducted

using a genetics approach, proteomics may be invaluable to population biology and structure studies, since the proteome more accurately represents physiology and phenotypic plasticity [18.55, 79].

Gonzalez et al. [18.79] investigated the potential of population proteomics as a tool for detecting differences between populations of commercially important fish. Two distinct stocks of the European hake (*Merluccius merluccius*, Linnaeus 1758), namely an Atlantic Ocean and a Mediterranean Sea group, have been defined on the basis of genetic population studies. Two-dimensional DIGE and MS analysis of protein expression in liver and brain tissue samples from hake captured in the Mediterranean Sea, Cantabrian Sea, and Atlantic Ocean identified 84 and 145 protein spots in the liver and brain, respectively, that had significantly different expression levels between the three groups [18.79]. Using a variety of statistical tools, *Gonzalez* et al. [18.79] were able to reduce the number of proteins required to assign fish samples to a particular population group to just three, achieving a discriminant score of 90–100% accuracy. The study found that differences in the expression of two brain proteins, involved in cell signaling and metabolism/energy, discriminated between the three fish populations significantly better than differences in expression of the liver proteins, suggesting that brain protein profiles may more accurately reflect the functional adaptation of populations [18.79]. This study clearly demonstrates the value of population proteomics as a tool for defining and monitoring fish populations which are at a critical point in terms of ensuring the sustainability of the fishing industry and preserving the biodiversity of the oceans.

18.6 Natural Products

Antibiotic discovery in the twentieth century enabled treatment of diseases caused by previously untreatable infectious bacteria. However, the situation has changed dramatically over the past few decades with rapidly emerging bacterial resistance to antibiotics as a consequence of over-prescription and inappropriate use of antibiotics as prophylactics in farmed animals, including aquacultured fish and shellfish [18.80–82]. The problem has been exacerbated by a steady decline in the discovery of novel antibiotics, with just one new antibiotic class, the oxazolidinones, added to the approved list during the 1990s [18.80]. Traditionally, drug discovery from natural products has depended on high-throughput screening of microbial, plant, and animal extracts. The majority of bioactive compounds with medical applications such as antibiotics, anticancer therapeutics, anti-inflammatories, etc., have been obtained from microorganisms, particularly the filamentous bacteria belonging to the order Actinomycetales and filamentous fungi [18.83]. However, as stated earlier, the discovery of novel pharmaceuticals has significantly decreased due to frequent re-isolation of the same compounds. Since marine organisms comprise approximately half of the total biodiversity on earth, the marine ecosystem has the greatest potential as a source of novel bioactive compounds [18.82–84].

Since sessile marine invertebrates such as sponges, bryozoans, soft corals, seaweeds, and tunicates generally lack defence structures, they have developed a broad range of secondary-metabolites with novel molecular structures, and thus, are proving to be an invaluable source of novel pharmaceuticals [18.4, 84–87]. Interestingly, many of the bioactive compounds thought to be produced by marine invertebrates are, indeed, synthesized by endosymbiotic bacteria associated with these animals [18.85, 88]. The latter has broadened the potential of the marine environment as a source of novel therapeutics since the biodiversity of marine microorganisms is immense, especially when one considers that only 1–5% are culturable using standard laboratory techniques [18.89]. Consequently, metagenomics is a technique that has been adopted for screening for novel bioactive compounds from the marine environment, since it involves generating gene libraries from DNA isolated directly from environmental samples and screening the gene sequences in the libraries for those that may code for proteins with novel functions or structures [18.88, 90]. These candidates would be expressed in a heterologous host in order to produce sufficient quantities of the gene product for further analysis. Unfortunately, this approach is not simple, since many bioactive compounds are produced via multigene pathways, all of which would need to be cloned and expressed correctly [18.88].

A further complicating factor is that very low yields of cloned proteins are obtained due to poor levels of gene expression in heterologous hosts [18.89]. Although proteomics has great potential as a tool that

could assist in identifying novel bioactive proteins, proteomic techniques have not been utilized to any great extent in marine bioprospecting [18.4]. Nevertheless, there are a few studies which have employed a proteomic approach to identify or investigate bioactive products from marine organisms.

Evans et al. [18.91] employed iTRAQ as a means of characterizing and quantifying expression of the secretome of the marine bacterium *Pseudoalteromonas tunicate*. The bacterium, which is associated with marine eukaryotes, produces a broad spectrum of extracellular compounds that are active against invertebrate larvae, algal spores, diatoms, fungi, heterotrophic flagellates, and bacteria, and are thought to provide the bacterium with a competitive advantage in mixed communities [18.91]. The study compared the wild-type secretome to that of a transposon mutant that was no longer pigmented and did not produce the bioactive compounds as a consequence of a disrupted type-II secretion pathway. *Evans* et al. [18.91] found a range of cytosolic proteins and an ABC-transporter (ABC: ATP-binding cassette) that were significantly differentially expressed between the two strains. They were unable to determine the functions of ≈23% of the proteins comprising the *Pseudoalteromonas tunicate* secretome, and suggested that the type-II secretion pathway may play a role in iron uptake. The authors make the point that the data obtained from this study will lead to a better understanding of the regulation of pigmentation and production of the bioactive compounds in *Pseudoalteromonas tunicate*, as well as elucidate the strategies the bacterium uses to eliminate competitors and survive as a surface-associated bacterium in the marine environment [18.91].

It is essential that macromolecular targets of small bioactive molecules are identified in order to understand their mechanism of action and develop new pharmaceuticals. *Margarucci* et al. [18.92] used chemical proteomics [18.93] to investigate the target of petrosaspongiolide M (PM), a γ-hydroxy butenolide marine terpenoid isolated from the sponge *Petrosaspongia nigra* that has anti-inflammatory properties. The protocol involved chemically immobilizing PM by covalently linking the molecule to solid beads which are subsequently incubated with cell lysates. Proteins anchored to the beads are released, resolved by SDS-PAGE, and finally identified by LC MS/MS analysis [18.92]. The protein mixture eluted from the beads included a number of proteins known to comprise the ubiquitin–proteasome system responsible for degrading proteins involved in the cell cycle, apoptosis, signal transduction, and the NF-$\kappa\beta$ (nuclear factor) pathway. Since abnormal expression of the ubiquitin–proteasome system is responsible for many human diseases such as cancer, inflammation, cardiovascular diseases, and neurodegenerative disorders, *Margarucci* et al. [18.92] concluded that the ability to block proteasome activity using PM suggests that the molecule has great potential as a new lead therapeutic agent. Chemical proteomics was also used in two independent studies that showed that the eukaryotic translation initiation factor eIF4A is the target of pateamine A from the marine sponge *Mycale* sp., which is a potent cytotoxin against rapidly growing cells (such as P388 leukaemia cells; IC50 0.15 ng/ml [18.94]) [18.95, 96].

The genus *Conus* is comprised of ≈700 species of cone snails, which are carnivorous marine gastropods that use venom for defence, competition, and predation [18.97–100]. Their venoms, termed conotoxins or conopeptides, have been extensively studied due to the number and diversity of the neuropharmacologically active peptides they contain (50 to >1000 per species), which specifically target a broad range of therapeutically relevant receptors and ion channels [18.97, 99, 100]. Indeed, the drug Ziconotide (Prialt), derived from the venom of *Conus magus*, has been approved for treating severe chronic pain [18.101, 102]. A number of proteomic studies have been conducted to characterize the venom gland peptidome and proteome of cone snails in order to increase our understanding of conotoxin biosynthesis, maturation, secretion, and interspecies variation. A total of 161 and 157 proteins and protein isoforms were identified in the venom glands of *Conus novaehollandiae* and *Conus victoriae*, respectively, with a large fraction of the proteins found to function in protein/peptide translation, folding, and protection events [18.99].

In another study, *Tayo* et al. [18.97] used an LTQ-Orbitrap tandem mass spectrometer to investigate the venom proteome in the proximal, central, and distal portions of the tubular venom duct of *Conus textile* in order to elucidate the overall envenomation strategy employed by *Conus* species. 31 conotoxin sequences and 25 post-translational modification variants were identified following searches using SEQUEST (tandem mass spectrometry data analysis program used for protein identification) and ProLuCID (name of a tandem mass spectrabased protein identification program) for unmodified and post-translationally modified peptides, respectively. The study found both qualitative and quantitative differences in the conotoxin components sampled from the different sections of the

Conus textile venom duct and that post-translational modification variants significantly enrich the peptide pool for the combinatorial mechanism of envenomation, which may contribute to the production of toxin groups suitable to a particular predatory or defence requirement [18.97].

Since there is a paucity of information regarding the global protein content of injected venom, *Violette* et al. [18.100] used liquid chromatography electrospray ionization mass spectrometry (LC-ESI-MS) to analyze native injectable venom of *Conus consors* and coupled the data to extensive venom duct transcriptomic data to match the results and deduce nucleic and amino acid sequences. This approach resulted in identification of 105 components out of ≈400 molecular masses detected in the venom, which included new conotoxins belonging to the A, M, and O1-superfamilies, as well as a novel super family of disulphide-free conopeptides. The study demonstrated that it is possible to identify more than 100 peptides and proteins in injectable cone snail venom using a combined proteomic/transcriptomic approach and established a promising strategy for the discovery of novel therapeutics from cone snail venom [18.100].

18.7 Algal Toxins

Marine algal toxins are produced by unicellular algae that proliferate and/or aggregate to form dense concentrations of cells or *blooms* in response to favorable environmental conditions often associated with upwelling systems of the eastern boundaries of the world's oceans (Fig. 18.3) [18.103–105]. Only 2% (60–90 species, belonging to the dinoflagellate and diatom groups) of the 3400–4000 known phytoplankton taxa are toxic and responsible for more than 60 000 intoxication incidents per year worldwide, with an overall mortality rate of 1.5% [18.103, 105]. The incidence, geographic ranges, and variety of harmful algal blooms (HABs) and their toxins appears to be increasing, possibly due to increased anthropogenic nutrient loading and/or climate change [18.16, 103, 105]. HABs impact human health as a consequence of consuming contaminated seafood (such as filter-feeding shellfish), causing diseases which include paralytic shellfish poisoning (PSP), diarrhoeic shellfish poisoning (DSP), ciguatera fish poisoning, neurotoxic shellfish poisoning, amnesic shellfish poisoning, and azaspiracid shellfish poisoning [18.16, 103, 105]. Since vaccines to protect against dinoflagellate toxins have not yet been developed, prevention of HAB-related diseases relies on monitoring algal blooms and seafood, as well as surveillance of human populations for the incidence of disease [18.16, 105].

PSP is caused by consumption of shellfish contaminated with paralytic shell-fish poisoning toxin (PST), which is a mixture of saxitoxin analogs of approximately two dozen naturally occurring cyclic perhydropurine compounds that differ in their specific toxicities [18.106]. PSTs are produced by several dinoflagellates, particularly species belonging to the genera *Alexandrium, Gymnodinium* and *Pyrodinium* [18.106]. Although rapid identification of dinoflagellates present in a particular bloom would allow an accurate assessment of the potential health risk of the event, allowing appropriate contingency measures to be set in place, dinoflagellate identification is currently accomplished by light and scanning electron microscopy, which are both time consuming and complicated due to the difficulty associated with employing morphology as a sole criterion of unicellular algal taxonomic identity [18.107]. Consequently, *Chan* et al. [18.107] employed 2D-PAGE to generate proteome reference maps for nine species responsible for HABs off Hong Kong on the basis that the proteome of unicellular algae is simple and unique to each species. Species-specific

Fig. 18.3 Dinoflagellate bloom at Elands Bay, South Africa on 26th March, 2012. The bloom, clearly recognized by its red-brown color, consisted of *Alexandrium catenella* and a *Ceratium* species (photograph by C.J. Foord)

2D-PAGE protein profiles were obtained for all species and could be used to distinguish between closely related species belonging to the same family, confirming 2D-PAGE as an excellent monitoring tool for distinguishing dinoflagellate species comprising a HAB [18.107].

Since some dinoflagellate species are morphologically similar, and/or toxic and nontoxic varieties of the same species exist and sometimes even co-occur, the ability to use 2D-PAGE to differentiate between toxic and nontoxic variants of a species was investigated [18.106, 108]. Although the protein profiles of a toxic and nontoxic strain of *Alexandrium minutum* were essentially similar, reflecting the absence of significant morphological variation between the strains, pronounced differences were detected [18.106]. Thus, four proteins (designated NT1, NT2, NT3, and NT4) could be consistently detected in all nontoxic strains, while proteins T1 and T2 were associated with the toxic strains regardless of the culture conditions.

A similar study, employing a combination of 2-PAGE and MS was conducted on several strains of *Alexandrium tamarense* with different toxin compositions and originating from different geographical locations, identified several proteins that were always present in all toxic *Alexandrium tamarense* strains [18.108]. Interestingly, MS analysis indicated that the proteins associated with toxic *Alexandrium tamarense* are isoforms of the same protein, which shares amino acid similarity to that of T1 from toxic *Alexandriunm minutum*. Since the peptide mass fingerprints of these toxicity biomarkers were highly strain- and species-specific, differentiating between toxic and nontoxic strains as well as *Alexandrium tamarense* and *Alexandrium minutum*, the study has made a significant contribution to the complex task of monitoring HABs for toxic species. Indeed, the use of these toxicity biomarkers was validated by western blot experiments using a murine AT-T1-polycolonal antibody that detected all the toxic *Alexandrium tamarense* and *Alexandrium minutum* strains, but not the nontoxic *Alexandrium tamarense* strain [18.108].

Besides monitoring HABs in the ocean, it is also of utmost importance to monitor seafood destined for human consumption for toxin contamination. Although this may be accomplished using analytical techniques, the diversity of toxins and their analogs that may contaminate seafood makes this approach problematic due to the lack of specific standards and reference compounds required to ensure the accuracy and specificity of the protocol. Consequently, *Ronzitti* et al. [18.109] investigated a proteomics approach that would provide a functional assay for toxin-contaminated seafood by screening for toxin biomarkers in situ. They used 2D-PAGE to analyze digestive gland samples obtained from mussels harvested from four sites in the Adriatic Sea for biomarkers of contamination with okadaic acid and related dinophysis toxins, responsible for diarrhoeic shellfish poisoning in humans. Two proteins that correlated with okadaic acid contamination of the digestive gland samples were identified as a component of photosystem II and a subunit of NADH dehydrogenase, the former being identical to its counterpart in *Dinophysis* species that produce this group of toxins [18.109].

Ronzitti et al. [18.109] concluded that the photosystem II component originated from *Dinophysis* dinoflagellates ingested by the filter feeding mussels, and the amount ingested is reflected by the quantity of this protein which correlated with the degree of okadaic acid contamination of the mussel digestive gland samples (as determined by chemical analysis). Thus the study demonstrated the feasibility of biomarkers for monitoring seafood, where the biomarkers can either reflect the origin of the toxin (photosystem II component) or the animal's response to the toxin (NADH dehydrogenase subunit – possibly functions as a component of a protective response to the presence of a strong apoptogenic compound in the mussel digestive gland) [18.109].

Besides inducing diarrhoeic shellfish poisoning in humans after consuming bivalves contaminated with *Dinophysis* dinoflagellates, okadaic acid has been recognized as a general tumor promoter in various murine organs, including the skin, glandular stomach, and liver [18.110, 111]. Although the genes and signaling pathways affected by okadaic acid toxicity have been elucidated using a mouse toxicological microarray that identified a total of 177 differentially expressed genes [18.111], almost all the available knowledge concerning the toxicological mechanisms of okadaic acid has been obtained from in vitro assays. Furthermore, because the effects of okadaic acid on cell transformation, cell proliferation, and apoptosis vary considerably, the molecular events underlying the effects of okadaic acid are not well understood [18.110, 111]. Consequently, *Wang* et al. [18.110] employed 2D-DIGE and MALDI-TOF-TOF MS to investigate the acute toxicity of okadaic acid in mice at the proteomic level to further elucidate the molecular mechanism of okadaic acid-induced diarrhoea in mammals. Male Imprinting Control Region (ICR) mice were treated with 750 μg/kg okadaic acid, administered in a single dose by gavage, and protein profiles of the small intestines were de-

termined at four time points (0, 3, 6, and 24 h post-treatment). The study identified 58 proteins that were differentially expressed over the 24 h period which functioned in macromolecular metabolism, cytoskeleton reorganization, signal transduction, molecular chaperoning, and oxidative stress [18.110]. Although it has been known for some time that okadaic acid acts as an inhibitor of types 1, 2a, and 3 serine/threonine protein phosphatases (PPs), which results in the diarrhoeic effects as a consequence of the accumulation of phosphorylated proteins that regulate metabolism, transport, and secretion, the data obtained from the in vivo proteomic study suggests that okadaic acid toxicity in mouse intestines is complex and diverse, involving multiple proteins other than PP in the diarrheic process [18.110]. Indeed, the proteomic analysis revealed that okadaic acid toxicity interrupted cytoskeleton reorganization of intestinal epithelial cells, destroyed the digestive enzyme system by affecting lipid, amino acid, and sugar metabolism, induced oxidative stress, and simultaneously interfered with cell signal transduction in intestinal cells [18.110]. The authors suggested that villin 1 (cytoskeletal protein; down-regulated by okadaic acid) and hnRNP F (RNA binding protein that may function in apoptotic pathways; up-regulated by okadaic acid 3 h post-administration) may be key triggers that induce diarrhoea by interrupting cytoskeleton reorganization and cell apoptosis in the mouse small intestine, and thus, may be candidate biomarkers for acute okadaic acid toxicity [18.110].

18.8 Conclusion

It is clear that proteomics is a tool that will strongly influence all aspects of marine biotechnology, since it provides information on a scale that reflects the new omics era that is a hallmark of twenty-first century science. The technology is constantly improving, and as such, our ability to better understand the biology of marine organisms, their interactions with each other, and the environment will be enhanced by new developments in proteomics that are expected to be realized in the near future.

Goals anticipated to be achieved over the next 5 years include a 100 to 1000-fold increase in the sensitivity of MS-based protein identification that will allow characterization of biologically relevant, low abundance proteins; increased sensitivity will reduce the amount of sample required for proteomic analysis from 10^6 to 10^3 cells and eventually to single cells, while enhanced throughput of proteomics assays will allow the analysis of hundreds of specimens per day, which would be beneficial to research areas that investigate large numbers of samples such as in marine natural product identification and characterization [18.112].

Nagaraj et al. [18.113] used a high-performance benchtop quadrupole Orbitrap mass spectrometer to identify the majority of proteins expressed in the yeast *Saccharomyces cerevisiae* W303 MATα (an average of 4000 proteins per run), which allowed almost complete coverage of the yeast proteome in a few hours using a minute amount of sample (4 µg of peptide sample). Indeed, the proteomics field is said to be moving rapidly from a *second generation* state to a *third generation* phase where it is expected that MS-based proteomics will be routinely used to determine absolute protein levels as opposed to relative quantification, as is currently the case, and to characterize the dynamic response of entire proteomes in both space and time [18.114].

The development of new software that will allow integration of proteomics data with that obtained from next-generation sequencing and metabolomics will allow a systems biological approach to the study of marine organisms. Thus, proteogenomics is expected to provide a more holistic understanding of marine organisms, since proteomics data can be used to validate and annotate genome sequences as well as identify novel genes and pseudogenes which may be missed during DNA sequence annotation [18.3, 115]. The study of marine organisms will be elevated to an unprecedented level through the detailed information that will be gained with regard to their functional genetics, the regulation of these processes and in turn their metabolism, physiology, and interaction with the environment. This knowledge will significantly influence all aspects of marine biotechnology in that the impact of climate change and anthropogenic pollution on marine organisms will be understood in greater depth, the discovery of novel bioactive compounds will be greatly facilitated, aquaculture will benefit through a deeper understanding of reproduction, metabolism and stress leading to improved quality, survival and growth rates in farmed species, and most importantly, a greatly improved balance between exploitation and conservation of resources from the marine environment.

19. Marine Metagenome and Supporting Technology

Tetsushi Mori, Haruko Takeyama

Bacteria are known to be highly diverse and unique to the various environments they reside in. Covering more than 70% of the earth's surface, marine bacterial ecosystems in particular have long been regarded as reservoirs for novel and unique genes important to industry and pharmaceutics. In the first part of the chapter, we reviewed the importance and potential of bacteria from marine environments as an important genetic resource and some of the recent efforts in the implementation of marine metagenomic research to screen for genes applicable in bioprocesses, bioremediation and bioethanol production. Nevertheless, metagenomic research has also provided new challenges that will need to be addressed in order to use these resources efficiently. Here, in the second part of the chapter, we introduced several supporting technologies that show great potential in assisting metagenomic research to overcome such challenges including high-throughput screening using microfluidics, single-cell analysis and in silico data mining of metagenomic data. The introduction of such technologies, with metagenomic research, does not only allowed us to exploit these genetic resources to the fullest but may also provide new perspectives and insights towards living organisms and natural ecosystems.

19.1 Bacteria and Marine Ecosystems

Nature, as we know it, comprises various unique environments that have provided shelter and homes to diverse organisms. These unique environments have long been regarded as treasure boxes that have yet to be revealed and explored. It not only provides a unique environment to large vertebrates, invertebrates, plants, etc., but to microorganisms, including bacteria. Based on recent studies, it seems prominent that the bacteria present in each environment is highly diverse and their existence is not coincidental but instead they are comprised of microecosystems that are highly specific to the environment [19.1, 2]. It is, therefore, considered that bacteria living within these microecosystems harbor unique and novel characteristics that allow them to thrive and survive in their natural environment. The presence of these specific bacterial populations clearly indicates that they play a direct and crucial role either for the benefit of the bacteria themselves or for the environment they reside in [19.3]. In the exploration of the terrestrial environment, for example, mainly soil has led to the identification of numerous bacterial ecosystems comprised of diverse bacterial species [19.4–6]. The marine environment on the other hand, which covers more that 70% of the earth's surface, provides both mild and extreme conditions that allow the presence of bacterial species that harbor unique characteristics, which have evolved to thrive in such conditions. Although large collections of bacterial species are constantly being studied and identified, we are merely at the tip of

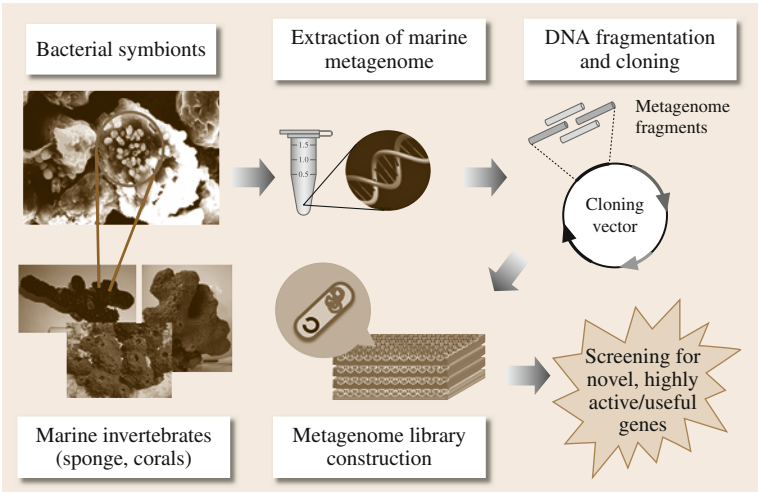

Fig. 19.1 Schematics of metagenome library construction from environmental samples

the iceberg and there is still much to be learned and discovered.

In the marine environment, bacteria in particular, are highly diverse and harbor unique and novel enzymes that are indispensable to research, pharmaceutics, and industry. Extracellular-polymer-degrading enzymes, DNA-modifying (DNA: deoxyribonucleic acid) enzymes and many others have been attained from bacteria in marine environments [19.7]. In addition, secondary metabolites or natural products that are of high pharmaceutical value have also been abundantly discovered from marine bacteria [19.8, 9]. Nevertheless, even with the availability of such unique resources, we still face the challenge of fully exploiting them due to a lack of technologies or techniques. Techniques for the bacterial culture have been and still are being introduced constantly, but it is regarded that culturable bacteria represent only $< 1\%$ of the currently identified bacteria, while the remaining $> 99\%$ are still considered as uncultivable. Thus, in this chapter we focus on metagenomic research, a tool introduced for the exploitation of novel and useful genes from bacteria, and the introduction of several tools that have been established to support metagenomic research.

19.1.1 Marine Metagenomic Research

As was briefly described above, the challenge for the extraction of novel and unique genes from bacteria surviving within the natural environment has been hindered due to the presence of uncultivable bacteria. Therefore, such a challenge has led to the introduction of a powerful tool that is currently known as metagenomics [19.10–12]. Metagenomics integrates molecular biology with genetics, enabling us to assess *nonassessable* genetic materials from the natural environment, thus, allowing the exploitation of such a resource to the fullest. The principle of this technique involves the extraction of genetic materials, such as DNA, directly from a pool of bacteria, regardless of their cultivability, and cloning them into cultivable hosts, namely *Escherichia coli*, resulting in the establishment of a *metagenome* library. The constructed metagenome library would then comprise millions of clones, individually harboring a random DNA fragment, which may potentially be comprised of useful and unique genes to be identified from subsequent large-scale screening of specific target genes via protein expression and functional analysis (Fig. 19.1).

Marine metagenomics, which describes the exploitation of samples from oceanic or marine samples, is supposed to have begun with initial work conducted by *Schmidt* et al., who proposed the idea to extract bulk DNA directly from picoplankton communities and to use the bacterial 16S small subunit ribosomal DNA (rDNA) as a reference to identify microorganisms in natural samples without the requirement of laboratory cultivation [19.13]. Subsequent work was followed by the exploration of bacterial diversity from larger pools of 16S rDNA sequences conducted by *Hugenholtz* et al. [19.1]. *Stein* et al. presented one of the first reports on the construction of a metagenome library using fosmids from marine picoplankton, but this research was directed at marine archaea [19.14]. In 2003, the Global Ocean Sampling Expedition (GOS) led by *Venter* conducted a global expedition to collect oceanic

metagenome samples among which one of their analysis conducted in the Sargasso Sea, resulted in the identification of at least 1800 different species, including 148 previously unknown bacterial phylotypes [19.15]. Based on these efforts, the application of marine metagenomic research has further expanded to other marine microorganisms, including viruses [19.16], archaea [19.17], and cyanobacteria [19.18].

In addition to the large amount of research conducted on marine ecosystems thus far, our research is mainly focused on bacteria associated with marine sponges collected from Ishigaki island, Okinawa, Japan. Bacterial symbionts were isolated from the marine sponges *Stylissa massa* and *Hyrtios erecta*, two species that are widely distributed on the ocean floor. Metagenome DNA was extracted from these sponges and 16S rRNA analyses of the diversity of bacterial symbionts and metagenome libraries were prepared. Based on the diversity of the analyses, it was observed that sponges show similarity in bacterial populations (phylum level) between individual sponges. As for the metagenome libraries, libraries comprised of DNA fragments in the range of 3–40 kbp were established, and subsequent gene annotation and in silico screening of useful genes via large-scale paired end sequencing also resulted in the establishment of a database. We would also like to introduce several unique and novel enzymes that have been discovered from marine metagenomes in the course of the work conducted by our research group.

Esterase Screening from a Sponge Metagenome Library

Esterases are enzymes that function in the breakdown of esters into alcohol and acid via hydrolysis and are regarded as potentially important enzymes of industrial value since they degrade natural materials, industrial pollutants, and toxic wastes. They can also be useful in the synthesis of drugs, cosmetics, and antioxidants [19.19]. Although numerous cultivable bacterial strains and species have been reported thus far, novel esterases showing high activity, thermostability, or unique characteristics are still in demand. In this study, we show the efforts to identify novel or unique esterases from a metagenome library constructed from marine sponge bacterial symbionts [19.20].

The sponge metagenome library MGSB3, comprised of 26 496 clones harboring DNA fragments of 3–5 kbp in size, was constructed from metagenomic DNA extracted from bacterial symbionts of the marine black sponge *Hyrtios erecta* collected off the coast of Ishigaki Island, Okinawa, Japan. Screening for esterase activity was carried out on agar plates containing Tween-20 and $CaCl_2$, in which screening of all the clones resulted in the identification of only one positive clone. Upon sequencing and further gene annotations, the clone harbored an approximate 3.4 kbp insert comprised of four putative open reading frames (ORFs). Among these ORFs, the third putative ORF had a 54% sequence identity with an arylesterase isolated from *Marinobacter aquaeolei* VT8 [19.21]. Designating the putative ORF as *EstHE1*, alignment of its encoded protein, EstHE1, amino acid sequences with several other esterases revealed that EstHE1 had the characteristic GDSLS amino acid consensus sequence (GDSLS: an amino acid residues considered as an important motif in the EstHE1 esterase) within its N-terminus and five distinct blocks of sequence homology to the GDSL family of esterases (GDSL: amino acid motif specific to the esterases) (Fig. 19.2a). In addition, the highly conserved catalytic residues Ser (S), Gly (G), Asn (N), and His (H) were identified in the conserved blocks, I, II, III, and V, respectively.

It is known that many esterases and lipases contain the pentapeptide motif GxSxG, which is well

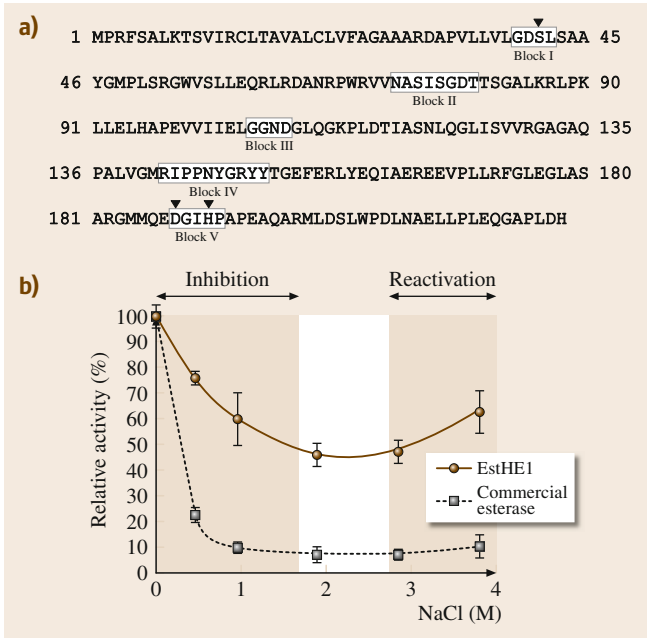

Fig. 19.2a,b The (a) structure and (b) relative activity of the esterase EstHE1

conserved among lipolytic enzymes [19.22], but enzymes conserved with the SGNH (SGNH: a motif representing amino acid residues) amino acid residues is seen in a new subfamily of hydrolytic/lipolytic enzymes [19.23–26]. These four residues are the namesake of the SGNH superfamily and utilize a different catalytic mechanism for hydrolase activity from that of common α/β-hydrolases [19.27]. While SGNH hydrolases are well represented in eukaryotic organisms, the isolation and characterization of SGNH hydrolases from bacteria is limited [19.27, 28]. This further suggests that EstHE1 may be novel, belonging to the SGNH hydrolases superfamily. Furthermore, a signal peptide (Met1-Ala29) was identified at the N-terminus of EstHE1, also suggesting that EstHE1 may function extracellularly.

For the biochemical characterization of EstHE1 esterase activity, the functional domain of EstHE1, excluding the signal peptide sequence was cloned, purified by nickel nitrilotriacetic acid (Ni-NTA) column chromatography, and identified by immunoblot analysis. EstHE1 was also proven to be an esterase rather than a lipase via a substrate specificity assay showing that the enzyme hydrolyzed chain-fatty acid substrates (C_6>) and not triglycerides or tributyrin (C_4). To determine the optimal temperature for esterase activity and to evaluate the thermostability of EstHE1, *p*NP-acetate was used as the substrate. The optimal temperature for EstHE1 activity was near 40 °C; however, the enzyme was active over a broad range of temperatures, retaining over 50% of its relative activity between 25−55 °C. The thermostability of EstHE1 was tested by incubation at 40 °C, whereby the retention of esterase activity was analyzed. EstHE1 retained more than 80% of its relative activity after 3 h at 40 °C, and 58% of its relative activity even after 12 h at 40 °C (Fig. 19.2b).

Since EstEH1 originated from marine bacteria, stability of the enzyme was also tested in various NaCl concentrations. Upon a gradual increase in NaCl concentration, enzyme activity showed a gradual reduction in esterase activity, eventually showing 55% of its activity at 1.9 M NaCl. However, as we further increased the salt concentration from 1.9 M to 3.8 M, esterase activity was recovered to 62% (Fig. 19.1). This result indicates that EstHE1 exhibits halotolerance, however, similar to the actinidain esterase found in kiwifruit, and increased salt appears to re-activate EstHE1 esterase activity [19.29].

As described above, the behavior of EstHE1 for halotolerance is very unique and its thermostability is desirable for application in the industry.

Cadmium Accumulation Protein from Sponge Metagenome

Heavy metals such as cadmium, lead, mercury, manganese, etc., are regarded as important industrial materials, if applied in the appropriate manner, due to their use in the energy and fuel production, the fertilizer and pesticide industry, and their applications in metallurgy, iron and steelmaking and electroplating. Nevertheless, the misuse or inappropriate handling of these metals can also result in generation of environmental pollutants that threaten human health and the ecosystem [19.30, 31].

In contrast to their organic counterparts, heavy metals are not degraded or destroyed. In developing countries, heavy metal pollution has become a problem since sanitary sewers are not equipped to treat toxic wastes [19.32]. Conventional techniques or technology to remove heavy metal ions such as chemical precipitation, filtration, ion exchange, electrochemical treatment, and membrane technologies have been introduced but the large-scale use of these technologies is hindered mainly because of problems due to high cost and low efficiency [19.33]. Therefore, such a challenge has been approached by the use of natural materials, termed biosorbents, including plants (mostly algae), fungi, yeast, and bacteria, resulting in the decrease of heavy metal ion concentrations in solution from ppm to ppb levels [19.34]. These biological systems, acknowledged for their low cost and high efficiency, have now resulted in the establishment of new technologies such as bioremediation and phytoremediation [19.35]. In addition, the use of useful genes for the expression of heavy metal accumulation proteins identified from various organisms or from metagenomic samples has also promoted this field [19.35, 36].

To contribute to the requirements of *environmental friendly* novel accumulation proteins or peptides, here, we focused our research on the screening of heavy metal accumulation genes from a metagenome library that was constructed from the marine sponge *Stylissa massa*. It is stated that 40% of the sponge body comprises of sponge-associated bacteria [19.37], and numerous antibiotics and important enzymes have been extracted from them [19.20, 38]. A total of approximately 3000 clones from the library were evaluated with the presence of cadmium (Cd), manganese (Mon), strontium (Sir), chromium (Cr), nickel (Ni), gadolinium (Gd), and selenium (Se). As a result, we were successful in identifying a novel Cd accumulation gene that showed unique protein structural features and Cd binding properties higher than the currently

known Cd accumulation proteins, metallothionein or phytochelatin. Currently we are in the process of analyzing the characteristics and properties of this novel protein.

Screening for Saline Tolerant Enzymes

Salt or saline tolerant enzymes have long been regarded as important enzymes required in industry, since many industrial processes are highly dependent on conventional salt removal steps that result in high-energy consumption. Thus, the isolation and use of salt-tolerant enzymes in such processes may greatly contribute to overcoming this problem. Several attempts have resulted in the isolation of salt-tolerant enzymes from microorganisms found in high saline marine environments. Serine hydroxymethyltransferase (SMTH), for example, commonly found in living organisms and is a key enzyme in the cellular one-carbon pathway. *Waditee-Sirisattha* et al. successfully identified this enzyme from the halotolerant cyanobacterium *Aphanothece halophytica*, expressed it in *Escherichia coli* and further showed that enzyme activity was promoted in the presence of high salinity [19.39]. *Mai* et al. on the other hand, successfully cloned a β-glucosidase from a marine streptomycete showing that the enzyme also showed remarkable activity enhancements under saline conditions [19.40]. In addition, salt-tolerant enzymes such as general stress proteins, enoyl-CoA hydratase [19.41] and bacterial lipolytic enzymes [19.42] have also been identified from metagenome library screening.

In our efforts, we have also been successful in identifying a gene encoding for the FtsH protein from our metagenome libraries. Upon comparison of the isolated FtsH protein with that of *Escherichia coli*, our isolate showed high saline resistant properties, suggesting the possibility of it being a novel enzyme originating from a marine bacterium. Although further functional analyses are in progress, the potential of this enzyme is promising, since FtsH proteins are known to function as crucial enzymes that play key roles in bacterial survival, and it has been suggested that it participates in several cellular processes, including protein assembly, export, and degradation [19.43, 44]. Further studies may provide important insights to the function of FtsH proteins in high salinity environments.

Potential of Marine Metagenomic in Bioethanol Production

Bioethanol is a renewable energy that has received much attention due to its potential in replacing current fossil fuel. Its production is dependent on biomass resources such as starch-based biomasses (corn, sugarcane), cellulose or lignocellulose biomasses (wheat grain), and marine biomasses (seaweed, microalgae). Although conversion of sugar to ethanol is relatively easy, starch-based biomasses conflict with the food industry. Thus, the latter two types of biomasses play a more important role in providing the resource for bioethanol production. Nevertheless, conversion of these biomasses to bioethanol is much more challenging. In countries like Japan, providing resources for land-cultivated biomasses is problematic due to limited land resources, but marine biomasses show greater potential. Marine biomasses grow relatively fast and produce a higher yield [19.45]. For example, *Laminaria japonica* (brown algae) yields six and a half times more than sugarcane. Nevertheless, although it has great potential, the conversion of marine biomasses to bioethanol is still challenging.

Marine biomasses, seaweed in particular, are composed of polysaccharides such as ulvans (green algae), agarans and carrageenans (red algae), and alginates, fucans, and laminarin (brown algae), which are required to be processed in order to be utilized [19.46]. Oligosaccharides from alginate, for instance, undergo saccharification by partial acid and alkali hydrolysis. These saccharification processes are complex and by-products can pose technical, environmental, and economic problems [19.47]. Thus, in order to overcome this problem, the use of polysaccharide degrading enzymes extracted from the environment has received much attention. Recent reports on the identification of novel genes encoding for enzymes such as porphyranases, agarases [19.48], ulvan lyases [19.49], cellulase, alginate lyase, laminarinase, and kelp-lyase [19.50] from various marine resources have shown that microorganisms may, in fact, provide an ideal source for the identification of highly active algae degrading enzymes to assist in the processing of marine biomasses.

Therefore, in order to attain highly active algae degrading enzymes, it is believed that the application of metagenomes from microorganisms can be very useful. As described above, by implementing metagenomic research, these enzymes can be fully exploited from both cultivable and uncultivable microorganisms. Furthermore, it is speculated that metagenomic research may play a major role and be of importance to this area of research.

19.2 Technologies Supporting Metagenomic Research

In the first part of this chapter, we described the advantages and new insights attained from metagenomic research, whereby the technology has opened doors to a new way to exploit environmental gene resources. Nevertheless, metagenomic research has also provided new challenges that will need to be addressed in order for us to use gene resources to their fullest. Two major challenges that have arisen from metagenomic research are 1) the techniques required for the screening of clones from large metagenomic libraries and 2) the approaches required to process or analyze the metadata attained from large-scale sequencing. Here, we introduce several supporting technologies that show great potential in assisting metagenomic research to overcome these challenges (Fig. 19.3).

19.2.1 High-Throughput Analysis/Screening of Metagenome Samples

Currently, metagenomic libraries can be constructed with the use of commercially available kits by introducing large fragmented DNA extracted from environmental samples into fosmids, cosmids, or bacterial artificial chromosome (BAC) systems. These libraries may comprise of tens to hundreds of thousands of clones that are required to be screened in order for a gene of interest to be obtained. Thus far, screening of target genes can be conducted mainly via polymerase chain reaction (PCR) analysis (genetic approach) or plate assays (functional approach). PCR analysis serves as a reliable tool if genetic information of the target gene is available, whereby degenerate primers can be specifically designed to amplify novel genes within a gene cluster or family. Plate assays, on the other hand, serve as a useful tool for the direct screening of genes based on the functional characteristics of the target gene. Although these conventional techniques have provided new information and novel insights on unique ecosystems for the discovery of novel proteins or enzymes of significant use, they are still incompatible for the exploitation of the potential of metagenomic samples. PCR analyses, for instance, can only be effective if sufficient information is available for the class of proteins that one is interested in. In the case of plate assays, it is rather challenging in the sense that in order to conduct screening for an unknown compound of enzymes, new assay development for the screening of these enzymes is required, which is very time consuming [19.51].

Therefore, in reference to these current techniques, it is clear that time and number is a very important aspect in the analysis of metagenome samples. In our group, in addition to metagenomic research, we have begun to include supporting technologies to assist us in optimizing throughput.

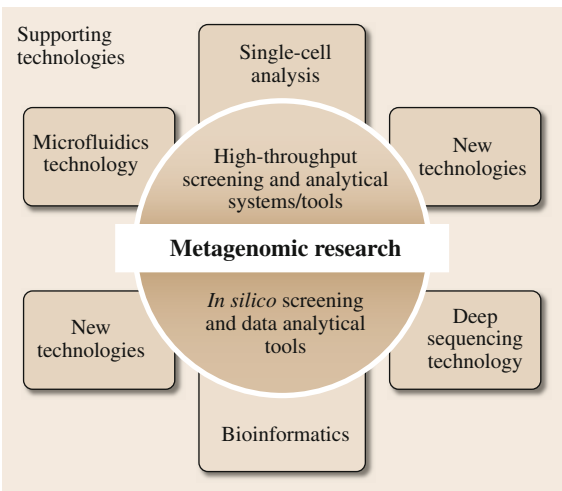

Fig. 19.3 Metagenomic research (core technology) and its supporting technologies

19.2.2 Increasing Throughput Using Microfluidics

Microfluidics is an area of research that has received much attention due to its ability to manipulate liquid flow at micrometer scale via devices that have been uniquely designed to include miniaturized pumps, mixers, valves, and channels [19.52, 53]. In recent years, this technology has niched itself to various fields ranging from synthetic chemistry and biology, right up to information technology. It also holds the promise of integrating an entire laboratory onto a single chip, termed lab-on-a-chip [19.54]. Among the various types of microfluidic systems, droplet-based microfluidics is a rapidly growing interdisciplinary field that has been shown to be compatible with many chemical and biological reagents, making it an ideal high-throughput platform for biomedical research, biotechnology applications, biochemistry, and many more [19.55]. Thus far, this technology has been applied in protein crystallization, biological assays against living cells, in single-cell

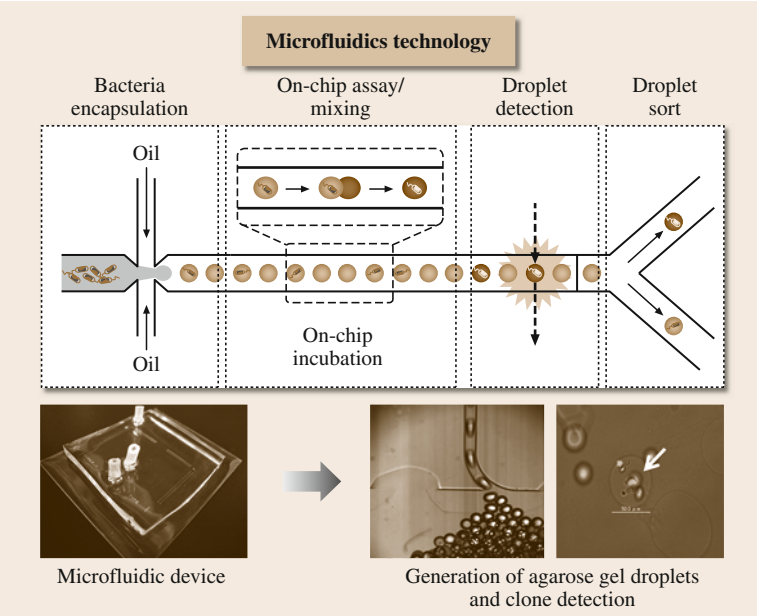

Fig. 19.4 Microfluidics technology and its application in metagenome library screening

analysis, and even in the cultivation of uncultivable bacteria [19.56–59].

Looking at the advantages of such a technology, we believe that metagenomic research can greatly benefit from it. In fact, some examples of microfluidics in the screening of enzymes and other related applications have recently been reported. *Aharoni* et al. showed the screening of paraoxonase (PON1) mutants for improved thiolactonase activity from a bacterial library by encapsulating each variant at the single-cell level using water-in-oil-in water emulsion [19.60]. Using this approach, they isolated a range of new PON1 variants that were catalytically active, approaching 100-fold higher than the wild type PON1. *Leung* et al. showed the development of a programmable droplet-based microfluidic device that can be tuned for various applications, including cell sorting, culture, PCR-based genotyping of bacteria, and whole genome amplification (WGA) [19.61]. They also showed the applicability of their system with environmental samples by showing taxonomic profiles from metagenomes of a marine enrichment culture, deep-sea sediments, and the human oral cavity. As such, our group is also focused on the establishment and development of droplet-based microfluidic systems, whereby we are currently establishing a system for the handling of single bacterial variants from metagenomic libraries directed towards the screening of intra and extracellular enzymes (Fig. 19.4).

19.2.3 Single-Cell Analysis

Metagenomic research has allowed us to identify unique and novel genes from pools of uncultivable and cultivable bacteria. However, the setback of this technology comes once a gene of interest has been identified; it is often the case where one may be curious to know more about the producer of the gene of interest. However, identification of the producers from metagenomic resources is not feasible particularly if one's interest involves novel genes where online database information is scarce. Therefore, with reference to metagenomic data or analysis, a new approach would be required to support this challenge.

Single-cell analysis is a field that was introduced to understand various biological phenomena such as cellular mechanisms, protein functionality, gene expression, etc., which occur within individual cells in a heterogeneous population [19.62]. Since its introduction, single-cell analysis has emerged as a technology that is constantly applied in genomics, transcriptomics, proteomics, and metabolomics [19.63–65]. Working in this field since its introduction, we have also assisted in the development of single-cell techniques for mammalian systems [19.66, 67]. Nevertheless, although the approaches introduced for single-cell analysis thus far have proven to be highly applicable and promising,

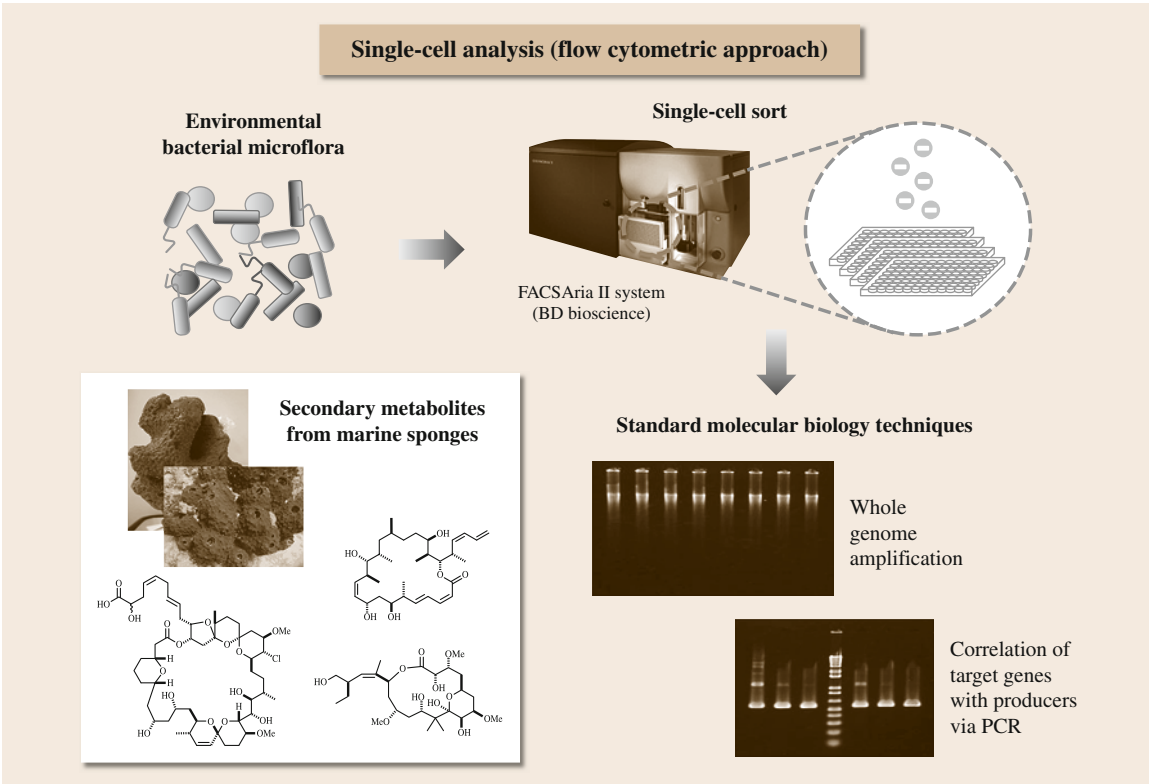

Fig. 19.5 Single-cell analysis in the identification of secondary metabolite producers

the majority has been directed at analytical studies on mammalian or eukaryotic cells. Currently, single-cell analysis has even expanded its application to the analysis of prokaryotes, using tools such as raman microscopy [19.68], flow cytometry [19.69], and microfluidic digital PCR [19.70].

In our group, we have established a single-cell analysis workflow using flow cytometry to investigate the producers of biosynthetic compounds from marine sponges (Fig. 19.5). Marine sponges are invertebrates that possess a chemical defense mechanism to survive in harsh ecosystems, resulting in them remaining the most important phylum, as they provide numerous novel biocompounds showing interesting biomedical potential, pharmaceutical relevance, and diverse biotechnological applications [19.71, 72]. Recent speculations however, suggest that such natural compounds may not originate from the sponge but instead from bacteria associated to them [19.73]. This theory is currently attracting considerable interest, since it shows that there may be interaction between host and bacteria in order for either to survive in such harsh environments. As a proof-of-concept in the establishment of our research, the marine sponge *Theonella swinhoei* was used as a model, with the research goal of identifying the bacteria symbiont producing the biocompound onnamide A as described by *Piel* et al. [19.73]. By utilizing flow cytometry, with the combination of molecular biology-based techniques such as multiple displacement amplification (MDA) and nested-PCR, we were successful in identifying the true producer of the biocompound. Our results suggest that the implementation of the single-cell approach was useful in allowing us to verify the producers of a desired enzyme or protein, thus allowing us to take the first step to combine such a method with metagenomic analysis to search for important or novel bacteria that could be of pharmaceutical or industrial value.

19.2.4 In silico Analysis of Metadata from Metagenome Samples

As was previously mentioned, in addition to the requirements for supportive technology in the screen-

ing of large metagenome libraries, technologies are also required for the analysis of the huge amounts of data generated by metagenomic studies. Already in the *post-genomic* era, in the past few years many of us have experienced the dramatic change from capillary sequencing approaches to the recent next-generation sequencing platforms. What was considered known already from capillary sequencing was the ability for one to identify sequences of new genes from unknown samples was completely changed with the introduction of deep sequencing platforms such as the 454 (Roche), Solexa (Illumina), SOLiD (Applied Biosystems), HeliScope (Helicos), PACBIO (Pacific Biosciences), and Ion torrent (Life technologies) [19.74, 75] systems. These platforms can generate giga or terabases of sequencing reads in an equal amount of time to capillary sequencing, allowing not only genes but genomes of organisms be sequenced in a matter of days or weeks. In addition, software and techniques have also been developed to support the vast amount of data generated by these sequencing platforms [19.76]. Even in metagenomics, several analytical and annotation tools such as the meta genome analyzer (MEGAN) [19.77] and the metagenomics RAST server (MG-RAST; RAST: rapid annotation using subsystem technology) [19.78], and databases such as the Genomes OnLine Database (GOLD) [19.79] and Genomic Encyclopedia of Bacteria and Archaea (GEBA, http://genome.jgi.doe.gov) project have been established to assist researchers in their respective metagenomic analyses and studies.

In our group, we have taken approaches to analyze the data attained from metagenome sequencing (approximately 110 Mbp) by conducting in silico screening for homologs to 45 enzymes that are of industrial value. Using analysis of homologs at $> 80\%$, $50–80\%$, and $< 50\%$ similarity against a total of 4075 genes, hits rates were 1%, 29%, and 70%, respectively.

19.3 Summary

To summarize this chapter, it is clear that since the very first introduction of metagenomic research for the analysis of various natural environments, not only have we gained new insights or discovered numerous new and novel genes that are of great use, we have also come to realize that new technology and techniques are required for the field to grow further. High-throughput analytical systems, such as microfluidics and single-cell analysis are just some examples of technology that have shown its potential in supporting the rapidly growing metagenomic research field. With the rate at which the amounts of data are being generated, it is almost certain that in the very near future, and with the support of bioinformatics, methods or software for data processing and analysis will also be required. Judging from the rate at which the field is expanding and evolving, our perspective towards living organisms or natural ecosystems will certainly change drastically.

20. Microfluidic Systems for Marine Biotechnology

Morgan Hamon, Jing Dai, Sachin Jambovane, Jong W. Hong

During the past decade, rapid progress in physics, electronics, and material sciences has facilitated the development of miniaturized microfluidic systems, also known as Lab-on-a-Chip (LOC), that represent the next generation of analytical laboratories, miniaturized to be held in one's hand. Microfluidics has appeared as a concrete alternative than can address problems and overcome limitation in various biological and chemical domains, including stem cell research, drug discovery, and food sciences just to name a few, and has proven to be more than state-of-the-art techniques. Microfluidic techniques provide accurate and fast results with small amounts of reagents and can bring various analytical tools for in situ studies. In this chapter, we describe some of the systems developed to overcome the limitations of conventional marine biotechnology processes.

Occupying three-fourths of our planet, oceans are vital to human beings [20.1], providing us in kelp, food, recreation, mining, natural resources (such as gas and oil), shipping and transportation, and biomedical and cosmetic products; more than 80% of the Earth's living organisms are found only in marine ecosystems [20.2] and about two-thirds of the world's population live within 100 km of the coastline [20.3]. Although the importance of seas on our lives is evident, marine ecosystems remain relatively unknown, underexploited and under-protected compared to those from terrestrial and freshwater environments. In this context, marine biotechnology aims to develop technologies to enable scientists to differentiate sea populations, to address emerging diseases to protect fishery and ecological resources, and to discover the life-enhancing and lifesaving properties these populations possess, while identifying sources of ecological stress to develop strategies to protect and restore coastal resources and ensuring the safety of the seafood we eat.

In this chapter, we will discuss how microfluidics can provide cheap and portable systems to help marine biotechnology to study marine ecosystems, to protect human health and safety, and to provide resources for research, using a reduced amount of samples in a shorter time when compared with conventional methodology.

20.1 Basic Principal of Microfluidics

Microfluidics encompasses many multidisciplinary areas, including physics, chemistry, engineering, and biotechnology. More precisely, it deals with the science and technology of systems that manipulate very small fluid volumes, 10^{-9}–10^{-18} L, through channels with dimensions in the range of tens to hundreds of micrometers [20.4]. Microfluidics emphasizes many advantages compared to conventional fluidic handling and may be summarized as follows: lower consumption of sample volumes, less reagent wastage, cost savings of samples, faster reaction times, faster diffusion, quick heating and cooling, better process control, and integration of reaction steps on a single chip [20.5, 6]. Integration is the key part of microfluidics, and integrated microfluidic systems manipulate very small fluid volumes in micro/nanometer scale channels for the automation and integration of many biological or chemical processes [20.4]. However, the integration aspect of microfluidics is still very young, and hence to fully utilize the above-mentioned advantages further engineering innovation of different strategies and optimization processes is required [20.4].

The seed of microfluidics started around three decades ago with the development of gas chromatography and the inkjet printer [20.5]. Since then a significantly large number of applications of microfluidics has been successfully demonstrated for chromatography, electrophoretic separation systems, electro-osmotic pumping systems, diffusive separation systems, micromixers, deoxyribonucleic acid (DNA) amplification, cytometers, and chemical microreactors, nearly in chronological order [20.6]. In recent years, integrated microfluidic systems have captured diverse application fields such as flow cytometry [20.7], protein crystallization [20.8], DNA extraction [20.9], digital polymerase chain reaction (PCR) amplification [20.10], stem cell culture [20.11], and for synthetic ecosystems consisting of *Escherichia coli* populations [20.12], determination of enzyme kinetic parameters with a single experiment [20.13], dose response analysis [20.14], catalytic competence analysis [20.15], and cytotoxicity analysis [20.16].

The field of microfluidics has many peculiar features from physics and chemistry, and because of this the above-mentioned advantages of microfluidics could be exploited successfully and few of these features are explained below.

20.1.1 Laminar Flow

Laminar flow consists of well-streamlined flow where particles move parallel to the direction of flow. The flow inside the microfluidic channels is characteristically laminar. The presence of laminar flow inside the microchannel is decided by the value of Reynolds number and by ensuring the parabolic velocity profile (Fig. 20.1a).

20.1.2 Surface Area to Volume Ratio

Surface area to volume ratio (SAV) could be defined as the ratio of surface area to the volume of fluid under consideration. In microfluidics, SAV increases significantly with a decrease in channel dimensions. A higher SAV value increases the rate of reaction and heat transfer. A higher SAV value creates adsorption of

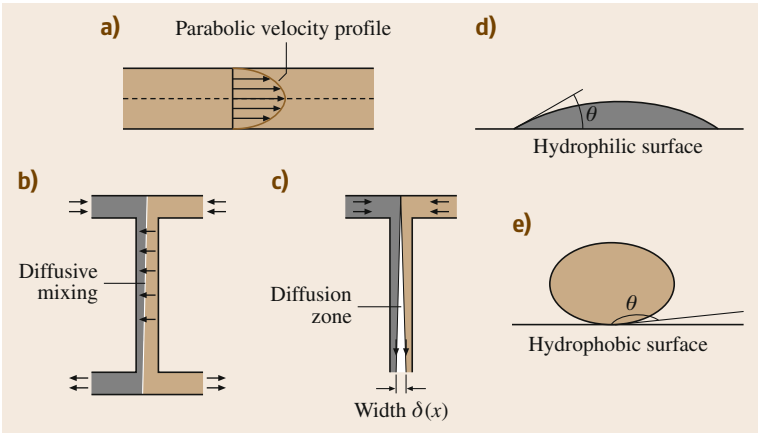

Fig. 20.1 Physical features involved in microfluidics. **(a)** Laminar flow in microchannel, **(b)** diffusion between two coflowing fluids, **(c)** diffusive mixing between two co-flowing laminar flows, **(d)** droplet on hydrophilic surface, **(e)** droplet on hydrophobic surface

macromolecules to the channel wall. A higher SAV of liquid in the microchannel helps in conducting efficient capillary electrophoreses.

20.1.3 Diffusion

Diffusion arises when two fluids with a concentration gradient come into contact with each other (Fig. 20.1b). In microfluidic systems, diffusion is an inefficient way of mixing two or more fluids because of the presence of a laminar regime. Mixing at microscale mainly occurs by the process of diffusion and due to the absence of turbulence.

20.1.4 Mixing

In microfluidics, quick mixing of fluids flowing through the microchannel is one of the key challenges. In the microchannel, the Reynolds number is very small due to the smaller channel dimensions. In the laminar flow regime, mixing of fluids occurs mainly by diffusion and, hence, happens very slowly (Fig. 20.1c). To solve this problem, various micromixers, such as chaotic flow micromixers, electrokinetic micromixers, peristaltic micromixers, etc., have been developed in recent years [20.17–21].

20.1.5 Wetting

Wetting is an interfacial phenomenon due to the balance of surface energies at gas-liquid-solid interfaces. The value of contact angle (θ) determines the type of wetting on the surfaces, viz. hydrophilicity and hydrophobicity. The behavior of fluid wetting on hydrophilic and hydrophobic surfaces is shown in Fig. 20.1d and e, respectively. The principle of wetting is exhaustively used in droplet-based microfluidic devices [20.4, 15].

20.2 Microfluidic Devices for Marine Biology and Ecosystem Studies

A major challenge in the field of marine biotechnology is to develop an efficient procedure for the discovery of novel biomolecules in the marine environment or marine bioprospecting. Because of the high level of biodiversity of marine organisms, an understanding of marine biology and ecology is an important first step to the discovery of new active molecules.

20.2.1 Microfluidics for Cell Analysis (RNA Amplification, Single-Cell Analysis, and Fish Embryology)

In this part, we will describe how microfluidic systems can be used to study marine organisms at different levels: molecular (genomics), cellular, and multicellular (tissues and the whole organism).

Genomics

Genome sequencing is a powerful tool that can be applied to explore the genetic materials of organisms, such as microorganisms [20.22–24]. Recently, single-cell genomics (SCG) emerged both as a potent complement to cultivation and metagenomics [20.25] and as an independent analytical tool [20.26, 27], by providing genomic information and delivering unequivocal information about the organization of the genes discovered within genomes [20.28–34]. However, to obtain high-quality SCG, expensive and large instrumentation (e.g., cell sorters, robotic liquid handlers, DNA sequencers) and infrastructure (clean rooms, high-performance information technology (IT)) are required, which limit their use in most individual research groups. Microfluidic technology provides an alternative to conventional methods, offering numerous advantages including automation, enhanced sensitivity and reaction efficiency in small volumes [20.35, 36], and the potential for scalable and cost effective small volume assays [20.37] that can be used for genomics (Fig. 20.2a) [20.9, 38]. It effectively addresses the three classes of contamination with the potential to compromise single-cell amplification reactions: the laboratory environment, amplification reagents, and cells/DNA from the sample itself [20.39]. Microfluidic devices produced by *Blainey* et al. illustrate the capability to perform SCG analysis on a chip [20.39]. The device, shown in Fig. 20.2b, originally developed by *Marcy* et al. [20.26], was used to perform multiple displacement amplification (MDA) reactions with nanoliters of reagent. The microfluidic chip was composed of 32 microchambers implemented with a laser tweezer system [20.40, 41]. A mixture of ammonia-oxidizing archaea (AOA) microorganisms was introduced into the device. Single cells, smaller than 1 μm, were selected upon microscopic inspection and then guided with a laser trap

into separate chambers, where each sorted cell was lysed individually. The genome of each individual cell was then amplified by MDA in 50 nL volumes [20.29]. Amplified genomic DNA from each cell was then separately recovered from the chip and sequenced by high-throughput DNA pyrosequencing. Combining SCG genome amplification with metagenomics, *Blainey* et al. sequenced and identified the genome of *Candidatus Nitrosoarchaeum limnia* SFB1, an AOA from low-salinity sediments in San Francisco Bay, using single-cell and metagenomic genome sequence data [20.39]. Another interesting example demonstrates the possibility of combining different genome analysis techniques in the same chip for marine cell genome analysis. *Leung* et al. [20.42] developed a microfluidic device capable of running multiple single-cell applications, such as phenotypic sorting of bacteria followed by clonal analysis of growth rates, taxonomic identification of single bacteria by small subunit ribosomal ribonucleic acid (RNA) gene quantitative PCR (qPCR) and sequencing, and high-throughput single-cell whole genome amplification (WGA) and sequencing. Interestingly, this device, shown in Fig. 20.2c, combines a programmable droplet-based microfluidic device with the reconfigurable flow-routing capabilities of integrated microvalve technology. It is composed of 95 individual microchambers, a reagent-metering module, a cell-sorting module, and an integrated nozzle that allows for automated recovery of on-chip reaction products without cross-contamination. A three-valve peristaltic pump is used to deliver arbitrary picoliter droplets of eight separated reagents in discrete increments from eight separate inlets. Reagent droplets are dispensed directly into a flowing stream of carrier fluid; delivered to a selected storage chamber it merges with any previously dispensed droplets. When a cell of interest is identified, it is pumped into a droplet and delivered to a microchamber where it can be analyzed by qPCR and WGA. This device was used to analyze the genome of single cells and microbial consortia from diverse environmental samples, such as marine enrichment cultures and deep-sea sediments.

Cell Analysis

A variety of analytical methods have been deployed to identify and study populations of marine microorganisms with a view to understanding both the organisms and their behavior. Optical microscopy is generally used to study marine microorganisms but the large ratio between the size of the target cell and the size of the culture system (plate, petri dish, or tube) makes the study labor intensive and time consuming. In the early 1980s, flow cytometry was introduced as a complementary technique to analyze mixed microbial populations [20.30, 31, 45]. However, the high cost and the large size of the apparatus limited its use as a standard tool for laboratory-based research and in situ analysis. Toward the realization of a portable and affordable microfluidic cytometer, *Benazzi* et al. [20.46] have developed a microfluidic chip capable of high-speed analysis of phytoplankton. The chip was made from a glass substrate with planar microelectrodes patterned on the surface. A microfluidic channel made of polydimetylsiloxane (PDMS) was bonded on the surface of the patterned glass substrate, perpendicularly to the microelectrodes. The chip was placed above a microscope objective and the cells were pumped into the microchannel with the use of a syringe pump. The phytoplankton flowed through the detection zone where optical and electrical properties were measured simultaneously. When a mixture of different species of phytoplankton (here *Synechococcus* sp., *Rhodosorus m.*, and *I. galbana*) were introduced into the chip, measurement of the optical properties differentiated cells in function of their autofluorescence, while electrical

impedance, measured at different frequencies, characterized the cells in function of their size and the capacitance of their membrane. The results obtained by this microfluidic flow cytometer were comparable with those obtained with a commercial flow cytometer, and the low-frequency electrical impedance signal used to size the particles was analogous to the forward scatter signal obtained in a flow cytometer. However, the mi-

croflow cytometer, with its present dimensions, was not able to measure particles with sizes $< 2\,\mu m$.

In addition to the distinction between the different cells in the same solution, microfluidic technology can be used to separate cells with different characteristics to study their functions. *Sasaki* et al. [20.47] developed a microfluidic device to separate bioluminescent bacteria in function of their motility. The device is made of PDMS and composed of two inlets connected to two separated channels that merged in one main channel. The end of the channels, which is 35 mm long, was split into two channels connected to two outlets. This configuration of the microchannel allows the formation in the main channel of two parallel flows, each coming from a different inlet, without mixing the two liquids. *Sasaki* et al. used this property to separate luminescent *Photobacterium kishitanii* bacteria according to their motility [20.47]. The cell suspension was introduced in one inlet and filtered liquid broth in the other. In the main channel, motile bacteria swim and crossed the flow to reach the liquid broth while nonmotile cells remain in the cell suspension flow. Suspensions collected from both outlets were analyzed. The luminescent intensity of the separated samples was measured using a luminometer. The luminescent intensity per cell was calculated. The result was that the value from the mobile (swimmers) bacteria was larger than the nonmobile cells (nonswimmers).

So far, very few systems have been used to study marine cells. However, other microfluidic reactors have been developed to analyze the cell proteins from multiple or single cells [20.37, 38, 48–51], which could be used in marine biotechnology.

Tissues and Whole Organisms

Fish embryogenesis-based biotechnologies have various promising applications in the field of marine biotechnology, from commercially valuable fish production to threatened marine species protection [20.52]. Conventionally, handling of embryos, treatment, and analysis are performed manually, in 96–384 microtiter plates, [20.53–56] and combined with laborious imaging methodology [20.57]. Under such conditions, analysis and imaging of fish embryos and juveniles in a high-throughput and high-content manner remains challenging [20.53, 55, 57, 58]. These limitations can, however, be overcome with miniaturized LOC technologies that can provide an automated platform for the manipulation and immobilization of micron-sized organisms [20.53, 59–62] and for high-throughput screening [20.63]. Recently, several microfluidic-based methodologies have been developed that involve droplet-based microfluidic systems [20.43, 64] or continuous-flow systems [20.44, 65–68]. Droplet-based microfluidic systems were the first technology to be used for controlled fish embryogenesis. In 2006, *Funfak* et al. studied the behavior of multicellular systems, in particular embryonic development in a microfluidic system [20.43]. The system, which is schematically represented in Fig. 20.2d, is composed of a Teflon microtube in which fish eggs in aqueous solution are introduced into the tube, perfused with immiscible perfluoromethyldecalin (PP9), resulting in droplets containing one single embryo each. The development processes of fish embryos were observed over a time period of 80 h. Finally, after 5 days, the fish larvae were collected from the droplets and transferred into breeding reservoirs for further experiments. More recently, *Akagi* et al. introduced a miniaturized embryo array that automatically traps, immobilizes, and perfuses fish embryos [20.44]. The device, which is shown in Fig. 20.2d, is composed of a serpentine channel that contains embryo traps (where embryos are trapped and immobilized), suction channels (to attract embryos in the embryo trap), and hydrodynamic deflectors (to enhance embryo trapping). Embryos were loaded in the chip one by one every 5 s. After entering the serpentine channel, embryos rolled on the bottom surface of the main channels under the influence of drag force. Embryos approaching an empty trap were affected by the flow passing through the suction channel and directed toward the trap, which was designed to assure single-embryo occupancy, and unobstructed passage of other embryos in the main channel. The following embryo rolled freely in the serpentine channel toward the next available trap. The process was repeated until all traps were occupied. After loading, the chip was perfused for long-term culture (up to 72 h), and normal and uniform development of all embryos was observed. Although most microfluidic technology techniques for fish embryological studies were performed on *Danio rerio* (a freshwater fish), one can easily transpose those techniques to marine fish embryogenesis studies and engineering.

20.2.2 Microfluidic Systems for Cell Behavior Studies

In the last decade, microfluidic systems have been widely used for the study of cell behavior, mainly with respect to how cells sense mechanical, electrical, and chemical signals, and for the measurement

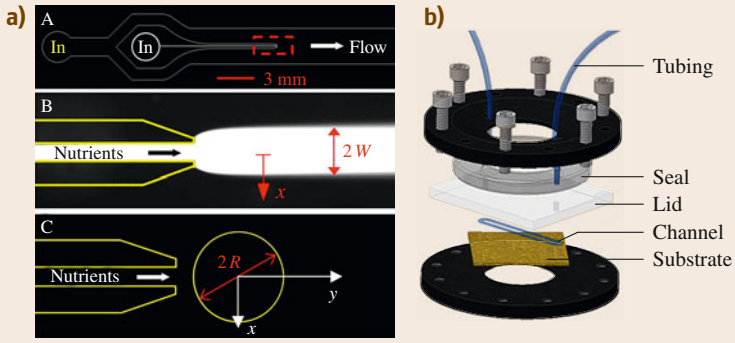

Fig. 20.3a,b Microfluidic system for cell behavior studies. **(a)** Microfluidic system for the study of marine bacteria motility response to microscale nutrient patches (after [20.69]). **(b)** Microfluidic setup for the study of marine bacteria biofouling on modified substrate (after [20.70])

of events and their biological responses surrounding and within cells. More specifically, the study of cell behavior in microfluidic systems includes: cell growth [20.11], differentiation [20.71], signal transduction [20.72], protein secretion and transport [20.73], gene expression [20.74], cell and extracellular matrix behaviors [20.75], and cell cytoskeleton dynamics [20.76]. Applied to marine microorganisms, microfluidic systems have been successfully developed for the study of cell behavior. For example, to investigate how marine bacteria are capable of exploiting ephemeral nutrient patches generated at environmentally realistic spatiotemporal scales, *Stocker* et al. [20.69] used a simple microfluidic system (shown in Fig. 20.3a) that creates two types of patches (a purely diffusive pulse and a plume governed by diffusion and advection) with spatial and temporal scales consistent with those expected in the ocean [20.77]. By simultaneously measuring the spatiotemporal distribution of nutrients and cells, they quantified the nutrient exposure experienced by chemotactic marine bacteria, indicating that the response time scale of opportunitrophs can be commensurate with patch evolution time scales, enabling the utilization of a wide range of patchily distributed nutrient resources in the ocean.

Arpa-Sancet et al. developed a microfluidic system to quantify the adhesion of marine bacteria [20.70]. The quantification of bacterial adhesion is of major importance for the understanding and support of the development of new materials with environmental or medical applications. For marine application, the colonization of submerged surfaces (artificial or natural) by undesired biological organisms is a major problem for many marine industries, which results in environmental and economic penalties [20.78–80]. With increasing restrictions in the application of biocidal antifouling, fouling-release (FR) coatings are currently considered as an alternative. Bacteria are among the first microorganisms to colonize submersed interfaces to form biofilms [20.78] that will influence subsequent colonization by invertebrates, algae [20.81], and tube worms [20.82, 83], resulting in fine in ship damage [20.84]. The microfluidic chip is composed of a single microchannel in PDMS sandwiched between a glass window and the coated surface, as shown in Fig. 20.3b. The window, the channel, and the sample of interest were mechanically held together by two disks connected by screws. Different shear stresses were generated by flowing liquid in the channel at different pressure (between 0.002−700 Pa, resulting in shear stresses between 0.02−7000 dyn/cm^2). Observation with an optical microscope showed that in these conditions, bacteria detached when a shear stress between 40−200 dyn/cm^2 was applied. To quantify bacteria adhesion, microfluidic assays have a number of advantages: the adhesion strength can be quantified on relatively small sample areas with only small amounts of bacteria in a very short time (few hours), and different substrates can easily be tested in parallel. The main advantage of a microfluidic assay lies in the possibility of analyzing the effect of the variation of the shear force across several orders of magnitude on the adhesion on the substrate of each single cell [20.85–87].

Microfluidic Systems for Water Analysis

Seawater analysis is essential in marine biology for the exploration and classification of underwater environments, particularly when investigating the distribution and diversity of microbial communities, underwater marine geology [20.89], and various other marine biotechnology-based industrial applications, including civil and environmental monitoring, soil and geotechnical engineering, plant and crop science, food, and bio-based and industrial chemistry.

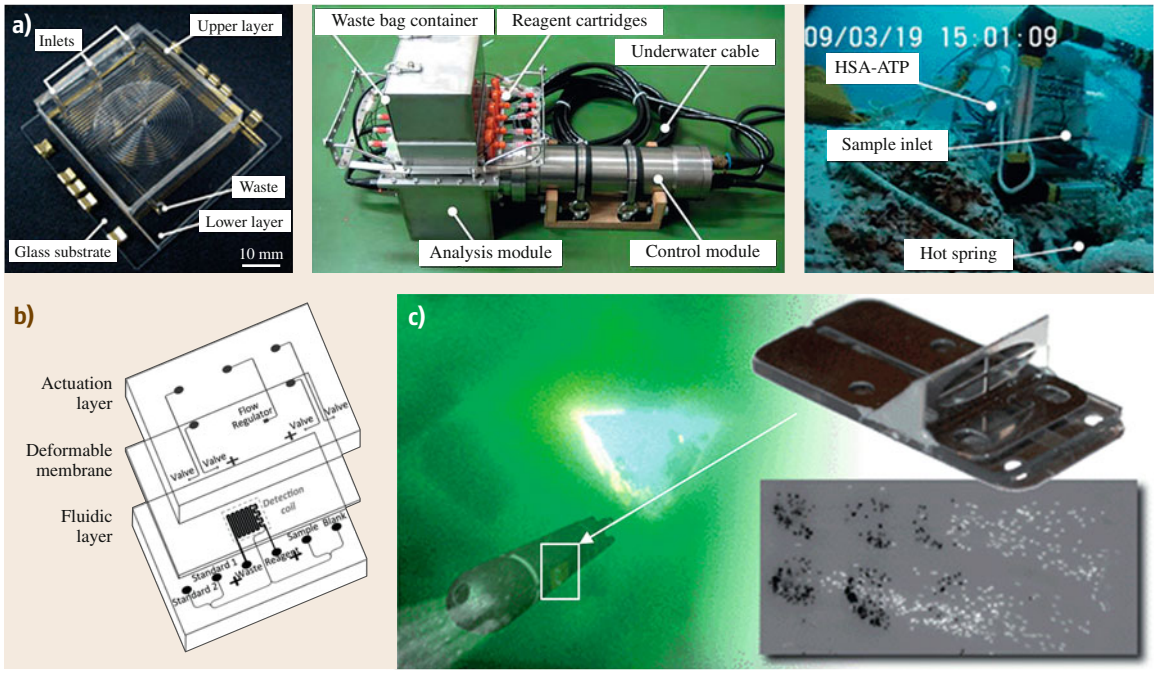

Fig. 20.4a–c Microfluidic systems for in situ water analysis. **(a)** Microfluidic in situ analyzer for ATP quantification in ocean environments. *Left*: picture of the microfluidic chip. *Middle*: photo of the completed IISA-ATP system for in situ operation. *Right*: photo of the IISA-ATP on the seafloor during the in situ operation at the bubbling site in the Taketomi submarine hot spring area (after [20.88]). **(b)** Schematic exploded view of the integrated microfluidic device for manganese anomaly detection composed of three layers: actuation, membrane, and fluidic layers (after [20.89]). **(c)** Representation of a microfluidic system for yeast cell detection at a depth of 1200 m attached to a submersible. *Right, top*: photo of the microchip. *Right, bottom*: images of the particles captured on the device (after [20.90])

Microfluidic systems have been developed to detect the presence of ion concentration in seawater, [20.89], which is essential for the maintenance and management of reinforced concrete structures in harsh saltwater environments [20.91, 92], and to detect and evaluate new hydrothermal sources in the sea [20.89]. However, the main advantage of using microfluidic systems for seawater analysis is the possibility of integrating fully functional LOC in submersible vehicles for in situ seawater analysis. The use of submersible vehicles as carriers for microfluidic LOC allows the investigation of hardly accessible environments, such as large deep-water or ice-covered bodies of water and can replace the large and powerful pump needed for sample collection and filtration. Such microfluidic systems have been used to analyze the composition of seawater in microbes by detecting the presence of adenosine triphosphate (ATP) in water (Fig. 20.4a) [20.88] or by trapping and collecting microorganisms, such as yeast, for further investigations (Fig. 20.4c) [20.90]. For example, *Fukuba* et al. [20.88] developed and tested a functional IISA (IISA) system for the detection of ATP, called IISA-ATP (shown in Fig. 20.4a), for microbial activity assays based on the total ATP quantitative determination in ocean environments. The device utilizes a PDMS-glass hybrid microfluidic device as its core functional element and can perform cell lysis and total ATP quantification by a luciferin–luciferase bioluminescence assay in situ. As a result of the evaluation using the microfluidic device with ATP standard solutions, the bioluminescence intensity was linearly correlated with 2×10^{12} to 2×10^{8} M of ATP, with a detection limit of 11.1×10^{11} M. The system was successfully operated in situ at a shallow submarine hot spring area in Okinawa, Japan, and the total ATP was determined to be 3.4×10^{10} M [20.88]. Another example was presented by *Provin* et al. [20.89], who created a miniaturized and integrated microfluidic system (Fig. 20.4b) for the detection of Mn in deep-sea environments, called ISSA for Mn^{2+} (IISA-Mn). This

high-sensitivity detection system is based on the chemiluminescence reaction of Mn contained in the seawater sample with a luminol-based reagent. It is composed of a microdevice for mixing and reaction, a pumping unit, several valving units, and a photomultiplier (PMT) detector. Mn concentrations above 280 nM in seawater were detected, and a quite linear response was obtained until 500 nM. In addition, this device worked continuously during the 8 h of an actual remotely operated vehicle dive and led to the discovery of a previously unknown hydrothermal site in the Okinawa Trough.

20.3 Microfluidic Devices for Sea-Related Health and Safety

Microfluidic-based marine biotechnology provides a promising approach for rapid and accurate in situ detection of toxic microorganisms, toxins, or pollutants that can threaten human and animal health and safety.

20.3.1 Microfluidics in Toxic Algae Detection

The detection of algae proliferation in drinking water and marine recreational water is an important environmental and public health issue. Traditional laboratory-based identification of algae in water requires sophisticated and expensive procedures that result in delays of effectively reacting to an outbreak. However, increased governmental and public concerns on algae-related health and safety issues has raised the demands for low-cost, portable, and real-time algae monitoring. The development of microfluidic devices provides a promising approach for toxic algae detection. To date, optical detection [20.93–95], flow cytometry [20.95, 96], electrical impedance [20.97–99], and nucleic acid amplification [20.38, 100] are successfully exploited on microfluidic platforms.

Optical detection has been use for algae detection based on shapes, structures, or pigments. *Schaap* et al. [20.101, 102] developed a femtosecond laser to construct a waveguide in a microfluidic device (Fig. 20.5a) to qualitatively distinguish various algae types in a water stream by detecting the distinctive wavelets that are associated with the particular algae geometry. This sensing principle relies on distorted transmitted wavelet-like signals induced by an alga crossing a monochromatic coherent light beam when moving along a microfluidic channel.

Flow cytometry is a common optical approach used to detect algae by measuring the a number of optical and side scatter properties. For example, the ratio of chlorophyll (CHL) to algae size (side scatter signals) and/or to phycoerythrin (PE) or phycocyanin (PC) has been used to identify different algae with conventional macroscale experiments [20.105]. In 2007, *Benazzi* et al. [20.46] developed a microfluidic flow cytometry that measures fluorescence, which was used to distinguish three mixed algae with similar results to those obtained from a commercial flow cytometry. More recently, *Hashemi* et al. [20.103, 106] developed an improved microfluidic flow cytometry for algae species evaluation using CHL, PE, and side scatter. The chip was composed of chevron grooves, as shown in Fig. 20.5b, combined with PDMS-embedded optical fibers, and external optical filters and photomultiplier tubes were used to collect fluoresced and scattered lights. The device generates a sheath stream that focuses the sample stream in the center of channel horizontally and reduces the impact of pulses from the peristaltic pump on the sample stream. The chevron grooves formed on the top and bottom of channels directs the sheath flow toward the top and bottom to compress the sample stream vertically.

Impedance spectroscopy is a noninvasive electrical method used for measuring size and dielectric characterization of cells when they pass over electrodes that have an alternating current (AC) potential. This method has been applied to LOC devices to differentiate cells [20.107, 108]. *Benazzi* et al. [20.46] developed a microfluidic device integrated with a impedance spectroscopy and fluorescence measurements to distinguish a mixture of three algae. A microfluidic channel made from PDMS was placed on a glass substrate where microelectrodes were patterned (Fig. 20.5c). Two frequencies (327 kHz and 6.030 MHz) were used to measure the electrical impedance; the lower frequency was chosen to measure the cell size, while the higher one was used to probe small changes in the membrane capacitance of the cells. The magnitude of the electrical impedance signal and fluorescent measurement were used to resolve three algae species (Fig. 20.5c).

The detection of harmful marine organisms can be achieved by using a benchtop isothermal nucleic acid sequence-based amplification (NASBA) method [20.109]. Recently, a hand-held system integrated

Illustration of the microfluidic chip (called lab-card), (after [20.104])

disposable microfluidic cartridges for cell concentration, lysis, RNA extraction/purification, and quantitative RNA detection was developed to detect harmful algal blooms [20.110]. The microfluidic cartridges (lab-cards) were fabricated by injection molding into a cyclic olefin co-polymer (COC). Fluid control was achieved by using seven polymer valves integrated within the lab-card. The cell sample and reagent master-mix were prepared and preserved in the lab-card. The lab-card reader system is an assembly of fluid control, temperature control, real-time fluorescence detection, and tablet computer. This portable analytical system (shown in Fig. 20.5d) was demonstrated to address the significant demand for in situ phytoplankton analysis [20.104].

Microfluidics in Marine Toxin Detection

Of the 4000 marine planktonic microalgae, around 80 species (mainly dinoflagellates and diatoms) are known to produce marine toxins (phycotoxins) that are potentially harmful to shellfishes, fishes, and humans, causing direct or indirect impacts to fisheries, aquaculture, tourism, and even public health [20.112]. The toxins produced by algae accumulate in fish, crabs, or shellfish and can cause severe intoxication when substantial amounts of contaminated seafood are consumed by humans. In order to protect human health from seafood poisoning, legislation has been established worldwide to limit and monitor the toxin content of seafood. Currently, the most widely used methods are in vivo bioassays (mouse bioassays and rat bioassays) that are conducted by administrating seafood extracts to laboratory animals and monitoring symptoms and time to death. However, the lack of specificity and sensitivity, the high rate of generating false positive results, and the ethical concerns of using laboratory animal are making this method unacceptable [20.113–115]. In vitro cytotoxicity assays have been developed as an alternative to in vivo bioassays, using cell types and cytotoxicity markers to detect marine toxins. For example, immuno-based methods, such as enzyme-linked immunosorbent assay (ELISA),

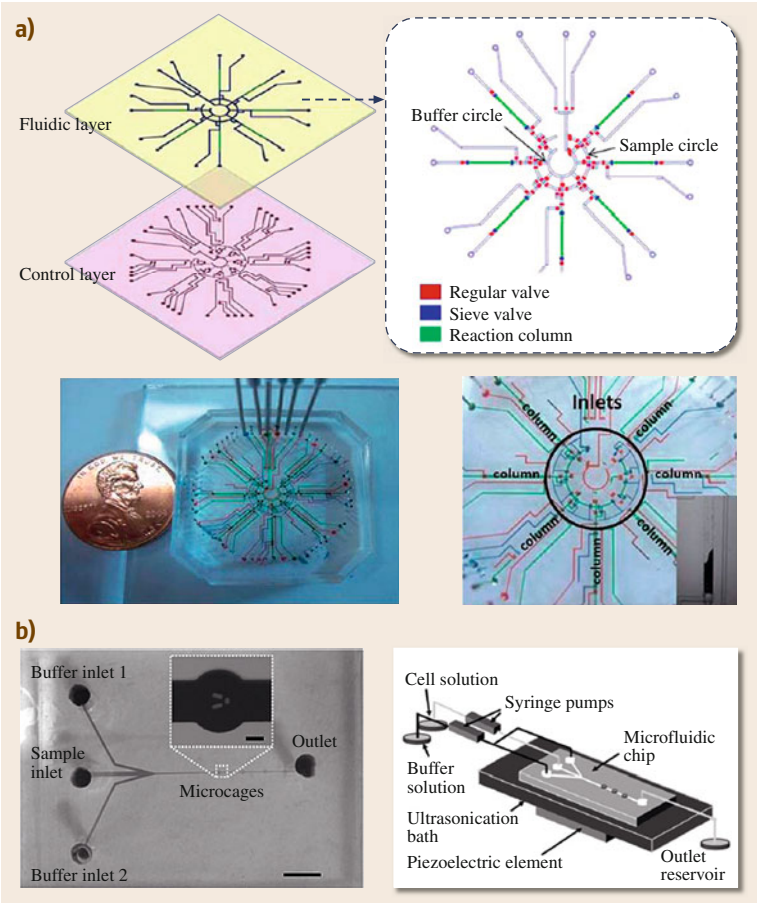

Fig. 20.6a,b Microfluidic device for algal toxin detection. **(a)** Immunoreaction chip used for rapid detection of algal toxin. *Top*: schematic representation. *Bottom*: optical micrography of the entire chip (*left*) and of the immune-reaction columns (after [20.103]) **(b)** Picture and schematic representation of a microfluidic device with cell trapping and lysis parts for toxin detection (after [20.111])

have been widely used to detect marine toxins. Analytical methods, such as liquid chromatographic and mass spectrometry techniques are used for the detection of toxins [20.113]. Recently, biosensors have been developed as fast, cheap, reliable, and more sensitive bioanalytical tools to screen toxicity of marine samples [20.116]. However, this methodology remains time consuming, which limits the capability to promptly provide an adequate answer to protect the population from food-borne intoxication.

Microfluidic-based analytical methodologies are a promising alternative as they provide rapid and accurate tools for marine toxin detection and analysis, and can bring the detection process on the field for in situ analysis. A microfluidic chip-integrated ELISA has been developed for rapid and automatic analysis of algal toxin [20.117]. The platform includes a core microfluidic chip, cartridges for reagents, a digital camera, the control system, digital inlet/outlet (I/O), and a laptop computer. The two-layered PDMS microfluidic device shown in Fig. 20.6a was fabricated to complete immune reactions based on a succession of specific steps. First, protein A coated microbeads were loaded into the chip. Then a secondary antibody was introduced and incubated with the beads, followed by the introduction of the toxin-specific antibody. Finally, the antigen and HRP-labeled (HRP: horseradish peroxidase) antigen were introduced, incubated, and revealed with load enzyme substrate solution. The fluorescence signal after enzyme catalysis reaction was measured. The use of this microfluidic-based detection system significantly reduced the time to detect toxins two to fourfold, with the limit of detection (LOD) much lower than that of common methods.

Recently advanced microdevices, such as microelectromechanical systems (MEMS), enable handling and processing of biological cells [20.121]. With one

of these devices, microfluidic methods can be used for single marine cell isolation to detect and study toxin [20.122]. *Wu* et al. [20.111] reported a microfluidic method to trap and lyse single marine algae prior to toxin detection. The system, shown in Fig. 20.6b, contained 3 microcages in a single channel for cell trapping and was coupled to an ultrasonic method for cell lysis to prevent chemical reagent contamination which can observed in conventional cell lysis methods. After lysis, toxin from the algae can be collected for further analysis. This method can be further incorporated into a biodetection system for in-field rapid toxin detection.

20.3.2 Microfluidics in Sea Pollutant Detection

The rapid industrialization in chemical, biological, and medical fields has resulted in the release of toxic chemicals or potentially harmful pollutants into water sources, including sea, groundwater, and rivers. These pollutants are a great threat to human health. Therefore, a rapid and highly sensitive trace analysis of water pollutants and minerals in marine and different water sources needs to be investigated according to the stringent guidelines provided by different environmental protection agencies (EPA). Thus, the development of a highly sensitive detection system for monitoring trace amounts of various pollutants and minerals has become very important. A number of bulky and conventional systems based on fluorescence, chromatographic, capillary electrophoresis, chemiluminescence, and electrochemical detection methods were reported previously. However, these bulky methods have many limitations, such as a long sample preparation time, a low detection limit, a lengthy measurement time, and indirect measurement results.

Recently, there have been reports of various portable microfluidic systems with extreme sensitivity for pollutants and minerals, such as phosphate levels in treated wastewater [20.123] or fecal indicator in coastal recreational water [20.124]. Another interesting approach uses whole-cell biosensor technology to detect pollutants like herbicides and metal ions from agricultural run-offs [20.125]. This technology presents great advantages compared with conventional methodology, including portability, low cost, ease-to use, and real-time monitoring. Unicellular microalgae have been extensively exploited for evaluating toxicity of pollutants in aquatic ecosystems, due to their high sensitivity to a number of pollutants and reproducibility [20.126]. Algae-based biosensors for water pollutant detection have been reported by many groups [20.126–128]. For example, a microfluidic platform for water pollutant detection was developed to improve detection sensitivity by integrating an algal fluorescence sensor [20.118]. This device consists of an organic light emitting diode (OLED) and an organic photodetector (OPD) integrated into a microfluidic chip. OLED and OPD were used to detect algal fluorescence, as shown in Fig. 20.7a. The presence of herbicides or metal ions was detected with the diminution of the algae's chlorophyll fluorescence. This device demonstrated a 10 times higher sensitivity ($\approx 10^{-8}$ M) towards herbicide than values detected with a commercial fluorescence sensor, and 100 times higher compared to amperometric algal biosensors. Another device developed by *Beaton* et al. has demonstrated the possibility to measure with high resolution in situ nitrate and nitrite [20.119]. The circular poly (methyl methacrylate) (PMMA) microfluidic chip shown in Fig. 20.7b contains a fluidic manifold that allows selection of standards, sample, and blank solutions. The chip integrated a Griess assay and a spectrophotometric method for colorimetric nitrite analysis. This LOC system demonstrates the potential of nutrient analysis for inclusion in large-scale networks for ocean pollution monitoring.

Another microfluidic device developed by *Zheng* et al. (Fig. 20.7c) [20.120] has been reported for the assessment of heavy metals in water, based on the measurement of motility of marine microalgae. The device consists of a toxicant concentration gradient generator where serial concentration gradients are generated by diffusion, and a chemostatic module where cells are seeded and migrate under different concentrations of toxic heavy metals. It is known that marine microorganisms are often motile [20.129], and heavy metals, such as, Cd and Cu, can directly inhibit cellular respiration processes that provide energy for motility [20.130, 131]. Therefore, a dose-response manner of Cd and Cu on the motility of two marine bacteria was observed on their microfluidic device.

20.4 Microfluidic Systems for Other Marine Biotechnology Applications

20.4.1 Synthesis of Marine Chemicals

Marine life forms are an important source of structurally diverse molecules with various biological properties, including toxic, pharmacological, and cosmetic ones, as well as being important in biomedical research. However, although nature provides structurally diverse molecules with varying biological activities, it is not always possible to obtain the required quantities of the desired molecule for research or commercialization; either because the quantity of raw material is not sufficient to obtain the required amount of active product of interest, or because active chemicals can only be isolated from endangered species protected by the Washington Convention (Convention on International Trade in Endangered Species of Wild Fauna and Flora). This

lack of material has inspired innovative chemistry that develops new methodologies for the synthesis and modification of natural products [20.132–135]. Still, these methodologies, realized at conventional macroscale, are labor intensive, time consuming, and expensive. In addition, scale-up from research to mass production remains troublesome because of the volume to surface ratio that affects the thermal and mass transport properties of the reaction and requires readjustment in the process at each stage of the scale-up.

Microreaction technology provides the means of addressing those limitations. Single microfluidic devices can be used in a laboratory to reduce the cost, time, and labor of the experiments. In addition, microfluidic technologies render easier scale-up of a reaction process from research to mass production, as multiple devices can be used simultaneously. For example, a recent study reported the use of microfluidic systems for the synthesis of pristine [20.136] (or 2,6,10,14-tetramethylpentadecane), a saturated isoprenoid isolated from the basking shark, *Cetorhinus maximus* [20.139, 140]. The synthesis of pristane involves different steps, namely oxidation, alkylation, dehydratation, and hydrogenation. In this process, dehydration is the most challenging part. When the reaction is performed at a gram scale, purity of the final product does not exceed 20%, even with repeated distillation or silica gel chromatography, which cannot be used for kilogram-scale mass production. Using ten commercially available Comet X-01 micromixers arranged in parallel (Fig. 20.8a), *Tanaka* et al. successfully performed an 8 kg-scale dehydration over 3–4 days in one batch [20.136]. The solution eluted from the micromixing system was then quenched, extracted, and concentrated. The mixtures were quickly passed through a short silica gel pad to remove hydrophilic byproducts. Finally, hydrogenation in the presence of 10% Pd/C under hydrogen atmosphere provided pristane in 50–55% overall yields (≈ 5 kg) with $> 99\%$ purity, based on gas chromatographic analysis. In addition, the synthetic pristane obtained with the microfluidic system was confirmed to induce antibody production in mice twice as efficiently as natural pristane or other synthetic products, due to the non-negligible contamination of the other hydrophobic compounds [20.136].

20.4.2 Marine Bacteria–Based Microrobot Fabrication and Control

With the development of MEMS and robotics [20.141–145], microrobotics has become the focus of attention worldwide for its potential applications in medical diagnosis, targeted delivery, in vivo sensing, cell manipulation, and material removal in the human body [20.146–149]. However, because of the size limitation, energy supply is always one of the bottlenecks in the development of microrobots [20.145, 149–151]. Recently, *E. coli* [20.152] and marine bacteria [20.137] have been successfully integrated in the design of microrobots and has been used as a propulsion system [20.151]. Obviously, the use of conventional cell culture system, such as flasks or plates, is not the most suitable for studying the control of microrobot behavior, because of the high surface ratio between the substrate and the bacteria. The ability to easily control biological conditions and the dynamic fluidic environment within the system [20.150–155] makes microfluidics ideal tools for microrobot-based studies. *Quifeng* et al. recently developed a microfluidic device to control and track marine magnetotactic bacteria (MBT) ovoid MO-1 cell-based microrobot (MBT-microrobot) [20.137]. The system is shown in Fig. 20.7b. In this study, MO-1 bacteria were used as a carrier system on which microbeads were attached. The control and tracking system consisted of an inverted microscope tracking device, a set of electromagnetic coil devices embedded in the stage of the inverted microscope brackets, and a microfluidic chip at the center of the set of the electromagnetic coil device. The microfluidic chip was made of PDMS and composed of a single channel with two pools, as shown in Fig. 20.8b. The control and tracking device could manipulate the movement of the MTB-microrobots within the microfluidic channels and trap the swimming cells within the pools where circular magnetic fields were applied, showing the possibility to use the circular field as a *stop control* system.

20.4.3 Seawater Desalination

The shortage of fresh water is one of the most important challenges facing today's world. Population growth, enhanced living standards, and the expansion of industrial and agricultural activities have created unprecedented demands on clean water supplies all over the world. Nowadays, nearly half a billion people in 31 different countries, mainly in Africa and the Middle East, suffer from water shortage. In 2025, this will grow to four billion people in 48 countries [20.156, 157]. Converting seawater, which represents about 97% of the total water resources on Earth, into freshwater may provide the solution to the worldwide water-shortage problem. However, current desalination methods, such

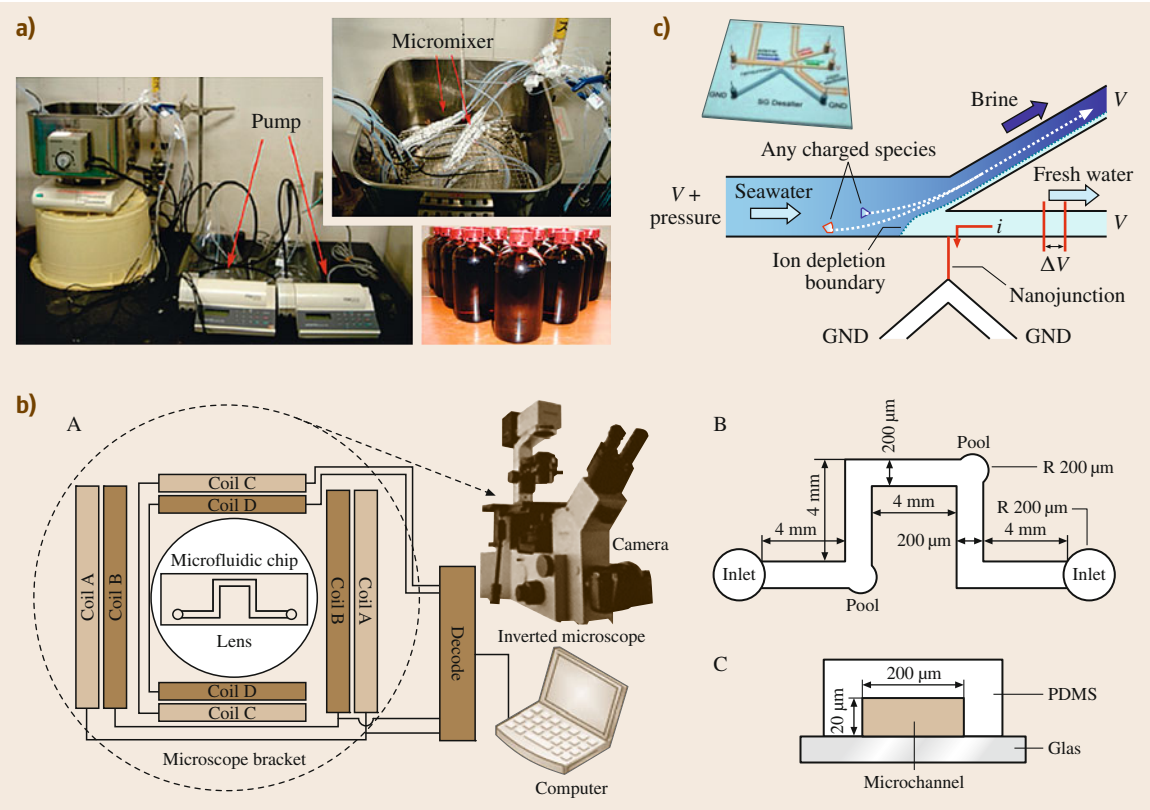

Fig. 20.8a–c **(a)** Microfluidics-based system for the in vitro synthesis of precious marine chemicals (here pristane) and photo of the quantity obtained in one single operation during 3–4 days (after [20.136]) **(b)** Schematic representation of microfluidic chip for the study of MO-1 magnetotactic bacteria-based microrobot (after [20.137]). **(c)** Schematic of micro/nanofluidic desalination system with embedded microelectrode for measuring the potential drop (*top*) and electrokinetic desalination operations associated with the external pressure field (*bottom*) (after [20.138])

as distillation, reverse osmosis (RO), and electrodialysis (ED), require high power consumption and operating costs or large-scale infrastructures, which make them difficult to implement in resource-limited areas, which are often in the poorest, most underdeveloped countries that lack the necessary and expensive power and water-delivery infrastructures to use these methods. Microfluidic technology that can be used to create small-scale and affordable seawater desalination systems with low power consumption and high throughput would be very useful in resource-limited areas. Toward the realization of such systems, *Kim* et al. [20.138] have reported an on-chip desalinization process that uses ion concentration polarization (ICP) for membraneless direct desalination of seawater. The device is made of PDMS with a perm-selective nanojunction [20.158]. It is composed of two microchannels connected by a nanojunction, as shown in Fig. 20.8c. The nanojunction preferentially conducts only cations (cation exchange membrane) that do not match the ion conductivities in the bulk electrolyte, which generate ion concentration gradients on both sides of the membrane. Once ICP is triggered near the cation exchange membrane, the concentrations of both cations and anions decrease on the anodic side of the junction (ion depletion) and increase on the cathodic side (ion enrichment) [20.158, 159]. The use of the nanojunction instead of classical membrane geometry, prevents the blocking of fluid flow by the membrane and rather flows in directions tangential to it. Gold microelectrodes, with titanium as an adhesion layer, were deposited on a glass slide. The device was then bonded with the patterned glass plate by means of plasma treatment in a way that the electrodes were located at the inlet, desalted

and salted microchannels for electric potential measurement, using an evaporation/lift-off process. To perform seawater desalinization, seawater from Crane Beach, Massachusetts, was physically prefiltered to remove any precipitation and debris larger than the channel dimension (dirt, sand, and seaweed) and then loaded (using an external pressure pump) into the reservoir of the chip. Once the ICP process was initiated, a depletion zone formed and diverted charged ions into the *salted* stream. In addition, the ICP layer acted as a virtual barrier for any charged particles found in the seawater (both negative and positive), including solid particles, microorganisms, and biomolecules (including proteins, bacteria, viruses, red blood cells, and white blood cells (WBCs)), because most water-borne microorganisms and microparticles have a nonzero zeta potential. Consequently, both small salt ions and large microorganisms could be removed simultaneously from the output desalted stream, making this process highly attractive for direct desalination of seawater from natural sources. However, this system cannot remove neutral particles and must be associated to other conventional system, such as charcoal absorption, in order to to obtain drinkable water. The present technology would not replace large-scale RO or ED plants for general seawater desalination (for agricultural and industrial purposes), but the technique could be used as a small portable unit with low power consumption. It is, therefore, suitable for seawater desalination in disaster and poverty-stricken areas where the necessary infrastructures for operating large-scale desalination systems are unavailable.

20.5 Conclusion

Microfluidic technologies are powerful tools that can revolutionize marine biotechnology. In this chapter, we described some of the systems and concepts that overcome a number of limitations imposed by conventional macroscale experimentations, including expensive and time-consuming methods, the supply of rare and large volumes of reagents, and the large space and apparatus required. With the miniaturization of the biological and chemical processes on a single chip, there is a new set of tools that dramatically changes the approach to marine biotechnology. These tools render marine biotechnology studies faster, cheaper, and easier. In addition, because of their small size, these tools are highly suitable for in situ studies and analysis, and consequently perfect to increase the response time during biological or chemical pollution of costal seawater or to prevent sample deterioration after harvesting. However, microfluidics is still an infant in marine biotechnology, and various applications, such as marine-based drug discovery, have not been investigated. In the field of drug discovery, microfluidics has demonstrated its potential. Marine biotechnology will benefit highly from the development of such tools, making the discovery of active marine biocompounds much easier and faster. Moreover, in order for microfluidic-based marine biotechnology to efficiently grow and substitute conventional methodologies, several challenges must be overcome. For example, in order to bring about lab-in-the-field, portability of the system should remain one of the main cornerstones of chip development and important efforts must be made to get rid of all external tubings, pumps, gas tanks, and other bulky components that anchor the chip into the lab. More importantly, mindsets need to be changed and researchers in marine biotechnology need to be convinced of the suitability of these systems by increasing the number of validation studies.

21. Genome Mining for Bioactive Compounds

Soumya Haldar, Kalpana H. Mody

Coral reef environments are a rich source of biologically active natural products. However, due to their vulnerable nature and stringent environmental laws, it is always difficult to explore such environments physically. With the advent of molecular biology, many new strategies have evolved for the discovery of novel natural bioproducts from sensitive marine environments. Analyses of plant and microbial genome sequences have revealed many genes and gene clusters encoding proteins similar to those known to be involved in the biosynthesis of structurally complex natural products. The concept of genome mining evolved from this concept, where large-scale deoxyribonucleic acid (DNA) sequencing approaches have been used. Basically, this strategy involves two approaches: sequence-based metagenomics and functional metagenomics. Although many breakthroughs have been achieved, presently, the global pharmaceutical pipeline consists of few approved drugs and a large number of marine chemicals in different stages of preclinical trials. It is anticipated that with the advent of new molecular techniques, the metagenomics approach will be more useful for the discovery of natural bioactive compounds.

References 538

In the present chapter, an attempt has been made to gather detailed information on the present status of coral-derived bioactive compounds and on the reasons for momentary halt in biodiscovery of marine natural products, and to outline future prospects of research on marine/coral associated bioactive compounds.

21.1 Overview

Marine organisms contain many potential novel bioactive compounds because of the unique environmental conditions (high ionic strengths, low level of light, cold or warm temperatures, and pressure) prevailing in their habitats. Several groups of marine organisms, including soft-bodied sessile invertebrates, such as tunicates, soft corals, and certain sponges, appear defenceless yet they produce bioactive compounds to protect themselves from predators. These organisms are rich in nutritionally important substances and use an arsenal of chemical defences and chemical repellents to protect themselves when competing for space. The incidence of predation is low because of the production of toxic compounds and the possession of some form of calcareous sclerites. The abundance and diversity of natural products having potential biological activities have provided scientists with the opportunity to discover new drugs. In the recent past, bioprospecting of new marine natural products (NMNP) has resulted in the discovery of several thousand novel molecules. The rich biodiversity

of the ocean, which prevails over the diversity of land, shows a huge promise as a source of potential natural products in future. In a recent study, *Leal* et al. [21.1] compiled yearly reviews from 1990 to 1999 and 2000 to 2009 on marine natural products, which were published in the journal Natural Products Reports. The reviews pointed out that there was a noticeable increase in the discovery of new natural products from porifera in the first five years of the 1990s, which subsequently maintained a flat trend. However, the discovery of NMNP from Cnidaria increased over the decades with a noticeable increase in the last 20 years. The class Anthozoa generally comprise 99% of NMNP, which belongs to the phylum Cnidaria. Further, most scleractinian corals are representative of this class. The discovery of new natural products from the Anthozoa class increased by 72% from the 1990s to the 2000s.

The investigation of natural products as novel human therapeutics reached its peak in the western pharmaceutical industry during 1970–1980 . It was reported that between 1981 and 2002, a total of 877 small molecules, new chemical entities (NCEs), were introduced and interestingly, approximately half of these were derived from natural products, semisynthetic natural product analogs, or synthetic compounds based on natural product pharmacophores [21.2].

Recently, *Cheng* et al. [21.3] discovered three new diterpenoids designed as gyrosanols A–C from the soft coral *Sinularia gyrosa*. An in vitro cytotoxicity study with these compounds revealed activity against human lung carcinoma (A-459), human colon adenocarcinoma (HT-29), and mouse lymphocytic leukemia (P-388) cancer cell lines. It also showed antiviral activity against the human cytomegalovirus and antibacterial activity against five pathogenic bacterial strains, *Enterobacter aerogenes*, *Salmonella enteritidis*, *Serratia marcescens*, *Shigella sonnei*, and *Yersinia enterocolitica*.

Initially, studies on another species, *S. crassa*, yielded sphingosine and steroids possessing anti-inflammatory activity. A further study by *Cheo* et al. [21.4] confirmed isolation of eight new cembranoids showing bioactivity against selected human carcinoma cells.

In a recent study, five new polyoxygenated steroids were derived from the bamboo coral *Isis hippuris*, with anti-HCMV (HCMV) activity as well as cytotoxicity against selected cell lines. One of these compounds showed inhibitory activity against HCMV, with an EC_{50} value of 6.0 μg/ml [21.5].

Nematocyst venom of fire warm *Millepora platyphylla* (Mp-TX) was extracted and simultaneous biological and biochemical assays were performed to monitor the hemolytic, using washed human red blood cells (RBC) and phospholipase A2 (using radio labeled sn-2 C14-arachidonyl phosphatidylcholine as a substrate) active venom fractions. The magnitude of both hemolysis and phospholipase A2 activity was found in a fraction rich in proteins of molecular masses of approximately 30 000–34 000 Da. The former fraction was purified by ion exchange chromatography, and a major bioactive protein factor (approximately 32 500 Da, here named milleporin-1) was recovered. Milleporin-1 enzymatic activity showed a significant contribution to the overall hemolysis of human RBCs [21.6]. *Su* and *Wen* [21.7] recently isolated five membrane-based diterpenoids from the Taiwanese soft coral *Sinularia triangular*. Among them, triangulenes A and B were reported to be new metabolites and 3 and 5 exhibited moderate cytotoxicity to human tumor cell line (CCRF-CEM) and DLD-1 (dihydrolipoamide dehydrogenase). Metabolites 4 and 5 also effectively reduced the expression of the COX-2 protein of the macrophages.

Pharmaceutical research, especially the development of different antibiotics based on the screening of different microbes expanded rapidly following the discovery of penicillin just after the Second World War. By 1990, about 80% of drugs were either natural products or analogs inspired by them. Antibiotics (e.g., penicillin, tetracycline, erythromycin), antiparasitics (e.g., avermectin), antimalarials (e.g., quinine), lipid control agents (e.g., lovastatin and analogs), immune suppressants for organ transplants (e.g., cyclosporine, rapamycin), and anticancer drugs (e.g., taxol) revolutionized the pharmaceutical industry.

Bryozoans are an independent group of animals closely related to corals and are the source of many potent bioactive compounds. A common bryozoan species, *Bugula neritina*, is a potent source of the protein kinase C inhibitor called bryostatin. Bryostatin-1 has been granted orphan drug status by the Food and Drug Administration (FDA) and has been designated as an orphan medicinal product in Europe for oesophageal cancer in combination with paclitaxel [21.8].

21.2 Temporary Halt in the Discovery of Bioactive Compounds

Koehn and *Carter* [21.2] accumulated the numbers of natural products derived from small molecules for which patents were granted between 1984–2003. According to report, increasing patent activity was observed throughout the 1980s, a flattening or even slight decline between 1990–1999, and a pick up of activity between 2000–2003. The number of natural product-derived drugs declined further during the period of 2003 to 2007 (Fig. 21.1). The decreased emphasis in the pharmaceutical industry on the discovery of natural products during the last decade can be attributed to many factors, such as: the introduction of high throughput screening (HTS) against defined molecular targets, which prompted many pharmaceutical industries to move from the natural products library towards the synthetic chemical library. Further adoption of new strategies to offer the prospect of simpler, more drug-like screening libraries of wide diversified chemicals also reduced the thrust on the search for natural compounds. In the recent past, major pharmaceutical companies have reduced the emphasis on infectious disease therapy, a traditional area of strength for natural products [21.9]. Finally, stringent rules for collection of natural products from eco-sensitive environments has also prompted many companies to shift the focus from the discovery of natural products to other modes of discovery. This is mainly because infectious disease treatment with antibiotics is of short duration in relation to that with other drugs, such as cholesterol lowering or hypersensitive agents, which are consumed daily for prolonged periods and relieve symptoms rather than provide a cure. However, development costs, standards for safety, and requirements for limited side effects are similar for both antibiotics and long-term drugs [21.10].

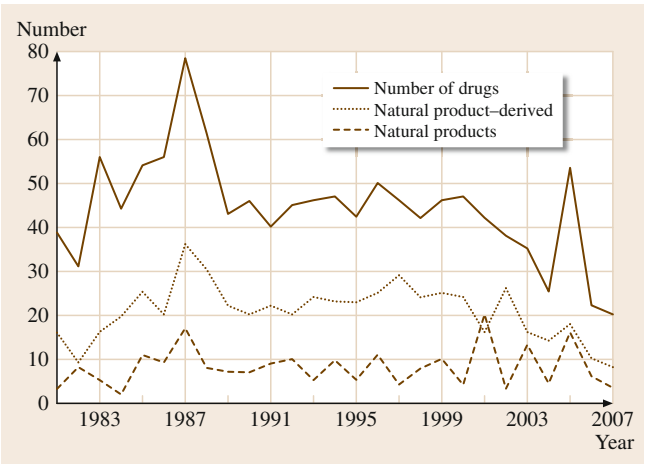

Fig. 21.1 Number of drugs approved in the US between 1981–2007

21.3 Future Directions

With the current strategies, the numbers of new natural product-derived drugs may be reduced; however, this is likely to be temporary. Access to rapid and inexpensive genome sequencing has enabled novel applications such as rapid sequencing of environmental DNA samples and has substantially widened the scope of discovery of new compounds from extreme environmental conditions. These technologies are not only changing our genome sequencing approaches and associated timelines and costs, but also accelerating and altering a wide variety of biological enquiries, including characterization of ecological diversity and identification of unknown natural compounds [21.11].

21.3.1 Genome Mining

Sequencing of huge set of data has opened up a new avenue in genomic research. The analysis of microbial genome sequences has revealed the potential to direct the production of novel, structurally complex natural products. A dramatic and sustained increase in the understanding of the genetics and enzymology of biosynthesis of microbial natural products throughout the 1990s has facilitated the identification and analysis of gene clusters likely to encode for biosynthetic pathways. At the onset of the last decade, publicly deposited genomic data began to accumulate rapidly and analysis of these data revealed that most sequenced microorganisms or plants contain a large number of genes that encodes proteins involved in the biosynthesis of secondary metabolites, the products of which are unknown at the metabolome level. To date, only a fraction of natural products has been analyzed, and the majority ia waiting to be discovered. The discrepancy between the small numbers of isolated compounds and the huge biosynthetic capacity and diversity demonstrated by various organisms on the genomic level highlights the huge potential of genomic mining for the discovery

of novel natural products and represents a strategy to access tremendous sources of new, biologically active metabolites [21.12]. The concept of genome mining for the discovery of novel natural products appears to be more suitable for vulnerable and sensitive natural environments like the coral reef ecosystem, the mangrove ecosystem, etc., which are difficult to access, although they have great potential as a repository of many novel bioactive compounds.

21.3.2 Functional Metagenomics

A functional metagenomics approach is the most effective and suitable for the screening novel gene products or genome mining from any sensitive ecosystem including the coral reef ecosystem. This is because this method mainly focuses on the screening of DNA library clones directly for a phenotypic trait, i. e., the genes are recognizable by their function rather than by their sequence.

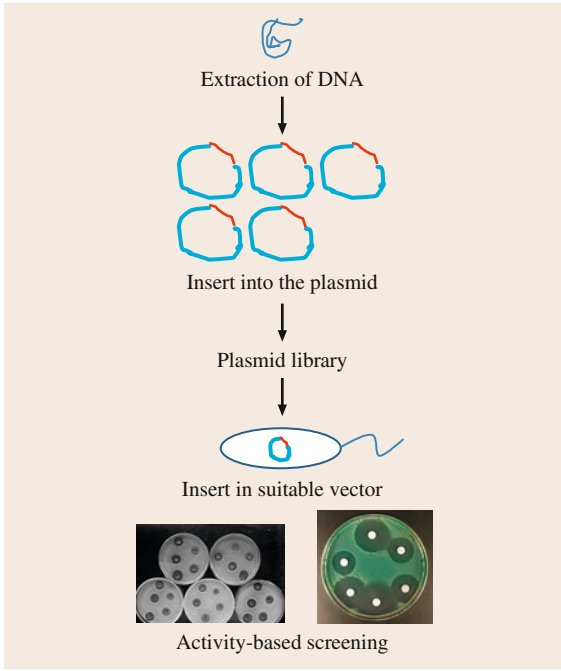

Fig. 21.2 Functional metagenomics

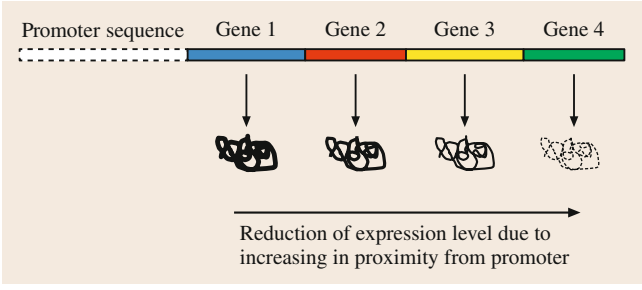

Fig. 21.3 Schematic diagram showing reduction of gene expression with the proximity of the promoter sequence ◄

The basic strategy for functional metagenomics is outlined in Fig. 21.2. In this method the total community DNA can be extracted from an environmental sample, e.g., seawater or marine invertebrate. The isolated DNA is then used to generate a metagenomics library using a suitable cloning vector. This library is then transferred to a suitable host strain, usually *Escherichia coli*, and individual clones can then be screened for the presence of enzymatic or other bioactivities encoded by the environmental DNA fragment. When coupled with a robust and high-throughput screen, this is an extremely effective method to isolate novel bioactivities from otherwise inaccessible microbes (Fig. 21.2) [21.13].

Most of the screens for the isolation of genes encoding novel biomolecules are based on the metabolic activities of metagenomic-library-containing clones. As sequence information is not required, this is the only strategy that bears the potential to identify novel target genes with encoding known functions [21.14–19]. Three different function driven approaches have been used to recover novel biomolecules: phenotypical detection of the desired activity [21.16, 19, 20], heterologous complementation of host strains or mutants [21.21–23], and induced gene expression [21.24–26].

21.3.3 Phenotypic Detection of the Desired Activity

In this type of screening, some chemical dyes are incorporated into the growth medium that showed phenotypic change in the presence of a specific enzyme. There are two distinct strategies taken in functional metagenomics according to the primary goal. Large insert libraries are constructed for archival and sequence homology screening purposes. The main advantage of this approach is the capacity to capture the largest amount of available genetic resources in the sample and to archive it for further studies/interrogation. Although some genes in such libraries are expressed and may be found in active screens, these will be biased towards genes from organisms related to the host, since

they generally lie far from vector expression signals and, therefore, are expressed from their own expression signals (Fig. 21.3). On the other hand, small insert expression libraries, especially those made in lambda phage vectors, are constructed for activity screening. The small size of the cloned fragments means that most genes present in the appropriate orientation will be under the influence of extremely strong vector expression signals and thus have a good chance of being expressed and detected by activity screens [21.15].

Another function-driven screen is based on the principle of heterologous complementation of host strains or their mutants, which requires the targeted genes for growth under selective conditions. This technique allows a simple and fast screening of complex metagenomic libraries comprising millions of clones [21.27]. Recently, *Donato* et al. [21.28] isolated genes that confer resistance to tetracycline, β-lactams or amino glycoside antibiotics from a complementation-based screen of 446 000 clones derived from specialized soil samples.

Resistance genes were identified by subcloning and/or in vitro transposon mutagenesis with the Genome Priming System, GPS-1TM (New England Biolabs). Subcloning was accomplished by partial digestion of plasmid DNA with *Sau*3AI, ligation into the *Bam*HI site of pUC19 (encoding ampicillin resistance) and selection for subclones on Luria-Bertani (LB) broth with the appropriate antibiotics. Subclones were sized by gel electrophoresis after digestion with *Pvu*II. In vitro transposon mutagenesis inserts transposons randomly into plasmid DNA, and antibiotic-susceptible mutants were identified by patching cells onto media containing the appropriate antibiotic. Sequencing reactions, using M13 forward and M13 reverse primers or primers specific for the transposon ends, were performed on both DNA strands [21.18].

It is well known that marine invertebrates, including corals, produce many secondary metabolites, including antimicrobials. Different functional metagenomic approaches can be very useful tools to explore novel bioactivities.

21.3.4 Induced Gene Expression

This is a novel method to screen small molecules. In this intracellular screen, the biosensor that detects active clones is inside the same cell along with the metagenomic DNA. The biosensor detects small diffusible signal molecules that generally induce quorum sensing. Generally, when the signal molecules reach a sufficient concentration, they start binding to the transcriptional activator (LuxR) which activates promoters of the *lux* gene and induces expression of target genes, commonly green fluorescent protein (GFP) [21.26]. This method is highly accurate and there is minimum chance of a false positive result. Coral environments

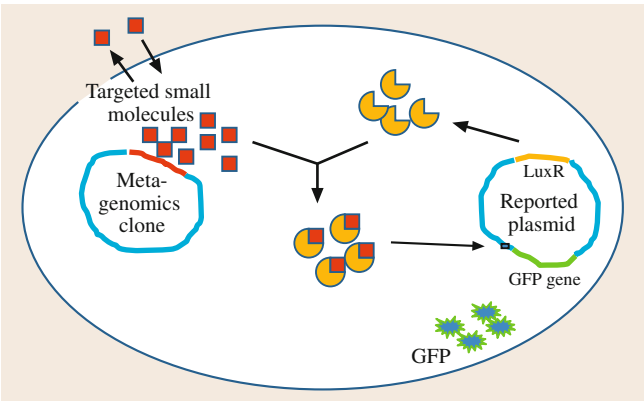

Fig. 21.4 Both biosensor and active clones present inside the same cell as the metagenomic DNA. When target molecules reach a sufficient concentration they bind the LuxR transcriptional activator, which activates Plux and induces expression of the signal molecule (GFP) (after [21.26])

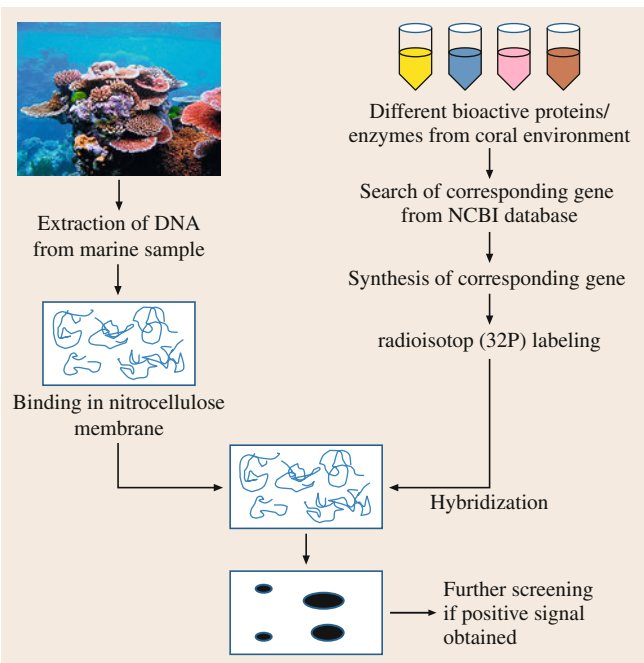

Fig. 21.5 Targeted metagenomics

generally harbor many such small molecules, which can be screened well with induced gene expression. However, the main hindrance in this method is that only specific types of molecules can be screened out (Fig. 21.4).

21.3.5 Sequence-Based Metagenomics

This method generally involves the design and use of polymerase chain reaction (PCR) primers or hybridization probes for the gene being targeted, which for enzymes is usually based on conserved regions of an already well-characterized protein family (Fig. 21.5).

In brief, an environmental sample is collected and then the total community DNA is extracted from the sample. The isolated DNA is then embedded into the suitable nitrocellulose membrane.

Preparation of the Probe

A list of the novel compounds reported to be present in this environment should be made. A detailed search for corresponding genes should be made through Basic Local Alignment Search Tool (BLAST) and the probe can be designed either by PCR amplification or by synthesis of part of these target genes. The targeted probe is labeled in vitro with [5' c¢32p]dCTP (375−3000 mCi mM^{-1}) with a Nick translation kit following the recommended protocol supplied with the kit. ^{32}P-labeled oligonucleotides are separated from the ^{32}P-labeled probe by elution through a 3 cm 3 Sephadex G-50 column with a column buffer that contains 0.25 M NaC1, 0.05 M Tris, 0.002 M EDTA, and 0.5 SDS (pH 8.0) [21.29].

Hybridization

Binding of the ^{32}P-labeled DNA probe with a complementary sequence of the DNA-bound nitrocellulose membrane is a crucial and tricky step in this method. In brief, the DNA-bound nitrocellulose membrane is deeped in a prehybridization buffer for initial washing of the membrane. Subsequently, the prehybridization buffer is replaced by a hybridization buffer with the addition of the required amount of DNA probe. After completion of hybridization, a final washing is performed in a temperature fixed on the basis of the required stringency condition.

21.4 The Hurdles of Drug Discovery

The prevention of different forms of cancer is the biggest challenge to the medical scientist at present. However, the development of new anticancer medicines is an arduous task that requires the coordinated efforts of a team of scientists from chemical and biological sciences. Any potential cancer chemotherapeutic candidate must undergo a rigorous series of tests prior to gaining FDA approval for commercialization. The process generally starts with in vitro tests against a panel of 60 different types of cancer cells. Additionally, xenograft models are also conducted on many occasions. Determination of the effective dose (ED_{50}) is the next step. A molecule becomes a candidate for testing in humans if it displays both toxicity against cancer cells and tolerance by healthy cells and in the later stage by whole animals. Human testing generally follows a three-phase protocol. Initially, Phase I involves treatment of a small number of healthy (paid) volunteers with the drug candidate in order to ascertain whether humans tolerate the compounds. If no adverse effects are detected, then the drug is generally used on a small number of patients with different cancers that do not respond to conventional treatment (Phase II). Drug candidates that continue to show therapeutic potential at this point then enter Phase III trials, in which they are administered to a broad range of cancer patients. Eventually, if the drug candidate survives these experimental challenges, FDA sanctions the approval after analyzing all the data. It is reported that generally more than 99.9% preclinical drug candidates fail this rigorous screening method [21.30]. Only a handful of compounds was discovered in the last 10 years. In fact, the National Cancer Institute (NCI) maintains an ever-expanding repository of over 60 000 plant and marine samples available for testing, and about 700 new marine samples are added each year.

21.5 Marine Pharmaceuticals Under Clinical Trials

The first reported structure of marine product was in 1880 by *Vosmaer* et al. [21.31]. The development of different chromatographic techniques increased the number of structurally-complex molecules obtained from

Table 21.1 Drugs in pharmaceutical clinical pipeline

Clinical status	Compound name	Trademark	Major organism	Clinical trial	Chemical class	Company	Disease area

bioactive natural extracts. In the last 10 years, more than 1000 reports on bioactive molecules isolated from marine organisms have been published [21.32]. Several antitumor marine natural products, derived mainly from marine sponges or molluscs and also from bryozoans and cyanobacteria, have exhibited potent antimitotic properties. Presently, the global marine pharmaceutical pipeline consists of 3 FDA approved drugs, 1 EU (European Union) registered drug, 13 natural products (or derivatives thereof) in different phases of clinical trials, and a large number of marine chemicals in the preclinical pipeline [21.33]. Three FDA-approved drugs in US pharmacopeia are cytarabine (Cytosar-U, Depocyt), vidarabine (Vira-A), and ziconotide (Prialt). Currently, Trabectedin (Yondelis) has been approved by the European Agency for the Evaluation of Medicinal Products (EMEA) and is completing key Phase III studies in the US for approval. A list of marine-derived compounds that have been FDA approved or are in Phases III, II, or I of drug development (as determined at http://clinicaltrials.gov/, as of January 2012) are shown in Table 21.1 with slight modifications [21.34]. It is reported that the majority of compounds are derived from marine invertebrate such as sponges, molluscs, tunicates, etc. Significantly, the majority of compounds showed activity against cancer and some serious diseases. So far, corals do not figure prominently in the clinical pipeline. However, due to the enormous species diversity, the coral reef environment is always considered to be a repertoire of many potential bioactive compounds [21.35]. However, due to their highly endangered status and limited permissibility, coral reef ecosystems throughout the world are less explored.

22. Cell Wall Polysaccharides of Marine Algae

Andriy Synytsya, Jana Čopíková, Woo J. Kim, Yong Il Park

Marine algae are interesting as a plentiful source of many bioactive compounds, including polysaccharides, which represent various structurally different polymers of high diversity in monosaccharide composition, absolute and anomeric configuration, glycosidic linkages, molecular mass, and the presence and distribution of various functional groups. These polysaccharides are used by algae as cell wall structural components or food reserve. Algal polysaccharides are highly indicative for main algal taxa. Sulfated galactans of periodical unit/linkage sequence (agars, carrageenans) are typical for red algae, alginates, and fucoidans for brown algae; sulfated glucuronoxylorhamnans (ulvans) and other sulphated glycans for green algae. Algal cell wall polysaccharides are extracted from the raw material and further purified by preparative chromatography and/or chemical treatment. Many algal polysaccharides are assigned as phycocolloids due to their good solubility in water and their ability to create colloid systems, including gels and films. They also demonstrate various biological activities (immunomodulation, antitumor, anticoagulant, antiviral, and many other activities), which are prerequisites of pharmaceutical and medicinal applications. Finally, initially inactive or weakly active natural algal polysaccharides can be partially degraded or structurally modified to be fitted to various medicinal applications.

22.1 Overview

Marine algae are a plentiful source of many bioactive compounds. Among these chemical components, polysaccharides are of interest because of their physical and chemical properties, which are useful for food and medicinal applications. Algae synthesize various types of polysaccharides as cell wall structural components or energy reserves. Algal polysaccharides demonstrate a high specificity to raw algae, which has been used by phycologists to clarify the phylogenetic relationship between main algal taxa and higher (vascular) plants [22.1–3]. Several species of common marine algae that are the source for the isolation of polysaccharides for food and medicinal purposes are shown in Fig. 22.1.

22.1.1 Structure of Algal Cell Walls

Algal cell walls are composed of a highly integrated network of biopolymers, mainly polysaccharides, which interact with water, metal cations, and other molecules [22.2]. Structural specificities, including substitution patterns and degrees, are prerequisites of the physical and functional properties of cell wall polysaccharides in marine algae. Crystalline and fibrous parts (cellulose, xylans, hemicelluloses, etc.) are embedded in a gel-like matrix made of carboxylic and/or sulfated polysaccharides. Other biopolymers (proteins, proteoglycans, and polymeric phenolics) may also participate in cell wall formation.

22.1.2 Polysaccharides as Taxonomic Markers of Marine Algae

The great variability of cell wall polysaccharides in marine algae is determined by the specie/taxa [22.3–7], anatomical part of the alga [22.7], the developmental and life-cycle stage [22.7–11], and season and habitat [22.12, 13]. Algae represent a diverse group of photosynthetic eukaryotes with a wide range of cell wall types [22.2]. Besides pigmentation and food reserve specificity, matrix cell wall polysaccharides are useful as structural and taxonomical markers of marine algae. Cell wall polysaccharides from various marine algae of three main divisions, i. e., *Clorophyta* (green algae), *Rhodophyta* (red algae), and *Phaephyta* (brown algae), are summarized in Table 22.1.

Green algae produce various sulfated and/or carboxylic cell wall polysaccharides of specific structure. Red algae have complex composite cell walls made of cellulose, xylan, or mannan fibrils and sulfated galactans (agars, carrageenans) as the main matrix components [22.14]. Brown algae produce cell walls containing cellulose fibrils and two main types of matrix polysaccharides (alginates, fucoidans). Cell walls of all marine algae are rich with sulfated matrix polysaccharides. This is an adaptation to marine habitats that has also been observed for many other marine organisms, including angiosperms and invertebrates [22.15]. There are two groups of algal sulfated polysaccharides (SPS) [22.16], i. e., (i) uronic acid-rich (UA: uronic acid) and (ii) UA-limited ones. In the green algae of Ulvophyceae [22.3], the first group is represented by ulvans (genera *Ulva*, *Monostroma*, *Gayralia*, and *Acetabularia*) [22.5]; the second

Table 22.1 Major cell-wall polysaccharides in the main groups of algae [22.1–3]

Polysaccharides	Chlorophyta	Rhodophyta	Phaeophyta (Phaleophycea)
Crystalline	Cellulose – (1 → 4)-β-D-glucan (1 → 4)-β-D-mannan (1 → 4)-β-D-xylan (1 → 3)-β-D-xylan		
Hemicelluloses	Xyloglucan Mannans (1 → 4)-β-D-glucuronan (1 → 3)(1 → 4)-β-D-glucan	Glucomannan (1 → 3)(1 → 4)-β-D-xylan	Sulfated xylofucoglucan Sulfated xylofucoglucuronan (1 → 3)(1 → 4)-β-D-glucan
Matrix	Ulvans Sulfated glycans	Sulfated galactans (agars, carrageenans)	Alginates Fucoidans

one includes sulfated (1 → 3)-β-D-galactans [22.17–22], (1 → 3)-β-L-arabinopyranans [22.23], and β-(1 → 4)-D-mannans [22.24] (genera *Caulerpa*, *Codium*, and *Bryopsis*). In addition, alkali-soluble linear (1 → 4)-β-D-glucuronan found in some green algae plays the role of hemicellulose [22.25]. Red algae contain linear and branched sulfated galactans having no uronic acids. By contrast, brown algae have specific kinds of carboxylic and sulfated polysaccharides, namely alginates and fucoidans; some of the latter ones may also contain galactose or glucuronic acid residues. More complex highly branched sulfated heteropolysaccharides (xylofucoglucans, xylofucoglucuronans, etc.) of brown algae were assigned as hemicelluloses.

22.2 Structural Diversity of Algal Polysaccharides

Algal cell wall polysaccharides are structurally variable polymers showing significant differences in molecular mass, monosaccharide composition, absolute and anomeric configuration of sugar units, glycosidic linkages, presence and distribution of functional groups (carboxylates, methyl ethers, acetyl esters, sulfate semiesters, 3,6-anhydro and others). There are linear and branched polysaccharides, the latter may have stubs, longer side chains or even very complex branching with defined core, inner and peripheral parts. Basic structure of common algal polysaccharides is demonstrated in Fig. 22.2. Structural variability of specific algal polysaccharides is reviewed below.

22.2.1 Alginates

Alginates are matrix cell wall polysaccharides of brown algae (Phaeophyceae). They are linear co-polymers of (1 → 4)-linked units of β-D-Man*p*A and its C-5 epimer α-L-Gul*p*A. These uronic acids are distributed in three types of blocks containing (i) only β-D-Man*p*A (M-blocks, M: mannuronic acid), (ii) α-L-Gul*p*A (G-blocks, G: guluronic acid), or (iii) alternating sequences of both these residues (MG-blocks) [22.44]. In algal cells alginates are synthesized as homomannuronan polymeric chains and then β-D-Man*p*A units are partially converted to α-L-Gul*p*A ones by enzyme C-5 epimerase. This conversion is irreversible and both types of blocks are formed. The $^4C_1$ and $^1C_4$ conformations were confirmed for β-D-Man*p*A and α-L-Gul*p*A alginate units, respectively [22.30, 45]. In the homopolymeric blocks the units are bound with diequatorial (M-blocks) and diaxial (G-blocks) glycosidic linkages, while in the alternating sequence the units are bound by mixed equatorial-axial (MG) and axial-equatorial (GM/MG – alternating blocks in alginates) linkages (Fig. 22.2a). The homopolymeric blocks form helical structures stabilized by intra-molecular hydrogen bonds involving hydroxyls, ring oxygens, and/or carboxyls; the MG-blocks take up disorder conformations. These helices demonstrate different stiffnesses: G-blocks look like *buckled ribbons* and they are stiffer than *flat-ribbon* M-blocks [22.41, 46, 47]. The M/G ratio (molar ratio between mannuronic and glucuronic acids in alginates) and distribution of co-monomer residues along an alginate chain depend on the source and geographic location of raw algal material, season of collection, the age of the parts of the plant, and extraction methodology used. The M/G ratio of alginates originating from Indian algae (the coast of Ki-

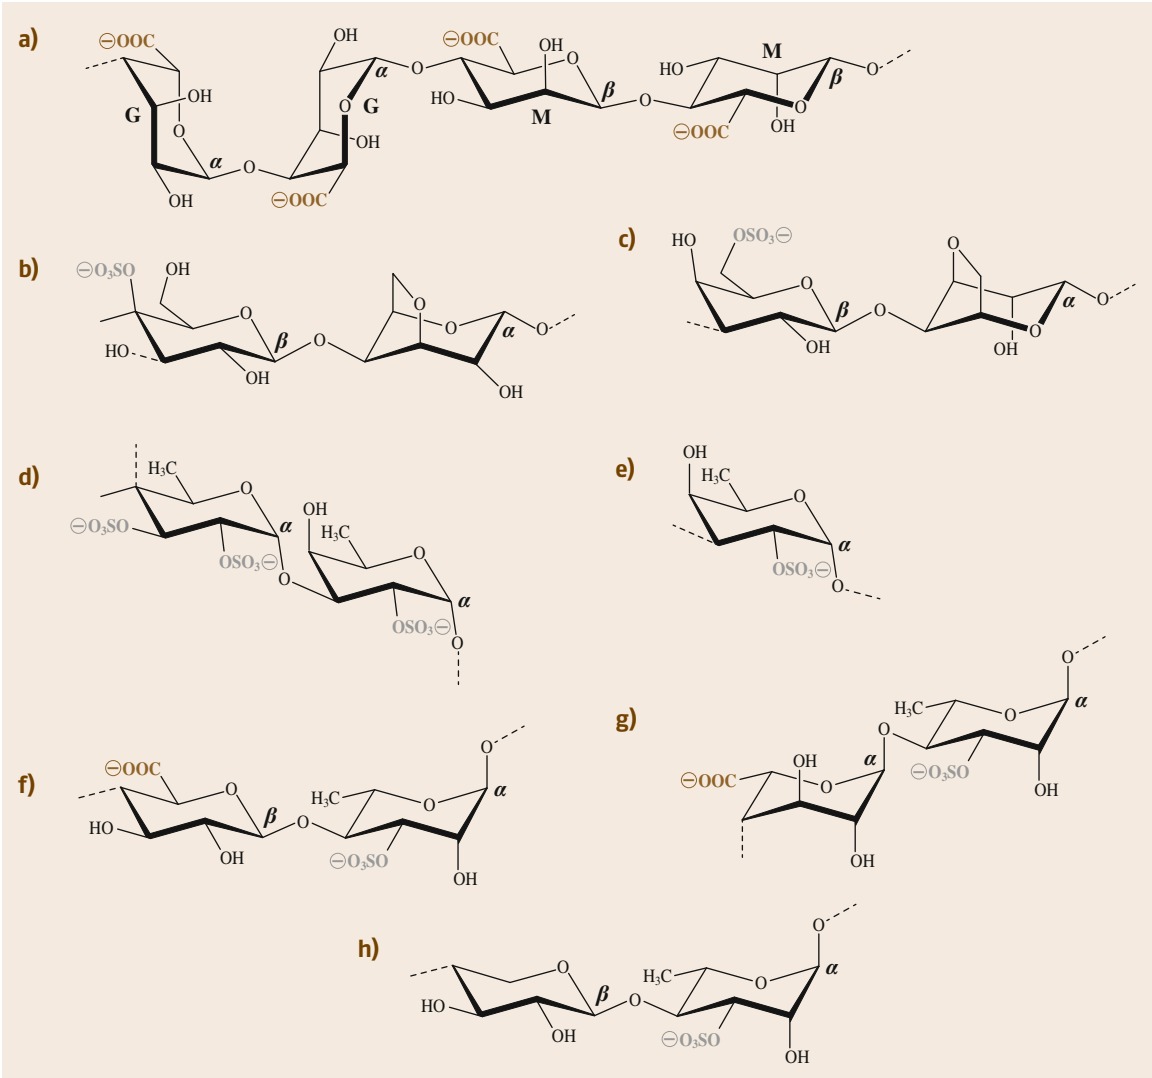

Fig. 22.2a–h Basic structures of marine algal polysaccharides: **(a)** alginate (G – guluronic acid, M – mannuronic acid); **(b)** κ-carrageenan; **(c)** agarose-6-sulfate; **(d,e)** fucoidans; **(f–h)** ulvans

lakarai, the Gulf of Mannar, South India) was reported to be maximal in summer and minimal in premonsoon seasons; this value also depends on the anatomical part of algal thalli used for isolation [22.12, 13]. The high variability of the M/G ratio for alginates from various brown algae is illustrated in Table 22.2. The block composition of alginates was investigated by a partial acidic hydrolysis (0.3 mol L^{-1} HCl, 100 °C, 2 h) followed by precipitation of the resistant fragments [22.11, 32]. Strong acidic hydrolysis of alginates from *Laminaria brasiliensis* gave rise mainly to M and G-oligosaccharide blocks, indicating preferential hydrolysis of glycosidic bonds in the MG-regions [22.42]. Two types of alginates were defined based on the distribution of monomers [22.32], i. e., those containing (i) many G-blocks, less MG-blocks, and even less M-blocks (GG > MM > MM), and (ii) a small proportion of GG and near equal proportions of MG and M-blocks (GG < MG≈MM). Alternatively, algal alginates could be classified as being high-M, low-M (or high-G), or intermediate type [22.27]. Well-defined MG-blocks were detected only for the intermediate alginates, whereas

the high-M and low-M alginates consist mainly of homopolymeric blocks (GG, MM), which are almost directly connected and contain few or no heteropolymeric blocks. It was also found that young algal tissues are rich in M-blocks, and that the difference between the alginates from different species was mainly due to the contribution of the older parts of thalli [22.11].

22.2.2 Sulfated Galactans

Sulfated galactans are common cell wall matrix polysaccharides of green (*Clorophyta*) and red (*Rhodophyta*) algae. They are polymers of partially sulfated β-D- sand/or α-D(L)-galactopyranosyl (Gal*p*) units.

Sulfated galactans from cell walls of green algae (genera *Codium* and *Bryopsis*) were reported to be both homo and heteropolysaccharides, depending on the species [22.17, 19, 20, 22, 51]. Polysaccharides isolated from *Codium isthmocladum* [22.20] and *Codium yezoense* [22.17, 52] are sulfated homogalactans containing similar backbones, composed mainly of (1 → 3)-linked β-D-Gal*p* units and short oligosaccharide side chains bound at *O*-6. The units were sulfated mainly at *O*-4 and rarely at *O*-6, and nonreducing terminal residues were pyruvylated forming cyclic 3,4-ketals. Sulfated galactan isolated from *Bryopsis plumosa* (Bryopsidales, Chlorophyta) consist of a (1 → 3)-linked β-D-Gal*p* partially sulfated on *O*-6 and substituted with pyruvic acid, forming 4,6-ketals [22.19]. A branched sulfated (1 → 3), (1 → 6)-β-D-galactan was isolated from *Codium fragile*. This polysaccharide has a (1 → 3)-linked partially 4-*O*-sulfated β-D-Gal*p* backbone with some 3,4-pyruvated β-D-Gal*p* stubs at *O*-6 positions [22.21]. By contrast, galactans isolated from *Codium fragile* [22.51] and *Codium cylindricum* [22.22] contain other sugar units – arabinose and glucose, respectively. Nevertheless, the →3)-β-D-Gal*p*4S-(1→ units still predominate in these polysaccharides. Water-soluble highly sulfated arabinans, galactans, and/or arabinogalactans were isolated from *Codium fragile* and *Codium vermilara* [22.18]. These polysaccharides are composed of (1 → 3)-linked β-D-Gal*p* and β-L-Ara*p* residues; they are partially substituted with pyruvic acid ketals.

Red algal cell walls contain (1 → 3), (1 → 4) – mixed linkage α, β-D(L)-galactans. Most of these polysaccharides are nonbranched. Their backbone is made of disaccharide repeating fragments of alternating (1 → 3)-β- and (1 → 4)-α-linked Gal*p*. The former units (G) always have D-configuration, whereas the latter ones (D or L) are present as the D- (the carrageenan family) or L- (the agaran family) enantiomers (Fig. 22.2b,c). Sulfate hemiesters, methyl ethers, and pyruvic acid are commonly bound to these polysaccharides. Sulfate and/or occasionally methyl groups may occur at the *O*-2 and/or *O*-4 position(s) of the (1 → 3)-β-linked Gal*p* units and at *O*-2, *O*-3-, and/or *O*-6 position(s) of the (1 → 4)-α-linked Gal*p* units; pyruvic acid may be attached to (1 → 3)-β-D-Gal*p* residues as ketals at *O*-4 and *O*-6 positions [22.81, 82]. The 3,6-anhydro derivatives of D(L) units may be present in the backbone of carrageenose (agarose) after elimination of sulfate from *O*-6 by enzymatic or alkali treatment. Agarose, a simplified structure of agar, is a sequence of

[a] International Union of Pure and Applied Chemistry (IUPAC); [b] first unit in agarans and carrageenans (G); [c] 3,6-anhydro units (LA, DA); [d] second unit in agarans (L); [e] second unit in carrageenans (D); [f] sulfation of hydroxyls (S); [g] pyruvation of hydroxyls (Pyr)

identical disaccharide (agarobiose) fragments without sulfates. By contrast, real agars have some α-L-Gal*p*6S (porphyran), pyruvic acid 4,6-ketals, *O*-methyl, or sulfate groups attached to β-D-Gal*p* residues [22.81, 83]. Similarly, carrageenans may have a structure described by one of the defined disaccharides (carrabioses) and thus are classified by Greek prefixes according to their structural specificity, i. e., sulfation patterns and the presence of 3,6-anhydro groups (Table 22.3). More often, however, they contain several types of disaccharide fragments, i. e., hybrid types (Table 22.4). Structural and conformational analysis of κ/ι hybrid carrageenans from *Sarcothalia crispala*, *Mazaella laminarioitles*, and *Chonrlrus crispus* showed that they are not a mix of pure carrageenans but have a mixed chain containing both κ and ι-disaccharide fragments [22.84]. Gametophyte and sporophyte generations of the algal biological cycle contain carrageenans of different structure, especially sulfate and 3,6-anhydride groups. Carrageenans of *Phyllophoraceae* and *Gigartinaceae* were described to be hybrids of κ, ι, and ν forms for gametophytes and rather λ subfamily forms (λ, ξ, and π) for tetrasporophytes [22.9, 10, 64, 68, 69, 85, 86]. Carrageenans usually contain more sulfates than agarans, while the latter often contain more methyl and glycosyl groups (Table 22.3). The structural variability of red algal galactans, especially of their substitution patterns, has been described for different species, harvesting location, or seasons. Sometimes the structure of red algal galactans (α/β anomers, D/L enantiomers, sequence of linkages, substitution patterns, etc.) deviates from the defined structural types of agars and carrageenans. Other sugars (Xyl, Glc, GlcA, Ara, or Man) are bound to some of them as backbone or side chain parts [22.87]. There are also some polysaccharides, named DL-galactan hybrids, having both D and L-units distributed within the same polysaccharide chain [22.88]. The real structure of red algae sulfated galactans is probably a result of the following stepwise biosynthesis: (i) formation of the regular polymer backbone, (ii) sulfation, methylation, and/or pyruvation of specific hydroxyls, and (iii) enzymatic

[a] More κ/ι hybrid carrageenans are reviewed by [22.80]; [b] methylation of hydroxyls (Me); [c] pyruvation of hydroxyls (Pyr)

conversion of some (1 → 4)-α-linked Gal*p*6S residues to 3,6-anhydro derivatives. According to this sequence, porphyran is a precursor of agarose, and, similarly, it is true for the pairs of carrageenans. Formation of 3,6-anhydrogalactose, similar to the final step of biosynthesis, is possible by the treatment with heated dilute alkali on the corresponding precursor. The corallinans, which are agar-like branched sulfated and methylated galactans from red algae of the order *Corallinales*, have (a) an agaran backbone, (b) a β-D-Gal*p* unit almost completely substituted at *O*-6 mostly with β-D-xylosyl side chains and less by sulfate, and (c) α-L-Gal*p* units partly substituted by methoxyl and sulfate groups at *O*-2 [22.89]. In addition, the latter units can be substituted at *O*-3 or *O*-6 with partially *O*-methylated α-D- or α-L-Gal*p* side chains (Table 22.5). Polysaccharides from various algae may differ in the position of these branches. There is a balance between the hydrophobic (methoxyl) and the hydrophilic (sulfate) groups, so the algal enzymatic system equilibrates their proportions to fulfill their biological design [22.90]. Decalcified tissue from *Calliarthron cheilosporioides* contains sulfated galactan, highly methoxylated but lowly glycosylated with xylose at *O*-6 of the β-D-Gal*p* units [22.91]. By contrast, calcified segments of this alga produce xylogalactans with high levels of xylose and low levels of 6-*O*-methyl ethers. Therefore, decalcification of algal tissues led to replacing xylosyl branches by methyl groups. These structural changes are caused by specific methoxyl transferase blocking xylosylation in decalcified tissue.

22.2.3 Fucoidans

Fucoidans are sulfated matrix cell wall polysaccharides of brown algae (Phaeophyceae). Simple fucoidans are sulfated homofucans, i. e., polysaccharides consisting of sulfated fucose only. However, in some reports this term is used to describe complex fucose-containing heteropolysaccharides. The chemical composition and structure of fucoidans are complex and variable, reflecting the differences in biosynthesis [22.6, 152]. Very often the exact structure of these polysaccharides remains unclear even when modern methods of structural analysis like selective enzymatic cleavage or correlation NMR analyses are applied. This problem is caused by significant irregularities in the structure of algal fucoidans, including the presence of numerous minor sugar and nonsugar components, random sulfation, and/or acetylation [22.6, 153]. There are two main types of backbone structure

Table 22.5 Side chain positions in corallinans and other agar-like branched sulfated xylogalactans

Source	Side chain	Position	References

[a] Sulfation of hydroxyls (S); [b] methylation of hydroxyls (Me)

found in fucoidans [22.152–154] (Fig. 22.2d,e, Table 22.6). The first type of fucoidan backbone structure consisting of (1 → 3)-linked partially or completely sulfated α-L-Fuc*p* units revealed fucoidans from orders *Ectocarpales* and *Laminares*: *Adenocystis utricularis* [22.141], *Analipus japonicus* [22.114], *Chordaria flagelliformis* [22.140], *Chorda filum* [22.127], *Ecklonia kurome* [22.123], and *Saccharina latissima* [22.128]. The second type is characterized by alternating the (1 → 3) and the (1 → 4)-linked α-L-Fuc*p* sequence. This backbone structure is common for fucoidans from *Stoechospermum marginatum* (order Dictyotales) [22.116] and from algae of the order Fucales, i. e., *Ascophyllum nodosum* [22.117], genera *Fucus* [22.118–120] and *Sargassum* [22.121]. Single α-L-Fuc stubs or short fuco-oligosaccharide sequences are present in many fucoidans as side chains attached mainly at *O*-2 of the backbone units. Structurally different fucoidans are commonly produced by the same algal species. For example, fucoidan isolated from *Ascophyllum nodosum* has a linear structure of alternating (1 → 3) and (1 → 4)-linked sulfated α-L-Fuc*p* [22.116]. By contrast, another fucoidan isolated from this alga is defined as a highly-

[a] FOS – fucooligosaccharides

branched polysaccharide with mainly (1 → 3) and a few α-(1 → 4)-linked sulfated α-L-Fuc in the core region; branch points are at *O*-2 position of the (1 → 3)-linked backbone units [22.115]. Three fucoidans from *Sargassum hornery* have a different backbone structure: (1 → 3), (1 → 4), and mixed (1 → 3),(1 → 4)-linked α-L-fucans; the latter polysaccharide was nonsulfated [22.122].

Some fucoidans were identified as not true fucans but rather complex heteropolysaccharides containing fucose as the major or minor component of the backbone (core), stubs, or longer side chains [22.152–154]. The structural features of these polysaccharides are summarized in Table 22.7. The core of such fucoidans is commonly built of alternating hexuronic acids–hexose sequences. This backbone is very sta-

ble and other sugars including sulfated or nonsulfated α-L-Fuc*p* can be attached to it as stubs or longer side chains. The complete highly branched molecule is thus structurally similar to rhamnogalacturonans of higher plants and may perform similar functions in algal cell walls. For example, highly branched fucoidan (92.7 kDa) isolated from *Hizikia fusiforme* contains a fucose-free core composed of the alternating sequence → 2)-α-D-Man*p*6S-(1 → 4)-β-D-Glc*p*A-(1 → with a little amount of → 4)-β-D-Gal*p*-(1 → [22.146]. The α-D-Man*p*6S units are sulfated or glycosylated (branching points) at the *O*-6 position. Side chains are formed by α-D-Xyl*p*, sulfated α-L-Fuc*p*, fuco and xylo-oligosaccharides, and longer → 6)-β-D-Gal*p*3S-(1→

Ulvanobiuronic acid 3-sulfate A	→ 4)-β-D-Glc*p*A-(1 → 4)-α-L-Rha*p*3S-(1→	$\mathbf{A_{3s}}$	*Ulva rigida*
Ulvanobiuronic acid 3-sulfate B	→ 4)-α-L-Ido*p*A-(1 → 4)-α-L-Rha*p*3S-(1→	$\mathbf{B_{3s}}$	*Ulva* sp.
Ulvanobiose 3-sulfate	→ 4)-β-D-Xyl*p*-(1 → 4)-α-L-Rha*p*3S-(1→	$\mathbf{U_{3s}}$	*Ulva rigida*
Ulvanobiose 2′, 3-sulfate	→ 4)-β-D-Xyl*p*2S-(1 → 4)-α-L-Rha*p*3S-(1→	$\mathbf{U_{2's,3s}}$	*Ulva rigida*
Ulvanobiuronic acid 2′-glucuronic acid 3-sulfate A	→ 4)-β-D-Glc*p*A[β-D-Glc*p*A-(1→2)]-(1 → 4)-α-L-Rha*p*3S-(1→	$\mathbf{A_{2'g,3s}}$	*Ulva rigida*

chains. Another variant of the core was found in fucoidan of *Padina gymnospora* [22.144]. The backbone of this polysaccharide is glucuronan, consisting mainly of (1 → 3)- or (1 → 4)-linked β-D-GlcA. Ascophyllan, a branched xylofucoglycuronan isolated from *Ascophyllum nodosum*. It has a backbone made of uronic acid, mainly (1 → 4)-linked β-D-Man*p*A, and branches containing sulfated α-L-Fuc*p* and β-D-Xyl*p* [22.145]. Sargassan, a complex polysaccharide from *Sargassum linifolium*, has a glucuronomannan core with internal side chains of (1 → 4)-linked sulfated β-D-GlcA and peripheral side chains made of sulfated α-L-Fuc*p* and β-D-Xyl*p* [22.148–151].

Complex highly branched polysaccharides have been isolated from *Sargassum stenophyllum* [22.147]. One of these had a linear galactomannan core formed by (1 → 6)-β-D-Gal*p* and/or (1 → 2)-β-D-Man*p* units with side chains containing β-D-Xyl*p*, (1 → 3)- and/or (1 → 4)-linked α-L-Fuc*p*, (1 → 4)-linked α-L-Glc*p*A, and α-D-Glc*p*. Two polysaccharides obtained from *Adenocytis utricularis* were identified as galactofucan and glycuronofucan [22.141].

22.2.4 Ulvans

Ulvans are principal matrix cell wall polysaccharides of green algae, genus *Ulva* [22.155]. The composition of these polysaccharides varied according to species, harvest season, growth conditions, and method of isolation [22.5, 156]. Four monosaccharides, i. e. α-L-Rha*p*, β-D-Xyl*p*, β-D-Glc*p*A and α-L-Ido*p*A, and sulfate are the main constituents of ulvans [22.155, 156]. Like in the case of alginates, these two uronic acids are C-5 epimers. All these types of sugar units are commonly arranged in the backbone, while single β-D-Glc*p*A can also constitute the side chains. The basic structure of ulvans is described by several repeating disaccharide fragments called ulvanobiuronic acids or ulvanobioses. Ulvanobiuronic acids (Fig. 22.2f,g) contain α-L-Rha*p* and uronic acid residues, while ulvanobioses contain

β-D-Xyl*p* instead of uronic acid (Fig. 22.2h). Ulvans isolated from several Ulvales species are composed of variable proportions of these disaccharides. Table 22.8 summarizes various oligosaccharides defined as structural fragments of ulvans.

22.2.5 Other Polysaccharides

Cell walls of many green algae contain alkali soluble linear (1 → 4)-β-D-glucuronans [22.25, 157–159]. Sulfated rhamnans have been isolated from *Monostroma nitidum* and *Monostroma latissinum* (Ulotrichales, Chlorophyta) [22.25, 160–165] and from *Gayralia oxysperma* (Ulvales, Chlorophyta) [22.25, 166]. Similar polysaccharides but in smaller amounts have been detected in *Bryopsis plumosa* (Bryopsidales, Chlorophyta) [22.19]. These polysaccharides have mainly (1 → 2)-linked, but also (1 → 3) and/or (1 → 4)-linked partially sulfated α-L-Rha*p* units. Moreover, they have single stubs of uronic acid residues as side chains. Rhamnan sulfate from *Monostroma nitidum* consists of (1 → 3)-linked α-L-Rha*p* residues, some of which are sulfated mainly at *O*-2 [22.162]. Minor amounts of internal (1 → 2)-linked and branched α-L-Rha*p* linkages have also been found. Branched sulfated glucorhamnan has been isolated from the same alga [22.162]. This polysaccharide is mainly composed of (1 → 2) and (1 → 3)-linked α-L-Rha*p* (1 : 2) partially sulfated at the *O*-3 and *O*-2 positions, respectively. In addition, (1 → 4)-linked β-D-Glc*p* fragments are bound at *O*-2 of some (1 → 3)-linked backbone units. By contrast, polysaccharide from *Monostroma latissinum* is defined as highly sulfated rhamnan composed mainly of (1 → 2)-linked α-L-Rha*p* residues with sulfate groups substituted at *O*-3 and/or *O*-4 [22.163]. Sulfated heterorhamnan isolated from *Gayralia oxysperma* has (1 → 3) and (1 → 2)-linked α-L-Rha*p* units in the backbone [22.166]. The latter units are partially substituted at C-3 by side chains containing single Glc*p*A, Gal*p*A or Xyl*p*. Both types of Rha*p* units are partially sulfated at *O*-2 and/or *O*-4; side chain uronic acids are also sulfated but only at *O*-2.

Sulfated xylomannans, linear or containing single stubs of β-D-Xyl*p*, or 3-*O*-methyl-β-D-Xyl*p* at *O*-2, have been described for many red algae. Branched sulfated xylomannans (33–222 kDa) have been isolated from two species of the genus *Chondrophycus* (Ceramiales, Rhodophyta) [22.167]. These polysaccharides consist of (1 → 4)-linked β-D-Man*p*2S backbone carrying stubs (15–25%) of single β-D-Xyl*p* (70–80%) and β-D-Man*p*2S (20–30%). Several fractions from *Nothogenia fastigiata* (Nemaliales, Rhodophyta) have been identified as xylomannans with a backbone of (1 → 3)-linked α-D-Man*p* sulfated at the *O*-2 and *O*-6 positions and single stubs of β-D-Xyl*p* at *O*-2 [22.168, 169]. Sulfated xylomannan (150 kDa) has been isolated from *Sebdenia polydactyla* (Sebdeniales, Rhodophyta) [22.170]. This polysaccharide contains a backbone of (1 → 3)-linked α-D-Man*p* units, partially substituted with a single stub of β-D-Xyl*p* at *O*-6. The main polysaccharide fraction isolated from *Nemalion helminthoides* (Nemaliales, Rhodophyta) has been identified as (1 → 3)-α-D-mannan sulfated at the *O*-4 and *O*-6 positions; other fractions are similar mannans but they contain single stubs of β-D-Xyl*p* [22.171, 172]. Sulfated arabinopyranan has been isolated from the green alga *Enteromorpha clathrata* [22.173]. The backbone of this polysaccharide is mainly composed of (1 → 4)-linked β-L-Ara*p* residues, partially sulfated at the *O*-3 position. Two sulfated polysaccharides, i. e., arabinan and arabinogalactan, have been isolated from *Codium dwarkense* (Bryopsidales, Chlorophyta) [22.174]. Two water-soluble sulfated polysaccharides from *Codium vermilara* (Bryopsidales, Chlorophyta) have been identified as (i) partially 2-*O*-sulfated (1 → 4)-β-D-mannan and (ii) (1 → 3)-β-L-arabinopyranan highly sulfated at the *O*-2 and *O*-4 positions [22.23, 24].

22.3 Isolation from Algal Raw Material

Crystalline, fibrilar, and matrix polysaccharides of algal cell walls can be successfully isolated from raw material by subsequent extractions. The isolation is based on the difference in solubility of these polysaccharides in various media at neutral, acidic, or alkali conditions. Usually matrix polysaccharides are well soluble in hot water, hemicellulose components are soluble in alkali solutions, while crystalline cellulose and, in some cases, xylans or mannans, remain insoluble at these conditions. Before subsequent extraction of polysaccharides, raw material is usually washed with organic solvents to remove lipids, pigments, and other small molecules, and then washed with distilled water to remove small hydrophilic molecules. Finally, raw material is dried and milled.

22.3.1 Extraction Procedures

The subsequent extraction steps vary depending on whether the polysaccharides contain sulfate and/or carboxylic groups. Routine procedures of common extraction of polysaccharides from various algae are outlined in Table 22.9. Extraction with cold water is followed by extractions with hot water and alkali solutions at different pH and temperatures [22.175]. This approach could be defined as universal because it is effective for the isolation of major polysaccharides from red algae (sulfated galactans, agars, and carrageenans), brown algae (sulfated fucoidans and xylans), and green algae (heteroglycuronans, ulvans). Neutral sugar (NS) and UA compositions vary significantly for crude water and alkali extracts, so it is possible to separate water and alkali soluble polysaccharides. For example, sulfated galactans predominate in water extracts, while floridean starch predominates in the alkali extracts. Heterofucan was assigned as the major polysaccharide in extracts from brown algae; however, alginates were not analyzed in this report. Alternatively, a combination of other media can be used for extractions.

In other work [22.176], brown algae (*Ascophyllum nodosum*, *Fucus vesiculosus*, and *Saccharina longicruris*) were subsequently treated with selective extraction media at 70 °C to obtain three fractions: fucoidan in a mixture with laminaran (2% aq. $CaCl_2$), fucoidan (0.01 mol L^{-1} aq. HCl) and alginate (3% aq. Na_2CO_3). Three different ways of sodium alginate isolation from brown algae *Macrocystis pyrifera* (Table 22.10) were compared in [22.49]. Acid pre-treatment was used in order to eliminate polyvalent cations prior to the extraction.Alginate was then solubilized under basic conditions and purified in different ways. Three methods of precipitation/purification (ethanol, HCl, and $CaCl_2$ routes) were used to study the influence of process conditions on the final products. Both HCl and $CaCl_2$ routes give low M_w alginates of poor mechanical properties owing to the partial acidic hydrolysis of the polymeric chain by the treatment with 1 mol L^{-1} HCl. By contrast, the ethanol route showed the highest yield and good rheological properties of the products. The diluted acid pre-treatment improved the yield of the ethanol route, avoiding the acidic hydrolysis of alginate.

Extraction of agars and carrageenans needs different conditions because these polysaccharides have a marked difference in sulfate contents [22.178]. Carrageenophytes (*Mastocarpus stellatus, Chondrus crispus, Calliblepharis jubata, Chondracanthus acicularis*, and *Chondracanthus teedei*) have been used for carrageenan extraction by alkali treatment (1 mol L^{-1} of NaOH, 80 °C, 3 h), whereas agars have been isolated from agarophyte (*Gracilaria gracilis*) by hot water extraction (90 °C, 4 h). Two major cell-wall polysaccharides have been extracted from the green seaweed *Ulva rigida* sequentially with oxalate and KOH containing media [22.157]. Sulfated glucuronorhamnoxylan (ulvan) has mainly been extracted with oxalate, while two hemicelluloses, i. e., (1 → 4)-β-D-glucuronan and glucoxylan, have been isolated at alkali conditions.

Kinetic modeling (KM) is often used for optimization of extraction procedures and to obtain good quality products. For example, a kinetic model has been proposed for the alkaline extraction of alginate from the fresh brown alga *Laminaria digitata* in order to predict the yield as a function of the stirring level and the size of algae pieces [22.179]. Such models may help to

Table 22.9 Extraction of marine algal polysaccharides

Extraction media/reagents	Main polysaccharides			References
	Red algae	Green algae	Brown algae

reduce the extraction time of high-quality alginate production. The proposed model was defined as a first step in the more complete extraction kinetic model, taking into account the effect of temperature. The effects of various variables (alkali treatment, relative amount of water, soaking/extraction time, and temperature) have been investigated on agar extraction from the red alga *Gracilaria cliftonii* [22.180]. The agar yield was significantly affected by all these variables.

Response surface methodology (RSM) has been used to determine the optimum extraction conditions for yield and further parameters of agar extraction from *Hydropuntia cornea* [22.177] and carrageenan extraction from *Kappaphycus alvarezii* [22.181]. This method explores the relationships between several explanatory (reaction conditions of designed experiments – temperature, extraction time, pH, concentration of reagents, etc.) and response (yield, molecular weight, structural features, and physical properties of extracted polysaccharides) variables [22.182]. Among the parameters of reaction conditions, the extraction temperature is supposed to be the most important for increasing of the yield. Extraction procedures can be also optimized by the assistance of other additional factors like extrusion, microwaves (MW), or specific enzymes. Alkaline extraction of alginates from *Laminaria digitata* has been modified by reactive extrusion, which enables process time savings, yield increase, and improvement of the rheological properties of the products [22.183].

Microwave-assisted extractions (MAE) of algal polysaccharides have been tested and optimized [22.183]. A combination of mathematical and statistical techniques allowed us to determine the optimal experimental conditions for MAE extraction of agar from *Gracilaria vermiculophylla*. Enzyme-assisted extraction has also been used in the processing of marine algae [22.184] using endoprotease (Neutrase) for enzymatic digestion. A novel enzymatic extraction of marine algal polysaccharides with cellulase using RSM to search for the optimal conditions (enzyme concentration, ratio of medium/raw material, and extraction time) has been developed to reach high yields [22.185].

22.3.2 Purification of Crude Extracts

The crude extracts of algal polysaccharides are usually concentrated, dialyzed against distilled water, and then freeze-dried or precipitated with an excess of ethanol. Crude extracts usually contain a mixture of two or more polysaccharides, for example, pairs of carboxylic and sulfated ones like an alginate/fucoidan mixture from brown algae or an ulvan/glucuronan mixture from green algae. These components are effectively separated by changing the pH or by treatment with Ca^{2+} cations [22.49]. Alginic acids are insoluble due to protonation of carboxyls. In addition, G-blocks in alginates are able to form egg-box complexes with Ca^{2+}, which leads to calcium alginate precipitation. By contrast, fucoidans remain soluble at low pH and weakly interact with divalent cations. Glucuronans are often co-extracted together with ulvans from the cell wall of *Ulva* sp. with the use of hot water that often contains a calcium chelating agent such as sodium oxalate; ion-exchange chromatography has been used to eliminate glucuronans from the ulvan preparations [22.157, 158].

By contrast to ulvans, $(1 \rightarrow 4)$-β-D-glucuronans are insoluble at lower pH. Based on this difference, acidic precipitation (pH 2) has been used to separate ulvan and glucuronan from the hot oxalate buffer extract (0.05 mol L^{-1}, pH 6, 90 °C, 3 h) of *Ulva lactuca* [22.159]. The high amount of uronic acids (94% m/m) and the absence of sulfate groups have confirmed the purity of precipitated glucuronan. Extracts of crude algal polysaccharide have further been fractionalized and/or purified on various preparative columns using gel permeation and/or ion exchange chromatography with isocratic or gradient elution [22.83, 173]. These procedures lead to separation of polysaccharides according to their specific retention times and to removal of impurities like proteins, phenolics, or other polysaccharide admixtures. Proteins are also removed by the treatment with various chemical reagents or proteases; phenolics

by the treatment with oxidative agents. Fucoidan was purified from its natural complex with polyphenols by the treatment with 5% H_2O_2 (pH 8.3–8.7, 18 °C), and this treatment did not lead to marked desulfation of the polysaccharide [22.83, 186]. Fucoidans treated with H_2O_2 have not demonstrated any significant changes in backbones or sulfation degrees compared with the raw polysaccharide [22.83, 187]. However, a decrease in M_w is possible at higher reaction temperatures, H_2O_2 concentration, and reaction time.

22.4 Algal Polysaccharides such as Phycocolloids

Algal matrix cell wall polysaccharides can be assigned as phycocolloids (or phycohydrocolloids) because they are soluble in water and can create colloid systems in aqueous media or participate in their formation. Some of these polysaccharides can form gels and films at appropriate conditions; the films are commonly obtained by solution casting and solvent evaporation. The physical and chemical properties of phycocolloids, including gel formation, have been reviewed in connection with their structure [22.188]. The geometry of glycosidic linkages and the ability to form intra and intermolecular junctions are prerequisites of gel and film formation. These associations may be affected by (i) negatively charged groups (sulfates and carboxylates), which tend to expend a polysaccharide chain due to mutual electrostatic repulsion; (ii) various substituents (methyls, acetyls, pyruvate ketals, glycosylation, etc.), which cause steric hindrance and/or participate in various intra and intermolecular interactions; and (iii) dissolved small molecules or metal cations that influence the hydratation property of water. Conditions such as temperature, pH, and ionic strength may also influence gel formation.

22.4.1 Alginic Acid/Alginate Gels and Films

Alginates of alkali metals and alginic acids form transparent, flexible, and water soluble films by casting of their aqueous solutions. Films prepared from Gul*p*A rich alginate demonstrate lower plasticity and have proved to be better moisture barriers than those prepared from Man*p*A rich alginate under the same conditions [22.189, 190]. Alginate films are effective cation exchangers. Their solubility may significantly decrease in the presence of multivalent metal cations [22.191, 192]. The Ca^{2+} and Zn^{2+} cations make alginate film water insoluble, increase its tensile strength, and decrease elongation. These effects are less pronounced for Cu^{2+} and Al^{3+} cations and little pronounced for Fe^{3+} and Mg^{2+} cations. Metal cations of smaller ionic radius cause tighter cross-linking of alginate films [22.193]. Cross-linking by Ca^{2+} produces significantly thicker and stronger, but less elastic alginate films; water vapor permeability decreases significantly only for highly cross-linking films [22.194]. The incorporation of multivalent metal cations into the alginate films may partially replace the weak polar interactions between polysaccharide chains by stronger cation mediated electrostatic junctions [22.195].

Alginates are able to form two types of gels: (i) alginic acid gel at acidic conditions (pH < pK_a of uronic carboxyls) and (ii) cross-linking thermostable gels at neutral conditions in the presence of Ca^{2+}. Acidic gels are stabilized by intermolecular hydrogen bonds and the junction zones of these gels are probably composed of random aggregates [22.196]. G-blocks are the most important fragments for both acidic and Ca^{2+} gel formation, whereas M-blocks support only acidic gel formation. Alternating or random sequences destabilize alginic acid gel formation due to their lack of repeating structure. In the case of neutral gels, cations of other alkaline earth metals, excluding Mg^{2+} or other divalent metal cations, can be used instead of Ca^{2+}. G-blocks, but not GM or M-blocks, of alginates interact strongly and cooperatively with these cations, forming *egg-box* type structures [22.47, 197]. Ca^{2+} ions can replace carboxylic protons in the G-blocks, which are zipped into cavities [22.198, 199]. The Ca^{2+} binding capacity does not depend on the M/G ratio of alginates, but Gul*p*A exhibit much stronger affinity to these cations than Man*p*A [22.200]. In this model, the cations (*eggs*) are situated in the cavities inside *puckered boxes* formed by four Gul*p*A units of the two superimposed chains. The individual *boxes* potentially possess oxygen ligands from COO^-, 2-OH, 3-OH, O-5 pyranoid rings, and O-4 of glycosidic bonds in the G-blocks; some of these ligands directly interact with Ca^{2+}, others participate in intra and intermolecular hydrogen bonds stabilizing the *egg-box* complex [22.201]. Based on FTIR (Fourier transformed infrared) spectroscopic analysis of ionic alginate gels with various divalent metal cations, different coordination geometry was proposed for the metal-carboxylate complexes in G-blocks (*pseudo-bridged* unidentate) and M-blocks (bidentate

bridging) [22.202]. The strength of alginate gels depends on the M/G ratio and distribution of GG, MM, and GM-blocks in the polysaccharide chain [22.203, 204]. Alginates with a low M/G ratio and a high content of G-blocks form dense and brittle gels, whereas alginates with a high M/G ratio and a high content of M-blocks give more elastic gels [22.12, 13, 205].

There are three distinct and successive steps in the binding of Ca^{2+} to alginate with increased concentration of Ca^{2+} ions [22.206]: (i) interaction of Ca^{2+} with a single Gul*p*A unit forming mono-complexes, (ii) propagation and formation of *egg-box* dimers via pairing of these mono-complexes, and (iii) lateral association of these dimers, generating *egg-box* multimers. In freshly prepared gels, junction zones are assumed to consist of *egg-box* dimers only. At higher Ca^{2+} concentration upon drying, these dimers may associate laterally into ordered domains (*egg-box* multimers) by different ways, including the most probable electrostatic interactions between Ca^{2+} and carboxylates [22.198, 207]. Lateral association of alginate chains is reduced by removing Ca^{2+} excess from the gel beads in a washing step prior to air drying. The *egg-box* multimers are disrupted by noncross-linking cations (Na^+, K^+ or Mg^{2+}), which replace the Ca^{2+} bound to the alginate. The result is swelling of the alginate gel. Ca^{2+} alginate gelation has been described as random cross-linking of multifunctional monochains [22.208]. Alginate gels showed strain-hardening behavior at large deformations, which was explained by (i) the re-orientation of chain segments longer than the distance between cross-links [22.209], (ii) structure densification or highly cross-linked polymer systems [22.205], and (iii) the deformation of rod-like junction zones [22.210].

22.4.2 Gels and Films Based on Sulfated Galactans

Some red algal sulfated galactans (agars and carrageenans) are able to form films and thermally reversible hydrogels by cooling of their hot aqueous solutions. Agar films demonstrate a lower tensile strength, water vapor permeability, swelling ratio, and water solubility than κ-carrageenan films. Each property of the mixture agar/κ-carrageenan films varies depending on the ratio of each component [22.211]. Gelation of sulfated galactans is a complex process that depends on temperature, structure, and concentration of polysaccharide, and on the presence of metal cations, which can induce conformational changes in the polymer chain. As a result, the initial coil-to-helix transition is followed by subsequent aggregation of these helices [22.212–215].

The final gel structure is the result of mutual interactions between conformational transition, molecular cross-linking, and phase-separation processes [22.216]. A honeycomb-like network has been observed for aqueous solutions both of agars and carrageenans at various temperatures. Its structure depends on the gelling stage, the structural type (D- or L- absolute configuration of the 3,6-anhydro-α-Gal*p* units), and the concentration of sulfated galactan. Honeycomb-like structures are gradually replaced by more homogeneous networks during the formation of brittle and strong agar-type hydrogels; they are retained, however, in the case of highly elastic carrageenan-type hydrogels. Therefore, the gelation mechanisms should be different for agars and carrageenans. In addition, sulfated galactan gels of high polysaccharide concentration may be structurally different from those of low polysaccharide concentration. Three possible mechanisms of carrageenan/agar gel formation focussing on the specificity of junction zones have been proposed: (i) the double-helical model based on intertwined double helices [22.217, 218], (ii) the domain model with cation-mediated aggregates of double helices [22.212, 219], and (iii) the nested, single-helix model with cation-specific salt bridges between ordered chain segments [22.220, 221]. To date, the step-by-step mechanism of gel formation as well as corresponding conformational transition, i. e., coil-helix or coil-double helix are still unclear [22.216]. Metal cations may be involved in gel formation depending on the presence and distribution of sulfate semiester groups. The shielding effect of alkali metal cations prevents electrostatic repulsion of sulfate groups in κ-carrageenan gels and thus stabilizes the double helices. Agarose gel is not influenced so much by these cations because of the lack of sulfate groups [22.222].

Carrageenan films have randomly distributed sets of pores [22.223]. Their mechanical properties depend on the sulfate/anhydro substitution of carrageenan. Pure κ-carrageenan films are stronger, less flexible, and exhibit a higher tensile strength than pure ι-carrageenan films. The tensile strength of the mixture of κ/λ and κ/ι-carrageenan films decreases with an increasing contribution of κ-carrageenan and is lower than that of pure λ and ι-carrageenan films. Reciprocal relations have been demonstrated for the elongations and water vapor permeability [22.224]. The gelation properties of carrageenans strongly depend on their structure, first of all on the presence of sulfate semiester and 3,6-anhydro groups. The high density of charged sulfates

supports extensive conformation of the carrageenan chain. The presence of the 3,6-anhydro-link in λ-carrageenan allows the α-D-Gal*p* residues to revert to their $^1C_4$ conformation, which is necessary for the initial double helix formation required for gelling. Alkali treatment of carrageenans or their precursors during processing increases the gelling properties of the final polysaccharide and the strength of gels due to conversion of α-D-Gal*p*6S to the 3,6-anhydride. As a result, κ-carrageenans and furcellaran (κ/β-carrageenan) with less sulfates but more 3,6-anhydro groups form a firm gel with K^+. By contrast, more sulfated but less or no anhydrated ι- and λ-carrageenans are slightly affected by these cations; ι-carrageenan needs Ca^{2+} to form soft elastic gels, and λ-carrageenan cannot form gels at all. Hot solutions of κ and ι-carrageenans form gels after cooling of their hot aqueous solutions to 40–60 °C in the presence of the appropriate metal cations. These gels are stable at room temperature, can be re-melted by heating to 5–20 °C above the gelling temperature, and re-gel after repeated cooling. Highly flexible carrageenan molecules are able to form helical structures when their concentration increases or temperature decreases. The mechanism of κ-carrageenan gelation in the presence of K^+ and other alkali metal cations (Na^+, Rb^+) is thus based on the cation supported aggregation of helical dimers, which consist of two single [22.225] or double [22.210] helices.

In any case, a two-step gelation mechanism has been proposed for both ι and κ-carrageenans [22.212, 214]. Thermally reversible carrageenan gels exhibit hysteresis or a difference between setting and melting temperatures. The gelation of κ-carrageenan solutions is independent of liquid-liquid phase separation due to the rapid formation of cross-linking points [22.226]. Furcellaran (κ/β-carrageenan) and κ-carrageenan gels are relatively rigid and undergo syneresis, but ι-carrageenan yields soft and elastic gels with very little tendency to undergo syneresis. In this case, the 2-*O*-sulfate groups on the 3,6-anhydro-α-D-Gal*p* units prevent the tightly-packed aggregation responsible for the rigidity of κ-carrageenan gels.

Agar is commonly defined as the mixture of neutral agarose and highly sulfated agaropectin. The ratio between these parts depends on the algal source of agar. Agarose demonstrates a much higher gelling ability than amylopectin. Agarose is well soluble in hot water (up to 80 °C) because it has chains at stiff random coil conformation [22.227–229]. Upon cooling below the gelation temperature (40 °C), the coils reorder to form helices that subsequently laterally aggregate into a network of thick bundles to form a gel. It is unclear, however, if the proposed high-ordered structure is made of a single helix [22.228–230] or a double helix [22.218]. Agarose gels (≈ 4 m/v %) are typically rigid and turbid, and undergo hysteresis between the melting and setting temperatures. The length of helices suitable for stable association increases with heating. Slow cooling leads to longer helices than rapid cooling, and longer helices promote better aggregation. As a result, the gels formed by slow cooling are stronger and more turbid than those obtained by rapid cooling [22.231]. The gelation process is followed by liquid–liquid phase separation because the network formation based on aggregated bundles leads to the dilution of solute agarose in the network interspaces [22.226, 232]. The agar chains form bundles of aggregates, generating a network at the temperature of sol–gel transition. Longer agar chains preferably aggregate, while shorter agar chains are retained in the solute and form isolated aggregates upon further cooling. Reheating leads to easy dissociation of the loose aggregates, whereas bundles of aggregates are thermostable like the whole gel [22.233].

22.4.3 Gelling/Film Forming by Fucoidans and Ulvans

In contrast to other phycocolloids, there is a little evidence about the gelling and film forming properties of fucoidans. There are, however, several reports that confirm that this polysaccharide by itself or in a mixture with other polymers is able to form gels and films [22.234]. Varying amounts of fucoidan in a liquid medium may provide specific rheological properties of the resulting gel.

Green seaweed polysaccharide ulvans are well soluble in water. However, despite their high negative charge, they demonstrate condensed conformation and low intrinsic viscosity in aqueous saline or acidic solutions, which is probably due to the hydrophobic contribution of CH_3 in Rha*p* [22.156]. This polysaccharide is probably not fully dissolved but forms free condensed spherical nanostructures (10–18 nm) dispersed in the solvent. At strong alkali conditions (pH 13) these structures collapse into a dense homogeneous network, which is the basis for strong films and gels. Gelation and film formation at lower pH levels needs divalent cations and/or boric acid. Ulvan forms thermoreversible gel in the presence of boric acid, Ca^{2+}, or other divalent metal cations (but not Mg^{2+}), and narrow region of pH around 7.5 [22.11]. The mechanism of gel formation

Table 22.11 Composite algal polysaccharide (phycocolloid) films and gels containing other hydrocolloids

Phycocolloids	Other hydrocolloids	Composite films	Composite gels
Alginate	Starch	[22.235, 236]	[22.235, 237–239]

	Chitosan	[22.298]	
	Protein	[22.299]	
Ulvan	Chitosan		[22.300]

is unique, very complex, and not well understood. The role of borate and cations in ulvan gelation is unclear. Both these reagents probably promote the aggregation of ulvan nanostructures mentioned above, which are interconnected by more hydrophilic parts of non-condensed polysaccharide chains. Ulvan gels should be stabilized by weak reversible interactions, so borate ester bridges between ulvan macromolecules are improbable [22.301, 302]. NMR spectroscopy has not confirmed formation of ulvan borate esters [22.303]. On the other hand, Ca^{2+} may link borate ester, sulfate semi-ester, and/or carboxylate groups forming junction zones. The unique properties of ulvan gel are interesting for systems of controlled gelation, for example, in drug delivery systems [22.303, 304].

22.4.4 Interaction with Other Hydrocolloids

Phycocolloids can interact with other natural and chemically modified hydrocolloids and between each other, forming mixed films, gels, and other structures. Some composite films and gels containing phycocolloids are overviewed in Table 22.11. Among these examples, the alginate–pectin mixtures are interesting due to their ability to form thermoreversible synergistic gels at pH < 3.8 without the addition of sucrose [22.246, 247]. The strength and melting points of these gels increase at lower pH and M/G ratios of alginates. Gelation depends on the sequential distribution of monomeric units in the alginate chain and needs tetrameric or longer G-blocks. Mixtures containing alginates with low M/G ratio and high methoxy (HM) pectins show the strongest synergism, the highest storage modulus, and the fastest kinetics of gel formation [22.245]. By contrast, gels based on alginates with high M/G ratio and low methoxy (LM) or low methoxy amidated (LMA) pectin demonstrate lower storage modulus and slower kinetics. Pectin, but not alginate, affects the network density and the strand characteristics of mixed gels, whereas the homogeneity in the gel microstruc-

ture decreases with the addition of alginate content but is independent of the pectin. Specific interactions between hydrocolloids may significantly change the properties of hydrogels. For example, the addition of starch, alginate, or κ-carrageenan decreases the strength of agar gels, while plant seed galactomannans demonstrate marked synergistic effects on the strength of agar and κ carrageenan gels [22.278, 290, 292].

Rheological properties of starch colloid systems can be regulated by the addition of fucoidan [22.297]. At lower concentrations, fucoidan probably damages the junction zones between starch macromolecules, but these polysaccharides are not mutually excluded. By contrast, at higher concentrations, fucoidan may induce considerable mutual exclusion through a phase separation process. Mixed films and gels can be prepared based on the electrostatic interaction between negatively charged phycocolloids and positively charged chitosan or protein. For example, a combination of sodium alginate and gelatine provides synergism in the rheological properties of the resulting mixed gels [22.276]. Chitosan-alginate films exhibit low solubility, good tensile properties, permeability to water vapor, and biocompatibility, which is important for biomedical applications [22.259, 260]. The addition of fucoidan to chitosan films increases their mechanical robustness and elasticity, making composite chitosan-fucoidan films more suitable as wound dressings than pure chitosan films [22.298]. Ulvan-chitosan ionic complex gels are also prepared and characterized as more stable than alginic acid (alginate)-chitosan gel under the appropriate conditions [22.300].

22.5 Biological Activities and Medicinal Applications

Besides hydrocolloid properties, both sulfated and carboxylated algal matrix cell wall polysaccharides are known to have various specific biological activities, which are prerequisites of pharmaceutical and medicinal applications. Partially sulfated algal polysaccharides exhibit immunomodulatory, anticoagulant, antithrombotic, antimutagenic, anti-inflammatory, antitumor, antiprotozoal, antimicrobial, and antiviral activities [22.305]. Generally, these biological activities are related to the structure, composition, and sulfate substitution of polysaccharide macromolecules. Among the activities mentioned above, the immunomodulating and anticoagulant activities seem to be immediate and, therefore, the most important for understanding the mechanism of action. As potential anticoagulants, algal polysaccharides are able to compete with the commonly used heparin. Because they affect the immune system, they may enhance antitumor, antibacterial, and antiviral resistance. In medicaments they can be used as an active substance if they possess the specific biological activity necessary for curing, or as a drug carrier if they are able to interact with an active substance (commonly small or nonpolymeric molecules), and thus improve its activity or provide its delivery to specific parts of the organism.

22.5.1 Immunomodulation and Related Activities

Immunomodulation is based on the specific enhancement or suppression of the host response with the aim to reach the desired immune effect [22.306]. This approach allows enhanced natural mechanisms of the immune response without the use of therapeutics like antibiotics. Immunomodulators are substances that affect the immune system. They can stimulate, suppress, or modulate any specific part of the immune system, including both adaptive and innate arms of the immune response [22.307]. Immunomodulators can be classified into three categories: (i) immunoadjuvants or specific immune stimulants, (ii) nonspecific immunostimulants, and (iii) immunosuppressants. Immunoadjuvants are true modulators that select between various types and mechanisms of immune responses. Thus, these agents are used to design vaccines or enhance their efficacy. Nonspecific immunostimulants enhance the basic level of immune response and are thus used for prophylactic purposes or for strengthening the impaired immune system. Both specific and nonspecific immunostimulants activate immunity directly or indirectly to be effective against cancer cells and various infection agents (prions, viruses, bacteria, or microscopic *Eukaryota*). Therefore, antitumor, antiprion, antiviral, antimicrobial, antifungal, or antiprotozoal activities of algal polysaccharides are often mediated by immune stimulation. By contrast, immunosuppressants are able to weaken the immune response that is often applied to reduce inflammation in various pathological states. Sulfated algal polysaccharides (fucoidans, galactans, etc.) may stimulate/inhibit cell immunity by activation/inhibition of macrophages and/or other cells of the immune systems and enhance/suppress the production of specific antibodies. Macrophages are critical in reg-

ulating innate immunity as well as adaptive immune responses by producing an array of cytokines such as interleukins (IL) IL-1β and IL-6, tumor necrosis factor (TNF)-α and interferon-γ (INF-γ), and various types of chemokines such as RANTES (regulated on activation, normal T-cell expressed and secreted), monocyte chemotactic protein (MCP)-1, macrophage inflammatory protein (MIP)-1α, thymus and activation regulated chemokine (TARC), etc. [22.308, 309]. Polysaccharide macromolecules may interact with specific membrane receptors of macrophages including Toll-like receptor (TLR)-4, cluster of differentiation (CD)-14, complement receptor (CR)-3 and scavenger receptors (SR). As a result, the intracellular signaling pathways are promoted, involving mitogen-activated protein kinases (MAPK) and transcription factors. Activation of macrophages via MAPK induces the production of both nitric oxide (NO) and cytokines. Partially, interleukin-12 (IL-12) stimulates the development of T-cells, which produce interleukin-2 (IL-2) that, in turn, activates proliferation of natural killer (NK) cells, representing a first line of defence organism against both primary tumors and metastases. NK cells produce other cytokines, including interferon (INF)-γ, which can further provoke macrophages in their stimulation of T-cells via induction of IL-12. NK-mediated killing of target cells by apoptosis is facilitated by activation of caspase cascades [22.310]. Many algal polysaccharides have been reported for their immunomodulatory activities as they stimulate the activity of macrophages. Polysaccharides from the red algae *Porphyra yezoensis* [22.311, 312] and *Gracilaria verrucosa* [22.313] are reported to have macrophage-stimulating activity in vitro and in vivo. A fucoidan isolated from the sporophyll of brown alga *Undaria pinnatifida* (Korean *Miyeokgui*, Japanese Mekabu) stimulated macrophages to produce cytokines (IL-6, TNF-α) and chemokines (RANTES, MIP-1α) from macrophages and splenocytes [22.125]. Carrageenan isolated from red algae promotes mice leukocytes to produce TNF-α [22.314]. A sulfated water-soluble polysaccharide isolated from the green alga *Capsosiphon fulvescens* is reported to stimulate macrophage to release TNF-α and IL-6, and induce the expression of inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2). These enzymes are responsible for the production of NO and prostaglandin E2 (PGE2), respectively [22.315]. A sulfated glucuronorhamnan, an ulvan, of the green algae *Ulva rigida*, is also reported to stimulate macrophage to secrete PGE_2 and induce an increase in COX-2 and NOS-2 expression [22.316]. Immunomodulation and other biological activities of marine algal polysaccharides are reviewed in Table 22.12.

22.5.2 Antitumor and Antimutagenic Activities

The antitumor effect of fucoidans and other sulfated algal polysaccharides that are nontoxic for tumor cells is commonly associated with the following indirect activities:

1. The inhibition of tumor cell proliferation
2. The stimulation of the apoptosis of tumor cells
3. Blocking tumor cell metastasis
4. The inhibition of blood vessel formation
5. The enhancement of various immune responses [22.393].

Partially, antitumor and antimetastatic activity of these polysaccharides is mediated by increased NO production by stimulated macrophages [22.364], activation of NK cells via specific cytokines, and/or induction of caspase-dependent cancer cell apoptosis via inhibition of specific MAPK [22.310, 381, 394]. Fucoidan may also activate caspase-independent apoptosis via activation of ROS-mediated MAPK and regulation of the Bcl-2 family protein-mediated mitochondrial pathway [22.395]. Fucoidan from *Cladosiphon okamuranus* significantly inhibited in vivo and in vitro growth and induced apoptosis of human T-cell leukaemia virus type 1 (HTLV-1) infected T-cells. This fucoidan also inhibited in vivo growth of model HTLV-1-induced tumors based on subcutaneously transplanted infected T-cell lines in immune deficient mice [22.396]. Both Miyeokgui (*Undaria pinnatifida* sporophyll) and commercial (*Fucus vesiculosus*) fucoidans showed antitumor activity against four types of cancer, i. e., PC-3 (prostate cancer), HeLa (cervical cancer), A549 (alveolar carcinoma), and HepG2 (hepatocellular carcinoma) cells [22.137]. Fucoidans blocked tumor cell adhesion that could be important for antimetastatic effects [22.397, 398]. Fucoidan from *Fucus evanescens* produced an inhibitory effect against metastasis and potentiated antimetastatic, but not antitumor, effects of cyclophosphamide [22.348]. Fucoidans suppress angiogenesis and thus reduce the supply of tumor tissues [22.399, 400]. Fucoidans stimulate proliferation of macrophages [22.401] and mediate tumor destruction through Th1 cell and NK cell responses [22.380]. Fucoidans activate lymphocytes and macrophages mediated by the production of NO, H_2O_2, and cy-

tokines (TNF-α, IL-6), contributing to their effectiveness against tumors [22.402].

22.5.3 Anti-Inflammatory Activity

Inflammation is a complex physiological phenomenon that responds to injury, infection, and stress. Anti-inflammatory activity is the ability to reduce inflammation and is used, partially, for pain remedying. Cytokines, such as interleukins IL-1β, IL-6, TNF-α, and NO have been known to play important roles in pro-inflammatory responses involving various types of cells [22.393]. NO is synthesized by inducible nitric oxide synthase (iNOS) isophorm, which is expressed in response to activation of nuclear factor κB (NF-κB) and MAPK induced by various effectors, such as bacterial lipopolysaccharides (LPS) or Concanvalin A (ConA). PGE2, COX-2, and monocyte chemoattractant protein-1 (MCP-1) are also related to inflammatory states. Sulfated polysaccharide from *Sargassum hemiphyllum* significantly reduces secretion of NO and pro-inflammatory cytokines (IL-

1b, IL-6, TNF-α) by LPS-activated macrophages; it also inhibits LPS-triggered messenger ribonucleic acid (mRNA) expressions of IL-1b, iNOS, and COX-2, which may be attributed to the downregulation of NF-jB in the nucleus [22.373]. Similarly, fucoidan from *Ecklonia cava* inhibits NO and PGE2 production by LPS-stimulated macrophages via the inhibition of enzymes iNOS and COX-2 [22.375]. Microglial activation plays an important role in the pathogenesis of neurodegenerative diseases, and fucoidans significantly inhibit LPS-stimulated microglial production and mRNA/protein expression of the mentioned inflammatory factors involving suppression of specific MAPK [22.350, 361]. Mekabu (*Undaria pinnatifida* sporophyll) fucoidan enhanced Th1 cell response and inhibited Th2 cell response in normal mice, reducing the immunoglobulin E (IgE) level in mice serum [22.379]. Fucoidan also induces IL-10 production in plasma and liver, inhibits the production of ConA-induced proinflammatory cytokines, and thereby prevents liver injury [22.352]. Fucoidan improves murine chronic colitis by inhibition of IL-6 production in colonic epithelial cells [22.370]. The gastro-protective (anti-ulcer) effect of fucoidan against aspirin-induced ulceration may take place through the prevention of the elevation of proinflammatory cytokines IL-6 and IL-12 [22.353]. The anti-ulcer property of fucoidan might contribute to protecting inflammatory cytokine-mediated oxidative damage to gastric mucosa [22.354]. The anti-obesity effect of fucoidan is also related to its anti-inflammatory activity. Miyeokgui (Mekabu) fucoidan suppresses adipogenesis via the inhibition of major markers and inflammation-related cytokines in adipocytes. Hence, it may afford some potential to control or reduce obesity [22.378]. Fucoidan from *Fucus vesiculosus* can be useful for the prevention or treatment of obesity due to its stimulatory lipolysis [22.358].

22.5.4 Activities Against Infection Agents

Marine algal polysaccharides, especially sulfated ones, have attracted considerable attention in recent years for their antiviral activities against animal viruses [22.325, 403, 404], such as HSV types 1 and 2 [22.113, 133, 170, 405], human immunodeficiency virus type-1 (HIV-1) [22.406, 407], the influenza virus [22.408], and the human cytomegalovirus (HCMV) [22.133]. Although the use of these polysaccharides and oligosaccharides as drugs is in its infancy, currently, some are already in various phases of clinical trials [22.409–412]. An *Undaria pinnatifida* extract comprising predominantly sulfated galactofucan (60−70% in mass and with relatively higher molecular weight of over 30−1000 kDa) has been patented for its in vivo antiviral activity including HSV-1 [22.413]. The antiviral activity of algal sulfated polysaccharides may have a direct or an indirect mechanism, i. e., based on (i) hindering the adsorption of viral

particles onto the host cell surface and/or direct inhibition of viral replication, or (ii) activation of immune pathways. Many viruses are able to bind to cell surface proteoglycans (heparan sulfates), which is important for the entrance of viral particles into the cell. Because they have a strong affinity to viruses, algal sulfated polysaccharides may inhibit the adhesion of viral particles onto the cell surface and thus put obstacles into the viral life circle [22.170]. If the antiviral effect of polysaccharides is significant only at the early stage of the viral replication cycle, viral adsorption is proved. By contrast, antiviral activity after infection confirms that the polysaccharide directly inhibits the viral replication and transition of virions between uninfected and infected cells (virucidal effect). For example, sulfated galactans from red algae *Sphaerococcus coronopifolius* and *Boergeseniella thuyoides* inhibit in vitro replication of both HIV and HSV-1. However, in the case of the HSV-1 cycle, these polysaccharides block the adsorption step, while a direct virucidal effect was observed for HIV-1 replication [22.341]. Antimicrobial and antiprotozoal activities of algal sulfated polysaccharides may be caused by direct interaction with microorganisms, blocking of microorganism-binding cell receptors, or by modulation of the immune response. For example, fucoidan (sulfated galactofucan) from *Undaria pinnatifida* sporophyll might inhibit cryptosporidiosis by direct binding to the *Cryptosporidium parvum*-derived functional mediators in the intestinal epithelial cells of neonatal mice [22.385]. This polysaccharide also exhibits anti-malarial activity against cultured *Plasmodium falciparum* parasites in vitro and on *Plasmodium berghei*-infected mice in vivo [22.414].

22.5.5 Anticoagulant and Antithrombotic Activities

The anticoagulant activity of sulfated polysaccharides, including those from algal sources is based on the interactions with plasma cofactors, which are natural inhibitors of coagulation proteases [22.415]. These interactions are complex and depend on the monosaccharide composition, the molecular weight, and the structure and distribution of sulfate groups. Sulfation is always important for both anticoagulant and antithrombotic activities, but the charge density is not always critical. Commonly anticoagulant activity of algal hydrocolloids, i. e., sulfated galactans, mannans, rhamnans, fucans, or more complex polysaccharides, is described as *activated partial thromboplastin time* (aPTT), *thrombin time* (TT), *prothrombin time* (PT), and *antithrombin to anticoagulation factor Xa* activities in comparison with corresponding values of heparin obtained at the same in vitro and/or in vivo experimental conditions [22.416]. The anticoagulant activity of algal sulfated polysaccharides is mainly attributed to thrombin inhibition mediated by antithrombin and/or heparin cofactor II, while other mechanisms have also been proposed. For example, several different fucoidan preparations from various algal species, including *Fucus versiculosus* [22.417, 418], *Laminaria brasiliensis* [22.417], *Ecklonia kurome* [22.418], *Ascophyllum nodosum* [22.419], *Pelvetia caniculata* [22.420], and the sporophyll of *Undaria pinnatifida* [22.384], have been reported for their anticoagulant activity. Fucoidans have potent anticoagulant activity mediated by antithrombin and/or heparin cofactor II [22.421]. The differences in anticoagulation mechanisms could be explained by the structural diversity of these polysaccharides and the interaction with several target proteases. The driving force for the formation of the sulfated polysaccharide/protein complex is the nonspecific electrostatic interaction between these macromolecules; then the complex is stabilized by other (polar or nonpolar) short-range interactions [22.422]. Anticoagulant polysaccharide should undergo appropriate conformational transitions to possess distorted ordered conformation suitable for protein binding. Model invertebrate sulfated α-L-fucans and sulfated α-L-galactans of regular linear structure show in vitro anticoagulant activity; some of them also express antithrombotic activity on in vivo models [22.421]. More complex algal sulfated polysaccharides having similar structural patterns may exhibit similar activities, which are not determined by charge density, but rather depend on monosaccharide composition and sulfation pattern. Partially, disulfated internal monosaccharide residues probably have the highest potential for anticoagulant activity due to their ability to place sulfate groups in spatial positions adequate for interaction with proteins. Slight differences in the proportions and/or distribution of sulfated residues may be critical for the interaction between proteases, inhibitors, and activators of the coagulation system, resulting in a distinct pattern in anti and pro-coagulant activities and in the antithrombotic action of algal sulfated galactans [22.337]. Sulfated galactans need much longer chains for the anticoagulant effect than heparin. Macromolecules of $\approx$15–45 kDa are able to bind antithrombin but are too short to link the plasma inhibitor and thrombin. Binding to different sites on antithrombin, sulfated galactans are less effective than heparin at promoting antithrombin conformational ac-

tivation. A different mechanism predominates over the conformational activation of antithrombin in ensuring the antithrombin-mediated anticoagulant activity of the sulfated galactans. Possibly, sulfated galactan connects antithrombin and thrombin, holding the protease in an inactive form. The conformational activation of antithrombin and the consequent formation of a covalent complex with thrombin appear to be less important for the anticoagulant activity of sulfated galactan than for heparin [22.338]. The $(1 \rightarrow 3)$-α-L-galactan, but not α-L-fucan, sulfated at *O*-2 is a potent thrombin inhibitor mediated by antithrombin or heparin cofactor II; these two polysaccharides show similar inhibitions when factor Xa is used instead of thrombin [22.423]. The proportion and/or distribution of 2,3-disulfated α-Gal*p* units along the galactan chain may be a critical structural motif to promote the interaction of the protease with specific protease and coagulation inhibitors [22.338, 424]. In contrast to the linear fucans from echinoderms and mammalian glycosaminoglycans, which need thrombin inhibitors (antithrombin or heparin cofactor II) for a reasonable anticoagulant effect, branched fucans (fucoidans) from brown algae are direct inhibitors of thrombin [22.425]. The occurrence of 2,4-di-*O*-sulfated units is an amplifying motif for 3-linked α-fucan-enhanced thrombin inhibition by antithrombin. If we replace antithrombin by heparin cofactor II, then the major structural requirement for the activity becomes single 4-*O*-sulfated fucose units, while the presence of 2-*O*-sulfated fucose residues always inhibits anticoagulant activity [22.424]. Therefore, the anticoagulant activities of sulfated galactans and fucans are not determined only by their charge density. The structural requirements for interaction of sulfated galactans and sulfated fucans with coagulation cofactors and their target proteases are stereospecific and not merely a consequence of their charge density and sulfate content [22.423, 424]. The unusual sulfated D-galactan (hybrid carrageenan) from *Botryocladia occidentalis* demonstrate marked anticoagulant activity via enhanced inhibition of thrombin and factor Xa by antithrombin and/or heparin cofactor II [22.62]. Disulfated α-Gal*p* units seem to be necessary for effective anticoagulant action, while high negative charge density itself is not so important. Sulfated galactofucan from *Spatoglossum schroederi* does not show any in vitro anticoagulant activity but demonstrates a potent antithrombotic activity in vivo and strong stimulation of the synthesis of heparan sulfate by endothelial cells. These effects have not bee observed after desulfation [22.142].

22.5.6 Antioxidant Activities

Because they are important for living organisms, enzymatic or nonenzymatic oxidative reactions can be destructive in some cases. Many products, including reactive oxygen species (ROS) and other free radicals are commonly produced by the oxidation of lipids and other biomolecules. These products promote chain reactions that cause the destruction of cellular structures and hence cell death. Antioxidants, in turn, may terminate chain reactions by free radical scavenging. Living organisms, including marine algae, have developed regulator systems based on natural antioxidants, both enzymatic (peroxidases, superoxide dismutase, and catalase) and nonenzymatic (glutathione, vitamins A, C, and E). If such systems do not work well, oxidative stress may occur and lead to various pathological states. Therefore, antioxidants might prevent many diseases, including degenerative ones, and thus promote human health and longevity. Algal antioxidants including sulfated polysaccharides have been reviewed in the context of algal biology and utilization [22.426]. The antioxidant activity of algal polysaccharides is defined as their ability to inhibit model oxidation processes; some examples are given in Table 22.12. The antioxidant properties of algal polysaccharides and associated compounds are commonly established as (i) DPPH (2,2-diphenyl-1-picrylhydrazyl) free-radical scavenging, (ii) oxygen radical absorbance capacity (ORAC), (iii) ferric ion reducing antioxidant power (FRAP) or ferrous ion chelating ability (FCA), (iv) ABTS (2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid)), and (v) ROS scavenging assays [22.427]. Structure and sulfation patterns may influence these antioxidant effects of algal polysaccharides. It has been reported that ι-carrageenan demonstrates higher hydroxyl radical scavenging than λ and κ-carrageenans [22.328]. Alternatively, algal polysaccharides have been tested in accordance with in vitro and in vivo responses to experimental oxidative stress. For example, it has been reported that ulvan-like sulfated polysaccharide from *Ulva lactuca* stabilizes mitochondrial and microsomal membranes by prevention of the oxidative stress induced by D-GalN [22.319].

22.5.7 Medicinal Materials Based on Algal Polysaccharides

Algal cell wall polysaccharides have great potential for medicinal applications because of their biocompatibility with human tissues, their biodegradability, and

their nontoxicity. Among these polysaccharides, commercially available, low-cost alginates are known to be the most suitable for the preparation of biomedical materials based on pure and composite films, gels, and fibers [22.428, 429]. Due to the high water content, porosity, elasticity, permeability, and the ability to create a moist environment, alginate gels are effective in wound healing, drug delivery, and tissue engineering. Partially, calcium alginate hydrogels demonstrate both haemostatic activity due to Ca^{2+} and promotion of the aggregation of platelets and erythrocytes. The hydration, swelling, and erosion behavior of alginate matrices depend on pH, which is also true for drug release mechanisms [22.430]. As was mentioned above, alginic acid/alginate is able to form two types of gel at acidic and neutral conditions, which is a good prerequisite for the construction of controlled-release systems [22.431, 432]. Two types of diffusion systems have been prepared based on alginates [22.431]: (i) the polymer membrane system, in which the drug formulation (solid, suspension, or solution) is inside semipermeable gel-like polymeric capsules, and (ii) the polymer matrix system, in which the drug is homogeneously dispersed in a rate-controlling polymeric matrix of swelling microspheres or conventional tablets. Sodium alginate matrices can effectively sustain drug release even for highly water-soluble drugs [22.433, 434]. Alginate-based dressings are widely used to treat various surgery wounds [22.435–437]. The medicinal effect of calcium alginate as a wound dressing is based on its cation exchange properties [22.435]. After application, Ca^{2+} of the film/fibre surface is partially replaced by Na^{+} from blood serum, which leads to swelling, partial dissolution of the polysaccharide, and gelation. The effectiveness of this process depends on the structure and source of the alginate. Some properties of alginate films like transparency, thermal stability, water absorption, and swelling behavior improve with the presence of various additives, for example *Aloe vera* [22.438]. Composite materials consisting of alginate and other natural or modified polysaccharides have been shown to be potentially useful in drug delivery systems and other medicinal applications [22.131, 439]. Much fewer references in the literature are devoted to using fucoidan for wound healing. Because it has various biological activities, this polysaccharide is interesting as a component of wound dressing materials. Fucoidan-chitosan films might be a potential treatment system for dermal burns [22.298]. Local administration of fucoidan films safely reduced post-surgical adhesion in model animals [22.440]. Fucoidan improves the physical/chemical properties (roughness, hydrophilicity and surface sulfate content) of silk fibroin films, and brings about anticoagulant activity and enhanced endothelial cell affinity to silk fibroin [22.441]. Thus, fucoidan/silk fibroin films can be applied as blood-contacting biomaterials.

22.5.8 How to Improve Algal Polysaccharides

There are many ways to improve initially inactive or weakly active natural algal polysaccharides to fit various medicinal applications. First of all, partial degradation of algal polysaccharides leads to obtaining polymeric molecules of lower molecular mass, smaller oligomeric molecules (oligosaccharides), and small molecules (monosaccharides or their fragments). Smaller fragments of algal polysaccharides are more soluble in water, less viscous, and may interact with various biological targets like cell receptors or viral particles. Marine algal polysaccharides or derived oligosaccharides can be also chemically modified by the addition of polar or nonpolar groups. Partially, sulfation of nonsulfated polysaccharides (alginate) or oversulfation of sulfated algal polysaccharides (galactans, fucoidans) is the way to increase the negative charge density of the macromolecules, which may have a beneficial effect on their immunomodulation, anticoagulant, and other properties.

22.5.9 Partial Degradation

Marine algal polysaccharides can be degraded by the use of chemical or enzymatic treatment. Examples of microbial enzymes and microorganisms that are able to cleavage algal polysaccharides are shown in Table 22.13. Biological functions of oligosaccharides originating from marine algae were reviewed by [22.454]; some of these activities are similar to the corresponding activities of native polysaccharides. For example, both native algal polysaccharides and their oligomeric fragments may stimulate defence responses and protect plants against various pathogens [22.455]. However, in other cases, algal oligosaccharides exhibit novel activities that are nontypical for the initial polysaccharides, even the way of cleavage could be important. Partially, alginate oligosaccharides obtained by enzymatic degradation promote growth and influence the fatty acid composition of the biohydrogen producer of the green algae

Table 22.13 Examples of microbial enzymes and microorganisms degrading marine algal polysaccharides

Polysaccharide	Enzyme	Microbial source	References
Alginate	Alginate lyases	*Vibrio* sp. 510	[22.442]
		Pseudomonas sp. HZJ 216	[22.443]
		Pseudoalteromonas sp. Y-4	[22.444]
Carrageenans	Carrageenases	*Cytophaga* sp. MCA-2	[22.445]
		Pseudoalteromonas carrageenovora IFO12985	[22.446]
		Pseudoalteromonas carrageenovora	[22.4]
		Alteromonas fortis	[22.4, 59, 60]
Agar	Agarase	Unidentified marine bacteria	[22.447]
		Bacillus sp. MK03	[22.448]
		Agarivorans sp. HZ105	[22.449]
		Pseudomonas vesicularis MA103	[22.450]
		Aeromonas salmonicida MAEF108	[22.450]
Fucoidan	Fucoidanase	*Sphingomonas paucimobilis* PF-1	[22.135, 136]
		Fusarium sp. LD8	[22.451]
		Luteolibacter algae H18	[22.452]
	Acetyl esterase	*Luteolibacter algae* H18	[22.452]
Ulvan	Ulvan lyases	*Persicivirga ulvanivorans*	[22.453]

Chlamydomonas reinhardtii, which may significantly enhance biomass production [22.456]. By contrast, partial acidic hydrolysis of alginate does not lead to products that are able to affect the growth of these algal cells. Alginate oligosaccharides also promote the growth of the microalga *Nannochloropsis oculata*, which is used as a feed for sea animals and zooplankton [22.457]. Alginate oligosaccharides stimulate epidermal growth factor (EGF)-dependent growth of human keratinocytes [22.458] and vascular endothelial growth factor (VEGF)-mediated growth and migration of human endothelial cells [22.459]. Alginate oligosaccharides stimulate the in vivo growth of probiotic bacteria of the genus *Bifidobacterium* [22.460]. Alginate oligosaccharides inhibit colonization of *Salmonella enteritidis* in broiler chickens [22.461]. Alginate oligomers affect the growth and quality of biofilms, as well as the state of bacterial cells inside and also reduce the tolerance of wound biofilms to antibiotics [22.462]. Alginate oligosaccharides have a high scavenging •OH activity, while fucoidan oligosaccharides demonstrate good Fe^{2+} chelation [22.463]. Low-molecular weight fuco-oligosaccharides (< 3749 Da) have been prepared by enzymatic degradation of fucoidan (sulfated and acetylated galactofucan) from the Korean *Undaria pinnatifida* sporophyll [22.135, 136]. These fucoidan oligomers exhibit strong anticoagulant activities at which APTT and TT are significantly prolonged. Unlike intact fucoidan, these fuco-oligosaccharides do not affect PT. Therefore, the molecular weight and/or sulfate content may be important factors for the anticoagulant activities of fucoidans. Fucoidan oligosaccharides can markedly reduce the arterial blood pressure and plasma angiotensin II of the resting heart rate (RHR), and the respiration of RHR has the same change trend as blood pressure [22.464]. Carrageenan and agar oligosaccharides have also been prepared and tested on various bioactivities. Various biological activities of these oligosaccharides have been observed, and often these activities depend on the molecular weight and degrees/patterns of sulfation. An oligosaccharide (2 kDa) obtained from κ-carrageenan effectively inhibits influenza A H1N1 virus replication, as well as mRNA and protein expression inside the cell [22.465]. Both κ and λ-carrageenan oligomers demonstrate antitumor activity via a complex modulation of the immune response [22.466, 467] or organ-mediated defence reactions [22.445]. The κ-carrageenan oligosaccharide fraction exhibits a relatively higher antitumor activity against the three types of cancer cells (KB, BGC, and Hela) than the initial polysaccharide [22.466]. The κ-carrageenan oligosaccharides inhibited in vitro growth of five microorganisms, i. e., *Escherichia coli*, *Staphylococcus aureus*, *Saccharomyces cerevisiae* (maximal effect), *Penicillium citrinum*, and *Mucor* sp. [22.465]. The short agaro-oligosaccharides (2–4 units) suppress TNF-α production and iNOS expression [22.468], while somewhat longer oligosaccharides (6–8 units) can elicit a physiological response in red algae [22.469, 470]. Agar oligosaccharides obtained by enzymatic cleavage demonstrate antioxidative activities in ROS scavenging (•OH, $\bullet O_2^-$) and inhibit lipid peroxida-

tion [22.447]. Sulfated and longer fragments show stronger antioxidant activities than nonsulfated and shorter ones.

22.5.10 Chemical Modification

Sulfation (or oversulfation) of marine algal polysaccharides is an effective way of obtaining biologically active derivatives that are especially interesting as potential anticoagulants. The patterns of sulfation are often an important factor of expected biological activity. The inactive partially sulfated and 3,6-anhydro-substituted κ, ι, and θ-carrageenans have been oversulfated regioselectively, and the anticoagulant activity of the derivatives obtained has been studied by aPTT *in vitro* assay [22.471]. The results confirmed that sulfation at *O*-2 of 3,6-anhydro-α-D-Gal*p* and at *O*-6 of β-D-Gal*p* increases the anticoagulant activity. The oversulfated κ-carrageenan showed a 30 times higher anticoagulant activity on doubling the PT time in comparison with the native polysaccharide [22.472]. This derivate also gave a threefold enhancement of the glutamic plasminogen (Glu-Plg) activation by tissue plasminogen activator (t-PA) or by urokinase (u-PA), while both native κ-carrageenan and crude heparin were less active. Similarly, oversulfated fucoidan showed four times higher anticoagulant activity in doubling PT time and gave higher stimulations of Glu-Plg activation by t-PA and by u-PA in comparison to the native fucoidan [22.473]. Oversulfation of fucoidan also enhances its antiangiogenic and antitumor activities [22.474]. Similarly what was mentioned above, oligomers of marine algal polysaccharides can be sulfated or oversulfated as well. Alginate oligosaccharides obtained by treatment with alginate lyase from *Vibrio* sp. 510 [22.442] have been sulfated by the formamide-chlorosulfonic acid method [22.475]. One of the derivatives obtained showed significant inhibition of tumor growth without direct cytotoxic effect, which was proposed to be caused by immunomodulation. Oversulfated, acetylated, and phosphorylated derivatives of κ-carrageenan oligosaccharides have been prepared and their in vitro antioxidant activities tested [22.476, 477]. In certain antioxidant systems some of these derivatives exhibit higher activities than the initial poly and oligosaccharides. The κ-carrageenan oligosaccharide derivatives inhibit tumor growth and stimulate macrophage phagocytosis and spleen lymphocyte proliferation [22.478]. Among them, the oversulfated derivative shows the highest antitumor activity expressed both in the decrease of tumor weight and in eliciting NK cell activity. These effects are significantly higher than those of the unmodified oligosaccharides. There are two ways to obtain novel materials based on marine algal polysaccharides: (i) covalent cross-linking via previously added substituents and/or cross-linking agents (dialdehydes, epichlorohydrin, phenolics, etc.), and (ii) interaction with synthetic polymers or their fragments. Porous scaffolds based on alginate derivative bearing phenolics has been prepared using horseradish peroxidase catalyzing cross-linkage formation between phenolic hydroxyls [22.479]. These materials have been shown to be suitable for cell immobilization. Cross-linking carrageenan beads (microgels) have been prepared for controlled release delivery systems using epichlorohydrin as the cross-linker [22.480]. The swelling/shrinking behavior of these cross-linked microgels in saline solutions has shown great potential for the application in food or pharmaceutical products. Highly stretchable and tough hydrogels have been prepared from cross-linked algal polysaccharide and synthetic polymers [22.481]. Both types of macromolecules form networks based on ionic (alginate) and covalent (polyacrylamide) cross-linkages. Because they contain $\approx$ 90% water, composite gels can be stretched beyond 20 times their initial length, and notched samples exhibit a stretch of 17 times. These novel material containing marine algal polysaccharides (cross-linked alginate) significantly enlarge the area of hydrogel applications.

23. Iodine in Seaweed: Two Centuries of Research

Frithjof C. Küpper

This paper provides a historic overview of the research on iodine in seaweeds, starting with historic uses of iodine-containing seaweeds in ancient China and Greece. Iodine as a novel element was discovered by Courtois in Napoleon-era France. This triggered research on the chemical properties of the novel element and also started an iodine-producing seaweed industry. However, iodine-containing seaweeds did not receive much academic attention until the end of the nineteenth century, when the release of molecular iodine from red algae was discovered, followed by similar findings in brown algae (kelp) three decades later. The 1950s saw the rise of studies of iodine uptake in kelp, based on the availability of radioactive iodine isotopes. Since the 1970s, a wealth of studies has investigated the emission of iodo- and other halocarbons from seaweeds and their role in the atmospheric and marine environments. Our group has addressed the physiology and biochemistry of iodine uptake in *Laminaria* since the 1990s. This has established the involvement of both hydrogen peroxide and vanadium haloperoxidases in the process and led to the finding of iodine efflux upon oxidative stress. X-ray absorption spectroscopy identified the accumulated form as iodide, constituting an antioxidant protecting the cell wall space and surface of kelp against oxidative stress. Iodide in *Laminaria* constitutes the first inorganic and chemically simplest antioxidant known from a living system. Upon exposure to atmospheric ozone, this leads to the emission of molecular iodine and, together with high irradiance, to the formation of ultrafine particles.

References 594

As early as the third millennium B.C., the goiter-preventing effects of seaweeds had been known to the legendary emperor Shen-Nung in ancient China. The use of burnt seaweeds and sponges as diet supplements for the same purpose was common in the era of the Greek physician Hippocrates (460–370 B.C.; [23.1]). However, iodine as a novel element was discovered in the context of the Napoleonic Wars in Europe. For more detailed historical accounts, several excellent reviews are available (e.g., [23.2–4]). Bernard Courtois, a manufacturer of saltpeter (KNO_3), was trying to contribute to the war effort – and to gain a livelihood – by obtaining saltpeter from novel sources [23.2]. When replacing wood ashes as the raw material for soda by the ashes of brown seaweeds (mainly *Fucus* sp. and *Laminaria* sp., which are abundant on rocky French Atlantic coasts) in (probably November) 1811, his copper vessels not only underwent strong corrosion, but the addition of concentrated sulfuric acid also resulted in the emission of a previously unobserved violet vapor based on the reaction

$$2I^- + H_2SO_4 \rightarrow I_2 + {SO_3}^{2-} + H_2O\,.$$

Tragically, Courtois was not able to pursue his research on this new substance himself due to a lack of money and 2 years passed. Still, he managed to incite Charles Bernard Desormes and Nicolas Clément, two of his chemist friends, to pursue the work, together with André M. Ampère and the most eminent French chemist of that era, Joseph Louis Gay-Lussac. On behalf of Courtois, Clément also presented the findings to the Imperial Institute of France (Conservatoire des Arts et Métier, where he held a professorship) on November 29, 1813, which led to their original publication in the *Annales de Chimie* [23.5]. Based on the Greek *ιώδης* i. e., *violet*, due to the beautiful violet color of its vapor, the name *iode* was already used in this paper for the new substance. It also mentions the metal-like appearance of its solid, elemental

state. Soon afterwards, on December 6 and 20 of the same year, *Gay-Lussac* presented his results about the compounds that this novel element forms with others [23.6, 7].

Amazingly, despite the war in which most of Europe was embroiled in at that time, scientific exchange between opposing powers was little affected. Sir Davy, the leading British chemist of the time, corresponded with his French colleagues (mail was transported between the warring countries by smugglers and cartels). Napoleon himself, enthusiastic about science, gave him free passage to France and onwards to Italy. Ampère gave Davy a sample of iodine, inducing him to conduct his own research on the new substance (Davy was traveling with a portable chest for chemical experiments). After initially believing that it was merely a compound of chlorine, *Davy* ultimately came to conclude that it was an element in its own right [23.8], and competed for a while with Gay-Lussac over priority rights (even though both Davy and Gay-Lussac always acknowledged Courtois as the discoverer of iodine). Despite the scientific fame of the discovery and rising commercial interest in iodine, e.g., for the treatment of wounds, Courtois failed to capitalize on his discoveries and, sadly, died in poverty on September 27, 1838, aged only 62 [23.3]. Iodine production from seaweeds became a major economic activity in coastal regions of Europe – in particular, in parts of Brittany, Normandy, Ireland, and Scotland, and it features in many historic and travel accounts of these places (e.g., [23.9]).

While the chemical knowledge of the novel element progressed, iodine-accumulating seaweeds did not receive much research attention until the end of the nineteenth century. Exemplary for this period are the studies of *Eschle* [23.10], who investigated the iodine content of *Fucus vesiculosus* and *Laminaria digitata*. As early as 1894 *Golenkin* reported on the release of free iodine by the red alga *Bonnemaisonia asparagoides* – detected by a blue stain of starch in paper [23.11]. Several decades passed until this was more widely accepted by the community, in particular by the studies of *Sauvageau* [23.12] on red algae and of *Kylin* [23.13] and *Dangeard* [23.14] in the 1920s. The latter, obviously working in competition, were the first to report the emission of molecular iodine (I_2) from kelp (*L. digitata*) surfaces, termed *iodovolatilization*. Remarkably, their discovery was forgotten or ignored until the re-discovery of molecular iodine emissions in recent years [23.15, 16].

The rise of nuclear physics and the availability of radioisotopes enabled studies of the uptake mechanism of iodine in brown algae, notably those of *Tong* and *Chaikoff* on the Pacific kelp *Nereocystis luetkeana* [23.17], of *Bailey* and *Kelly* on *Ascophyllum nodosum* [23.18], and of Shaw on *Laminaria* [23.19, 20]. In about the same era, the requirement of macroalgae for iodine as a micronutrient was recognized [23.21].

The implications of iodine emissions for atmospheric and marine chemistry were not recognized until the findings of strongly increased methyl iodide concentrations around kelp beds by *Lovelock* [23.22]. The vast majority of these studies focused on organic iodine compounds, curiously ignoring the findings of inorganic, molecular iodine emissions made more than half a century earlier [23.23]. More evidence for the impact of kelp forests on the coastal atmosphere came from research by *Alicke* et al. [23.24], detecting iodine oxide, and *O'Dowd* et al. [23.25], highlighting the role of iodine oxides in aerosol formation in the marine boundary layer (however, postulating diiodomethane as the precursor). Not until the work of *McFiggans* et al. [23.15] and *Palmer* et al. [23.16], however, did the importance of inorganic iodine emissions for coastal, ultrafine particle formation become clear.

Our research on iodine metabolism in *Laminaria* started with a study on its uptake mechanism, based at the Station Biologique de Roscoff in the 1990s. Initially, this work confirmed that iodide (and not iodate, present at roughly equal levels in surface sea water, with a total iodine concentration of around 0.5 µM [23.31, 32]) is the species taken up. Total iodine concentrations of up to over 5% dry weight were observed in young *Laminaria* thalli – effectively constituting the strongest iodine accumulators observed so far among all living systems. It also revealed that an intact cell wall is required for sustained iodine uptake – protoplasts (i. e., algal cells, from which the cell wall has been enzymatically removed) do no take up iodine [23.26]. However, iodine uptake in protoplasts can be restored to levels corresponding to those observed in *Laminaria* tissues under physiological conditions when either exogenous H_2O_2 or a constitutively H_2O_2-producing, enzymatic system are added. These results highlighted the importance of hydrogen peroxide in iodide uptake. Subsequently, experiments were conducted with *Laminaria* tissues, investigating the effect of exogenously added H_2O_2. Remarkably, exogenous H_2O_2 did enhance iodide uptake – but only up to H_2O_2 levels of around 25 µM. Higher hydrogen peroxide levels resulted in a pronounced efflux of previously accumulated iodine – providing first clues of the biological significance of iodine accumulation in

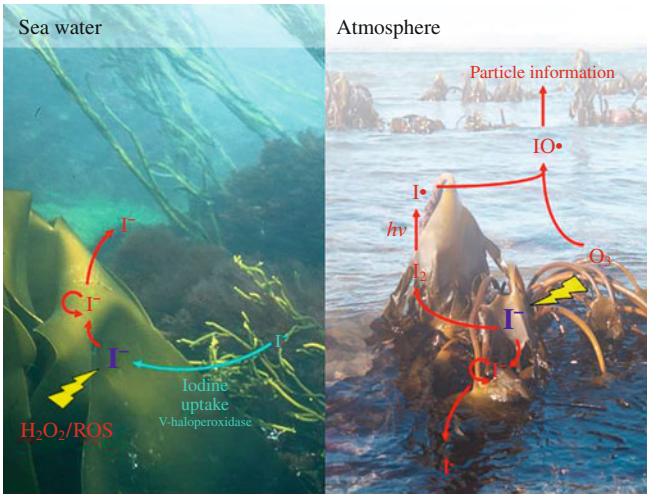

Fig. 23.1 Known pathways of iodine between algal metabolism and the environment in the brown alga *Laminaria digitata*, the strongest accumulator of this element among all living systems. Most of the time, kelp forests are covered by water (*left*). In this largely unstressed steady state (*turquoise*), iodide from sea water is taken up by a mechanism driven by low micromolar levels of hydrogen peroxide and vanadium haloperoxidases [23.26] and stored in the apoplast of cortical cells [23.27]. Iodide is the accumulated species. Upon oxidative stress (*red*) such as an oxidative burst [23.28], this accumulated iodide is mobilized and scavenges hydrogen peroxide by a pseudocatalase-like reaction sequence known as iodide-(halide-)assisted disproportionation of hydrogen peroxide (iodide acts as catalyst, i. e., it is regenerated at the end of a reaction cycle – there is no accumulation of oxidized or organic iodine species [23.29]). When kelp forests are partially exposed (*right*), e.g., during spring tides, significant oxidative stress from various causes can occur, including both atmospheric oxidants such as ozone but also hydrogen peroxide from the photosynthetic Mehler reaction accumulating in the liquid microlayer on the wet algal surface. Ozone reacts directly with iodide, resulting in the release of volatile, molecular iodine (I_2) at flux rates so high that it can easily be detected in the marine boundary layer of the atmosphere photometrically, using starch paper or even by the human nose. Molecular iodine becomes photolyzed rapidly and rapidly reacts further with ozone, forming ultrafine particles consisting of iodine oxides. These are highly hygroscopic and thus provide cloud condensation nuclei [23.30]. In contrast to ozone, hydrogen peroxide from the Mehler reaction is scavenged by iodide-assisted disproportionation as described above

general. This work also established the involvement of vanadium haloperoxidase in iodine uptake: Only the macroscopic *Laminaria* sporophytes take up significant levels of iodine, the haploid, filamentous gametophytes do not. The former have high levels of haloperoxidases, the latter do not. However, iodine uptake can be induced in gametophytes upon addition of exogenous H_2O_2 and haloperoxidase. Subsequently, the Roscoff group identified *Laminaria* iodoperoxidase, a novel subclass of the vanadium haloperoxidases [23.33, 34] which may explain the selectivity for iodide uptake in *Laminaria*.

We joined forces with the Norwich group to investigate iodocarbon emission rates from a range of ecologically relevant seaweed species from the European Atlantic cost [23.35]. These studies went in parallel with a survey of natural *Laminaria* populations on different parts of the European coast. Oral traditions of Breton seaweed gatherers (goémoniers) had suggested that kelp contained more iodine in the winter than in the summer, and also that seaweeds from northerly locations in Europe had more of the precious commodity than in the south (*Kloareg*, personal communication). Interestingly, this could be confirmed; at about 1% dry weight total iodine, fully-grown *Laminaria* thalli contain about twice as much iodine in the winter as in the summer [23.36]. Recently, *Verhaeghe* and the Roscoff group demonstrated that iodine accumulation occurs in the apoplast of cortical *Laminaria* cells [23.27].

Ultimately, we turned our attention to what we considered the core question, which had remained hitherto unanswered, despite almost two centuries of research on iodine in seaweeds: why do these algae actually

have to accumulate this element to such extreme levels? For this, it seemed crucial to first unambiguously clarify the chemical speciation of accumulated iodine. In fact, various and sometimes contradictory opinions existed about the chemical state of iodine in *Laminaria*. To this end, we used a non-invasive technique, X-ray absorption spectroscopy, thus excluding the possibility of artifacts upon extraction [23.37]. This approach revealed that the accumulated form is, indeed, iodide, which is contained in a largely organic (rather than hydrated) environment. Upon oxidative stress such as an oxidative burst [23.28, 38–40], a transition to a more hydrated form occurs. Concomitantly, a strong efflux of accumulated iodide occurs. Altogether and in light of the hypothesis of *Venturi* [23.41], our results suggest that iodide serves the function of an antioxidant, protecting the apoplast (cell wall space) of the cortical cell layers. This constitutes the description of the first inorganic and of the chemically simplest antioxidant known from a living system [23.29]. Indeed, the reaction of iodide with the major reactive oxygen species is both thermodynamically and kinetically favorable. With the involvement of vanadium haloperoxidase and in the absence of organic co-substrates, iodide effectively degrades H_2O_2 (halide-assisted disproportionation of hydrogen peroxide). Furthermore, the millimolar iodide levels on the *Laminaria* surface exposed at low tide effectively scavenge atmospheric ozone, leading to the release of I_2 – at rates up to about five orders of magnitude higher than the combined iodocarbon emissions. These studies [23.16, 29] unambiguously clarify the biochemical origin of particle-forming iodine oxides. Molecular iodine is photolyzed and further oxidized by ozone in the marine boundary layer, producing hygroscopic iodine oxides. The latter form ultrafine particles, leading to aerosol formation and establishing a unique link between a biological antioxidant and climatic processes [23.30].

The current understanding of iodine metabolism is summarized in Fig. 23.1. Using X-ray absorption spectroscopy in combination with other techniques, we have recently demonstrated that bromide complements iodide as an antioxidant in particular with regards to superoxide detoxification and that overall, its function is more diverse than that of iodide in algal physiology [23.42].

In the 200 years since its discovery, research on iodine has developed into multiple areas of science, far beyond marine algae where it was originally found and beyond the scope of this chapter. In this context, we would like to highlight a recent interdisciplinary review article by an international consortium [23.43] that covers the many fascinating facets of iodine science and applications ranging from the history of its discovery to general, marine, atmospheric, environmental, radio- and geochemistry, medicine and physiology, materials science (in particular including semiconductors and solar cells), and organic synthesis.

24. Marine Macrophytes: Biosorbents

Chiara Pennesi, Fabio Rindi, Cecilia Totti, Francesca Beolchini

Biosorption is a biological method suggested as a cheaper and more effective technique for heavy metal ion removal and recapture from aqueous solutions such as industrial wastewater. A large range of biomass, principally bacteria, algae, seagrasses, crab shells, yeasts, and fungi have received increasing attention for heavy metal ion removal and recovery. In particular, through this method, nonliving aquatic macrophytes (i. e., macroalgae and seagrasses) can be used for heavy metal removal due to their large availability, easy regeneration, and low costs. In recent years, macrophytes have been shown to be able to remove pollutants by surface adsorption or by bioaccumulation, incorporating metals into their tissues or storing them in a bound form. The type of biomass used in the treatment procedure can make a significant difference for the removal of pollutants. Furthermore, the knowledge of metal kinetic biosorption parameters for nonliving macrophytes has become crucial for treatment design to improve the efficiency of metal removal in artificial systems for their recycling. In this chapter, the properties of dried macrophytes in the treatment of wastewater and their cell wall and cuticle compartments are described. Moreover, the procedures for biosorption experiments are analyzed.

24.1 Marine Macrophytes

The term *macrophytes* indicates aquatic organisms capable of performing oxygenic photosynthesis that are sufficiently large-sized to be observed with the bare eye. They typically grow submerged or floating in riverine, estuarine, and marine coastal environments, where they play a key role as primary producers. Marine macrophytes form the bulk of the photosynthesizing biomass in coastal habitats; they belong to two different groups, indicated with the common names of algae and seagrasses.

24.1.1 The Algae

The term algae designates the complex of all oxygenic photosynthesizers other than embryophyte plants [24.1]. As such, algae represent a heterogeneous assemblage of organisms belonging to many separate evolutionary lineages, which in modern classifications are distributed in no less than four eukaryotic supergroups (Archeplastida, Chromalveolata, Excavata, Rhizaria) [24.2]. Due to such vast evolutionary diver-

sity, different groups of algae exhibit striking differences in terms of morphology, ultrastructure, ecology, biochemistry, and physiology.

The benthic macroalgae, or seaweeds, are the most common macrophytes on marine shores where stable substrata exist (natural rock, artificial reefs, concrete, or wood pillars). They belong to three different groups, empirically recognized on the basis of thallus color: the red algae (phylum Rhodophyta), the brown algae (phylum Heterokontophyta, class Phaeophyceae), and the green algae (phylum Chlorophyta, class Ulvophyceae). Although they co-exist in the same coastal habitats, these three groups are phylogenetically distinct and are characterized by different biochemical and physiological traits. This has important implications with regard to their biosorption properties.

24.1.2 Marine Benthic Green Algae (Chlorophyta, Ulvophyceae)

The Viridaeplantae, formed by the embryophyte plants and the complex of algae generally called green algae, is one of the most diverse evolutionary lineages within the eukaryotic supergroup Archaeplastida [24.3, 4]. Molecular and ultrastructural studies conducted in the last 20 years suggest that the Viridaeplantae evolved from a unicellular flagellate ancestor, from which an early separation in two lineages took place [24.3, 4]. One of these, the Streptophyta, radiated in freshwater environments and eventually gave rise to terrestrial embryophyte plants. The other, the Chlorophyta, had a more complex evolutionary history and gave rise to several different groups of green algae. The class Ulvophyceae is the most diverse of these groups in terms of thallus complexity and cellular sophistication, and includes the vast majority of the green benthic macroalgae (about 1600 species) [24.4].

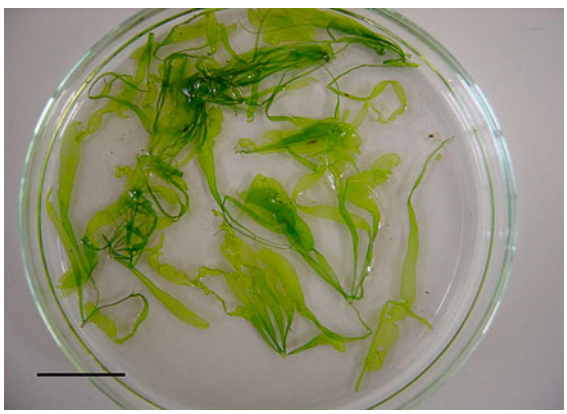

Fig. 24.1 Thallus of *Ulva compressa* (green algae) from Portonovo, Ancona, Adriatic sea (Italy). Scale bar: 2 cm

Species of Ulvophyceae occur in all oceans and are most abundant in the intertidal and shallow subtidal zones of rocky shores. They mostly consist of pluricellular macrophytes (up to 1 m in size) growing attached to stable substrata, but some species (particularly in the genus *Ulva*) (Fig. 24.1, *Ulva compressa* Linnaeus) can get detached and survive floating for a long time. Their morphologies range from microscopic unicells to macroscopic multicellular plants, and giant-celled organisms with unique cellular and physiological characteristics [24.4]. Four main cytomorphological types are recognized in this class [24.5]: nonmotile uninucleate cells (e.g., *Oltmansiellopsis*); multicellular filaments or blades composed of uninucleate cells (e.g., *Ulva*); multicellular filaments composed of multinucleate cells, with nuclei organized in regularly spaced cytoplasmic domains (e.g., *Cladophora, Chaetomorpha*); siphonous thalli, i. e., consisting of a single giant tubular cell, which often contains thousands to millions of nuclei (e.g., *Acetabularia*, *Caulerpa*, *Codium*, and *Halimeda*).

The Ulvophyceae possess chlorophylls a and b and a characteristic set of accessory pigments including the xanthophylls lutein, zeaxanthin, violaxanthin, antheraxanthin, and neoxanthin [24.6]. Siphonein and siphonoxanthin are found in the siphonous representatives. The main reserve polysaccharide is starch, which occurs as grains. The chloroplasts are surrounded by two membranes and may contain one or more pyrenoids. Flagellate cells possess two, four, or numerous flagella, which are similar in structure and in the basal part exhibit a transition zone with stellate structure. Details in the ultrastructure of the flagellar apparatus and mitosis differentiate the Ulvophyceae from other classes of green algae.

24.1.3 The Red Algae (Rhodophyta)

The Rhodophyta are one of the most ancient groups of photosynthetic eukaryotes (fossils of *Bangiomorpha pubescens*, considered the oldest red alga, are approximately 1.2 billion years old [24.7]). This phylum includes about 6200 species, which occur primarily in marine environments (150 species are found in freshwater). Red algae are ubiquitous on rocky shores of all oceans and represent the dominant group in seaweed floras throughout the world. They are also the benthic macroalgae with the widest ecological range, occurring at all levels of the photic zone. Some species occur in

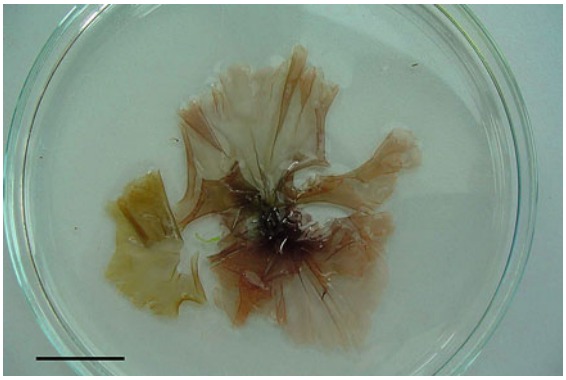

Fig. 24.2 Thallus of *Porphyra leucosticta* (red algae) from Portonovo, Ancona, Adriatic sea (Italy). Scale bar: 2 cm

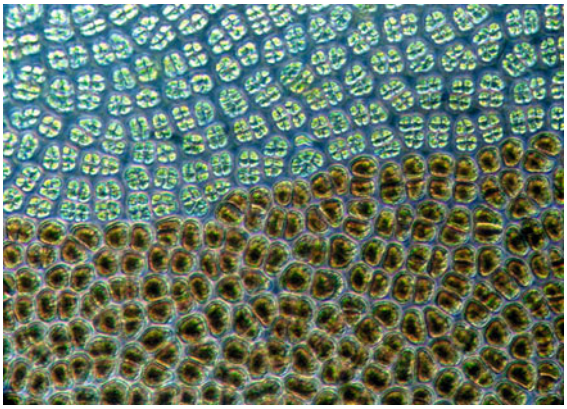

Fig. 24.3 Vegetative and reproductive cells of the thallus of *Porphyra leucosticta* (red algae) from Portonovo, Ancona, Adriatic sea (Italy). Magnification: 40×

the upper intertidal zone, where they are able to tolerate prolonged desiccation (e.g., members of the genus *Porphyra*) (Figs. 24.2, 24.3, *Porphyra leucosticta* Thuret). Most Rhodophyta, however, occur in subtidal habitats, and some species can reach considerable depths. The deepest-living benthic algae known are coralline red algae recorded at −268 m depth off the shores of Bahamas, where the available light irradiance was 0.001% as at the surface [24.8]. From a morphological point of view, this group is equally diverse and includes spherical unicells, thin uniseriate filaments, expanded blades with variable shape, encrusting forms growing attached to the substratum, and corticated macrophytes with parenchymatous structure [24.9].

Chlorophyll a is the only chlorophyll present in this group. Accessory pigments include phycobiliproteins (phycoerythrin, phycocyanin, allophycyanin), carotenoids (α-carotene, β-carotene), and xanthophylls (lutein, zeaxanthin, antheraxanthin, violaxanthin). The main reserve product is a polysaccharide called floridean starch, which is accumulated in grains in the cytoplasm. The chloroplasts are enveloped by two membranes and contains numerous parallel thylakoids, arranged singly and not stacked; numerous phycobilisomes (structures formed by phycobiliproteins) occur on the surface of the thylakoids. A distinctive feature of the red algae is the complete absence of flagella and centrioles in all stages of the life history; the male gametes, called spermatia, are small and spherical and are carried by water currents to the female gamete (called carpogonium). The cytokinesis is brought about by the development of a cleavage furrow that in the majority of the species does not complete the separation between adjacent cells and leaves a protoplasmic connection called pit connection.

24.1.4 The Brown Algae (Heterokontophyta, Phaeophyceae)

The class Pheophyceae, or brown algae, includes approximately 1800 species distributed almost entirely in marine environments (with a few freshwater species). Although they coexist with red algae and ulvophyte green algae, they are not closely related to these groups and belong to a different eukaryotic supergroup, the Chromalveolata [24.10]. They are believed to have arisen between 200 and 150 mya [24.11].

The Phaeophyceae are present in all seas of the world, but are most diverse and abundant in cold seas. This group includes the largest-sized seaweeds and

Fig. 24.6 Transverse section of the thallus of *Dictyota dichotoma* (brown algae) from Portonovo, Ancona, Adriatic sea (Italy). Magnification: 40×

represents a major component of the algal biomass on many rocky shores. In many temperate regions the lower part of the intertidal zone is occupied by dense canopies of brown algae of the order Fucales (*Cystoseira* in the Mediterranean, *Fucus* and *Ascophyllum* in the North Atlantic, *Hormosira* in Australia and New Zealand) (Fig. 24.4, and *Cystoseirabarbata* (Stackhouse) C. Agardh). Species of the order Laminariales (mainly of the genera *Laminaria*, *Ecklonia*, *Lessonia*, and *Macrocystis*) can reach 70 m in length and form large submerged forests in cold seas of both hemispheres.

Brown algae exhibit a great variation in habit, ranging from thin, uniseriate filaments to complex pseudoparenchymatous thalli (Figs. 24.5, 24.6, *Dictyota dichotoma* (Hudson) J.V. Lamouroux). They possess chlorophylls a and c (in the forms c_1, c_2, and c_3), and β-carotene and fucoxanthin as main accessory pigments. The main storage polysaccharide is chrysolaminaran, a β-1,3 glucan deposited in liquid form in special vacuoles. The chloroplasts are surrounded by four membranes, two of which are formed by endoplasmic reticulum; the thylakoids are packed in stacks of three parallel to each other and a peripheral thylakoid called girdle lamella usually encloses the others. The flagellate cells possess two flagella which differ in length and structure; one is long, pleuronematic (i. e., provided with thin tripartite tubular hairs), and directed forward; the other is short, smooth, and possesses a basal swelling in proximity of which the photoreceptor apparatus of the cell is located.

24.1.5 Seagrasses

The phylum Magnoliophyta includes the plants generally known as angiosperms, or flowering plants. This is the most specialized and successful group of vascular plants, which is currently represented by about 275 000 species and dominates the vegetation of most terrestrial ecosystems. The oldest angiosperm fossils date back approximately 135 mya, with the major lineages evolving between 130 and 90 mya [24.12]. Between 100 and 65 mya some lineages of angiosperms moved back to aquatic environments, and a few of them acquired the capability to live in seawater. Marine angiosperms, or seagrasses, are represented today by 60 species belonging to 13 genera and 4 families (Cymodoceaeceae, Hydrocharitaceae, Posidoniaceae, Zosteraceae). As vascular plants, they have a body that can be divided into roots, stem, and leaves, and a vascular apparatus

Fig. 24.7 Thallus of *Cymodocea nodosa* from Gabicce, Pesaro and Urbino, Adriatic sea (Italy). Scale bar: 4 cm

for the transportation of nutrients, water, and gases. Overall all species of marine angiosperms have developed a similar habit, characterized by a prostrate stem (rhizome) supporting bundles of ribbon-like leaves with parallel veins connected by short transversal veins (Fig. 24.7, *Cymodocea nodosa* (Ucria) Asch.).

24.2 Heavy Metals: Definition and Toxicity

Heavy metals such as arsenic (As), cadmium (Cd), chrome (Cr), copper (Cu), nickel (Ni), lead (Pb), and zinc (Zn), have a specific gravity (i. e., measure of density) at least five times that of water. Because of their solubility in the water environments, heavy metals can be absorbed by living organisms [24.13–15]. It is known that in small quantities heavy metals are essential for human nutrition, however, when consumed in high amounts they can cause health problems. Indeed, elements like iron, copper, nickel, manganese, selenium, and zinc are common in nature and are normally ingested with food (foodstuffs, fruits, vegetables, multivitamin products) [24.16–18]. The anthropogenic impact on the environment has increased the presence of heavy metals, which is of major concern because of their toxicity and threat to plant and animal life. The main anthropogenic sources of heavy metals released into the environment are:

a) Acid mine drainage (AMD), caused by mining operations
b) Electroplating industry waste solutions (e.g., zinc plating, nickel plating, chrome plating, oxidation)
c) Coal-burning applications for power generation and
d) Nuclear technology for power generation (uranium mining/processing and special waste generation).

Moreover, heavy metals are common in industrial applications like the manufacture of batteries, textile dyes, pesticides, alloys, steel, and others. The risks for human health and the toxicity associated with heavy metals are now well known [24.19–21]. Heavy metals in significant quantities are released into freshwater bodies and seas. These substances can be accumulated and biomagnified along sediment, water, and aquatic food chains, resulting in fatal effects in fish populations, and for humans. They become toxic when they are not metabolized by organisms and accumulate in the soft tissues [24.19, 20]. The Agency for Toxic Substances and Disease Registry (ATSDR), based in Atlanta (Georgia), is one of the largest federal public health agencies of the USA. It provides trusted health information to prevent harmful exposures and diseases related to toxic substances.

24.3 Biosorption

Biosorption is a method that can be used for the removal of pollutants from wastewater, especially those that are not easily biodegradable like heavy metals and industrial dyes. Furthermore, this process can remove low heavy metal concentrations as an inexpensive, simple and effective alternative to conventional methods like activated carbon [24.22–26]. The recapture of heavy metals from industrial wastewater is of dual interest: (i) the prevention of threats to health (metal toxicity) [24.19–21], and (ii) society is realizing the importance of recycling these substances for metal costs [24.27–29]. When the concentrations of wastewater contaminants are above 100 mg/L, the biological treatment processes for removing heavy metals are the most effective [24.30]. The treatments used are precipitation, electrodialysis, and reverse osmosis, which become costly and difficult to manage at low metal concentrations (< 100 mg/L) [24.31, 32]. The potential of metal biosorption by biomass materials has been well established in the last 15 years. This technique uses a variety of biological materials for binding of these pollutants, including fungi [24.33], bacteria [24.34–36], plants [24.37], macroalgae [24.24–26, 38], microalgae [24.39, 40], and agricultural and industrial wastes [24.41–43]. For economic reasons, particular interest must be given to large biomass types, either generated as a waste by-product of large-scale industrial fermentations or certain metal binding macrophytes found in large quantities in the sea. Recent studies showed that aquatic macrophytes (i. e., seaweeds and seagrasses) can be used as potential biosorbents for the removal of heavy metals [24.24–26, 38, 44–46]. This is considered one of the most promising types of biosorbents in view of its high capacity for uptake, its low

cost, and its abundance in many parts of the world. Indeed, a comprehensive collection of algae for food and algal phycocolloids (agar, carrageenans, alginates) is in excess of 3 million tons per year, with a potential estimated at around 2.6 million collected for red algae and 16 million for brown algae [24.47].

The biosorbent ability of the macrophytes resides in the structure of the cell walls of seaweeds and the cuticle of seagrasses, which are responsible for this phenomenon. Indeed, in biosorption, the ability of active sites on the surface of macrophytes to bind and concentrate heavy metals from even the most dilute aqueous solutions is exploited. The cell wall intervenes in the mechanisms of biosorption through physicochemical processes like ion exchange, complexation, microprecipitation, and electrostatic interactions. Specifically, in solution heavy metals can form ions (cations or anions), which create a passive binding with nonliving biomass through a mechanism that is not metabolically controlled, in contrast to bioaccumulation by living cells [24.48–50]. The use of dried nonliving macrophytes as adsorbent material has considerable advantages, such as:

a) High efficiency in detoxification of diluted effluents
b) Minimizing the volume of waste, biological and/or chemical
c) No demand for nutrients, and
d) Low cost.

An additional advantage is represented by the possible recovery of heavy metals: once the binding of metals reaches saturation, the biomass can be regenerated with acid solutions and/or hydroxyl, which release small volumes of heavy metal concentrates [24.51–53]. These may be subsequently treated with techniques of co-precipitation, flocculation, and electro-deposition.

24.3.1 Cell Wall of the Algae

The cell wall is the portion of the algal cell directly involved in biosorption; its chemical structure has a major effect on the mechanisms by which this phenomenon takes place. The electrostatic attraction and the complexation of the groups present on the surface of the cell wall with the metal in solution play a key role in this regard [24.25]. The polysaccharides present in the cell walls of algae contain chemical groups such as carboxyl, hydroxyl, and sulfate, which may act as binding sites [24.54]. They are effective ion exchangers and, therefore, important sites for complexation of metal cations [24.55, 56]. Proteins, lipids and, occasionally, nucleic acids may also be present on the surface of the cell walls. These molecules, however, occur mainly in the plasma membrane and in the cytoplasm; they are, therefore, bound to metal ions through their functional groups (aminic, carboxylic, imidazolic, thiolic, thioesteric, nitrogen, and oxygen in peptidic bonds) mostly within the cell [24.57]. In all algae and plants the cell wall consists of a fibrillar fraction, which is responsible of the mechanical strength of the wall, and an amorphous fraction, which provides flexibility. The composition and relative amounts of these two fractions vary in different taxonomic groups [24.6].

Chlorophyta (Green Algae)

The composition of the cell wall of the Ulvophyceae shows some variation between different orders (in some cases even between different life history stages in the same species) [24.6]. In many groups, the fibrillar component forms an internal layer that lies directly against the plasmalemma, whereas the amorphous portion is predominantly on the outer side of the wall, forming a slimy outer layer and containing relatively few and randomly orientated microfibrils [24.6]. The fibrillar layer consists of microfibrils with diameters varying between 3 and 35 nm. In many ulvophytes, the microfibrils consist of crystalline cellulose and are arranged in numerous parallel layers; in orders with siphonous construction (Bryopsidales and Dasycladales), however, the most abundant constituents are mannans, xylans, and glucans. The structural component is embedded in an amorphous, mucilaginous matrix, which also varies in different orders. This may be formed by acidic, partially sulfated heteropolysaccharides (as in the case of the Ulvales) or highly sulfated arabinogalactans (e.g., in the Cladophorales) [24.6]. Polysaccharides extracted from *Ulva* (order Ulvales) contain 16% sulfates and 15−19% uronic acid [24.58]. Several genera of siphonous ulvophytes (*Acetabularia*, *Avrainvillea*, *Penicillus*, *Halimeda*, *Udotea*) are encrusted with calcium carbonate, which is deposited on the cell wall in the form of aragonite crystals. Members of these genera are among the most important contributors to calcium carbonate deposition on tropical reefs.

Rhodophyta (Red Algae)

In the red algae the fibrillar fraction is constituted by cellulose, which is deposited in the form of microfibrils arranged to produce an irregular felt-like network [24.6, 59] immersed in the amorphous matrix. In some genera, such as *Bangia* and *Porphyra*, cellulose is replaced by xylans and mannans. The amorphous matrix forms up

to 70% of the dry weight of the wall and consists of mucilaginous material that may be extracted with hot water. It is constituted by several types of highly hydrophilic sulfated polygalactans, polymers of β-(1 → 4) galactose, and α-(1 → 3) linked 3,6 anhydrogalactose, which are mostly combined to form two types of polysaccharides: agars and carrageenans. The presence of D-galactose and anhydro-D-galactose distinguishes the more highly sulfated carrageenans from the less highly sulfated agars (anhydro-L-galactose) [24.60]. Agar and carrageenans have colloidal properties and for this reason are widely used in many industrial applications [24.61]. Carrageenans consist of a repeating disaccharide backbone: β-(1 → 4)-D-galactopyranosyl-α-(1 → 3)-D-galactopyranosyl. There are 17 different types of carrageenans, which occur in different species and can also vary within a species. Agars are formed by alternating 3-O-linked β-D-galactopyranose and 4-O-linked 3,6 anhydro-α-L-galactopyranose, but the repetition can be interrupted by blocks of repeated units of either one of the two constituents [24.60].

In all species of the order Corallinales and some species belonging to other orders (Nemaliales, Peyssonneliales), the cell wall is encrusted by calcium carbonate. In the Corallinales this compound is present primarily as crystals of calcite (rhomboid crystals), whereas the calcified members of other orders deposit it mainly as crystals of aragonite (orthorhombic crystals) [24.59]. In other red algal genera (e.g., *Mazzaella*) the surface of the alga is covered by a continuous layer of proteinaceous material [24.60]. This cuticle is neither homologous or biochemically similar to the cuticle of vascular plants.

Phaeophyceae (Brown Algae)

In this group the fibrillar portion of the wall is formed by a felt-like network of cellulose, which is probably strengthened by insoluble alginates [24.6]. The amorphous portion constitutes most of the wall mass and is composed of alginates and fucans. Alginates are salts of alginic acid, a polymer formed by monomers of two acid sugars (D-mannuronic acid and L-guluronic acid) connected by β-1,4 bonds. The residues can form salts with various cations, such as Ca^{++}, Mg^{++}, Na^{+} (this is the predominant form of alginates linked with the cellulose fibrils in the fibrillar portion). Fucans (or fucoidans, or ascophyllans) are sulfated polysaccharides containing, in addition to the monosaccharide L-fucose, varying proportions of galactose, mannose, xylose, and glucuronic acid [24.6]. The amorphous portion is responsible for the elasticity of the cell walls and contributes to prevent desiccation of the thallus during emersion.

Alginates confer flexibility upon the thallus, help prevent desiccation, and function in ion exchange [24.60]. They are used extensively in industry because of their colloidal properties. In alginates, the relative proportion of mannuronic acid and guluronic acid vary, depending on species, age of the thallus, tissue, time of the year, and geographic location. The sequence and the relative amounts of these two sugars produce different chemical structures, and, therefore, different physical properties of these polysaccharides. Haug showed that the affinity of some metal cations (Pb^{2+}, Cu^{2+}, Cd^{2+}, Zn^{2+}) for alginates differs in relation to the relative amounts of the two sugars, increasing with the content of guluronic acid. The high specificity of alginates containing high amounts of guluronic acid for bivalent cations is explained by their zig-zag structure. In the presence of these ions, the alginates develop a network-like arrangement by dimerization of polyguluronic sequences, which allows the pairing of two chains and the formation of spaces suitable to accommodate Ca^{++} and other bivalent cations similar to Ca^{++} in size. These spaces are produced by the grouping of polyguluronic chains determined by the alignment of carboxylates and other atoms of oxygens of the guluronic units. This structure is known as the egg-box model.

Alginates contain three different functional groups to which metal cations may bind, carboxyl (−COO), ether (C−O−C), and hydroxyl (−OH). Carboxyl groups are usually the most abundant acidic groups in brown algae, and most metals (Cd, Co, Cu, Fe, Ni, Pb) are adsorbed at pH close to the pH of dissociation of carboxyl groups in these algae (pK_0 close to 5) [24.62]. The second most abundant acidic group is the sulfonic acid of fucoidans [24.25]; this compound occurs both in the amorphous matrix and in close association with the cellulose microfibrils in the innermost portion of the wall [24.63–65]. Sulfonic acid plays a secondary role in the bond with metals, except when this happens at low pH. This is also the case for the hydroxyl groups present in all polysaccharides, which are negatively charged only at pH > 10 [24.25].

Proteins represent a minor component in the cell wall of brown algae [24.66]. This implies that the carboxyl groups of the alginates are more abundant than the carboxyl groups and the amine groups of proteins and represent the majority of the binding sites [24.58]. The role of the carboxyl groups in adsorption processes has been clearly demonstrated by the uptake of Cd and

Table 24.1 Binding groups for biosorption in macrophyte

Binding group	Chemical formula	Ligand atom	Occurrence in biomolecules	Phylum
Amine	$-NH_2$	Hydrogen	Protein	Chlorophyta
			Metallothionein	Magnoliophyta
Carboxyl	$-COOH$	Oxygen	Cutin	Magnoliophyta
			Alginic acid	Heterokontophyta
Carbonyl	$> C{=}O$	Oxygen	Alginic acid	Heterokontophyta
			Protein	Chlorophyta
			Alginic acid	Heterokontophyta
Hydroxyl	$-OH$	Oxygen	Polysaccharides	Chlorophyta
			Cutin	Magnoliophyta
			Agarose (agar), carrageenan	Rhodophyta
			Fucoidan (sulfated polysaccharide)	Heterokontophyta
			Agaropectin (agar), carrageenan	
Sulfonate	$-SO_2{=}O$	Oxygen	(Sulfated polysaccharides), porphyran, furcellaran (sulfated galactans)	Rhodophyta
Sulfhydryl (thiol)	$-SH$	Sulfur	Metallothionein	Magnoliophyta

Pb by *Sargassum* following partial or complete esterification of carboxyl sites [24.62].

24.3.2 Seagrass Cuticles

As all vascular plants, the seagrasses possess a wall of microfibrils of cellulose embedded in a matrix that consists mainly of pectins and cross-linking glycans [24.12]. The surface of the leaves is covered by a layer of polymeric material called cuticle, which consists of two types of polymers: cutin and cuticular waxes. This layer serves to avoid water loss, reduce penetration by chemicals and pathogenic organisms, and perhaps prevent adhesion of organ surfaces during development [24.12]. Since seagrasses live mostly submerged, they do not need protection against desiccation (which is the main function of cuticle); in these plants the cuticle is, therefore, thinner than in terrestrial angiosperms and the stomata are absent. The thin cuticle also facilitates uptake of ions and carbon; seagrasses are able to uptake nutrients and carbon directly through the leaves. In order to facilitate the exchange of solutes and gases, the cuticle of seagrasses is porous and perforated [24.67].

The cuticle forms an external layer around the surface of the leaves. Cutin and cuticular waxes, the main constituents of the cuticle, are large molecules with a complex tridimensional arrangement. Cutin is a complex compound formed by omega hydroxy acids and their derivatives interlinked via ester bonds and forming a polyester polymer of indeterminate size [24.68, 69]. Waxes are esters of fatty acids and long-chain alcohols; within the cutin network they exist in an amorphous state, but at the outer surface they crystallize to form plates and protrusions that may be very elaborate [24.12]. The cuticle may also contain several nonlipidic components such as carbohydrates and phenols [24.70]. It is also known that the polymeric matrix includes a considerable amount of dissociable groups [24.71] and is a polyelectrolyte with an isoelectric point around 3 [24.71].

24.3.3 Macrophytes: Key Chemical Functional Groups

Biosorption is based on the ability of biological materials to sequester metals [24.25, 53] through chemical-physical mechanisms [24.72] ranging from electrostatic forces, or Van der Waals interaction to ionic and covalent bonds [24.32]. Macrophytes show several chemical groups that have been suggested as being responsible for biosorption of heavy metals, such as carboxyl, hydroxyl, carbonyl, sulfhydryl, and sulfonate (Table 24.1) [24.24, 25, 38, 73, 74]. In particular, the matrix of the brown algal (phylum Heterokontophyta) cell wall consists mainly of alginic acid with carboxyl groups and a smaller amount of sulfated polysaccharides, such as fucoidan with sulfonic acid. In red algae (phylum Rhodophyta) the amorphous portion is formed by a number of sulfated galactans such as carrageenan, agar, furcellaran, porphyran. Green algae (phylum Chlorophyta) may have an external capsule

that is composed of protein or polysaccharides or both (Table 24.1) [24.60]. In the leaves of seagrasses, carboxylic groups present on the cutin layer are probably responsible for the binding of heavy metal ions [24.24]. The biosorption ability of different chemical groups depends on many factors: the number of sites on the adsorbent material, accessibility of the site, their chemical status (i. e., availability), and the affinity between site and metal ions (i. e., bond strength) [24.25, 58, 75]. So it is important to understand what kind of interaction takes place between the functional groups present on the adsorbent material and ionic metal speciation in solutions; MEDUSA software can be used for this [24.76].

24.3.4 Chemical and Physical Mechanisms

Mechanisms involved in the biosorption process have a chemical-physical nature. More specifically, heavy metal chelation depends on the constituents of the outer layers of macroalgae and seagrasses. The biosorption capacity of different chemical groups depends on several factors: the number of sites on the adsorbent material, accessibility, their chemical status (availability), and the affinity between site and metal (bond strength) [24.77]. In particular:

1) Key functional groups (Table 24.1)
2) Ion-exchange processes, and
3) Ionic speciation of metals

have a fundamental role in biosorption studies. The carboxylic groups are abundant in brown algae, due to the presence of alginic acid, and in the cutin of seagrasses. The adsorption capacity of the macrophytes is directly associated with the presence of these sites on cell walls and on the cuticles of the nonliving biomass. Ionic speciation of metals in solution is important for metal uptake and frequently depends on the pH of the sorption system. The MEDUSA software [24.76] creates theoretical predictions of ionic dissociation of metals as a function of pH. The most common metals investigated, such as Pb^{2+}, Cd^{2+}, Cu^{2+}, Zn^{2+} and Fe^{2+}, show a maximal or nearly maximal sequestration at pH near the apparent dissociation constant of carboxylic acids (R−COOH), which indicates adsorption on carboxyl groups. The role of carboxylic groups in the adsorption process has been widely demonstrated through the adsorption capacity of lead and other metals cations by dried biomass of *Cystoseira*, *Scytosiphon*, *Sargassum*, *Ascophyllum* (brown algae), *Posidonia*, and *Cymodocea* (seagrasses) following partial or complete esterification of the carboxylic sites [24.24, 45, 75, 78–81]. The other acidic functional group that is important in biosorption activity is the sulfonate group of fucoidans (brown algae) and sulfated polysaccharides (red algae) (Table 24.1). Sulfonic acid groups have an important role when metal binding occurs at low pH values. Hydroxyl groups present in all macrophytes studied except brown algae (Table 24.1) become negatively charged at high pH values (about pH > 10), and consequently have a minor role at low pH [24.25, 75, 80]. Concerning heavy metals that have negative ionic speciation in solution, such as As(V), recent studies have demonstrated that red algae (phylum Rhodophyta), which are known to be bad binders of cationic metals, showed very good arsenic sorption performance at pH values higher than 7 [24.38].

Ion-exchange is an essential mechanism at the base of biosorption. It is the process in which ions are exchanged between a solution and an insoluble solid, usually a resin. During the biosorption activity, dried macrophytes can be viewed as natural ion-exchange materials that contain weakly acidic and basic groups (Table 24.1). In the pH range 2.5−5, the binding of heavy-metal cations is determined primarily by the state of dissociation of the weakly acidic groups (acid–base equilibrium theory) [24.25, 41]. In studies of biosorption, maintaining a low pH (around pH 4.5−5) in the sorption system, microprecipitation of metals and their contribution to the uptake are avoided. pH control in the system is important both for its effects on the configuration of the active ion-exchange sites and for the ionic state of the metals in the solution. In solution, at low pH the concentration of protons is high, and the ion-exchange sites, therefore, become solidly protonated. This allows displacing the metals sequestered on the biosorbent by a simple acidic wash. The regeneration of the biosorbent biomaterial allows its multiple recycling, further increasing the economy of its use [24.82, 83]. Consequently, the use of a biosorbent such as dried algae and seagrasses in wastewater treatment often depends not only on the biosorptive capacity, but also on how well the biosorbent can be regenerated and recycled.

24.4 Biosorption Experiments: Procedure

24.4.1 Biosorption: Kinetic Curves

The kinetic curves of adsorption describe the time evolution of the concentration of metal in solution, in the presence of the adsorbent biomaterial. A stock solution containing a known amount of metal salts is prepared to test the ability of the adsorbent macrophytes. Dried biomass of the macrophytesis is suitably fragmented to increase the adsorbing surface area and is placed in a beaker with deionized water. The pH of the solution is adjusted using solutions of NaOH and HCl (in general, 0.1 M) according to the experimental plan followed. Indeed, pH check control is important to avoid metal precipitation in solution. Subsequently, a stock solution with metals is added according to experimental conditions. Aliquot amounts of solution are then periodically sampled to determine the concentration of metal. In general, the kinetic curves are set for investigation of different pH values.

24.4.2 The Langmuir Adsorption Isotherm

The equilibrium isotherms represent the concentration of the metal on the solid (q, mg/g) as a function of the respective concentration in solution at equilibrium (C_{eq}, mg/L). The determination of isotherms is essential to define the capacity of the adsorption of metal ions by the adsorbent material, such as dried macrophytes. For the determination of curves, a known amount of dried and fragmented biomass is added to a solution of deionized water with varying concentrations of metals established from the experimental plan. The pH of the solutions is adjusted to predetermined values with solutions of NaOH (general 0.1 M) and HCl (general 0.1 M) [24.24, 38]. 1 mL aliquots of test solution are sampled periodically and centrifuged for metal determination. Metal uptake, q (mg g^{-1}), is calculated as the difference in metal concentration in the aqueous phase before and after sorption, according to (24.1)

$$q = \frac{V\left(C_i - C_{eq}\right)}{W}\,, \tag{24.1}$$

where V is the volume of metal solution (L), C_i and C_{eq} are the initial and equilibrium concentration of metal in solution (mg/L), respectively, and W is the mass of dry macrophytes (g).

Through regression analysis, the Langmuir adsorption isotherm [24.84] given in (24.2) was adapted to the experimental data

$$q = \frac{q_{max} b C_{eq}}{1 + b C_{eq}}\,, \tag{24.2}$$

where q_{max} (mg/g) and b (L/mg) are the Langmuir constants, which represent the maximum adsorption capacity and the affinity between the metal ion and adsorbent dried biomass, respectively.

24.5 Conclusions

Macrophytes represent particularly efficient biosorbents compared with other biomass types for the treatment of wastewater [24.24, 26, 37, 38, 45, 46]. Furthermore, due to their economic value in many food, cosmetic, and pharmaceutical applications, there is a large bulk of information about their cell wall structure and biochemical composition of the thalli [24.85–89]. Brown algae, in particular the orders Laminariales and Fucales, are the most important algae with respect to biosorption because of the abundance of their cell wall matrix polysaccharides and extracellular polymers (Table 24.1). Alginates and fucoidans (sulfated mucopolysaccharides) are mainly responsible for the natural ion exchange ability of brown algae. In fact, previous studies support the possibility that the biosorption process consists essentially of ion exchange, which involves the carboxyl group in the alginate polymer and sulfonic acid in the fucoidan [24.24, 26, 38]. The cuticle of seagrasses is also rich in carboxyl groups, which are involved in the bond with the protonated metal, while red and green algae have a lower capacity to immobilize protonated metals due of the presence of groups other than carboxylic ones (Table 24.1). In general, it is assumed that the number of binding sites identified decreases in the order brown algae > seagrasses > green algae > red algae.

Moreover, recent literature confirms that the structure of the thallus affects the adsorption performance of the algae [24.24–26, 38, 45]. *Pennesi* et al. [24.24] concluded that the sorption abilities of the red algae *Porphyra* and *Polysiphonia* might be related to the simple structure of the thallus (i. e., monostromatic blades

and uncorticated filaments, respectively) compared to species of *Gracilaria*, which possess a more complex, parenchymatous thallus. Accordingly, it may be supposed that there is a direct relationship between the complexity of the thallus and the adsorption of lead [24.90].

As a whole, these results have opened new perspectives for the utilization of marine macrophytes as low-cost sorbents in the removal of heavy metals from wastewater; this is a key step towards the implementation of biosorption technology in industrial and environmental remediation.

25. Marine Algae Biomass for Removal of Heavy Metal Ions

Laura Bulgariu, Dumitru Bulgariu, Constantin Rusu

The increase of industrial activities has accentuated environmental pollution problems, due to the accumulation of harmful pollutants, such as heavy metals. In regard to its simplicity, biosorption on nonconventional and low-cost materials has gained credibility in the last few years, because it offers an efficient and cost-effective alternative to the conventional decontamination techniques. From this perspective, numerous applications of marine algae biomass have been developed for the efficient removal of heavy metal ions from aqueous environments. In this chapter, the biosorptive characteristics of marine algae biomass (marine algae and marine algae wastes) for different heavy metal ions from aqueous solution are described, as a function of experimental conditions (solution pH, biosorbent dose, contact time, temperature, etc.) and the experimental procedure used in the biosorption process. Application of isotherm and kinetic models used for the mathematical description of experimental data is also reviewed. The biosorption mechanism has been found quite complex, including adsorption, surface precipitation, ion exchange and complexation.

25.1 General Remarks

Nowadays, the intensification of industrial activities has intensified more environmental problems as seen for example in the deterioration of several ecosystems due to the accumulation of dangerous and harmful pollutants, such as heavy metals [25.1]. Industrial and municipal wastewater frequently contain heavy metal ions, and represent the major sources of natural water pollution with heavy metals.

Toxic heavy metals are still used in various industries, such as textile, pigments, plastics, mining, plating, chemical, and smelting, due to their technological importance, and are considered stable and persistent environmental contaminants, because they cannot be destroyed or degraded [25.2, 3]. In addition, these metal ions are reported as priority pollutants due to their mobility, persistency, and accumulation tendency in natu-

ral water ecosystems [25.4, 5], and water contaminated by such pollutants remains an important problem with serious ecological and human health consequences.

The presence of some heavy metals, such as copper, zinc, cadmium, lead, mercury, cobalt, nickel, and others, has a potentially damaging effect on human health and other biological systems, when the tolerance levels are exceeded [25.6, 7]. In order to prevent the deterioration of environment quality, legislation governing the levels of heavy metals, discharged from waste stream is becoming progressively stricter [25.8].

Under these conditions, it is desirable for the benefit of environment to eliminate the heavy metal ions from industrial waste stream, and this could also be important from economical considerations, due to the high value of these metals. Together with pollution prevention and detection, the elimination of a wide range of pollutants from aqueous waste stream is an absolute requirement for sustainable development [25.9].

The most widely employed methods for removing heavy metals from metal-bearing effluents include chemical precipitation, ion exchange, adsorption, flocculation, solvent extraction, membrane-related processes, electrochemical and biological techniques, and different combination of these [25.10–14]. Low efficiency performances, particularly when are used for small concentrations of heavy metal ions, low selectivity, the necessity of using expensive chemicals in some methods, and the generation of high amount of toxic sludge or high energy consumption, are the main drawbacks of these conventional methods [25.13, 15]. Therefore, the development of new methods for the removal of heavy metal ions from aqueous environments that minimize these disadvantages is an actual scientific issue, which has great applicative importance.

In regard to its simplicity and high-efficiency characteristics, the adsorption is looked upon as a better method that is recommended for the removal of low concentrations of heavy metal ions in wastewater (1−100 mg/l dissolved metal ions) [25.16], because it is rapid, reversible, economical and environmental friendly in contrast with the mentioned conventional methods [25.17, 18]. Well-designed adsorption processes have high efficiency, resulting in high-quality effluents after treatment, which can be recycled.

The adsorption process, generally implies the presence of solid material, called *adsorbent*, that binds metal ions from contaminated aqueous solutions by physical attractive forces, ion exchange, or/and chemical binding. Cheap and efficient adsorbents are advisable for the treatment of aqueous effluents containing heavy metal ions. Thus, natural materials available in large quantities or waste products from industry or agriculture, generally designated *low-cost adsorbents*, have been proved suitable for this purpose. This is due to the fact that most such materials have high number and variety of superficial functional groups (e.g., carboxyl, hydroxyl, amino, phosphate, etc.), which can retain the metal ions through different kinds of mechanisms. Moreover, because such cost adsorbents are cheap and easily regenerable, they are an attractive alternative over commonly used adsorbing materials, such as activated carbon, which is costly to use for the removal of such dangerous chemicals from industrial wastes [25.12, 19].

In the past few decades, biosorption using microorganism biomass as the adsorbent has emerged as a potential alternative method in the removal of contaminants from aqueous effluents. The use of biological materials, including living and nonliving microorganisms for the removal of heavy metals from industrial wastewater, has gained important credibility in the last few years, because of the good efficiency, minimization of secondary (chemical or biological) wastes, and low cost of these materials [25.16, 18]. The microorganisms, such as bacteria, algae, fungi, or yeasts, can uptake heavy metals from aqueous solutions, both actively (metabolically mediated – bioaccumulation) and passively (by physical–chemical pathways, named biosorption) [25.20, 21].

Although in the beginning most studies have been focused on heavy metal accumulation and concentration within living organisms [25.22, 23], upon noticing that dead biomass possesses high metal retention capacity [25.24], the interest was shifted to biosorption [25.25, 26]. This is mainly due to the fact that the nonliving biological materials are easier and cheaper to obtain, and their utilization as biosorbents has been shown to be an economical and effective method to remove the heavy metals from wastewater.

The term *biosorption* indicates a metabolism-independent binding of heavy metals by dead (nonliving) biological materials, and is defined as the ability of these materials to bind the metal ions to the surface of cellular walls or membrane, in the equilibrium process [25.21, 27, 28]. In the biosorption processes, the nonliving biological materials (biomass) act as a chemical substrate of biologic origin and the main advantages of their utilization are: (i) the variety of functional groups from the biosorbent surface, (ii) relatively small and uniform distribution of binding sites on biosorbent surface, and (iii) the preference of alkali and alkali-

earth metal ions for the binding sites is less than in the case of ion exchange resins [25.16].

The marine algae are available in large quantities in many regions of the world, and are a kind of promising biological resources [25.29]. Even, though the red and brown algae have been the most used biosorbents for the removal of heavy metals [25.30], their utilization may cause serious secondary pollution due to organic substances release, such as alginate dissolving from biosorbents, during of the biosorption process. Another problem of brown algae utilization is that the leaching of some retained compounds may also lead to a loss of biosorption capacity [25.31]. These secondary processes drastically limit their industrial application.

In the case of green algae, the effect of secondary pollution is significantly lower, and many studies from the literature [25.17, 32, 33] have shown that these posses high metal binding capacities, due to the presence of polysaccharides, proteins, or lipids from the cell walls surface. The marine green algae are mainly cellulose, and high percentages of the cell wall are proteins bonded to polysaccharides to form glycoproteins. These compounds contain several functional groups (amino, carboxyl, sulfate, hydroxyl, etc.) which could play an important role in the biosorption process [25.34–36]. In addition, the marine green algae are particularly useful in the biosorption process of heavy metals due to their relatively simple structure, high surface area, and small and uniform distribution of binding sites [25.37, 38].

However, the marine algae are frequently used for the extraction of oil in the cosmetic industry and for the production of biofuels [25.39, 40]. This utilization is more economically efficient than the removal of heavy metal ions from wastewater, and for this reason high quantities of marine algae are used for this purpose. After the extraction process, the remained marine algae biomass is considered to be a waste and is discharged or incinerated, becoming a serious problem for environmental protection. In order to avoid this problem, the marine algae waste biomass can also be used as biosorbent for the removal of heavy metals ions from wastewater. Recent studies performed by *Bulgariu* and *Bulgariu* [25.41, 42] have shown that the biosorption capacity of the marine green algae waste biomass obtained after extraction of oils from marine green algae (*Ulva lactuca* sp.) can be successfully used for the removal of heavy metal ions from aqueous solution, and that the metal uptake capacity is not significantly affected by the extraction step.

In this chapter, the biosorptive characteristics of marine algae biomass (marine algae and marine algae wastes) for different heavy metal ions from aqueous solution, as a function of the experimental procedure used in the biosorption process and experimental conditions (solution pH, biosorbent dose, contact time, temperature, etc.) are presented. The most important isotherm and kinetic models used for the mathematical description of experimental biosorption data are also reviewed. The biosorption mechanism has been found to be quite complex, including adsorption, surface precipitation, ion exchange, and complexation.

25.2 Chemical Characteristics of Marine Algae Biomass

Marine algae (or seaweeds) are relatively undifferentiated simple biological organisms that fall into the general category of *plants*. Their size varies from tiny microscopic unicellular forms (3−10 μm) to large macroscopic multicellular forms (up to 70 m long). Most of the marine algae are photosynthetic biological organisms that have chlorophyll, but they also contain additional pigments, that are the basis of classification [25.43].

Even if they are considered the oldest member of the plant kingdom (existing back many hundreds of millions of years), the marine algae do not form a homogeneous group. They are found throughout the world's oceans and seas, and are divided into several categories, namely: (i) brown algae (*Phaeophyta* division), (ii) red algae (*Rhodophyta* division), and (iii) green algae (*Chlorophyta* division), as a function of the color of additional pigments. The mixture of pigments in their chloroplasts lends characteristic colors to the marine algae, and many of their scientific names are based on these colors [25.44]. The differences between these types of marine algae are mainly in the structure of cell walls, where the retention of heavy metal ions takes place.

The cell walls of brown algae generally contain three main components: cellulose (that is the structural support), alginic acid (a polymer of mannuronic and guluronic acids, and the corresponding salts of sodium, potassium, magnesium and calcium and represent 14−40% of the dry weight of the biomass)

and sulfated polysaccharides [25.35, 46]. Red algae also contain cellulose as structural support, but their biosorptive properties are mainly determined by the sulfated polysaccharides made from galactanes (agar and carragenates) [25.35, 47]. Green algae are mainly cellulose and a high percent of cell walls are proteins bonded to polysaccharides to form glycoproteins [25.35, 48]. These constituents contain numerous reactive functional groups (e.g., amino, hydroxyl, carboxyl, sulfate, etc.) that can be involved in chemical binding with metal ions, and could play an important role in the biosorption processes. Table 25.1 summarizes the main constituents that are present in the structure of some marine algae.

Besides these main constituents, the marine algae also contain several extractive compounds (such as fat, fatty acids, fatty alcohols, phenols, terpenes, steroids, resin acids, and waxes) [25.21], that have also reac-

tive functional groups in their structure. Unfortunately, these components are little involved in chemical binding with metal ions, because they are easily extracted in organic and/or aqueous solvents, being responsible for the secondary pollution observed during of the biosorption process [25.16]. Thus, by removing such compounds by extraction with organic solvents or alkaline treatment [25.49, 50], the main classes of functional groups are not affected, and the obtained marine algae waste biomass has comparable or even higher uptake capacity, for different metal ions from aqueous solutions.

The presence of different functional groups in the structure of marine algae and marine algae waste biomass can be easily proved using FT-IR spectra, recorded for dry samples. For exemplification, Fig. 25.1 illustrates the FT-IR spectra obtained for *Ulva lactuca* sp. (marine green algae) before and after extraction of oils (marine algae waste biomass).

A detailed analysis of the FT-IR spectra of these biosorbents has indicated that in the structure of marine algae, numerous functional groups (such as hydroxyl, amine, carbonyl, carboxylic, sulfate) are present and these can interact with heavy metals during the biosorption process. The same functional groups can also be identified in the FT-IR spectra of all types of marine algae, whatever class they belong [25.26, 29, 30, 35, 48]. It was also observed that the nature of functional groups is not changed significantly after the extraction step. These low-cost biosorbents will act as a chemical substrate and will bond heavy metal ions from aqueous solutions by characteristic chemical (electrostatic and/or complexation) interactions.

Although the constituents of the cell walls provide an extensive array of ligands with various functional groups capable of binding metal ions, the role that any functional group has in the biosorption process depends on several factors. Thus, the number of active sites on the biosorbent material surface, their accessibility and chemical state, and the affinity of metal ions for a given functional group play an important role in metal binding interactions, and will influence the efficiency of the biosorption process.

25.3 Experimental Methodology

Generally, the marine algae used as biosorbents in the experimental studies are collected from their natural environment (seawater), washed several times with distilled water to remove the impurities and dried in air at 50–60 °C for 6–10 h, and then crushed and sieved to a given granulation (0.5–1.5 mm). In the case of marine waste algae biomass obtained after extraction steps with organic solvents and an additional washing step with a NaOH solution is required, in order to remove the trace of organic solvents. The obtained materials are stored in desiccators and can be directly used as biosorbent, without any additional pretreatment. Because these kinds of biosorbents are easily obtained and require only few numbers of operations, they can be included in the category of low-cost biosorbents.

From the experimental point of view, the assessment of a biosorption system is usually based on two types of methodologies: equilibrium batch biosorption tests and dynamic continuous-flow biosorption studies. Both have several important advantages and disadvantages, and choosing a specific methodology depends on the objective of the study.

25.3.1 Equilibrium Batch Biosorption Technique

The batch (or discontinue) methodology is relatively simple and easy to use in the laboratory, especially for the experimental study of single-metal ions biosorption. This methodology is preferred when we want to establish the optimum conditions for retention of a given metal ion on certain biosorbent, or to test the biosorptive performances of a new biosorbent.

In this case, a small amount of marine algae biomass (biosorbent) is mixed with well-measured volume of aqueous solution containing a given metal ion, in certain conical flasks, with intermittent or continuous stirring for a required period of time. At the end of the biosorption procedure, the biosorbent is separated through filtration, and the concentration of the studied metal ion in filtrate is analyzed, using an adequate analysis method.

It should be mentioned that in the biosorption systems, the experimental parameters (solution pH, biosorbent dose, metal ion concentration, contact time, temperature, etc.) should be carefully controlled at the

Table 25.2 Some utilizations of marine algae biomass for the removal of heavy metal ions from aqueous solutions, by the batch technique

given value over the entire period of contact, until the biosorption equilibrium is reached. This may take few minutes or few hours, depending on the nature of marine algae biomass used as biosorbent. The contact time required to attain the biosorption equilibrium can be establish by a preliminary test, and represents the time period after that the metal ion concentration in the solution remains unchanged.

Table 25.2 presents several examples of marine algae biomass utilization for the removal of heavy metal ions from aqueous solutions, by the batch technique.

In each of the presented examples, the performances of marine algae biomass in the biosorption process were quantitatively evaluated using the amount of heavy metal ions retained on weight unit of biomass (q, mg/g) and the percent of heavy metal removed (R, %), calculated from experimental data with the following equations:

$$q = \frac{(c_0 - c) \cdot (V/1000)}{m} \tag{25.1}$$

$$R, \% = \frac{(c_0 - c)}{c_0} \cdot 100 \tag{25.2}$$

where c_0 is the initial concentration of heavy metals solution (mg/l), c is the equilibrium concentration of heavy metals solution (mg/l), V is the volume of solution (ml), and m is the biosorbent mass (g).

25.3.2 Dynamic Continuous-Flow Biosorption Technique

Unfortunately, the batch-technique biosorption has limited applicability to the pilot or industrial scale. The industrial utilization of biosorption processes required the use of continuous systems, where the marine algae biomass can be used in multiple biosorption–desorption cycles [25.64]. In addition, the heavy metal ions biosorption is more effective if it is carried out in a packed-bed column and the requirement of biosorbent and the operation cost of the process are substantially reduced [25.65].

Generally, the experimental study of biosorption processes in dynamic conditions is performed in cylindrical columns, with variable dimensions (do not typically exceed 1.5 m in diameter and 5 m in height), which are filled with a layer of biosorbent material. In this case, aqueous solution containing heavy metal ions is normally passed in up-flow mode through the column, and at the bottom of this is collected aqueous solution where the heavy metal ions were removed (named the effluent solution). By plotting the variation of heavy metal ion concentration of the effluent solution as a function of the operating time of the column, or the volume of the treated aqueous solution, the breakthrough curves are obtained (Fig. 25.2).

One the main tools used in the investigation of the performances in the biosorption column is the breakthrough analysis, which is based on the calculation of several parameters from the experimental breakthrough curves [25.66].

The breakthrough time (t_b) and volume (V_b) represent the time and volume at the breakthrough point, where the effluent concentration of the heavy metal ion reaches a value of $0.1 \cdot c_0$ (breakthrough concen-

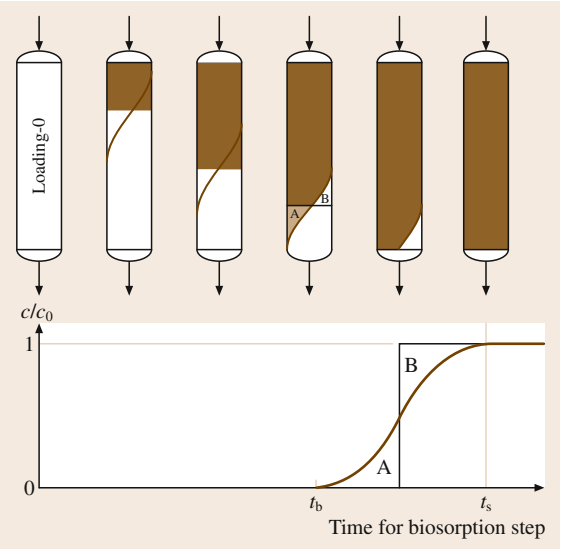

Fig. 25.2 Schematic representation of the breakthrough curves for the biosorption processes in dynamic continuous-flow conditions

tration). The saturation time (t_s) and volume (V_s) are the time and volume at saturation point, and were selected as the time and volume when the effluent concentration achieved a constant value around $0.95 \cdot c_0$ (where c_0 is the initial concentration of the heavy metal ion), although the biosorbent bed was not fully saturated.

The efficiency in the overall use of the biosorbent mixture in the column is indicated by the mass transfer zone (MTZ), which is defined as the length of the biosorption zone in the column, and can be calculated by using the following equation:

$$\mathrm{MTZ} = H \cdot \frac{(t_s - t_b)}{t_s} \tag{25.3}$$

where MTZ is the length of the mass transfer zone (cm); H is the length of the biosorbent bed (cm); t_b is the time required to reach the breakthrough point (min); and t_s is the time required to reach the saturation point (min).

The longer the mass transfer zone, the more biosorbent is not fully utilized at the end of the biosorption process. So, for the process to be economical it is important to minimize the length of the transfer zone and increase, thus, biosorbent utilization.

Practically, the dynamic continuous-flow biosorption is accomplished by using batteries of multiple columns that work in parallel and/or in series, to optimize the performance of the process. Some examples of using marine algae biomass in continuous-flow biosorption systems are presented in Table 25.3.

Generally, the smaller the biosorbent particles, the more difficult is the passing of aqueous solution through the column. However, the small dimension of biosorbent particles makes the metal uptake process to be more effective and rapid. When, the particles of biosorbent from the packed bed are larger, aqueous solution of metal ions can pass through the column easily, but the efficiency of biosorption

Table 25.3 Some utilizations of marine algae biomass for the removal of heavy metal ions from aqueous solutions, by dynamic continuous technique

Ulva lactuca	Mixture: algae waste: Purolite A-100 = 1 : 2	Pb(II)	[25.81]

process is lower due to the decrease of the specific surface area. Thus, for the best mass transfer and utilization, the biosorbent granules should be as small as possible. Practically, the recommended biosorbent dimension rages between 0.5 and 2.0 mm.

The main disadvantage of using marine algae biomass in dynamic continuous-flow biosorption systems is the easy with which the column is clogged, due to the small size of biosorbent. In consequence, the flow rate of aqueous solution through the column will be obstructed, and thus the efficiency of the biosoption process will be drastically affected. To solve this problem, some studies from the literature have proposed the conversion of marine algae biomass into granules by including them in various organic polymer matrices (see Table 25.3). But, by using this procedure, some functional groups from the marine algae biomass surface become unavailable for the heavy metal ions from aqueous solution, because they are blocked by interactions with the polymer matrix. This makes the biosorption capacity of marine algae biomass decrease, and the efficiency of the biosorption process in continuous-flow conditions less than those obtained in batch systems [25.65]. In order to avoid this inconvenience, *Bulgariu* and *Bulgariu* [25.42] propose the mixing of marine algae waste biomass with commercially available anion exchanger resin (Purolite A-100), and the obtained biosorbent mixture has proven to be efficient in the removal of Pb(II) ions from aqueous media. Because on this resin the retention of Pb(II) ions is insignificant, it can be considered an inert material, which has the role to prevent the clogging of the column, due to the larger size of its particles. In addition, the Purolite A-100 resin has an excellent retention capacity for some inorganic anions (such as nitrate or sulfate) [25.81], which are also present in wastewater and are also pollutants for aquatic environment.

25.4 Influence of Experimental Parameters

The removal of heavy metal ions from aqueous solutions by biosorption on marine algae biomass takes places with maximum efficiency only in well-defined experimental conditions. In consequence, an important part of the studies related to the removal of heavy metal ions by biosorption on low-cost materials such as marine algae biomass was the study of the influence of several experimental parameters on the retention process efficiency. As a function of the experimental technique used in the biosorption studies, the experimental parameters that should be considered in the experimental studies are as follows:

i) For batch technique – solution pH, biosorbent dose, initial metal ion concentration, contact time between the two phases, and temperature.
ii) For the dynamic continue-flow technique – height of biosorbent bed, aqueous solution flow rate, and initial concentration of heavy metal ions.

The experimental results obtained in these studies have provided a complete view of the biosorption process and allowed us to establish the optimal conditions for that the removal efficiency of metal ions from aqueous solutions is maximum.

25.4.1 Influence of Experimental Parameters on Batch-Technique

Effect of Solution pH

The pH of heavy metal ions solutions is the most important experimental parameter that governs the biosorption process. When designing a process for metal ions removal from wastewater, both optimal pH value for metal biosorption and pH value required for effluent discharge to comply with regulation must be taken into consideration before making a final decision [25.82].

Many studies from the literature [25.16, 28–38] have shown that the low-cost materials, including marine algae and marine algae waste biomass, act as a good biosorbent in a rather narrow pH range. The solution pH strongly influences not only the dissociation degree of functional groups from biomass surface, considered as biosorption sites, but also the solution chemistry of heavy metal ions (hydrolysis, complexation by organic and/or inorganic ligands, redox reactions, precipitation, etc.), the speciation and the biosorption availability of the heavy metals [25.83–85].

In Sect. 25.2 it was already shown that the marine algae and marine algae biomass contains in their structure various functional groups (such as carboxyl, hydroxyl, amino, sulfate). With the change in the so-

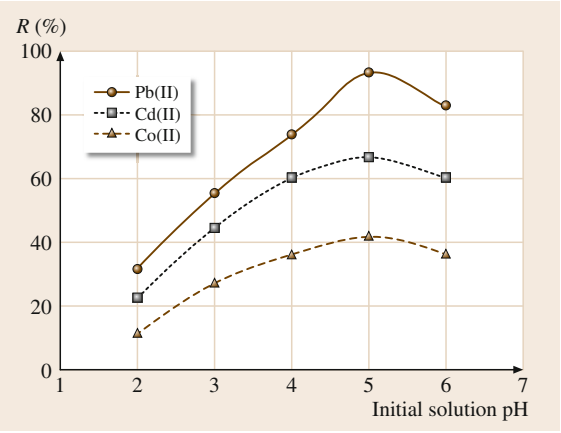

Fig. 25.3 Influence of solution pH on the removal efficiency of some heavy metal ions on marine algae – *Ulva lactuca* sp. (after [25.41, 49, 88])

lution pH, the behavior of each of these groups is changed. Thus, at highly acidic pH values most of these functional groups are protonated and act as a positively charged species [25.86]. Deprotonation of functional groups occurs due to increasing pH, when they behave as negatively charged groups, and start to interact with positively charged metal ions. On the other hand, certain functional groups such as amino contain lone pairs of electrons and thus can form with the metal ions coordinate bonds. The coordination process is highly pH dependent and occurs only at some specific pH value [25.87]. Thus, a change of initial solution pH can affect the achievement of complexing interactions and can determine a change in the biosorption efficiency.

The speciation and solubility of heavy metal ions are also affected by the value of solution pH. Generally, the biosorption efficiency of heavy metal ions gradually increases with increasing solution pH, but not in a linear relationship. In most of cases, this effect is more pronounced as initial heavy metal ion concentration of solution also increases. On the other hand, a too high pH value may cause the precipitation of metal species, and in consequence it should be avoided during experiments. Figure 25.3 illustrates a typical effect of solution pH on the biosorption efficiency of some heavy metal ions onto marine algae biomass (*Ulva lactuca* algae).

Such biosorption behaviors may be attributed to competition between heavy metal ions and protons for the binding sites from the biomass surface. At low pH values (< 4.0), the excess of protons from the systems can compete with heavy metal ions, and in consequence the amount of heavy metals retained is low. Increasing the solution pH determined a reducing of proton concentration and an increase of dissociation degree of functional groups from the biosorbent surface, which make the amount of retained heavy metal ions increase, until a maximum is attained. This pH value corresponding to the maximum of biosorption represents the optimum value and a further increase of pH makes that the biosorption efficiency subsequently decrease. The strong pH dependence of the biosorption process suggests that the electrostatic interactions between negatively charged functional groups and positively charged heavy metal ions may be one of the specific biosorption mechanisms [25.89].

For most biosorption systems, the uptake of heavy metal ions from aqueous solutions using marine algae or marine algae waste biomass as biosorbent occurs with maximum efficiency in a pH range between 4.0 and 6.0 (see Table 25.4). This is because, in this pH range most of heavy metals exist in solutions predominantly as free metal ions (M^{2+}) [25.83], and the ionization degree of functional groups from adsorbent surface is higher enough to allow the electrostatic interactions [25.29, 38].

However, metal anions, such as Cr(VI), exhibits different pH features in comparison with heavy metal cations. In general, a low pH value is favorable for the biosorption, and a much lower optimum pH (1.5–2.0) has been reported for different types of brown, red or green marine algae biomasses (Table 25.4). This is determined by the fact that the anions could be retained only by the protonated active sites of the biosorbent, primarily by electrostatic interactions. At very low pH values where the concentration of protons is very high, the most of functional groups are undissociated or positively charged. This will enhance the interactions of Cr(VI) with the binding sites from the biosorbent surface, by attractive electrostatic forces. As the solution pH increased, the overall surface charge on the biosorbent became negative, and decreased the biosorption efficiency [25.108].

In most of experimental studies presented in the literature, the optimum value of solution pH is adjusted by adding small volume of mineral acids (HCl, HNO_3, H_2SO_4) or alkaline base (NaOH, KOH) solutions. But, due to the interactions between heavy metal ions and functional groups from biomass surface during biosorption process protons are released. In consequence, the solution pH decreases (with 0.5–1.0 units) and this make that the biosorption efficiency to decrease, mainly

due to the change of dissociation degree of superficial functional groups of marine algae biomass.

In order to maintain a constant dissociation degree of superficial functional groups of marine algae biomass during biosorption process, buffered solutions can be used. These are obtained by adding certain buffer solution to aqueous solutions of heavy metal ions before mixed with the solid biosorbent. Even if this procedure can be successfully applied in the case of peat moss, when the presence of acetate buffer improves the adsorption capacity for Pb(II) ions [25.109], in the case of marine algae biomass an opposite effect is observed. The experimental results obtained by *Lupea* [25.110] have shown that in the presence of buffer solutions (such as acetate buffer) the amount of heavy metal ions retained on weight unit of *Ulva lactuca* sp. marine algae is lower compared to unbuffered solutions, regardless of the solution pH value (Fig. 25.4).

The decrease of the biosorption efficiency of heavy metal ions in buffered solutions is mainly determined by the fact that the marine algae biomass has in its structure a high number of hydroxyl and carboxyl groups that can be involved in specific interactions (such as esterification) with organic ligands (acetate, in this case) from buffer. These interactions drastically decrease the availability of reactive functional groups from the biosorbent surface to bind heavy metal ions, and thus the efficiency of the biosorption process decreases. Under these conditions, it is recommended that

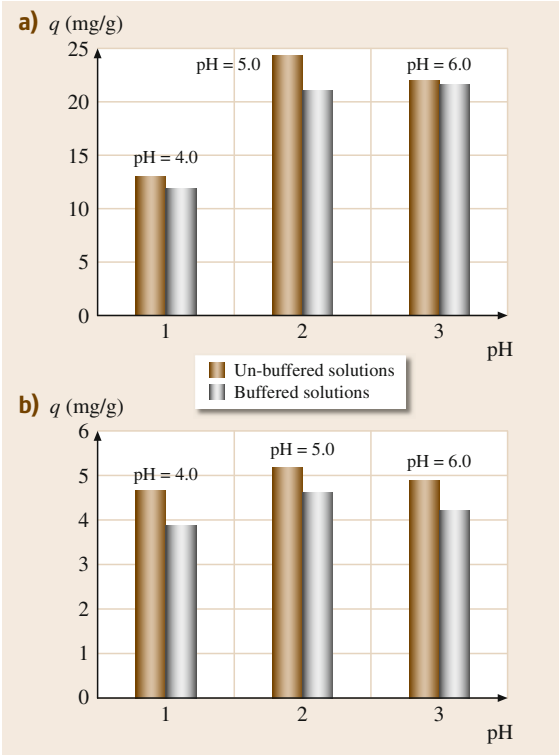

Fig. 25.4a,b Effect of buffer solution on the biosorption efficiency of Pb(II) **(a)** and Cd(II) **(b)** ions onto *Ulva lacuta* sp. marine algae [25.88, 110]

the removal of heavy metal ions from aqueous solutions by biosorption onto marine algae and marine algae waste biomass be done at the optimal value of pH in unbuffered solution.

Effect of Biomass Dose

The biomass dose is another important experimental parameter which has a great influence on the biosorption process and determined the potential of biosorbent through the binding sites available to remove heavy metal ions, at a specific concentration [25.16]. Thus, in order to optimize the experimental conditions for the removal of heavy metal ions by biosorption onto a given low-cost biosorbent, it is necessary to establish the optimum dose, and this could also be advantageous from economical considerations.

In general, it has been shown that a given initial heavy metal ion concentration, the higher efficiency of biosorption process is obtained for a lower dose of biosorbent. This is because the lower the dose of biosorbent, the higher will be the metal ion/biosorbent ratio, and the metal ion is retained onto the biosorbent unit, unless the biosorbent reaches saturation. High dose of biosorbent can exert a shell effect, by protecting the functional groups from being occupied by heavy metal ions. The result of this is a lower specific heavy metal ion uptake that means smaller amount of metal ion retained per biosorbent unit [25.87]. On the basis of these considerations, for all the biosorption systems the influence of the biosorbent dose should be studied and the obtained results analyzed carefully.

In the experimental studies, the marine algae and marine algae waste biomass dose usually varied from one hundred milligrams to few tens of grams for 1 l of aqueous solution. A typical representation of the influence of biosorbent dose on the removal efficiency of heavy metal ions obtained in the case of biosorption of Pb(II) and Co(II) ions from aqueous solution onto marine algae and marine algae waste biomass is illustrated in Fig. 25.5.

At equilibrium, the metal biosorption capacity (q, mg/g) decreases with the increasing biosorbent dose, in both the cases. This decrease can be due to the concentration gradient between the biosorbent and metal ions; an increase in the biosorbent concentration causes a decrease in the amount of heavy metal ion retained onto a unit weight of the biosorbent material. But, in the selection of optimal biosorbent dose, the variation of removal percent (R, %) must be also taken into account. It can be observed (Fig. 25.5) that the removal percent generally increases with the increase of the biomass dose. It reaches a maximum at certain value of biosorbent dosage, and then remained almost constant (as is the case of metal ions biosorption onto *Ulva lactuca* sp. marine algae) or varies very little (as is the case of metal ions biosorption onto other marine algae biomass). By analyzing these dependences the biosorbent dose that is sufficient for the quantitative removal of heavy metal ions from aqueous solutions can be selected, and this value is considered to be the optimum.

Similar trends have been reported in the literature for different adsorption systems using low-cost biological materials [25.16, 18, 82, 111], and the positive correlation between biosorbent dose and heavy metals removal efficiency, observed experimentally, can be related to the increase in the number of active sites and available surface area.

Therefore, in order to design an economical biosorption system for heavy metal ions removal, the optimum biosorbent dose should be chosen after a careful comparison of the experimental variations obtained for both parameters (q, mg/g and R, %). Table 25.4

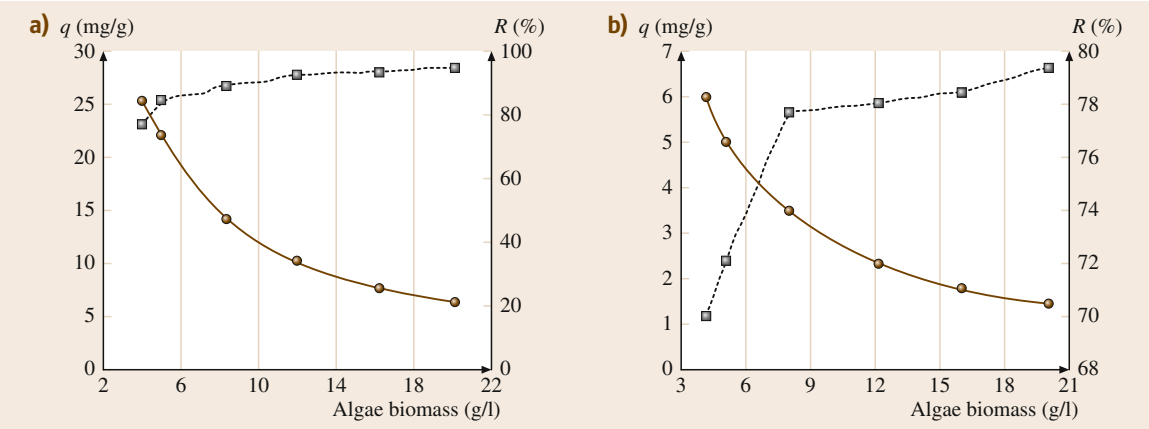

Fig. 25.5a,b Effect of biosorbent dose on the removal efficiency of Pb(II) – **(a)** and Co(II) – **(b)** ions from aqueous solution on *Ulva lactuca* sp. marine algae, in optimum experimental conditions (*q – continue line*; *R*, *% – dotted line*) (after [25.49, 88])

summarizes the values of optimal biosorbent dose used for the removal of heavy metal ions from aqueous environments, in the case of different types of marine algae biomasses.

Effect of Contact Time

As the biosorption proceeds, the biosorbent reaches the saturation state and then the retained metal ions tend to desorbs back into solution. When the system reaches this state of equilibrium, no further net biosorption occurs [25.16]. For this reason it is necessary to determine the time at which the biosorption equilibrium is attained.

The contact time between the two phases required to reach the equilibrium state is a very important experimental parameter for the biosorption process optimization of heavy metal ions from aqueous solution. The unsatisfactory value of this parameter drastically limits the practical use of a given biosorption process, even if its efficiency in the heavy metal ions removal is high. This is the main reason why in all the biosorption studies, the effect of contact time is included in the experimental protocol.

The effect of contact time between the solid phase – biosorbent material (marine algae or marine algae waste biomass) – and aqueous phase – heavy metal ions solution is generally investigated at room temperature, in considered optimum conditions (solution pH and biosorbent dose), for a given value of initial concentration of metal ions. The biomass is kept in contact with metal-bearing solution for different periods of time (usually no more than 3 h), and the general shape of

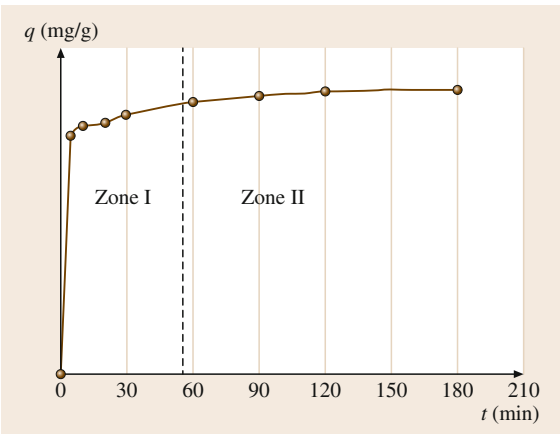

Fig. 25.6 General shape of the experimental dependences obtained in the study of the contact time influence on the removal efficiency by biosorption onto marine algae or marine algae waste biomass, in optimum experimental conditions

experimental dependencies obtained under these conditions is illustrated in Fig. 25.6.

In all the cases, the amount of heavy metal ions retained onto certain biomass increase with the increase in contact time, and the biosorption process reaches the equilibrium state after no more than 180 min. The biosorption process of heavy metal ions from aqueous solutions onto marine algae biomass generally occurs in two steps, a fast initial step (zone I) where the amount of heavy metal ions retained increase sharply (up to 90% in the first 20–60 min), followed by a much slower

gradual biosorption, near to the equilibrium (zone II). In most of the biosorption studies using marine algae or marine algae waste biomass as biosorbent, no further significant biosorption is noted after 3 h [25.24].

By analyzing the experimental dependences obtained in the study of the influence of contact time on the removal efficiency of heavy metal ions from aqueous solutions, the optimum value of this parameter can be establish. In Table 25.4 are summarized the values of contact time required for the efficient removal of heavy metal ions from aqueous environments, in the case of different types of marine algae and marine algae waste biomass. No more than 120 min of contact time is necessary in these biosorption processes. Such low values of contact time required to attain the equilibrium state indicate that the biosorption of heavy metal ions onto marine algae biomass is mainly controlled by the chemical (electrostatic) interactions between positively charged metal ions and negatively charged functional groups form biomass surface; the share of elementary diffusion processes, especially the intraparticle type, is much smaller [25.112].

Such two-steps adsorption behavior has been reported in most studies of metal ion retention in various low-cost materials [25.16, 18, 112–114], and is mainly determined by the presence of sites with different binding affinities for metal ions on the adsorbent surface, thereby yielding different binding sites. According to *Qin* and co-workers [25.25, 89], the rapid initial biosorption step is generally the result of the fast transfer of metal ions to the surface of the biosorbent particles, while the subsequent slow biosorption process is a consequence of the slow diffusion on metal ions into the pores of the biosorbent particles. The very fast biosorption and settling of marine algae biomass make these materials suitable for continuous flow wastewater treatment systems.

Effect of Temperature

Temperature is also an important experimental parameter for the removal of heavy metal ions, dealing with the thermodynamics of the biosorption process. This parameter is directly related to the kinetic energy of the metal ions, and an increase or decrease in temperature should cause a change in the amount of heavy metal ions removed or retained by biosorbent [25.87].

In general, the temperature affects the removal efficiency of the heavy metal pollutants from aqueous solution, but to a limited extent in a certain range of temperature. In case of marine algae biomass the most experimental studies were performed in the temperature range of 5–50 °C, at a contact time lower than 4 h. This is because in this temperature range, the biosorbent materials do not suffer secondary processes of thermal degradation [25.16], and the low value of contact time do not make the volume of aqueous solutions vary significantly, due to the evaporation phenomena.

The effect of temperature on the heavy metal removal by biosorption onto marine algae biomass depends on the nature of the heavy metal ion and on the nature of biomass used as biosorbent, and usually was observed in two stages. The biosorption equilibrium occurs rapidly at lower heavy metal ion concentrations, for all temperature values, and becomes relatively constant at higher concentrations. Table 25.4 presents the values of temperature considered as optimum for the removal of some heavy metal ions from aqueous solution, using different types of marine algae and marine algae waste biomass as biosorbents.

Such processes are normally exothermic, so biosorption capacity increases with decrease of temperature, and indicate that the ion exchange interactions exist in the biosorption process to some extent. The decrease of biosorption capacity of marine algae biomass at higher temperatures may be due to the damage of active binding sites in the biomass [25.115]. When the temperature is too high, a distortion of some available functional groups from the cell surface occurs, and in consequence the efficiency of the biosorption process decreases.

However, *Gupta* and *Rastogi* [25.102] have found that the Pb(II) biosorption on *Spirogyra* sp. marine algae increases with increasing temperature, in the range of 25–45 °C. They explained that higher temperature would lead to higher affinity of sites for metal ions, and the energy of the systems facilitates the binding of Pb(II) ions on the functional groups from cell surface to some extent. Such behavior has been observed and for the other removal processes of heavy metal ions using marine algae and marine algae waste biomass [25.76, 110].

The variation of temperature does not always significantly change the biosorption capacities of marine algae biomass. *Bulgariu* and *Bulgariu* [25.41] have shown that temperature (in the 10–40 °C range) has minor effect on the removal of the Pb(II), Cd(II), and Co(II) ions from aqueous solution onto marine green algae waste biomass. Thus, the increase of temperature with 30 °C determined a decrease of biosorption

capacity of the biomass with 0.07 mmol/g in the case of Pb(II), with 0.06 mmol/g in the case of Cd(II) and with 0.03 mmol/g in the case of Co(II), respectively.

On the basis of these experimental results, it is recommended that at large scale, the removal of heavy metal ions from aqueous solutions by biosorption on marine algae and marine algae waste biomass to be performed at ambient temperature, and this is dictated especially by economical considerations [25.116].

On the other hand, the change in temperature causes a change of thermodynamic parameters, such as free Gibbs energy change (ΔG), enthalpy change (ΔH) or entropy change (ΔS), which contribute to help understand the biosorption mechanisms [25.117]. Temperature data are usually used to determine these parameters, because they provide valuable information about the biosorption process. The negative value of free Gibbs energy change (ΔG) shows that the process is feasible and spontaneous. The increase of the ΔG value, in the negative direction, with temperature is an indication of the increase of biosorption process probability [25.24]. Also, the standard enthalpy change (ΔH) shows the route of energy in the system, and has an important contribution to deciding whether a certain biosorbent can be used for the removal of heavy metal ions at elevated temperature or not. A positive value indicates an endothermic process that will be favored by high temperatures, while a negative value of this parameter shows an exothermic process, which is more efficient at low temperatures.

Table 25.5 summarizes the values of thermodynamic parameters for some removal processes of heavy metal ions from aqueous media, using marine algae biomass as biosorbents.

The positive value of the entropy change indicates the increasing randomness at the solid/liquid interface during the biosorption process, whereas the negative value of this parameter suggests a decrease in the randomness at the solid/liquid interface during the biosorption process [25.76]. Thus, even if some biosorption processes are endothermic, in some conditions these can be spontaneous because of the positive entropy change.

All these parameters should be considered in the experimental studies of heavy metal ions removal by biosorption onto marine algae biomasses, and the obtained results will allow us to establish the optimum conditions, to ensure the maximum efficiency of the biosorption process.

25.4.2 Influence of Experimental Parameters in a Dynamic Continuous-Flow Technique

The process of heavy metal ions biosorption in a dynamic continuous-flow technique is mainly influenced by three key experimental parameters: bed height, flow rate of aqueous solution, and initial concentration of heavy metal ions.

As the heavy metal ions solution passes through the column, the biosorption zone (where the bulk of biosorption takes place) starts moving out of the column and the effluent concentrations start rising with time. As a consequence, the variation of these parameters will change the characteristics of the breakthrough curve (breakthrough point and saturation point), and this will also affect the applicability of the heavy metal ion removal process. For this reason, in the experimental studies, for each of these parameters the optimal values that should be established to ensure the efficient delivery of the biosorption process.

Effect of Bed Height

Accumulation of heavy metal ions in a packed-bed column is largely dependent on the quantity of biosorbent (marine algae biomass) inside the column. This is mainly due to the higher contact time between heavy metal ion solution and available biomass in the column, and also due to more number of binding sites and functional groups available for biosorption of heavy metal ions [25.118].

Generally, the characteristics of the breakthrough curves (breakthrough time (volume) and saturation time (volume)) increases with the rise in the bed height, and this can be easily observed from Fig. 25.7 chosen for exemplification. This may be due to an increase in the surface area of the biosorbent as the quantity of biomass packed in the column increase.

However, the increase in the quantity of algae biomass deposited in the column also results in a broadened mass transfer zone, which makes breakthrough curves less steeper. The more gradual shape of the curves as the bed height increased implies that the biosorbent bed was more difficult to be completely saturated, and the decrease in the slope of the breakthrough curves with the increase of this parameter clearly reflects this fact [25.66]. Even if a high biosorbent bed height increases the usage time of the column, a too high value of this parameter has several disadvantages, the most important being the increase in the difficulty of solution flow through the column and the quantity of

Table 25.5 The values of thermodynamic parameters obtained for some biosorption processes of heavy metal ions onto marine algae biomass

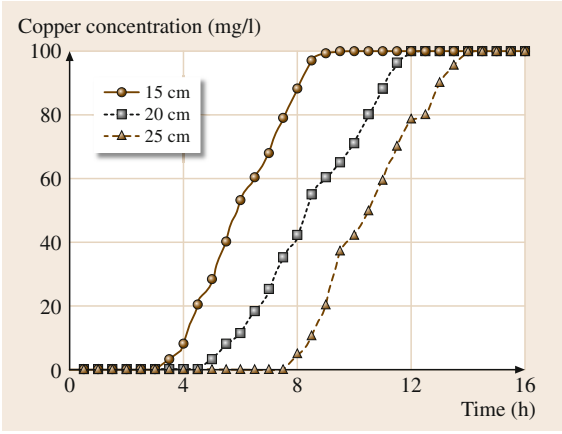

Fig. 25.7 Breakthrough curves for biosorption of copper by *Ulva reticulate* at different bed heights (flow rate = 5 ml/min; pH = 5.5; initial concentration = 100 mg/l; temperature = 30 °C) (after [25.75])

biosorbent required for the biosorption process. On the other hand, if the biosorbent bed height is too low, the column becomes quickly saturated, and biosorbent bed must be regenerated before another use.

Table 25.6 presents the experimental values of the biosorbent bed height used for the removal of some heavy metal ions from the aqueous environment on various algae biomasses, in dynamic continuous-flow conditions.

Lodeiro et al. [25.66] have shown that in the case of Cd(II) ions removal on protonated *Sargassum muticum* marine algae the breakthrough curves showed no *tail* toward saturation time when the biosorbent mass inside of column was low. Moreover, when the quantity of algae biomass is increased a slower increase of the breakthrough parameters toward saturation of the bed can be observed. The broad tailing edge of breakthrough curves could be a consequence of the rate limiting intraparticle diffusion mechanism or flow nonidealities, which may occur when an excessive quantity of algae biomass is present in the column [25.75].

Effect of Solution Flow Rate

The solution flow rate is an important parameter affecting biosorption of metal ions in a packed-bed column, because the retention process, especially at low metal ions concentrations, is usually controlled by the mass transfer process [25.123].

Generally, the characteristics of the breakthrough point (breakthrough time and volume) decrease when the solution flow rate through the biosorbent bed increases. In addition, the volume of solution which is efficiently treated until a breakthrough point, decreases significantly with the increase of flowrate, and therefore the useful time of biosorbent bed is significant reduced. Initially, the biosorption process is very fast at lower solution flow rate, probably associated with the availability of functional groups from the biosorbent surface. During the use, these functional groups are gradually occupied, and the uptake process becomes less effective. The breakthrough curves become steeper when the solution flow rate is increased, and the breakthrough point and the retained metal ion concentration decreases.

For exemplification, in Fig. 25.8 is illustrated the effect of solution flow rate obtained in the case of

Table 25.6 Experimental conditions for biosorption of some heavy metal ions onto marine algae biomass, in dynamic continuous-flow conditions

Heavy metal ion	Marine algae biomass	Bed height (cm)	Flow rate (ml/s)	Initial concentration (mg/l)	Reference

Pb(II) removal on biosorbent mixture (marine algae waste biomass: Purolite A-100) bed [25.42], but similar results have been reported for the most dynamic continuous-flow systems that use marine algae biomass as biosorbents.

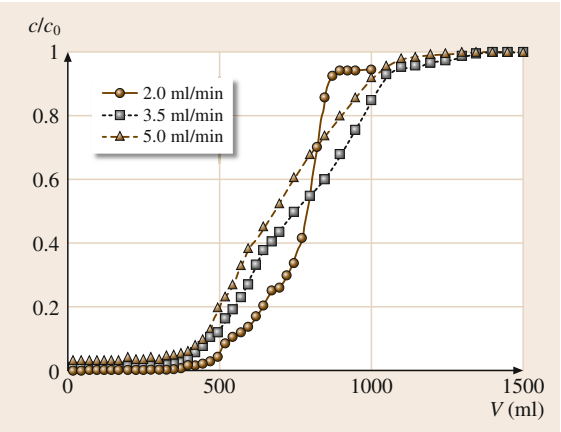

Fig. 25.8 Breakthrough curves for biosorption of Pb(II) by the biosorbent mixture-bed column (*Ulva lactuca*: Purolite A-100 = 1 : 2), at different flow rates (pH = 5.0; $c_0 = 0.34$ mmol/l; $H = 2.5$ cm; temperature = 20 °C) [25.42]

Lower solution flow rate favor biosorption of heavy metal ions, and as a consequence the biosorption capacity of marine algae biomass is significantly improved. This is because at lower solution flow rate the metal ions have more time in contact with the biosorbent and the diffusion of metal ions to the binding sites from the algae waste biomass surface occurs. If the solution flow rate is higher, the metal ions have a short diffusion time and will interact predominantly with the functional groups for which they have higher affinity and availability. When these binding sites are occupied, the biosorbent bed becomes saturated early, and the biosorption process is stopped. On the other hand, when the flow rate is lower, the contact time inside the column is longer, and the diffusion process becomes effective. The heavy metal ions have more time to diffuse amidst the biosorbent particles and will interact with the available superficial functional groups that have lower affinity for metal ions. In consequence, a longer breakthrough time is obtained and better biosorption efficiency.

Therefore, the choice of the best solution flow rate values should be a compromise between these two opposite situations [25.124]. Several such *compromise* values of solution flow rate, used for the removal of some heavy metal ions onto marine algae biomass in dynamic continuous-flow conditions, are presented in Table 25.6.

It should also be noted that a too little solution flow rate has two undesirable consequences, from the applicative point of view: (i) the saturation point not reached, which means that the obtained breakthrough curves cannot be modeled and characteristic parameters cannot be calculated, and (ii) the reach of the saturation point is so slow and the metal ions concentration in the effluent becomes early high for that the removal process is considered to be efficient, even if the biosorbent is not exhausted. Under these conditions, the biosorption process becomes unfeasible from economical considerations.

Effect of Initial Heavy Metal Ions Concentration

The variation of initial heavy metal ions concentration changes the shape of breakthrough curves. An increase in the initial concentration of heavy metal ions, when other experimental parameters are kept constant, significantly affects the breakthrough curves, as is illustrated in Fig. 25.9.

In all the studied biosorption systems that use marine algae biomass as biosorbent, the increase of the initial heavy metal ions concentration caused a faster breakthrough as expected. In addition, at a high initial heavy metal ions concentration, the breakthrough curves were steeper in comparison with those at a low initial heavy metal ions concentration, with a shorter mass transfer zone (MTZ). The steepness of the curve (dc/dt) is a measure of the efficiency of the column to reach the saturation, and a high value of this parameter is better for the column performances [25.65].

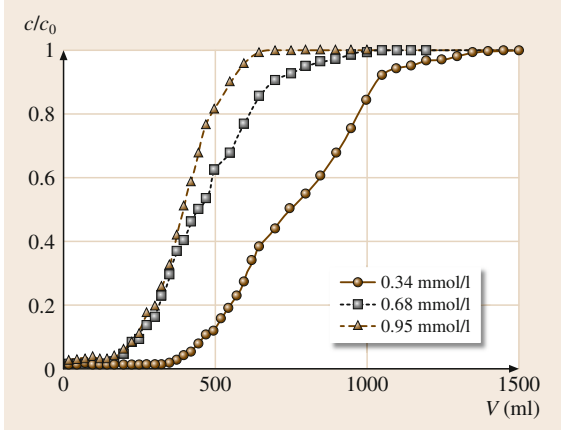

Fig. 25.9 Breakthrough curves for biosorption of Pb(II) by biosorbent mixture-bed column (*Ulva lactuca*: Purolite A-100 = 1 : 2), at different initial metal ions concentrations (pH = 5.0; flow rate = 3.5 ml/min; H = 2.5 cm; temperature = 20 °C) [25.42]

The experimental results demonstrate that an increase in the initial heavy metal ions concentration changes the biosorption rate through the packed bed and increases the biosorbent-bed capacity. Thus, biosorption of heavy metal ions at breakthrough and saturation was greater at high initial heavy metal ions concentration, because higher metal concentration provides better driving force to the metal biosorption process during continuous column run [25.42].

25.5 Modeling of Biosorption Process in Batch Conditions: Isotherm and Kinetic Models

Biosorption of heavy metal ions is a passive non-metabolically mediated process of metal ions binding by biosorbent. Many kinds of marine algae or marine algae waste biomass can be used as biosorbents for the removal of heavy metal ions from aqueous solution. Biosorption can also be defined as a number of passive accumulation processes, which may include, in any particular cases, ion exchange, coordination, complexation, adsorption, and microprecipitation [25.18]. For this reason, biosorption is considered to be a fast physical/chemical process, and its rate is determined by the type of elementary interactions.

Proper analysis and design of biosorption removal processes requires relevant equilibrium and kinetic data, as the vital information. In equilibrium, a certain relationship prevails between heavy metal ions concentration from aqueous solution and biosorbent state. So, it is both fundamentally and economically important to correlate the equilibrium and kinetic data between various heavy metal ions and biosorbents, in order to asses the biosorption capacity for different heavy metal

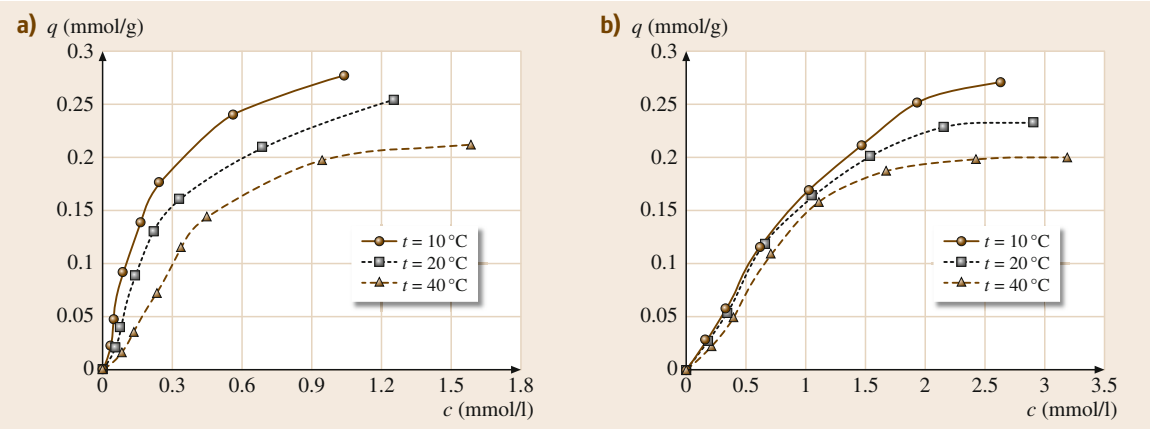

Fig. 25.10a,b Biosorption isotherms for retention of Pb(II) **(a)** and Cd(II) **(b)** on green algae waste biomass (pH = 5.0; biosorbent dose = 8 g/l; contact time = 4 h) (after [25.41])

ions and as a prerequisite for the design of commercial treatment systems. The more complex is the wastewater composition, the more accuracy is required in describing and selecting the biosorption systems [25.18, 112].

25.5.1 Equilibrium Modeling of Biosorption

The uptake capacity of a certain biosorbent (marine algae or marine algae waste biomass) for a given heavy metal ion from aqueous solutions, in specified experimental conditions, can be described by the equilibrium biosorption isotherms. The biosorption isotherms represent the equilibrium distribution of the studied heavy metal ions between the phases of the solid biosorbent and aqueous solution. Because the heavy metal ions equilibrium concentrations are function of temperature, obtaining equilibrium biosorption isotherms for different temperatures are necessary for the thermodynamic modeling of the biosorption process. Figure 25.10 illustrates, for exemplification, the biosorption isotherms obtained for Pb(II) and Cd(II) ions retention on *Ulva lactuca* sp. marine algae, but similar dependences have been obtained for almost all biosorption systems, which use marine algae biomass as biosorbents.

Most of biosorption isotherms obtained experimentally have a similar shape with those presented in Fig. 25.10, being nonlinear and composed from two regions. In the first region – corresponding to low concentrations of heavy metal ions, the biosorption equilibrium arises rapidly, while in the second region, the biosorption equilibrium occurs more slowly, and this is a characteristic of the high concentrations of heavy metal ions. The value of metal ions concentration that separates the two regions depends on the nature of marine algae biomass used as biosorbent and the metal ion involved in the biosorption process. Therefore, for the optimization of the biosorption process design, it is necessary to obtain the appropriate correlation for the equilibrium biosorption isotherms. These isotherms are characterized by definite parameters, whose values express the surface properties and affinity of biosorbent for different heavy metal ions, and these are obtained by using equilibrium isotherm models.

The equilibrium isotherm models are usually classified in two categories [25.16, 125]:

a) *Empirical equations* – These equations are used to describe the biosorption equilibrium, and can provide information of metal-uptake capacity of various biosorbent materials, and can be used to describe mono- or multimetal ions biosorption systems. In Table 25.7 are presented some well-known empirical models for single and multicomponents systems. However, the empirical models do not reflect any mechanism of metal ions uptake and can hardly explain the biosorption behavior with adequate physical interpretation. In addition, predictive conclusions cannot be drawn, for the systems operating in different conditions.
b) *Mechanistic models* – These models are based on the mechanism of metal ions biosorption, and these can be used not only to represent experimental behavior but also to explain and predict the biosorption behavior; based on the understanding of biosorption mechanisms. The most important mechanistic models are the ion exchange model and

Table 25.7 Frequently used equilibrium isotherm models (after [25.15, 18])

Isotherm model	Mathematical equation	Observations
Single-component isotherm models		
Freundlich	$\ln q_e = \ln K_F + \frac{1}{n} \ln c_e$	q_e is the equilibrium metal biosorption capacity; c_e is the equilibrium metal ions concentration in solution; K_F is a biosorption equilibrium constant, representative of the biosorption capacity; n is a constant related to the biosorption intensity
Langmuir	$q_e = q_{max} \cdot \frac{K_L \cdot c_e}{1 + K_L \cdot c_e}$	q_{max} is the maximum adsorption capacity upon complete saturation of biosorbent surface; K_L is the Langmuir constant, related to the biosorption/desorption energy
Dubinin–Radushkevich	$\ln q = \ln q_{max}^{DR} - \beta \cdot \varepsilon^2$	q_{max}^{DR} is the maximum amount of heavy metal retained on weight unit of biosorbent; β is a constant related to the adsorption energy and ε is the Polanyi potential, defined by the mathematical relation: $\varepsilon = RT \ln(1 + 1/c_e)$; where: R is the gas constant; T is the absolute temperature, c_e is the equilibrium concentration of heavy metals in solution.
Temkin	$q_e = \frac{R \cdot T}{b} \ln(a \cdot c_e)$	R is the gas constant; T is the absolute temperature; a, b are constants directly correlated to the biosorption heat
BET model	$q = \frac{K_B \cdot q_{e,max} \cdot c_e}{(c_s - c_e) \cdot [1 + (K_B - 1) \frac{c_e}{c_s}]}$	K_B is BET constant, indicating the energy of interaction between metal ions and the biosorbent surface; $q_{e,max}$ is a constant indicating the amount of metal ions retained to form a complete monolayer; c_s is the saturation concentration of the biosorbed component
Redlich–Peterson	$q_e = \frac{K_{RP} \cdot c_e}{1 + a_{RP} \cdot c_e^{\beta}}$	K_{RP}, a_{RP} and β are the Redlich–Peterson parameters. The exponent β lies between 0 and 1. For $\beta = 1$, the equation converts to the Langmuir form
Sips	$q_e = q_{max} \cdot \frac{(K_S \cdot c_e)^{\gamma}}{1 + (K_S \cdot c_e)^{\gamma}}$	K_S and γ are Sips parameters; q_{max} is the maximum adsorption capacity upon complete saturation of biosorbent surface
Multiple-component isotherm models		
Langmuir (multicomponent)	$q_{e,i} = \frac{K_{L,i} \cdot q_{max,i} \cdot c_{e,i}}{1 + \sum_i K_{L,i} \cdot c_{e,i}}$	$c_{e,i}$ and $q_{e,i}$ are the concentration and the retained quantity of metal ion per weight unit of biosorbent for each component; $q_{max,i}$ and $K_{L,i}$ are derived from the corresponding individual Langmuir isotherm equations
Combined Langmuir–Freundlich model	$q_{e,i} = \frac{a_i \cdot c_{e,i}^{1/n_i}}{1 + \sum_i b_i \cdot c_{e,i}^{1/n_i}}$	a_i and b_i are phase concentration of a single biosorbed component in equations
Competitive Redlich–Peterson model	$q_e = \frac{K_{RP,i} \cdot c_{e,i}}{1 + \sum_i a_{RP,i} \cdot c_{e,i}^{\beta_i}}$	$K_{RP,i}$, $a_{RP,i}$ and β_i are the Redlich–Peterson parameters derived from the corresponding individual Redlich–Peterson isotherm equations
IAST: Ideal Adsorbed Solution	$\frac{1}{q_t} = \sum_i \frac{Y_i}{q_i^0}$	Y_i is the solute concentration of component i in the solid phase; q_i^0 is the phase concentration of a single retained component, with concentration c_i^0.

surface complexation model [25.108]. Both these models take into account the nature of interaction between metal ions and functional groups of biosorbent, and modeling the biosorption process considering that metal biosorption mechanism involve ion exchange or complexation interactions [25.126, 127]. By using these models, they have predicted the isotherms of different metal ions biosorption (e.g., Cd(II), U(IV), etc.) on different types of nonliving marine algae biomass, in various experimental conditions [25.126, 128]. Unfortunately, the use of these models is limited to a small number of biosorption systems, because they assume the existence of a single type of interaction between metal ion and functional groups of biosorbent, which does not happen in the case of marine algae biomass.

In the equilibrium modeling studies, two classical empirical isotherm models, Freundlich and Langmuir, were most frequently selected to fit the experimental data obtained for various biosorption systems that use marine algae biomass for the removal of heavy metal ions from aqueous solution. Although the basic assumptions of these models were not fulfilled due to

the heterogeneity of the biosorbent surface, they were quite successful in predicting the practical biosorption capacity and optimization of the biosorption system design [25.129]. Generally, the linear regression is used to find the most adequate model that could describe the biosorption isotherms of heavy metal ions on marine algae biomass. Even though nonlinear method provides better results, the linear least-square method is still often preferred in favor of its simplicity and convenience.

The Freundlich isotherm model is originally of empirical nature (Table 25.7). This model is one of the the most widely used isotherm model for description of adsorption equilibrium, both for organic and inorganic compounds on a wide variety of adsorbents, including biosorbents [25.18]. The Freundlich isotherm model has been interpreted as biosorption to heterogeneous surface or surface supporting sites of different affinity, and assumed that the stronger binding sites are occupied first and that the binding strength decreases with increasing degree of occupation [25.87]. Generally, the Freundlich isotherm model is used to estimate the biosorption intensity of heavy metal ions toward a given biosorbent.

The graphical representation of $\ln q_e$ versus $\ln c_e$ has a slop with the value of $1/n$ and an intercept magnitude of $\ln K_F$. A favorable biosorption process tends to have the Freundlich constant n between 1 and 10 [25.18]. Larger value of n (smaller value for $1/n$) indicates strong interactions between biosorbent and heavy metal ions, while a value of n equal to 1, suggests linear biosorption process, leading to identical biosorption energy for all sites [25.130].

The Freundlich isotherm model can be successfully used to analyze most of the experimental biosorption data, and is especially excellent for fitting data from systems that use highly heterogeneous biosorbents, as listed in Table 25.8. Even, the biosorption capacities for marine algae biomasses (obtained from the Freundlich K_F constant) summarized in Table 25.8 are quite low in comparison with commercially activated carbons, these biosorbents are still attractive due to its biosorption advantages and cost-effectiveness for the removal of heavy metal ions.

Nevertheless, in some cases, the Freundlich isotherm model could not fit the experimental data well due to the low values of obtained correlation coefficients, or is not suitable to describe the biosorption equilibrium. Thus, the Freundlich isotherm model cannot be use to predict the biosorption equilibrium data at extreme concentrations of heavy metal ions. This is because the mathematical equation is not reduced to a linear expression at very low concentrations, and do not has limit expression at very high concentrations [25.18]. Fortunately this is not a problem, because a moderate concentration range is frequently used in most of biosorption studies.

The Langmuir isotherm model is probably the best known and the most widely used sorption isotherm for describing heavy metals biosorption on marine algae biomass, which produced good agreement with a wide variety of experimental data. In the simplest case, the Langmuir model is based on the following assumptions [25.4, 18]:

i) The biosorption process is limited to monolayer coverage,
ii) The surface of biosorbent is homogeneous and all surface sites (constant heat of biosorption);
iii) There is only one sorbate,
iv) One sorbate molecule reacts with one active site, and
v) The ability of a molecule to be retained on a given site is independent of the surface occupancy.

This model assumed that biosorption forces are similar to the forces in chemical interactions, and can be used to estimate the maximum biosorption capacity (q_{max}, mg/g), corresponding to biosorbent surface saturation. Usually, the parameters of the Langmuir isotherm model (q_{max} and K_L) are evaluated from the intercepts and the slopes of linear plots of c_e/q versus c_e. Table 25.8 summarizes a number of studies that draw upon the Langmuir isotherm to analyze the biosorption equilibrium data of heavy metal ions onto marine algae biomass.

According to the Langmuir model, the maximum biosorption capacity (q_{max}, mg/g) should coincide with saturation of the monolayer coverage, and as a consequence it should be independent of temperature. The experimental results have shown that a relatively small increase or even decrease in the maximum biosorption capacity is usually observed in the case of heavy metal ions biosorption on marine algae biomass (Table 25.8). This is because in biosorption processes that use marine algae biomass as biosorbents, saturation of certain biomass depends on the accessibility of the binding sites, the chemical state, and the affinity of studied metal ions for these sites. The temperature variation may affect one or more of these factors, and this will lead to the variation of the maximum biosorption capacity.

In addition, the variation of the Langmuir constant (K_L) with temperature indicates whether the biosorption process is exothermic or endothermic. Thus, the decrease of K_L value with temperature rise signifies the exothermicity of the biosorption process (physical biosorption), while the decrease of K_L with temperature indicates that the biosorption process need supplementary (thermal) energy (is endothermic), leading to chemosorption. These observations are very useful in the optimum design of biosorption systems. Thus, in the case of physical biosorption, the bonds between heavy metals and active sites of biosorbent are weak, and desorption occurs simply, by treating the loaded biosorbent with water. In the case of chemosorption, the bonds between heavy metals and active sites of biosorbent are stronger, and for desorption are needed more aggressive chemical reagents (mineral acids, complexing agents, etc.).

In order to appreciate the nature – physical or chemical – of the biosorption process, the Dubinin–Raduskevich model (Table 25.7) is more adequate for the analysis of equilibrium biosorption data. This model takes into account the energetically nonuniform surface of biosorbent, and the model parameters (q_{max}^{DR} and β) are obtained from the graphical representation of $\ln q_e$ versus ε^2. Using the value of β, the mean biosorption energy (E, kJ/mol) can be calculated using the following equation,

$$E = \frac{1}{\sqrt{2\beta}} . \qquad (25.4)$$

The mean energy of biosorption (E, kJ/mol) gives information about the biosorption mechanism. Therefore, if the biosorption process has a mean energy of biosorption in the range of 1−16 kJ/mol, then it indicates that the physical electrostatic interactions are potentially involved in the biosorption mechanism [25.32, 143]. Some values of the Dubinin–Raduskevich model parameters obtained for biosorption of heavy metal ions onto marine algae biomass are given in Table 25.9.

One of the main advantages of the Dubinin–Raduskevich model is that it is temperature dependent. If the biosorption data at different temperatures are graphical represented, all the suitable data shall in general lay on the same characteristic curve. This curve can be used to measure the applicability of the Dubinin–Raduskevich model in analysis of the biosorption equilibrium data, together with the value of correlation coefficient. When the fitting procedure gives high correlation coefficient, but the analyzed data does not lie in the same characteristic curve, the validity of calculated parameters is questionable. Anyway, the characteristic curve for a given biosorption systems cannot be examined if the experiments were performed for a single value of temperature [25.18].

The other isotherm models presented in Table 25.7, even commonly appearing in the biosorption literature, have a much lower applicability in the analysis of equilibrium experimental data. This is mainly determined by the fact that these models do not always reflect the physicochemical principles of the biosorption process, and in most of the cases, are not well understood. From the practical point of view, they are just mathematical models that describe the experimentally observed relation between amount of heavy metal retained on weight unit of biosorbent (q_e) and its equilibrium concentration from solution (c_e), without to offer information about biosorption mechanism, or taking into account the influence of the experimental parameters.

Most of biosorption studies of heavy metal ions by diverse kinds of biosorbents, including marine algae biomass, have been performed on the single metal uptake. In contrast to this ideal situation, the real wastewater commonly contain a mixture of metal ions, and therefore the modeling of multimetal biosorption systems is essential in the design of treatment systems. The biosorption of heavy metal ions in real systems that contain more than one component (multicomponent systems) involves the study of the biosorption equilibrium in conditions of competition between different types of heavy metal ions, and are required for better understanding of the system and for design purpose.

Only few isotherm models have been developed to describe the biosorption equilibrium in such systems. The most used multimetal biosorption models applied for the modeling of biosorption equilibrium are listed in Table 25.7. These models range from simple equations associated with the individual isotherm parameters (nonmodified biosorption models) to more complex models; exploiting the individual isotherm parameters along with correction factors (modified biosorption models) [25.144].

The most frequent use of multicomponent biosorption models is the multicomponent Langmuir model including its modification as well as multicomponent Freundlich models. *Lee* and *Chang* [25.60] have use the multicomponent Langmuir and Freundlich models to describe the simultaneous biosorption of Pb(II) and Cu(II) ions into two types of marine algae: *Spirogyra* sp. and *Cladophora* sp. They noticed that the co-ion

effect on the equilibrium uptake became more significant as the concentration of metal ions in solution is increased. In addition, they also showed that these two types of marine algae displayed stronger biosorption inhibition of Cu(II) compared to Pb(II), which can be explained by the higher affinity of Pb(II) ions toward the functional groups from marine algae biomass surface.

Other studies of binary biosorption of heavy metal ions on marine algae biomass were carried out by *Sing* et al. [25.146] and *Kleinubing* et al. [25.72]. *Sing* et al. [25.146] examined single and binary component biosorption of Pb(II) and Cu(II) from aqueous solution using *Spirogyra neglecta* green algae. Equilibrium uptake of Pb(II) and Cu(II) is improved by increment of its initial concentration up to 100 mg/l. In contrast, the presence of increasing concentration of other metal ions brought about the deterioration in equilibrium uptake value. Also, they observed that Pb(II) ions are more severely inhibited Cu(II) biosorption than vice versa; thus reflecting greater affinity of Pb(II) ions for the marine algae biomass.

The binary biosorption of Cu(II) and Ni(II) ions onto dried *Sargassum filipendula* algae was investigated by *Kleinubing* et al. [25.72]. Biosorption data in their binary systems showed that the retained amount of one metal ion declines as the concentration of the other competitive metal ion increases in the solution. The consequence is quite substantial for Ni(II) biosorption as the process is strong suppressed by the presence of higher Cu(II) ions in solution.

Nevertheless, the researches on co-ions biosorption models are only in their preliminary stage. How to use the mathematical models with multiparameters to describe the competitive biosorption of heavy metal ions from aqueous solution is a future direction of biosorption research [25.15]?

25.5.2 Kinetic Modeling of Biosorption

The studies of biosorption equilibriums are very important to determine the efficiency of biosorption systems in the removal processes of heavy metals from aqueous media. Besides this, it is also necessary to identify the biosorption mechanism type in a given systems, and this can be achieved by kinetic studies. The information obtained from kinetic studies is used in the design of adsorption systems because they provide valuable information about the biosorption mechanism and its potential rate-controlling step, as either mass transfer or chemical interactions, in order to obtain the optimum operating conditions for industrial-scale batch metal removal processes [25.147].

In batch systems, the kinetics of biosorption processes is described by a number of models based on biosorption equilibrium [25.16, 18, 112], which are used to fit the experimental results obtained for a given initial metal ion concentration, biosorbent dose, solution pH, temperature, and different values of contact time between biosorbent and metal ions from aqueous solution. These include the pseudo-first Lagregen model, pseudo-second order

Table 25.10 The mathematical expressions of the pseudo-first order Lagregen and pseudo-second order Ho kinetic models (after [25.16, 18, 112, 145])

Kinetic model	Differential equation	Integral equation	Significance of terms
Pseudo-first order Lagregen model	$\frac{dq_t}{dt} = k_1(q_e - q_t)$	$\ln(q_e - q_t) = \ln q_e - k_1 \cdot t$	q_e, q_t are the amounts of heavy metals retained on weight unit of biosorbent at equilibrium and at time t, (mg/g); k_1 is the rate constant of the pseudo-first order kinetics equation (min^{-1})
Pseudo-second order Ho model	$\frac{dq_t}{dt} = k_2(q_e - q_t)^2$	$\frac{t}{q_t} = \frac{1}{k_2 \cdot q_e^2} + \frac{t}{q_e}$	q_e, q_t are the amounts of heavy metals retained on weight unit of biosorbent at equilibrium and at time t, (mg/g); k_2 is the rate constant of pseudo-second order kinetics equation (g/mg min)

c_0 is the initial concentration of heavy metal ions; [a] marine green algae (*Ulva lactuca* sp.) waste biomass obtained after extraction of oils; [b] waste algae biomass obtained from agar extraction industry.

Ho model [25.145], Weber–Morrison kinetic model, Adam–Bohart–Thomas kinetic model [25.148], first-order reversible kinetic model [25.149], external mass transfer model [25.32], etc. The first-order Lagregen model and the pseudo-second order Ho model are the most frequently used kinetic models to study the

biosorption kinetics of heavy metal ions on marine algae biomass, and they are listed in Table 25.10.

A plot of $\ln(q_e - q_t)$ versus t should generate a straight line, according to the pseudo-first order Lagregen model, and the kinetic parameters can be calculated from the slope (k_1) and the intercept ($\ln q_e$). In the case of the pseudo-second order Ho model, the graphical representation of (t/q_t) versus t will give a straight line with the intercept of $1/k_2$, and slope of $1/q_e$. The calculated values of q_e, from both the kinetic models are then compared with that experimental values.

The shape of graphical dependences and comparison of experimental and calculated values of biosorption capacity at equilibrium (q_e) can help deciding which kinetic model is followed by the biosorption process. On the other hand, to obtain the best-fitting kinetic model, the linear regression is used to analyze the experimental data [25.145]. So, the value of the linear regression coefficient (R^2) is another factor that influences such decision. A value of $R^2 > 0.98$ shows that the model is suitable for describing the biosorption kinetics [25.150].

Table 25.11 summarizes the values of kinetic parameters of the pseudo-first and pseudo-second order kinetic models together with the corresponding correlation coefficients (R^2) for biosorption of some heavy metal ions on various types of marine algae and marine algae waste biomass.

It is clear that most of biosorption processes that use marine algae or marine algae waste biomass for the removal of heavy metal ions from aqueous solutions are very well described by the pseudo-second order kinetic model.

The pseudo-second order kinetic model is based on the assumption that the rate-controlling step in the adsorption process, are the chemical interactions between superficial functional groups of biosorbent and heavy metal ions from aqueous solution, and similar behaviors have been reported for various types of adsorbent materials [25.15, 16, 18]. The great advantage of this model is its great accuracy in describing the whole kinetic experimental data. In addition, the high values of rate constants (k_2, g/mg min) obtained in the case of these biosorbents (Table 25.11) indicate that the rate of the biosorption process is limited by the availability of heavy metal ions and functional groups from the biosorbent surface to interact. When the availability of the superficial functional groups is higher, the rate of adsorption process is also higher.

In the biosorption system where the possibility that the intraparticle diffusion to be the rate-controlling step, the intraparticle diffusion approach described by Weber and Morrison is used. The kinetic equation of the intraparticle diffusion model [25.151] is

$$q_t = k_{dif} \cdot t^{1/2} + c \qquad (25.5)$$

where: k_{dif} is the intraparticle diffusion rate constant (mg/g min$^{1/2}$), and c is the concentration of heavy metals from solution at equilibrium (mg/l).

If the intraparticle diffusion process is the rate-controlling step, the amount of heavy metal retained on weight unit of biosorbent (q_t, mg/g) varied with the square root time. The graphical representation of q_t versus $t^{1/2}$ dependences obtained in the case of Pb(II) and Cd(II) biosorption onto *Lobophora variegate* brown algae [25.133] or in the case of Pb(II), Cd(II), and Co(II) biosorption on green algae waste biomass (Fig. 25.11) does not go through origin, and two separated region exists, in all cases.

The deviation of the straight line from the origin indicates that the intraparticle diffusion process is not the only rate-controlling step [25.151, 152], and the boundary diffusion controls biosorption up to a certain degree, in all cases. The first region (Region 1) is attributed to the mass transfer of heavy metals from the bulk solution to biosorbent surface, while the second region (Region 2) indicates the intraparticle diffusion. The significant differences between these two regions is given by their slopes, when the first region has a pronounced slope, the slope of the second region is much lower. This indicates that the binding sites are located on biosorbent surface and are readily accessible for the heavy metal

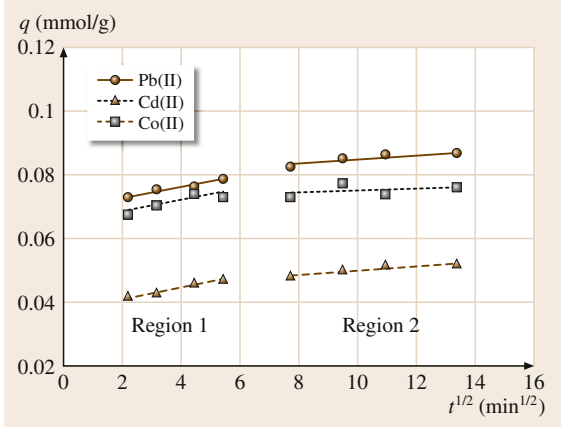

Fig. 25.11 Intraparticle diffusion kinetics for biosorption of Pb(II), Cd(II), and Co(II), respectively, onto green algae waste biomass, at a temperature of 20 °C (after [25.41])

ions, or at external intralayer surface. Hence, the experimental data suggest a limited contribution of mass transfer and boundary layer diffusion in the biosorption process of heavy metal ions, onto marine algae biomass, and that the intraparticle diffusion influenced the biosorption process up to a certain degree.

25.6 Modeling of Biosorption Process in Dynamic Continuous-Flow Conditions

The large-scale utilization of biosorption processes for the removal of heavy metal ions from aqueous environments requires the use of continuous systems, where the biosorbent (marine algae biomass) can be used in multiple biosorption–desorption cycles [25.64]. In addition, the heavy metal ions biosorption is more effective if it is carried out in a dynamic continuous-flow column, and these systems allow the treatment of very large volumes of wastewater and have lower operating cost [25.146]. The recording of the variation of heavy metal ions concentration of the effluent solution, as a function of the operating time of the column, or the volume of treated aqueous solution, gives usually a typical S-shaped breakthrough curve whose shape and slope is a result of the equilibrium biosorption isotherm relationship, the mass transfer to and throughout the biosorbent in the column, and operation macroscopic flow parameters.

Any optimized column system is based on the accurate prediction of the characteristic of the breakthrough curve under given specific operating conditions. When the heavy metal ions concentration in the effluent solution reaches a predefined level, the column operation is terminated. At this point, the regeneration process may begin before activation for the next cycle of operation. Therefore, successful design of a column biosorption process required prediction of breakthrough curves for the effluent, and for this purpose various mathematical models can be used [25.65, 153, 154].

The Bohart–Adams, Thomas, and Yoon–Nelson models have been frequently used for modeling of the metal ions biosorption process on various types of materials in continuous systems. These models are able to describe the breakthrough curves with accuracy in most of the cases, and at the same time, they provide important system parameters that can be used to predict the useful time of the column for the scale-up of the experiments.

The Bohart–Adams model is mainly used when the effluent concentration is lower than $0.35 \cdot c_0$ [25.155], so to describe the initial part of the breakthrough curve. This model assumed that the biosorption rate is proportional to the residual capacity of the solid and the concentration of the sorbent substances [25.156]. The mathematical expression of this model is as follows,

$$\ln \frac{c_t}{c_0} = k_{BA} \cdot c_0 \cdot t - k_{BA} \cdot N_0 \cdot \frac{H}{v} \tag{25.6}$$

where c_0 is the initial heavy metal ions concentration, c_t is the effluent heavy metal ions concentration at time t, k_{BA} is the kinetic constant of the Bohart–Adams model, N_0 is the saturation concentration of column, H is the bed height of column, and v is the linear velocity calculated by dividing the flow rate by the column section area.

The parameters k_{BA} and N_0 of the Bohart–Adams model can be estimated from the slope and intercept of $\ln c_t/c_0$ versus t dependence.

The Thomas model is one of the most general and widely used to describe the biosorption process in a packed-bed column [25.65, 156]. This model assumes that biosorption is not limited by the chemical interactions, but by the mass transfer at the interface [25.66, 69]. The linear expression of the Thomas model is

$$\ln\left(\frac{c_0}{c_t} - 1\right) = \frac{k_T \cdot q_0 \cdot m}{F} - \frac{k_T \cdot c_0}{F} \cdot V_{eff} \tag{25.7}$$

where k_T is the Thomas rate constant, m is the biomass packed in the column, F is the solution flow rate through the column, q_0 is the maximum concentration of solute in the solid phase, and V_{eff} is the effluent volume.

Most commonly, the Thomas model is applied to analyze the obtained data between breakthrough and saturation points of the experimental breakthrough curves, and the characteristic parameters (k_T and q_0) were determined from the slope and intercept of the linear plot $\ln(c_0/c_t - 1)$ versus V_{eff}.

The Yoon–Nelson model is based on the assumption that the rate of decrease in the probability of adsorption for each adsorbate molecule is proportional to the

probability sorbate and the probability of sorbate breakthrough on sorbent [25.156]. The linear equation of this model can be written as

$$\ln\left(\frac{c_t}{c_0 - c_t}\right) = k_{YN} \cdot t - \tau \cdot k_{YN} \qquad (25.8)$$

where k_{YN} is the Yoon–Nelson model rate constant and τ is the time required for 50% sorbate breakthrough.

The model parameters (k_{YN} and τ) can also be calculated from the slope and intercept of linear dependence $\ln(c_t/(c_0 - c_t))$ versus t.

Table 25.12 summarizes, for exemplification, the values of Bohart–Adams, Thomas, and Yoon–Nelson models parameters, obtained at the removal of Pb(II) ions by biosorption on various kinds of marine algae biomass.

The values of Bohart–Adams model parameters indicate that the saturation concentration of column (N_0) increases with the increase in initial metal ions concentration and decreases with increase in the solution flow rate. In addition, the kinetic constant (k_{BA}) decreases with increase in initial heavy metal ions concentration, but increases with the increase in the flow rate. Therefore, for better saturation concentration (N_0) and lower kinetic constant, which means minimum resistance of the column, the initial concentration of heavy metal ions should be higher, while the flow rate needs to be lower [25.42, 65].

The values of the Thomas model parameters obtained in the case of Pb(II) ions biosorption on various types of marine algae biomass (Table 25.12) indicate that the equilibrium biosorption capacity (q_0, mg/g) is higher at higher initial lead(II) concentrations and higher flow rates of metal solution through the column. Also, the Thomas kinetic constant (k_T) was generally higher at lower initial metal ions concentrations.

The Yoon–Nelson constant (k_{YN}) usually increases with increase in initial Pb(II) concentration and the solution flow rate. The greatest value of Yoon–Nelson constant when the initial Pb(II) concentration is higher could be related to the increase in the forces that control the mass transfer in the liquid phase [25.65]. The value of τ, which represent the time required for 50% breakthrough, decreases with the increasing in initial Pb(II) concentration and flow rate. It should be noted that in all cases these values are close to the values obtained from experimental breakthrough curves.

However, the most complete column model is the mass transfer model. This model take into account the dominant intraparticle mass transfer and was developed by *Tan* and *Spiner* [25.157] for the ion exchange processes. In principle, the mass transfer model can predict the breakthrough curves for most of chemical species that can be removed by the biosorbents, and even also for the elution curves obtained during the biosorbent regeneration [25.122]. Unfortunately, the mathematical methodology of this model is quite complex, and to solve it, some simplifications are necessary.

The use of different models to analyze the experimental breakthrough curves yields important informa-

tion from the biosorption process feasibility stand-point by providing the time intervals between the breakthroughs of the different marine algae biomass used as biosorbents, and the magnitude of the overshoots that inside the column translate as concentration extremes [25.4].

In the design of the biosorption process for the removal of heavy metal ions, the biosorption/desorption performances of marine algae biomass and some of these characteristic properties (such as mass transfer, chemical stability, etc.) should be well known. While batch-biosorption experiments yield some basic information, the possible applicability of biosorption systems at the industrial level should be tested under dynamic continuous-flow conditions. The performances assessment of biosorption systems and prediction based on both equilibrium as well as dynamic studies eventually leads to sizing of the equipment.

25.7 Mechanism of Biosorption

The influence of any of the experimental parameters on the efficiency of biosorption process can be quantitatively evaluates when the biosorption mechanism is known. The binding of heavy metal ions to the functional groups of marine algae biomass can be done by several types of elementary mechanisms, such as ion exchange, complexation, chelation adsorption, microprecipitation, etc. [25.24]. But, the biosorption processes are quite complex, and the overall metal uptake mechanisms are obtained by combination of different elementary mechanisms that take place at the same time.

As a generalization, the uptake of heavy metal ions from aqueous solution by biosorption on marine algae biomass can be done via two major mechanisms:

a) Ion exchange – when the heavy metal ions are binding by ionisable functional groups (such as carboxyl, hydroxyl, phosphate, sulfate, etc.) from marine algae biomass surface;
b) Complexation – in this case the metal ions from aqueous solution form complexes (even chelates) with functional groups of biosorbents, by electron pair interactions. The most likely electron donor atoms in marine algae biomass are nitrogen atoms, neutral oxygen, or sulfur atoms.

Even if, for the removal of heavy metal ions by biosorption on marine algae biomass, numerous types of marine algae and marine algae waste biomass were used as biosorbent in various experimental conditions; a little attention has been paid to investigation of the biosorption mechanism. The understanding of the metal uptake mechanisms can help to quantify the heavy metal ions – marine algae biomass interactions that are fundamental for the evaluation of potential implementation methodology.

The key factors that controll and characterized the biosorption mechanism are: (i) the type of functional groups present on the surface of biosorbent, (ii) chemical speciation of metal ions present in aqueous solution, and (iii) characteristics of heavy metal ions solution (such as pH, presence of other inert or competing ions, etc.) [25.158].

25.7.1 Ion Exchange

According to *Davis* et al. [25.30], the ion exchange is an important type of interactions which may occur in the biosorption process, and that can explain many of the observations made during the heavy metal ions uptake experiments. It should be noted that the ion exchange does not clearly identify the mechanism of heavy metal ions retention on marine algae biomass. This is because the ion exchange interactions may range from physical (such as electrostatic or van der Waals forces) to chemical (such as ionic or covalent), but they are useful in describing the experimental observations [25.4].

In the most general sense, the ion exchange mechanism assumes that the functional groups from the biosorbent surface can bind the heavy metal ions from aqueous solution, according to the reaction

$$R^- - X^+ + M^+ \leftrightarrows R^- - M^+ + X^+ \qquad (25.9)$$

where R^- is the binding site from the biosorbent surface, X^+ is a mobile cation (e.g., Na^+, K^+, Ca^{2+}, Mg^{2+}, etc.), and M^+ is the heavy metal ions present in aqueous solution.

However, a one-to-one stoichiometry is not complied with as typical two mobile ions are released upon the binding of one divalent heavy metal ion; the ion exchange approach is considered to be the most sim-

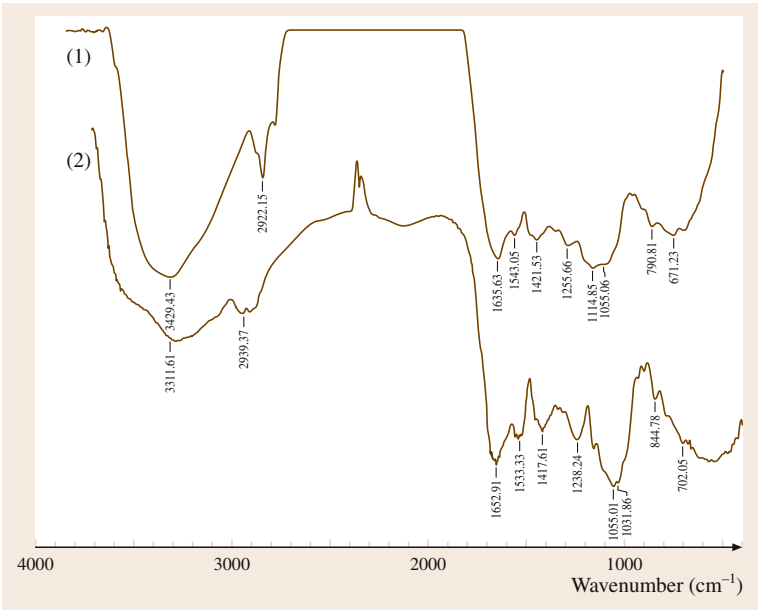

Fig. 25.12 FT-IR spectra dry Ulva lactuca marine algae before (1) and after (2) Cd(II) ions biosorption

ple but not very accurate to describe the biosorption mechanism [25.60].

The marine algae biomass can be considered as a natural complex material that contains various functional groups, with weakly acid and basic character. These functional groups can be ionized in aqueous solution, at a certain value of pH, and can bind the heavy metal ions from aqueous solution, mainly by electrostatic interactions. In this case, it is observed that: (i) the biosorption efficiency is strongly influenced by the solution pH, and (ii) in the FT-IR spectra recorded for the marine algae biomass before and after retention of considered heavy metal ions, no supplementary bands appear. In most of the cases are observed only some shifted of the maximum absorption wave number, corresponding to the functional groups involved in the uptake process.

For exemplification, Fig. 25.12 illustrates the FT-IR spectra of *Ulva lactuca* marine green algae before and after retention of Cd(II) ions from aqueous solution. The change in the wave number of some absorption bands suggests that several functional groups (such as amino, C=O, and C−O) are involved in the biosorption process of Cd(II) ions [25.88].

On the other hand, it is known that marine algae biomass generally contains alkali and alkaline earth metal ions (such as Na^+, K^+, Ca^{2+}, and Mg^{2+}), that are abundant in the seawater. Thus, untreated algae biomass can retain heavy metal ions from aqueous solution, and release these mobile cations. In this case, the solution pH varies very little during the biosorption process, but a significant increase in the concentration of these ions is observed. Thus, *Kuyucak* and *Volesky* [25.159] have reported an enhancement release of Ca^{2+} ions from the *Ascophyllum nodosum* brown algae when is in contact with a cobalt aqueous solution, rather than cobalt-free solution. In addition, when this marine alga was treated with $CaCl_2$ and HCl, a 2 : 3 stoichiometric relationship between Co^{2+} uptake and Ca^{2+} release was observed [25.60]. This means that the alkali and alkaline earth metal ions play a key role in the ion exchange properties of the marine algae biomass, regardless the nature of metal ion from aqueous solution to be retained.

The importance of the ion exchange mechanism in the biosorption process of heavy metal ions on marine algae biomass has been demonstrated by various studies from the literature, performed both in batch- and dynamic continuous-flow conditions [25.4, 17, 26, 28, 30, 35]. However, it has been suggested by many researchers that ion exchange is neither the sole nor the main mechanism for heavy metal ions biosorption on marine algae biomass [25.158]. The ion exchange mechanism is very fast and predominant at low concentration of heavy metal ions in aqueous solution, while at higher concentration the binding of heavy metal ions can occurs and by complexation.

Table 25.13 pH value for the maximum biosorption of some heavy metal ions on brown marine algae biomass (after [25.161–163])

Heavy metal ion	Brown algae biomass	pH	Biosorption capacity (mg/g)
Cd(II)	*Ascophyllum nodosum*	4.9	214.68
	Sargassum natans	3.5	131.51
	Fucus vesiculosus	3.5	73.06
Cu(II)	*Sargassum vulgare*	4.5	59.05
	Sargassum filipendula	4.5	56.52
	Fucus vesiculosus	4.5	74.93
Pb(II)	*Ascophyllum nodosum*	3.5	271.43
	Sargassum natans	3.5	253.15
	Fucus vesiculosus	3.5	229.91
Zn(II)	*Sargassum fluitans*	4.5	77.17
	Fucus vesiculoses	4.5	52.32

25.7.2 Complexation

Complexation is another possible mechanism that plays an important role in the biosorption processes of heavy metal ions, from aqueous environments [25.60]. In general, the complex formation of heavy metal ions with functional groups from marine algae biomass involves the presence of an atom or atoms having lone pair electrons to donate (such as RNH_2). The complexes are formed by electrostatic or covalent interactions, and can be neutral, positively, or negatively charged, and may have different coordination numbers (most common coordination number ares 4 and 6) [25.24]. When one functional group interact with the heavy metal ions through two ore more coordination atoms, the formed complex is called chelate, and its formation process is named chelatization.

To explain the formation of the complexes between heavy metal ions from aqueous solution and functional groups from marine algae biomass surface, the acid–base (Pearson) classification is used. According to this classification, the hard acids (metal ions such as Na^+, K^+, Ca^{2+}, Mg^{2+}, etc.) will bind preferentially to the oxygen containing functional groups, such as HO^-, HPO_4^{2-}, $R\text{-}COO^-$, C=O, etc. On the other hand, the soft acids (most of heavy metal ions) are bonded covalently to the functional groups that contain nitrogen and sulfur donor atoms, named soft bases [25.160].

The marine algae biomass surface can be considered a heterogeneous ligand, which contains various functional groups. The binding of different heavy metal ions on such biosorbent depends on ionic properties, such as electronegativity, ionization, redox potential, and ionic radius of these metals. Thus, the more electronegative heavy metal ion will be, the more strongly is attracted to the surface, and the formed complex is more stable. In this case, it is observed that: (i) the biosorption process occur with maximum efficiency at a given pH value of aqueous solution, where the complex formed between metal ions and functional groups of biomass has higher stability (Table 25.13), and (ii) some changes in the characteristics of biomass surface can appear, visible by the microscopic technique.

The importance of complexation interactions in the biosorption processes of heavy metal ions from aqueous solutions have been evidenced; especially in the case of brown algae biomass. Thus, *Davis* et al. [25.30] review some studies from the literature and concluded that some of heavy metal ions, such as Pb(II), Cu(II), Cd(II), Co(II), Ni(II), Mn(II), etc. are covalent bonded on brown algae biomass, and in these interactions the functional groups from alginic acid are predominant involved. This preferential binding of heavy metal ions to the functional groups of alginic acid is mainly due to the stereochemical effects, since larger ions might better fit a binding site with two distant functional groups. This hypothesis has been experimentally proved by X-ray diffraction and NMR spectroscopic analysis. Also, in the study of *Tsezos* et al. [25.158] it has been shown that the complexation interactions have an important role in biosorption of precious metals on brown algae biomass. The biosorption mechanisms in this case, involve two steps: first the precious metal ions are covalent bonded on functional groups of marine algae biomass, and then the in-situ reduction of these occurs.

Nevertheless, the complexation interactions have been evidenced as elementary interactions in many biosorption processes on various types of marine algae biomass; especially at high initial concentration of heavy metal ions.

25.8 Final Remarks

Biosorption can be successfully used for the removal of heavy metal ions from aqueous environments. The major advantages of this method over the conventional treatment methods include:

- Economic viability
- High efficiency of heavy metal removal from dilute solutions
- Minimization of chemical and/or biological waste
- Easy regeneration of biosorbents
- Possibility of heavy metal ions recovery.

The marine algae are available in large quantities in many regions of the world, being a kind a promising biological resources, and their utilization as biosorbents in biosorption processes are mainly due to: (i) the variety of functional groups from the biosorbent surface, (ii) relatively small and uniform distribution of binding sites on biosorbent surface, and (iii) the preference of alkali and alkali-earth metal ions for the binding sites is less than in the case of ion exchange resins. In addition, the wastes obtained after extraction from marine algae of different compounds, can also be used as biosorbents, because their biosorptive characteristics are not very much changed.

In the design of the biosorption process for the removal of heavy metal ions, the biosorption/desorption performances of marine algae biomass and some of their essential characteristic (such as mass transfer, chemical stability, etc.) should be well known. Thus, the experiments must be started in batch conditions, when some basic information is obtained, and then the possible applicability of biosorption systems at large level should be tested under dynamic continuous-flow conditions. The performances assessment of biosorption systems and prediction based on both equilibrium as well as dynamic studies eventually leads to sizing of the equipment.

In the future development of the biosorption processes for the removal of heavy metal ions from aqueous environments, two trends can be mentioned, according to the studies from the literature. The first one concern to the use of hybrid technologies, where the biosorption processes will be a step in the overall removal process of heavy metal ions from aqueous environment. This trend is mainly determined by the difficulties existing in the utilization of biosorption processes, that made to be considered the applying the hybrid technologies to treat industrial wastewater. Unfortunately, until now no one variant was found to be economical viable. The second trend is to develop good commercial biosorbents derived from marine algae biomass, just like a kind of ion exchange resins that can be easily sale in the market. The failure of the marine algae biomass commercialization as biosorbents is mainly due to nontechnical barriers involved in commercialization of technological innovations. For implementation of innovative processes, a solid capitalization is always required, and this makes that choice of partners to be critical.

However, the utilization of biosorption processes along with other conventional methods (including chemical precipitation, flotation, membrane-related processes, electrochemical techniques, etc.) may also be helpful in the treating of industrial effluents at large scale, even for the simultaneous removal of organic substances and heavy metal ions from aqueous environments.

26. Biotechnological Potential of Marine Microbes

Gian M. Luna

The world's oceans, from the coasts to the abysses, harbor an incredible level of microbial diversity. This marine microbial biosphere is an enormous, untapped resource of biotechnological interest. This chapter reviews the potential of marine microbes in biotechnology. The biotechnological potential is considerable, ranging from the synthesis of bioactive molecules to the production of biofuels, cosmeceuticals, nutraceuticals, and biopolymers; from the engineering of marine microbes for biomedical purposes to the degradation of pollutants, and the use of microbial biosensors as sentinels for environmental quality. Marine viruses have great biotechnological potential, yet the exploration of the marine virome, and the associated gene and protein pool, is only beginning. Marine archaea have so far been exploited for the isolation of enzymes, yet many biotechnological exploitations can be foreseen. Bacteria and microbial eukaryotes, especially fungi and photosynthetic protists, provide an important contribution to biotechnology; the combination of *omics-driven* technologies and improved cultivation techniques is widening the knowledge on their biological diversity, paving the way for new biotechnological exploitations. The exploration of the marine microbial biosphere, and its extraordinary genetic and physiological diversity, will undoubtedly continue to offer chances for the development of new and sustainable blue biotechnologies, helping to solve important societal challenges of the twenty-first century.

26.1 Microbial Diversity in the World's Oceans and Biotechnological Applications of Marine Microbes

The world's oceans are the largest ecosystem on Earth. Life in global oceans is dominated by unicellular microbes, accounting for the largest fraction of biomass and biodiversity [26.1]. Although microbes play a fundamental role in the productivity, ecosystem functioning, and global biogeochemical cycles of the major elements [26.2], we still know little about marine microbial diversity, the patterns and driving forces, the genetic and metabolic repertoire, and the ecological role each microbial species plays in the ecosystem [26.3]. Little is known about the functions of marine microbes in the ecosystem and their metabolic capabilities because of the current inability to assign any function to a large proportion of their genes [26.4]. The vast majority of marine microorganisms cannot be cultured in the laboratory under standard laboratory conditions [26.5, 6]. It was only the development of molecular methods that made it possible to identify marine microbes [26.7–9], but scientists are merely beginning to gain a comprehensive understanding of the full extent of microbial biodiversity and functions in the world's oceans [26.10].

In the United Nations Convention on Biological Diversity, biotechnology was defined as [26.11]:

> *any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use.*

There is, however, no agreed upon definition of biotechnology, and definitions may range from *the uses of biology for the benefit of man* to *the use of biology to make money* [26.12]. Biotechnology is nowadays experiencing an increasing importance at the planetary scale, and is expected to increasingly contribute in addressing important socio-economic issues of our societies. The term *blue biotechnology* is typically utilized to describe the aquatic, either marine or freshwater, applications of biotechnology [26.4].

Marine organisms can be utilized as biotechnological agents to provide products and services that have useful applications for humans and their well-being. Among these, there are new medical technologies, food and feed ingredients (e.g., nutraceuticals), molecules useful in many industrial sectors, and biofuels [26.13]. Marine biotechnology has the potential to contribute significantly to key societal challenges, such as the sustainable supply of healthy and high-quality food, the production of bioenergy (such as biofuel production from many microalgae), the discovery and exploitation of pharmaceuticals or diagnostic tools for improving human health, the isolation of biopolymers useful in the cosmetic, food and health industries, and the synthesis of enzymes, proteins, or biomaterials of interest in several industrial processes. Marine bioresources (organisms and molecules) can be helpful in increasing stock production in aquaculture processes, in controlling infectious diseases of farmed organisms, as well as in addressing key environmental issues such as marine pollution (e.g., by the development of biosensing technologies for environmental monitoring, the use of microbes for degradation of pollutants, or the identification of natural antifouling technologies).

This chapter reviews the potential of marine microbes in biotechnology. Marine microbes include representatives from three domains of life: archaea, bacteria and eukarya [26.14]. Bacteria and archaea are the most abundant cells in all known marine ecosystems. Microbial eukaryotes, among which unicellular microbes (protists) and fungi (including either unicellular or multicellular forms), are ecologically important members of marine microbiota, and many studies are documenting their once-unimaginable diversity [26.15, 16]. This review also covers the biotechnological potential of marine viruses. Viruses do not have an organized cell structure, but represent the most abundant biological entities in the oceans. Phages are believed to be the most diverse biotic component in marine systems, and they are potentially interesting resources for biotechnology.

26.2 Why Do Marine Microbes Matter in Biotechnology?

In the twentieth century, research on marine natural products mainly involved the collection of macroorganisms from the sea, their extraction, and the analysis of the extracts [26.17]. Most frequently, algae and marine invertebrates were investigated. Several molecules with biological activity were isolated, and most of them were typically obtained from corals, sponges, or other invertebrates. The first marine bioactive compounds, spongouridine and spongothymidine, were isolated from the sponge *Cryptotheca crypta* in the Caribbean [26.17]. In the following decades scientists proved that these compounds had anticancer and antiviral activities ([26.18] and references therein). These nucleosides were the basis for the synthesis of Ara-C, the first anticancer agent derived from a marine organism, which is currently used in the treatment of patients affected by leukemia and lymphoma, and the antiviral drug Ara-A [26.19]. An overwhelming number of bioactive compounds of marine origin have subsequently been isolated and described, and more than 15 000 marine products have been described so far [26.20]. Recent estimates report some 20 000 marine high-value-added compounds, including a range of proteins, carbohydrates, and lipids [26.4, 21]. There are many examples in the marine pharmacology literature of antitumor and cytotoxic compounds isolated by marine animals (tunicates, nudibranchs, sponges, octocorals, bryozoans), algae, fungi, and bacteria [26.22]. Some of these substances have created new and exciting means for disrupting tumor specific cell signaling, cell division, energy metabolism, or gene expression, and have the potential to revolutionize cancer treat-

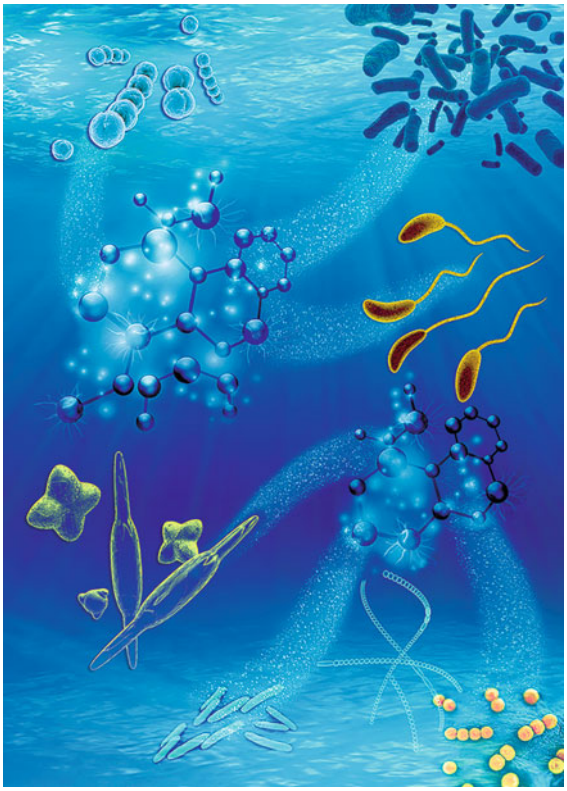

Fig. 26.1 Marine microbes are a source of bioactive molecules and secondary metabolites, many of which offer potential biotechnological opportunities. Photo courtesy of Marta Scandali (Ancona, Italy)

ment [26.22, 23]. Marine organisms can be important sources of useful molecules for treating infectious diseases, such as HIV-AIDS (HIV: human immunodeficiency virus; AIDS: Aquired Immuno Deficiency Snydrom; [26.22] and references therein). However, the application of many substances from marine macroorganisms has been hampered by difficulties regarding their reproduction and scaling up, or problems of supplying sufficient amounts of the pure substance [26.17]. Efforts in trying to cultivate marine macroorganisms, such as in the case of sponges, have been difficult [26.24], despite recent advances in the ability to cultivate organisms, cells, or their microbial symbionts [26.25]. Therefore, although a large number of marine natural products isolated from macroorganisms has been described from marine biota, only a few of them have so far entered preclinical or clinical trials [26.17].

The marine environment is incredibly heterogeneous, being characterized by a wide variability in the main physical and chemical variables. Temperature can range from values close to (or below) 0 °C to up to 370 °C in hydrothermal vents [26.26]. Salinity is typically more uniform across the ocean, but can vary significantly in specific areas, such as coastal transitional environments and estuaries, or reach nearly saturating concentrations in hypersaline environments, such as in the deep-hypersaline anoxic basins in the Mediterranean Sea [26.27]. The seabed, historically considered to be a flat, uniform, and biologically inert territory, where hydrostatic pressure can reach values up to 1100 bar, and light is typically absent, is now known to include a wide variety of habitats [26.28]. Despite these apparently inhospitable conditions for supporting life, the seafloor has been recognized as the largest biome on Earth, and hosts a significant proportion of global biomass and biodiversity.

Marine organisms, including microbes, have evolved to occupy a broad range of ecological niches, and their adaptation across the evolutionary time scale has originated an enormous array of physiological, genetic, and metabolic diversity. The marine biosphere, and particularly its microbial component, is an immense source of biodiversity, of bioactive compounds and secondary metabolites with potential applications in biotechnology (Fig. 26.1). Marine microbes have evolved specific adaptations to survive under different environmental challenges, resulting in different survival mechanisms, growth strategies, and genetic adaptations [26.29]. Some examples have been described recently. The photosynthetic pelagic bacterium *Prochlorococcus marinus* has adopted a minimalist approach and has reduced the size of its genome size, to gain a competitive advantage, given that conditions within its environmental niche vary only a little [26.29, 30]. *Pelagibacter ubique*, a marine α-proteobacterium, has no transposons, extrachromosomal elements, pseudogenes, or introns, and its genome, consisting of less than 1400 genes, is the smallest described for a free-living microbe [26.31].

The ability of marine microbes to adapt to changes in environmental conditions and to thrive under extremes conditions, coupled with their high genetic plasticity, have influenced their prowess to produce compounds and secondary metabolites. The marine microbial biosphere represents an important opportunity for bioprospecting, but the exploration of the potential of marine microbes in terms of the exploitation of molecules is still at an early stage [26.4]. As opposed to macroorganisms, which need to be collected from the sea for sufficient amounts of the searched metabolite to be extracted, marine microbes can be cultivated in the

laboratory in large quantities [26.17, 32]. Therefore, microbial blue biotechnology has the advantage of being a more sustainable activity, by avoiding the collection of marine organisms from their habitat.

26.3 Biotechnology of Marine Microbes, from Viruses to Microbial Eukaryotes

26.3.1 Marine Viruses

Viruses are ubiquitous biotic components of pelagic and benthic ecosystems. They influence lateral gene transfer, genetic diversity, and bacterial mortality [26.33, 34]. Marine viruses were not studied until 1989, but are now recognized as the most abundant biological entities in the sea (typically 10^7 viruses ml^{-1}; [26.35]. Phage diversity studies were initially restricted by the requirement for cultivated hosts, but recent applications of culture-independent techniques have revealed an enormous, and unexpected, viral diversity in marine ecosystems [26.35, 36]. Archaeal, bacterial, and eukaryotic viruses are cosmopolitan and abundant throughout the world's oceans [26.37]. Their host range covers all known marine organisms, from prokaryotes to fishes and mammals. Phages are particularly abundant in marine sediments, and viral infection represents a substantial source of mortality in deep-sea benthic ecosystems [26.38]. Many lines of evidence have suggested that phage diversity is virtually immense, but studies describing marine phage diversity are nowadays limited [26.39].

The genetic pool of marine viruses has enormous potential for biotechnology, but the use of marine viruses as biotechnological agents is still at an early stage. One potential application can be in medicine, to provide new solutions to sanitary problems for humans or other organisms. Potential applications of viruses in biomedicine, some of them already explored, include the use of viral vectors (gene transfer, gene therapy and vaccine development) and the use of viruses for protein expression and oncolytic viruses (e.g., virotherapy for treating tumors). There are currently no studies involving marine viruses but, given the magnitude of the diversity of marine phages, potential biotechnological exploitations can be expected.

Phages were used in early forms of biotechnology to control bacterial infections [26.33, 40]. Phage therapy was abandoned due to contrasting results and the discovery of antibiotics. It is, however, currently the subject of revived interest because of the emergence of antibiotic-resistance as either a biomedical and environmental problem. Some authors have explored the biotechnological usefulness of marine viruses as agents for curing coral diseases. The rapid emergence of infectious diseases in tropical stony corals is causing serious damage to coral reef ecosystems [26.41]. *Efrony* et al. [26.42] recently isolated two phages of known coral bacterial pathogens (*Vibrio coralliilyticus* and *Thalassomonas loyana*) and used them in controlled aquarium experiments to explore their utility in coral *phage therapy*. The results showed that diseases could be successfully controlled by the use of pathogen-specific phages, suggesting the possible usefulness of phage therapy. *Cohen* et al. [26.43] and other authors recently confirmed the potential application of marine viruses in the treatment of coral diseases. Other potential biotechnological applications of marine viruses are in the control of harmful algal blooms. *Onji* et al. [26.44] reported on the isolation of two virus-like agents that are able to suppress the growth of *Gymnodinium mikimoto*, a red-tide-forming marine dinoflagellate.

The exploration of the diversity of the marine virome has just begun. The discovery of novel genes and proteins with unknown functions, with potential biotechnological applications, can be expected, and deserves further in-depth investigations.

26.3.2 Marine Archaea

Archaea are evolutionarily unique prokaryotes, as genetically distant from bacteria as they are from eucarya [26.14]. They were historically assumed to live only in *extremophilic* habitats, but two decades of studies have revealed that they are abundant, widespread, and ecologically important members of the marine biota [26.45, 46]. The discovery of archaea was a significant breakthrough in the history of biology, leading to the replacement of the prokaryote/eukaryote dichotomy by a trinity of domains, the archaea, bacteria and eukarya [26.47].

Marine archaea are an interesting source for biotechnology, however only few fields of biotechnological exploitations have so far been successfully

investigated. One was the isolation of enzymes from some hyperthermophilic archaea. The vent polymerase was isolated from the marine archaeon *Thermococcus litoralis*, and is currently marketed as a useful alternative to the widely used *Taq* deoxyribonucleic acid (Taq DNA: a thermostable DNA polymerase named after the thermophilic bacterium *Thermus aquaticus*; Pfu DNA: a thermostable DNA polymerase named after the thermophilic bacterium *Pyrococcus furiosus*) polymerase. The *Pfu* DNA polymerase, isolated by the hyperthermophilic archaeon *Pyrococcus furiosus*, is commercially available and possesses a higher fidelity compared with other conventional Taq DNA polymerases [26.48]. Research into high-fidelity enzymes from marine archaea is still ongoing and is continuously yielding new findings [26.49].

Marine archaea have been also exploited in several industrial sectors. A heat and acid stable α-amylase, Valley Ultra-Thin, discovered from a deep-sea hydrothermal vent archaeon, has been developed to facilitate the processing of corn into ethanol [26.17]. Marine archaea can be important producers of biopolymers and bioplastics, such as PHA (polyhydroxyalkanoate), and a source of new secondary metabolites [26.17]. Recent studies have pointed out the importance of aquatic archaea as useful agents for hydrocarbon biodegradation and decontamination of polluted areas [26.50], indicating a potential, underexploited opportunity for biotechnological investigations.

26.3.3 Marine Bacteria

Bacteria are typically the most abundant and diverse members of the microbial biota in pelagic and benthic ecosystems. They typically outnumber archaea, despite exceptions in certain habitats [26.51, 52] and are the key players in biogeochemical processes and the fluxes of energy and matter in the ocean. Many bacterial species are distributed across marine ecosystems worldwide. *Candidatus Pelagibacter ubique*, a marine bacterium, is recognized as being one of the most abundant organisms on Earth [26.31].

Marine bacteria have been largely exploited for several biotechnological applications. Most of the marine bioactive compounds that have been successfully screened originate from bacteria [26.4]. Marine bacteria, especially actinomycetes, are important producers of antimicrobial secondary metabolites and antibiotics (see [26.32] for a review). Marine actinomycetes produce different types of secondary metabolites, a large fraction of which possess biological activities and have the potential to be developed as therapeutic agents [26.53]. Many other marine bacteria display significant antibacterial activity [26.54], and they are believed as an exciting resource for discovering new classes of therapeutics within the areas of oncology and infectious diseases [26.55]. Marine cyanobacteria also produce bioactive and cytotoxic molecules that are useful as drugs [26.56, 57].

Unique biosynthetic enzymes from marine bacteria have begun to emerge as powerful biocatalysts in medicinal chemistry and total synthesis [26.58]. Marine bacteria are important producers of biopolymers and biodegradable plastics [26.59], pigments (including melanin, which is potentially exploitable for sunscreens, dyes, and coloring), cohesive molecules that are useful as marine cements, and extracellular substances that are useful as surfactants ([26.22] and references therein).

The surface of many marine macroorganisms such as, to mention only a few, sponges [26.60], algae [26.61], tropical stony corals [26.62, 63], cold-water corals [26.64], hydroids [26.65], crabs [26.66, 67], and fishes, is a particularly interesting niche to study marine bacteria and other microorganisms with respect to biotechnology. The surface of virtually all marine macroorganisms hosts abundant and diverse communities of microbes [26.68]. For instance, the tissue of stony corals typically harbors an associated and diversified microbial community (Fig. 26.2), consisting of archaea, bacteria, and eukaryotes [26.69, 70]. Similarly, marine sponges typically contain diverse and abundant microbial communities, made up of bacteria, archaea, microalgae, and fungi, which comprise up to 40% of the sponge volume and contribute significantly to the host metabolism [26.60]. Microbial associates are believed to have several functions for the sponge, such as stabilization of the sponge skeleton, nutrient uptake, processing of metabolic waste, and secondary metabolite production. An increasing number of studies is documenting the existence of close associations between prokaryotes and higher eukaryotic organisms, typically forming mutualistic or symbiotic relationships [26.17]. Chemically-driven interactions are thought to be important in the establishment of relationships between epibiotic microorganisms and their eukaryotic hosts. For instance, soft-bodied marine organisms lack obvious structural defense mechanisms and rely on chemical defense, by production of bioactive compounds (either by themselves or the associated microflora), to survive [26.71]. Marine invertebrates are a rich source of bioactive metabolites, yet recent stud-

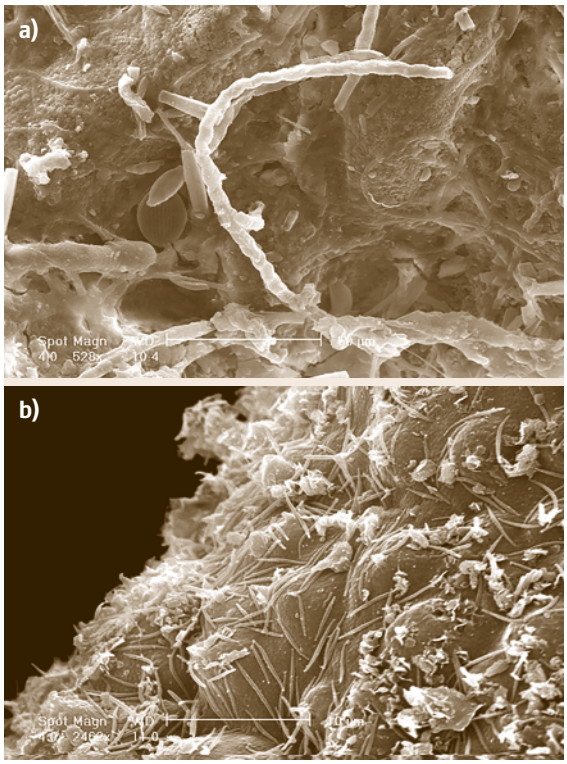

Fig. 26.2a,b Scanning electron microscopy (SEM) images of **(a)** the surface of the stony coral *Merulina ampliata* and **(b)** the colonial hydroid *Ectopleura crocea*. The surfaces of marine macroorganisms are typically hotspots of microbial diversity, and host a myriad of prokaryotic and eukaryotic microbes with interesting, underexplored biotechnological potentialities. Photo in b) courtesy of Dr. Cristina Gioia Di Camillo (Polytechnic University of Marche, Italy)

ies have shown that some bioactive compounds that were previously ascribed to the host are produced by the microbial symbionts [26.72]. Epibiotic microbes can produce a plethora of bioactive compounds, including antibiotics, antiviral, antitumor, and biopolymers. The investigation of the epibiotic microbial communities clearly deserves further study. Similarly, the study of other underexplored niches, such as the intestines of marine organisms [26.73, 74], is expected to provide important contributions to biotechnological developments.

Marine bacteria have enormous potential applications as biotechnological agents to remediate pollution in marine systems. These applications can range from the use of hydrocarbon-degrading bacteria for oil degradation [26.75–77] to the biosynthesis of surfactant and emulsifier molecules to be used in industrial processes, for environmental remediation or as drugs [26.78]. Hydrocarbon contamination is an important environmental issue, especially in coastal areas subjected to high anthropogenic input. Hydrocarbons, and similarly other pollutants such as pesticides, toxic metals, or herbicides, reach the marine environment from a wide variety of anthropogenic sources, including oil spills, urban runoff, shipping, and industrial activities. Hydrocarbons typically accumulate in the sediments, posing serious concerns for both the environment and human health. The success of petroleum bioremediation strategies relies on the ability to provide the optimal conditions to stimulate metabolism of those bacteria that are able to degrade hydrocarbons. Autochthonous bacterial communities can be used in the bioremediation of contaminated sediments, by stimulating their degradation processes with the addition of adequate substrates [26.77].

The aquaculture industry can also benefit from several biotechnological applications deriving from marine bacteria. They can contribute as probiotics, producers of functional foods and additives to increase biomass yields, to fight potentially pathogenic bacteria and to manage infectious diseases, or may serve as biodegraders of aquaculture wastes and organic pollutants [26.79]. Exploring the potential of marine bacteria and their metabolites will help in transforming aquaculture into a more sustainable and efficient industry.

26.3.4 Marine Microbial Eukaryotes

Protists (including photosynthetic protists or microalgae) and fungi are abundant and ecologically relevant members of marine microbial biota. A plethora of studies have documented their functional role, and recent studies are documenting their under-recognized genetic diversity and the spatial distribution across the ocean [26.80, 81].

Marine fungi form a taxonomically heterogeneous group, including *obligate* marine fungi (those able to grow and sporulate exclusively in seawater) and *facultative* marine fungi, which have a freshwater or terrestrial origin but can grow and sporulate in marine ecosystems [26.82]. There are currently about 800 described species of obligate marine fungi, mostly belonging to ascomycetes, anamorphs, and a few basidiomycetes [26.82]. Many fungi, such as thraustochytrids, play an important ecological and biogeochemical role in marine ecosystems, and mediate the

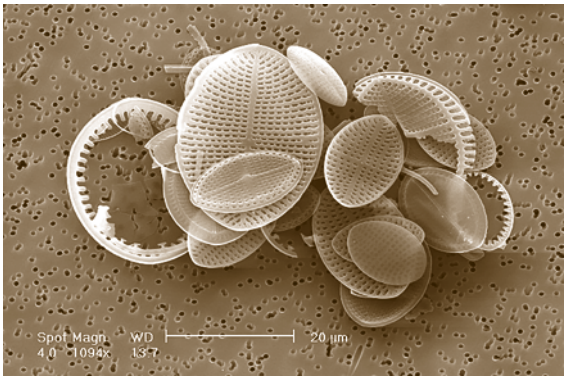

Fig. 26.3 SEM image of benthic diatoms (*Cocconeis* spp.). Marine microalgae can be important targets for biotechnology, especially for biofuel production. Photo courtesy of Dr. Chiara Pennesi (Polytechnic University of Marche, Italy)

degradation of organic matter by the production of extracellular degradative enzymes [26.83]. Historically, fungi have been believed to be rare in marine environments, but recent studies, based on molecular and metagenomics approaches, are revealing an unexpected diversity of fungal communities in coastal and deep-sea ecosystems [26.84, 85]. Recent authors reported on the discovery of 36 novel marine lineages of marine fungi [26.85]. Marine fungal biotechnology, or *blue mycotechnology*, is consequently an exciting and promising area of investigation [26.86]. The number of bioactive compounds isolated from marine fungi is increasing [26.32]. Marine fungi produce a plethora of compounds, among which are anticancer, antibiotic, antiangiogenesis, and antiviral compounds, and molecules having antiproliferative activity [26.87]. Deep-sea fungi have been less described in terms of their abundance, diversity, and ecological role, but are potentially important and productive sources of bioactive products. *Li* et al. [26.88] reported about the isolation of *Phialocephala* sp. in deep-sea sediments, which synthesizes new sorbicillin trimers with cytotoxic properties. *Damare* et al. [26.89] isolated barotolerant fungi in deep-sea sediments, and reported that some of them produce proteases active at low temperatures, with biotechnological potential for waste digestion, food processing, detergents for washing at cold temperatures, and preservation. Marine fungi may also serve as useful pollutant degraders [26.90].

Microalgae have an important biotechnological potential. Microalgal biotechnology is currently based on the production and synthesis of food and feed, additives, cosmetics, pigments (carotenoids), and biofuel [26.91]. They are used as additives in products for human consumption (to enrich the protein content or the nutritional value in food) or as live feed in the aquaculture industry for a variety of farmed organisms. Marine microalgae are important producers of bioactive compounds [26.92], which are useful as pharmaceuticals and cosmetics. An noteworthy line of biotechnological exploitation of microalgae is their use for the production of biofuels [26.93]. Combined with their fast growth rate, microalgae are considered one of the few realistic sources for the production of biofuels and as being superior to agricultural crop-derived bioethanol [26.94]. Many microalgae, such as diatoms and dinoflagellates [26.95] naturally accumulate large amounts of hydrophobic compounds, which can exceed 80% of the algal dry weight. Diatoms are among the most productive and environmentally flexible eukaryotic microalgae on the planet (Fig. 26.3). They are responsible for 20% of global carbon fixation by primary production [26.96, 97] and have several characteristics that make them useful for large-scale biofuel cultivation [26.98]. There has been substantial progress in the development of algal biofuels in the last decade, but more fundamental research is needed to better understand their physiology and metabolism and to develop efficient large-scale culture systems to grow algae and produce biofuel [26.99]. The biotechnological potential of diatoms and other marine microalgae also cover the production of pharmaceuticals, health foods, biomolecules, materials relevant to nanotechnology, and their use as bioremediators of contaminated waters [26.100]. The dinoflagellate *Karlodinium veneficum* synthesizes karlotoxins, a group of potent toxins that cause membrane permeabilization, having possible opportunities to construct new molecules to fight tumors and other human pathologies [26.101, 102].

26.4 Conclusions and Future Perspectives

Oceans are an enormous, untapped and sustainable source of biotechnological opportunities, yet are unexplored for the most part. Marine microbial diversity is almost unlimited, and offers a huge potential for biotechnological exploitations. Marine microbes may pose solutions to a variety of issues relevant for humans,

by favoring the discovery of more efficacious drugs, the production of biofuel from sustainable sources, the isolation of enzymes that are useful for the industry, the synthesis of biopolymers and biodegradable plastics, the remediation of environmental pollution, and the development of a sustainable aquaculture. The combination of improved cultivation techniques with new culture-independent, *omics-driven* approaches (such as metagenomics, metatranscriptomics, metaproteomics, and metabolomics) will multiply the possibilities of successfully exploring the biotechnological potential of marine microbes, with the hope of solving important societal challenges of the twenty-first century.

27. Marine Actinomycetes in Biodiscovery

D. İpek Kurtböke, Tanja Grkovic, Ronald J. Quinn

Marine natural products will be the driving force for interdisciplinary advancements bridging medicine, chemistry, and biology for sustainable future biotechnological advancements. Recent advances in sequencing technology and bioinformatics have revealed that actinomycete genomes encode far more secondary metabolite gene clusters than originally thought. The development of new culturing techniques from marine environments has enabled the isolation of previously uncultured actinomycetes resulting in the identification of new bioactive compounds deriving from these bacteria, including species-specific bioactive compounds. Advances in genomic technologies have renewed interest in marine actinomycetes as an attractive source of new therapeutic agents. Genome sequences of bioactive marine actinomycete taxa will continue to provide information on the bioactive potential of the genus/family members, and selective isolation protocols will be designed based on the taxon-specific information generated. This chapter provides an overview on the above highlighted advances from an eco-taxonomical perspective reflecting on the diversified natural product chemistry provided by marine actinomycetes.

27.1 Overview

27.1.1 Marine Actinomycetes in Biodiscovery

Advances in molecular ecology clearly indicate that novel bacterial taxa are present in marine environments including surface seawater and tidal mud flats [27.1–3]. These novel taxa can also be a source for novel chemistry leading to the discovery of, for example, new aminofuran antibiotics from *Verrucosispora maris* [27.4].

The impact of marine microorganisms can be seen from the annual reviews of marine natural products [27.5]. The review covering the 2005 literature showed that 45% of the accumulated literature on marine microorganisms had been published in the period 2001–2005 (as compared to 1965–2005). While analysis of the distribution of articles, compounds and species to the end of 2006 showed that 5% of the marine species examined originate from bacteria and > 95% are from marine Eukaryota [27.6] comparison of 2007 against the historic average for the period 1965–2005 showed a rise of 600% in the microorganism category [27.7].

The journey to establish that marine actinomycetes are unique and a source of diverse secondary metabolites has been long but it serves to illustrate that unique environments in particular the marine ones produce unique species and confirms that such natural product sources of new biologically active compounds will continue to be productive [27.1, 3, 8, 9]. Unique biosynthetic enzymes discovered from marine-derived bacteria also emerge as powerful biocatalysts in medicinal chemistry and total synthesis. The increasingly interdisciplinary field of marine natural product chemistry provides impetus for future developments in medicine, chemistry, and biology [27.10].

Pioneering work dates back to 1970s when *Okami* and co-workers at the Institute of Microbial Chemistry in Tokyo detected bioactive actinomycetes from shallow- and deep-water sediments from the coasts of Japan [27.11]. One of these bioactive actinomycetes was *Chainia purpurogena* SS-228, isolated from mud samples obtained from Sagami Bay, producer of a benzanthraquinone antibiotic [27.8, 12]. The search for marine bioactive actinomycetes continued and from the mid-1980s in Fenical's laboratory resulted in the isolation of the first true marine obligate bacteria in 1991 [27.8, 13]. A new marine actinomycete cluster was reported by *Mincer* et al. [27.14] and the genus *Salinispora* was established as seawater obligate marine actinomycete in 2005 [27.15]. In subsequent studies over 1000 *Salinispora* strains have been isolated from sediments collected from subtropical Atlantic, the Red Sea and the Sea of Cortez all requiring seawater and sodium for growth. In a study of a collection of 288 samples from around the island of Guam, actinomycete growth was obtained with 223 (77%) of samples. The most abundant actinomycetes recovered belonged to the genus *Salinispora* with 58% of the 984 strains obtained in pure culture assigned to this genus [27.16].

The species of *Salinispora* have been shown to be producers of potent compounds [27.17–21] and the genus has been the forerunner of the identification of other unique marine genera. These efforts resulted in the development of new approaches to sample the deep oceans. An autonomous bounce corer was developed that allowed replicate sampling from sediment cores from surface vessels [27.20].

The genus *Salinispora* has become a model concept to address species and species-specific metabolite production [27.21–23]. *Salinispora tropica* and *Salinispora arenicola* have been described as new species and the description of another new species *Salinispora pacifica* is underway [27.23, 24]. The close phylogenetic relationships among the three species is shown by the genus as a whole having 99% 16S rRNA (ribosomal ribonucleic acid) sequence identity and the pair-wise comparison differ by as few as five nucleotides [27.23]. The three currently known species of *Salinispora* co-occur at six widely separated and distinct locations and the strains produce different compounds [27.25].

Bioactive compounds reported from this genus include: arenimycin, an antibiotic effective against rifampin- and methicillin-resistant *Staphylococcus aureus* from *S. arenicola* [27.26] as well as cyanosporasides A and B, chloro- and cyano-cyclopenta[α]indene glycosides from *S. pacifica* [27.27].

Besides *Salinispora* there are other new bioactive marine genera described to date, examples include *Salinibacterium* [27.28], *Sciscionella* [27.29], *Serinicoccus* [27.30], and *Demequina* [27.31].

Marine-sourced actinomycetes have been shown to be a remarkable resource for the discovery of natural products showing potent biological activities. New antibiotics have been reported from marine actinomycetes such as the streptogramin antibiotic etamycin derived from a marine coastal-line-associated actinomycete from Fiji produced activity against methicillin resistant *S. aureus* [27.32]. Caboxamycin, a new antibiotic of the benzoxazole family has been isolated from the deep-sea *Streptomyces* species [27.33]. Indole alkaloid marine natural products have also been shown to contain anticancer activity [27.34] and three new chlorinated dihydroquinones were reported from a marine-derived streptomycete species by *Soria-Mercado* et al. [27.35].

Other examples include: thiocoraline, a new anticancer drug produced by a marine *Micromonospora* strain [27.4, 36], which is under preclinical assessment and the antiviral drug cyclomarin A produced by a marine *Streptomyces* strain [27.4, 37]. Chandrananimycins A, B, and C with anticancer activity were isolated from a marine-derived *Actinomadura* species [27.38]. Abyssomicin A–C polycyclic antibiotics from a marine *Verrucosispora* strain inhibit *p*-aminobenzoic acid/tetrahydrofolate biosynthesis pathway by blocking the *p*-aminobenzoate formation in the bacterial folate biosynthetic pathway [27.39]. The antimalarial potential of marine actinomycete-derived compounds has also recently been reported [27.40].

27.1.2 Novel Chemistry from Marine Actinomycetes

Marine-derived actinomycetes have been a prolific source of natural products containing diverse chemi-

cal structures and unique biological activities [27.9]. Listed below are some recent examples of bioactive natural products isolated from marine-sourced actinomycetes exemplifying the diversity of novel structures and molecular scaffolds.

A new marine actinomycetes genus, *Marinospora* (strain CNQ-140) was isolated from a sediment sample at 56 m offshore of La Jolla, California and shown to contain marinomycin A–D [27.41]. Marinomycin A was the most potent antibacterial agent showing in vitro minimum inhibitory concentrations (MIC_{90}) of 0.13 mM against both methicillin-resistant *S. aureus* (MRSA) and vancomycin-resistant *Enterococcus faecium* (VREF).

The marine actinomycetes *V. maris*, isolated from sediment collected in the Raune Fjord (Norway) produced the nonribosomal peptide synthetase (NRPS)-derived polypeptides proximicin A, B, and C [27.42]. Collection was achieved by box grab at 250 m. 16S rRNA gene sequencing showed similarity of 99.6% to the type strain *Verrucosispora gifhornensis* [27.43]. The proximicins contain a previously unknown γ-amino acid (4-aminofuran-2-carboxylic acid).

The lynamicins were discovered from a *Marinispora* sp. from sediment collected from Mission Bay, San Diego. Lynamicins A–E are chlorinated bis-indole pyrroles with broad spectrum activity against Gram-positive and Gram-negative organisms, in addition to activity against methicillin-resistant *S. aureus* (MRSA) and vancomycin-resistant *E. faecium* (VREF) [27.44].

Marinopyrroles A and B are halogenated axially chiral bispyrroles obtained from culture of a *Streptomyces* sp. from marine sediment collected near La Jolla, California. The marinopyrroles were isolated as single atropo-enantiomers and can be racemized at a higher temperature. Marinopyrrole A had a MIC_{90} of 0.61 mM and marinopyrrole B had a MIC_{90} of 1.1 mM against methicillin-resistant *S. aureus* (MRSA) [27.45].

A novel *Micromonospora* species was isolated from the marine ascidian *Didemnum proliferum* and produced diazepinomicin. Diazepinomicin represents a unique molecular class with a dibenzodiazepine core linked to a farnesyl side chain. Diazepinomicin showed modest activity against Gram-positive bacteria [27.46].

Lipoxazolidinones A, B, and C have been isolated form new marine actinomycetes, *Marinospora* sp. from a sediment sample collected in Cocos Lagoon, Guam. Lipoxazolidinones A had broad spectrum activity against Gram-positive bacteria (MIC values ranging from 0.5 to 5 mg/mL) and MIC values of 12 mg/mL against two strains of *Haemophilis influenzae*. The antibacterial spectrum and potency were similar to that of linezolid [27.47]. The lipoxazolidinones are 4-oxazolidinones while linezolid has a 2-oxazolidinone skeleton.

Cyclic meroterpenoid antibiotics merochlorins A–D have been isolated from a *Streptomyces* sp. (strain CNH-189) from a marine sediment sample collected from Oceanside, California. Merochlorins A and B showed strong inhibition or several methicillin-resistant *S. aureus* strains with MICs in the range of 2–4 μg/mL [27.48].

Salinosporamide A, containing an unusual γ-lactam-β-lactone bicyclic ring structure, was isolated from *S. tropica* [27.17]. The compound was shown to be a reversible inhibitor of the 20S proteasome and entered clinical trials for the treatment of cancer only three years after its initial publication. Moreover, the entire supply of salinisporamide A required for the preclinical developments and clinical trials has been manufactured by saline fermentation, bypassing the need for total synthesis [27.21]. Salinisporamide A exemplifies that marine-sourced actinomycetes have been shown to be abundant producers of new and novel structural classes of natural products and as such will continue to be an attractive resource for the discovery of new therapeutic agents [27.19].

27.2 Advances in the Field of Biodiscovery: Genomics and Genome Mining for Discovery of New Antibiotics

The genome sequencing studies of actinomycetes indicate that they possess larger genomes compared to other bacteria [27.49] and only a fraction of their coding capacity is used for the production of mostly cryptic secondary metabolites. Additionally, the genes responsible for production of many compounds can be found in the genomes of nonproducing strains. Their functions are still under investigation to determine whether these genes are nonfunctional, are not expressed under standard growth conditions or perhaps these genes require external signalling to turn them on [27.50]. Current techniques may not be powerful enough for

detection of the functions of these genes, and perhaps more efficient biochemical and chemical methods as well as genomic approaches will allow the discovery of large numbers of novel compounds coded by these genes. The new mass spectrometry (MS)-guided genome-mining method that connects the chemotypes of peptide natural products to their biosynthetic gene clusters by iteratively matching de novo tandem MS (MS^n) data to genomics-derived structures is an example of current effective approaches [27.51].

In a recent review, *Lane* and *Moore* [27.52] highlighted the advances made over the last decade (2000–2010) to improve understanding of the genetic basis of marine prokaryotic natural product biosynthesis. Initial studies focussing on identification and sequencing of individual gene clusters provided valuable insights, with examples including enterocins [27.53, 54] and wailupemycins [27.55]. However, in-depth understanding on the total quantity and diversity of biosynthetic pathways has not been achieved as exemplified in these early studies. The true genetic capabilities of marine microorganisms have only been revealed when genome sequencing has become an effective tool to explore the biosynthetic potential of marine microorganisms [27.52].

The first released genome sequences for marine microbes revealed that some of these organisms harbor genes for biosynthesis of far more natural products than previously recognized through cultivation-based studies. These orphan pathways, biosynthetic pathways for which corresponding natural products are unknown, bring an intriguing possibility that these pathways might be accessed for discovery of structurally unique, biomedically useful compounds [27.52].

Bioinformatics studies on the genome sequence of the first seawater-requiring marine actinomycete, *S. tropica*, revealed that this marine bacterial species owns a large proportion of genes (about 9.9%) responsible for natural product biosynthesis, while the corresponding numbers in *S. coelicolor* and *S. avermitilis* are 4.5 and 6%, respectively [27.56, 57].

The genome of *S. tropica* contains an amazingly large size of genes (516 kb) dedicated to polyketide synthase (PKS) and/or nonribosomal peptide synthetase (NRPS) biosynthesis, which are megasynthases that are responsible for many active natural product biosynthesis [27.57]. Genome sequence of the abyssomicin- and proximicin-producing marine actinomycetes *V. maris* AB-18-032 has also been completed [27.58]. Genome mining studies can reveal gene clusters for all known molecules from an organism, as well as biosynthetic gene clusters for natural products yet to be identified. Only through these studies will the total potential of an organism as a novel chemistry supplier be identified [27.52]. Discovery of salinosporamide K from *S. pacifica* by genome mining has provided insight into pathway evolution [27.59].

Recent advances in encoding precursor peptides or biosynthetic proteins, in silico mining of genomes combined with molecular biology approaches has also guided the discovery of a large number of new ribosomally derived natural products. Effective strategies were then designed for the identification of these ribosomally synthesized and post-translationally modified peptides (RiPPs) and the elucidation of their structures [27.60].

27.3 Ecological and Physiological Perspectives

27.3.1 Metagenomic Approaches

Marine microbial communities have been investigated using cultivation-independent genomic approaches [27.61, 62]. Large scale sequencing of environmental genomes has brought higher resolution insights into microbial diversity [27.61]. These studies are thus currently providing a more comprehensive description of the organisms and processes which define microbial community structure, function, and dynamics in the sea [27.52].

A more comprehensive view of uncultivated microbial species, gene, and biochemical pathway distributions, and naturally occurring genomic variability is also becoming clearer as well as fundamental principles that drive microbial ecological and evolutionary processes are being defined [27.52, 63, 64], with an ultimate goal of sustained development of marine biotechnology [27.63].

27.3.2 Exploring Marine Physiological Adaptations of Actinomycetes for Selective Recovery

Penn and *Jensen* [27.65] recently studied marine adaptations of *Salinispora* species using comparative ge-

nomics. They observed relatedness between marine and nonmarine actinobacteria through constructed phylogenic trees which might indicate recent introduction to marine environments.

Sponga et al. [27.66] indicated that the presence of a few antibacterial activities expressed when marine-derived actinomycetes were incubated in a fermentation medium diluted with sea water might be an indication of adaptation of these isolates to the marine environment rather than originating from those environments. The establishment of the marine affinity of organisms isolated from the sea requires generation of scientific evidence beyond laboratory studies [27.67]. Initial growth on complex laboratory media prepared with sea water, or on media made isotonic with sea water by the addition of NaCl, may not be an absolute criterion of marine adaptation as many terrestrial origin microorganisms also grow on such media [27.67]. True marine bacteria might be differentiated from their land counterparts through their need for Na^+ in the medium for growth but not by having requirements for sea water [27.67, 68]. Our knowledge is still poor about specific, natural nutrients and growth factors required for their cultivation. As stated by *Fenical* [27.8] common media constituents such as peptone, simple sugars etc. are unrealistic marine nutrients. These are apparently replaced with complex carbon sources such as chitin, sulfated polysaccharides, and marine proteins in the marine environment. In addition, there is still little understanding of the effects of uncommon inorganic elements, such as lithium, silicon, etc., which are also abundant in marine sediments. All these factors are still today greatly limiting our ability to isolate and culture the majority of the interesting and new bacterial forms present [27.8].

There is a need to develop a full understanding on the survival and marine adaptations of bacteria which can then be translated into development of effective selective isolation protocols [27.69]. One successful approach for the terrestrial ones has been the use of data deriving from physiological and growth requirements of terrestrial streptomycetes to design target-specific selective isolation methods [27.70]. Adaptation of such an approach for marine-derived taxa would result in effective recovery as well as generating information on the physiology and growth requirements of marine bacteria. *Imada* et al. [27.71] investigated the growth and antimicrobial compound production of marine actinomycetes in the presence of seawater. While the optimal concentration of growth ranged from 10 to 30 % (v/v), the production of antibacterial substances was observed in the concentration range 60–110 % (v/v) despite poor growth, indicating that the production of antibiotics is seawater-dependent.

27.3.3 Bacteriophage-Guided Route to Detection and Recovery of Marine Actinomycetes

When detection of rare actinomycetes is targeted, particularly the marine derived ones with low abundance frequency unless highly selective pressures are used, these taxa could not easily be isolated [27.69]. One approach has been the use of indicator phages specific towards targeted taxa using their close relatives as propagation hosts, and provided clues whether such species would be present in those environments [27.72–75].

An interesting finding was the occurrence of polyvalent *Salinispora* phages infecting members of *Micromonosporacea* including the type strains of terrestrial origin in Germany [27.74].

Stadler et al. [27.76] isolated cinnabaramides A–G, analogs of lactacystin and salinosporamide from a terrestrial streptomycete. These observations and findings might be in agreement of the above mentioned fact by *Penn* and *Jensen* [27.65] that a recent introduction of genera like *Salinispora* occurred into the marine environments and terrestrial relatives of these genera might also carry similar biosynthetic genes coding for the production of similar bioactive compounds. *Udwary* et al. [27.77] however, have indicated that due to the current lack of information on the other *Micromonosporacea* genome sequences, it is unclear whether this natural product diversity is common to this family or whether the diversity in *Salinispora* derives from environmental pressures present in marine environments.

Once the presence of bioactive taxa is indicated by bacteriophages in an environmental sample, they can also be used to reduce the numbers of unwanted taxa on isolation plates making the growth medium available for consumption by targeted organisms without competition [27.73, 75, 78].

Bacteriophages can also indicate the relatedness of unknown bacteria to their closest relatives [27.72]. In recent reviews *Kurtböke* [27.75, 79] provided insights into bacteriophage–host interactions. Examples included multiple strategies evolved by bacteriophages to interfere with bacterial growth. Such host conquering strategies used by the bacteriophages can provide clues towards detection of new bioactive compounds such as turning phage endolysins to enzybiotics [27.80].

27.4 An Australian Example: Exploring the Biosynthetic Potential of a Marine-Derived Streptomycete

Through systematic screening of marine environments in the Sunshine Coast Region of Australia using the information derived from indicator phages, a novel marine streptomycete species USC-633 was isolated from near shore marine waters [27.81] with an optimum growth temperature at 28 °C. Growing very slowly (over 3–4 weeks) in both salt dependent and independent media this near shore marine actinomycete was highly susceptible to low temperatures and lost viability immediately in cold storage temperatures (e.g. 4 °C) indicating it was an organism truly deriving from subtropical marine waters. Following the 16S rRNA sequencing investigation it occupied a distinct position on the phylogenetic tree (Fig. 27.1) and displayed only 68% similarity to other previously described bioactive marine streptomycete species such as the DQ448742 [27.82].

27.4.1 Morphology, Physiology, and Secondary Metabolite Production

The isolate displayed a range of growth characteristics when grown on different media. Only on oatmeal agar (3% yeast extract, 20% oats, and 20% agar) scarce aerial mycelium formation and sporulation were observed both visually and through electron microscopy studies (Fig. 27.2, 27.3a,b). On all other growth media including the Marine agar (Difco) used to grow the microorganism, extensive aerial mycelium development and subsequent sporulation were absent even after 4–6 weeks of incubation (Fig. 27.4).

However, well-defined chemical profiles were obtained on bold cultures of the isolate such as when it was grown on glucose yeast extract and malt extract agar (GYM; medium 65, www.dsmz.de) (Figs. 27.5, 27.6). These observations might correlate with the findings of *Ng* et al. [27.83] where increased rifamycin production was recorded after 31 days of growth with darkened color colony with *S. arenicola*.

In most actinomycetes including the streptomycetes the vegetative mycelia directly develops by germinated spores in a parallel disposition of the mycelium [27.83]. Such growth structure allows for the efficient utilization of the nutrients in the agar due to the hydrolytic enzymes secreted by the microorganisms allowing the efficient use of polymers [27.83–85].

Production of hydrolytic enzymes has also been linked to bioactivity. Of 116 chitinolytic actinomycetes isolated from marine sediments, 85 were found to possess antimicrobial activity by *Pisano* et al. [27.86]. They noted a high correlation between chitinolysis and bioactivity. Furthermore, addition of $CaCO_3$ by *Macedo* et al. [27.87] resulted in higher values of maximum lignin peroxidase activity. GYM agar contained $CaCO_3$ which might be triggering increased enzyme activity and in turn bioactivity. Deep dark green color produced on the GYM agar by the USC-633 might be related to the presence of such hydrolytic ability resulting in increased bioactivity.

Dark coloration was also evident with co-culture inoculations with other bacteria and fungi on the same solid state fermentation environment. Perhaps a wide array of characteristic demonstrated by the isolate making it adaptable to different substrates including marine ones highlights the fact that occurrence and adaptation is an ecological factor perhaps in response to environmental stresses rather than a true taxonomical separation [27.66, 67]. As soon as the culture was given the marine conditions a brominated compound was produced as a response to its new environment.

A large variety of aromatic and aliphatic carbon centers have been reported to be halogenated during natural product biosynthesis, with over 95% of the cases involving chlorine or bromine. In the marine environment where bromine is in higher concentration than in fresh water a comparable bromination of aromatic and heteroaromatic molecules as well as bromination of isoprenoid metabolites have been reported [27.88].

Magarvey et al. [27.89] investigated the obligate growth requirements of the PNG1 and UMM518 clades and concluded that they do not have an obligate requirement for salt like the true marine clade MAR1, but do complete a full developmental cycle in submerged cultures (liquid saltwater growth medium containing 3% NaCl). Both of these slowly growing actinomycetes were capable of sporulating under submerged conditions in the presence of a salt concentration of 3%, typical of seawater, consistent with their ability to grow and divide in the marine environment.

It has frequently been reported that small changes in culture conditions can have a major influence in the spectrum of secondary metabolites [27.50]. In-depth information gained from physiological studies can further be used to manipulate secondary metabolite production in conjunction with the reflected information deriving from secondary metabolism. Co-culture exper-

sortium as a whole [27.50]. Microorganisms co-exist in tiny ecosystems. As a result, these microbial communities can hold the potential for production of novel compounds through diverse signalling, and cross-feeding between organisms that might elicit production of novel compounds [27.50, 90, 91]. *Burgess* et al. [27.92] showed that bacteria associated with starfish and seaweed have the ability to produce antimicrobial compounds against other marine bacteria and also against terrestrial pathogenic bacteria. Furthermore, when culture supernatants were added, antibiotic production in marine surface-associated bacteria was elicited. Following cross-species induction enhanced microbial activity in marine bacteria has also been shown by *Mearns-Spragg* et al. [27.93] as well as by *Slattery* et al. [27.94] on the competition-mediated antibiotic induction in the marine bacterium *Streptomyces tenjimariensis*.

27.4.2 Natural Product Chemistry

In order to explore the secondary metabolite production of the marine-derived actinomycete USC-633, the strain was grown on several different agar-based media, and the ethyl acetate extracts analyzed by high performance liquid chromatography (HPLC), liquid chromatography mass spectrometry (LC-MS), and proton nuclear magnetic resonance (^{1}H NMR). Isolation and compound identification work revealed that the strain produces phenazine-related natural products, with the secondary metabolite production being media dependent. When cultured on oatmeal agar medium, USC-633 afforded 1-methoxyphenazine as a main natural product while the GYM agar culture afforded *N*-monoterpenoid substituted phenazine lavanducyanin and 2-chlorolavanducyanin. Marine agar culture yielded lavanducyanin and 2-chlorolavanducyanin as well as 2-bromolavanducyanin indicating that the microbe is adapting to the new nutrient environment. The diversity of USC-633 secondary metabolite production is depicted in Fig. 27.7.

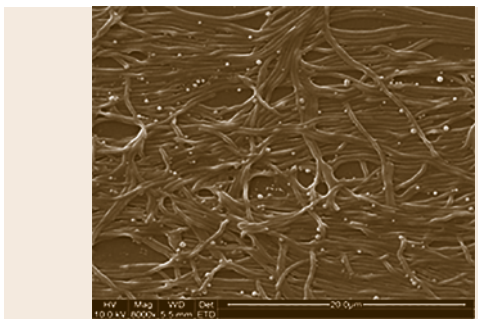

Fig. 27.6 Electron micrograph of the growth characteristics of USC-633 on GYM agar after 4 weeks of incubation (*bar* indicates 20 μm)

Phenazines are produced by many different groups of bacteria including *Streptomyces* [27.95, 96]. They are reported to be involved in pathogenesis and competi-

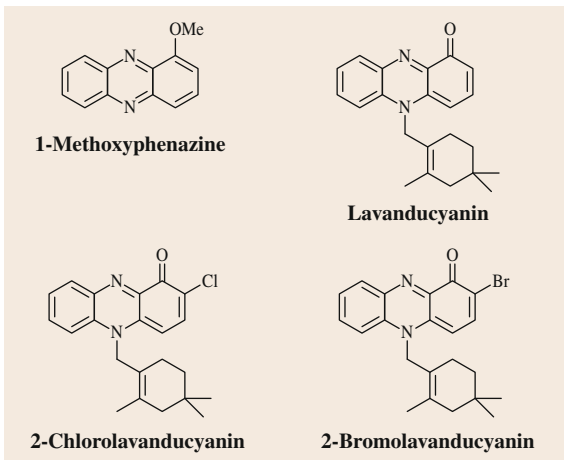

Fig. 27.7 Natural products identified from USC-633

tive fitness of the bacteria attributed primarily to their ability to generate reactive oxygen in other organisms and tissues [27.96]. The competitive environment of the near shore marine environments including pollution from human activities and presence of marine macroorganisms might be triggering the production of these compounds.

Penn et al. [27.97] has recently identified that genomic islands can harbor functional traits that differentiate ecologically distinct populations of environmental bacteria. Their comparative analysis of the complete genome sequences of the marine actinobacteria *S. tropica* and *S. arenicola* revealed that 75% of the species-specific genes were located in 21 genomic islands. These islands were enriched in genes associated with secondary metabolite biosynthesis providing evidence that secondary metabolism linked to functional adaptation. Brominated and chlorinated compounds produced by the USC-633 might also be as a result of such functional adaptation.

27.5 Future Prospects

Traditional approaches have been successful at identifying many successful therapeutic agents since the discovery of penicillin. However, growing antibiotic resistance and need for potent agents to combat many incurable diseases indicate the urgent need for new approaches. The application of genome mining, metabolomics, and proteomic tools has recently been a leading force in developing novel advances in the drug discovery area. They will continue to be the driving forces for discovery and design of potent therapeutic agents from microbial sources in the years to come. Through these advances the true biosynthetic potential and metabolic diversity of marine microorganisms will be revealed [27.98, 99]. Cross-country advances in bioinformatics tailored for the marine field, consistent data acquisition and exchange and design of relevant marine bacterial models is now a recognized priority in Europe resulting in an EU funded series of workshops and projects [27.100].

Genome sequences will continue to provide valuable insights for activation of silent gene clusters [27.99]. One of the most successful outcomes via the use of genomic approaches has so far been through the studies conducted on *Salinispora* species. Examples include the exploration and engineering of biosynthetic pathways in the marine actinomycetes *S. tropica* [27.101] and the discovery and assembly line biosynthesis of the lymphostin pyrroloquinoline alkaloid family of mammalian target of rapamycin (mTOR) inhibitors in *Salinispora* [27.102].

High-throughput genome scanning methods will also facilitate discovery of metabolic loci-independent of expression. Genome sequence tags (GSTs) are genes involved in natural product biosynthesis and they can be utilized as probes for screening of specific genes within clonal libraries. Subsequently, any clone that contains a GST can then be screened for novel natural product gene clusters such as the identification of more than 450 natural product clusters [27.50, 103]. Genome inspired-technologies will also unveil new metabolites which were overlooked under standard fermentation and detection conditions.

Advances in the chemistry field will continue to facilitate rapid discovery of bioactive molecules using improved ability to dereplicate, isolate, and elucidate the structure of natural products from reduced sample quantity [27.3]. Emerging physiology-oriented engineering strategies based on improved understanding into microbial physiological responses to environmental stresses, will also result in productive physiological performances of industrial microorganisms [27.104].

Microbial *ecotypes* [27.105] or *geovars* [27.106] can also be specific to a geographical–ecological region, for example more than 200 secondary metabolites have been isolated from various *Streptomyces hygroscopicus* strains of different geographical origin. Moreover, strains of the same subspecies may produce different compounds [27.50]. *Jensen* and *Mafnas* [27.25] following their studies using tropical and subtropical ocean sediments conclude that *Salinispora* species are globally distributed and speciation within this genus is driven by ecological selection not geographical isolation. The reported presences of indicator bacteriophages specific to *Salinispora* type strains in different geographical regions by *Kurtböke* [27.74] also support their conclusions.

Biogeographical information combined with metagenomics-derived data will give insight into population dynamics of predominantly unculturable microbial communities. It will also provide information into the capabilities of microorganisms that allow them to collaborate and compete to survive in a wide range of environments [27.107]. The application of new molec-

ular and genomic techniques to the ocean will be driving a scientific revolution in marine microbiology by defining marine *genotypes* representing the potential biological capacity, and *phenotypes* reflecting the complex interactions of individuals and populations within their physical and chemical environment and with each other [27.108]. Furthermore, information derived from marine adaptational responses of bioactive taxa will enable development of effective search strategies to identify sites of bioactivity. Bacteria in marine environments are often under extreme conditions in terms of pressure, temperature, salinity, and depletion of micronutrients. Microbial ability to survive and proliferate is dependent on the ability to produce biologically active compounds [27.109]. Bacteria can produce molecules that prevent the attachment, growth and/or survival of challenging organisms in competitive environments [27.109] and such molecules can be of interest for therapeutic reasons especially against antibiotic resistant bacteria. There is now an opportunity to pair metagenomic analysis with other genomic approaches to evaluate gene expression and bioactive compound production which will in turn pave the way to unprecedented discoveries [27.62]. This paired approach will also challenge our perception of community structure and function in environmental systems as well as offering opportunities for novel gene discovery and biotechnological advancements. Community diversity and ecosystem functions of microorganisms will be revealed. As a result, information deriving from these molecular approaches will sharpen our focus during design of selective isolation techniques to culture bioactive microorganisms. Detection of environmental function-related bioactivity and its exploitation for pharmaceutical and biotechnological purposes will be achieved in a relatively shorter time span. When such approaches are combined with an improved understanding of the natural product metabolome, application of rational approaches for more effective exploitation of natural products will be facilitated [27.110].

28. Biotransformation of Nitriles by Marine Fungi

Julieta Rangel de Oliveira, Mirna H. Reagli Seleghim, André L. Meleiro Porto

In this study, a screening of 12 marine fungi (*Penicillium miczynskii* CBMAI 930, *Penicillium raistrickii* CBMAI 931, *Aspergillus sydowii* CBMAI 933, *Aspergillus sydowii* CBMAI 934, *Aspergillus sydowii* CBMAI 935, *Bionectria* sp. CBMAI 936, *Penicillium oxalicum* CBMAI 1185, *Penicillium citrinum* CBMAI 1186, *Penicillium decaturense* CBMAI 1234, *Penicillium raistrickii* CBMAI 1235, *Cladosporium* sp. CBMAI 1237, and *Aspergillus sydowii* CBMAI 1241) was conducted in order to evaluate the enzymatic potential of these microorganisms for biotransformation of phenylacetonitrile **1**. These microorganisms were isolated from sponges and algae collected on the northern part of the coast of São Paulo State, Brazil. The screening was carried out on a solid mineral medium supplemented with glucose and phenylacetonitrile **1** as the only source of nitrogen. Afterwards, the microorganisms adapted were tested in a liquid medium containing 20, 40, and 60 μL of phenylacetonitrile **1**. The phenylacetonitrile **1** was biotransformed into the 2-hydroxyphenylacetic **1a** acid by eight of the marine fungi selected. The enzymes which hydrolyzed nitriles in these catalytic systems were inducible. Since the mycelium of *A. sydowii* CBMAI 934 grew strongly in solid and liquid mineral media in the presence of phenylacetonitrile **1**, this fungus was selected for the enzymatic hydrolysis reactions using other nitriles, such as 4-fluorophenylacetonitrile **2**,4-chlorophenylacetonitrile **3**, 4-methoxyphenylacetonitrile **4**, cyclohexenylacetonitrile **5**, and 2-cyanopyridine **14**, yielding their corresponding carboxylic acids: 4-fluorophenylacetic **2a** (51%), 4-chlorophenylacetic **3a** (55%), 4-methoxyphenylacetic **4a** (43%), cyclohexenylacetic acid **5a** (28%), and the amide, 2-pyridinecarboxamide **14a**, respectively. This chapter reports on the study on the biotransformation of nitriles by marine microorganisms which is summarized in the context of directions for future research.

28.1 Overview

28.1.1 Biocatalysis and Biotransformation

Biocatalysis and biotransformation refer to processes in which enzymes are used to catalyze chemical reactions, but outside their normal biochemical systems, with non-natural substrates for their metabolic pathways. The term biotransformation is applied to specific structural modifications or interconversions of compounds in multiple stages by living organisms [28.1, 2].

Biocatalysis is an area of biotechnology utilized in chemistry to promote organic reactions with one or more steps, to produce compounds of interest, especially of high enantiomeric purity. In addition to the importance of biocatalysis for synthesis in chiral blocks, focused on the production of chiral drugs, there has been much stress lately on its applicability to the production of raw materials for products in the cosmetics, polymers, agrochemicals, and fuel industries [28.3, 4].

To establish an effective process of biotransformation, it is necessary to make a detailed analysis of the factors that influence the development and optimization of the integrated biotechnological process, which depend on: i) the biocatalyst, ii) the bioconversion, and iii) the isolation and purification of the product. The purpose of this chapter is to investigate the biotransformation of nitriles using marine fungi isolated on the Brazilian coast.

28.1.2 Marine Microorganisms

While most industrial enzymes are derived from terrestrial sources, the potential of marine microorganisms is being explored with a view to industrial use. In recent years, marine microorganisms have attracted the interest of researchers aiming to exploit various enzymes in biotechnological applications. An example is proteases, a very important industrial-type enzyme, which are used in the processing of leather, food, and detergents [28.5].

The occurrence of fungi in the marine environment was recorded in the late nineteenth century; the oceans cover over 70% of the land surface. Nevertheless, the known species of marine fungus are far fewer than known terrestrial species [28.6]. The first facultative marine fungus, *Phaeosphaeria typharus*, was described in 1849, and the first obligate marine fungus, *Halotthia posidoniae* in 1869 [28.7]. Marine fungi can be divided into two major groups. The obligate marine fungi grow and sporulate exclusively in marine or estuarine habitats, while the facultative group inhabits inland water ecosystems and terrestrial environments, but also grow and survive in marine environments [28.7]. Marine fungi, among other organisms present in the complex and vast array of marine ecosystems, represent a valuable source of new and rarely studied species for the scientific laboratory and for ecological, evolutionary, and biotechnological study. These fungi can be found associated with various marine organisms, such as sponges, fishes, cnidarians, tunicates, and algae. The isolation of fungi from the ocean does not necessarily signify that these organisms are active in the marine environment. Therefore, it is possible to isolate a terrestrial fungus that has adapted or is simply present in the marine environment. Also, the fungus could be isolated in the dormant form of spores or fragments of hyphae, awaiting conditions in the laboratory that are favorable for germination, growth, and sporulation. Several strains of fungi isolated from the marine environment are not demonstrably marine fungi, having been identified as facultative or optional. Therefore,

a generalized expression *marine-derived fungi* has been used [28.8].

Recently, studies were performed to assess methods of isolating marine-derived fungi on various culture media, resulting in a set of 688 fungal strains isolated from ascidians, sponges, and algae. In addition, with the advance of techniques in molecular biology, it has been possible to isolate and identify obligate marine species of bacteria and fungi from the oceans [28.9].

Marine microorganisms have specific biochemical properties that can provide new enzymes with unique characteristics, which can be more active and stable than the corresponding enzymes of terrestrial organisms [28.10]. The complexity of the marine environment with its high salinity and pressure, low temperature, and special lighting may give rise to the significant differences between the enzymes produced by marine microorganisms and the homologous enzymes from terrestrial microorganisms. Such differences boost the technological potential of enzymes from marine microorganisms in the production of valuable compounds of scientific and economic interest [28.10].

28.1.3 Nitriles

Organic compounds of various classes containing the cyano group occur naturally in the environment and are synthesized by plants, fungi, bacteria, seaweed, sponges, insects, etc. Plants and microorganisms are able to produce both aliphatic and aromatic nitriles, such as cyanoglucosides, cyanolipids, ricinine, and phenylacetonitrile (Fig. 28.1) [28.11]. These compounds can serve not only to store nitrogen, but also to protect the organism against herbivory [28.11, 12].

The enzymatic pathways leading to nitriles are little known. *Kato* et al. showed that the aldoxime dehydratase is responsible for the formation of nitriles from aldoximes-degrading microorganisms, e.g., *Bacillus* sp. OxB-1 and *Rhodococcus* sp. YH3-3, from soil [28.13]. It is known that the metabolism of compounds containing the cyano group involves a wide spectrum of reactions, among which stand out hydrolysis by nitrilase or nitrile hydratase, followed by amidase, reactions catalyzed by oxygenase and oxynitrilase, and reductions catalyzed by nitrogenase (Fig. 28.2) [28.14].

Oxygenases of plants and insects catalyze the oxidation of nitriles to cyanohydrins (α-hydroxynitriles), which are converted to aldehydes and hydrogen cyanide (HCN) by oxynitrilases (hydroxynitrile lyases) [28.15].

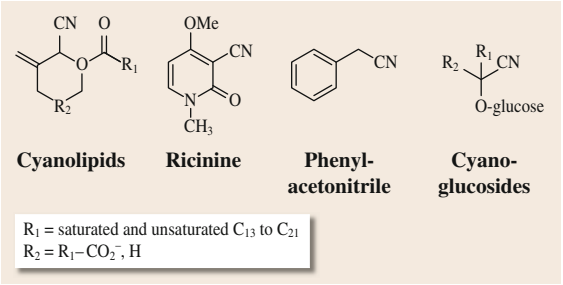

Fig. 28.1 Organic nitriles of natural occurrence

HCN can also be converted by cyanase to CO_2 and NH_3 or by cyano hydratase to formamide, while cyanide dihydratase produces formic acid and NH_3. Nitrogenases present in nitrogen-fixing organisms in soil are capable of reducing organonitrile compounds to the corresponding hydrocarbons and NH_3 (Fig. 28.2) [28.14].

Most nitriles found in nature are toxic, mutagenic, and carcinogenic. In general, the toxicity of organonitriles to humans causes gastric problems, nausea, shortness of breath, and bronchial irritation. Despite the high toxicity of most nitriles, they are widely used as intermediates in organic chemistry for the synthesis of amines, amides, amidines, carboxylic acids, esters, aldehydes, ketones, and heterocyclic compounds (Fig. 28.3) [28.14, 16].

The chemical hydrolysis of nitriles requires the use of strong bases or acids, salts of toxic metals, and elevated temperatures. However, enzymatic hydrolysis provides a means of promoting reactions under mild conditions and does not produce any by-products [28.17–19].

Enzymatic Hydrolysis of Nitriles

Enzymatic hydrolysis is the commonest pathway for microbial metabolism of nitriles; it occurs by two routes:

i) *Nitrilase* (NLase): directly hydrolyzes the cyano group of organonitriles to the corresponding carboxylic acid, via the addition of two molecules of water.
ii) *Nitrile hydratase* (NHase): converts the cyano group of organonitriles to the corresponding amide, via the addition of one water molecule. Next, an *amidase* converts the amide group to the corresponding carboxylic acid via the addition of one water molecule [28.14]. The two pathways for the enzymatic hydrolysis of nitriles are shown in Fig. 28.4.

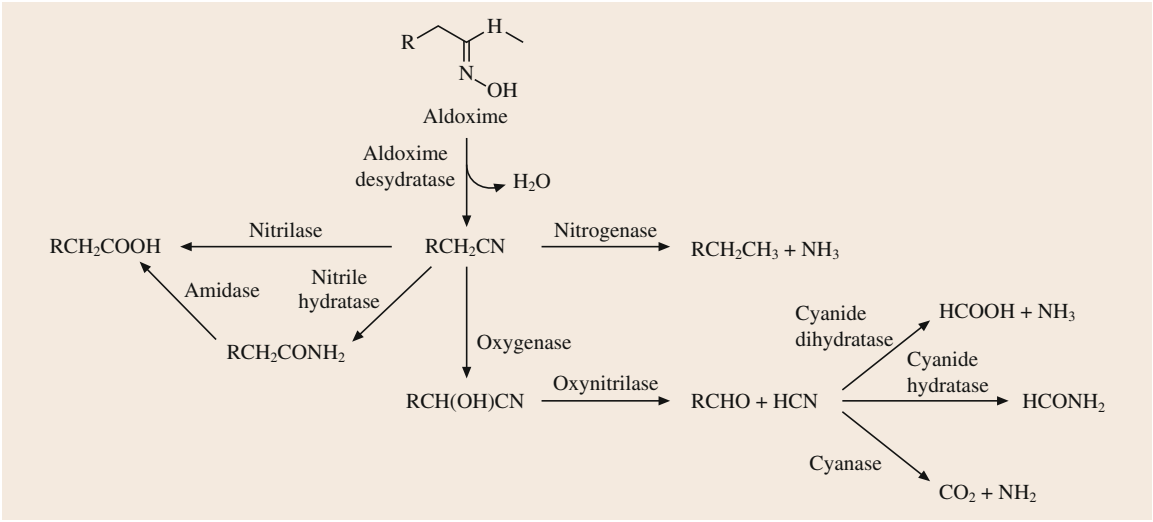

Fig. 28.2 Different pathways for biotransformation of nitriles

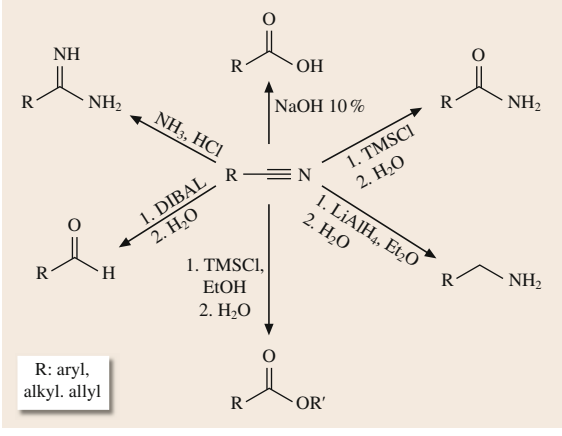

Fig. 28.3 Syntheses of organic compounds from nitriles

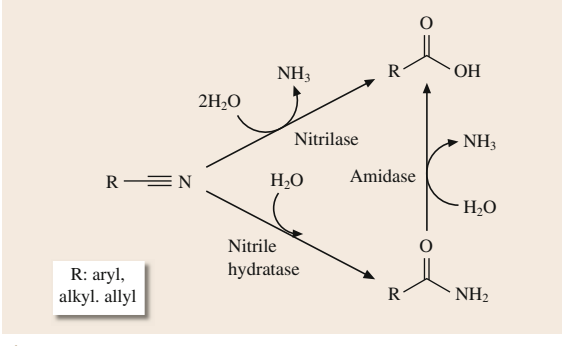

Fig. 28.4 Enzymatic hydrolysis of nitriles

A simplified proposal for the mechanism enzymatic of hydrolysis of nitrile by *nitrilases* is shown in Fig. 28.5. The main steps are:

a) At the catalytic site of the enzyme, there are three amino acid residues, glutamic acid (Glu), cysteine (Cys), and lysine (Lys), and a water molecule.
b) Initially, an interaction occurs via hydrogen bonding between the substrate (nitrile) and the Lys protonated in the catalytic site. In addition there is hydrogen bonding between the water and the nitrile, Cys and Glu. Glu is hydrogen-bonded to the Lys and water, further stabilizing the active site.
c) In the first step of the reaction, the electrophilic carbon of the cyano group undergoes nucleophilic attack of the sulfhydryl group of cysteine for forms an enzyme-covalent complex thioimidate. The nucleophilic character of cysteine is enhanced by hydrogen-bonding interactions with water.
d) The thioimidate-enzyme complex is subsequently hydrolyzed by a water molecule to form a tetrahedral intermediate.
e) The nitrogen of the tetrahedral intermediate is protonated by capturing a proton from glutamic acid.
f) Subsequently, the protonation of this nitrogen favors the elimination of ammonia and promotes the formation of a covalent thioester-enzyme complex.
g) Finally, the thioester-enzyme complex is hydrolyzed by a water molecule to form the corresponding free carboxylic acid.

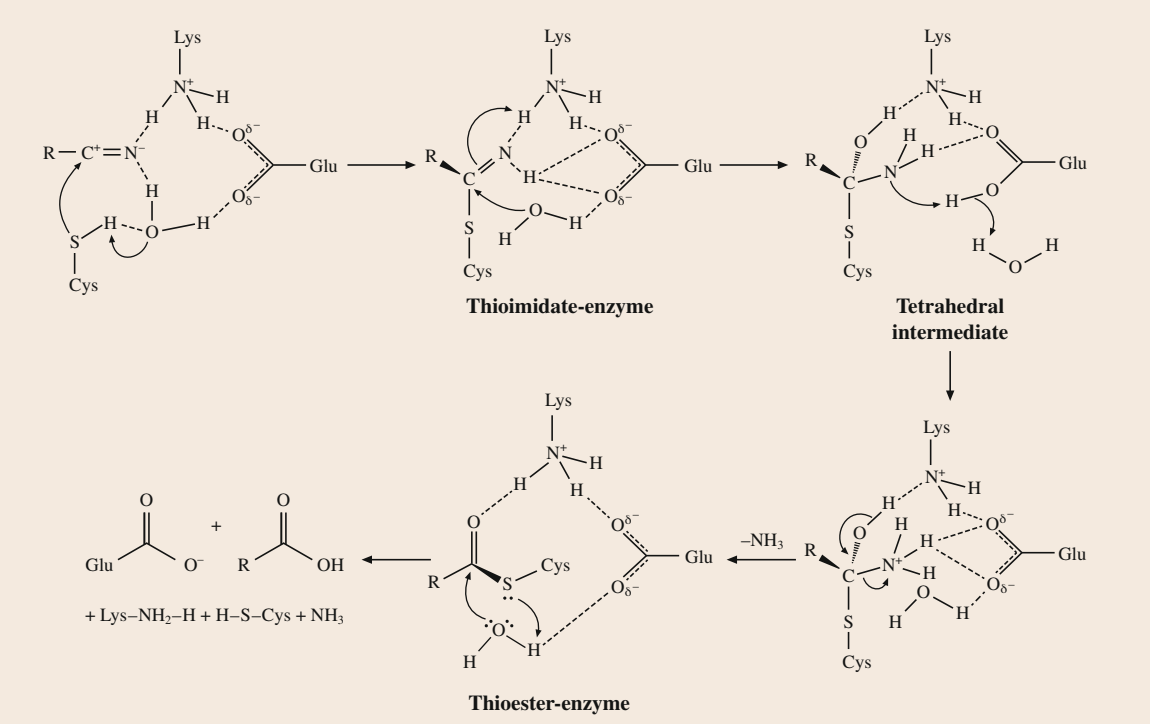

Fig. 28.5 Mechanism proposed for hydrolysis of nitriles by nitrilase [28.20]

In the active site of the nitrilases, a cysteine is involved in the catalysis of the cyano group. The nitrile hydratases have a metal cation in the active site that is believed to play a catalytic role [28.21].

The NHases carry the metal ions, Fe^{3+} or Co^{2+} at the active site. Thus, they can be classified into two groups: NHases dependent on iron(III) and NHases dependent on cobalt(II) [28.14]. For example, NHases from *Pseudomonas chlororaphis* B23, *Brevibacterium* sp. R312, and *Rhodococcus* sp. require iron, while those from *R. rhodochrous* J1 and *Pseudomonas putida* NRRL 18668 require cobalt [28.22]. However, the NHases from *Agrobacterium tumefaciens* need both metal ions. There are two main reasons for the presence of the metal ion at the active site of the enzyme. First, these metal ions are great catalysts for hydration of the cyano group. Second, the metal ions are essential to enhance the flexibility (bending) and stability of the polypeptide chain (α and β-subunit) of the NHases [28.14, 16].

The activity of NHase has unique features when the enzyme is exposed to light. The chromophore involved in this photo-activation is an iron complex in the β-subunit. Light irradiation of the complex induces a conformational change in the β-subunit. Because of this, an endogenous NO molecule that is bound to the non-heme iron(III) center in the inactive NHase is released, resulting in the recovery of the original NHase activity [28.14, 23]. Two possible mechanisms of action of NHase are shown in Fig. 28.6.

All ligands coordinated to the metal are in the α-subunit of the protein; these ligands are three cysteine thiolates (Cys110, Cys112, Cys114) and two nitrogen atoms (Ser113, Cys112). Five amino acids occupy the vertices of the octahedron and the sixth position can be occupied by a hydroxide ion. The main steps of these mechanisms are:

- *Mechanism I*: The electrophilic carbon of the cyano group undergoes nucleophilic attack by the hydroxide ion that is coordinated to the metal ion at the catalytic site of the enzyme, leading to the formation of an imidate. The imidate undergoes rearrangement to the more stable amide.
- *Mechanism II*: The hydroxide ion coordinated to the of the catalytic site metal ion enzyme acts as a base,

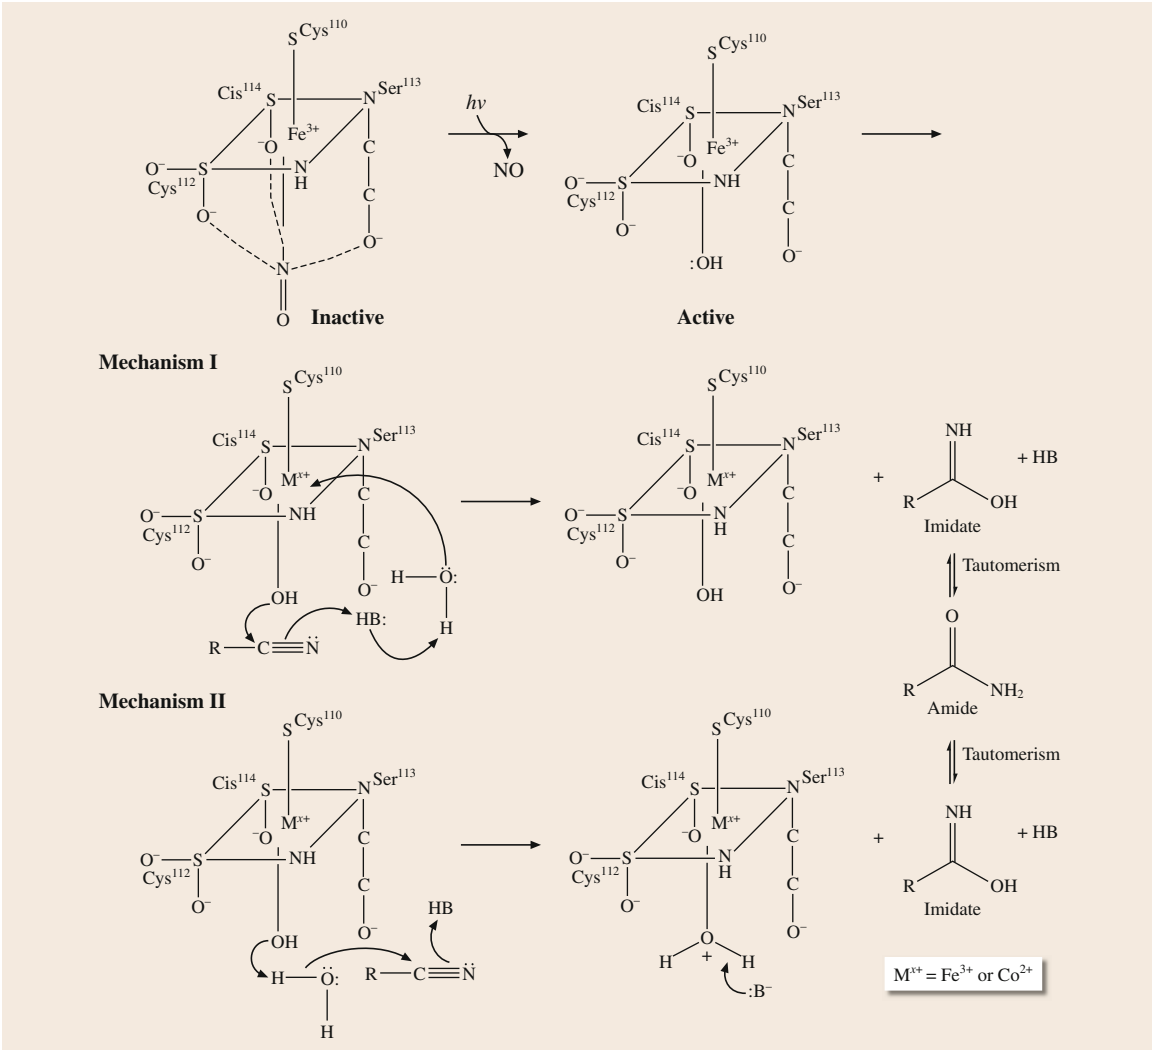

Fig. 28.6 Mechanism proposed for NHase. Photoactivation and enzymatic catalysis [28.14]

activating a water molecule to promote nucleophilic attack on the cyano group carbon to form an imidate. The imidate forms the amide as in mechanism I, by tautomerization.

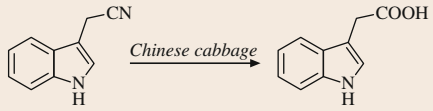
28.1.4 Nitrilases, Nitrile Hydratases, and Amidases

The nitrilases (EC 3.5.5.1) and amidases (EC 3.5.1.4) are enzymes that belong to the class of hydrolases, while the nitrile hydratases (EC 4.2.1.84) belong to the class lyases [28.24, 25].

Nitrilases (EC 3.5.5.1)

Since their discovery in plants (in 1958) and in bacteria (in 1964), over 30 nitrilases have been reported in many organisms, including fungi [28.11]. The nitrilase enzyme was first recognized by the biotransformation of indoleacetonitrile (IAN) to indoleacetic acid (IAA) in barley leaves; the enzyme responsible was named indole acetonitrilase (Fig 28.7) [28.26]. It is also found in the cabbage family.

The first bacterial nitrilase to be purified and partially characterized was isolated from *Pseudomonas* sp.; this catalyzed the biotransformation of *N*-methyl-3-



Indoleacetonitrile **Indoleacetic acid**

Fig. 28.7 Biotransformation of indole acetonitrile by *Chinese cabbage*

cyano-4-methoxy-2-pyridone to *N*-methyl-3-carboxy-4-methoxy-2-pyridone (Fig. 28.8) [28.26].

The biochemical and biological properties of nitrilases and their substrates (nitriles) indicate that the functions of these enzymes are probably protection, detoxification, and the use of the nitrogen atom as a nutrient source and for synthesis of plant hormones [28.11].

The nitrilases of plants are better characterized than microbial nitrilases with respect to their biological functions, particularly NIT1, NIT2, NIT3, and NIT4 of *Arabidopsis thaliana*. Plant nitrilases form two distinct groups according to the type of substrate they catalyze: nitrilases with high activity for hydrolysis of arylacetonitriles (phenylpropionitrile) and those with high hydrolytic activity for aliphatic nitriles (β-cyano-L-alanine; Fig. 28.9) [28.11].

Most of the nitrilases characterized to date are of bacterial origin and were isolated on a selective medium that allows only Gram-positive strains to develop in the presence of nitrile as the sole nitrogen source [28.27, 28]. Culturing microorganisms on selective media is an efficient way to isolate strains capable of hydrolyzing nitriles. The nitrilases and amidases convert the cyano group in their respective substrates to ammonia, which is readily used as a nitrogen source. Thus, these microorganisms, which produce the enzymes of interest, can grow in the presence of nitriles or amides as the sole source of nutrients. In some cases, the carboxy-

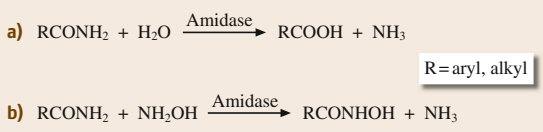

Fig. 28.11 **(a)** Enzymatic hydrolysis of amides. **(b)** Biotransformation of amides by amidases in the presence of hydroxylamine

lates derived from hydrolysis of nitriles or amides are also utilized by the microorganisms, thereby promoting the complete degradation of the substrate [28.29].

Bacteria of the genera *Rhodococcus, Alcaligenes*, *Bacillus*, *Pseudomonas*, *Acinetobacter*, *Corynebacterium*, *Arthrobacter*, and *Nocardia* are sources of nitrilases with a variety of substrate specificities, which have been purified and characterized [28.14, 26, 30]. Fungal nitrilase was first isolated from *Aspergillus niger* and was characterized and sequenced by biochemical methods. Other genera were then identified as producers of these enzymes, such as *Fusarium, Gibberella*, and *Penicillium* [28.20, 31].

Nitrile Hydratase (EC 4.2.1.84)

In 1980, the novel enzyme acetonitrile hydratase was detected, degrading aliphatic nitriles [28.32]. The first occurrence of this nitrile hydratase was reported in the bacterium *Rhodococcus rhodochrous* J1, initially identified as *Arthrobacter* sp. J1, which catalyzed the biotransformation of acetonitrile to acetamide (Fig. 28.10) [28.16].

Nitrile hydratases were initially considered specific for aliphatic nitriles, but later these enzymes were re-

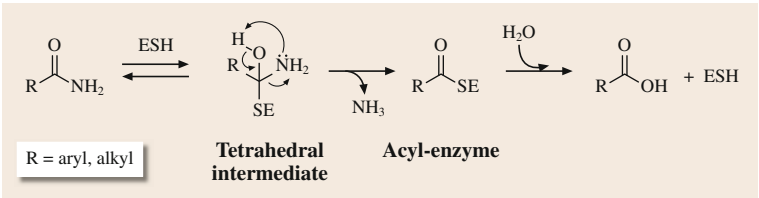

Fig. 28.12 Mechanism of catalysis of amide hydrolysis by amidases [28.33]

ported to act on heteroaromatic nitriles [28.29]. Like the nitrilases, the nitrile hydratases are also usually inducible. It is noteworthy that the metal ions Fe^{3+} and/or Co^{2+} are essential to their catalytic activities [28.16].

Amidases (EC 3.5.1.4)

The amidases are enzymes that catalyze the hydrolysis of amides to the corresponding carboxylic acids and ammonia. Analogously, amidases catalyze the biotransformation of amides to the corresponding hydroxamic acid in the presence of hydroxylamine (Fig. 28.11a,b) [28.16].

The steps of the reaction catalyzed by amidases are shown in Fig. 28.12:

i) The carbonyl group of the amide undergoes a nucleophilic attack by the enzyme, leading to formation of a tetrahedral intermediate.
ii) The tetrahedral intermediate is converted to the acyl-enzyme complex, releasing a molecule of ammonia.
iii) The carbonyl carbon of the acyl-enzyme complex undergoes nucleophilic attack by a water molecule, yielding carboxylic acid.

The amidases are involved in the metabolism of both prokaryotes and eukaryotes and can be divided into:

i) *Aliphatic amidases* that catalyze the hydrolysis only of short-chain aliphatic amides and that catalyze the hydrolysis of medium-chain aliphatic amides.
ii) *Arylamidases* that catalyze the hydrolysis of aromatic amides [28.33].

The amidases may also catalyze other reactions, such as ester hydrolysis, conversion of esters to hydroxamic acids, conversion of carboxylic acids to hydroxamic acids, and hydrolysis of isonicotinic acid hydrazide (Fig. 28.13a–d).

It is important to note that the majority of amidases are enantioselective and have been used in the synthesis of chiral carboxylic acids, by combination with the nitrile hydratases. Reactions catalyzed by enantioselective amidases have provided optically pure compounds of pharmaceutical importance such as amino acids and 2-arylpropionic acid [28.16].

Recently, a number of products that can be used as intermediates for pharmaceuticals, chemical additives in foods, and so on, have been obtained by enzymatic reactions. The enzymes that convert nitriles (nitrilases and/or nitrile hydratases and amidases) are potential catalysts for the production of carboxylic acids and amides of interest for industrial applications.

28.1.5 Application of Nitrilases, Nitrile Hydratase, and Amidases to Biocatalysis

Nitrilases, nitrile hydratases, and amidases are important biocatalysts in the fine chemicals and pharmaceuticals industry for their high specificity due to chemoselectivity, regioselectivity, and enantioselectivity. In addition, they are used in the detoxification of industrial waste and degradation of herbicides containing the cyano group [28.34].

Hydrolysis of Racemic Nitriles by Nitrilases

Chemoenzymatic resolution of *rac*-nitriles has been carried out with the aim of producing α-arylpropionic acids of *S*-configuration, such as ketoprofen, ibuprofen, and/or naproxen, which are widely used as anti-inflammatory drugs [28.12].

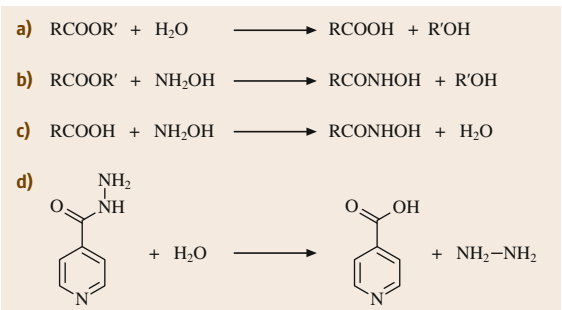

Fig. 28.13a–d Reactions catalyzed by amidases

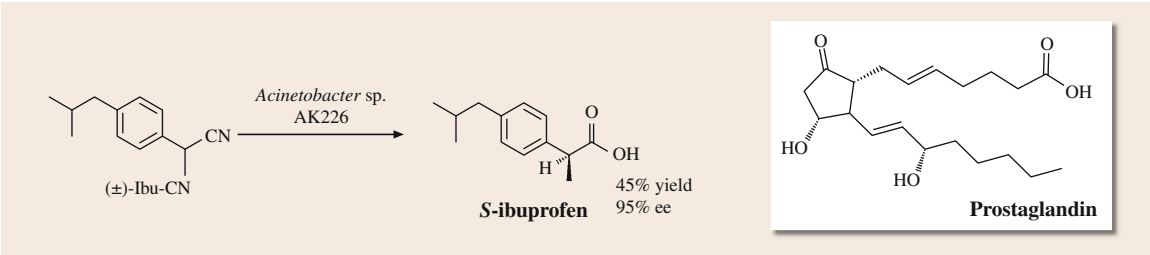

Fig. 28.14 Production of *S*-ibuprofen by the nitrilase of *Acinetobacter* sp. AK226

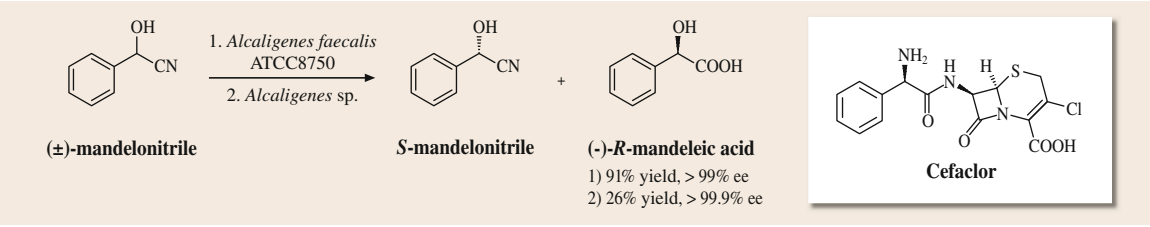

Fig. 28.15 Hydrolysis of (±)-mandelonitrile catalyzed by bacterial nitrilase

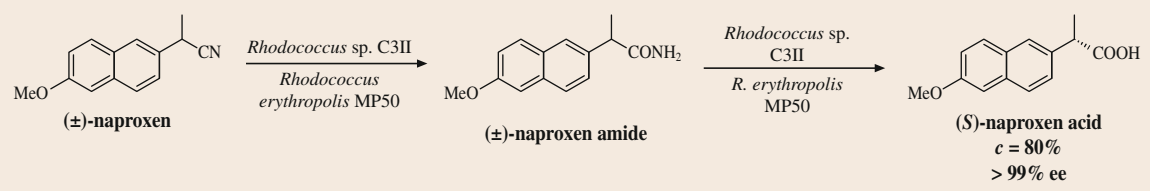

Fig. 28.16 Hydrolysis of the (±)-naproxen by *Rhodococcus* sp. C3II and *Rhodococcus erythropolis* MP50

The (+)-(*S*)-2-(4′-isobutylphenyl)propionic acid (*S*-ibuprofen) was produced by kinetic resolution of (±)-2-(4′-isobutylphenyl)propanonitrile (Ibu-CN) by *Acinetobacter* sp. AK226, with 95% of enantiomeric excess (ee) and 45% yield (Fig. 28.14) [28.35]. Reports have shown that *S*-ibuprofen is more active than *R*-ibuprofen in vitro inhibition of prostaglandin biosynthesis [28.36].

Another important commercial application of nitrilases is in the production of (-)-*R*-mandeleic acid by the bacteria *Alcaligenes faecalis* ATCC8750 (91% yield and > 99% ee) [28.34] and *Alcaligenes* sp. ECU0401 (26% yield and > 99.9% ee; Fig. 28.15) [28.37]. (-)-*R*-Mandeleic acid has wide application as an intermediate for the production of pharmaceutical products such as Cefaclor, a cephalosporin-type antibiotic [28.38].

Hydrolysis of Racemic Nitriles by Nitrile Hydratase

In general, nitrile hydratases are associated with amidases in living organisms and, in most cases, the formation of amides and optically pure acids is due to the higher enantioselectivity of amidases compared to nitrile hydratases. A number of acids and amides have been obtained by enzymatic methods; for example, *S*-naproxen was synthesized by *Rhodococcus* sp. C3II and *Rhodococcus erythropolis* MP50. The two bacterial strains, by combining nitrile hydratase and amidases, were able to convert the cyano group of the substrate into *S*-naproxen acid [(+)-(*S*)-2-(6-methoxynaphthalen-2-yl)propanoic acid] with an enantiomeric excess > 99% and conversion 80% (Fig. 28.16) [28.16].

Another interesting example is the enantioselective hydrolysis of (±)-1,4-benzodioxane-2-carbonitrile under mild conditions to (+)-(*S*)-1,4-benzodioxane-2-carboxylic acid (46% yield and 99% ee) and (-)-(*R*)-1,4-benzodioxane-2-amide (50% yield and 94% ee) by the bacterium *Rhodococcus* sp. AJ270 (Fig. 28.17) [28.16]. These compounds are important for the pharmaceutical industry, as intermediates in the synthesis of drugs [28.16]. (-)-(*S*)-1,4-Benzodioxane-2-carboxylic

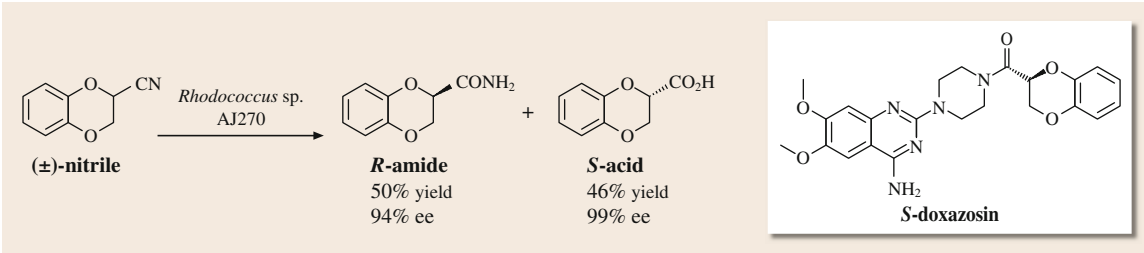

Fig. 28.17 Biotransformation of the (±)-1,4-benzodioxane-2-carbonitrile by *Rhodococcus* sp. AJ270

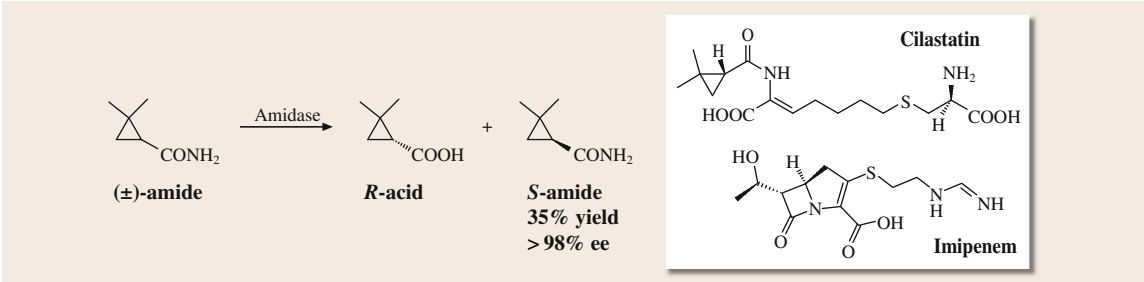

Fig. 28.18 Biotransformation of the (±)-2,2-dimethylcyclopropanecarboxamide by amidase from *Comomonas acidivorans*

acid is a chiral intermediate in the synthesis of *S*-doxazosin. (±)-Doxazosin is a drug produced by Pfizer named Canduran, indicated for the treatment of hypertension. *S*-enantiomer doxazosin has been shown to be effective in the treatment of benign prostatic hyperplasia [28.39].

Hydrolysis of Racemic Nitriles by Amidases

One example of industrial biotransformation catalyzed by the amidase from *Comomonas acidivorans* is the enzymatic resolution of (±)-2,2-dimethylcyclopropanecarboxamide yielding the (*S*)-isomer (35% yield and > 98% ee; Fig. 28.18) [28.40]. The *S*-isomer is used as an intermediate in the production of the antibiotic cilastatin, an inhibitor of renal dehydropeptidase. Cilastatin is commonly administered together with the antibiotic imipenem in a formulation named Tienam, indicated for the treatment of urinary tract infections [28.41]. This combination has the advantage of inhibiting the renal biotransformation of imipenem, making the treatment more effective [28.40].

Stereoselective amidases, isolated from bacterial cells, have been used in the kinetic resolution of racemic piperazine-2-carboxamide to the (*S*) and (*R*)-piperazine-2-carboxylic acids. The bacterial strain *Klebsiella terrigena* DSM 9174 catalyzed the biotransformation of (±)-piperazine-2-amide to (-)-(*S*)-piperazine-2-carboxylic acid (41% yield, 99.4% ee), while *Burkholderia* sp. DSM 9925 yielded the (+)-(*R*)-piperazine-2-carboxylic acid (22% yield and 99% ee; Fig. 28.19) [28.42].

The acids obtained belong to the class of non-proteinogenic amino acids and are used as precursors for numerous bioactive compounds [28.16]. For example, (-)-(*S*)-piperazine-2-carboxylic acid is an intermediate in the synthesis of Crixivan (Merk), a drug used in the treatment of HIV virus infections [28.42]. The biocatalytic synthesis of (-)-(*S*)-piperazine-2-carboxylic acid by *Klebsiella terrigena* DSM 9174 for commercial purposes was developed by Lonza AG.

Regioselective Hydrolysis of Dinitriles

Nishise et al. reported the synthesis of *trans*-4-cyanocyclohexane-1-carboxylic acid (*t*-MCC) from *trans*-1,4-dicyano cyclohexane by nitrilases of the bacterium *Acremonium* sp. (Fig. 28.20). *t*-MCC is an intermediate used in the synthesis of tranexamic acid (*trans*-4-aminomethyl-cyclohexane-1-carboxylic acid), which is a drug used to treat fetal hemorrhage [28.43].

A similar process is the regioselective biotransformation of adiponitrile to 5-cyanovaleric acid, which is used as an intermediate in the synthesis of the polymers

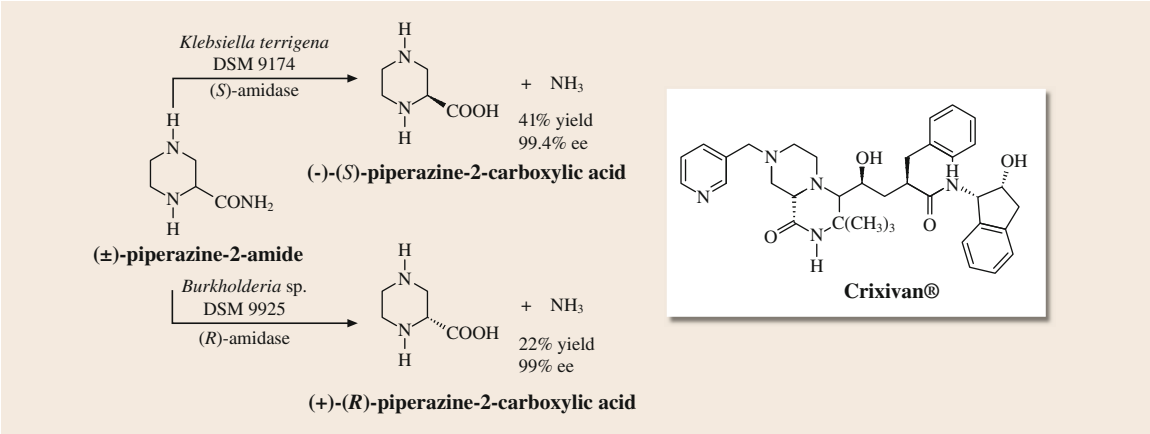

Fig. 28.19 Enantioselective hydrolysis of the (±)-piperazine-2-amide by bacterial amidases

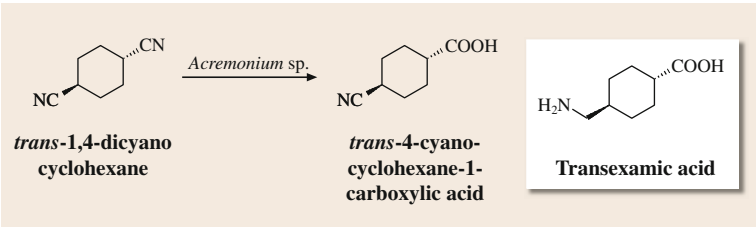

Fig. 28.20 Regioselective hydrolysis of the trans-1,4-dicyano cyclohexane by *Acremonium* sp.

nylon-6 e nylon-6,6. This reaction was catalyzed by nitrilases of the bacterium *Rhodococcus rhodochrous* K22 (Fig. 28.21) [28.14].

Desymmetrization of Dinitriles

One of the most important features of enzymes that metabolize nitriles is their ability selectively to convert one cyano group of a prochiral dinitrile; this reaction is very difficult to achieve by conventional chemical methods [28.14].

An example of enantioselective desymmetrization was the biotransformation of 3-hydroxyglutaronitrile to (*R*)-4-cyano-3-hydroxybutyric acid, catalyzed by the *R*-specific nitrilase BD9570, which was expressed in *Pseudomonas fluorescens*. This acid was obtained with enantiomeric excess ranging between 98.6–99.4%, and a conversion of approximately 99% (Fig. 28.22) [28.44]. (*R*)-4-Cyano-3-hydroxybutyric acid after esterification is used as an intermediate for the synthesis of Lipitor, a drug marketed by Pfizer to control cholesterol [28.20].

Desymmetrization of nitriles is not restricted to nitrilases. It can also be achieved with nitrile hydratases. For example, the transformation of 3-(benzyloxy)glutaronitrile to 3-(*S*)-(benzyloxy)pentanoic acid was catalyzed by the combined action of nitrile hydratase and amidases in *Brevibacterium* sp. B312 with 65% yield and 88% enantiomeric excess. 3-(Benzyloxy)pentanoic acid is an intermediate in the synthesis of the drug Lovastatin, used in the treatment of hypercholesterolemia and cardiovascular disease (Fig. 28.38) [28.45].

Chemoselective Hydrolysis of Nitriles

As for the performance of nitrile hydratases, two significant industrial applications are based on the bacteria *Rhodococcus rhodochrous* J1. More than 30 000 t/yr of acrylamide are produced by Nitto Chemical Industry Ltd. (Yokohama, Japan) from acrylonitrile. The reaction is extremely efficient, producing more than 7 kg of acrylamide per g cells in 99.97% conver-

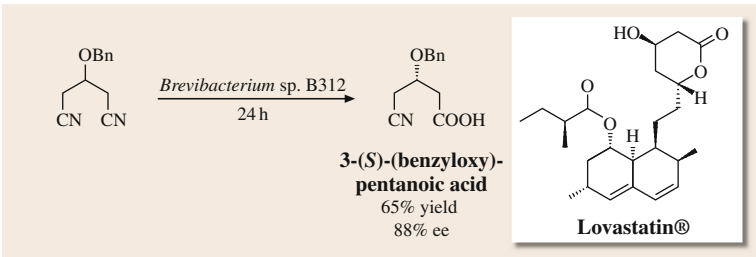

Fig. 28.23 Desymmetrization of the 3-benzyloxyglutaronitrile by *Brevibacterium* sp. B312

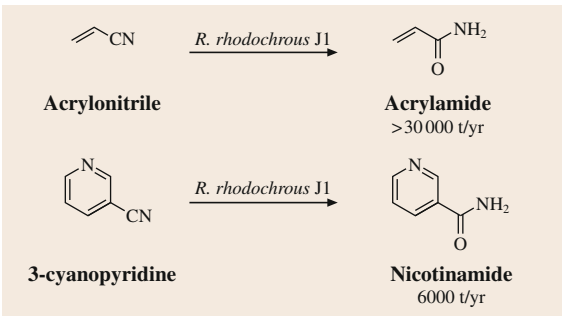

Fig. 28.24 Production of acrylamide and nicotinamide by nitrile hydratases from *Rhodococcus rhodochrous* J1

sion (Fig. 28.24). In addition to this bacterial strain, acrylamide was also produced by the bacteria *Pseudomonas chlororapis* and *Brevibacterium* sp., with > 99% yield [28.21, 22]. Acrylamide is an important chemical commodity for the synthesis of various polymers.

Another large-scale industrial process is the production of nicotinamide by the conversion of 3-cyanopyridine, which is marketed by Lonza. This process reaches 6000 t/year (Fig. 28.24). Nicotinamide is an essential nutrient in the diet of humans and animals. In contrast to the chemical process, the enzymatic process does not to form nicotinic acid as a by-product [28.12, 22].

The nitrile hydratase of *Rhodococcus rhodochrous* J1 was also effective in catalyzing the biotransformation of 4-cyanopyridine to isonicotinamide ($1.099\,g \cdot L^{-1}$), a precursor of isonicotinic acid hydrazide, a tuberculostatic agent (Fig. 28.25) [28.12, 46].

The bacterium *Rhodococcus rhodochrous* J1, induced by ε-caprolactam, activated its nitrilases to produce acrylic acid from acrylonitrile, providing $390\,g\,L^{-1}$ of the biotransformed compound (Fig. 28.26) [28.47]. Acrylic acid is a chemical commodity and the scale of this biotransformation exceeds 30 000 t/year [28.12]. Acrylic acid and its esters are used in paints, polymers, and paper [28.16].

The bacterium *Alcaligenes* sp. ECU0401 produced the glycolic acid (2-hydroxy-acetic acid) from glycolonitrile (2-hydroxy-acetonitrile) by the action of nitrilases, with a yield of 96.5% (Fig. 28.27). Gly-

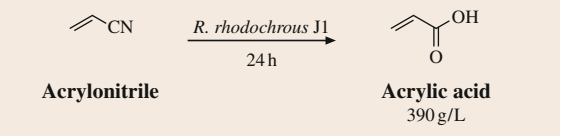

Fig. 28.26 Hydrolysis of acrylonitrile by *Rhodococcus rhodochrous* J1

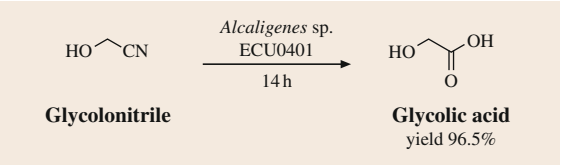

Fig. 28.27 Hydrolysis of glycolonitrile by *Alcaligenes* sp. ECU0401

colic acid has many applications in cosmetic products and is also an important ingredient in the processing of metals, automotive oil additives, and biodegradable polymers [28.48].

28.1.6 Biodegradation of Nitriles

Nitriles are highly toxic, carcinogenic, and mutagenic. Therefore, it is necessary to control the disposal of organonitriles into the environment and to monitor their presence there.

Typically, compounds such as acrylonitrile, acetonitrile, benzonitrile, and so on are widely used in laboratories and industry as solvents or as intermediates for pharmaceuticals (chiral blocks), plastics, synthetic rubber, and pesticides and herbicides, such as bromoxynil (3,5-dibromo-4-hydroxybenzonitrile), ioxynil (3,5-diiodo-4-hydroxybenzonitrile and dichlobenil (2,6-dichlorobenzonitrile; Fig. 28.28) [28.16].

Many experiments have been performed on the biodegradation of nitriles, harnessing the huge potential demonstrated by enzymes that convert the cyano group. For example, prolonged exposure to the herbicides bromoxynil and dichlorobenil (Fig. 28.28) may result in symptoms such as weight loss, vomiting, fever, or headache [28.14]. Thus, enzymes that metabolize nitriles may be used to prevent these herbicides entering the food chain and causing harm to human health. The herbicides bromoxynil, ioxynil, and dichlobenil were degraded by the soil bacterium *Agrobacterium radiobacter*, by means of its nitrile hydratase. The efficacy of degradation was enhanced by adding iron or cobalt ions to the culture medium [28.49, 50].

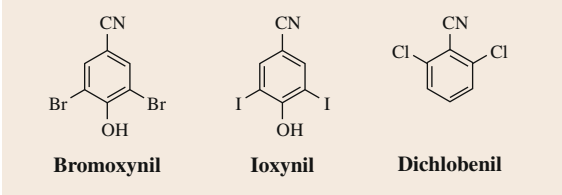

Fig. 28.28 Examples of herbicides containing the cyano group

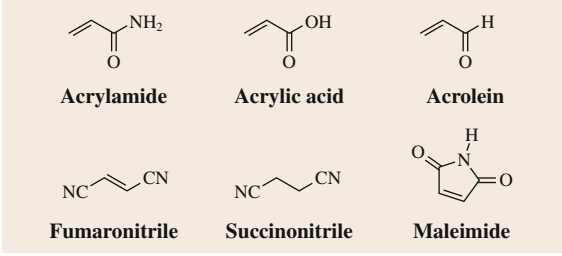

Fig. 28.29 Structures of the compounds present in industrial waste waters from acrylonitrile synthesis

The effluents from the synthesis of acrylonitrile contain acrylamide, acrylic acid, acrolein, cyanopyridine, fumaronitrile, succinonitrile, and maleimide, in addition to acrylonitrile (Fig. 28.29). *Wyatt* and *Knowles* [28.51] performed a study on degradation of acrylonitrile in industrial wastewater by microorganisms. A mixed culture of bacteria was grown in the presence of industrial effluents from the synthesis of acrylonitrile. In this study was observed that all components of the residual mixture were degraded by the mixed bacterial culture.

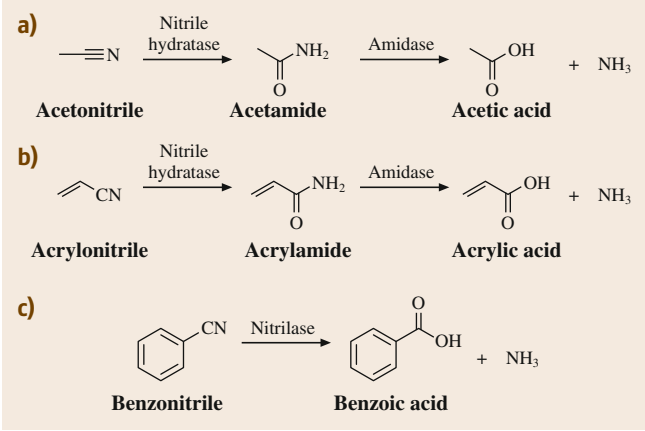

Fig. 28.30a–c Biodegradation of nitriles by a consortium of microorganisms

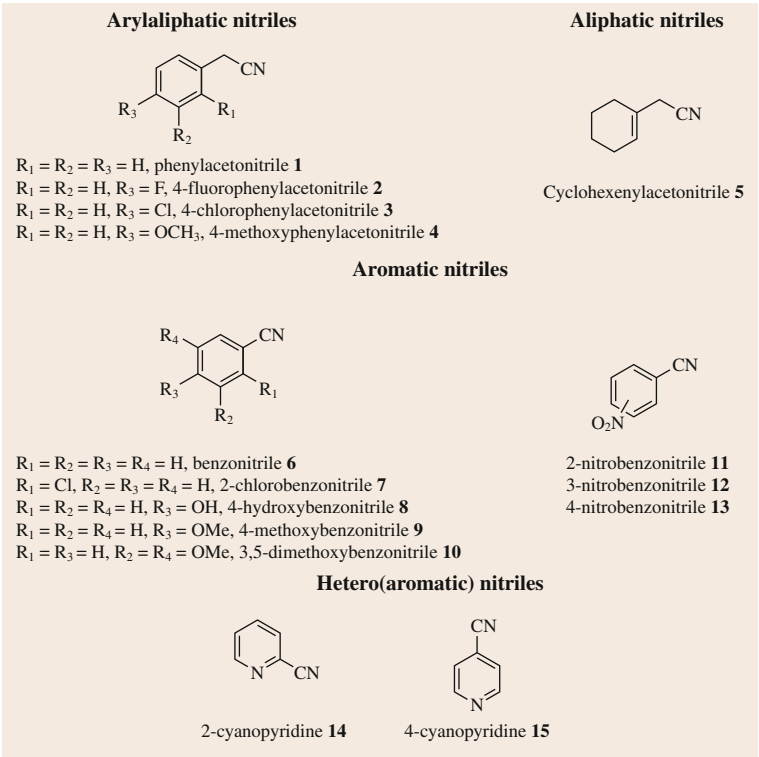

Fig. 28.31 Organonitriles selected for biotransformation by marine fungi

Recently, a process for microbial degradation of organonitriles (acetonitrile, benzonitrile, and acrylonitrile) in waste water from the pharmaceutical industry was assessed [28.16]. The degradation of these nitriles was investigated with microorganisms present in activated sludge in pharmaceutical the sewage water waste, whose growth was adapted in the presence of acetonitrile as the sole source of carbon and nitrogen [28.52]. The biodegradation of acetonitrile and acrylonitrile to their corresponding carboxylic acids occurred in two steps. Initially, the corresponding amides (acetamide and acrylamide) were obtained, then the acrylic and acetic acids, both reactions forming ammonia. On the other hand, biodegradation of benzonitrile occurred in a single step, with the direct production of benzoic acid and ammonia (Fig. 28.30).

The results obtained by *Li* et al. showed that irrespective of the substrate, a mixed culture of these microorganisms can develop distinct pathways of degradation, either via the nitrile hydratase followed by amidase or via nitrilase [28.52].

In most studies reported in the literature, the enzymatic hydrolysis of nitriles is carried out by microorganisms (fungi, yeasts, and bacteria) or plants. Recently, we reported the biotransformation of the phenylacetonitrile to 2-(2-hydroxyphenyl)acetic acid by marine fungi. This compound is often used in the pharmaceutical industry as an intermediate in the preparation of some biologically active products, such as antihypertensives [28.53, 54].

In view of the shortage of studies on biotransformation of organonitriles by marine microorganisms, in this chapter we aim to describe the methodology applied in our laboratory to select marine fungi capable of biotransforming nitriles. The methods will be described in detail and then the results achieved. The types of nitriles selected for enzymatic hydrolysis reactions by marine fungi are shown in Fig. 28.31.

28.2 Experimental Methods

28.2.1 Isolation, Identification, and Preparation of Stock Cultures of Marine Fungi

The fungal strains *Aspergillus sydowii* CBMAI 933 and *Penicillium miczynskii* CBMAI 930 were isolated from the marine sponge *Geodia corticostylifera*. *A. sydowii* CBMAI 934, *A. sydowii* CBMAI 935, *Bionectria* sp. CBMAI 936, and *P. raistrickii* CBMAI 931 were isolated from marine sponge *Chelonaplysilla erecta*. *A. sydowii* CBMAI 1241, *P. raistrickii* CBMAI 1235, *P. decaturense* CBMAI 1234, and *Cladosporium* sp. CBMAI 1237 were isolated from marine sponge *Dragmacidon reticulate*. *P. oxalicum* CBMAI 1185 and *P. citrinum* CBMAI 1186 were isolated from the marine alga *Caulerpa* sp. The sponges and algae were collected in the South Atlantic Ocean off the northern coast of the state of São Paulo at São Sebastião, Brazil. The fungi were identified by both conventional and molecular methods at the Chemical, Biological and Agricultural Pluridisciplinary Research Center at UNICAMP, São Paulo, Brazil (http://www.cpqba.unicamp.br/). Stock cultures of the fungi were stored on a solid culture medium [K_2HPO_4 (1.0 g L^{-1}), $MgSO_4 \cdot 7\ H_2O$ (0.5 g L^{-1}), KCl (0.5 g L^{-1}), $FeSO_4 \cdot 7\ H_2O$ (0.01 g L^{-1}), $CoCl_2 \cdot 6H_2O$ (0.001 g L^{-1}), $ZnSO_4 \cdot 7\ H_2O$ (0.0067 g L^{-1})], glucose (15.0 g L^{-1}), phenylacetonitrile **1** (0.2, 0.4 or 0.6 g L^{-1}) and agar (15.0 g L^{-1}) in Petri dishes maintained at 4 °C in the refrigerator.

28.2.2 Cultivation of Marine Fungi on a Solid Medium in the Presence of Phenylacetonitrile 1

Marine fungi were cultured on Petri dishes (10 × 1 cm) containing solid mineral culture medium (glucose) supplemented with phenylacetonitrile **1** 5.0 µL (0.04 mmol), 10.0 µL (0.08 mmol), 15.0 µL (0.12 mmol), and 20.0 µL (0.17 mmol) per plate. Phenylacetonitrile **1** was added to the agar at 40–45 °C and the homogenous mixture was poured into Petri dishes. Fungal mycelia were inoculated to the surfaces of the agar plates with an inoculating loop. Next, the fungi were incubated at 32 °C, and the tolerance to phenylacetonitrile **1** was estimated by the size of the colony formed on the surface of the plates after 8 days. Control plates of mineral medium and glucose were prepared, without the addition of phenylacetonitrile **1**.

28.2.3 Biotransformation of Phenylacetonitrile 1 by Marine Fungi in a Liquid Medium

Small slices of solid medium (0.5 × 0.5 cm) bearing the mycelia of eight marine fungal strains were cut from the solid stock cultures and used to inoculate 100.0 mL of liquid culture mineral medium containing 15.0 g glucose in 250 mL Erlenmeyer flasks. The cultures were incubated at 32 °C on a rotary shaker (124 rpm), with various volumes of phenylacetonitrile **1** added to the medium (20.0 µL, 0.17 mmol; 40.0 µL, 0.34 mmol; 60.0 µL, 0.52 mmol; Table 28.1). After the growth of the strains in liquid medium for 8 days, the mycelia were filtered on a Buchner funnel and the mycelial dry weight was determined after drying at 70 °C for 24 h. The results are summarized in Table 28.2. The biotransformation of phenylacetonitrile **1** was monitored every 2 days by collecting 2.0 mL samples, which were extracted by stirring with ethyl acetate (2.0 mL), centrifuged (6000 rpm, 6 min), and analyzed by analyzed by GC-FID (Gas Chromatography-Flame Ionization Detector) and GC-MS (Gas Chromatography-Mass Spectrometry) (Table 28.3).

28.2.4 Isolation of 2-Hydroxyphenylacetic Acid 1a from Culture Media Produced by *A. sydowii* CBMAI 934

An additional experiment was performed with the fungus *A. sydowii* CBMAI 934 for isolation and purification of the biotransformed product. Biocatalytic reactions were carried out for 96 h in quintuplicate, with 60.0 µL (0.52 mmol) of phenylacetonitrile **1** in 100.0 mL medium per Erlenmeyer flask. Next, another 60.0 µL of phenylacetonitrile **1** was added and the reactions were maintained on the orbital shaker (124 rpm, 32 °C) for a further 96 h. The reaction mixtures were filtered, the combined filtrates were extracted with EtOAc (3 × 50.0 mL), and the organic phase was dried over anhydrous Na_2SO_4, filtered and evaporated under vacuum. The mycelia (16.0 g) were transferred to an Erlenmeyer and stirred for 30 min with 50.0 mL of distilled water. Next, 50.0 mL of EtOAc was added, and the mixture was stirred for 30 min. The mycelia were filtered off, and the filtrate was extracted with ethyl acetate (3 × 50.0 mL). The organic phase was dried over anhydrous Na_2SO_4, filtered, and the solvent evaporated

under vacuum. The extracts obtained were analyzed by GC-FID and GC-MS. The extracts obtained from the filtered medium and the mycelia were combined and purified by flash column chromatography (CC) over silica gel to yield 2-hydroxyphenylacetic acid **1a** (51% yield). The spectroscopic data of the isolated 2-hydroxyphenylacetic acid **1a** were in agreement with those reported in the literature [28.55].

28.2.5 Biotransformation and Isolation of Phenylacetonitrile Derivatives 2–4 by *A. sydowii* CBMAI 934

Small slices of solid medium (0.5 × 0.5 cm) bearing mycelia of the fungal strain were cut from the solid stock cultures and used to inoculate 100.0 mL of liquid culture mineral medium with glucose (15.0 g L^{-1}), containing 60 µL of phenylacetonitrile **1** (0.52 mmol), in 250 mL Erlenmeyer flasks. The marine fungus was grown at 32 °C on a rotary shaker (124 rpm). After growth of the strain in liquid medium for 96 h, the following nitriles were added separately to each experiment: 4-fluorophenylacetonitrile **2** (20.0 µL (0.17 mmol), 40 µL (0.34 mmol), 60 µL (0.51 mmol)), 4-chlorophenylacetonitrile **3** (20.0 µL (0.16 mmol), 40.0 µL (0.32 mmol), 60.0 µL (0.48 mmol)), and 4-methoxyphenylacetonitrile **4** (20.0 µL (0.15 mmol), 40.0 µL (0.30 mmol), 60.0 µL (0.45 mmol)). The biotransformations of nitriles **2–4** were monitored every 24 h by collecting

2.0 mL of samples, which were extracted by stirring with EtOAc (Ethyl Acetate) (2.0 mL) and then centrifuged (6, 000 rpm, 6 min) and analyzed by GC-FID (Fig. 28.32).

28.2.6 Biotransformation of Cyclohexenylacetonitrile 5 by *A. sydowii* CBMAI 934

Initially, the fungal strain was cultured as described in Sect. 28.2.5. After the initial growth of the mycelia, cyclohexenylacetonitrile **5** (20.0 µL (0.16 mmol), 40.0 µL (0.32 mmol), and 60.0 µL (0.48 mmol)) was added to the flasks. In a second experiment, after fungal growth as in Sect. 28.2.5, the mycelia were pooled (3 in 1) and transferred to a 1 L Erlenmeyer flask, and then further cyclohexenylacetonitrile **5** (60.0 µL, 0.48 mmol) was added. The biotransformation of nitrile **5** was monitored every 24 h for 96 h by collecting 2.0 mL samples, which were extracted by stirring with ethyl acetate (2.0 mL), centrifuged (6000 rpm, 6 min) and analyzed by GC-FID (Fig. 28.33).

28.2.7 Biotransformation of Aromatic Nitriles

After the growth of the fungal strain in 100.0 mL liquid culture mineral medium supplemented with glucose (15.0 g/L) and phenylacetonitrile **1** (60.0 µL, 0.52 mmol) for 96 h in 250 mL Erlenmeyer flasks, the respective aromatic nitriles were added: benzonitrile **6** (20.0 µL, 0.19 mmol), 2-chlorobenzonitrile **7** (20.0mg, 0.15 mmol), 4-hydroxybenzonitrile **8** (20.0 mg, 0.17 mmol), 4-methoxybenzonitrile **9** (20.0mg, 0.20 mmol), 3,5-dimethoxybenzonitrile **10** (20.0mg, 0.12 mmol), 2-nitrobenzonitrile **11** (20.0mg, 0.14 mmol), 3-nitrobenzonitrile **12** (20.0mg, 0.13 mmol) and 4-nitrobenzonitrile **13** (20.0mg, 0.14 mmol). The reactions were monitored every 24 h by collecting 2.0 mL aliquots, which were extracted by stirring with EtOAc (2.0 mL), fol-

lowed by centrifugation (6000 rpm, 6 min), and analyzed by GC-FID.

28.2.8 Growth of Marine Fungus *A. sydowii* CBMAI 934 in the Presence of 2-Cyanopyridine 14 in Solid and Liquid Media

Marine fungus was cultured on plates (10 cm × 1 cm) of solid culture mineral medium, with glucose (15.0 g L^{-1}) and supplemented with 5.0 µL 2-cyanopyridine **14** (0.052 mmol) per plate as follows. The 2-cyanopyridine **14** was added to the agar at 40–45 °C and the homogenous mixture was harvested in Petri dishes. Fungal mycelium was transferred to the surface of the agar with an inoculating loop, and the plates were incubated at 32 °C for 8 days. The tolerance to 2-cyanopyridine **14** was estimated by the size of the colony formed on the surface of the plate after 8 days. Next, small slices of solid medium (0.5 × 0.5 cm) bearing mycelium of the marine fungal strain were cut from the solid stock cultures and used to inoculate 100.0 mL of liquid culture mineral medium containing glucose (15.0 g L^{-1}) and 2-cyanopyridine **14** (20.0 µL, 0.21 mmol) in a 250 mL Erlenmeyer flask. The marine fungus was grown at 32 °C on a rotary shaker (124 rpm) for 96 h. The reactions were monitored every 2 days by collecting 2.0 mL samples, which were extracted by stirring with EtOAc (2.0 mL), followed by centrifugation (6000 rpm, 6 min), and analyzed by GC-FID.

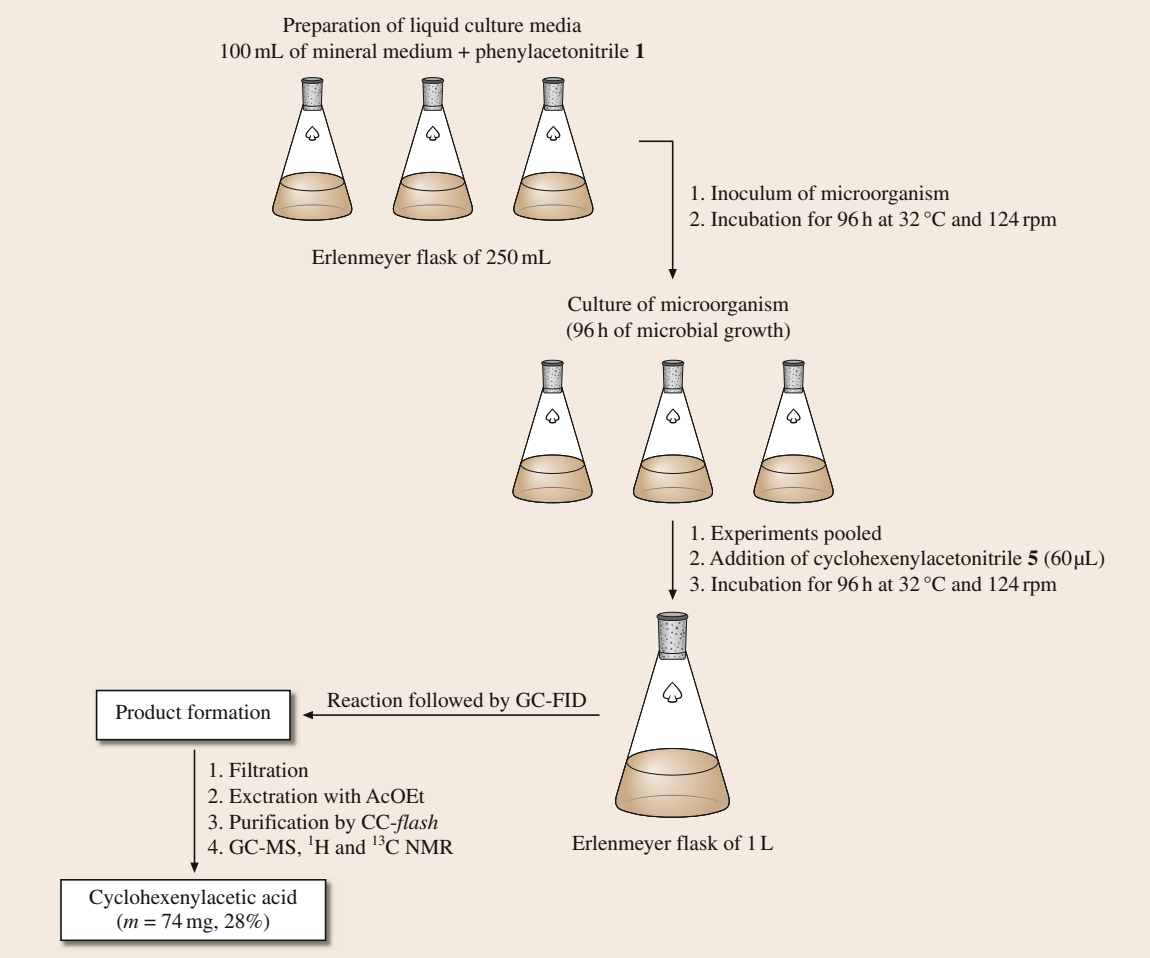

Fig. 28.33 Biotransformation of cyclohexenylacetonitrile **5** by *A. sydowii* CBMAI 934

28.2.9 Biotransformation of Benzonitrile 6 and 2-Cyanopyridine 14

Two different experiments were carried out with these nitriles. In the first, after the fungus had grown in 100.0 mL of the liquid culture mineral medium in Erlenmeyer flasks (250 mL) for 96 h in the presence of glucose (15.0 g L^{-1}) and phenylacetonitrile **1** (60.0 µL, 0.52 mmol), benzonitrile **6** (20.0 µL, 0.19 mmol) and 2-cyanopyridine **14** (20.0 µL, 0.21 mmol) were added simultaneously. In the second experiment, after the fungal growth in the presence of glucose (15.0 g L^{-1}) and phenylacetonitrile **1** (60.0 µL, 0.52 mmol) for 96 h, 2-cyanopyridine **14** (20.0 µL, 0.21 mmol) alone was added to the liquid culture mineral medium. The reactions were monitored every 24 h by collecting 2.0 mL samples, which were extracted by stirring with EtOAc (2.0 mL), centrifuged (6000 rpm, 6 min), and analyzed by GC-FID and GC-MS.

28.3 Results and Discussion

28.3.1 Screening of Marine Fungi with Phenylacetonitrile 1 in Solid and Liquid Media

Initially, the biotransformation of phenylacetonitrile **1** by marine fungi was conducted on solid culture media. The microorganisms were grown on plates of a mineral medium supplemented with glucose and phenylacetonitrile **1**, as carbon and nitrogen sources, respectively. The growth of the fungal colonies was observed on the surface of agar containing phenylacetonitrile **1** (5.0 μL, 0.04 mmol) per plate at 32 °C for 8 days. Table 28.1 summarizes the results of the qualitative growth test of 12 marine fungi on the solid culture media in the presence of phenylacetonitrile **1**. Eight strains exhibited good colony formation, while four isolates (*P. miczynskii* CBMAI 930, *P. oxalicum* CBMAI 1185, *P. citrinum* CBMAI 1186, and *Cladosporium* sp. CBMAI 1237) did not grow under these conditions (Table 28.1).

Control experiments were conducted on the 12 strains by inoculating the mineral agar medium supplemented with glucose and without addition of phenylacetonitrile **1**. In these experiments, more of the marine fungi grew on the agar. This result was important for the selection of marine fungi with a potential for biotransformation of phenylacetonitrile **1**, since there strains used **1** effectively as a nitrogen source. The conditions described here were responsible for the excellent results obtained in the biotransformation of phenylacetonitrile **1**. The marine fungi cultured with phenylacetonitrile **1** at a concentration of 5.0 μL per plate were evaluated with 10.0 μL (0.08 mmol), 15.0 μL (0.12 mmol), and 20.0 μL (0.17 mmol) per plate (Table 28.1). Several strains showed better growth at intermediate concentrations of phenylacetonitrile **1** (10.0 and 15.0 μL), while the growth of the strains of *Penicillium* remained unchanged from 5.0 to 15.0 μL (Table 28.1). These results showed that increasing the concentration of phenylacetonitrile **1** as the sole nitrogen source favored the growth of the marine fungi. However, all the microorganisms were inhibited at 20.0 μL of phenylacetonitrile **1** per plate (Fig. 28.34).

In order to investigate the biotransformation of phenylacetonitrile **1**, experiments were conducted in liquid mineral medium in the presence and absence of nitrile **1** (Table 28.2).

To confirm the biotransformation of the phenylacetonitrile **1**, aliquots of liquid medium were collected every 24 h, extracted, and analyzed by GC-FID. The chromatograms showed a product peak, with a retention time of 10.4 min, with a total consumption of phenylacetonitrile **1** at 96 h of reaction (Fig. 28.35). However, no biotransformation of nitrile **1** occurred in the malt extract medium, and the added nitrile was recovered unchanged and in quantitative yield. In conclusion, the marine fungi catalyzed the biotransformation of phenylacetonitrile **1** to 2-hydroxyphenylacetic acid **1a**, only when previously cultured in a liquid mineral medium. The marine fungi cultured in the liquid mineral medium in the absence of the nitrile showed no biotransformation of the nitrile added later. When the fungi were cultured under nutrient-rich conditions, as in 2% malt

medium, the enzymes capable of the biotransforming phenylacetonitrile **1** were probably not active. Thus, enzymes capable of hydrolyzing the cyano group present in the marine fungi are probably inducible enzymes, which require an inducer (such as nitrile **1**) in the growth medium of the microorganism.

For the isolation and characterization of 2-hydroxyphenylacetic acid (**1a**), experiments were carried out in quintuplicate in a liquid culture medium inoculated with *A. sydowii* CBMAI 934. This fungus showed favorable growth on the Petri plate within 8 days and in liquid culture, and compared to other fungi adapted to growth in a mineral medium supplemented with glucose and phenylacetonitrile **1**.

Initially, phenylacetonitrile **1** (60.0 µL, 0.52 mmol) was added to each flask, and the fungus was inoculated and incubated on a rotating orbital shaker platform (96 h, 124 rpm, 32 °C). Next, a further 60.0 µL of phenylacetonitrile **1** was added per Erlenmeyer flask, and the reactions were maintained in the rotary shaker (96 h, 124 rpm, 32 °C). The mycelia were harvested by filtration and the extract obtained was purified. The product was identified and characterized as 2-hydroxyphenylacetic acid **1a** by NMR (Nuclear Magnetic Resonance), IR (Infrared Spectroscopy) and HRMS (High Resolution Mass Spectrometry) analyses [28.53].

The production of 2-hydroxyphenylacetic acid **1a** from phenylacetonitrile **1** by marine fungi involved a sequence of enzymatic reactions. In this case, the fungi cultured in the presence of phenylacetonitrile **1**, in a liquid mineral medium, developed an efficient enzy-

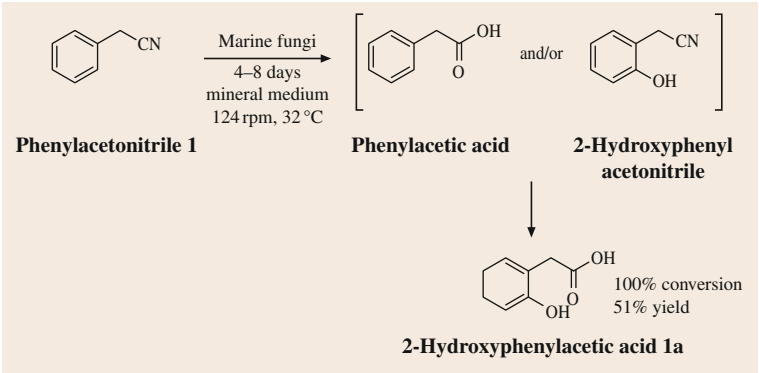

Fig. 28.36 Possible pathway for the biotransformation of phenylacetonitrile **1** to 2-hydroxyphenylacetic acid **1a** by induced marine fungi in liquid medium containing mineral salts, glucose, and phenylacetonitrile **1** (after [28.53])

matic pathway to produce 2-hydroxyphenylacetic acid **1a** (Fig. 28.36). Two pathways are possible: phenylacetonitrile **1** may be hydrolyzed to the carboxylic acid, after which enzymatic hydroxylation occurs at the *ortho* position of the aromatic ring, leading to 2-hydroxyphenylacetic acid **1a**. In an alternative route, the hydroxylation could occur first and subsequently the hydrolysis of the nitrile group. Intermediate compounds such as phenylacetic acid or 2-hydroxyphenylacetonitrile were not observed (Fig. 28.36).

Possibly, the phenylacetonitrile **1** is first hydrolyzed to the corresponding carboxylic acid by a nitrilase and/or nitrile hydratase followed by amidase. The phenylacetic acid obtained may then be hydroxylated regioselectively at the *ortho* position by a mono-oxygenase providing 2-hydroxyphenylacetic acid **1a**. *Mason* et al. observed that mono-oxygenases are often involved in hydroxylation of aromatic rings [28.56].

Selective hydroxylation of aromatic compounds catalyzed by enzymes is of great interest to the pharmaceutical and agrochemical industries [28.57]. Recently, a pathway for the total degradation of phenylacetonitrile **1** by the yeast *Exophiala oligosperma* R1 was investigated and two key intermediates were

found, phenylacetic acid and 2-hydroxyphenylacetic acid **1a** [28.58, 59]. This type of reaction catalyzed by microorganisms in a single step is a promising method to synthesize products of interest under mild conditions. 2-Hydroxyphenylacetic acid **1a** is often used in the pharmaceutical industry as an intermediate in the preparation of some biologically active products, such as antihypertensives [28.54].

28.3.2 Biotransformation of Phenylacetonitrile Derivatives 2–4 by the Marine Fungus *A. sydowii* CBMAI 934

Selective biotransformations of the phenylacetonitrile derivatives, 4-fluorophenylacetonitrile **2**, 4-chlorophenylacetonitrile **3**, and 4-methoxyphenylacetonitrile **4**, as well as cyclohexenylacetonitrile **5**, which contains the nitrile group linked to an sp^3 carbon atom, were investigated in the presence of *A. sydowii* CBMAI 934 (Tables 28.3 and 28.4). The aim of this experiment was to test whole mycelia of this fungus, to assess its behavior with arylaliphatic and aliphatic nitriles, so as to catalyze the biotransformation of this class of compounds. The nitrile-converting enzyme activity was first induced in *A. sydowii* CBMAI 934 by phenylacetonitrile **1**, in solid and liquid mineral media [28.53].

The nitriles **2** and **3** were completely converted into carboxylic acids **2a** and **3a** (20.0, 40.0, and 60.0 µL nitrile per reaction) in 24 h, after total conversion of phenylacetonitrile **1** (which took 96 h), while nitrile **4**

Conditions of GC-FID analysis: $T_i = 120\,^{\circ}C$ (1 min), $T_f = 210\,^{\circ}C$ (5 min), $r = 10\,^{\circ}C/min$, $t_c = 15$ min

was converted into **4a** in 96 h (20.0, 40.0, and 60.0 μL nitrile per reaction; Table 28.3). GC-FID analyses of the reactions with nitriles **2–4** are shown in Figs. 28.37–28.39.

The carboxylic acids **2a–4a** were obtained at high conversions ($c = 100\%$), while the carboxylic acid **5a** was obtained in lower conversion. The phenylacetonitrile-induced reaction produced significant amounts of carboxylic acids **2a–5a** from nitriles **2–5**.

From the data obtained in these studies and previous work published by the authors, we conclude that the nitrile-hydrolyzing activities of marine fungus *A. sydowii* CBMAI 934 may be applied to in a variety of phenylacetonitrile derivatives. Biotransformation of organonitriles by filamentous fungi is not easily achieved, but by selective screening and induction, new biocatalysts can be obtained that provide effective reactions with excellent yields. These

reactions are eco-friendly and sustainable, as they are carried out in an aqueous medium, at near neutral pH and mild temperatures, in the absence of oxidizing and hazardous reagents. Conversely, the chemical hydrolysis of nitriles to carboxylic acids requires severe conditions, such as strong bases, acids, and/or high temperatures, producing unwanted by-products and/or appreciable amounts of inorganic waste [28.17].

In order to widen the applicability of the methodology developed here by selection of the fungus *A. sydowii* CBMAI 934 and induction by phenylacetonitrile **1**, we decided to test another substrate containing a cyano group attached to an sp^3 carbon atom, but without an aromatic ring. For this test, cyclohexenylacetonitrile **5** was selected.

28.3.3 Biotransformation of Cyclohexenylacetonitrile 5 by the Marine Fungus *A. sydowii* CBMAI 934

Initially, the nitrile **5** was biotransformed at the concentrations of 20.0, 40.0, and 60.0 µL per reaction flask, but at low conversion rates. The best conversion of this nitrile was achieved when the three mycelial cultures were pooled in a 1 L flask and then a further 60 µL of the nitrile was added (Sect. 28.2.6; Table 28.4, Fig. 28.40). Thus, it was possible to obtain an isolated

yield of the biotransformed product, the cyclohexenylacetic acid **5a** (28%). We conclude that the marine fungus *A. sydowii* CBMAI 934 induced by phenylacetonitrile **1** in a mineral medium was also effective in transforming a nitrile group linked to a non-aromatic sp^3 carbon atom.

28.3.4 Biotransformation of Aromatic and Hetero(aromatic) Nitriles by the Marine Fungus *A. sydowii* CBMAI 934

To observe the behavior of the cyano group connected directly to the aromatic ring, experiments were carried out on eight aromatic nitriles: benzonitrile **6**, 2-chlorobenzonitrile **7**, 4-hydroxybenzonitrile **8**, 4-methoxybenzonitrile **9**, 3,5-dimethoxybenzonitrile **10**, 2-nitrobenzonitrile **11**, 3-nitrobenzonitrile **12**, and 4-nitrobenzonitrile **13**. In these tests, no biotransformation of any these aromatic nitriles occurred with the phenylacetonitrile-induced by fungus *A. sydowii* CBMAI 934.

In order to extend the application of the mycelium of the fungus *A. sydowii* CBMAI 934 induced by the presence of phenylacetonitrile **1**, the biotransformation reaction was performed in a mixture of benzonitrile **6** and 2-cyanopyridine **14** (Table 28.5). Surprisingly, all three substrates were biotransformed. Phenylacetonitrile **1** was converted to 2-hydroxyphenylacetic acid **1a** and 2-cyanopyridine **9** to 2-pyridinecarboxamide **14a** (Fig. 28.41). Benzonitrile **10** was possibly catalyzed to benzoic acid, but it was not possible to identify this reaction product.

Šnajdrová et al. reported that the benzonitrile **6** was the best substrate for biotransformation to its corresponding carboxylic acid; however, the benzoic acid formed was consumed by the fungus *Aspergillus niger* during the reaction [28.60]. Interestingly, benzonitrile **6** was biotransformed by *A. sydowii* CBMAI 934 in the presence of phenylacetonitrile **1** and 2-cyanopyridine **14**, whereas this biotransformation in the presence of phenylacetonitrile **1** alone was not possible.

In part, our results with the fungus *A. sydowii* CBMAI 934 corroborate studies performed by *Martínková* et al. that confirmed that 2-cyanopyridine **14** may act as a universal inducer in biotransformations of aromatic nitriles by filamentous fungi [28.30]. In our case, both phenylacetonitrile **1** and 2-cyanopyridine **14** may have acted as inducers in the biotransformation of benzonitrile **6**.

Another reaction was carried out on 2-cyanopyridine **14**, in the absence of benzonitrile **6**, which confirmed that phenylacetonitrile **1** induced the biotransformation of 2-cyanopyridine **14** (Fig. 28.42, Table 28.6).

The biotransformation of 2-cyanopyridine **14** was confirmed by comparative analysis with the synthetic standard in GC-FID (Figs. 28.41–28.42) and by analysis in GC-MS (Fig. 28.43).

Additionally, in a reaction carried out with the fungus *A. sydowii* CBMAI 934, it was previously grown on agar plates for 8 days in the presence of 2-cyanopyridine **14** (5.0 µL, 0.052 mmol per plate) which restricted growth on the plate. However, without phenylacetonitrile **1** the biotransformation of the 2-cyanopyridine **14** in liquid medium was not observed. The 2-cyanopyridine **14** remained in the reaction medium.

Thus, the phenylacetonitrile **1** was essential to the biotransformation of 2-cyanopyridine **14** to 2-pyridinecarboxamide **14a** and, under in these conditions the marine fungus *A. sydowii* CBMAI 934 demonstrated its ability to hydrolyze, of hetero(aromatic) nitriles.

Thus, we conclude that the selective biotransformation by fungus *A. sydowii* CBMAI 934 induced with phenylacetonitrile **1** may be used to hydrolyze arylaliphatic **1-4**, aliphatic **5**, and hetero(aromatic) **14** nitriles.

28.4 Conclusion

By screening 12 strains of marine fungi on solid mineral medium supplemented with glucose and phenylacetonitrile **1**, as the only nitrogen source, it was possible to select 8 of these strains, all of which showed good growth in liquid mineral medium in the presence of 20.0, 40.0, and 60.0 µL phenylacetonitrile **1**. In control experiments (without phenylacetonitrile) there was no microbial growth, demonstrating the ability of phenylacetonitrile **1** to induce the growth of these microorganisms, acting as the sole nitrogen source.

The phenylacetonitrile **1** was biotransformed to 2-hydroxyphenylacetic acid **1a**, showing that the fungi selected had the potential to biotransform derivatives of phenylacetonitrile **1**.

The direct biotransformation of nitriles **2**–**5** to the corresponding carboxylic acids **2a**–**5a** suggests the en-

zymatic route of the biotransformation of phenylacetonitrile **1**. First came the hydrolysis of the nitrile group and later, hydroxylation (insertion of hydroxyl in the *ortho* position of the aromatic ring), because the corresponding carboxylic acids **2a**–**5a** were produced only by hydrolysis of the cyano group. The biotransformation of nitriles is not trivial, and here we describe an efficient method for the production of phenylacetic acid derivatives under mild and environmentally-friendly conditions.

The induced biotransformation of specific nitrile groups by whole mycelia of the marine fungus *A. sydowii* CBMAI 934 was highly effective, using an eco-friendly methodology. The enzymes produced by this marine fungus showed substrate specificities typical of arylaliphatic and aliphatic nitrilases and hereto (aromatic) nitrile hydratases. The enzymes present in this catalyst system of the fungus *A. sydowii* CBMAI 934 exhibited activity only on addition of the inducer, indicating that these enzymes are constructive. The biotransformation of nitriles **1–5**, containing a cyano group attached to an sp^3 carbon atom, to the corresponding carboxylic acids **1a–5a** was achieved with good yields. The marine fungus *A. sydowii* CBMAI 934 is thus a promising biocatalyst for the preparation of important arylaliphatic and aliphatic carboxylic acids.

29. Drugs and Leads from the Ocean Through Biotechnology

José de Jesús Paniagua-Michel, Jorge Olmos-Soto, Eduardo Morales-Guerrero

The ocean's uniqueness represents an excellent source of resources and inspiration of diverse marine natural products with novel chemical entities and leads for the development of pharmaceutical agents. During the last 10 years, interest in research and development by the scientific community in this niche have continued as evidenced from joint ventures between academics, mainly partnered with industry. Drugs of marine origin that have now been approved represent excellent and novel alternatives for the following therapies and disease treatments. For neuropathic pain, a synthetic version of omega-conotoxin, produced by the tropical marine *Conus* snail is already on the pharmaceutical market. The ecteinascidins (ET-743) are marine alkaloid, anticancer agents isolated from *Ecteinascidia turbinate*, a colonial tunicate found in the Caribbean and Mediterranean Sea, and are successfully used for soft tissue sarcoma and relapsed ovarian cancer. The synthetic pyrimidine nucleoside Cytarabine, was originally isolated from the Caribbean sponge *Tethya crypta*, and approved as a chemotherapeutic to treat different forms of leukemia (e.g., meningeal leukemia, lymphocytic leukemia). From this marine sponge, also the synthetic purine nucleoside analog, Vidarabine, was developed as an antiviral drug against the herpes simplex virus and the varicella-zoster virus for the treatment of epithelial keratitis, viz, ophthalmic applications. In 2012, squalamine was been awarded Fast Track designation by the US Food and Drug Administration (FDA) for the potential treatment of the wet form of macular degeneration. These successful advances have had to overcome difficulties characteristic of marine natural products to become drugs, viz, sustainable sources, structural complexity, and toxicity, the same as the marine molecules in preclinical and clinical trials. In this chapter, the current advances and modern approaches of marine natural products and respective bioactive metabolites with potential and real functions as drugs leads are succinctly reviewed and particularly exemplified. An important aspect of this chapter is the analysis of marine natural products in relation to new paradigms and particularities of other disciplines, such as genomics, combinatorial chemistry, biosynthesis, and functional foods.

29.1 Overview and Current Status

29.1.1 The Marine Environment, a Unique and Prolific Source of Bioactive Natural Products

A natural product can be defined as a compound that is present in or produced by living systems in nature and is not artificial or man-made [29.1]. Natural products are often structurally complex compounds that possess a well-defined spatial orientation. Their activity due to chemical compounds has evolved to interact efficiently with their biological targets and provides important clues for drug discovery. Many of these compounds exert their bioactive properties as secondary metabolites, in ecological, defensive, antifeedant, attractant, and pheromone roles. In nature, as in the marine environment, every natural product is believed to have emerged as a result of exerted pressure on the first living organisms from the sea, more than 3500 million years ago, under a context of evolution which enables marine organisms to survive in an extremely competitive milieu, such as extreme temperatures, changes in salinity and pressure, among others [29.2]. In this way, molecules acquired biochemical specialization and diverse metabolic roles and functions, as is now known. All these characteristics and properties have created conditions with a high degree of chemical diversity and a rich source of biologically active natural products found in marine environments, which are of remarkable novelty [29.3] as medicines. Expectations are high with respect to the ocean as the most chemically and biologically rich environment on the planet [29.4] is also the last frontier, unexplored and unexploited. A great number of these biologically active molecules from marine natural products has developed roles as biological receptors in a co-evolution process and allow interaction with human proteins, expressed lately as drug leads. The marine environment is characterized by physical and chemical properties that are markedly different from those of the terrestrial environment [29.5]. For instance, marine natural products have higher molecular weights than their synthetic counterparts and are characterized as having fewer nitrogen, halogen, or sulfur atoms, and a larger proportion of oxygen atoms, and are sterically complex (more bridgehead atoms, rings, and chiral centers) [29.6]. As a consequence, the development and evolution of biosynthetic pathways displayed specialized molecules, as defense, deterrents, ferhormones, and for hunting strategies. This wide range of bioactivities produced by compounds of marine organisms emphasizes the great potential of compounds for biomedical applications, which has encouraged further large-scale programs of bioprospection and systematic screening of marine organisms. Recent technological and scientific advances in the sciences have led to a multitude of discoveries of carbon skeletons and molecules hitherto unseen on land [29.4] and to contribute to the discovery of new functionalities for common targets of human diseases, and consequently new drugs from the marine environment.

Considering that unexplored marine organisms harbor the widest biological and chemical diversity, the possibilities to discover novel structures (to date, more than 21 855 compounds have been discovered) with novel modes of action, are high [29.7]. The uniqueness of marine natural products lends them to applications as preclinical and clinical lead compounds for the treatment of the most important challenge to human diseases, viz, cancer and other important neurodegenerative diseases. Presently, marine natural products and their metabolites are recognized as biologically active leads for therapeutic agents.

The field of marine natural products is now close to 50 years old. Thousands of natural products have been described through academic and industrial screening efforts for pharmaceutical candidates, but with limited success in certain targets, such as cancer, pain, or inflammation [29.8]. The natural products platform has attracted the interest of the pharmaceutical industry because of the low number of new developments in biopharmaceuticals on the market and the increasing incidence of recurrent diseases. The need for new drugs to face current and rare diseases, viz, new classes of antibiotics [29.9], many cancers, and chronic and neurodegenerative diseases is still lacking effective treatments, mainly for vulnerable populations in developing countries, which are rich in their potential of natural products. In spite of these evident needs, the number of drugs from the sea represents only a discrete number of marine-derived compounds that have been approved for the treatment of human disease, such as: Vidarabine (Ara-A) and cytarabine (Ara-C), which were derived and inspired by nucleosides found in marine sponges, ziconotide (Prialt1), a synthetic version of omega-conotoxin, produced by a tropical marine cone snail, and approved for the treatment of chronic pain; trabectedin (Yondelis) found in a tunicate was approved as an anticancer compound in the European Union.

All these successful examples represent an important effort by joint ventures of pharmaceutical companies with scientists and government, as succinctly described below.

An unfair comparison with conventional drugs on the market with a long history of research and development, in some cases discourages primary initiatives and high expectations for drugs from the sea. However, the best is yet to come, if we consider all the experience gained during these almost 50 years, which in some way is reflected in the approved products and in the impressive pipeline of marine-derived compounds in clinical and preclinical trials, suggesting that several more marine drugs, should soon be approved for pharmaceutical use [29.10]. In some way, as part of a relatively recent area, viz, marine biotechnology, and the integrated efforts of other disciplines may contribute to new developments, and on the focus on deep sea micro and macroorganisms as sources of natural products and of novel bioactivities. Actual progress in genomics, metagenomics, manipulation of biosynthetic pathways, and combinatory chemistry are promising new discoveries of pharmaceutical lead drugs. The integration, with other areas and applications of biotechnology will contribute to the development of this important area of marine biotechnology.

In this review, recent developments, mainly during the last decade, of marine natural products and the respective metabolites, are emphasized, considering their interesting biological properties and actual developments as approved marine-derived drugs and promissory compounds. The high degree of innovations per se from marine natural products, have led and will lead to a resurgence of new drugs and pharmaceutical applications for new and recurrent challenges of modern human diseases.

An important aspect of this chapter is the analysis of marine natural products in relation with other disciplines, such as genomics, combinatorial chemistry, metabolic pathways, and functional foods. Some are cases of success, others offer great potential application in other areas of biotechnology and the bioindustry.

29.2 Approved Marine Drugs as Pharmaceuticals

A high number of marine-derived chemical entities with biological activity in different therapeutic settings has been discovered during the last couple of decades. Advances and proven evidence of a positive therapeutic index indicates a favorable tolerability profile in the different clinical settings assessed. In addition, a number of approaches incorporating target-based discovery models are yielding to the identification of novelties with therapeutic potential in a number of diseases. Finally, selected interactions with other thematic fields are expected to emerge in the near future, and to lead to new developments in genome mining, biosynthetic pathways of gene holders and functional foods, and to contribute to changing the way that marine-derived drugs are discovered, thus making a significant contribution to welfare and cure of human diseases.

There are actually several excellent reviews on marine natural products and the respective pharmacology [29.10, 11]; we intend to succinctly emphasize fundamental and particular issues that will contribute to the integration and advancement of this innovative discipline and the respective drug pipeline in the context of biotechnology. It is our conviction that these initiatives will rapidly develop and expand in different approaches of human interest over the next decade.

29.2.1 ω-Conotoxin MVIIA: An Analgesic for Neuropathic Pain

The ω-conotoxins are poisons produced by piscivorous cone snails, originally isolated from *Conus magus* by *Olivera* and coworkers in 1979 [29.2]. These toxins are highly selective antagonists of N-type voltage-gated calcium channels (VGCCs)voltage-gated calcium channels [29.12, 13]. The venom of this gastropod mollusc, is a combination of 100–200 peptides (length from 9–100 amino acids), which exert inhibitory effects on the neuromuscular system of their prey [29.14, 15]. ω-Conotoxin MVIIA is a linear 25 amino acid, polycationic peptide containing six cysteine residues linked by three disulphide bridges that stabilize its well-defined three-dimensional structure [29.11] (Fig. 29.1). Compared to difficulties of chemical synthesis in other marine natural products, the complete synthesis of this peptide was successfully concluded in 1987 [29.12]. Subsequent studies on this toxin led to the identification that N-type voltage-sensitive calcium channels (NVSCCs) were its target site. The pharmacological activity of conus-derived toxins is currently used for its classification, viz, α-conotoxins are antagonists of both muscle and neuronal-type nicotinic acetyl-

choline receptors, while μ-conotoxins inhibit skeletal muscle voltage-gated Na^+ channels [29.16]. Both (α- and μ-conotoxins) produce paralysis through blocking neuromuscular transmission in vertebrates, which limits the clinical application of these conotoxins. The ω-conotoxins, are recognized as inhibitors of ion of VGCCs in an isoform-dependent manner, a property that explains the exerted role of paralysis in the prey. The synthetic equivalent of ω-conotoxin MVIIA from conus is commercially known as Ziconotide, or SNX-111 and is considered as the first venom-derived drug of VGCC antagonists. It is used as an analgesic in neuropathic pain with clinical applications [29.17–19]. Analgesia is provided by this toxin via binding to N-type voltage-sensitive calcium channels in the spinal cord. The fact that ziconotide does not easily cross the blood–brain barrier because of its poor tissue penetration as well as its hypotensive effect, promoted the development of the intrathecal adapted methods for its delivery. Thus, a special delivery strategy via an intrathecal catheter or by an external microinfusion device [29.10, 11, 20] has led to improved patient treatability and acceptability of this venom toxin as a pharmaceutical. Studies conducted on post Phase III clinical trials corroborate the benefiting effect of intrathecal ziconotide in living systems. Strikingly, ziconotide is 1000 times more potent than morphine and unlike opiates does not produce tolerance [29.21]. Another ω-conotoxin, CVID from *Conus catus*, in spite of assessed as the most potent of all N-type VGCC peptide blockers, finally exhibited the Achilles tendon problematic of marine toxins: the severe side effects in clinical trials [29.22–24]. Small molecules derived from ω-conotoxins, Z160, have actually advanced through Phase II clinical trials aimed to increase oral bioavailability [29.20, 24], and are intolerant of or refractory to other treatments (systemic analgesics, adjunctive therapies or IT morphine). The European Commission approved ziconotide for the treatment of severe, chronic pain in patients, specifically requiring intrathecal analgesia [29.11, 25]. Actually, Ziconotide is commercialized under the trade name of Prialt by pharmaceutical companies in USA and the European Union.

29.2.2 Ecteinascidins: A Therapy for Soft Tissue Sarcoma

Ecteinascidins (ET-743) are marine alkaloid, anticancer agents isolated from *Ecteinascidia turbinate*, a colonial tunicate found in the Caribbean and Mediterranean Sea [29.26]. ET-743 and its N-demethylated analog ET-729 are lactone members. Their structural features are a distinctive feature of the ecteinascidins [29.11]. Structurally, they are conformed of three fused tetrahydroisoquinoline rings connected to the base structure by a thioether bridge, giving rise to a ten-membered lactone, which is characteristic of ecteinascidins [29.26, 27]. These alkaloids are produced by semisynthesis after controlled fermentation of the marine bacterium *Pseudomonas fluorescens*, which leads to ET-743 from cyanosafracin B [29.28]. ET-743 also is named trabectedin or goes under the trade name Yondelis (Fig. 29.1).

The covalent binding of trabectedin to the deoxyribonucleic acid (DNA) minor groove has been used to explain its mechanism of action [29.29]. Trabectedin interacts with binding proteins of the nucleotide excision repair (NER) system [29.30, 31] to exert its cytotoxic activity [29.10] and induces an apoptotic effect by arrest at the G2/M stage of the cell cycle of tumors; a condition that seems independent of p53. Studies with ET-743 have shown dose limiting toxicities that include neutropenia and thrombocytopenia, and transaminase elevation [29.32]. Analysis of the effects of trabectedin in vivo and in vitro systems have evidenced positive results in the control of soft tissue sarcoma [29.33], and it has been approved in the European Union for the treatment of refractory ovarian cancer.

29.2.3 Cytarabine to Treat Meningeal Leukemia; Vidarabine, An Ophthalmic, Non-Corticosteroid Antiviral

The synthetic pyrimidine nucleoside Cytarabine was developed from the nucleoside spongothymidine, originally isolated from the Caribbean sponge *Tethya crypta*, the first-derived product of which was named Ara-C, arabinosylcytosine, or cytosine arabinoside (Fig. 29.1). Cytarabine is a specific cytotoxic compound that inhibits DNA polymerase and DNA synthesis by competition for deoxycitidine triphosphate, once converted to cytosine arabinoside triphosphate. In treatment programs it is also named antimetabolites; it main role is slowing or stopping the growth of cancer cells in human body. Vidarabine is the named assigned to the synthetic purine nucleoside, arabinofuranosyl adenine, or adenine arabinoside (Ara-A) developed from

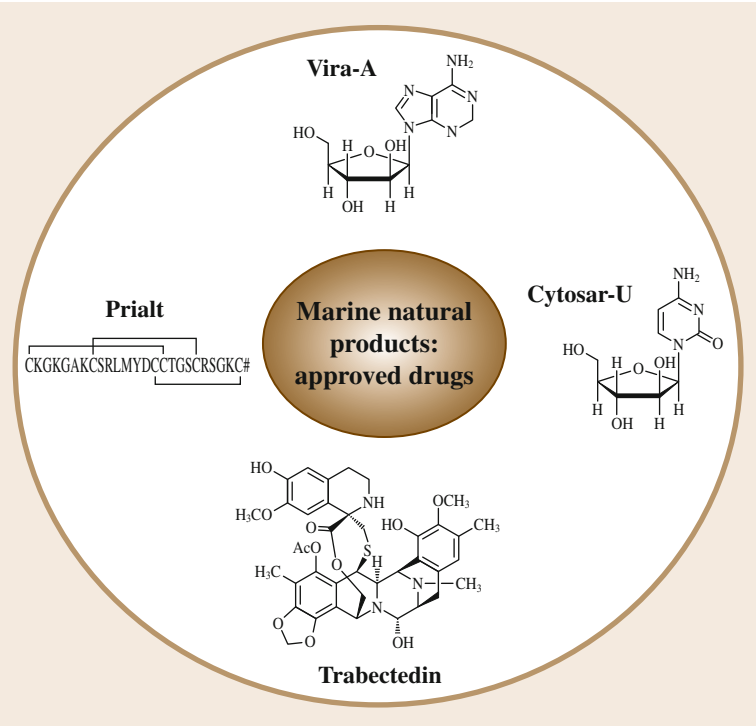

Fig. 29.1 Chemical structures of marine natural products or derivatives thereof approved by the FDA (modified after [29.10, 11])

spongouridine and isolated also from the sponge *Tethya crypta* [29.34].

Cytarabine (Ara-C) and Vidarabine (Ara-A), were among the first FDA-approved marine-derived drugs, as an anticancer drug in 1969 and as an antiviral agent in 1976, respectively [29.35]. The importance of Cytarabine and Vidarabine on preclinical and clinical antiviral pharmacology can be seen from the 4183 and 14 239 publications, respectively, in the peer-reviewed literature, upon a perusal search of their status (March 2013) in The USA National Center for Biotechnology Information-PubMed. According to the FDA, Cytarabine is recommended for the treatment of certain classes of leukemia affecting the white blood cells, mainly acute myeloid leukemia, acute lymphocytic leukemia, and chronic myelogenous leukemia [29.36, 37], and can be used in combination with chemotherapeutic drugs or alone to treat meningeal leukemia [29.10, 37]. A liposomal scheme of administration of cytarabine (Depocyt1) is recommended for intrathecal lymphomatous meningitis. Commercial presentation of Cytarabine is designed to be administered intravenously by injection, subcutaneously, or intrathecally [29.38]. On the other hand, Vidarabine has been applied to eye, which infection of the herpes simplex virus by corticosteroids alone is not recommended. One presentation of Vidarabine was designed under the trade name VIRA-A, which is also recommended for the treatment of keratoconjunctivitis, epithelial keratitis caused by the herpes simplex virus, and superficial keratitis caused by the herpes simplex virus [29.39]. *Mayer* et al. [29.10] mentioned that this drug has been discontinued by the FDA in the US market. A series of side effects derived from Cytarabine, like any similar medicine for such types of diseases, are: fever, sore throat, ongoing cough and congestion, or other signs of infection; unusual bleeding or bruising, and bloody vomit. Vidarabine (Vira-A1) received FDA approval in 1976.

Among the common side effects that could occur with the use of Vira-A1 as medication, are: burning, stinging, pain, irritation, redness, blurred vision, and sensitivity to light. Both cytarabine (Cytosar-U1) and liposomal cytarabine (Depocyt1) are marketed and have been approved for use as an antitumor agents [29.33]. Cytarabine 5′-monophosphate (CAS 7075-11-8) has been commercialized by a company in California for research purposes only and not for diagnostic or therapeutic use. In 2013, the current price for 10 mg was $US 240.

29.2.4 Marine Natural Products in Advanced Clinical Trials

Aplidine

Aplidine is a marine depsipeptide that was first reported in 1991 [29.40] by *Rinehar* and *Lithgow-Bertelloni* from *Aplidium albicans*, a tunicate that thrives in the Mediterranean Sea (Fig. 29.2). It is characterized by high antitumor activity [29.26] and has been shown to induce apoptosis by interruption of the cell cycle at the G1 and G2/M phases of leukemia cell lines, as a way to induce p53-independent apoptosis [29.41]. Its chemical structure is very similar to that of didemnin B, the only difference being that the lactate residue in didemnin B is present in the oxidized pyruvate form. In some way, the accumulated experience of more than 20 years in its closely related compound, didemnin B from the tropical *Tridemnum solidum* has contributed to the development of aplidine in advanced clinical trials. These peptides are obtained by chemical synthesis structured of six amino acid subunits as the main backbone and three amino acids in the side chain: (R)-N-Me-Leu linked to the Thr and piruvil-(L)-Pro. The aplidine named plitidepsin has demonstrated efficacy in two different Phase II clinical trials in refractory multiple myeloma and T cell lymphoma [29.42, 43]. In human leukemia, aplidin inhibits the vascular endothelial growth factor (VEGF) secretion and autocrine VEGF-VEGFR-1 stimulation [29.42–44], in principle, induced perturbations by Aplidin in cell cycle proceeds without any effect on cycling-dependent kinases [29.41]. Aplidine has also shown preclinical activity in vitro on haematological and solid tumor cell lines. This effect might contribute to the antineoplastic activity of aplidine. One bottleneck in the yield of peptides from Aplidine is the lack of a feasible production system. The supply is currently produced by total synthesis of these peptides from constituent amino acids in an iterative multistep process. It is believed that the future use of this compound will depend on the sustainable supply, which at present is limiting its production. In 2003, Aplidine was granted the status of orphan drug by the European Medicines Agency for treating lymphoblastic leukemia.

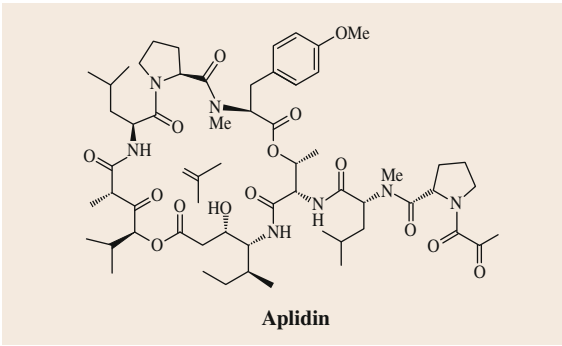

Fig. 29.2 Chemical structure of aplidin

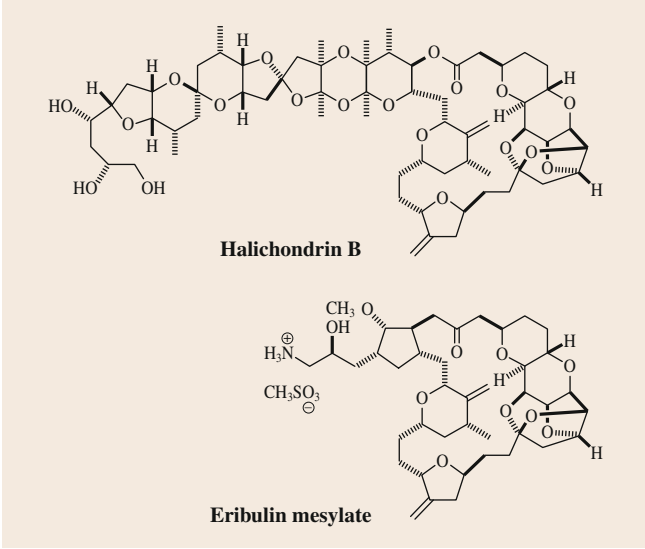

Fig. 29.3 Chemical structure of halichondrin B

Halichondrin B

Halichondrin B, also known as eribulin mesylate (E 7389), is a polyether isolated from the Japanese sea sponge *Halichondriaokadai*, which was discovered in 1986 by *Uemura* and co-workers [29.45, 46]. This macrolide (Fig. 29.3) is a member of a new class of synthetic cytotoxic agents that binds to the vinca domain of tubulin and inhibits its polymerization, which is considered as a new treatment option for metastatic breast cancer or locally advanced breast cancer [29.47]. Hence, this cytotoxic halichondrin, exhibits broad antiproliferative activity against tumor cells by binding to tubulin and arresting the cell cycle at mitosis [29.48], and leading to cell death by apoptosis [29.49]. These natural products display pharmaceutical benefits, including water solubility and chemical stability [29.50]. Clinical results from Phase II trials of eribulin mesylate as a monotherapy for refractory breast cancer were reported in 2006 [29.51]. Eribulin mesylate has been approved for the treatment of metastatic breast cancer in patients who have received at least two prior chemotherapeutic agents. The adverse effects of eribulin, which

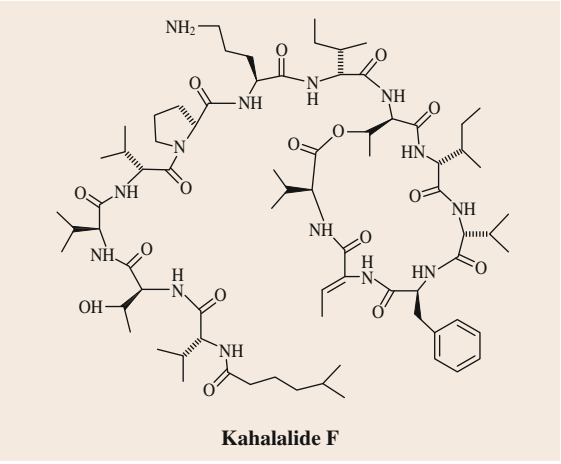

Fig. 29.4 Chemical structure of KF

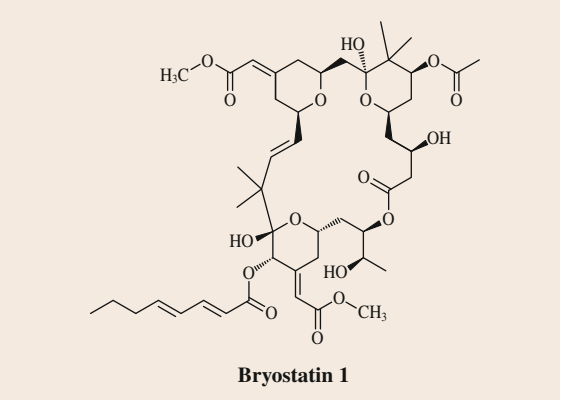

Fig. 29.5 Chemical structure of Bryostatin 1

consist mainly of neutropenia and fatigue, have been associated with a low incidence of peripheral neuropathy. In United States and in Europe, eribulin mesylate is currently under Phase III clinical trials [29.33].

Kahalalide F (KF)

Kahalalide F (KF) is a desipeptide isolated by *Scheuer* [29.52] from the hervivorous marine mollusk sacoglossan (sea slug), *Elysia rufescens* and their algal diet of *Bryopsis pennata*. It seems that both organisms use this cyclic tridecapeptide KF as a chemical defense against predation [29.52]. Even when the mechanism of action of KF (Fig. 29.4) still deserves to be fully elucidated, it seems that it is active mainly at the lysosomal level and induces vacuolization [29.53]. Hence, KF actively secrets lysosomal proteins, such as prostate cells. Induction of cell death of human prostate cell lines and breast cancer cell lines by KF takes place by oncosis [29.54]. In several human cell lines sensitive to KF, breast, vulval, hepatic, and colon carcinomas have exhibited a necrotic-like effect [29.55]. The inhibitor effect of KF on the tyrosine kinase and the phosphatidyl inositol 3-kinase-akt signaling pathway, were identified as determinants of its citotoxicity [29.56]. The apparent positive therapeutic index of KF on advanced solid tumors, melanoma, non-small cell lung cancer (NSCLC), and hepatocellular carcinoma [29.57] have promoted this compound for Phase II clinical trials.

Bryostatin 1

The bryozoan *Bugula neritina* was obtained from the Gulf of Mexico in 1968. It exhibits remarkable activity against murine P338 lymphocytic leukaemia cells [29.58]. As a Lactone, Bryostatin 1 (Fig. 29.5) is a complex molecule with 11 stereocenters and a unique polyacetate carbon backbone [29.59]. Hence, subsequent characterization of an important number of bryostatin homologs and analogs was carried out based in differences in the molecular structures of these compounds, such as their substitution at C7 and C20 by different acyloxy substituents [29.10, 11, 60]. Bryostatin 1 demonstrated potent in vitro activity against the P388 lymphocytic leukaemia cell and also other different bioactivities, such as modulation of the immune system [29.61], induction of cell differentiation [29.62], and synergistic interactions with other anticancer agents such as ara-C, paclitaxel, tamoxifen, auristatin PE, dolastatin, vincristine, doxorubicin, and prednisone [29.11, 63, 64]. This lactone has been the subject of an important number of Phase I and II clinical trials for myeloid leukaemia, lymphocytic leukaemia, melanoma, non-Hodgkin's lymphoma and NSCLC, metastatic myeloma, relapsed lymphoma, and chronic lymphocytic leukaemia [29.65]. The toxicity of this natural product is expressed as myalgia by muscular vasoconstriction, a condition originating from impaired oxidative metabolism and proton efflux from muscle cells [29.66].

Squalamine

Squalamine (Fig. 29.6) is a water-soluble aminosteroid derived from the internal organs (primarily the liver) of the dogfish shark *Squalus acanthias*. This cationic steroid is characterized by a condensation of an anionic bile salt intermediate with spermidine. As an aminosteroid, it displays strong antimicrobial action [29.67, 68] and has great potential for the treatment of some human viruses. As a broad spectrum antibiotic,

squalamine exhibits potent bactericidal activity against both Gram-negative and Gram-positive bacteria, and induces osmotic lysis of protozoa. It was established that it may be useful in the treatment in a topical eye drop formulation, diseases characteristic of elderly people, and diseases related to vision disorders (macular degeneration) [29.69, 70]. Squalamine has been shown to interrupt and reverse the process of angiogenesis. Squalamine is not a protein, instead, it is the first known example of a class of compounds called aminosterols, which the body readily uses to carry out its normal anti-angiogenesis function. By using different types of mouse cancer, squalamine was found to inhibit angiogenesis and to stop the growth of tumors. Nevertheless, squalamine was found to intensify the therapeutic effect of paclitaxel and carboplatin, inhibiting some growth factors, for instance VEGF, and causing a decrease in the amount of blood vessels around the tumor and apoptosis of tumor cells. Pharmacological investigations of squalamine are at clinical Phase I and II (pulmonary and ovarian cancers) [29.70]. Recently, Ohr pharmaceuticals Inc. announced that its squalamine eye drops have been awarded Fast Track acceptation by the US FDA for the wet form of macular degeneration.

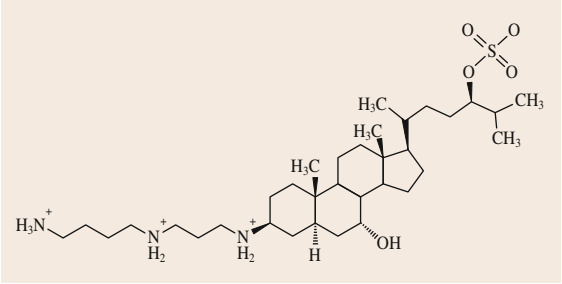

Fig. 29.6 Structure of Squalamine, an aminosterol isolated from the stomach and liver of the spiny dogfish, *Squalus acanthus*

29.3 Marine Natural Products – Overcoming Hurdles

Marine natural products face several challenges, which need to be overcome before they can enter advanced clinical trials. Apart of their inherent particularities, viz, biosynthesis and supply, target identification, toxicity, and complex structure, their role as secondary metabolites in marine organisms needs to overcome hurdles of survival in a competitive saline environment, which is quite different of that on earth. These properties of marine natural products may contribute to explain aspects of their toxicity and secondary effects in humans, which still limit its acceptance in advanced clinical trials.

29.4 *Quo Vadis*? Marine Natural Products and Clinical Trials

The potential of marine natural products to become new pharmaceuticals raises the question: *Quo vadis*? Even when these molecules seem highly promising, the aforementioned obstacles still need to be overcome in order to achieve successful clinical trials; a situation that invites us to ponder on Latin phrase *Quo Vadis*, or *Where are you going?*. During the next decade, these promissory metabolites of the global marine pharmaceutical pipeline could be part of advanced clinical trials, as in the case of marine natural products that have already acceded to the drug market. Particular features of many of these promising compounds are still waiting to be approved (Table 29.1). In 1981, the compound didemnin B, originally isolated from the Caribbean tunicate *Tridemnum solidum* [29.71] attracted interest due to its antiviral and cytotoxic activity exhibited in in vitro tests when applied in mice leukemia cell lines, as well as a potential antitumor, antiviral, and immunosuppressive agent. In principle, didemnin B binds to palmitoyl protein thioesterase and interferes in the protein synthesis in target cells [29.72]. Because of its high toxicity and secondary effects it was taken out of clinical trials at the end of the 1990s. Probably an aspect of didemnin B that is considered to be of less importance is that the accumulated experience in the management of this compound has helped to address particularities in clinical trials of other marine-derived products. In 1994, the tripeptide antimitotic *Hemiasterlin* (HTI-286/E7974) was isolated from the marine sponge *Hemiasterellaminor* by *Kashman* and co-workers [29.73]. The chemical synthesis allowed them to obtain derived analogs from substitutions of the NH 2-terminal amino acid and yielded in vitro analogs with high potency, exhibiting resistance to p-glycoprotein and positive pharmaceutical properties. The results obtained from Phase I studies showed dose-limiting toxicities, viz, neutropenia or febrile neu-

Table 29.1 Marine natural products and inspired compounds in clinical trials and their collected source, chemical class, and bioactivity (after [29.10, 70])

Metabolites	Marine organism	Chemical class	Bioactivity
Aplidine	*Aplidium albicans*	Cyclic depsipeptide	Cancer/ antitumor
Bryostatin 1	*Bugula neritina*	Polyketide	Cancer/ Alzheimer's
Kahalalide F	*Elysia rufescens*	Cyclic peptide	Lysosomes antitubuin
Salinosporamide A	*Salinispora tropica/ arenicola*	Lactam/ Lactone derivative	Proteosomal inhibitor
Pseudopterosins	*Pseudopterogorgia elisabethae*	Diterpene glycoside	Wound healing

tropenia, with other adverse events including fatigue, constipation, nausea, and vomiting [29.74]. The potent cytotoxicity of hemiasterlin is due to the induction of mitotic arrest in the metaphase with cellular dynamics similar to those of known tubulin binders, such as the chemotherapeutics paclitaxel or vinblastine. Unfortunately, Phase II trials have been interrupted. Nevertheless, high antitumor activity obtained with mice studies applying HTI-286 and in refractory prostate cancer [29.75] make hemiasterlin highly promising.

29.4.1 (C)-Discodermolide

In 1990, *Gunasekera* and co-workers [29.76] isolated (+)-Discodermolide from the sponge *Discodermia dissoluta* in Florida, USA. Discodermolide is a drug that functions as an immunosuppressant [29.77, 78] and induces G2/M phase cell-cycle arrest in lymphoid and non-lymphoid cells [29.79]. The cytotoxicity of (+)-discodermolide cause cell-cycle arrest by mitosis [29.80, 81] and an important alteration at the level of microtubules [29.82]. At present, Phase I trials with (+)-discodermolide has been discontinued as a consequence of unsafe efficacy and toxicity results. However, potential remains for its use in combination drug therapy. Dolastatin 10 is the name assigned to a series of cytotoxic peptides that were isolated from the sea hare *Dolabella auricularia* found in the Western Indian Ocean in 1972 [29.83]. In spite of its extremely low yields (90 mg of Dolastatin 10 per of *D. auricularia*), dolastatin 10 exhibited outstanding in vitro cytotoxic activity against cancer cells, specifically against murine lymphocytic leukaemia cells. Dolastatin 10 is a potent antimitotic agent that inhibits microtubule assembly and tubulin polymerization.It has demonstrated in vitro inhibitory activity against various human cancer cell lines, including melanoma, sarcoma, and ovarian cancer cells [29.85]; it entered several Phase I and II clinical trials. Because of the negative results of the Phase II clinical trials, dolastatin 10 has been withdrawn from antitumor clinical trials [29.86]. Nevertheless, the new synthetic derivative TZT-1027 [29.87] is currently being evaluated in Phase I clinical trials in Japan, Europe, and the US [29.87, 88]. In 1990, the cyanobacteria *Nostoc* spp. (ATCC 53789) was used to isolate a group of tubulin-binding compounds named *Cryptophyincs* by Schwartz and co-workers (Fig. 29.7). A Phase II study involving patients that had previously been treated with platinum-containing chemotherapy agents was unsatisfactory, and cryptophycin-52 was withdrawn from clinical trials. More recently, the analogs cryptophycin-309 and 249 have been studied in preclinical trials as anticancer drugs and seem promising for the next level of clinical trials [29.89]. Salinosporamide A or Marizomib (Fig. 29.11) are natural product discovered and derived from the marine *actinomycetes Salinispora tropica* in [29.90], and from *Salinispora arenicola* respectively. This marine strain contains the particular and characteristic β-lactone and exerts a potent inhibition of proteasome through a particular process of acylation of N-terminal Thr1O$^{\gamma}$ residue [29.91–93]. The commercial production of salinosporamide, marizomib, involves a peculiar process of saline fermentation using *Salinispora tropica* strain NPS21184 [29.90, 91]. This compound has completed Phase I clinical trials and has been shown to be effective against solid tumors and multiple myeloma, as well as demonstrating promissory bioactivity for use in combination with chemotherapeutics.

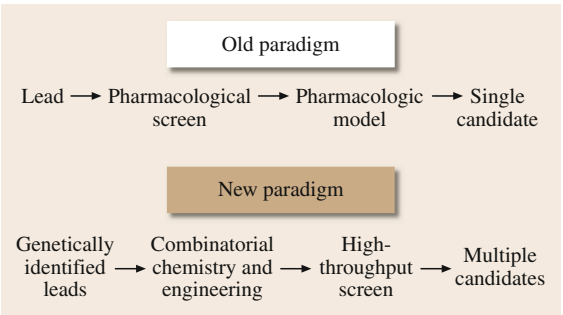

Fig. 29.7 Old and the new paradigms for drug discovery (modified after [29.84])

29.5 Marine Natural Products: New and Recurrent Challenges

29.5.1 Facing Supply Obstacles: Advances and Strategies

Marine natural products have yielded actual and promissory novel molecules with biological activity and an opportunity for the discovery of drugs. Besides the achievements reached so far, marine natural products face many difficulties. Indeed, the relation of bioactive molecules to biomass is not always enough to ensure an adequate supply for pursuing drug development based on a natural product. Bioprospecting is a key issue in this context of using natural marine compounds and at the same time protecting the source organism and its habitat from overexploitation. In some ways, a balance between sustainability and conservation is desired when collecting target marine organisms as natural product source material. However, the development of preclinical in vivo evaluation assessment of marine natural products has been hampered by a lack of material. Inventive solutions to the supply problem of these and other marine natural products with therapeutic properties may ultimately determine their future use, even if clinical outcomes are favorable [29.11]. Indeed, the supply issue concerning obtaining drugs from marine natural products and sustainable production, is still is an obstacle to be overcome and is one of the limiting and recurrent challenges for most pharmacologically active marine natural products, which can only be isolated in minute yields [29.94] (Table 29.2). The limited supply or large-scale exploitation can destroy the environment, and the complexity of the molecular structures in many cases makes the synthesis unfeasible. Currently, the methods of production include: large-scale collections, aquaculture, chemical synthesis, fermentation, and genomics (Table 29.3). The selection of the proper method to obtain any marine natural product will depend on the characteristics or complexity of the compounds of interest and their source [29.86].

Table 29.2 Limiting factors of marine derived therapeutics drugs (after [29.2])

Potential limiting factors of marine therapeutics drugs
Sustainable supply of clinical and industrial activities
Preclinical pharmacokinetics, bioavailability and half life
Pharmacogenetics, metabolic pathways
Physiological dose/therapeutics index
Toxicities, formation of possible metabolites

Among the available strategies biotechnology is an option for the production of bryostatins through the mariculture of the bryozoan *Bugula neritina* (ET-743) and the tunicate *Ecteinascidia turbinate*. However, again, this strategy is not feasible due to the costs associated with the destruction of culture facilities and stocks by storms and oceanographic phenomena or by diseases, which make production predictability unsure and unsafe. Total synthesis has been successfully established for halichondrin B, ET-743, bryostatins, and others, but in many cases has resulted in being economically infeasible due to the complexity of the molecular structures and the low yields of the final products achieved. For example, 1 t of the sponge *Lissodendoryx* sp. yields 300 mg of halichondrin analogs [29.95]. Contrary to this, the peptide ω-conotoxin MVIIA (SNX-111) from the marine mollusk *Conus magus*, known under the generic name of Ziconotide, can be obtained through synthesis in virtually unlimited amounts [29.16, 94].

When chemical synthesis is not feasible, and given the limited availability and regulation of marine resources, it is clear that product supply could never be completed successfully by these methods [29.94, 96]. In *E. turbinate*, nearly 1 t (wet weight) needs to be harvested in order to obtain approximately 1 g of ET-743 [29.97]. Another option is partial synthesis from precursors that are biotechnologically available, as in the case of ET-743, obtained through 21-step synthesis from the marine bacterium *Pseudomonas fluorescens*. However, a low overall yield of 1.4% was obtained because the starting material was generated by fermentation [29.86], a finding that exemplifies the process developed by a Spanish pharmaceutical company. Some bioactive compounds can be produced by

Table 29.3 Strategies to supply marine-derived therapeutics for clinical and industrial development (after [29.2, 10])

Potential limiting factors of marine therapeutics drugs

Genomics/metagenomics

microorganisms that invertebrates take up from the food chain, such as in the case of bryostatin 1, which is actually produced by a symbiotic microorganism living in the host bryozoans *B. neritina* [29.98, 99]. Hence, new methods for the development of marine natural products could diversify and facilitate production. It is hoped that synthesis and fermentation simultaneously with biotechnology may be the major methods for the development of marine natural products to reach industrial production.

29.5.2 Marine Natural Products: Paradigms, Genomics, and Biosynthesis Exemplified

The sustainable biotechnological production of pharmacologically important metabolites from marine organisms may be improved by genomics and with cloning and expression of the respective key biosynthetic gene clusters. A combination of the available biotechnological strategies must definitely be considered due the complexity of the structure and the novelty of marine natural products. Particular and more orientated approaches will open up new avenues for biotechnological production of drugs or drug candidates from the sea. In some ways, many compounds from marine organisms do not receive the required consideration that they deserve from pharmaceutical companies because of concerns about a sustainable, economic supply of the compounds [29.9]. The traditional process of drug discovery and delivery has been undertaken largely through the effects of a natural product or a derived synthetic agent on a living system (physiological process or pathological state) and a process of testing in vivo, as well as chemical synthesis. Thus, discoveries were achieved by a one molecule at a time process. The new paradigms in drug discovery are dominated by genomic-based approaches which are expected to lead to multiple new targets [29.84], which could represent a significant increase of approximately thousands of targets in the pharmacognosia of natural products (Fig. 29.7).

These approaches coupled and integrated with the tools of combinatorial chemistry, high-throughput screening, and bioinformatics would yield not just one clinical drug candidate, but rather up to hundreds of new candidates (Fig. 29.8).

The advanced and accelerated drop in the cost of DNA sequencing by new technologies makes it feasible for the highest performance and most economic approach to explore the biosynthetic potential of marine organisms and possibly to directly sequence their genomes. As many of these gene products are entirely novel, their activity cannot be inferred from a comparison to known protein databases, thus a functional metagenomics approach has the ability to identify novel genes on the basis of phenotypes, which lend themselves to high-throughput screens [29.100].

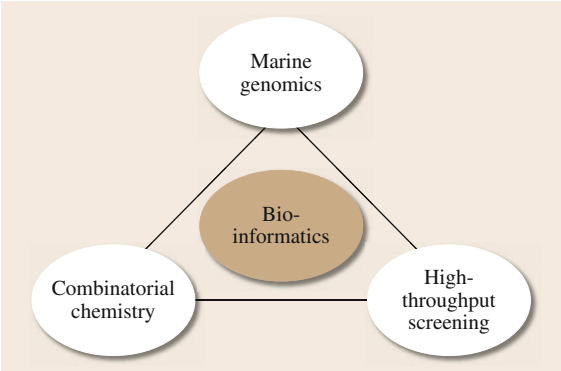

Fig. 29.8 A new model of drug discovery by coupling and integration of genomics, combinatorial chemistry, and high-throughput screening with bioinformatics (modified after [29.84])

Basically, functional metagenomics rely on screening DNA library clones for a phenotype, and the genes are recognizable by their function rather than by their sequence, while metagenomics only compares sequence data from sequences deposited in databases. When the genes of interest do not require any sequence analysis, this represents a great advantage for directly identifying new classes of genes for both known and indeed novel functions (Fig. 29.9). An environmental sample, e.g., seawater or marine invertebrate, is collected and then THE total community DNA is extracted from the sample.

The isolated DNA is then used to generate a metagenomic library using a suitable cloning vector. This library is then transferred to a suitable host strain, usually *Escherichia coli*, and individual clones can then be screened for the presence of enzymatic or other bioactivities encoded by the environmental DNA fragment. When coupled with a robust and high-throughput screen, this method is an extremely effective way of isolating novel enzymes from otherwise inaccessible microbes [29.100], as exemplified in Fig. 29.10. Advances in DNA sequencing and bioinformatic technologies make it possible to rapidly identify the gene cluster of bioactive compounds and in silico predict their chemical structure based on genomics informa-

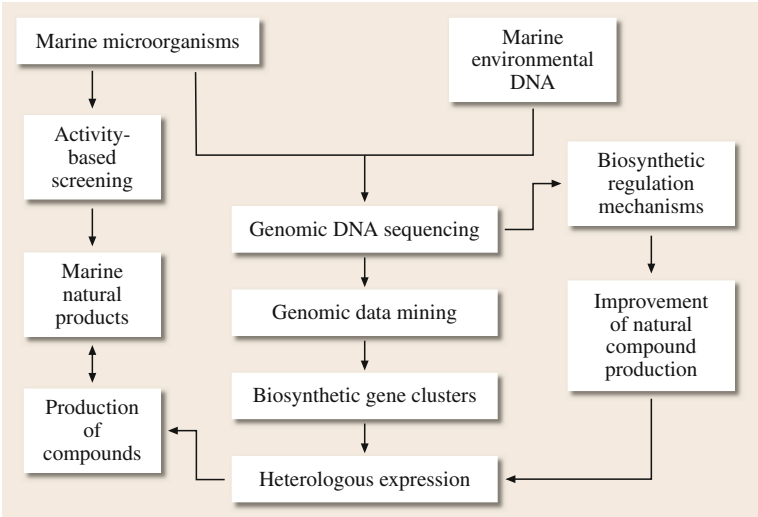

Fig. 29.9 Sequential steps of combined genome mining with activity-based screening for the discovery, generation, and production of marine natural products (modified after [29.101])

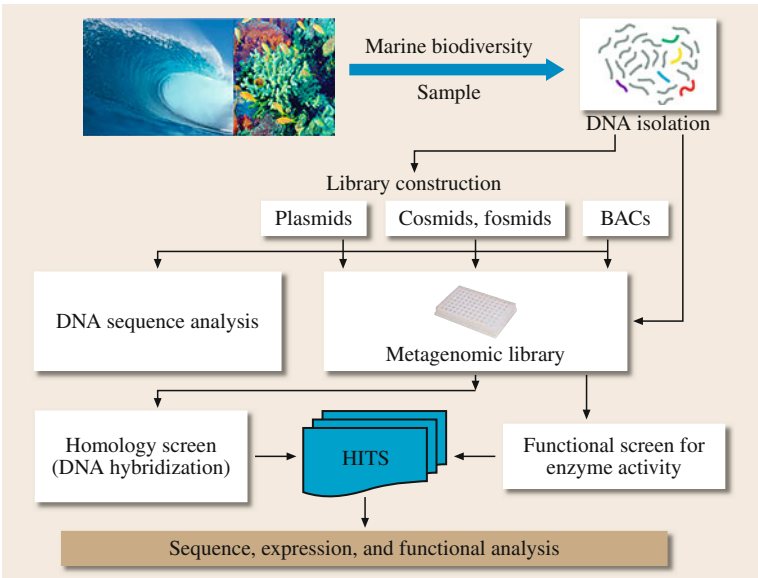

Fig. 29.10 Schematized diagram of the steps of functional metagenomics for the discovery of enzymes from samples of marine biodiversity, (after [29.100])

tion. These structural predictions can be used to guide compound purification and structure confirmation, and to identify new chemical entities.

In the case of *Salinispora tropica*, the compounds produced include the potent proteasome inhibitor salinosporamide A, the unprecedented halogenated macrolide sporolides A and B lymphostin, and salinilactam. Knowing the genomic sequence is the prerequisite to understanding and harnessing the diversity of the natural product producers. The genome sequence of the first seawater-requiring marine actinomycete, *Salinispora tropica*, was reported as containing large size of genes (516 kb) dedicated to polyketide synthase polyketide synthase (PKS) and/or non-ribosomal peptide synthetase (NRPS) biosynthesis. These megasynthases are responsible for many active natural product and are basic tools for combinational biosynthesis [29.101]. A truncated biosynthetic gene cluster was identified in the draft genome of *S. pacifica*, which is related to the 41 kb gene cluster in *S. tropica* for salinosporamide A biosynthesis, but the gene coding for the enzymes in the chloroethyl malonyl-CoA pathway

are absent in *S. pacifica*. From these results salinosporamide K was isolated, which structurally resembles salinosporamide A. The structures of salinilactam A and salinosporamide K described above are presented in Fig. 29.11; these were discovered by genome mining by [29.102].

Major advances in the biosynthesis of marine natural products have occurred during the last decade as a result of the integrated efforts in modern analytical technologies for the understanding of marine natural product biosynthesis at the genetic, enzymatic, and small-molecule natural product levels [29.103]. Amongst the vast array of marine natural products, the isoprenoids are one of the more commonly reported and discovered to date. In biosynthetic studies isoprenoids (C25, C30, C40) [29.104] represent the group of compounds of major distribution in the marine environment. Biosynthetic studies of early metabolic pathways in these molecules have been elucidated because of the differences between the mevalonate (MVL) versus the non-mevalonate 1-deoxy-xylulose-5-phosphate (DXP) route. Until quite recently, it was thought that isopentyl pyrophosphate (IPP) and dimethylallyl pyrophosphate (DMAPP), the monomeric units in terpenoid biosynthesis, were made exclusively by the mevalonate pathway [29.104]. After the pioneering work of [29.105], it was demonstrated that there is an alternative non-mevalonate pathway for the formation of IPP and the isomeric DMAPP [29.106, 107] in the carotenogenesis of microalga, the richest source of natural β-carotene. This carotenoid plays an important role in cancer prevention and treatment as the major source of pro-vitamin A.

29.5.3 Marine Natural Products at the Crossroad Between Functional Foods and Pharma

Functional food is known to play an important role in reducing health risks and improving health quality. Marine natural products have been recognized as rich sources of structurally diverse biologically active compounds and as functional ingredients in diets with health beneficial effects [29.108]. The relationship between nutrition and health has led to the concept of *functional foods* or *pharmaceutical foods*, which is a practical and new approach to achieving optimal health and possibly reducing the risk of disease. Natural products with bioactive properties that are consumed in a normal diet for enhanced health or reduced risk of disease are named functional foods according to the Food and Agriculture Organization of the United Nations (FAO. These products exhibit properties and benefits for the use in medicines, for safety and economical status reasons, and have fewer side effects than current drugs being prescribed. As is generally accepted, these metabolites have low potency as bioactive compounds when compared to pharmaceutical drugs, but since they are ingested regularly and in significant amounts as part of the diet, they may exhibit positive long-term physiological effects [29.109]. Marine natural products with functional ingredients include omega-3-oils, carotenoids, phycobiliproteins, complex polysaccharides, many bioactive metabolites and many other derivatives from alkaloids, terpenoids, and polyketides with different pharmacological properties such as cytotoxic, antitumor, anti-inflammatory, antioxidant, and therapeutic pain relievers [29.5], among others. Recently, the design of prebiotics (dietary ingredients that stimulate the growth or activity of beneficial bacteria in the gut) targeted at specific probiotics are expected to promote the general physiology and health of consumers, an aspect of great value in the emerging field of *symbiotics* (i. e., combinations of probiotics and prebiotics with enhanced health benefits). In the case of non-digestible oligosaccharides (prebiotics), a wide range of such compounds, including fructo-galacto and xylo-oligosaccharides, which specific functions have been poorly studied on target organisms. Also, the metabolism of oligosaccharides by probiotics may lead to the development of prebiotics

with specific functional properties and their associated health outcomes. Soluble polysaccharides from marine bacteria and algae are promissory for human dietary fiber and as possible prebiotic compounds. The need to incorporate functional natural products and ingredients in foods in living systems, animals and human, is a challenge to overcome. In 2006, *Ochoa* and *Olmos-Soto* [29.110] assessed functional feed supplemented with vegetable protein-carbohydrates and a *Bacillus* strain (GRAS, generally recognized as safe) as probiotic due to the high enzyme level production and secretion of antimicrobial peptides in a shrimp model (*Litopenaeus vannamei*). In this approach, the enzymatic action produced by the bacteria and the shrimp enzyme activity enhances carbohydrate digestion and assimilation and, induced a healthy condition in *L. vannamei*. Similar results were obtained when applying this biotechnology to edible fish such as Tilapia (*Orechromisaureus*) [29.111].

Moreover, natural products as well as primary and secondary metabolites from marine sources have been reported to promote various functionalities like growth enhancers, immune stimulation, antioxidants, antistress, ferhormones, and antimicrobial properties in finfish and shrimp larviculture, due to active principles such as alkaloids, carotenoids, pigments, phenolics, terpenoids, steroids, and essential oils. Functional metabolites like carotenoids are bioactive ingredients with physiological or health benefits beyond basic nutritional functions in organisms. In the case of carotenoids as bioactive molecules in shrimp, the functionality resides, to a large degree, on their conversion to retinoids. These molecules are derived from vitamin A and are involved in the activation of hormonal nuclear receptors and play a prominent role in many developmental processes, including embryonic development and differentiation of various cell types. Studies on the bioactive roles of carotenoids and retinoids in shrimp *Litopenaeus vannamei* have been undertaken [29.112, 113]. According to the excellent results obtained, authors emphasized the positive effect of these metabolites as bioactive ingredients and hormone-like compounds in shrimp maturation and reproductive performance. The anticancer properties of carotenoids via shrimp food could improve the health of consumers and accomplish the required doses for these non-produced, de novo metabolites. Innovative technologies will help to understand the relation of the functions of human genes in relation to disease, and in particular the extent to which nutrition and food components can influence health promotion and disease prevention, and to approach therapeutic pharmacology through food. World population, at all levels, is demanding natural medicines as healthier foods with special properties, mainly acting as passive immune protective and therapeutic agents, in some ways, as was the intention of the Greek philosopher Aristotle, over 2000 years ago, in his phrase: *Let food be your medicine – let your medicine be your food.*

30. Biocatalysts from *Aplysia*: Sweet Spot in Enzymatic Carbohydrate Synthesis

Antonio Trincone

Speaking in general terms, glycosylation is considered to be an important method for the structural modification of compounds with useful biological activities. Glycosylation allows conversion of lipophilic compounds into hydrophilic ones, thus improving their pharmacokinetic properties or giving access to new drug delivery systems (prodrugs). Examples include synthetic carbohydrate-based polymers used as coating agents and as biomedical materials, or novel dietary carbohydrates introduced as food additives. Finally, chromophoric oligosaccharides are of widespread interest for the kinetic analysis of hydrolytic activities and to characterize the mode of action of particular enzymes (i. e., exo or endoglycosidases). Hence carbohydrate-based compounds have proved to be a valuable tool in different fields of applicative interest, such as clinical, biological, and food chemistry. Different enzymes acting on these molecules are commercially available, but a greater interest would entail a search for biocatalysts with new catalytic characteristics. The marine environment has been shown to be a very interesting source for new glycosyl hydrolases both for hydrolytic and synthetic applications. *Aplysia* is a genus of sea hares belonging to the family *Aplysiidae*, containing different species of organisms. *Aplysia fasciata* and *Aplysia kurodai* are two examples; they are herbivorous animals and eat a variety of red, green, or brown algae and have been revealed to be potent producers of a library of glycoside hydrolases applied in the synthesis and hydrolysis of glycosidic bonds. In this chapter, examples of applications of such enzymes will be discussed.

30.1 Biocatalysis, Glycosylation and Marine Enzymes

In the field of biocatalysis the need for new biocatalysts is a current topic that involves a series of different points. Particular attention must be paid to several characteristics of enzymes if they are to be used on an industrial scale, and different key properties are recognized for this aspect. Broad substrate specificity, which generally characterizes extracellular fungal enzymes and is useful for the general application of a biocatalyst, may not be strictly requested in fields such as the production of fine chemicals and pharmaceuticals or the hydrolysis of specific linkages for analytical purposes, where very selective biocatalysts ensure fidelity towards very specific linkages and good yields. Substrate specificity and affinity somehow play leader roles among other catalytic characteristics. As an evolved property the specificity of a biocatalyst is linked to the

metabolic function and strictly related to the natural source and environment.

In comparison with chemical glycosylation, including methods that are generally based on harsh conditions or necessitate toxic (heavy metals) catalysts, enzymatic routes are particularly useful for accessing new products or for the modification of complex natural products such as carbohydrates [30.1]. Actually, enzymes may represent an imperative choice in fields related to the food domain or cosmetics in which adopting synthetic chemistry is sometimes not acceptable at all.

As sources of biocatalysts alternative to microorganisms, like plants or animals, almonds and pig and horse livers furnished few but relevant examples [30.2]. Carbohydrates are important molecules in various technological domains. In the field of polymer chemistry, for example, synthetic carbohydrate-containing polymers have a wide range of applications in medical biotechnology as coating agents or molecular recognition biomedical materials. Molecular networks presenting as hydrogels may find application as biomaterials because of their high water content, homogeneity, stability, and expected nontoxicity [30.3]. In food technology, during the last decade, a number of novel dietary carbohydrates produced by enzymatic synthesis have been introduced [30.4]. Resulting from advances in fine chemicals production, the easy synthesis of chromophoric oligosaccharides (such as nitrophenyl and 4-methylumbelliferyl glycosides and others) of defined structure is of widespread interest because these products are valuable tools for the kinetic analysis of hydrolytic activities and for characterization of the action of new enzymes (i. e., exo or endoglycosidases). Finally, in cosmetics the prodrug action of enzymatically glycosylated natural lipophilic antioxidants is nowadays often considered. Thus, glycosylation is considered to be an important method for the structural modification of compounds with useful biological activities. It allows conversion of lipophilic compounds into hydrophilic ones, improving pharmacokinetic properties and producing more effective drug delivery systems (prodrugs) [30.5].

The marine ecosystem is an almost absolutely new and unexplored source of biological material and can be also a surprising source of enzymes carrying new and interesting catalytic activities to be applied in biocatalysis [30.6]. Marine sources are represented by marine microorganisms, including extremophiles and marine plants or animals. Marine microorganisms may be used for industrial production of many enzymes [30.7]; moreover, although not numerous, examples of different enzymes from marine plants and animals are also reported in the literature [30.8]. Marine enzymes are characterized by well-known habitat-related features such as salt tolerance, hyperthermostability, barophilicity, and cold adaptivity . In addition, their novel chemical and stereochemical characteristics have increased the interest of biocatalysis practitioners from academia and research. Marine (micro)organisms should be considered as an important source of biocatalysts for the degradation of complex polysaccharides. Herbivorous marine molluscs such as abalone, sea hares, and small snails possessing various kinds of polysaccharide-degrading enzymes could efficiently depolymerize alginate, mannan, laminarin, and cellulose. These enzymes play important roles in the metabolism of the organism digesting polymeric materials to oligosaccharides and monosaccharides as carbohydrate nutrients. However, these molecules (poly and oligosaccharides) are known to exhibit various therapeutical functions and are recognized as potential raw materials for biofuels [30.9].

Different interesting results related to the presence of glycosyl hydrolases have been reported for *Aplysia fasciata* and *Aplysia kurodai* in the last decade. Both species have been revealed to be potent producers of a library of glycoside hydrolases applied in the synthesis and hydrolysis of glycosidic bonds. In this chapter, examples of applications of such enzymes will be discussed.

30.2 Biocatalytic Methodologies to Access Glycosides and Oligosaccharides

30.2.1 Enzymes

Nowadays there exists a copious amount of information concerning the synthesis and transformation of complex saccharides in living organisms. Glycosidic linkage is by far the most common chemical bond joining a carbohydrate to another molecule. It is one the most important chemical characteristic of a saccharide, although diverse functional groups can be found in carbohydrate chains (ester, sulphate, etc.) in various positions, which

can alter or modulate biological functions. Enzymes responsible for the synthesis of glycosidic linkage have been recognized as transglycosylases and named glycosyltransferases, specifying the glycosyl donor and the reaction product. These enzymes transfer sugar moieties from the activated donor to specific acceptors, forming a specific glycosidic bond, and are responsible in vivo for the synthesis of most cell-surface glycoconjugates, using eight common sugar nucleotides as activated donors (Leloir pathway). Sugar phosphates can act as donors for other glycosyltransferases (non-Leloir pathway).

Glycoside hydrolases (glycosidases), represent another widespread group of enzymes involved in the carbohydrate metabolism, being responsible for the hydrolysis of glycosidic linkages; these enzymes can act as exo or endoglycosidases and are involved in a series of biological events of important nature, such as energy uptake in processes inherent in cell wall metabolism, in glycan processing during in vivo glycoprotein synthesis, etc. Glycosidases and endoglycosidases are enzymes that are currently leading to new expectations in research and development due not only to their natural capability to act on the internal part of an oligosaccharide chain, but also to the possibility of transferring a whole carbohydrate block to a new acceptor, thus enabling easy reconstruction of complex glycoconjugates (e.g., glycopeptides, bioactive oligosaccharides, etc.). In addition, the profitable use of the hydrolytic capabilities of glycosyl hydrolases for mass preparation of oligosaccharides from natural marine or terrestrial polymers should be mentioned here [30.10].

The stereochemistry of the mechanisms of glycoside hydrolases, analyzed more than 50 years ago [30.11], allowed the classification of glycoside hydrolases in inverting and retaining enzymes in accord to the anomeric configuration found in the product with respect to that in the starting substrate. Very recently, it has become clear that other mechanisms are evolved, such as the one based on elimination [30.12].

In the inverting glycoside hydrolases, the glycosidic substrate, a water molecule, and two carboxylic acid groups represent the key elements of the chemical machinery within the active site of the enzyme. The two carboxyl groups acting as general acid and general base are distant; between them there is a (10.5 Å) value double that of retaining enzymes. This creates room for the substrate and a water molecule to access the active site. Hydrolysis occurs via a single displacement mechanism that involves an oxocarbenium ion-like transition state. The product has the opposite configuration at the anomeric center with respect to the substrate. If an inverting enzyme catalyzes a transglycosylation reaction transferring the sugar on an acceptor other than water, the product of this reaction would be the inverted anomer of the starting glycoside. This transglycosylating activity is never found with these enzymes; in fact, they would have to be anomerically indiscriminate to possess such activity. However, inverting enzymes catalyze oligosaccharide synthesis via reversal of the hydrolysis reaction; in the presence of a free sugar and alcohol acceptor, back reaction can produce a glycoside (see below).

A reaction characterized by a double displacement mechanism is operative in retaining glycoside hydrolases; two sequential steps can be distinguished in this case. In the first, the substrate binds the active site, then a nucleophilic group (aspartic acid, glutamic acid, or histidine) attacks the anomeric carbon atom. Protonation of aglycone oxygen by an acid proton, with concomitant glycosidic bond cleavage and ester bond formation, leads to the formation of the covalent ester glucosyl-enzyme intermediate, characterized by anomeric inversion at C1. In the second step, a hydroxyl group from a water molecule (in the case of the hydrolysis reaction) or from a different residue (for transglycosylation reactions) attacks the ester bond of the intermediate with re-inversion of configuration of the anomeric carbon. As a result, the final product has the same anomeric configuration as the initial substrate. The degree of bond cleavage may significantly vary in the transition states for each step, according to nature of the enzyme and substrate structure [30.10]. The retaining mechanism for α and β-glycosidases appears to have similarities and differences, as, for example, the complementary stereochemical configuration at the glycosyl enzyme intermediate. Speaking in general terms, evidence for ring distortions in transition states is collected for different biocatalysts. The distortion is driven by interactions between the enzyme and the substrates and greatly assists bond cleavage, allowing in-line attack of the nucleophile at the anomeric center. It can also help the substrate to acquire a conformation closer to that of the oxocarbenium transition state. Inhibition of these enzymes through the action of compounds mimicking the structure of the transition states is considered a major area for the development of new therapeutic agents. A collection of detailed studies for the elucidation of the role of single amino acids in the active sites, which could be propaedeutic for genetically tailored production of synthetic enzymes (glycosynthases, see below), can be found in literature [30.13].

A new four-step mechanism for the hydrolysis of glycosidic bonds involving oxidation-elimination-addition-reduction reactions has been reported for family 4 [30.14] of glycoside hydrolases. Members of this family require divalent metal ion and a NAD^+ cofactor for activity. Also, α-1,4-glucan lyases, cleaving glycosidic linkages in starch and glycogen, and polysaccharide lyases which are involved in the degradation of glycosaminoglycans and pectin, belong to the class of enzymes that employ elimination chemistry.

30.2.2 *Natural* and Engineered Methods for Synthesis

Two general protocols are in use for the utilization of glycoside hydrolases in the synthesis of glycosidic linkage: the reverse hydrolysis procedure and the kinetic approach. The former, starting with free monosaccharide and an acceptor, is reported as an efficient and cost-effective methodology for just a few enzymes and as a poor-yielding procedure for others [30.15]. The alternative kinetic approach is based on the use of a glycosyl donor which produces an intermediate glycosyl enzyme. In presence of a nucleophile other than water, this ester intermediate is resolved into products that as new glycosides could still be substrates for the enzyme, hence the reaction must be carefully monitored to achieve good yield. Both these systems could be considered unnatural due to the natural hydrolytic nature of glycosyl hydrolases. However, they can be called *natural* in comparison to the ad hoc produced mutant enzymes, known as glycosynthases, introduced several years ago as an elegant approach to solve the back-hydrolysis problem encountered using wild type biocatalysts. This topic has been extensively reviewed, and readers are referred to reports on this technology [30.16–18]. Synthesis of oligosaccharides by this engineered methodology can always be considered as an emerging alternative for a possible scale-up of oligosaccharide production for each single example of a newly isolated biocatalyst transformed in the glycosynthase version.

A stereochemical outcome of a glycosidase-based reaction includes natural absolute anomeric selectivity derived from the chemistry of the reaction mechanism. However, regioselectivity and other aspects are dependent on the nature of the enzyme towards the donor(s) and product(s) formed. Depending on the structure of the active site, the biocatalyst can accommodate certain sugar acceptor(s) and promote regiospecific formation of glycosidic linkages. The impressive variety of available glycosidases clearly indicates that the potential biodiversity of these enzymes (and also of the possibly derived glycosynthases) is still largely unexplored and that potential applications of these biocatalysts will increase in the near future starting from the knowledge of wild-type biodiversity.

30.3 The Marine Ecosystem as a Source for New Glycoside Hydrolases

The importance of the marine environment as a source of different and interesting glycosyl hydrolases can be found in the literature as overall results of several research projects conducted in different nations in the world from the beginning of the 1960s. Attention was focused mainly on the hydrolytic selectivity of these enzymes, since efforts of the structural identification of carbohydrate molecules then faced the complexity of oligosaccharide structures, before the flourishing development of instrumental analysis that started in the 1980s. Various potent activities were found in marine organisms such as *Charonia lampas*, *Turbo cornutus*, and others [30.19–21]. However, the interest in these enzymes also led to a raised interest in the study of phylogenetic position and feeding habits of various molluscs [30.22]. The sea still continues to furnish glycosyl hydrolases, which can be used in different fields: (i) to solve the structural complexity of new oligosaccharides obtained purely by improved chromatographic techniques, (ii) to help in the treatment of waste material for the recovery of important value-added molecules, and (iii) to allow synthesis of glycosidic bonds.

The distribution of fucoidan hydrolases and other glycosidases, for example, was only recently investigated in 33 species of marine invertebrates [30.23], although the presence of cellulases has been assessed in *Littorina* sp. [30.24] and in *Telescopium telescopium* [30.25] for a long time. It is of interest to note that both marine microorganisms and invertebrates such as *Haliotis*, *Mizyhopecten yessoensis*, and sea urchins all contain fucoidan hydrolases and other important glycosyl hydrolases [30.26–29]. Fucoidan hydrolases are important enzymes for structural identification of com-

plex structures of fucoidan, a sulphated polysaccharide from brown algae exhibiting biological activity in mammalian systems, which is very promising for human therapeutics[30.30].

An α-L-fucosidase from the liver of the marine gastropod *Charonia lampas* was purified to homogeneity [30.31]. Substrate-specificity studies using a number of fucosylated oligosaccharides of the lacto-N and lacto-N-neo series and a synthetic disaccharide confirmed that the enzyme catalyzes the hydrolysis of a broad range of fucosidic linkages. *Rhodothermus marimus* ATCC 43812, a thermophilic bacterium isolated from marine hot springs, possesses hydrolytic activities for depolymerizing substrates such as carob-galactomannan [30.32]. The Antarctic marine ecosystem has also been the source for the cold-adapted α-galactosidase as found in *Pseudoalteromonas* sp. 22b [30.33]. An updated overall analysis of the literature can be found in different articles, and readers are referred to [30.7–9] and references cited therein.

Different aspects should be considered for marine glycosidases. In the first place, scientific attention has been focused on biocatalysts from marine extremophiles because of the stability and novelty of catalytic properties that these proteins can offer and the simplicity in which they can be expressed. Marine glycosidases, as resulting from our analysis, are well placed in the expanding field of glycobiology. Among the examples, the marine α-galactosidase from *Pseudoalteromonas* [30.34], which is capable of removing immunodeterminant sugar residues and the sialidase from a tentatively assigned *Pseudomonas* used for the preparation of GM1 from a mixture of polysialogangliosides [30.35], are two exciting cases. It is outside the scope of this section to list each glycosyl hydrolase isolated from sea organisms. Above, only few examples are mentioned while in the following sections remarkable examples restricted to sea hares belonging to the family *Aplysiidae* will be reported.

Aplysia is a genus of sea hares belonging to the family *Aplysiidae* to which *Aplysia fasciata*, *Poiret* 1798, and *Aplysia kurodai* belong; these molluscs are very common. They are herbivorous and eat a variety of red, green, or brown algae and eelgrass [30.36]. Animals belonging to the *Aplysiidae* family of sea hares are often quite large and have a rounded body shape with long rhinophores on their heads. The Californian black sea hare, *Aplysia vaccaria*, could be considered the largest living shell-less gastropod (20—75 cm, weighing well over 2 kg). They are cosmopolitan and found in temperate and tropical seas where they inhabit shallow coastal areas or sheltered bays with vegetation. The genus *Aplysia* has proved useful as a model in neurobiology for the study of electrical synapses, which mediate the release of clouds of ink [30.37].

30.4 Glycoside Hydrolases Present in the Genus *Aplysia*

Various interesting results related to the presence of glycosyl hydrolases have been reported on *Aplysia fasciata* and *Aplysia kurodai* in the last decade. Both species have been revealed to be potent producers of a library of glycoside hydrolases applied in the synthesis and hydrolysis of the glycosidic bond. In this section we analyze the results obtained in the isolation and applications of biocatalysts from *A. fasciata* and *Aplysia kurodai* with emphasis on products, reaction conditions, yields, and regioselectivity.

The author's group started a general survey of glycosidase activities present in the mollusc *Aplysia fasciata* several years ago [30.38]. Three main parts of the animal were analyzed: (i) the mantle and other external parts, including oral tentacles, rhinophores, eyes, foot, and parapodia; (ii) the hepatopancreas; and (iii) other visceral mass, including the digestive, excretory, blood-vascular, and reproductive systems. Many glycosyde hydrolase activities were assayed by using chromophoric substrates of different sugars (fucose, galactose, glucose, mannose, *N*-acetyl glucosamine, and xylose), and interesting results were obtained. The extracts from hepatopancreas and from visceral mass resulted rich in glycoside hydrolases; their activities were in the range found in other marine molluscs [30.39]. By contrast, the extract of external parts did not hydrolyze any of the substrates tested. Interestingly, the β-D-galactosidase and the β-D-glucosidase enzymes from hepatopancreas and visceral mass, respectively, were present in large amounts. An interesting α-mannosidase was also noticed.

The ability of α-glucosidases to perform transglucosylation reactions is a relevant issue from the biotechnological point of view (in the food industry, for the production of glycoconjugates, etc.).

Products of various molecular structures, from simple alkyl glucosides to different complex oligosaccharides used in industrial applications, are enzymatically synthesized by the use of α-glucosidases of bacterial, fungal, animal, and vegetal origin [30.1]. The β-D-glucosidase activity was the most abundant glycosyl hydrolase activity found in the visceral mass homogenate of *Aplysia fasciata*. The purified enzyme gave only one band of 69 kDa on SDS-PAGE (SDS: sodium dodecyl sulphate, PAGE: polyacrylamide gel electrophoresis), while the molecular mass of the native enzyme was 255 kDa, indicating that this protein is a homotetramer. It showed a pH optimum at 5.8, and the optimum temperature at this pH was in the range 36–44 °C; pH 5.8 and 34 °C were identified as the best conditions for performing both hydrolytic and transglycosylation experiments [30.40]. Organic solvent resistance was also of interest in view of the low solubility of aryl substrates that can be used as donors and for conceivable use of hydrophobic acceptors in transglycosylation reactions. Enzymatic resistance to organic solvents was studied at 10% concentration. A good resistance of the enzyme to dimethyl sulfoxide (DMSO, 80% residual activity after 24 h), high sensitivity to acetonitrile and dimethylformamide (DMF, total loss of activity after few minutes), and an intermediate resistance to acetone (50% residual activity after 24 h) were recorded. The study of substrate specificity started using starch, amylopectin, amylose, isomaltose, panose, pullulan, and saccharose were not hydrolyzed by this enzyme, although a feeble reaction using trehalose was observed. Moreover, no enzymatic hydration of glucal (with formation of 2-deoxyglucose) was detectable. Nitrophenyl glucoside (*p*NP-α-D-Glc) and the α-maltoside derivative (*p*NP-α-D-Glc-(1,4)-α-D-Glc) were highly hydrolyzed, while the β-form (*p*NP-β-D-Glc-(1,4)-α-D-Glc) was hydrolyzed to a lesser extent. The α-glucosidase from *Aplysia fasciata* was very active on the α-1,4 glucosidic linkage, as it was assessed by measuring the kinetic parameters for the hydrolysis of maltose (V_{max} 115 U mg^{-1}, K_M 5.70 mM, k_{cat} 489 s^{-1}), *p*NP-α-D-Glc (k_M 0.26 mM, k_{cat} 163 s^{-1}), and *p*NP-β-D-Glc-(1,4)-α-D-Glc (k_M 2.06 mM, k_{cat} 75.9 s^{-1}). The α-1,6 glucosidic linkage was only poorly hydrolyzed as it was noticed that the specific activity for maltose was 40 times higher than that for isomaltose (V_{max} 2.9 U mg^{-1} by using 22 mM substrate). According to the Michaelis constants for *p*NP-α-D-Glc and maltose, it could be suggested that the subsite +1 of this enzyme has a higher affinity for the aryl group than for glucosyl residue. Although the k_{cat} value for maltose was three times higher than that for *p*NP-α-D-Glc, the catalytic efficiency showed that in vitro the former is the preferred substrate for this enzyme ($k_{cat}/k_M = 627$ mM^{-1} s^{-1}). A still good catalytic efficiency was observed in the hydrolysis of *p*NP-β-D-Glc-(1,4)-α-Glc (k_{cat}/K_M 36.8 mM^{-1} s^{-1}), while no hydrolytic activity was detected when the pure enzyme was incubated in the presence of *p*NP-β-D-Gal or *p*NP-β-D-Man. This overall picture of substrate specificity, together with the fact that this enzyme is not able to hydrate glucal, suggested that the enzyme from *Aplysia fasciata* may belong to family I type α-glucosidases [30.41], corresponding to family 13 of glycoside hydrolases (GH), however sequence similarity studies are necessary to establish this.

Because maltose was a very good substrate for this marine α-glucosidase, its bioconversion was studied in detail (Fig. 30.1). The time course for the bioconversion of maltose was studied using 93 mM maltose and 18 µg of pure protein per ml. Aliquots were withdrawn at different time intervals and analyzed by HPAEC-PAD (High-Performance Anion-Exchange Chromatography with Pulsed Amperometric Detection) using a CarboPacTM PA1 analytical column (Dionex). In these conditions, within the first hour of reaction ca. 60% of maltose was consumed, forming maltotriose and panose; the concentration of maltotriose decreased to a very low value after 360 min, and the concentration of the regioisomer panose increased to a plateau (after ca. 180 min), reaching a value of ca. 8 g L^{-1} in

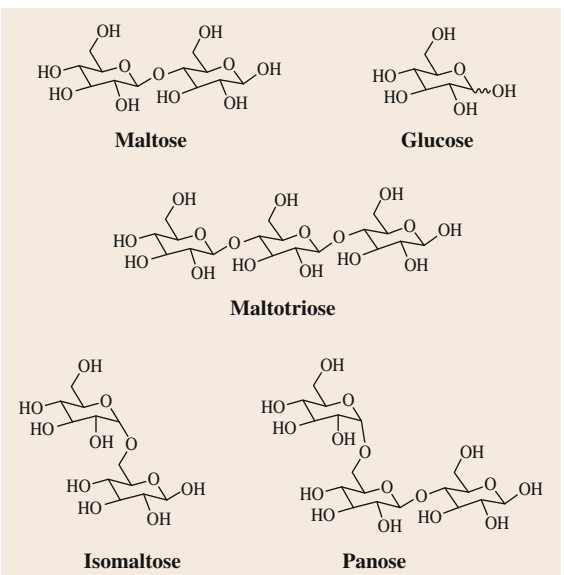

Fig. 30.1 Bioconversion of maltose

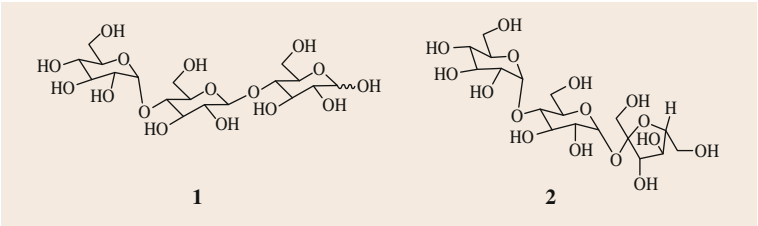

Fig. 30.2 Trisaccharides formed by transglycosylation from cellobiose and sucrose using α-glucosidase of the marine mollusc *Aplysia fasciata*

the reaction mixture. The disaccharide was identified as isomaltose (6-O-α-D-glucopyranosyl-D-glucose) by comparison of ^{1}H and ^{13}C NMR spectra of the acetylated derivative with an authentic standard sample. COSY (correlation spectroscopy), TOCSY (total correlation spectroscopy), and ^{1}H–^{13}C NMR correlation spectra of the acetylated derivative of the trisaccharide showed unambiguously the panose structure; the tetra and pentasaccharidic nature of the remaining products was established both by their R_fs in and by mass spectroscopy (ESI-MS, electrospray ionization positive ions) of acetylated derivatives. It led to the formation of several products, the most abundant being the trisaccharide panose and the disaccharide isomaltose whose structures were determined by nuclear magnetic resonance (NMR) spectroscopy. Maltotriose was also a good substrate with a pattern of products similar to that observed using maltose: maltotetra up to maltohexaose were found in the early stages of reaction but panose and isomaltose were later identified as end products also in this reaction. Using maltoheptaose the enzyme performed a reaction which is in agreement with the reaction of maltose [30.40].

Transglycosylation reactions are possible using the aryl substrate *p*NP-α-D-Glc or maltose as donors. Interestingly, polyglycosylation was often observed. When maltose was the donor and *p*NP-β-D-Glc was the acceptor, *p*NP-β-D-Glc-(1,4)-α-D-Glc was the sole product in the early stages of reaction (30 min), then the isomaltoside derivative, *p*NP-β-D-Glc-(1,6)-α-D-Glc, was also formed and it accumulated up to the end when it became the most abundant isomer with a yield of ca. 15–20%. Using *p*-nitrophenyl β-cellobioside (*p*NP-β-D-Glc-(1,4)-β-D-Glc) as acceptor; the formation of a trisaccharidic product was observed while both α and β-anomers of *p*-nitrophenyl galactopyranoside were not glycosylated in significative amounts. The preferential enzymatic formation of α-1,4 linkages (Fig. 30.1) in the early stages of reaction and the accumulation of α-1,6 products were confirmed by time course experiments. The body of these results suggested an intramolecular arrangement from maltotriose for the production of panose from maltose, instead of the alternative intermolecular direct α-1,6 glucosylation of maltose itself. Furthermore, as is indicated by the absence of higher molecular weight (MW) products in the maltoheptaose reaction, a possible molecular limit in the acceptor site of the enzyme is conceivable [30.40].

Reactions with different acceptors such as cellobiose and saccharose (Fig. 30.2), pyridoxine (Fig. 30.3), naringin and other antioxidants (Fig. 30.4), and 9-fluorenone derivatives (Fig. 30.5) were studied in detail.

The most abundant (90% at 25% yield, ca. 4 g L^{-1}) product, **1** (Fig. 30.2), from cellobiose was recognized as the α-1,4 glucosyl derivative; however, other minor isomers were also present. Also sucrose was α-glucosylated at position 4 of glucose unit forming erlose (4G-α-D-glucosyl sucrose), **2** (Fig. 30.2). Compounds of type **1**, (Fig. 30.2), α-glucosyl cellobioses, have recently been produced from sucrose donor and cellobiose acceptor by alternansucrase [30.42], while type **2** (Fig. 30.2) products, glucosyl sucroses, were also synthesized enzymatically by α-glucosidase from spinach [30.43] and other enzymes.

Glucosylation of pyridoxine by purified α-glucosidase from *Aplysia fasciata* gave the products shown in Fig. 30.3 [30.44]. The reaction was conducted adding pyridoxine portionwise (keeping its concentration at 7.8 mg mL^{-1} as the highest level) to a 1 M maltose solution containing 15.5 μg of enzyme $mmol^{-1}$ of maltose, it was possible to add four aliquots of pyridoxine (during 55 h total reaction time) that were well consumed (81% conversion), forming monoglucosidic **1** and **2** (molar yield 40%, 72 mM,

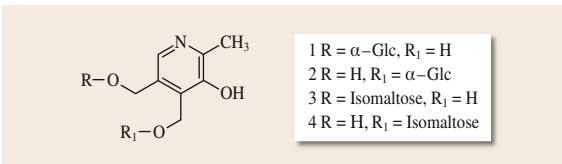

Fig. 30.3 Pyridoxine glucosides obtained by transglycosylation using the α-glucosidase from *Aplysia fasciata*

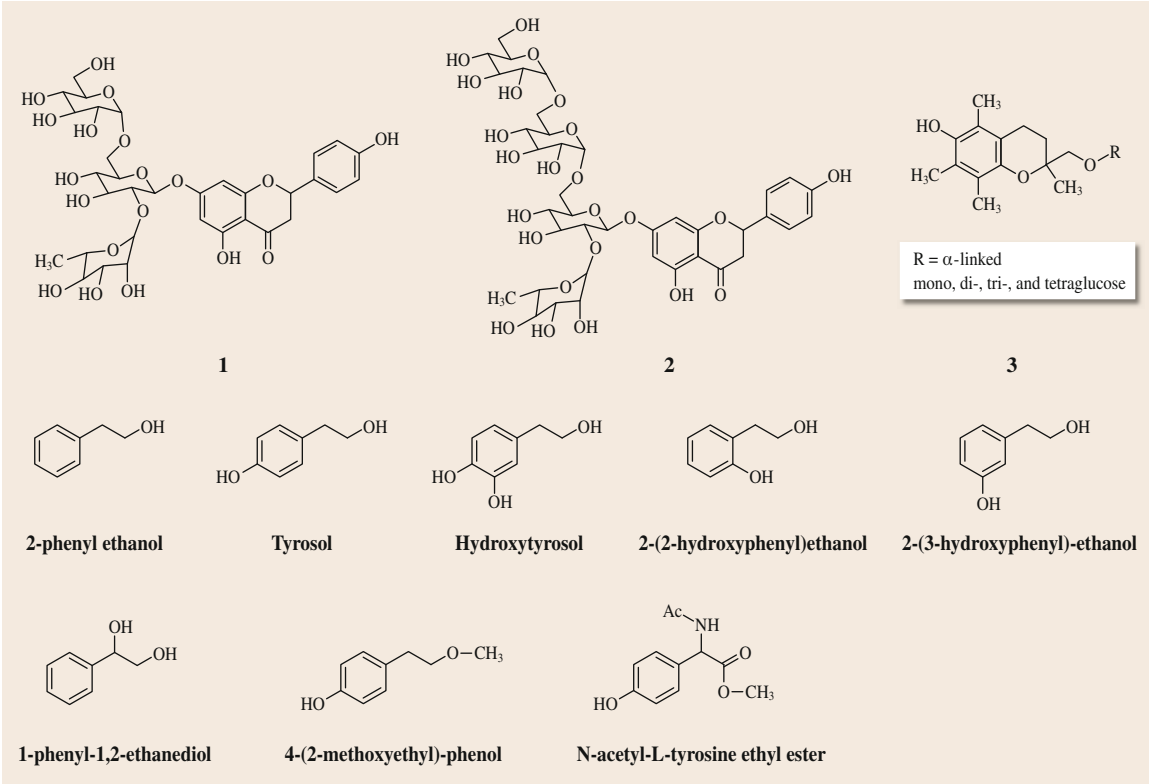

Fig. 30.4 Products formed by naringin glycosylation and substrates tested for the study of chemoselection, using α-glucosidase from *Aplysia fasciata*

24 g L^{-1}) and diglucosidic **3** and **4** (molar yield 41%, 71 mM, 35 g L^{-1}) and also traces of triglucosidic derivatives of pyridoxine. Glucosides of pyridoxine are more stable against light and heat with respect to the aglycone, and these glucosides and other derivatives are important molecules not only from a nutritional but also from a pharmaceutical perspective [30.45]. Two monoglucosides of pyridoxine are synthesized in different proportion, with **1** (Fig. 30.3) being the most abundant (75%). The disaccharide mixture is almost totally (95%) composed by compound **3** (Fig. 30.3), and it has been also found that the observed selectivity is entirely expressed only during the two transglycosylation events and it is not due to a possible differential hydrolysis of regioisomeric products **3** and **4** [30.44].

The enzymatic modification of naringin and other related compounds in citrus is of current biotechnological interest for food and pharmaceutical industries, both for the efficient and food-compatible reduction of the bitter taste of juice and for the modification of pharmacological activities of the molecule. Debittering grapefruit juices has been achieved by different techniques, including transglycosylation reaction. Glucosylation of naringin by marine α-D-glucosidase from *Aplysia fasciata* is a very efficient process in terms of regioselectivity and yield of reaction. The reaction can be conveniently conducted in a wide range of naringin content, and almost complete conversion of naringin can be obtained. Suspensions of naringin can be used up to 90 mg mL^{-1} initial acceptor concentration. In different experiments it was demonstrated that the enzyme was still active after 48 h in the presence of this high amount of acceptor and that one of the diastereomers of the naringin is preferred by the enzyme from *Aplysia fasciata* during glucosylation/deglucosylation enzymatic steps. One out of eight possible mono-glucosylated derivatives was obtained, **1** (Fig. 30.4). Further functionalization took place on the new α-glucose moiety at the C-6 specific position just added, forming only isomaltosyl derivative **2** (Fig. 30.4). Remarkably, most of the naringin naturally occurring in fresh grapefruit juice can be directly modified to form the two products shown in Fig. 30.4 [30.46].

The synthesis of interesting and potentially useful α-oligoglucosides of 2-hydroxymethyl-2,5,7,8 tetramethylchroman-6-ol, **3**, Fig. 30.4 can be effectively achieved by using the polyglycosylating α-glucosidase from the marine mollusc *Aplysia fasciata*. The conversion of the acceptor is almost total at moderate concentration of maltose (150 mM), at a molar excess of 30. At the beginning of the enzymatic reaction (20% conversion achieved in 1 h), only (S)-diastereomer of the glucoside of **3** (R = α-D-Glc) Fig. 30.4 was obtained. This is an intriguing result in that chemoenzymatic routes to enantiopure (R) and (S)-2-hydroxymethyl-2,5,7,8-tetramethylchroman-6-ol are of current interest [30.47]. At the end of the polyglycosylation reaction, a number of oligoglucosides possessing different structures were observed in the reaction mixture. The percentage composition of the reaction mixture at 24 h was as follows: monosaccharide, 47%; two disaccharides, 42%; three trisaccharides, 9.4%; and a tetrasaccharide, 1.6%. The isomaltoside, the most abundant disaccharide produced, showed a radical scavenging activity similar to that of the aglycone **3** (R=H) Fig. 30.4, so that it can be proposed as a new hydrosoluble antioxidant agent. The green-based methodology by which it is synthesized allows the inclusion of various technological fields (cosmetics, the food industry, etc.) for exploitation. Furthermore, an intriguing correlation between the nature of the interglycosidic linkage and scavenging activity was noticed both in disaccharides and in trisaccharides. This structure–activity relationship deserves further investigation and the synthesis of pure diastereomeric material will be of fundamental importance [30.48].

An efficient enzymatic two-step procedure for the synthesis of hydroxytyrosol and tyrosol α-glucosidic derivatives based on α-glucosidase from *Aplysia fasciata* and a commercial tyrosinase from mushrooms, was described very recently [30.49]. Considering the entire double enzymatic process for the formation of these glycosidic derivatives of hydroxytyrosol from tyrosol, it was possible to glycosylate regioselectively only the alcoholic primary position for producing hydroxytyrosol mono and disaccharidic derivatives, with a reaction total yield which was of ca. 20% for each product obtained at final concentrations of 9.35 and 10.8 g L^{-1} of reaction, respectively. Their antioxidant activity was evaluated by a DPPH test. However, in the first part of this work, the ability of α-D-glucosidase from *Aplysia fasciata* to glycosylate an array of naturally occurring phenolic compounds with alcoholic and/or phenolic hydroxyl groups in their molecular skeleton was analyzed and the regio and chemoselectivity in their transglycosylation processes were qualitatively examined. The interesting results are briefly summarized here: 2-phenylethanol, tyrosol, and similar compounds such as 2-(2-hydroxyphenyl)-ethanol, 2-(3-hydroxyphenyl)-ethanol, hydroxytyrosol, (±)-1-phenyl-1,2-ethanediol, *R*(-)- and *S*(+)-1-phenyl-1,2-ethanediol, 4-(2-methoxyethyl)-phenol, *N*-acetyl-L-tyrosine ethyl ester monohydrate (Fig. 30.4) were all tested as acceptors in analytical scale transglycosylation reactions, and a different qualitative distribution of products at 4, 24, and 48 h was recorded. Accumulation of mono and disaccharidic derivatives was noticed for almost all acceptors up to 24 h. In many cases, at early reaction times, glycosylations were not chemoselective with the involvement of phenolic and alcoholic hydroxyls, but after 24 h, a prevalent accumulation of products glycosylated at the alcoholic position was observed, as in the case of hydroxytyrosol, tyrosol, and its regioisomers.

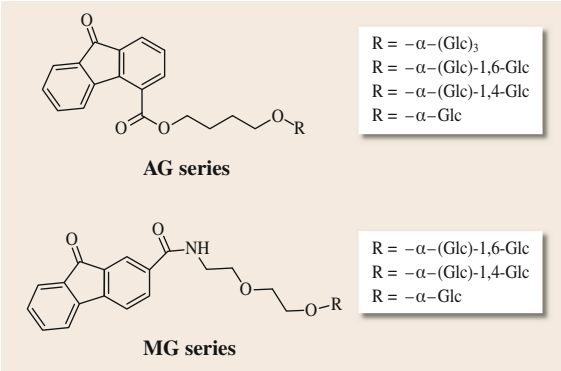

Fig. 30.5 Glucosylated products formed by glucosylation of 9-fluorenone derivatives. Carboxyhydroxyesters, indicated by AG and carboxyhydroxamides indicated by MG

For the protected derivative of tyrosol, 4-(2-methoxyethyl)phenol, disaccharidic products were still present at 24 h, and this result is in line with the characteristics of this enzyme (see above), while monoglucosides of 2-phenylethanol and *N*-acetyl-L-tyrosine ethyl ester monohydrate were partially or totally hydrolyzed, respectively. Racemic 1-phenyl-1,2-ethanediol and their pure enantiomers were polyglycosylated and partially (racemic and *R*(-)-substrate) or totally (*S*(+)-substrate) hydrolyzed after 24 h.

Compounds of pharmaceutical interest were also synthesized by α-D-glucosidase from *Aplysia fasciata*. Two new series of compounds were prepared and pharmacologically explored in the framework of research on

the antiviral and immunomodulatory activity of tilorone congeners: 9-fluorenone carboxyhydroxyesters (AG series Fig. 30.5) and 9-fluorenone carboxyhydroxamides (MG series Fig. 30.5). The α-glucosidase provided several α-*O*-glucosides of both model acceptors. The easy biocatalytic access to these polyglucosylated derivatives is very interesting for the quick screening of the pharmaceutical profiles of these drugs as modified by carbohydrate(s) moieties with respect to their parental aglycones [30.50].

The homogenate from the hepatopancreas of *Aplysia fasciata* contained a β-galactosidase activity, which after purification was shown to be a homodimer with a molecular mass of 164 kDa as estimated by gel-filtration and 78 kDa by SDS-PAGE [30.51]. β-D-Galactosidase activity measured as a function of pH revealed that the activity increases going from pH 5.5–2.3 and drastically drops at lower pH. At pH 3.7 a maximum activity around 75 °C was observed. The enzyme completely retains its activity after 23 h incubation at pH 4.7 in K-acetate buffer, while it retains 81% of its activity when incubated at pH 3.9 in Na-citrate buffer for 23 h. At pH 2.8 in glycine-HCl, the half-life time was 0.6 h. At 50 °C in K-acetate buffer pH 4.5 the half-life was 15 h. This enzyme is highly specific for *p*NP-β-D-galactopyranoside (*p*NP-β-Gal) and is completely inactive on other substrates; it is also able to hydrolyze the glycosidic linkage present in lactose, although to a much lesser extent than those of *p*NP-β-Gal and *o*NP-β-Gal. In transgalactosylation reactions this enzyme showed interesting characteristics. Due to the specificity of the acceptor site of most galactosidases for compounds with phenyl groups [30.52], the yields obtained in the reactions using free or methyl derivative of xylose and methyl β-galactopyranoside and D-galactose are interestingly high. The uncommon β-1,3 selectivity is also of interest; using free xylose or its β-allyl or methyl derivative, the β-1,3 isomer was always selectively formed. The same result was obtained by using methyl β-D-galactopyranoside and glucal. With β-aryl linked aglycones for both xylose and galactose, this β-1,3 selectivity is again expressed, although it is lost with α-anomers. However the influence of aryl groups as aglycones is not limited to the regioselectivity of reaction but also to the yield as shown when comparing the results of the reactions using the p-nitrophenyl and benzyl xylopyranosides [30.53]. o-Nitrophenyl β-D-galactopyranoside (*o*NP-β-Gal) was used as glycosyl donor in reactions with 5 equivalents of nucleoside acceptors (uridine, fluorouridine, thymidine, adenosine, cytidine, 5-chlorocytosine arabinoside, and 3′azido-3′-deoxythymidine) in the presence of this enzyme. The regioselectivity was extremely high, in all reactions only the product of galactosylation in 5′ position of the nucleoside was observed. Reaction yields were satisfactory in most cases, and very high for uridine derivatives. In particular, 5′-*O*-β-galactosyl-5-fluorouridine, the galactosylated derivative of the anticancer drug fluorouridine, was synthesized with a 60% yield, and 5′-*O*-β-galactosyl-3′-azido-3′-deoxythymidine, the derivative of the anti-HIV drug, was obtained in 43% yield [30.54]. This was the first report dealing with a glycoside hydrolase used for the modification of nucleosides with such convenient yields. Nucleoside analogs play an important role in antiviral and anticancer therapy. In addition, it has been found that many natural antibiotics possessing significant antitumor and antiviral activities have the structure of a nucleoside connected to oligosaccharides [30.55].

There are at least three main points stating the importance of enzymes acting on mannose-based carbohydrates. The first is that the β-mannopyranoside linkage is one of the most difficult glycosidic bonds to synthesize using chemical strategies [30.56], because the steric and polar effects favor the formation of α-anomer. Hence, alternative biological methodologies based on β-mannosidases are very attractive. However, natural examples of new β-mannosidase are needed also for the advancement of conformational studies of the enzymatic transition state and for the possibility of genetic manipulation of such enzymes to produce efficient synthetic catalysts (mannosynthase) [30.57]. As a third point it could be stated that β-mannosidases and β-mannanases are of interest for the reutilization of waste materials. In this context, both the degradation of β-1,4-mannan to simple sugars and the direct β-mannosidase-catalyzed synthesis of alkyl β-D-mannosides from mannobiose by β-mannosidase are possible [30.58]. β-D-Mannosidase activity was identified in the hepatopancreas of *Aplysia fasciata* and with higher specific activity in the visceral mass homogenate [30.38]. The apparent molecular mass for the purified protein was 229 kDa, while the molecular mass as determined by SDS-PAGE was 130 kDa, indicating that the purified enzyme is a homodimer. It showed an optimal activity at pH 4.5 and 45 °C [30.59]. At optimal pH the enzyme showed a half-life of 23 h. The enzyme retained most of its activity (82%) after 24 h incubation in the presence of 10% DMSO, while in the presence of other co-solvents the activity quickly dropped down (a half-life of 1 h was estimated in the presence of 10% acetonitrile, while in

acetone the half-life was 8.5 h). The K_M and V_{max} values for pNP-β-Man were determined to be 2.4 mM and 50.3 U mg^{-1}, respectively. From the body of these and other results, β-D-mannosidase from *Aplysia fasciata* was judged to possess a very good catalytic efficiency, in fact the k_{cat}/K_M obtained is 4800 min^{-1} mM^{-1}, which is higher than those of analogous enzymes from other species. This enzyme is also extremely specific for *p*NP-β-Man, a useful and needed characteristic when using a glycosydase for structural determination purposes. Self-transfer of a β-mannosyl unit was observed when *p*NP-β-man is treated with the β-D-mannosidase, in fact the most abundant disaccharidic product obtained (10–15% yield) possessed the β-1,4 intermannosydic linkage as established by the analysis of mono and two-dimensional NMR spectra of products (*p*NP-β-Man-(1,4)-β-Man). The transmannosylation was also studied using *p*NP-β-Man as donor and *o*-nitrophenyl α-D-2-deoxy-*N*-acetyl glucopyranoside as heteroacceptor, the molar ratio used was 1 : 3. Two regioisomers (12% global yield) due to the β-mannosylation of the heteroacceptor were formed in 85 : 15 ratio (by high-performance liquid chromatography, HPLC). The products were the β-1,4 and the β-1,6 derivatives as assessed by two-dimensional NMR spectroscopy.

As stated above, the production of mannooligosaccharides from mannan is based on endo-β-1,4-mannanase (EC 3.2.1.78) as biocatalyst. β-mannanases have already been established as useful biocatalysts in various industrial processes [30.60]. *Aplysia kurodai* was considered to use two mannan-degrading enzymes, namely a β-mannanase and a β-mannosidase, for the complete depolymerization of mannan from seaweeds for nutritional purposes [30.61]. The β-mannanase acted on the linear structure of mannans, producing heterooligosaccharide residues. It could degrade mannooligosaccharides larger than mannotetraose; from M5 (mannopentaose) it produced M3 and M2, and from M6 it produced M3, suggesting that the size of substrate binding site is similar to the size of mannnopentaose-mannohexaose, and splitting of the central mannosidic linkage of the mannohexaose unit occurred [30.62]. β-mannosidase and β-mannanase acted on linear mannan, degrading it to mannose in a more efficient manner [30.61]. Unfortunately, no results have been reported on these interesting enzymes about their possible transmannosylation properties on heteroacceptors. A bacterial expression system for this β-mannanase was reported to acquire information about the primary structure and other characteristic properties. The recombinant protein showed a broad pH optimum in the acidic range, as did native protein; however, heat stability was lower, indicating that the stability is derived from an appropriate folding and/or some posttranslational modifications in *Aplysia* cells [30.63].

Aplysia kurodai also contains two alginate lyase isozymes [30.64] that could be useful in the determination of fine structures of natural polymers and in the bio-production of functional monosaccharides and oligosaccharides from alginate. To improve the knowledge of primary structure and catalytic residues of marine alginate lyases, cloning complementary DNA (cDNA) encoding an alginate lyase from *Aplysia kurodai* and assessing catalytically important residues by site-directed mutagenesis were also described [30.65].

Two β-1,3-glucanases with the molecular masses of 36 kDa and 33 kDa were also isolated from the digestive fluid of *Aplysia kurodai*. They act as endolytic (EC 3.2.1.6, AkLam36) and exolytic enzymes (EC 3.2.1.58, AkLam33) degrading laminarin and related oligosaccharides to laminaritriose, laminaribiose, and glucose in the first case, while producing glucose directly from polymer laminarin in the second case. Although both these catalysts acted on laminaribiose, they were capable of degrading the disaccharide via transglycosylation reaction with laminaritriose. Both enzymes belong to the glycosyl hydrolase family 16 like other molluscan β-1,3-glucanases. According to the authors it is still unclear whether the transglycosylation is a physiologically important event in the metabolism since the transglycosylation reaction requires a relatively high concentration of laminaribiose [30.66].

Other enzymes related to chitin could be expected to be present in organisms of the *Aplysia* species. It was, in fact, long known in the literature that chitosan-based radulae and jaws of the opisthobranch *Aplysia sp*. give very strong chitosan color tests [30.67].

30.5 Other Enzymatic Activities of Interest Present in *Aplysia* sp.

Other examples of interesting enzymes have been reported in the literature on *Aplysia* sp. This marine organism, in fact, has proved to be useful as a model in neurobiology and in other scientific sectors. Some of the enzymes cited in the present section may be of interest for biocatalyst practitioners and it appears to be

worth noting them, although they are not related to the carbohydrate chemistry but to protein and lipid fields.

A large number of *Aplysia* neuropeptides were identified and some of these biomolecules show remarkable sequence similarities to mammalian neuropeptides. Enzymes acting specifically on these substrates could be of interest for their specificity in the biocatalytic field as well in other physiological studies [30.68, 69].

Lipoxygenases are also identified in *Aplysia*. These enzymes act on lipids and are of interest for the production of bioactive molecules both in vivo and in vitro. Arachidonic acid is converted to (8*R*)-hydroperoxyeicosa-5,9,11,14-tetraenoic acid (8-HPETE) during incubations with homogenates of the central nervous system of the marine mollusc, *Aplysia californica*. The product can be then reduced to the corresponding hydroxy acid or enzymatically converted to other metabolites [30.70]. In this field, enzymes of marine origin are characterized by regio and stereoselective output of reactions different from those found in terrestrial counterparts. From the synthetic chemist's point of view asymmetric oxygenation reaction of unnatural substrates has a tremendous potential [30.71].

30.6 Conclusion

Enzymatic routes are particularly useful to access new products or for the modification of complex natural products such as carbohydrates, which are very important molecules in various technological domains. Herbivorous marine molluscs possessing various kind of polysaccharide-degrading enzymes could efficiently act on these molecules. These enzymes play important roles in the metabolism of the organism digesting polymeric materials to oligosaccharides and monosaccharides as carbohydrate nutrients. They can also be used in a diverse manner for biocatalyzed synthesis of the glycosidic bond. Different interesting results related to the presence of glycosyl hydrolases have been reported in the literature on *Aplysia fasciata* and *Aplysia kurodai*. The examples have been judged to be of interest to the biocatalysis community. In *A. fasciata* β-D-galactosidase and α-D-glucosidase enzymes are present in large amounts, and an interesting β-mannosidase has also been noticed; in *A. kurodai* different enzymes acting on polysaccharides were evidenced.

31. Antimicrobial Peptides from Marine Organisms

Venugopal Rajanbabu, Jyh-Yih Chen, Jen-Leih Wu

Antimicrobial peptides (AMP), also known as host defense peptides or alarmins, are among the first lines of defense against infection in many organisms. Marine organisms have proved to be a rich source of AMPs, and several uniquely structured marine AMPs have been isolated using biochemical, in silico and genetic approaches. Hemolymph is the main source of AMPs in marine invertebrates, although other tissues may also contain these peptides. Based on their three-dimensional structure, AMPs may be classified into peptides with α-helix structures, peptides with β-sheets and cysteine residues, peptides enriched for modified and rare amino acids, and peptides with ring structure amino acids. This chapter describes AMPs of each structure, in terms of their antibacterial, antiviral, antifungal, insecticidal, nematicidal, and immunomodulatory functions. It is hoped that the diversity of marine AMPs may facilitate the identification of effective substitutes to existing antibiotics, thereby helping to minimize the development of antibiotic-resistant pathogen strains in response to the continuous application of a single antibiotic therapy.

31.1 Marine Antimicrobial Peptides

Antimicrobial peptides (AMP) are short amino acid chain molecules involved in the first line of defense against invading pathogens. AMPs are synthesized by the ribosomal machinery as pro-peptides, consisting of an N-terminal signal sequence, a pro-sequence, and a C-terminal sequence with antimicrobial activity once it is cleaved from the rest of the pro-peptide.

To date, nearly 3000 AMPs have been isolated from organisms as diverse as plants, mammals, fish (marine, fresh water and aquaculture), and insects and other invertebrates. Marine organisms produce numerous AMPs to combat specific and large invading pathogens in an aquatic environment. Marine organisms are relatively understudied, and only a presumed fraction of marine AMPs has been identified. As such, it is likely that with further research we will isolate a considerable number of AMPs from marine sources. In a similar manner to the development of drug resistance, pathogens evolve to evade host AMPs. By targeting pathogens with functionally similar, yet structurally unique marine AMPs, it may be possible to prevent the evolution of resistant strains. The growing interest in the study of marine AMPs has led to the discovery of peptides similar to mammalian equivalents, but with unique differences. This chapter briefly describes the methods employed in the isolation of marine AMPs, before describing the antimicrobial functions and other applications of structurally grouped AMPs.

31.2 Isolation of Antimicrobial Peptides

Biochemical, bioinformatic, and genetic approaches have been used to identify and isolate AMPs. A biochemical approach involving solid phase extraction, followed by reverse phase high-performance liquid chromatography (HPLC) and size exclusion chromatography, was utilized to isolate a 2.7 kDa AMP from *Penaeus vannamei*, and 7.9 kDa and 8.3 kDa AMPs from *Penaeus stylirostris* [31.1].

The samples were acidified to a pH of up to 4.0 and then neutralized, before being stepwise eluted with 5, 40, and 80% aceto-nitrile water and subsequently lyopolized. Then fractions from reverse phase HPLC were collected separately, and the antimicrobial activity of the fractions were determined; active fractions were then further purified by size exclusion chromatography. Bioinformatics has been used to predict AMPs by in silico analysis; by comparing a candidate sequence to those of AMPs in an available database, it has been possible to identify AMPs like CsHepcidin from the half-smooth tongue sole, *Cynoglossus semilaevis* [31.2]. Finally, a genetic approach involving analysis of the transcriptome from shrimp *Litopenaeus stylirostris* that survived *Vibrio penaeicidae* infection was used to identify the AMP Ls-stylicin [31.3].

31.3 Characterization and Functions of AMP

Nuclear magnetic resonance (NMR) spectroscopy has been used to reveal the three-dimensional structure of AMPs [31.4]. Based on their structure, AMPs can be divided into five groups: peptides with α-helix structures, peptides with β-sheets and cysteines, peptides enriched for regular amino acids, peptides enriched for modified and rare amino acids, and ring structured amino acid peptides (which may result in a cyclic structure) [31.5]. Most marine AMPs of the β-sheet class exhibit antimicrobial function against Gram-positive and Gram-negative bacteria, and a few exhibit antiviral and antifungal activities. The α-helix AMPs are well known for their antimicrobial function at very low concentrations, but this comes with the drawback of high cytotoxicity. Cyclic AMPs form a ring structure and possess insecticidal, nematicidal, antitumor, and immunomodulatory functions. The following paragraph describes the properties of marine AMP subgroups.

Fig. 31.1 Structure of the cecropin family antimicrobial peptide

31.3.1 Alpha Helical AMPs

Cecropin (Fig. 31.1) was the first AMP of this group to be studied [31.6]. The AMPs styelin A–E (Fig. 31.2), clavanin, clavaspirin, and dicynthaurin obtained from tunicates show antibacterial activity, as they interact with lipid bilayers and thus target the membrane [31.7–11]. Clavanin (Fig. 31.3) kills *Micrococcus flavus* by permeabilizing its cytoplasmic membrane [31.12]. Stylins from *Styela clava* are phenylalanine-rich peptides with antimicrobial activity against Gram-negative and Gram-positive marine bacteria, human bacterial pathogens, *Psychrobacter immobilis*, and *Planococcus citreus* [31.7]. Styelin A and B possess strong antimicrobial activity against marine bacteria, *Psychrobacter immobilis* and *Planococcus citreus* [31.7]. Stylin C, D, and E exhibit bactericidal ability at acidic pH and high salinity. Styelin D is effective against methicillin-resistant *Staphylococcus aureus* (MRSA). Clavaspirin (Fig. 31.4a) is effective at acidic pH, at which it permeabilizes the outer and inner membranes of *Escherichia coli*, lyses liposomes and erythrocytes, and has anti-MRSA activity [31.10]. Dicynthaurin (Fig. 31.4b) acts intracellularly within the phagosome and exhibits antimicrobial activity against the Gram-positive bacteria *Micrococcus luteus*, *Staphylococcus aureus*, and *Listeria monocytogenes*, and the Gram-negative bacteria *Escherichia coli* and *Pseudomonas aeruginosa* [31.11]. Two AMPs isolated from the tunicate *Halocynthia papillosa*, halocyntin (Fig. 31.5a)

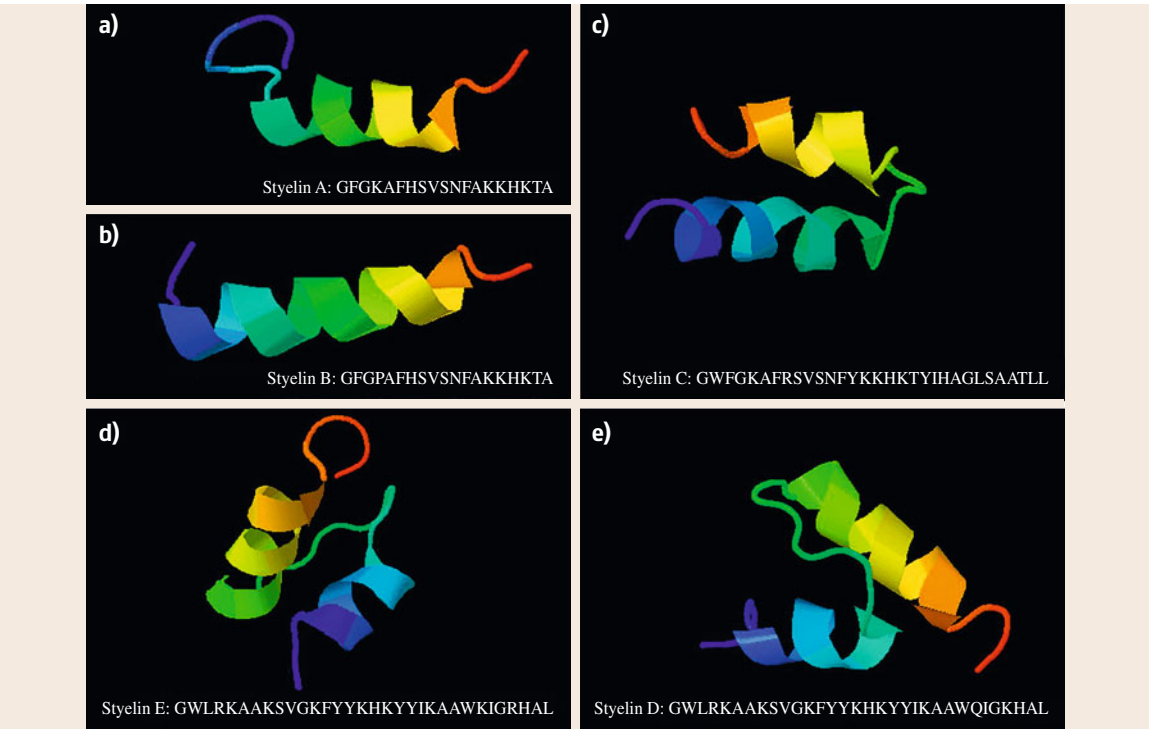

Fig. 31.2a–e Amino acid sequence and structure of the mature styelins. **(a)** Styelin A, **(b)** styelin B, **(c)** styelin C, **(d)** styelin D, and **(e)** styelin E

and papillosin (Fig. 31.5b) have two α-helical structures and exhibit antibacterial activity against Gram-positive and Gram-negative bacteria [31.13]. Ci-MAM-A (Fig. 31.5c) and Ci-PAP-A (Fig. 31.5d) are AMPs isolated from *Ciona intestinalis*; these peptides are active at high salt concentrations, and kill Gram-negative and Gram-positive bacteria by permeabilizing their cytoplasmic membranes [31.14]. Ci-MAM-A is not cytolytic to mammalian erythrocytes, but is toxic to several human and marine pathogens, as well as the yeast *Candida albicans* [31.15]. Hedistin (Fig. 31.6a), isolated from *Nereis diversicolor*, is a helix-turn-helix moiety AMP with C-terminal-amidation and bromotryptophan residues; hedistin shows activity against a large spectrum of bacteria, including MRSA and *Vibrio alginolyticus* [31.16]. Hedistin expressed in circulating natural killer (NK) cells possibly plays an important role in immunity [31.16]. Centrocin (Fig. 31.6b–c) is an AMP from *Strongylocentrotus droebachiensis*, with an alpha helix heterodimeric structure. It consists of a heavy chain with 30 amino acids and a light chain with 12 amino acids; the heavy chain has activity against bacteria, fungi, and yeasts [31.17].

31.3.2 Beta Sheet/Cysteine-Rich AMPs

Cysteine-rich peptides, such as hepcidin (Fig. 31.7), are able to form disulphide bonds. Penaeidins derived from shrimp possess a proline-rich domain at their N-terminus, and a cysteine-rich domain stabilized by three conserved disulfide bonds at their C-terminus [31.18]. Sb-BDef1 is the big defensin AMP of *Scapharca broughtonii*; it has a β-sheet strand and a highly amphipathic hydrophobic N-terminal structure, and is involved in the immune response to Gram-negative microbial infections [31.19]. The big defensin (Fig. 31.8) of *Tachyplesus tridentatus* has both antibacterial activity and anti-fungal activity against the filamentous fungi *Candida albicans* [31.20]. AiBD, a big defensin peptide in *Argopecten irradians*, possesses an α-helix and β-sheet, and is effective against bacterial and fungal infections [31.21]. The antifungal polypeptides HCt1, 2, 3 are hemocyanin C-terminal region peptides with β-sheets isolated from *Penaeus vannamei* and *Penaeus stylirostri* [31.22]. The BDS-I and II peptides (isolated from *Anemonia sulcata*) have a compact disulfide core and a stranded antiparallel β-sheet structure; they

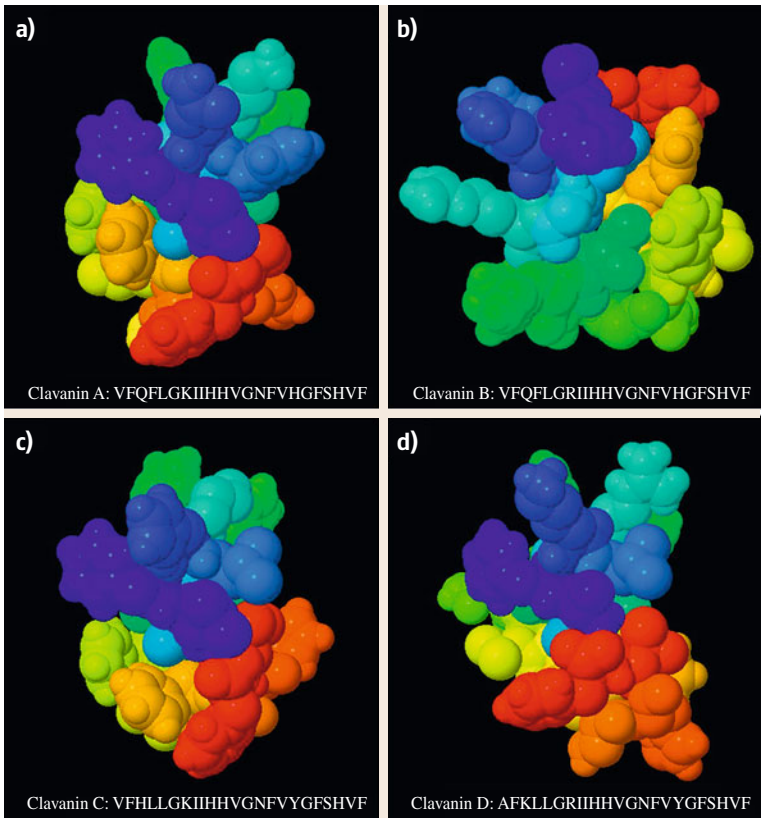

Fig. 31.3a–d Amino acid sequence and structure of the histidine rich mature clavanins from sea squirts and tunicates. **(a)** Clavanin A, **(b)** clavanin B, **(c)** clavanin C, and **(d)** clavanin D

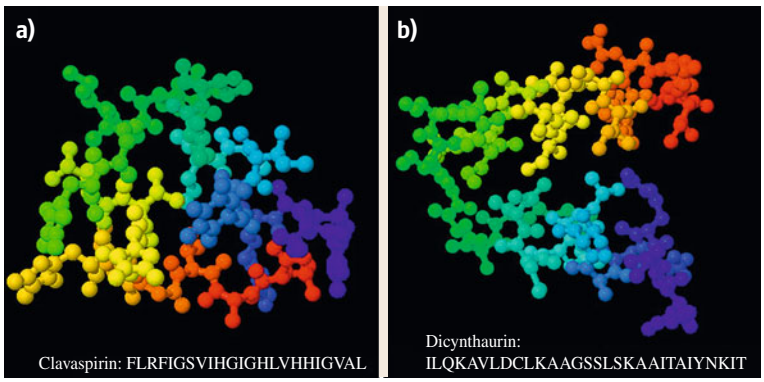

Fig. 31.4a,b Amino acid sequence and ball-and-stick structure of the mature **(a)** clavaspirin and **(b)** dicynthaurin

exhibit antiviral and antihypertensive functions, and modulate Kv3 potassium and sodium channels [31.23].

The AMP Cg-Def (isolated from *Crassostrea gigas*) possesses a cysteine-stabilized α-β motif structure, and displays antibacterial and antifungal activity [31.24]. The crustins observed in *Litopenaeus* spp. have a conserved cysteine pattern of C1(Xn)C2(Xn)C3(X5)C4(X5)C5C6(X3-5)C7(X5)C8 (where *X* is any amino acid) [31.25]. Crustin Cm-1 of *Carcinus maenas* is stable at high temperatures up to about 100 °C [31.26]. Crustin Cm1 may be used to clear bacterial pathogens that are able to survive at high temperatures. Crustin Pm1-7 binds to the cell wall components lipopolysaccharide (LPS) and lipoteichoic acid (LTA), and induces bacterial agglutination and inner membrane permeabilization [31.27]. The penaei-

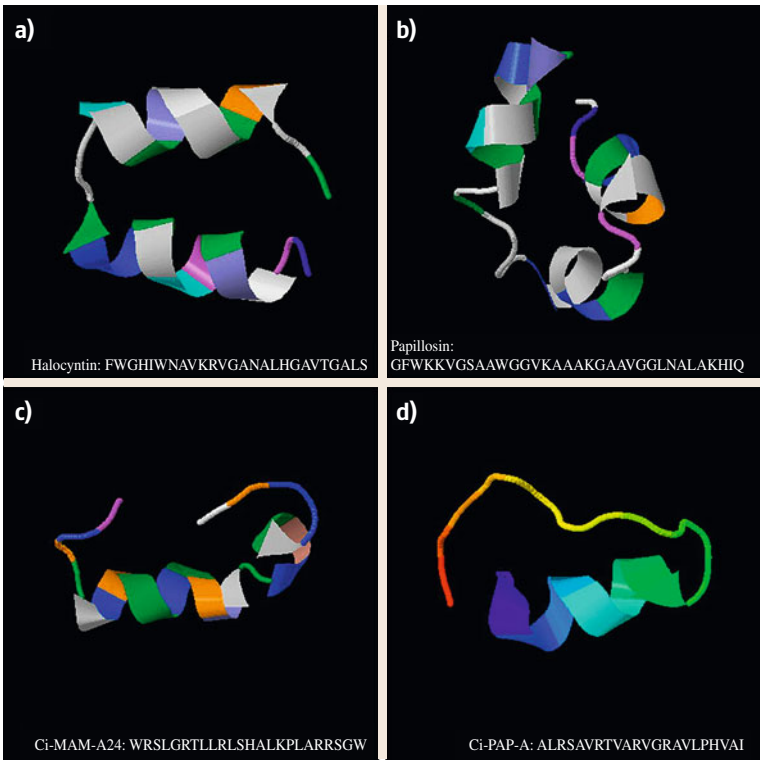

Fig. 31.5a–d Amino acid sequence and structure of the mature **(a)** halocyntin, **(b)** papillosin, **(c)** Ci-MAM-A24, and **(d)** Ci-PAP-A

dins (Fig. 31.9a) from the Hemolymph of the Pacific white shrimp contain a conserved Pro-Arg-Pro motif in the N-terminus and a cysteine-rich C-terminus [31.28]. Penaeidins possess chitin-binding activities, and bacteriostatic and bactericidal activity against *Aerococcus viridians* and *Vibrio alginolyticus*. Penaeidin-5 of the black tiger shrimp *Penaeus monodon* inhibits the growth of the filamentous fungi *Fusarium pisi* and *Fusarium oxysporum* [31.29]. The proline, cysteine, and arginine-enriched AMPs arasin-1 (spider crab, Fig. 31.9b), tachyplesins (horseshoe crabs, Fig. 31.9c), polyphemusins (American horseshoe crab, *Limulus polyphemus*, Fig. 31.9d), and callinectin (blue crab) have antibacterial activity against *Corynebacterium glutamicum* and several Gram-positive bacteria [31.30]. The arasin-like peptide of *Scylla paramamosain* has antibacterial activity against a range of Gram-negative and Gram-positive species, including the crustacean pathogens *Aerococcus viridans*, *Vibrio harveyi*, and *Vibrio anguillarum* [31.31]. Another AMP in the same species, Gastrin-releasing peptide, Scylla paramamosain (GRPSp), contains two cysteine residues at the C-terminus and two glycine-rich repeats (GGYG and GYGG); GRPSp has antibacterial activity specific to Gram-positive strains [31.31]. Tachyplesin I is a 17-residue β-sheet peptide that forms a complex with bacterial lipopolysaccharide and functions against Gram-positive and Gram-negative bacteria [31.32]. Tachyplesin III of *Tachyplesus gigas* shows strong antimicrobial activity, reducing endotoxin and tumor necrosis factor (TNF)-alpha concentrations in *Escherichia coli*-infected mouse models. Mytilins (Fig. 31.10a) destroy bacterial pathogens by membrane pore formation [31.33]. Myticin C of *Mytilus galloprovincialis* is a chemokine/cytokine-like molecule of marine invertebrates [31.34]. Mytilin B, C, and D all demonstrate strong antifungal activity against *Fusarium oxysporum* [31.35], and myticin B also exhibits antimicrobial activity against *Escherichia coli* D31 [31.36]. Dolabellanin-B2 (Fig. 31.10b) is an AMP with antibacterial and fungicidal activity, isolated from *Dolabella auricularia*; it contains a β-sheet and two disulfide bonds, and its methionine residues may be oxidized to form methionine sulfoxides [31.37]. Strongylocins of *Strongylocentrotus droebachiensis* have a β-defensin structure with a novel cysteine pattern; they are potent against *Staphylococcus aureus* and a range of other bacteria [31.38]. The AMP aurelin has

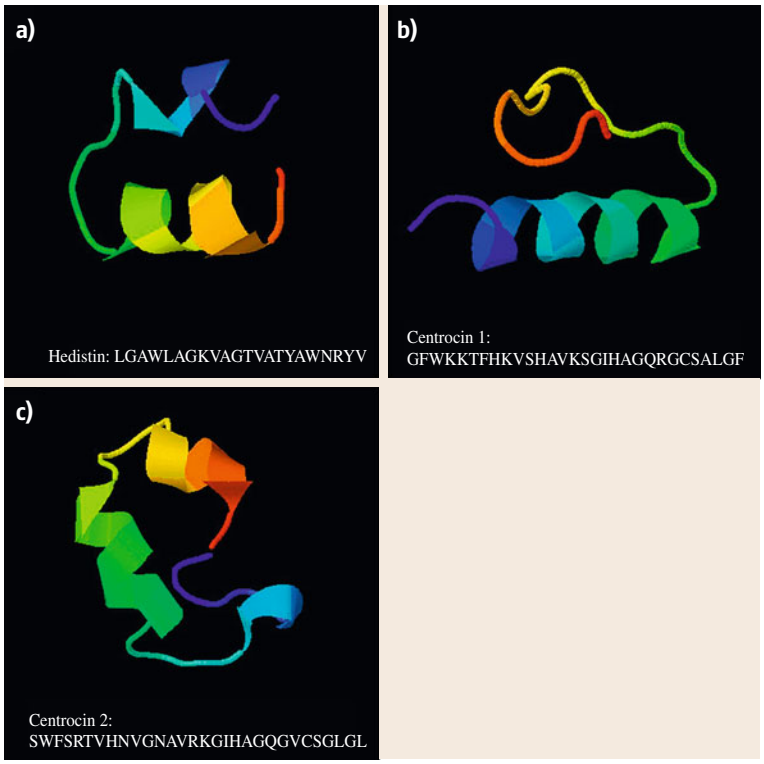

Fig. 31.6a–c Amino acid sequence and structure of the mature **(a)** hedistin from marine annelids, and **(b)** centrocin 1, **(c)** centrocin 2 from green sea urchin

β-sheet structure and partial similarity with defensins and K^+ channel-blocking toxins of sea anemones; it is toxic to a wide range of bacteria [31.39].

31.3.3 AMPs with Coil Structure and Modified Amino Acids

Plicatamide (Fig. 31.11a) is a modified octapeptide, the C-terminus of which is the oxidatively decarboxylated delta-DOPA (decarboxy (E)-alpha,beta-dehydro-3,4-dihydroxyphenylalanine) [31.40, 41]. Halocidin (Fig. 31.11b) of *Halocynthia aurantium* is a dimer, in which the two subunits are linked covalently by a single cystine disulfide bond [31.42]. Halocyamine A and B, purified from the solitary ascidian *Halocynthia roretzi*, are tetrapeptides with the structures L-histidyl-L-6,7-dihydroxyphenylalanylglycyl-6-bromo-8,9-didehydotryptamine and L-threonyl-L-6,7-dihydroxyphenylalanyl-L-histidyl-6-bromo-8,9-didehydrotryptamine, respectively [31.43]. Crustins contain a whey acidic protein (WAP) domain, characterized by a four-disulfide core (4-DSC) structure [31.25]. A 6.5 kDa AMP isolated from *Carcinus maenas* shares sequence similarity with bactenecin 7 (Fig. 31.11c), and has antibacterial activity against a range of Gram-negative and Gram-positive bacteria [31.44]. Carcinin, a cysteine and glycine-rich WAP domain-containing AMP has antimicrobial activity at NaCl concentrations of up to 500 mM [31.26]. Another WAP-domain containing AMP, homarin, has bacteriostatic activity, as well as protozoastatic and protozoacidal activity against the parasites *Mesanophrys chesapeakensis* and *Anophryoides haemophila* [31.45]. Ls-Stylicin 1 (Fig. 31.11d), an AMP with a proline-rich N-terminus and 13 cysteine residues in its C-terminus, was demonstrated to have strong antifungal activity against *Fusarium oxysporum*, and to agglutinate *Vibrio penaeicidae* in vitro [31.3]. Hyastatin, an AMP isolated from the spider crab has an N-terminus enriched in glycine residues, a short proline/arginine-rich region, and a C-terminus that contains 6 Cys residues, and is presumably amidated in the mature peptide [31.46]. Hyastatin has N-terminal chitin binding activity, and antimicrobial activity against yeasts, and Gram-positive and Gram-negative bacteria [31.46]. The AMPs tachycitin and tachystatin of *Tachypleus tridentatus* are single chain proteins containing five disulfide bonds with no N-linked sugar; they exhibit

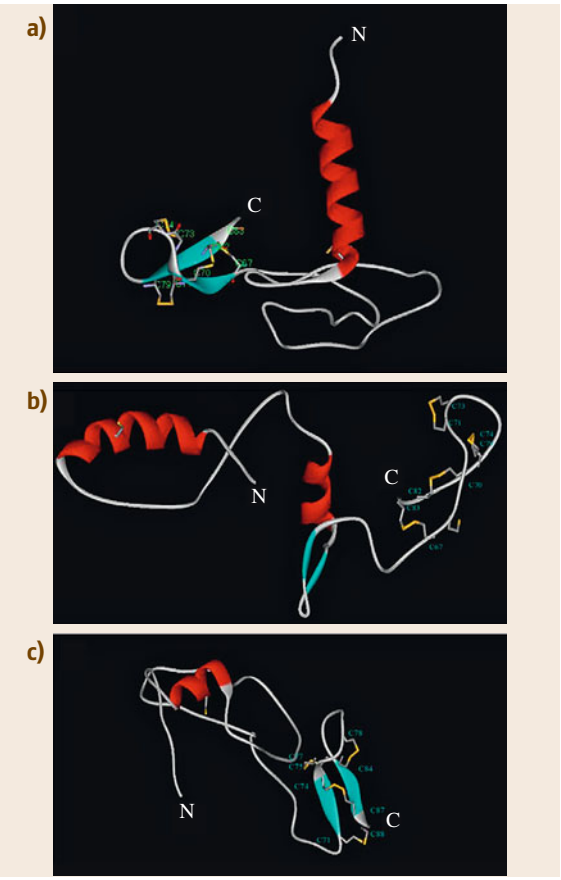

Fig. 31.7a–c Structure of beta sheet antimicrobial peptides **(a)** tilapia hepcidin (TH)1-5. **(b)** TH2-2 and **(c)** TH2-3

antibacterial and antifungal activity, and also possess bacterial agglutinating properties [31.47]. Tachycitin and big defensin act synergistically in their antimicrobial activities. The N-terminus of tachycitin shows sequence homology to chitin-binding regions found in antifungal chitin-binding peptides, chitin-binding lectins, and chitinases [31.47]. Tachycitin binds with chitin, but not to the polysaccharides cellulose, mannan, xylan, or laminarin [31.47]. Scygonadin is an anionic, hydrophobic peptide with antimicrobial activity against *Staphylococcus aureus* and other Gram-positive as well as Gram-negative species [31.48]. The *Sebastes schlegeli* antibacterial protein (SSAP), another AMP of *Tachypleus tridentatus*, is an antibacterial anionic peptide, containing an α-helix, β-sheet, and cysteine residues [31.49]. Perinerin of *Perinereis aibuhitensis Grube* has bactericidal and fungicidal activity, and an α-helix and β-sheet structure with two potassium channel toxic motifs [31.50]. Theromyzin, an anionic linear peptide isolated from *Theromyzon tessulatum*, was the first invertebrate anionic AMP observed to have bacteriostatic activity [31.51]. Astacidin 1 and 2, of *Pacifastacus leniusculus*, are proline and arginine-rich peptides with an amidated C-terminus and bactericidal activity [31.52, 53].

31.3.4 Ring Structured AMPs

Arenicin 1 and 2, bactericidal and fungicidal AMPs isolated from *Arenicola marina*, have β-hairpin structures, and each isoform has a single disulfide bond (Cys3–Cys20) forming an 18-residue ring [31.54]. The cyclic antifungal peptides aciculitin A–C of *Aciculites orientalis* effectively inhibit the growth of *Candida albicans* [31.55]. Jasplakinolide (also known as jaspamide) is a cyclic depsipeptide and polyketide of *Jaspis johnstoni*, with insecticidal activity against *Heliothis virescens* and fungicidal activity against *Candida albicans*, and the ability to inhibit breast cancer cell growth [31.56]. Calyxamides A–B, isolated from *Discodermia calyx*, are cyclic peptides containing 5-hydroxytryptophan and thiazole moieties; they are cytotoxic to P388 murine leukemia cells [31.57]. Polydiscamide B–D are depsipeptides of *Ircinia* sp. that act as sensory neuron-specific G protein coupled receptor agonists [31.58]. Polydiscamide A is a depsipeptide isolated from *Discodermia* sp., with lactonized-threonine residues in its C terminus; it inhibits growth of the human lung cancer A549 cell line. Phoriospongins A (1) and B (2), isolated from *Phoriospongia* sp. and *Callyspongia bilamellata*, have a depsipeptide structure and nematicidal function [31.59]. Finally, cyclolithistide A is a cyclodepsipeptide of *Theonella swinhoei* with fungicidal activity [31.60].

31.4 Future Directions in Marine AMP Applications

The major advantage of AMPs is their small size. They can be synthesized under lab conditions in a short time, to exacting specifications. The sequences of mature peptides were obtained from antimicrobial

database [31.61], and the structure were predicted with Mobyle@RPBS [31.62]. This chapter mainly emphasized the antimicrobial function and other applications of AMPs isolated from marine organisms. As fish AMPs are extensively discussed elsewhere, we chose to focus on AMPs from marine invertebrates. At the time of writing, nearly 80 AMPs had been isolated from marine invertebrates, most of which exhibit antibacterial activity, and a few of which exhibit antiviral and/or antifungal activity. In addition, AMPs with insecticidal, nematicidal, tumor suppression, potassium channel blocking, and immunomodulatory activity have also been reported. Certain AMPs are undergoing clinical trials as potential treatments for skin infections. Such ongoing exploitation of marine AMPs through clinically-oriented studies can be expected to provide novel therapeutic agents in the near future. The present review highlights that marine organisms are a source of unique AMPs, and these AMPs may eventually become effective substitutes for several antibiotics.

32. Marine-Derived Fungal Metabolites

Sherif S. Ebada, Peter Proksch

Marine-derived metabolites continue to be a prolific source for bioactive natural products with a high tendency to become drug candidates. Recently, eribulin mesylate (E7389), a synthetic derivative of halichondrin B, was approved by the US FDA (Food and Drug Administration) for the treatment of breast cancer metastases, going under the trade name Halaven. Some other marine-derived pharmaceuticals have likewise already been approved and launched onto the market, including Yondelis (trabectedin), Prialt (ziconotide), Retrovir (zidovudine), Cytosar (cytarabine, Ara-C), and Vira-A (vidarabine, Ara-A). Research interests in marine natural products have increased in the last few decades, in particular with respect to compounds isolated from marine-derived fungi. In this chapter, a historical background of marine-derived pharmaceuticals and fungal metabolites will be presented, including potential classes of bioactive chemical compounds. In addition, a perspective on the sustainability of marine-derived fungi with regard to a continuous supply of bioactive compounds for market needs rather than a pursuit of other strategies such as aquafarming will be discussed.

32.1 Overview

Natural products continue to be a gold mine of lead structures for pharmaceuticals used for the treatment of various human diseases. More than two-thirds of active drug ingredients are either natural products or derivatives thereof [32.1]. In spite of the great advances in medicine that have been achieved, there are still no cures for some of the most deadly and crippling ailments, such as AIDS, several types of cancer, and many viral and fungal diseases. In addition, the emergence of resistant strains of previously curable illnesses, e.g., strains of tuberculosis, malaria, and the Ebola virus towards standard drug therapy has made new therapeutic regimens necessary as much as ever to save and improve human lives.

Marine ecosystems, occupying about 70% of the planet's surface area, represent an unexploited source of potential pharmaceuticals. These compounds have proved to be a pipeline of secondary metabolites featuring unprecedented chemical scaffolds and unique pharmacological properties which have encouraged natural product chemists during the last 60 years to explore marine organisms [32.2, 3]. Several marine natural products have succeeded in reaching the pharmaceutical market or are in clinical trials for the treatment of serious human disorders ranging from severe pain and microbial infections to immune diseases and cancer [32.4]. Moreover, a huge number of marine natural products have been reported

to have the potential for the development of drugs or drug leads from various marine invertebrates including sponges, ascidians, and soft corals. However, the sustainable and sufficient supply of these substances to meet the demands of clinical trials and the future market needs has been problematic and opposed the development of further marine-inspired pharmaceuticals.

Alternative production procedures and strategies, such as total and/or partial chemical synthesis, or the production of these natural compounds through microbial fermentation of endosymbionts associated with the marine host organism have been developed and in some cases they have successfully overcome the supply problems [32.5]. Due to the aforementioned conditions, relatively few marine secondary metabolites have entered preclinical or clinical trials compared to the huge number of natural products reported from marine organisms with potential bioactivities [32.3, 4].

In this chapter, we will briefly survey the history of marine-inspired pharmaceuticals and discuss marine-derived fungal metabolites according to chemical classes. In addition, a future overview of marine-derived fungi is presented as an alternative to provide a sustainable supply of lead compounds replacing other production methods, such as aquafarming which mostly failed to yield significant results contrary to earlier expectations.

32.2 Drug Screening from Marine Organisms

In this section, we will provide in brief a historical background of marine-inspired pharmaceuticals and those marine natural products that have successfully reached preclinical or clinical trial phases.

32.2.1 US FDA-Approved Marine-Inspired Pharmaceuticals

Bergman and *Feeney* succeeded in the early 1950s to identify hitherto unprecedented nucleosides from the marine sponge *Tethya crypta* [32.6, 7], which inspired the first marine-derived pharmaceuticals Ara-C (cytarabine, Cytosar, Fig. 32.1) and Ara-A (vidarabine, Vira-A). Both were approved by the FDA as anticancer and antiviral drugs, respectively [32.8]. However, the latter has been recently withdrawn from US market by an executive FDA decision in 2001, probably due to its diminished therapeutic window compared to other antivirals [32.3].

In 1987, zidovudine was the first reverse transcriptase (RT) antagonist approved by the FDA for the treatment of human immunodeficiency virus (HIV)/aquired immuno deficiency syndrom (AIDS) under the trade name Retrovir (Fig. 32.1) [32.9]. Zidovudine is structurally a 3′-azido, 3′-deoxy derivative of 2′-deoxythymidine, which was first reported from the starfish *Acanthaster planci* in 1980 [32.10, 11]. In the mid-1990s, other derivatives were also developed and approved by the FDA, such as lamivudine (Epivir) and stavudine (Zerit), which were approved as RT antagonists for HIV/AIDS and the hepatitis B virus (HBV) [32.12, 13].

Afterwards, it took about a decade to introduce the next marine-based pharmaceutical, ziconotide, which received FDA approval in December 2004. Ziconotide is the synthetic form of the naturally-occurring peptide ω-conotoxin MVIIA, which was first isolated from the Pacific piscivorous marine cone snail *Conus magus* by Olivera and co-workers in 1979 [32.14]. It took more than two decades of research and development to get ziconotide launched, under the brand name Prialt, as the first marine-inspired pharmaceutical for the specific indication of severe chronic pain (Fig. 32.1) [32.15].

Later, in July 2007, trabectedin, the synthetic form of ecteinascidin-743 isolated from the marine tunicate *Ecteinascidia turbinata*, was approved by the Committee for the Evaluation of Medicinal Products from the European Medicines Agency (EMEA) for the treatment of refractory soft tissue sarcoma and ovarian cancer [32.16]. To fulfill the supply needs during the clinical trial phases and the market needs thereafter, different strategies were evaluated, such as aquaculture and chemical synthesis [32.17, 18]. However, no promising outcomes have been achieved from either of them, but a breakthrough took place when PharmaMar, the license holder of trabectedin (ET-743), managed to develop a large-scale semisynthetic protocol starting with cyanosafracin B, an antibiotic produced on multikilogram scale by *Pseudomonas fluorescens* [32.19].

Recently, on November 15th, 2010, eribulin mesylate (E7389), a fully synthetic ketone analog of the polyether marine macrolide halichondrin B first isolated from the marine sponge *Halichondria okadai* [32.20, 21], was approved by the FDA for use

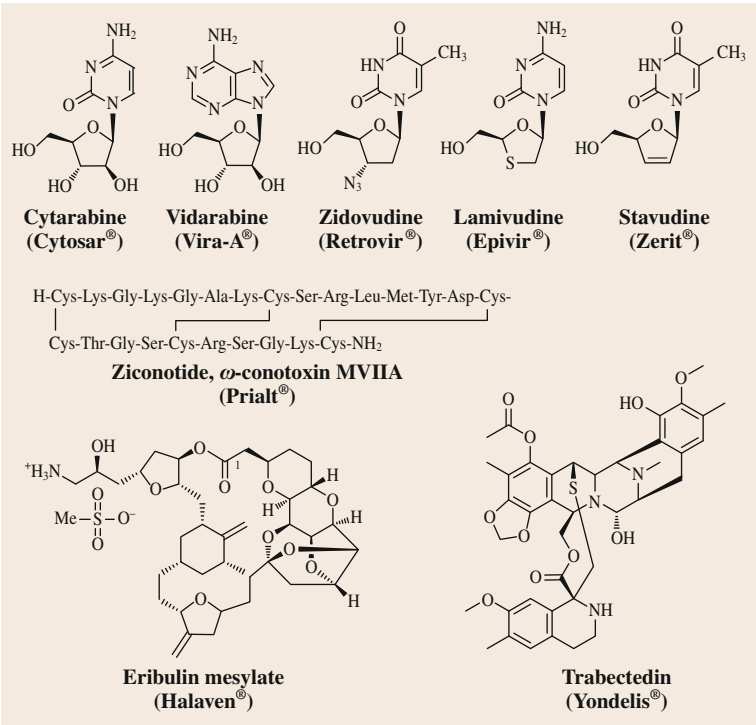

Fig. 32.1 Chemical structure of US FDA-approved marine inspired pharmaceuticals

with patients with metastatic breast cancer who have received at least two prior chemotherapy regimens for late-stage disease, including both anthracycline and taxane-based ones. Eribulin mesylate is currently marketed by Eisai pharmaceuticals under the trade name Halaven (Fig. 32.1).

32.2.2 Marine Pharmaceuticals in Phase III Clinical Trials

Soblidotin (TZT-1027, Fig. 32.2) is a synthetic derivative of the cytotoxic peptide dolastatin 10, originally isolated from the sea hare *Dolabella auricularia* [32.22]. Soblidotin revealed potent antimitotic activity through inhibiting microtubule assembly and tubulin polymerization by binding to tubulin at a site close to the vinca binding sites [32.23, 24]. Currently, TZT-1027 is under phase III clinical trials for advanced or metastatic lung cancer and non-small cell lung cancer (NSCLC).

Brentuximab vedotin (SGN-35, Fig. 32.2) is an antibody-drug conjugate consisting of the chimeric monoclonal antibody brentuximab, targeting the cell-membrane protein CD30, and linked to three to five units of the antimitotic agent monomethyl auristatin E (MMAE). The antibody portion of the drug conjugate attaches to CD30 on the surface of malignant cells, delivering MMAE, which affords therapeutic activity [32.25, 26]. In August 2011, the FDA approved brentuximab vendotin for the treatment of relapsed systemic anaplastic large cell lymphoma (ALCL) and refractory Hodgkin's lymphoma under the trade name Adcertis [32.27].

Plitidepsin (aplidine, Aplidin, Fig. 32.2) is a dihydro-derivative of the marine-derived peptide didemnin B. Plitidepsin and didemnin B were isolated by the Rinehart research group from two different tunicate genera, namely *Aplidium albicans* [32.28] and *Tridemnum solidum* [32.29], respectively. This notion supports the assumption that these metabolites are, in fact, produced by a common symbiont. Didemnin B revealed promising activity during Phases I and II clinical trials in patients with advanced pretreated cancers. These trials have now been discontinued due to the emergence of serious adverse effects, including severe fatigue [32.30] and anaphylaxis [32.31]. Therefore, plitidepsin represented an alternative which was further supported by the results of preclinical in vitro and in vivo studies. Clinically, plitidepsin exhibited preliminary efficacy in two different Phase II

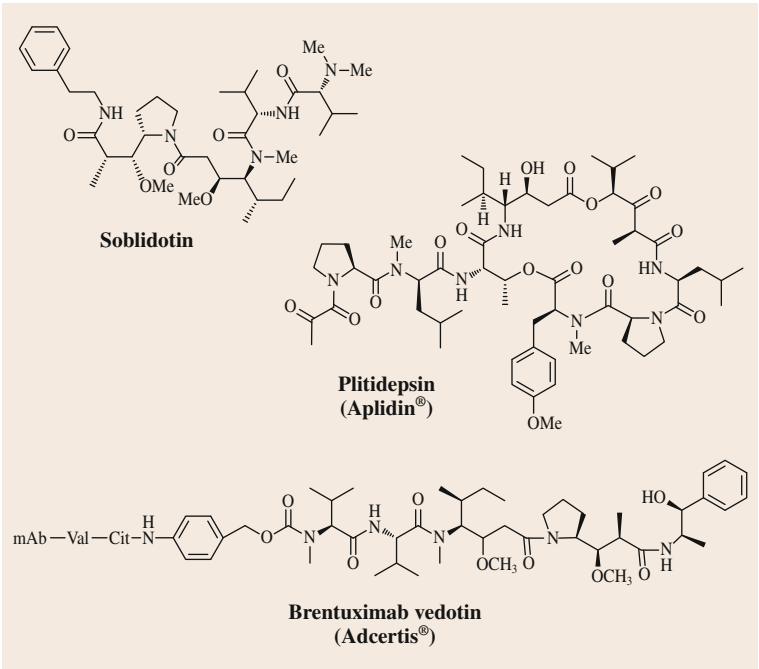

Fig. 32.2 Chemical structure of marine pharmaceuticals in Phase III clinical trials

trials against relapsing multiple myeloma and T cell lymphoma [32.32]. Currently, plitidepsin is undergoing Phase III clinical trials in spite of being accompanied by some adverse effects, including muscular toxicity, transient increase in transaminases, fatigue, diarrhoea, and cutaneous rash [32.33]; however, but no severe bone marrow toxicity was detected under plitidepsin therapeutic regimens.

32.2.3 Marine Pharmaceuticals in Phase II Clinical Trials

3-(2,4-dimethoxybenzylidene)-anabaseine (DMXBA, GTS-21, Fig. 32.3) is a synthetic derivative of anabaseine, a marine alkaloid isolated from several species of marine worms of the phylum Nemertea [32.34]. Structurally, DMXBA is a 3-(2,4-dimethoxybenzylidene)-anabaseine, which displays a selective $\alpha 7$ nicotinic acetylcholine receptor agonistic activity. DMXBA was found to improve cognitive functions [32.35]. GTS-21 has successfully completed Phase I clinical studies revealing significant improvement of cognitive functions in healthy young males [32.36] and schizophrenics [32.37]. A Phase II clinical trial using DMXBA for schizophrenics has been conducted and it has disclosed improvement of cognitive functions compared to the placebo, but only with high DMXBA doses [32.38].

Plinabulin (NPI-2358, Fig. 32.3) is a synthetic analog of halimide, a diketopiperazine alkaloid produced by the marine-derived fungus *Aspergillus* sp. CNC-139 isolated from the alga *Halimeda lacrimosa* [32.3]. Plinabulin acts as a vascular disrupting agent (VDA) through inhibiting tubulin polymerization resulting in selective collapse of tumor endothelial vasculature, in addition to its direct apoptotic effects [32.39, 40]. In Phase I clinical trial on patients with solid tumors or lymphomas, plinabulin revealed a significant reduction in tumor vasculature at doses $\geq 13.5\,\mathrm{mg\,m^2}$ and was tolerated up to $30\,\mathrm{mg\,m^2}$ [32.3]. Based on the principle that VDAs can augment chemotherapeutics and antiangiogenic agents, plinabulin is currently undergoing Phase II clinical trials [32.3].

Elisidepsin (PM02734, Irvalec, Fig. 32.3) is a marine-derived peptide of the kahalalide family, namely kahalalide F first reported from seasonal collections of the marine sacoglossan *Elysia rufescens* and the green alga *Bryopsis* sp. [32.41]. In preclinical in vitro studies, elisidepsin exhibited potent antineoplastic activity against a wide range of tested human tumor cell lines. Elisidepsin is currently in Phase II clinical trials with preliminary evidence of antitumor activity and with a favorable therapeutic index [32.42].

Zalypsis (PM1004, Fig. 32.3) is a synthetic deoxyribonucleic acid (DNA)-binding alkaloid related

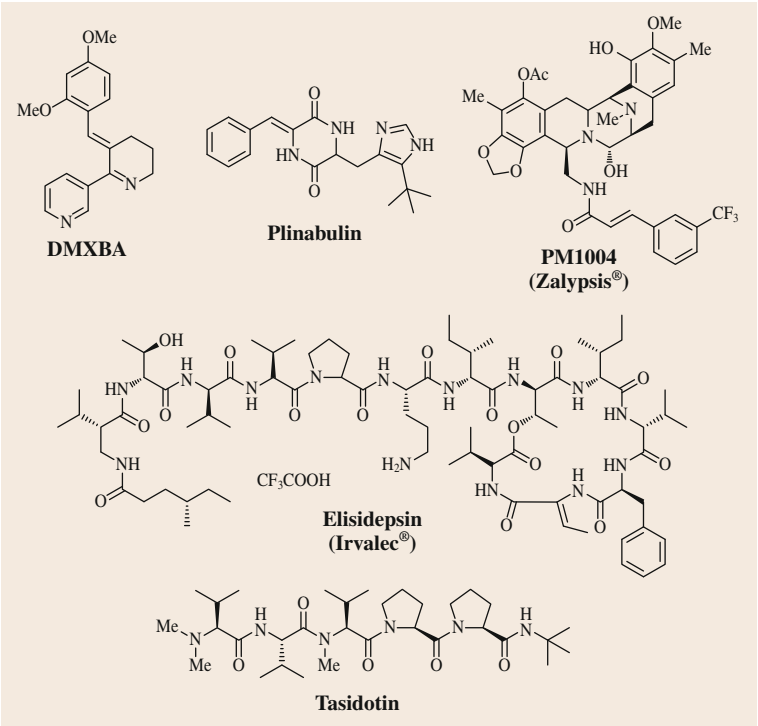

Fig. 32.3 Chemical structure of marine pharmaceuticals in Phase II clinical trials

to renieramycins and jorumycins, first isolated from the marine sponges *Reniera* sp. [32.43, 44] and the Pacific marine nudibranch *Jorunna funebris* [32.45]. Mechanistically, PM1004 acts through breaking the DNA helix by binding to guanines in selected DNA triplets, which leads to freezing cancer cells in DNA synthesis (S) phase and inducing apoptosis [32.46]. Zalypsis was promising in preclinical in vitro studies with significant antitumor activity against breast, prostate, and renal cancers. The main adverse effects that accompanied Zalypsis in Phase I clinical trials were hematological abnormalities and/or elevated transaminases, but these were transient and temporary [32.46].

Tasidotin (synthadotin, ILX-651, Fig. 32.3) is a synthetic analog of dolastatin 15 originally isolated from the sea hare *Dolabella auricularia* [32.47]. A detailed mechanistic investigation of tasidotin disclosed a potent inhibition of tubulin assembly. The active metabolite is probably the pentapeptide formed by hydrolysis of the *C*-terminal amide bond [32.48, 49]. ILX-651 has undergone Phase II clinical trials and the results showed that it was orally active and well tolerated but the efficacy was not good enough for it to proceed as a single agent therapy [32.3].

32.2.4 Marine Pharmaceuticals in Phase I Clinical Trials

Salinosporamide A (marizomib, NPI-0052, Fig. 32.4) is a rare β-lactone produced by the marine actinomycete *Salinospora tropica* recovered from deep-sea sediment [32.50, 51]. Mechanistically, marizomib exhibited a potent selective inhibition of p26 proteasome by acylation of the *N*-terminal Thr1O^{γ} residue followed by chloride displacement [32.52] resembling the marketed proteasome inhibitor bortezomib (Velcade, Millennium/Janssen-Cilag) that is approved for treatment of multiple myeloma. Moreover, salinosporamide A was able to overcome resistance to bortezomib in patients with refractory myeloma [32.53]. Salinosporamide A has successfully completed Phase I clinical trials for treatment of multiple myeloma, lymphoma, leukemia, and solid tumors [32.51, 54].

Hemiasterlins (Fig. 32.4) are antimitotic tripeptides isolated from marine sponges of different genera [32.55–57]. Hemiasterlins displayed significant in vitro cytotoxicity with IC_{50} values in the nanomolar range, which was attributed to the inhibition of the cell cycle in the mitosis (M) phase [32.56, 58]. Structure–activity relationship (SAR) studies revealed

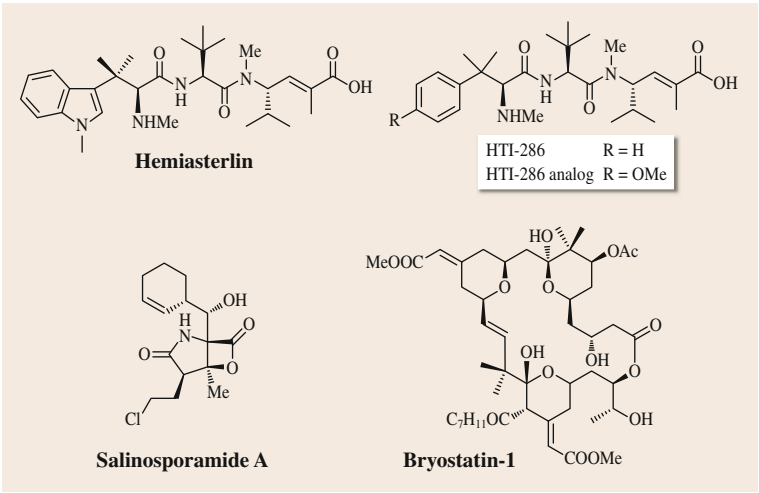

Fig. 32.4 Chemical structure of marine pharmaceuticals in Phase I clinical trials

that HTI-286, a simpler synthetic derivative of hemiasterlin possessing a phenyl moiety instead of the abrine (*N*-methyltryptophan) residue, is more potent than hemiasterlin [32.59], whereas the analog of HTI-286 with a *para*-methoxy functionality on the aromatic ring was even more potent [32.57]. HTI-286 inhibited tumor progression in preclinical studies with mice [32.60], which encouraged starting Phase I clinical trials in patients with advanced solid tumors. Results were disappointing, with no significant response accompanied with toxicities, including neutropenia, nausea, alopecia, and pain [32.61]. Therefore, Phase II studies of HTI-286 were postponed. However, the compound is still an interesting candidate, particularly after recent results illustrating its high antitumor activity against refractory and resistant prostate cancers [32.62].

Bryostatin 1 (NSC 339555, Fig. 32.4) is a 26-membered macrocyclic lactone with a hitherto unprecedented polyacetate carbon skeleton, which was first reported form the bryozoan *Bugula neritina* [32.63]. Bryostatin 1 is the parent compound for a family of 19 additional derivatives differing in the presence of acyloxy substituents [32.64]. The limited biological abundance of bryostatin 1 from its natural source was a major obstacle hindering its progression into preclinical and clinical trials. Moreover, the total synthesis of bryostatin 1 was not successful in offering an economically feasible supply of the compound; hence, the major interest was directed toward aquaculture of the bryozoans to obtain sufficient supply of bryostatin 1 from its natural source [32.65]. In Phase I clinical study against acute leukemia and B-cell malignancy, bryostatin 1 revealed encouraging results as an adjuvant therapy with Cytosar (cytarabine, Ara-C) [32.66] and Oncovin (vincristine) [32.67], respectively. As a single therapy, bryostatin 1 did not yield promising results in either Phase I or Phase II clinical trials; however, it is still of interest to be tested as a co-therapy with other chemotherapeutic agents such as Taxol (paclitaxel) against advanced gastroesophageal adenocarcinoma rather than using paclitaxel alone [32.68].

32.2.5 Marine Pharmaceuticals in the Preclinical Phase

In preclinical studies, a huge number of marine natural products have been introduced during the last two decades; these can be grouped according to their main pharmacological activities, including antitumor, antimicrobial, anti-inflammatory, anticoagulant, and antiplasmodial activities, whereas other compounds target the cardiovascular, immune, or nervous systems [32.69, 70]. The current status of marine natural products in preclinical studies is promising, and they seem to be potential sources for new pharmaceuticals that will enrich pharmacopeia for treatment and/or management of serious human diseases.

Some marine natural products showed interesting activities during the in vitro and in vivo preclinical evaluation, which suggested that they are potential drug candidates for entering clinical trial phases. These compounds include, for example, manzamine A (antimalarial, antituberculosis, anti-HIV), lasonolides (antifungal), jaspamides and geodiamolides (antitumor), and azumamides and psammaplin A (histone deacetylase inhibitors) [32.71].

It is nowadays assumed for many secondary metabolites originally isolated from macroorganisms that endosymbiotic microorganisms, including fungi and bacteria, are the real producers. This is highlighted by the isolation of paclitaxel (Taxol) from an endophytic fungus *Taxomyces andreanae* obtained from the inner bark of *Taxus brevifolia* [32.72], the production of camptothecin (Campto) by the endophytic fungus *Entrophospora infrequens* isolated from *Nothapodytes foetida* [32.73], and the production of trabectedin (Yondelis) through a semisynthetic protocol starting with cyanosafracin B, through fermentation of *Pseudomonas fluroscens* on multikilogram scale [32.19]. Therefore, there has been a sharp increase in research interests with regard to the exploration of secondary metabolites produced by endosymbiotic microorganisms such as fungi and bacteria, aiming at establishing a sustainable supply of bioactive natural products that can be further developed into pharmaceuticals through industrial fermentation or semisynthetic synthesis.

In the next part, we will survey recent reports on bioactive secondary metabolites from marine-derived fungi from 2010–2012 classified into chemical classes of compounds with particular attention placed on their structures and reported pharmacological activities.

32.3 Marine Organic Compounds

32.3.1 Alkaloids

Xylarin (**1**, Fig. 32.5), a [11]cytochalasin derivative, was purified from the mycelial extract of a marine-derived species of the genus *Xylaria* isolated from the gorgonian sea fan *Annella* sp. collected near the Similan Islands (Thailand) [32.74]. Structurally, xylarin (**1**) features a highly substituted perhydroisoindole moiety to which an octaketide macrocyclic ring derived from a head-to-tail condensation of eight acetate units affording an unbranched C_{16}-polyketide (PKS) moiety is linked. Antimicrobial activity assay of the crude extract revealed only weak antibacterial activity against *Staphylococcus aureus*, whereas the extract was inactive against methicillin-resistant Staphylococcus aureus (MRSA) [32.74].

Another species of the same fungal genus, obtained from marine sediment collected in the South China Sea, produced two new cytochalasins (**2** and **3**) together with four other known analogs (**4**–**7**) [32.75]. All isolated compounds were tested for their in vitro cytotoxicity against three different human tumor cell lines MCF-7 (breast), SF-268 (central nervous system, CNS), and NCI-H460 (lung) using cisplatin as a positive control [32.75]. Among the compounds tested, 21-*O*-deacetylcytochalasin Q (**3**) was most active against SF-268 cells ($IC_{50} = 44.3\,\mu M$), while cytochalasin D **7**) revealed the best activity against MCF-7 cells and NCI-H460 ($IC_{50} = 18.6$ and $14.4\,\mu M$, respectively). Moreover, cytochalasin Q (**4**) and 19,20-epoxycytochalasin (**5**) were active against NCI-H460 cells with IC_{50} values of 19.7 and $22.6\,\mu M$, respectively. However, 18-deoxycytochalasin Q (**2**) and 21-*O*-deacetyl-19,20-epoxycytochalasin Q (**6**) showed only moderate activity or were inactive against the cell lines tested [32.75].

Seven new dihydroquinolin-2-one-containing alkaloids, trivially named aflaquinolones A–G (**8**–**14**), were isolated from two different marine fungal isolates of the genus *Aspergillus* NRRL58570 and SF-5044 collected in Hawaii and Korea, respectively [32.76]. In addition, several known compounds belonging to aspochalasins and curvularins were also isolated from the Hawaiian isolate. An absolute configuration of aflaquinolone B (**9**) was established based on a nuclear Overhauser and exchange spectroscopy (NOESY) spectrum, a comparison of calculated and experimental electronic circular dichroism (ECD) data, and analysis of its Mosher's ester derivative [32.76]. All isolated aflaquinolones, except for **11**, were subjected to a cytotoxicity assay against four different human tumor cell lines, however, no significant activity was reported for the compounds tested at concentrations up to $80\,\mu M$ [32.76].

From the mycelial extract of the marine-derived fungus *Aspergillus fumigatus*, isolated from a Japanese zoanthid *Zoanthus* sp., two new indole alkaloids, 2-(3,3-dimethyl-prop-1-ene)-costaclavine (**15**) and 2-(3,3-dimethylprop-1-ene)-epicostaclavine (**16**), together with the known compounds costaclavine and fumgaclavines A and C, were obtained [32.77]. Relative and absolute configurations of **15** and **16** were determined based on NOESY, ^1H–^1H coupling constants, and CD (circular dichroism) spectra. Compounds **15** and **16** revealed weak cytotoxicity against mouse leukemia P388 cells [32.77].

Five unusual alkaloids (**17**–**21**) were purified from the culture broth of the endophytic fungus *Fusarium*

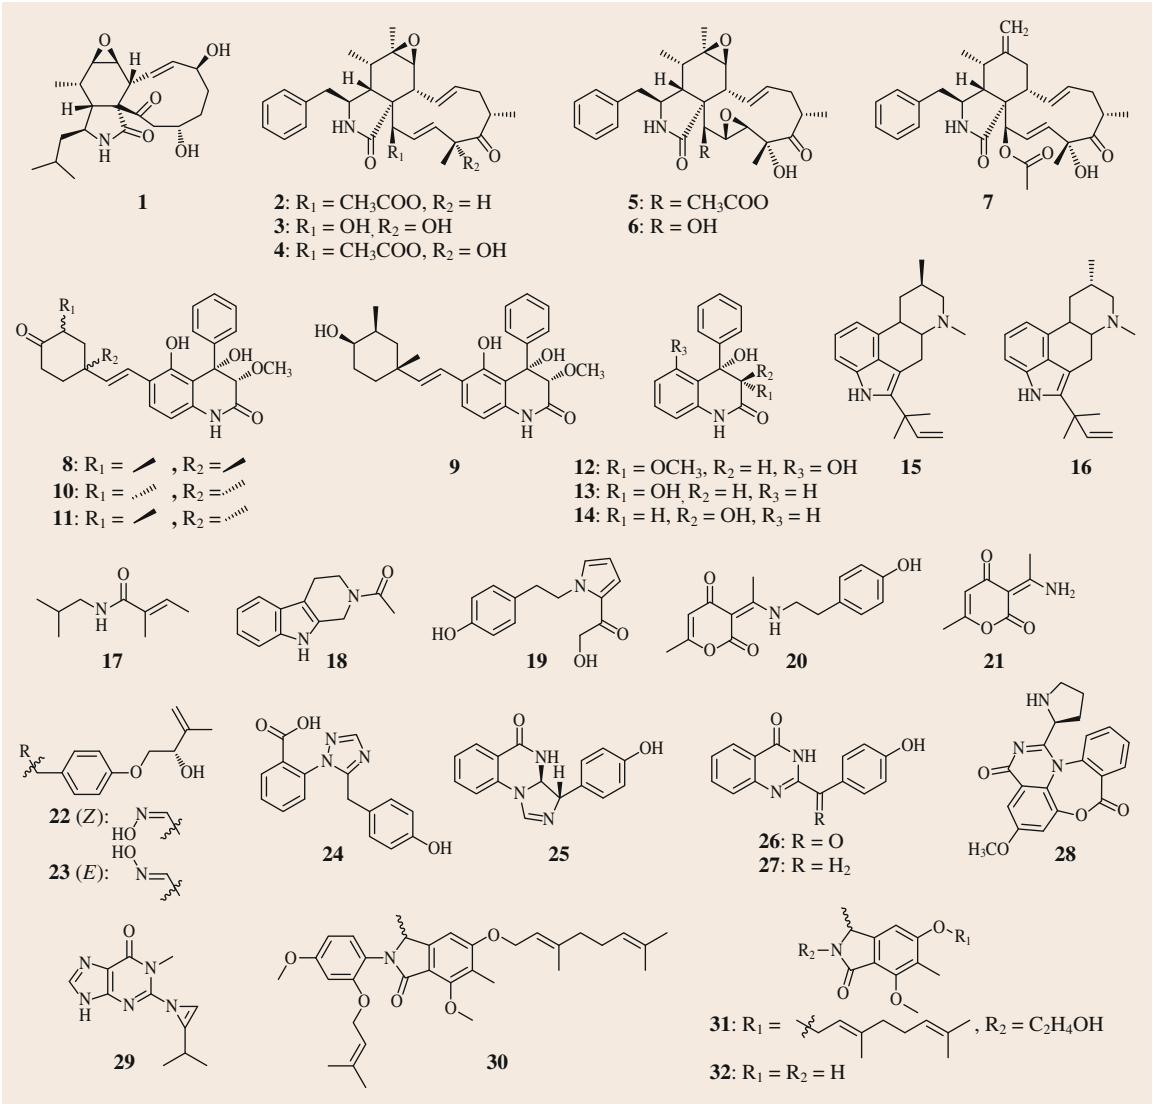

Fig. 32.5 Chemical structures of compounds **1**–**32**

incarnatum (HKI0504), isolated from the mangrove plant *Aegiceras corniculatum* [32.78]. In the antiproliferative activity assay, only 2-acetyl-1,2,3,4-tetrahydro-β-carboline (**18**), fusamine (**20**), and 3-(1-aminoethylidene)-6-methyl-2*H*-pyran-2,4(3*H*)-dione (**21**) exhibited weak cytotoxic activities against human umbilical vascular endothelial cells (HUVEC), human cervix carcinoma cells (HeLa), and human chronic myeloid leukemia cells (K562) with IC_{50} values of 41.1, 23.3, and 9.0 μM, respectively [32.78].

Two putative tyrosine-derived metabolites, stachylines A (**22**) and B (**23**), together with two *O*-prenylated derivatives, stachylines C and D, were purified from the fungal extract of *Stachylidium* sp., a marine-derived fungus isolated from the Australian sponge *Callyspongia* cf. *C. flammea* [32.79]. Stachylines are tyrosine-derived metabolites featuring oxime moiety which is incorporated in biosynthesis of marine natural products such as bastadins and psammaplins, which may suggest a metabolic relation between the marine-de-

rived fungus and its host. The isolated stachylines were subjected to a large number of bioactivity assays including cytotoxicity, antidiabetic, antimicrobial, NF-κB inhibitory activity assay, and protein kinase inhibition assays, but no activity was recognized in any of these assays [32.79].

Penipanoid A (**24**), an unprecedented triazole carboxylic acid derivative, together with two quinazolines alkaloids, penipanoids B (**25**) and C (**26**), and a quinazoline derivative (**27**) were isolated from the marine sediment-derived fungus *Penicillium paneum* SD-44 [32.80]. The structure of **24** was confirmed by X-ray crystallography establishing the compound as the first triazole metabolite from marine sediment-derived fungi, whereas **25** featured an unusual quinazolinone structure possessing a dihydroimidazole ring system [32.80]. In the antiproliferative activity assay, penipanoid A (**24**) revealed activity against the SMMC-7721 cell line ($IC_{50} = 54.2\,\mu M$), while penipanoid D (**27**) exhibited significant activity against A-549 and BEL-7402 cell lines with IC_{50} values of 17.5 and 19.8 μM, respectively, compared to fluorouracil which displayed IC_{50} values of 13.0, 13.7, and 21.8 μM against the above three cell lines [32.80].

Aspergicin (**28**) was reported as a new alkaloid together with the previously known neoaspergillic acid from mixed culture mycelia of two epiphytic fungi from the genus *Aspergillus* isolated from a rotten fruit of the marine mangrove plant *Avicennia marina* [32.81]. Both aspergicin and neoaspergillic acid revealed significant antimicrobial activity against some Gram-positive and Gram-negative bacteria with minimum inhibitory concentrations (MICs) between 2.2 and 43.0 μM [32.81].

Acremolin (**29**), an unprecedented modified base featuring a 1*H*-azirine moiety, was purified from the culture broth of the marine-derived fungus *Acremonium strictum*, isolated from an unidentified Korean Choristida sponge [32.82]. Structurally, acremolin (**29**) is a modified guanine base attached to an isoprene unit via a 1*H*-azirine moiety. In the cytotoxicity assay, acremolin (**29**) revealed only weak activity against A549 cells with IC_{50} of 200 μM [32.82].

Together with stachylines (**23** and **24**), and marilines A–C (**30**–**32**), phthalimide derivatives reported as novel metabolites were obtained from the same extract of the marine-derived fungus *Stachylidium* sp. [32.83]. The absolute configurations of the enantiomeric congeners marilines A_1 (**30a**) and A_2 (**30$_b$**) were established by a combination of experimental circular dichroism (CD) investigations and quantum chemical CD calculations. Marilines A_1 (**30a**) and A_2 (**30$_b$**) inhibited the serine protease human leukocyte elastase (HLE) with an IC_{50} value of 0.86 μM for both enantiomers [32.83]. HLE is an enzyme considered to be a main cause of tissue damage accompanying inflammatory diseases such as chronic obstructive pulmonary disease, cystic fibrosis, and adult respiratory distress syndrome [32.84, 85]. Therefore, inhibitory activity exhibited by marilines A_1 (**30a**) and A_2 (**30$_b$**) against HLE potentiates the tendency to use them as therapeutically useful candidates for the treatment of those diseases. Mariline B (**31**) did not exhibit inhibitory activity against HLE. Marilines A_1 (**30a**), A_2 (**30$_b$**), and B (**31**) showed antiplasmodial activity against the liver stages of *Plasmodium berghei* with IC_{50} values of 6.7, 11.6, and 13.8 μM, respectively [32.83]. Mariline A_1 (**30a**) and A_2 (**30$_b$**) were assessed for their cytotoxic activity against panels of 5 and 19 cancer cell lines with mean GI_{50} values of 24.4 and 11.0 μM, respectively [32.83].

Unusual polyketide-type alkaloids, (-)-cereolactam (**33**, Fig. 32.6) and (-)-cereoaldomine (**34**) comprising a lactam ring and an iminine functionality, respectively, were produced together with the related metabolite (-)-trypethelone by the marine endophytic fungus *Coniothyrium cereale* obtained from the green alga *Enteromorpha* sp. [32.86]. Both **33** and **34** selectively inhibited the activity of HLE with IC_{50} values of 9.3 and 3.0 μM, respectively [32.86].

Auranomides A–C (**35**–**37**) are three new alkaloids that have been reported from the marine-derived fungus *Penicillium aurantiogriseum* [32.87]. Structurally, auranomides A (**35**) and B (**36**) featured a new scaffold containing a quinazoline-4-one substituted with a pyrrolidin-2-iminium moiety. In the cytotoxicity assay against human tumor cell lines, auronamide B (36) was the most potent compound with an IC_{50} value of 97 μM [32.87].

Two new epimeric alkaloids, namely tumonoic acids K (**38**) and L (**39**), were isolated together with several known compounds from the marine-derived fungus *Penicillium citrinum* [32.88]. Compounds **38** and **39** represent the first example of tumonoic acid analogs derived from a fungus [32.88]. Tumonoic acids K and L revealed weak cytotoxic activity against A-375 cell lines with IC_{50} values of 65.7 and 124.6 μM, respectively [32.88].

Fumiquinazoline K (**40**), a quinazoline-type alkaloid, was isolated from a marine strain of *Aspergillus fumigatus* KMM 4631 associated with the soft coral

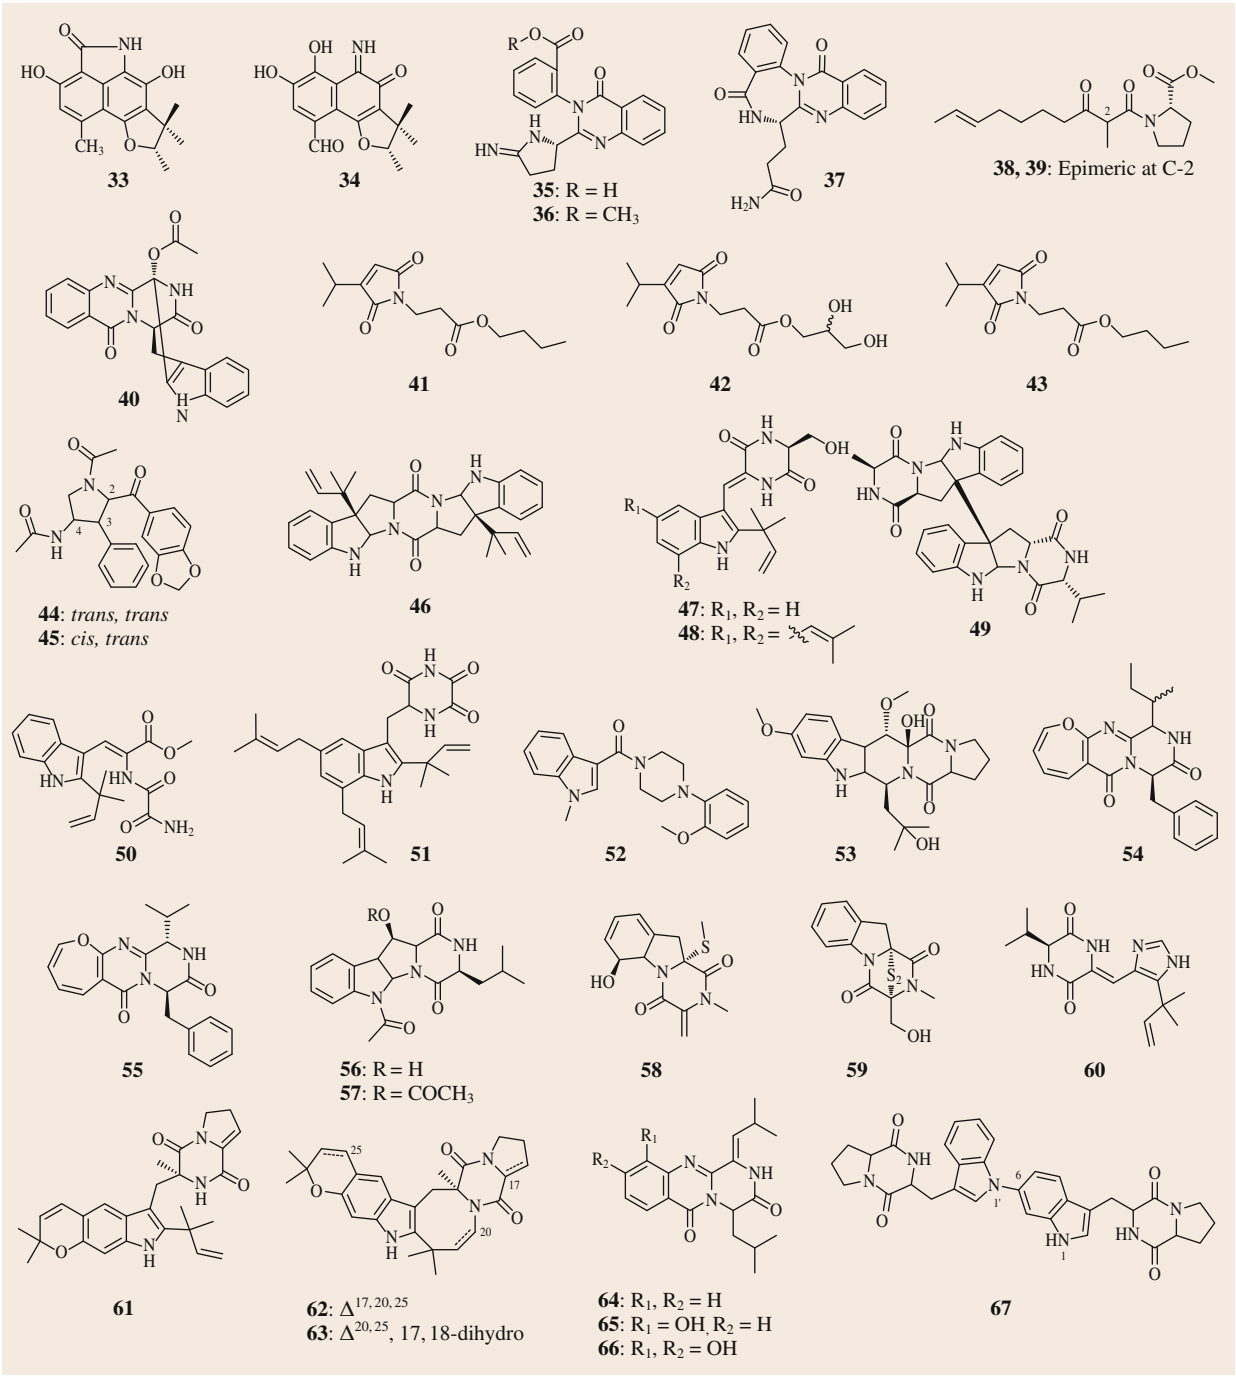

Fig. 32.6 Chemical structures of compounds **33–67**

Sinularia sp. [32.89]. Fumiquinazoline K revealed neither cytotoxic nor antibacterial activity [32.89].

Farinomaleins C–E (**41**–**43**), three new dioxopyrrole derivatives, together with one new indole metabolite were isolated from an unidentified endophytic fungus derived from the mangrove plant *Avicennia marina* [32.90]. All isolated farinomaleins were investigated for their cytotoxic and antimicrobial activities; however, none exhibited significant activities [32.90].

Aspergillamides A (**44**) and B (**45**), two new pyrrolidine alkaloids, were isolated together with the known compound aurantiamine from the marine fungus *Aspergillus ustus* derived from the Mediterranean sponge *Suberties domuncula* collected from the Adriatic Sea [32.91]. In the cytotoxicity assay against the murine lymphoma (L5178Y) cell line, neither **44** nor **45** exhibited more than 10–20% activity compared to controls [32.91].

32.3.2 Diketopiperazines

Amauromine (**46**), an indole diketopiperazine alkaloid, was isolated from the fungus *Auxanthron reticulatum* derived from the marine sponge *Ircinia variablis* [32.92]. Amauromine (**46**) was identified as the first fungal metabolite that revealed high and selective affinity for the human cannabinoid receptor CB_1 recombinantly expressed in Chinese hamster ovary (CHO) cells ($K_i = 178$ nm) [32.92]. Based on the selective antagonistic potency, **46** may be a potential candidate for further development as a lead structure for drug development.

Four further indole alkaloids, cristatumins A–D (**47**–**50**), were isolated together with six known derivatives from the endophytic fungus *Eurotium cristatum* EN-220, obtained from the marine alga *Sargassum thunbergii* [32.93]. In the antimicrobial activity assay, cristatumin A (**47**) displayed moderate activity against *Escherichia coli* and *Staphylococcus aureus*, while cristatumin B (**48**) provoked modest lethality in brine shrimp *Artemia salina* [32.93].

From the ethyl acetate (EtOAc) extract of the solid rice culture of the marine-derived endophytic fungus *Eurotium rubrum*, a new dioxopiperazine alkaloid, namely 12-demethyl-12-oxo-eurotechinulin B (**51**) was isolated together with one new anthraquinone derivative and ten other known compounds [32.94]. In the cytotoxicity assay against seven human tumor cell lines, **51** revealed only moderate activity against SMMC-7721 cells with IC_{50} of 65.5 μM, while in the antimicrobial activity assay it showed no activity [32.94].

Bioassay-guided fractionation of the mycelial extract of the marine fungal strain *Aspergillus sydowii* (SCSIO00305), obtained from the gorgonian coral *Verrucella umbraculum*, led to the isolation of two new natural products, [4-(2-methoxyphenyl)-1-piperazinyl][(1-methyl-1*H*-indol-3-yl)]-methanone (**52**) and cyclotryprostatin (**53**) together with eight known natural products [32.95]. Both **52** and **53** were subjected to a cytotoxicity (microculture tetrazolium assay, MTT), but only **52** revealed significant cytotoxic activity against human melanoma (A375) cell line with IC_{50} of 5.7 μM [32.95].

Two new oxepin-type alkaloids, protuboxepins A and B (**54** and **55**) and two diketopiperazine alkaloids, protubonines A and B (**56** and **57**), were reported from the EtOAc extract of the marine sediment-derived fungus *Aspergillus* sp. SF-5044 [32.96]. Compounds (**54**, **56**, and **57**) were subjected to a cytotoxic activity assay against five different cancer cell lines. Results revealed that only protuboxepin A (**54**) showed weak antiproliferative activity against five tested cancer cell lines, namely HL-60 (leukemia), MDA-MB-231 (breast), Hep3B (liver), 3Y1 (fibroblast), and K562 (chronic myeloid leukemia, CML) with IC_{50} values of 75, 130, 150, 180, and 250 μM, respectively [32.96].

Two new gliotoxin-related metabolites, **58** and **59**, were isolated together with other five known derivatives from the fungus *Penicillium* sp. (JMF034) obtained from deep sea sediment collected off Suruga Bay (Japan) [32.97]. The absolute configuration of the new compounds was established based on the modified Mosher's method. All isolated compounds showed significant cytotoxic activity when tested against murine leukemia cells (P388), except for bis(dethio)-10a-methylthio-3a-deoxy-3,3a-didehydrogliotoxin (**58**) which exhibited only marginal activity [32.97]. However, compounds with disulfide or tetrasulfide bonds exhibited potent inhibitory activity against histone methyltransferases (HMT) G9a and HMT Set7/9 (lysine-specific histone methyltransferases). 6-Deoxy-5a,6-didehydrogliotoxin (**59**) containing a disulfide bond showed only weak activity, which suggested that the C-6 hydroxy group interfered with the G9a inhibitory activity based on the significant activity of other metabolites lacking this hydroxyl group [32.97].

A new diketopiperazine alkaloid, pre-aurantiamine (**60**) was isolated together with two new itaconic acid derivatives from the culture broth of the fungus *Aspergillus aculeatus* CRI322-03, which was obtained from the marine sponge *Stylissa flabelliformis* collected

off the shores of Thailand [32.98]. The structure and absolute configuration of pre-aurantiamine (**60**) was established based on extensive 1-D and 2-D nuclear magnetic resonance (NMR) and X-ray crystallographic analysis.

Carneamides A–C (**61**–**63**), prenylated indole diketopiperazines, and carnequinazolines A–C (**64**–**66**), quinazoline-type alkaloids, were reported as new natural products from the marine-derived fungus *Aspergillus carneus* KMM 4638 isolated from the marine brown alga *Laminaria sachalinensis* [32.99]. Structurally, carneamides A–C (**61**–**63**) represented the first prenylated indole alkaloid possessing a 2,2-dimethyl-2,8-dihydropyrano[3,2-f]indole ring system, and in particular **62** and **63** featured a rare indoloazocine tricyclic subunit. However, carnequinazolines A–C (**64**–**66**) were identified as quinazoline alkaloids with additional oxidation and alkylation patters, whereas **64** and **65** are aryl *C*-glycosides containing glucopyranoside units of $^4C_1$ conformation [32.99].

Recently, a diketopiperazine dimer possessing a rare *N*-1 to *C*-6 linkage was purified from the culture extract of the fungus *Aspergillus taichungensis* derived from the mangrove plant *Acrostichum aureum* and it was trivially named aspergilazine A (**67**) [32.100]. The chemical structure and absolute configuration of aspergilazine A was established based on spectroscopic evaluation and on Marfey's method. In the antiviral activity assay, **67** revealed only weak activity against the influenza A (H_1N_1) virus [32.100].

32.3.3 Polyketides

Three new α-pyrone metabolites, curvulapyrone (**68**, Fig. 32.7), curvulalide (**69**), and the curvulalic acid (**70**), were identified as new compounds together with six further metabolites from the sea fan-derived fungus *Curvularia* sp. PSU-F22 [32.101]. In the antimicrobial activity assay against *Staphylococcus aureus*, MRSA, and *Microsporum gypseum*, none of the isolated compounds revealed activity at concentrations up to 200 $\mu g\,mL^{-1}$ [32.101].

Nidurufin (**71**), a new cell cycle inhibitor, was isolated from the marine sediment-derived fungus *Penicillium flavidorsum* SHK1-27 [32.102]. In the in vitro cytotoxicity assay, **71** exhibited significant antiproliferative activity against the K562 cell line (IC_{50} = 12.6 μM) by inducing cell cycle arrest at G_2/M transition [32.102].

Trichodermaquinone (**72**) and trichodermaxanthone (**73**) were isolated from the marine-derived fungus *Trichoderma aureoviride* PSU-F95 isolated from the gorgonian sea fan *Annella* sp. [32.103]. In the antimicrobial assay, neither **72** nor **73** exhibited activity against MRSA [32.103].

A new aflatoxin, aflatoxin B_{2b} (**74**), was isolated together with six known compounds from the marine fungus *Aspergillus flavus* 092 008 derived from the mangrove plant *Hibiscus tiliaceus* [32.104]. Aflatoxin B_{2b} revealed significant antimicrobial activity against *Escherichia coli*, *Bacillus subtilis*, and *Enterobacter aerogenes*, with MIC values of 22.5, 1.7, and 1.1 μM, respectively [32.104]. In addition, **74** showed cytotoxic activity against A549, K562, and L-02 cell lines, with IC_{50} values of 8.1, 2.0, and 4.2 μM, respectively [32.104]. The results disclosed that hydration and hydrogenation of the Δ^8-double bond significantly reduce the cytotoxicity of aflatoxins, while the esterification at *C*-8 increases the cytotoxicity [32.104].

Marilones A–C (**75**–**77**), three new phthalide derivatives, were isolated together with the known compound silvaticol (**78**) from the biomalt culture of *Stachylidium* sp., a marine fungus derived from the sponge *Callyspongia* sp. cf. *C. flammea* [32.105]. Marilones A (**75**) and B (**76**) featured an unusual skeleton, suggesting unique fungal biosynthetic reactions. Among the isolated compounds, marilone A (**75**) revealed antiplasmodial activity against *Plasmodium berghei* liver stages with an IC_{50} of 12.1 μM, whereas marilone B (**76**) showed selective antagonistic activity towards the serotonin receptor 5-HT_{2B} with a K_i value of 7.7 μM [32.105].

Aspergilones A (**79**) and B (**80**), two novel benzylazaphilone derivatives with an unprecedented skeleton, were isolated from the culture broth of the marine-derived fungus *Aspergillus* sp. obtained from the gorgonian *Dichotella gemmacea* [32.106]. Structurally, aspergilone B (**80**) represents a symmetrical dimer of **79** with a characteristic methylene bridge. The absolute and relative configurations of aspergilones A and B were established based on X-ray crystallography and NMR spectral analysis. Interestingly, only the monomer aspergilone A (**79**) exhibited in vitro selective cytotoxicity toward HL-60, MCF-7, and A-549 cell lines with IC_{50} values of 8.3, 72.5, and 95.85 μM, respectively [32.106]. Moreover, **79** also exhibited potent antifouling activity against the larval settlement of the barnacle *Balanus amphitrite* at EC_{50} of 20 μM [32.106].

Penicacids A–C (**81**–**83**), together with two known analogs, namely mycophenolic acid (MPA) and 4′-hydroxy-MPA, were isolated from the fungus *Penicillium* sp. SOF07 derived from a marine sediment col-

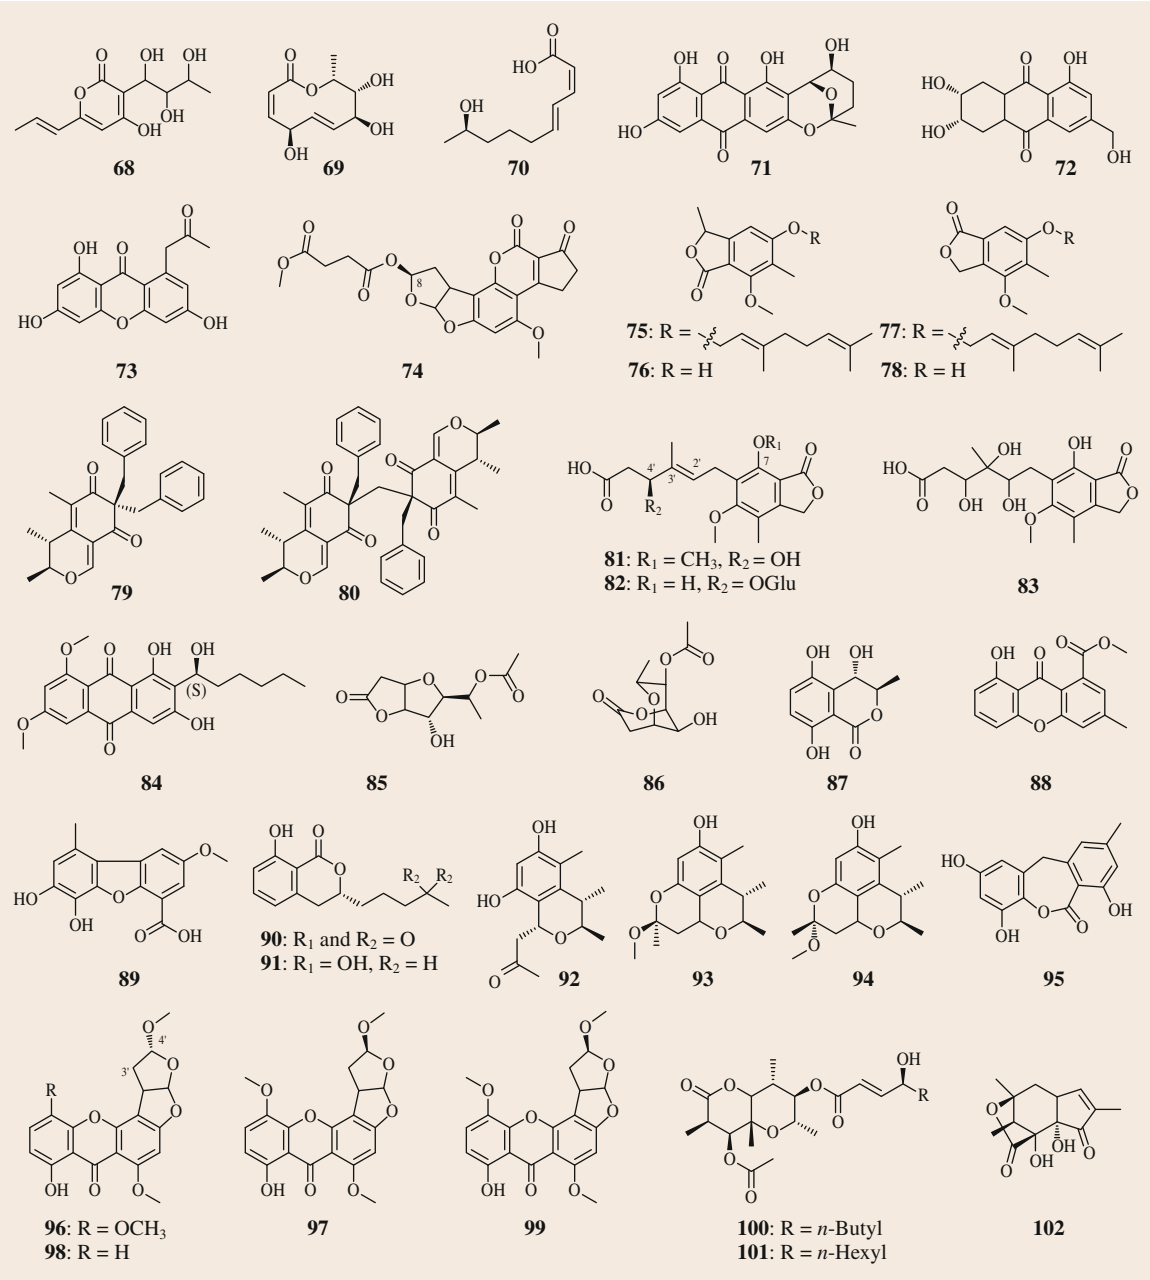

Fig. 32.7 Chemical structures of compounds **68–102**

lected in the South China Sea [32.107]. All compounds were assessed for their inhibitory activity against inosine 5′-monophosphate dehydrogenase (IMPDH), revealing IC_{50} values between 0.63 and 73 μM [32.107]. IMPDH is an essential rate-limiting enzyme controlling the guanine nucleotide pool which, in turn, controls replication, transcription, signaling, and translocation. Hydroxylation at *C*-4′, methylation at *C*-7-*OH*, or dual hydroxylation at the *C*-2′/*C*-3′ double bond of MPA diminished bioactivity, whereas glucosyl hydroxyla-

tion at *C*-4′ had no effect on the activity compared to MPA [32.107].

A new anthraquinone derivative, 6,8-di-*O*-methylaverantin (**84**), was isolated together with six known congeners from a culture of *Aspergillus versicolor* EN-7 derived from the brown alga, *Sargassum thunbergii* collected off the Qingdao coastline (China) [32.108]. Compound **84** exhibited only weak inhibition against *E. coli* but not against *S. aureus* or *Candida albicans* [32.108].

Protulactones A (**85**) and B (**86**), two polyketide-derived fungal metabolites, were been isolated from an EtOAc extract of the marine sediment-derived fungus *Aspergillus* sp. SF-5044 [32.109]. The structures of **85** and **86** were established based on NMR spectroscopy and mass spectroscopy (MS) data, along with chemical methods such as Mosher's method [32.109]. Compounds **85** and **86** represented new polyketide derivatives, possessing unique ring systems among the fungal metabolites produced by the genus *Aspergillus* [32.109].

A new isochroman, (3*R*,4*S*)-3,4-dihydro-4,5,8-trihydroxy-3-methylisocoumarin (**87**), was purified from the marine fungus *Phomopsis* sp. ZH-111 together with two known compounds [32.110]. Compound **87** accelerated the growth of subintestinal vessel plexus (SIV) branches [32.110].

A new xanthone derivative, 8-hydroxy-3-methyl-9-oxo-9*H*-xanthene-1-carboxylic acid methyl ester (**88**), was isolated from the co-culture broth of two mangrove-derived fungi (K38 and E33) [32.111]. Primary bioassays showed that **88** possesses inhibitory activity against five microorganisms, including *Gloeasporium musae* and *Peronophthora circhoralearum* [32.111].

Porric acid D (**89**), a new dibenzofuran derivative, was obtained from the methanolic extract of a marine-derived fungus, *Alternaria* sp., isolated from the Bohai Sea [32.112]. Porric acid D exhibited mild antimicrobial activity against *S. aureus* with a MIC of $100\,\mu g\,mL^{-1}$.

Aspergillumarins A (**90**) and B (**91**), two new dihydroisocoumarin derivatives, were isolated from the marine fungus *Aspergillus* sp., derived from the Chinese mangrove *Bruguiera gymnorrhiza* [32.113]. Aspergillumarins A and B revealed weak antibacterial activity against *S. aureus* and *Bacillus subtilis* at a concentration of $50\,\mu g\,mL^{-1}$ [32.113].

Three new citrinin derivatives, penicitrinols C–E (**92–94**), were isolated along with two known compounds from *Penicillium citrinum* [32.114]. The structures of the isolated citrinin derivatives were established based on spectroscopic methods and X-ray crystallographic analyses [32.114]. In the in vitro cytotoxicity assay against P388 and HL-60 cell lines, only penicitrinols C (**92**) and E (**94**) revealed modest antiproliferative activity against HL-60 cells with IC_{50} values of 52.8 and 41.2 μM, respectively [32.114].

In addition to a new diketopiperazine (**51**), a new anthraquinone derivative, 9-dehydroxyeurotinone (**95**), was purified from the fungal strain *Eurotium rubrum*, an endophytic fungus isolated from the semi-mangrove plant *Hibiscus tiliaceus* [32.94]. Compound **95** revealed weak antibacterial activity against *E. coli* with an inhibition zone of 7.0 mm at $100\,\mu g$/disk compared to amphotericin B with an inhibition zone of 11.0 mm at $20\,\mu g$/disk [32.94]. However, in the cytotoxic activity assay, 9-dehydroxyeurotinone revealed mild but selective activity against human cholangiocarcinoma cell line SW1990 ($IC_{50} = 92.0\,\mu M$) when tested against seven tumor cell lines [32.94].

Three new sterigmatocystin derivatives, oxisterigmatocystins A–C (**96–98**), together with the known compound 5-methoxysterigmatocystin (**99**), were isolated from the deep sea-derived fungus *Aspergillus versicolor* [32.115]. All isolated sterigmatocystin derivatives were assessed for cytotoxic activity against A-549 and HL-60 cell lines, and interestingly, only **99** revealed significant cytotoxicities with IC_{50} values of 3.86 and 5.32 μM, respectively [32.115]. This result implied that the double bond between *C*-3 and *C*-4 is a crucial pharmacophoric functionality in sterigmatocystins, and the activity disappeared upon saturation [32.115].

Two new botcinin derivatives, botcinin A (**100**) and B (**101**), were isolated from the fungus *Botryotinia* sp. SF-5275 derived from an unidentified marine alga collected off Seongsan Port (Korea) [32.116]. Botcinins A and B were evaluated for their in vitro inhibitory activity against protein tyrosine phosphatase 1B (PTP1B), an insulin-antagonizing protein influencing negative regulation of the insulin pathway, which is a promising target for the treatment of diabetes and obesity. Results revealed that botcinin A (**100**) possesses higher activity than **101** with IC_{50} values of 53.6 and 340.7 μM, respectively, compared to ursolic acid that was used as a positive control ($IC_{50} = 3.1\,\mu M$) [32.116]. These data disclosed that the hexahydropyrano[3,2,b]-pyran-2(3*H*)-one moiety is an essential structural feature required for activity.

Acremostrictin (**102**), a highly oxygenated tricyclic lactone of an unprecedented skeletal class, was isolated from the culture broth of *Acremonium strictum*, a marine fungus derived from a Korean Choris-

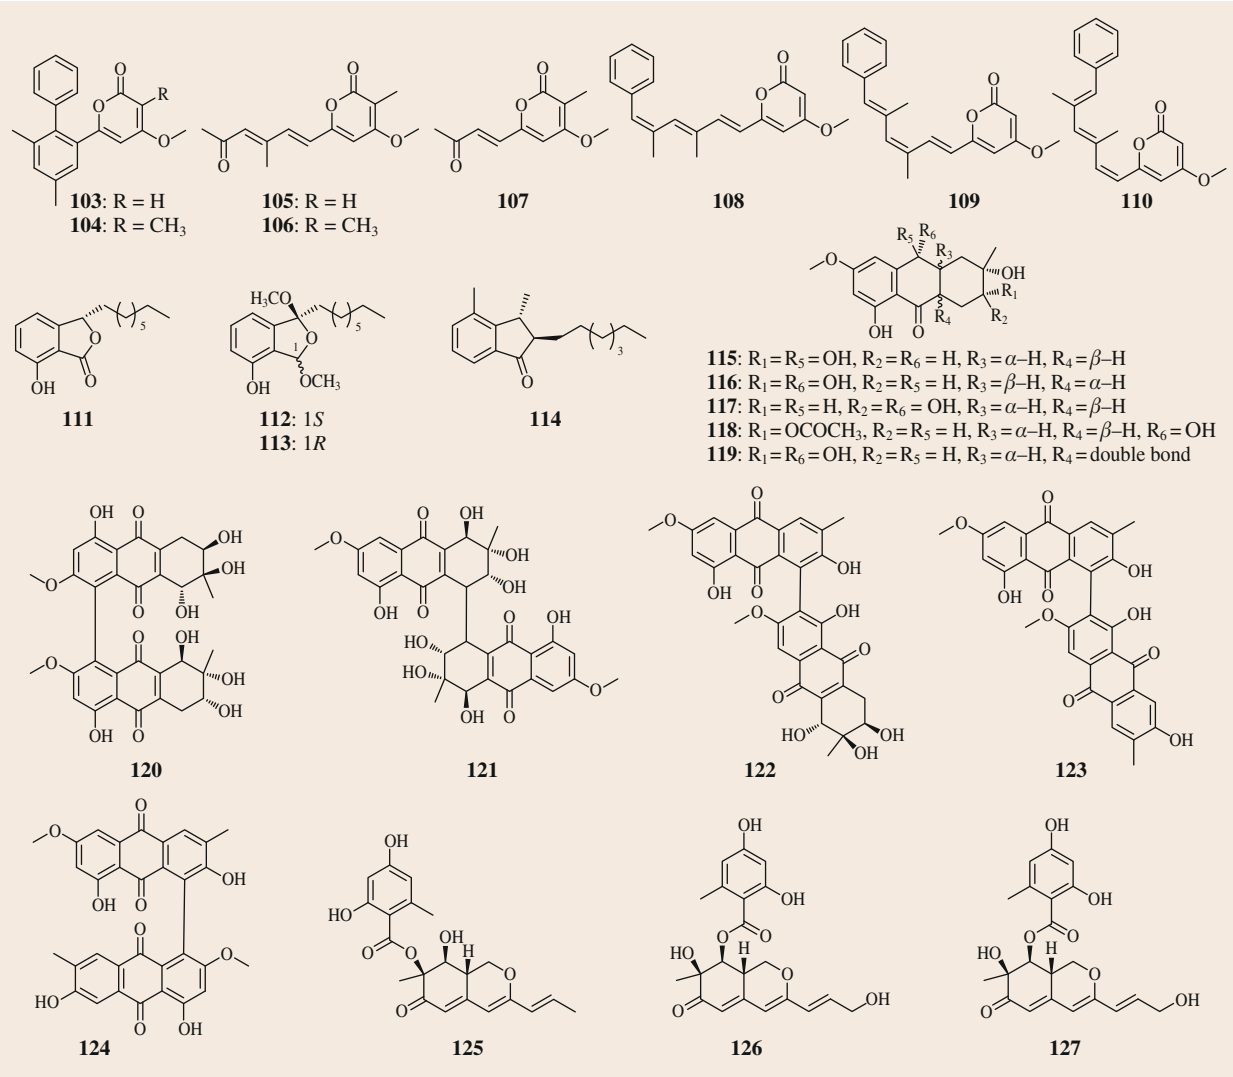

Fig. 32.8 Chemical structures of compounds **103**–**127**

tida sponge [32.117]. The structure of acremostrictin (**102**) was established based on combined spectroscopic and X-ray crystallographic analyses. In the antimicrobial activity assay, **102** revealed moderate activity with MIC values between 50 and 200 μM against *Micrococcus luteus* (IFO 12708), *Salmonella typhimurium* (ATCC 14028), and *Proteus vulgaris* (ATCC 3851) [32.117].

Eight new α-pyrone derivatives, namely nigerapyrones A–E (**103**–**110**, Fig. 32.8), were isolated from the endophytic fungus *Aspergillus niger* MA-132, derived from the Chinese mangrove plant *Avicennia marina* [32.118]. All isolated compounds were assessed for their cytotoxic and antimicrobial activity against a panel of eight tumor cell lines, two bacteria, and four plant-pathogenic fungi. Among the compounds tested, only compounds **104**, **106**, and **107** showed moderate to weak cytotoxicity against some of the tested tumor cell lines with IC_{50} values between 38 and 120 μM [32.118].

Paecilocins A–D (**111**–**114**), four new polyketide derivatives, were isolated from the fungus *Paecilomyces variotii*, derived from the jellyfish *Nemopilema nomurai* [32.119]. In the antimicrobial activity assay,

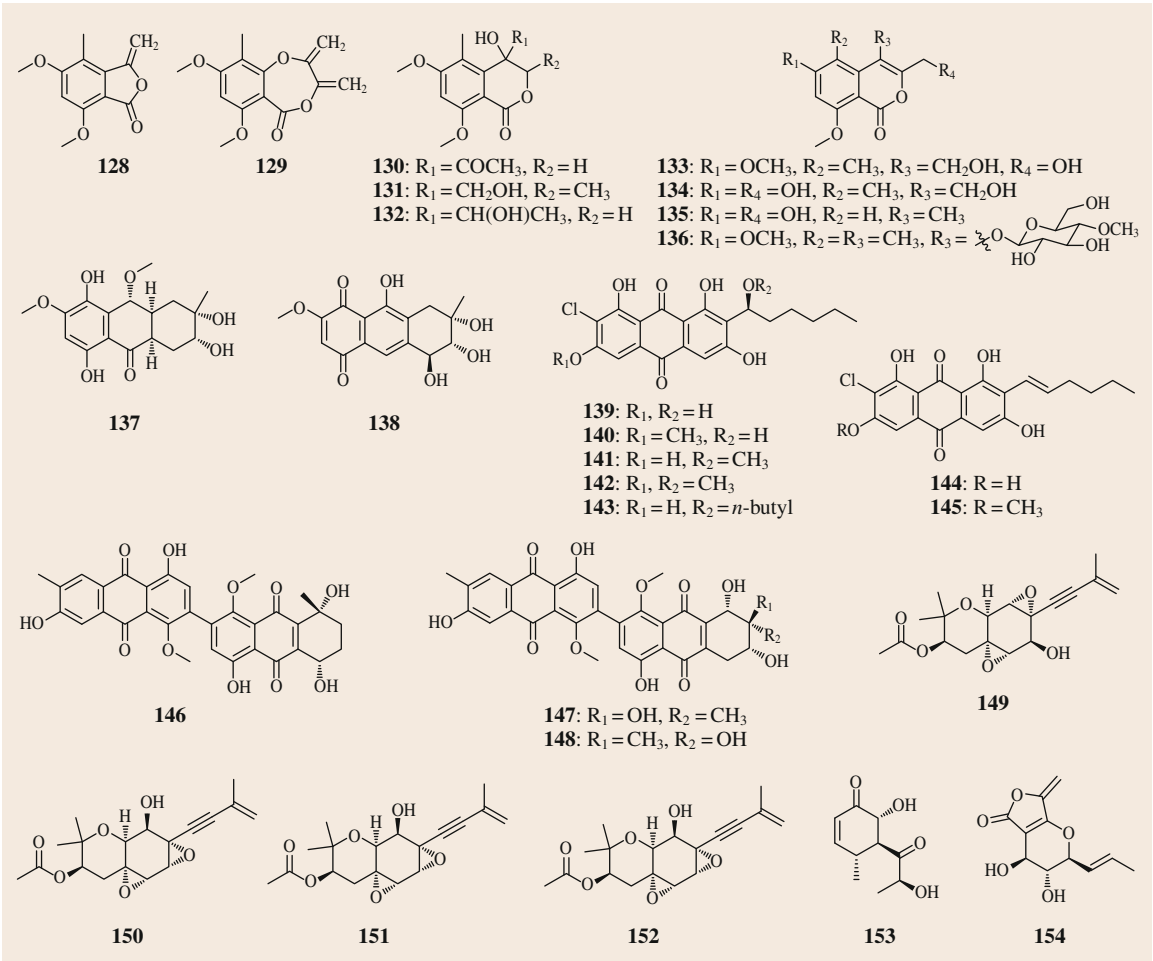

Fig. 32.9 Chemical structures of compounds **128**–**154**

paecilocins A–D revealed inhibitory activity against pathogenic bacteria including MRSA 3089 and multidrug-resistant *Vibrio parahemolyticus* 7001 with MIC values between 20 and 130 μM [32.119].

Five new hydroanthraquinone derivatives, tetrahydroaltersolanols C–F (**115**–**119**) and five new alterporriol-type anthranoid dimers, alterporriols N–R (**12**–**124**), were isolated along with seven known congeners from the culture broth of the fungus *Alternaria* sp. ZJ-2008003 obtained from the Chinese soft coral *Sarcophyton* sp. [32.120]. Structures and relative configurations of the isolated compounds were established based on extensive NMR spectroscopic analyses and single-crystal X-ray crystallography. Tetrahydroaltersolanol C (**115**) and alterporriol Q (**123**) exhibited antiviral activity against the porcine reproductive and respiratory syndrome virus (PRRSV) with IC_{50} values of 65 and 39 μM, respectively [32.120]. Alterporriol P (**122**) showed antiproliferative activity against PC-3 and HCT-116 cell lines, with IC_{50} values of 6.4 and 8.6 μM, respectively [32.120].

New hydrogenated azaphilones, pinophilins A (**125**) and B (**126**), together with Sch 725680 (**127**) were isolated from the fungal cultures of *Penicillium pinophilum* Hedgock derived from a seaweed [32.121]. Compounds **125**–**127** selectively inhibited the activities of mammalian DNA polymerases but not the activities of four X-family pols. Pinophilin A (**125**) revealed the highest activity with IC_{50} values of 48.6–55.6 μM through noncompetitive inhibition of both α and κ activities [32.121]. Interestingly, compounds **125**–**127** suppressed cell proliferation in five human cancer cell

lines, but had no effect on the viability of normal human cell lines [32.121].

Acremonide (**128**, Fig. 32.9), one new phthalide derivative and eight new isocoumarin derivatives, acremonones A–H (**129–136**) together with ten known compounds were obtained from *Acremonium* sp. PSU-MA70 isolated from a branch of the mangrove *Rhizophora apiculata* [32.122]. In the antifungal activity assay, some of the isolated compounds revealed only moderate antifungal activity with MIC values of 32 $\mu g\,mL^{-1}$ when tested against *Candida albicans* and *C. neoformans*, whereas against the latter the activity was lower [32.122].

Two new hydroanthraquinone analogs, 4a-*epi*-9α-methoxydihydrodeoxybostrycin (**137**) and 10-deoxybostrycin (**138**), together with seven known anthraquinone congeners were isolated from the fungus *Nigrospora* sp. derived from an unidentified sea anemone [32.123]. All isolated compounds were evaluated in vitro for their antibacterial activity against a panel of nine different bacterial strains. Among the isolated compounds, 10-deoxybostrycin (**138**) and 3-acetyl-4-deoxybostrycin revealed the most promising activities against *Bacillus subtilis* and *B. cereus* with IC_{50} values of 62.5 and 48.8 nM, respectively compared to ciprofloxacin as a positive control with IC_{50} values of 31.2 and 1250 nM, respectively [32.123].

Chemical investigation of the cultural extract of the marine-derived fungus *Aspergillus* sp. SCSIO F063 afforded seven new chlorinated anthraquinones (**139–145**) related to averantin [32.124]. Interestingly, the chlorinated anthraquinones were obtained upon using sea salt-containing potato dextrose broth with the addition of sodium bromide to the broth. In the cytotoxicity (MTT) assay, 6-*O*-methyl-7-chloroaveratin (**140**) displayed antiproliferative activity against three human tumor cell lines, SF-268, MCF-7, and NCI-H460, with IC_{50} values of 7.11, 6.64, and 7.42 μM, respectively [32.124].

Alterporriols K–M (**146–148**), three bianthraquinone derivatives, were reported for the first time from extracts of the endophytic fungus *Alternaria* sp. ZJ9-6B, isolated from the mangrove *Aegiceras corniculatum* collected in the South China Sea [32.125]. Compounds **146–148** were identified as the first alterporriols with a *C*-2-*C*-2 linkage. Alterporriols K and L revealed moderate cytotoxic activities towards MDA-MB-435 and MCF-7 cells with IC_{50} values between 13.1 and 29.1 μM [32.125].

Oxirapentyns B–D (**149–151**) and one known oxirapentyn A (**152**) were isolated from the lipophilic extract of the marine-derived fungus *Isaria felina* KMM4639 [32.126]. The absolute configuration of **149** was established to be 2*R*, 4*S*, 5*S*, 6*S*, 7*R*, 8*S*, 9*S* based on both the modified Mosher's method and X-ray analysis together with NOESY data [32.126]. In the cytotoxicity assay, oxirapentyn A (**152**) exhibited moderate activities against T-47D, SK-Mel-5, and SK-Mel-28 cell lines with IC_{50} values of 25, 19, and 17 μM, respectively [32.126].

Two new polyketides, arthropsadiol C (**153**) and massarilactone H (**154**), together with six known derivatives were isolated from the marine-derived fungus *Phoma herbarum* [32.127]. Some of the isolated compounds revealed moderate neuraminidase inhibitory activity with IC_{50} values between 4.15, and 9.16 μM [32.127].

Sorbiterrin A (**155**, Fig. 32.10), a novel sorbicillinoid featuring an hitherto unprecedented skeleton, was isolated from the marine sediment-derived fungus *Penicillium terrestre* [32.128]. The structure including its absolute configuration was elucidated based on NMR, MS data, and time-dependent density functional theory (TDDFT) CD calculations. Sorbiterrin A showed a moderate acetylcholinesterase (AChE) inhibitory effect with IC_{50} of 70 μM [32.128].

Two novel chlorinated sorbicillinoids, namely chloctanspirones A (**156**) and B (**157**), featuring an unprecedented bicyclo[2.2.2]octane-2-spiro cyclohexane skeleton, together with two precursors terrestrols K and L were isolated from a marine sediment-derived fungus *Penicillium terrestre* [32.129]. In the in vitro cytotoxicity assay, **156** revealed antiproliferative activity against both HL-60 and A-549 cells with IC_{50} values of 9.2 and 39.7 μM, respectively, while **157** showed only activity against HL-60 cells (IC_{50} = 37.8 μM) [32.129].

Five new polyketide derivatives including two benzopyrones (**158** and **159**), one isochroman (**160**), and two anthraquinone-citrinin derivatives (**161** and **162**) were isolated from the sea fan-derived fungus *Penicillium citrinum* PSU-F51 [32.130]. In the antimicrobial activity assay, compound **161** revealed moderate activity against both *S. aureus* and MRSA with equal MIC values of 30.8 μM [32.130].

Seven new phenalenone derivatives (**163–169**) were obtained from the fungus *Coniothyrium cereale* derived from the green alga *Enteromorpha* sp. collected from the Baltic Sea [32.131]. Conioscleroderolide (**167**) showed antimicrobial activity toward *S. aureus* SG 511 with a MIC value of 24 μM, which was suggested to

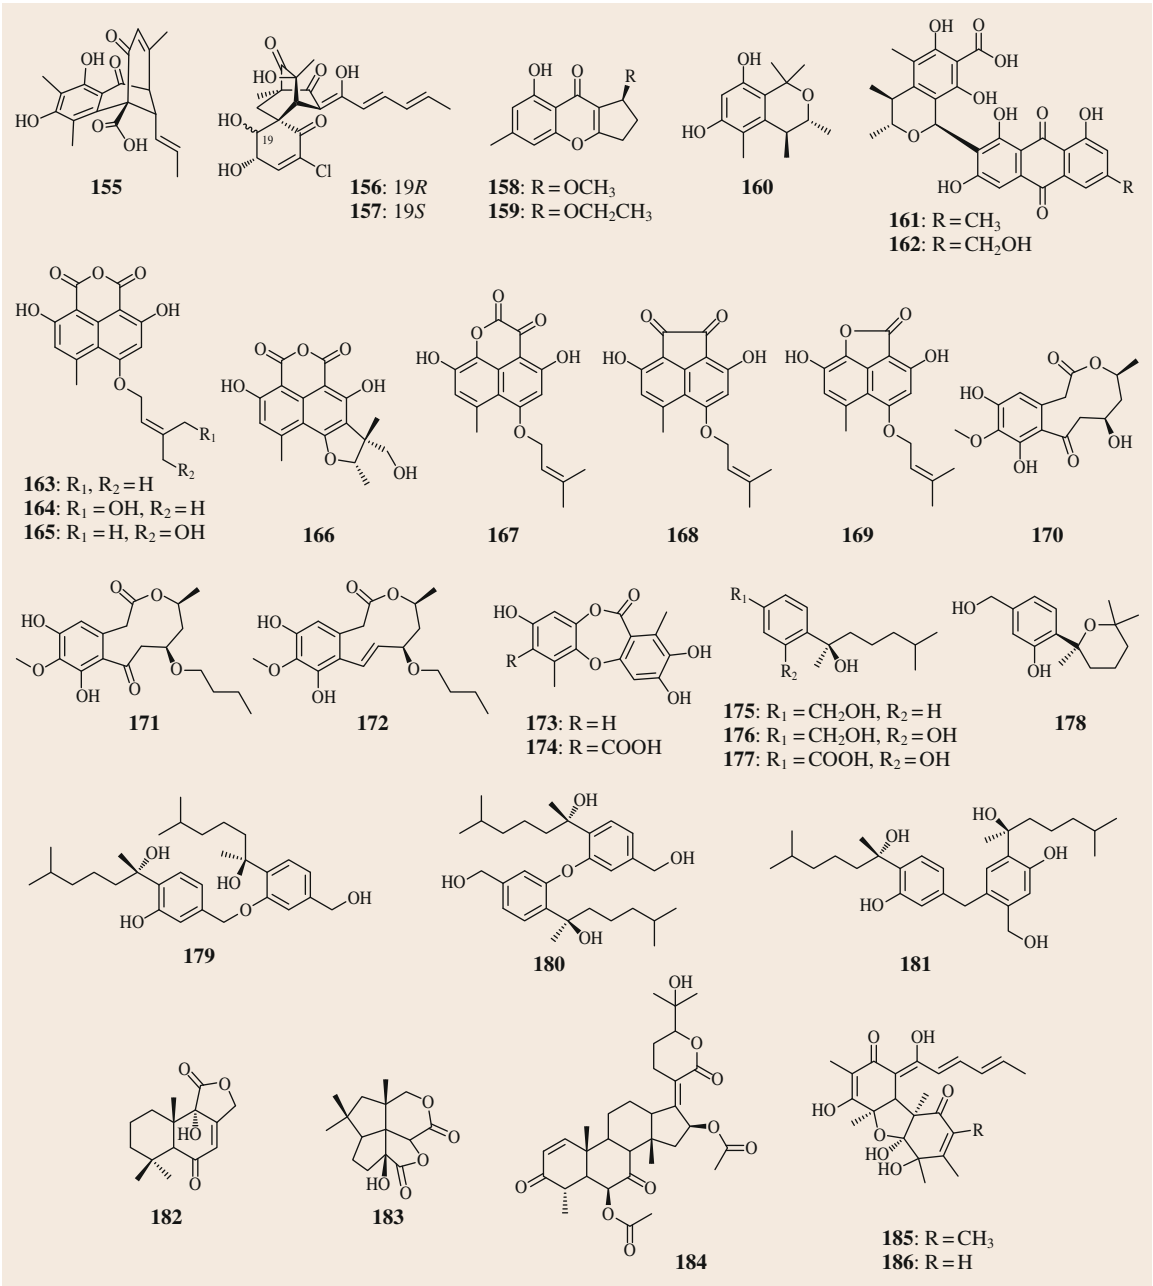

Fig. 32.10 Chemical structures of compounds **155**–**186**

be due to the diketo-lactone ring [32.131]. Moreover, in the agar diffusion assay against *Mycobacterium phlei*, considerable inhibition zones were observed for compounds **164**, **166**, and **169**, whereas **163** and **167** showed potent cytotoxic effects toward human leukocyte elastase (HLE) with IC_{50} values of 7.2 and 13.3 μM, respectively [32.131].

Five new polyketides, xestodecalactones D–F (**170**–**172**), corynesidone C (**173**), and 6-(3′-hydroxybutyl)-7-*O*-methylspinochrome B (**186**), were isolated from

the EtOAc extract of the endophytic fungus *Corynespora cassiicola*, isolated from the inner leaf tissues of the Chinese mangrove medicinal plant *Laguncularia racemosa* [32.132]. Absolute configurations of **170**–**172** were established by TDDFT ECD calculations of their solution conformers, proving that they belong to the (11*S*) series of xestodecalactones, opposite to the (11*R*) configurations of the known xestodecalactones A–C [32.132]. Compounds **170**–**174** were subjected to antibacterial, antiproliferative, antifungal, and antitrypanosomal activities. None of them proved to be active in any of these cellular screens. However, in a biochemical protein kinase activity assay using 16 different human protein kinases, only corynesidone B and 6-(3′-hydroxybutyl)-7-*O*-methylspinochrome B (**174**) exhibited significant activities against several kinases with IC_{50} values in the low micromolar range [32.132].

32.3.4 Terpenes

Aspergiterpenoid A (**175**), (−)-sydonol (**176**), (−)-sydonic acid (**177**), and (−)-5-(hydroxymethyl)-2(2′,6′,6′-trimethyltetrahydro-2*H*-pyran-2-yl)phenol (**178**), four new bisabolane-type sesquiterpenoids, were isolated from the fermentation broth of a marine-derived fungus *Aspergillus* sp. derived from the sponge *Xestospongia testudinaria* [32.133]. All isolated compounds revealed selective antibacterial activity toward eight bacterial strains with MIC values between 1.25 and 20.0 μM [32.133]. In the antifouling assay, only **178** inhibited larval settlement of the barnacle *Balamus amphitrite* at 100 μM concentration [32.133].

Another isolate of the fungus *Aspergillus* sp. was obtained from the same marine sponge *X. testudinaria* collected in the South China Sea and afforded three new phenolic bisabolane sesquiterpenoid dimers, namely disydonols A–C (**179**–**181**) [32.134]. The isolated compounds were evaluated for their cytotoxic activity against HepG-2 and Caski human tumor cell lines using MTT assay. Results revealed that only disydonol A (**179**) and C (**181**) exhibited potent cytotoxic activities toward these two cell lines with IC_{50} values between 6.0 and 26.0 μM, while disydonol B (**180**) was found to be relatively noncytotoxic (IC_{50} > 200 μM) [32.134].

In addition to prenylated indole alkaloids, carneamides A–C (**61**–**63**, Fig. 32.6) and quinazoline derivatives, carnequinazolines A–C (**64**–**66**), a new drimane sesquiterpenoid, 9α-hydroxy-5α-drim-7-ene-6-one-11,12-olide (**182**, Fig. 32.10), was isolated from the fungus *Aspergillus carneus* derived from the brown alga *Laminaria sachalinensis* [32.99]. Structurally, **182** was identified as a drimane sesquiterpenoid featuring a γ-lactone ring and enone group in its molecule and biologically it revealed no significant activity in either cytotoxic or antimicrobial assays [32.99].

Asperaculin A (**183**), an unprecedented sesquiterpenoid featuring a novel [5,5,5,6]fenestrane ring system, was isolated from the fungus *Aspergillus aculeatus* CRI323-04 isolated from the marine sponge *Xestospongia testudinaria* [32.135]. Asperaculin A (**183**) did not exhibit cytotoxic activity (at 50 μg mL^{-1}) against HepG2, MOLT-3, A549, and HuCCA-1 cancer cell lines [32.135].

In addition to the alkaloid fumiquinazoline K (**40**, Fig. 32.6), a new nordammarane triterpenoid, 6β, 16β-diacetoxy-25-hydroxy-3,7-dioxo-29-nordammara-1,17(20)-dien-21,24-lactone (**184**, Fig. 32.10), was isolated from the marine fungus *Aspergillus fumigatus* KMM-4631 associated with the soft coral *Sinularia* sp. [32.89]. Compound **184** did not exhibit activity in either cytotoxic or antimicrobial activity assays [32.89].

A novel antioxidant agent, JBIR-124 (**185**), was purified from the marine sponge-derived fungus *Penicillium citrinum* [32.136]. Structurally, **185** is identical to the known antioxidant agent JBIR-59 (**186**) and it differs only in the presence of additional methyl group at *C*-2. In the radical scavenging (2,2-Diphenyl-1-picryl-hydrazyl, DPPH) assay, JBIR-124 (**185**) and JBIR-59 (**186**) exhibited potent antioxidant activities with IC_{50} values of 30 and 25 μM, respectively, compared to α-tocopherol as a positive control (IC_{50} = 9 μM) [32.136].

Penicisteroids A (**187**, Fig. 32.11) and B (**188**), two polyoxygenated steroids, were reported as new metabolites from the endophytic fungus *Penicillium chrysogenum* QEN-24S isolated from an unidentified species of the red algal genus *Laurencia* [32.137]. Penicisteroid A (**187**) featured tetrahydroxy and *C*-16-acetoxy functionalities and exhibited potent antifungal and selective cytotoxic activities compared to penicisteroid B (**188**) and anicequol (**189**) [32.137]. These differences in bioactivity illustrated that the hydroxyl group at *C*-6 in the B ring is likely to be an important structural feature for the antifungal activity, whereas the moderate activity of **187** and **189** illustrated that one or more substitutions of hydroxyl group at the B ring could contribute to the antifungal activity. Moreover, the hydroxyl group at *C*-6 in the B ring proved to be essential for the cytotoxicity as in penicisteroid A (**187**) compared to **188** and **189** [32.137].

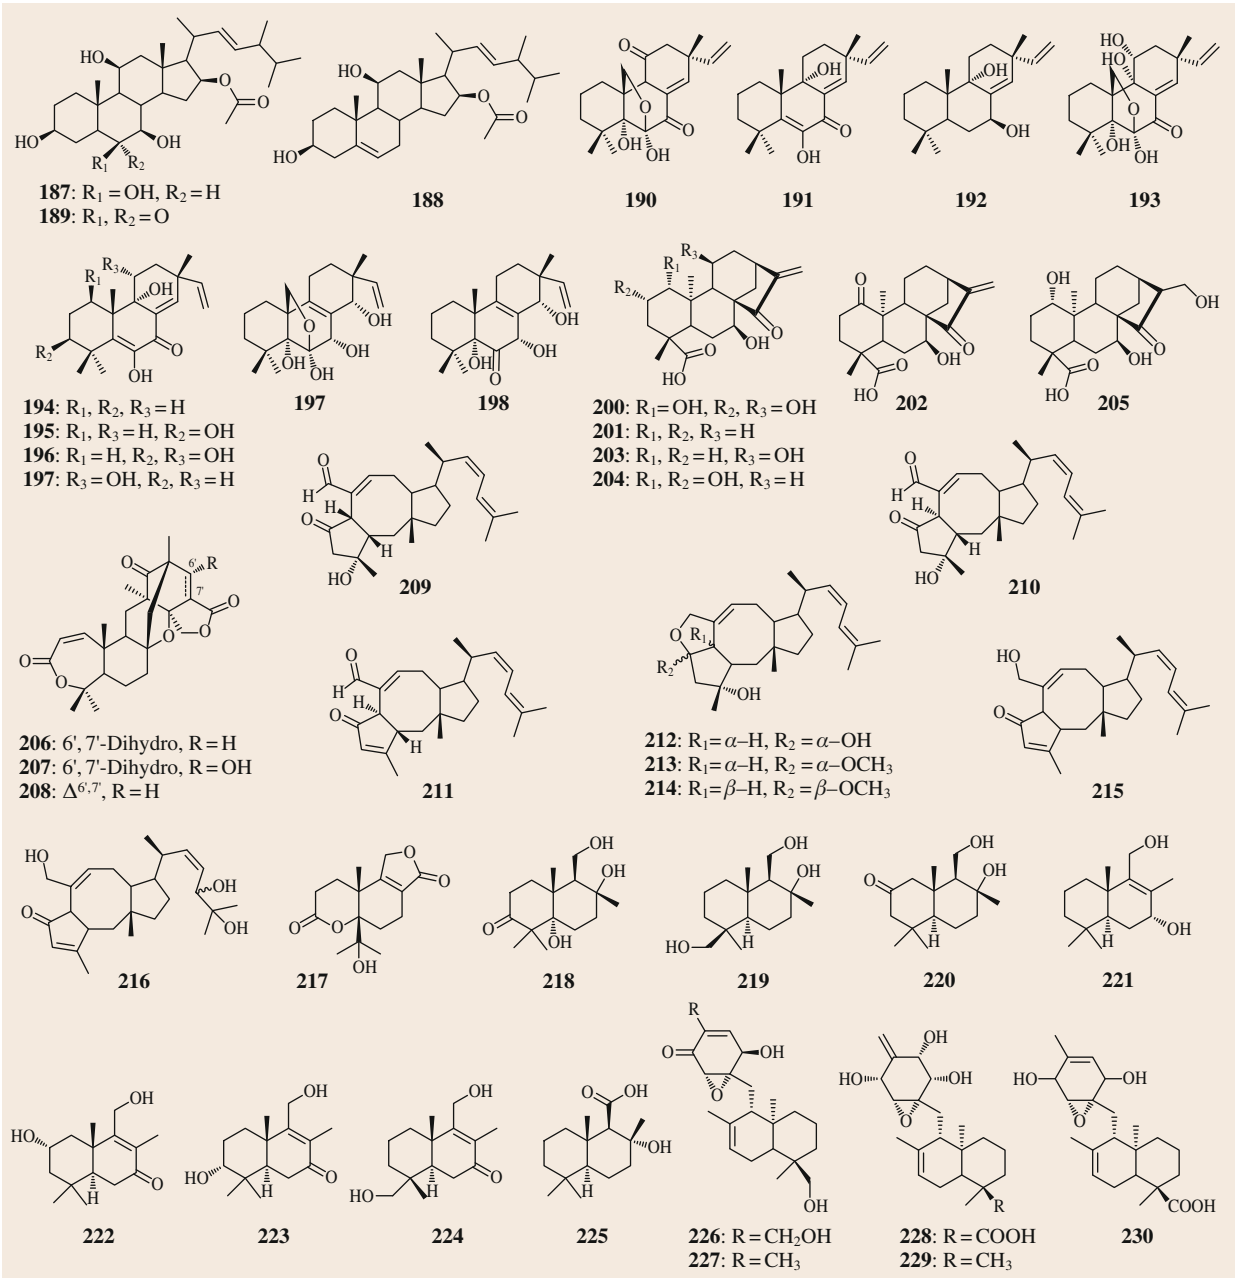

Fig. 32.11 Chemical structures of compounds **187**–**230**

Three new pimarane diterpenes, aspergilones A–C (**190**–**192**), together with the known compound **193**, were isolated from the marine-derived fungus *Epicoccum* sp. HS-1 associated with *Apostichopus japonicus* [32.138]. Absolute configurations of compounds (**190**–**192**) were determined by CD spectroscopy [32.138]. In the cytotoxicity (MTT) assay, compounds **190** and **193** revealed potent activities against KB and KBv200 cell lines with IC_{50} values of 10.0, 6.4 μM, and 11.2 and 18.0 μM, respectively [32.138].

Scopararanes C–G (**194**–**198**), five new oxygenated pimarane diterpenes, were isolated from the culture of a marine sediment-derived fungus *Eutypella scoparia* FS26 obtained from the South China Sea [32.139]. All isolated scopararanes (**194**–**198**) together with the known metabolite, libertellenone A (**199**), were subjected to cytotoxicity (MTT) assay against three human tumor cell lines, namely SF-268 (glioma), MCF-7 (breast), and NCI-H460 (NSCLC). Scopararanes C (**194**) and D (**195**) possessed moderate cytotoxic activities against MCF-7 with IC_{50} values of 35.9 and 25.6 μM, respectively. However, libertellenone A (**199**) displayed variable activities with IC_{50} values between 12.0 and 40.2 μM, whereas the other remaining scopararanes E–G (**196**–**198**) displayed weak cytotoxic activities against the MCF-7 cell line with IC_{50} values of more than 70 μM [32.139]. Conclusively, the structure–activity relationship study of compounds **194**–**199** revealed that the carbonyl group at *C*-7, the olefinic bond between *C*-8 and *C*-14, and the furan ring formed of *C*-20 methyl, *C*-6, *C*-5, and *C*-10, in addition to the number and positions of hydroxyl groups, could be important structural features influencing the cytotoxic activities [32.139].

Geopyxins A–E (**200**–**205**), new *ent*-kaurane diterpenoids, were isolated from endolichenic fungal strains of the genus *Geopyxis* [32.140]. The structures and absolute configurations of geopyxins were established based on their spectroscopic data and conducting the modified Mosher's ester method [32.140]. Methylated and acetylated derivatives of geopyxins were also prepared and all were assessed for their cytotoxic and heat-shock induction activities. Results revealed that geopyxin B (**201**), and the methylated derivatives of all geopyxins except geopyxin E (**215**), exhibited cytotoxic activities in the low micromolar range against five tumor cell lines, whereas the acetylated derivatives were found to activate the heat-shock response at similar concentrations [32.140]. Based on these findings, the preliminary structure-activity motif was deduced to be the electrophilic α,β-unsaturated ketone carbonyl functionality, but this was not sufficient for both cytotoxicity and heat-shock activation [32.140].

Insuetolides A–C (**206**–**208**), three novel meroterpenoids, together with other drimane sesquiterpenes were isolated from the fungus *Aspergillus insuetus* (OY-207), derived from the Mediterranean sponge *Psammocinia* sp. [32.141]. Insuetolides featured a hitherto unprecedented carbon skeleton derived from the cyclization of farnesyl and 3,5-dimethylorsellinic acid. Insuteloide A (**206**) exhibited weak antifungal activity toward *Neurospora crassa* with a MIC value of 140 μM, while insuetolide C (**208**) exhibited mild cytotoxicity towards MOLT-4 human leukemia cells [32.141].

Three new sesterterpenes, namely ophiobolin K (**209**), its 6-epimer (**210**), and 6-*epi*-ophiobolin G (**211**), were isolated from the marine-derived fungus *Emericella variecolor* [32.142]. Ophiobolins (**209**–**211**) inhibited biofilm formation of *Mycobacterium smegmatis* with MICs of 4.1−65 μM; however these compounds did not show antimicrobial activity at the same concentrations [32.142]. Moreover, ophiobolin K (**209**) inhibited also the biofilm formation of *M. bovis* BCG and enables restoring the antimicrobial activity of isoniazid against *M. smegmatis* through inhibiting biofilm formation [32.142].

In addition to aspergillamides A (**44**) and B (**45**, Fig. 32.6), five new ophiobolin-type sesterterpenoids (**212**–**216**, Fig. 32.11) were isolated from the marine-derived fungus *Aspergillus ustus* derived from the marine sponge *Suberites domuncula* [32.91]. None of the isolated sesterterpenoids revealed cytotoxic activity against L5178Y cells at a concentration up to 10 $\mu g\,mL^{-1}$ [32.91].

Diaporol A (**217**), possessing a unique tricyclic lactone ring, together with eight further new drimane sesquiterpenoids, diaporols B–I (**218**–**225**) were purified from the culture medium of the endophytic fungal strain *Diaporthe* sp., derived from the Chinese mangrove *Rhizophora stylosa* [32.143]. The absolute configurations of compounds **217**–**221** were established based on single-crystal X-ray crystallography [32.143]. In the cytotoxicity assay, no compound revealed significant activity against the cell lines tested at concentrations up to 20 μM [32.143].

Three new epoxyphomalins C–E (**228**–**230**), together with the parent congeners **226** and **227**, were isolated from *Paraconiothyrium* sp. fermentation extracts [32.144]. The cytotoxic activities of epoxyphomalins A–E (**226**–**230**) were investigated toward a panel of 36 human tumor cell lines. Results disclosed that **229** possesses selective cytotoxic activities toward PC3M (prostate) and BXF1218L (bladder) cancer cell lines with IC_{50} values of 0.72 and 1.43 μM, respectively [32.144]. Moreover, the inhibitory activity of epoxyphomalin A (**226**) and B (**227**) toward chymotrypsin-, caspase-, and trypsin-like activity of purified 20S proteasomes indicated that their cytotoxic effects are mediated through potent inhibition of the 20S proteasome [32.144].

Three new tetranorlabdane diterpenoids, asperolides A–C (**231**–**233**, Fig. 32.12) and five related

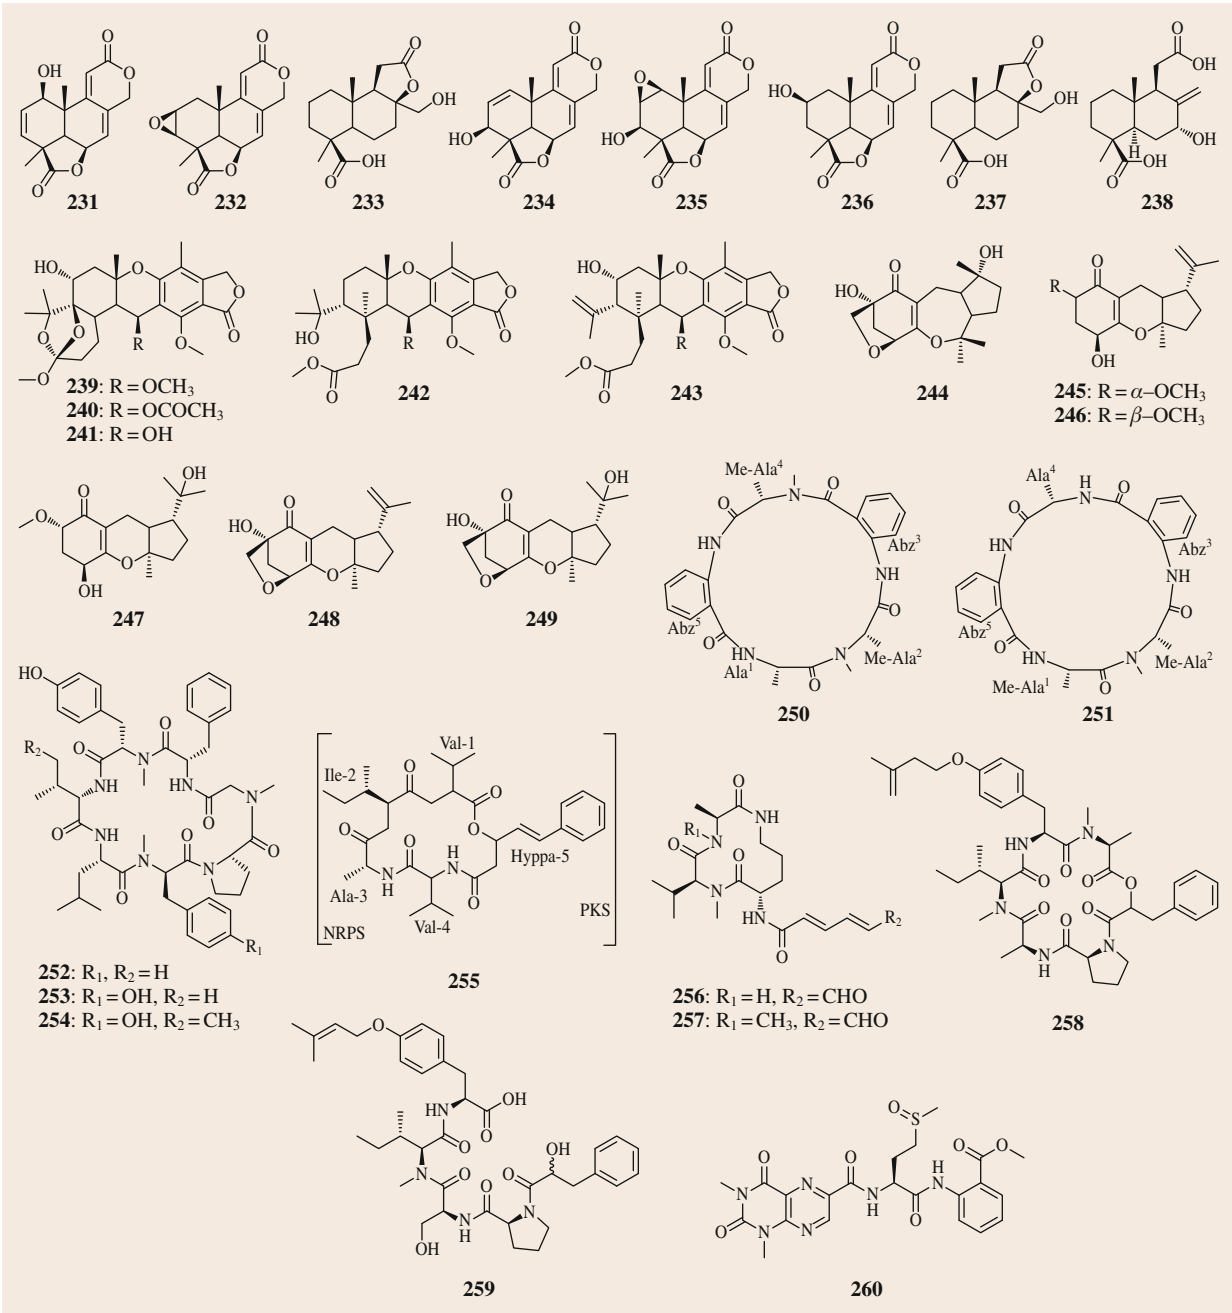

Fig. 32.12 Chemical structures of compounds **231**–**260**

derivatives (**234**–**238**) were obtained from a culture extract of *Aspergillus wentii* EN-48, an endophytic fungus isolated from an unidentified marine brown algal species of the genus *Sargassum* [32.145]. The absolute configurations of asperolide A (**231**) and wentilactone (**236**) were established based on X-ray crystallographic analysis [32.145]. All isolated compounds were assessed for their cytotoxic activities against seven differ-

ent human tumor cell lines, but only wentilactone (**236**) exhibited a potent activity among the compounds tested ($IC_{50} = 17\,\mu M$) [32.145]. However, in the antimicrobial activity assay, compound **234** revealed a considerable antifungal activity against *C. albicans* with a MIC value of 56 μM [32.145].

Chemical investigation of the crude extract of the fungus *Aspergillus* sp. obtained from the Mediterranean sponge *Tethya aurantium* afforded five new meroterpenoids, austalides M–Q (**239**–**243**), together with nine known compounds [32.146]. Absolute configurations of **239** and **242** were established by TDDFT ECD calculations, allowing the assignment of the absolute configuration of analogs **240**, **241**, and **243** [32.146]. All isolated austalides were assessed for their cytotoxic activity toward L5178Y cells using the MTT assay; however, they exhibited only weak or no activity in this assay [32.146].

Four new meroterpenes, guignardones F–I (**244**–**247**), together with two known guignardones A (**248**) and B (**249**), were obtained from the endophytic fungus A1 isolated from the mangrove plant *Scyphiphora hydrophyllacea* [32.147]. Chemical structures and relative configurations of the isolated compounds were determined based on spectroscopic data and single-crystal X-ray crystallography [32.147]. In the antibacterial activity assay against MRSA, only guignardones I (**247**) and B (**249**) exhibited inhibition zones of 9.0 and 8.0 mm at 65 μM, respectively [32.147].

32.3.5 Marine Peptides and Proteins

Versicotides A (**250**) and B (**251**), cyclic pentapeptides containing an L-alanine residue, two anthranthilic acid (2-aminobenzoic acid) residues, and two *N*-methyl-L-alanine residues were isolated from the marine sediment-derived fungus *Aspergillus versicolor* ZLN-60 [32.148]. The chemical structures of versicotides A and B were established on the basis of chemical and spectroscopic analyses. In the cytotoxicity (MTT) assays, neither versicotide A (**250**) nor versicotide B (**251**) exhibited antitumor activity [32.148].

Cordyheptapeptides C–E (**252**–**254**), three new cycloheptapeptides, were purified from the culture extract of the marine sediment-derived fungus *Acremonium persicinum* SCSIO115 [32.149]. The absolute configurations of the amino acid residues were determined by single-crystal X-ray diffraction, Marfey's method, and chiral-phase high performance liquid chromatography (HPLC) analysis. In the antiproliferative activity assay, only cordyheptapeptides C (**252**) and E (**254**) revealed cytotoxic activities toward SF-268, MCF-7, and NCI-H460 tumor cell lines with IC_{50} values ranging between 2.5−12.1 μM [32.149].

EGM-556 (**255**), a cyclodepsipeptide of hybrid biosynthetic origin of both polyketide (PKS) and nonribosomal peptide (NRPS) syntheses, was prepared through implementing the histone deacetylase (HDAC) inhibitor suberoylanilide hydroxamic acid (SAHA) to turn on its biosynthesis in the Floridian marine sediment-derived fungus *Microascus* sp. [32.150]. EGM-556 (**255**) represents an interesting example for a fungal metabolite produced through induction of silent biosynthetic genes activate by means of epigenetic manipulation [32.150].

Two new tripeptides, namely pre-sclerotiotide F (**256**) and sclerotiotide F (**257**), were isolated from a marine sediment-derived fungus *Aspergillus insulicola*, along with five known compounds [32.151]. Both compounds **256** and **257** were inactive at 100 μM for in vitro cytotoxicity (MTT) assay against PC3 (prostate), MCF-7 (breast), and RAW (murine macrophage) cancer cell lines [32.151]. Moreover, this pair of tripeptides did not illustrate any inhibitory activity on NF-κB or iNOS pathways when tested in the presence of LPS [32.151].

Pullularins E (**258**) and F (**259**), two new peptides, were isolated from the endophytic fungus *Bionectria ochroleuca*, derived from the mangrove plant *Sonneratia caseolaris* collected from the island of Hainan (China) [32.152]. The chemical structures and absolute configurations of amino acids were determined by HPLC analysis of acid hydrolysates using Marfey's method [32.152]. In the cytotoxicity assay, pullularins E (**258**) and F (**259**) revealed moderate inhibitory activity toward the L5178Y cell line with IC_{50} values of 7.0 and $> 14.0\,\mu M$ [32.152].

Penilumamide (**260**), a novel lumazine peptide, was obtained from the fungal strain *Penicillium* sp. CNL-338, isolated from the red alga *Laurencia* sp. collected in the Bahamas Islands [32.153]. The chemical structure of penilumamide revealed a lumazine system with L-methionine sulfoxide and anthranilic acid ester [32.153]. Penilumamide (**260**) was assessed for its cytotoxicity, antibacterial and antifungal activities, and its influence on the Ca^{2+} levels in neuroendocrine cells (PC12); however, it revealed no activity in any of the aforementioned bioassays [32.153].

32.4 Conclusions

Marine-derived fungi continue to be a prolific source of new and novel bioactive secondary metabolites. Some examples of bioactive marine natural products such as bryostatins obtained from macroorganisms are implicated by endosymbiotic microorganisms as true producers. This notion has provoked marine natural product chemists and pharmacologists to explore marine-associated fungi for interesting chemical entities that can be developed into drug candidates. The principle of implementing marine-derived fungi to produce bioactive secondary metabolites has resolved the main obstacle facing the development of marine-inspired pharmaceuticals, which is that yields are limited, even through aquaculturing efforts. However, industrial fermentation of marine-derived fungi on a large scale will in future enable the mass production of bioactive compounds, which can be optimized to face market needs in the case of the development of a marine-inspired pharmaceutical.

The high productivity of marine-derived fungi has attracted natural product chemists to invest more research effort in this area, aiming to find a new or novel entity of bioactive natural product(s) that can be used as milestones for developing new pharmaceuticals for the treatment of serious ailments.

32.93 F.-Y. Du , X.-M. Li, C.-S. Li, Z. Shang, B.-G. Wang: Cristatumins A–D, new indole alkaloids from the marine-derived endophytic fungus *Eurotium cristatum* EN-220, Bioorg. Med. Chem. Lett. **22**, 4650–4652 (2012)

32.94 H.-J. Yan, X.-M. Li, C.-S. Li, B.-G. Wang: Alkaloid and anthraquinone derivatives produced by the marine-derived endophytic fungus *Eurotium rubrum*, Helv. Chim. Acta **95**, 163–168 (2012)

32.95 F. He, Y.-L. Sun, K.-S. Liu, X.-Y. Zhang, P.-Y. Qian, Y.-F. Wang, S.-H. Qi: Indole alkaloids from marine-derived fungus *Aspergillus sydowii* SCSIO 00305, J. Antibiot. **65**, 109–111 (2012)

32.96 S.-U. Lee, Y. Asami, D. Lee, J.-H. Jang, J.S. Ahn, H. Oh: Protuboxepins A and B and protubonines A and B from the marine-derived fungus *Aspergillus* sp. SF-5044, J. Nat. Prod. **74**, 1284–1287 (2011)

32.97 Y. Sun, K. Takada, Y. Takemoto, M. Yoshida, Y. Nogi, S. Okada, S. Matsunaga: Gliotoxin analogues from a marine-derived fungus, *Penicillium* sp., and their cytotoxic and histone methyltransferase inhibitory activities, J. Nat. Prod. **75**, 111–114 (2012)

32.98 B.S. Antia, T. Aree, C. Kasettrathat, S. Wiyakrutta, O.D. Ekpa, U.J. Ekpe, C. Mahidol, S. Ruchirawat, P. Kittakoop: Itaconic acid derivatives and diketopiperazine from the marine-derived fungus *Aspergillus aculeatus* CRI322-03, Phytochemistry **72**, 816–820 (2011)

32.99 O.I. Zhuravleva, S.S. Afiyatullov, V.A. Denisenko, S.P. Ermakova, N.N. Slinkina, P.S. Dmitrenok, N.Y. Kim: Secondary metabolites from a marine-derived fungus *Aspergillus carneus* Blochwitz, Phytochemistry **80**, 123–131 (2012)

32.100 S. Cai, X. Kong, W. Wang, H. Zhou, T. Zhu, D. Li, Q. Gu: Aspergilazine A, a diketopiperazine dimer with a rare N-1 to C-6 linkage, from a marine-derived fungus *Aspergillus taichungensis*, Tetrahedron Lett. **53**, 2615–2617 (2012)

32.101 K. Trisuwan, V. Rukachaisirikul, S. Phongpaichit, S. Preedanon, J. Sakayaroj: Madiolide and pyrone derivatives from the sea fan-derived fungus *Curvularia* sp. PSU-F22, Arch. Pharmacal Res. **34**, 709–714 (2012)

32.102 H. Ren, W.-W. Liu: Nidurufin as a new cell cycle inhibitor from marine-derived fungus *Penicillium flavidorsum* SHK1-27, Arch. Pharmacal Res. **34**, 901–905 (2011)

32.103 N. Khamthong, V. Rukachaisirikul, K. Tadpetch, M. Kaewpet, S. Phongpaichit, S. Preedanon, J. Sakayaroj: Tetrahydroanthraquinone and xanthone derivatives from the marine-derived fungus *Trichoderma aureoviride* PSU-F95, Arch. Pharmacal Res. **35**, 461–468 (2012)

32.104 H. Wang, Z. Lu, H.-J. Qu, P. Liu, C. Miao, T. Zhu, J. Li, K. Hong, W. Zhu: Antimicrobial aflatoxins from the marine-derived fungus *Aspergillus flavus* 092008, Arch. Pharmacal Res. **35**, 1387–1392 (2012)

32.105 C. Almeida, S. Kehraus, M. Prudencio, G.M. König: Marilones A–C, phthalides from the sponge-derived fungus *Stachylidium* sp., Beil. J. Org. Chem. **7**, 1636–1642 (2011)

32.106 C.-L. Shao, C.-Y. Wang, M.-Y. Wei, Y.-C. Gu, Z.-G. She, P.-Y. Qian, Y.-C. Lin: Aspergilones A and B, two benzylazaphilones with an unprecedented carbon skeleton from the gorgonian-derived fungus *Aspergillus* sp., Bioorg. Med. Chem. Lett. **21**, 690–693 (2011)

32.107 Z. Chen, Z. Zheng, H. Huang, Y. Song, X. Zhang, J. Ma, B. Wang, C. Zhang, J. Ju: Penicacids A–C, three new mycophenolic acid derivatives and immunosuppressive activities from the marine-derived fungus *Penicillium* sp. SOF07, Bioorg. Med. Chem. Lett. **22**, 3332–3335 (2012)

32.108 Y. Zhang, X.-M. Li, B.-G. Wang: Anthraquinone derivatives produced by marine-derived *Aspergillus versicolor* EN-7, Biosci. Biotechnol. Biochem. **76**, 1774–1776 (2012)

32.109 J.H. Sohn, H. Oh: Protulactones A and B: Two new polyketides from the marine-derived fungus *Aspergillus* sp. SF-5044, Bull. Kor. Chem. Soc. **31**, 1695–1698 (2010)

32.110 J.X. Yang, Y. Chen, C. Huang, Z. She, Y. Lin: A new isochroman derivative from the marine fungus *Phomopsis* sp. (No. ZH-111), Chem. Nat. Comp. **47**, 13–16 (2011)

32.111 C. Li, J. Zhang, C. Shao, W. Ding, Z. She, Y. Lin: A new xanthone derivative from the co-culture broth of two marine fungi (Strain No. E33 and K38), Chem. Nat. Comp. **47**, 382–384 (2011)

32.112 X. Xu, S. Zhao, J. Wei, N. Fang, L. Yin, J. Sun: Porric acid D from marine-derived fungus *Alternaria* sp. isolated from Bohai Sea, Chem. Nat. Comp. **47**, 893–895 (2011)

32.113 S. Li, M. Wei, G. Chen, Y. Lin: Two new dihydroisocoumarins from the endophytic fungus *Aspergillus* sp. collected from the South China Sea, Chem. Nat. Comp. **48**, 371–373 (2012)

32.114 L. Chen, W. Liu, X. Hu, K. Huang, J.-L. Wu, Q.-Q. Zhang: Citrinin derivatives from the marine-derived fungus *Penicillium citrinum*, Chem. Pharm. Bull. **59**, 515–517 (2011)

32.115 S. Cai, T. Zhu, L. Du , B. Zhao, D. Li, Q. Gu: Sterigmatocystins from the deep-sea-derived fungus *Aspergillus versicolor*, J. Antibiot. **64**, 193–194 (2011)

32.116 M.-Y. Kim, J.-H. Sohn, J.-H. Jang, J.S. Ahn, H. Oh: Two new botcinin derivatives encountered in the studies of secondary metabolites from the marine-derived fungus *Botryotinia* sp. SF5275, J. Antibiot. **65**, 161–164 (2012)

32.117 E. Julianti, H. Oh, K.H. Jang, J.K. Lee, S.K. Lee, D.-C. Oh, K.-B. Oh, J. Shin: Acremostrictin, a highly oxygenated metabolite from the marine fungus *Acremonium strictum*, J. Nat. Prod. **74**, 2592–2594 (2011)

32.118 D. Liu, X.-M. Li, L. Meng, C.-S. Li, S.-S. Gao, Z. Shang, P. Proksch, C.-G. Huang, B.-G. Wang: Nigerapyrones A–H, α-pyrone derivatives from the marine mangrove-derived endophytic fungus *Aspergillus niger* MA-132, J. Nat. Prod. **74**, 1787–1791 (2011)

32.119 J. Liu, F. Li, E.L. Kim, J.L. Li, J. Hong, K.S. Bae, H.Y. Chung, H.S. Kim, J.H. Jung: Antibacterial polyketides from the Jellyfish-derived fungus *Paecilomyces variotii*, J. Nat. Prod. **74**, 1826–1829 (2011)

32.120 C.-J. Zheng, C.-L. Shao, Z.-Y. Guo, J.-F. Chen, D.-S. Deng, K.-L. Yang, Y.-Y. Chen, X.-M. Fu, Z.-G. She, Y.-C. Lin, C.-Y. Wang: Bioactive hydroanthraquinones and anthraquinone dimers from a soft coral-derived *Alternaria* sp. fungus, J. Nat. Prod. **75**, 189–197 (2012)

32.121 Y. Myobatake, T. Takeuchi, K. Kuramochi, I. Kuriyama, T. Ishido, K. Hirano, F. Sugawara, H. Yoshida, Y. Mizushina: Pinophilins A and B, inhibitors of mammalian A-, B-, and Y-family DNA polymerases and human cancer cell proliferation, J. Nat. Prod. **75**, 135–141 (2012)

32.122 V. Rukachaisirikul, A. Rodglin, Y. Sukpondma, S. Phongpaichit, J. Buatong, J. Sakayaroj: Phthalide and isocoumarin derivatives produced by an *Acremonium* sp. isolated from a mangrove *Rhizophora apiculata*, J. Nat. Prod. **75**, 853–858 (2012)

32.123 K.-L. Yang, M.-Y. Wei, C.-L. Shao, X.-M. Fu, Z.-Y. Guo, R.-F. Xu, C.-J. Zheng, Z.-G. She, Y.-C. Lin, C.-Y. Wang: Antibacterial anthraquinone derivatives from a sea anemone-derived fungus *Nigrospora* sp., J. Nat. Prod. **75**, 935–941 (2012)

32.124 H. Huang, F. Wang, M. Luo, Y. Chen, Y. Song, W. Zhang, S. Zhang, J. Ju: Halogenated anthraquinones from the marine-derived fungus *Aspergillus* sp. SCSIO F063, J. Nat. Prod. **75**, 1346–1352 (2012)

32.125 C.-H. Huang, J.-H. Pan, B. Chen, M. Yu, H.-B. Huang, X. Zhu, Y.-J. Lu, Z.-G. She, Y.-C. Lin: Three bianthraquinone derivatives from the mangrove endophytic fungus *Alternaria* sp. ZJ9-6B from the South China Sea, Mar. Drugs **9**, 832–843 (2011)

32.126 O.F. Smetanina, A.N. Yurchenko, S.S. Afiyatullov, A.I. Kalinovsky, M.A. Pushilin, Y.V. Khudyakova, N.N. Slinkina, S.P. Ermakova, E.A. Yurchenko: Oxirapentyns B–D produced by a marine-sediment fungus *Isaria felina* (DC.) Fr., Phytochem. Lett. **5**, 165–169 (2012)

32.127 G.F. Zhang, W.B. Han, J.T. Cui, S.W. Ng, Z.K. Guo, R.X. Tan, H.M. Ge: Neuraminidase inhibitory polyketides from the marine-derived fungus *Phoma herbarum*, Planta Medica **78**, 76–78 (2012)

32.128 L. Chen, T. Zhu, Y. Ding, I.A. Khan, Q. Gu, D. Li: Sorbiterrin A, a novel sorbicillin derivative with cholinesterase inhibition activity from the marine-derived fungus *Penicillium terrestre*, Tetrahedron Lett. **53**, 325–328 (2012)

32.129 D. Li, L. Chen, T. Zhu, T. Kurtán, A. Mándi, Z. Zhao, J. Li, Q. Gu: Chloctanspirones A and B, novel chlorinated polyketides with an unprecedented skeleton, from marine sediment derived fungus *Penicillium terrestre*, Tetrahedron **67**, 7913–7918 (2011)

32.130 N. Khamthong, V. Rukachaisirikul, S. Phongpaichit, S. Preedanon, J. Sakayaroj: Bioactive polyketides from the sea fan-derived fungus *Penicillium citrinum*, Tetrahedron **68**, 8245–8250 (2012)

33. Marine Dinoflagellate-Associated Human Poisoning

Samanta S. Khora

Seafood poisoning in humans is caused by consumption of toxin-containing seafood that is contaminated with marine dinoflagellates. This has been a concern for many years. There are a number of dinoflagellate species that produce strong neurotoxins, which are often associated with the phenomenon called *red tide*. Outbreaks of red tide are caused by harmful algal blooms (HABs). HABs are not a new phenomenon, with written references dating back to biblical times. The most common type of HAB is referred to as a red tide because the bloom discolors the water, making it appear red. Humans eating seafood from infested areas during dinoflagellate bloom can become poisoned. With respect to the contaminants of toxic dinoflagellates in seafood, there are two main types of poisoning in humans. The terms *fish* and *shellfish* are associated with these illnesses because the toxins are concentrated in fish and shellfish that ingest the harmful dinoflagellates. According to the species of toxigenic dinoflagellates the poisoning syndromes have been given the names paralytic (PSP), diarrhetic (DSP), neurotoxic (NSP), and azaspiracid shellfish poisoning (AZP). Another human illness, ciguatera fish poisoning (CFP) is caused by the ciguatoxins produced by dinoflagellates that attach to surfaces in many coral reef communities [33.1]. Besides these well-known poisoning types, several new poisoning syndromes resulting from newly appearing dinoflagellate toxins, such as yessotoxin (YTX) and palytoxin (PTX), have been reported and characterized recently, and this has increased global public concerns regarding dinoflagellates associated with humans poisoning.

33.1 Preface

Dinoflagellates are an important group of phytoplankton in marine and freshwater. Dinoflagellates are considered to be protists, under the phylum *Dinoflagellata* (*Dinophyta*) and class *Dinophyceae* [33.2]. They move in marine and fresh water using two tail-like structures called flagella. Dinoflagellates are microalgae, mostly unicellular, eukaryotic algae inhabiting freshwater and marine waters [33.3]. They have the characteristics of both plants and animals. They are known to botanists as *Pyrrophyta*, while to zoologists they are *Mastigophora*. They may be photosynthetic or non-photosynthetic; about half the species fall into each category. The photosynthetic dinoflagellates are second only to diatoms as primary producers in coastal wa-

ters. Dinoflagellates mostly fall prey to small animals, such as small crustaceans and fish larvae, and to other protists, including other dinoflagellates. Dinoflagellates are common and widespread. As they are so plentiful, they cover a large size range and fulfill so many different ecological *roles*. They are a very important source of food for many other marine organisms. Both nontoxic and toxin-producing species of dinoflagellates are present. Algae include *cyanobacteria*, *dinoflagellates*, *diatoms*, *raphidophytes, haptophytes*, and various other species, many of which produce potent toxins. The primary sources of toxins have been identified as dinoflagellates, bacteria, and blue-green algae. About 75–80% of toxic phytoplankton species are dinoflagellates [33.4]. The high abundance blooms of these toxic phytoplankton species are named harmful algal blooms (HABs). HABs causing red discoloration of water are commonly known as *red tides* [33.5, 6]. It is known that certain HAB species can produce potent toxins that impact human health through the consumption of contaminated shellfish, coral reef fish, and finfish, or through water or aerosol exposure [33.7]. Around the world, marine algal toxins cause more than 60 000 poisoning events annually with an associated mortality rate of 1.5%. It is reported that algal toxins result in more than 50 000–500 000 intoxication incidents per year, with an overall mortality rate of 1.5% on a global basis [33.8]. Poisoning caused by the ingestion of toxin-containing foods has been a part of mankind's existence and concern for centuries. Most harmful species have a restricted distribution pattern but some harmful species have a worldwide distribution [33.5, 6].

Dinoflagellates are the major group producing toxins in the marine ecosystem that impact humans [33.7, 9]. Under specific circumstances more than 40 species of dinoflagellates and diatoms are known to produce phycotoxins (marine toxins) [33.10]. Dinoflagellates are responsible for producing a wide variety of toxins that accumulate through marine food chains. The biogenetic process by which the toxins accumulate in fish and shellfish was explained by the food chain. Marine biotoxins, usually produced by phytoplanktons during harmful algal blooms, are some of the most potent toxins in the world and are extremely dangerous. For some toxins, doses at a microgram per kilogram level are more than sufficient to kill a human. When enough toxins are accumulated in fish or shellfish, small amounts of cooked or raw tissue can kill a human. For example, recorded harmful algal blooms have produced enough PSP toxin in mussels that the consumption of one or two small mussels could killed a normal, healthy adult human. While some toxins are very potent, i. e., only small amounts are required to produce illness or to bring death, other less potent toxins may accumulate to such high levels that they can still cause harm. Some dinoflagellates produce compounds that cause death only when they are extracted and injected into laboratory animals, usually mice.

In the past few decades, extensive studies have been devoted to the toxicology and pharmacology of dinoflagellate toxins [33.11]. Dinoflagellate toxins are structurally and functionally diverse, and many show unique biological activities. Phycotoxins can accumulate in various marine species such as fish, crabs, or filter feeding bivalves (shellfish) such as mussels, oysters, scallops, and clams. In shellfish, toxins mainly accumulate in the digestive glands without causing adverse effects on the shellfish itself. However, when substantial amounts of contaminated shellfish are consumed by humans, this may cause severe intoxication of the consumer. The human intoxications known so far have been associated with mollusc consumption. The toxic manifestation that develops after ingestion of seafood contaminated with toxic dinoflagellates is best known of all due to their most violent form of poisoning.

This chapter concentrates on the dinoflagellate species found in marine waters, whose toxins can cause human poisoning. The major seafood poisoning syndromes caused by toxins have been identified to come from the dinoflagellates: paralytic shellfish poisoning (PSP), neurotoxic shellfish poisoning (NSP), diarrheic shellfish poisoning (DSP), and ciguatera fish poisoning (CFP). Besides these well-known types of poisoning, several new poisoning syndromes resulting from newly appearing dinoflagellate toxins, such as AZAs, YTX, and PTX have been reported and characterized recently (Table 33.1), and this has increased global public concerns regarding dinoflagellate associated toxins. Dinoflagellate toxins can be functionally categorized as neurotoxins and hepatotoxins, according to their clinical symptoms.

33.2 Historical Perspective

Dinoflagellates have been found in the fossil records for millions of years. As early as 77 A.D. the Greek naturalist, *Pliny*, in a book of notes on his observations wrote, *There are sudden fires in the waters*, most likely referring to what we now recognize as dinoflagellate bioluminescence [33.12]. In 1753, the first modern dinoflagellates were described by Henry Baker as *Animalcules which cause the sparkling light in sea water*, and named by Otto Friedrich Müller in 1773. In 1773 O.F. Muller became the first man to use the newly invented microscope on a dinoflagellate. In the 1830s, the German microscopist Christian Gottfried Ehrenberg examined many water and plankton samples and proposed several dinoflagellate genera that are still used today, including *Peridinium, Prorocentrum*, and *Dinophysis*. Dinoflagellates remained mysterious until F. Stein published his dinoflagellate monographs in 1878–1883. To this day, many genera carry the name originally coined by Stein in his famous monographs. In the last 10 years, the lists of identified dinoflagellates have exploded. The number of identified species has doubled – and our understanding of the vital roles that they play has exploded with it. Harmful algal blooms are not new phenomena; there are written references dating back to biblical times. These blooms have been recorded since the Spanish explorations in the late sixteenth century. The term red tide is now part of common language and is associated with *Gymnodinium breve* blooms that have occurred along Florida's western shelf since the 1950s. There have been restrictions on the consumption of shellfish in North America by European settlers and Red Indians [33.13]. It has been 40 years since the first recorded toxic bloom of *Pyrodinium bahamense* occurred in Papua New Guinea in 1972. Subsequently, this species has increased in importance as a paralytic shellfish poisoning toxin (PSTs) producer in several regions of the world, especially in the Indo-West Pacific [33.14].

Poisoning caused by the ingestion of toxin-containing seafood has been part of mankind's existence and concern for centuries. Ciguatera poisoning has been known since the sixteenth century and appears to be the most commonly occurring risk associated with seafood [33.15]. The recorded outbreaks of ciguatera, both in the New Hebrides aboard the vessel of the Portuguese explorer Pedro Fernandez de Queiros in 1606 and in 1774 aboard Captain Cook's Resolution, were probably two of the earliest vivid accounts of the illness. In 1866 in Cuba, Mr. Poey reported intoxication due to the consumption of a gastropod (*Livona pica*), which was known locally as *cigua*. This way the name ciguatera was introduced. While the name has its origin in the West Indies, the phenomenon was observed and recorded in the Indian and Pacific Oceans as early as the sixteenth century. *Gambierdiscus toxicus*, a dinoflagellate, was discovered in the Gambier Islands (French Polynesia) during an epidemic of ciguatera in 1976. There were many proposed theories on the occurrence of poisonous shellfish during the eighteenth and nineteenth centuries [33.16]. Illness related to *tainted shellfish* was documented in 1880 with dead birds and killed fish in Tampa [33.17].

Intoxication after consumption of shellfish is a syndrome that has been known for centuries, the most common being the PSP. It is caused by a group of toxins, saxitoxins (STXs) and derivates, produced by dinoflagellates of the genera *Alexandrium*, *Gymnodium*, and *Pyrodinium*. First reports of PSP intoxication dates back to 1920 in California, USA when at least six people were reported to have died from it [33.18].

Until the 1970s, PSP toxins had only been detected in European, North American, and Japanese waters. *Walker* was the first to record NSP in 1880 on the West Coast of Florida. It was not until the 1950s that the relationship between red tide events and NSP was better understood and researched [33.19, 20]. The first documented human intoxication caused by DSP toxins was in The Netherlands in 1961 [33.21]. DSP is a relatively recent and new type of shellfish poisoning, which was first discovered in Japan [33.22]. In 1995, the first intoxication due to AZP was reported when at least eight people got ill in The Netherlands after consumption of mussels imported from Ireland. AZP was first reported in The Netherlands but later spread in Europe [33.23]. It is a newly identified marine toxin disease. The first recorded observation on algal blooms in Indian waters was by *Hornell* in 1908 [33.24]. The first record of PSP was made in 1981 from the coastal areas of Tamilnadu, Karnataka, and Maharashtra in India [33.25]. In 1981, PSP resulted in the death of 3 persons and the hospitalization of 85 people due to consumption of affected mussel *Meretrix casta* in Tamil Nadu [33.26]. Until now, the understanding of the ecology and oceanography of these species, and how they affect other organisms, including people, continues to be a challenge for researchers.

33.3 Marine Dinoflagellates

The latest estimates suggest a total of 2294 living dinoflagellate species, which include marine, freshwater, and parasitic dinoflagellates [33.27]. Of the 2000 living species, more than 1700 are marine and about 220 are from freshwater [33.28]. Among them extant species have been described, approximately only half of which are photosynthetic. They include autotrophs, mixotrophs, and grazers. These species possess chloroplasts with chlorophyll a and c pigments. Other species are heterotrophic and can absorb small particles or other cells. The other pigments they contain are carotenes and various xanthines, including peridinin, a unique xanthine pigment specific to this group of organisms. Photosynthesizing dinoflagellates accumulate starch as a food reserve. The remaining obligate heterotrophs can have a diverse range of nutritional lifestyles, including saprophytic, parasitic, phagotrophic, or carnivorous forms [33.27, 28]. This dual animal–plant behavior within the group has led to their being classified under both the zoological and botanical nomenclature, but they are now generally classified under botanical rules. They can have complex life cycles but, for most species, the major life stage is a free-living flagellated form. They form an important component of aquatic phytoplankton, but there are also many benthic species [33.29].

Several aspects of the behavior, physiology, and ecology of dinoflagellates are notable and can be highlighted, such as: swimming behavior, bioluminescence, heterotrophy, symbiosis, and toxicity.

33.3.1 Swimming Behavior

Free-living dinoflagellates live in most wet environments, but in the open ocean they are extremely numerous, especially in more tropical waters and when concentrations of nutrients are high. As motile cells, dinoflagellates are capable of directed swimming behavior in response to a variety of parameters. These include chemotaxis, phototaxis, and geotaxis, for which movement is controlled by chemical stimuli, light, or gravity, respectively. It has long been observed that many dinoflagellates do not move randomly through the water column but instead aggregate at specific depths that can vary with the time of day. This vertical migration has proven to be a highly complex process that varies between species and with environmental or nutritional conditions [33.30].

33.3.2 Heterotrophy

About half of the extant dinoflagellates lack a plastid or pigments to carry out photosynthesis [33.31]. Most naked heterotrophic dinoflagellates have flexible cell walls that allow them to engulf living cells and particles (phagotrophy), which can then be seen inside the colorless dinoflagellate. The phagotrophic dinoflagellate *Gyrodinium fusus* has been shown to be an important grazer of *Azadinium* cf. *spinosum* during the first bloom, suggesting that its grazing activity could have acted as a modeling factor in population levels of its prey. There are also many parasitic forms, but in most cases they are very difficult to recognize as dinoflagellates. Some species will parasitize other organisms, such as zooplankton and other protists, filamentous algae, or fish. Roughly 5% are parasitic on aquatic organisms.

33.3.3 Symbiosis

Some dinoflagellates (zooxanthellae) are capable of forming symbioses with a phylogenetically wide range of marine protists and invertebrate animals. Energy generated by zooxanthellae through photosynthesis is taken up by the host (a reef coral). The energy from the zooxanthellae can amount to more than the daily requirement of the host. It is thought that the evolution of the association between dinoflagellates and corals may have been instrumental in the development of the coral reef ecosystem and might be essential for its maintenance. Within the dinoflagellate lineage, at least seven genera from four orders are found in symbiotic associations [33.32]. The hosts in dinoflagellate associations with other organisms include foraminifera, radiolarians, flatworms, anemones, jellyfish, and even bivalve mollusks. Some dinoflagellates may themselves possess endosymbionts.

33.3.4 Bioluminescence

The spectacular display of blue sparkling light seen as waves break on beaches or as a boat passes through the water in the night is called bioluminescence. The Dinoflagellata are sometimes called Pyrrophyta, meaning *fire plants*. This is because some species are capable of bioluminescence, in which chemicals made by the organism produce light in a chemical reaction. The phenomenon was first noted in the genus *Noctiluca*,

which resulted in its name (*night light*), but the reaction is now known to occur in several marine species. Many organisms in the ocean emit such light, although dinoflagellates are the only photosynthetic organisms capable of this behavior [33.33]. It is widely accepted that dinoflagellates account for much of the planktonic bioluminescence in the ocean [33.34]. The dinoflagellates begin to glow, which is often seen in the waves of the ocean on a moonless night, but will brighten considerably when disturbed, such as in the wake of a ship.

33.3.5 Toxicity

As they are biochemically diverse, they vary in photosynthetic pigments and toxin production ability. The taxonomy of harmful dinoflagellates was reviewed by *Taylor* et al. [33.35]. A number of dinoflagellate species are known to produce potent neurotoxins, which are often associated with the phenomena commonly called red tide. These outbreaks are now called HABs. Documentation of HABs has expanded greatly over the last few decades, and at present, nearly every country with marine waters is known to be affected by these blooms [33.36]. HAB toxins can affect humans, other mammals, seabirds, fish and many other animals and organisms. One major category of impact occurs when toxic species are filtered from the water as food by shellfish, which then accumulate the algal toxins to levels that can be lethal to humans or other consumers.

33.4 Algal Blooms and Red Tide Dinoflagellates

Of the 5000 marine algal species, 300 have a high proliferation rate, resulting in high dense algal clouds called blooms. Algal bloom is due to species that quite innocently cause coloring of seawater. It is their photosynthetic pigments that can tint the water during blooms. These blooms may discolor the sea to various shades of brown, orange, purple, yellow, or red. Red tide gets its name from the phenomenon by which pigmented phytoplankton reproduce to such a high concentration that it turns the water red or dark brown. This can be misleading because nontoxic algae can also cause this to happen. With the hope of clarifying this, the scientific community has uses the term HAB for toxic red tides. Dinoflagellate blooms (red tides) are regular seasonal phenomena occurring in some part of the world. Blooms of toxic algae are known as HABs. The most common type of HAB is referred to as a red Tide because the bloom discolors the water, making it appear red. However, HABs may also be yellow, orange, brown, green, white, or pink, depending on which one of the three primary types of phytoplankton is responsible for the problem; dinoflagellate, diatoms, or blue-green algae.

Dinoflagellates are perhaps best known as causing HABs. Although the dinoflagellates responsible for most red tides are comparatively simple organisms, some have the ability to synthesize potent toxins as by-products of metabolism. Among the most effective poisons known, these toxins may affect nearby marine life if ingested, or may even indirectly poison humans through the food chain. The detrimental effects of HAB can range from cell and tissue damage to organism mortality, and can be caused by a number of mechanisms, including toxin production, predation, particle irritation, induced starvation, and localized anoxic conditions. As a result, a bloom may affect many living organisms of the coastal ecosystem, from zooplankton to fish larvae to people. Other harmful algal blooms produce toxins with no identifiable effects on humans but devastating impacts on coastal living resources. For example, the flagellate *Heterosigma akashiwo* is thought to produce an ichthyotoxin that kills fish [33.37], resulting in significant threats to penned fish in mariculture operations. Dinoflagellate blooms can also cause massive killing of fish and shellfish, often causing significant economic damage.

At least 90 species of marine microalgae are known to produce toxins. Of these species, 70 are dinoflagellates [33.38]. The effects of HABs on aquatic organisms have been reviewed by [33.39]. Red tides occur in all marine regions with a temperate or warmer climate. Sometimes the dinoflagellates involved with red tides synthesize toxic chemicals. *Red tide* is due to certain species of dinoflagellates that contain neurotoxins. Toxic dinoflagellates (Pyrrhophyta, Desmophyceae, and Dinophyceae), for example, numbered 22 known species in 1984 [33.40], but increased to 59 species a little more than a decade later [33.41]. Blooms of dinoflagellates produce red tides, which injure marine life. Dinoflagellates' algal blooms create red tides, which can release strong neurotoxins, such as STX, which can be ingested by shellfish and passed on to humans who eat the infected shellfish. These toxins have been responsible for incidents of wide-scale death

of sea-life and are increasingly responsible for human intoxication.

However, no color is visible in other harmful species, such as the chlorophyll-free dinoflagellate *Pfiesteria piscicida*, several *Dinophysis* species, and a benthic one (*Gambierdiscus*) that grow on the surfaces of larger macroalgae in tropical waters. Both *Pfiesteria* and *Dinophysis* also impart toxicity at very low densities, generally less than 1000 cells L^{-1} [33.42, 43].

Unfortunately, a small number of species produce potent neurotoxins that can be transferred through the food web where they affect and even kill higher forms of life such as zooplankton, shellfish, fish, birds, marine mammals, and even humans that feed either directly or indirectly on them. Algal bloom is due to toxin-producing species, so that the poison is concentrated via the food chain and may reach humans.

Marine toxins can also affect local ecosystems by poisoning animals. Health effects range from cell damage to organism mortality through such mechanisms as toxin production and localized conditions of low oxygen. Under some conditions, so much oxygen is consumed to support the decomposition of dead algal biomass that anoxic conditions develop. This can cause severe stress or mortality in a wide range of organisms that are intolerant to low-oxygen conditions.

Genera that are commonly associated with poisonous red tides are *Alexandrium*, *Dinophysis*, and *Ptychodiscus*. The algal poisons can accumulate in marine organisms that feed by filtering large volumes of water, for example, shellfish such as clams, oysters, and mussels. If these shellfish are collected while they are significantly contaminated by red tide toxins, they can poison the human beings who eat them. Some toxins, such as that from *Ptychodiscus brevis*, the organism that causes Florida red tides, are airborne and can cause throat and nose irritations.

33.5 Toxigenic Dinoflagellate-Associated Human Poisoning

The possible presence of natural toxins in fish and shellfish has been known for a long time. The most important marine phycotoxins are shellfish toxins and finfish-ciguatoxins. Most of these toxins are produced by species of naturally occurring marine dinoflagellates (phytoplankton). A proportion of the toxic phytoplankton has a reddish-brown pigmentation, giving rise to calling algal blooms red tides. Visible red tides may contain from 20 000 to > 50 000 algal cells mL^{-1} concentrations, and as low as 200 cells mL^{-1} may produce toxic shellfish. Some dinoflagellates produce toxins that become concentrated in the bodies of organisms higher in the food chain, such as fish and shellfish. Marine animals such as oysters, crustacea, and different types of fish may eat the toxic dinoflagellates storing the toxins. The toxins are accumulated in the digestive gland of the shellfish (hepatopancreas) and do not affect the shellfish themselves. They often accumulate in shellfish or fish, and when these are eaten by humans they cause diseases. People are exposed principally to the toxins produced by harmful dinoflagellates through the consumption of contaminated seafood products. During dinoflagellate blooms humans eating seafood from infested areas can be poisoned. This can lead to serious poisoning.

Based on contaminants of toxic dinoflagellates in seafood there are two main types of human poisoning. The terms *fish* and *shellfish* are associated with these illnesses because the toxins concentrate in the fish and shellfish that ingest the harmful dinoflagellates. Fish and shellfish poisoning occur worldwide. According to the species of toxigenic dinoflagellates the poisoning syndromes have been given the names paralytic, diarrhetic, neurotoxic, and azaspiracid shellfish poisoning. A fifth human illness, CFP is caused by ciguatoxins produced by dinoflagellates that attach to surfaces in many coral reef communities [33.1]. Broadly these can be classified as shown below (see also Table 33.1).

Those caused by eating fish, namely: CFP. Those caused by eating shellfish, until now, seven groups of syndromes have been distinguished, namely:

1. Paralytic shellfish poisoning (PSP)
2. Neurotoxic shellfish poisoning (NSP)
3. Diarrheic shellfish poisoning (DSP)
4. Azaspiracid shellfish poisoning (AZP)
5. Palytoxins poisoning (PTX)
6. Yessotoxins poisoning (YTX).

Amnestic shellfish poisoning (ASP) is also a related poisoning affecting humans, which was recently discovered but will not be discussed in this chapter because it is caused by marine red algae and is tracked to certain benthic diatoms (Bacillariophyceae) of the genus *Chondria* and diatoms of the *Pseudonitzschia f. multiseries* but not by a dinoflagellate [33.44–47].

Table 33.1 Marine dinoflagellates – biotoxins and the associated poisoning in humans [33.35, 48]

Poisoning in humans	Causative dinoflagellates (examples)	Usual transvector(s)	Distribution	Main toxins	Action target	Major references
Paralytic shellfish poisoning (PSP)	*Alexandrium acatenella, A. andersonii, A. catenella, A. cohorticula, A. fundyense, A. fraterculus, A. leei, A. minutum, A. monilatum, A. tamarense, A. ostenfeldii, A. pseudogonyaulax, A. tamiyavanichii, Gymnodinium catenatum, Lingulodinium polyedrum, Pyrodinium bahamense var. compressum, Cochlodinium catenatum, C. polykrikoides*	Clams, mussels, oysters, cockles, gastropods, scallops, whelks, lobsters, copepods, crabs, fish	Temperate areas worldwide Cosmopolitan (Northwest, West, Northeast, Florida)	Saxitoxins (STXs), Gonyautoxins	Voltage-gated sodium channel 1	[33.49–52]
Diarrhetic shellfish poisoning (DSP)	*Dinophysis acuta, D. acuminata, D. caudata, D. fortii,D. norvegica, D. mitra, D. rotundata, D. sacculus, D. fortii, D. miles, D. norvegica, D. tripos, Prorocentrum. arenarium, P. balticum, P. belizeanum, P. concavum, P. faustiae, P. hoffmannianum, P. lima, P. maculosum, P. mexicanum, P. micans, P. minimum, P. ruetzlerianum, P. arenarium, P. belizeanum, P. cassubicum, P. concavum, P. faustiae, P. hoffmannianum, P. maculosum, P. reticulatum, Coolia sp. Protoperidium oceanicum, P. pellucidum, Phalacroma rotundatum*	Mussels, scallops, clams, Gastropods	Europe, Japan, Cold and warm-temperate Atlantic, Pacific, Indo-Pacific (Canada, Northeast?)	Okadaic acid, dinophysis toxins (DTXs), yessotoxins (YTXs) and pectenotoxins (PTXs)	Inhibitors of protein phosphatases 1A and 2A. They are possibly carcinogenic	[33.53]
Ciguatera fish poisoning (CFP)	*Gambierdiscus toxicus, Prorocentrum micans, P. lima, P. concavum, P. hoffmannianum, P. mexicanum, P. rhathytum, Gymnodinium sanguineum, Gonyaulax polyedra, G. polygramma Ostreopsis heptagona, O. lenticularis, O. mascarenensis, O. ovata, O. siamensis Amphidinium sp., Coolia monotis*	Fish, snail, shrimps, crabs	Tropical coral reefs (Southeast, Hawaii, Puerto Rico)	Ciguatoxins (CTXs), maitotoxins (MTXs), palytoxin, gambierol	Voltage-gated sodium channel 5 Voltage-gated calcium channel	[33.53–55]
Neurotoxic shellfish poisoning (NSP)	*Karenia brevis, K. papilonacea, K. sellformis, K. bicuneiformis, K. Concordia, Procentrum borbonicum?, Gymnodinium breve, G. catenatum, G. mikimotoi, G. pulchellum, G. veneficum Gyrodinium galatheanum*	Oyster, clams, mussels, cockles, whelks	Gulf of Mexico, southern USA coast, New Zealand subtropical/warm temperate Gulf Coast, eastern Florida, North Carolina	Brevetoxins (PbTxs)	Voltage-gated sodium channel 5	[33.56, 57]

33.5.1 Fish Poisoning in Humans

Fish constitute almost half the number of vertebrate on earth, and approximately 22 000 species of fish are contained in some 50 orders and 445 families. People love to eat marine and freshwater fish. However, like other organisms, some tropical reef fish also ingest some toxic dinoflagellates. The toxins become progressively concentrated as they move up the food chain from small fish to large fish that eat them, and reach particularly high concentrations in large predatory tropical reef fish. Barracuda are commonly associated with ciguatoxin poisoning, but eating grouper, sea bass, snapper, mullet, and a number of other fish that live in tropi-

Table 33.1 (continued)

Poisoning in humans	Causative dinoflagellates (examples)	Usual transvector(s)	Distribution	Main toxins	Action target	Major references
Azaspiracid shellfish poisoning (AZP)	*Protoperidinium crassipes*	Mussels, oysters	Europe, Ireland, UK, Norway, France, Portugal, Northern Africa (Morocco), South America (Chile) and the USA	Azaspiracids (AZAs)	Voltage-gated calcium channel	[33.58–62]
Palytoxin poisoning	*Ostreopsis siamensis*	Crabs, sea urchin	Brazil, Mediterranean Sea (Italy, Spain, Greece, and France)	Palytoxins (PTX)	Na^+-K^+ ATPase	[33.63–66]

cal oceans have also caused the disease. People may be poisoned and have a specific syndrome by eating these contaminated fish: CFP.

Ciguatera Fish Poisoning (CFP)

Ciguatera fish poisoning (CFP) is caused by eating contaminated tropical reef fish. CFP is considered to be the most common seafood-borne poisoning related to the consumption of finfish. It is most commonly associated with larger reef-dwelling fish. As the concentration of toxin is highest in the viscera, the consumption of whole, ungutted fish generally has the most severe consequences. Ciguatoxic fish are not recognizable as such by means of external features. Contaminated fish smell and taste normal. Frying, boiling, deep-freezing, or smoking the fish do not decontaminate it.

Source

More than 400 fish species have been described that may contain ciguatoxin. They belong to the following families: Murenidae (Moray eels), Sphyraenidae (barracudas), Lutjanida (snappers), Serranidae (broupers), Carangidae (jacks), Acanthuridae (surgeon fish), Balistidae (trigger fish), Scaridae (parrot fish) and to a lesser extent: Belonidae (needlefish), Holocentridae (soldierfish and squirrelfish), Labridae (wrasses), Mugilidae (mullets), Mullidae (surmullets, goatfish) and Scombridae (mackerels and their allies) [33.69].

Prevalence

The last estimate of the annual global incidence of CFP range from 25 000 to 500 000. The incidence in travelers to highly endemic areas has been estimated as high as 3%. Due to tourism and the increased export of tropical fish throughout the world, more and more doctors outside endemic regions are encountering cases of ciguatera poisoning. Regular outbreaks are reported in the Caribbean, including Florida, the South Pacific Islands, and Hawaii in the North Pacific, as well as the northeast coast of Australia (Queensland, Northern Territory). In the Pacific, the severity and incidence of poisoning increase from west to east. Ciguatera outbreaks are difficult to predict, and cases of poisoning often occur in the form of an epidemic. There are probably some 10 000–50 000 cases each year, but estimates show wide variation. The average incidence in endemic regions varies from 5–50 cases per 100 000 inhabitants per year, but in some years this can reach as high as 500/100 000 in the South Pacific.

Range

Ciguatera is widespread in tropical and subtropical waters, usually between the latitudes of 35° N and 35° S; it is particularly common in the Pacific and Indian Oceans and the Caribbean Sea.

Causative Dinoflagellates and Poisonous Ingredients (Toxins)

The main causative marine dinoflagellate is *Gambierdiscus toxicus*, which originally produced maitotoxins (MTXs), the lipophilic precursors of ciguatoxin [33.70]. MTX was first isolated in 1971 from surgeon fish (*Ctenochaetus striatus*), known as *Maito* in Tahiti. Three forms of MTX, MTX-1, MTX-2, and

MTX-3 have been identified from *Gambierdiscus toxicus* [33.71]. MTX has been proved to be the most potent toxin identified on a weight basis: the lethal dose 50 (LD_{50}) of MTX in mice is less than 0.2 μg kg^{-1} (intraperitoneally) and it is at least fivefold more toxic than tetrodotoxin. These precursors are biotransformed to ciguatoxins by herbivorous fish and invertebrates grazing on *Gambierdiscus toxicus* and then accumulated in higher trophic levels [33.72]. In ciguatera poisoning, the poisonous ingredient is ciguatoxin.

Ciguatoxin was originally isolated in Hawaii in 1967. The toxins form a family of very closely related structures with a molecular weight of 941–1117 Da. There are a number of variants, depending on whether or not certain chemical groups (−H, $-CH_3$, etc.) are present. The ciguatoxins are a family of heat-stable, lipid-soluble, highly oxygenated, cyclic polyether molecules with a structural framework reminiscent of the brevetoxins [33.73–75], and more than 20 toxins may be involved in CFP [33.76]. Scaritoxin was isolated in 1976 in Tahiti from a parrotfish (*Scarus gibbus*). It is a metabolite of ciguatoxin, but dinoflagellates are also said to be able to produce the poison in in vitro culture.

Action Mechanism

Ciguatoxin and the closely-related MTX both cause symptoms by interfering with ion channels on cell membranes. Ciguatoxin opens sodium channels and MTX opens calcium channels, disrupting the signaling between nerves and muscles.

Lethal Dose

In mice, ciguatoxin is lethal at 0.45 μg kg^{-1} ip, and MTX at a dose of 0.15 μg kg^{-1} ip. Oral intake of as little as 0.1 μg ciguatoxin can cause illness in the human adult. The pathogenic dose for humans is 23–230 μg.

Regulatory Tolerances by the Food and Drug Administration (FDA)

The FDA safety levels of CFP – 0.01 ppb P-CTX-1 equivalents for Pacific ciguatoxin and 0.1 ppb C-CTX-1 equivalent for Caribbean ciguatoxin.

Incubation Period

Ciguatoxin usually causes symptoms within a few minutes to 30 h after consumption of contaminated fish, and occasionally it may take up to 6 h.

Symptoms

Since more than 20 toxins are involved they produce more than 175 ciguateric symptoms, classified into four categories: gastrointestinal, neurological, cardiovascular, and general symptoms [33.77, 78]. It should be emphasized that the symptoms of ciguatera vary in different oceans: in the Pacific Ocean neurological symptoms predominate, while in the Caribbean Sea gastrointestinal symptoms dominate due to the difference in toxin composition. The onset of GI and neurologic symptoms after the consumption of fish are the hallmarks of ciguatera poisoning. Symptoms are usually evident within 2–6 h after ingestion and usually resolve within 24 h, although a late-presenting and extended course is not uncommon. Gastrointestinal (GI) symptoms generally consist of diaphoresis, abdominal cramps, nausea, vomiting, profuse watery diarrhea, and dysuria. GI symptoms are usually reported to occur prior to neurological symptoms. Interesting, however, is that the predominance of GI or neurologic symptoms seems to vary according to regions, with GI-predominant illness seen in the Caribbean, while neurologic symptoms predominate in the Indo-Pacific region.

Neurologic symptoms tend to occur later (up to 72 h) and may persist for months. These are predominantly paresthesias, but a myriad of other sometimes bizarre neurologic symptoms may also be observed, including pruritus; the sensation of loose painful teeth; tingling in the lips, tongue, throat, and perioral tissues; metallic taste; reversal of temperature sensation; and the sensation of heat in the superficial tissues of the extremities with concomitant sensation of cold in the deeper tissues. Further neurologic symptoms can include vertigo, ataxia, visual changes, and seizures. In more severe poisoning, bradycardia with hypotension and cardiovascular collapse may occur.

Common, nonspecific symptoms include nausea, vomiting, diarrhea, cramps, excessive sweating, headache, and muscle aches. The sensation of burning or *pins-and-needles*, weakness, itching, and dizziness can occur. Patients may experience reversal of temperature sensation in their mouth (hot surfaces feeling cold and cold surfaces hot), unusual taste sensations, nightmares, or hallucinations. Symptoms of exposure include eye and respiratory irritation, headache, and gastrointestinal complaints, skin irritation, and difficulties with learning and memory [33.79].

Mortality

Ciguatera poisoning is rarely fatal. The overall death rate from ciguatera poisoning is approximately 0.1%, but varies according to the toxin dose and availability of medical care to deal with complications. Death from CFP is rare (< 1% worldwide).

Treatment

Treatment is primarily supportive. Intravenous mannitol was thought to be the most promising of the pharmacotherapy treatments; however, it has experienced a relative decline in acceptance after a randomized, double-blind trial in 2002 failed to confirm its efficacy [33.79–81]. However, with recent case reports supporting its use and a better understanding of ciguatera poisoning, many experts in the field believe that the use of mannitol for the treatment of acute ciguatera poisoning arguably deserves revisiting [33.79, 82].

33.5.2 Human Shellfish Poisoning

Toxic illness caused by shellfish has been recognized for several hundred years. Native Americans are known to have warned early settlers to avoid shellfish during the summer months, as red tide is favored by warmer weather. Molluscan shellfish are filter feeders and continually pump water through their gills where particulate matter is removed and ingested. Mussels ingest food particles of any type of 2–90 mm in size with a rate of ingestion dependent on water temperature and environment. Optimally, they can filter 2.5 L h^{-1}, extracting 98% of the available algae. Consequently, any toxin associated with the phytoplankton ingested can rapidly accumulate and hence become concentrated in the bivalve mollusk. Bivalve mollusks such as clams, scallops, oysters, and mussels that filter feed on toxic algae can accumulate large amounts of toxins in their tissues, posing a toxic threat to humans who make shellfish a part of their diet. Shellfish are usually unaffected by toxic algae themselves but can accumulate toxins in their tissue to levels that can be lethal to humans. High concentrations of marine biotoxins in these animals can cause illness amongst people who eat contaminated shellfish. Shellfish that have fed on toxic dinoflagellates retain the toxin for varying periods of time depending on the shellfish. Some clear the toxin very quickly and are only toxic during the actual bloom. Others retain the toxin for a long time, even years. The most serious threat posed to human health by marine toxins is through shellfish contamination. The consumption of these toxic shellfish by humans causes illness, with symptoms ranging from mild diarrhoea and vomiting to memory loss, paralysis, and death. Illnesses that result from marine biotoxins are not related to the manner in which food is handled or prepared, but the exposure that shellfish has to microscopic organisms while living in the marine environment.

Several forms of shellfish poisoning may occur after ingesting filter-feeding bivalve mollusks such as mussels, oysters, clams, scallops, and cockles, or crustaceans such as crabs and lobsters that accumulate potent marine toxins produced by single-celled microscopic marine algae (dinoflagellates or diatoms) associated with algal blooms or red tides. The most common medical problems resulting from marine biotoxins, are the human shellfish poisoning syndromes PSP, NSP, DSP, and AZP. These poisoning syndromes are distinctly clear and the cases can be serious (Table 33.2).

Paralytic Shellfish Poisoning (PSP)

PSP of humans is caused by the consumption of shellfish that have been contaminated with STXs. *Blooms* of neurotoxic dinoflagellates from several genera result in outbreaks of PSP, probably the most widespread of the poisoning syndromes [33.83]. PSP is not only the most common form of shellfish poisoning, but it is also the deadliest, with a mortality rate of 6% worldwide (higher in developing countries) [33.84–86]. PSP usually occurs in outbreaks and is observed most commonly in recreational diggers.

Source

Filter-feeding bivalve molluscs (e.g., oysters, mussels, clams) nonbivalve shellfish (whelks, moon snails, and dogwinkles) or tomalley of crustaceans (crabs, lobster).

Prevalence

Clinically documented PSP outbreaks with several dozen to around 200 patients have been described in Western Europe, Taiwan, and Guatemala. Cases have also been described in Massachusetts and Alaska. Between 1927 and 1985, 505 PSP cases were recorded in California, of which 32 ended fatally. In contrast, in 10 PSP epidemics in the USA between 1971 and 1977, there were no recorded fatalities. 2/116 died in an epidemic in Taiwan. In September 1997, an outbreak of PSP was reported in Vizhinjam, Kerala, resulting in the death of 7 persons and hospitalization of over 500, following consumption of the mussel, *Perna indica* [33.87]. Recently, in September 2004, an unusual nauseating smell emanating from the coastal waters was recorded in Kollam to Vizhinjam on the southwest coast of India. More than 200 persons, especially children, complained of nausea and breathlessness for a short duration due to the smell.

Table 33.2 Summary of clinical entities of human poisoning by marine dinoflagellates

Entities	CFP	PSP	NSP	DSP	ASP	PTXs	YTXs
Incubation period	24 h	30′–3 h	5′–3 h	30′–2 h	15′–38 h	In minutes to 2–4 d	Unknown
Early Symptoms	Abdominal cramps, nausea, vomiting, profuse diarrhea, dysuria	Nausea, vomiting, tingling mouth, lips, throat. Floating feeling	Nausea, vomiting, diarrhoea, abdominal pain	Nausea, vomiting, diarrhoea, abdominal pain	Nausea, vomiting, abdominal pain	Muscle cramps include fever inaction	Unknown
Mild	Paresthesias, pruritus, painful teeth, vertigo, ataxia, visual change, seizures	Paresthesia ++ Muscular weakness, ataxia, headache	Paresthesia, vertigo, ataxia, headache	Severe diarrhoea, dehydration	Diarrhoea, headache, memory problems, mutism	Haemolysis, rhabdomyolysis, ataxia, drowsiness	Unknown
Severe	Bradycardia with hypotension and cardiovascular collapse	Dysphagia, dysarthria, diplopia, paralysis	Bradycardia, convulsions, mydriasis, no paralysis	Shock	Hemiparesis, ophthalmoplegia, convulsions, hypotension, cardiac arrhythmias	Weakness of limbs followed by death	Unknown
Foremost	GI and neurologic	Paralysis	Paresthesia	Severe diarrhoea	Progressing paralysis	Respiratory failure	Unknown
Duration	1–4 weeks	2–5 d	2–3 d	3 d	1–100 d Sometimes permanent memory problems	1–2 weeks	Unknown
Mortality	0.1%	6% average	0%	0%	4%	0.1%?	Unknown
Treatment	Supportive care and treatment with mannitol	Supportive care and mechanical ventilation	Supportive care	Supportive care	Supportive care	Supportive care	Supportive care

Range

Until 1970, cases of PSP had only been reported in the Northern Hemisphere, but by 1990, PSP had spread to southern Africa, Australia, New Zealand, India, Thailand, Brunei, Sabah, the Philippines, and Papua New Guinea. Since 1990, PSP has continued to spread. PSP is the most widespread shellfish poisoning and outbreaks are occurring worldwide.

Causative Dinoflagellates and Poisonous Ingredients (Toxins)

Members of the three dinoflagellate genera *Alexandrium, Gymnodinium*, and *Pyrodinium* have been reported to be the major sources of PSP associated toxins [33.49]. STX is produced by *Alexandrium (Gonyaulax) tamarense*, *Alexandrium catenella*, *Pyrodinium bahamense*, *Gymnodinium catenatum*, and *Cochlodinium catenatum*. PSTs are the causative agents of paralytic shellfish poisoning (PSP) and are mostly associated with marine dinoflagellates (eukaryotes) and freshwater cyanobacteria. PSTs are produced in varying proportions by different dinoflagellate species and even by different isolates within a species. STX and its 57 analogs are a broad group of natural neurotoxic alkaloids, commonly known as PST. PSP is the result of ingestion of saxitoxin, a purine alkaloid. Saxitoxin takes its name from the Alaskan butter clam *Saxidomus giganteus*. STX is the poisonous molecule in these organisms that causes paralysis by blocking sodium channels necessary for muscles to contract. Saxitoxin is the most toxic and also the most well studied among the PSP associated toxins. Many derivatives of STX are known as gonyautoxins. The name refers to *Gonyaulax*, the former name of *Alexandrium* dinoflagellates. The basic chemical structure of these gonyautoxins is identical, but they are distinguished by chemical side-chains such as: $-H$, $-OSO_3$, $-CONH_2$, $-CONHSO_3$. The toxins are heat stable and water soluble. STX blocks sodium channels, which leads to paralysis. PSP tox-

ins are heat-stable and water-soluble nonproteinaceous toxins. The basic structures of PSP toxins are 3,4-propinoperhydropurine tricyclic systems. STX and its analogs can be divided into three categories: the carbamate compounds, which include STX, neosaxitoxin, and gonyautoxins 1–4; the *N*-sulfo-carbamoyl compounds, which include the C and B toxins; and finally the decarbamoyl compounds with respect to the presence or absence of 1-*N*-hydroxyl, 11-hydroxysulfate, and 21-*N*-sulfocarbamoyl substitutions, as well as epimerization at the C-11 position. In the past few decades at least 24 structurally related imidazoline guanidinium PSP derivatives have been identified and characterized from dinoflagellate species [33.88, 89]. STX and its analogs are very dangerous compounds, with possible military potential and have been listed by the Organization for the Prohibition of Chemical Weapons (OPCW) as a Schedule 1 chemical intoxicant, the manufacture, use, transfer, and reuse of which are now strictly regulated by the OPCW (Chemical Weapons Convention, September 1998, The Hague, The Netherlands).

Action Mechanism

The pharmacological action of the PSP toxins strongly resembles that of TTX. STX and several other PSP toxins block the voltage-gated sodium channel with great potency, thus slowing or abolishing the propagation of the action potential. However, they leave the potassium channel unaffected.

Lethal Dose

The lethal dose for humans is 0.1–1 mg. It is estimated that 0.5–1 mg can be fatal to humans [33.90]. There is evidence that children are more susceptible to STX than adults. The pathogenic dose for humans 0.1–2 mg. The lethal oral dose in humans is 1–4 mg (5000–20 000 mouseunits), depending on the gender and physiological condition of the patient [33.91].

Regulatory Tolerances by FDA

The FDA regulatory tolerance is 0.8 ppm STX equivalent (80 μg/100 g tissue) in all fish.

Incubation Period

Symptoms may occur within a few minutes and up to 10 h after ingestion.

Symptoms

The symptoms of PSP include a tickling sensation of the lips, mouth and tongue, numbness of the extremities, gastrointestinal problems, difficulty in breathing, and a sense of dissociation followed by complete paralysis [33.92]. In the case of serious intoxication, PSP leads to a variety of neurological symptoms culminating in respiratory arrest and cardiovascular shock or death. Paralysis is foremost here.

Mortality

Based on mortality figures from recent outbreaks, children appear to be more sensitive to the STXs of PSP than adults. The case-fatality ratio averages 6%. The death rate may be particularly high in children. If a patient survives the first 12–18 h, the prognosis is good. Muscle weakness can persist for days to weeks. In cases of severe poisoning, muscle paralysis and respiratory failure occur, and in these cases death may occur in 2–25 h. Its high mortality rate in some areas is caused by poor access to advanced life support capabilities. In an epidemic in Guatemala, the mortality rate was 26/187, whereby young children of < 6 years had a mortality rate of 50% and adults of > 18 years of 7%.

Treatment

No specific treatment exists. Victims require supportive care that may include mechanical ventilation. It is symptomatic and supportive. Since respiratory depression can develop surreptitiously, extreme vigilance should be exercised to monitor and support patients, especially during the first 12 h. The use of monoclonal neutralizing antibodies has been proposed. Endotracheal intubation and artificial respiration may be necessary for a period of several days.

Neurotoxic Shellfish Poisoning (NSP)

NSP shellfish poisoning is caused by the unarmored dinoflagellates *Gymnodinium breve* (*Ptychodiscus breve*, also called *Karenia brevis*) producing brevetoxins. The polyether brevetoxins are toxic to fish, marine mammals, birds, and humans, but not to shellfish. An unusual feature of *Gymnodinium breve* is the formation by wave action of toxic aerosols, which can lead to asthma-like symptoms in humans. Until 1992/1993, NSP was considered to be endemic to the Gulf of Mexico and the east coast of Florida, where red tides had been reported as early as 1844. NSP is the least common of the shellfish poisonings. The illness is self-limiting and resolves within several days with no lasting effects.

Sources

People can become ill after ingesting filter-feeding bivalve shellfish (e.g., oysters, mussels, clams) that concentrate the toxin and are subsequently consumed by predators, including humans.

Prevalence

The largest documented outbreak of NSP occurred in New Zealand in 1992–1993 with over 180 cases reported over a period of several weeks. Green mussel, cockles, and oysters were implicated in the New Zealand clusters [33.93–98]. Scattered reports of cases have occurred in Florida in recent years with two cases in 1995, three in 1996, two in 2001, and four in 2005 [33.99, 100]. Many reports of NSP involve a single case or small case series [33.101–104] with few large outbreaks recorded. The largest and best documented outbreak in the USA occurred in North Carolina, 48 documented cases. It began in October 1987 when a *Karenia brevis* bloom became entrained in the Gulf Stream off eastern Florida and was transported up the eastern seaboard [33.105].

Range

NSP causes health problems around the Gulf of Mexico and the Atlantic coast of the southern USA, The Caribbean, and New Zealand.

Causative Dinoflagellates and Poisonous Ingredients (Toxins)

The classic causative dinoflagellate *Gymnodinium breve* (*Ptychodiscus brevis*) is found in the Caribbean and the Gulf of Mexico, although similar species occur throughout the world. The *Gymnodinium breve* is relatively fragile and easily breaks open, releasing the endotoxins. It produces two types of lipid soluble toxins: hemolytic and neurotoxic. The neurotoxic toxins are known as brevetoxins. The major brevetoxin produced is PbTx-2; lesser amounts of PbTx-1, PbTx-3, and hemolytic components are produced. The massive fish kills are due to neurotoxin exposure, with a possible contribution of the hemolytic fraction. They disturb neuromuscular transmission. After being inhaled as aerosol they cause bronchial spasms. This may be manifested as an asthma crisis, rhinitis, sneezing, cough, or burning eyes after walking on the beach while a strong breeze splashes up water (with the toxin). With the inhalation of the aerosolized red tide toxins (especially the brevetoxins) from the sea spray, respiratory irritation and possibly other health effects have been reported in both humans and other mammals.

Action Mechanism

Brevetoxins act by disrupting the flow of Na^+ ions in nerve cells. They bind to sites near the voltage gated sodium channels, allowing an unchecked flow of Na^+ ions into or out of the cell. This disruption of ion flow within nerve cells is responsible for the neurological effects associated with NSP. Incidentally, brevetoxins have nearly the opposite effect to STXs, which bind to a different site and effectively block Na^+ ions from passing through the sodium channel (NIEHS 2000).

Lethal Dose

The pathogenic dose for humans is in the order of 42−72 mouse units. In human cases of NSP, the brevetoxin concentrations present in contaminated clams have been reported to be 30−18 µg (78−120 µg mg^{-1}).

Regulatory Tolerances by FDA

The FDA tolerances are 0.8 ppm brevetoxin-2 equivalent (20 mouse units/100 g) in clams, mussels and oysters. In the USA, legislation has been set by the FDA; the current regulatory limit is 800 µg brevetoxin-2 (PbTx-2) equivalents kg^{-1} shellfish [33.102]. At the time of writing, the European Food Safety Authority (EFSA) had not published a scientific opinion on NSP-type toxins.

Incubation Period

The time to onset is anywhere from 15 min to 12 h (mean time of 3 h).

Symptoms

Symptoms begin 1−3 h after eating the contaminated shellfish and include numbness, tingling in the mouth, arms and legs, incoordination, and gastrointestinal upset. As with ciguatera poisoning, some patients report temperature reversal. In addition, formation of toxic aerosols by wave action can produce respiratory asthma-like symptoms. They are similar to ciguatoxins in that they are sodium channel openers that cause neuroexcitatory effects. This results in neurological complaints such as paresthesia, temperature reversal, and ataxia, as well as GI symptoms such as nausea, abdominal pain, and diarrhoea. Symptoms are generally mild and self-limited. NSP presents itself as a milder gastroenteritis with neurologic symptoms compared with PSP. The symptoms of NSP include nausea, tingling and numbness of the perioral area, loss of motor control, and severe muscular pain [33.106, 107]. Paresthesia is foremost here.

Mortality

No deaths have been reported and the syndrome is less severe than ciguatera, but nevertheless debilitating.

Treatment

There is no antidote. Treatment is supportive care. In the case of inhalation: treatment of asthma attacks. Supportive care is given to help the patient feel more comfortable while recovering. Recovery normally occurs in 2–3 d.

Azaspiracid Shellfish Poisoning (AZP)

AZP is one of the more recently discovered seafood poisonings and was first reported in the Netherlands but later became a continuing problem in Europe [33.108]. It was identified following cases of severe GI illness from the consumption of contaminated mussels from Ireland, and now contamination has been confirmed throughout the western coastline of Europe. Azaspiracids (AZAs) are a group of lipophilic polyether toxins implicated in incidents of shellfish poisoning in humans. *Azadinium spinosum* has been identified as a species producing AZAs, formerly called Killary toxin-3 or KT3, reported to cause human poisoning etiologically similar to diarrheic shellfish poisoning. AZAs are accumulated by molluscs via the food web which, in turn, may cause human poisoning after consumption of contaminated shellfish.

Source

AZAs are accumulated by molluscs via the food web, which, in turn, may cause human poisoning after consumption of contaminated shellfish. The implicated toxins, AZAs, accumulate in bivalve mollusks that feed on toxic microalgae. AZAs were identified in mussels (*Mytilus galloprovincialis*), 0.24 $\mu g\,g^{-1}$, from Galicia, Spain, and scallops (*Pecten maximus*), 0.32 $\mu g\,g^{-1}$, from Brittany, France. Toxin profiles were similar to those found in the equivalent shellfish in Ireland in which AZA1 was the predominant toxin. They may accumulate in shellfish and can result in illnesses when consumed by humans.

Prevalence

Although its first discovery was thought to be in Ireland, but the search for the causative toxins, named azaspiracids, in other European countries has now led to the first discovery of these toxins in shellfish from France and Spain. Incidents of human intoxications throughout Europe, following the consumption of mussels have been attributed to AZP, particularly in northern Europe, which are produced by the small marine dinoflagellate *Azadinium spinosum*.

Range

Since then several AZP outbreaks have occurred in Ireland and by now AZAs have been detected in Ireland, UK, Norway, France, Portugal, Northern Africa (Morocco), South America (Chile), and the USA [33.109–114]. According to current EU legislation the total amount of AZAs should not exceed 160 $\mu g\,kg^{-1}$ AZA1-equivalents [33.115].

Causative Dinoflagellates and Poisonous Ingredients (Toxins)

Recently, it was discovered that AZAs are actually produced by a minute dinoflagellate [33.116]. This dinoflagellate, *Azadinium spinosum*, is smaller (12–16 μm) than any of the other toxin-producing dinoflagellates known so far. It is caused by consumption of contaminated shellfish associated with the dinoflagellate *Protoperidinium crassipes*, which can produce high intracellular concentrations of AZA1, a lipophilic, polyether toxin. To date about one dozen derivatives (AZA2 to 11) of AZA1 have been identified and characterized from *Protoperidinium crassipes* and contaminated shellfish. Until now, 24 different AZAs have been described, with AZA1, AZA2, and AZA3 as the predominant ones [33.117]. These compounds were detected in three species/strains, i. e., in North Sea isolates of *Azadinium poporum* (molecular mass: 845.5 Da), in a Korean isolate, which has been designated as *Azadinium* cf. *poporum* (molecular mass: 857.5 Da) and in *Amphidoma languida* isolated from Bantry Bay, Ireland (molecular masses: 815.5 and 829.5 Da). Toxicological studies have indicated that AZAs can induce widespread organ damage in mice and that they are probably more dangerous than previously known classes of shellfish toxins [33.110, 118]. AZAs differ significantly from other dinoflagellate toxins; they have unique structural features characterized by a trispiro assembly, an azaspiro ring fused with a 2,9-dinoxabicyclononane and a terminal carboxylic acid group.

Action Mechanism

The action mechanism of AZAs is unknown at present. Some studies indicate that AZAs might have different targets, since AZA1 and AZA2 increase $(Ca^{2+})_i$ by activation of Ca^{2+}-release from internal stores and Ca^{2+}-influx, while AZA3 induces only Ca^{2+}-influx. AZA5 does not modify intracellular Ca^{2+} homeosta-

sis. Recent investigation of the effect of AZA4 on cytosolic calcium concentration $[Ca^{2+}]_i$ in fresh human lymphocytes demonstrated that AZA4 inhibits store-operated Ca^{2+} channels (SOC channels) and Ca^{2+} influx, and that this process is reversible. It was postulated that AZA4 inhibits SOC channels by direct interaction with the channel pore, with another region of channel protein or with a closely associated regulatory protein, and it was also found that AZA4 acts through another type of Ca^{2+} channel, probably some nonselective cation channel usually activated by MTX [33.119]. AZA groups are novel inhibitors of Ca^{2+} channels, SOC, and non-SOC channels.

Lethal Dose

Recently, EFSA reviewed all available toxicity data and suggested that a safe level of AZA toxins in shellfish is below the acute reference doses (ARfD) of 30 µg AZA-1 equivalents kg^{-1} shellfish regulatory tolerances by FDA: 160 µg AZA equivalents kg^{-1}.

Regulatory Tolerances by FDA

FDA tolerances are 160 µg azaspiracid equivalents kg^{-1}.

Incubation Period

The incubation period ranges from 15 min to 38 h.

Symptoms

The symptoms of AZP include nausea, vomiting, severe diarrhoea, and stomach cramps. Neurotoxic symptoms have also been observed [33.119–121].

Mortality

To date, no deaths and no fatalities have ever been observed.

Treatment

Treatment is symptomatic and supportive.

Palytoxin (PTX) Poisoning

PTX is a large, water soluble polyalcohol first isolated from the soft coral of the genus *Palythoa*, and subsequently found in a variety of marine organisms ranging from dinoflagellates to fish, and implicated in seafood poisoning with a potential danger to public health. PTX is a polyhydroxylated compound that shows remarkable biological activity at an extremely low concentration. This toxin was first isolated from the soft coral *Palythoa toxica* and subsequently from many other organisms such as seaweeds and shellfish. PTX, a polyether marine toxin originally isolated from the zooxanthid *Polythoa toxica*, is one of the most toxic nonprotein substances known. Fatal poisonings have been linked to ingestion of PTX-contaminated seafood, and effects in humans have been associated with dermal and inhalational exposure to PTX containing organism and water.

Source

Cases of death resulting from PTX have been reported to be due to consumption of contaminated crabs in the Philippines [33.122], sea urchins in Brazil [33.123], and fish in Japan [33.124–126]. PTX has become of worldwide concern due to its potential impact on animals, including humans.

Prevalence

Results from 2008 and 2009 showed that there is a real danger of human poisoning, as these demonstrated bioaccumulation of the PTX group (PTX and ovatoxin-a) in both filter-feeding bivalve molluscs (mussels) and herbivorous echinoderms (sea urchins) [33.127]. So far in temperate areas, *Ostreopsis ovata* blooms have been reported to cause intoxications of humans by inhalation and irritations by contact [33.128].

Range

PTX is found in the Caribbean Sea, the Mediterranean Sea, the Pacific Ocean, and the Indian Ocean.

Causative Dinoflagellates and Poisonous Ingredients (Toxins)

Recently, PTX was also found in a benthic dinoflagellate, *Ostrepsis siamensis*, which caused blooms along the coast of Europe [33.129–134], leading to extensive death of edible mollusks and echinoderms [33.131, 132] and human illnesses [33.130, 131]. PTX is a large, very complex molecule with both lipophilic and hydrophilic regions, and has the longest chain of continuous carbon atoms in any known natural product. Recently several analogs, ostreocin-D (42-hydroxy-3, 26-didemethyl-9, 44-dideoxypalytoxin) and mascarenotoxins were identified in *Ostrepsis siamensis*.

Action Mechanism

Over the past few decades much effort has been devoted to define the action mechanisms of PTXs; however these have not been identified. Pharmacological

and electrophysiological studies have demonstrated that PTXs act as a haemolysin and alter the function of excitable cells. PTX selectively binds to the Na^+, K^+-ATPase with an equilibrium dissociation constant K_D of 20 pM and transforms the pump into a channel permeable to monovalent cations with a single-channel conductance of 10 pS [33.135–137]. Presently, three primary sites of action of PTXs have been postulated: PTX first opens a small conductance, nonselective cationic channel, which results in membrane depolarization, K^+ efflux and Na^+ influx. Subsequently, the membrane depolarization may open voltage-dependent Ca^{2+} channels in synaptic nerve terminals, cardiac cells, and smooth muscle cells, while Na^+ influx may load cells with Na^+ and favor Ca^{2+} uptake by the Na^+/Ca^{2+} exchanger in synaptic terminals, cardiac cells, and vascular smooth muscle cells. Then the increase of $[Ca^{2+}]$ stimulates the release of neurotransmitters by nerve terminals of histamine by mast cells and of vasoactive factors by vascular endothelial cells as a signal. It also induces contractions of striated and smooth muscle cells. Additional effects of a rise in $[Ca^{2+}]$ may be activation of phospholipase C [33.138] and phospholipase A2 [33.139]. There are reports that PTX opens an H^+ conductive pathway, which results in the activation of the Na^+/H^+ exchanger [33.140, 141]. Other investigators suggest that PTX raises $[Ca^{2+}]$ independently of the activity of voltage-dependent Ca^{2+} channels and Na^+/Ca^{2+} exchange [33.142]. The last two actions might act as the opening of H^+ specific and Ca^{2+} specific channels. Overall, PTX might possess more than one site of action in excitable cells and acts as an agonist for low conductance channels conducting Na^+/K^+, Ca^{2+} and H^+ ions.

Lethal Dose

PTX is regarded as one of the most potent toxins known so far [33.143], LD_{50} 24 h after intravenous injection varies from 0.025 µg kg^{-1} in rabbits and about the same in dogs to 0.45 µg kg^{-1} in mice, with monkeys, rats, and guinea pigs around 0.9 µg kg^{-1}. By extrapolation, a toxic dose in humans would range between 2.3 and 31.5 µg [33.144].

Regulatory Tolerances by FDA

FDA makes no recommendations and has no specific expectations with regard to controls for PTX.

Incubation Period

The incubation period ranges from minutes to 2–4 d.

Symptoms

Symptoms include fever inaction, ataxia, drowsiness, and weakness of limbs, followed by death.

Mortality

The onset of symptoms is rapid, with death occurring within minutes.

Treatment

Treatment is symptomatic and supportive therapy probably as for a coronary spasm.

Yessotoxin (YTX) Poisoning

YTXs are a group of structurally related polyether toxins produced by the dinoflagellates *Protoceratium reticulatum*, *Lingulodinium polyedrum*, and *Gonyaulax spinifera* [33.145]. YTX is a sulfated polyether compound originally isolated in Japan from the digestive gland of the scallop *Patinopecten yessoensis*, and is produced by phytoplanktonic microalgae of some dinoflagellate species.

Source

YTX is found in scallops and mussels of different origins [33.146, 147].

Prevalence

YTX and its analogs, which are disulfated polyether compounds, occur increasingly in seafood and are a worldwide concern due to their potential risk to human health.

Range

YTX was originally isolated from the scallop *Patinopecten yessoensis*, collected at Mutsu Bay, Japan [33.148]. Since then, YTXs have been found in Europe, South America, and New Zealand, and have become a worldwide concern due to their potential risk to human health.

Causative Dinoflagellates and Poisonous Ingredients (Toxins)

Three dinoflagellate species, *Protoceratium reticulatum*, *Lingulodinium polyedrum*, and *Gonyaulax spinifera* produce YTXs [33.146, 149]. YTX and its derivatives, 45-hydroxy YTX (45-OH-YTX), 45,46,47-trinor YTX, homo YTX, and 45-hydroxyhomo YTX [33.150, 151] are disulfated polyether lipophilic toxins [33.146]. Recently, several new YTX analogs: carboxyyessotoxin (with a COOH group on the C_{44} of YTX instead of a double bond); carboxyhomoyesso-

toxin (with a COOH group on the C_{44} of homo YTX instead of a double bond); 42,43,44,45,46,47,55-heptanor-41-oxo YTX and 42,43,44,45,46,47,55-heptanor-41-oxohomo YTX in Adriatic mussels (*Mytilus galloprovincialis*) were identified in dinoflagellates [33.152, 153]. Originally, YTXs were classified among the toxins responsible for DSP, mainly because they appear and are extracted together with the DSP toxins, okadaic acid (OA) and DTXs [33.146]. However, YTXs are proved to be not diarrheagenic compared to OA and its derivatives, the DTXs, which cause intestinal fluid accumulation or inhibition of protein phosphatase 2A.

Action Mechanism

Recently, it was demonstrated that YTX is a potent neurotoxin for neuronal cells. However, the action site and the mechanism are unknown [33.154]. YTX was observed to induce a twofold increase in cytosolic calcium in cerebellar neurons, which was prevented by the voltage-sensitive calcium channel antagonists nifedipine and verapamil. These results suggest that YTX might interact with calcium channels and/or sodium channels directly. Previous studies also showed that YTX activated nifedipine-sensitive calcium channels in human lymphocytes [33.155], and YTX was postulated to activate noncapacitative calcium entry and inhibit capacitive calcium entry by emptying internal calcium stores.

Lethal Dose

Toxicological studies indicate that acute oral administration at doses up to $10\,mg\,kg^{-1}$ YTX or repeated (7 days) oral exposure to high ($2\,mg\,kg^{-1}\,d^{-1}$) doses of the toxin causes neither mortality nor strong signs of toxicity in mice [33.156–158]. YTX causes motor discoordination in mice before death due to cerebellar cortical alterations [33.158, 159]. A histopathological study revealed that YTX provoked alterations in the Purkinje cells of the cerebellum, including cytological damage to the neuronal cell body and changes in the neurotubule and neurofilament immunoreactivity [33.159].

Regulatory Tolerances by FDA

The tolerance regulated by the FDA is 1 mg yessotoxin equivalent kg^{-1}. The FDA implemented a maximum permitted level (MPL) of 1 mg YTX equivalents kg^{-1} shellfish intended for human consumption (Directive 2002/225/EC) [33.160].

Incubation Period

The incubation period is unknown.

Symptoms

Symptoms of intoxication produced by YTX in humans are relatively unknown due to the fact that no human intoxication has been reported to date. However, it seems clear that YTX does not produce diarrhoea in humans. The scarcity of toxicological studies on YTX and its analogs, which are necessary for the assessment of its human health risks, have been hampered until now by the limited availability of the toxin.

Mortality

There is no information about the mortality rate.

Treatment

There is no known treatment.

33.6 Biotechnological Significance of Toxic Marine Dinoflagellates

As stated above, dinoflagellates are not only important marine primary producers and grazers, but also the major causative agents of HABs. Many dinoflagellates are associated with the production of various natural marine toxins. Most of these natural toxins are neurotoxins which present themselves with highly specific effects on the nervous system of animals, including humans, by interfering with nerve impulse transmission. Neurotoxins are a varied group of compounds, both chemically and pharmacologically. They vary in both chemical structure and mechanism of action, and produce a very distinct biological effect, which provides a potential application of these toxins in pharmacology and toxicology. These toxins can be extremely toxic and many of them are effective at far lower dosages than conventional chemical agents. Dinoflagellate toxins and bioactives are of increasing interest because of their commercial impact, influence on the safety of seafood, and potential medical and other applications [33.38]. The lack of sufficient quantities of toxins for investigational purposes remains a significant limitation. The production of quantities of dinoflagellate bioactives requires the ability to mass culture them. Concerns relating to bioreactor culture of gen-

erally fragile and slow-growing dinoflagellates are of important consideration. Dinoflagellate bioactives are inaccessible in large quantities, and this severely limits research in potential applications of these compounds. Some of the toxins that are available in small amounts are quite expensive. Chemical synthesis of most dinoflagellate toxins is complex and expensive. Gaining access to toxins requires the ability to mass culture dinoflagellates. These microorganisms appear to be extremely sensitive to hydrodynamic shear forces and pose new challenges in photobioreactor engineering. Bioprocess engineering studies to enable economic use of dinoflagellates as cell factories are only just beginning.

33.7 Control and Prevention

Due to the complexities, current knowledge of bloom dynamics and the secondary effects that arise from intervention procedures, its control, mitigation, and prevention are becoming difficult. Because of the large impacts of coastal HABs, the control and prevention of problem species are of major interest. Geographic expansion of known toxic species has been linked, in some cases, to introductions by ballast water transport along shipping routes [33.161, 162]. Most long-known harmful taxa appear to operate independently from human influences other than physical transport [33.40, 163]. However, government agencies are working closely with academic institutions and nonprofit organizations to mitigate the effects of HABs and to develop prevention technologies for the future.

Toxic seafood poisonings are more common in summer than in winter because dinoflagellates grow well in warmer seasons. It is estimated from cases with available data that 1 person dies every 4 years from toxic seafood poisonings. In moderate and colder regions, the occurrence of shellfish poisoning is largely limited to the warm summer months. The rule of thumb says that shellfish should not be eaten during the months in which there is no *r* (May, June, July, August in the Northern Hemisphere). This phenomenon has led to the general teaching in North America that shellfish are safe to eat only if harvested in a month containing the letter *r*. In tropical and subtropical zones, there is no seasonal dependency. Shellfish poisoning usually occurs in the form of epidemics in these regions, but outbreaks in areas remote from the coast, where poisonous shellfish have been imported are also possible.

Ciguatoxin cannot be identified by odor, taste, or appearance. It is also temperature stable, so cooking or freezing will not destroy it. Ciguatoxin cannot be eliminated by salting, drying, smoking, or marinating either. The contaminated fish can remain toxic for years, even on a nontoxic diet. Apart from the avoidance of the consumption of large predatory fish, animal screening tests are the only tools presently available to prevent intoxication. It is important to notify public health departments about even one person with marine toxin poisoning. Investigators can then try to determine if a specific restaurant, oyster bed, or fishing area has a problem. This prevents others becoming ill. Finfish or shellfish sold as bait should not be eaten. Bait products do not need to meet the same food safety regulations as seafood for human consumption.

Natural toxins are very heat stable. Normal household cooking (e.g., boiling, steaming, frying) has no or very little effect on toxin levels. The primary preventive tool for intoxication with natural toxins is the monitoring of toxin levels in algae in the harvesting areas. Based on the presence of toxins, waters can be classified and harvesting of shellfish forbidden, if levels of toxin are too high. Other elements of a control program will include (FDA, 1998):

- A requirement that containers of in-shell molluscan shellfish bear a tag that identifies the type and quality of shellfish, harvester, harvest location, and date of harvest.
- A requirement that molluscan shellfish harvesters be licensed.
- A requirement that processes the chuck molluscan shellfish or ship, repack the chucked product, and certify.
- A requirement that containers of chucked shellfish bear a label with the processor's name, address, and certification number.

Depuration and ozonation are not effective and are not used in reducing toxins in shellfish. Many countries have their own guidelines for acceptable toxin levels. If these levels are exceeded, the government will close commercial mussel and oyster banks, forbid the sale of certain seafood, and advise against the use of it. For example, for STXs the limit is set at more than 500 cells

of *Pyrodinium bahamense* per liter of sea water or more than 40 µg of STXs per 100 g of mollusc. For brevetoxin there is a guideline that only the total absence of the toxin is acceptable. A guideline such as this leads to practical problems.

Programs that monitor toxins in shellfish food supplies have proven successful in limiting shellfish poisoning in the USA, Canada, and Europe. Expanding these programs to other parts of the world would further diminish the threat of marine dinoflagellate toxins to human health. The most reliable method to measure the amount of toxins in shellfish is by mouse bioassay. PSP is associated with relatively few reported outbreaks, most likely because of the effective control programs that prevent human exposure to toxic shellfish. PSP can be a serious public health problem, as was demonstrated in Guatemala in a 1987 outbreak in which 187 cases with 26 deaths resulted from the ingestion of clam soup [33.164].

In the USA, approximately 30 cases of poisoning by marine toxins are reported each year. Because healthcare providers are not required to report these illnesses, and because many milder cases are not diagnosed or reported, the actual number of poisonings is much greater.

There is very little published literature or formal epidemiologic studies on the human health effects of the diseases, by either ingestion of NSP or inhalation of aerosolized red tide toxins causing respiratory irritation. As a nonreportable disease, NSP is highly under-reported and under-diagnosed; for example, there are no existing statistics for the incidence of NSP or aerosolized red tide toxin respiratory irritation, even in endemic areas, nor on possible chronic health effects in humans. There are no established biomarkers for either of the Florida red tide toxin-associated conditions in humans, nor have there been any formal studies published on aerosolized red tide toxin respiratory irritation surveillance monitoring. There is very little information on the appropriate treatment and prevention methodologies [33.165–167].

33.8 Discussion and Conclusion

HABs have become a global epidemic. The number of harmful algal blooms has increased over the last 40 years, especially in regions with large increases in coastal populations and overfishing. It is feared that blooms of dinoflagellates are becoming more common due to human activities that increase nutrient levels in the ocean (e.g., run-off from fertilized pastures, sewage disposal). It is also thought that the indiscriminate dumping of ballast water may allow toxic strains to spread rapidly over long distances. Dinoflagellates can move and hence can seek deeper layers for nutrients to overcome surface nutrient deficiency. This may lead to an increased number of HABs as a result of climate change when upper stratification of surface layers occur. Human shellfish poisoning may result from the presence of large numbers of toxic dinoflagellates in seawater. The species of marine dinoflagellates responsible for human illness depend on the geographical location. In the Southern Hemisphere *Pyrodinium* species will be responsible for PSP, while *Alexandrium, Gymnodinium* and *Dinophysis* are responsible for PSP, NSP, and DSP in the Northern Hemisphere. *Gonyaulax tamarensis* sometimes blooms in the North Sea, while in California *Gymnodinium catenatum* causes poisoning problems. Most clinical cases occur between late spring and early autumn, which corresponds to the bloom season of these photosynthesizing organisms.

Human poisoning by contaminated shellfish is not a pandemic global problem that poses grave health risks to humans as a whole. The typical year will see relatively few deaths or severe illnesses caused by consumption of contaminated shellfish. Nevertheless, shellfish poisoning is a persistent and annoying problem that regularly affects consumers of seafood, which is a large portion of the population in some areas. Monitoring of shellfish supplies for toxins has proved very successful in limiting human shellfish poisoning in developed countries and this monitoring should be continued and expanded to lesser-developed nations as soon as possible.

PSP, CFP, and NSP poisoning have been known for centuries, although their toxins were only recently described [33.10]. Diarrheic shellfish poisoning was recognized in the 1960s. A new human toxin syndrome, AZP came to light in the 1990s [33.168]. Of all these marine dinoflagellates-associated human poisonings, PSP poses the greatest threat to public health, and fatal cases have been reported around the world. PSP is caused by several species of dinoflagellate organ-

isms including *Alexandrium tamarense*, *Gymnodinium catenatum*, and *Pyrodinium bahamense* [33.169]. *Azadinium spinosum* has been identified as a species producer of AZAs, the marine toxins which are reported to cause human poisoning etiologically similar to diarrheic shellfish poisoning.

Many countries rely on biotoxin monitoring programs to protect public health and close harvesting areas when toxic algal blooms or toxic shellfish are detected. Because of the risks of poisoning associated with eating marine shellfish, many countries routinely monitor the toxicity of fish and shellfish using various sorts of assays. One commonly used mouse bioassay gives an indication of contamination of the fish and shellfish by marine dinoflagellate toxins. However, the mouse bioassay is increasingly being replaced by more accurate methods of determining the presence and concentration of marine toxins using analytical biochemistry. In nonindustrialized countries, particularly in rural areas, monitoring for harmful algal blooms does not routinely occur and death due to red tide toxins commonly occurs. According to *Dr. Don Anderson*, who carries out research on algal speciesat the Woods Hole Oceanographic Institute in Massachusetts:

> *There are more toxic algal species, more algal toxins, more fisheries resources affected, more food-web disruption, and more economic losses from harmful algal blooms than ever before.*

Their occurrence and persistence represent a significant and expanding threat to human health and marine resources across the nations [33.170].

Consumption of raw molluscan shellfish poses well-known risks of food poisoning, however, intoxication from finfish is not so well known. Most algal toxins associated with seafood poisoning are heat stable and are not inactivated by cooking. It is also not possible to visually distinguish toxic from nontoxic fish and shellfish. The rule of thumb is that shellfish should only be eaten during months with an *R* in them, and not during May to August.

Human poisoning arising directly or indirectly as a result of exposure to the noxious metabolites produced by marine dinoflagellates during red tides are global in occurrence. Understanding the causes of these phenomena, and mitigating and preventing their consequences are international concerns. World public health authorities must assume responsibility consider the problem properly, establish a proper diagnosis and universal therapy program, and develop specific assay kits for red tide toxins. They should also invest in the geographic localization of the wide variety of toxins, and in chemical tests capable of detecting all toxins in any suspected food source.

34. Carotenoids, Bioactive Metabolites Derived from Seaweeds

Ratih Pangestuti, Se-Kwon Kim

Health is top priorities for many people worldwide. Food diets and dietary components play a vital role in accomplishing these needs. With the increasing knowledge of health benefits associated with seaweeds and utilization of these materials has accelerated. Seaweeds represent a valuable resource of bioactive materials, in association with a healthy lifestyle including correct dietary habits and moderate physical activity. Hence, isolation and investigation of bioactive ingredients with biological activities from seaweeds have attracted great attention. Among bioactive ingredients identified from seaweeds, carotenoids have received particular attention. These carotenoids exhibit various beneficial biological activities such as antioxidant, anticancer, anti-inflammatory, anti-obesity, and anti-angiogenic activities. This chapter focuses on biological activities of seaweeds-derived carotenoids and emphasizing their potential applications in foods as well as pharmaceuticals areas.

34.1 Seaweeds

In recent years, seaweeds have served as an important source of bioactive natural substances. Many metabolites isolated from seaweeds have shown to possess biological activities and potential health benefits. Therefore, a new trend has been emerged to isolate and identify bioactive compounds and constituents from seaweeds [34.1]. One particular interesting feature in seaweeds is their richness in carotenoids. Besides their role in photosynthetic and pigmentation effects, carotenoids have also been reported to biological activities (Table 34.1). Therefore, various carotenoids isolated from seaweeds have attracted much attention in the fields of food, cosmetic and pharmacology [34.2]. Novel extraction and separation techniques, such as supercritical CO_2 extraction, centrifugal partition chromatography and pressurized liquid method have recently been employed in the development of carotenoids derived from seaweeds [34.3].

Carotenoids are linear polyenes that function as light energy harvesters and antioxidants that inactivate reactive oxygen species (ROS) formed by exposure to light and air [34.4, 5]. Carotenoids are considered to be accessory pigments; since they augment the light-harvesting properties of seaweeds by passing on light excitation to chlorophyll [34.6]. Carotenoids can be classified into two types: carotenes, which are unsaturated hydrocarbons; and xanthophylls, which present one or more functional groups containing oxygen [34.7]. One very visible carotenoid in seaweeds is fucoxanthin; the brown pigment which colours kelps and other brown seaweeds as well as the diatoms. Fucoxanthin is one of the most abundant carotenoids contributing around 10% estimated total production of carotenoids in nature [34.8]. It has a unique structure including an unusual allenic bond and a 5,6-monoepoxide in its molecule.

34.2 Biological Activities of Carotenoids and Health Benefit Effects

34.2.1 Antioxidant Activity

Recently, there is a considerable interest in the food and pharmaceutical industries for the development of antioxidants from natural sources, such as marine flora and fauna. Seaweeds are rich sources of structurally diverse bioactive compounds with valuable antioxidant activities. Antioxidants may have a positive effect on human health as they can protect the human body against damage by ROS, which attack macromolecules such as membrane lipids, proteins and deoxyribonucleic acid (DNA), lead to many health disorders such as cancer, diabetes mellitus, aging and neurodegenerative diseases [34.16]. Furthermore, deterioration of some foods has been identified due to the oxidation of lipids or rancidity and the formation of undesirable secondary lipid peroxidation products. Lipid oxidation by ROS such as superoxide anion, hydroxyl radicals and H_2O_2 also causes a decrease in nutritional value of lipid foods, and affect their safety and appearance. Therefore, in food and pharmaceutical industry, several synthetic commercial antioxidants such as butylated hydroxyanisole [34.17], butylated hydroxytoluene (BHT), tert-butylhydroquinone (TBHQ) and propyl gallate (PG) have been used widely to retard the oxidation and peroxidation processes [34.18–20]. However, the use of these synthetic antioxidants must be under strict regulation due to potential health hazards [34.21, 22]. Hence, the search for natural antioxidants as safe alternatives is important in food and pharmaceutical industry Recently, there is a considerable interest in the food as well as pharmaceutical industry for the development of antioxidants from natural sources, such as marine flora and fauna. Among marine resources, seaweeds represent one of the richest sources of natural antioxidants [34.23].

Fucoxanthin was identified as the major antioxidant of *Hijikia fusiformis*. Although it has been previously reported that carotenoids such as zeaxanthin, β-carotene and lutein did not show 1,1-Diphenyl-2-picryl-hydrazyl (DPPH) scavenging activity, fucoxanthin possess a strong radical scavenging activity. The potential involvement of fucoxanthin in radical scavenging activity may correlate to the presence of unusual double allenic bonds at C-7′ position. These findings were confirmed in a recent study carried by *Sachindra* et al. [34.24] which isolated fucoxanthin from *Undaria pinnatifida* and prepared two fucoxanthin metabolites, fucoxanthinol and halocynthiaxanthin. The antioxidant activities of these three carotenoids were assessed by DPPH, hydroxyl radical scavenging activity and singlet oxygen quenching activity. The order of scavenging activity of each carotenoid followed a pattern of fucoxanthin > fucoxanthinol > halocynthiaxanthi [34.24]. The major structural differences in these three carotenoids are the presence of an allenic bond in fucoxanthin and fucoxanthinol, suggesting that the allenic bond is responsible for the higher scavenging activity of fucoxanthin and fucoxanthinol. Therefore, fucoxanthin may have great potential for use as nutraceuticals and pharmaceuticals as a substitute for synthetic antioxidants. In addition, when fucoxanthin added to ground chicken meat at a content level of 200 mg kg^{-1} the formation of secondary oxidation products including TBA reactive substances were reduced in the same level as α-tocopherol. Oral administration of fucoxanthin has been reported to improve plasma antioxidant status and meat color in broiler chicks [34.25]. Moreover, fucoxanthin obtained from *Padina tetrastromatic* has shown higher potential to be used as antioxidant than β-carotene in modulating antioxidant enzyme in plasma and liver of retinol deficiency rat [34.17, 26]. However, the exact mechanisms of action how fucoxanthin exerts antioxidative effect in rat induced by retinol deficiency are not yet completely understood. In addition, cytoprotective effect of fucox-

Table 34.1 Biological activities of seaweeds-derived carotenoids

Carotenoids	Biological activities	Seaweeds sources
Fucoxanthin [34.9–14]	Antioxidant	*Hijikia fusiformis*, *Undaria pinnatifida*, *Fucus serratus*, *Padina tetrastromatic*
	Anticancer	*Undaria pinnatifida*
	Anti-inflammatory	*Myagropsis myagroides*

Siponaxanthin [34.15]	Anticancer Anti-angiogenic	*Codium fragile* *Codium fragile*
Lutein [34.3]	Antimutagenic	*Porphyra tenera*
β-carotene [34.3]	Antimutagenic	*Porphyra tenera*

anthin against ROS formation induced by H_2O_2 has been observed in vitro [34.27]. Two hydroxyl groups present in the ring structure of fucoxanthin may correlate to the inhibition of ROS formation. Several studies have indicated that the number of hydroxyl groups on the ring structure of fucoxanthin is correlated with the effects of ROS suppression.

34.2.2 Anticancer Activity

Many recent studies have been carried out to find cancer chemopreventive and/or chemotherapeutic agents from edible and natural resources such as fruits, vegetables, and terrestrial plants. Seaweeds also emerged as one of the important sources for dietary supplements and a number of them are potentially active and useful. Seaweeds have been used as a source of food and medicine and their metabolites are also well-known. The marine seaweeds have a variety of chemo-protective compounds such as carotenoids.

Exciting research studies have been published regarding carotenoids and its anticancer qualities. *Ishikawa* et al. [34.28] showed anti-adult T-cell leukemia effects of fucoxanthin and its deacetylated metabolite fucoxanthinol. The inhibitory activities of fucoxanthin and fucoxanthinol were stronger than those of β-carotene and astaxanthin [34.28]. Adult T-cell leukemia is a fatal malignancy of T lymphocytes caused by human T-cell leukemia virus type 1 infection and remains incurable. Therefore, carotenoids could be potentially useful therapeutic agents for adult T-cell leukemia patients. A recent study from Japan demonstrates that anticancer activity of fucoxanthin goes way beyond its ability to induce apoptosis. Apoptosis inducing effect of fucoxanthin on human leukemia cells (HL-60) has been reported [34.29, 30]. The apoptosis induction was associated with activation of caspase-3, -8 and -9 which can be thought of as central executioner of the apoptotic pathway [34.31]. Very recently, siphonaxanthin derived from *Codium fragile* showed more potent growth-inhibitor against HL-60 cells than fucoxanthin. The structural differences between these two carotenoids are fucoxanthin contains epoxide and an allenic bond in its structure, whereas siphonaxanthin does not contain those functional groups; however, siponaxanthin has an additional hydroxyl group. Since esterified form of siphonaxanthin showed lower inhibitory effect, suggesting that the presence of that hydroxyl group are contributed to the strong inhibitory effect of siphonaxanthin [34.32]. Meanwhile, anti-proliferative effect and apoptosis induction by fucoxanthin in human colon cancer cells (Caco-2, HT-29 and DLD-1) have also been demonstrated. Fucoxanthin remarkably reduced the viability of human colon cancer cell lines and treatment with fucoxanthin induced DNA fragmentation. Exposure to fucoxanthin decreased the level of apoptosis suppressing protein (Bcl-2), suggesting that anticancer mechanism of fucoxanthin bring through apoptosis mechanism. Apoptosis inducing effect of fucoxanthin in human prostate cancer cells (PC-3, DU 145 and LNCaP) has also been observed [34.33, 34]. Although current knowledge of relationship between the structure and apoptosis activity of the fucoxanthin is limited, some researchers suggest that conjugated double bonds and 5,6-monoepoxide are thought to be highly susceptible to acids, alkali and oxygen lead to their prooxidant actions which might cause apoptosis induction in the several cancer cells.

34.2.3 Anti-Obesity Activity

Obesity is a contributing factor in many diseases. However, many peoples are not aware of this association and do not consider obesity to be a serious health concern. A detrimental effect of obesity on reproductive system has also been demonstrated consistently. Furthermore, it is reported that media and socio-cultural continues to pressures young generations to be thin which promotes body dissatisfaction, eating disturbance, depression and negative effect in young generations. Many categories of natural and synthetic compounds which demonstrated as anti-obesity drugs have been used to reduce weight. However, synthetic anti-obesity agents are believed to have certain side effects such as unacceptable tachycardia, hypertension, improve lipid blood levels, improve glucose metabolism and disturbance of reproductive system. Hence, more scientific efforts have been dedicated to study medicinal foods that can act as anti-obesity agents. Since the excessive growth of adipose tissue in obesity has been suggested to result from adipocyte hypertrophy and the recruitment of new adipocytes from precursor cells, regulation of adipogenesis also appears to be a potential strategy for the treatment of obesity [34.35]. Fucoxanthin isolated from *Undaria pinnatifida* and fucoxanthinol have been reported to inhibit the differentiation of 3T3-L1 preadipocytes into adipocytes [34.9]. The inhibitory effect of fucoxanthin and fucoxanthinol on adipocyte differentiation might be mediated through the down-regulation of adipogenic transcription factors, such as peroxisome proliferator-activated receptor-γ. Structure suppressive effect on adipocyte differentiation has been

reported by *Okada* et al. [34.36]. In their study, they used 13 naturally occurring carotenoids found in human diet. Interestingly, carotenoids with keto group, epoxy group, hydroxyl carotenoid, epoxy-hydroxy carotenoid and keto-hydroxy carotenoid did not showed suppressive effect on adypocite differentiation. Meanwhile treatment with fucoxanthin and neoxanthin showed significant suppressive effect suggesting that allenic bond is crucial factor for the anti-obesity effect. The result of those studies leads to the hypothesis that other carotenoid with an allenic group and an additional hydroxyl group in the end may also effective in suppressing adypocite differentiation.

Another interesting studies revealed that oral treatment with fucoxanthin significantly reduced the abdominal white adipose tissue (WAT) weight of obese mice model, KK-Ay female mice and normal mice fed with a high-fat diet [34.10–12, 37]. Moreover, no reductions on normal mice fed with normal diet were found. Those results suggest that fucoxanthin specifically suppress adiposity in the obese mice. The mechanisms of action for the observed antiobesity effect of fucoxanthin were mainly mediated by the induction of uncoupling protein 1 (UCP1) in abdominal WAT. UCP1 is inner-membrane mitochondrial protein that has the ability to dissipate energy through uncoupling of oxidative phosphorylation which, instead of adenosine triphosphate (ATP) , produces heat. UCP1 is expressed exclusively in brown adipose tiss and known as a significant component of whole body energy expenditure. However, adult humans have very little BAT, making it unlikely to be a major contributor to human weight regulation. In humans, most of fat is stored in WAT which is the predominant type of adipose tissue and commonly called as *fat* in mammals [34.38]. Besides its role in energy storage, WAT is now recognized as an endocrine and active secretory organ through its production of biologically active mediators termed, adipokines [34.39]. As nutrigenomic study revealed that fucoxanthin induces UCP1 expression in WAT, fucoxanthin will be an important and attractive agent for the development of anti-obesity therapies. However, further efforts to clarify the molecular mechanisms various intracellular signaling pathways also need to be investigated in order to obtain a better understanding of the underlying UCP1 induction by fucoxanthin.

Dietary fucoxanthin has been reported to suppress insulin levels and hyperglycemia in diabetic/obese KK-Ay mice [34.12, 40, 41]. Furthermore, the release and expression levels of pro-inflammatory adipocytokines were also attenuated by fucoxanthin [34.40]. Several studies demonstrated that pro-inflammatory adipocytokines secretions are elevated through the accumulation of fat in adipocytes and causes insulin resistance in obese animal models. Hence, fucoxanthin could be used as an inhibitor in regulating pro-inflammatory adipocytokines, insulin and hyperglycemia. Furthermore, fucoxanthin may assist therapeutic treatment of diabetic diseases. Moreover, dietary intake of fucoxanthin and fucoxanthinol has been demonstrated to enhance the amount of DHA and arachidonic acid content in the liver of C57BL6J/6J normal male mice [34.42, 43]. However, further studies are needed to clarify the molecular mechanisms how fucoxanthin promotes DHA and AA synthesis in the mice liver.

34.2.4 Anti-Inflammatory Activity

Inflammation is a response by an organism to injury related to biological, chemical or physical stimuli. In acute inflammation, this response is intended to inactivate or destroy invading organisms, remove irritants, and finally set the stage for tissue repair. In chronic inflammation, however, this response is involved in multiple diseases, such as periodontal disease, colitis, arthritis, atherosclerosis, asthma, multiple sclerosis and inflammatory bowel diseases. Nowadays, much attention has been paid to the development of anti-inflammatory agents from seaweeds.

Secondary metabolites derived from seaweeds are known to have promising anti-inflammatory activities [34.13]. However, the scientific analysis of anti-inflammatory activity of seaweeds-derived carotenoids has been poorly carried out and until now only few studies were reported. For example, *Shiratori* et al. reported that anti-inflammatory effect of fucoxanthin is comparable with predinisolone, a commercially available steroidal anti-inflammatory drug [34.44]. Supporting those finding, *Heo* et al. [34.45] screened inhibitory effect of NO production from nine species of brown seaweeds and confirmed that inhibition of NO production were correlates with fucoxanthin contents. In addition, they also demonstrated anti-inflammatory effect of fucoxanthin isolated from *Myagropsis myagroides* in LPS-stimulated RAW 264.7 cells [34.46]. Fucoxanthin treatment attenuates the productions of NO and PGE_2 by inhibiting inducible NO synthase (iNOS) and cyclooxigenase-2 (COX-2) expressions. The release and expression levels of inflammatory cytokines (TNF-α, IL-6 and IL-1β) were attenuated by fucoxanthin in a dose-dependant fashion [34.45]. The anti-inflammatory activities of fucoxanthin were due to

the suppression of nuclear factor-κB (NF-κB) and the phosphorylation of mitogen activated protein kinases (MAPKs) [34.47]. Production of pro-inflammatory mediators has been continuously reported in many inflammatory tissues, along with increased expression of their messenger ribonucleic acid (mRNA) and proteins. Therefore, inhibition of pro-inflammatory mediators by carotenoids suggests its potential for the treatment of inflammatory and other related diseases.

34.2.5 Anti-Angiogenic Activity

Cancer is a serious disease with a complex pathogenesis, which threats human life greatly. The invasion and metastasis of cancer depend on the angiogenesis of tumorous stroma and the degradation of extracellular matrix. Therefore, tumor angiogenesis is a common hallmark of various cancers. Angiogenesis refers to the process of new blood vessel formation from a pre-existing vasculature that occurs under, either physiological or pathological conditions. *Sugawara* et al. [34.48] showed that fucoxanthin significantly suppressed human umbilical vein endothelial cells (HUVEC) proliferation and tube formation at more than 10 μM. Fucoxanthin effectively suppressed the differentiation of endothelial progenitor cells into endothelial cells involving new blood vessel formation. Fucoxanthin and fucoxanthinol suppressed microvessel outgrowth in vivo and ex vivo angiogenesis assay using a rat aortic ring [34.48]. Anti-angiogenic effect of siphonaxanthin derived from green seaweeds, *Codium fragile*, has been demonstrated in a recent study. Anti-angiogenic effects of siponaxanthin were comparable with fucoxanthin [34.15]. The structure similarity between fucoxanthin and siponaxanthin are the presence of hydroxy group on the 3 and 3′ position. Therefore, the presence of those hydroxyl groups might conceivably parted of their anti-angiogenesis effect.

34.2.6 Other Biological Activities

Fucoxanthin isolated from *Laminaria japonica* has been reported to suppress tyrosinase activity in UVB-irradiated (UVB: ultraviolet B radiation) guinea pig and melanogenesis in UVB-irradiated mice. Oral treatment of fucoxanthin significantly suppressed skin mRNA expression related to melanogenesis, suggesting that fucoxanthin negatively regulated melanogenesis factor at transcriptional level [34.14]. Moreover, fucoxanthin has been demonstrated to possess photoprotective properties in human fibroblast cells via inhibition of DNA damage and enhance antioxidant activity [34.49]. These studies suggest that oral administration of fucoxanthin might prevent or minimize the negative effects of ultraviolet (UV) radiation such as melanin formation.

34.3 Concluding Remarks

Collectively, carotenoids are a valuable source of bioactive compounds and could be introduced for the preparation of novel functional ingredients in food and also a good approach for the treatment or prevention of chronic diseases. Recently, much attention has been paid by the consumers toward natural bioactive compounds as functional ingredients in foods, and hence, it can be suggested that, carotenoids are an alternative source for synthetic ingredients that can contribute to consumer's well-being, by being a part of new functional foods and pharmaceuticals. Furthermore, the wide ranges of biological activities associated with seaweeds-derived carotenoids have potential to expand its health beneficial value in food, and pharmaceutical industries.

35. Marine Bioactive Compounds from Cnidarians

Joana Rocha, Miguel Leal, Ricardo Calado

Cnidaria is a large, diverse and ecologically important phylum of marine invertebrates, which includes corals, sea fans, anemones, and jellyfishes. It contains over 11 000 species, 7500 of them belonging to the class Anthozoa. Over 3000 marine natural products have been described from this phylum alone, most of them in the twenty-first century. The present work provides an overview of some of the most promising marine bioactive compounds, from a therapeutic point of view, isolated from cnidarians since the year 2000. The order Alcyonacea (class Anthozoa) exhibits the highest number of species yielding promising compounds. Antitumor activity has been the major area of interest in the screening of cnidarian compounds, the most promising ones being terpenoids (monoterpenoids, diterpenoids, and sesquiterpenoids). Future trends and challenges for the bioprospecting of new marine bioactive compounds produced by cnidarians are also discussed, with emphasis on the sustainable production of target cnidarians biomass and the role played by symbiotic microorganisms in the synthesis of important biomolecules.

35.1 Cnidarians

The phylum Cnidaria is a large, diverse and ecologically important group of marine invertebrates that contains over 11 000 extant species (Table 35.1) [35.1], including hydroids, jellyfish, anemones, and corals, among others (Fig. 35.1). This group of invertebrate animals is found exclusively in aquatic environments, mostly in marine ecosystems. Cnidarians have simple body forms, usually of a polyp or medusa (Fig. 35.2) [35.2]. For instance, an anemone is a single polyp, whereas corals are, in general, a colony of individual polyps, which are typically tubular and attached to a surface at their base. Both forms may occur during the life cycle of some cnidarians. All species within the phylum Cnidaria have tentacles surrounding the opening (mouth), with stinging cells in their tips that are used to capture and subdue prey. The stinging cells are coiled structures that shoot out and inject toxins via a dart-like tip [35.2].

Cnidarians are usually found in a wide geographic range: from deep waters near hydrothermal vents to polar seabeds and tropical reefs. Some cnidarian species, mostly from the class Scyphozoa (jellyfish), are pelagic and live in the water column. Cnidarians lack mechanical means to prey and have optimized their mechanisms to feed throughout evolutionary history, such as stinging cells with powerful toxins that help to disable their prey and drive off predators [35.3]. In addition to these chemical weapons present in the stinging cells, cnidarians also display other potent compounds that are useful for deterring predators and keeping competitors away [35.4–6]. For instance, tropical reefs are ecosystems with a vast biodiversity, where the substrate available for benthic cnidarian species to settle and develop is scarce [35.7]. Chemical interactions between different species are thus an important mechanism for inter-

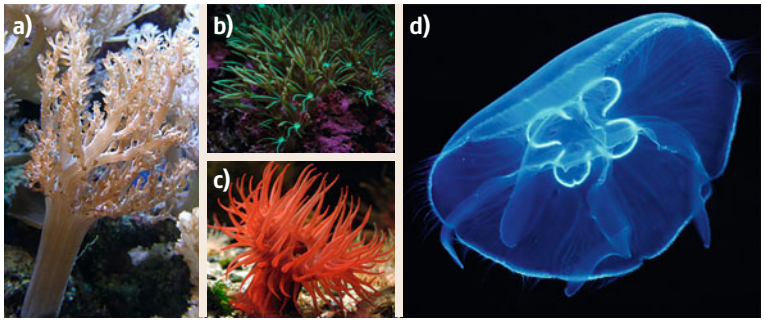

Fig. 35.1a–d Marine invertebrates from the phylum Cnidaria (all images by Ricardo Calado). **(a)** Soft coral (*Sinularia* sp.), **(b)** soft coral (*Briareum* sp.), **(c)** sea anemone (*Actinia equina* sp), **(d)** jellyfish (*Aurelia aurita*)

specific competition, which may have dramatic consequences for the organism being outcompeted in this *chemical war*. Therefore, organisms inhabiting highly biodiverse tropical areas, particularly coral reefs, have developed a large array of chemical compounds that have been the focus of recent bioprospecting efforts [35.8].

Corals form the structure and foundation of tropical coral reefs and are also important structural elements of some highly diverse deep-sea habitats. Other cnidarian species, such as anemones, are also very diverse and abundant in these tropical ecosystems [35.9]. These benthic cnidarians display a great variety of molecules that have different biological functions. The harsh chemical and physical environmental conditions of the areas inhabited by these organisms may have been important drivers for the production of a variety of molecules with unique structural features. For instance, the incidence of predation in the majority of these organisms is low due to the toxic compounds they produce to deter predators [35.10]. Other examples of biological functions of these compounds are defensive functions against pathogens, as well as against fouling organisms, herbivores, and microorganisms [35.11]. Such chemical compounds have been targeted by scientists searching for new chemical entities from the sea, usually known as marine natural products (MNP). Although more than 20 000 compounds have been discovered since the field of MNP began in the mid 1960s, only a very limited number have reached the end of the drug discovery pipeline [35.12].

Table 35.1 Classes and orders in the phylum Cnidaria (according to the classification proposed in the World Register of Marine Species (WoRMS)) [35.1]

Phylum	Class	Order
Cnidaria (≈ 11 287 species)	Anthozoa (≈ 7500 species)	Actiniaria; Zoanthidea Antipatharia; Alcyonacea Ceriantharia; Gorgonacea Corallimorpharia; Helioporacea Scleractinia; Pennatulacea
	Cubozoa (≈ 36 species)	Carybdeida; Chirodropida
	Hydrozoa (≈ 3500 species)	Anthoathecata Leptothecata; Limnomedusae Siphonophorae; Narcomedusae Actinulida; Trachymedusae
	Polypodiozoa (1 species)	Polypodiidea
	Scyphozoa (≈ 200 species)	Coronatae Rhizostomeae; Semaeostomeae
	Staurozoa (≈ 50 species)	Stauromedusae

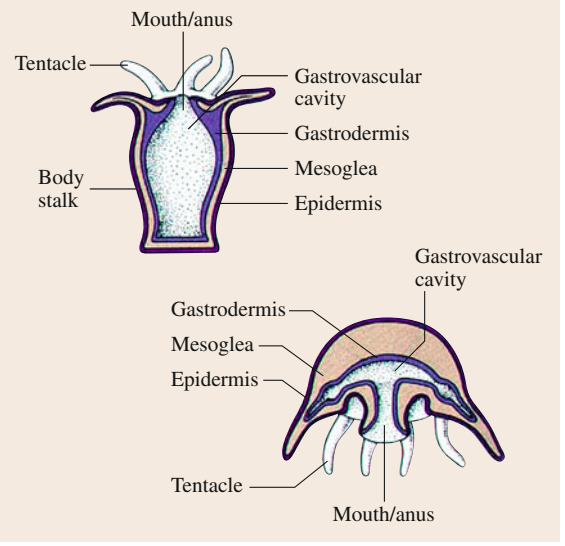

Fig. 35.2 Diagram of polyp and medusa forms of cnidarians

This chapter focuses the compounds that have been discovered from marine cnidarian species, providing a brief overview of this topic and discussing the role of biodiversity and biogeography in the chemical diversity of cnidarians. Cnidarian molecules discovered since the year 2000 that display important bioactivities and promising biotechnological applications are discussed in detail. The rationale for this approach is that the drug discovery pipeline, i. e., the time between discovering a new natural product and the commercialization of that marine drug, is a relatively long process that usually takes between 10–15 years. In this view, natural products discovered before 2000 had already had time to go through this pipeline, which means that their biotechnological potential is already fully exploited if the compound did not fail any step of the drug discovery process. Finally, we will discuss the challenges that we foresee for future research on bioactive compounds from cnidarians, as well as their biotechnological application to the industry.

35.1.1 Overview of Natural Product Discovery from Cnidarians

Research on marine natural products began in the 1950s [35.13], at a time when important breakthroughs in the taxonomy of marine animals took place [35.14]. This research field expanded during the 1970s and 1980s. It was only at the end of the 1980s and the beginning of the 1990s that an economically appealing activity started to take shape [35.6, 15]. Since the beginning of MNP, sponges (phylum Porifera) have been recognized as the most interesting group of marine invertebrates [35.16]. However, with growing bioprospecting efforts, and the screening of previously unexplored marine habitats and organisms, the biotechnological potential of other groups of marine invertebrates has also started to become appealing for researchers. The phylum Cnidaria is a large, diverse and ecologically important group of marine invertebrates, which is renowned for the ability to produce powerful toxins and venoms [35.17]. A total of 3244 marine natural products have been described from this phylum alone since 1990 (and until 2011), which shows the importance of cnidarians for marine natural product research. Since the early 1990s, the number of new compounds from marine cnidarians has been higher than the discovery of compounds from sponges [35.8], and the trend that we currently observe is still a continuous increase of natural product discovery (Fig. 35.3). This shows that bioprospecting efforts on these organisms have been continuously increasing.

Fig. 35.3 Number of new marine natural products from cnidarians discovered between 1990 and 2011

The quest for new MNP from cnidarians has benefited from a renaissance since 2005, namely due to the development of new methods in analytical technology, spectroscopy, and high-throughput screening [35.18]. It has also benefited from the failure to deliver new drug leads in significant numbers by competing technologies, such as chemical synthesis. These two different reasons may support the continuous growth of natural product discovery from cnidarians in the last decade.

Bioprospecting efforts have not been evenly distributed among cnidarian taxa. From the 3244 new compounds yielded by marine cnidarian species since 1990, 99% were discovered in within class Anthozoa. The remaining 1% is associated with species from class Hydrozoa. Anthozoans display a higher biodiversity, with a higher number of orders (Table 35.1). Nonetheless, 94% of the 3244 compounds were discovered in organisms from a single anthozoan order: the Alcyonacea. Only through the analysis of the taxonomic level below order, e.g., the family level, is it possible to observe a more even distribution of new compounds among taxa. Figure 35.4 shows the cumulative number of natural products discovered from alcyonaceans according to family level. It is important to emphasize the Alcyoniidae family due to the continuous increase of new compounds relative to other Aclyonacea families.

The overall increase of new compounds associated with different Cnidaria taxa is displayed in Table 35.2. Of the most representative families from the order Alcyonacea, only the family Briareidae showed a small decrease in the number of new compounds discovered in the last two decades. All other families represented in

Table 35.2 Number of new compounds discovered in the most representative taxa of the phylum Cnidaria in the 1990s and 2000s (after [35.8])

Taxon	New compounds in the 1990s	New compounds in the 2000s	Variation of new compounds per decade (%)
Phylum Cnidaria	1031	1773	+72%
Class Anthozoa	1017	1758	+73%
Sub-class Octocorallia	963	1715	+78%
Order Alcyonacea	934	1694	+84%
Family Alcyoniidae	293	489	+67%
Family Briareidae	158	156	−1%
Family Clavulariidae	41	150	+266%
Family Gorgoniidae	109	165	+51%
Family Nephtheidae	58	227	+291%
Family Plexauridae	97	99	+2%
Family Xeniidae	72	147	+107%

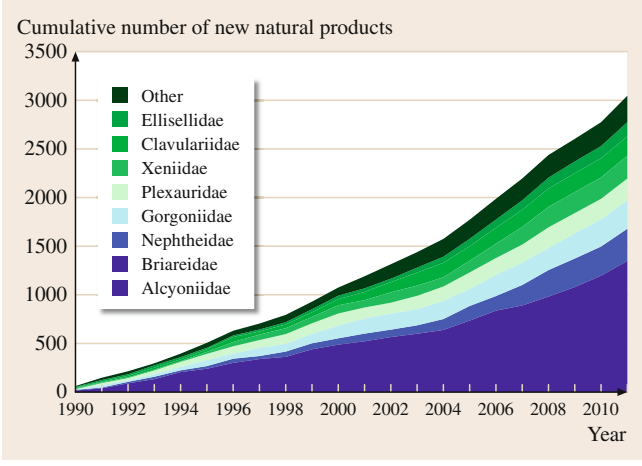

Fig. 35.4 Cumulative number of new marine natural products from cnidarians according to the taxonomical level *family*. The group *other* refers to the families Acanthogorgiidae, Anthothelidae, Coelogorgiidae, Isididae, Melithaeidae, Nidaliidae, Paragorgiidae, Paralcyoniidae, Primnoidae, Subergorgiidae, and Tubiporidae

Table 35.2 showed an increase, which in some particular cases was relatively high (e.g., families Clavulariidae and Neptheidae). These results recorded by *Leal* et al. [35.8] show that the popularity of cnidarians in bioprospecting efforts continues to increase, with large numbers of new compounds being discovered every year.

The high chemical diversity associated with cnidarians may be related to the high biodiversity displayed by this group. While about 11 000 cnidarian species are currently known [35.1], new compounds have only been recorded from 337 species (distributed over 117 genera). This means that only ≈ 3.1% of cnidarian biodiversity has yielded new chemical compounds. This does not necessarily mean that the remaining ≈ 97% of cnidarian species do not display any different compounds. Most likely, this is a result of the preference of scientists to search for new chemical entities in a relatively low number of species. For instance, the most popular species among the Alcyoniidae are *Clavularia viridis*, *Briareum excavatum*, and *Antillogorgia elisabethae* (Fig. 35.5), which have been important cnidarians in the history of MNP research [35.8]. Diversification of bioprospected species has been relatively low, as can be observed in Fig. 35.5. In this figure, we plot the number of new compounds discovered in cnidarian species since 1990 and sort that information according to the number of new compounds discovered in each species. The uneven result among bioprospected species is clearly observed. As most cnidarian species displaying a high number of new compounds inhabit tropical areas, this may suggest that bioprospecting efforts have been biased toward these particular species, probably driven by previous studies showing the high chemical diversity displayed by such taxa [35.8]. Although the assumption the all cnidarian species display similar chemical diversity is incorrect, Fig. 35.5 shows that a large number of new molecules associated to other cnidarians are yet to be unveiled. This is particularly evident if we consider that the compounds that are currently known were discovered from only ≈ 3% of total cnidarian biodiversity.

Another issue that should be noted is biodiscovery hotspots of new cnidarian compounds. Although

biogeography itself is a well-studied topic, its investigation in MNP research is still scarce. This is probably justified by the lack of precise geographical information on collection sites. However, recent studies already started to address this topic and clearly reveal bioprospecting efforts to be biased towards tropical areas [35.8, 19]. New molecules discovered from cnidarian species over the past decades have mostly resulted from bioprospecting on Asian territories close to tropical areas, particularly in Taiwan, Japan, and China. Remarkably, 50% of such new molecules discovered in cnidarians since 1990 resulted from organisms collected in the marine environment surrounding these two territories.

The compounds discovered in cnidarian species belong to various chemical groups, although the majority are terpenoids. *Leal* et al. [35.19] showed that in the last decade, 66% of the compounds discovered in cnidarians were terpenoids, which contrasts with the relatively low percentage of discovered alkaloids (10%), steroids (9%), aliphatic compounds (8%), and carbohydrates (6%). This data shows that particular chemical groups, such as terpenoids in the case of cnidarians, have been unquestionably more popular among researchers searching for new compounds. Terpenoids are secondary metabolites that are not directly involved in critical physiological processes. These compounds often play a role in interspecific and other ecological interactions. In terrestrial ecosystems, particularly in plants, terpenoids are known to be very abundant and structurally diverse [35.20]. Terpenoids are the chemical group that includes most natural products isolated so far from marine environments [35.21, 22]. This may be related to the large range of structural types that can be included in this group, which is, in part, associated with the fact that their biosynthetic unit can be rearranged and highly oxidized [35.14, 23]. Terpenoids also display a wide array of known bioactivities and biological functions [35.24–26]. Indeed, it was probably because previous studies showed that terpenoids usually display remarkable bioactivities that researchers would increase the chances for successful drug discovery and consequent patenting and commercialization by preferentially targeting molecules of this chemical group [35.27]. Several examples are already described

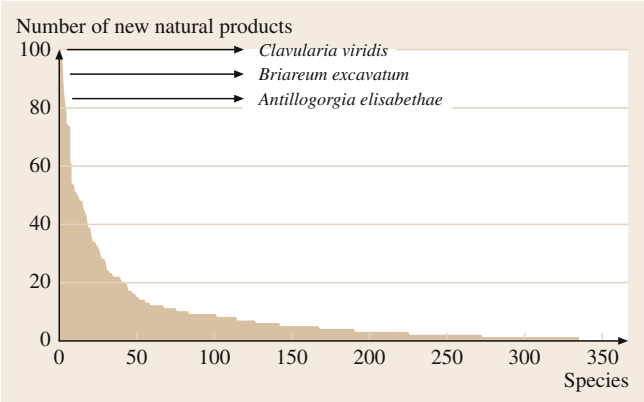

Fig. 35.5 Number of new natural products discovered per cnidarian species. Each bar corresponds to a single species (total of 337 species). The three species yielding the highest number of natural products are indicated

for the application of terpenoids in the pharmaceutical and food industry due to their potential and effectiveness as medicines and flavor enhancers [35.20, 27].

Besides bioprospecting efforts directed towards particular groups of organisms and chemical structures, researchers have also been narrowing their searches to particular molecules, with emphasis on the type and relevance of bioactivity displayed, in order to identify the most promising targets for their drug discovery pipelines [35.28]. These marine molecules display various types of biological activities, such as anticancer, anti-inflammatory, antitumor, antimalarial ones, etc. It is not surprising that over the past 40 years major advances in the discovery of marine drugs have been recorded in clinical trials for cancer [35.29]. Although there are several marine bioactive compounds in preclinical and clinical trials, only a relatively small number of molecules have reached this stage of the drug discovery pipeline. This process is very complex and encompasses several steps: target identification and validation, assay development, lead identification and optimization, predevelopment, preclinical development, clinical research phase I to phase III, regulatory approval, and phase IV (post-approval studies) [35.12, 18, 30]. The drug discovery pipeline usually takes 10–15 years from the first to the last step.

35.2 The Most Promising Marine Natural Products from Cnidaria

In this section, we overview the most promising marine bioactive compounds isolated from cnidarians in the twenty-first century. This information was assembled through the survey of the most relevant peer reviewed literature published during this period covering marine natural products [35.31–52]. Over 2000 molecules from cnidarians have been described in the twenty-first century. In order to address only those compounds displaying a high potential for industrial applications, it was decided to use the values of IC_{50} (half maximal inhibitory concentration) as guidelines. IC_{50} is a quantitative measure that indicates how much of a particular substance (inhibitor) is needed to inhibit a given biological process or component of a process by half. It is important to highlight that the NCI has renamed the IC_{50} to GI_{50} [35.53] in order to emphasize the correction for cell count at time zero in cancer cells; in this way, some results of this quantitative measure are now also presented under these directives. Additionally, ED_{50} (the median dose that produces the desired effect of a drug in half the test population) was also used to identify promising marine bioactive compounds produced by cnidarians. Only the compounds displaying an $IC_{50} \leq 10.0\,\mu g\,mL^{-1}$, or μM (except where stated otherwise), and $ED_{50} \leq 4.0\,\mu g\,mL^{-1}$ were considered in the present review, as these values are commonly used in the surveyed literature to ascertain relevant bioactivity (e.g., [35.54, 55]). In the few cases where neither IC_{50} nor ED_{50} values were described for an MNP in a study, that compound was selected to be part of the present survey only if either the authors of that study, or those citing it, clearly stated that the results recorded were highly promising for industrial applications. All species producing the compounds selected for the present topic were grouped into classes and orders of the phylum Cnidaria (Table 35.1) (according to the latest classification proposed in WoRMS) [35.1].

This approach allowed us to identify which taxonomic groups of cnidarians screened so far display the highest potential to yield new drugs or pharmacological products derived from marine bioactive compounds. Nonetheless, it is important to highlight that the identification of cnidarian species is a challenging task, and it is possible that some of the species (or even genera) referred to in the scientific literature may have been misidentified. In this way, it is of paramount importance that in future work, the authors addressing marine bioactive compounds produced by cnidarians provide a detailed description on how the target species was identified [35.28].

35.2.1 Class Anthozoa

The class Anthozoa currently includes 10 orders and over 7500 valid species (about $\frac{2}{3}$ of all known cnidarian species; Table 35.1). Within the Anthozoa class, the order Alcyonacea (soft corals and sea fans) is the one that has contributed with the highest number of promising bioactive marine compounds, although other orders, such as Actiniaria (sea anemones) and Scleractinia (hard corals), have also yielded relevant compounds [35.56–59].

The Order Alcyonacea (Soft Corals and Sea Fans)

Soft corals are generally brightly colored and rich in nutritionally important substances. However, the incidence of predation in the majority of these organisms is low due to the toxic compounds they produce to deter predators [35.60]. Several biosynthetic studies have been carried out on the metabolites of soft corals [35.61] and some of those compounds have already shown great potential for the development of new pharmaceuticals and antifoulants. Sea fans are also well-known sources of compounds exhibiting significant biological activity [35.62]. Table 35.3 summarizes the most promising compounds from the order Alcyonacea (class Anthozoa).

Soft corals are rich sources of secondary metabolites such as diterpenes, sesquiterpenes, furanoditerpenes, terpenoids, capnellene, and steroids (e.g., *Lobophytum*, *Sinularia*, *Sarcophyton* [35.141], *Capnella* [35.142], and *Dendronephthya* [35.143]), that have been shown to display HIV-inhibitory [35.73], cytotoxic [35.144, 145], anti-inflammatory [35.146, 147], anticancer [35.148, 149], and antimicrobial activity [35.150], as well as cardiac and vascular responses [35.151].

Chemical investigations on octocorals belonging to the genus *Cladiella* have resulted in a series of interesting diterpenoids. Terpenoids have been found to display complex structures and various bioactivities [35.63], especially anti-inflammatory properties. *Cladiella australis* produces an anti-inflammatory natural product, austrasulfone, which was found to

Xenia plicata	Antitumor	Blumiolide C	Diterpenoid	TAIW	[35.54]

exhibit potent neuroprotective effect against the 6-hydroxydopamine (6-OHDA)-induced neurotoxicity in neuroblastoma SH-SY5Y, a human dopaminergic neuron often used for the study of Parkinson's disease. The cytotoxicity of 6-OHDA on SH-SY5Y cells was effectively and dose-dependently inhibited by pretreatment at concentrations of 10^{-3}–10 μM. The ED_{50} was 0.011 ± 0.014 μM [35.65]. Hirsutalins B-D and H, diterpenoids from *Cladiella hirsuta*, at a concentration of 10 μM, displayed significant in vitro anti-inflammatory activity in LPS (LPS)-stimulated RAW 264.7 macrophage cells by inhibiting the expression of the inducible nitric oxide synthase (iNOS), with hirsutalin B also effectively reducing the level of COX-2 (COX) protein. These compounds, in particular hirsutalin B and D, could be promising anti-inflammatory agents [35.66]. Cladielloide B and cladieunicellin C, diterpenoids from a non-identified *Cladiella*, displayed significant inhibitory effects on superoxide anion generation (IC_{50} 5.9 ± 0.7 and IC_{50} 8.1 ± 0.3 μg mL^{-1}, respectively). The first compound also showed significant inhibitory effects against elastase release (IC_{50} 6.5 ± 1.9 μg mL^{-1}) by human neutrophils at 10 μg mL^{-1} [35.63, 64]. The same species that produces cladieunicellin C also produces cladieunicellin B and E, two diterpenoids that exhibited significant cytotoxicity against human colorectal adenocarcinoma (DLD-1, IC_{50} 2.0 μg mL^{-1}) and human promyelocytic leukemia (HL-60, IC_{50} 2.7 μg mL^{-1}) cells, respectively [35.64].

Soft corals of the family Nephtheidae are known for their content of sesquiterpenes and particularly capnellenes [35.41]. Some sesquiterpenes isolated from *Capnella imbricate* [35.142, 152–154] showed anti-inflammatory activity and a dihydroxycapnellene (capnell-9(12)-ene-8β, 10α-diol) from *Dendronephthya rubeola* demonstrated antiproliferative activity against murine fibroblasts cell line (L-929, GI_{50} 6.8 μM L^{-1}) and cytotoxicity against cancer cell lines implicated in human leukemia (K-562, IC_{50} 0.7 μM) and human cervix carcinoma (HeLa, IC_{50} 7.6 μM) [35.143]. Capnell-9(12)-ene-8β, 10α-diol strongly inhibits the interaction of the oncogenic transcription factor Myc with its partner pro-

tein Max [35.155, 156], making it a therapeutically interesting compound in oncology [35.143]. *Nephthea chabroli* also produces a nor-sesquiterpene compound named chabranol, which displays moderate cytotoxicity against mouse lymphocytic leukemia cells (P-388) with an ED_{50} 1.81 $\mu g\,mL^{-1}$ [35.126]. *Nephthea erecta* produces two proteins in mediated inflammatory responses, the oxygenated ergostanoids 1 and 3. At a concentration of 10 μM, these two compounds significantly reduced the levels of the iNOS (45.8 ± 9.9 and $33.6 \pm 20.6\%$, respectively) and COX-2 protein (68.1 ± 2.3 and $10.3 \pm 6.2\%$, respectively), when compared with the control cells stimulated with lipopolysaccharides (LPS) [35.131]. Soft corals of the genus *Paralemnalia* and *Lemnalia* have been found to be rich sources of sesquiterpenoids of nardosinane-type. *Lemnalia flava* produces flavin A, a sesquiterpenoid, that showed significant in vitro anti-inflammatory activity by exhibiting concentration-dependent inhibition of LPS-induced iNOS and COX-2 protein expression (ED_{50} values toward both proteins were $4.8 \pm 0.3\,\mu g\,mL^{-1}$ ($20.5 \pm 1.3\,\mu M$) and $6.2 \pm 0.6\,\mu g\,mL^{-1}$ ($26.5 \pm 2.6\,\mu M$), respectively). This compound and flavin B also exhibited significant neuroprotective activity [35.125]. This neuroprotective activity using 6-OHDA-induced neurotoxicity in neuroblastoma SHSY5Y, a human dopaminergic neuron often used for study of Parkinson's disease, was also demonstrated for paralemnolins Q and S [35.132, 157] and 2-deoxy-7-*O*-methyllemnacarnol [35.157] from *Paralemnalia thyrsoides*. Nonetheless further investigation for their therapeutic potential against neurodegenerative diseases is suggested.

Species in the genus *Xenia* (family Xeniidae) are a rich source of diterpenoids. Xeniolides I, isolated from *Xenia novaebrittanniae* demonstrated antibacterial activity at a concentration of 1.25 $mg\,mL^{-1}$ in *Escherichia coli* ATCC and *Bacillus subtilis* [35.140]. Blumiolide C, a diterpenoid from the *Xenia blumi* (presently accepted as *Xenia plicata*), exhibited potent cytotoxicity against mouse lymphocytic leukemia (P-388, ED_{50} 0.2 $\mu g\,mL^{-1}$) and human colon adenocarcinoma (HT-29, ED_{50} 0.5 $\mu g\,mL^{-1}$) cells [35.54].

Polyoxygenated cembranoids, crassocolides H–P [35.84, 85] from *Sarcophyton crassocaule*, demonstrated cytotoxicity against cancer cell lines of human medulloblastoma (Daoy cells). Crassocolides I, M, and P were found to be more active (IC_{50} 0.8, 1.1, and 1.9 $\mu g\,mL^{-1}$, respectively). Crassocolide H and N inhibited the growth of human oral epidermoid carcinoma (KB) cells (IC_{50} 5.3 and 4.7 $\mu g\,mL^{-1}$, respectively), and crassocolide N and crassocolide L were also active against human cervical epitheloid carcinoma (HeLa) cells (IC_{50} 4.7 and 8.0 $\mu g\,mL^{-1}$, respectively) [35.84, 85]. Other cembrenoids from the same species, sarcocrassocolides F–L, were found to exhibit anti-inflammatory activities by significantly reducing the levels of iNOS protein. Furthermore, sarcocrassocolide I could also effectively reduce COX-2 expression with LPS treatment. All these compounds might be useful anti-inflammatory agents, sarcocrassocolide I being a promising anti-inflammatory lead compound [35.86]. Lobophytone Z, from *Lobophytum pauciflorum*, inhibits NO production in mouse peritoneal macrophages induced by LPS (IC_{50} 2.6 μM) [35.83]. NO is an important signaling molecule that acts in many tissues to regulate a diverse range of physiological and cellular processes. Overproduction of NO is associated with various human diseases, including inflammatory and neuronal disorders [35.158]. The level of NO released may reflect the degree of inflammation and provides an indicator to assess inflammatory processes [35.83].

Lobophytum durum and *Lobophytum crassum* produce durumolides A–C [35.79], durumhemiketalolide A–C [35.80], and crassumolides A and C [35.74], with anti-inflammatory effects. They have been shown to inhibit up-regulation of the proinflammatory iNOS and COX-2 proteins in LPS-stimulated murine macrophage cells at $IC_{50} < 10\,\mu M$ [35.74, 79]. From *Lobophytum crassum*, lobocrassin B displayed significant inhibitory effects on the generation of superoxide anion and the release of elastase by human neutrophils (IC_{50} 4.8 and 4.9 $\mu g\,mL^{-1}$, respectively). Cytotoxicity of this cembrenoid toward tumor cells showed that it exhibited only modest cytotoxicity against human erythromyeloblastoid leukemia (K562), human T-cell acute lymphoblastic leukemia (CCRF-CEM), human acute lymphoblastic leukemia (Molt4), and human hepatocellular liver carcinoma (HepG2) cells [35.76].

Another example of a potential new therapeutic anticancer agent is a cembranolide diterpene from *Lobophytum cristagalli*, which has shown a potent inhibitory activity (IC_{50} 0.15 μM) [35.78] over farnesyl protein transferase (FPT), an important protein in signal transduction and regulation of cell differentiation and proliferation [35.159]). This type of FPT inhibition enhanced interest in this group of metabolites [35.141]. Other species of this genus also showed cembranoids with significant cytotoxic activity against human lung adenocarcinoma (A549, lobophytene [35.72], lobophytosterol [35.82], and 13-

acetoxysarcophytoxide [35.75]), human colon adenocarcinoma (HT-29, lobophytene [35.72]; DLD-1, culobophylin A [35.77], and HCT-116 lobophytosterol [35.82]), and human promyelocytic leukemia (HL60, lobophytosterol [35.82], and culobophylin A and B [35.77]) cell lines. The diterpenoids, lobohedleolide, (7*Z*)-lobohedleolide, and 17-dimethylaminolobohedleolide were isolated from the aqueous extract of *Lobophytum* species and exhibited moderate HIV-inhibitory activity (IC_{50} approximately $7-10\,\mu g\,mL^{-1}$) in a cell-based in vitro anti-HIV assay [35.73]. Additionally, other significant antiviral activity against human cytomegalovirus (IC_{50} of $5.2\,\mu g\,mL^{-1}$) [35.81] was described for the compound durumolide Q produced by *Lobophytum durum*.

Eunicellin-based diterpenoids are secondary metabolites often isolated from the genus *Klyxum*. *Klyxum molle* has been shown to produce molecules (e.g., klymollin F and G) with interesting bioactivities, such as anti-inflammatory agents [35.71]. *Klyxum simplex* also produces diterpene compounds, such as simplexin E, klysimplexins J–N, R, and S, and klysimplexin sulfoxide A–C, which at a concentration of $10\,\mu M$ were found to considerably reduce the levels of iNOS protein. The compounds simplexin E, klysimplexins R and S, and klysimplexin sulfoxide C could also effectively reduce the level of COX-2 protein. These results have shown that this compound significantly inhibits the accumulation of the pro-inflammatory iNOS and COX-2 proteins in LPS-stimulated RAW 264.7 macrophage cells, being potential anti-inflammatory agents [35.67, 69, 70]. This species also produces two diterpenes, klysimplexins B and H, which exhibit moderate cytotoxicity towards human carcinoma cell lines. Klysimplexin B exhibits cytotoxicity toward human hepatocellular carcinoma (Hep G2, IC_{50} $3.0\,\mu g\,mL^{-1}$, and Hep 3B, IC_{50} $3.6\,\mu g\,mL^{-1}$), human breast carcinoma (MDA-MB-231, IC_{50} $6.9\,\mu g\,mL^{-1}$ and MCF-7, IC_{50} $3.0\,\mu g\,mL^{-1}$), human lung carcinoma (A549, IC_{50} $2.0\,\mu g\,mL^{-1}$) ,and human gingival carcinoma (Ca9-22, IC_{50} $1.8\,\mu g\,mL^{-1}$) cell lines. Metabolite klysimplexin H demonstrated cytotoxicity toward human hepatocellular carcinoma (Hep G2, IC_{50} $5.6\,\mu g\,mL^{-1}$, and Hep 3B, IC_{50} $6.9\,\mu g\,mL^{-1}$), human breast carcinoma (MDA-MB-231, IC_{50} $4.4\,\mu g\,mL^{-1}$, and MCF-7, IC_{50} $5.6\,\mu g\,mL^{-1}$), human lung carcinoma (A549, IC_{50} $2.8\,\mu g\,mL^{-1}$), and human gingival carcinoma (Ca9-22, IC_{50} $6.1\,\mu g\,mL^{-1}$) cell lines [35.68].

A tetraprenylated spermine derivative – sinulamide – has been isolated in *Sinularia* sp., which revealed an H,K-ATPase inhibitory activity. H,K-ATPase is a gastric proton pump of the stomach and is the enzyme primarily responsible for the acidification of the stomach contents. Its inhibition is a very common clinical intervention used in diseases including dyspepsia, peptic ulcer, and gastroesophageal reflux (GORD/GERD). Sinulide is a potential antiulcer drug, as it inhibits production of gastric acid by H,K-ATPase (IC_{50} $5.5\,\mu M$) [35.87]. Although it has been chemically synthesized [35.160], no clinical trials seem to have been reported. The steroid gibberoketosterol [35.92], isolated from *Sinularia gibberosa*, and the diterpenoid querciformolide C [35.93] isolated from *Sinularia querciformis*, showed significant inhibition of the up-regulation of the pro-inflammatory iNOS and COX-2 proteins in LPS-stimulated murine macrophages at a concentration of $< 10\,\mu M$ [35.92, 93]. *Paralemnalia thyrsoides* showed significant inhibition of pro-inflammatory iNOS protein expression (70% at IC_{50} $10\,\mu M$) [35.157]. *Sinularia* species produce significant bioactive molecules. Lipids from *Sinularia grandilobata* and another unspecified species of *Sinularia* possess antibacterial and antifungal activity [35.88]. The diterpene 11-episinulariolide from *Sinularia flexibilis* is an interesting antifoulant exhibiting strong algacidal properties [35.91]. This species also produces cembrenoids, named flexilarins, which evidenced cytotoxic activity in cancer cell lines. Flexilarin D exhibited potent cytotoxicity in human hepatocarcinoma (Hep2) cells with IC_{50} $0.07\,\mu g\,mL^{-1}$ and moderate cytotoxic activity against human cervical epitheloid carcinoma (HeLa, IC_{50} $0.41\,\mu g\,mL^{-1}$), human medulloblastoma (Daoy, $1.24\,\mu g\,mL^{-1}$), and human breast carcinoma (MCF-7, $1.24\,\mu g\,mL^{-1}$) cell lines [35.90]. Capilloquinol from *Sinularia capillosa* displayed cytotoxicity against P-388, with an ED_{50} of $3.8\,\mu g\,mL^{-1}$ [35.89].

Antifouling agents from natural sources are of increasing interest since the International Maritime Organization (IMO) banned the use of certain antifouling agents, such as tri-*n*-butyltin (TBT), due to the ecological impacts of these biocides in the marine environment. Several studies have demonstrated that soft corals can yield large quantities of promising antifouling metabolites [35.161, 162]. In fact, 17.95% of potential antifouling natural compounds are from cnidarians (e.g., soft corals) [35.163]. One of the most promising natural antifouling agents identified so far is an isogosterone isolated from an unspecified *Dendronephthya* [35.128]. Also 3β-methoxyguaian-10(14)-en-2β-ol, a sesquiterpene from the gorgonian *Echinogorgia pseudossapo*, was evaluated for its antilarval activity against *Am-*

phibalanus amphitrite and *Bugula neritina* larvae. The results showed that this compound had significant antilarval activity towards *Amphibalanus amphitrite* larvae with an EC50 value of 17.2 $\mu g\,mL^{-1}$ (68.2 μM), and showed 50% inhibition towards the settlement of *Bugula neritina* larvae at concentration of 25 $\mu g\,mL^{-1}$. This EC_{50} value is lower than the standard requirement of an EC_{50} of 25 $\mu g\,mL^{-1}$ established by the US Navy program as an efficacy level for natural antifoulants, indicating that 3β-methoxyguaian-10(14)-en-2β-ol is a potential natural antifouling agent [35.133].

Most of the bioactive substances from the family Clavulariidae with promising biotechnological potential are antitumor molecules from the genus *Clavularia*. Even so, *Carijoa* sp. produces a sterol glycoside, carijoside A, that displayed significant inhibitory effects on superoxide anion generation (IC_{50} 1.8 $\mu g\,mL^{-1}$) and elastase release (IC_{50} 6.8 $\mu g\,mL^{-1}$) by human neutrophils in anti-inflammatory activity testing [35.104]. As was previously mentioned, genus *Clavularia* contains promising secondary metabolites with unique structures and remarkable biological activities. Some of the species in this genus produce prostanoids (icosanoids) [35.55, 101, 103, 164–166], steroids [35.102], and diterpenoids [35.99, 167]. The bioactive marine diterpene, stolonidiol, isolated from an unidentified *Clavularia*, showed potent choline acetyltransferase (ChAT) inducible activity in primary cultured basal forebrain cells and clonal septal SN49 cells, suggesting that it may act as a potent neurotrophic factor-like agent on the cholinergic nervous system [35.98]. Cholinergic neurons in the basal forebrain innervate the cortex and hippocampus, and their function may be closely related to cognitive function and memory. The degeneration of neuronal cells in this brain region is considered to be responsible for several types of dementia, including Alzheimer's disease. One of the neurotransmitters, acetylcholine, is synthesized from acetyl coenzyme A and choline by the action of ChAT. Therefore, induction of ChAT activity in cholinergic neurons may improve the cognitive function in diseases exhibiting cholinergic deficits [35.168–170].

Prostanoids (claviridic acid) isolated from *Clavularia viridis* exhibited potent inhibitory effects on phytohemagglutinin-induced proliferation of peripheral blood mononuclear cells (PBMC, 5 $\mu g\,mL^{-1}$), as well as significant cytotoxic activity against human gastric cancer cells (AGS, IC_{50} 1.73–7.78 $\mu g\,mL^{-1}$) [35.100]. Claviridenone extracts also showed potent cytotoxicity against mouse lymphocytic leukemia (P-388) and human colon adenocarcinoma (HT-29), and exceptionally powerful cytotoxicity against human lung adenocarcinoma (A549) cells, with ED_{50} between 0.52 pg/mL and 1.22 $\mu g\,mL^{-1}$ [35.55]. Claviridins A–D exhibited potent cytotoxicity against four human cancer cell lines: Hep2 (ED_{50} 0.19–0.35 $\mu g\,mL^{-1}$), Doay (ED_{50} 0.18–0.29 $\mu g\,mL^{-1}$), colon adenocarcinoma (WiDr, ED_{50} 0.22–0.34 $\mu g\,mL^{-1}$), and HeLa (ED_{50} 0.31–0.88 $\mu g\,mL^{-1}$) [35.103]. Halogenated prostanoids also showed cytotoxic activity against human T lymphocyte leukemia cells (MOLT-4, IC_{50} 0.52 $\mu g\,mL^{-1}$), human colorectal adenocarcinoma (DLD-1, IC_{50} 0.6 $\mu g\,mL^{-1}$), and human diploid lung fibroblast (IMR-90, IC_{50} 4.5 $\mu g\,mL^{-1}$) cells [35.101]. The cyclopentenone prostanoid, bromovulone III is a promising marine natural compound for the treatment of prostate, colon, and hepatocellular carcinoma, which showed antitumor activity against human prostate (PC-3) and human colon (HT29) cancer cells at an IC_{50} of 0.5 μM [35.164], and induced apoptotic signaling in a sequential manner in Hep3B cells [35.171]. In the case of prostate cancer cells, this compound displayed an antitumor activity 30–100 times more effective than cyclopentenone prostaglandins (known to suppress tumor cell growth and to induce apoptosis in prostate cancer cells), by causing a rapid redistribution and clustering of Fas (member of the tumor necrosis factor (TNF) receptor superfamily). Apoptotic stimulation of Fas by specific ligand or antibodies caused the formation of a membrane-associated complex comprising Fas clustering) in PC-3 cells [35.172]. *Clavularia viridis* also produces steroids that show cytotoxic activity against human colorectal adenocarcinoma (DLD-1, $0.02 < IC_{50} < 50\,\mu g\,mL^{-1}$) and also against human T lymphocyte leukemia cells (MOLT-4, $0.01 < IC_{50} < 10\,\mu g\,mL^{-1}$) in the case of yonarasterols [35.102]. Additionally, stoloniferone displayed potent cytotoxicity against mouse lymphocytic leukemia (P-388), human colon adenocarcinoma (HT-29), and human lung adenocarcinoma (A549) cells [35.55]. This species produces several compounds with antitumor activity in different types of human tumors, although more in vitro studies are needed to determine which compounds are potential anticancer agents. *Clavularia koellikeri* produces diterpenoids as secondary metabolites, which display cytotoxic activity against human colorectal adenocarcinoma (DLD-1, IC_{50} 4.2 $\mu g\,mL^{-1}$) and strong growth inhibition against human T lymphocyte leukemia cells (MOLT-4, IC_{50} 0.9 $\mu g\,mL^{-1}$) [35.99].

In the genus *Cespitularia*, several interesting diterpenes of cembrane and neodolabellane skeletons have

been identified. In *Cespitularia hypotentaculata* (family Xeniidae) a significant production of diterpenoids was detected. Cespitularin C exhibited potent cytotoxicity against mouse lymphocytic leukemia (P-388, ED_{50} 0.01 $\mu g\,mL^{-1}$) and human lung adenocarcinoma (A549, ED_{50} 0.12 $\mu g\,mL^{-1}$) cells, while cespitularin E exhibited potent cytotoxicity against human lung adenocarcinoma (A549, ED_{50} 0.034 $\mu g\,mL^{-1}$) cell cultures [35.139]. A less active diterpene, Asterolaurin A, from *Asterospicularia laurae* (a species from the same family) exhibited cytotoxicity against human hepatocellular carcinoma (HepG2) cells with an IC_{50} of 8.9 μM [35.138].

Telesto riisei produces punaglandins, highly functional cyclopentadienone and cyclopentenone prostaglandins. Cyclopentenone prostaglandins have unique antineoplastic activity and are potent growth inhibitors in a variety of cultured cells. These punaglandins have been shown to inhibit P53 accumulation (a tumor suppressor protein) and ubiquitin isopeptidase activity (IC_{50} between 0.04 and 0.37 μM) (enzyme involved in protein degradation system) in vitro and in vivo [35.105]. Since these proteasome inhibitors exhibit higher antiproliferative effects than other prostaglandins [35.173], they may represent a new class of potent cancer therapeutics.

Sea fans are well-known sources of compounds exhibiting significant biological activity [35.62]. Studies on *Isis hippuris* resulted in the isolation of a series of novel metabolites such as sesquiterpenes [35.124], steroids [35.174], A-nor-hippuristanol [35.127], and isishippuric acid B [35.127]. These compounds exhibit potent cytotoxicity against cancer cell lines of human hepatocellular carcinoma (HepG2 and Hep3B, IC_{50} 0.08–4.64 $\mu g\,mL^{-1}$, and 0.10–1.46 $\mu g\,mL^{-1}$, respectively) [35.127, 175], human breast carcinoma (MCF-7, IC_{50} 0.20–4.54 $\mu g\,mL^{-1}$ and MDA-MB-231, IC_{50} 0.13–2.64 $\mu g\,mL^{-1}$) [35.175], mouse lymphocytic leukemia (P-388), human lung adenocarcinoma (A549), and human colon adenocarcinoma (HT-29) with ED_{50} of values less than 0.1 $\mu g\,mL^{-1}$ [35.127, 174] and IC_{50} of 0.1 $\mu g\,mL^{-1}$ [35.124]. Polyoxygenated steroids were also isolated from this species and showed moderate cytotoxicity against cultured NBT-T2 rat bladder epithelial cells (IC_{50} between 1.8 and 7.5 $\mu g\,mL^{-1}$) [35.122], P-388 and A549 cell lines (ED_{50} 3.2 and 3.86 $\mu g\,mL^{-1}$, respectively), and inhibitory activity against HCMV (EC_{50} 2.0 $\mu g\,mL^{-1}$) [35.123].

Species from the genus *Pseudopterogorgia* (currently accepted as *Antillogorgia* sp.) are a rich source of unusual biologically active diterpenoids, sesquiterpenes, and polyhydroxylated steroids, which exhibit diverse structures [35.109, 176, 177]. A sample of the organic extract of *Antillogorgia bipinnata* (formerly *Pseudopterogorgia bipinnata*) was included in an initial screening carried out as part of an effort in the discovery of new antimalarial agents. This extract was found to be active in inhibiting the growth of *Plasmodium falciparum* (a protozoan parasite responsible for the most severe forms of malaria). Caucanolide A and D demonstrated significant in vitro antiplasmodial activity against chloroquine-resistant *P. falciparum* W2 (IC_{50} 17 $\mu g\,mL^{-1}$ and IC_{50} 15 $\mu g\,mL^{-1}$, respectively) [35.110]. Three secosterols isolated from an unidentified gorgonian from genus *Pseudopterogorgia* inhibited human protein kinase C (PKC) α, βI, βII, γ, δ, ε, η, and ζ, with IC_{50} values in the range 12–50 μM [35.121]. PKC is a key player in cellular signal transduction and has been implicated in cancer, cardiovascular and renal disorders, immunosuppression, and autoimmune diseases such as rheumatoid arthritis [35.159]. Semisynthetic derivatives also showed a similar activity [35.121]. Promising antimicrobial substances were also reported from *Antillogorgia rigida* (formerly *Pseudopterogorgia rigida*) (e.g., curcuphenol) [35.118] and from *Antillogorgia elisabethae* (formerly *Pseudopterogorgia elisabethae*) (e.g., pseudopterosin X and Y) [35.111]. Ileabethoxazole, homopseudopteroxazole, caribenols A and B and elisapterosin B from *A. elisabethae* and bipinnapterolide B from *Antillogorgia bipinnata* inhibit *Mycobacterium tuberculosis* H37Rv at a concentration of 12.5 $\mu g\,mL^{-1}$ [35.113, 115] (for elisapterosin B and homopseudopteroxazole) and at a concentration range of 128–64 $\mu g\,mL^{-1}$ [35.112, 114, 178] (for other compounds). In fact, the inhibition of *Micobacterium tuberculosis* H37Rv is within the range recorded for rifampin [35.112]. *A. elisabethae* and *A. bipinnata* also produce antituberculosis compounds. Bielschowskysin, a naturally occurring diterpene isolated from *Antillogorgia kallos* (formerly *Pseudopterogorgia kallos*) [35.117] and aberrarone isolated from *A. elisabethae* [35.116] exhibited antiplasmodial activity (IC_{50} 10 $\mu g\,mL^{-1}$) when tested against *P. falciparum*. The first compound was also found to display strong and specific in vitro cytotoxicity against the EKVX non-small cell lung cancer ($GI_{50} < 0.01\,\mu M$) and CAKI-1 renal cancer (GI_{50} 0.51 μM) [35.117]. Bis(pseudopterane) amine from *Antillogorgia acerosa* (formerly *Pseudopterogorgia acerosa*) was found to exhibit selective activity against HCT116 (IC_{50} 4 μM)

cell lines [35.108]. Astrogorgol F, a secosteroid produced by *Astrogorgia* sp., showed significant inhibition against protein kinases IGF-1R (insulin-like growth factor receptor-1), SRC and VEGF-R2 with IC_{50} of 3.16, 2.40, and 4.95 μM, respectively. These kinases are currently regarded as very important therapeutic targets for cancer. Protein IGF-1R activates crucial signaling pathways that benefit cancer cells. Inhibition of this protein function has shown to significantly decrease cancer cell proliferation and increase sensitivity to chemotherapy and radiation treatment. Kinase VEGF-R2 plays an important role in tumor angiogenesis, and its relevance as pharmacological target for the treatment of a large variety of solid cancers has been extensively described in the literature. The potent inhibitory activity of secosteroids toward VEGF-R2 indicates that they may induce the inhibition of tumor angiogenesis. SRC family kinases play a critical role in cell adhesion, invasion, proliferation, survival, and angiogenesis during tumor development. It was reported that the three kinds of kinases (SRC, VEGF-R2, and IGF-1R) involved in the different signaling pathways are influenced by crosstalk and interaction with each other [35.129].

Fuscosides, originally isolated from *Eunicea fusca* [35.135], selectively and irreversibly inhibited leukotriene synthesis. Leukotrienes are molecules of the immune system that contribute to inflammation in asthma and allergic rhinitis and their production is usually related to histamine release [35.179]. Pharmacological studies indicated that fuscoside B inhibits the conversion of arachidonic acid (AA) to leukotriene B4 and C4 (LTB4 and LTC4) [35.135, 180] by inhibiting the 5-lipoxygenase (5-LO), in the case of LTB4 with an IC_{50} of 18 μM [35.180]. These selective inhibitors of lipoxygenase isoforms can be useful as pharmacological agents, as nutraceuticals, or as molecular tools [35.159]. Fuscoside B and E were also used in the classical experiment of acute inflammation, the TPA-induced ear edema model, which allows evaluation of the anti-inflammatory properties of some natural products. The topical application on the mouse ear edema of the of these two compounds extracts showed high inflammation inhibition levels of 80.5% and 81.5%, respectively, when compared to the activity shown by the anti-inflammatory commercial drug indomethacin (77.3%) used as reference [35.136]. A diterpenoid, dolabellane, and sesquiterpenoids metabolites isolated from *Eunicea* sp. displayed antiplasmodial activity against the malaria parasite *P. falciparum* W2 (chloroquine-resistant) strain, with IC_{50} values of 9.4 μM, and IC_{50} values ranging from 10–18 $\mu g\,mL^{-1}$, respectively [35.130, 134].

The gorgonian *Junceella fragilis* produces secondary metabolites, frajunolides B and C, with anti-inflammatory effects towards superoxide anion generation and elastase release by human neutrophils, with an $IC_{50} > 10\,\mu g\,mL^{-1}$ [35.106]. When properly stimulated, activated neutrophils secrete a series of cytotoxins, such as the superoxide anion ($O_2^{\bullet -}$), a precursor of other reactive oxygen species (ROS), granule proteases, and bioactive lipids [35.181, 182]. The production of the superoxide anion is linked to the killing of invading microorganisms, but it can also directly or indirectly damage surrounding tissues. In contrast, neutrophil elastase is a major secreted product of stimulated neutrophils and a major contributor to the destruction of tissue in chronic inflammatory disease [35.183]. The anti-inflammatory butenolide lipide [35.184] from the gorgonian *Euplexaura flava* [35.137] can be currently synthesized, which opens the possibility of advancing into a new level of anti-inflammatory pharmaceuticals.

Some of the most interesting compounds identified so far in the on-going search for new antifouling agents have been recorded in the order Gorgonacea. Notable examples of such compounds are juncin ZII from *Junceella juncea* [35.107], homarine from *Leptogorgia virgulata* and *Leptogorgia setacea* [35.119], and pukalide and epoxypukalide so far only recorded from *Leptogorgia virgulata* [35.120].

Species of the genus *Briareum* (family Briareidae) (which commonly exhibit an incrusting appearance rather than the fan-like shape of many gorgonians) are widely abundant in Indo-Pacific and Caribbean coral reefs. These organisms have been recognized as a valuable source of bioactive compounds with novel structural features. Briarane-related natural products are a good example of such promising compounds due to their structural complexity and biological activity [35.185, 186]. Briaexcavatin E, from *Briareum excavata*, also occasionally referred to as *Briarium excavatum*, inhibited human neutrophil elastase (HNE) release with an IC_{50} between 5–10 μM [35.96]. Briaexcavatolides L and P, diterpenoids from the same species, exhibited significant cytotoxicity against mouse lymphocytic leukemia (P-388) tumor cells with ED_{50} of 0.5 [35.97] and 0.9 $\mu g\,mL^{-1}$ [35.187], respectively. Brialalepolides B and C, from a non-identified *Briarium* species, reduced the expression of COX-2 in human colon adenocarcinoma (RAW 264.7) cells, as well as in murine macrophage cells. This is significant because the metabolic products of COX-2 have

been implicated in the pathogenesis of colon cancer and other diseases. Additionally, mouse macrophages cells are used to test the effects of drugs on inflammation pathways. These data support the idea that briaranes such as brialalepolides B and C might be interesting candidates for therapeutic consideration as dual-acting cancer cell cytotoxins and inflammatory response inhibitors [35.94]. Diterpenoids produced from *Briareum polyanthes* (presently accepted as *Briareum asbestinum*), namely Briarellin D, K, and L, exhibited antimalarial activity against *P. falciparum* with an IC_{50} between 9–15 $\mu g\,mL^{-1}$ [35.95].

Other Orders

Sea anemones (order Actiniaria) are a rich source of biologically-active proteins and polypeptides. Several cytolytic toxins, neuropeptides, and protease inhibitors have been identified from this group of organisms [35.56]. In addition to several equinatoxins, potent cytolytic proteins and an inhibitor of papain-like cysteine proteinases (equistatin) were isolated from the sea anemone *Actinia equina* [35.188]. Equistatin has been shown to be a very potent inhibitor of papain and a specific inhibitor of the aspartic proteinase cathepsin D [35.189]. While papain-like cysteine proteases have been implicated in various diseases of the central nervous system, such as brain tumors, Alzheimer's disease, stroke, cerebral lesions, neurological autoimmune diseases, and certain forms of epilepsy [35.190], aspartic proteinase cathepsin D is involved in the pathogenesis of breast cancer [35.191] and possibly Alzheimer's disease [35.192]. An acylamino acid, bunodosine 391 (BDS 391) was isolated from the venom of the sea anemone, *Bunodosoma cangicum*. Intraplantar injection of BDS 391 into the hind paw of a rat induced a potent analgesic effect. This effect was not altered by naloxone (an opioid receptor antagonist), but was completely reversed by methysergide (a serotonin receptor antagonist), indicating that the effect is mediated by activation of serotonin receptors [35.193].

Cycloaplysinopsin C, a bis(indole) alkaloid isolated from *Tubastraea* sp. (order Scleractinia), was found to inhibit growth of two strains of *P. falciparum*, one chloroquine-sensitive (F32/Tanzania) and another chloroquine-resistant (FcB1/Colombia) with IC_{50} 1.48 and 1.2 $\mu g\,mL^{-1}$, respectively [35.59]. Cladocorans A and B, isolated from *Cladocora caespitosa* (order Scleractinia) [35.57], are marine sesterterpenoids that possess a γ-hydroxybutenolide moiety, which is thought to be responsible for the biological activity of these compounds. The potent anti-inflammatory activity of these natural metabolites was attributed to the inhibition of secretory phospholipase A2 (sPLA2, IC_{50} 0.8–1.9 μM). Given the general role of inflammation in diseases that include bronchial asthma and rheumatoid arthritis, the identification and development of potent inhibitors of sPLA2 continues to be of great importance for the pharmaceutical industry, with this type of metabolite being of paramount importance for future research [35.58].

A sphingolipid, 2S*,3S*,(4E,8E)-2N-[35-tetradecanoyl]-4(E),8(E)-icosadiene-1, 3-diol and a steroid (22E)-methylcholesta-5,22-diene-1a,3b,7a-triol, were isolated from the black coral *Antipathes dichotoma* (order Antipatharia) and screened for antibacterial activity against Gram-positive and Gram-negative bacteria at 1 mg/ml concentration. Data obtained showed that the sphingolipid exhibits potent activity against *Bacillus subtilis* and *Pseudomonas aeruginosa* (MIC 0.4 and 0.2 $mg\,mL^{-1}$, respectively), while the trihy droxy steroid showed potent activity against *B. subtilis* (MIC 0.6 $mg\,mL^{-1}$) [35.194].

35.2.2 Class Hydrozoa

The class Hydrozoa includes 7 orders and nearly 3500 valid species (Table 35.1), some of which are solitary while others are colonial. Among the most emblematic species are probably hydroids and the Portuguese man-o-war (*Physalia physalis*). Despite the large number of species in the class Hydrozoa, only a few have yielded interesting marine natural products in the last decade.

Immune escape plays an important role in cancer progression and, although not completely understood, it has been proposed that indoleamine 2,3-dioxygenase (IDO) plays a central role in the evasion of T-cell-mediated immune rejection [35.195]. IDO catalyzes the oxidative cleavage of the 2,3-bond of tryptophan, which is the first and rate-limiting step in the kynurenine pathway of tryptophan catabolism in mammalian cells [35.196]. The polyketides annulins A, B, and C, purified from the marine hydroid *Garveia annulata* (order Anthoathecata), potently inhibited IDO in vitro (Ki 0.12–0.69 μM) [35.197]. These annulins are more powerful than most tryptophan analogs known to be IDO inhibitors. These compounds are active at concentrations higher than $\approx 10\,\mu M$ and are, therefore, more effective than 1-methyltryptophan (Ki 6.6 μM), one of the most potent IDO inhibitors currently available [35.198]. Solandelactones C, D, and G are cyclopropyl oxylipins isolated from the hydroid *Solan-*

deria secunda (order Anthoathecata) and exhibit moderate inhibitory activity against FPT (69, 89, and 61% inhibition, respectively) at a concentration of 100 $\mu g\,mL^{-1}$ [35.199]. Note that FPT is associated with cell differentiation, and proliferation and its inhibition may be a target for novel anticancer agents (as was already mentioned above for the soft coral *Lobophytum cristagalli*).

35.2.3 Class Scyphozoa

Approximately 200 species are currently classified in the three orders of the class Scyphozoa (Table 35.1). However, in the last decade, only a single marine natural product was purified from the mesoglea of the jellyfish *Aurelia aurita* (order Semaeostomeae) and considered to be promising enough to be included in the present overview. This compound, aurelin, is a novel endogenous antibacterial peptide that exhibited activity against Gram-positive and Gram-negative bacteria. As an example, aurelin displayed an IC_{50} of 7.7 $\mu g\,mL^{-1}$ for *Escherichia coli* (Gram-negative bacteria) [35.200].

35.2.4 Other Classes

Staurozoa, Cubozoa, and Polypodiozoa are the classes with the least number of species in the phylum Cnidaria (Table 35.1). This fact may explain the current lack of data on secondary metabolites produced by these organisms. It is possible that with growing bioprospecting efforts new compounds may be revealed once these cnidarian species are screened. Cubozoa (box jellies), for example, produce some of the most harmful cnidarian toxins known to humans [35.201].

35.3 Concluding Remarks and Future Challenges

The intense pressure to find and develop more profitable molecules for all sorts of industries continues to fuel bioprospecting efforts of marine invertebrates. While the phylum Cnidaria is not the most significantly bioprospected at present, this chapter shows that some cnidarian species are promising sources of marine bioactive compounds of medical, economic, and scientific interest. Green fluorescent protein (GFP), GPF-like proteins, red fluorescent, and orange fluorescent protein (OPF) are good examples of biotechnological metabolites derived from cnidarians that are currently employed as molecular biomarkers. They were first purified from a fluorescent hydrozoan medusa [35.202] and have since been recorded in other cnidarian species [35.203–208].

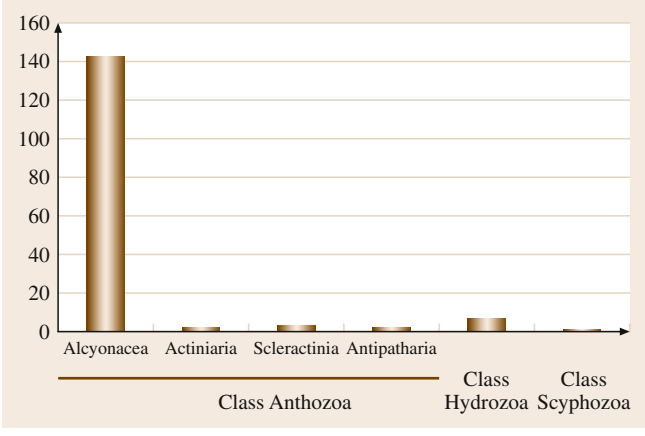

Fig. 35.6 Marine bioactive compounds with high biotechnological potential studied from the phylum Cnidaria in the twenty-first century (after [35.28])

In the present survey of the most promising bioactive marine natural products from cnidarians, only about 0.57% of extant cnidarian species are represented, with the class Anthozoa displaying by far the highest number of promising bioactive marine natural products (91%) (Fig. 35.6). This result is probably due to the fact that this class displays the highest number of species in the phylum (Table 35.1). Additionally, many anthozoans occupy marine habitats that can be readily accessed for the collection of biomass (e.g., coral reefs and intertidal regions), which facilitates bioprospecting. Of all the compounds presented in this review, 89% were detected in cnidarians collected from tropical waters (mostly from Southeast Asia and the Caribbean Sea), with the remaining 11% recorded from species that are mostly present in temperate waters (e.g., European countries and Japan).

Antitumor drugs are the main area of interest in the screening of marine natural products from cnidarians (39%, Fig. 35.7). This is not surprising, as the major financial effort for the screening of new marine compounds is made by cancer research [35.209]. Terpenoids (terpenoids, diterpenoids, sesquiterpenoids, sesterterpenoids, cembranoids) [35.14] (Fig. 35.8) are

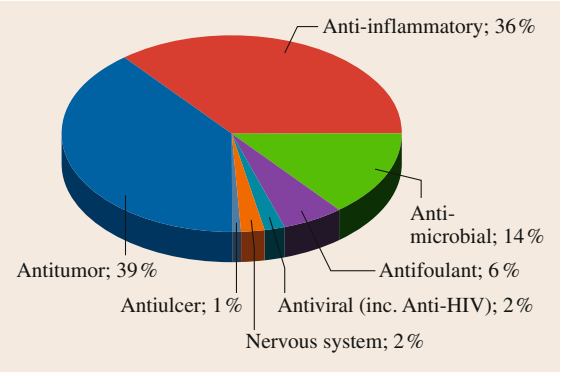

Fig. 35.7 Distribution in drug classes of marine bioactive compounds with high biotechnological potential studied from cnidarian species in the twenty-first century (after [35.28])

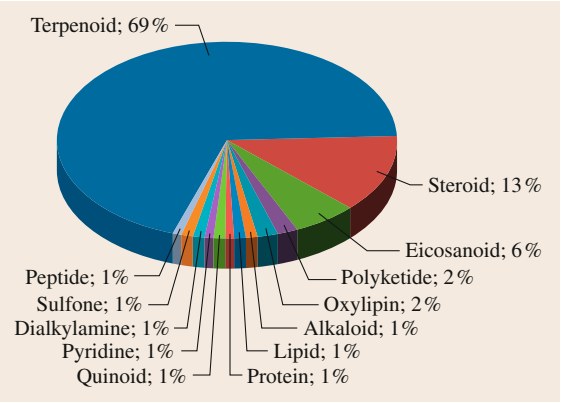

Fig. 35.8 Distribution of chemistry classes of marine bioactive compounds with high biotechnological potential studied from cnidarian species in the twenty-first century (after [35.28])

the main chemistry group in the MNPs analyzed in this survey.

Even though most pharmaceutical industries abandoned their natural product-based discovery programs over a decade ago, the lack of new compounds in their pipelines in some strategic areas (e.g., antibiotics) suggests that a renewed interest in this field is imminent. The establishment of small biotechnology companies can play a decisive role in the initial discovery of promising marine bioactive compounds, as these enterprises will work closely together with academics and governmental agencies to take the initial steps in the discovery of new chemical entities. Collaboration between private companies and public institutions can be of paramount importance for financial support in the discovery process. On the other hand, crude extracts and pure compounds produced by academic laboratories may be screened by diverse bioassays as part of broader collaboration programs, nationally and internationally, with private biotechnology companies. One challenge for universities is to devise mechanisms that protect intellectual property and simultaneously encourage partnerships with the private sector, by recognizing that the chances of a major commercial pay-off are small if drug discovery is pursued by a single institution [35.29].

The commercial use of some promising marine bioactive compounds isolated from cnidarians may still be several years away. However, new compounds other than toxins and venoms produced by members of this highly diverse group of marine invertebrates may soon be discovered in the ongoing quest for new MNP.

As with most marine organisms, the bioprospecting of cnidarians has been mostly limited to shallow habitats accessible either by foot, snorkeling, or SCUBA diving. In recent years, with the advent of deep-sea exploration it has been possible to bioprospect several unique ecosystems that had remained inaccessible to researchers [35.210, 211]. Deep-sea habitats (including hydrothermal vents and cold seeps), as well as seamounts, are commonly colonized by unique cnidarian species [35.212–214] that exhibit remarkable adaptation to extreme environments [35.215] and are promising candidates for the discovery of new MNPs [35.216]. Marine biodiversity conservation has been capturing the growing attention of nations worldwide. The growing concerns towards the conservation of marine habitats are already conditioning the bioprospecting of coral reefs, deep sea and other endangered marine habitats [35.217–219]. Even so, it is likely that in the years to come bioprospecting for new marine natural products will continue to grow and that new cnidarian groups will be targeted by researchers.

Modern screening techniques rely on the use of a significantly lower amount of biomass (micrograms) than what was required a decade ago for the discovery of new chemical compounds [35.18]. The incorporation of modern molecular biology and bioinformatics to complement the use of chemical approaches in the study of biosynthetic pathways has allowed researchers to make significant breakthroughs in the production of marine drugs [35.220]. Nonetheless, the production of such compounds at a commercial level is still a remarkable challenge. Large-scale production of a given com-

pound can be possible either through chemical synthesis or through its extraction from the source organism. Unfortunately, the first option is not always possible, as several complex molecules are simply impossible to produce or incur production costs that cannot be afforded by commercial applications [35.221, 222]. The harvest of the source animal from the wild for the extraction of a compound is invariably an unsustainable practice and rarely a long-term option [35.219]. On the other hand, the production of source organism biomass (either *in* situ or *ex* situ) has been considered as a potential alternative to the collection of wild specimens [35.223]. Additionally, the production of source organisms under controlled conditions may help to control the ecophysiological diversity promoted by environmental interactions and maximize the production of target marine molecules. Unfortunately, the culture of most target organisms has turned out to be more technically challenging and significantly more expensive than initially assumed [35.224, 225].

There is growing evidence that microorganisms associated with marine invertebrates may be the true producers of some of the MNPs isolated from these animals and may even be responsible for the variation of chemical diversity at species level [35.226–228]. The microbiome present in marine invertebrates is likely to shift geographically [35.229, 230], which may enhance the production of different secondary metabolites. Whether this is also the case of most cnidarians remains to be confirmed [35.231]. Nonetheless, it has already been recognized that one of the promising compounds recorded from the gorgonian *Antillogorgia elisabethae* is, in fact, produced by its symbiotic dinoflagellates [35.232]. In this way, it is possible that future bioprospecting efforts may shift from invertebrate hosts towards symbiotic microorganisms. Under this scenario another constraint for the commercial use of these compounds must be overcome, as the culture of symbiotic microorganisms is generally not possible using classic/standardized methodologies. Once isolated from their host symbiotic microorganisms rarely thrive in vitro or no longer produce the desired compound [35.223–228].

The early impetuous of natural product-based discovery programs by pharmaceutical industries has decreased in the twenty-first century [35.233]. Nonetheless, the lack of new compounds in some of the strategic pipelines for drug discovery impels researchers to consider the new tools available for blue biotechnology [35.234] and the importance of joining efforts with academic institutions for the early stages of marine organisms bioprospecting. New drugs derived from MNP isolated from cnidarians may still be several years away, but it is unquestionable that more chemical entities, besides toxins and venoms, will be recorded from cnidarians [35.28]. In conclusion, this diverse group of marine invertebrates is destined to play a major role in the pursuit of new drugs from the sea.

36. Fatty Acids of Marine Sponges

Pravat Manjari Mishra, Ayinampudi Sree, Prasanna K. Panda

Among all organisms, thus also marine sponges, accumulate fatty acids (FAs) with a very rich chemistry and are the source of an unprecedented diverse range of chemical structures. This chapter accounts the most recent developments concerning the occurrence of different FA structures in marine sponges and their potential applications. While the first section of the chapter deals with the importance of FAs in various applications, the second section of the chapter focuses on the diversity of FAs with different structural features in marine sponges. FAs in marine sponges differ in the number of olefinic bonds, the extent of branching, the length of the hydrocarbon chain, and the number of functional groups. The last section of the chapter deals with the biomedical potential of the FAs of marine sponges including antibacterial, antifungal, antimalarial, and cytotoxic activities, etc.

36.1 Fatty Acids – Pharmaceutical and Biomedical Importance

36.1.1 Fatty Acids – An Introduction

Fatty acids (FAs) are ubiquitous metabolites of all organisms, characterized by the presence of a carboxyl group (−COOH) at one end and a methyl group at the other end. Fatty acid molecules are usually joined together in groups of three, forming a molecule called triglyceride. As an important source of energy, FAs play a number of biological roles in the body. In the absence of glucose the body uses FAs to fuel cells to obtain energy. They are needed for the construction of cell membranes and also play a key role in protein acylation, signal transduction, growth, etc.

FAs are either saturated or unsaturated. Most FAs are straight-chain compounds with the frequent occurrence of an even number of carbon atoms. Chain lengths range from 2 to 80, but most commonly from 12 to 24. With a chain length from 2 to 6 (or 4) they are referred to as short-chain, from 8 (or 6) to 10 as medium-chain, and 12–24 as long-chain FAs. Among straight-chain FAs, the simplest are referred to as saturated FAs. When double bonds are present, FAs are said to be unsaturated; monounsaturated (MUFAs) if only one double bond is present, and polyenoic (or polyunsaturated fatty acids = PUFAs) if they have two or more double bonds generally separated by a single methylene group (methylene-interrupted unsaturation).

Various conventions are used for indicating number and position of the double bond in the structure of an unsaturated FA. For example, in the structure of palmitoleic acid (16 : 1), the end methyl carbon is known as the ω carbon or the n carbon. $\omega 7$ or (n-7) indicates a double bond on the seventh carbon counting from ω or the n carbon,

$$\begin{array}{ll} \omega & 2\ \ 3\ \ 4\ \ 5\ \ 6\ \ 7 \\ & \mathrm{CH_3CH_2CH_2CH_2CH_2CH{=}CH(CH_2)_7COOH} \\ n & \qquad 16:1\ \omega 7 \text{ or } 16:1(n\text{-}7)\,. \end{array}$$

IUPAC-IUB (International Union of Pure and Applied Chemistry and International Union of Biochemistry and Molecular Biology) Commissions have agreed to 16 : 1 (*n*-7) form of the nomenclature rather than 16 : 1 ω7 because of its convenience to biochemists with interests in fatty acid metabolism in animals. In mammals, additional double bonds are introduced only in between the existing double bond and the carboxyl carbon, yielding three series of FAs known as the ω-9, ω-6, and ω-3 families, respectively.

Some uncommon PUFAs have two adjacent double bonds separated by more than one methylene group, and they are named polymethylene-interrupted FAs. In some organisms, the structures of FAs may be more complex since they can have an odd number of carbon atoms, branched chains, or a variety of other functional groups, including acetylenic bonds, epoxy, hydroxy, or keto groups, and even ring structures (cyclopropane, cyclopropene, cyclopentene, furan, and cyclohexyl) or a coenzyme A moiety (acyl CoA).

36.1.2 Importance of Fatty Acids

Use of Fatty Acids in Cosmetics

A large variety of FA derivatives are used in cosmetics [36.1]. Stearic acid, oleic acid, lauric acid, palmitic acid and myristic acid are used in a variety of cosmetic creams, cakes, soaps, and pastes. The use of lipids and FAs in hair products is based on their ability to hold hair in place and to make the hair glossy. They also play a critical role as vehicles for the application of various drugs to the skin and as bases for pigmented decorative cosmetics. The applications of FAs in cosmetics are mostly based on the adhesive properties of the lipid/FAs [36.2].

Nutritional Importance

Food lipids enhance the palatability of foods, such as taste, texture, and create a sensation in the mouth. Dietary fats and oils provide an important source of concentrated food energy [36.3, 4]. They also provide a source of fat-soluble vitamins (A, D, E, and K) and help to facilitate the digestion and absorption of these vitamins [36.4]. The saturated FAs 12 : 0, 14 : 0, and 16 : 0 elevate the circulating levels of plasma low-density lipoprotein (LDL)-C [36.5], a major risk factor for atherosclerosis. Conversely, consumption of (*n*-6) and (*n*-3) PUFAs are associated with decreased blood pressure [36.6]. Consumption of *n*-3 PUFAs reduces the risk of cancer, cardiovascular disease, and diabetes [36.7–10].

Application of Fatty Acids in Pharmaceuticals

The majority of FAs and their derivatives are used as:

1. Processing aids such as antifoaming agents and tablet lubricants that assist in manufacturing operations.
2. Pharmaceutical components or excipients such as emulsifiers, stabilizers, solubilizers, carriers, suppository bases, coatings, adjuvants, etc.
3. Active pharmaceuticals.

Processing Aids.

In Antibiotic Manufacture. Antibiotic yields have been shown to increase markedly in the presence of specific FAs. The addition of unsaturated FAs enhances the growth and antibiotic production by streptomyces [36.11].

As Tablet Lubricants. A widely known application of FA derivatives, in particular the metallic salts of FAs, involves their use as tablet lubricants [36.12]. Magnesium, calcium, sodium and aluminium stearates, sodium myristate, and stearic acid have been employed preferentially as tablet lubricants.

As Pharmaceutical Components and Excipients. In parenterals. A number of FA derivatives, in particular those classified as nonionics, have been used in the preparation of parenterals. Polyoxyethylene sorbitan monolaurate and monooleate, sorbitan trioleate, and aluminium stearate have been used as surface active agents in the preparation of parenteral dispersions [36.13].

As Protective Coatings. Oleic and stearic acid were shown to be essential components of a coating formulation that released aspirin at pH 6.5. Ethyl esters of stearic acid and oleic acid were used for preparing protective coating for metal surfaces [36.14]. Polyethylene glycol esters of C12–C18 FAs have been employed in the preparation of medicinal capsules having delayed action. Glyceryl monostearate and glyceryl monopalmitate have been used for enteric coatings. Dimers of C6–C26 unsaturated FAs in combination with glyceryl or polyoxyethylene monostearate were found to be suitable as thin film coatings for pharmaceuticals.

In Ointment Bases. Fatty acid esters have found widespread use in ointment bases for the administration of pharmaceuticals. The diethanolamine condensates of

lauric acid have been used as an ointment base for steroidal hormones such as corticosteroids. Silicone oil, in combination with calcium salts of FAs or polyhydric alcohol esters of FAs, has been found to be an effective base for pharmaceutical ointments.

In Suppositories. Suppositories for the nasal, urethal, vaginal, and rectal insertion of local or systemic medicinals, such as steroids, hypnotics, diuretics, analgesics, sedatives, and so forth, have been prepared from FAs and their derivatives. An effective water-soluble suppository base having a high melting point range and a high percentage of medicinal release has been developed, which contains polyoxyethylene stearate, wax, water, and sodium dioctyl sulfosuccinate [36.15].

As Gastrointestinal Absorption Aids. Various FA derivatives have been used to increase the absorption of difficult absorbing substances in the gastrointestinal tract. Thus, polyoxyethylene sorbitan monooleate or monopalmitate have been used to facilitate the resorption of iron and vitamin B_{12} from the digestive canal to the blood. The ingestion of polyoxyethylene sorbiton monolaurate in combination with iron salts has resulted in an adequate haemoglobin response brought about by increased enteric iron absorption [36.16].

As Active Pharmaceuticals.

As Antimalarial, Antimycobacterial, and Antifungal Agents. The antimalarial, antimycobacterial, and antifungal properties of novel FAs are reviewed by *Carballeira* [36.17]. C18 FAs have shown antimalarial activity and oleic acid (9–18 : 1) was the most inhibitory fatty acid with an IC_{50} of 23 μg/mL [36.18]. Some methoxylated FAs derived from marine sponges have shown antimycobacterial activity [36.19]. Propylene glycol mono and diesters of C_2–C_{10} FAs have been shown to be effective antifungal agents in the treatment of epidermophytosis. *Carballeira* et al. studied the antifungal activity of acetylenic FAs [36.20].

As Bactericides, Germicides, and Nematoxic Agents. Unsaturated FAs derived from cod-liver oil were found to be an effective therapeutic treatment of pulmonary tuberculosis, which showed that its addition in amounts of 1 : 50 000 retards growth of tubercle bacilli in vitro [36.21]. Neomycin salts of FAs, such as lauric, palmitic, and stearic acid, have been shown to demonstrate remarkable germicidal properties for the reduction of transient and resident bacteria present on the human skin. The C2–C11 FAs have been shown to be effective agents in suppressing nematode parasites. Inhibitory effects of C8 and C10 saturated FAs on Gram-positive and Gram-negative organisms have also been reported [36.22].

As Spermicidal Agents. The glyceryl, ethylene glycol, propylene glycol monoesters of C10–C18 unsaturated FAs, polyethylene glycol, polypropylene glycol esters of C10–C18 unsaturated FAs, glyceryl monolactate monoesters of C10–C18 unsaturated FAs or higher FAs, a C10 unsaturated FA or higher in combination with a sulfonated FA or in combination with alkyl phenoxyethanols, polyoxyethylene glycol mixed esters of C6 or higher FAs, e.g., dodecaethylene glycol monolaurate monooleate, polyoxyethylene glycol monoesters of C6 or higher FAs and their acetylated derivatives have been recommended for use as spermicides [36.23].

36.1.3 Biological Functions of PUFAs and Their Biomedical Applications

PUFAs fulfil many structural and functional roles and are unequalled amongst FAs in the wide spectrum of biological events in which they participate. First, PUFAs are critical components of cells and organelle membranes [36.24–26]. They are crucial for regulating the architecture, dynamics, phase transitions, and permeability of membranes, and for the control of membrane-associated processes. Moreover, they regulate membrane-bound proteins such as ATPase, transport proteins, and histocompatibility complexes, and modulate interactions with extracellular components such as fatty acid-binding proteins. In addition, PUFAs also regulate the expression of certain genes, including those coding for fatty acid synthase, nitric oxide synthase, sodium channel proteins, and cholesterol-7-α-hydroxylase and, thereby, affect processes including fatty acid biosynthesis, cancer induction and cholesterol regulation [36.27] and, thus, exhibit an impact on cellular biochemical activities, transport processes, and cell-stimulus responses. They are also implicated in physiological processes, including lipid metabolism and targeting immune responses and cold adaptation by lymphocyte stimulation, and are involved in pathological conditions such as carcinogenesis and cardiovascular disease [36.24–27].

Especially, some specific *n*-3 and *n*-6 PUFAs play an important role in human and animal health. The lack of such acids in animals and humans has slowed down

growth, induced skin diseases (eczema), and stopped the normal function of kidneys and the reproductive system [36.28]. The long-chain *n*-3 PUFAs are important for the brain and retina. Learning disabilities and loss of visual activity were reported in animals consuming low levels of *n*-3 essential FAs [36.29]. These FAs have a variety of beneficial effects in protecting against atherosclerotic disease. Diets (fish oils) enriched in FAs (especially EPA (EPA) (C20 : 5) and DHA (DHA) (C22 : 6) have produced effects associated with lowered serum triacylglycerols or plasma cholesterol and blood pressure [36.30], reduced platelet aggregability (prevention of thrombosis) and platelet function [36.31], and lower incidences of coronary heart disease, diabetes, rheumatism, and immunological responses associated with psoriasis [36.32].

36.2 Sponge Fatty Acids

Marine sponges are the most primitive multicellular animals and contain many bioactive metabolites including lipids [36.33, 34]. The study of sponge lipids is as important as other secondary metabolites. In depth studies on lipids of sponges started in the 1970s [36.35] and have been stimulated because of the great diversity of FAs, which have unusual and sometimes unique structures. Investigators focus on sponge lipids mainly for an interpretation new FA structures, biological activity, sources of biologically important major PUFAs, chemotaxonomy, etc.

Some unusual FAs of sponges exhibit biological activity and they are found to be antimalarial, antimycobacterial, and antifungal agents [36.17, 36]. Various application of lipids, phospholipids, and saturated and unsaturated FAs in pharmaceutical formulations have also been reported [36.37, 38]. Sponges (Demospongiae) are a source of novel FAs; especially unusual long-chain Δ5,9 FAs, sometimes have a third double bond or a bromine atom in their structures [36.39, 40]. Many new FAs were identified in sponge lipids, like unsaturated FAs with unusual distribution of double bonds [36.41], branched chain FAs [36.42], and FAs with unusual substituents in the carbon chain, such as the cyclopropane group [36.43], the methoxy group [36.44], the acetoxy group [36.45], etc. Demosponges possess unusual membrane lipids reflecting specific enzyme systems which control biosynthetic properties such as carbon chain elongation and the introduction of distinctive double bonds. In particular, many investigations revealed the presence of unique long-chain fatty acids (LCFA, >24) in demosponges, so-called demospongic acid. Demospongic acids like 23 : 2 Δ5,9 and 24 : 2 Δ5,9 were found to be antimycobacterial agents [36.46] and (5*Z*,9*Z*)-22-methyl-5,9-tetracosadienoic acid was found to be cytotoxic to cancer cells [36.47]. These compounds provide excellent targets for chemotaxonomic analyses at the class level [36.35, 48]. Sponge classification needs to be supported by chemotaxonomic criteria, in particular regarding FA. Particular FAs appear as biomarkers for such organisms. Complete and correct information on the lipid and fatty acid composition of sponges is necessary for the elucidation of biosynthetic pathways and functional role of FAs in these archaic organisms. Many sponges are able to synthesize lipids and FAs that can be extracted; some of these are presented below.

36.2.1 Saturated Fatty Acids

Linear Saturated Fatty Acids

Marine sponges are a good source of saturated FAs. They contain both short-chain as well as long-chain saturated FAs. Linear saturated FAs from C8 : 0–C32 : 0 are identified in the lipids of marine sponges. Among them, the percentage of C16 : 0 and C18 : 0 is much higher than in other FAs in most of sponges. Marine sponges such as *Spirastrella inconstans* and *Hyattella cribriformis* contain 95.8 and 63.9% C16 : 0, respectively [36.49]. C18 : 0 is found to be dominant in *Acanthella elongata* (39.1%) and *Acanthella cavernosa* (38.57%) [36.49]. Short-chain linear saturated FA C8 : 0 was identified in marine sponges like *Plakina monolopha* Schulze, *Cinachyrella alloclada*, and *Cinachyrella kukenthali* [36.49, 50]. C10 : 0, C11 : 0, and C12 : 0 were identified in *Hymeniacidon sanguinea* [36.51]. However, there are other sponge species that have a major content of long-chain saturated FAs. For example, in *Azorica pfeifferae*, C25 : 0 is the major constituent among the saturated FAs [36.52]. A long-chain saturated FA C28 : 0 was identified from the marine sponge *Xestospongia* sp. [36.53]. C29 : 0 was identified from the marine sponge *Cinachyrella alloclada* [36.50]. Linear saturated FAs from marine sponges are presented in Table 36.1.

It is interesting to note that the percentage content of saturated FAs of a marine sponge varies based on the depth of collection and the locations from which it is collected. The same sponge species collected from two different depths have different content of saturated FAs. It is mostly observed that the sponge species collected at shallow water contain a high content of saturated FAs. *Axinella carteri* collected in shallow water has a higher content of saturated FAs than the same species collected at a greater depth [36.54]. The content of saturated FAs of a sponge species also varies based on the location of where it was collected. The marine sponge *Phycopsis* sp. collected at two different regions was found to have a different content of saturated FAs [36.55]. Long-chain saturated FAs C22 : 0–C32 : 0 are identified in sponge lipids.

Monobranched Saturated Fatty Acids

Monobranched saturated FAs (most of them being iso- and anteiso – i. e. with methyl branching on the penultimate and antepenultimate carbon atoms, respectively) were particulary abundant in the marine sponges and their content may reach 40–50% of the FA total. The content of mono branched saturated FA in *Phycopsis* sp. 1 and 2 is 44.87 and 38.83%, respectively. While a long-chain monobranched FA i. e. 27-methyl octacosanoic acid was identified in the lipid of a marine sponge *Petrosia pellasarca* [36.30], a number of other monobranched long-chain FAs i. e., i-Me-C23 : 0, br-C25 : 0, br-C26 : 0, br-C27 : 0, br-C25 : 0 were identified from a marine sponge *Cinachyrella alloclada* [36.50]. Other marine sponges like *Axinella carteri*, *Didiscus oxeata* contain rarely found long-chain mono branched saturated FAs [36.54, 64]. These acids have bacterial origin and the high content of these acids in some sponges is due to the bacterial symbionts [36.65, 66]. Monobranched saturated FAs from marine sponges are presented in Table 36.2.

Table 36.1 Linear saturated FAs from marine sponges

Polybranched Saturated Fatty Acids

Polymethyl-branched saturated FAs are often found in marine sponges. The most abundant are 4,8,12-trimethyltridecanoic acid (TMTD) and phytanic acid. It was observed that the percentage composition of C16 : 0(3,7,11,15-tetramethyl) varied from species to species of the class Demospongiae. There are species of the Demospongiae class having no or trace amounts of 3,7,11,15-tetramethyl-C16 : 0 [36.59, 61], while the content was more than 20% in *Axinella carteri* [36.54]. The *Spheciospongia vesparium*, marine sponge contains 23% of 4,8,12-trimethyltridecanoic acid [36.67]. It was suggested by *Carballeira* et al. that these two acids do not occur together in the same sponge [36.67]. However, interestingly, the two isoprenoid FAs mentioned above occurred concomitantly in the marine sponges *Halichondria magniconulosa* and *Dragmaxia undata* [36.64]. Some sponges belonging to the genus *Cinachyrella* contain both 4,8,12-TMTD and 5,9,13-trimethyltetradecanoic acid. *Hymeniacidon sanguinea*, a marine sponge collected from the Canary Island contains 3, 13-di-Me-C14 : 0 [36.51]. A rare 4,8,11-trimethyl-C16 : 0 FA was found in *Suberites domuncula* [36.57]. 18,14-di-Me-C26 : 0 was identified from *Cinachyrella alloclada* [36.50]. A list of some of the polybranched saturated FAs from marine sponges is presented in Table 36.3.

Table 36.3 Polybranched saturated FAs found in marine sponges

36.2.2 Unsaturated Fatty Acids

Monounsaturated Fatty Acids

Linear MUFAs. Marine sponges are specified by great diversity of monoenic FAs (MUFAs) [36.69]. Among the monounsaturated FAs, C16 : 1 and C18 : 1 are widespread. C16 monoenic acids such as, C16 : 1(5), C16 : 1(6), C16 : 1(7), C16 : 1(8), C16 : 1(9), C16 : 1(11), and C16 : 1(18) have been identified in marine sponges, among which C16 : 1(9) is the most commonly found in sponges [36.54, 56, 58]. However, there are sponge species which are completely devoid of C16 monoenic acids [36.52]. Among C18 monoenic acids, C18 : 1(9) and C18 : 1(11) are found abundantly in marine sponges [36.69]. *Myrmekioderma granulata* contains a good amount of C18 : 1(9) acid. C18 monoenic acids such as C18 : 1(8) and C18 : 1(11) were reported from a marine sponge *Axinella carteri* [36.54]. C18 : 1(13) was identified in a marine sponge *Azorica pfeifferae*. C17 and C19 monoenic acids are rarely found in marine sponges. C19 : 1(11) was identified in some marine sponges like *Aplysina fistularis* and *Azorica pfeifferae* [36.52, 69].

Some marine sponge such as *Callyspongia fallax*, *Cinachyrella schulzei* and *Dysidea fragilis* contain C17 monoenic acids. C20 and C22 monoenic acids with double bonds at different positions have been identified in marine sponges. C20 : 1(11) monoenic acid has been found in a marine sponge *Fasciospongia cavernosa*, while the sponge *Axinella carteri* contains a C22 : 1(13) monoenic acid [36.54, 56]. Long-chain monoenic FAs with double bonds at different positions are also found in marine sponges. C23 : 1(16) was identified from *Amphimedon compressa* Pallas and *Mycale laevis* [36.70], C23 : 1(17) and C23 : 1(18) have been identified from *Microciona prolifera* and *Amphimedon compressa* Pallas, respectively [36.70, 71]. Both C24 : 1(7) and C24 : 1(9) monoenic acids occur in *Dysidea fragilis* [36.72], while C24 : 1 with

double bonds at 11 and 15 positions were identified from *Pseudaxinella* aff. *Lunaecharta* [36.73]. A C24 : 1(17) was also identified in the lipid of *Calyx podatypa* [36.74]. C25 : 1 with double bonds at 16 and 18 positions were identified from *Mycale laevis* [36.70], while C25 : 1 monoenic acid with double bonds at 17, 19, and 9 positions were reported from *Geodia gibberosa, Amphimedon compressa* Pallas and *Dysidea fragilis*, respectively [36.70, 72, 75]. 19-Hexacosenoic (26 : 1) was identified from *Cinachyrella alloclada* [36.50]. C27 : 1 monoenic acids, with double bonds at 18 and 20 positions were reported from *Cinachyrella* aff. *Schulzei*. C28 : 1 monoenic acids with double bonds at 5, 19, and 21 positions were identified from *Cinachyrella* aff. *Schulzei*, *Haliclona cinerea* and *Amphimedon compressa* Pallas [36.70, 76, 77]. 21-Triacontaenoic acid (30 : 1) and 23-triacontaenoic acid (30 : 1), two long-chain monoenic acids were identified from *Haliclona cinerea* [36.77]. A list of long-chain monoenic acids from marine sponges is presented in Table 36.4.

Branched MUFAs. Branched monoenic acids with branching at different positions have been identified from marine sponges. A number of monobranched monoenic acids such as 13-Me-C14 : 1(4), i-Me-C16 : 1(9), ai-Me-C16 : 1(6), 14-Me-C17 : 1(5), and i-Me-C17 : 1(9) have been identified from the marine sponge *Hymeniacidon sanguinea* [36.51]. Dimethyl monoenic acids like 7, 8-di-Me-C15 : 1(7) and 8,17-di-Me-C18 : 1(5) were identified from *Hymeniacidon sanguinea* and *Halichondria lutea*, respectively [36.51, 64]. 10,14-di-Me-15 : 1(6), a novel monoenic FA was reported in three marine sponges such as *Lissodendoryx pulviliformis, Tedania dirhaphis* and *Poecillastra* sp. collected from the Sea of Okhotsk [36.78]. The unique monounsaturated FA 15-Me-24 : 1(14) was observed for the first time in the sponge *Forcepia uschakowi* [36.79]. Novel monoenic acids like 2-Me-24 : 1 and 2-Me-26 : 1 along with br-C25 : 1 and br-C27 : 1 were revealed in the marine sponge *Halichondria panicea* [36.80]. The presence of long-chain monobranched monoenic acids such as 19-Me-C26 : 1(5), 19-Me-C27 : 1(5), and 19-Me-C28 : 1(5) have been reported in the marine sponge *Strongylophora durissima* [36.81]. The occurrence of 20-Me-C24 : 1(18) and 23-Me-C24 : 1(8) have also been reported in *Celtodoryx ciocalyptoides and Axinyssa ambrosia*, respectively [36.64]. A list of branched monoenic acids in marine sponges is presented in Table 36.5.

Polyunsaturated Fatty Acids

Linear PUFAs. Important polyunsaturated fatty acids (PUFAs) such as linoleic acid (36.C18 : 2(9,12), *n*-6) 7-linolenic acid (36.C18 : 3(6,9,12), *n*-6), dihomo-γ-linolenic acid (36.C20 : 3(8,11,14), *n*-6), α-linolenic acid (36.C18 : 3 (9,12,15), *n*-3), eicosatetraenoic acid (36.C20 : 4 (8,11,14,17), *n*-3) arachidonic acid (36.C20 : 4 (5,8,11,14), *n*-6) EPA (36.C20 : 5 (5,8,11,14,17), *n*-3), DHA (36.C22 : 6 (4,7,10,13, 16,19), *n*-3), etc. have been identified from several marine sponges. *Oceanapia* sp. and *Callyspongia fibrosa* contain 71.3 and 65.1% of C22 : 6, respectively [36.49]. *Acanthella elongata* contains 28.59% of α-linolenic acid [36.49]. Five numbers of PUFAs such as C18 : 2, C18 : 3, C20 : 4, C20 : 5, and C22 : 4 have been reported in *Raspailia* sp. [36.49]. A high percentage of linoleic acid was reported in *Fasciospongia cavernosa* [36.56]. Linoleic acid, α-linolenic acid,

eicosatetraenoic acid, eicosatetraenoic acid, eicosapentaenoic acid, docosatetraenoic acid, docosapentaenoic acid, and docosahexaenoic acid have been reported in the lipid composition of *Halichondria panicea* [36.60]. Linoleic acid, eicosatetraenoic acid, and eicosapentaenoic acid have been identified in the marine sponge *Verongia aerophoba* [36.61]. PUFAs such as linoleic acid, α-linolenic acid, 7-linolenic acid, and eicosatetraenoic acid along with rare PUFAs, such as C18 : 2(11,14), C18 : 2(5,11), C18 : 4(6,9,12,15), and C18 : 5(3,6,9,12,15) have been identified from the marine sponge *Hymeniacidon sanguinea* [36.51]. A rare polyenic acid i. e., C16 : 4(4,7,10,13) has been reported from the marine sponge *Callyspongia* sp. [36.86]. Two important PUFAs i. e., C22 : 6(4,7,10,13,16,19, *n*-3) and C22 : 5(7,10,13,16,19, *n*-3) have been reported in the marine sponge *Petromica ciocalyptoides* [36.64]. 7,13,16-docosatrienoic acid, a rare PUFA, has been identified from the marine sponge *Petrosia ficiformis* [36.87]. C28 : 2(9,21), a polyenic FA that is new for sponges, has been identified from *Mycale* sp. [36.78]. Very long-chain PUFAs such as 15,18,21,24-triacontatetraenoic acid (C30 : 4, *n*-6), and 15,18,21,24,27-triacontapentaenoic acid (C30 : 5, *n*-3) have been reported from the marine sponge *Cliona celata* [36.88]. 15,18,21,24-Tetratriacontatetraenoic (C34 : 4) and 19,22,25,28,31-tetratriacontapentaenoic acid (C34 : 5) have been reported from *Amphimedon compressa* and *Petrosia pellasarca*, respectively [36.30, 89]. A list of polyenic FAs from marine sponges is listed in Table 36.6.

Linear Δ5,9 FAs. Nonmethylene-interrupted dieneic FAs of various structures are found in marine sponges. In recent extensive review work on non-methylene-interrupted FAs of marine sponges and other marine invertebrate it has been reported that among all, Δ5,9 long-chain FAs are commonly found in marine sponges [36.91]. Δ5,9-FAs as with unbranched carbon chain and branched iso and anteiso structures and FAs with midbranched chains and sometimes with a third double bond occur among them the most often. Marine sponges (Demospongiae) are a good source of these FAs called demospongic acids. A number of FAs with double bonds at 5,9 positions have been reported from marine sponges. *Trikentrion loeve* and *Pseudaxinella* cf. *lunaecharta* contain 15 (25.7% of the total acid mixture) and 13 (30.4%) Δ5,9 FA, respectively [36.92]. *Axinella carteri* contains more than 40% C26 : 2(5,9) [36.54]. A marine sponge *Halichondria panicea* contains a good amount of C26 : 2(5,9). C25 : 2(5,9) is present in a good amount in the marine sponge *Azorica pfeifferae* [36.52]. C30 : 2(5,9) has been reported from the marine sponge *Petrosia pellasarca* [36.30]. A very long-chain FA

C34 : 5(19,22,25,28,31)	*Petrosia pellasarca*	[36.30]

C31 : 2(5,9) along with C22 : 2(5,9), C23 : 2(5,9), C24 : 2(5,9), C25 : 2(5,9), C26 : 2(5,9), C27 : 2(5,9), C28 : 2(5,9), and C31 : 2(5,9) have been reported from *Verongia aerophoba* [36.61].

C25 : 3(5,9,17) and C25 : 3(5,9,19) have been identified from *Dysidea fragilis* [36.72]. 26 : 3(5,9,19) was the main PUFA in marine sponges like *Hymeniacidon assimilis*, *Haliclona* sp., and *Mycale* sp. [36.78]. C27 : 3(5,9,19) and C27 : 3(5,9,20) have been identified from *Microciona prolifera* and *Halichondria panicea*, respectively [36.71, 93]. C28 : 3(5,9,19) was reported from *Xestospongia halichondroides* [36.94]. C28 : 3(5,9,21) was the main PUFA in sponges like *Poecillastra* sp., *Polymastia* sp., *Tedania dirhaphis*, *Lissodendoryx pulviliformis*, and *Myxilla incrustans* [36.78]. In the marine sponge *Tedania dirhaphis*, C28 : 3(5,9,21) constitutes 63.3% of the total FA content [36.95]. C28 : 3(5,9,23) was reported from the marine sponge *Aplysina fistularis* [36.96]. A new PUFA 28 : 3 Δ5,9,22 has been identified in *Stelodoryx toporoki* and *Myxilla incrustans* [36.78]. C29 : 3(5,9,22) has been identified from the marine sponge *Verongia aerophoba* [36.61]. C30 : 3(5,9,23) is the principal FA of the marine sponge *Chondrilla nucula*, which constitutes 34% of the total FA content [36.97]. A list of linear Δ5,9 FAs from marine sponges is given in Table 36.7.

Branched PUFAs. Branched PUFAs with various structures are reported from marine sponges. A rare branched Δ5,9 FA i. e., 15-Me-C16 : 2(5,9) has been identified from the marine sponge *Didiscus oxeata* [36.64]. Novel Δ5,9 FAs i. e., 17-Me-C19 : 2(5,9) and 18-Me-C19 : 2(5,9) were identified for the first time in the marine sponge *Pseudospongosorites suberitoides* [36.99]. 17-Me-C24 : 2(5,9) has been identified from *Chondrosia reniformis* [36.59]. Both iso-24 : 2(5,9) (30% of the total free FA) and anteiso-24 : 2(5,9) (19.5%) have been reported from the marine sponge *Geodinella robusta* [36.47]. ai–25 : 2(5,9) has been identified from a marine sponge *Haliclona* sp. [36.78]. 24-Me-C25 : 2(5,9) has been identified from *Petrosia ficiformis* [36.87]. 24-Me-25 : 2(5,9), 23-Me-25 : 2(5,9), 25-Me-26 : 2(5,9), 24-Me-C26 : 2(5,9), 25-Me-27 : 2(5,9), and Me-C28 : 2(5,9) have been reported from the marine sponge *Cinachyrella kukenthali* [36.50]. br-C27 : 2 has been identified from *Halichondria panicea* [36.60]. 22-Me-28 : 2(5,9) has also been reported from *Verongia aerophoba* [36.61]. A dimethyl Δ5,9 PUFA i. e., 22,27-di-Me-C28 : 2(5,9) has been reported from the marine sponge *Didiscus oxeata* [36.64]. A list of some branched PUFAs found in marine sponges is presented in Table 36.8.

36.2.3 Fatty Acids with Unusual Structures

Many new FAs with unusual substituents in the carbon chain, such as the cyclopropane group [36.4], the methoxy group [36.44], the acetoxy group [36.45] etc., have been reported from marine sponges.

Three novel cyclopropane FAs such as 17-Me-4,5-methylene-C18 : 0, 18-Me-4,5-methylene-C19 : 0, and 17-Me-4,5-methylene-C19 : 0 were reported for the first time from the marine sponge *Pseudospongosorites suberitoides* [36.99]. 19,20-Methylene-C26 : 0 has been identified in the sponge *Calyx niceansis* [36.101], while the sponge *Amphimedon* sp., collected in Australia, contains 10,11-methylene-C27 : 2(5,9), a topoisomerase I inhibitor with an IC_{50} = 1.21M [36.102]. 9,10-Cyclopropyl-C16 : 0 and 11,12-cyclopropyl-C18 : 0 were reported from marine sponges like *Hymeniacidon sanguinea, Chondrosia reniformis* and *Verongia aerophoba* [36.51, 59, 61].

The marine sponge *Polymastia gleneni* contains nine saturated long-chain (C22–30)-acetoxy FAs with an acetoxy group in the second position of the carbon chain [36.45]. Methoxylated FAs from marine sponges were reviewed by *Carballeira* in 2002 [36.103]. 2-Methoxy-14-methylpentadecanoic acid and the novel 2-methoxy-14-methylhexadecanoic acid have been identified in the sponge *Agelas dispar* [36.104]. 2-Methoxy-12-methyltetradecanoic acid was identified for the first

time from *Pseudospongosorites suberitoides* [36.99]. 2-Methoxylated saturated FAs such as 2-methoxytetradecanoic acid, 2-methoxypentadecanoic acid, and 2-methoxyoctadecanoic, as well as the monoenoic methoxylated FAs such as 2-methoxy-6-tetradecenoic acid, 2-methoxy-6-pentadecenoic acid, and 2-methoxy-13-methyl-6-tetradecenoic acid were identified for the first time in nature in the phospholipids from the Caribbean sponge *Callyspongia fallax* [36.105]. 2-Methoxy-C15 : 0 has been reported from the marine sponge *Petromica ciocalyptoides* [36.64]. Novel fatty acid 2-methoxy-C16 : 2(5,9), 2-methoxy-C18 : 2(5,9), 2-methoxy-C19 : 2(5,9), and 2-methoxy-C20 : 2 along with the iso-methyl-branched FAs such as 2-methoxy-15-methyl-C16 : 1(9) and 2-methoxy-15-methyl-C16 : 2(5,9) have been identified in *Erylus goffrilleri* [36.106].

2-Hydroxy-C20 : 0, 2-hydroxy-C21 : 0, 2-hydroxy-C22 : 0, 2-hydroxy-C24 : 0, 2-hydroxy-23-methyl-C24 : 0, and 2-hydroxy-C25 : 0 have been isolated from the Caribbean sponges *Verongula gigantea* and *Aplysina archeri* [36.107]. 2-Hydroxy-C22 : 0 and 2-hydroxy-C23 : 0, have been identified in the Caribbean sponge *Amphimedon compressa* and constitute 52% of the total FA content [36.89]. 2-Hydroxy-C20 : 0, 2-hydroxy-C22 : 0, 2-hydroxy-C24 : 0, and 2-hydroxy-C26 : 0 have been reported from the marine sponge *Dragmaxia undata* [36.64]. 2-Hydroxy-C24 : 0 and 2-hydroxy-C25 : 0 have been found in *Halichondria lutea* [36.64]. 2-Hydroxy-C26 : 0 has been found in the marine sponge *Axinyssa ambrosia* [36.64].

Many acetylenic FAs have been reported from marine sponges. 12-Methyloctadeca-17-ene-5-ynoic acid, 2-methoxy-12-methyloctadeca-17-ene-5-ynoic acid, and 2-methoxy-12-methyloctadeca-17-ene-5-ynoic anhydride are the new acetylenic FAs reported from marine sponges of the genus *Stelletta* [36.108]. Bioactive brominated acetylenic acids have been reported from marine sponges like *Petrosia volcano* Hoshino, *Xestospongia muta*, *Xestospongia testudinaria*, etc. [36.109–111].

Brominated $\Delta 5,9$ FAs have been reported from marine sponges. 6-Br-26 : 2(5,9) has been reported from the marine sponge *Forcepia uschakowi* [36.79]. Very long-chain brominated FAs such as 6-Br-C24 : 2(5,9), 6-Br-23-Me-C24 : 2(5,9), 6-Br-C25 : 2(5,9), and 6-Br-24-Me-C25 : 2(5,9) have been reported from *Agelas* sp. [36.112]. 6-Br-C24 : 2(5,9), 6-Br-C25 : 2(5,9), and 6-Br-C26 : 2(5,9) have been reported from *Amphimedon terpenensis* [36.113]. 6-Br-C27 : 2(5,9), a bioactive FA has been reported from the marine sponge *Xestospongia* sp. [36.114]. Branched brominated FAs such as 6-Br-24-Me-C26 : 2(5,9) and 6-Br-25-Me-C26 : 2(5,9) have been revealed in marine sponges like *Petrosia ficiformis* and *Petrosia hebes* [36.100]. 6-Br-23-Me-C24 : 2(5,9), 6-Br-C25 : 2(5,9), and 6-Br-24-Me-C25 : 2(5,9) have been reported from the marine sponge *Axinyssa ambrosia* [36.64].

36.3 Bioactive Lipids/FAs from Marine Sponges

Marine FAs are of interest for the different roles and biological properties they exhibit in the cells of marine organisms. Some of these FAs have displayed interesting biological activities. The literature survey indicates that antimicrobial activity is exhibited by many lipids of sponges [36.115–118], including FAs [36.119, 120]. *cis*-9-octadecenoic and *cis*-9,12-octadecadienoic acids [36.118, 121] have maximum antimicrobial activity. Among a series of linear-chain saturated FAs (C_2–C_{20}), myristic acid displays the strongest bactericidal activity at 0.04 mM against a highly virulent strain (Ravenel) of *Mycobacterium bovis* and an avirulent strain ($H_{37}Ra$) of *Mycobacterium tuberculosis* [36.132]. Many reports on the study of antibacterial and antifungal activity of synthetic saturated, monounsaturated FAs and PUFAs are available [36.120, 133–136]. The anti-inflammatory properties of marine lipid compositions have also been studied [36.137]. Recent findings on the antimalarial, antimycobacterial, and antifungal properties of novel FAs derived from marine sponges are well documented in an extensive review by *Carballeira* [36.17]. The antimicrobial activity of FAs derived from marine sponges was reviewed by *Abad* et al. [36.138]. Methoxylated FAs derived from

Table 36.9 Bioactive FAs from marine sponges

Bioactive FAs	Marine sponge	Bioactivity	Reference
Mixture of 23-Me-C24 : 2(5,9) and 22-Me-C24 : 2(5,9)	*Geodinella robusta*	Cytotoxicity	[36.47]
6-Br-C27 : 2(5,9)	*Xestospongia* sp.	Cytotoxicity	[36.114]

6-Bromo-icosa-3*Z*,5*E*,8*Z*,13*E*,15*E*-pentaene-11,19-diynoic acid	*Haliclona* sp.	Cytotoxicity against NBT-T2 rat bladder epithelial cells	[36.123]
Methyl-18-bromooctadeca-9*E*,17*E*-diene-7,15-diynoate	Unidentified sponge	Antimicrobial	[36.124]
6-{5-[(5*E*)-Oct-5-en-7-ynyl]thiophen-2-yl}hex-5-ynoic acid	*Paragrantia* cf. *waguensis*	Antimicrobial	[36.125]
12-Methyloctadeca-17-ene-5-ynoic acid 2-Methoxy-12 methyloctadeca-17-ene-5-ynoic acid 2-Methoxy-12-methyloctadeca-17-ene-5-ynoic anhydride	*Stelletta* sp.	Cytotoxicity against human leukemia cell-line (K562)	[36.108]
Callysponginol sulfate A	*Callyspongia truncata*	MT1-MMP Inhibitor	[36.126]
7*E*,11*E*-Tetradecadiene- 5,9-diynoic acid.	*Oceanapia* sp.	Antimicrobial	[36.127]
10,11-Methylene-C27 : 2(5,9)	*Amphimedon* sp.	DNA Topoisomerase I inhibitor	[36.102]
Brominated C18 acetylenic acids	*Petrosia volcano* Hoshino	Antifungal	[36.109]
Brominated polyacetylenic acids	*Xestospongia muta*	HIV Protease inhibitors	[36.110]
Xestospongic acid and ethyl ester of xestospongic acid	*Xestospongia testudinaria*	Antimicrobial	[36.111]
Brominated C14 PUFAs	*Oceanapia* sp.	Cytotoxicity against KB cells	[36.128]
Carticatic acids A–C	*Petrosia carticata*	Antifungal	[36.129]
Br-C27 : 3(5,9,24) Br-C28 : 3(5,9,24)	*Xestospongia* sp.	Cytotoxicity against L1210 murine leukaemia cells and KB human epidermoid carcinoma cells	[36.114]
18-Brominated C23 acetylenic acids	*Phakelia carduus*	Antibacterial	[36.130]
C30 : 3(5,9,23)	*Chondrilla nucula*	Elastase inhibitor	[36.117]
C30 : 3(5,9,21)	*Amphimedon* sp.	DNA Topoisomerase I inhibitor	[36.102]
cis C23–C26 Δ5,9 FAs	*Agelas oroides*	Enoyl reductase inhibitor Antiprotozoal activity	[36.46]
Amphimic acids A and B	*Amphimedon* sp.	DNA Topoisomerase I inhibitor	[36.131]

marine sponges have been found to have antimycobacterial activity [36.19]. Methoxylated FAs display biological activities like antibacterial, antifungal, antitumor, and antiviral activities [36.103]. 2-methoxy-5-hexadecenoic acid and 2-methoxy-6-hexadecenoic acid have shown antimicrobial activity [36.139]. The antifungal activity of FAs was also studied by *Carballeira* et al. [36.20]. The antimalarial properties of *n*-3 and *n*-6 PUFAs have been studied, where acids such as 22 : 6 (*n*-3), and 20 : 5 (*n*-3) have been found to be the most effective for the in vitro killing of intraerythrocytic forms of *Plasmodium falciparum* [36.140]. Again, consumption of *n*-3 highly unsaturated FAs, such as linolenic acid, EPA (20 : 5, *n*-3), and DHA (22 : 6, *n*-3), is correlated with a reduced risk of cancer and cardiovascular disease in clinical and animal studies [36.7, 8]. Epidemiological studies suggest that there is low prevalence of diabetes in populations with a high intake of *n*-3 PUFAs [36.9, 10]. Δ5,9 long-chain FAs of marine sponges are good topoisomerase inhibitors as well as some of them are cytotoxic to cancer cells. C27 : 2(5,9) inhibited human topoisomerase I with an IC_{50} of 0.9 μM [36.102, 131], while a mixture of 23-Me-C24 : 2(5,9) and 22-Me-C24 : 2(5,9) was cytotoxic to mouse Ehrlich carcinoma cells with ED_{50} of 1.8 μg/mL and showed a hemolytic effect on mouse erythrocytes [36.47]. A brominated Δ5,9 i. e. 6-Br-C27 : 2(5,9), showed cytotoxicity towards L1210 murine leukaemia cells (IC_{50} = 11 μg/mL) and KB human epidermoid cancer cells (IC_{50} = 18.5 μg/mL) [36.114]. A marine FA, 2-methoxy-13-methyltetradecanoic acid was cytotoxic to human chronic myelogenous leukemia K-562 (EC_{50} = 238 ţm), histiocytic lymphoma U-937 (EC_{50} = 250 mM) and promielocytic leukemia HL-60 (EC_{50} = 476 mM) in RPMI 1640 medium [36.141]. A list of some bioactive FAs from marine sponges is presented in Table 36.9.

36.4 Summary

Marine sponges are bestowed with a remarkable diversity of FAs. The first work of research on the lipid composition of marine sponges was carried out by *Litchfield* and colleagues [36.35], who studied 31 species of Demospongiae sponges. Similarly, *Bergquist* and *Lawson* and their colleagues [36.142, 143] compared the FA composition of 80 sponge species from New Zealand and Australia. *Thiel* and colleagues [36.144] also studied the FA composition of marine sponges. The composition of FAs and other lipids of marine sponges have been well documented in a series of extensive reviews by *Berge* et al. [36.69, 145]. They are the important sources of some enriched saturated and unsaturated FAs and contain biomedically important (*n*-3) or (*n*-6) PUFAs viz., linoleic acid (C18 : 2), α-linolenic acid (C18 : 3), dihomo-γ-linolenic acid (C20 : 3, *n*-6), arachidonic acid (C20 : 4), EPA (C20 : 5), etc. Further, LCFAs, important MUFAs, branched and polybranched saturated and unsaturated FAs, and FAs with unusual structures are also reported in most of the marine sponges. Some of the FAs of marine sponges are active and possess anticancer, antifungal, antibacterial, etc., properties.

These studies lead to the conclusion that the composition of different individual FAs vary greatly within the marine sponges. The FA characteristics of marine sponges can reveal the characteristic chemotaxonomic attributives of sponges in a family at genus levels and permit further interpretation of LCFA biosynthetic pathways in sponges. Further studies on the FA profile of marine sponges will lead to the discovery of new FA structures and certainly other important FAs that possess new biological activities.

37. Marine Biotoxins

Aníbal Martínez, Alejandro Garrido-Maestu, Begoña Ben-Gigirey, María José Chapela, Virginia González, Juan M. Vieites, Ana G. Cabado

This chapter revises current knowledge on marine biotoxins that are known nowadays, considering all the distinct groups based on chemical structure and lipophilic or hydrophilic characteristics. Diarrheic shellfish poisoning (DSP), paralytic shellfish poisoning (PSP), amnesic shellfish poisoning (ASP), azaspiracid shellfish poisoning (AZP), ciguatera fish poisoning (CFP) are some of the groups that will be reviewed in this chapter.

The recent development and application of advanced technologies from the generically defined *-omics* sciences coupled with bioinformatics platforms has been included in this chapter in order to understand the ecology and evolution of phytoplankton species and bloom dynamics. Dinoflagellate toxins are structurally and functionally diverse, and many present unique biological activities.

The literature and information regarding the biological activities and the potential application of these phycotoxins has been gathered in this book section.

Marine biotoxins are natural compounds mainly produced by marine microalgae, dinoflagellates, and diatoms. A small percentage of algae produce toxins that can harm human beings and also pose a deadly risk. Toxins are nonproteinaceous metabolites with different and complex structures, physical properties, and specific mechanisms of action. In general, they have low molecular weight ranging from 250 to 3000 Da. Shellfish and fish may become contaminated with these phycotoxins due to accumulation through marine food webs. Risk to humans often results in gastrointestinal disease, loss of short-term memory, neurological disorders, paralytic effects, or even death. In addition, the threat of marine biotoxins is not only a major cause of concern on human health and food safety, but it is also detrimental to the explotation of marine resources

around the world and the economy of shellfish producers and associated industries, including tourism. This chapter revises current knowledge on marine biotoxins that are known nowadays, considering all the distinct groups based on chemical structure and lipophilic or hydrophilic characteristics. Diarrheic shellfish poisoning (DSP), paralytic shellfish poisoning (PSP), amnesic shellfish poisoning (ASP), azaspiracid shellfish poisoning (AZP), ciguatera fish poisoning (CFP) are some of the groups that will be reviewed in this chapter. Contamination by marine biotoxins often involves more than one group of toxins and monitoring programs typically cover a range of toxins. There has been an increased effort to develop rapid and feasible screening methods for marine biotoxins. Many methods to detect toxins and phytoplankton have several technical and, sometimes, ethical limitations and generally lack an adequate validation. Functional assays, rapid screening tests, generally based on immunological methods and molecular biology techniques, among others are attractive alternatives to toxins and microalgae characterization. In this chapter, different approaches to monitor and specific detection of shellfish toxins and dinoflagellates are reviewed taking into account the availability of resources. The potential use of several techniques for marine biotoxins or phytoplankton characterization, such as biosensors, applied immunology, PCR, sequencing, radioisotopic, flow cytometry, metabolomics, and proteomics will be explained along the chapter. Marine phytoplankton comprised both prokaryotic and eukaryotic species that share a common ability to photosynthesize and thus thrive in the upper, euphotic zone of the worlds' oceans. Together, the prokaryotic and eukaryotic phytoplankton support marine food webs, including valuable fisheries and play a key role in the regulation of global biogeochemical cycles. Identification and quantification of individual species remains a difficult task. The recent development and application of advanced technologies from the generically defined *-omics* sciences coupled with bioinformatics platforms has been included in this chapter in order to understand the ecology and evolution of phytoplankton species and bloom dynamics. Dinoflagellate toxins are structurally and functionally diverse, and many present unique biological activities. At present, marine biotoxins include an extraordinary potential source of new bioactive compounds for pharmaceutical or medical uses constituting an emergent field of interest. Sometimes, the toxin itself is directly used as a drug, although more often the toxin lead compound provides a design idea for the development of a drug molecule. The biological activities of these phycotoxins are harmful to the target organisms, since the function of the toxin is either to protect the toxic species from attack by a predator or to immobilize the potential preys. Despite the damage in the target organism, toxins have a great potential for not target organisms, in particular for therapeutic purposes in humans. For instance, the target of many marine neurotoxins is the Na^+ channel, though the sites of interaction and, thus, the pharmacological effects differ among compounds. In this context, phycotoxins can be invaluable tools to recognize and identify ionic channels and the specific role of each channel subtype in controlling cell function, exocytosis, or the Ca^{2+}-dependent release of a given neurotransmitter. The literature and information regarding the biological activities and the potential application of these phycotoxins has been gathered in this book section.

37.1 Marine Toxins

Marine biotoxins are produced by certain species of toxic phytoplankton and can accumulate in various marine species: fish, crustacean, or molluscs such as mussels, clams, oysters, and scallops. In shellfish, toxins mainly accumulate in the digestive glands without causing adverse effects on the shellfish itself. However, when contaminated shellfish is consumed by humans this may lead to a severe intoxication or even death, causing public health and economic problems.

Currently, five groups of marine toxins are regulated in Europe: amnesic shellfish poisoning toxins (ASP), paralytic shellfish poisoning toxins (PSP), okadaic acid (OA) and pectenotoxin group (DSP), azaspiracid group, and yessotoxin group (EC/853/2004) [37.1]. Another group, neurotoxic shellfish poisoning (NSP) toxins (e.g., brevetoxin) is regulated in United States, New Zealand, and Australia. Many cases of tetradotoxin food poisoning are reported in Southeastern Asia as well as ciguatera fish poisoning (CFP) that was limited to tropical and subtropical areas. Other emerging toxins (Palytoxin, cyclic imines,) are not on the radar of the European Legislation or in other regions of the world. Scientists and legislative authorities are aware of these toxins but do not have sufficient amount of information related to their activity, estimation of the toxicity and risk assessment in humans [37.2].

37.2 Lipophilic Toxins

37.2.1 Okadaic Acid-Group (OA) Toxins and Pectenotoxin-Group Toxin (PTXs)

OA-group toxins are a class of marine biotoxins that include OA and dinophysis toxins (DTX1, DTX2, and DTX3). These toxins cause Diarrhetic Shellfish Poisoning (DSP), which is characterized by symptoms such as abdominal pain, diarrhea, nausea, and vomiting. These toxins are produced by planktonic dinoflagellates, *Dinophysis* genus, and the benthic *Prorocentrum* genus and can be found mainly in shellfish.

They were first reported in Netherlands in 1960s [37.3, 4] and in Japan in 1978 [37.5]. Nowadays, their distribution is considered worldwide, Europe, Japan, North and South America Australia, Indonesia, and New Zealand [37.6].

OA-group toxins are heat-stable polyether compounds [37.7]. While OA and DTX2 only differ by the position of one methyl group in the molecule, DTX1 has one additional methyl group. DTX3 represents a wide range of derivatives of OA, DTX1, and DTX2 that form *acylated* analogues when they are esterified with saturated and unsaturated fatty acids. Acylated analogs were reported to contribute considerably to the concentration of total OA-group toxins [37.7, 8].

OA and DTXs act by inhibiting serine/threonine phosphoprotein phosphatases PP1 and PP2A.These enzymes perform the dephosphorylation of numerous proteins; this function is closely related to many essential metabolic processes in eukaryotic cells [37.9, 10].

Pectenotoxins (PTXs) frequently co-occur with the OA-group. The presence of PTXs in shellfish was discovered due to high acute toxicity in mouse bioassay (MBA) after intraperitoneal (*i.p.*) injections of lipophilic extracts. Animal studies indicate that they are much less potent via the oral route and they do not induce diarrhea. PTXs have been detected in microalgae and/or bivalve mollusks in Australia, Italy, Japan, New Zealand, Norway, Portugal, and Spain and they are produced by *Dinophysis* spp.

PTXs are cyclic polyether macrolides that include over 15 analogs. PTX1 to PTX 5 were originally isolated from Japanese scallops, *Patinopecten yessoensis* [37.11]. More recently, other PTXs were found but only four analogs (PTX2, PTX12, PTX11, and PTX13) have been identified as actual biosynthetic products of the algae. Other PTXs seem to be either product of the shellfish metabolism or artifacts [37.12].

37.2.2 Yessotoxin-Group Toxins (YTXs)

Yessotoxins (YTXs) are a group of structurally related polyether toxins produced by the dinoflagellates *Protoceratium reticulatum*, and *Lingulodinium polyedrum*, and *Gonyaulax spinifera* [37.13]. YTXs had traditionally been included within the DSP group but the EU has excluded the YTXs from the DSP group in 2004, and nowadays, YTXs are considered as a separate group in the current regulation [37.1].

YTXs was first isolated in Japan, in 1986 [37.14] from the digestive gland of *P. yessoensis*, a scallop that gave its name to the toxin. More recently, YTXs have been reported worldwide, in Korea [37.15], Chile [37.16], and New Zealand [37.17]. In Europe, it has been described in mollusks in Norway, Italy, Spain, and Russia [37.13].

YTXs are disulfated polyethers, with a characteristic ladder-shape formed by 11 adjacent ether rings of different sizes and a terminal acyclic unsaturated side chain consisting of nine carbons and two sulfate ethers [37.13, 14]. The presence of the sulfo-ether group makes these molecules the most polar of the lipophylic toxins. More than 90 YTXs congeners have been reported but structures for most of them have not been determined and only 30 have been isolated [37.13, 18].

There is discrepancy between the toxicity via oral administration and *i.p.* injection and the precise mechanism of action is not yet known [37.13]. Several studies have been carried out to clarify this, it seems clear that YTXs do not inhibit phosphatases PP1 and PP2A [37.19]. They modulate Ca^{2+} homeostasis in human lymphocytes [37.20] and produce a cytotoxic effect during in vitro experiments in various cellular models, F-actin decrease, alter cell adhesion and cause apoptotic events [37.6].

37.2.3 Azaspiracid-Group Toxins (AZAs)

Azaspiracids (AZAs) are a group of marine biotoxins that accumulate in shellfish and represent an emerging human health risk [37.21]. They were originally isolated from blue mussels from Killary Harbour (Ireland) and produced an outbreak of shellfish poisoning in the Netherlands, in 1995. Afterward, seafood contamination by AZAs have been reported in different coastal localizations, including Europe, North and South America, Africa, and Japan [37.22–26].

There have been several attempts to identify the AZA-producing organism(s). *James* et al. [37.27] have detected the presence of AZA-1, 2, and 3 in extracts from the heterotrophic dinoflagellate *Protoperidium crassipes*. However, this organism is supposed to act as a vector and nowadays, *Azadium spinosum* is considered the organism that produces these compounds [37.28].

AZAs are nitrogen-containing polyether toxins involving a unique spiral ring assembly containing a heterocyclic amine and an aliphatic carboxylic acid moiety [37.6, 27, 29]. They have been identified as AZA1 to AZA5 and numerous natural analogs and artifacts of methanolic solution (methyl ester analogs). AZA4 and AZA5 seem to be a biotransformation product of primary compounds into shellfish.

AZA1 is highly potent and capable of producing an important degradation of the intestinal tract and finally the death of rodent. In vitro assays, AZAs elevate caspase activity, increase cellular concentrations of Ca^{2+} and cAMP, induce irreversible cytoskeletal rearrangements, deplete cellular ATP, inhibit neuronal ion flux and bioelectrical activity, inhibit cell–cell adhesion and stimulate cholesterol biosynthesis [37.21, 25]. Human symptoms of intoxication include nausea, vomiting, and stomach cramps, but thus far, no deaths have been attributed to AZAs [37.25].

37.3 Hydrophilic Toxins

37.3.1 Saxitoxin-Group Toxins (STXs)

Saxitoxin (STXs)-group toxins include various naturally occurring neurotoxic alkaloids that induce the so-called paralytic shellfish poisoning (PSP) in humans. PSP is characterized by symptoms varying from a slight tingling sensation or numbness around the lips to fatal respiratory paralysis [37.30]. The intake of toxins necessary to induce PSP symptoms varies greatly. This may be due to differences in susceptibility as well as a lack of precision in exposure assessments due to problems with sampling and analysis of contaminated shellfish at the time of intoxication.

They have been detected in bivalve mollusks from various areas of the world. Several decades ago, few localizations appeared to be affected by PSP; but nowadays they are found worldwide [37.31–33].

STXs are mainly produced by toxic dinoflagellates belonging to the genus Alexandrium: e.g., *A. tamarensis*, *A. minutum* (*syn. A. excavata*), *A. catenella*, *A. fraterculus*, *A. fundyense*, and *A. cohorticula*, *Gymnodimium, Pyrodinium* and they have also been identified in some cyanobacteria which may occur in fresh and brackish waters.

Most of STX-group toxins are water-soluble and heat-stable nonproteinaceous compounds whose basic structure is composed of a 3,4-propinoperhydropurine tricyclic system. Up to 57 different STX analogs have been described and they can be divided into subgroups based on substituent side chain such as carbamate, sulfate, hydroxyl, hydroxybenzoate, or acetate and also decarbamoyl variants [37.6]. STX, NeoSTX, GTX1, and dc-STX seem to be the most toxic analogs. These neurotoxins produce a blockade of ion conductance through the voltage-gated Na^+ channel (VGSC) in nerves and muscles fibers [37.30].

37.3.2 Domoic Acid

Domoic acid (DA) is a potent neurotoxic amino acid that accumulates in high concentrations in shellfish, anchovies, and sardines that feed on the toxic phytoplankton. DA can affect marine animals, seabirds, and humans via consumption of this contaminated shellfish causing amnesic shellfish poisoning (ASP). DA was first reported in Canada in 1987 when it caused various human deaths after consuming DA-contaminated mussels [37.34]. Effects on both gastrointestinal tract and nervous system were observed including vomiting, nausea, diarrhea, abdominal cramps, and hemorrhagic gastritis; neurological symptoms are headache, dizziness, vision disturbances, disorientation, loss of short-term memory, motor weakness, seizures, profuse respiratory secretions, hiccoughs, unstable blood pressure, cardiac arrhythmia, and coma. Neurological symptoms may occur after a delay of a few hours or up to 3 days [37.35]. DA especially harms the hippocampus and amygdaloid nucleus in the brain and damages the neurons by activating α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and kainate receptors, causing an influx of Ca^{2+} and cell degeneration [37.36, 37].

DA is produced by the red alga *Chondria armata* and also from the diatoms *Pseudo-nitzschia* spp. and

Nitzschia [37.38]. It is a water-soluble and heat-stable cyclic amino acid and it is structurally very similar to another known neurotoxin, the kainic acid [37.39]. Several isomers of DA (epi-domoic acid (epi-DA), (domoic acid C5′-diastereomer) and isodomoic acids A, B, C, D, E, F, G, and H (iso-DA A–H)) have been reported as well [37.7]. Iso-DA A, B, and C have not been detected in shellfish tissue. DA transforms into epi-DA through long-term storage [37.40] and degrades and transforms to epi-DA and iso-DAs through exposure to ultraviolet light [37.41–43]. In addition, the epimerization is also accelerated by heating [37.44].

37.4 Other Toxins

37.4.1 Ciguatoxins-Group Toxins

Ciguatoxins (CTXs) are a class of marine biotoxins that cause CFP. CTXs occur in fish as a result of biotransformation of precursor gambiertoxins produced by the benthic dinoflagellate *Gambierdiscus* spp. They are mainly associated to tropical and subtropical areas, but recently CTX-group toxins were identified for the first time in fish in Europe [37.45]. Various congeners of CTXs have been identified according to differences in their molecular structure: Pacific (P-CTX), Caribbean (C-CTX), and Indian (I-CTXs) [37.46].

Symptoms of the intoxication of ciguatera in humans include gastrointestinal and neurological effects [37.47]. Although, *Gambierdiscus toxicus* has been traditionally considered the main species responsible for CTXs production, nowadays it is known that *Gambierdiscus* spp. shows a high degree of complexity and it is composed of genetically and morphologically toxin producer species. Thus, distantly related groups co-occur across geography. Ten *Gambierdiscus* species were reported in the Atlantic and in the Pacific region [37.48, 49], and other new species were found in European Atlantic waters and in the Mediterranean Sea [37.50].

The congeners of CTXs are lipophilic polyethers compounds consisting of 13−14 rings fused by ether linkages into a rigid ladder-like structure. CTXs are colorless, tasteless, odorless, and relative heat stable, devoid of heteroatoms other than oxygen and bear few conjugated bonds. Nowadays, over 50 chemical congeners of CTXs have been identified whose toxicity can vary significantly: more than 100-fold among species of *Gambierdiscus* spp. compared with a 2 to 9-fold within species variation due to changing growth conditions [37.49]. The chemical structures of more than 20 P-CTXs analogs, main CTX in Pacific areas, have been identified, and structural modifications are seen in both termini of the toxin molecules, mostly by oxidation. Two CTXs from Caribbean sea (C-CTXs) were first isolated by *Vernoux* and *Lewis* in 1997 [37.51], and then were identified structurally. Other additional congeners were identified in 2002 [37.52]. More recently, four Indian Ocean CTXs (I-CTXs) have been reported [37.53], but their structural determination remains to be established.

The VGSC (Na_V) is the primary molecular target of CTXs, and their binding to the neurotoxin receptor site 5 of Na_V causes the opening of the ion pore, activation of the channels, and Na^+ entrance into the cells. Membrane depolarization and functional impairment of excitable cells are produced due to Na^+ entry into the cell. Secondary responses observed in cells exposed to CTXs include Ca^{2+} into the cell by reverse action of Na^+/Ca^{2+} exchangers eventually leading to muscular contraction and neurotransmitter release. Na^+ influx also affects the entrance of water into the cell, leading to cell swelling, blebbing, and cytotoxicity [37.45].

37.4.2 Brevetoxins (BTX)

Brevetoxin-(BTX) group toxins are neurotoxic polyether biotoxins which can accumulate in shellfish and fish. They are primarily produced by a dinoflagellate *Karenia brevis* (formerly called *Gymnodinium breve* and *Ptychodiscus brevis*) first identified in the Gulf of Mexico in 1947 [37.54–56]. However, other algae species (*Chattonella antiqua*, *Chattonella marina*, *Fibrocapsa japonica*, *Heterosigma akashiwo*) have also been reported to produce BTX-like toxins [37.57]. BTXs have been described in several localizations such as North America, New Zealand, Australia, Japan and Scotland [37.57–59]. *K. brevis* or *K. brevis*-like species have also been reported from Japan, New Zealand, West-Atlantic, Spain, Portugal, and Greece [37.57]. Nevertheless, no intoxication outbreaks in humans or occurrence of BTX-group toxins in shellfish or fish have been reported in Europe [37.55].

They are grouped into types A and B based on their molecular backbone structures. BTX-1 (or PbTx-1)13 (type A) and BTX-2 are considered to be the parent toxins from which other BTX-group toxins derive [37.60]. BTX A has a backbone of 10 fused cyclic ether rings; BTX B (most abundant in *K. brevis*) has a backbone of 11 fused cyclic ether rings [37.60–62]. It is important to highlight that BTX-group toxins are metabolized in shellfish and fish, yielding several metabolites of BTX-group toxins that finally affect to consumers [37.55, 63].

Ion channels are the principal target of BTXs by binding to receptor site 5 of the VGSC in cell walls [37.60] leading to an uncontrolled Na^+ influx into cells and depolarization of neuronal and muscle cell membranes. The response to BTXs in different cells, organs or in vivo models is dependent on various factors, such as the existence of different VGSC subtypes expressed.

37.4.3 Tetrodotoxin (TTXs)

TTX (11-[^{3}H]-tetrodotoxin) is a neurotoxin that has been identified from taxonomically diverse marine organism. Its name derives from *Tetraodontiformes*, an order that includes pufferfish, ocean sunfish or mola, triggerfish, among others. However, TTX has been described in a diverse range of phylogenetically unrelated organism, such as newts, frogs, nematodes, starfish, crabs, mollusk, and others. It has also been suggested that TTX is produced by symbiotic bacteria. Actually, there has been a debate between source of production of TTX from animals or bacteria, and nowadays it has not been firmly established a conclusion. TTX may serve as an antipredator defense, offensive weapon, or for within- and between-species communication [37.64].

Although TTX is associated to tropical waters, mainly South Asia and more specifically Japan, it has been also identified in Mexico and United States [37.65]. In Europe, TTX has been reported in migrant puffer fish in Greek waters [37.66] and in a gastropod *Charonia lampas lampas* in Portugal [37.67].

TTX is a heat-stable and water-soluble heterocyclic guanidine with a highly unusual structure containing a single guanidinium moiety attached to a highly oxygenated carbon backbone that consists of a 2,4-dioxaadamantane structure with five hydroxyl groups [37.68].

Tetrodotoxin binds to site 1 of the fast VGSC [37.33]. Site 1 is located at the extracellular pore opening of the ion channel. The binding of any molecules to this site temporarily disables the function of the channel. Saxitoxin, neosaxitoxin also bind the same site although TTX has different affinities for the variant Na^+ channel isoforms that confer resistance to various species [37.69]. TTX causes paralysis of voluntary muscles (including the diaphragm and intercostal muscles, stopping breathing), and reduced blood pressure, predominantly by vasodilatation. Early symptoms of this effect might include among others weakness, tingling of the lips, and dizziness [37.70]. Gastrointestinal symptoms are often severe and include nausea, vomiting, diarrhea, and abdominal pain. Cardiac arrhythmias may precede complete respiratory failure and cardiovascular collapse.

37.4.4 Palytoxin (PITXs) and Analogs

Palytoxin (PlTX) is one of the most poisonous nonprotein substances known to date. PlTX was first isolated and purified from *Palythoa toxica* [37.71] and currently present a worldwide distribution [37.71, 72]. PlTXs have also been detected in other marine zoanthids (soft corals) of the genus *Palythoa* (e.g., *P. tuberculosa*, *P. vestitus*, *P. mammilosa*, *P. carobaeorum*, *P. aff. Margaritae*) and benthic dinoflagellates of the genus *Ostreopsis* (e.g., *Ostreopsis siamensis*, *O. mascarenensis*, *O. ovata*) [37.73]. Blooms of *Ostreopsis* spp. have also been reported in European countries such as Spain, France, Italy, and Greece [37.74].

The PlTX-group toxins are complex polyhydroxylated compounds with both lipophilic and hydrophilic areas. They are white, amorphous, hygroscopic solids. At least eight different PlTX analogs are known: PlTX, ostreocin-D, ovatoxin-A, homopalytoxin, bishomopalytoxin, neopalytoxin, deoxypalytoxin, and 42-hydroxypalytoxin [37.75].

The main accepted molecular action of palytoxin is blockage of the Na^+/K^+-ATPase pump [37.76–78]. This binding inhibits the active transport of Na^+ and K^+ across the cell membrane that is essential for cell homeostasis, by transforming the pump into a nonspecific permanently open ion channel [37.79]. Symptoms of PlTX-group toxins intoxication are not well defined, but include weakness and myalgia, fever, nausea, and vomiting.

37.4.5 Cyclic Imines (CIs)

Cyclic imines (CIs) are a recently discovered group of marine biotoxins formed by: spirolides (SPXs), gymnodimines (GYMs), pinnatoxins (PnTXs), pte-

riatoxins (PtTXs), prorocentrolides, and spiroprorocentrimine. These toxins are macrocyclic compounds with imine- (carbon–nitrogen double bond) and spiro-linked ether moieties. They are grouped together due to that imino group acts as functioning pharmacophore [37.80] and the similarities in their *i.p.*, toxicity in mice [37.6, 81].

SPXs are the largest group of cyclic imines and together with GYMs are the best characterized. SPXs were described for the first time in contaminated shellfish, in 1991, in Canada [37.82]. These toxins are metabolites of dinoflagellates *Alexandrium ostenfeldii* and *Alexandrium peruvianum* and are sometimes found in the presence of other toxins such as PSP toxins [37.83]. Up to 14 SPXs analogs have been described of which 13-desmethyl SPX C is the most commonly found in shellfish [37.81].

GYMs are produced by the dinoflagellates *Karenia selliformes* and first isolated in oysters from New Zealand [37.84]. PnTXs and PtTXs are the CI structurally and synthetically more related to SPXs. PTXs were first discovered in extracts from the digestive glands of pen shell, *Pinna attenuata* in China and Japan [37.85]. Seven PnTXs analogs (PnTXs A-G) have been characterized [37.81]. Pteriatoxins A, B, and C, were isolated from the Okinawan bivalve *Pteria penguin* in 2001 [37.86]. *Torigoe* et al. [37.87] isolated the Prorocentrolide A for the first time from *Prorocentrum lima* and then the Prorocentrolide B was first isolated from *P. maculosum* in 1996 [37.88]. Finally, Spiro-prorocentrimine was isolated from a laboratory-cultured benthic *Prorocentrum* species of Taiwan by *Lu* et al. [37.89]. At present, it is accepted that nicotinic and muscarinic acetylcholine receptors are their principal target.

37.4.6 Maitotoxins (MTXs) and Gambierol

Maitotoxins (MTXs) and gambierol are a group of water-soluble toxins produced by species of dinoflagellates of the genus *Gambierdiscus*, which grow on algae in tropical waters around the world. *Gambierdiscus* is known to produce both MTX and CTXs, which accumulate in the body of herbivorous fish and are transmitted through the tropical food chain to carnivorous species.

MTX is a polyketide-derived polycyclic ether integrated by four rigid polyether ladders connected by mobile hydrocarbon chains. Maitotoxin includes 32 ether rings, 22 methyls, 28 hydroxyls, and 2 sulfuric acid esters and has an amphipathic structure [37.90–92].

Maitotoxin activates Ca^{2+} permeable, nonselective cation channels, leading to an increase in levels of cytosolic Ca^{2+} ions. It is thought that maitotoxin leads to the formation of pores on these ion channels. Finally, a cell death cascade is activated, resulting in membrane blebbing and ultimately cell lysis [37.93]. Maitotoxin is known to activate cytosolic Ca^{2+}-activated proteases calpain-1 and calpain-2, contributing to necrosis [37.94].

Gambierol was described as a potent potassium voltage-gated channel blocker that exhibits potent acute lethal toxicity against mice (minimal lethal dose: 50 µg/kg, *i.p.*) and it is suspected to participate in the symptoms of CFP.

37.5 Biotechnological Techniques Used to Study Toxic Microalgae and Marine Biotoxins

The potential use of several techniques for marine biotoxins or phytoplankton characterization are explained along the chapter. In general, the sensitivity of the analytical methods and bioassays depends on the toxins studied. Combination of several approaches, including chromatography-based techniques, to identify individual toxins and the overall toxicity of the mixture, should provide an ideal alternative. Thus, a synergistic complement can be obtained by coupling biological and or functional assays with analytical techniques based on the physicochemical properties of the toxins.

37.5.1 Immunological Methods

The main advantage of the immunological techniques is the variety of immunoglobulins for the specific detection of different targets. These are characterized by sensitivity, specificity, fast performing, and automation. However, the corner stone for these methods seems to be the quality of the antibody presenting cross-reactivity limitations.

An unequivocal identification of phytoplancton and detection of phycotoxins can be obtained by using a species-specific antibody against the target organism

or group of toxins. Specific polyclonal or monoclonal antibodies can be reactive to one epitope and therefore more specific. Combination of some of them, allows the identification, counting, and examination of marine phytoplankton. Use of antibodies with fluorescent markers has made possible to apply different technologies, such as microscopy, flow cytometry, or flow cam. The light emitted by a labeled antibody can be detected by a fluorescent microscope, equipped with a UV light, a flow cytometer a confocal microscope or a flow cam. For instance, several monoclonal antibodies were obtained against different species of *Alexandrium* allowing the unequivocal identification of the dinoflagellate *A. minutum* [37.95]. Then, using immunofluorescence could help to identify different species in natural samples during coastal monitoring.

To discriminate and count small cells or a large number of samples, flow cytometry can be used. Designed to automate the rapid analysis and identification of cells, flow cytometry is a reliable method for the routine monitoring of the abundance of phytoplankton species, leading to an early detection of HABs. This is an optimal instrument for analyzing cells ranging from 0.5 to 20 μm in diameter (concentrations between 10^6 to 10^9 cells/L [37.96].

In this context, a modified flow cytometer, known as FlowCam, was developed to handle larger cells. It is an integrated system combining the capabilities of flow cytometry, microscopy, imaging, and fluorescence that counts, takes images and analyses the particles that range in size from 20 to 200. In addition, to monitor harmful species of microalgae, other potential applications of immunodetection include studies of plankton community structure and ocean optics. Other authors used Imaging FlowCytobot that combines video and flow cytometric technology to capture images of nano- and microplankton and to measure the chlorophyll fluorescence associated with each image. The images are of sufficient resolution to identify many organisms to genus or even species level [37.97].

The use of immunological assays has become a promising alternative for detecting small molecules such as marine biotoxins and many kits are commercially available.

Enzyme-Linked Immunosorbent Assays (ELISAs)

The enzyme-labeled immunosorbent assay ELISA is a powerful analytical tool for natural toxins detection. Specific antibodies recognize toxins and this bound complex is quantified by labeling the free component with a reporter enzyme, usually horseradish peroxidase (HRP) acting as an amplifier to produce many signals. The use of the 96-well microtitre polystyrene plate, the automation and the competitive principle are the most commercial immunoassays for natural toxins.

The ASP ELISA for the determination of DA was approved by the EU as an alternative to the official chemical method HPLC-UV detection [37.98]. This kit is a direct competitive immunoassay where free DA in the sample competes with DA-conjugated protein coated on plastic wells for binding to antidomoic acid antibodies in the solution. Other ELISA tests were developed as the Ridascreen Fast PSP, a competitive ELISA for the quantitative analysis of STX and related toxins. A monoclonal antibody with high affinity against brevetoxin B was used to develop a competitive ELISA for detection of brevetoxins in molluscs [37.99]. Production of monoclonal antibodies for immunoassays by immunizing mice with a synthetic hapten conjugate, instead of the natural toxins, allowed the detection of Pacific ciguatoxins using a direct sandwich ELISA [37.100, 101]. Recently, an improvement of the efficiency and simplification of a colorimetric competitive indirect immunoassay ELISA was carried out based on direct labeling via a covalent bond to the anti-OA antibody [37.102, 103] and a chemiluminiscent ELISA method for this toxin was also developed [37.104].

The challenge of designing antibodies with the optimal specificity and matching toxicity with toxic levels is further complicated by the structural and toxicological diversity within a toxin group together with a potential chemical conversion and biotransformation. However, since recombinant antibodies have been successfully constructed against PITX [37.105], similar strategies could help the challenge for complex toxins groups. Lack of standardization and transferability of in house ELISA tests between laboratories should be overcome by increasing the focus on validation, based on new strategies for production of high-quality antibodies. Nevertheless, a comparative evaluation of ELISAs and EU reference methods for the detection of the hydrophilic toxins ASP and PSP was carried out in many seafood products [37.106]. The high correlation coefficient between official and immunoassays proves that these tests can be used as screening systems in a variety of species without matrix interference. However, the best sensitive bioassay will depend on the toxins evaluated. In this context, the advantages and disadvantages of ELISA and cytotoxicity assays to detect BTXs were recently reviewed [37.107].

Phage Display Technology

The phage display technology refers to the expression of peptides, proteins, or antibodies on the surface of filamentous bacteriophage viruses. This in vitro strategy provides a valuable system for easy and rapid generation of specific antibodies fragments directed against different antigens, including difficult targets as small molecules. Semisynthetic phage display libraries were used to select recombinant antibodies against PlTX. Some antibodies proved high affinity for immobilized and free PlTX in a competitive ELISA with a low detection limit, a very reproducible standard curve and a wide working range [37.105].

Biosensors

Biosensors are measuring systems based on a biological recognition component with three functioning parts: a biological element, cells, microorganisms, antibodies, the transducer, capable of measuring a biomolecular interaction and converting it into a signal, and the electronics, responsible for the display of the results easily interpreted.

Most of the biosensors developed for shellfish toxins are immunosensors and the optical biosensor with surface plasmon resonance (SPR) is the most widely used in the large majority of reported platforms [37.108]. It has been incorporated into a wide range of devices to measure the analytes present in a sample. For most biomolecules, the change in response is proportional to the mass of the material bound to the surface of the sensor chip. The measure of the binding response against time is called *sensorgram* [37.109]. Small molecular weight compounds, as many drugs and toxins, are very difficult to measure. Then, an inhibition assay approach that relies upon the immobilization of analytes to the chip surface and the injection of the binding partner over the chip surface was developed. Using this assay format, the level of binding to the surface is inversely proportional to the concentration of the target analyte present in the sample. There are three key elements that determine the way in which the methods perform.

- The binding protein, often an antibody, is essential in terms of delivering a specific molecular interaction with the target analyte.
- The surface chemistry is a very important parameter in an SPR assay. Small compounds can be immobilized via the production of an analyte–protein conjugate and this, in turn, is immobilized onto the surface on a sensor chip via an amine or carboxyl coupling strategy. While this approach can be relatively straightforward, it has two main disadvantages. Firstly, during the regeneration of the chip surface, the immobilized conjugate can alter its three-dimensional structure and, thereby, bring about a different level of interaction with antibodies during subsequent interaction measurements. Secondly, the lifespan of an immobilized conjugate on a chip surface tends to be very short. The sensor chips tend to be the most expensive part of the assay, resulting in a high costper test. A much better way to produce chip surfaces is through the direct immobilization of the analyte onto the sensor surface, being much more robust and stable than the conjugate approach.
- The type of method used for sample preparation has to be compatible with this analytical approach. In general, due to the advantages of SPR over conventional immunoassays, i. e., as they are nonequilibrium based and flow through based, in many cases the requirement for a highly purified sample extract can be avoided [37.96].

Some examples of biosensors for DA, OA, PSP, or TTX have been developed, tested and/or validated [37.96, 110–113]. However, one challenge for these assays is the ability to simultaneously measure multiple biotoxins in a single bioanalytical system as was performed in a Framework 7 Project entitled CONFFIDENCE (www.conffidence.eu). Within this project, the SPR methods developed for DSP, ASP, and PSP are being combined onto a single sensor chip using a multichannel biosensor developed as part of another European project Biocop (www.biocop.org).

Comparison of ELISA and SPR biosensor technology for detection of PSP toxins shows that the method of choice will depend on the end-user needs. Some authors point out the reduced manual labor and simplicitiy of SPR biosensor compared to ELISA, ease of sample extraction, and superior real time semiquantitave analysis [37.114], although lower costs and high sensitivity are some advantages of the ELISA.

DNA-biosensors have specific probes that target only DNA-sequences present in the organism of interest and can be used on-site and therefore circumvent the need to return samples into the laboratory. A DNA-biosensor was adapted by *Metfies* et al. to the electrochemical detection of the toxic dinoflagellate *A. ostenfeldii* [37.115]. The technical background of this device is explained in detail in the German patent application DE 10032 042 A1 (Elektrochemischer Ein-

wegbiosensor für die quantitative Bestimmung von Analytkonzentrationen in Flüssigkeiten). The device could facilitate the work that must be undertaken in the course of monitoring toxic algae by eliminating the need to count algae and reduce the toxins tests.

An immunosensor based on magnetic beads as support to immobilize OA on the surface of SPE and then to perform indirect competitive immunoassay using differential pulse voltammetry as a method of electrochemical detection [37.116]. Modifications of this automated flow-through amperometric immunosensor were performed for highly sensitive detection of OA [37.117, 118]. Other sensors include the molecularly imprinted polymer (MIP)-based sensors that use templates to provide polymers with specific recognition properties and chemosensors based on the photoinduced electron transfer (PET) sensing of the toxins by synthetic fluorophores.

Lateral Flow Immunochromatography

Lateral flow immunochromatographic assays are based on a competitive immunoassay format, similar to the home pregnancy test and provide a qualitative indication to the presence of OA and analogs, and DA. These methods also faced the same antibody cross-reactivity challenge.

37.5.2 Enzymatic, Colorimetric, and Other Tests

Several studies based on the mechanism of action of OA-group toxins, inhibition of the enzyme PP2A, were designed and adapted. Some systems as fluorimetry or colorimetry were the most common employed [37.119, 120], although other as electrochemical biosensors were also reported [37.102, 121].

Numerous colorimetric protein phosphatase inhibition assays have been recently reviewed [37.102, 103]. An enzymatic colorimetric test, OkaTest, based on the OA-group of toxins mechanism of action, was recently internationally validated to be used as an alternative or complementary to the reference method for monitoring the OA toxins group in molluscs [37.122] according to Commission Regulations (EC) No. 2074/2005 [37.123] and No. 15/2011 [37.124].

Recently a ligand binding assay was developed to detect cyclic imine in the frame of the Atlantox project, within the Atlantic Area Operational Programme (Atlantox 2008-1/003): www.atlantox.com. This assay, under patent, is based on the mechanism of action of these toxins that act on the nicotinic acetylcholine receptor.

A fast, simple, and sensitive capillary electrophoresis-based immunoassay with electrochemical detection was developed for STX and analogs in shellfish. The method was based on competitive reactions between HRP-labeled antigen and free antigen with a limited amount of antibody [37.125].

The feasibility of OA detection in real-time by using an acoustic wave platform with a microfluidic feature and an ELISA-like protocol was recently reported [37.126].

37.5.3 Receptor Binding Assay (RBA)

The receptor binding assay (RBA) is a high-throughput method for detection of toxins in extracts of seawater and shellfish. This method is based upon the competition between radiolabeled and unlabeled toxins for available receptor sites. The radioactive toxin is displaced from its receptor by toxin present in an unknown sample, thereby, reducing the total radioactivity. Thus, the amount of radioactively labeled toxin that is displaced is proportional to the amount of toxin in the unknown sample. Then, the toxin present in an unknown sample can be quantified by comparison to a standard curve obtained using pure toxin.

RBA was developed from the isolation of VGSC obtained from animal tissues, and was basically implemented by competitive measures of radioactivity using tritiated saxitoxin ([^{3}H]-STX) or brevetoxin (PbTx). Vieytes et al. published a rapid and sensitive method that used Na^+ channels obtained from rat brain membranes to detect PSP toxins. Na^+ channels were coated onto microtiter plates and were used to develop a direct solid-phase binding assay [37.127]. Years later, more developed method was described by *Doucette* et al. based on microplate scintillation technology. Good quantitative agreement of the assay with MBA and HPLC analysis of crude extracts of contaminated shellfish, as well as PSP toxin-producing algae, was observed [37.128]. Usup reported about binding properties of six saxitoxin congeners using [^{3}H]-STX and a preparation rich in Na^+ channels. In this study, EC50 values ranged from 4.38 nM for STX to 142 nM for GTX5 [37.129].

RBA has been refined in the last decade for the detection of PSP toxins. These methods suffer from limitations such as the availability of radio-labeled materials. Restrictions on the world-wide distribution of [^{3}H]-STX imposed by the international Chemical

Weapons Convention in 1997 served to other radiolabeled toxin development such as 11-[^{3}H]-tetrodotoxin (TTX) [37.130, 131]. In 2004, thanks to collaborative efforts among the US Food and Drug Administration (FDA), International Atomic Energy Agency (IAEA), and the National Oceanographic and Atmospheric Administration (NOAA), the worldwide unavailability of ^{3}H saxitoxin was solved temporarily. A relative stable [^{3}H] STX is now distributed worldwide by IAEA and was used in collaborative trials of the PSP toxins using receptor binding assay [37.132]. The assay used a competition among PSP toxins, in shellfish extracts, and a labeled ^{3}H STX diHCl for binding to VGSC in a rat brain membrane preparation. Quantification of binding was carried out using a microplate or traditional scintillation counter. The study focused on the ability to measure the PSP toxicity of samples below, near, or slightly above the regulatory limit of 800 µg STX diHCl equiv/kg [37.1]. The correlation with the MBA (OMA 959.08) yielded a correlation coefficient (r2) of 0.84, while correlation with the precolumn oxidation HPLC method (OMA 2005.06) yielded a (r2) of 0.92. This method has been accepted as official method of analysis AOAC (OMA 2011.27) [37.133].

Similar to PSP toxins method; BTX RBA is a functional bioassay in which an unknown quantity of nonradiolabeled BTX competes with radiolabeled BTX [^{3}H]PbTx-3, for the site 5 receptor of VGSC. Although, the assay using direct detection of a radiolabeled probe, bound to rat brain membranes, is a simple and robust format of pharmacological assays; other variations have been also tested using phospholipid vesicles [37.134] and membranes from other animals than rats [37.135, 136]. More recently other study has compared various extracts of BTX using four independent methods: RBA, radioimmunoassay (RIA), neuroblastoma (N2A) cytotoxicity assay, and liquid chromatography/mass spectrometry (LC-MS). As determined by LC/MS, the RBA, RIA, and N2A cytotoxicity assay detected 73, 83, and 51% of the total BTX concentration [37.137].

RBA designed for CTXs traditionally measures the binding competition between CTX in the sample and a [^{3}H]PbTx standard for the Na^+ channel receptor. The use of [^{3}H]PbTx is a necessity, as nowadays no tritiated CTXs is available. It should to be noted that RBA was successfully applied for monitoring programs on ciguatera risk in three islands of French Polynesia [37.138, 139].

In the case of ASP toxins, the RBA quantifies DA activity by the competitive displacement of radiolabeled kainic acid from a cloned glutamate receptor by DA in a sample. In 1997, *Van Dolah* et al. [37.140] reported the further development of the receptor assay using a cloned rat GLUR6 glutamate receptor. The limit of detection and selectivity of the assay were optimized through inclusion of the glutamate decarboxylase (GLDC) pretreatment step to eliminate potential interference due to high concentrations of endogenous glutamate in shellfish. However, as GLDC was difficult to obtain from suppliers, other variations were introduced [37.141].

Due to limitations of the standard AOAC MBA for estimation of toxins levels there was a need for alternative testing protocols. The relevance of RBA tools is high, but the need for specific equipment and licensing requirement for the use of radiolabeled compounds may lead to obvious limitations in the application of this assay. Some main disadvantages include the high dependency on the receptor source, it does not provide any information on the toxin profile, it cannot be easily automated, and it has been validated only for a few toxins. However, RBA is adequately sensitive and more specific than MBA [37.45]. Attempts to modify this assay to use label other than tritiated forms has led to the development of a competitive RBA based upon the use of BTX-B2 labeled with a chemiluminescent acridinium moiety. The acridinium brevetoxin-B2 seems to be a promising alternative to the conventional radioactive ligand in order to avoid constraints associated with RBA [37.46, 142].

37.6 Biotechnology Application for Phytoplankton Detection, Monitoring, and Toxins Production

Recent development and application of advanced technologies from the generically defined *-omics* sciences (genomics, transcriptomics, proteomics, and metabolomics) coupled with bioinformatics platforms has already provided deep and often revolutionary shifts in understanding the ecology and evolution of phytoplankton species and bloom dynamics [37.143].

Harmful algal blooms (HABs) are natural events that have become common in coastal waters worldwide during the last years, being recurrent in Euro-

pean coastal waters. The toxic microalgae responsible for these blooms are mainly dinoflagellates, which display heteromorphic life cycles, including motile planktonic stages, as well as immotile benthic resting cysts [37.144, 145].

Monitoring of harmful species is important to understand population dynamic activities related to the exploitation of coastal areas. To distinguish species by their morphological characteristics, cells must be examined by light, epifluorescence, or electron microscopy. This can be time consuming, and requires taxonomic expertise. Moreover, in some cases, morphology-based diagnostic tests lead to misidentification due to the existence of morphologically closely related species. Molecular methods, generally based on the DNA probe hybridization and PCR techniques, have been developed for the rapid and sensitive identification of HAB species [37.145–147]. The target DNA genes are generally within ribosomal RNA operons, which are repeated in high copy number in the microalgae genome and can be genus or species specific, as 18S, 28S, 5.8S, ITS1, and ITS2 among others.

37.6.1 Genomics

Conventional genomics is often based upon the sequencing and annotation of whole genomes, with subsequent bioinformatics focus on the structure and function of key groups of genes. However, the ability to perform genetics experiments with microalgae has been accelerated in recent years by the availability of genome sequences. The application of emerging genomics techniques to phytoplankton research is likely to become widespread in the future.

Sequencing

Currently, there are more marine cyanobacterial genome sequences available than eukaryotic phytoplankton genome sequences, primarily due to differences in genome size and complexity. The average cyanobacterial genome size is 2–3 million base pairs (Mbp), although they range up to 9 Mbp. In contrast, eukaryotic genomes tend to be orders of magnitude larger [37.148]. Completed genome projects have focused on species with relatively small genomes, ranging from 12 [37.149] up to 57 Mbp [37.150]. The recent availability of marine phytoplankton genome sequences has prompted a wealth of research in diverse fields including ecology, evolution, biochemistry, and biotechnology.

Concerning eukaryotic marine phytoplankton, it must be considered that it includes phylogenetic lineages resulting from primary, secondary, and tertiary endosymbiosis events. This phylogenetic and physiological diversity is translated into a wide range of potential genome sizes, structures, metabolic pathways, life histories, and evolutionary relationships. Of the four major lineages of eukaryotic phytoplankton, whole genome sequences are currently available for two; the heterokonts [37.150, 151] and the prasinophytes [37.149, 152]. Additional members of the heterokont and haptophyte lineages are in the pipeline for sequencing or draft genomes are being analyzed (e.g., the haptophyte *Emiliania huxleyi*; http://genome.jgi-psf.org/Emihu1/Emihu1.home.html) [37.148].

Genomics are more than simply genome sequencing including transcriptional analyses of both sequenced [37.153, 154] and unsequenced organisms [37.155], and also targeted metagenomics of ecologically important but uncultured phytoplankton [37.156].

One of the challenges in examining structural diversity in eukaryotic phytoplankton is the large number of novel genes identified in each newly sequenced genome that have no homology to genes with known or suspected functions. Often, they are similar only to genes of unknown function in closely related organisms. Depending on the genome, the number of novel genes ranges from 20 to nearly 40% highlighting the limitations of homology-based approaches. Differences in gene structure (e.g., novel splice sites, signal peptides, and untranslated regions) constitute a challenge to gene-calling algorithms designed for higher plants and metazoans. One solution has been the development of tiling arrays for sequenced genomes [37.148] that differs from traditional microarrays in the nature of the probes. Instead of probing for sequences of known or predicted genes that may be dispersed throughout the genome, tiling arrays probe intensively for sequences which are known to exist in a contiguous region. This is useful for characterizing regions that are sequenced, but whose local functions are largely unknown. Using tiling arrays *Mock* et al. [37.154] predicted 3470 new genes in the *Thalassiosira pseudonana* genome that were not previously identified using standard gene-calling algorithms. This 33% of increase in the total number of genes predicted in the *T. pseudonana* genome suggests that gene density and number are not fully captured using standard gene-finding algorithms. Sequenced genomes also highlight the phyloge-

netic and metabolic diversity that characterizes marine phytoplankton. Description of new lineages, such as the uncultured picohaptophytes suggests that probably many ecologically important lineages have yet to be discovered [37.156].

Investment in genetic techniques both available and robust in a diverse array of marine phytoplankton will greatly help in understanding gene function, especially for the large number of hypothetical and conserved hypothetical genes [37.148]. New approaches have emerged and will continue to emerge that rely on genome sequence data. For example, whole genome microarrays include a range of targets such as all annotated genes or even the whole genome. New directions in this area will use genome information from diverse keystone species to create microarrays for use in characterizing environmental samples; mRNA sequencing approaches such as Illumina sequencing generate only short reads and can take advantage of available genomes to examine gene expression. For example, mRNA from two conditions is used to generate cDNA libraries that are sequenced to obtain quantitative gene expression profiles that can be compared.

The application of these emerging genomics techniques to phytoplankton research is likely to become widespread in the future. One challenge beyond the genomics revolution is to apply these techniques in the marine environment to examine phytoplankton physiology in situ. This will mean synthesizing many different types of data simultaneously such as real-time physical and chemical environmental variables, community species composition, gene expression profiles, and protein signatures. This system-level approach has the potential to greatly expand our understanding of how phytoplankton acts in their environment [37.148].

PCR and Real-Time PCR (qPCR)

qPCR is a very promising technique in terms of sensitivity, specificity, enumeration capability, and costs reduction [37.145, 157]. Molecular approaches, when used together with other morphological characters, may help to solve taxonomical problems. The nuclear rDNA internal transcribed spacer regions and the 5.8S rRNA gene are widely used to characterize the phylogenetic aspects of a great variety of these organisms [37.147, 158–160].

Even though these applications are very valuable regarding human health, the use of PCR and qPCR for the direct detection and identification as well as monitoring of toxic phytoplankton is of special interest. Several studies have been developed for simplex and multiplex detection of different groups, genus and/or species, as *Alexandrium*, *Ostreopsis*, or different cyanobacteria [37.161–164]. It is important to highlight the fact that environmental samples often contain complex mixtures of organic matter, which may inhibit PCR/qPCR, thus an internal amplification control (IAC) should be included to avoid misinterpretation of false-negative results. Additionally, different strategies have been applied to overcome the problem of PCR/qPCR inhibition caused by contamination substances: the use of thermostable DNA polymerase, commercial nucleic acid extraction kits that remove inhibitors and facilitate purification, dilution of template DNA prior to PCR/qPCR assays and the use of bovine serum albumin in the PCR/qPCR assay [37.144, 163]. Several studies have been published applying PCR/qPCR for monitoring HAB worldwide, from the Mediterranean Sea to Australia [37.157, 164–166].

Regarding toxin quantification/detection, it is more often performed by other techniques, but different studies have also been performed applying PCR/qPCR. In 2011, *Murray* et al. developed a method targeting the unique core gene *sxtA* to identify saxitoxin-producing HABs in Australian marine water [37.165]. Their method was tested against different species and strains of *Alexandrium*, *Ostreopsis*, *Gymnodinium* among others. *Al-Tebrineh* et al. also developed a qPCR method capable of detecting SXT producing species, but they took advantage of the higher throughput of multiplex formats of qPCR and also targeted the genes coding for microcystin (*mcy*), nodularin (*nda*), cylindrospermopsin (*cyr*) in a multiplex qPCR experiment to specifically detect toxin producing species [37.163].

Microarrays

In a microarray study, gene-specific probes are spotted onto precise positions on a solid surface and targeted with an unknown DNA or RNA sample. Microarrays represent the scaling up, miniaturization, and automation of well-known hybridization techniques. Recently, a FP7 European research project called MIDTAL (Microarrays for the detection of toxic algae) aimed to construct a universal microarrayfor the detection of harmful algae and their toxins (htpp://www.midtal.com/). Results obtained showed the third generation of the MIDTAL microarray that includes between 140 and 163 probes for various toxic algal species including ASP, DSP, and PSP producers. The designed microarray has great potential to be used as a monitoring tool for toxic algae detecting multiple species simultaneously although improvements in RNA extraction

and tests are still needed [37.167]. The most obvious advantage of the microarray is its ability to identify species that cannot be identified with traditional methods, such as *Pseudo-nitzschia*, *Alexandrium*, and *Heterosigma* [37.168, 169].

Other Genomic Techniques

Other techniques different from sequencing and PCR have been also applied in phytoplankton studies. These include restriction fragment length polymorphism (RFLP), the first DNA-based technique used in phytoplankton studies; denaturing gradient gel electrophoresis (DGGE); single stranded conformation polymorphism (SSCP); random amplified polymorphic DNA (RAPD); amplified fragment length polymorphism (AFLP); Microsatellites or short sequence repeats (SSRs); molecular probes and single nucleotide polymorphisms (SNPs). Most of these techniques were quite useful to study phytoplankton especially when no sequences were available because they can be used without prior knowledge of the genome [37.170].

37.6.2 Transcriptomics

Transcriptomic studies gather efforts to isolate all the RNA transcripts, i. e., the transcriptome, from a sample of cells, and determine the presence and abundance of each particular species of gene-encoding RNA or mRNA. These studies help to elucidate genes involved in nutrient acquisition and metabolism (including those involved in synthesizing or regulating the synthesis of toxic molecules), aid in annotating genomes, and also have the potential to find novel transcripts or transcripts with unusual structures that may hint at the mechanism of gene regulation [37.143, 171, 172].

For many organisms with either large and/or complex genomes, transcriptome sequencing may be a more immediate and cost-effective route than whole genome sequencing to obtain ecological and evolutionary information.

An expressed sequence tag or EST is a short subsequence of a cDNA. They may be used to identify gene transcripts in gene discovery and sequence determination. The identification of ESTs has proceeded rapidly, with approximately 74.2 million ESTs now available in public databases (e.g., GenBank 1 January 2013, all species). The cDNAs used for EST generation are typically individual clones from a cDNA library. The resulting sequence is a relatively low quality fragment whose length is limited by current technology to approximately 500–800 nucleotides. Because these clones consist of DNA that is complementary to mRNA, the ESTs represent portions of expressed genes. They may be represented in databases as either cDNA/mRNA sequence or as the reverse complement of the mRNA, the template strand. ESTs can be mapped to specific chromosome locations using physical mapping techniques, such as radiation hybrid mapping, Happy mapping, or FISH. Alternatively, if the genome of the organism that originated the EST has been sequenced, one can align the EST sequence to that genome using a computer.

EST analysis of the dinoflagellate *A. minutum* revealed 192 genes that were differentially expressed between isolates that produced PSP toxins and those that did not [37.173]. In terms of the functional ecology of *A. minutum*, the 192 genes are putative candidates for genes involved in toxin synthesis and regulation or acclimation to intracellular PSP toxins. The sequences in the EST library also suggest that PSP toxins generated by this alveolate did not arise from a recent gene transfer from cyanobacteria, as was previously hypothesized [37.173]. Other dinoflagellate EST sequencing projects have yielded further insights into toxin production, predator–prey interactions, genome architecture, and trophic status. As sequencing costs drop and capabilities increase, transcriptome analyses of marine phytoplankton species and strains within species will soon become not only feasible but also common. This approach has also been recently applied to *A. ostenfeldii* [37.143, 174].

37.6.3 Proteomics

The field of proteomics is complementary to genomics and transcriptomics since it provides additional information on gene expression and regulation. Proteomics include the determination of protein expression levels and protein–protein interaction studies. Moreover, proteomics aim to identify posttranslational modifications of proteins, as well as the organization of proteins in multiprotein complexes and their localization in tissues [37.172].

In the past decade, genomics began to explore the diversity, cellular evolution and adaptive abilities of marine phytoplankton. Although this has provided the community with a huge amount of information, it is not necessarily being translated into biochemical expression or phenotype. Genomics demonstrates which genes are shared, but proteomics can show clearer relationships by illustrating functional similarities and phe-

notypic variances. With a well-designed experiment, researchers can examine the conditions under which a protein is expressed; its cellular location, the relative quantities, and what protein–protein interactions take place [37.175].

Chan et al. [37.176, 177] studied protein profiles under different environmental conditions found in *Prorocentrum triestinum*. He showed both constancy of protein profiles and variability of the relative abundance of some proteins under different and culture conditions. Differentially expressed protein patterns of *P. triestinum* indicated that *P. triestinum* growing under nitrogen-limited conditions possessed higher growth potential since its protein expression profiles are more similar to that of the blooming stage. These results are consistent with the observations that it is possible to rapidly trigger a bloom by the addition of a supply of nitrates. A more detailed analysis of the differential synthesis of proteins in these various stages and studies to elucidate the functions of these proteins will be critical for understanding the molecular mechanisms involved in blooming. Phytoplankton proteomic approaches that use whole genome sequences to examine protein expression by matching protein MS/MS spectra to those predicted from whole genome sequences are already available [37.150]. Cell surface proteins (CSPs) of *Alexandrium catenella* have been also studied in detail. Protein profiles at different toxin biosynthesis stages, were analyzed and 53 differentially expressed proteins were identified. These were involved in various biological processes, nine of which might be involved in the PST biosynthesis of *A. catenella* using the quantitative proteomic approach to compare protein profiles at different toxin biosynthesis stages.

Proteomics studies should help to reveal the toxin biosynthesis mechanisms and pathways in dinoflagellates [37.178]. Proteomics has provided valuable information on the effects and also the mode action of the dinoflagellate metabolite yessotoxin on a human liver cell line. Also, analysis of the plastid proteome of the Florida red tide dinoflagellate *K. brevis* detected an electron transfer protein (plastocyanin) inherited from green algae that may contribute to ecological success in iron use. Nevertheless, much promise remains to be fulfilled in the application of proteomics to studies of HAB ecophysiology and bloom dynamics [37.179].

37.6.4 Metabolomics

The term metabolomics is usually defined as the comprehensive and quantitative analysis of all small molecules in a biological system [37.180]. Metabolomics allows monitoring and mapping the dynamic range of bioactive secondary metabolites under different conditions. The most commonly used gas chromatography-time-of-flight mass spectrometry (GC-TOF-MS)-based method facilitates the identification and robust quantification of a few hundred metabolites. The merging of metabolomics and metagenomics has the potential to be a particularly powerful combination in shedding light on planktonic and microbial interactions in marine ecosystems. Statistical evaluation of data provides insight into the metabolic changes within the cells as well as into the released metabolites. The knowledge of the complex patterns of chemicals released by microalgae will reveal new mechanisms for processes such as: community function, food location, or complex defensive and allelopathic interactions [37.181].

A great number of metabolic pathways and regulatory mechanisms could be predicted based on the genomic sequences. Nevertheless, some of the genes might not be functional in vivo. Recent technical developments make metabolomics a suitable tool to define their genes function and regulation in microalgae. Analyses of diatom genomes have suggested tight connection between a number of novel pathways and regulatory steps in diatom metabolism. However, there are still several important open questions to be addressed. Given the massive recent acceleration in genome sequencing capacities we will shortly have an enormous resource of genetic information for marine phytoplankton. Combining this information with details on their metabolic complement will greatly enhance our understanding of the metabolic processes by and how they interact with their environment, as well as the evolution of their underlying metabolic pathways [37.182].

Metabolomics approach has already been successfully applied to the dinoflagellate endosymbiont *Symbiodinium* [37.179]. As an emerging technique, metabolomics have not been widely applied in toxic phytoplankton studies, but some research groups are developing databases for identification of marine biotoxins using metabolomics approaches [37.183].

37.7 Potential Pharmacological Uses of Phycotoxins

In the past few decades, extensive studies have been devoted to investigate the toxicology and pharmacology of biotoxins [37.184, 185]. A renewed interest is seen in marine alkaloids and their analogues, including the STX-group toxins (STXs), with regards to their use as therapeutic agents or as a drug lead [37.186]. STXs bioactivity studies and molecular modeling could lead to the design of unnatural analogs with improved pharmaceutical characteristics. Recently, a group of toxins isolated from marine cone snails (genus *Conus*), known as conotoxins, have been shown to contain over 2000 peptide analogs. Conotoxins are able to specifically target a broad range of ion channels and membrane receptors and are currently under investigation for possible clinical trials. In 2004, a synthetic version of a conotoxin analogue, ω-conotoxin MVIIA, also known as ziconotide (trade name Prialt) was the first marine natural product to be approved for use by the US FDA [37.186]. Ziconotide acts by targeting N-type voltage sensitive Ca^{2+} channels and is used for the treatment of chronic pain in spinal cord injury.

Ion channels triggered by voltage changes along the cell membrane are termed voltage-gated ion channels (VGICs), include channels that conduct Na^{+}, Ca^{2+} and K^{+}. Activation of Na^{+} or Ca^{2+} VGICs produces cell stimulation by membrane depolarization, while K^{+} channel activation results in inhibitory hyperpolarization. Toxins that bind VGICs can serve as powerful molecular probes to study the channel structure and function, as well as serve as models for studying evolutionary targets and drug discovery [37.187]. Some marine biotoxins are classified as neurotoxins due to their ability to interact with these channels [37.188]. As we will discuss later in this section many marine biotoxins have affinity by one or more VGICs and therefore could have an important pharmaceutical potential.

37.7.1 Lipophilic Toxins (LTs)

Okadaic Acid-Group (OA) Toxins and Pectenotoxin-Group Toxins

OA is a marine biotoxin that presents a great value in medical research and has facilitated the understanding of several cellular processes [37.189]. OA-group toxins have interest due to their high cytotoxic activity and the extraordinary ability to promote tumors [37.190, 191]. It is considered that their effect varies depending on the cell type and concentration used [37.192].

It has been a model for analyzing therapeutic effects of some drugs in treating neurodegenerative diseases [37.193]. OA acts as a potent neurotoxin that induces apoptotic events in various cell lines and promotes tumors in several organs. Mechanisms are dependent on cell type, the antioxidant status of each cell and the ability to metabolize OA [37.194–199].

OA-group toxins are specific inhibitors of PP1 and PP2A that are involved in the regulation of many cellular processes and modulate the extent of phosphorylation or dephosphorylation of proteins. Other cellular targets for OA have been suggested [37.189, 200–203]. OA has been used to analyze the mechanisms by which the conjugated linoleic acids can act as antitumor agents in breast cancer cells due to its activity as an inhibitor of PP2A [37.189]. In addition it has been reported that the extent of OA-induced injuries and the toxin organotrophicity are dose-related and may be determined by the administration route. After intravenous administration, OA acts as a hepatotoxin with undetectable effects on the intestine but also has an impact on cytoskeletal elements at sublethal doses [37.204].

PTXs are potent cytotoxic compounds against several human cancer cell lines. They are hepatotoxic whose mechanism of action has not yet been fully elucidated [37.205–207]. Among other effects, the induction of apoptosis in rat hepatocytes, in salmon and p53-deficient cell lines have been reported [37.208].

PTX2 is an inhibitor of actin and cytokinesis and it is known to be used as a chemotherapeutic agent against tumors type p53 [37.209]. It was demonstrated that a loss of p53 sensitizes tumor cells to actin damage. PTX2 was first identified as a cytotoxic entity in marine sponges, which depolymerizes actin filaments and it was found to be highly effective and more potent to activate an intrinsic pathway of apoptosis in p53-deficient tumor cells compared to those with functional p53 both in vitro and in vivo. Other agents that depolymerize or knot actin filaments were also found to be toxic to p53-deficient tumors. In p53-deficient cells, PTX2 triggers apoptosis through mitochondrial dysfunction, and this is followed by the release of proapoptotic factors and caspase activation. Furthermore, Bax activation and Bim induction was observed only in p53-deficient cells after PTX2 treatment. Therefore, these results suggest that Bim triggers apoptosis by activating Bax in p53-deficient tumors upon actin damage, and that actin inhibitors may be potent chemotherapeutic agents against p53-deficient tumors.

Recent studies demonstrated that this congener do not induce diarrhea or any other signs of disease by oral administration. Body distribution of PTX2 and PTX2 seco acid (PTX2SA) was analyzed in mice after oral and intraperitoneally administration. Cytotoxicity assays in vitro have been the first step to the discovery of many drugs used in antitumor therapy. However, more information is needed about its toxicity to humans and their pharmacokinetics [37.210].

Yessotoxins-Group Toxins

YTXs are polyether compounds that were discovered due to their high acute toxicity during MBA by *i.p.*, injection for lipophilic toxin analysis of mollusks [37.211, 212]. There are no published reports of human poisonings caused by YTXs and no available data on chronic exposure, carcinogenicity, or genotoxicity [37.213]. Various authors have suggested that the target organ following *i.p.* administration is the heart [37.214]; however, other authors consider that YTX is involved in neurological disorders and its main target is the thymus [37.215]. *Tereo* et al. have reported severe microscopic alterations in cardiac muscle [37.214]. Difference between these studies is not clear and has been proposed that discrepancies may be due to different purities of the toxins and the use of different strains of mice [37.213]. YTX administration to human lymphocytes leads to an increase in cytosolic Ca^{2+} concentration [37.20] and in specific activity of cyclic nucleotide phosphodiesterase 3′, 5′ [37.216]. Other studies have reported that cellular Ca^{2+} homeostasis is not related to its cytotoxic effect [37.217]. Furthermore, YTX causes dose-dependent decrease in the levels of GMPc and AMPc after incubation due to the activity of phosphodiesterases. These effects depend on Ca^{2+} and can be changed by phosphodiesterases [37.216, 218].

YTX induced a decrease in F-actin filaments in several cell models as cerebellar granule cells (CGCs), mouse fibroblast, rat L3, mouse myoblast cell lines, and MCF-7 human breast adenocarcinoma cells [37.217, 219]. However, this seems not to be a universal effect, since no effects over F-actin levels were detected in M17 neuroblastoma cell line, in rabbit enterocytes, or in human Caco-2 cells [37.220, 221]. YTXs cause selective disruption of the E-cadherin-catenin in epithelial cells and could potentially suppress tumor functions of E-cadherin [37.222]. Pathway degradation of E-cadherin is affected by YTX at long incubation times and low doses. Since E-cadherin has been linked to tumor spreading and metastasis, it has been a concern if the disruption of E-cadherin by YTX could affect tumor expansion in YTX-contaminated mollusk consumers. However, in vivo experiments demonstrated that although the resulting molecule of E-cadherin disruption had increased, YTXs did not induce any effect on E-cadherin system in in vivo experiments [37.223].

YTX-induced apoptotic events in different cellular lines, including cancer cells, primary cell cultures, and cell lines. There are reports related to YTX-induced apoptosis in rat hepatocytes, rat glioma cells, HeLa S3 cells, rat cerebellar neurons, BE(2) neuroblastoma cell line, L6 myoblast cell line, BC3H1 myoblast cell line, mouse fibroblast NIH3T3 cell line, CaCo-2 cells, MCF-7 cancer cells, and HepG2 cell cultures. In this sense, YTX could be used in therapeutic applications, for instance, as an antitumor drug [37.224]. Thus, the European patent application EP1875906 [37.225] considers to use YTX as an antitumor drug, and protoceratin I, the major compound with cytotoxic activity against human tumor cell lines isolated from *P. cf. reticulatum*, was proved to be identical to homo YTX [37.226].

It has also been investigated the activity of various YTXs analogs on MCF-7 tumor cell lines; structural modification in homoYTX do not change the activity of the toxin, while the side chain structure of carbon 9 seems essential. Thus, carboxiYTX and hidroxihomoYTX present less activity than YTX [37.227]. These data have been confirmed by kinetic studies between phosphodiesterases and YTX, hidroxiYTX and carboxiYTX, proving the lower affinity between these proteins and the last two analogs [37.228].

Azaspiracid-Group Toxins

Molecular targets of these toxins are not well known, but some studies were focused on the study of second messengers: increased intracellular Ca^{2+} and AMPc [37.229–232], effects of reorganization of the actin cytoskeleton [37.233–236] and effects on adhesion by activation of adhesion protein fractionation (claudins and cadherins) [37.234, 237, 238].

Although, symptoms observed during episodes of AZAs poisoning were similar to those typically observed with DSP, administration of toxic AZAs materials to mice led to great differences with the DSP. Mice injected with low doses of AZAs did not present diarrhea [37.239], and in a few hours develop slowly progressive paralysis, difficulty in breathing, and finally death [37.240]. A 200 mg/kg *i.p.* dose appears to be the minimal lethal dose in mice to AZA1 while AZA3 and AZA2 showed a higher toxicity (110 and 140 mg/kg, respectively) [37.240, 241]. Damages in liver, pancreas,

spleen, thymus and stomach were observed. Moreover, after administration of AZA sublethal doses by gavage, alterations were observed in the small intestine, affecting epithelial cells with a degree of damage progressively increasing from 4 to 24 h after administration [37.242, 243]. AZA cytotoxicity was first observed by *Flanagan* et al. [37.244] in hepatoblastoma and bladder carcinoma cells exposed to contaminated crude mussel extract. *Twiner* et al. [37.235] observed that AZA1 causes cytotoxicity in kidney, lung and immune, neuronal, and pituitary cells. However, neurons appear to be particularly sensitive to AZAs, causing irreversible morphological changes with relatively short exposure times and cytotoxicity with longer exposures to these toxins [37.231, 236]. It also requires longer exposure times to achieve complete cytotoxicity in primary cultures of cerebellar granule cells [37.200]. Also, they induce apoptosis through caspase activation [37.210, 245].

AZAs are implicated in upregulation on gene expression and protein levels of low-density lipoprotein receptor (LDLR). This effect seems to be a response to the decreased level in intracellular cholesterol caused by AZA1 [37.25]. It was shown that T lymphocytes exposed to AZA1 up regulated gene expression and protein levels of LDLR due to decreased levels of intracellular cholesterol. Although premature to determine decisively, yet consistent with currently available in vitro data, AZA1 appears to be targeting a membrane protein such as a claudin, cadherin, or LDLR, in turn eliciting an effect on intracellular signaling molecules and the cytoskeleton, ultimately resulting in cytotoxicity.

37.7.2 Hydrophilic Toxins

Saxitoxin-Group Toxins (PSP)

STX-group toxins are closely related water-soluble tetrahydropurine compounds acting by interfering with VGSC functioning. The toxin acts from the exterior of the cells by getting access to the extracellular cavity of the channel and binding to the so-called site 1 of the α-subunit in the Na^+ channel [37.246]. Site 1 is shaped by a short portion (SS2) of the amino acid stretches connecting the S5 and S6 trans-membrane helices in the four domains of the α subunit, giving rise to a cavity that accommodates the toxin. STX then forms hydrogen bonds and electrostatic interactions with the side chains of several amino acids that participate to the ion selectivity filter of the channel. The interaction of one STX molecule with the site 1 of the α-subunit in the Na^+ channel essentially plugs the channel and blocks its ion flux. The loss of Na^+ conductance in excitable cells prevents membrane depolarization and the transmission of the action potential, representing the molecular basis of the toxic effects of STX. As a consequence of VGSC blockade, a progressive loss of neuromuscular function ensues, leading to the reported neurotoxic symptoms that can result in death by asphyxia. Skeletal analogs of STX with a fused-type tricyclic ring system, designated FDSTX, were synthesized as candidate Na^+ ion channel modulators [37.247]. Their inhibitory activity on Na^+ ion channels was examined by means of cell-based assay. Two of the analogs showing moderate inhibitory activity were further evaluated by the use of the patch-clamp method in cells that expressed $Na_V1.4$ (a TTX-sensitive Na^+ channel subtype) and $Na_V1.5$ (a TTX-resistant Na^+ channel subtype). These compounds showed moderate inhibitory activity toward $Na_V1.4$, and weaker inhibitory activity toward $Na_V1.5$. Uniquely, however, the inhibition of $Na_V1.5$ by one of the analogs was *irreversible*.

Some STXs have demonstrated pharmaceutical potential as a long-term anesthetic in the treatment of anal fissures and for chronic tension-type headache. The recent elucidation of the STX biosynthetic gene cluster in cyanobacteria and the identification of new STX analogs will present opportunities to further explore the pharmaceutical potential of these intriguing alkaloids [37.186]. A specific suite of analogs can be isolated from a single STXs-producing organism, which is directly a result of the evolution of genes present within the organism's genome. Naturally occurring STXs can also be precursors for extracellular metabolic or chemical transformations into new analogs. Knowledge of these transformations may have important implications for the detection, toxicity, and removal of STXs from a contaminated source. Other medicinal uses for STXs may become more established by screening the bioactivity of less toxic analogs, since their use as a potential local anesthetic has long been known. The characterization of STX biosynthesis genes [37.165, 248] and their potential use in combinatorial biosynthesis, together with the constant discovery of novel analogs (either natural or transformed), is likely to expand the possibilities for their pharmaceutical use.

STX also has a huge pharmaceutical potential for its ability to induce anesthesia through interaction with the VGSC [37.186]. It has been suggested that site 1 blockers prolong the duration of anaesthesia in a synergistic manner when combined with other local anaesthetics. In spite of this, the push for STX to enter clinical tri-

als has been hindered by its systematic toxicity. The use of STX as a slow release, prolonged anesthetic was recently demonstrated using a novel controlled release system in male rats. Liposomal formulations of STX, either alone or in conjunction with dexamethasone and/or bupivacaine, were able to block the sciatic nerve in rats for long periods with no damaging myotoxic, cytotoxic, or neurotoxic effects and little associated inflammation. Liposome formulations of STX for slow and site-directed release for prolonged anaesthesia have been postulated as a putative treatment of localized and severe joint pain.

GTX2 and GTX3 also have clinical potential and have been utilized for the treatment of anal fissures by their direct injection into both sides of the fissure. A success rate of 98% with remission after 15 and 28 days for acute and chronic conditions respectively was observed. Both toxins have also been used in the treatment of chronic tension type headache, with 70% of patients responding to treatment. These studies recognize that several STXs have potential as future pharmaceutical leads; therefore, more investigation is needed in this field [37.6].

NEO-STX has being developed as a local anesthetic. Doses of 100 μg have been used by local infiltration in anesthetized adult humans without adverse effect. *Wylie* et al. hypothesized that similar doses could cause significant respiratory, neuromuscular, and cardiovascular impairment [37.249].

Domoic Acid (ASP)

DA belongs to the kainoid class of compounds, which is a class of excitatory neurotransmitters. Pharmacological studies reported that DA isomers are not as toxic as DA because they bind less strongly to the kainate receptor proteins than DA itself; however, 5′-epi-domoic acid has a similar toxicity [37.35]. *Mayer* and *Hamann* [37.250] reviewed the available literature on pharmacological and toxicological studies with marine natural products including articles reporting on the bioactivity and/or pharmacology of 106 marine chemicals. They included DA in the group of compounds that affect the immune system. Moreover they reported that DA at in vitro concentrations that were toxic to neuronal cells (1 mM) was shown to trigger a limited activation of rat brain microglia, an immune cell type that contributes to circa 10% of the total glial population in the central nervous system, and the concomitant release of two potentially neurotoxic mediators, namely TNF-α and matrix metalloproteinase-9.

DA acts as a potent glutamate receptor agonist. Although mechanisms of domoic acid neurotoxicity are poorly defined, an excitotoxic mechanism is believed to be involved. DA inhibits astrocytes glutamate uptake in a dose-dependent manner, leading to accumulation of glutamate in the extracellular compartment and thus producing neurotoxicity [37.251].

In vitro studies have shown that, depending on its concentration, DA causes necrotic or apoptotic cell death in mouse cerebellar granule neurons (CGN). Necrosis is observed at higher concentrations of DA (10 μM) and involves activation of both AMPA/kainate and *N*-metyl-D-aspartic acid (NMDA) receptors, the latter activated by DA-induced glutamate release. In contrast, apoptotic damage predominates at lower concentrations of DA (e.g., 100 nM) and is solely due to activation of AMPA/kainate receptors [37.252]. Both, necrosis and apoptosis have been shown to be mediated by oxidative stress. Upon oral administration, DA is poorly absorbed, has a short half-life in blood, and poorly permeates the blood–brain barrier, limiting the access of low levels of DA in the central nervous system, but this might not be the case during development, a period of suggested particular sensitivity to DA neurotoxicity. The authors evaluated if a prolonged exposure to low DA levels would result in neurotoxicity and/or in altered susceptibility to a subsequent exposure in cultured mouse CGNs. Neurons from wild-type mice and from mice lacking the glutamate cysteine ligase (GCL) modifier subunit (*Gclm*$^{-/-}$) (already known to be highly susceptible to DA neurotoxicity) were compared. They found that prolonged exposure to low-level DA in vitro provides protection against toxicity of a higher DA acute exposure, apparently due to the ability of chronic low dose of DA to up-regulate glutathione (GSH) synthesis. Genetic conditions leading to low GSH levels, which already increase susceptibility to DA neurotoxicity, could potentially negate such protective mechanisms [37.252].

37.7.3 Other Toxins

Ciguatoxins (CTXs)

CFP is the most frequently reported seafood-toxin illness in the world. It produces gastrointestinal, cardiovascular, neurologic, and neuropsychiatric symptoms which can last from days to even months. CTXs derive from benthic dinoflagellates and are transferred through the food web from the algae to herbivorous and carnivorous fish, and finally to humans.

CTXs are among the most potent natural substances known. One of the Pacific Ocean ciguatoxins, P-CTX-1, poses a health risk at concentrations as low as 0.08–0.1 μg/kg although CTXs rarely accumulates in fish at levels that are lethal to humans [37.253]. CTXs activate the VGSCs in cell membranes, which increases Na^+ ion permeability and depolarizes the nerve cell. This depolarization is believed to cause the array of neurological signs associated with CFP. Voltage-clamp studies suggested that CTXs cause spontaneous, and enhance evoked, action potentials by lowering activation thresholds and delayed repolarization of VGSCs. Several studies further elucidated cellular effects and molecular mechanisms of CTXs actions including selective binding and competition with BTX for site 5 on VGSCs, elevation of intracellular Ca^{2+} levels, stimulation of spontaneous and evoked neurotransmitter release from synaptosomes and motor nerve terminals, axonal and Schwann cell edema, induction of TTX-sensitive leakage current in dorsal root ganglion neurons and blockade of voltage-gated potassium channels [37.254]. Neurological symptoms are consistent with CTXs' interactions with VGSCs; however, all the symptoms produced during CFP may not be exclusively due to VGSCs [37.46]. The chronic fatigue syndrome that may last for weeks or months has been related to high nitric oxide (NO) production. Penil and muscular relaxation, as well as L-type Ca^{2+} channel activation, were shown to be NO-mediated via the nitric oxide synthetase pathway.

CTX also caused rapid hypothermia in mice, which lose their ability to regulate their own body temperature and became poikilothermic. This reduction in body core temperature was found to be due to neuroexcitatory actions of ciguatera on regions of the brain stem receiving vagal afferents and ascending pathways associated with visceral and thermoregulatory responses [37.255]. These authors reported a complete review on the pharmacological effects of CTXs, including cardiovascular and gastrointestinal effects, effects on other smooth muscle, actions on ganglionic and neuromuscular transmission and on VGIC, and other Na^+-dependent actions. Despite the multiple pharmacological effects no medical applications of these toxins have been reported so far.

Brevetoxin-Group Toxins

BTXs are lipid soluble cyclic polyethers (M.W. ≈ 900) and potent neurotoxins that open VGSCs leading to Na^+ influx into the cell. BTXs exert their toxicity by interacting with neurotoxin receptor site 5 associated with domain IV of the α subunit of the VGSC. BTXs binding to tissues that contain VGSCs on excitable cells results in membrane depolarization, repetitive firing, and increase in Na^+ currents [37.256]. At the Na^+ channel, at least four actions of BTXs have been identified leading to the depolarization of excitable cell membranes: shift of the voltage dependence, inhibition of inactivation, increase of mean open times and multiple subconductance levels. A description of these actions and the mammalian BTXs toxicity was recently review [37.63].

BTXs exert a variety of actions in vivo affecting both the peripheral as well as the central nervous systems, probably due to their high lipid solubility and ability to penetrate the blood–brain barrier. Humans exposed to the toxin usually exhibit neurotoxic shellfish poisoning symptoms, which include nausea, difficulties in movement, and seizures [37.257]. Cellular effects associated with exposure to BTXs have been observed in the immune system of many species, although the mechanisms of action of BTXs on immune cells and immune competence are not well understood. Several potential mechanisms for BTX immunotoxicity have been suggested, including the inhibition of cathepsin, apoptosis, release of inflammatory mediators, and oxidative stress [37.58]. In vitro experiments have demonstrated possible DNA damage, chromosomal aberrations and effects on cellular growth [37.256, 258]. Other immune system effects include mast cell degranulation [37.259] and histamine release which may contribute to observed airway responses following the inhalation of aerosolized BTXs.

There are over 10 different BTXs isolated in seawater blooms and *K. brevis* cultures, as well as multiple analogs and derivatives from the metabolism of shellfish and other organisms [37.58]. *Cao* et al. [37.260], quantified the potencies and efficacies of an array of lipophilic VGSCs gating modifiers by measuring Na^+ influx in murine neocortical neurons. An assay using a Na^+-sensitive fluorescent dye to primary cultures of neurons afforded a highly quantitative assessment of the increments in neuronal Na^+ level produced by gating modifier toxins. The relative efficacies differ substantially; the rank order of efficacy of several naturally occurring BTXs and semisynthetic analogs as Na^+ channel gating modifiers was PbTx-1 > PbTx-desoxydioxolane > PbTx-2 = PbTx-3 < PbTx-3α-naphthoate. *K. brevis* cultures also produce shorter ring structures, hemi-BTXs and brevenals, likely to be incomplete products of the BTX biosynthetic pathway. These smaller cyclic ether ring

structures exhibit reduced biological activity, yet they are still consistent with a site of action common to the BTXs [37.63]. An interesting discovery was the finding that brevenal (produced both in *K. brevis* laboratory cultures and in the environment during *K. brevis* blooms), is a brevetoxin antagonist. This is a case of a toxin producing organism that also secretes its own antagonist. Brevenal is synthesized by *K. brevis* in significant amounts and it acts at a different receptor site on nerve cells than the brevetoxins. It is a new and important natural product which could treat chronic obstructive pulmonary disease and cystic fibrosis [37.58].

Taupin [37.261] studied the activity of four generic formulae of BTX derivatives – formulae I–IV – and their compounds on the growth of neurites. He reported that BTX derivatives stimulate neurite growth, particularly the growth of minor processes from which the axons form, on neurons in primary cultures. The activity is mediated by VGNC and the *N*-methyl-D-aspartate-mediated intracellular Ca^{2+} pathway. They proposed the use of BTX derivatives for enhancing neuronal growth and for the treatment of neurodegenerative and neurological disorders, such as Alzheimer's disease, amyotrophic lateral sclerosis, cerebral strokes, traumatic brain, and spinal cord injuries.

Tetrodotoxin

TTX is a very well-known marine neurotoxin due to its frequent involvement in fatal food poisoning, unique chemical structure, and specific action of blocking Na^+ channels of excitable membranes [37.262]. The toxicity of TTX relates to two factors: paralysis of skeletal muscle, including the diaphragm and intercostal muscles, leading to respiratory failure, and reduced blood pressure, predominantly due to vasodilatation. Early signs of this effect might include weakness, tingling of the lips and dizziness [37.70]. Pharmacological activity of TTX on various animals, their organs and tissues has been extensively studied, and it was found that TTX strongly inhibits nerve conduction and has inhibitory effects on Na^+-K^+-ATPase activity. Recently, TTX has been shown to block L-type Ca^{2+} current (ICa) in canine cardiac cells [37.263]. These authors studied the TTX-sensitivity of Ca in isolated canine ventricular myocytes as a function of channel phosphorylation, extracellular pH, and the redox potential of the bathing medium using the whole cell voltage clamp technique. They demonstrated that TTX inhibits L-type Ca channels in the heart by binding to its selectivity filter.

TTX has been extensively used to elucidate the role of specific VGSCs subtypes in a wide range of physiological and pathophysiological processes in the nervous system. VGSCs play a key role in pain and TTX-sensitive subtypes have received much attention over the past few years because these channels have been strongly implicated in normal and pathological pain. Since TTX blocks this subset of VGSCs in a highly selective manner, this toxin may have a potential role in relieving pain [37.264, 265]. *Nieto* et al. [37.266] evaluated the effect of the acute systemic administration of low, nontoxic, doses of TTX on the expression of different signs (heat hyperalgesia, mechanical- and cold allodynia) of paclitaxel-induced neuropathic pain in mice. They reported that low doses of TTX can be useful to prevent and treat this pain since inhibited hyperresponsiveness to thermal and mechanical stimuli. Their findings suggest that TTX-sensitive subtypes of Na^+ channels play a role in the pathogenesis of chemotherapy-induced neuropathic pain.

Hagen et al. [37.267] evaluated the analgesic activity of TTX administered subcutaneously in a randomized, placebo-controlled, parallel design study, in patients with moderate or severe unrelieved cancer pain. This trial suggested that TTX could potentially relieve moderate to severe, treatment-resistant cancer pain in a large proportion of patients, and often for prolonged periods following treatment. In a later study [37.268] it was assessed the long-term safety and efficacy of subcutaneous TTX treatment in reducing the intensity of chronic cancer-related pain. They conducted a multicenter open-label longitudinal trial, in which 30 µg TTX was administered subcutaneously for 4 days in a heterogeneous cohort of patients with persistent pain. Onset of pain relief in no more than half the patients was typically cumulative over days, and after administration ended, the analgesic effect subsided over the course of a few weeks. Toxicity was usually mild or moderate and remained so through subsequent treatment cycles, with no evidence of cumulative toxicity or tolerance. They concluded that long-term treatment with TTX is associated with acceptable toxicity and, in a substantial minority of patients, resulted in a sustained analgesic effect. *Berde* et al. [37.70] reported that prolonged duration percutaneous sciatic nerve blockade could be achieved in rats using combinations of site 1 Na^+ channel toxins with either bupivacaine or epinephrine. Addition of either bupivacaine or epinephrine increases the LD_{50} of TTX in rats, i. e., reduces systemic toxicity from TTX, and also increases the potency of TTX by producing sensory blockade, thereby substantially improving the therapeutic index of TTX.

Thus, combination of formulations seems desirable from the standpoint of both efficacy and safety. TTX, formulated as Tectin, underwent Phase III trials as an injectable systemic analgesic for chronic cancer pain. *Berde* et al. [37.70] examined dose–duration relationships and sciatic nerve histology following local nerve blocks with combinations of Tectin with bupivacaine 0.25% solutions, with or without epinephrine 5 μg/mL in rats. Three-way combinations of TTX, bupivacaine and epinephrine produced significant prolonged sciatic nerve blockade in rats, compared to bupivacaine plain or bupivacaine + epinephrine. Their studies indicate that clinically relevant combinations of Tectin with commercially available bupivacaine 0.25% and epinephrine 5 μg/mL warrant further study for prolonged-duration local anesthesia. Moreover they suggest that a single-injection approach to prolonged local anesthesia would provide good pain relief as a component of multimodal analgesic regimens, reducing postoperative opioid requirements and improving the course of postoperative recovery and acute rehabilitation.

A review by *Nieto* et al. [37.269] focuses on the preclinical and clinical evidence supporting a potential analgesic role for TTX. In addition they compiled data on the contribution of specific TTX-sensitive VGSCs to pain. They conclude that the therapeutic use of TTX as an analgesic agent seems hopeful although further preclinical and clinical research is needed to clarify its potential use during painful conditions. *Wang* et al. [37.270] examined the effect of TTX, applied topically to the rat cornea, on the duration of corneal anesthesia, administered with either proparacaine (PPC) or the chemical permeation enhancer octyl-trimethyl ammonium bromide (OTAB). The effect of test solutions on corneal healing was also studied. Combination of TTX and PPC resulted in corneal anesthesia that was 8 to 10 times longer in duration than that from either drug administered alone, whereas OTAB did not prolong anesthesia. The rate of corneal healing was moderately delayed after coadministration of TTX and PPC. They concluded that coadministration of TTX and PPC significantly prolonged corneal anesthesia, but in view of delayed corneal reepithelialization, caution is suggested in the use of the drug combination.

Bragadeeswaran et al. [37.262] isolated three TTX-producing bacteria (*Kytococcus sedentarius*, *Cellulomonas fimi* and *Bacillus* species) from the pufferfish *Arothron hispidus*. Their partially purified filtrates exhibited hemolytic activity on chicken and human erythrocytes and also presented ATPase, Mg^{2+}-ATPase, Na^+K^+-ATPase, and AchE enzymatic activities. The authors also evaluated if the viability of leukemia cell line (P388) was adversely affected upon adding the crude microbial extracts and found a dose-dependent growth inhibition. These TTX-producing bacteria hold promise for the development of effective antitumor compounds.

Palytoxin and Analogs

PlTXs are a group of complex, extremely potent, and marine natural products. PlTX is a large (molecular weight: 2681), water-soluble polyalcohol first isolated from zoanthids (genus *Palythoa*) even though dinoflagellates of the genus *Ostreopsis* are postulated as the PlTX origin [37.77]. PlTX has been found in a variety of marine organisms ranging from dinoflagellates to fish and it is implicated in seafood poisoning with potential danger to public health. The most commonly reported complications of PlTX poisoning appears to be rhabdomyolysis, a syndrome injuring skeletal muscle, causing muscle breakdown, and leakage of large quantities of intracellular (myocyte) contents into blood plasma. Other symptoms associated with PlTX poisoning in humans are characterized by abdominal cramps, nausea, vomiting, diarrhea, paresthesia, bradycardia, renal failure, cyanosis, and respiratory distress [37.79]. The latter two precede death in fatal cases.

Toxicological studies with these compounds show repeatedly low LD_{50} values in different mammals, revealing an acute toxic effect on several organs, as demonstrated by different routes of exposure. Acute oral administration in mice induced histological and ultrastructural changes in several organs, such as liver, pancreas, cardiac, and skeletal muscle cells. The recognition of its wide distribution coupled with the poisoning effects that these toxins can have on animals, and especially on humans, have concerned the scientific community [37.79]. The toxin is known to affect cellular functions by selective binding to the Na^+-K^+ ATPase and converting the pump into a nonselective channel [37.195, 271]. The induced ion flux alterations are reported to target pathways involved in cytoskeletal dynamics within different cellular models [37.77]. Na^+-K^+ ATPase also functions as a signal transducer to relay messages from the plasma membrane to the intracellular organelles. The toxicological effects of acute oral administration of 42-OH-PlTX were evaluated in mice, as well as its in vitro delayed hemolytic effects [37.272]. The compound showed a toxicity profile comparable with that of the parent compound palytoxin (LD_{50} = 651 and 767 mg/kg, respectively), both

as lethality and acute pathological effects. Also the in vitro hemolytic activity of 42-OH-PlTX was similar to that of PlTX in agreement with the common mechanism of action on the Na^+/K^+ pump, to which the two compounds bind with the same affinity.

Franchini et al. [37.204] used the Frog Embryo Teratogenesis Assay-Xenopus (FETAX) to verify the effects of PlTX in mortality, delayed growth, and embryo malformation. The toxicological effects of PlTX evaluated by FETAX assay revealed evident impacts on embryo mortality, teratogenesis and growth. The histological analysis of the surviving young larvae revealed structural changes compared with controls in the nervous and muscle tissue, even if some specimens did not show any significant histopathological modifications. A general reduction in the size of the main inner visceral organs (i. e., intestine, pancreas, and liver) was reported, but no morphological changes. Severe injury to the heart structure was observed in some specimens.

PlTX is a novel skin tumor promoter, which has been used to probe the role of different types of signaling mechanisms in carcinogenesis. The multistage mouse skin model indicates that tumor promotion is an early, prolonged, and reversible phase of carcinogenesis. Understanding the molecular mechanisms underlying tumor promotion is therefore important for developing strategies to prevent and treat cancer [37.273]. PlTX stimulates a wide range of cellular responses that are likely to play a role in carcinogenesis. Stimulation of arachidonic acid metabolism and the production of prostaglandins modulation of the epidermal growth factor receptor, and modulation of mitogen-activated protein (MAP) kinase cascades are the best studied [37.273]. MAP kinases are a family of serine/threonine kinases that relay a variety of signals to the cellular machinery that regulates cell fate and function. This author [37.274] investigated how palytoxin stimulates MAP kinase activity and how MAP kinases mediate the response of cells to PlTX concluding that MAP kinases appear to be important mediators of PlTX-stimulated signals. The central role of MAP kinases in regulating a variety of critical cellular functions, ranging from enzyme activity to gene expression and ultimately to proliferation and apoptosis, may help explain how palytoxin can stimulate the variety of effects that are characteristic of tumor promoters. Other author suggests that PlTX conjugates could be used as prodrugs in cancer chemotheraphy due to its high cytotoxicity in vitro indicating that targeting the prodrug to a tumor, and there releasing the toxin, selective destruction of neoplastic cells could be achieved [37.275].

Many findings on the involvement of PlTX and analogs acting on different cellular targets and modulating the actin cytoskeleton within different cellular models were published [37.77, 276, 277]. *Louzao* et al. suggest that also cytoskeleton is necessary for PlTX activity and that this may find important applications in biomedical research, with particular interest toward the discovery and development of cytotoxic compounds providing novel antitumor therapy [37.77].

Cyclic Imines

CIs toxins are a very diverse group of marine biotoxins containing an imino functional group as part of its cyclic structure. In many of them, it was found that the toxicity is greatly diminished if imino group is reduced or destroyed [37.278]. Nowadays, there is no evidence of human poisoning caused by cyclic imines but the toxicity observed in experimental animals requires a deeper study of their activity and distribution [37.279]. Only the toxicity of spirolides (SPXs) and gymnodimines (GYMs) has been studied in depth. Spiroimine moiety has been established as the common pharmacophore unit of CIs group, although structural change in other parts of the molecules can also affect the toxicity [37.280]. Primary studies on mechanism of action of CIs suggested that it could be related to the interference on transmission of nervous impulses at neuromuscular junction level. It has been demonstrated that SPXs and GYMs act as potent antagonists of nicotinic (nAChRs) and muscarinic (mAChRs) acetylcholine receptors [37.281–283]. *Kharrat* et al. [37.281] demonstrated that GYM A broadly interferes in neuromuscular transmission by directly blocking muscle-type nAChRs. GYM A interacts with a wide range of muscular and neuronal types of nAChRs, larger than other well characterized toxins that also act on nicotinic receptors [37.281]. *Bourne* et al. [37.282] confirmed the interaction of SPX and GYM with several muscle and neuronal types of nAChRs by competition binding experiments against labeled α-bungarotoxin and epibatidine. No agonist effect was observed with SPX or GYM, but both toxins showed a dose-dependent antagonism in muscle- and neuronal-type receptors. The study concluded that SPX and GYM toxins display high affinity and potent antagonism but limited selectivity for the muscle type versus neuronal subtypes of nAChR [37.282].

SPXs effects on mAChRs were studied by *Wandscheer* et al. in a human neuronal model. They observed that 13-desmethyl SPX C caused a dose- and time-dependent inhibition on neuroblastoma to acetylcholine

extracellular stimulation. They demonstrated by competitive binding assays that the 13-desmethyl SPX is a competitive antagonist of mAChRs and also causes an internalization of the M3-type muscarinic receptor that might contribute to the inhibitory effect of the toxin on the Ca^{2+} response to acetylcholine stimulation [37.283].

Maitotoxins and Gambierol

Many bioactive compounds have been isolated from *Gambierdiscus* spp., i. e., maitotoxins (MTXs), gambierols, and gambieric acid. MTX increases intracellular Ca^{2+} and is considered one of the most potent marine biotoxins when injected intraperitoneally (ip) in mice, with an LD_{50} (24 h) of 50 ng/kg. However, MTX has no proven role in human intoxication due to its low capacity for accumulation in fish flesh and low oral potency [37.46]. At cellular level, MTX causes an increase in Ca^{2+} and Na^{+} by activating Ca^{2+}-permeable nonselective cation channels, resulting in potent membrane depolarization. This causes, in excitable cells, the opening of voltage-gated Ca^{2+} and Na^{+} channels. The massive influx of ions could exceed cell buffering mechanisms affecting cell viability [37.284]. Due to its ability to activate Ca^{2+}-permeable nonselective cation channels, MTX is considered a powerful tool in the study of Ca^{2+}-dependent mechanisms. Another MTX effect is the formation of cytolytic/oncotic pores that finally conduce to cell membrane blebbing and oncotic cell death. For this reason, MTX could be a unique tool to explore oncotic/necrotic cell death [37.284].

Gambierol has moderate inhibitory activity against VGSCs and modified Ca^{2+} homeostasis. High concentrations of this toxin activate Na^{+} channels in human neuroblastoma cells, and, as a consequence, gambierol induces a cytosolic Ca^{2+} increment [37.285]. *Cagide* et al. tested the effect of gambierol on the shape and F-actin cytoskeleton of neuroblastoma. Cells remained with spread morphology and a well-defined actin cytoskeleton, without showing evidence of alterations. Moreover, gambierol was able to produce depolarization, as well as a Ca^{2+} influx, in neuroblastoma cells and scarcely reduced their metabolism [37.286]. *Alonso* et al. [37.287] designed and synthesized truncated skeletal analogs of gambierol with inhibitory activity against voltage-gated potassium (Kv) channels. They examined the effect of these compounds in an in vitro model of Alzheimer's disease obtained from triple transgenic ($3 \times$ Tg-AD) mice, which expresses amyloid beta ($A\beta$) accumulation and tau hyperphosphorylation. In vitro preincubation of the cells with the compounds resulted in significant inhibition of K^{+} currents, a reduction in the extra- and intracellular levels of $A\beta$, and a decrease in the levels of hyperphosphorylated tau, reducing these two cellular pathologies. Thus, these compounds could be useful chemical probes for understanding the function of Kv channels and for elucidating the molecular mechanism of $A\beta$ metabolism modulated by NMDA receptors. Moreover, since both $A\beta$ peptides and phosphorylated tau proteins are supposed to interact with NMDA receptors and to be implicated in the glutamate enhancement of AD pathology, they could have a potential pharmacological use.

Gambieric acids isolated from the culture medium of *G. toxicus* were described as potent antifungal polyether compounds [37.46].

38. Marine Microbial Enzymes: Current Status and Future Prospects

Barindra Sana

Due to unique metabolic capabilities the marine microorganisms are excellent natural resource for screening of novel molecules. Marine microbial enzymes are of special interest for their distinct habitat-related features. Published literatures agree with potential biotechnological, biomedical and industrial applications of several marine microbial enzymes. These enzymes attracted substantial attention for their novel chemical and stereochemical characteristics that may be exploited in chemical or pharmaceutical synthesis. A couple of marine microbial enzymes are already being used for industrial and pharmaceutical purposes. Marine biotechnology research is boosted by recent development of several molecular biology and bioinformatics tools. Study of marine microbial enzymes is now focused on multiple directions including screening, recombinant production, characterization and structure analysis of enzymes, and optimization of process parameters for their systematic and inexpensive production. Published literatures suggest potential applications of marine microbial enzymes in wide range of industries but more focused application-oriented research is essential for exploitation of their full biotechnological potential.

38.1 Overview

In recent years, enzymes attracted huge attention for their potential industrial, pharmaceutical, cosmetics, and daily-life applications. Enzyme-based industrial processes are ecofriendly and less energy consuming. High specificity of enzymatic reactions minimizes bi-product formation in industrial processes and thus prevents wastage of expensive raw materials. High substrate specificity also suggests minimum side-effects of enzyme-based therapeutic systems. Extraordinary enzymes can be used for unique bioprocesses development or treatment of life-threatening diseases. However, in most cases industrial processes could not be operated in mild conditions or sometime substrates for industrial processes have complex chemical structure and no known enzyme is suitable to catalyze the reaction for such processes. Hence, there is a constant urge for discovering new enzymes that are active on novel substrates or can catalyze reactions at extreme environment. Screening of large number of microorganisms is the most promising method for searching novel enzymes and marine microorganisms are revealed as the source of numerous novel biocatalysts. This chapter focuses on distinct features of marine microbial enzymes, their current uses, current research

status and future prospects with reference to major challenges for commercialization of marine microbial enzymes and some potential way to overcome them.

For the enzyme-based bioprocess development, the enzymes should be stable and active at the industrial reaction conditions – many marine microbial enzymes showed that potential. They are found to be suitable for various industrial process development, biomedical applications, organic synthesis, and biotechnological research [38.1–3]. Activity and stability at extreme conditions are the most useful features of marine microbial enzymes. They are reported to be active at extreme pH or temperature, in the presence of organic solvents or high salt concentration – each of these characteristics could be potentially exploited for some industrial applications [38.3–5]. Several marine extremozymes are key tools of current biotechnological research while others are being used in textile industry, biofuel industry, and pharmaceutical industry [38.4, 6]. Several other enzymes are reported to have potential industrial applications, and currently being studied for feasible large-scale production and industrial process development. Solvent-tolerant marine microbial enzymes are suitable for synthesis of pharmaceutically important stereoselective compounds.

Isolation of a novel enzyme with unique application is a challenging job and search for marine microbial enzymes got extreme importance for their vast potential application. Instead of huge potential of engineered enzymes fewer researches are being conducted for protein engineering and directed modification of the isolated marine enzymes. Bulk production at reasonable cost, development of large-scale downstream processing, and feasible industrial processes development are also important considerations for industrial exploitation of any enzyme. Unfortunately, such important industrial aspects are grossly neglected in the field of marine biotechnology. Recently, a few research groups are focusing on scale-up and downstream processing of marine microbial products but still the efforts cannot match with the huge number of potential industrial enzymes that are being reported from marine microbial environments. Future prospects of marine microbial enzymes are crucially dependent on the success of specific researches, which are focused on large-scale production, engineering, downstream processing, and industrial exploitation of these enzymes.

38.2 Marine Extremozymes and Their Significance

Marine microbial enzymes attract special interest due to their habitat related properties that enable them to be active in extreme environments. In the course of evolution, marine microorganisms faced extreme environmental challenges and adapted their metabolic pathways to survive in diverse environments. As a result, they produce unique metabolites, which are seldom reported from terrestrial sources. Several marine enzymes were reported to be stable and active at extreme temperature or pH. Some are tolerant to extreme saline condition, active in the presence of different chemicals or even in organic solvent system. A number of marine enzymes have novel stereochemical properties that can catalyze (stereoselective) chemical reactions, which are impossible otherwise. Importance of these habitat-related characteristics is vastly recognized from general biotechnological perspective and blending of two such features in a single enzyme is extremely useful for the development of unique bioprocesses. For example, thermostable alkaliphilic proteases are used as additive in laundry detergents and these enzymes can be useful in dry-cleaning if they can work in the presence of organic solvents. Another example is the use of thermostable solvent-tolerant enzymes in the biofuel industries and these enzymes have potential application for biofuel production from seaweed biomass if they are active in saline environment. The following sections highlight on the importance of various extremozymes with special reference to the marine isolates.

38.2.1 Thermostability

Thermostable extremozymes can be used in industrial reactions that are not feasible at ambient temperature. Higher temperature is preferable in many chemical reactions due to higher solubility of substrates, lower viscosity, better mixing, faster reaction rate, and decreased risk of microbial contamination. Moreover, thermostable enzymes are easy to purify by heat treatment. Thermostable proteases, lipases, amylases, cellulases, chitinases, carragenases, xylanases, polymerases, and oxidases have several applications in food processing industry, detergent industry, paper industry, textile industry, biofuel industry, and biotechnological research. Thermostable marine microbial enzymes are reported mostly from ther-

mophilic members of *Thermotoga*, *Thermus*, *Thermococcus*, *Pyrococcus*, *Bacillus*, and *Sulfolobus* family. Thermostable archaeal enzymes were reported to have higher stability towards high pressure, detergents, organic solvents, and proteolytic degradation [38.7]. Several thermostable enzymes were screened from hyperthermophilic archaea of deep-sea hydrothermal vents [38.8–10]. A crude esterase from *Pyrococcus abyssi* exhibited 22 h half-life at 99 °C that can retain entire initial activity after 8.5 h incubation at 90 °C [38.8]. A thermostable amylase from *Rhodothermus marinus* was reported to produce branched glucan from amylase and showed maximum activity at 80 °C [38.11]. *Taq* polymerase and *Pfu* polymerase are two mostly used thermostable DNA (deoxyribonucleic acid) polymerases isolated from two thermophilic archaea *Thermus aquaticus*, and *Pyrococcus furiosus* respectively [38.4, 12]. The latter species was isolated from a geothermally heated marine sediments having temperature in between 90−100 °C.

38.2.2 Cold Adaptivity

Cold adaptive enzymes are essential to catalyze the bioprocesses that need to be performed at low temperature to avoid degradation or evaporation of reaction components or products. Low-temperature reactions are preferred in industrial processes because it minimizes corrosion of the metallic reactors. Many cold active enzymes can be easily inactivated by mild heat treatment that can prevent undesired prolonged activity; this property is also useful in multistep process if the enzyme has undesired effect in subsequent reaction step. For example, stonewashing with cellulases in the textile industry where long-term enzyme activity could lead to the loss of mechanical resistance of the cotton fibers. Cold adaptive enzymes are abundantly isolated from a broad range of psychrophilic marine microorganisms including the members of the genus *Psychrobacter*, *Methanococcus*, *Alteromonus*, *Aquifex*, and *Bacillus*. Arctic and Antarctic microorganisms are well-known source of cold adaptive enzymes. A cold adaptive alkaline phosphatase isolated from an Antarctic bacterium shown interesting property for application in molecular biology research [38.13]. It is highly active at low temperature and after use can be easily inactivated by mild heat treatment (at 55 °C) that eliminate the need of separating the DNA after alkaline phosphatase treatment. Several others cold adaptive enzymes were reported to have potential applications in baking industry, bioremediation and as cold-wash additive [38.14–16]. Cold adaptive polysaccharolytic enzymes are being studied for applications in textile and paper industries. Several cold active lipases were reported from Antarctic deep-sea sediments metagenome and microbial isolates including *Pseudomonas* and *Psychrobacter* species [38.17–19]. Some of these enzymes retained their activity at very low temperature but inactivated at ambient temperature. A cold-active lipase was reported from a psychrophilic isolate of the Southern Ocean deep sea that retains 37% of its maximum activity at 0 °C [38.20]. Cold active lipolytic enzymes could be exploited in specific industrial processes such as bioremediation of fat-contaminated aqueous systems [38.16]. A cold active esterase was reported from *Pseudoalteromonas arctica* that showed optimum activity at 25 °C and retained 50% of maximum activity at 0 °C [38.21]. It can hydrolyze several members of nonsteroidal anti-inflammatory drugs including ibuprofen.

38.2.3 Extreme pH Tolerance

In general, proteins are unstable at extreme acidic or basic environments and average enzymes have optimum activity near neutral pH. Several bioprocesses are favored in acidic or alkaline conditions where most typical enzymes are inactivated – such reactions can be catalyzed only by enzymes that can tolerate extremely low or high pH, respectively. Many marine microorganisms can survive at extreme acidic or alkaline conditions and, extracellular enzymes from these microorganisms are often active at extremely low and extremely high pH, respectively. Detergent industry consumes more than 30% of industrial enzymes as additive in laundry detergents that includes alkaliphilic protease, lipase, amylase, and cellulase. These enzymes also have potential application in contact lens cleaning. Several thermostable alkaliphilic proteases from marine microorganisms have potential application as cleansing enzyme [38.22–24]. Alkaline phosphatase is another useful alkaliphilic enzyme frequently reported from marine microorganisms [38.5, 25]. *Kobori* et al. (1984) reported an alkaline phosphatase from marine microorganisms that can be inactivated by mild heat treatment (at 55 °C) and has potential application in biotechnological research [38.13]. Acidophilic digestive enzymes are useful in food and pharmaceutical industries. Numerous alkaliphilic enzymes were reported from marine *Bacillus* whereas marine fungi produce a range of acidophilic enzymes. Several thermostable alkaline proteases from marine *Bacillus* are reported to

be active in the presence of surfactants and bleaching agents; potentially they can be used as additive in commercial detergent [38.22, 23, 26]. An alkaline protease from marine shipworm bacterium was reported to have strong cleansing power and it can degrade lysozyme more efficiently than subtilisin [38.24]. This enzyme is active in the presence of hydrogen peroxide that is usually used to sterilize contact lenses. Two thermostable alkaliphilic amylases from marine microorganisms are active in the presence of surfactants and commercial detergents that suggests their potential applications in detergent industry [38.27, 28].

38.2.4 Halotolerance and Organic Solvent Stability

Most characteristic feature of the marine environment is high salinity and extracellular enzymes from marine microorganisms are reasonably active in the presence of high salt concentration. Salts present in reaction systems usually as contaminant, reactant, or product; sometimes salts are used to stabilize proteins essential in the bioprocess. Salt-tolerant enzymes can be exploited to catalyze the bioprocesses where reaction mixture contains high salt concentrations that inhibit most common industrial enzymes. Halotolerant proteolytic enzymes are used in peptide synthesis and fish/meat processing industries. Salt-tolerant polysaccharolytic enzymes are being studied for application in biofuel production from marine microalgae and seaweed biomasses. A halotolerant amylase-producing marine bacterium was reported to be used in saccharification of marine microalgae in the presence of high NaCl concentration [38.29]. Halotolerant enzymes are uniquely adapted to function in conditions with low water availability and some of them are inactive without high salt concentration. An amylase from marine *Streptomyces* sp. D1 was reported to retain almost 100% activity in the presence of 7% (w/v) NaCl after 48 h incubation but its activity drastically decreases after 48 h incubation without NaCl [38.27].

Several halotolerant enzymes are reported to be active in the presence of organic solvents, which is likely to be related with their adaptability in low water containing reaction system [38.30, 31]. An organic solvent tolerant lipase was reported from the marine *Aeromonus hydrophila* where the enzyme production was highly dependent on NaCl concentration within the production media. However, tolerance to both high salt and organic solvents gives a new blend of extremophilic properties in these enzymes that can be exploited for certain applications. In organic systems, enzymes may catalyze reactions even impossible in pure aqueous media. Organic solvent-tolerant enzymes can catalyze reactions in biphasic mixtures and some of them are useful for synthesis of chirally pure drug molecules. An organic solvent-tolerant enantioselective alcohol dehydrogenase from *P. furiosus* showed potential applications in reduction of ketones with low solubility in aqueous buffers [38.3]. This enzyme is highly stable and active in organic solvents like *iso*-propanol, DMSO, methyl *tert*-butyl ether, and hexane. Catalytic properties, substrate specificity, and enantioselectivity of this enzyme are vastly studied. It catalyzes reduction of aryl ketones for production of enantiomerically pure chiral alcohols and enzyme activity increases at enhanced temperature without affecting enantioselectivity. Several organic solvent tolerant esterase/lipase were isolated from marine microorganisms that have potential application in biodiesel production and synthesis of chirally pure compounds [38.32, 33].

38.2.5 Barophilicity

The effect of pressure on a reaction is dependent on sign and magnitude of the activation volume. Reactions accompanied by negative volume change are promoted by increased pressure and biocatalysis of these reactions may require barophilic enzymes. Deep-sea piezophilic microorganisms are natural source of barophilic enzymes. Pressure-tolerant enzymes could be useful in food processing industries, in particular where high pressure is applied for processing and the sterilization of food materials [38.34]. Biotechnological aspects of a few high-pressure-tolerant marine microbial enzymes are being studied but this group of extremozymes is yet to be understood in terms of their structure, activity, flexibility, and potential applications [38.35]. A protease produced by a deep-sea fungus that was isolated from 5000 m depth of Central Indian Basin reasonably retains its activity at elevated pressure as high as 300 bar [38.36]. The barophilic and extremely thermophilic protease isolated from another deep-sea microorganism *Methanococcus jannaschii* is an excellent example of extremozyme from marine microorganism [38.37]. Enzyme activity and thermostability of this protease increased with pressure – raising the pressure to 500 atm at 125 °C enzyme activity and thermostability enhanced by 3.4-fold and 2.7-fold, respectively. Similar behavior was observed in

a partially purified hydrogenase from the same organism [38.38]. The hydrogenase activity was increased more than three times when the pressure was raised from 7.5 to 260 bars at 86 °C. Thermostability of this hydrogenase was also stabilized by enhanced barophilic pressure.

38.3 Current Use of Marine Microbial Enzymes

Detail discussions on the research and applications of marine enzymes are presented in some recent reviews [38.16, 39–41]. From these discussions, it is clear that biochemical characterization of several marine microbial enzymes showed their potential biotechnological or biomedical applications but most of them are yet to be exploited for industrial purposes. Only a few marine microbial enzymes are currently used in industrial and research purposes.

Until now, thermostable DNA polymerases are most widely used marine microbial enzymes. PCR (Polymerase Chain Reaction) is a very strong tool of molecular biology research but wide use of PCR was practically impossible without a thermostable DNA polymerase. Two marine microbial enzymes, the Vent polymerase from *Thermococcus litoralis* (New England Biolab) and *Pfu* polymerase from *Pyrococcus furiosus* (Stratagene) solved this problem. *Pfu* polymerase is one of the most widely used DNA polymerase in molecular biology research. These enzymes showed optimum activity at ≈72 °C and are stable at >95 °C. They are almost solely used enzymes for this purpose. *Tth* DNA polymerase from *Thermus thermophiles* is another marine microbial enzyme used for biotechnological research. It is a 5′→3′ polymerase enzyme and showed reverse transcriptase activity in the presence of Mn^{2+} ion. *Tth* polymerase has optimal activity at 70–80 °C and is used for some special PCR applications including one-step reverse transcription polymerase chain reaction (RT-PCR) and real-time PCR [38.42]. ArcticZymes AS, a subsidiary of Biotec Pharmacon ASA announced several marine enzymes for molecular biology research though exact source of the enzymes were not revealed. They are marketing uracil DNA glycosylase and several nucleases including thermolabile DNAses and salt-active nucleases [38.43].

Vernium Corporation revealed the discovery of a thermostable α-amylase from deep-sea microorganism [38.6]. The enzyme with brand name Fuelzyme is highlighted as a next generation α-amylase for starch liquefaction. By a unique mechanism of action it randomly hydrolyzes α-1,4 linkage of starch and produces lower molecular weight soluble dextrin and oligosaccharides of uniform size. It is active over a broad range of temperature and is used to increase fuel ethanol yields due to improved starch hydrolysis at much lower concentration in comparison to other competitive enzymes. Currently this enzyme is being marketed by Verenium Corporation and is expected to significantly improve the efficiency and economics of fuel ethanol production.

Two recombinant lipases *Candida antarctica* Lipase A and Lipase B are being marketed by Sigmaaldrich. These enzymes were originally reported from the marine fungie *C. antarctica* isolated from Lake Vanda in Antarctica. They are used industrially for the resolution of chiral compounds and the transesterification production of biodiesel. Lipase B is an enantioselective enzyme that can catalyze the synthesis of esters of ethyl D-glucopyranoside from fatty acids larger than octanoic acid. It can catalyze a wide variety of organic reactions including enantioselective syntheses. It is used in enzymatic acylation of nelarabin for production of a highly soluble antileukemic agent, nelarabin 5′-monoacetate [38.44]. The end-product has better bioavailability than nelarabin. This enzyme is tolerant to organic solvents and the best substrate conversion is achieved when the reaction takes place in anhydrous dioxane. It can convert almost 99% substrate to the desired stereoisomer, which is almost impossible in conventional chemical acetylation processes.

38.4 Current Research Status of Marine Microbial Enzymes

Extracellular enzymes from marine microorganisms need to be exposed in extreme environments and logically most extremozymes belong to this category. Several preliminary researches were concluded with enzymatic activity of intact microorganisms or extracellular culture supernatants. For many years, research articles reported mainly physicochemical characterization of crude, partially purified, or purified enzymes.

Recent development of biological and engineering tools is slowly leveraging the marine biotechnology research. Cloning and overexpression of marine-derived enzymes is a common practice now a day. Structures of a few marine enzymes were resolved and a marine microbial enzyme is reported to be engineered to achieve the desired characteristics [38.45–47]. Bioinformatics is playing a key role for the development and analysis of huge databases, which are useful for sequence analysis, analysis of gene expression, identification of microorganisms, prediction of structure and function of unknown proteins and, in primer design and mutant construction for protein engineering. Metagenome analysis becomes a routine technique for searching proteins from uncultivable marine microorganisms. On the other hand, several mathematical models are used for optimization of media composition and fermentation parameters. Marine-derived enzymes are also being studied for potential nontraditional applications including waste management and biofuel production [38.48–50].

38.4.1 Genetic Engineering and Related Research

Molecular biology and recombinant DNA technology are widely used in current research on marine microbial enzymes. Large-scale enzyme production from a native host is less economic due to low productivity and wastage of nutrients for cellular maintenance. Marine microorganisms often need expensive media components and sometime special fermentation conditions for production of desired enzymes. Cloning of marine-derived genes is essential for enzyme production in normal expression hosts – it can bypass the challenges of large-scale cultivation of marine microorganisms and extracellular enzyme purification from the complex marine media.

Alkaline protease genes were amplified from complementary DNA (cDNA) and genomic DNA of the marine yeast *Aureobasidium pullulans* 10 and *A. pullulans* HN2-3 [38.51, 52]. The gene from *A. pullulans* 10 was cloned and overexpressed in *Yarrowia lipolytica* as an extracellular protein that was purified from the culture medium. The gene from *A. pullulans* HN2-3 was cloned into a surface display vector pINA1317-YlCWP110 and expressed in *Y. lipolytica* cell for production of the surface-displaying alkaline protease [38.52]. The overexpressed protease on *Y. lipolytica* surface can produce bioactive peptides that showed angiotensin-converting enzyme (ACE) inhibitory activity and antioxidant activity. Other marine enzymes may be useful for production of bioactive peptides from various raw materials using different surface displaying proteases. *Tsujibo* et al. cloned two alkaline serine protease encoding genes from a marine *Alteromonas* sp. strain O-7 and overexpressed into *E. coli* [38.53, 54]. The amino acid sequence revealed that both the proteins are composed of four domains including a signal peptide and a mature protease region with high sequence homology to other class-I or class-II subtilases. Another alkaline protease gene was isolated from the marine fungus *Engyodontium album* and cloned in *E. coli* system [38.55]. Homology modeling of translated amino acid sequence suggests the gene encode an extracellular protease that belongs to the subtilase family of serine protease. Comparative homology modeling revealed that the protease has broad substrate specificity with preference for bulky hydrophobic residues at P1 and P4. Also the model suggests that the protease structure is stabilized by two disulfide linkage and more than two Ca^{2+} binding sites. Partial sequence of a lipase-encoding gene from an Antarctic *Psychrobacter* sp. was identified by PCR-based screening using primers obtained from multiple sequence alignments of a group of prokaryotic lipases [38.56]. By application of a fast and efficient genome-walking technique, a complete 1293 bp gene sequence was obtained and, the promoter and downstream sequences of the gene were also determined. The gene was cloned into pMAL-c2E expression vector and a recombinant MBP fusion protein was over expressed in *E. coli*. The fusion protein showed high lipolytic activity and retained the psychrophilic property with optimum activity at 20 °C. Oxidative stability of an α-amylase was studied by site-directed mutagenesis [38.46]. The enzyme was purified from a deep-sea marine *Bacillus* isolate and reported to retain almost complete activity even after 1 h incubation with 1.0 M H_2O_2. Mutagenesis study showed that the presence of a nonoxidizable Leu198 in place of a conservative methionine residue results exceptional oxidative stability of this enzyme.

Several marine enzymes were identified by metagenomic approach. *Hardeman* et al. (2007) reported a marine lipase from a metagenomic library of Baltic Sea sediment bacteria [38.57]. A library of 47 000 clones was generated by extracting the prokaryotic DNA and cloning it into a pCC1FOS plasmid. The inserts within the clones are ranging from 24 to 39kb. The lipolytic gene was detected by activity-based screening followed by subcloning and sequencing of positive clones. The isolated gene with 978 bp ORF encodes a 35.4 kDa lipase that shows 54% amino acid similarity and several

conserved region with a *Pseudomomas putida* esterase. In another study, two novel esterase genes were isolated by functional screening of a marine microbial metagenomic library [38.58]. Two esterase containing 277 and 328 amino acids were purified and biochemically characterized. Site-directed mutagenesis showed one of the esterase contained classical catalytic triad containing S146–D222–H255 and the second esterase contained an unusual catalytic triad made up with S–E–H. The latter esterase was highly stable in the presence of organic solvents. *Xu* et al. (2010) reported cloning, expression, and characterization of another novel esterase from marine sediment microbial metagenomic library [38.59]. The expressed protein was a psychrophilic esterase that showed 71% sequence identity to another esterase (ADA70030) identified from marine sediment metagenome. Another esterase was reported from metagenomic library constructed from bacteria associated with the marine sponge *Hyrtios erecta* [38.60]. The esterase gene was PCR-amplified, cloned in pET22b plasmid and overexpressed in *E. coli*. The purified protein is moderately thermostable and active in the presence of high NaCl concentration. One α-amylase encoding gene was isolated from a marine metagenomic library, cloned in pUC19 vector and overexpressed in *E. coli* [38.61]. The full-length amino acid sequence showed very low similarity with known α-amylases but revealed the presence of a conserved catalytic domain of α-amylase superfamily. It exhibited the highest sequence identity (50−72%) to four putative glycosidases from four different marine bacteria.

38.4.2 Structural Study

Structure elucidation of marine microbial enzymes is rarely reported instead of more than two decades extensive research in the field of marine biotechnology and characterization of numerous marine microbial enzymes. Understanding of 3-D structure of enzymes is extremely useful to study structure activity relationship and improvement of the enzyme activity by protein engineering. Structure of the catalytic domains gives an idea regarding substrate specificity of enzymes while other domains determine several important features need to be considered for enzyme activity such as stability and ligand binding of the enzyme.

Crystallization and preliminary X-ray analysis were done to study catalytic domain of a β-1,3-xylanase from the marine bacterium *Vibrio* sp. AX-4 [38.47]. The protein contains an N-terminal catalytic module and two *C*-terminal xylan-binding modules. Successful crystallization was possible with a deletion mutant composed of a catalytic module without a xylan-binding module. The crystal diffracted to 1.44 Å resolution and the crystal data analysis suggests that the crystal belongs to the orthorhombic space group $P2_12_12_1$, with unit-cell parameters $a = 51.6$, $b = 75.8$, $c = 82.0$ Å. A similar study was done with a methanol dehydrogenase from the marine bacterium *Methylophaga aminisulfidivorans* MP^T [38.45]. The mechanism of activity of this enzyme was predicted from preliminary X-ray crystallographic analysis of the native heterotetrameric $\alpha_2\beta_2$ methanol dehydrogenase complex. X-ray diffraction data were collected to 1.7 Å resolution and it was revealed that the crystal belongs to the monoclinic space group $P2_1$ (unit-cell parameters $a = 63.9$, $b = 109.5$, $c = 95.6$ Å, $\beta = 100.5°$). Matthews coefficient and solvent content of the asymmetric heterotetrameric complex were calculated as 2.24 $Å^3\,Da^{-1}$ and 45.0%, respectively. In two other studies, psychrophilic alkaline proteases from two different marine microorganisms (Antarctic *Pseudomonas* sp. and Chinese Yellow Sea *Flavobacterium* YS-80 sp.) showed a homologous structure [38.62, 63]. Both the proteases have two domain structures where N-terminal domains have proteolytic activity and the C-terminal domains are responsible for stability of protein structure. Several Zn^{2+} and Ca^{2+} ions are associated with crystal structure of both the proteins. The tertiary structures of these psychrophilic proteases are comparable to their mesophilic counterparts. The Yellow Sea *Flavobacterium* protease is more thermostable and is more rigid in structure than Antarctic *Pseudomonas* protease but is more flexible than its mesophilic counterpart. These properties are consistent with the respective habitat of the enzyme producing microorganisms and would be helpful for elucidating the structure-environment adaptation of these enzymes. Crystal structure of the Yellow Sea *Flavobacterium* protease was solved at 2.0 Å resolution and was refined to a crystallographic R_{work} and R_{free} of 0.16 and 0.21, respectively. Structure of the psychrophilic Antarctic *Pseudomonas* protease was studied in two crystal forms with 2.1 Å and 1.96 Å resolutions. Comparative studies showed that the overall structures of this psychrophilic enzyme is similar to its mesophilic counterparts but conformation of its substrate-free active sites are similar to substrate-bound form of the mesophilic proteases.

38.4.3 Fermentation and Related Research

Continuous supply in ample quantity and cost of large-scale production are major challenges for commercial-

ization of most marine natural products. Optimization of media composition and fermentation parameters is key consideration for the scale-up of microbial enzyme productions. Cultivation of most marine microorganisms needs special media composition and in many cases physical conditions of their native habitat have influence in optimum fermentation conditions. Cost-effective production media are reported for solid-state and submerged fermentation of several marine microbial enzymes. High NaCl concentration, addition of trace metals or sea water was reported to enhance productivity of several enzymes.

Media and fermentation parameters for protease production by the marine yeast, *A. pullulans* was optimized in a 2 L fermenter [38.64]. Maximum protease activity was achieved after 30 h fermentation at 24.5 °C in a medium containing 2.5 g soluble starch, 2.0 g $NaNO_3$ and 100 mL seawater (per liter) with initial pH 6.0. Thermostable alkaline protease production by a marine *Bacillus* sp. was optimized and scaled up in a stirred tank bioreactor using cheap and readily available substrates [38.23]. Maximum protease production was achieved after 40 h fermentation at 42 °C with an aeration rate of 1.5 vvm and constant agitation at 400 rpm in a soybean-casein medium (pH 9.6). Protease production by the marine bacterium *Teredinobacter turnirae* was optimized for solid-state fermentation as well by immobilization the microbial cells on solid matrixes [38.65, 66]. Media composition, initial pH, inoculums concentration, and effect of different salts and carbon sources were studied to optimize protease production by solid state fermentation in a soybean-based media. The maximum protease production was obtained using 1% (w/v) of soybean concentration, initial pH 7.34, and 2.5% (v/v) inoculum level. In the other study, material and particle size of the immobilizing media and, method and conditions for cell immobilization was optimized for repeated batch fermentation of the alkaline protease by *T. turnirae*. Ceramic support, different size of broken pumice stone and silicone foam enhanced enzyme production by more than 200%, when compared to free cells. Electron micrograph evident *T. turnirae* colonization in porous support matrices and five repeated batch fermentation was achieved without significant decrease of the enzyme production. When the same strain was immobilized in calcium alginate beads maximum protease activity was achieved at 3% (w/v) sodium alginate and 3% $CaCl_2$ concentrations with a 1 : 2 ratio of cell and alginate. Protease production was independent on bead size but decreases significantly when the beads were treated with glutaraldehyde. The immobilized cells were used for eight cycles each lasting 72 h. Protease production increased with increased number of fermentation cycles and maximized at fourth cycle when the enzyme activity reached about 3.5 times than that of the first cycle. *Estrada-Badillo* et al. (2003) studied the effects of agitation and aeration rate on biomass and extracellular protease production by a marine *Vibrio harveyi* sp. using a seawater/Zobell-based medium [38.67]. Maximum protease activity was obtained at 700 rpm agitation and 0.5 vvm air flow rate. Addition of skim milk in Zobell medium enhanced the extracellular protease production by fivefold. Growth of the culture was highly dependent on agitation rate and most protease activity was achieved at stationary phase after 3 h culture. *Sarkar* et al. (2011) developed a special conico-cylindrical flask with an inner arrangement to enhance protease production by an intertidal marine isolate [38.68]. The conico-cylindrical flask was attached with eight equidistant rectangular strips mounted radially on a circular disk to provide additional surface area for microbial attachment. 35% higher protease production was achieved in this system in compare to Erlenmeyer flask. The influence of surface material (hydrophobic versus hydrophilic) was also studied for growth and protease production by this marine isolate. Esterase fermentation of the marine *Bacillus licheniformis* MP-2 strain was optimized by response surface methodology [38.69]. Eleven factors related to esterase fermentation were studied with Plackett–Burman design. Amount of peanut cake, soybean cake, and inoculum volume was observed to have major influence on the MP-2 esterase fermentation. The critical level of these three parameters was further studied by response surface methodology. The optimal process conditions were determined by solving the quadratic regression model equation and analyzing the response surface contour plots. Practical enzyme production was increased from 258.8 to 318.2 U mL^{-1} using peanut cake, soybean cake and inoculum ratio of 0.9%, 2.29%, and 5.98%, respectively, while theoretical optimum esterase activity of MP-2 was predicted as 334.46 U mL^{-1} under these conditions. A similar approach was reported for optimization of fermentation parameters and media composition for a cold adapted amylase production by marine bacterium *Wangia* sp. 52 [38.70]. At optimized condition experimental amylase production reached very close to the yield predicted by statistical model. Tenfold increase of the amylase production was achieved in compared to the control shake flask culture. An efficient, simple and reliable

production process was developed for a thermostable esterase production by a thermophilic marine *Pyrococcus* sp. [38.71]. The gene was cloned and overexpressed in *E. coli* and, fermentation and downstream processing of the recombinant protein was scaled-up to industrial scale. This method is potentially competitive for industrial application due to high enzyme concentration (2 g/L) and product recovery yield (>70%).

38.5 Future Prospects

Several marine microbial enzymes showed immense potential for industrial applications but there is lack of effort for their commercialization. Significant numbers of enzymes are not further reported after physicochemical characterization though some interesting enzymes went through cloning and gene over-expression, lab-scale product optimization, and structure elucidation. However, scale-up of marine enzyme production or large scale process development with marine enzyme is rarely reported [38.72]. Only a few marine-derived enzymes are already reported to be used as industrial enzymes and in biotechnological research. Few more enzymes are in trial for industrial or biomedical applications but a countable numbers are facing challenges in early stage development on their way to practical application. A major challenge for commercializing marine enzymes comes from the lack of cost-effective large scale production methods. Extremophiles are source of most potential commercial enzymes but their optimum growth and enzyme production often need extreme environments. This problem can be overcome by cloning and expression of the respective gene in a suitable host microorganism that can grow in ambient environmental condition. However, to ensure continuous supply of enzymes in large quantity, more intensive research is essential in the area of scale-up and downstream processing. Industrial process development with existing potential enzymes is another big challenge. More research efforts can be diverted for industrialization of the existing potential enzymes than searching for an unknown one but matching an enzyme with a process is not always an easy job. Though many industrial plants can be modified to accommodate the limitations of an existing enzyme, in most cases it is not cost effective. Finding a more suitable enzyme for the existing industrial process may be easier but an extremely uncertain approach. Marine ecosystem has a lot room for searching novel enzymes while protein engineering may be complementary research strategy. Enzymes can be engineered to increase their activity, enhance tolerance to organic solvents or other chemicals, to manipulate substrate specificity and to enhance tolerance to extreme physical conditions. Manipulating activity or physical characteristics of an enzyme is tough but systematic approach. Protein engineering became more practicable with current tools of biotechnology and it is advancing every days – it may be the future of industrial enzyme development. Understanding of 3-D structure and their analysis by bioinformatics tools would be helpful to design engineered enzymes with improved properties. Unfortunately, structural biology and protein engineering is grossly neglected in marine biotechnology. Marine biotechnology is no more a nascent research field – sufficient work is done with marine microbial enzymes to step forward for exploring the chance of using multidisciplinary knowledge and techniques of biotechnology for their commercialization.

After detail characterization several marine microbial enzymes reported to have potential applications in food processing industry, chemical and pharmaceutical synthesis, and bioremediation. Potential applications of psychrophilic xylanases were reported from Antarctic microorganisms in baking industry and the enzymes are already patented [38.14, 73, 74]. Organic solvent tolerance is a common feature of many marine microbial enzymes. Numerous marine microbial esterases and lipases showed high tolerance to organic solvents [38.33]. These enzymes can catalyze some reactions ever impossible in aqueous systems and have potential applications in chemical synthesis. They are also well known for catalyzing chemical reactions for enantioselective product formations; these enzymes can be exploited for synthesis of enantiospecific drug molecules [38.75]. An organic solvent-tolerant enantioselective alcohol dehydrogenase from the hyperthermophilic marine archaeon *P. furiosus* is being considered for its potential applications in industrial biocatalysis [38.3]. Catalytic properties, substrate specificity, and enantioselectivity are widely studied for this enzyme. It catalyzes reduction of aryl ketones for production of enantiomerically pure chiral alcohols. The activity of this enzyme increases at enhanced temperature without affecting enantioselectivity. Marine microbial enzymes can also be exploited for biomedical application. L-asparaginase is a drug of choice in combination therapy for treatment of children lym-

phoblastic leukemia [38.76]. L-glutaminase also has a similar antineoplastic activity. Both of these enzymes were reported from marine sources. The L-glutaminase from the marine bacteria *Pseudomonas fluorescens* was studied for antineoplastic activity [38.77, 78]. However, potential immunogenic issues need to be addressed before use of these microbial enzymes in human system. Some marine microorganisms showed potential application for bioremediation of industrial and agricultural wastages [38.48, 79–82]. Use of marine enzymes is proved to be advantageous for degradation of organic wastes generated in seafood farming [38.83]. A strain of the marine fungus *Geotrichum marinum* was reported to degrade crude petroleum and petroleum products [38.84]. It can be useful in pollution control for treatment of effluents from petrochemical industries. Oil spillage on sea surface is frequently reported from damaged ships or broken pipelines, which cause severe damage to marine ecology. A salt-tolerant petroleum-degrading enzyme would be extremely useful to degrade the residual petroleum products – may be the solution is hidden under the sea.

38.6 Conclusion

Scientific publications suggest that the enormous biodiversity of the marine ecosystem is an excellent source of novel enzymes. The extremophilic nature and versatile biocatalytic capabilities confirm potential industrial application of marine microbial enzymes. Marine microbial enzymes already provided some extremely important tools for biotechnological research. A few marine enzymes are also being used in biofuel and pharmaceutical industries. Several marine microbial enzymes showed potential applications in chemical and pharmaceutical synthesis, food processing industries, and environmental managements. With the development of high-throughput screening techniques there are lot room for discovering novel enzymes from vast marine ecosystem. The advancement of genetic engineering, better understanding of protein structure, and availability of several biotechnology tools is leading to the development of engineered enzymes with improved properties such as higher catalytic activity, better tolerance to organic solvents and more stability to adverse environments. Published research works suggest extensive industrial scope of marine microbial enzymes but further application-oriented researches are essential for exploitation of their full biotechnological potential.

39. Marine-Derived Exopolysaccharides

Christine Delbarre-Ladrat, Vincent Boursicot, Sylvia Colliec-Jouault

Marine biotechnology still remains a new and emergent science, which is closely linked to marine biodiversity and to the technological capacities of investigating more atypical ecosystems. Marine microorganisms show a unique biodiversity since they have to adapt to various marine environmental conditions such as low or high temperatures, alkaline or acidic water, high pressure, and limited nutrients. Marine natural products, especially marine polysaccharides, are attracting more and more attention. Microbial polysaccharides are of growing interest for many sectors of industry, resulting in isolation of new exopolysaccharide (EPS)-producing bacteria. The diversity of these polysaccharides arises from the structural variations (glycosidic bonds, side branching chains, monosaccharidic content) controlled through a genetic basis. A lower molecular weight and functionalized derivatives together with the native form of the polysaccharide have been shown to possess a variety of biotechnological activities. Therefore, the biophysical and biological properties have made them useful in many pharmaceutical, food, and industrial applications. This chapter gives information on EPS-producing bacteria from the marine environment, as well as on the carbohydrate molecule they produce, including the chemical composition or structure when available, the putative pathways of biosynthesis, and the potential applications in industry with a focus on healthcare and glycosaminoglycan-like compounds.

39.1 In Search of New Polysaccharides

Polysaccharides constitute the most abundant and the most diverse materials found on earth and in the oceans. Polysaccharides (PSs) form a class of biotechnological molecules that find applications in many industrial fields. They consist of monosaccharides (sugar units) that are linked to each other, generally in a repeated sequence order. By composition, PSs may be divided into homopolysaccharides, composed of single monosaccharide type and heteropolysaccharides with several different monosaccharides. Interest in carbohydrates was first very low due to their extreme structural complexity and the lack of understanding of their key role in different biological systems or processes. The type of glycosidic bond, the chain length, the degree and

type of branching, as well as the presence of organic or chemical groups are important features of the molecular structure, which are also of great importance for the biophysical or biological properties. Except for the PS used traditionally in the food industry, the structure of most PS, as well as the structure–function relationships are mostly unknown.

For biotechnological purposes, marine PSs have been studied in animals (chitin from crustaceans, chondroitin sulfate from fish, sulfated PSs from sponge and glycosaminoglycans from scallops and abalone), plants (ulvans, agarans, carrageenans, alginates, fucans, laminarin from seaweeds), and microorganisms such as fungi, microalgae, and bacteria. In bacteria, several kinds of PS exist, depending on their cellular localization and structure. Exopolysaccharides (EPSs) represent an important component of the biofilm matrix and serve as functional elements for adhesion, protection, and recognition. They also have chelating properties especially of heavy metals. The main advantages of microbial EPSs over plants or macroalgal and animal PSs lie on a stable supply independently of climatic or physiologic variations. Moreover, new structures have been described in bacteria, in particular in marine bacteria, giving the opportunity for the development of new applications, especially in the pharmaceutical field.

Marine-derived PSs and their oligosaccharidic derivatives have been studied for a variety of biological activities such as antithrombotic, antitumor, antiviral, antioxidant, and immunomodulatory effects. A high specificity linked with highly beneficial properties compared with the reference molecules already existing on the market are the major conditions of the development of new molecules, especially if these molecules present a cheaper production cost.

There is in particular a big diversity in the abundant microbial life in the oceans. The marine environments include coastal ecosystems, the deep ocean with hydrothermal vents, sediments, and the cold water of the poles. The extremes of temperature, pressure, and acidity met in the ocean, and the availability of the sources of energy and nutrients results in different strategies of microorganisms to survive. The combination of the diversity, the quantity, and the rate of metabolism makes the oceanic world a vital for the earth. Indeed, marine microbes are responsible for the global cycle of nutriments and other elements and are involved in the chemistry of the ocean, the composition of the atmosphere, and climate. As microorganisms quickly reproduce when conditions are favorable, the huge number of generations allows, by selection and natural evolution, the appearance of new species or other groups of the classification. The microbial genetic diversity also results in a biochemical diversity offering opportunities of biotechnological and pharmaceutical applications.

This chapter will focus on PS from bacterial microorganisms, presenting an overview of microbial marine biodiversity, structures of the produced polymers, some molecular aspects of their biosynthesis, as well as some of their applications driven by their features and biological properties with a focus on the human health domain.

39.2 Marine Biodiversity

For a long time, oceans have been considered as unlimited to human beings, who have always wanted to exploit the attractive resources. However, the industrial exploitation of the oceans only began 100 years ago. Studies to understand oceans and their ecosystems with the aim to exploit molecules produced by marine organisms or to develop new drugs inspired by marine molecules have started to reveal secrets, new biodiversity, and innovative molecules of biotechnological interest.

39.2.1 Ecosystems in the Oceans

The oceans cover 71% of the earth's surface, with an average depth of 3800 m. Depths reach 6000 m for the abyssal plains; the deepest point is the Mariana Trench in the Pacific Ocean (estimated to be 11 000 m). Smaller seas of salt water also exist; they are partly or fully enclosed by land.

Except on the surface and in temperate or tropical areas, most of seawater is characterized by a temperature lower than 5 °C, low nutrients, and no sunlight to allow photosynthesis. The open ocean is a huge ecosystem but particular habitats sometimes qualified as extreme have also been discovered: underwater salt lakes, volcanos, mountains, hot smokers, cold seeps, ...

In the deep sea, pressure is very high, the temperature is between 2 and 5 °C, and there is total darkness. A remarkable variety of deep-sea habitats exist: cold seeping waters, sinking particles, sediments, animal

guts and surfaces, deep sediments, and hydrothermal vents [39.1]. These latter areas are unstable due to high volcanic activity; they are characterized by a large gradient of temperatures [39.2], high amounts of dissolved compounds, gas, as well as very low pH values. The first deep-sea hydrothermal vent was discovered in 1977, near the Galapagos islands, on the East Pacific Rise, and the first *black smoker* in 1979 on the East Pacific Rise, 21° North. Deep-sea hydrothermal vents are mainly located on the active Mid-Atlantic Ridge, the East Pacific Rise, and back-arc basins (Fiji, Okinawa, Lau Basin). They come from the seeping of seawater down into the crust through rock cracks in the seafloor. During course of the water, several chemical processes enrich it in minerals, such as calcium, sulfates, magnesium, sodium, hydrogen sulphide, and metals, and it also becomes hotter. Jetting upwards by chimneys called black or white smokers formed by compound deposits or diffusing out of cracks, the hydrothermal fluid gives rise to the development of a luxuriant life contrasting with the apparently deserted surrounding water. Various vent fauna, bivalves, crustaceans, and worms take their energy and resources from endosymbiotic and episymbiotic chemoautotrophic microorganisms capable of oxidation of H_2 and sulfur compounds [39.3–5]. To survive under extreme conditions, such organisms must be adapted by appropriate metabolic pathways and protective mechanisms.

Some other volcanic areas also exist near the coast [39.1]. Shallow hot springs have been studied [39.6, 7]. Cold seeps are also characterized by hydrocarbon-rich fluids emanating from the ocean floor and are also the center of ecosystems with a large biodiversity [39.8, 9].

Near-shore sediments and deep-sea sediments have also been explored (the Ocean Drilling Project) and have revealed microbial life down to 1600 m in the sediment under the sea floor [39.10].

In polar areas, the environment is perennially cold, and in some cases permanently covered with ice; therefore, microbes need to adapt to cold temperatures and fight against freezing. However, even in these extreme conditions, some bacteria have been collected at around 0 °C in the Antarctic [39.11–13].

High saline water in inland water (the Dead Sea) together with high pH, high saltwater lakes situated underwater of seas such as the Black Sea, the Red Sea, the Mediterranean sea, or Gulf of Mexico have also been explored [39.14].

French Polynesia microbial mats are characterized by variable parameters such as pH values between 6 and 10.5, salinity ranging from 5–42 $g\,L^{-1}$, and temperatures between 20 and 42 °C. Microbial mats are laminated abundant communities of phototrophic and chemotrophic microorganisms. *Pseudomonas*, *Alteromonas*, *Paracoccus*, and *Vibrio* bacteria from these environments have been shown to produce EPSs [39.15, 16].

Marine surfaces and especially marine eukaryotes are covered with microorganisms embedded in a matrix forming a biofilm. The microbial epibiotic consortia differ significantly from microorganisms living in the surrounding environment and highlight the close relationships between microbial epibionts and hosts [39.17].

From deep-sea vents to surface-sea ice and open ocean, nutrient sources and physic-chemical conditions may be highly fluctuant, making quick adaptive responses necessary; the adaptation is possible on the basis of genetic diversity and has led to huge biochemical diversity.

39.2.2 Microbial Diversity and the Limitation of Collections

A high diversity of ecosystems exists within the world's oceans; they are different from terrestrial and freshwater environments; some endemic species have, therefore, been identified resulting in specific diversity.

Most of the biodiversity is microbial. The genetic diversity of microorganisms is far larger than that of plants and animals all together. Due to their large population size and since they grow rapidly, prokaryotes have an enormous potential to accumulate mutations, allowing them to adapt, and thus acquire genetic diversity. By weight, more than 95% of all living organisms found in the oceans are microbial. Microorganisms are the most abundant life form in the ocean, they are the basis of the marine food web, drive energy and nutrient cycling, and are at the origin of life on the earth [39.18]. This genetic resource is mainly unknown and underexploited and will probably be the major source for biochemical diversity resulting in novel molecules in the future.

Isolating new species requires the ability to cultivate them. Cultivation efficiency only allows the isolation of 1–5% of microbial species present in marine ecosystems [39.19]. Therefore, microbial diversity is largely undiscovered. From oceanographic cruises or sampling campaigns, several academic or industrial teams all over the world have developed marine microbial collections. These they are a good source of screening for innovative biomolecules. These collections, except

private ones, offer marine microorganisms and other services such as various screening. However, these collections shelter only cultivable microorganisms and, therefore, are limited. Nevertheless cultivation is a prerequisite to isolate compounds of biotechnological value such as PSs [39.20].

Culture-independent molecular techniques such as metagenomics, also named environmental genomics, have been adopted to explore the actual diversity of natural assemblages of microbes. Their sensitivity allows the detection of taxa at very low abundance. They have also revealed the incredible richness of marine life.

For several years, J. Craig Venter's Sorcerer II (Venter's Global Ocean Sampling Expeditions) sailed all around the sea world to collect samples of near-surface sea water every 200 miles. After filtration and freezing to collect and store microorganisms in the samples, DNA was extracted in the J. Craig Venter Institute laboratory and sequenced. Results revealed the power of metagenomic approaches to obtain a good estimation of microbial diversity and biochemical diversity; they also revealed a high proportion of new bacterial and viral sequences, which suggested that until now marine microorganisms have not been well isolated, especially viruses [39.21]. Many of these sequences must have potential as sources of new drugs and they are also studied for protein evolution, discovery of new enzymes, and microbial ecology concerns.

Tara Oceans expeditions [39.22] started on 2004 to study the impact of climate change on marine ecosystems, especially marine plankton including microorganisms such as viruses and bacteria, and other organisms such as medusas. It sailed all over the seas to collect samples and data and provide them to the world's scientific community. In 9 years, 8 expeditions have been organized with the aim to establish a time zero of marine ecosystems, to discover new organisms in each size class, to obtain a good estimation of oceanic biodiversity and its distribution, and to develop new models to estimate this biodiversity.

Deep-sea microbial diversity has been explored by metagenomic [39.23] or cultivation approaches [39.24, 25]. Sea floor sediments as well as hydrothermal vents with black or white smokers have been sampled. Studies on the genomic diversity of water columns [39.26] or sea floor sediments [39.27] have also been carried out as well as on microbial communities as associations with marine invertebrates, sponges [39.28] or with corals [39.29, 30].

In all cases, sequences related to fungi, bacteria, archaea, viruses and phages have been detected in variable ratios in a site-specific manner or isolated on culture media. The orders Thermococcales, Archaeoglobales, and Methanococcales are widely encountered in extremophilic archaea. On the other hand, the vast majority of bacterial sequences are mainly assigned to Thermotogales: *Proteobacteria*, *Firmicutes*, *Cyanobacteria*, and *Actinobacteria*, and 80–95% of marine bacteria are Gram-negative rather than Gram-positive.

Global Ocean Sampling Expeditions revealed that the archaea are nearly absent from the list of dominant organisms in the near-surface samples. Based on 16S ribonucleic acid (RNA) data, the most abundant phyla or classes are *Proteobacteria*, *Bacteroidetes*, *Cyanobacteria*, *Firmicutes*, *Actinobacteria*, and *Planctomycetes* [39.21]. The sequences mainly cluster within *Alphaproteobacteria* and *Gammaproteobacteria*. However distribution of these ribotypes is not homogeneous all over the ocean and different microbial communities can be distinguished.

The diversity of seawater habitats results in diversity of the organisms, and subsequently of the metabolites they produce. Thus marine genomics provide sequence data for microbial ecology but also biodiscovery [39.31]. This renders marine ecosystems really interesting to discover innovative molecules for biotechnological purposes. Extremophiles will provide new molecules or pathways for novel biotechnological processes but are also models to investigate how biomolecules are stabilized under extreme conditions. Several studies on marine biodiversity for biotechnological applications have been carried out on particular habitats such as deep-sea hydrothermal vents for extremophiles and thermostable enzymes, polar areas for psychrophilic ones, for exopolysaccharides [39.1, 32–36], microbial mats from French Polynesia [39.16].

These bacteria may produce new enzymes and bioactive compounds, including exopolysaccharides (EPSs) with innovative structures (Table 39.1). Many known marine bacteria can produce molecules of biotechnological interest, some of which have unique properties, and the search for new microorganisms of biotechnological value is still promising.

39.3 Bacterial Polysaccharides

Different types of PSs exist within or around the bacterial cell depending on their location:

i) Polysaccharides found in the cytoplasm that serve as carbon and energy reserve,
ii) Cell wall PSs including teichoic acids and peptidoglycans,
iii) Extracellular PSs which are released outside the cell: exopolysaccharides (EPSs) or capsular polysaccharides (CPS).

CPSs are extracellular but remain attached to the cells through covalent bonds to other outer surface polymers thus forming the capsule.

Intracellular PSs are produced when bacteria are grown in excess of sugar and may serve as reserve, since the cell also produces enzymes to degrade them. They usually appear as granules of glycogen or amylopectin type PSs and may be related to sporulation of *Clostridium* sp., for example. However, bacteria synthesize only very few intracellu-

lar PSs but they produce many diverse extracellular PSs.

The cell wall is complex and rich in carbohydrate compounds. Among these, peptidoglycans are linear macromolecules consisting of PSs cross-linked by peptide moieties. The PS part is composed of alternating *N*-acetylmuramic acid (MurNAc) and *N*-acetylglucosamine (GlcNAc) linked by β-1,4-glycosidic linkages. Carboxylic groups from *N*-acetylmuramic acids are involved in the linkage to peptidic chains. Teichoic acids, which are only found in Gram-positive bacteria, may be glycerol phosphate units, or ribitol phosphate units linked by phosphodiester bonds. Glycerol and ribitol may also be associated with glucose, galactose, or *N*-acetylglucosamine. Teichoic acids are closely connected to the peptidoglycan network and make it more cohesive. Gram-negative bacteria also produce lipopolysaccharides (LPS) whose lipidic part (lipid A) is set inside the external membrane. They are composed of two carbohydrate parts, the O-specific chain, and the core [39.81]. The O-specific chain is highly variable, especially in pathogens such as *Vibrio cholerae* [39.81]. Lipid A is composed of aliphatic chains linked to glucosamine residue. LPS is also called endotoxin.

The following paragraph deals specifically with extracellular PSs and EPS.

39.3.1 Bacterial Exopolysaccharides

From different carbon sources, bacterial cells synthesize extracellular PSs; sugar units are synthesized within the cytoplasm before being excreted outside and polymerized. Extracellular PSs may remain attached to the cell membrane, forming a capsule or a slime, while the other part is released into the surrounding environment.

Depending on the enzymatic machinery, EPS are usually constituted of a regular repeating unit. They may be linear or branched. Homopolysaccharides are composed of a unique type of sugar residue type, while heteropolysaccharides contain different ones [39.82].

In heteropolysaccharides, glucose, galactose, and glucuronic or glacturonic acids are common. However, other neutral or acid sugars, hexosamines or *N*-acetylhexosamines, and some rarer sugars are also found. The presence or absence of a repeating unit containing up to 16 or 18 monomers [39.42], linear or branched, the presence of organic (lactate, pyruvate, *N* and *O*-acetates...) or chemical (sulfate, phosphate...) groups give a very large structural diversity of the molecules with consequently very diverse physicochemical or biological properties [39.83].

Depending on both sugar chain and osidic linkages, the behavior of the homopolysaccharides in solution may be different [39.84, 85]. Scleroglucan or pullulan are soluble and highly viscous, while curdlan lacking side-chains is poorly soluble and forms a gel; bacterial cellulose is insoluble; however, these three PSs are only composed of glucose. The presence of side-chains renders the polymer insoluble; acyl and non-sugar substituents may affect the physical features as well as uronic acids. β-1,4-linkages are rigid, while α-1,4-bonds found in dextrans confer flexibility of the structure [39.85].

EPS chain length may vary from one species to another, but also within a species; the molecular weight may range from 50 000 to over several million g mol^{-1}.

39.3.2 EPS from Marine Bacteria

A number of species of marine microorganisms can produce EPSs: cyanobacteria, bacteria, and archaea [39.86]. These strains are screened for mucoid phenotypes on a solidified medium supplemented with a carbohydrate source, for a high viscosity in liquid medium, by staining specifically EPSs.

Chitin, the main marine polymer composed of β-1,4-linked *N*-acetylglucosamine residues, is one of the most abundant PSs in nature after cellulose and is usually prepared from the shells of crabs and shrimps [39.87, 88]. Until now, unlike for cellulose [39.89, 90], no bacterium has been shown to produce chitin. Nevertheless, many marine bacteria species exhibit chitinolytic activity and also produce chitosan from chitin, the *N*-deacetylated product [39.91]; bacteria are, therefore, involved in the turnover of the PS in the marine environment [39.87]. Some non marine bacteria species still produce polyglucosamine exopolymers with a structural homology with chitosan [39.92].

Alginates, another kind of the most common marine PSs, are currently mainly obtained through brown seaweed harvesting; the non-marine bacteria *(Pseudomonas aeruginosa* and *Azotobacter vinelandii)* are also capable of producing acetylated alginates that bind some divalent ions but fail to form gels in the manner of their algal analogs.

Polysaccharide-producing bacteria have been isolated from the Gulf of Naples [39.7], from microbial mats [39.16, 58, 93], the Antarctic [39.11], and deep-sea hydrothermal vents [39.43, 94–98]. Psychrotolerant *Pseudoalteromonas*, *Shewanella*, *Polaribacter*, or

Flavobacterium sp. have been isolated from Antarctic water [39.56] and are able to produce high molecular weight EPS.

Some EPS-producing marine bacteria are listed in Table 39.1. The vast majority of marine bacteria producing exopolysaccharides are *Alteromonas* or the *Pseudoalteromonas*, *Pseudomonas*, *Shewanella*, and *Vibrio* species. In contrast only a few extremophilic bacteria or archaea have been studied for EPSs [39.36, 55, 64].

EPS production by microorganisms has the advantages of a rapid production (a few days compared to the 3–6 months in the case of plants), of a production in bioreactors on different substrates of possibly hydrocarbon residues and of easier extraction since they are exuded in the extracellular environment.

39.3.3 Benefits for the Bacterial Cell

Many marine bacteria produce EPS as a strategy for growth and survival, adhesion to surfaces, and resistance to adverse conditions. EPSs have also been involved in virulence and host contamination. The physiologic roles of EPS for bacteria have not been completely identified, but a protective or adhesive role has frequently been proposed. Most of the time, EPSs are not degraded by the bacteria producing them and thus do not represent a carbon source [39.99]. In a variable nutrient environment such as the ocean, bacteria need greater adaptability in the pathways involved in the detection of nutrients and in metabolism to utilize them. This could explain the diversity of already found polysaccharidic structures.

Therefore, EPSs have an effect on the interactions between the cells and the surrounding environment [39.86]. CPS or slime may help bacterial cells to overcome the various stresses encountered in the environment or to adhere to the surfaces, providing survival advantage. In aquatic environments, the majority of bacteria adhere in a selective manner or not to inert surfaces or living organisms. In biofilms, microbial cells aggregate within a matrix of extracellular polymeric substances composed of PSs, proteins, nucleic acids, peptidoglycan and lipids. Extracellular PSs are generally considered to be the main part of the biofilm matrix [39.100] and are involved in the flexibility of the biofilm shape under shear force as well as in some of the functional properties of the matrix [39.101].

Moreover, anionic EPSs slimes or from capsules allow the aggregation and storage of the soluble nutriments necessary for the growth of the cell or other particles and may chelate metals and ions [39.11]. Bacterial symbionts have been involved in the resistance of polychaetes to the high metal levels around deep-sea hydrothermal vents [39.3] and in environments anthropogenically polluted with metals [39.102]. In other respects, several anionic EPSs from marine bacteria have been shown to bind toxic compounds [39.13, 37, 62, 94]. The presence of bacteria on marine worms may protect them against toxic metals.

39.3.4 Putative Pathways of Biosynthesis

Oceans contain huge bioresources. To exploit them in a manner respectful to the environment, researchers are trying to decipher their production mechanisms. The first particular mechanism of biosynthesis was encountered for homopolysaccharides such as dextran, glucan, levan, inulin, and fructan; it involves an extracellular enzyme (glycan-sucrase) secreted at the cell surface of Gram-positive bacteria such as *Leuconostoc* and other lactic acid bacteria; it has not been yet described in Gram-negative bacteria [39.84, 103]. A specific glycosyltransferase (GT) transfers the sugar residue to the nascent polymer from a disaccharide, usually saccharose.

The other kinds of biosynthesis concern homo and heteropolysaccharides with repeating units. This biosynthesis usually involves three steps: sugar precursor production, repeating unit synthesis, export and polymerization (Fig. 39.1). The whole process is not fully understood, in particular for polymer exportation and synthesis regulations.

The synthesis of heteropolysaccharides has been widely studied in Gram-negative bacteria (*Escherichia coli* [39.104]) as well as lactic acid bacteria and appears to involve a common mechanism. Several enzymes are involved in the assemblage of the repeating unit; they are encoded by genes located within large EPS gene clusters ranging up to 15–20 kb. They are sometimes located on plasmids, especially when considering lactic acid bacteria [39.105]. The biosynthetic machinery involves activated sugar precursors such as nucleoside sugar diphosphate (UDP-sugar), which are produced in the central metabolic pathways. EPS biosynthesis from cytoplasmic activated UDP-sugar precursors is common. However, alternative activated sugar donors are encountered: nucleoside sugar monophosphates, lipid sugar phosphates or pyrophosphates, or unsubstituted sugar phosphate [39.106]. EPSs are usually synthesized inside the cytoplasm in the form of repeating units by glycosyltransferases before being ex-

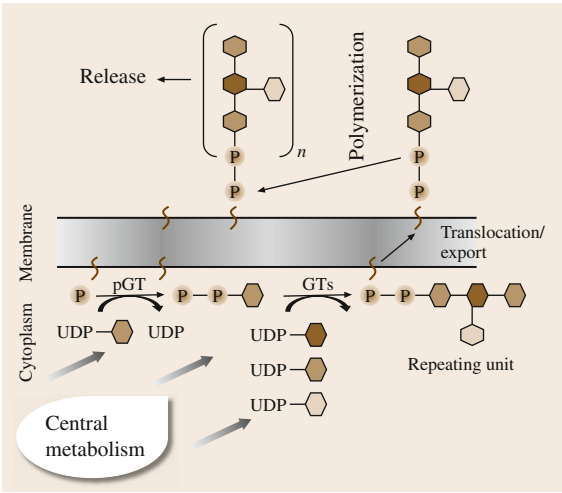

Fig. 39.1 Common biosynthetic mechanism of PSs with repeating units (the biosynthesis begins within the cytoplasm with the synthesis of activated precursors. The repeating unit is then assembled by GT on a carrier located on the membrane. The repeating unit is then translocated across the membrane, polymerized on the nascent polymer within the periplasm or outside the cell, and then released in the surrounding environment or slime)

creted [39.104]. The repeated unit is assembled on a carrier molecule, anchored in the cytoplasmic membrane. Different molecular acceptors on the membrane for the carbohydrate in formation have been proposed; in particular, a lipidic transporter such as undecaprenyl phosphate or isoprenoid pyrophosphate is used in EPS biosynthesis [39.95]. The first monomer is linked to the lipid-carrier by the priming-glycosyltransferase or phosphoglycosyltransferase. The following sugar monomers are linked by appropriate GTs to the growing repeating unit. After completion, the repeating unit is exported outside the cell and subsequently polymerized by addition to the reducing end of the growing EPS chain on the outer face of the cell membrane (Fig. 39.1). Regulations are also involved but not well understood. In particular, a chain length determination factor regulates the extension of the PS molecule; the efficiency of this regulation may depend on whether or not the chain length feature is important for the cell. Various exportation mechanisms have been described; some of them involve ATP (adenosine triphosphate)-binding-cassette (ABC)-transporters and others an externalization of the lipid carrier by a Wzx flippase [39.104, 107].

A specific biosynthesis mechanism involves a bifunctional glycosyltransferase called synthase. Cellulose [39.108] and hyaluronan (HA) [39.109, 110] are examples of the molecular pathway of that biosynthesis. The EPS chain is built by repetitive, non-processive addition of monosaccharides to the nascent polymer. Therefore, it seems that this mechanism can only exist for simple heteropolysaccharides (up to two sugar residues in the repeating unit). The EPS is subsequently exported out of the cell by an ABC transporter; synthase has also been described to be able to form a pore across the cell membrane, allowing the polymer to be exported while synthesized [39.107, 110].

Alginate is a linear, anionic heteropolysaccharide consisting of β-D-mannuronic acid (ManA) and α-D-guluronic acid (GulA). The primary structure of alginate relies on ManA-blocks containing homogeneous $(ManA)_n$, GulA-blocks or $(GulA)_m$, and alternating ManA–GulA-blocks. The relative amount of ManA and GulA as well as the length and distribution of the blocks are dependent on the producing species but are fundamental to the swelling and gelling features, as well as the solubility [39.111]. The bacterial alginate biosynthesis mechanism is particular since the polymer is not constituted of a repeating unit [39.112].

Except for xanthan production (up to 23 g L^{-1} in the culture broth) or pullulan production, production yields upon fermentation seem low (up to 4 g L^{-1} usually). However, an improved activity or a new one resulting in new applications may have a good chance of success for industrial applications.

Engineering of microbial production as well as of genetic material of bacteria, together with the exploration of biodiversity, are different promising approaches to find new PSs with innovative properties.

39.4 Applications of EPSs

Several PSs are well established in different industrial fields. The large range of these existing applications together with the potential ones reflects the many proposed functions in nature as well as their biochemical biodiversity.

Polysaccharides as texture agents of thickening or stabilizing additives are already widely used, such as xanthan, gellan, or some algal PSs (agars, alginates, carrageenans). Therefore, a large number of applications exploit the rheological properties of EPSs. Marine

EPSs having particular functional properties render them more resistant to extreme temperatures, pH, or salinity are of great value for industry [39.113].

Alginate PSs form hydrogels and have found applications in explosives as gelling agents, in the paper industry and textile printing as water-holding agents, in antifoams and lattices because of their emulsifying properties, and in cleaners and ceramics as stabilizers. Alginates are also used in the controlled release of active ingredients that are entrapped in calcium alginate beads, and as new biomaterials for cell immobilization and tissue engineering [39.111]. Research on chitin and chitosan have resulted in applications in various industrial and biomedical fields [39.88].

In plant and animal cells, PSs participate in many central biological processes through the interaction with key proteins such as chemokines, cytokines, growth factors, enzymes, and adhesion molecules involved in cell development, cell signaling, and cell integrity. Therefore, glycobiology, which studies these interactions, and impact on human health have resulted in an increased demand for PSs for therapeutic purposes in cancer, inflammatory diseases, pathogen infections, and thromboembolic disease [39.114, 115]. The potential in this domain of bacterial PSs is now well recognized [39.116, 117].

EPS from the bacteria *Xanthomonas campestris* (xanthan), *Sphingomonas paucimobilis*, or *Sphingomonas* (formerly *Pseudomonas*) *elodea* (gellan), *Acetobacter xylinum* now called *Gluconacetobacter xylinus* (cellulose), *Rhizobium* sp. (succinoglycan), *Agrobacterium* sp. (previously *Alcaligenes faecalis*) (curdlan), and from the fungi *Sclerotium rolfsii* (scleroglucan) and *Aureobasidium pullulans* (pullulan), as well as dextrans from various bacteria have been commercialized and are the most utilized PSs [39.84, 118]. Microbial hyaluronic acid (*Streptococcus* sp.) is also at commercial level and is mainly used in cosmetics, in ophthalmology, and in wound healing [39.119].

39.4.1 Food Products

Polysaccharides are used as ingredients in food products, as carbohydrate and dietary fibre source but also as hydrocolloid to influence rheology and texture. Therefore, in addition to the sensory benefits of EPS in food products, they also impact human health and nutrition [39.120]. EPSs are also produced in situ by bacteria involved in food processing, such as probiotic lactic acid bacteria, and act as functional or prebiotic ingredients. Alginates and various vegetal gums are thickeners, gelling agents, and emulsifiers in food products [39.121].

39.4.2 Environment

The biotechnologies applied to the domain of the environment are being developed and concern essentially the depollution and the rehabilitation of ground, water, and effluents by means of microbial techniques (bioremediation, biodetoxification). Thus, research projects relative to the applications of the bacterial biopolymers in the problems of environmental protection have been conducted for a few years. These concerns are mainly due to the biosorbent properties of the PSs to remove toxic metal pollutants [39.113].

39.4.3 Cosmetics

Cosmetics is a fast growing branch of industry that responds to a societal demand. The lifetime of new molecules ranges between 3–5 years, leading to a constant search for new molecules. Polysaccharides act in feeding, regenerating, and maintaining the skin. Among the most popular products are molecules with moisturizing, smoothing, and/or antiwrinkle activity, as well as those active in the cellular repair or the regeneration of dermic cells and UV protection. Polysaccharides represent more than 20% of the molecules used in the cosmetic field (hyaluronic acid, chitosan, and β-glucane).

The PS deepsane is produced by *Alteromonas macleodii* subsp. *fijiensis biovar deepsane* [39.43] and is used in cosmetics. This EPS shows a protective action of keratinocytes, which are the main cells of the skin, from a proinflammatory agent. Protective effects were also found for cells sensitive to ultraviolet attacks and involved in the cutaneous immune defense system. This EPS would, therefore, contribute to the repair of the skin [39.122].

39.4.4 Medical Applications

The most expected contribution from biotechnologies in the healthcare field concerns the development of new molecules with new biological activities or a better profit–risk ratio. This search inevitably passes by a phase of bioprospecting, and the marine environment constitutes a privileged field of investigations. Therefore, bacterial EPSs offer new and innovative approaches to handle a large number of diseases and to replace certain drugs. Moreover, bacterial EPSs are not

dependent on climatic or physiologic variation, since they are produced in a controlled environment in bioreactors.

The first kind of medical applications derives from the functional properties of the PS molecule (rheology, water-holding, or gelification) [39.123]. As an example, dextran, even widely used as chromatographic supports for purifications of molecules, is also developed in the therapeutic field as artificial plasma. Some bacterial EPSs may also serve as encapsulating agents for a controlled release of drugs near the target, in medical textiles for wound care, in artificial skin and tissue engineering scaffolds [39.121]. *Streptococcus zooepidermicus* produces a hyaluronate with a structure identical to the mammalian one. This EPS is used in ophthalmic surgery. Some other uses are under study, such as various biomaterials and prosthetic surgery to improve biocompatibility. Hydrogels based on natural polymers are close to living tissues and can help during the healing process. Most of these PSs are high molecular weight PSs.

Biological properties constitute the basis for the second type of applications. Some pathogenic bacteria exhibit PSs on their surface; this is the principal factor for immune response. Consequently, they are potential vaccines. Examples of PS vaccines are those against pneumonia (*Streptococcus pneumoniae*) and pneumococcal disease (*Neisseria meningitidis* serogroups A, C, Y, and W135).

Some EPSs have been studied for their antiviral effects [39.124–126], e.g., microbial β-1,3-D-glucans, including levan as well as sulfated dextran [39.127, 128]. Other bacterial PSs exhibit diverse bioactivities, which could also find interest in the biomedical field as therapeutics. Curdlan [39.127] shows antitumor activity. The marine *Geobacillus thermodenitrificans* produces an EPS having immunomodulatory and antiviral effects [39.49]. Some PSs may exhibit innovative structure similar to heparin, a mammalian PS with biological activities such as anticoagulant, antitumor or antiviral. Indeed within the structural diversity, some homologies of new bacterial EPSs have been identified with molecules from animal and bacterial molecules might advantageously replace animal ones. CPSs from *Escherichia coli* are usually antigenic but the *Escherichia coli* K5 strain produces an extracellular PS, called K5, whose structure, [4-D-GlcA β-1,4-D-GlcNAc α-1,]$_n$, is similar to a heparin precursor, *N*-acetylheparosan [39.129]. Because of this structural relationship, chemically and/or enzymatically modified K5 PS is of considerable interest for biomedical applications. Such a project is currently being undertaken by several research teams. This concern is developed in the following paragraph with a focus on marine EPSs.

39.5 Marine EPSs as Glycosaminoglycans (GAGs)

Glycosaminoglycans (GAGs) constitute a class of glycans found ubiquitously in mammalian tissues as components of proteoglycans that have various cellular and intercellular matrix functions. Vertebrates utilize GAGs in structural, recognition, adhesion, and signaling roles. GAG chains are negatively charged by the presence of uronic acids and sulfate groups. They are made up of hexuronic acid and *N*-acetylhexosamine in alternating linear sequence. These PSs exhibit polydisperse high molecular weights in the range of several thousands to

Table 39.2 Structural diversity of GAGs

Name	Hexuronic acid/hexose	Hexosamine	Major repeating unit
Chondroitin sulfate	GlcA or GlcA(2S)	GalNAc or GalNAc(4S) or GalNAc(6S) or GalNAc(4S,6S)	GlcA β-1,3 GalNAc(4S) β-1,4
Dermatan sulfate	GlcA or IdoA or IdoA(2S)	GalNAc or GalNAc(4S) or GalNAc(6S) or GalNAc(4S,6S)	IdoA α-1,3 GalNAc(4S) β-1,4
Keratan sulfate	Gal or Gal(6S)	GlcNAc or GlcNAc(6S)	Gal β-1,4 GlcNAc(6S) β-1,3
Heparin	GlcA or IdoA(2S)	GlcNAc or GlcNS or GlcNAc(6S) or GlcNS(6S)	IdoA(2S) α-1,4 GlcNS(6S) α-1,4
Hyaluronan	GlcA	GlcNAc	GlcA β-1,3 GlcNAc β-1,4

(2S): 2-*O*-sulfo, (4S): 4-*O*-sulfo, (6S): 6-*O*-sulfo, Gal:D-galactose, GalNac: D-*N*-acetylgalactosamine, GlcA: D-glucuronic acid, Glc: D-glucose, GlcNAc: D-*N*-acetylglucosamine, GlcNS: D-*N*-sulfoglucosamine, IdoA: L-iduronic acid

millions g mol^{-1}. GAG structural diversity comes from isomers differing in sulfate presence and position and uronic acid epimerization (Table 39.2). Among them, heparin and heparan sulfate (HS) represent the most heterogeneous structural group because of different sulfation degrees and position as well as various extents of uronic acid epimerization. Postpolymerization modifications of the PS backbone varies depending on the tissue and developmental stage [39.130]. HA is the only non-sulfated GAG.

Heparin is widely used in the clinical treatment of thrombosis as an intravenous anticoagulant with 100 000 kg produced annually through extraction from porcine intestinal mucous membranes.

39.5.1 Biological Activity and Structure–Activity Relationship

The high negative charge of GAG molecules allows binding to many cellular compounds (receptors, growth factors, ...), which results in various bioactivities [39.131]. Medical applications for GAGs are manifold. They are used as surgical aids, moisturizers, for drug delivery, in tissue engineering, as anticoagulants, and for their anticancer activities [39.123, 130, 132, 133]. These biological activities are dependent on the key structural features. Advances in the understanding of the relationships between biological activity and structure are important for the development of safer bioactive analogs.

Sulfation of carbohydrate compounds enhances their biological activity such as their antiviral [39.125, 126] or anticoagulant activity [39.115]. Although the mechanisms are not clear, it has been proposed that sulfates contribute to a molecular conformation that is essential for the activity which, in the case of spirulan, is dependent on calcium ion chelation by sulfates [39.125].

HA, heparin, and chondroitin sulfate (CS) are currently used in various medical applications. Linear HA is mainly used in cosmetics to reduce wrinkles, in drug delivery, in ophthalmology, and in wound healing for its hydratation capability and viscoelasticity [39.119]. Derivatized HA and cross-linked HA are also used in healthcare as non-surgical dermal tissue fillers and in the treatment of osteoarthritis and in tissue engineering [39.119].

The key pentasaccharide of heparin has been well studied and shown to be involved in the interaction with antithrombin, inhibiting blood coagulation [39.134]. In addition, some trisaccharides have been identified to be responsible for binding with fibroblast growth factors having an important role in cell proliferation, differentiation, and migration, as well as angiogenesis and, therefore, can inhibit cancer tumor development. The production of low molecular weight heparinoid would allow us to obtain more efficient preparations with lower side effects by targeting the structural features involved and consequently to obtain more specific preparations [39.131]. In addition, low molecular weight compounds are easier to inject as therapeutics drugs. The use of EPSs as active ingredients does, indeed, concern mainly low molecular weight polymers with bioactivity in cardiovascular and cancer domains.

39.5.2 Modifications to Create GAG-Like Molecules

When an active drug is extracted from animals (heparin from porcine intestinal mucosa, HA from rooster comb, CS from bovine trachea or shark cartilage) or marine invertebrates (scallop, whelk, crustacean, sea squirt), a risk of allergic response to contaminating compounds, or of contamination by non-conventional agents, e.g., prions or viruses [39.130], exists and some new molecules are searched for. In actual fact, GAGs also exhibit undesirable side effects such as hemorrhagic risk; therefore, new analog drugs are being developed [39.132].

For future applications, GAGs derived from bacteria seem to be safer materials with higher purity. Molecules similar to GAGs have been found in microbial sources [39.130]. As has already been presented, *Streptococci* as well as *Pasteurella* produce an EPS identical to HA acid [39.119]. Recently, the recombinant production of HA has been achieved in *Bacillus subtilis* [39.135] and *Lactococcus lactis* [39.136]. Both HA produced by extraction from rooster combs or by microbial fermentation are structurally identical and it can, therefore, be used for its physical properties such as viscosification in ophthalmology, orthopaedic surgery, rheumatology, dermatology, plastic surgery, and wound healing without any modifications of the structure [39.137].

The marine bacterium *Vibrio diabolicus* isolated on the Pompei worm from deep-sea hydrothermal vents has been shown to produce the HE800 polymer constituted of a tetrasaccharidic repeating unit [3-D-GlcNAc-β-(1,4)-D-GlcA-β-(1,4)-D-GlcA-β-(1,4)-D-GalNAc-α-(1] [39.66, 67]. This EPS shows structural similarities to HA. Bioactivity in bone re-

pair has also been described [39.138]. The HE800 EPS in its native form has found application in skin and cartilage therapy [39.133]. Microbial-derived HA has now been commercialized and even if research on marine bacteria may produce analogs, research is also directed at producing heparin via microbial fermentation [39.139].

Beside natural the PSs available, some PS derivatives exhibiting enhanced bioactivity or features can be generated by chemical, biochemical, and genetic methods, or a combination thereof to modify the PS structure through depolymerization and regioselective functionalization. The current challenge, in addition to improving the productivity of EPSs from bacteria, is to produce EPSs of a structure and size that allow the desired activity. In particular, the sulfation degree and pattern must be controlled since the biological activity of heparinoid relies greatly on the specific modification pattern (*N*-deacetylation, *N* and *O*-sulfation, and epimerization of glucuronic acid to iduronic acid). Tailoring the structure is currently performed in chemical ways, but enzymatic ways are also under study.

Pullulan was modified by chemical sulfation to produce new anticoagulant drugs as a potential heparin substituent [39.140]. Some analogs of GAG sugar backbones have also been found in bacteria such as *Escherichia coli* K4 and K5, as well as in marine bacteria. *E. coli* K4 and K5 have been shown to produce PSs with a basic structural similarity to chondroitin sulfate and heparin, respectively [39.139, 141]. The *E. coli* K5 polysaccharidic antigen is similar to a precursor of heparin (desulfoheparin). Much in vitro chemoenzymatic production of heparin, in which the EPS backbone of *E. coli* K5 is subjected to chemical and/or enzymatic modification, have been described [39.110, 139, 142–145].

Alteromonas infernus, a deep-sea marine bacterium has been isolated from seawater samples collected around a dense population of giant worms *Riftia pachyptila* [39.38]. It produces an anionic complex heteropolysaccharide with a high molecular weight and around 10% sulfate content [39.39]. Some other sulfated EPSs from marine bacteria have been described in *Alteromonas macleodii* strains and *Pseudoalteromonas* sp. [39.42, 60]. There are very few bacterial sulfated PSs whose structure has been determined (Table 39.1), but they provide the basis for future applications and basic research on GAG-like molecules from marine environments. On the other hand, L-iduronic acid resulting from 5-epimerization of glucuronic acid has been described in one bacterial PS [39.146]. Since sulfated PSs and L-iduronic acid exist in bacteria, one can expect the isolation of enzymes involved in their biosynthesis in the near future. These enzymes would then be very useful tools to produce engineered GAG-like PSs.

The *A. infernus* EPS repeating unit is a nonsaccharide composed of glucuronic acid, galacturonic acid, and neutral sugars (Gal and Glc), as well as one sulfate group on a galacturonic acid residue (Table 39.1). This PS prepared in a hydrogel exhibited interesting activity in cartilage tissue engineering applications [39.147]. Chemically oversulfated low molecular weight derivatives have been synthesized by two processes that differ in the order of the same steps (radical depolymerization and sulfation). Surprisingly, the two kinds of derivatives did not exhibit the same biological features: one was able to stimulate the proliferation of mature endothelial cells, whereas the other was not [39.148], which suggested that the modification pattern catalyzed by both processes is not the same; therefore, the sulfation pattern appears to be critical for bioactivity. However, *lteromonas infernus* EPS derivatives presented anticoagulant activity similar to that of heparin with a lower hemorrhagic risk [39.149]. These derivatives have also shown interesting properties for cell therapy and tissue engineering [39.133], and also in cartilage regeneration [39.150].

These studies have highlighted the crucial roles of molecular weight and the the sulfation pattern [39.151]. Chemical reactions may be selective to some extent but are not specific enough for such molecules. In particular, it is very difficult to obtain compounds with specific sulfated positions [39.151, 152]. Therefore, the use of enzymatic methods in the modification process leading to bioactive oligosaccharidic derivatives may have clear advantages, such as a better control of reaction selectivity and an easier reaction in a single step (without functional group protection and de-protection steps) under mild conditions. Most enzymes involved in GAG modification are very specific, especially sulfotransferases [39.114, 153, 154]. Moreover, the PAPS (3′-phosphoadenosine 5′-phosphosulfate) molecule required for the sulfation reaction as the sulfate donor is expensive. Therefore, approaches to regenerate this cofactor have been developed [39.153, 155]. However, finding active enzymes on each PS backbone is likely to be the main bottleneck of such a strategy; therefore, enzyme design and optimization by molecular techniques will surely need to be envisaged.

In the future, one can also expect that genetic engineering will be performed to tailor carbohydrate

biomolecules in vivo. This will depend on a deep understanding of biosynthetic mechanisms of EPSs to be able to engineer them and of how the structure of EPSs determines the final activity. The development of improved characterization methods is also required, especially to determine the distribution of functional groups as well as new methods to modify the PS backbone in a regiospecific manner.

39.6 Conclusion

Life emerged from the ocean; nowadays, oceans shelter large biomasses that are mainly microscopic. Among these, marine bacterial diversity, associated with the original ecosystem and biochemical metabolim, is a huge reservoir for the identification of new species and the extraction of new molecules of biotechnological interest, resulting in both fundamental and applied research. It is pointed out that the ocean provides renewable resources for different industrial fields.

The putative or demonstrated benefits of some new PSs and their derivatives are still being studied. Crucial knowledge has been gained on how the structural composition influences the functional properties and on how these features can be applied in biomedical research. In vitro and in vivo structural design of PSs to tailor targeted PS derivatives might produce important bioactive materials in the future. The growing demand will probably lead to the establishment of an adequate and efficient microbial production process.

Only a few marine products have reached commercial production. Indeed, the search for new molecules for healthcare rarely encounters success, and it is always a long time before they are released on the market. The number of marine molecules used as drugs is very low; anticancer, antiviral, and pain-fighting molecules are available on the market, but none are carbohydrates. However, oceans are not only a source of molecules but also a source of inspiration for the synthesis of new drugs [39.156].

In biotechnology, the development of new marine molecules is linked to the progress in the sustainable production process. Moreover, one will have to take into consideration the evolution of legislation regarding the use of natural products, intellectual property rights, the availability of the resource, the ease of implementation, and naturally the production costs.

40. Sulfated Polysaccharides from Green Seaweeds

MyoungLae Cho, SangGuan You

With the growing interest in the development of novel bioactive compounds from marine resources, underutilized marine green algae have been considered as valuable sources of structurally diverse bioactive compounds. Among their various constituents, water-soluble sulfated polysaccharides possess innovative and unique structures and numerous beneficial biological activities, such as anticoagulation, antioxidation, anticancer, and antivirus activities. The sulfated polysaccharides derived from green seaweeds, therefore, have great potential as ingredients in nutraceutical, pharmaceutical, and functional food products. An overview of the diverse structural features and biological activities of sulfated polysaccharides from green seaweeds along with a brief mention of the structure–bioactivity relationship are presented in this chapter.

40.1 Overview

Green algae are part of a large group called Chlorophyta and are very common algae distributed worldwide. Most of them live in freshwater and some (about 10%) can be found in seawater or brackish water, particularly in estuaries. The chlorophyll a, b in green algae absorb red light, which is available in shallow water but absent in deep water. Therefore, green seaweeds are commonly found on the surfaces of rocks in middle to low intertidal zones [40.1]. Green seaweeds are known as an indicator for water recycling in aquatic environments such as with integrated invertebrates or aquacultured fish systems because of their harmful effects which could cause hypoxia and death of aquatic organisms [40.2]. Most of the collected green seaweed biomass has been considered to be of little value and has thus been used as a compost or animal feeds, or otherwise simply wasted. In some countries, however, green seaweeds, particularly the *Ulva* and *Enteromorpha* species, are used as food ingredients and nutritional supplements [40.3, 4]. Recently, commercial exploitation has made green seaweeds attractive to produce functional or health promoting foods due to their nutritional bioactive constituents, such as dietary fiber, proteins, polysaccharides, essential minerals, antioxidants, vitamins, and bioactive peptides [40.2, 5–11].

Among the various components in green seaweeds, the cell wall polysaccharides representing 38–54% of the dry algae matter display physicochemical and biological features that are of potential interests for different applications. Four types of cell wall polysaccharides are reported to be included in the biomass of *Ulva* sp.: water soluble sulfated polysaccharides, water insoluble cellulose, alkali soluble xyloglucan, and glucuronan [40.12]. Most work on the polysaccharides of green seaweeds have focused on sulfated polysaccharides because of their various biological activities,

such as anticoagulation, anticancer, antihyperlipidemia, and immunomodulation activities [40.13–16]. Sulfated polysaccharides from marine seaweeds are considered to be a unique compound with distinct structures and novel bioactivities. So far, studies on sulfated polysaccharides from marine seaweeds have mainly focused on those of brown seaweeds, known as fucoidans, sargassan, and glucuronoxylofucan, and those of red seaweeds including agar and carrageenans, due to their potent bioactivities [40.17–19]. Green seaweeds such as *Ulva* sp., *Enteromorpha* sp., *Capsosiphone* sp., and *Codium* sp. have also been found to be rich sources of sulfated polysaccharides [40.20–23]. Among sulfated polysaccharides, ulvan consisting of sulfated-rhamnose and uronic acids such as glucuronic acid and iduronic acid has been isolated from *Ulva* and *Enteromorpha* sp., and sulfated rhamnan and sulfated galactans were obtained from *Monostroma* sp. and *Codium* sp., respectively [40.12, 24, 25]. Ulvans are also known to form gels in the presence of borate and calcium ions and to resist digestion and fermentation by human digestive enzymes and colonic flora [40.26, 27]. Their resistance to digestion and fermentation is due to their structural features rather than their chemical compositions [40.27]. Numerous research efforts have shown that the structural characteristics of sulfated polysaccharides from green seaweeds vary mostly depending on their origins [40.12]. It has been reported that the bioactivities of sulfated polysaccharides are dependent, among other factors, on their glycosidic linkages, molecular weight, sulfate content, and conformation [40.13, 28]. Therefore, a basic understanding of the primary and secondary structures of the sulfated polysaccharide may lead to the successful interpretation of their biological activities. The objective of this chapter is to review the fine structures, bioactivities, and structure-function relationship of sulfated polysaccharides originating from various green seaweeds.

40.2 Extraction and Chemical Composition of Sulfated Polysaccharides

The extraction of alcohol from a raw alga before extraction of the sulfated polysaccharides has been reported to enrich the cell walls of the polysaccharides, thus increasing the total sugar content in the material and decreasing the content of minor sugars and glucose [40.29]. Therefore, this preliminary step appears to be desirable to obtain the less contaminated sulfated polysaccharides from green seaweeds. The extraction of the sulfated polysaccharides from green seaweeds has generally been conducted by H_2O in the presence of chelating agents [40.26]. The enzyme treatment was often included in the extraction procedures using amyloglucosidase, cellulase, and protease in order to improve the extraction efficiency of the sulfated polysaccharides entrapped in the cell walls [40.26, 29]. The extraction of the sulfated polysaccharides was also carried out in an acidic condition (acidic pH below the pK_a of glucuronic acid) to prevent their aggregation [40.26, 30]. The acidic condition seemed to be also efficient to improve their extraction yield. However, the decrease in the molecular weight of polysaccharides is a drawback of this treatment if texturing ability is required [40.29]. After the extraction, the crude extract of sulfated polysaccharides is often purified using ion-exchange chromatography. The yield of extracted polysaccharide usually ranges from 8 to 29% of the dry weight of the algae, depending on the extraction and purification procedures applied (Fig. 40.1) [40.26].

Sulfated polysaccharides from green seaweeds mainly consist of rhamnose, xylose, and uronic acids such as glucuronic and iduronic acids in the major repeating units, and include minor amounts of other sugars, such as glucose, galactose, mannose, and arabinose [40.31, 32]. In addition, the presence of sulfate groups has been identified as the main constituent of polysaccharides [40.29, 33].

40.3 Structural Characteristics of Sulfated Polysaccharides

Despite the structural variation originating from methodology, taxonomy, and ecophysiology, the structural features of sulfated polysaccharides of green seaweeds varies mostly depending on their origins [40.12]. According to *Zhang* et al. [40.21], the proximate composition and the methylation analysis demonstrated that the polysaccharide from *Monostroma latissimum* was a high rhamnose-containing sulfated polysaccharide and included 1,3-; 1,2-; 1,2,3-; 1,2,3,4-; and 1,2,4-linked rhamnose. This indicates that the sulfated polysaccharides from *M. latissimum* are branched polysaccharides with major monosaccharide unit of

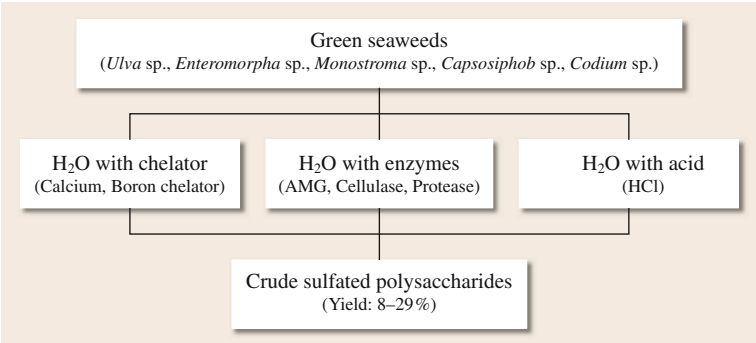

Fig. 40.1 Extraction methods of sulfated polysaccharides from green seaweeds. The extraction of the sulfated polysaccharides was generally treated with H_2O, with chelating agents, enzymes, and acid conditions

rhamnose. It was also found that the sulfate substitution mainly occurred at C-3 or C-4 of the 1,2-linked rhamnose residues [40.21]. The sulfated polysaccharide from *Monostroma nitidum* exhibited a high proportion of 1,2 and 1,3-linked L-rhamnose. The sulfate substitutions were deduced to be at C-2 and C-4 of 1,3-linked L-rhamnose or to be at C-3 and C-4 of 1,2-linked L-rhamnose residues [40.13]. On the other hand, a heteroglycan obtained from *Enteromorpha compressa* contained the major units of 1,4 and 1,2,4-linked rhamnose and 1,4-linked xylose. Sulfates were present either at C-3 of 1,4-linked rhamnose unit or C-2 of 1,4-linked xylose unit [40.32].

Determining the sugar sequence in the sulfated polysaccharides from marine seaweeds is a major challenge. Accurate determination of the glycosidic linkages of the sulfated polysaccharides requires desulfation without cleavage of the chain linkages. The solvolytic desulfation procedure using a pyridinium salt has been preferably used to desulfate the sulfated polysaccharides because of their mild reaction, minimizing the chain degradation [40.34]. However, the desulfation has also been carried out by methyl sulfoxide-pyridine because the method was rapid and complete, resulting in a better recovery yield (55–57.5%) [40.20].

The chemical structures of sulfated polysaccharides from various green seaweeds are shown in Fig. 40.2. The major repeating sugar sequence of the sulfated polysaccharides from *Ulva rigida* was determined as β-D-GlcpA-(1 → 4)-α-L-Rhap 3-sulfate (A_{3S}). It was found that on the sugar sequence GluA could occur as a branch on C-2 of rhamnose. In addition, GluA could flank on the sugar sequence having an extra 4-linked β-D-GlcpA residue, which might be a cleavage site by glucuronan lyase [40.31, 40]. The sulfated polysaccharides from *Ulva armoricana* includes a large amount of α-L-IdopA-(1 → 4)-α-L-Rhap 3-sulfate (B_{3S}), which is resistant to the glucuronan lyase, indicating the major structural differences among the sulfated polysaccharides from the *Ulva* species [40.35]. Also, those of *Ulva clathrata* are deviants of the A_{3S} and B_{3S} ulvanobiuronic acids [40.4] and the mixed structures of the ulvanobiuronic acid 3-sulfate type A and B were observed in those from *Ulva rotundata* [40.41].

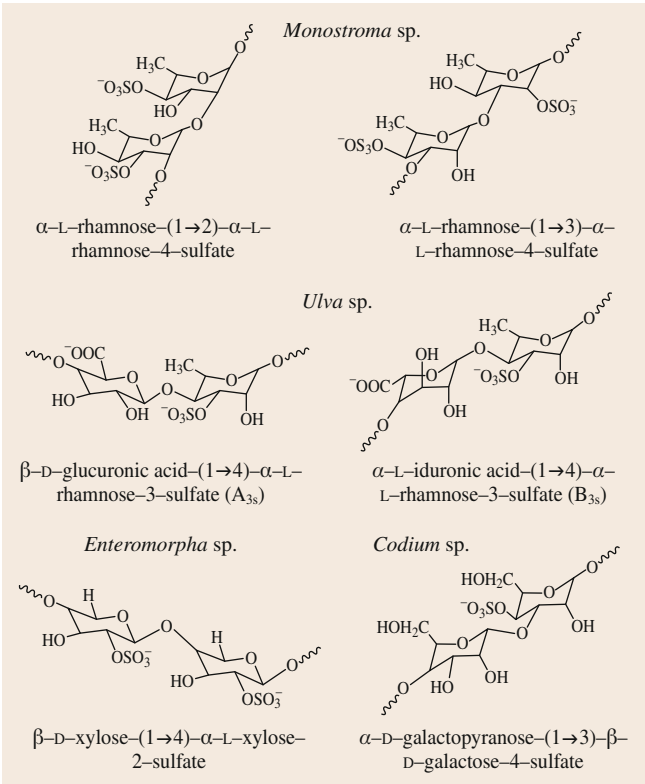

Fig. 40.2 The chemical structure of sulfated polysaccharides from green seaweeds

Table 40.1 Representative chemical structures from different green seaweeds

Species	Oligosaccharide/repeating structure	References
Monostroma nitidum	α-L-Rhap-(1 → 2)-α-L-Rhap-3-sulfate	[40.13]
	α-L-Rhap-(1 → 2)-α-L-Rhap-4-sulfate	
	α-L-Rhap-(1 → 3)-α-L-Rhap-2-sulfate

	(1 → 4)-β-D-Manp-(1 → 2)-β-D-Manp	
	(1 → 4)-β-D-Manp-(1 → 2)-β-D-Xylp	
	(1 → 2)-β-D-Manp-(1 → 4)-β-D-Manp-(1 → 2,3S)-D-Rhap	
	(1 → 2)-β-D-Manp-(1 → 4)-β-D-Manp-(1 → 2)-D-Rhap-(1 → 4)-β-D-Manp	
Ulva pertusa	(1 → 4)-α-L-Rhap-(1 → 4)-β-D-Glc-(1 → 2)-β-L-Rhap-(1 → 4)-β-D-Xylp	[40.39]

A large amount of galactose is included in the sulfated polysaccharides from *Codium* sp., which reveals their significant heterogeneity. Sulfated galactan from *Codium isthmocladum* is composed preponderantly of 3-linked β-D-galactopyranose residue mainly sulfated at C-4 position and, in lower amounts, it is sulfated and glycosylated at C-6. In addition, pyruvate groups have also been found, forming five-membered cyclic ketals as 3,4-*O*-(1′-carboxy)-ethylidene-β-D-galactose residues [40.36]. Such a highly complex, pyruvylated and sulfated galactan has also been found in *Codium yezoense* in which the sulfated galactan has essentially linear backbone segments of 3-linked β-D-galactopyranosyl units with short oligosaccharides attached at C-6. Sulfate groups are substituted mainly at C-4 and in lower amounts at C-6. The sulfated galactan from *Codium fragile* also consist of 3-linked β-D-galactopyranose residue but are highly ramified at C-6 through β-D-Galp units; sulfate esters have mainly been found at 4-*O*-positions of nonreducing terminal galactose residues [40.37]. Therefore, the most dominant component in the backbone of sulfated galactan from *Codium* sp. appears to be the 1,3-linked β-D-Galp 4-sulfate units [40.42]. Structural analysis of the sulfated polysaccharides from *Capsosiphon fulvescens* has revealed that their main glycosidic linkages were β-(1 → 4)-D-Manp, (1 → 2)-D-Rhap, (1 → 2,3-sulfate)-D-Rhap and (1 →)-β-D-Xylp with minor (1 → 2), (1 → 3) and (1 → 2,4)-D-Manp residues [40.38]. In addition, *Tabarsa* et al. [40.39] reported a unique structural feature of sulfate position on glucose and glucuronic acid at O-3 position from the sulfated polysaccharides in *Ulva pertusa*, which are mainly composed of α-(1 → 4)-L-Rhap, β-(1 → 4)-D-Glc, β-(1 → 2)-L-Rhap, and β-(1 → 4)-D-Xylp residues with branches at O-2 position of rhamnose. The sulfate groups are mostly found on glucuronic acid at O-3 position (Table 40.1).

The variations on chemical compositions and repeating sequences of the sulfated polysaccharides from green seaweeds clearly demonstrate the differences in glycosidic linkages, monosaccharide distribution, branching, and sulfation patterns. It appears that such variations mainly derive from the differences in their species. However, whether their varied nature and proportion of chemical features are species-specific or methodological differences remains to be clearly established.

40.4 Biological Activities of Sulfated Polysaccharide from Green Seaweeds

Recently, various sulfated polysaccharides isolated from marine seaweeds have attracted much attention in the areas of food, cosmetics, and pharmacology due to their physicochemical and biological properties. Among the sulfated polysaccharides from various marine algae, carrageenans from red algae and fucoidans from brown algae are commercially available from various cheap sources and are widely used as food additives and ingredients in novel drugs and functional foods [40.43–45]. Sulfated polysaccharides from green seaweeds also display physicochemical and biological features that are of potential interest for functional food, pharmaceutical, and chemical applications [40.12]. In addition, most of the positive health effects are generated by the presence of sulfate groups in the polysaccharides [40.46]. In vitro and in vivo beneficial biological effects of sulfated polysaccharides have been reported in broad ranges of biological activities including antioxidant, anticoagulant, anticancer, antihyperlipidemic, and immunomodulating activities (Table 40.2) [40.18, 21, 47–49].

40.4.1 Antioxidant Activity

Excessive amounts of reactive oxygen species (ROS) generated in living organisms during metabolism may be a primary cause of bio-molecular oxidation, which may lead to various diseases, such as cancer, stroke, and diabetes, as well as the degenerative processes associated with aging (Fig. 40.3) [40.50–53]. Antioxidants may have a positive effect on human health by protecting the human body against damage by ROS.

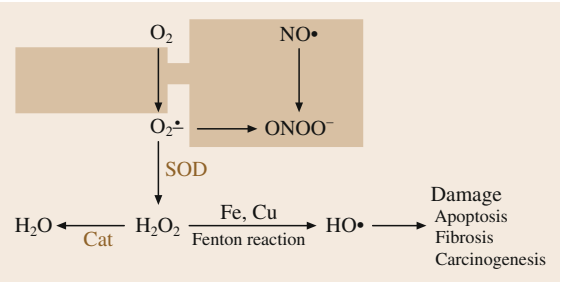

Fig. 40.3 Cellular generation of reactive oxygen species (ROS) and antioxidant system. O_2 = oxide, H_2O_2 = hydrogen peroxide, OH^- = hydroxyl radical, NO = nitric oxide, $ONOO^-$ = peroxynitrite

In addition, deterioration of some foods has resulted from the oxidation and/or rancidity of lipids due to the formation of lipid peroxidation products, which causes a decrease in the nutritional value of lipid containing foods. The negative effects of oxidative stress in foods have been mitigated by many synthetic antioxidants, such as butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), and propyl gallate (PG). However, the use of these synthetic antioxidants is under strict regulation due to their potential health hazards [40.54, 55]. Therefore, concerns related to synthetic antioxidants have led to a considerable interest in the development of safe and inexpensive alternatives from natural origins.

Antioxidant activity of sulfated polysaccharides has been determined by various methods such as ferric reducing antioxidant power (FRAP), nitric oxide (NO) scavenging, lipid peroxide inhibition, 1,1-diphenyl-2-picryl hydrazil (DPPH) radical, 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS)

radical, superoxide, and hydroxyl radicals scavenging assays. Various types of sulfated polysaccharides from brown and red algae, including fucoidans, laminarans, and carrageenans, have shown potential antioxidant activity [40.61–63]. *Kim* et al. [40.64] reported that the sulfated polysaccharides of a brown alga, *Sargassum fulvellum*, exhibited stronger NO scavenging activity than commercial antioxidants such as BHA and α-tocopherol.

The sulfated polysaccharides from a green seaweed, *Ulva pertusa*, are also potent free radical scavengers. The antioxidant activity of the sulfated polysaccharides depends on their structural features, such as molecular weight (M_w), degrees of sulfate group, and functional groups. It was observed that the lower M_w sulfated polysaccharides showed stronger antioxidant activity [40.56]. It seemed that the lower M_w polysaccharides might incorporate into the system more efficiently and donate protons to scavenge free radicals more effectively compared to the high M_w polysaccharides. It was also found that the antioxidant activity was deeply affected by the amount and distribution of functional groups inside the polysaccharide. The enhancement of their antioxidant activity may be desirable by the envisaged application and has been successfully investigated both by increasing the degree of sulfate group and by introducing suitable functional groups (acetyl and benzoyl) that can boost the activity of the native polysaccharides [40.47, 57].

40.4.2 Immunomodulatory Activity

Macrophage cells are known to be important components of host defense against bacterial infections and various types of cells, including cancer cells [40.48]. Activated macrophages release cytokines such as tumor necrosis factor-α (TNF-α), PGE_2, and various interleukins (IL-12, IL-6, and IL-1β) to kill external pathogens and inhibit cancer cell growth (Fig. 40.4). Sulfated fucans from *Fucus vesiculosus* has been reported to activate macrophages, producing nitric oxide (NO) through the expression of inducible nitric oxide synthase (iNOS) induced by IFN-γ [40.65]. According to *Lee* et al. [40.23], the sulfated polysaccharides from a green seaweed, *Codium fragile*, also enhanced the production of NO and various cytokines by activating macrophages. The authors observed an increased release of proinflammatory (IL-1, IL-6, IL-12, and TNF-α) and anti-inflammatory (IL-10) cytokines, which suggests that the sulfated polysaccharides might possess the potent immunomodulating activity by stimulating macrophages while preventing potential detrimental inflammatory effects from excessive macrophage activation. Similar trends of pro and anti-inflammatory cytokine releases were observed by the sulfated polysaccharides from *Capsosiphon fulvescens* and *U. pertusa* [40.38, 39]. It appears that the induction of various cytokines by sulfated polysaccharides can be attributed to the up-regulation of their messenger ribonucleic acid (mRNA) [40.9, 14, 15]. Sulfated polysaccharides from *Enteromorpha prolifera* also stimulated a macrophage cell line Raw 264.7, inducing considerable NO and various types of cytokine production via their up-regulated mRNA expression. In addition, an in vivo experiment exhibited an increase in IFN-γ and IL-2 secretions, implying that sulfated polysaccharides can activate T cells by up-regulating the Th-1 response (Fig. 40.4). These results, therefore, suggest that sulfated polysaccharides might be an immunostimulator with an immunomodulatory effect through cell-mediated immune response [40.15].

40.4.3 Anticoagulant Activity

Blood coagulation proceeds by coagulation factors both through intrinsic and extrinsic pathways in order to stop the flow of blood inside the injured vessel walls when an abnormal vascular condition and exposure to nonendothelial surfaces at sites of vascular injury occur (Fig. 40.5). Blood coagulation can be prolonged or stopped with endogenous or exogenous anticoagulants by inactivating and restricting the coagulation factors [40.66]. Heparin, a glycosaminoglycan of animal origin with carboxylic acid and sulfates, has been used for more than 50 years as a commercial anticoagulant for the prevention of venous thromboembolic disorders [40.67]. However, several side effects and the high cost of the extraction of heparin have led to demands for alternative sources of anticoagulants with safe and economic values.

Since the investigation of the potential anticoagulant activity of fucoidan from marine brown algae [40.68], it has been reported that sulfated polysaccharides may be alternative sources for developing novel anticoagulant drugs. A few studies have reported that sulfated polysaccharides may not interfere with and/or inhibit the extrinsic coagulation factors directly related with the prolongation of prothrombin time (PT) [40.69, 70]. Therefore, the anticoagulant activity of sulfated polysaccharides is mostly determined by prolongation of activated partial thrombinplastin time (APTT)

and thrombin time (TT), which suggests inhibitions of the intrinsic factors and thrombin activity of the sulfated polysaccharides. Various anticoagulant sulfated polysaccharides have been isolated and characterized from marine algae. Among them, sulfated galactans known as carrageenans from red algae and fucoidans from brown algae are identified with high anticoagulant activity [40.71–75].

The sulfated polysaccharide isolated from the green seaweed *Monostroma nitidum* also has potent anticoagulant activity, showing a sixfold higher heparinoid activity than that of standard heparin [40.58]. Due to the heparinoid-like structure, the sulfated polysaccharides from *Monostroma latissimum* partially affect both the activated thromboplastin time (APTT) and thrombin time (TT), displaying the inhibition of both the intrinsic pathways of coagulation or thrombin activity and the conversion of fibrinogen to fibrin [40.21]. High anticoagulant activity is also observed by the sulfated polysaccharides from *M. nitidum*, which mediated thrombin inhibitors by heparin cofactor II [40.13].

The anticoagulant activity of sulfated polysaccharides depends on their structural features such as M_w, and the degree and position of the sulfate groups. According to *Zhang* et al. [40.21], the decrease in the molecular size of sulfated polysaccharides dramatically reduces their anticoagulant activities, which indicates that M_w of sulfated polysaccharides has an important effect on the anticoagulant activity. The considerable anticoagulant activity of sulfated polysaccharides is also closely correlated to the content and position of the sulfate groups inside the polysaccharide chains [40.76].

40.4.4 Antihyperlipidemic Activity

Sulfated polysaccharides are known to resist degradation of human endogenous enzymes and be able to reduce cholesterol levels like dietary fibers [40.78]. According to *Guillon* and *Champ* [40.79], dietary fibers with ion-exchange capacity are more potent to lower cholesterol levels, therefore, sulfated polysaccharides appear to have the potential to be used as dietary fibers. During the last decade, many new classes of hypolipidemic agents have been widely used for the improvement of hyperlipidemia associated with atherosclerosis [40.80–82]. Currently, the most commonly used lipid regulators are statin and fibrates. However, recent reports of undesirable side effects of some *super statins* required the development and utilization of effective

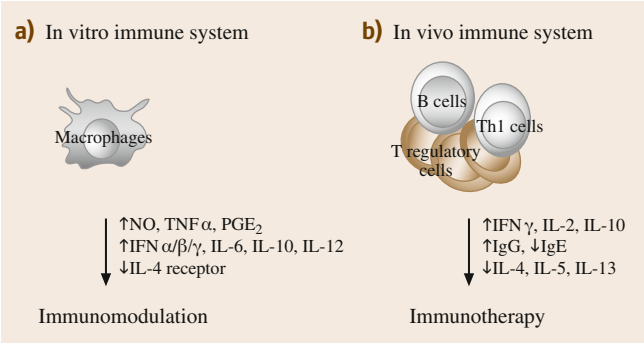

Fig. 40.4 (a) In vitro and (b) in vivo immune systems of sulfated polysaccharides from green seaweeds. NO = nitric oxide, TNF = tumor necrosis factor, PGE_2 = prostaglandin E_2, IFN = interferon, IL = interleukin, Ig = immunoglobulin

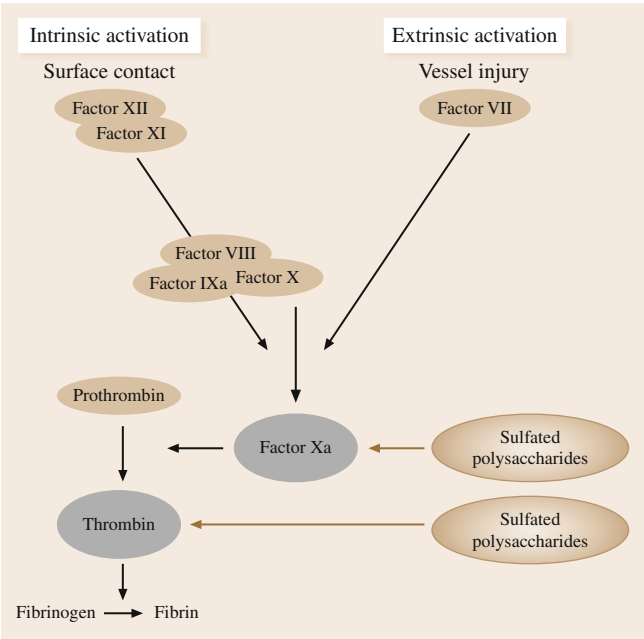

Fig. 40.5 Intrinsic and extrinsic pathways of blood coagulation systems [40.77]

and natural lipid regulators, protecting the human body from hyperlipidemia [40.16, 83]. It has been observed that porphyran from the red algae *Porphyra yezoensis* reduced the secretion of an essential component of very low density lipoprotein (VLDL) synthesis, apolipoprotein B100, mainly through suppression of lipid synthesis in human liver derived cells, revealing its use as a potent antihyperlipidemic agent [40.84, 85]. The

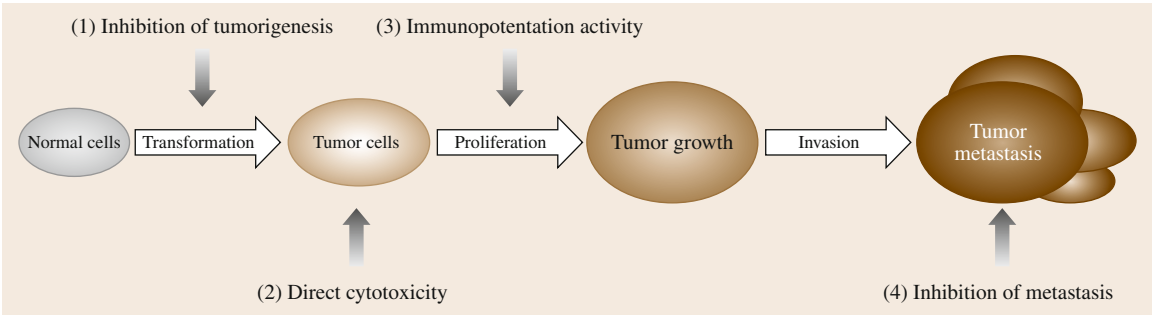

Fig. 40.6 The different inhibition pathways of sulfated polysaccharides from green seaweeds in cancer development. (1) the prevention of tumorigenesis, (2) direct cytotoxicity, such as the induction of tumor cell apoptosis, (3) immunopotentiation activity in combination with chemotherapy, and (4) the inhibition of tumor metastasis

high M_w sulfated polysaccharides from *Ulva pertusa* also demonstrated the effective reduction of serum total and LDL-cholesterol (LDL: low density lipoprotein) levels. On the other hand, the low M_w ulvan derivatives increased serum HDL-cholesterol (HDL: high density lipoprotein) but decreased serum TG level [40.49]. *Qi* et al. [40.16] reported that highly sulfated polysaccharides isolated from *U. pertusa* considerably decreased triglycerides (TG) and LDL-cholesterol levels. These results revealed that M_w and the sulfate contents of sulfated polysaccharides may be determinant factors on lipid metabolism.

40.4.5 Anticancer Activity

The anticancer activity of polysaccharides was first reported by *Nauts* et al. [40.86]. Since then, numerous studies have suggested that polysaccharides have anticancer effects, such as:

1. The prevention of tumorigenesis by oral consumption of active preparations.
2. Direct cytotoxicity, such as the induction of tumor cell apoptosis.
3. Immunopotentiation activity in combination with chemotherapy.
4. The inhibition of tumor metastasis (Fig. 40.6). [40.87, 88].

Most natural anticancer compounds are able to manipulate the growth of cancer cells with no or minor side effects. Identification of novel effective natural cancer therapeutic agents has become an important worldwide strategy in cancer prevention. Several studies have revealed that sulfated polysaccharides from brown and red seaweeds has direct cytotoxic effects on cancer cell lines, as well as suppressive activity of tumor growth in mice [40.61, 89]. In addition, antimetastatic activity of fucans has also been reported, which appears to block the interaction between cancer cells and the basement membrane [40.90].

Sulfated polysaccharides from green seaweeds also exhibit anticancer activities. According to *Karnjanapratum* and *You* [40.14], the sulfated polysaccharides from *Monostroma nitidum* have direct cytotoxic effects on human gastric cancer cells. *Kwon* and *Nam* [40.59] reported that the sulfated polysaccharide from *Capsosiphon fulvescens* inhibits the proliferation of human cancer cells, and they observed a marked increase in caspase-3 activation but a considerable decrease in Bcl-2 expression, and the phosphorylation of the insulin-like growth factor-I receptor (IGF-IR). In addition, sulfated polysaccharides suppress IGF-I-stimulated recruitment of p85 to IGF-IR and IRS-1. These results suggest that the sulfated polysaccharide from *C. fulvescens* might inhibit cell proliferation through the induction of apoptosis by inhibiting IGF-IR signaling and the PI3K/Akt pathway. On the other hand, the sulfate polysaccharide isolated from *Enteromorpha intestinalis* has in vivo anticancer activity with no direct cell cytotoxicity by increasing the relative spleen and thymus weight, and facilitating the release of tumor necrosis factor α (TNF-α) [40.48].

40.4.6 Antiviral Activity

Sulfated polysaccharides from various marine species have been shown to inhibit the replication of enveloped viruses such as flavivirus, togavirus, arenavirus, rhabdovirus, orthopoxvirus, and herpesvirus families [40.91]. According to *Harden* et al. [40.92], the evaluation of sulfated polysaccharides containing

seaweed extracts from *Undaria pinnatifida, Splachnidium rugosum, Gigartina atropurpurea*, and *Plocamium cartilagineum* against HSV-1 and HSV-II revealed that their antiviral activities are potent when they are added during the first hour of viral infection; however, they were not effective if added later. It has been reported that the chemical structures including the degree of sulfate content, molecular weight, constituent sugars, conformation, and dynamic stereochemistry are important factors to determine their potency of antiviral activity [40.93, 94]. Sulfated polysaccharides such as fucoidans and carrageenans have been extensively investigated for their antiviral activities. They appear to inhibit the entry of enveloped viruses, including herpes and human immunodeficiency virus (HIV), into cells [40.91]. In addition, *Hidari* et al. [40.95] found inhibitory potency of fucoidans on dengue virus type 2 infection, suggesting that fucoidans are able to directly bind to virus particles.

Compared to research on sulfated polysaccharides from brown and red seaweeds, little research has been performed on sulfated polysaccharides from green seaweeds. According to *Lee* et al. [40.96], the sulfated polysaccharides from various green seaweeds have antiherpes simplex virus type 1 (HSV-1) activities. The water soluble sulfated polysaccharides not only show the inhibition of the early stages of HSV-1 replication, but also interfere with late steps of virus replication. The homogeneous sulfated heterorhamnan obtained from *Gayralia oxysperma* also has high and specific activity against HSV-1 and HSV-2. The early step of HSV-2 replication is significantly interfered with through the presence of the sulfated polysaccharide from *Monostroma nitidum*. However, it has no effect on the replication of influenza A virus [40.23]. A sulfated heteropolysaccharide isolated from *Caulerpa racemosa* has been shown to be a selective inhibitor of TK-acyclovir-resistant strains of HSV-1 and HSV-2 [40.60]. It was reported by *Cassolato* et al. [40.19] that high M_w and sulfation (75% and 80% of the rhamnosyl and uronic acids, respectively, are substituted by sulfates) of the polysaccharide are desirable with potent antiherpetic activity, implying a correlation between M_w and the degree of sulfation, and the antiviral activity.

40.5 Conclusion

In order to gain a deeper insight into the potentiality of using sulfated polysaccharides from green seaweeds in various bioapplications, the structural characteristics and the biological activities have been discussed in this chapter. Most of the positive health effects induced by these polysaccharides appear to be generated by the presence of sulfate groups inside the structure. However, due to the heterogeneities and difficulties in identifying the structural features, the structure–bioactivity correlation is not clearly understood. Therefore, further systematic work is required to explore their structural diversity in relation with their bioactivities. In addition, the elucidation of the interaction mechanism between the polysaccharides and the receptors triggering the bioactivity may provide a better understanding of the relationship between structure and bioactivity. This will provide the key to improving the biological activity of the sulfated polysaccharides from green seaweeds and broaden their utilization as a material in various bioapplications.

41. Marine-Derived Pharmaceuticals and Future Prospects

Kalpa W. Samarakoon, Don A. S. Elvitigala, You-Jin Jeon

Over the last decades, the ocean has been identified as a sustained source for the requirements of human beings. The marine environment has an enormous biodiversity and is a source with huge potential for scientific applications. Among the potentials, the pharmaceutical perspective has been identified as having an important and substantial role for future therapeutic uses. Marine-derived secondary metabolites have become a promising source for the design and development of drugs. Therefore, in this chapter, we describe the recent findings of marine derived-secondary metabolites, including halogenated terpenes, steroids and sterols, and polyphenols, along with their therapeutic potentials. Marine proteins and lipids are also targeted to speculate on their role in human health. Moreover, molecular biology approaches and future trends in pharmaceuticals with a view of current drug developments will also be discussed.

41.1 Marine Bioresources

Nature is an attractive prolific source with a tremendous chemical diversity of the organisms living on earth. More than 70% of the earth's surface is covered by oceans and it is conceived that life originated from the ocean. Despite the richness of plant and animal diversity in terrestrial life, the demand to explore natural products in the marine environment has been increased. Interestingly, many marine organisms and microorganisms have a greater chemical diversity and are richer sources of secondary metabolites than terrestrial organisms [41.1]. This fact can be reflected through evolutionary process of natural selection and progression of self defense mechanisms against predators in the life cycle. Intriguingly, new therapeutic candidates are discovered as novel marine metabolites from this exceptional reservoir of bioactive secondary metabolites, as frequently reported in literature [41.2]. Therefore, promising biological activities associated with these chemical entities are useful for finding new drugs with greater efficacy for the treatment of human diseases [41.3]. Hence, marine organisms, such as marine bacteria, fungi, sponges, algae (macro or micro), crustaceans, mollusks, fish, and small vertebrates in the ocean are indispensable sources of functional metabolites.

The emerging diversity of the marine environment and its untapped resources are becoming of great interest and have attracted the curiosity of scientific community. In fact an impressive amount of exploration of biochemicals has been carried out by many research pioneers from different countries in the last few decades. Especially, scientists from the USA, Europe, Korea, Japan, and China have contributed to a great deal of research effort to bring these amazing marine biofunctional ingredients to pharmacological applications. Thus, this chapter focuses on the pharmaceutical

value of some marine secondary metabolites, proteins, and lipids, as well as molecular biology approaches to sustain these bioresources for future prospects. Furthermore, this chapter presents recent developments of drug design and discoveries of pharmaceutical innovations for future therapeutic use.

41.2 Marine Secondary Metabolites

Marine natural products or secondary metabolites are quite species specific and have been employed for the defense mechanisms against predation, infection, parasitism, or interspecies communication and maintenance of homeostasis in marine organisms [41.4]. With the huge diversity of marine organisms, there is an extraordinary potential for the discovery of various natural products. Indeed, evolutionary selection has pronounced that exposure to extreme environmental conditions such as a broad range of variable pHs, high hydrostatic pressure, and very low and very high temperatures may change the morphology of marine organisms. In fact, our understanding of the adaptation strategies can gain a better insight into discovering novel secondary metabolites from marine systems. Most marine secondary metabolites play a physiological role in marine ecological systems and are known to be involved in specific binding mechanisms with desired target receptors. These physiological functions may have been conceived to comply with biochemical and physiological phenomena of humans. Furthermore, these biomolecules are found in their terrestrial analogs and furnished the focus of formulating new classes of drugs [41.1, 5]. Thus, identification and isolation of many of these compounds can play a substantial role in the designing and development of pharmaceutical products.

Over the last three decades, more than 35 000 novel marine natural products have been isolated and structurally identified from marine sources [41.6]. Reported bioactivities of marine secondary metabolites have commonly shown anticancer activity [41.7], matrix metalloproteinase inhibitory activity [41.8], antioxidant activity [41.9], antiviral activity [41.10], anti-inflammatory activity [41.11], hepatoprotective activity [41.12], antibiotic [41.13], and antidiabetic activity [41.14]. However, with higher demands on global pharmaceutical market value, the design and development of new drugs need to be increased massively. In fact, major research areas with respect to the burden of human health diseases such as cardiovascular diseases, cancers, gastrointestinal disorders, and infective and central nervous system diseases need to be met with innovative drugs and medicines with selective and specific mechanisms of actions. In order to achieve these targets, mining of bioactive molecules should be carried out using high-throughput screening. Thus, recently reported marine secondary metabolites or drug-like molecules and their pharmacological effects are open for further discussion.

41.2.1 Halogenated Terpenes

Terpenes are derived from five carbon isoprene molecules and described as a unique type of secondary metabolites. The wide range of chemical and structural diversities of terpenoid compounds are associated with significant biological properties. Due to structural variations, certain classes of terpenes have been reported, from 5 carbon units (C5; hemiterpenoid) to 40 carbon units (C40; tetraterpenoid) [41.15]. Figure 41.1 depicts an isolated diterpenoid, flexibilide **(1)** and dihydroflexibilide **(2)** from soft coral *Sinularia flexibilis* showing tissue necrosis effects due to toxicity against near sea organisms [41.16]. In addition, in the marine sponge *Dysidea* sp. a major sesquiterpene, 7-deacetoxyolepupuane **(3)** was isolated, showing an allelopathic effect [41.17].

The biomedical potential of terpenes isolated from marine seaweeds has been studied recently. The marine red algae, genus *Laurencia* (family Rhodomelaceae, order Ceramiales) was reported to have around 135 species worldwide [41.18]. It could be a major source of isolated halogenated terpenes and was found to possess biofunctional effects, which could be easily used as drug-like molecules for the pharmaceutical industry [41.11]. Hence, *Laurencia* spp. was the first recognized source of halogenated natural products [41.6]. In this case, isolated laurinterol **(4)** was the first reported brominated terpene. Despite that, recently isolated terpenes, 5β-hydroxypalisadin B **(5)**, palisadin B **(6)**, palisol **(7)**, and pacifigorgiol **(8)** from *Laurencia snackeyi* were reported to show potential in vitro anti-inflammatory effects. In addition, a novel brominated diterpene, **(9)** with antibacterial activity was isolated from Malaysian *Laurencia* spp. [41.13].

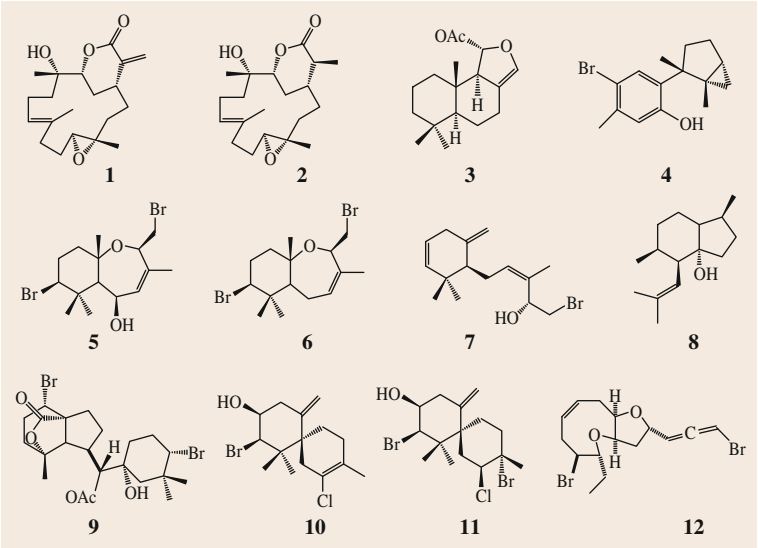

Fig. 41.1 Chemical structures **(1–12)** of halogenated terpenes as possible analogs for future pharmaceuticals from marine bioresources

Furthermore, interesting halogenated metabolites, elatol **(10)** and isoobtusol **(11)** with an antibacterial effect have reported from *Laurencia majuscule* [41.19]. *Ji* et al. reported on the isolation of halogenated terpenes including seven diterpenes, two polyether triterpenes, and one C_{15}-Acetogenin, neolaurallene **(12)** from *Laurencia saitoi* [41.20]. These molecules are described as halogenated and cyclic terpene structures with a unique substrate selectivity that confers the stereo-specific and regiospecific reactivity for promising bioactivities.

41.2.2 Steroids and Sterols

A steroid comprises a characteristic arrangement of four cyclic rings joined together. Sterols are a form of steroids and contain a hydroxyl attachment at the 3-carbon position. Steroids are derived biochemically from the squalene precursor, and a few important sterols are identified such as, acylated, alkylated, sulfated, free sterols, and sterol glycosides [41.21]. The exploration of marine steroids and sterols started when a significantly larger amount of structural variations was found in the marine ecosystem than in terrestrial life. Thus, these steroids and sterols are gaining attention in the newest drug design and developments [41.22]. The number of different biological activities of these compounds were attributed to the unusual side chains that attached to the steroid skeleton. In particular, because they have unusual carbon atoms at C-24 as quaternary alkyl, cyclopropane, and cyclopropene rings, allenes and acetylenes have offered a wide range of biosynthesis applications for drug designers [41.23].

Among the marine organisms, sponges are the richest source with a high content of sterols (Fig. 41.2). The marine sponge *Petrosia weinbergi* was found to contain major sterols, isofucosterol **(13)**, and clionasterol **(14)** with antiviral activities [41.21]. Microalgae sterols usually represent C-27 ≈ C-29 skeletons with different alkylations at C-24, along with double bonds in the rings (Δ5, Δ8, or Δ8, Δ14), and in the side chains (Δ22, Δ24). In fact, dinoflagellates possess a typical steroid composition and are commonly used as biomarkers (e.g., dinosterols **(15)**) [41.24, 25]. The unique structure of oxysterols has shown a protective effect against β-amyloid peptides and is found in plaques in Alzheimer's diseased brains. However, only the isolated oxysterols, 5α-cholestane-hexanol **(16)** are found in starfish, *Hippasteria kurilensis* [41.26]. A low amount of sterols is found in brown algae, and the only dominant sterol is reported as fucosterol **(17)**. Fucosterol isolated form *Pelvitia siliquosa* shows antidiabetic activity [41.27] and antioxidant activity [41.28]. Moreover, saringosterol **(18)**, a derivative of fucosterol, was found to inhibit the growth of *Mycobacterium tuberculosis*, and is isolated from the brown algae *Lessonia nigrescens* [41.29]. According to further studies, this compound has not shown cytotoxicity for the mammalian cell, thus representing a good candidate for tuberculosis drugs. The starfish *Linckia laevigata* was reported to bear the most different type of sterols, for example, linckoside

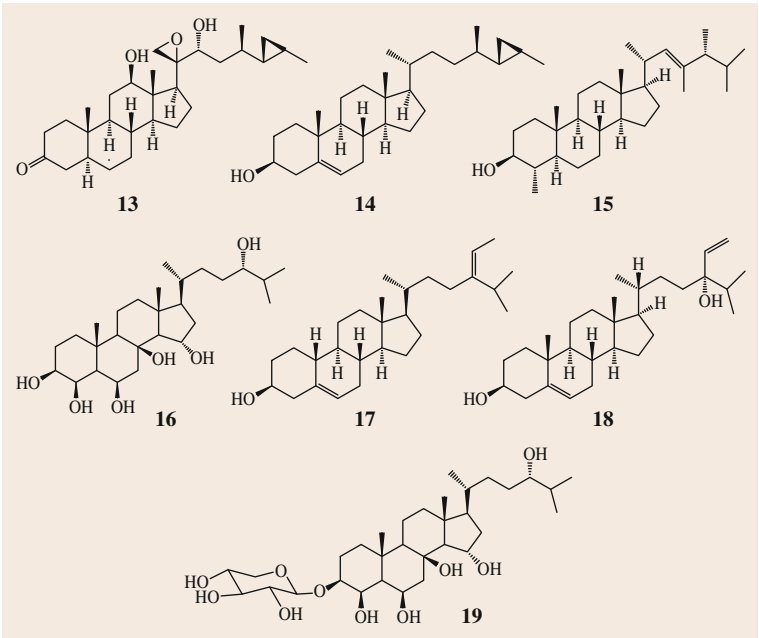

Fig. 41.2 Isolated different steroid and sterol skeletons **(13–19)** from marine bioresources

L1 **(19)** identified as polyhydroxylated steroid glycosides [41.30]. This compound was reported to be neuritogenic and thus might help to treat damaged neuronal cells and can potentially be used as a drug for neurodegenerative disease. Each of these steroid molecules shows significant variations throughout the marine ecosystem and shows a broad range of bioactivities. Therefore, these biomolecules may contribute as templates or drug analogs for future therapeutic uses.

41.2.3 Polyphenols
