Polyphenols are a class of large secondary metabolites associated with multiple phenol structural units. Polyphenols serve as a reactive species, tend to be oxidized and are attributed as antioxidants, which can commonly be found in plant materials. However, marine seaweeds have had a wide acceptance with the latest studies reporting that they contain phenolic compounds or polyphenols [41.31]. In fact, polyphenols can interact with tannins and may be derived as a special form of secondary metabolites in brown algae, known as phlorotannins [41.32]. These molecular components make the integral part of the cell walls of brown algae. Basically they play an important role as secondary metabolites to as protection from ultraviolet (UV) radiations and oxidative stress.

Among the high biodiversity of marine seaweeds, brown algal species such as *Ecklonia cava*, *Eisenia arbora, Ecklonia stolinifera* and *Eisenia bicyclis* have been reported that comprise of high content phlorotannins [41.33–35]. Figure 41.3 shows that the isolated phlorotannin structures from marine brown algae and phloroglucinol **(20)** is the basic unit which is polymerized through the acetate-malonate biosynthesized pathway to form phlorotannins. Functional benefits from different phlorotannins which accumulated in marine brown algae are widely studied recently. There are four subclasses of phlorotannins reported in marine system such as phlorethols (with ether linkages), fucols (with a phenyl linkage), fucophloroethols (with an ether and phenyl linkage) and eckols (with a dibenzodioxin linkage) [41.36].

Eckol **(21)** isolated from *E. bicyclis* was reported to show anti-diabetic properties as inhibitory activity against glycation and α-amylase [41.33]. Moreover, a brown alga *E. cava* has been provisioned to extract eckol and dieckol **(22)** and showing the inhibitory effect of melanogenesis and protective effects against photo-oxidative stress induced by UV-B radiation [41.34]. Inducing apoptosis by dioxinodehydroeckol **(23)** and 7-phloroeckol **(24)** were isolated from *E. cava* and having a promising potential to use as anticancer drugs for human breast cancers [41.7]. In addition, *Ecklonia stolonifera* extract phlorotannins were identified

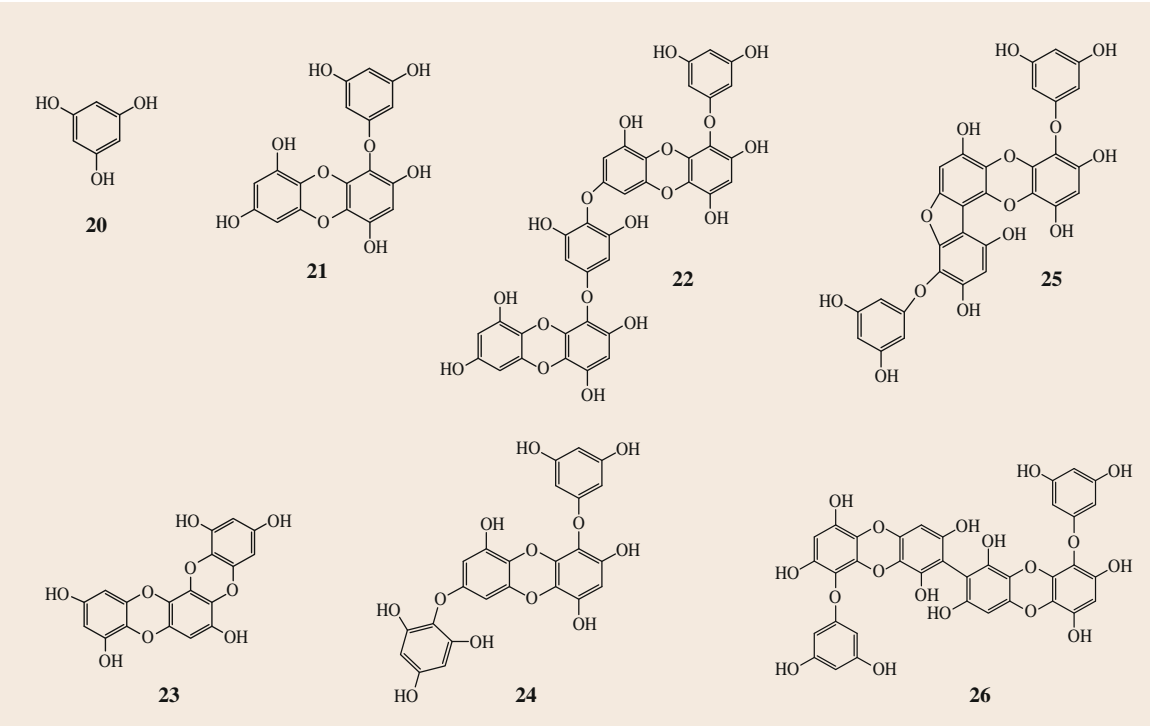

Fig. 41.3 Phloroglucinol derivatives (phlorotannins) **(20–26)** isolated from marine brown algae

as phlorofucofuroeckol A **(25)** with the lowering effect of Cu^{2+} induced low-density lipoproteins (LDL) oxidation [41.37]. Moreover, angiotensin converting enzyme (ACE) inhibitory activity was also proven by this molecule [41.38] and confirmed that the future opportunistic for drug development against cardiovascular diseases. *Ahn* et al. (2004) reported on the promising effect of inhibitory activity on human immunodeficiency virus type 1 (HIV-1), reverse transcriptase (RT), and protease from the *E. cava* phlorotannins, including eckol, phlorofucofuroeckol A and 8,8′-bieckol **(26)** [41.39]. There is an abundant chemical distribution of phlorotannins among brown seaweed, which is described as a multifunctional approach for biological and pharmacological applications. Most of the burden of human health issues can be managed using phlorotannins, which will be a good candidate for future drug design strategies.

41.3 Marine Proteins

Importantly, most marine bioresources are composed of a higher content of proteins than other components. Marine microalgae, muscle tissues of fish, shellfish, and other invertebrates show a range of 15–65 w/w% proteins [41.75]. On the other hand, marine fish and shellfish waste as processing by products are also considered to contain large quantities of high-quality proteins (10–23 w/w%). These sources are considered as being a potential source forming active proteins and bioactive peptides [41.76]. The significance of marine-derived proteins and peptides are due to their advantage over conventional drugs with a high bioavailability and biospecificity to the targets. In addition, the properties of low toxicity, structural diversity, and little or no accumulations in the body tissues of these molecules make them promising candidates for therapeutic purposes [41.77]. Marine enzymes are described as a promising biotechnological tool that can be synthesized from marine bioresources [41.78]. Interestingly, their high speci-

VKAGFAWTANQQLS	*Katsuwonus pelamis*	Fish – tuna	Antioxidant	[41.49]
TFPHGP/HWTTQR	*Syngnathus schlegeli*	Fish – pipefish	Antihypertensive	[41.50]
LLEYSI/LLEYSL	*Crassostrea gigas*	Shellfish – oyster	Anti HIV-1 protease	[41.51]
EVMAGNLYPG	*Mytilus edulis*	Shellfish – blue mussel	ACE inhibitory	[41.52]
MEGAQEAQGD	*Acaudina molpadioidea*	Sea cucumber	ACE inhibitory	[41.53]
AHIII	*Styela clava*	Sea squirt	Antihypertensive	[41.54]
MLLCS	*Styela plicata*	Sea squirt	ACE inhibitory	[41.55]
DDTGHDFED/TGEAM	*Brachionus rotundiformis*	Rotifer	ACE inhibitory	[41.56]
Marine enzymes				
Chymotrypsin	*Gadus morhua*	Fish – Atlantic cod	Protein hydrolysation	[41.57]
Transglutaminase	*Cyprinus carpio*	Fish – carp	Modification of viscoelastic properties-transferase	[41.58]
α-D-glucosidase	*Aplysia fasciata*	Shellfish – mollusc	Enzymatic synthesis of oligosaccharides	[41.59]
Citrate synthase/pyruvate kinase	*Meganyctiphanes norvegica*	Shellfish – northern krill	Metabolic key enzymes	[41.60]
Cholinesterase	*Mytilus edulis*	Shellfish – blue mussel	Aquatic biomarker	[41.61]
(2′-5′) oligoadenylate synthetase	*Geodia cydonium*	Sponge	Immunologically related proteins	[41.62]
ATP *N*-glycosidase	*Axinella polypoides*	Sponge	Nucleosidase enzymatic activity-transferase	[41.63]
Fibrinolytic	*Basillus clausii* ICTF-1	Marine bacteria	Treatment of cardiovascular diseases	[41.64]
Hydrolases	*Oscillatoria willei* BDU 130511	Cyanobacteria	Bioremediation	[41.65]
Marine lipids				
Galactolipids	*Phaeodactylum tricornutum*	Microalgae	Apoptosis inducing	[41.66]
EPA (eicosapentaenoic acid)	*Phaeodactylum tricornutum*	Microalgae	Reduce the risk of heart disease	[41.67]
GLA (γ-linolenic acid)	*Spirulina platensis*	Microalgae	Reduce the risk of heart disease	[41.68]
Oleic acid	*Haematococcus pluviales*	Microalgae	Antioxidant	[41.69]
Palmitic, α-linolenic & oleic acids	*Dunaliella salina*	Microalgae	Antimicrobial	[41.70]
Sterols and fatty alcohols	*Euphasia Superba*	Shellfish – krill oil	Reduce the risk of heart disease	[41.71]

Table 41.1 (continued)

Functional ingredients	Source of origin	Marine source	Pharmaceutical value	Reference
Marine lipids				
EPA and DHA	*Perna canaliculus*	Shellfish – Green-lipped mussels	Reduce the risk of heart disease	[41.72]
EPA and DHA	*Oncorhynchus gorbuscha*	Fish – salmon	Reduce the risk of heart disease	[41.73]
Diacylglycerol (DAG)	*Katsuwonus pelamis*	Fish – tuna	Anti-obesity	[41.74]

ficity and high reactivity at low concentrations may encompasses the efficacy of marine enzymes in different applications, including molecular biology research, food processing, diagnostics and pharmacology [41.79]. The interesting proteins, enzymes, and bioactive peptides isolated from different marine sources with their therapeutic uses are presented in Table 41.1.

41.4 Marine Lipids

The consumption of seafood has been proven to prevent lifestyle diseases and give long-term health benefits [41.80]. One of the characteristic components in marine resources are lipids. The lipid factions of marine bioresources consist of polyunsaturated fatty acids (PUFA), including omega-3 and omega-6 fatty acids [41.81]. Over many years, there impressive work on PUFA has been carried out, and they have been proven to reduce or prevent the burden of diseases. Especially, the consumption of seafood once or twice a week may have a protective effect against coronary heart disease, may reduce the death risk by 36% and 17% from total mortality due to a high content of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) in the diet [41.82]. These health benefits may bring about relievable effect against physiological conditions [41.83] such as diabetes [41.84], cancers [41.85], and inflammatory diseases [41.86].

As presented in Table 41.1, many food components serve the essential fatty acid molecules for the food industry. These PUFA sources can be used directly in pharmaceutical applications and, on the other hand, may be utilized as food supplements or in neutraceutical applications.

41.5 Molecular Biology Approaches

Molecular biology approaches in biotechnology and pharmacology are interesting. In this regard, the structures and functions of macromolecules like nucleic acids and proteins, with respect to their roles in life processes are investigated. However, applications of this promising discipline of marine bioresources such as microorganisms, algae, invertebrates, and vertebrates including economically important fish species have become valuable recently. Marine ecosystems consist of a huge diversity of organisms and are a prominent source of a wide array of therapeutic agents that can be developed as pharmaceuticals. Novel developments in molecular biology, including genomics, metagenomics, transcriptomics, proteomics, and bioinformatics, along with the refinement of technologies, such as genetic engineering and bioactivity screening offer unique opportunities to establish marine natural products as interesting drug candidates.

Several explorations have been made based on genomic and metagenomic approaches, including the identification of the putative bryostatin polyketide synthase gene cluster from the marine bacterium *Candidatus Endobugulase ertula*. In fact, this gene cluster encodes crucial constituents in the biosynthesis of pharmaceutically potent bioactive compounds, known as bryostatins [41.87]. Moreover, polyketide bio-synthesis was already characterized from an noncultivable bacterial symbiont of the marine sponge; *Theonellaswinhoe*, with respect to its corresponding genes, such as polyketide synthase (PK) and non-ribosomal peptide synthase (NRPS) which are known to produce antitumor molecules [41.88–90]. In addition, polyke-

tide coding genes were identified from *Streptomyces* species, proving the secretory properties of antitumor and antibacterial agents from marine bacteria as their secondary metabolites [41.91]. Particularly, PKs and NRPS can be used in screening approaches to pre-select new isolates with promising bioactivities for natural product analysis. Moreover, the discovery of novel antimicrobial peptides (AMP) originating from marine invertebrates; such as penaedin, crustin, and defensin, etc., is facilitated by the development of new drug candidates by molecular biological approaches. Especially, the isolation of complementary DNA (cDNA) transcripts or express sequence tag (EST) clones which show homology with already characterized AMP sequences furnishes ease and success of such investigations of AMPs from marine species as desirable [41.92]. Marine organisms, especially marine microorganisms, algae, and sponge-like invertebrates can also be considered prospective candidates to be subjected to genetic improvements, as described above, to improve them as sustainable resources of bioactive compounds. Finally, the overall insights on the impact of molecular biology on the development of marine bioresources points us to a flourishing future, especially with respect to drug discovery programs.

41.6 Future Trends in Marine Pharmaceuticals

Over the last few decades, the number of marine natural products isolated from marine bioresources has increased significantly [41.93]. However, a limited number of natural products gained market value throughout this period. It is believed that there is a lowering of the ecological niche of sample sources or a lack of sufficient quantities of the compounds and difficulties with isolation and purification. In addition, to face the challenges in vivo, pre-clinical and clinical phase studies, drug-like activities need to be proven prior to the commercial chemical synthesis. Nevertheless, these obstacles in the chemical synthesis of the desired drug-like molecules may be described as the major issue while determining bioactivities with the conformational changes of the molecules. Moreover, to obtain regulatory approval of a drug from the FDA for sale and marketing, from the discovery of natural products until the success of preclinical, clinical, and phase studies may cost about US$ 802 million and takes about an average of 10 ≈ 15 years [41.94]. Despite this, some marine drugs with prominent pharmaceutical value are available in

Table 41.2 Marine-derived pharmaceutical agents

Compound name	Trade name	Marine organism	Approval or clinical status	Medicinal value
Ziconotide	Prialt	Cone snail – *Conus magus*	Approved by FDA in 2004	Analgesic (Chronic pain)
Cytarabine	Cytosar-U	Sponges – *Cryptotheca crypta*	Approved by FDA in 1969	Cancer and leukaemia
ET-743	Yondelis	Tunicate – *Ecteinascidia turbinate*	Approved by EMEA in 2007	Ovarian cancer
Pseudopterosin A	Resilience	Sea fan – *Pseudopterogorgia elisabethae*	Approved for skin care products	Anti-inflammatory
Diazonamide A	NA	Sea squirt – *Diazona angulata*	NA	Cytotoxic and antimicrobial
Vidarabine	Vira-A	Sponge – *Tethya crypta*	Approved by FDA	Antiviral
Eribulin mesylate	E7389	Sponge – *Halichondria okadai*	Phase III	Cancer treatment
Soblidotin	TZT-1027	Bacterium – *Symploca sp.*	Phase III	Cancer treatment
Plitidepsin	Aplidin	Tunicate – *Aplidin albicans*	Phase II/III	Cancer treatment
Kahaladide F	NA	Mollusc – *Elysia rubefescens*	Phase II	Antitumor
Aplyronine A	NA	Sea hare – *Aplysia kurodai*	Phase I	Antitumor
Dideminin B	NA	Tunicate – *Tridemnum soldium*	Phase II	Antitumor
Granulatimide	NA	Tunicate – *Ascidian didemnum*	Phase II	Cancer treatment

FDA: Food and Drug Administration, EMEA: European Medicines Agency, NA: Not applicable

the market and some of which are presented in Table 41.2.

The drug development process can be provided with recent molecular biological strategies, including genomics, metagenomics, transcriptomics, proteomics, and bioinformatics. The current contributions from the diverse areas of secondary metabolites are promising for future pharmacological developments. In fact, the knowledge of the advances of biotechnology and pharmacology may lead to a better understanding of the infrastructures of scientific communities and strengthen the development of innovative drugs in the future.

42. Marine Functional Foods

Ana C. Freitas, Dina Rodrigues, Ana P. Carvalho, Leonel Pereira, Teresa Panteleitchouk, Ana M. Gomes, Armando C. Duarte

In line with consumer awareness that a relationship between diet, health, and disease prevention exists, the research and development of new functional foods have been the target of many studies over the last years. The increasing ageing of populations, the decrease in quality of life due to stress, the high incidence of so-called modern diseases (cardiovascular disease, obesity, cancer, diabetes, and allergies) represent the driving forces in the quest for different foods and diets to promote healthy active ageing, improve well-being, and counteract the incidence of many diseases. The marine environment provides a huge source of many healthy foods, including seaweeds, which is an example of a marine product that has been part of the diet in several countries around the world. Additionally, marine specimens are also sources of a plethora of chemicals, many of them with biological properties and, therefore, called bioactive compounds. These chemicals can be extracted and incorporated in several food matrices leading to new potential functional foods. This chapter is a review summarizing those marine organisms with healthy properties that are consumed all over the world, as well as the potential of using marine organisms as sources of food ingredients towards applications in new functional foods. Recent findings on functional foods based on marine-derived ingredients are described and discussed.

42.1 General Overview

Since ancient times, man has always had the perception that a direct relationship between diet and human health exists. As *El-Sohaimy* [42.1] described in his review on functional food and nutraceuticals, the phrase postulated by Hippocrates over 2500 years ago *Let food be thy medicine and medicine be thy food* is a clear indication of this perception. Despite the fluctuations in the economy, wars, and social politics that occurred in

the last century, the human diet has evolved over the last 100 years and nowadays evidence shows that consumers are able to make informed choices based on their improved knowledge on the existing relationship between diet, health, and disease prevention. Consumption of healthy foods such as cereals, vegetables, and fruit, as well as marine foods rich in polyunsaturated fatty acids (PUFAs) goes beyond meeting basic nutritional needs; they are also crucial for health promotion and/or maintenance, as well as for disease risk reduction [42.2]. Additionally, research progress over the past decade has correlated diet and some chronic diseases that still have high mortal rates and are extremely expensive for public or private healthcare systems. Nutritional science has been evolving from a focus on identifying nutrients and the respective amounts to prevent deficiency diseases to a focus on improving quality of life and health [42.3]. According to several authors several foods can play an important role by preventing or hindering the progression of chronic diseases such as atherosclerosis, obesity, diabetes, hypertension, osteoporosis, cancer, and cardiovascular disease [42.4–7], as well as relieving symptoms in osteoarthritic patients, for example [42.8]. However, independent of a higher level of nutritional knowledge, today's consumer and populations as a whole still need to pinpoint strategies that may enable us to overcome modern age diseases such as those previously mentioned. For example, the positive role of functional foods and nutraceuticals in the primary prevention of cardiovascular diseases was recently reviewed by *Allisa* and *Ferns* [42.6].

From a different standpoint, the increasingly ageing population as a consequence of medicinal advances in the last years, also demands an active response from food formulators and offers an excellent opportunity for the development of adapted foods and diets in order to contribute to healthy, active ageing and improved well-being [42.9].

Based on the above rationale, research, development, and commercialization of functional foods has been in the limelight for the last years and also offers an alternative way for some producers and industries to diversify their products, especially those based on marine-derived products [42.1, 2]. However, much has yet to be done regarding the acceptance of functional foods, namely in terms of health claims as stated in current legislation. Claims should be based on solid scientific evidence, which to date is often lacking [42.1] but is becoming increasingly important. A regulatory framework protecting consumers, promoting fair trade, and encouraging product innovation in the food industry is urgently needed [42.3]. *Hayes* [42.10] reviewed the claims and current legislation on marine-derived functional foods that have been applied in China, Japan, United States of America (USA) and in the European Union (EU). These authors also describes the recently approved health claims in the EU related with omega-3 fatty acids and with chitin-glucan, which is a known fiber-boosting weigh management food ingredient.

As discussed by *Freitas* et al. [42.11], there is still no recognized standard definition for functional foods – in general, the term refers to a food, and according to Health Canada, a functional food is similar to a conventional food, which is consumed as part of a usual diet that either provides physiological benefits or reduces the risk of chronic disease beyond basic nutritional functions [42.12]. According to the Food Agriculture Organization (FAO) [42.13], functional foods are those foods similar to conventional food in appearance, intended to be consumed as part of a normal diet containing biologically active compounds that offer potential for enhanced health or reduced risk of disease. *Ramesh* et al. [42.3] presented six proposed definitions of functional foods established by six different agencies; in five of them the concept that they should provide health benefits beyond basic nutritional functions is clearly present. For nutraceutical and/or dietary supplements, there is also no consensual definition and there is still ambiguity about the regulatory requirements concerning these compounds [42.14]. In certain countries, nutraceuticals and functional foods are still used interchangeably [42.2] since some nutraceuticals are used as conventional foods or as sole items of a meal or diet. According to *El-Sohamy* [42.1], nutraceuticals and functional foods are two recent designations used to describe health-promoting foods or their extracted compounds.

From the point of view of the authors, nutraceuticals or dietary supplements are those defined as functional ingredients but sold as powders, pills, and other medicinal forms not associated with food. Nevertheless, in functional foods, nutraceuticals, or dietary supplements, the main focus is to improve health and diminish as much as possible the risk of disease through prevention toward improvement of quality of life and well-being contributing to an increased healthy longevity [42.2].

Taking in consideration the previous discussion, functional foods belong to foods that besides their nutritional effects, have demonstrated that they improve the state of health or well-being, reduce the risk of disease, as well as benefit one or more functions of the human

organism. According to *Freitas* et al. [42.11], functionality could be intrinsic to a feature introduced in the food matrix, improving health or reducing any adverse health effect, accomplished, for example, by:

i) Elimination or promotion of a chemical change of a harmful ingredient.
ii) Addition of new health-promoting food ingredients or probiotic microorganisms in an effective concentration.
iii) Addition of an existing health-promoting food ingredient, increasing its concentration.
iv) Increasing the bioavailability or stability of the health-promoting food ingredient.

The development of foods containing a group of compounds with desired properties is, in general, particularly challenging for biotechnology and the food industry.

Functional ingredients exist in many different reservoirs from both terrestrial and marine environments [42.11], it being known that the terrestrial environment (for example, fruit, vegetables, cereals, and mushrooms) is far more explored than the marine environment (for example, fish, sponges, macro and microalgae) for bioactive compounds. There are many functional marine ingredients that are presently known, yet it is of general consensus that other marine ingredients remain to be evaluated and new sources to be discovered. According to *Zhang* et al. [42.15] bioprocessed marine products are alternative sources for synthetic ingredients that can contribute to the consumer's well-being as a part of nutraceuticals and functional foods. By citing *Gates* [42.16] with his statement *The ocean is considered Mother Nature's medicine cabinet*, the importance of the marine environment as a major reservoir of bioactive compounds that have potential to be applied in several fields such as medicine or food becomes quite clear. For example, the marine environment represents a huge source of many healthy foods, including seaweeds, a marine product that has been part of the diet in some countries around the world. According to *Zhang* et al. [42.15], to date more than 20 000 new compounds have been isolated from marine biomaterials.

The characteristics of the marine environment such as various degrees of temperature, salinity, light, pressure, and nutrients are of special importance, since due to their broad range of values marine organisms had to evolve some protective mechanisms and metabolites [42.17, 18]. Therefore, research on the identification of biologically active marine-derived compounds can be seen as an almost unlimited field. In fact, in the last years much research has been pursued to discover and produce marine-derived bioactive compounds [42.19, 20]. Recommendations detail that although functional ingredients do not need to be nutrients they should be dietary, biologically active components added to a food vehicle or present in unmodified whole food [42.13]. Recent advances in genetics, namely in nutritional genomics, have also spiked interest in functional ingredients [42.14], since it has been shown that food may play a role in the individual needs and predispositions [42.11]. Marine specimens are sources of a plethora of chemicals, many of them with biological properties that can be extracted and incorporated in several food matrices, leading to new potential functional foods.

42.2 Marine Sources as Healthy Foods or Reservoirs of Functional Ingredients

Marine sources are well known for their phenomenal biodiversity, which offers a strong basis for their use as a natural source of healthy foods as well as of many novel functional food ingredients with biological properties. Crustaceans, macro or microalgae, fish, and fish by-products, as well as bacteria and fungi are the most representative groups of organisms of potential interest as healthy food or as a source of functional ingredients, which include polysaccharides, chitin, proteins and peptides, lipids, pigments, vitamins, minerals, and phenolic compounds (Fig. 42.1).

The interest in functional food marine-derived ingredients with biological properties derived from lipids, proteins, polysaccharides, and pigments, has increased tremendously in the last years due to their beneficial effects in terms of disease prevention or maintenance of health and well-being. Considering this perspective the next sections describe, in a summarized way, the properties of the above-mentioned groups of marine organisms: seaweeds, microalgae, fish and fish-by-products, crustaceans, as well as marine fungi and bacteria. The target of much scientific debate, there have been many

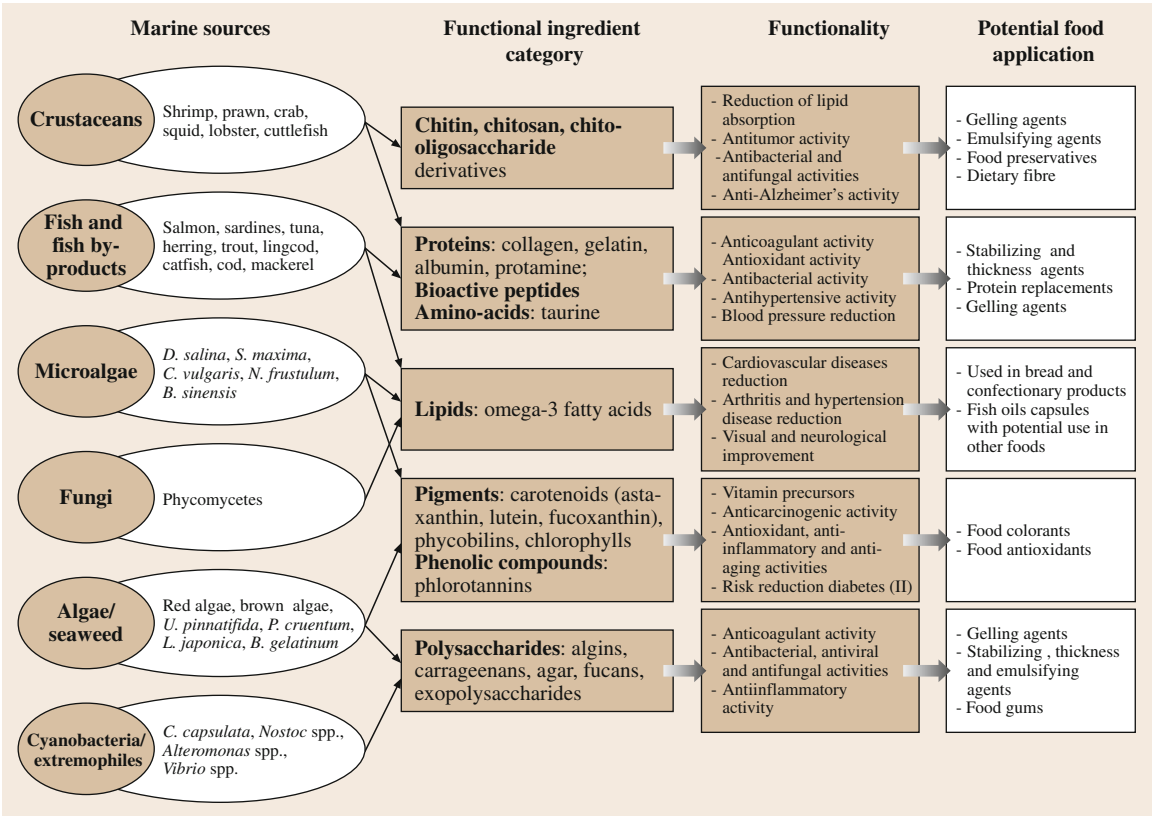

Fig. 42.1 Main marine functional ingredients with potential food applications, sources, and inherent functionality (after [42.11, 21, 22], courtesy of Elsevier)

recent reviews concerning these organisms, some of which will be mentioned in this chapter.

42.2.1 Seaweeds

Considering their great taxonomic diversity, algae, in particular, edible marine macroalgae or seaweeds, are a very interesting source of healthy foods as well as a natural source of compounds with biological activity that could be used as functional ingredients constituting a research area with much to explore for food purposes. According to *Chojnacka* et al. [42.23], there are about 10,000 identified species of algae and about 5% of them are used as food for either humans or animals. More than one hundred macroalgae species are used worldwide, especially in Asian countries as sea vegetables [42.24]. Seaweeds are of potential interest for incorporation in diet as foods because they are claimed to have a low cholesterol content, fight obesity, reduce blood pressure, tackle free radicals, and promote healthy digestion [42.25]. Seaweeds are known to be of low calorie content, rich in polysaccharides, minerals, vitamins proteins, steroids, and dietary fibers [42.26]; furthermore, some of them have demonstrated biological properties such as antibacterial, antioxidant, anti-inflammatory, anticoagulant, antiviral and/or apoptotic activities [42.27]. According to *Lordan* et al. [42.26], the ingestion of such compounds has the advantage of presenting high bioavailability, of natural origin and, in general, their isolation does not require an effectively high cost and, more importantly, affects some pathologies positively. In *Holdt* and *Kraan*'s [42.28] review one can find an exhaustive description of bioactive compounds that are present in seaweeds, their application in functional foods, as well as emerging legislation issues. The perspective of seaweeds as a sustainable functional food for complementary and alternative therapy has been reviewed by *Mohamed* et al. [42.29].

In fact, research advances have shown that seaweed can be used as a rich source of polysaccharides,

pigments such as carotenoids, phycobilins and chlorophylls, as well as of phenolic compounds (Fig. 42.1) that can be incorporated in several food products. Furthermore, seaweeds extracts are practically fat and calorie-free, making them increasingly pursued for commercial purposes. Macroalgae, i. e., the *Sargassum* species (Phaeophyceae, brown algae), have been found to be good sources of dietary fiber and carotenoids with antioxidant activity and play important roles in the prevention of neurodegenerative diseases [42.30–32]. Some algae live in complex habitats where they are subject to extreme conditions, being forced to quickly adapt to new environmental conditions, and in order to survive they produce a wide variety of biologically active secondary metabolites [42.25] like acetogenins, terpenes, derivatives of amino acids, phenols, and polyphenols, which are compounds that, in general, differ from plant products because they are often halogenated.

It is known that not all algae use and need the same light intensity to perform photosynthesis and, therefore, are generally classified in three divisions by the presence of specific pigments: brown macroalgae (phylum Ochrophyta, class Phaeophyceae), red macroalgae (phylum Rhodophyta), or green macroalgae (phylum Chlorophyta) [42.26, 33]. According to *Bocanegra* et al. [42.34], green macroalgae abound more in coastal waters because they absorb large amounts of light energy, whereas red and brown algae are found at greater depths where penetration of sunlight is more limited. Brown algae owe their color to the presence of the carotenoid fucoxanthin. Food reserves of brown algae are characteristically complex polysaccharides including laminarins, fucans, and cellulose, as well as higher alcohols; many bioactive metabolites with different pharmacological activities such as antioxidant, anti-inflammatory, antitumor, cytotoxic antifungal, and nematocidal activities, have been isolated from these algae [42.32, 35]. Green algae owe their color to the dominant presence of chlorophylls *a* and *b*, and the main polysaccharides present are normally ulvans. In turn, red algae, which are also considered an important source of many biologically active metabolites [42.35] possess phycoerythrin and phycocyanin as the main pigments, and the primary polysaccharides are agars and carrageenans [42.27].

42.2.2 Microalgae

Microalgae are microscopic marine organisms ($< 20\,\mu m$) that can be found in benthic and littoral habitats but also in the ocean identified as phytoplankton comprising blue–green algae (phylum Cyanobacteria, class Cyanophyceae), diatoms (phylum Ochrophyta class Bacillariophyceae), dinoflagellates (phylum Myzozoa, class Dinophyceae), as well as green and yellow–brown flagellates (chlorophyta, prasinophyta, prymnesiophyta, cryptophyta, and others) [42.26, 36, 37]. Microalgae play a key role in the productivity of oceans, constituting the basis of the marine food chain [42.35] but are also considered important producers of some highly bioactive compounds. For example, they can be used to improve the food nutritional profile due to their abundance in PUFAs and pigments such as carotenoids and chlorophylls [42.35]. Chlorophyll a, phycocyanins, and phycoerythrin (phycobilins) are the pigments of interest found in blue–green algae, which possess a secondary metabolism responsible for the production of distinct compounds in terms of health. In fact, not all of these compounds are desirable in terms of public health, for example, some are strong hepatotoxins or neurotoxins, however, other compounds are of potential interest because they present biological properties such as anticancer, antifungal, antibacterial, and immunosuppressive properties; this subject was reviewed by *Gamal* [42.35]. Hence, due to this large diversity and depending on the species, microalgae can be used as a nutritional supplement or represent a source of natural food colorants as soon as their safety is assured [42.37].

Diatoms are also specific organisms that dominate the phytoplankton of cold and nutrient rich waters [42.38]. Diatoms are photosynthetically organisms with a high degree of flexibility to adapt to different environments, which is of interest for biotechnological applications. In addition, they are able to produce compounds for functional foods [42.39]; some of the most important functional ingredients are PUFAs such as eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and other omega-3 FAs, as well as the antioxidants fucoxanthin and chlorophyll. Dinoflagellates are also recognized as eukaryotic primary producers in marine coastal waters containing chlorophyll and carotenoids as well as PUFAs [42.38].

42.2.3 Fish and Fish By-Products

All over the world several million tons of fish and fish by-products are discarded as waste representing a large environmental problem. However fish and fish

by-products are known sources of potential bioactive ingredients such as fish oils rich in PUFAs from fish livers, calcium from fish bones, protein hydrolysates of high biological value, peptides with biological properties such as antihypertensive activity, amino acids such as taurine, which have antioxidant activity and positive effects on cardiovascular system, as well as vitamins and minerals [42.30, 40–50]. According to *Ferraro* et al. [42.42] fish heads, viscera, skin tails, blood, and seafood shells possess a plethora of compounds with the potential to be used as functional food ingredients with biological properties. In a review by *Kim* and *Mendis* [42.43] the bioactive compounds resulting from marine processing by-products are described; these can be obtained by extraction and purification procedures enabling the preparation and isolation of bioactive peptides, oligosaccharides, as well as fatty acids (FAs) suitable for biotechnological applications.

42.2.4 Crustaceans

Chitin is extractable from crustaceans, being the second most abundant natural polymer [42.44]. Chitosan is a biodegradable and biocompatible polymer chitin derivative, which results from crab, shrimp, and cuttlefish, and from processing shells and bones; it has been associated with antibacterial activity that can be used as a food preservative. Its ability to absorb fat justifies its potential use as an anticholesterol agent [42.45]. The biological activities of chitosan and chitooligasaccharides (antioxidant antitumor, anticancer, hypocholesterolemic, immunity-enhancing, antimicrobial) and the potential application in food, among other applications, are reviewed by *Xia* et al. [42.46].

42.2.5 Marine Fungi and Bacteria

Marine bacteria and fungi have drawn increasing attention from researchers from all over the world since they are considered as sources for new marine natural compounds [42.20, 47]. Marine extremophilic bacteria, for example, are of particular interest since they have metabolic pathways adapted to various extreme marine environments. According to *Laurienzo* [42.48], extremophiles are still a huge source of unknown and uncultivated bacteria with much to be explored in terms of bioactive compounds; many microbial enzymes and exopolysaccharides from extremophiles have potential and unique properties. Bacteria derived from intestinal tracts of marine organisms such as fish have also been researched with interest, since these strains may be new probiotics or have additional functions such as antibacterial activity [42.49]. For example, it was observed that *Lactococcus lactis* subsp. *lactis* isolates from the intestinal tract of freshwater fish possess different phenotypic properties, suggesting additional functions in comparison to those derived from a cheese starter [42.49].

Much interest has also been focused on marine fungi, which have been studied for their metabolites [42.50, 51]. *Masuda* et al. [42.52] reported a unicellular marine fungi with high concentration of γ-amino-butyric acid (GABA), which is a promising functional and healthy food ingredient. In addition, marine fungi are a promising source of novel bioactive compounds with anticancer, antibacterial, antiplasmodial, anti-inflammatory, and antiviral properties [42.20]. Compounds isolated from marine fungi have been the target of reviews [42.53], as well as the analytical techniques to search for bioactive compounds [42.20].

42.3 Food Marine-Derived Ingredients with Biological Properties

As discussed before, polysaccharides, proteins, peptides, amino acids, FAs, pigments, and phenolic compounds are some of the major groups of compounds that have been studied for their biological properties as well as extracted and purified for food and medicinal applications The literature on marine-derive biological compounds is extremely dense and in the last years the number of publications that have been written on this subject is outstanding. Therefore, in the following sections, the authors intend to give an overview of the main marine-derived compounds with the potential to be used as functional food ingredients to be incorporated in new food products; although the last topic to be covered it may be considered the main one of this chapter.

42.3.1 Polysaccharides

Polysaccharides, polymers of monosaccharides linked by glicosidic bonds, have been used in numerous commercial applications such as stabilizers, thickeners, and emulsifiers in foods and beverages [42.28, 54]. Several polysaccharides have been associated with biological properties such as antitumor, antiviral, antimutagenic, or hematopoietic activities [42.23]. The most known

and studied polysaccharides with potential interest as marine-derived functional ingredients are of macro and microalgae origins and the focus will be mostly, but not exclusively, on these.

The total concentration of polysaccharide in seaweeds can range from 4–76% of dry weight [42.28] depending on the macroalgae species, geographical origin, season, water temperature, location, method of cultivation, harvesting time, and other factors [42.26, 55]. Agar, algins, and carrageenans are examples of polysaccharides derived from algae that are widely used as stabilizers and thickeners in gels, as well as in foods [42.38]. Sulfated fucans, such as ulvans from green algae, carrageenans from red algae, and fucoidans from brown algae, have been known to act as modulators of coagulation as well as to reveal anti-inflammatory, antithrombotic, antioxidant, antidiabetic, and anticancer activities, among others [42.56, 57].

Soluble polysaccharides from algae have tremendous potential as dietary fiber for human nutrition and are being evaluated as possible new prebiotic compounds; the use of algal fiber promotes control and maintenance of intestinal flora [42.17]. For example, sulfated polysaccharides can also act as prebiotics exerting growth-promotion of beneficial bacteria in the gastrointestinal tract, imparting health-improving benefits to the host [42.28].

Seaweeds are recognized as a major source of sulfated polysaccharides with various biological activities, the structure of these compounds varies according to the species of algae. Sulfated polysaccharides found in red algae are manly galactans consisting entirely of galactose or modified galactose units, whereas in brown algae are fucans, which comprise families of polydisperse molecules based on sulfated L-fucose; heterofucans are also called fucoidans. In turn, the major water-soluble polysaccharides found in green seaweed are ulvans [42.58]; some of them are a significant source of sulfated galactans particularly in *Codium* species (Chlorophyta, green algae) [42.59, 60]. Sulfated polysaccharides from algae have been the target of much research in the last years because of their potential in terms of biological properties; anticoagulant, antioxidant, antitumor, anti-inflammatory, antiviral, antiproliferative, antipeptic, and antiadhesive activities have been associated to these compounds [42.61] and were recently reviewed by *Chojnacka* et al. [42.23].

Sulfated galactans are widely used in the food industry due to their jellifying and thickening properties [42.62]. Carrageenan and xylomannan sulfate are other sulfated polysaccharides that are found in some red seaweeds and that possess antiviral properties.

The carrageenan hydrocolloid is a linear sulfated polysaccharide of D-galactose and 3,6-anhydro-D-galactose extracted from some red algae species. There are three general forms (kappa, lambda, and iota) but, in general, seaweeds do not produce pure carrageenans, but rather a range of hybrid structures [42.63, 64]. Each of the copolymers kappa and iota carrageenan jellify with different properties and they are used in food production due to their excellent physical and functional properties (thickener, jelling, and stabilizer) in products such as yogurt, puddings, ice cream, sausages, hams, jams, among others. They also possess several applications in non-food industries, as well as pharmaceutical products with anticoagulant and anti-inflammatory properties [42.65].

Fucoidan is a type of complex sulfated polysaccharide that contains α-1,3-linked sulfated L-fucose as its main sugar unit and sulfate ester groups [42.55]. Antitumor and antiangiogenic activities are affected, increasing the number of sulfate groups in the fucoidan molecule [42.66], but fucoidan has also been reported to possess diverse biological activities such as anticoagulant, antioxidant[42.67], antitumor, anti-inflammatory, and antiviral activities [42.61, 68]. A review focusing fucoidan as a natural bioactive ingredient for functional foods was recently published by *Thanh-Sang* and *Kim* [42.69].

Agar is a water soluble long-chain polysaccharide which dissolves or disperses in water. This polysaccharide is widely used in the manufacture of gelatin. Agar consists of two fractions: agarose and agaropectin, considered a complex mixture of polysaccharides; agaropectin has low gelling power [42.28]. Agar-agar has been reported to decrease the concentration of blood glucose, to exert an antiaggregation effect on red blood cells, and to have antioxidant, antitumor as well as antiviral activities [42.28].

Laminarin is one of the major polysaccharides found in brown algae, which has been identified as a modulator of intestinal metabolism through its effects on intestinal pH, mucus composition, and short-chain fatty acid production [42.27, 70] with antiviral and antibacterial properties. The antioxidant activity of laminarin depends on its molecular weight and chemical structure. Its chemical structure consists of β-(1 $\rightarrow$ 3)-linked glucose in the main chain and random β-(1 $\rightarrow$ 6)-linked side chains [42.71], and their content in seaweeds is about 10% of the dry weight, but could seasonally reach up to 32% [42.28].

Alginates can be extracted from brown seaweeds, in which they can constitute up to 47% of dry biomass. Alginates are important soluble fibers due to their biodegradability, immunogenicity, and ability to form gel with a variety of cross-linking agents being used in several fields like the food industry, medicine, and biotechnology [42.72]. The acid form (alginic acid) is a polymer consisting of two types of hexuronic acid monomers linked by $1 \rightarrow 4$ bonds: β-D-mannuronic acid and α-L-guluronic acid, respectively [42.73]. This polysaccharide has shown antitumor, anticoagulant, and antiviral activities; furthermore, evidence shows its capacity to prevent obesity as well as large intestine cancer and diabetes and to reduce low-density lipid (LDL)-cholesterols in rats [42.74–77]. Alginic acid can also apparently reduce hypertension and porphyran from red seaweeds has been related with immune-regulatory, antioxidant, and antitumor activities [42.29].

Besides the previously mentioned anticoagulant [42.78, 79], anti-inflammatory [42.80], antiviral [42.81, 82], and antitumor activities [42.55] of fucoidans and alginic acid derivatives produced by brown seaweeds (*Ecklonia cava*, *Ascophylum nodusum* and *Undaria pinnatifida*, as well as other species), these have also been demonstrated to play an important role as free-radical scavengers and antioxidants preventing oxidative damage [42.83]. Evidence from different studies suggests that the antioxidant and anticoagulant activities of polysaccharides are strongly dependent on the content of sulfate groups, the molar ratio of sulfate/fucose and sulfate/total sugar, and the molecular weight [42.67].

Starch, glucose, sugars, and other polysaccharides can be found in microalgae [42.26]. Exopolysaccharides produced by cyanobacteria and by extremophilic deep-sea bacteria have been regarded with potential to be used as food functional ingredients. For example, polysaccharides produced by *Cyanospira capsulata* strains were reported to have interesting viscosity properties similar to xantham gums whereas exopolysaccharides produced by *Pseudoalteromona*s, *Alteromonas*, and *Vibrio* (bacteria) have the potential to be used as thickening agents [42.38].

Complex polysaccharides from *Chlorella pyrenoidosa* (Chlorophyta, green algae) produces complex polysaccharide such as β-1,3-glucan with potential immunostimulating properties and possess antioxidant properties [42.26, 37].

Another marine polysaccharide of interest is chitin, which is one of the major structural components of crustaceous shells and shellfish wastes. Chitin possesses a similar structure to cellulose built from n-acetyl-glucosamine monomers. Shrimp, crab, lobster, prawns, and crayfish have been reported to contain between 14 and 35% chitin [42.26]. Chitin, chitosan, and derivatives such as chito-oligosaccharides have potential to be used as functional ingredients since they may increase dietary fiber and act as a lipid absorption reducer. Chitin-glucan has been recently approved with a food claim by the European Union (EU) as a fiber-boosting weigh management product [42.10]. Several biological properties been attributed to chito-oligosaccharides, such as antimicrobial, angiotensin-I-converting enzyme inhibition, anticancer, antioxidant, hypoglycemic, hypocholesterolemic, and anticoagulant activities [42.84]. According to *Chen* et al. [42.85], chitosan could be used as a novel dietary fiber supplement for the prevention of Blackfoot disease since it is an effective adsorbent of humic acid in the gastrointestinal tract. Recently, *Alishhi* and *Aïder* [42.86] reviewed the various potential applications for chitosan including as a functional food.

42.3.2 Proteins, Peptides, and Amino Acids

The role of protein in the diet has been acknowledged worldwide, and currently dietary proteins are one of the major sources of bioactive compounds with a beneficial physiological impact on the health of humans and animals [42.87]. According to *Kim* et al. [42.88] marine-derived products seem to be one of the major sources of food-derived bioactive proteins and peptides. Proteins and peptides with biological properties have been isolated from macroalgae, microalgae, fish and fish by-products [42.26, 89]. In general, a higher content of protein is found in green and red seaweeds in comparison to brown seaweeds [42.28]. According to some authors, microalgae can be used as an alternative protein source because of the high protein content in the various species; 60–70% of protein with all essential amino acids and good bioavailability has been reported for some strains of *Spirulina* (Cyanobacteria, blue–green algae) [42.90, 91]. Collagen, gelatin, albumin, and protamine are some proteins that can be extracted from fish and fish by-products with several applications such as foaming capacity, gel forming, stabilizing agents, and antimicrobial activity; fish muscle proteins can be hydrolyzed enzymatically as a protein biomass of great interest [42.26, 38].

Extraction of protein from most seaweed is difficult due to the presence of large amounts of polysaccharides in the cell wall, such as alginates in brown algae

or carrageenans in red algae. Enzymatic hydrolysis by digestive enzymes or by proteolytic microorganisms has been a successful strategy to enhance extraction of peptides from seaweeds [42.92]. Some of the considered important bioactive proteins that can be extracted from macroalgae are lectins and phycobiliprotein [42.93]. Macroalgal lectins have been detected and isolated from red algae; lectins are generally bound to polysaccharides and participate in many biological processes like intercellular communication and have antibacterial, antiviral, or anti-inflammatory activities [42.23]. Lectins interact with specific glycan structures linked to soluble and membrane-bound glycoconjugates. It seems that it is the protein carbohydrate interactions that are responsible for lectin involvement in numerous biological processes such as cell–cell communication, host–pathogen interactions, cancer metastasis, induction of apoptosis and differentiation, as well as recognizing and binding carbohydrates [42.28]. Bioactive lectins are found in macroalgal species such as *Ulva* sp. (Chlorophyta), *Eucheuma* sp., and *Gracilaria* sp. (Rhodophyta), and have biotechnological applications in several scientific and medicinal fields of research [42.28]. Bioactive properties like mitogenic, cytotoxic, antibiotic, antinociceptive, anti-HIV, anti-inflammatory and antiadhesion activities have been reported for lectins [42.94, 95]. In turn, phycobiliproteins are oligomeric proteins, built up from two chromophore-bearing polypeptides found in macroalgae which have antioxidant, antidiabetic, and anticancer activities [42.89, 93].

Bioactive peptides usually contain 3–20 amino acid residues, and their activities are based on their amino acid composition and sequence and they are related to some biological functions such as antihypertensive, immune modulator, antioxidant, anticancer, antithrombotic, and antimicrobial activities [42.26, 96]. Bioactive peptides isolated from fish, molluscs, crustaceans, macroalgae, and microalgae proteins have been shown to possess anticancer, hypocholesterolemic, anticoagulant, antimicrobial, and antioxidant activities, among others [42.26, 96, 97]. *Suetsuna* et al. [42.98] isolated ten dipeptides from seaweed *Undaria pinnatifida* (Phaeophyceae) with four of these dipeptides containing the greatest ACE-inhibitory potential; their hypotensive effects were investigated in vivo and their results demonstrated a decrease of blood pressure in hypertensive rats. Numerous studies have been carried out to date that report on the antioxidant potential of macroalgae protein hydrolysates. *Harnedy* and *Fitzgerald* [42.99] reported a description of antioxidant potential of diverse macroalgae protein hydrolysates. In fact, several reviews have been published in the last 3 years on proteins and bioactive peptides from marine sources: on algae [42.99, 100], on marine organisms [42.96, 101], on processing marine waste and shellfish [42.102], and on fish-derived antioxidant peptides [42.103].

From microalgae such as *Navicula incerta* (Bacillariophyceae) and *Chlorella ellipsoidea* (Chlorophyta), antioxidative peptides have also been identified with demonstrated in vitro antioxidant properties [42.104, 105]. The high protein content found in some species of microalgae makes them of potential interest for their exploration as a source of bioactive peptides [42.87].

Bioactive peptides isolated from various fish protein hydrolysates have been reported as possessing several biological properties such as antithrombotic, antihypertensive, antioxidant, and anticoagulant activities. Several studies have reported on peptides with antioxidant activities from the skin of Pacific cod (*Gadus macrocephalus*), backbones (*Nemipterus japonicus*, *Exocoetus volitans*), muscles (*Nemipterus japonicas)*, and viscera *(Magalaspis cordyla)* [42.106–109].

In terms of amino acids, most seaweed species contain all the essential amino acids and are a rich source of the acidic amino acids. Brown seaweeds are a rich source of threonine, valine, leucine, lysine, glycine, cysteine, methionine, and histidine, among others [42.28]. In the majority of peptide sequences in antioxidant marine-derived peptides, the presence of hydrophobic amino acids such as leucine, valine, and proline is common, which contributes greatly to their potential antioxidant activity [42.110] and has a major role in the inhibition of lipid peroxidation [42.107]. Taurine (2-aminoethanesulfonic acid) is also an amino acid with potential interest for humans since it is mainly obtained through diet. The highest amount of this amino acid is found in seafood, namely in shellfish, especially scallops, mussels, and clams [42.111]. Taurine has the ability to conjugate bile acids, regulate blood pressure, act as an antioxidant and an anti-inflammatory agent [42.111] and has been associated with several positive effects on the cardiovascular system. According to *Elvevoll* et al. [42.112], supplementation with omega-3 FAs and taurine improved the blood lipid profiles to a greater extent than those supplemented with omega-3 FAs alone (one group ($n = 39$) received fish pâté ($36\,g\,d^{-1}$) enriched in omega-3 FAs (1.1 g EPA + DHA/day) and another group ($n = 41$) received an identical pâté enriched both in omega-3 FAs and taurine ($425\,mg\,d^{-1}$) for 7 weeks).

42.3.3 Fatty Acids

Phospholipids and glycolipids are the major classes of lipids found in algae, accounting for only 1–5% of cell composition [42.23]. Since at lower temperatures algae are able to accumulate PUFAs, species found in cold regions contain more PUFAs than those in moderate climates. PUFAs are known to regulate a variety of body functions such as blood pressure, blood clotting, and the proper development and function of brain and nervous system [42.113], and also play an important role in regulating inflammatory response through the production of inflammatory mediators termed eicosanoids [42.114]. PUFAs account for almost half of the lipid fraction, with much of it occurring in the form of omega-3 and omega-6 fatty acids such as EPA and arachidonic acid (ARA) [42.115]. The predominant FA in various seaweeds is EPA (C20:5, n-3), which is at concentrations as high as 50% of the total fatty acid content [42.28]. Red and brown algae are rich in omega-3 FAs (EPA and α-linolenic acid), omega-6 FAs (ARA and α-linoleic acid), along with relatively high levels of oleic and palmitic acids [42.116], whereas green seaweeds are more characterized by the presence of hexadecatetraenoic, oleic, and palmitic acids. EPA and DHA are found at high levels in various species of macroalgae but also in microalgae with relatively high oxidative stability compared to fish oils [42.117]. Under optimal culture conditions *Chlorella minutissima* can produce up to 45% of its total content of FAs and several species of diatoms, and dinoflagellates such as *Nitzschia frustulum*, *Navicula incerta*, and *Gymnodinium simplex* also have a high content of EPA and DHA [42.38]. High levels (2–30%) of long-chain omega-3 PUFAs can be found in tissues in many marine fishes mainly due to a transfer through the aquatic food chain with a good content of EPA and DHA. The liver of lean white fish such as cod species, and muscle from herring and mackerel are some examples of good sources of marine functional lipids [42.43]. Marine lipids and the long-chain omega-3 PUFAs are extensively reviewed by *Larsen* et al. [42.118].

It is important from a nutritional standpoint that an appropriate balance between omega-3 and omega-6 is maintained, since these FAs work together to promote health; most omega-6 FAs (precursors of arachidonic acid and prostaglandin E2) tend to promote inflammation and tumor growth [42.119], hence the intake of macroalgae and microalgae rich in omega-3 fatty acids would help to achieve this balance. *Van Ginneken* et al. [42.120] studied the efficiency of using marine macroalgae as a source of PUFAs and found a very low content of omega-6 fatty acids (only 3%) and, therefore, a very low omega-6 : omega-3 ratio compared to that indicated by experimental evidence as being optimum from a human body homeostasis point of view (ratios of 4 : 1–5 : 1 and no higher than 10 : 1 are suggested); this achievement is important and evidence that seaweeds lipids contents may help the prevention of inflammatory, cardiovascular, and neural disorders.

42.3.4 Pigments

Carotenoids, phycobiliproteins, and chlorophylls comprise the major categories of photosynthetic pigments that can be found in marine organisms [42.38]. The biological importance of macroalgae and their pigments can be found in *Gamal* [42.35] and *Pangestuti* and *Kim*'s [42.121] reviews.

Carotenoids are a group of pigmented compounds that act as a light energy harvester in photosynthetic marine organisms and are potent antioxidants that inactivate reactive oxygen species. Carotenoids include, for example, fucoxanthin and β-carotene in brown seaweeds; green seaweeds possess β-carotene, lutein, and violaxanthin, red seaweeds contain, for example, β and α-carotene and lutein, whereas astaxanthin is found in salmon [42.26, 118, 122, 123]. Some of the most important carotenoids are β-carotene, fucoxanthin, and tocopherol [42.23]. Fucoxanthin, present in species such as *Undaria pinnatifida* (Wakame), *Hijikia fusiformis* (Hijiki), *Laminaria japonica* (Ma-Kombu), and *Sargassum fulvellum* (Phaeophyceae), has been indicated to reduce obesity by inhibiting intestinal lipase activity [42.124] as well as to possess antiangiogenic and antiviral properties [42.123]. Fucoxanthin has also been shown to have an important antioxidant activity, as well as antidiabetic, antiphotoaging, and anticancer properties; these and other health properties of fucoxanthin were recently reviewed by *D'Orazio* et al. [42.122]. Based on the plethora of properties D'Orazio inclusively named fucoxanthin the treasure of the sea. Xantophylls, another type of carotenoids are the main pigment found in brown seaweed, namely in *Undaria pinnatifida*, and have been related with some activity against cerebrovascular diseases [42.125]. The biological functions and commercial applications of marine carotenoids can be found in the review by *Vílchez* et al. [42.126].

Phycobiliproteins are classified as protein–pigment complexes (red, phycoerythrobilin; purple–deep blue,

phycocyanobilin) found in algae, which are used as natural color pigments in food products [42.38].

Chlorophylls are green pigments that are used as natural colorants in foods and beverages in the food industry [42.38] and have been shown to possess some biological activity whereby they exhibit anticancer properties. In an era where the trend to natural products prevails in food product development, the use of these compounds as natural colorants instead of their synthetic counterparts is an effective alternative.

42.3.5 Phenolic Compounds

Polyphenols or phenolic compounds are found at high levels in algae that have very strong antioxidant properties and also other biological activities like anti-inflammatory or antimutagenic ones. In algae, these compounds are associated with chemical defenses to external conditions such as stress and herbivores [42.127]. Seaweed species such as *Undaria* sp., *Laminaria* sp., and *Fucus* sp. (Phaeophyceae, brown algae), *Porphyra* sp. (Rhodophyta, red algae) are rich sources of polyphenolic compounds [42.26]; cathechins, flavonols, and phlorotannins have been explored as functional food ingredients [42.118, 128].

The phlorotannins that have been identified in several brown algae are highly hydrophilic compounds with antioxidant, anti-inflammatory, antidiabetic, antitumor, antihypertensive, and antiallergic activities, and are inhibitors of hyaluronidase and of metalloproteinase enzymes, two virulence factors that may be expressed by some microorganisms [42.22, 129].

42.3.6 Minerals

It is well known that seaweeds are recognized as being rich in minerals (Ca, Mg, Na, P, and K) and trace elements (Zn, I, and Mn), which is related to their capacity to retain inorganic marine substances due to polysaccharides in the cell surface, accounting for up to 36% of dry matter in some species [42.26]. They are one of the most important sources of calcium and potassium [42.115], and some seaweeds are indicated to be used as food supplements to meet the recommended daily intake of some minerals and trace elements.

Selenium, iodine, and also zinc, magnesium, and calcium are other minerals that are more abundant in some seafood than, for example, meat [42.118]. Increased dietary intake of selenium has been related to protection against several cancers. In some countries or populations with low iodine intake, the seaweeds are an alternative way to deliver iodine trough diet instead of fortified salt with iodine. Seaweeds are one of the best natural sources of iodine [42.16].

42.4 Functional Foods Incorporating Marine-Derived Ingredients

As discussed throughout this chapter, marine resources are indeed a source of high value-added compounds with biological properties to be used as functional food ingredients. Several types of polysaccharides, such as sulfated polysaccharides, chitin or chitosan, proteins and protein hydrolysates, peptides, amino acids such as taurine, omega-3 oils, carotenoids, and other bioactive compounds [42.30] are examples of compounds that can be added at different stages, from processing to storage, of the food production process [42.11]. Marine-derived functional ingredients with biological properties constitute a research area with much to explore for food purposes. On the other hand, many foods already widely consumed all over the world are a potential vector for incorporating new marine-derived functional ingredients, which will enhance their value at both the nutritional and economic levels (Fig. 42.2). Since dairy products are widely accepted by consumers, the use of this type of product to deliver bioactive compounds has received attention from the food industry in the last years [42.130, 131]. Functional foods and natural health products are an emerging field in food science due to their increasing popularity with health-conscious consumers and are a source of new opportunities for the agri-food sector. In several countries of the EU, these types of products are already part of an industry that is already generating millions of euros per year. Food products containing marine-derived chitin, chitosan, as well as oils rich in omega-3 fatty acids, are some food products that are being commercialized in several markets around the world including Japan, the USA, and some European countries [42.30].

The consumption of functional foods can provide various nutritional/health benefits, since diet controls and modulates many functions of the body, maintaining its good health or homeostasis. Enhancement of immunity stimulation and antioxidant activity are the most studied health benefits and have driven con-

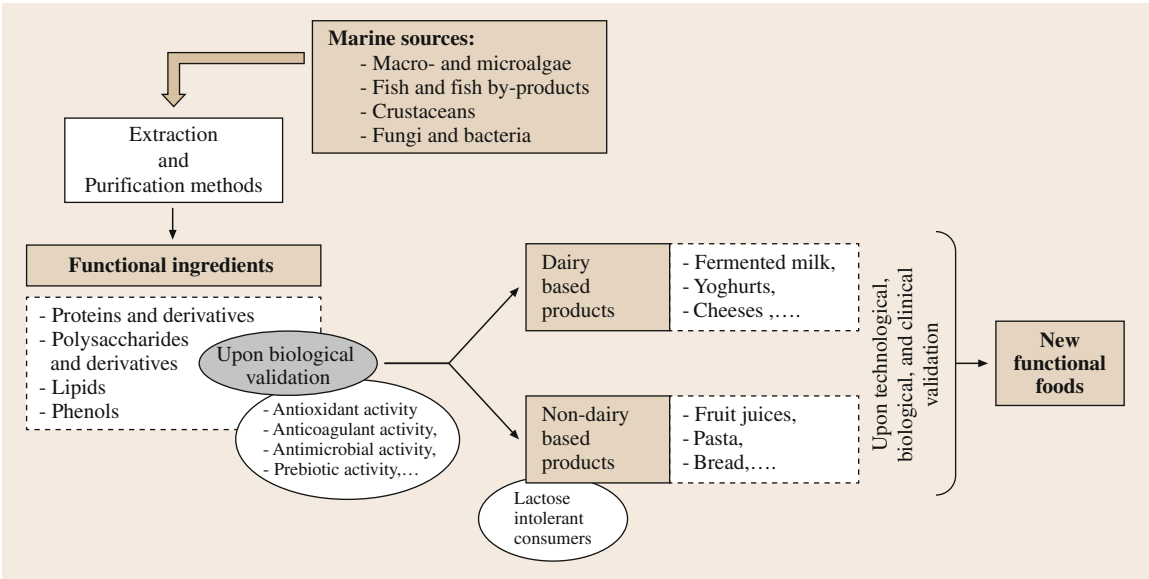

Fig. 42.2 New potential functional foods based on dairy or non-dairy products via incorporation of functional marine-derived ingredients

sumers to be more aware that diet can serve both nutrition and health promotion goals [42.11]. Nowadays, marine-derived functional ingredients such as fish oils, fish proteins, and seaweeds themselves have found application in bakery, dairy, confectionary, and pasta products. They are added as fortificants and nutritional enrichments in food, leading to the so-called functional foods. According to *Kadam* and *Prabhasankar* [42.30], more and constant efforts in research and design of novel functional foods based on marine functional ingredients is needed to contribute to the reduction of health problems through diet. Despite the scientific interest in the use of marine-derived food ingredients, there still are various challenges ahead that have to be overcome to design new functional foods, namely:

i) Efficient extraction methods and purification steps, to obtain food grade validated extracts or purified compounds with biological properties (antioxidant, antibacterial, prebiotic, and others). Isolated functional ingredients should rely upon food methods compatible with economically viable yields. Hence, different extraction methods must be applied in order to maximize the extraction efficiency of functional ingredients with biological properties.
ii) To design functional foods based on the incorporation of marine-derived functional ingredients upon biological validation. According to *Siegrist* et al. [42.132], consumers are more and more inclined to buy functional foods with physiological health claims.
iii) Foods should have good sensorial characteristics in order to be accepted by the consumer. In general consumers are not able to compromise taste for health [42.133]. This is, in fact, one of the most important challenges to overcome in the case of some of the marine compounds to be used, for example, fish oil.

42.4.1 Foods Incorporating Marine Organisms: Seaweeds

Dietary minerals (sodium, potassium, and iodine), fibers, as well as polyphenolic compounds are some compounds in which seaweeds are rich. Thus making use of seaweeds or their extracts to supplement foods of particular interest [42.17] enables the development of new functional foods from a nutritional standpoint. The possibility of adding seaweeds to food as natural antioxidants, antimicrobial and texturing agents, are other aspects of significant importance from an industrial point of view [42.17].

Meat and meat products, which are a good source of protein and vitamins but deficient in fibers and, in general, contain excess sodium are good candidates to

be supplemented with seaweeds to overcome the technological problem associated with low-salt meat products [42.17, 134]. According to *Cofrades* et al. [42.134] due to consumer awareness of the negative perceptions of meat in terms of overall fat content, in particular saturated fatty acids, cholesterol, and sodium, the meat industry should adapt to new meat functional foods to address consumer concerns without making radical changes in their eating habits. Several studies based on the formulation of meat-based functional foods incorporating marine compounds have been reported, some of which are described in Table 42.1. In general, all studies presented as main objective the development of low-salt meat products with improved nutritional profile by addition of different species of seaweeds [42.135–137]; some of these studies go one step further in terms of also reducing fat content by replacement with olive oil [42.138] or with konjac gel [42.139]. The major results reported in these studies are encouraging, and according to *Confrades* et al. [42.136], incorporation of seaweeds allows reformulation strategies to design and develop functional meat products with lower sodium, fat, and cholesterol content, and simultaneously with relevant contribution to the intake of dietary fiber, polyphenols, minerals, and unsaturated FAs acids. Technologically, the incorporation of seaweeds enables overcoming some of the negative sensorial impacts caused by low levels of sodium related to water-binding and fat-binding properties. In terms of organoleptical properties, some of the functional meat products developed have attained sensorial acceptability, but this is a subject that should be evaluated in a well-based sensorial analysis.

Pasta products incorporating seaweeds have also been developed and two studies thereof are described in Table 42.1. In fact, the design of functional foods based on incorporation of marine ingredients such as seaweeds, has been more successful in bakery and pasta products and was recently reviewed by *Kadam* and *Prabhasankar* [42.30]. For example the incorporation of 10–20% edible seaweed wakame (*Undaria pinnatifida*) in pasta has not only received sensorial acceptance but has also resulted in a product with improved amino acid and fatty acid profiles, an increase of antioxidant activity, and a higher content of fucoxanthin (concentration and activity were not affected by processing) and fucosterol [42.141]. Dietary ingestion of wakame has also been reported to reduce blood pressure [42.31].

According to *Gupta* and *Abu-Gannam* [42.17], seaweeds are currently receiving considerable consideration for the nutritional enrichment of meat, bakery, and pasta products because, as was previously demonstrated, the addition of seaweeds or seaweed extracts can not only improve the quality of the product but may even enhance its safety at high doses with respect to natural antioxidants and antimicrobials.

42.4.2 Foods Incorporating Marine-Derived Ingredients: Polysaccharides

Depending on their chemical composition and structure, complex marine-derived polysaccharides can possess several biological properties, as was described above. Therefore, their incorporation in food matrices is of potential interest to develop new functional foods. In Table 42.2 lists some studies based on the incorporation of marine-derived polysaccharides as functional ingredients such as alginates and carrageenan in bread, meat, or liquid foods. New types of healthier breads, especially gluten-free bread, a rising market due to the increasing diagnoses of celiac disease among adult individuals [42.142], has been a challenge to bakers and scientists. Agar-agar and carrageenan are two hydrocolloids that can be used as thickening, swelling, stabilizing, or humectant agents which can be used in gluten-free baking [42.142]. Different types of bread with the incorporation of sodium alginate and carrageenan has been attempted and investigated in terms of baking properties [42.143–145]. In general, marine derived polysaccharides are able to impart acceptable textural and sensorial characteristics. However, none of these studies carried out any nutritional evaluation that could enhance some healthy aspects due to the incorporation of marine-derived polysaccharides. Meat sausages as well as milk and apple juice were other food matrices tested with supplementation of carrageenan, chitosans, and chito-oligosaccharides (Table 42.2). Satisfactory technological and sensorial results were achieved by *Ayadi* et al. [42.146], but again no nutritional evaluation was performed. *Fernandes* et al. [42.147] studied the incorporation of commercial crab shells chitosans and chito-oligosaccharides in apple juice and milk to ascertain the influence of food components on their antimicrobial activity, evaluating in parallel the acceptance by a sensory panel. Once again, no nutritional evaluation was considered. In Japan, several foods (potato chips, soybean paste, and noodles) with added chitosan are available as cholesterol-lowering functional foods [42.148].

Results reported by *Fernandes* et al. [42.147] are an example of the difficulties that need to be overcome in

Table 42.1 Functional foods based on incorporation of seaweeds

	Product	Seaweed	Description	Major achievements	Sensory Characteristics	Reference
Meat	Frankfurter sausages	*Himanthalia elongata*	Low-fat frankfurters added with 5.5% seaweed	Addition of seaweed provided Ca-rich, low-Na sausages, better Na/K ratios, and a higher fiber content	No sensory analysis presented	[42.135]
			Low-fat, low-salt frankfurters added with konjac glucomannan gel (0–19.3%) and seaweed (0–3.3%)	• Incorporation of combination of konjac gel and seaweed increased cooking loss and reduced emulsion stability • Replacement of pork fat, reducing fat content in 15%, did not impart noticeable changes in the sensory quality of the frankfurters	• No significant differences among samples in terms of texture • No noticeable changes in sensory quality as a consequence of fat reduction and fat replacement • Samples with added seaweed with low score in terms of overall acceptability	[42.139]
	Beef patties	*Undaria pinnatifida*	Low-salt and low fat beef patties added with 3.3% of seaweed and partial fat replacement with olive oil	• Patties with seaweed presented lower thawing and cooking losses and were softer • Incorporation of seaweeds increased mineral contents but imparts similar Na/K ratio • Good technological, sensorial and nutritional properties in beef patties with seaweed and olive oil emulsion	• Freezing did not affect sensorial parameters studied • Total replacement of fat by olive oil emulsion improved appearance • Incorporation of seaweed affected the sensory properties	[42.138]
	Restructured poultry steaks	*Himanthalia elongata*	Low-salt restructured poultry with microbial transglutaminase and seaweed (3%)	• Addition of a cold binding agent (MTGase/caseinate) did not affect water binding properties • Incorporation of seaweed caused a slight increase in purge loss but reduced cooking loss • Addition of both seaweed and binding agent increased the Kramer shear force	• Addition of seaweed and MTGase/caseinate significantly affected most sensorial parameters • Flavor acceptability, juiciness, and general acceptability scored with values higher than 5 • Low-salt restructured products with seaweed and MTGase/caseinate were considered sensorial acceptable	[42.136]
	Pork patties	*Laminaria japonica*	Reduced-fat pork patties with added seaweed (0–5%)	Reduced-fat pork patties with seaweed had significantly higher moisture, ash, carbohydrate content, and lower protein and fat content, cooking loss, hardness than regular-fat control samples	Pork patties with fat content reduced to 10% and supplemented with 1–3% seaweed has improved quality characteristics, similar to control patties with 20% fat content.	[42.137]
Pasta	Fresh noodles	*Monostroma nitidum*	Noodles added with 4–8% seaweed powder with or without eggs	Addition of seaweeds increased crude fiber content, higher cooking yields and decreased springiness and extensibility	Sensory scores varied with the parameters evaluated, percentage of seaweed and addition of eggs; Higher scores for color and wetness were obtained in egg noodles with 8% of seaweed	[42.140]
	Pasta	*Undaria pinnatifida*	Pasta prepared with semolina and seaweed blends: 100 : 0, 95 : 5, 90 : 10, 80 : 20, and 70 : 30	• Fucosterol and fucoxanthin content higher in pasta with seaweeds, which were not affected by cooking step • Improved nutritional, amino acid, and FA profiles by incorporation of seaweed.	Pasta with 10% seaweed was considered acceptable sensory-wise with mild seaweed flavor tasting similar to control pasta	[42.141]

Table 42.2 Functional foods based on incorporation of marine-derived polysaccharides

	Product	Marine-derived polysaccharide	Description	Major achievements	Sensory characteristics	Reference
Bread	Bread	Sodium alginate κ-carrageenan	Bread produced with different hydrocolloids of 0.1–0.5% (flour basis)	• All hydrocolloids were able to reduce loss of moisture content during bread storage, reducing dehydration rate of crumb • Higher moisture content and specific volume index in bread with k-carragenaan than with sodium alginate • Alginate showed antistaling effect retarding the crumb hardening • No nutritional evaluation	• Bread with 0.5% alginate were scored higher in terms of visual appearance, crunchiness and overall acceptability than control bread or bread with 0.1–0.5% κ-carrageenan	[42.140]
	Wheat dough, Chinese steamed bread	Sodium alginate	Wheat dough Chinese steamed bread added with sodium alginate (0.2 w/w %) and konjac glucomannan (0.8 w/w %)	• Addition of alginate sodium and konjac glucomannan produced dough with rigid and weak network • Lower spread ratio and specific volume Chinese steamed bread with addition of alginate sodium and konjac glucomannan but softer and more resistant to staling through storage than control samples • No nutritional evaluation	• No sensory analysis presented	[42.141]
	Wheat Bread	Carrageenan	Wheat bread added with enzymes and hydrocolloids	• Lower volume and specific volume was observed in bread with carrageenan (0.075% flour basis) but higher when conjugated with xanthan gum (0.15%, flour basis) than in standard bread • Lower water losses in bread with carrageenan alone or mixed with xanthan gum than in standard bread • No nutritional evaluation	• Higher scores for sensorial properties (taste, color, shape, aroma, elasticity, hardness) in bread with carrageenan, especially when mixed with xanthan gum in comparison to standard bread	[42.143]
Meat	Sausages	Carrageenan	Turkey meat sausages with addition of carrageenan (0–1.5 w/w%)	• Carrageenan causes a decrease in emulsion stability but an increase in water holding capacity, hardness, and cohesiveness • Addition of 0.2–0.5% of carrageenan increases gel elasticity; higher percentage of carrageenan causes opposite effect • Higher percentage of carrageenan leads to a progressive appearance of an additional carrageenan gel network • No nutritional evaluation	• Addition of carrageenan did not cause significant effect in taste but improves sausage appearance and texture	[42.144]

the development of new functional foods. The antibacterial effect against pathogenic *Staphylococcus aureus* and *Escherichia coli* was dependent on the Gram nature of the bacteria the chitosans' molecular weight, yet their addition to apple juice led to some unpleasant off-flavors which steadily increased in intensity with the chitosan molecular weight (Table 42.2). In fact, the incorporation of marine ingredients in foods of different nature could lead the consumer to expect a negative influence on food [42.133]. The importance of the food vector has been shown in many studies and, indeed, a high correlation between the food vector and the origin of the functional ingredient is required in order to promote the acceptance of functional food [42.132].

Table 42.2 (continued)

	Product	Marine-derived polysaccharide	Description	Major achievements	Sensory characteristics	Reference
Beverage	Milk, fruit juice	Chitosans chito-oligosaccharides (COS)	Cow milk and apple juice added with 0.5 w/v % chitosan with low to high molecular weight (MW) and COS lower than 3 and 5 kDa	• Antimicrobial effectiveness against to *Escherichia coli* and *Staphylococcus aureus* by medium and high Mw chitosans when incorporated in milk and apple juice, COS lost their antimicrobial activity upon both bacteria after 4–8 h in milk • Chitosans and oligomers are more effective as food preservatives in low pH foods and with low protein content • No nutritional evaluation	• Addition of chitosans to apple juice causes unpleasant off-flavors: astringency and after taste especially for higher MW • No sensorial analysis was performed on milk added with chitosans and COS because milk become unsuitable for consumption	[42.147]

42.4.3 Foods Incorporating Marine-Derived Ingredients: Fish Oils and Fatty Acids

Due to the richness of marine-derived lipids in FAs such as long-chain omega-3 PUFAs, many attempts have been made worldwide over the past years to enrich foods such as bread and other bakery products, dairy products such as cheese and yoghurts, as well as nutrition bars, with fish oils [42.149–151]. Most nutritional guidelines nowadays include a recommendation for higher intakes of long-chain omega-3 PUFAs for preventing cardiovascular diseases; however, their dietary intake remains low, particularly in Western countries [42.152]. According to some dietary guidelines, two servings of fish of approximately 227 g should be consumed per week to reduce the risk of mortality from coronary heart disease [42.152]. Due to the higher content in EPA, α-linolenic acid (ALA), and DHA in foods enriched with fish oils, these products are considered functional foods that lead to the reduction of cardiovascular diseases, cancer, and arthritis [42.30, 152] and are, in fact, an alternative way of increasing their intake. However due to the high instability of long-chain omega-3 FAs to oxidative deterioration, the enrichment of foods with long-chain omega-3 PUFAs is still technologically challenging.

In Table 42.3 several examples of foods enriched with fish oil or FAs are given. Cereals and dairy-based products, as well as beverages and salad dressings were enriched with neat oil, microencapsulated, or even as an oil-emulsion [42.149–151, 153–157]. The oxidation and appearance of off-flavors such as fishy off-flavor was variable and dependent on the food matrix. This was particularly evident in the study performed by *Let* et al. [42.157], who studied the enrichment with neat fish oil or with oil-emulsion of three food products: milk, yoghurt, and salad dressing. According to the authors, the application of neat fish oil was a good option for preserving the quality of yoghurt and salad dressing, whereas pre-emulsion may still be considered for the fish oil enrichment of products such as milk. *Let* and co-workers have published several research studies over the last years related to attempts to enrich milk with fish oil [42.158–164]. In these studies, several approaches were attempted and should be researched further to overcome the low oxidative stability of long-chain omega-3 PUFAs; according to the main achievements of previous studies, possible solutions may be based on the use of appropriate combinations of emulsifiers and stabilizers, homogenization of milk, or by pursuing encapsulation procedures [42.130, 152, 157, 162].

In the field of dairy products, cheeses have also been the target of enrichment with fish oil, unfortunately not all results have been acceptable for the consumer [42.154], nor were the cheeses analyzed in terms of sensorial characteristics [42.155]. However, results published by *Hughes* et al. [42.150] are promising for a soft goat cheese in which negligible oxidation occurred, and cheeses enriched with 60 g fish oil per batch were acceptable to the consumer (Table 42.3). Cereal based products like oat and soy bars and spaghetti seem to be the more suitable food products to deliver long-chain omega-3 PUFAs to the consumers [42.151, 153] with negligible levels of oxidation. According to *Hughes* et al. [42.151] consumer acceptable nutritional cereal bars have been successfully enriched with non-encapsulated, non-emulsified tocopherol-enriched fish oil, oxidatively stable over 10 weeks of storage, able to

Table 42.3 Functional foods based on incorporation of fish oils or FAs

	Product	Fish oil, FAs	Description	Major achievements	Sensory characteristics	Reference
Cereals	Nutrition bar	Purified, non-emulsified, tocopherol-enriched fish oil	Oat and soy-based nutrition bars (35 g serving) with added fish oil replacing canola oil in 0–60%	• No significant differences in terms of proximate composition, water activity, or ALA content • Higher content of EPA and DHA: bars with 20% fish oil with 178.1 mg/serving of EPA and DHA • Negligible oxidation in all bars over 10 weeks of storage	No significant differences in aroma, texture, flavor, and overall acceptability between cereal bars with 20% fish oil and control cereal bars	[42.151]
	Spaghetti	Microencapsulated refined marine oil containing a minimum of 30% EPA and DHA	Spaghetti enriched with 0.6, 1.2 and 1.8% (flour basis) of microencapsulated oil	• Higher fat, EPA, and DHA in spaghetti enriched with microencapsulated oil • Spaghetti with 1.2% microencapsulated oil had lower loss of EPA and DHA (<10%)	• Spaghetti with 1.2% of microencapsulated oil had higher score in terms of acceptability	[42.153]
			Spaghetti enriched with 1.2 (flour basis) of microencapsulated oil	• Functional spaghetti had a shelf-life comparable to control pasta • Light exposure cause a fast propagation of oxidation regardless the fat content and PUFA in functional spaghetti; packaging based on paperboard is recommendable • Microencapsulation provided effective protection against deterioration of EPA and DHA	• No sensorial analysis presented	[42.149]
Beverage	Fruit juice	DHA from microalgae	Water-fruit juice concentrate enriched with 0.08 g/100 g of DHA	• Oxidatively stable over 20 days of cold storage • Fatty acidity of fatty phase in acceptable range over 30 days of cold storage	• Appearance of extraneous fishy taste and flavor • Some color change in juices containing DHA supplemented	[42.154]
Dairy product	Soft goat cheese	Purified fish oil	Cheese fortified with 60, 80 and 100 g of fish oil per cheese batch	• Fat, EPA and DHA contents higher in enriched cheese samples with fish oil • EPA and DHA content did not differ significantly in enriched samples, independently of the fish oil addition • Average of 127 mg of EPA and DHA per 28 g serving • Negligible oxidation over 4 weeks cold storage	• No significant differences in appearance, color and aroma between enriched and control cheeses • Lower values were observed for taste and overall acceptability in enriched cheeses; best scored cheese with 60 g fish oil per batch	[42.150]

Table 42.3 (continued)

	Product	Fish oil, FAs	Description	Major achievements	Sensory characteristics	Reference
Dairy product	Soft fresh Hispanic cheese	Cod liver oil	*Queso fresco* enriched with 1 w/w % fish oil prepared from unprocessed milk (pressure = 0 MPa)	• Moisture and fat content did not differ significantly between cheeses fortified with fish oil and control cheese • Increase of peroxide value in cheese with fish oil through 30 days of cold storage • Hardness, cohesiveness, and gumminess values did not differ significantly between cheeses fortified with fish oil and control cheese	No sensorial analysis was presented	[42.155]
	Cream cheese	Cod liver oil	Cream cheese enriched with 1.3% fish oil as neat oil or pre-emulsified	Lipid oxidation increased over 20 weeks of cold storage in cream cheese enriched with fish oil added as neat oil or pre-emulsified	Unacceptable sensory perception of the fish oil enriched cream cheeses in the later part of storage period	[42.154]
	Milk	Refined cod liver oil	Pasteurized milk enriched with 1 v/v % net fish oil or 2% (by weight of final product) fish-oil-in water emulsion	Milk enriched with oil emulsion had higher values of peroxide values than milk enriched with net fish oil after 10 days of storage at 5 °C	Both milk enriched with oil emulsion or oil emulsion presented high levels fishy off-flavor after 29 days of storage	
	Yoghurt		Yoghurt enriched with 1 w/w % net fish oil or 2% (by weight of final product) fish-oil-in water emulsion	• Yoghurt enriched with oil emulsion had higher values of peroxide values than milk enriched with net fish oil after 20 days of storage at 5 °C • Yoghurt could be a suitable system for fish oil enrichment due to its high oxidative stability	Higher levels of levels fishy off-flavor in yoghurt enriched with oil emulsion than with net fish oil after 29 days of storage	[42.157]
Other	Salad dressing		Dressing enriched with 10 w/w % net fish oil or 20% (by weight of final product) fish-oil-in water emulsion	Dressing enriched with net fish oil had higher values of peroxide values than milk enriched with oil emulsion after 25 days of storage at room temperature	Higher levels of levels fishy off-flavor in dressing enriched with oil emulsion than with net fish oil after 29 days of storage	

deliver 178 mg of EPA and DHA per 35 g serving. According to *Kadam* and *Prabhasankar* [42.30], bakery and pasta products are the best food products to incorporate marine functional ingredients because they are widely consumed all over the world.

The enrichment of food products with long-chain omega-3 PUFAs can also be achieved indirectly by feeding animals, namely chickens and cattle, with marine sources such as macroalgae or microalgae, or fish oil. Omega-3-enriched eggs are an example of this approach and are already well commercialized in several countries around the world. *Carrillo* et al. [42.165] reported higher contents of long-chain omega-3 PUFAs in eggs laid by hens fed with marine algae and sardine oil. A higher DHA content was found in broilers fed on DHA-rich microalgae [42.166].

42.5 Current Understanding and Future Trends

Marine organisms and the hundreds of tons of marine by-products available annually are, indeed, tremendous sources for many new value-added healthy food ingredients and biologically active compounds constituting a research area with still much to explore for food purposes. On the other hand, many foods that are already widely consumed all over the world are a potential vector for incorporating new marine-derived functional ingredients that will enhance their value at both the nutritional and economic levels. Therefore, more research needs to be pursued to investigate marine resources as potential sources of functional food ingredients, as well as to develop new functional foods via supplementation of marine-derived ingredients. Functional foods as described are food products to provide physiological benefits or reduce the risk of chronic disease but to be consumed as part of a balanced diet. Seafood diets and marine-derived ingredients have been proven to prevent and protect against many diseases, namely the so called epidemic lifestyle diseases [42.40] such as cardiovascular diseases, obesity, and diabetes, among others. Therefore, it is of utmost importance that more efforts should be made to confirm health evidence regarding the health-promoting effects of marine functional foods accompanied by proper communication to the consumers. In fact, overall consumer interest in new healthy food ingredients is driving research and commercialization in the area of functional foods, and marine functional foods are no exception to this trend. Nevertheless, the introduction of marine-derived ingredients in the human diet will always be a complex subject due to several types of constraints that cover not only global issues including cultural and ethnic aspects such as diet type and habits or environmental aspects such as fears about sea pollution and the use of sources in a sustainable manner (leading to a more efficient utilization of the sea's natural resources), but also more specific aspects such as the organoleptic properties of food and legislation in itself [42.11]. Whereas edible seaweeds are a product with a very long tradition in human eating habits in China, Korea, Japan, and the USA, in Europe some countries still present legal obstacles, which will most certainly delay approval [42.28]. On the other hand, consumer acceptance of new functional foods with marine-derived functional ingredients will undoubtedly depend on the balance between cultural habits and diet, knowledge and perception about health benefits of functional food, and sensorial characteristics.

Despite the already commercially available marine-derived ingredients and functional foods, the search for new marine-derived products continues to be a challenge both for scientists and food engineers. The search and use of marine-derived functional ingredients demands appropriate and sustainable harvesting, and that extraction of compounds with bioactive potential be based on food grade compatible, efficient, and sustainable procedures followed by procedures to obtain concentrated extracts or purified compounds in a controlled manner. The validation of biological properties of extracts and/or purified functional marine-derived ingredients is determinant for the development of new functional foods based on their incorporation in food matrices, which in turn should be followed by characterization thereof and assessment of stability and in vitro bioavailability of functional ingredients; the proof of the specific health benefits through human clinical trials is also an important requirement.

The design of functional foods based on the incorporation of marine ingredients has been more successful in bakery and pasta products, for example, fish oils that are rich in omega-3 oils are already used in bread and other products, which shows a considerable improvement in EPA and DHA contents, which helps to prevent the risk of cardiovascular disease. However, this scenario goes beyond this type of product, including dairy products and others, but much can still be done to develop new and pleasant marine functional foods.

Legislation is another bottleneck for new functional foods with marine-derived functional ingredients, since it is continuously changing or being updated with the publication of new regulations, and in some aspects there are very complex measures and requirements to be applied in any particular country. Marketing food ingredients with health benefits now requires proper scientific substantiation; for example, in Europe it is now necessary to provide evidence of any benefit before any health claim can be made on a functional food product [42.10]. The European Food Safety Authority is the legal authority in Europe responsible for managing novel food and respective health claims, whereas China, Japan, Brazil, and the USA has their own individual regulatory authorities and laws regarding functional foods and ingredients and respective health claims [42.10]. In addition, commercialization of functional foods or bioactive compounds with health claims entails an extensive scientific dossier necessary to prove scientific evidence via human clinical trials,

as was previously mentioned, which is highly expensive [42.28], and the targeted market niche may not be enough to cover the economical investment.

Nonetheless, there is still a sea of opportunities to be explored, some of which have been duly covered in this book chapter. The coming decades will continue to see efforts toward a sustainable exploitation and management of marine resources and by-products for the production of value-added bioproducts to be used by the food industry (among others); an interesting and challenging time for scientists, engineers, and formulators in this field in anticipated.

43. Marine Nutraceuticals

S.W.A. Himaya and Se-Kwon Kim

Marine resources are gaining much attention as a gold mine of biologically active materials with healing power. Most of these metabolites have shown unique structural and functional features compared to their terrestrial counterparts. With the understanding of the requirement and the benefits of nutraceutical supplementation to prevent increasing incidences of life-style-related diseases, marine nutraceuticals has gained high demands worldwide. Among large number of marine nutraceuticals, omega-3 fatty acids, carotenoids, chitin oligosaccharides, glucosamine, collagen, and fucoidan are popularly consumed. This chapter presents a brief review of the beneficial effects of these marine nutraceuticals and their market positioning. Moreover, the need for research and development in this area to overcome the market challenges is also discussed.

43.1 Marine Bioactives as Potential Nutraceuticals

Even though the popularity for health-promoting foods both in the common society and in the research field has raised recently, the concept drove back to thousands of years, which was well explained by the Hippocrates 2500 years ago as *let food be thy medicine and medicine be thy food*. Asian countries such as China, Japan, Korea, India, and Indonesia have used both terrestrial and marine resources as medicinal foods and traditional medicines. However, the awareness among the Western population has emerged much recently. With increasing incidences of life-style-related diseases such as cardiovascular disease, obesity, diabetes, and cancer have thrown a direct challenge to the food habits. While exploring the methods of disease prevention, use of nutraceuticals or functional foods was highly recommended. The term nutraceutical was coined by Stephen DeFelice, founder and chairman of the Foundation for Innovation in Medicine, USA in 1989 to define substances with *nutrition* and *pharmaceutical* values attached [43.1]. According to his definition a nutraceutical is any substance that is a food or a part of a food and provides medical or health benefits, including the prevention and/or treatment of disease. Even though the term nutraceutical is being commonly used in the marketing, strict regulatory definition has not been adapted. The awareness and understanding of the health-promoting abilities of edible natural materials beyond their nutritional benefits, paved the way to a highly growing market for nutraceuticals, worldwide. Vast array of products such as dietary supplements, purified nutrients or food ingredients, herbal products, processed, and genetically

engineered products are marketed worldwide under the category of nutraceuticals. The admiration toward nutraceuticals is increasing as they are safe materials to be consumed with significantly less or no side effects compared to synthetic drugs. And also nutraceuticals provides cost-effectiveness over drugs as they are considerably cheaper materials [43.2]. The boundaries between functional foods and nutraceuticals are hard to identify except for their method of intake where functional foods are in a form of a food and nutraceuticals are in a form of a supplement such as capsules or pills [43.3].

Till recent past most of the marketed nutraceuticals are of terrestrial origin. However, currently nutraceuticals originated from marine sources are gaining higher attention worldwide. Marine environment represents great biological diversity compared to that of terrestrial counterpart. This has resulted in marine nutraceuticals with unique features [43.4]. Large number of research evidences show that the marine resources bear a higher potential to be developed as nutraceuticals. Marine nutraceutical could be simply defined as functional ingredients derived from marine sources which show a potent health-promoting activity other than its nutritional value. Omega-3-fatty acids from fish skin and microalgae, functional pigments such as carotenoids, functional polysaccharides such as fucoidan, chitin and glucosamine, collagen, bioactive peptides, and calcium are few popular marine nutraceuticals which have gained much popularity worldwide for their promising functionality. This chapter presents a brief overview of the established marine nutraceuticals in the market with special focus on production and their beneficial effects. Moreover, the potential for the future products, ongoing research and development in this area, and the challenges are also discussed.

43.2 Functional Carbohydrates

Carbohydrates are one of the most widely distributed macromolecules in marine environment and offer unlimited variation in their structure and function with the ability of their monomeric units to connect to one another by many different linkage types. However, the same complexity of structures and the lack of knowledge on the variations have limited the applications of carbohydrates as functional ingredients. Nevertheless, with extensive research on this area it was revealed that the marine carbohydrates bear diagnostic and therapeutic potentials [43.5]. Among the sources of marine polysaccharides seaweeds are widely used to produce bioactive sulfated polysaccharides [43.6]. Moreover, chitin and glucosamine extracted from sea food processing by-products have gained a considerable attention due to their therapeutic potential against adverse physiological conditions [43.7].

43.2.1 Chitosan and Chitosan Oligosaccharides (COS)

Chitin, chitosan, and chitin oligosaccharides (COS) have brought a revolution in marine nutraceutical industry with their wide array of application possibilities. Chitin is abundant natural polysaccharides in terrestrial sources, cell wall of fungi, and insects. It was found that the exoskeleton of crustaceans and other arthropods are a rich source of chitin. This finding led to the utilization of marine food processing by-products, such as shells of shrimp, crab, and lobsters as commercial sources of chitin. Furthermore, the utilization of these crustacean shell walls solves the serious problem of waste disposal in crustacean processing plants as shell waste of crustaceans accounts for more than 45% by weight [43.7, 8]. Chitin is the second most abundant natural polymer after cellulose which is made of *N*-acetylglucosamine arranged with β $(1 \rightarrow 4)$ glycosidic bonds between each monomer [43.9] (Fig. 43.1). Chitin could be deacetylated by the treatment of hot alkali and over 60% deacetylation results the polymer of D-glucosamine monomers which is named as chitosan (Fig. 43.1). Chitin itself has great industrial value owing to its nontoxicity, biodegradability, hydrophobicity, and physiological inertness. For instance, enzyme immobilized chitin is used for clarification of fruit juices and processing of milk in food industry [43.10]. However, applications of chitin and chitosan have limited due to its poor solubility; despite their promising functionality in promoting health. Even though, chitosan soluble in aqueous acid solutions such as formic acid and acetic acid when compared to chitin, both fail to be soluble in water [43.11]. To overcome this limitation low molecular weight COS were produced via chemical (acid hydrolysis) [43.12], physical (ultrasonic degradation, thermodynamic degradation) [43.13], or enzymatic hydrolysis [43.14] of chitosan. It has been reported that COS produced from chemical hydrolysis are not favorable as a bioactive material due to syn-

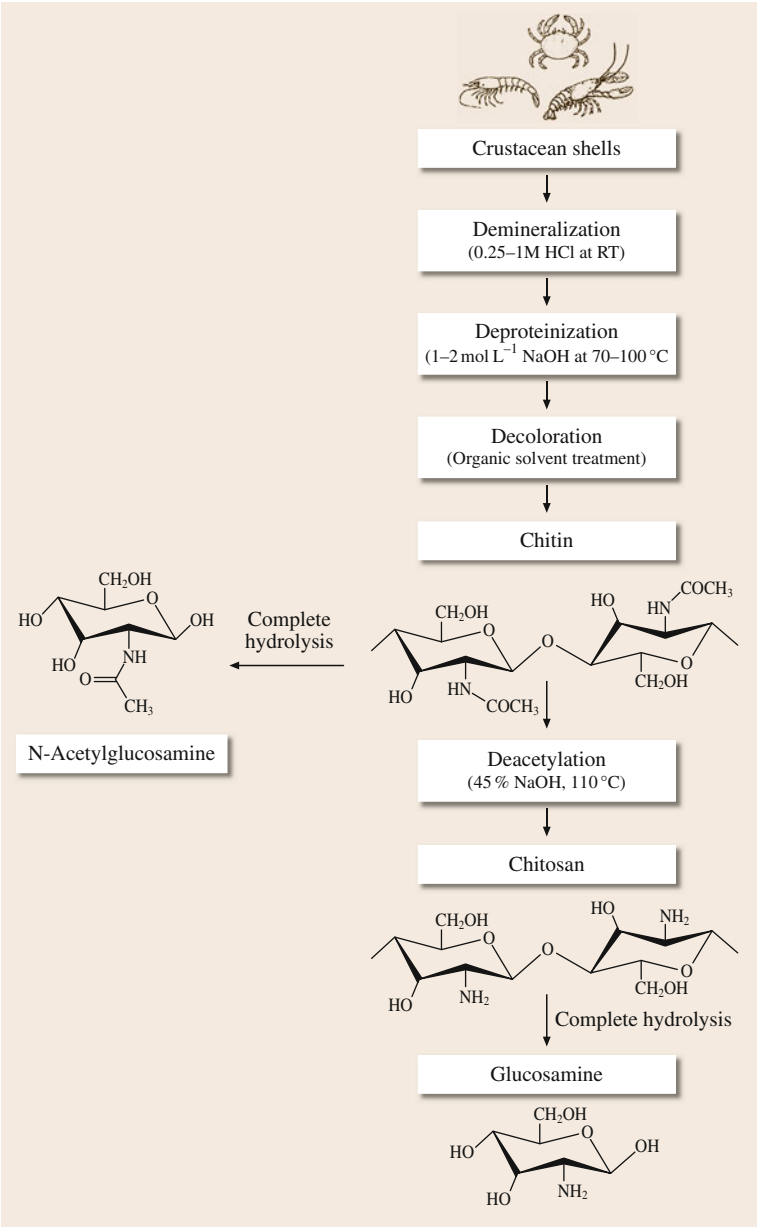

Fig. 43.1 Structures of chitin, chitosan, and glucosamine

thesis of other toxic compounds during the hydrolysis process [43.7]. Therefore, enzymatic hydrolysis for the production of bioactive COS is appreciated. COS have shown a wide array of biological activities. Evidently, COS is more potent and popular as a functional material due to its low molecular weight and water solubility. To enhance the functionality, COS derivatives have been synthesized by introducing structural modifications of COS by adding chemical groups (Fig. 43.2) [43.15]. A wide range of biological actives of chitin and chitosan have been reported. According to the review of *Aranaz* et al. the number of original articles and patents on chitin and chitosan after the year 2000, exceeds 50 000 [43.9]. However in this section, the potentials and applications of these molecules as nutraceuticals are discussed.

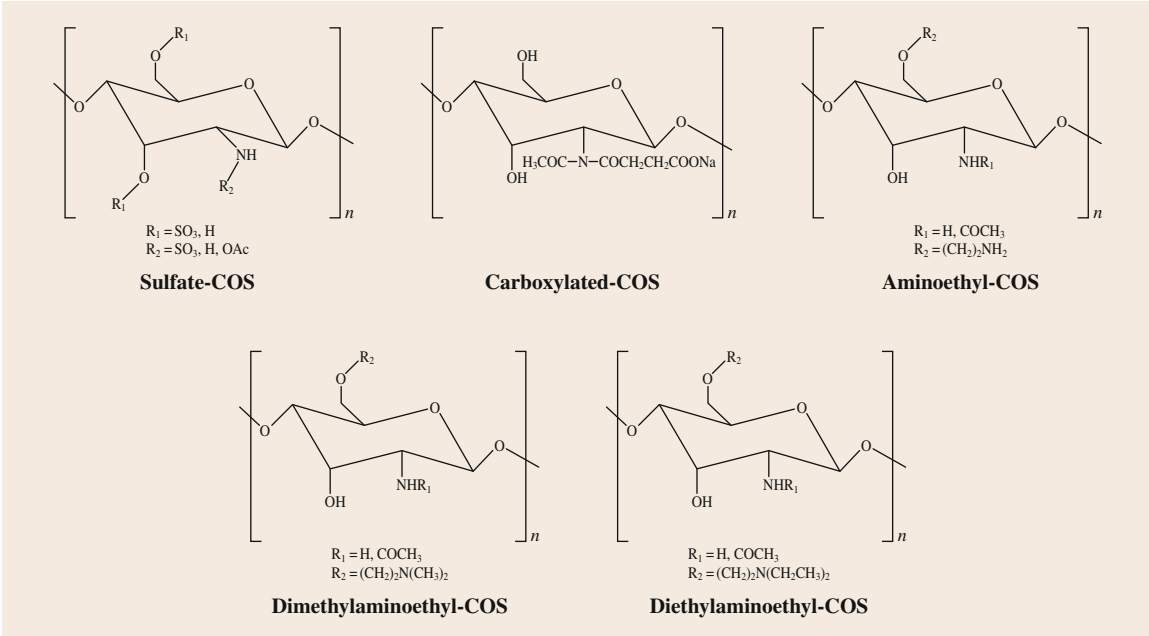

Fig. 43.2 Structures of bioactive chitosan oligosaccharide derivatives

43.2.2 Nutraceutical Potentials and Applications of COS and COS Derivatives

Biocompatibility, biodegradability, and nontoxicity of chitosan have gained growing interest in food and pharmaceutical industry. There have been a large number of studies carried out in the investigation of biological activities of chitosan and COS. They have shown promising activities against intracellular oxidative stress, aging, photo-aging, osteoarthritis, inflammation, asthma, allergy, diabetes, obesity, cancer, hypertension, and microbial infection. Table 43.1 gives an overview of biological activities of COS and its derivatives. The biological activities shown by both chitosan and COS could be attributed to its basic nature with overall positive charge and the molecular structure having reactive hydroxyl and amino groups [43.16]. One common attribute observed throughout these studies is that biological activities are greatly depend on molecular weight and degree of deacetylation of chitosan.

The anticancer and the wound-healing properties of chitosan and its derivatives are explained as their ability to stimulate the immune system. The chitosan-mediated immune-stimulation activates peritoneal macrophages and stimulate nonspecific host resistance followed by the removal of cancer cells [43.16]. In the same manner, the higher levels of macrophage production as a response to chitosan will release cytokines which are involved in the healing process [43.38]. The degree of deacetylation and the molecular weight are key factors for the biological activities of COS. Low molecular weight chitosans (below 5 kDa) with higher degree of deacetylation (90%) are found to be potent radical scavengers and enzyme inhibitors [43.39, 40]. This group of COS has effectively controlled the β-secretase enzyme and Angiotensin-1 converting enzyme activity which plays major roles in the progression of Alzheimer's disease and hypertension, respectively [43.27, 41].

Owing to their biological activities, both chitosan and its oligomers have been researched to develop as active ingredients in functional food and nutraceuticals [43.9, 42]. Chitosan have taken part of multiple formulations due to its promising hypocholesterolemic activity. The mechanism of hypocholesterolemic and antiobesity activity of chitosan and COS is explained as they are able to scavenge fat and cholesterol in the digestive tract and remove it through excretion. The positively charged amine groups on chitosan that could bond with the negative charges on fatty acids or bile acids by ionic interaction facilitate the excretion of fat and cholesterol from diets. The molecular weight (MW) and the degree of deacetylation (DD) are important determinants of hypocholesterolemic activity of chitosan.

Table 43.1 Biological activities of COS and COS derivatives

COS/COS derivative	Bioactivity	Reference
COS (< 1 kDa)	Antioxidant	[43.17]
N-acetyl-COS	Antioxidant	[43.18]
Gallate-COS	Antioxidant	[43.19]
Aminoethyl-COS (1−3 kDa)	Antioxidant	[43.20]
COS (< 1 kDa)	Photo-aging	[43.21]
Carboxylated-COS	ACE-inhiibtory	[43.22]
Aminoethyl-COS	ACE-inhibitory	[43.23]
COS (< 5 kDa)	Prevention of negative mineral balance	[43.24]
COS (3−5 kDa)	MMP-2 inhibitory activity	[43.25]
Carboxylated-COS	MMP-9 inhibitory activity	[43.26]
COS (3−5 kDa)	β-secratase inhibitory activity	[43.27]
Dimethylaminoethyl-COS Diethylaminoethyl-COS	Acetylcholinesterase inhibitory activity	[43.28]
Aminoethyl-COS	Anti-inflammatory	[43.29]
Aminoethyl-COS	Antineuroinflammatory	[43.30]
COS (< 1 kDa)	Antineuroinflammatory	[43.31]
Sulphated-COS	Antiarthritic	[43.32]
COS (1−3 kDa)	Antiallergy	[43.33]
Dimethylaminoethyl-COS Diethylaminoethyl-COS	Antitumor	[43.34]
COS (3−5 kDa)	Antidiabetic	[43.35]
COS (3−5 kDa)	Anti-HIV	[43.36]
COS (< 10 kDa)	Antimicrobial	[43.37]

It has been reported that chitosan showed higher fat-binding capacity than conventional cellulose and the capacity increased with both MW and DD. Further, the bile-salt-binding capacity of chitosan also greatly varying with the viscosity-average molecular weight, and the chitosan sample with the highest molecular weight showed the best binding capacity. It has been postulated that increased MW and DD increase the free amino groups which enhance the hypocolesterolaemic activity [43.43–45]. In relation to true commercial food application of chitosan, Japan food market has achieved considerable success. For instance, dietary cookies, potato chips, noodles, and pasta enriched with chitosan gained growing consumer attention. Incorporation of chitosan has also increased the shelf life of products via antioxidative and antimicrobial activity [43.46]. In dairy products such as yoghurts chitosan have ability to reduce the absorption of glucose and calcium than that of common dietary fibers [43.47]. Moreover, addition of chitosan into bakery products has been identified as one of the best options to utilize the physical properties as well as biological properties of chitosan. In addition, incorporation of chitosan into beverages such as orange juice and household products like vinegar to improve the functional properties and shelf life also became a viable approach to enjoy the biological activities of the chitosan.

Chitosan-based edible film is one of the promising approaches of chitosan in food industry. Both edible coatings and films have been developed using the film-forming properties of chitosan and it has been demonstrated that most mechanical properties are comparable to medium strength commercial polymers. Further, antimicrobial activity and antioxidant activity of chitosan enhance the quality and shelf life of products. It has been observed that other than the biological properties of chitosan and COS, they preserve and enhance the nutritional value of parent food [43.48–50]. All these evidences encourage the applications of chitosan and its derivatives as functional foods than supplementary pills which have lesser consumer demand, particularly in Asian population.

43.2.3 Glucosamine

Glucosamine (Fig. 43.1) is an amino sugar and one of the most abundant monosaccharaides. *N*-acetyl-glucosamine (2-(acetylamino)-2-deoxy-D-glucose) (Fig. 43.1), the monomer unit of chitin and chitosan, is an amide between glucosamine and acetic acid.

The extensive hydrolysis of chitin form crustacean exoskeleton produces glucosamine and *N*-acetyl-glucosamine which is the most common method of commercial production. However, glucosamine and *N*-acetylglucosamine are readily synthesized in the human body from glucose and higher glucosamine levels are found in bone tissues of humans. Glucosamine sulfate is a normal constituent of glycoaminoglycans in cartilage matrix and synovial fluid. It has been reported that the sulfate moiety strengthens the cartilages and facilitate glycosaminoglycan synthesis. Therefore in osteoarthritis conditions, supplementation of glucosamine is used to relieve from arthritic symptoms [43.51]. Clinical studies have also proved this hypothesis [43.52, 53] and currently, it is the most common nonvitamin, nonmineral, dietary supplements used by US adults. Moreover, glucosamine has been subjected to laboratory and clinical testing over all the other nutraceutical products in the world market. Other than the pain-relieving ability of glucosamine, it was found that it has cartilage building and lubricant properties for the joints [43.54]. In addition to the positive contribution for the joint pain relieving, it has shown anti-inflammatory activity by suppressing inflammatory activation of synovial cells, endothelial cells, and intestinal epithelial cells [43.55]. Due to these immense potentials, glucosamine has a high demand as a nutraceutical against inflammatory conditions in the market. Most of the commercially available glucosamine products; glucosamine hydrochloride, glucosamine sulfate, and *N*-acetyl-glucosamine are derived from hydrolysis of chitin even though several other sources have been identified. Even though a variety of glucosamine derivatives are available in the market as nutraceuticals, the sulfated form has been subjected to the majority of clinical trials. The recommended dosage of glucosamine nutraceuticals is 1500 mg per day and most of the time glucosamine-based nutraceuticals are well tolerated by the human body [43.56]. However, some mild gastrointestinal system related conditions among 12% of patients involved in random trials have been reported [43.57].

Other than the direct use as nutraceuticals, incorporation of glucosamine into food formulations was found to be an effective means to replace the supplementation pills which have lesser consumer demand. Currently, beverages containing glucosamine have taken part of food market of many countries. Glucosamine containing orange juice was the very first commercial product of glucosamine beverages. Following the concept, various kinds of beverages containing glucosamine as functional ingredient entered into food market and GRAS certification for glucosamine overcame one of the main barriers of the mass marketing. Hence, glucosamine-enriched beverage has become a more successful approach than other product such as cereals products [43.58]. Further, glucosamine become a very labile formulation when processed in a milk beverage which has a pH of around 6.5 even though neutraceutical manufactures prefer pH 4.5. It has been found that glucosamine-enriched milk can be developed as pasteurized product as a heat treatment of 100 °C or higher destabilize the milk protein [43.59]. High-performance liquid chromatography (HPLC) equipped with refractive index detector has developed as a simple method to determine the concentration of glucosamine in milk-based products [43.60].

43.2.4 Sulfated Polysaccharides

Sulfated polysaccharides (SPs) comprise a complex group of macromolecules which have high degree of structural diversity due to differences in molecular weight, disaccharide construction, and sulfation. It is believed that the structural heterogeneity and the strong negative charges are responsible for the affinity of the SPs to positively charged biological macromolecules. Therefore, SPs show a wide range of biological activities. This has resulted in opening up a broad discussion on structural diversity and functions of SPs. Marine algae are a well-known source of biologically active SPs. A variety of sulfated fucans and sulfated galactans present in marine algae have been extensively researched as therapeutic agents as well as potential candidates for the development of functional food and nutraceuticals [43.61, 62]. Large number of research outcome support that sulfated polysaccharides can enhance the innate immune response and thereby promote the tumoricidal activities of macrophages and natural killer cells [43.63]. Sulfated polysaccharides can enhance the adaptive immune response by promoting the migration of antigen presenting cells into the tumor cells and thereby presenting tumor antigen to be detected by T-helper cells. The T-helper cells stimulate the activation of T-cells which can exert a cytotoxic activity toward tumor cells [43.64]. Moreover, sulfated polysaccharides enhance the proliferation of T lymphocytes by binding to CD2, CD3, and CD4 receptors in T lymphocytes [43.65]. This mechanism of action is responsible for the anticancer activity of marine-sulfated polysaccharides such as fucoidan, heparin, pentosan polysulfate, chondroitin-4-sulfate, and

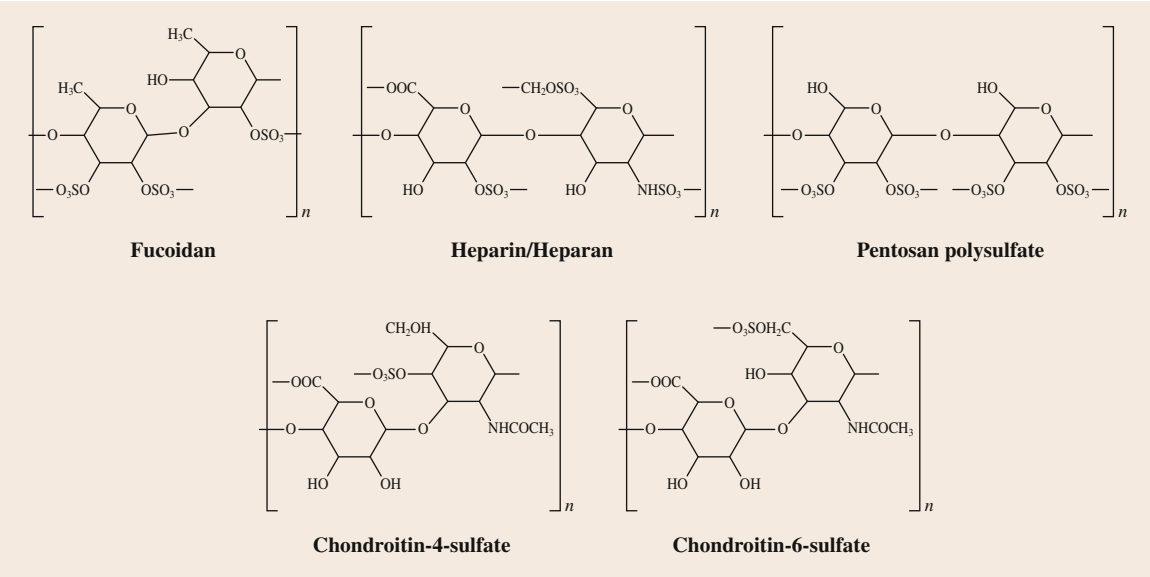

Fig. 43.3 Structures of anticancer sulfated polysaccharides

chondroitin-6-sulfate (Fig. 43.3). The potent of marine-derived sulfated polysaccharides as anticancer agents could be well adapted in cancer therapy.

Fucoidan (Fig. 43.3) is the most common and representative marine-sulfated polysaccharide. It is commonly extracted from the marine brown algae cell wall, and accounts for more than 40% of the dry weight of the cell wall. Small amount of fucoidan is also being extracted from echinoderms. Often fucoidan is consist of *O*-sulfated α-L-fucopyranose residues linked through (1−2), (1−3), and (1−4) linkages arranged in branched structures. The molecular weights of fucoidans vary from 100 to 1600 kDa [43.66]. Fucoidan is soluble in water and acidic solutions. The molecular characteristics such as sulfation, molecular weight, and confirmation of the sugar residues vary with the mother source [43.67]. Generally seaweed-derived fucoidans are highly branched and echinoderms, especially sea cucumber derived fucoidans are comparatively linear. Fucoidan is popularly extracted from edible seaweed species such as *Fucus vesiculosis*, *Cladosiphon okamuranus*, *Laminaria japonica*, and *Undaria pinnatifida*.

Diverse interesting biological functions of fucoidan have been extensively reviewed in the last decade. The activities are ranging from antioxidant activity [43.68], antivirus activity [43.69], cardioprotective activity (*Thomas* et al. [43.70]), anti-inflammatory activity [43.71], anticancer activity [43.72, 73], anticogulatory activity [43.74], and neuroprotective activity [43.75]. Among identified functional sulfated polysaccharides fucoidans have been extensively studied for their potential in developing drugs and nutraceuticals. There are large number of companies all over the world marketing nutraceuticals prepared from fucoidan (Fig. 43.4). The biological activities of fucoidan are dependent on the source, molecular weight, composition, structural arrangement, and the mode of administration [43.76]. Sulfation is a critical factor for its functionality and it was found that desulfated fucoidan

Fig. 43.4 Fucoidan-based nutraceutical products in the market

moieties fail to perform as bioactive molecules [43.77, 78]. The structural heterogeneity and high molecular weight are challenges faced by fucoidan as a therapeutic agent. Currently scientists are extensively working on identification of active fragments of fucoidan. This process will also direct to the identification of structure activity relationships of fucoidan and biological molecules, which is still an unresolved issue. Moreover, this will increase the therapeutic applications of fucoidan.

43.3 Polyunsaturated Fatty Acids

Polyunsaturated fatty acids (PUFAs) especially omega-3 fatty acids are for the metabolism and cannot be synthesized by the human body as human body do not synthesize the precursor for omega-3 fatty acids, α-linolenic acid (ALA). Therefore, external supplement of PUFA is required to maintain the physiological functions of the body. Besides its functions in regulating the normal metabolism, several PUFA such as eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and alpha linolenic acid (ALA) (Fig. 43.5) have proven to possess vast array of health benefits such as prevention of coronary heart diseases, hypertriglyceridemia, blood platelet aggregation, atherosclerosis, general inflammation, hypertension, type-II diabetes, ocular diseases, arthritis, cystic fibrosis, and several carcinomas [43.79–81]. PUFA are popularly consumed as nutraceuticals to protect against heart diseases. Findings suggest that high levels of EPA and DHA in blood which in turn reduce the rate of coronary heart diseases have an association with inhibition of lipid-rich atherosclerotic plaques growth, reduction in formation of thrombus, improving vascular endothelial function and lowering blood pressure [43.80]. In 2004, US Food and Drug Administration has declared a *qualified health claim* status to EPA and DHA [43.82]. Therefore, both EPA and DHA have been extensively used as therapeutics to prevent above mentioned adverse health conditions [43.83, 84]. In consideration to the promising therapeutic properties, worldwide demand for the fish-oil-based nutraceuticals is rapidly increasing.

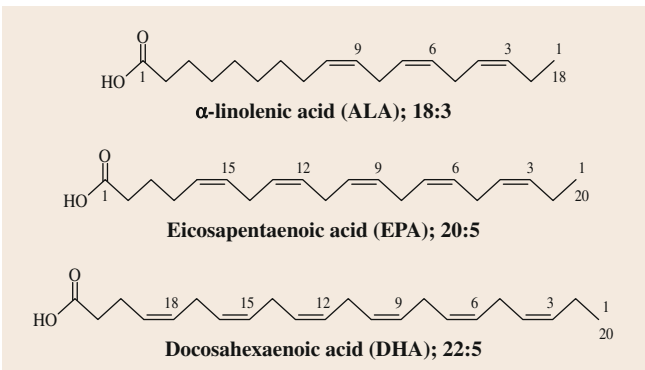

Fig. 43.5 Structures of polyunsaturated fatty acids

The principal dietary source of DHA and EPA is fish and fish by-products. Cold water oily fish such as salmon, herring, mackerel, anchovies, sardines, and fish oil derived from these fish have been recognized as well balance sources of omega-3 fatty acids, especially DHA and EPA. Due to highlighted health benefits of omega-3 fatty acids, world fish consumption reach to a level of which threaten the marine fish sources and thus fishing for oil extraction is not encouraged. Therefore, fish processing by-products have been identified as an ideal candidate for extraction of fish oil rich in omega-3 fatty acids while giving a positive insight on sustainable marine fisheries [43.85]. The processing leftovers head, skin, and internal organs are rich sources of omega-3 fatty acids and method and conditions for the extraction are determined based on the nature of fish source. Presently, several methods such as high-speed centrifugation, Soxhlet extraction, low temperature solvent, and supercritical fluid extraction are employed to extract fish oil [43.86]. Purification of omega-3 fatty acids form extracted fish oil seems as a challenge due to the presence of complex mixture of triacylglycerols and vulnerability of free fatty acids EPA and DHA to oxidize into hydro-peroxides. A recent study shows that enzymatic deacidification of high-acid crude fish oils is an effective approach to extract high amount of *n*-3 fatty acids [43.87]. These extracted fish oils are available in the market as nutraceutical pills.

However, due to unpleasant fishy odor and being a declining resource; there is a serious commercial and environmental issue related to the continued exploitation of fish in order to meet the demands of the expanding market [43.88, 89]. And also concerns have arisen on using nutraceuticals derived from fish oil as it can be contaminated with trace pollutants such as mercury, polychlorinated biphenyls, and dioxins from their habitats [43.90]. More importantly, the realization of the fact that fish itself do not have the ability to synthesize DHA and EPA, and microalgae in their diet is the

primary source of fatty acids for fish [43.91] arises the interest to explore marine microalgae as an alternative safe source of PUFA-based nutraceuticals and supplements, especially EPA and DHA.

Microalgae have been identified as a rich source of long chain polyunsaturated fatty acids where it accounts for 10–20% of cell weight in some species. Biosynthesis of PUFA in microalgae has been described by *Tonon* et al. (2004) which involves a series of desaturation and elongation steps starting with oleic acid [43.92]. As a commercially demanding source of PUFA, design of optimum culture conditions to yield maximum amount of PUFA in a cost-effective manner is essential. Environmental conditions have a significant influence on the PUFA compositions of microalgae and therefore the external factors such as the medium composition, nitrogen source, pH, incident light intensity, degree of aeration, and temperature should be optimally manipulated depending on the species [43.89, 93]. Use of ammonium or nitrate as the nitrogen source has produced the highest level of PUFA in *Chlorella minutissima* (44.4% of the total fatty acids) and *Tetraselmis gracilis* (46.6% of the total fatty acids) [43.94].

Studies on the EPA and DHA content of microalgae have reported an immense potential of several microalgal species as a primary source of ALA, EPA, and DHA. *Nannochloropsis* spp. (*Fuentes* et al. [43.95]), *Porphyridium cruentum* [43.95, 96], *Phaeodactylum tricornutum* [43.97, 98], and *Chaetoceros calcitrans* [43.99] are identified as the best EPA producing microalgae, while *Isochrysis galbana* [43.100], *Cryptecodinium* spp. [43.101], and *Schyzotrichium* spp. [43.102] have been reported as promising sources of DHA. Furthermore, *Pavalova lutheri* and *Thalassiosira pseudonana* have been identified as a rich source of both EPA and DHA [43.103–105]. Commercialization of these species as sources of EPA and DHA should be followed by extensive studies on the economically feasible culture and extraction conditions.

Fig. 43.6 Omega-3-based nutraceuticals derived from fish oil and marine microalgae in the market

The demand for the PUFA-based nutraceuticals and PUFA fortified functional foods are increasing at a high pace. According to the World Health Organization the daily recommendation for EPA and DHA per capita consumption is 0.3–0.5 g d^{-1} [43.106]. The average per capita consumption of EPA and DHA in the world is 0.38 g/d [43.107, 108]. To meet with this demand, large number of nutraceutical companies are producing and marketing omega-3-fatty acid encapsulated pills worldwide (Fig. 43.6). According to the global business of nutraceutical reports on 2012, the market demand for fish oils were around 3.08 billion USD in 2011. Encapsulation is highly necessary as the omega-3-fatty acids are highly susceptible for oxidation due to their higher degree of unsaturation [43.108]. Encapsulation protects the fatty acids from light and heat-mediated oxidation and thereby ensures longer storage times.

43.4 Carotenoids

Carotenoids are a class of terpenoid pigments, derived from a 40-carbon polyene chain, which provides distinctive molecular structures of carotenoids [43.109]. This polyene chain can be substituted with cyclic groups and oxygen containing functional groups in the biosynthesis of different carotenoid compounds. The oxygenated derivatives of carotenoids are denoted as xanthophylls. Xanthophylls are again classified depending on the nature of oxygen present, such as lutein (oxygen is present as –OH), cantaxanthin (as oxy-groups) and astaxanthin (combination of both –OH and oxy-groups) [43.109, 110].

There are number of carotenoids that have been identified from marine resources which bears pharmaceutical potential such as β-carotene, lycopene, zeaxanthin, fucoxanthin, astaxanthin, cantaxanthin, lutein, and violaxanthin (Fig. 43.7) [43.111, 112]. These carotenoids are potent antioxidants and this activity is well described by relating to its complex ring structure which has the ability to absorb the energy of oxida-

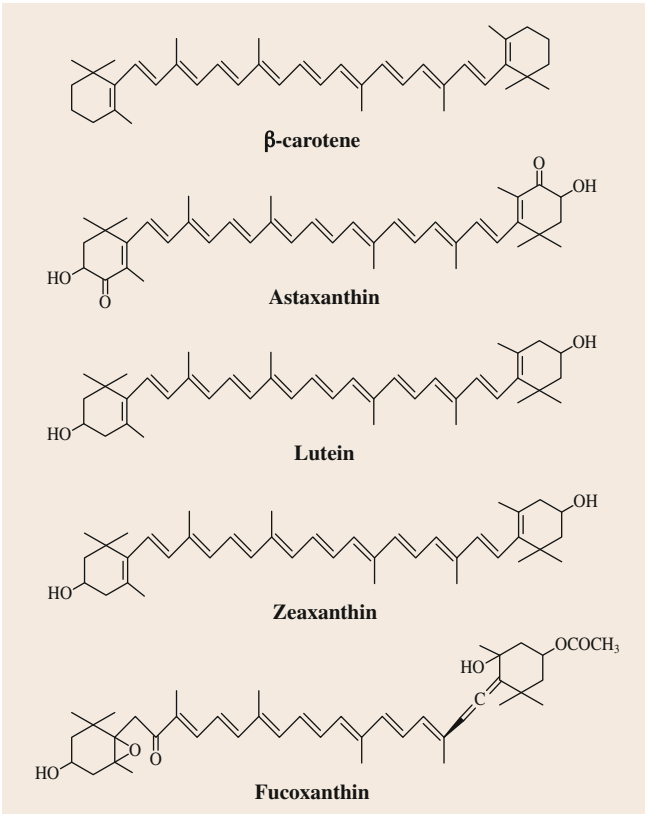

Fig. 43.7 Structures of carotenoids commonly isolated from marine sources

tive radical species [43.113]. And also it has been reported that carotenoids enhance the immunity via facilitating the monocyte function to increase the number of surface molecules expressed [43.114]. Based on this antioxidative and immune modulatory power of carotenoids, they can extend their activity in several disease conditions which have a direct relation to oxidative stress and chronic inflammation such as cancer, cardiovascular disease, eye disorders, rheumatoid arthritis, and several neurodegenerative diseases [43.115, 116]. Moreover, the use of fucoxanthin to reduce body fat has been well investigated and is popularly used as a nutraceutical to control body weight [43.117]. Some of the findings related to the biological activities of carotenoids are listed in Table 43.2.

The market for carotenoid-based nutraceuticals is booming with the understanding of their therapeutic potentials. Carotenoid nutraceuticals are marketed in different forms such as cold water soluble powders, oil emulsions and beadles of single pigments or blend of few [43.130]. The carotenoid amount in these products is ranging from 0.2 to 100 [43.116]. Until recent times synthetic carotenoids mimicking the properties of natural pigments are ruling the market. However, with the development of customer understanding on the beneficial use of the natural pigments, the demand for extracted natural pigments increased rapidly. Among the natural sources of carotenoids marine microalgae has gained much attention due to the higher content and possibility of sustainable production of carotenoids [43.131].

Table 43.2 Biological activities of carotenoids found in marine sources

Carotenoid	Bioactivity	References
β-carotene	Protect against heart diseases	[43.118–121]
	Provitamin A activity	[43.122]
	Anticancer activity	[43.123–125]
	Protection of skin against UV damage	[43.126]
Astaxanthin	Anticancer activity against prostate and liver cancers	[43.126, 127]
	Anti-inflammatory activity	[43.128]
Zeaxanthin	Liver protection	[43.123]
	Protects against heart diseases	[43.120]
	Helps in preserving normal visual functions	[43.129]
Lutein	Protect against heart diseases	[43.120]
	Helps in preserving normal visual functions	[43.129]

Green unicellular marine microalgae *Dunaliella salina* has been identified as one of the most promising source of β-carotene with 14% of dry weight being β-carotene at appropriate culture conditions [43.132]. The particular growth conditions of *D. salina* which yield the highest amount β-carotene at industrial scale ($100\,g\,kg^{-1}$ dry weight) and specific extraction methods of β-carotene has been extensively studied [43.133, 134]. With the development of optimum culture and extraction conditions, *D. salina* is commercially cultured as a source of β-carotene [43.91]. SFE of metabolites from *Haematococcus pluvialis* has also produced β-carotene and astaxanthin where astaxanthin was the main product (about 75%) [43.135]. Up to date *H. pluvialis* is considered the highest astaxanthin producing microalgae with approximately 1.5–3% by weight and therefore, it is been exploited commercially [43.136]. Interestingly, it has been reported that astaxanthin bears the highest antioxidative potential compared to other carotenoids and commercially available antioxidative

agents such as vitamin E [43.137]. Lutein is a highly polar carotene compound corresponding to the presence of hydroxyl groups on the cyclic ring structure and as a result it bears a higher antioxidative potential which could be effectively harvested to promote health and protect against chronic disease conditions. Specifically lutein has the ability to protect the aging eye-related complications such as cataract and macular degeneration via retarding the pathological mechanisms underlying these diseases [43.138]. Marigold is the most widely used source of lutein. However, mass plantation of marigold requires large areas and also it is climate dependent, and hence, the cultivation of *Chlorella pyrenoidosa* was discovered as the most promising alternative source of lutein with 2–4 mg g^{-1} dry weight which is comparable to that of marigold. *Wu* et al. (2007) has published SPF as the most appropriate method for optimal extraction of lutein which resulted in 87.0% extractive of lutein under the optimized conditions of 25 MPa and modified CO_2 with 50% ethanol [43.139]. In addition, it was found later that *Muriellopsis* sp., could also be economically employed for the extraction of high lutein content up to 35 mg L^{-1} [43.110]. Corresponding to this high growth rate and higher cell density, the culture of *Muriellopsis* sp. as the best source of lutein is practiced commercially [43.140].

The market value of carotenoids is in a continuous increasing phase. According to the business communications, the market value for carotenoids will raise from 766 million dollars in 2008 to 919 million dollars in 2015. The most demanded carotenoids includes beta-carotene, lycophene, astaxanthin, lutein, and cantaxanthin. The expected market demand value for beta-carotene will be 285 million dollar by 2015. Currently,

Fig. 43.8 Carotenoid-based nutraceuticals in the market

Chlorella vulgaricus derived nutraceuticals are sold to a price of 30–100 USD kg^{-1}. And the dry powder or tablets of *Isochrysis galbana*, *Phaeodactylum tricornutum*, *Arthrospira*, *Dunella salina* is marketed to price of more than 200 USD kg^{-1}, where the dry powder of *H. pluvialis* leads the group with a market price of more than 600 USD kg^{-1} [43.116]. Large number of companies in the world is marketing the carotenoid-based nutraceuticals in the form of tablets, pills, and capsules produced with carotenoid rich microalgae, *Arthrospira*, *Chlorella*, *Dunaliella*, *Spirulina* and *Aphanizomenon* (Fig. 43.8). Moreover, the dried powders of carotenoid rich microalgae are being used in food formulations such as pasta, snacks, drinks, etc.

43.5 Soluble Calcium

Calcium is an essential mineral and is acquired through diet. It has been found that calcium is necessary to maintain good health as it provides diverse biological functions. It is commonly known that calcium is needed to strengthen and maintain the bones and teeth; however it is also required for other physiological functions such as blood coagulation, nerve function, production of energy, muscle contraction, maintain heart function, and proper immunity [43.141]. Due to its role in bone strengthening, calcium also plays an important role in preventing the onset of bone-related diseases such as osteoporosis, osteopenia, osteomalacia, and rickets [43.142]. Even though, calcium is readily available in most of the dietary sources, the bioavailability of calcium of such sources are low, where milk and fish being the most common sources of soluble calcium [43.143].

Fish frame, account for approximately 10–15% of total fish biomass, is discarded as a waste from commercial fish fileting lines. But close observation on chemical composition of fish frame revealed that bones mainly composed of calcium phosphate and collagen protein with some special carbohydrates and lipids. The calcium and phosphorus content in the whole fish ac-

Fig. 43.9 Fish bone derived calcium supplements in the market

counts for 2% of the dry weight. Thus, the waste could be used as mineral source to obtain soluble calcium to be used in nutraceutical formulations. Even though the bioavailability of calcium of fish bones is not deeply studied, it is well-known fact that small fish are good source of balance calcium source and readily absorbed into human body. Moreover, in a recent study it was found that the calcium from salmon and cod bone are well absorbed in young healthy men [43.144]. Thus bones from fish processing waste can be used to produce fortified products with high biological value and several convenient methods have been developed to soften the fish bone to convert it into an edible form. With these findings on the beneficial and potential use of fish bone calcium, number of nutraceutical products has been introduced to market worldwide (Fig. 43.9). According to the market report of nutraceuticals published in the nutraceuticals world magazine calcium supplements have been identified as one of the demanding nutraceuticals in 2011 with 5.19 billion USD market value.

43.6 Fish Collagen and Gelatin

Collagen is the most abundant protein of animal origin, and there are 28 types of collagen have been identified. Type I and III collagen are the most naturally abundant collagen in animal and found in skin, tendon, vascular ligature, organs, and bone. Collagen has earned much interest as a biomaterial in medical applications due to its biodegradability and weak antigenicity [43.145]. It is generally composed of three similarly sized triple helix polypeptide chains which consist of around 1000 amino acids residues. Gelatin is structurally different form of the same macromolecules which make collagen and particularly a hydrolyzed form of collagen. The popularity of common source of collagen and gelatin such as bovine hide, pig skin, or chicken waste are rapidly decreasing due to biological contaminants and religious issues [43.146]. Fish waste has been identified as the best alternative source for collagen and gelatins for commercial purposes due to its unique features. Fish skin and bones are mainly used for collagen extraction and popular extraction methods include neutral salt solubilization, acid solubilization, and enzyme solubilization. During extraction of collagen triple helix structure of collagen which contributes its unique properties has to be secured. Generally, extracted collagen is solubilized with hot water treatment by breaking down the hydrogen and covalent bonds of the triple-helix, resulting in helix-to-coil transition, and conversion into soluble gelatin [43.16]. Collagen is mainly extracted from skin of cod, haddock, and salmon. Moreover, tilapia fish scales are also being used as a source of low molecular weight collagen (around 1000 kDa) [43.4].

Fig. 43.10 Fish collagen-based nutraceuticals in the market

Fish collagen is widely gaining popularity as an ingredient in cosmetics. Oral supplementation of collagen is also popularly used to maintain a healthy skin. Evidences of clinical investigations suggest that ingestion of collagen/gelatin hydrolysates are capable of pain re-

Table 43.3 Biologically active peptides isolated from fish skin

Source	Peptide sequence	Activity	Reference
Alaska pollack skin gelatin	Gly–Pro–Leu	ACE inhibitory activity	[43.147]
Alaska pollack skin gelatin	Gly–Pro–Hyp	Antioxidant activity	[43.148]
Jambo Squid skin gelatin	Phe–Asp–Ser–Gly–Pro–Ala–Gly–Val–Leu Asn–Gly–Pro–Leu–Gln–Ala–Gly–Gln–Pro–Gly–Glu–Arg	Antioxidant activity	[43.149]
Hoki skin gelatin	His–Gly–Pro–Leu-Gly–Pro–Leu	Antioxidant activity	[43.150]
Japanese Flounder Skin Gelatin	Gly–Gly–Phe–Asp–Met–Gly	Antioxidant activity	[43.151]
Pcific cod skin gelatin	Thr–Cys–Ser–Pro	Antioxidant and ACE inhibitory activity	[43.152]
	Thr–Gly–Gly–Gly–Asn–Val		
Pacific cod skin gelatin	Leu–Leu–Met–Leu–Asp–Asn–Asp–Leu–Pro–Pro	Antioxidant and ACE inhibitory activity	[43.153]

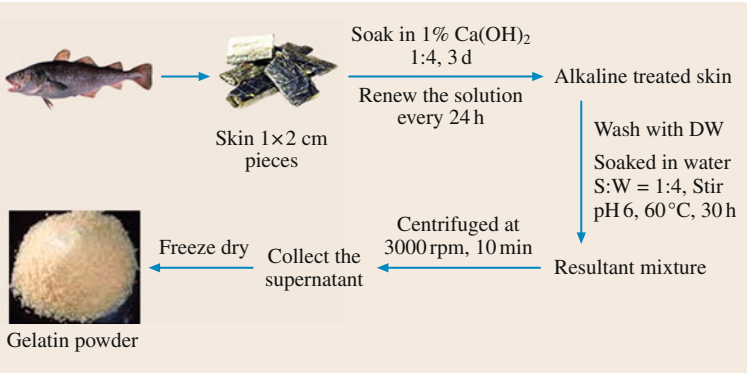

Fig. 43.11 Process of extracting gelatin from fish skin

lieving of the patients suffering from osteoarthritis and hydrolyzed collagen have been involved in cartilage matrix synthesis [43.154]. Also hydrolyzed collagen and gelatin are currently marketed as collagen peptide supplements to maintain of normal bone integrity, as a treatment for brittle nails and for the nourishment of scalp hair (Fig. 43.10) [43.16]. Fish-skin-derived collagen and gelatin were used as potential sources to isolate bioactive peptides. These peptides act as effective antioxidant and antihypertensive agents both in in vitro and in vivo models (Table 43.3). The biological activities of these peptides are attributed to their unique amino acid composition. The procedure of gelatin extraction from fish skin is shown in Fig. 43.11.

43.7 Marine Probiotics

The gastrointestinal tract is a harbor for large number of microbial species such as, *Bacteroides, Prevotella, Eubacterium, Clostridium, Bifidobacterium, Lactobacillus, Staphylococcus, Enterococcus, Streptococcus, Enterobacter, and Escherichia*. Gastrointestinal microbes could be both beneficial as well as harmful to the human health. Thus reducing the amount of potentially harmful or pathogenic species and promoting the growth of beneficial species are vital for wellbeing. A live microorganism which is beneficial for gut microflora and restricting the growth of disease causing bacteria is referred as a probiotic strain [43.155]. The applications of probiotics and prebiotics were boosted with modern nutraceutical and functional food market. Probiotics are considered as one of the highly demanded nutraceutical and food supplement in the world. Strains from the genera *Lactobacillus* and *Bifidobacterium* are predominantly used as probiotics [43.156]. Fermented

dairy products especially yoghurts, drinks, and capsules with freeze-dried bacteria are the most popular vehicles for delivering these organisms to the gastrointestinal tract [43.157]. Few strains of probiotic *lactobacillus* are identified from marine environments and they have shown unique characteristics in in vivo experiments. These findings revealed that marine-derived *Lactobacillus* species have advantages over conventional terrestrial species to use them as probiotics with advanced health benefits. Among the identified lactic acid bacterial species of marine origin, majority has been isolated form Pacific Ocean region of Japan and strains belong to genus *Caranobacterium*, *Marinilactobacillus*, *Halolactobacillus* [43.158].

43.8 Nutraceutical Market Trends and Quality Control

With the consumer knowledge on the health benefits of the foods increasing the use of foods or supplements with health promoting ability has gained alarming popularity. The ready-use supplements and attractive product range with beneficial effects have further enhanced the popularity of nutraceuticals and functional foods. Most people consume nutraceuticals to prevent the onset of life style related diseases such as heart disease, cancer, obesity, diabetes, etc. And also to delay the aging process by using antioxidants or skin regenerating supplements. The popularity of the nutraceuticals is also affected by the increase research on the identification of health benefits and constant communication of the benefits to the mass population via various marketing procedures. With the increasing popularity toward nutraceuticals, the gap between foods and drugs are getting narrower. Most nutraceuticals do not fall into both categories either a food or a drug; instead they reside in between the two. The nutraceutical market is mainly composed of two main categories including, functional foods and dietary supplements and herbal/natural products [43.159].

According to the market reports published worldwide, the global nutraceutical market has seen the maximum growth in the last decade from the emergence of the market in 1990. The annual average growth rate of the nutraceutical market from 2002 to 2010 is 14.7%, compared to that of 7.3% from 1999 to 2002. With the expansion of the nutraceutical market the growth is expected to rise till 2015. The United States also contributed to a market share of 140.1 billion USD by 2010. Among the marine nutraceuticals fish oil, carotenoids, calcium, and collagen peptides are highly demanded.

However, to maintain the market popularity, implementation of strict quality control and regulatory systems is of utmost importance. Even though there are no global regulations have been implemented to control the safety and quality of nutraceutical products till date, the regional regulatory agencies are controlling the key markets such as United States, European Union, China, Japan, and India. The regulatory bodies for these countries are; food and drug authority (USA), European food safety authority (EU), state food and drug administration (China), Japan health and nutrition food association (Japan), and food safety standards act (India).

43.9 R&D for Facing the Challenges and Supply for the Demand

Research and development on the marine nutraceuticals should be started out with improving the quality of existing products. For example, fishy odor in most of marine nutraceuticals such as fish oil, collagen, and peptides is a main drawback in expanding the market. Research on favor and odor masking of the products would be promising avenue for increasing the popularity for these products. And also development of novel concepts in the delivery systems instead of pills and capsules would also enhance the market popularity.

There are thousands of potential marine products which could be developed as nutraceuticals which are reported in the last few decades. However, only few have made their way up as nutraceuticals in the market. These potential products should be tested and developed as marine nutraceuticals as marine-active metabolites bears a promising capacity as nutraceuticals. The sustainable production of nutraceuticals is a major concern in the modern nutraceutical market. As most of the natural resources are declining, the investigation of marine microalgae and marine microorganisms as potential producers of active ingredients should be highly encouraged.

44. Cosmetics from Marine Sources

Elena M. Balboa, Enma Conde, M. Luisa Soto, Lorena Pérez-Armada, Herminia Domínguez

The application of marine resources for the formulation of cosmetics has been known for centuries. Marine organisms produce unique compounds, which are not found in terrestrial sources, to provide protection against hard environmental conditions. They have been used both to confer:

- Physicochemical *functional properties* to the cosmetic product, such as texture, emulsifying properties or color,
- *Bioactive properties*, including remineralizing, emollient, hydrating, antioxidant, sunscreening among others.

In this chapter, the major functional and biological activities of components isolated from marines sources, including micro and macroorganisms and with special emphasis on algae, are reviewed in relation to their application to cosmetics. Both the traditionally used compounds and fractions and those isolated and characterized in recent years are presented.

44.1 Scenario of Marine Sources in the Cosmetic Industry

In recent years, health concerns and the demand for natural products have provided incentive for research on the abundant and alternative sources for novel ingredients and additives. Cosmetic industries, also influenced by consumers' preferences, have been increasingly incorporating natural ingredients into different products. However, the natural cosmetic market still represents a smaller fraction in relation to conventional cosmetics [44.1, 2].

Terrestrial plant-derived constituents are gaining popularity [44.3], but the marine environment is a richer source of both biological and chemical diversity [44.4]. Probably induced by the environmentally extreme conditions, marine organisms possess the capacity to produce molecules with unique chemical and structural features, which warrant a variety of potent and selective biological actions. Marine resources represent an underexploited source of highly diverse valuable

compounds [44.4–6] with potential applications in nutraceuticals and cosmetics [44.7–9].

Micro and macroalgae are established on the market for face and skin care products, such as anti-aging and regenerant creams, refreshing products, emollients, anti-irritants, sun protection, and hair care products. Components from cultivated microalgae are commercially available [44.10]. Seaweed resources have undergone successive periods of over-exploitation and neglect, but macroalgae have traditionally been used as a source of food and medicines, have been included in cosmetic formulations, and have played a major role in the development of spa products [44.11]. However, less than 1% of the identified species are used in pharmacy, food, and in cosmetology.

In addition to macro and microalgae, providing vitamins, minerals, proteins, and amino acids, sugars, lipids, terpenoids, polyphenols, polysaccharides, pigments, and enzymes, different marine sources have been considered for their potential applications in cosmetics and cosmeceuticals. Fish is an excellent source of gelatin and collagen; corals and crustaceans can provide diguanosine tetraphosphate, chitin, chitosan, and astaxanthin, and sea mud and sea salts have cosmetic applications [44.12]. Most of these active agents can be found in already marketed products [44.4] with a variety of functions [44.13]. Recent progress in cosmeceutical applications of marine- derived bioactive substances, including antioxidants, growth factors, peptides, anti-inflammatory, and pigment lightening agents, has been published [44.12].

This chapter presents general aspects on cosmetics, emphasizing on the potential of marine sources to provide components with a variety of functions, including technological and biological actions. The most recent innovation in this field, i. e., active cosmetics or cosmeceutical products, are also presented.

44.2 Cosmetics: Definition and Regulations

Cosmetics have been applied from ancient times in many civilizations for artistic, beautifying, protective, cleansing, and ceremonial purposes [44.14]. In order to avoid negative impacts on the consumers' health and to warrant the safety of the products, regulatory controls are established on the different markets, although the legislation applied to cosmetic products differs among countries. The major normative obstacles faced by the cosmetic industries include the different restrictions in the use of the ingredients, the distinct classifications of the cosmetics, and the varied labeling requirements [44.15]. The International Nomenclature of Cosmetic Ingredients (INCI) tries to unify the nomenclature in order to facilitate the adaptation of the products to different markets.

The need for an international harmonization on the status and safety requirements of cosmetics products and their ingredients has been claimed since their safety assessment is based on scientific and epidemiologic knowledge and also on their regulatory status [44.16]. Comparative studies of the regulatory features in different countries impacting on the manufacture and sale of cosmetic products, such as: cosmetic definition, licensing, labeling, safety substantiation, stability studies, and legal authority, are available [44.17–19].

In the major world markets, cosmetics are regulated according to two general models:

i) A wide definition of cosmetics and the safety of the products is based on a few lists of ingredients (positive, prohibited, or restricted), followed in the European Union and Japan, although in this latter area another category of cosmetics (quasi-drugs) has been established.
ii) A more limited definition of cosmetics, with few restrictions on ingredients and safety tests carried out by the manufacturers [44.17], followed in the USA and Canada approaches this model, including a list of prohibited or restricted ingredients.

The Cosmetic Products Regulation (EC) No. 1223/2009 [44.20] has replaced the European Directive 76/768/EEC [44.21]. It was dictated with the purpose of guaranteeing the safety of the cosmetic products and to facilitate their marketing. This regulation is applicable with full effect since July 2013 and reinforces product safety considering the latest technological developments. The term cosmetic product refers to any substance or mixture intended to be placed in contact with the external parts of the human body (epidermis, hair system, nails, lips, and external genital organs) or with the teeth and the mucous membranes of the oral cavity

with an exclusively or mainly purpose of cleaning perfuming, changing their appearance, protecting, keeping them in good condition, or correcting body odors. This regulation includes skin whitening-products, anti-wrinkle products, and products with nanomaterials.

In the USA cosmetics are regulated by the Food and Drug Administration (FDA), and the two most important laws pertaining to cosmetics are the Federal Food, Drug, and Cosmetic Act (FD&C) and the Fair Packaging and Labeling Act (FP&LA). The FD&C Act defines two main categories of products: cosmetics and drugs, including the specific subcategory of over-the-counter (OTC) drugs, which can be sold without prescription. The definition of products as cosmetics or drugs depends on their intended use, which is established on the basis of claims made about the product. Cosmetic products and ingredients are not subject to FDA premarket approval authority, with the exception of color additives, and cosmetic firms are responsible for substantiating the safety of their products and ingredients before marketing. The FD&C Act defines cosmetics as articles intended to be rubbed, poured, sprinkled, or sprayed on, introduced into, or otherwise applied to the human body for cleansing, beautifying, promoting attractiveness, or altering the appearance without affecting the body's structure or functions. Among the products included are skin creams, lotions, perfumes, lipsticks, fingernail polishes, eye and facial makeup preparations, shampoos, permanent waves, hair colors, and deodorants, as well as any substance intended for use as a component of a cosmetic product. The products not included in this definition are regulated as medicines. The intermediate category of cosmetics intended to treat, cure, mitigate, treat or prevent disease, or those affecting the structure or functions of the human body, are not specifically regulated. Among the products that are drugs and cosmetics are anticaries toothpastes, suntanning lotions to protect against sunburn, antiperspirants that are also deodorants, and antidandruff shampoos [44.17].

44.3 Cosmeceuticals

Like cosmetics, cosmeceuticals are applied topically but differ in that they contain potent ingredients such as vitamins, phytochemicals, enzymes, antioxidants, essential oils, ... that can deliver nutrients and influence biological functions to promote healthy skin [44.12, 13]. Cosmeceutical science is a new branch aimed at utilizing the resources of the natural environment to obtain efficient products [44.22]. The term cosmeceutical, formed from the words *cosmetic* and *pharmaceutical*, refers to cosmetic products that have drug-like benefits that enhance or protect the appearance of the human body [44.23–25]. These products lie between cosmetics and pharmaceuticals and they are medium-volume/medium-value products that offer lower risk and a quicker potential return on investment than the high-risk high-reward pharmaceutical market. The value of the cosmeceutical market has been increasing, and it is likely that this trend will continue [44.8]. Cosmeceuticals meet consumer demands for higher efficacy and have become the fastest-growing segment of the personal care industry [44.13, 23, 26], converting it in the area of dermatology with a more rapid commercial expansion; the number of new products introduced yearly onto the market is superior than that of pharmaceuticals [44.23]. The global market value for marine skin care products was estimated in 15% of the cosmetics industry. For marine resources the world market value for cosmetics was one third of that for pharmaceuticals [44.7].

Despite the relatively recent appearance of this concept, over 400 suppliers and manufacturers of cosmeceutical products have been estimated. *Amer* and *Maged* [44.27] classified the products in the cosmeceutical market into four major categories: nonbleaching agents, antioxidants, peptides, and growth factors. The market estimations project increases in the demand of cosmeceutical ingredients. Annual growth rates ranging from 4–25% and 4–10% have been reported for the periods 2002–2007 and 2007–2012, the injectables and age-defying products being the most dynamic segments, especially in emerging economies [44.13].

Because of their unique position as neither cosmetics nor pharmaceuticals, no specific regulation exists for these products [44.13]. Depending on the regulations of different countries, a group of products can be considered as cosmetic, therapeutic goods, or drug [44.28]. Since the main concern for functional products is safety and efficacy, it is likely that legislation covering pharmaceuticals will change to include nutraceuticals and cosmeceuticals to make efficacy claims. Consumers are often exposed to product information that is not scientifically sound or backed by rigorous clinical stud-

ies since the multitude of cosmeceutical products are not specifically regulated [44.17, 23, 28]. Appropriate controls on the safety of products, consumer protection, the extent of regulatory definition, market fairness, and inconsistency between countries have been suggested [44.28]. Dermatologists should familiarize themselves with the available products and assess their quality before recommending cosmeceuticals to their patients [44.13, 29, 30]. For practical applications and to effectively bring a new material to the marketplace, the viewpoints of many different agents should be considered, including: environmentally sustainable production, performance of the ingredients, confirmation of the mechanisms of action, quality assurance, regulations in markets around the world; and adequacy of supply to fulfill market demand with competitive pricing [44.31].

Recent trends in cosmeceutical development include skin protection from radiation and oxidative damage and the discovery of bioactives with the ability to scavenge free radicals and to prevent aging [44.32]. Particular focus is given to nonirritating ingredients to develop safer naturally-derived products [44.27], with components from plants and marine organisms, particularly those pure and uncontaminated. One example are the Antarctic and Southern Ocean seaweeds and marine microalgae, which show great potential due to their adaptation to survive under stressing osmotic pressure and temperature conditions, resulting in increased phycocolloid and polyunsaturated fatty acids contents [44.33]. Recent studies have addressed the screening of bioactive compounds from cold [44.34] and tropical waters [44.9, 35]. The complex matrix of cosmetics usually contains a high number of ingredients and emulsions. Nanoemulsions have attracted considerable attention in recent years as potential vehicles for the controlled delivery of bioactives because of their technological advantages to improve the availability and efficacy of lipophilic bioactives and to avoid changes during storage [44.36]. Nutricosmetics are another type of product than combine the cosmetic effect with nutritional supplements that can support the function and the structure of the skin, but they are not considered in the present chapter.

44.4 Target Organs and Cosmetics Delivery Systems

The skin is the main objective of cosmetic treatments, the other target organs for cosmetic products are hair and nails. Skin forms the interface between the human body and the environment, and is made up of three distinct layers: the epidermis, the dermis, and the hypodermis. The epidermis represents a physical, biochemical, and immunological barrier. The outermost layer of the epidermis is the stratum corneum, a continuous layer of protein-enriched cells embedded in an intercellular matrix enriched in non-polar lipids and organized as lamellar lipid layers [44.37]. It is responsible for the prevention of the loss of water and electrolytes, immune defense, and protection against ultraviolete (UV) radiation and oxidative damage and it is also capable of withstanding mechanical forces and preventing toxic substances from penetrating the skin.

The changes in this epidermal barrier can alter the appearance and the functions of the skin. Skin undergoes aging mainly as a consequence of genetic and external factors; UV irradiation from the sun causes oxidative damage and is the primary environmental factor causing skin aging and increasing the risk of cutaneous neoplasms [44.38, 39]. Whereas some symptoms, such as skin laxity or dyschromia, are observed on the surface, the origin is in deeper layers: the dermis and subcutaneous tissues. The penetration routes of drugs into the skin include the hair follicles, interfollicular sites, and through corneocytes and lipid bilayer membranes of the stratum corneum [44.40, 41].

Traditionally, most skin treatments are applied topically. Semisolid ointments or emulsions are the primary active delivery systems and the biphasic nature of emulsions allows the placement of actives based on solubility and stability [44.42]. Novel skin care methods target multiple aging mechanisms by utilizing functional active ingredients in combination with innovative delivery systems to increase stratum corneum permeability for cosmetic formulations and novel delivery systems, such as lipid systems, nanoparticles, microcapsules, . . . [44.43].

44.5 Components of Cosmetics

The general composition of a cosmetic includes an active ingredient, some excipients, thickening agents, additives, preservatives, colorants, and perfumes.

44.5.1 Active Compounds in Cosmetics

The active ingredient is the main substance, or substances, which confer the required activity to the cosmetic, i. e., the tensioactive in a shampoo, the colorant or pigment in a nail polish, or the moisturizers (glycerin, lactic acid, or urea) in a hand cream. It will determine the function of the cosmetic and its classification.

44.5.2 Excipients

Excipients are the vehicle ingredients with the function of dissolving or dispersing the active agents and other cosmetic ingredients. It is essential to choose them correctly, since they determine and control the delivery and effectiveness of the cosmetic in the targeted area, as well as the cosmetic form and presentation to the end user. The same cosmetic could be presented in different forms if different excipients are used. The most used excipients are water, alcohol, glycerin, acetone, vaseline, and lanoline.

The main purpose of stabilizers is to disperse the additives, thicken the fluid, and maintain the stability of the cosmetic during its lifetime. Thickeners, such as polymers and methyl cellulose, increase the viscosity of the formula. Humectants avoid dehydration by binding water; among the most frequent are glycerine, propylene glycol, and sorbitol. Chelating agents form complexes by binding with undesirable ions present in the formula, which could interfere with the properties of the cosmetic. pH modifiers are added to adjust the pH level close to the values of the skin. Citric, tartaric, or lactic acids are used to acidify the media and triethanolamine to raise the pH. Suspending agents, such as tensioactives, are used to improve the solubilization of some active ingredients, i. e., the dispersion of oily perfumes in aqueous solutions.

44.5.3 Additives

Preservatives

Preservatives are added to prevent or delay alterations in cosmetics, at least until the expiration date. According to the modifications to be prevented, these agents can be classified into antioxidants and antimicrobials.

Antioxidants

Their function is to prevent oxidation of fats and oils and the active principles present in the cosmetic formulations. Oxidative rancidity of fats and oils is caused by the degradation by oxygen in the air and occurs in a series of chain reactions involving free radicals. Oxidized fats become yellowish in color and the undesirable odors produced impair the cosmetic. Depending on their mechanism of action, different categories of antioxidants are established:

- Reducing agents, they become readily oxidized, preventing the oxidation of the active compounds; ascorbic acid and thiourea are examples of this type.
- Blocking agents that stop the oxidation chain without being consumed, i. e., butylated hydroxytoluene (BHT) and tocopherols (vitamin E).
- Synergistic agents increase the effectiveness of some antioxidants, i. e., citric acid and tartaric acid.
- Chelating agents form complexes with metal ions that can act as catalysts for the oxidative processes; ethylenediaminetetraacetic acid (EDTA) is one of the most used.

Antimicrobials

Antimicrobials prevent and protect the cosmetic product from microbial contamination (bacteria and fungi). Their addition is required to avoid contamination and growth of pathogenic germs over some threshold values that could lead to both deterioration of the product (turbidity, presence of molds, ...) and to health damage (skin infections). Among those frequently used are: nipasol (propyl *p*-hydroxybenzoate), nipagyn (methyl *p*-hydroxybenzoate), triclosan (2,4,4′-trichloro-2′-hydroxy diphenyl ether), dowicyl 200 (Quaternium-15), and imidazolidinyl-urea (1,1′-methylenebis and alkyldimethylbenzylammonium chloride (ADBAC).

Some cosmetics do not require additional preservatives, such as those containing an antiseptic ingredient, i. e., ethyl alcohol, and those sold in sealed ampoules, in this case the protection is restricted to the period when the cosmetic is closed.

Perfumes and Colorants

Perfume and colorant compounds are added with the function of providing a pleasant odor and color to the

final cosmetic, thus increasing the consumer interest in the product. In some cases, they can also serve to mask unpleasant odors and color resulting from mixing and processing the components of the cosmetic. Usually perfumes and dyes are associated with certain natural products, i. e., pink with the scent of strawberries or roses, green with mint, yellow with lemon, blue with the sea, ... Due to the low amount of dye and perfume added to cosmetics, in many formulations, information on their content is not assigned or provided, leaving this amount to the criteria of the manufacturer.

Water

Since ancient times, water has been used for both hygienic and curative purposes. It has been suggested that cavemen used it for this latter purpose, since they observed that injured animals flocked to warmer springs and to the sea to relieve their injuries.

44.6 Major Functions of Some Marine Components in Cosmetics and Cosmeceuticals

In this section, a survey of the major activities provided by marine-derived components with application in cosmetics and cosmeceuticals is presented. The traditional classification into both additives or ingredients and active agents was followed. However, recent studies have evidenced the biological actions of some fractions, i. e., hydrocolloids or pigments, conventionally used for thickening or for coloring purposes, respectively, and they could also provide other beneficial actions.

44.6.1 Physicochemical and Technological Properties

Surfactants, Emulsifiers, Thickeners, Stabilizers, Moisturizers, and Gelling Agents

Surfactants and emulsifiers are amphiphilic compounds containing both hydrophilic and hydrophobic moieties with many potential applications related to emulsification foaming, wetting, dispersion, and solubilization of hydrophobic compounds [44.44]. Marine microorganisms have been studied for the production of biosurfactants and bioemulsifiers [44.45], including protein polysaccharide complexes from *Acinetobacter* [44.46], *Pseudomonas* [44.47], *Myroides* [44.48], *Streptomyces* [44.49], *Yarrowia* [44.50], *Rhodotorula* [44.51], and *Halomonas* [44.52]; glycolipids from *Halomonas* [44.53], *Rhodococcus* [44.54], and *Alcanivorax* sp. [44.55]; lipopeptides from *Bacillus* sp. [44.56, 57] and from the sponge-associated marine actinomycetes *Nocardiopsis* [44.58, 59]; bile from *Myroides* bacterial strains [44.60]; and exopolysaccharides from *Bacillus* [44.61], *Planococcus* sp. [44.62], and *Cyanothece* sp. [44.63]. Table 44.1 shows some examples of marine ingredients with cosmetic application and their major technological properties. Marine lecithins, a mixture of phospholipids comprising predominantly long-chain and highly unsaturated fatty acids esterified on the glycerol backbone, are natural emulsifiers with traditional cosmetic use. Lecithins show excellent gelation in non-polar solvents when combined with water [44.64] and serve as an organic medium to enhance dermal penetration of poorly permeable drugs by effectively partitioning into the skin.

Seaweeds are the major source for thickeners, stabilizers, and gelling agents in the cosmetic and pharmaceutical industries, the so-called phycocolloids that include alginate, carrageenan, and agar. Alginates, cell-wall polyuronic acids from brown seaweeds, exhibit gelling properties resulting from their anionic properties and differing ratios of β-D-mannuronic and α-L-guluronic acids. They act also as wound healers and as excipients absorbable by the epidermis. Carrageenans, isolated from marine red algae, are widely used as emulsifiers, gelling, stabilizers, or thickeners in toothpastes, lotions, sun ray filterers, shaving creams, shampoos, hair conditioners, and deodorants. In toothpaste, carrageenan is used as a stabilizer to prevent ingredients from separating. Shampoos and cosmetics creams contain carrageenans as thickening agent [44.65, 66].

Chitosan is a multifunctional bioactive compound and is widely used in food, biotechnology, cosmetics, and medicine. Chitosan, which is soluble in acidic media, is a natural polysaccharide that is obtained from the polysaccharide chitin [44.67]. Chitin (poly(β-(1 $\rightarrow$ 4)-*N*-acetyl-D-glucosamine)) is one of the most abundant biopolymers in nature after cellulose. Chitins are synthesized by sea animals, such as annelida, mollusca, previously named coelenterate and crustaceans (lobster, crab, shrimp, prawn, and krill), microorganisms such as green algae, yeast (β-type), fungi (cell walls), brown algae, spores, chytridiaceae, ascomydes, and blastocladiaceae [44.68]. Chitosan can be obtained from shrimp

Table 44.1 Technological properties of some ingredients from marine sources with cosmetic use

Active component	Source	References
Surfactants, emulsifiers, thickeners, stabilizers, moisturizers, and gelling agents		
Acid- and/or pepsin-soluble collagen	Fish species, *Illex coindetii* (squid), deep-sea redfish, threadfin bream, walleye pollock, brownstripe red snapper, or unicorn leatherjacket	[44.69]
Alginates	Brown algae	[44.65]
Bile acids	*Myroides*	[44.60]
Carrageenans	Red algae	[44.65]
	Myroides, Streptomyces, Yarrowia, Rhodotorula, Halomonas	[44.48–52]
Chitosan and chitin	Sea animals as annelida, mollusca, coelenterata, and crustaceans (lobster, crab, shrimp, prawn, and krill), microorganisms such as green algae, yeast (β-type), fungi (cell walls), brown algae, spores, chytridiaceae, ascomydes, and blastocladiaceae	[44.68]
Collagen	*Scylla serrata*; *Chondrosia reniformis*; bivalve molluscs; *Ircina fusca, Takifugu rubripes* skin	[44.70–74]
Exopolysaccharides	*Bacillus, Planococcus, Cyanothece*	[44.61–63]
Gelatin	Fish species (cod, Atlantic salmon, megrim, squid, Nile perch, hake, skate, grass carp, yellowfin tuna, and channel catfish)	[44.75, 76]
Glycolipids	*Halomonas*	[44.53]
Lipopeptides	*Bacillus, Nocardiopsis alba*	[44.56–58]
Colorants		
Phycocyanin	Cyanobacteria	[44.77]
β-phycoerythrin	*Porphyridium cruentum*	[44.78]
R-phycoerythrin	*Corallina elongata*	[44.79]
Astaxanthin	*Penaeus semisulcatus*	[44.80]

by-products, which are annually produced in high amounts [44.81]. Chitosan and its derivatives are ingredients in various cosmetics, nail lacquers, toothpaste, lotions, hand and body creams, and hair care products, where they are used as emulsifiers, surfactants, gelling, stabilizers, thickeners, film-former, and also to encapsulate active compounds [44.82]. Chitin-related products, particularly chitosan and its derivatives, are used in several fields as a new type of functional material, based on their diverse biological and physicochemical characteristics [44.83]. They promote wound healing and are suited for cosmetic restoration. The combination with other active agents has been proposed, i. e., with taurine, which has effects on cell proliferation, inflammation, and collagen synthesis, and exhibits antioxidant effects [44.84]. The cosmetic use of chitosan accounts for 5% in the global market, although at the European level this application represents 20% [44.83].

Gelatin is a soluble protein compound obtained by partial hydrolysis of collagen. The most important properties of collagen and gelatin are associated with their gelling and water binding behavior (gel formation, texturizing and thickening) and their surface behavior (emulsion formation and stabilization, adhesion and cohesion, and protective colloid function). Traditionally the cosmetic application of gelatin was based on its gel-forming and viscoelastic properties, but more recently it has been used as a moisturizer in cosmetic creams for dry skin and has high potency in tissue regeneration [44.69]. Collagen from sea animals, such as the marine sponges *Ircina fusca* [44.74] and *Chondrosia reniformis* [44.72], sea urchins [44.85], the marine crab *Scylla serrata* [44.70], or bivalve molluscs [44.73] is a safer alternative to those of terrestrial origin [44.71, 72]. The number of fish or marine species studied for gelatin extraction is continually growing due to the interest in valorization of by-products from the fish industry [44.69, 75, 76].

Moisturizers have beneficial effects in treating dry skin. Orange roughy (*Hoplostethus atlanticus*) oil, a marine-derived wax ester, performed comparably to a petrolatum-based moisturizer (vaseline) in clinical trials in subjects with moderate to severe skin dryness [44.86].

Colorants

A wide variety of pigments, like chlorophylls, carotenoids, and phycobiliproteins, which exhibit colors ranging from green, yellow, and brown to red are present in algae and in other marine organisms.

The carotenoid pigments have significant application in the cosmetic industry, especially astaxanthin, which is found in salmon, rainbow trout, sea bream, lobster and caviar, crustaceans, the marine bacterium *Agrobacterium aurantiacum*, and the green microalga *Haematococcus pluvialis* [44.80].

Phycobiliproteins, including phycoerythrin, phycocyanin, allophycocyanin, and phycoerythrocyanin, are a group of colored proteins commonly present in cyanobacteria (blue–green algae), in a class of biflagellate unicellular eukaryotic algae (cryptomonads), and in Rhodophyta (red algae). They are used in the cosmetic industry to replace synthetic dyes that may be toxic, carcinogenic, or otherwise unsafe [44.87, 88]. In Japan, where algal cultivation is a well-developed industry, some natural pigments from phycobiliproteins were have patented early [44.89]. β-phycoerythrin is the most valuable of the phycobiliproteins due to its intense and unique pink color [44.90], heat stability, and pH tolerant characteristics, and has been applied as natural pink and purple colorants for lipsticks, eyeliners, and also formulations for cosmetic products [44.91]. Phycocyanin, a blue pigment, is also used as a colorant in eyeliners [44.77].

Carotenoids are isoprenoid molecules synthesized *de novo* by photosynthetic plants, fungi, and algae. Carotenoids are lipophilic compounds, some of which act as provitamin A. These compounds are classified into two major groups based on their structural elements; carotenes, constituted by carbon and hydrogen (e.g., β-carotene, α-carotene and lycopene), and xanthophylls, constituted by carbon, hydrogen, and additionally oxygen (for example, lutein, β-cryptoxanthin, zeaxanthin, astaxanthin, and fucoxanthin). Industrially, these carotenoids are used as pigments in food, feed, cosmetics, and pharmaceuticals. They can be produced by chemical synthesis, fermentation, or isolation from natural sources; most commercially used carotenoids (for example, β-carotene, astaxanthin, and canthaxanthin) are obtained by chemical synthesis [44.92].

Many macroalgae and microalgae are rich in carotenoids, which aid in the absorption of sunlight. Compared to other sources, the production of carotenoids from algae has many advantages, including lower costs, easy and environmentally friendly extraction, and the possibility of supplying materials without limitations or seasonal variations [44.93]. Recently, there has been considerable interest in carotenoids associated to their antioxidant properties [44.94–96] and because of their antiobesity and anabolic effects [44.97–99].

Antioxidants

The antioxidant activity of many marine-derived substances has been studied extensively [44.100–102]. The interesting aspect of this property is not only in relation to the increase in shelf life of the products, by delaying or avoiding the oxidation of fats and oils, but also due to other biological actions. The imbalance between generation of the reactive oxygen species (ROS) and the scavenging or detoxification by the organisms causes oxidative stress, which could lead to disruptions in normal mechanisms of cellular signaling and be involved in the development of aging and chronic diseases. Different marine-derived compounds have been confirmed as potent antioxidants, including oligosaccharides, peptides, phlorotannins, carotenoids, and vitamins. Table 44.2 shows some examples of the major components obtained from marine sources, which could be responsible for antioxidant properties. Due to the extensive and growing number of publications, only review papers are mentioned to illustrate the potential of some fractions from macroalgae. In most studies crude extracts and fractions are evaluated, and the presence of a mixture of compounds can provide a more potent antioxidant action because of the synergistic interaction between them [44.100].

Mixtures of different compounds have also been proposed; one example is the combination of isolated and purified marine oligosaccharides with collagen peptides derived from tilapia fish skin. This preparation showed a higher radical scavenging activity than the individual components [44.103].

Algae are one of the most studied sources of marine antioxidants. Extracts from brown algae have been observed to be more effective than those from red and green algae in terms of antioxidant activity [44.102, 122]. One of the suggested reasons for this is the phlorotannin content, and the characterization of some phloroglucinol derivatives has been published [44.123–126]. However, other components, from the polysaccharide and carotenoid fraction [44.96], are efficient antioxidants and could contribute to this activity. Aqueous and solvent extracts are the most used, but alternative processes have been proposed, i. e., fermentation of the *Ecklonia cava* processing byproduct [44.127]. Other relevant sources include the microalgae to produce carotenoids, the fish protein fraction to obtain peptides [44.94, 128, 129], and fish roe as a source of gadusol [44.130]. Less explored organisms have been studied, i. e., the marine phanerogam *Syringodium filiforme*, growing associated to *Thalassia testudinum* [44.131] or less conventional agents, such as

Table 44.2 Major families of compounds from marine sources showing in vitro antioxidant activity

Component	Source	Antioxidant activity	References
Carotenoids and other terpenoids	Microalgae, macroalgae marine sponges	Radical scavenging: DPPH, 12-DS, NB-L, AAPH, ABTS, ABAP, superoxide anion, TRAP Cu–Zn SOD and activity catalase activity in rat plasma and erythrocytes	
		Protection against oxidation	[44.95, 104–106]
Peptides	Enzymatic hydrolysis of protein from fish by-products: skin, head, viscera, trimmings, liver, frames, bones, and roes	Reducing activity, scavenging activity against DPPH radical, ABTS radical superoxide anion, hydroxyl radical, hydrogen peroxide, lipid peroxidation inhibition activity, ferrous and cuprous ion chelating activity, prevention of oxidation in emulsion of β-carotene linoleic acid and in lecithin liposomes	[44.107–110]
Phlorotannins	Extracts from brown algae	Scavenging activity against DPPH radical, hydroxyl radical and superoxide anions, protection against oxidation, ferrous and cuprous ion chelating activity, reducing activity, protection against oxidative stress in cells, protection of membrane oxidation in cells	[44.102, 105, 111–113]
Vitamin C and E	Macroalgae and seagrasses; tropical, temperate, and polar fish	Scavenging activity against DPPH radical, reducing power, endogenous enzyme activity of superoxide dismutase and glutathione peroxidase	[44.12, 114, 115]
Low molecular weight fractions from algal polysaccharides	Aqueous extracts and fractions from seaweed further subjected to chemical and/or enzymatic hydrolysis	Scavenging activity against DPPH radical, hydroxyl radical and superoxide anions. Inhibition of H_2O_2 induced hemolysis of rat erythrocytes, protection on lipid peroxidation of liver homogenate, prevention of oxidation in emulsion of β-carotene linoleic acid, in phosphatidylcholine liposomal suspension, restoration of endogenous antioxidant enzymes: superoxide dismutase and glutathione peroxidase; ferrous ion chelating activity	[44.105, 116–121]

DPPH: 2,2-diphenyl-1-picrylhydrazyl; ABAP: 2,2′-azo-bis-2-amidinopropane; ABTS: 2′azinobis(3-ethylbenzothiazoline-6-sulfonic acid); SOD: superoxide dismutase; TRAP: total radical antioxidant parameter; AAPH: 2,2′-azobis(2-amidino-propane) dihydrochloride; 12-DS: 12-doxylstearic acid; NB-L: nitrobenzene with linoleic acid

5-hydroxymethyl- 2-furfural isolated from the red algae *Laurencia undulata* [44.132].

44.6.2 Biological Activities

Photoprotective and Anti-Photoaging

Skin is the largest part exposed in the human body, and it is well established that overexposure to UV radiation provokes acute sunburn reaction. Sun overexposure is clinically manifested as erythema, and chronically irradiated skin is associated with abnormal cutaneous reactions such as epidermal hyperplasia, accelerated breakdown of collagen, and inflammatory responses [44.133]. The use of photoprotective agents mainly determines the delay of the effects of photoaging by decreasing the adverse effects of free radicals. The increased public awareness towards the importance of skin care has fostered the study and the demand of compounds or extracts aimed at reducing the effects of UV irradiation as preventive or palliative agents. Recent studies have focused on marine organisms as a source of natural bioactive molecules and some UV-absorbing algal compounds are under investigation as candidates for new natural sunscreens, photoprotective, and antiphotoaging agents [44.134, 135]. Mycosporines and mycosporine-like amino acids (MAAs), which are accumulated by a wide range of microorganisms, prokaryotic (cyanobacteria), as well as eukaryotic (microalgae,

yeasts, and fungi), and a variety of marine macroalgae, corals, and other marine life forms, can be used as sunscreen compounds [44.136–138].

Solvent extracts from algae [44.135, 139, 140] and from other organisms, such as fungi, lichens, bacteria, cyanobacteria, and marine animals [44.141, 142] have been explored as a source of novel photoprotective compounds for the formulation of pharmaceutical and cosmeceutical products. Several pure algal compounds have shown this activity, for example, sargaquinoic acid and sargachromenol from *Sargassum sagamianum* [44.143], dieckol from *Ecklonia cava* [44.133], or fucoxanthin from *Sargassum siliquastrum* [44.144]. Bacterial exopolysaccharides, i. e., from the bacterium *Alteromonas macleodii*, have also been proposed to alleviate ultraviolet B radiation (UVB) aggression [44.145].

Anti-Wrinkling and Skin Regeneration

Skin aging involves changes in skin physical properties and visible signs on the surface due to the degradation of the extracellular matrix in both the epidermal and dermal layers, producing visible signs such as irregular dryness and pigmentation, sallowness, telangiectases, premalignant lesions, laxity, and wrinkling. Some anti-aging cosmetics are designed to treat premature aging caused by environmental factors [44.146]. The skin regeneration properties of some red algae, such *as Porphyra atropurpurea* and *Chondrus crispus*, have been used traditionally to treat wounds and burns [44.147]. The methanol extracts of the alga *Corallina pilulifera* reduced the expression of human matrix metalloproteinases MMP-2 and -9 induced by UV irradiation in fibroblasts [44.148]. *Joe* et al. [44.149] demonstrated the inhibitory effect of eckol and dieckol from *Ecklonia* species on MMP-1 expression in human dermal fibroblasts and suggested their use for the prevention and treatment of skin aging.

Depigmenting or Whitening

Tyrosinase, also referred to as polyphenol oxidase, is a metalloenzyme oxidase that catalyzes two distinct reactions of melanin synthesis in which l-tyrosine is hydroxylated to L-3,4-dihydroxyphenylalanine L-DOPA (monophenolase activity). The latter is subsequently oxidized to dopaquinone (diphenolase activity). Tyrosinase is the rate-limiting enzyme in melanin production, which occurs in melanocytes that are located within the basal epidermis [44.150]. Melanin has a photoprotective function in human skin, but its abnormal accumulation can result in hyperpigmentation with undesirable esthetic implications [44.151]. The downregulation of tyrosinase is an efficient method for the inhibition of melanogenesis, addressed by a number of approaches, including the direct inhibition of tyrosinase, the acceleration of tyrosinase degradation, the inhibition of tyrosinase mRNA (messenger ribonucleic acid) transcription, aberration of tyrosinase glycosylation or interference with melanosome maturation and transfer [44.151]. Accordingly, a huge number of compounds acting by alternative approaches have been identified successfully. The number of studies searching for potent melanogenesis inhibitors from natural sources for cosmetic uses is increasing, as there is a demand for tyrosinase inhibitors in the cosmetic industry due to their skin-whitening effect [44.152].

In a screening of 43 marine algae for antibrowning effects, *Endarachne binghamiae*, *Schizymenia dubyi*, *Ecklonia cava*, and *Sargassum siliquastrum* inhibited cellular melanin synthesis and tyrosinase activity similarly to kojic acid. Furthermore, whereas toxicity was observed in the positive controls, no toxicity was observed in the algal species [44.153]. Kojic acid was identified as the active compound isolated from the acetone extracts produced from selected strains in a screening study with 600 organisms of marine fungi [44.154]. Phlorotannins from marine brown algae are effective tyrosinase inhibitors and are potential ingredients for treating dermatological disorders associated with melanin [44.155]. Phloroglucinol, eckol, and dieckol from *Ecklonia cava* showed effects on melanogenesis via the inhibitory effect on tyrosinase and reduction of melanin synthesis, among them, dieckol showed higher activity than kojic acid [44.133] and also showed more effective melanin reducing activities than arbutin in B16F10 melanoma cells, without apparent cytotoxicity [44.156]. 7-phloroeckol from *Ecklonia cava* inhibited melanin production in melanoma cells more potently than arbutin and kojic acid [44.157]. In increasing order phlorofucofuroeckol A, eckstolonol, phloroglucinol, eckol, and dieckol from *Ecklonia stolonifera* inhibited tyrosinase [44.158]. Also diphlorethohydroxycarmalol demonstrated protective effects on melanogenesis [44.126]. Solvent extracts from bacteria of the *Pseudomonas* genus, associated with marine invertebrates, were found to be effective whitening agents in assays with cultured melanocytes, cultured skin, and in vivo zebrafish [44.156]. Other antimelanogenic compounds are fucoxanthin [44.144, 159], and geoditin A, an isomalabaricane triterpene isolated from the marine sponge *Geodia japonica*, with potent activity and relatively low cytotoxicity [44.160].

Human Skin Melanoma

Cutaneous melanoma is one of the most aggressive forms of skin cancer with high metastatic potential and strong resistance to radiation, immunotherapy, and chemotherapy [44.161]. The incidence of melanoma is rising at an alarming rate, possibly associated with the increased exposure to ultraviolet radiation, and has become a major public health concern in many countries [44.162].

The carotenoid fucoxanthin has antiproliferative effects in vitro and in vivo on melanoma B16F10 cells by inducing apoptosis and cell-cycle arrest [44.163]. A low molecular weight fraction of the water-soluble extract of *Porphyra yezoensis* inhibited proliferation of mouse B16 melanoma cells [44.164]. Several polysaccharide fractions, especially those from brown marine alga (*Ecklonia cava*, *Sargassum stenophyllum*, *S. hornery*, *Costaria costata*) decreased melanoma cell tumor growth [44.165–167]. Marine peptides and depsipeptides have shown antimelanoma activity. Among them aplidine, a cyclodepsipeptide isolated from the tunicate *Aplidium albicans*, and kahalalide F, a depsipeptide isolated from the herbivorous marine mollusk *Elysia rufescens*, *E. ornata*, or *E. grandifolia* has undergone phase III clinical study in patients with advanced malignant melanoma [44.129, 168].

Jaspine B, an anhydrophytosphingosine derivative isolated from the marine sponge *Jaspis* sp., decreases the viability of murine B16 and human SK-MEL-28 melanoma cells in a dose-dependent manner. Jaspine B is able to kill melanoma cells by acting on sphingomyelin synthase, an enzyme that converts de novo ceramide into the membrane lipid sphingomyelin, and may represent a new class of cytotoxic compounds [44.169]. Exposure of SK-MEL-2 cells to dideoxypetrosynol A, a polyacetylene from the sponge *Petrosia* sp., resulted in growth inhibition and induction of apoptosis in a dose-dependent manner [44.170]. Marinomycin A from a marine actinomycete of the genus *Marinispora* showed remarkable selectivity for melanoma cell lines in the US National Cancer Institute's (NCI) 60-cell panel [44.171]. A biindole, halichrome A, from the marine sponge *Halichondria okadai*, exhibited cytotoxicity against melanoma cells [44.172]. Also unusual polyunsaturated fatty acids (PUFAs), such as several $\omega 3$ fatty acids and the $\omega 7$ heneicosa-5,8,11,14-tetraenoic acid (21 : 4 n-7) from the marine opisthobranch *Scaphander lignarius*, were active against human cancer cell lines of melanoma [44.173]. Elatol, a sesquiterpene isolated from algae *Laurencia microcladia*, showed in vitro and in vivo antitumor properties [44.174]. Synthetic derivatives of marine natural products have also been proposed, i. e., sarcodiol, a derivative of sarcophine that inhibits melanoma cell proliferation [44.175].

Anti-Pruritic, Anti-Inflammatory Activity, and Antiallergic Activity

Inflammatory skin diseases such as contact dermatitis, atopic dermatitis and psoriasis are skin disorders that constitute a major health problem worldwide. One of the most challenging pruritic skin inflammatory diseases needing a better therapeutic approach is atopic dermatitis. This skin inflammatory disease can occur at any age and is characterized exclusively by the elevated serum immunoglobulin E (IgE) levels and peripheral eosinophilia. Inhibition of IgE production or reduction in the concentration of IgE would be the optimal therapeutic approach in treating inflammatory skin diseases [44.176].

Allergic diseases are caused by chemical or immunological activation of mast cells leading to a massive release of endogenous mediators, such as histamine, as well as a wide variety of other inflammatory mediators, such as eicosanoids, proteoglycans, proteases, and several proinflammatory and chemotactic cytokines. Among the inflammatory substances released from the effector cells, histamine remains the best characterized and most potent vasoactive mediator implicated in the acute phase of immediate hypersensitivity. An allergic reaction that produces mild to moderate symptoms can be easily treated with antihistamine compounds [44.177].

Many natural compounds from natural marine organisms exhibit antiallergic and anti-inflammatory properties and hyaluronidase inhibitory activities [44.178]. Hyaluronidase is an enzyme that depolymerizes the polysaccharide hyaluronic acid in the skin and is known to be involved in allergic effects, migration of cancers, and inflammation. Mainly marine algae have received much attention because they are a valuable source of chemically diverse bioactive compounds with numerous health benefits in the treatment of allergic disorders [44.177].

The levels of serum IgE and histamine were suppressed in rats fed a diet supplemented with a dried *Eisenia arborea* extract [44.179, 180]. Phlorotannins are the most studied group of compounds that have shown potential pharmacological applications as antipruritic, anti-inflammatory, and antiallergic agents [44.112, 155]. Several phlorotannins exhibit potential antiallergic action on human and rats

basophilic leukemia cultured cell lines, 6,6′-bieckol, 1-(3′,5′-dihydroxyphenoxy)-7 (2″,4″,6-trihydroxyphenoxy)-2,4,9-trihydroxydibenzo-1,4-dioxin, and dieckol suppressed binding activity between immunoglobulin E (IgE) and high-affinity receptor for the Fc region of immunoglobulin E (FcεRI) receptors [44.181], and fucodiphloroethol and phlorofucofuroeckol A reduced histamine release [44.182, 183]. Phlorotannins such as eckol, phlorofucofuroeckol A, dieckol, and 8,8′-bieckol isolated from *Eisenia bicyclis* and *Ecklonia kurome* have shown a stronger inhibition effect against hyaluronidase than well-known inhibitors such as catechin and sodium cromoglycate [44.184]. From these results, it is understood that phlorotannins can be useful in the management of allergic and inflammatory skin diseases through the reduction of IgE concentration and their histamine inhibitory activities. The carotenoid fucoxanthin was found to exhibit anti-inflammatory effects [44.185].

The polysaccharidic fractions of marine algae have promising anti-inflammatory activities [44.186]. Alginic acid exhibited an inhibitory effect on hyaluronidase and on histamine release from mast cells [44.187], suppressed antigen-induced Th2 development by inducing interleukin IL-12 production, and inhibited in vivo IgE production, suggesting its potential as an antiallergic agent [44.188]. Fucoidan significantly reduced IgE production in human peripheral blood mononuclear cells of patients and healthy donors, even after the onset of atopic dermatitis [44.189]. Oral administration of porphyran, a major component of the red algae *Porphyra tenera* and *P. yezoensis*, suppressed the contact hypersensitivity reaction (ear edema) induced by 2,4,6-trinitrochlorobenzene [44.190]. Epicutaneous application of sacran, a sulfated polysaccharide extracted from the alga *Aphanothece sacrum*, inhibited the development of allergic dermatitis skin lesions in mice [44.191].

PUFAs are metabolized by skin epidermal enzymes into anti-inflammatory and antiproliferative metabolites that are associated with a variety of benefits regarding inflammatory skin disorders [44.192, 193]. PUFAs can be recovered from marine protists and microalgae [44.194], Antarctic krill [44.195], marine and fish products, and by-products [44.196, 197]. Among the fatty acids, the ω3-PUFA, eicosapentaenoic acid (EPA, 20 : 5n-3), and docosahexaenoic acid (DHA, 22 : 6n-3), possess potent immunomodulatory activities [44.198] and can reduce the sensitivity of human skin to sunburn [44.199]. Animal experiments and clinical intervention studies indicate that diseases such as lupus erythematosis and psoriasis, characterized by a high level of IL-1 and the proinflammatory leukotriene LTB4 produced by ω-6 fatty acids, can be treated with ω-3 fish oil [44.198]. In this context, marinosomes, i. e., liposomes made of a natural marine lipid extract, were envisaged for the prevention and treatment of skin diseases [44.200].

Antimicrobial Activity

Bacterial skin infections are very common and can range from being merely annoying to deadly. Most bacterial infections of the skin are caused by two bacteria, *Staphylococcus aureus* and a form of *Streptococcus*. Viral infections of the skin are common and include warts, cold sores, chicken pox, shingles, molluscum contagiosum; and hand, foot, and mouth disease. The three main types of viruses that cause most viral skin infections are the human papilloma virus, the herpes simplex virus type 1 (HSV-1, HSV-2) and the pox virus. Whereas these viruses cannot be cured, their effects on the skin can be prevented or minimized through proper medical treatment. Examples of compounds from marine origin showing antimicrobial and antiviral action are listed in Table 44.3. This activity is also interesting with respect to the protection of cosmetic products from microbial contamination, thus having the role of preservatives.

A number of studies has been performed concerning the antimicrobial activity of phenolic compounds isolated from marine sponges. 2-(2′,4′-dibromophenoxy)-4,6-dibromophenol from the marine sponge *Dysidea granulosa* exhibited potent and broad spectrum in vitro antibacterial activity, especially against methicillin-resistant and sensitive *Staphylococcus aureus*, vancomycin-resistant and -sensitive *Enterococci*, and *Bacillus* sp. [44.198]. Marinomycin A from a marine actinomycete of the genus *Marinispora* [44.171] and dehydroxychlorofusarielin B, a diterpene from the marine-derived fungus *Aspergillus* sp., exhibited antibacterial activity against *Staphylococcus aureus* and methicillin-resistant *S. aureus* [44.207]. Parabens, widely used in cosmetics, can be biosynthesized by a marine bacterial strain belonging to the genus *Microbulbifer* [44.216]. To illustrate the potential of algae, examples related to recent studies are summarized, either evaluated as extracts [44.217] or as pure compounds and fractions. Phlorotannins (phloroglucinol, eckol, fucofuroeckol-A, phlorofucofuroeckol-A, dioxinodehydroeckol, 8,8′-bieckol, 7-phloroeckol, and dieckol; and triphloroethol A, 6,6′-bieckol and 8,4‴-dieckol) from brown algae were active against *Campylobacter jejuni*, *Escherichia coli*, *Klebsiella pneumonia*,

Table 44.3 Some active components and their bioactive properties

Active component	Source	Reference
Photoprotective and antiphotoaging		
Aqueous ethanolic extract: thalassiolin B	*Thalassia testudinum*	[44.141]
Carotenoids	Cyanobacteria, bacteria, fungi, phytoplankton, macroalgae, plants, and animals	[44.201]
Methanol extracts	*Corallina pilulifera*	[44.148]
Mycosporine-like amino acids (MAAs)	Cyanobacteria, microalgae, yeasts, fungi, macroalgae, corals Arthropods, rotifers, molluscs, fishes, cnidarians, tunicates, eubacteriobionts, poriferans, nemertineans, echinodermates, platythelminthes, polychaetes, bryozoans, and protozoans *Gracilaria birdiae, G. domingensis*	[44.136–138, 201–203]
Phenolic extracts	*Macrocystis pyrifera, Porphyra columbina Sarcothalia radula, Gigartina skottsbergii*	[44.139]
Phlorotannins (mainly dieckol)	*Ecklonia cava*	[44.133]
Polypeptide	*Chlamys farreri*	[44.204]
Sargaquinoic acid and sargachromenol	*Sargassum sagamianum*	[44.143]
Antimelanogenesis (antityrosinase and melanin synthesis)		
Anhydrophytosphingosine derivative Jaspine B	*Jaspis sp.*	[44.169]
Dieckol	*Ecklonia cava*	[44.150]
Diphlorethohydroxycarmalol	*Ecklonia cava*	[44.126]
Fucoxanthin	*Ecklonia cava*	[44.144, 159]
Geotidin A	*Geodia japonica*	[44.160]
Kojic acid	*Marine fungi*	[44.154]
Marinomycin A	*Marinispora*	[44.171]
7-Phloroeckol	*Ecklonia cava*	[44.157]
Phloroglucinol, eckol, and dieckol	*Ecklonia cava*	[44.133]
Phlorotannins	Brown algae	[44.155, 205]
Phloroglucinol, eckstolonol, eckol, phlorofucofuroeckol A, and dieckol	*Ecklonia stolonifera*	[44.158]
	Endarachne binghamiae, Schizymenia dubyi, Ecklonia cava and Sargassum siliquastrum	[44.153]
Polyacetylene dideoxypetrosynol A	*Petrosia* sp.	[44.170]
Sulfated polysaccharide: fucoidan	*Sargassum* sp., *Fucus vesiculosus*	[44.189]
Solvent extracts	*Pseudomonas*	[44.156]
Antiallergic and anti-inflammatory skin activity		
6,6′-bieckol, 1-(3′,5′-dihydroxyphenoxy)-7 (2″,4″,6 trihydroxyphenoxy)-2,4,9-trihydroxydibenzo-1,4-dioxin and dieckol	*Ecklonia cava*	[44.181]
Eckol and dieckol	*Ecklonia stolonifera*	[44.149]
Eckol, phlorofucofuroeckol A, dieckol, and 8,8′ -bieckol	*Ecklonia bicyclis* and *E. kurome*	[44.184]
Phlorofucofuroeckol-B	*Eisenia arborea*	[44.182]
Polysaccharide alginic acid	Brown algae	[44.187]
Sulfated polysaccharide fucoidan	Brown algae	[44.189]
Sulfated polysaccharide porphyran	*Porphyra tenera, P. yezoensis*	[44.190]
Sulfated polysaccharide sacran	*Aphanothece sacrum*	[44.191]

Sulfated polysaccharide naviculan	*Navicula directa*	[44.215]

Staphylococcus aureus, and *Vibrio parahaemolyticus*. Dieckol was also active against *Trichophyton rubrum*, a human tinea pedis fungus [44.111]. Methanol extracts of *Ulva fasciata* showed potent inhibition of the oral pathogenic bacteria *Actinomyces viscosus*, *Streptococcus mitis*, and *S. mutans*, suggesting possible uses in preventing and treating dental caries [44.218]. Laurene-type sesquiterpenes from the red alga *Laurencia obtusa* exhibited potent activity against the Gram-positive *Bacillus subtilis* and *Staphylococcus aureus*, and *Candida albicans* [44.219]. Diterpene sargafuran from *Sargassum macrocarpum* [44.208] and solvent extracts from *Ecklonia cava*, *E. kurome*, *Ishige sinicola*, and *Symphyocladia latiuscula* exhibited potent inhibition against *Propionibacterium acnes* [44.220], showing potential to be developed into new skin care cosmetics to prevent or treat acne. A crude sulfated polysaccharide from the red alga *Gracilaria ornata* inhibited the growth of *Escherichia coli* [44.221]. A polysaccharide from the green algae *Chaetomorpha aerea* exhibited selective antibacterial activities against Gram-positive bacteria [44.222]. Methanolic extracts of some cyanobacteria inhibited the growth of *Pseudomonas* [44.223]. Sea cucumber extracts were an efficient antibacterial and antifungal agent against *Escherichia coli*, *Aeromonas hydrophila*, *Enterococcus* sp., *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Staphylococcus aureus*, *Aspergillus fumigatus, Fusarium oxysporum*, *Cladosporium fulvum*, and *Monilia* sp. and *Vibrio harveyi*. The antimicrobial action has been ascribed to the presence of steroidal sapogenins, peptides, and triterpene glycosides [44.224].

Recently, great interest has been expressed regarding marine organisms such as algae, sponges, tunicates, echinoderms, mollusks, shrimp, bacteria, and fungi as promising anti-HSV agents [44.225]. Several researchers have investigated the inhibitory effects of sulfated polysaccharides on the herpes simplex virus strains HSV-1 and HSV-2 [44.186]. A sulfated polysaccharide from *Sargassum patens* significantly inhibits the in vitro replication of both the acyclovir-sensitive and resistant strains of HSV-1, in dose-dependent manners [44.210]. Galactofucan from *Undaria pinnatifida* [44.213] and *Adenocystis utricularis* [44.212], and a novel series of DL-galactan hybrids extracted from the red seaweed *Gymnogongrus torulosus* [44.211] showed a high inhibitory activity against herpes HSV-1 and HSV-2, with no cytotoxicity, whereas the uronofucoidans from *Adenocystis utricularis* carry no antiviral activity [44.212]. A sulfated polysaccharide from the marine microalga *Cochlodinium polykrikoides* showed antiviral activity against herpes HSV-1 [44.209]. A sulfated polysaccharide named naviculan was isolated from a diatom, *Navicula directa*, and showed antiviral activities against HSV-1 and HSV-2 [44.215]. A series of novel linear peptides, halovirs A–E, which are produced during the saline fermentation of the marine fungus *Scytalidium* sp., were potentin vitro against HSV-1 and HSV-2 [44.214].

44.7 Treatments Based on Marine Resources

Marine resources have traditionally been the basis of effective and safe therapies associated with well-being. Some aspects of thalassotherapy and, particularly, of algotherapy are discussed here.

The term thalassotherapy, from the Greek word for sea (thalasso), refers to the therapeutic use of seawater, sea products, and shore climate for their beneficial effects on the skin [44.226]. Standard procedures include hot seawater baths, underwater massage, jet showers, and algal and peloid therapy. Thalassotherapy is used as an alternative treatment for medical conditions and has become a popular tourist attraction for relaxation and stress reduction, and spa therapy is offered claiming prevention and treatment of dermatological diseases [44.227].

The term *peloid*, which was first defined in 1949 by the International Society of Medical Hydrology, during its 6th Conference held in Dax (France), refers to the therapeutic use in mask, cataplasm, or bath forms of naturally occurring clays and minerals mixed with organic matter after physical, chemical, biological, and geological modifications or maturation [44.228–230].

In thalassotherapy, trace elements found in seawater, such as magnesium, potassium, calcium, sodium, and iodine are believed to be absorbed through the skin. The marine water composition, with variable salinity content (usually 3.5%) is made up by the elements shown in Table 44.4 [44.231]. Filtered and processed by reverse osmosis membrane and electrodialysis seawater has shown antibacterial action, anti-inflammation potential, and superoxide anion radical scavenging capacity. It was proposed that magnesium, zinc, potassium, and calcium ions could be the bio-functional agents responsible for those effects. Acidic cosmetic water isolated from seawater decreased tyrosinase and melanin activities in human epidermal melanocytes (HEMn-MP) and presented anti-growth and antimigration effects on human skin melanoma cells (A375.S2) [44.235].

In contrast to other cosmetic ingredients, the benefits of topically appliedingredients, the benefits of topically applied mineral salts have been largely ignored and unexploited. The most famous example for balneotherapy is the Dead Sea minerals, reported to be safe and effective for dermatological disorders in both in vitro and in vivo studies [44.227, 236–238]. Magnesium, sulfur, sodium, bromine, and iodine are known for their healing properties for psoriasis sufferers and patients with rheumatic complaints, and appear to be the prominent actors in rheumatology and dermatology when incorporated in cream or mud [44.239]. Because of its effect in retention of water in the skin, regulation of the pH of the skin, acne repair and prevention, enhancing of blood circulation, and antiaging effect, sea mud has been added to cosmetic formulae, cosmetics, and therapeutic treatments [44.240].

Heated seawater baths have been recommended to stimulate a dilatation of cutaneous vessels. Baths at temperatures below 27 °C and between 28 °C and 32 °C can stimulate the individual and increase the amount of blood evacuated from the heart to the large vessels, decongest and smoothen articulation, and have been prescribed for the treatment of chronic evolutive polyarthritis. Showers prior to and after baths exert a dual thermal and mechanical action on vessels and nerve endings; alternation of short cold and warm water sprays may have the same tonifying ef-

Table 44.4 Chemical composition ($g\,kg^{-1}$) of seawater [44.228, 231–234]

Seawater chemical composition					
Cations	**($g\,kg^{-1}$)**	**Anions**	**($g\,kg^{-1}$)**	**Neutral compounds**	**($g\,kg^{-1}$)**
Na^{2+}	10.35	Cl^-	14.72–19.60	$B(OH)_3$	0.0197
Na^+	0.35–10.98	SO_4^{2-}	2.67–2.79	CO_2	0.0004
Mg^{2+}	0.56–1.37	HCO_3^-	0.1061–0.15		
Ca^{2+}	0.36–1.98	Br^-	0.05–0.0681		
K^+	0.36–0.4042	CO_3^{2-}	0.0145–0.02		
Sr^{2+}	< 0.0024–0.0080	$B(OH)_4^-$	0.0080		
Fe^{2+}	0.01–0.057	F^-	0.0012–0.0013		
		OH^-	0.0001		

fect as the Finnish sauna [44.66]. There are another treatments as such as ammotherapy or psammotherapy (partial or full-body warm sand baths), methodical exposure to the sun (heliotherapy), and marine climatotherapy (atmosphere, temperature, humidity, wind, barometric pressure, etc.) with beneficial effects to skin health [44.241].

Among the variety of marine resources available, algal extracts are being extensively demanded and used. Phytotherapy, and its component algotherapy, were officially recognized in 1986 by the French Ministry of Health as a reimbursable medical service by the National Health Scheme. However, this recognition is not found in other countries, and some of the claimed beneficial effects of these therapies have not been sufficiently contrasted with scientific and medical evidences.

Some examples of traditional algal treatments should be mentioned. *Lithothamnium calcareum* is a marine alga whose thallium is used in the treatment of decalcification, osteoporosis, painful joints, chronic fatigue, rheumatism, gingivitis, and stomach pains. A rather wide range of marine algae enter in the packs used in thalassotherapy, and algal flours or algal salts are sold for use in home bath therapy. Poultices of *Fucus*, *Laminaria*, *Ulva*, and *Ascophyllum* (with or without *Lithothamnium* powder) are heated to 40–50 °C and applied at thalassotherapy clinics to limbs to relieve rheumatism and arthritis pains. Other algae, such as the red *Porphyra* and *Eucheuma*, and the brown *Laminaria* and *Undaria* are frequently employed in algotherapy [44.66].

Cosmetic treatments with algae have stimulating and regenerating properties, associated with minerals, vitamins, and amino acids [44.242]. Other reported actions include tonifying, antiseborrheic, conditioning, moisturizing, bacteriostatic, UV-radiation blocking, and antioxidant [44.243–245]. Table 44.5 summarizes some studies confirming these actions. Seaweeds are particularly effective in slimming, firming, anticellulite, and the treatment of hair disorders and diseases.

44.7.1 Firming

These extracts are intended to restore the elasticity of the skin, contributing to its rejuvenation. They improve intercellular exchanges and also facilitate and potentiate the action of other drugs. Brown algal sulfated polysaccharide fucoidan is helpful in the maintenance of the skin's elasticity by increasing hydration and, thereby, improving the skin's elasticity [44.254].

Seaweed extracts, rich in oligo-elements, vitamins, marine plankton, amino acids, and other components are sold as potent lipolytic reducers. This action has been ascribed to the ability of releasing heat energy, increasing the metabolism of fat cells (adipocytes) and triggering combustion of triglycerides [44.66]. Fucoxanthin, which is characteristic of brown algae, has unique mechanisms of antiobesity properties [44.8]. The potential effect of the seaweed algae on weight reduction is associated with well-being, sleep amelioration, and an improvement of skin tonicity [44.255].

44.7.2 Cellulite

Cellulite is characterized by alterations on the skin surface of the buttocks and posterior and lateral thighs, and mainly affects women. Its pathogenesis is not completely understood, but it could be due to structural, inflammatory, morphological, and biochemical alterations of the subcutaneous tissue. Topical treatments for cellulite include activities related to increased microcirculation flow, reduced lipogenesis and promoted lipolysis, restoration of dermal and subcutaneous tissue, and free radical scavenging [44.256].

Table 44.5 Some studies about cosmetic treatments with algae

Active component	Source	Reference
Adipolysis and skin appearance enhancer		
Fucoxanthin	Brown algae	[44.246]
	Undaria pinnatifida	[44.8]
Sulfated polysaccharide: fucoidan	*Fucus vesiculosus*	[44.247]
Aqueous extract	*Fucus vesiculosus*, *F. lumbricalis*	[44.248]
Hydroglyceric extract	*Laminaria digitata*	[44.249]
Hydroglycolic extract	*Pelvetia canaliculata*	[44.249]
Oily extract rich in rhodysterol	*Gelidium cartilagineum*	[44.249]
Sea-salt	Seawater	[44.249]
Prevention of hair disorders		
Dieckol	*Ecklonia cava*	[44.250]
	Fucus vesiculosus	[44.66]
Diguanosine-tetra-phosphate	*Artemia salina*	[44.251]
Extract	*Grateloupia elliptica*	[44.252]
Burn shell	*Paracentrotus lividus*	[44.251]
Ethanolic extract	*Euchema cottonii*	[44.253]
Shell, ink	*Sepia officinalis*	[44.251]

Table 44.6 Examples of cosmetic products with marine ingredients in their formula classified by cosmetic uses

Products and action	
Face masks and creams, emulsions, lotions, gels, and oils for the skin	***Action***
Marine oligosaccharides and zinc	Antishine, antibacterial, anti-inflammatory
Exopolysaccharides from *Alteromonas* sp.	Soothing and reducing irritation of sensitive skin against chemical, mechanical, and UVB aggression
Polysaccharides from *Laminaria digitata* and proteins from *Enteromorpha* sp.	Calming, reduction of itching
Fiber from *Ascophyllum nodosum*	Skin protective action against environmental stress and extreme climates, moisturizer
Dictyopteris oil	Lips volume enhancer
Palmaria palmata extract	Microcirculation stimulator
Flavonoids from *Monostroma obscurum*	Antioxidant action
Corallina officinalis extract with high Ca, Mg content	Skin strength and brightness enhancer, vasoconstrictor, calming, soothing
Chlorella vulgaris extract and procollagen peptides	Circulation activation
Delesseria sanguinea extract	Microcirculation activation and eye contour decongestion
Asparagopsis armata extract	Skin purification and anti-imperfections
Laminaria ochroleuca and *Himanthalia elongata* extracts	Moisturizers
Proteins from caviar (Family Acipenseridae)	Moisturizing action
Lola implexa extract with high Mg and K content	Collagen synthesis stimulation, moisturizing action and skin protection against free radicals
Dead Sea mud (maris limus) with a high concentration of mineral salts	Absorption of liquids, skin protection
Collagen from salmon skin	Skin revitalization
Pearl powder	Skin brightening
α-hydroxy acids (AHAs) from *Porphyra yezoensis*, *P. umbilicalis*, *Lithothamnium calcareum*	Exfoliating action
Salt crystals	Exfoliant
Oily extract of *Chondrus crispus*	Moisturizing, antioxidant, and exfoliating action
Whitening	
Dictyopteris extract	
Slimming and anti-cellulite creams, gels and oils	
Palmaria palmata and Spirulina sp.	
Seawater	
Eicosanoic acid from *Odontella aurita*	
Fibers and vitamins B_3, B_5 and B_6 from *Laminaria digitata*	
Phyllacantha fibrosa, Durvillaea antarctica, *Halopteris scoparia* extracts	
Sterols from *Fucus vesiculosus*	
Ulva lactuca, *Chlorella pyrenoidosa* extracts	
Carrageenan and extract from *Chondrus crispus*	
Dead Sea mud (maris limus)	
Extract from sea cucumber, *Apostichopus japonicus* or *Stichopus japonicas*	
Sunbathing products	
Laminaria digitata, *Halopteris scoparia*, *Palmaria palmata* extracts	
Coral extract	
Polysaccharides from *Laminaria digitata*	

Table 44.6 (continued)

Products and action
Antiwrinkle, antiaging, and lifting products
Arthrospira and *Spirulina platensis* extracts
Polysaccharide from *Nannochloropsis oculata*
Extract and procollagen peptides from *Chlorella vulgaris*
Mannitol and extract from *Laminaria digitata*
Calliblepharis ciliata, Delesseria sanguinea, and *Dilsea carnosa* extracts
Fucoidan from *Undaria pinnatifida*
Phormidium persicinum extract
Exopolysaccharides produced by plankton
Fatty acids, vitamins, proteins, peptides, minerals, and free amino acids from salmon roe
Thalassiosira sp., *Codium* sp., *Ulva* sp.
Hydrating agents
Chondrus sp., *Asparagopsis* sp.
Ceramium rubrum extract
Sea urchin
Thalasso and algotherapy
Fucus sp., *Laminaria* sp.

44.7.3 Hair Growth Disorders

The demand for products that alter hair growth is a billionaire's market, but few natural effective products are available. Ethanol and aqueous extracts from *Eucheuma cottonii* enhances hair growth by higher proliferative activity [44.253]. The beneficial effect of *Ecklonia cava* extracts on the promotion of hair growth of immortalized vibrissa dermal papilla cells was reported [44.250].

44.8 Products Based on Marine Resources

Currently, a diversity of products based on marine-derived ingredients are marketed for different purposes, including: antiaging, whitening, moisturizers, UV-blocking, and skin or hair specific treatments. These formulations are sold as creams, gels, and lotions, depending on their penetration ability and efficiency and acceptance by consumers. Cosmetic companies are increasingly interested in the development of novel products with marine-based bioactives. Table 44.6 summarizes some representative actions and the active marine-derived ingredients that are found in some commercial formulae. Most of them are crude or refined extracts, but also purified fractions and compounds are used. Aqueous, solvent, and lipid extracts are available. Marine lipid extracts contain a large amount of PUFAs, such as (EPA, 20 : 5n-3) and (DHA, 22 : 6n-3), associated with a variety of benefits in skin disorders treatment. Their encapsulation in liposomes, good vehicles for cosmetic applications, has proved their suitability to improve storage stability of bioactives [44.200].

Some components are recognized ingredients with skin protecting and conditioning actions, or also provide some technological properties, such a viscosity controlling effect, a coloring effect, etc. On the other hand, some components traditionally used for conferring technological properties can be of interest as active agents. Furthermore, some compound used externally may also be effective when proposed for oral use, as nutraceuticals, fitting into the recent trend to provide beauty from within [44.254, 257, 258].

44.9 Conclusions

A great research effort related to the chemical structures, and physical and biological properties of marine natural products has emerged in recent years due to the fact that these resources are still largely unexplored and may have potential for further development of food, cosmetic, and pharmaceutical products. A variety of marine sources have been considered: microorganisms, fungi, macro and microalgae, and by-products from the food industry, such as fish skin, crustacean skeletons, or cartilages. Seawater and minerals are also sources of effective products. A continuous growth in the market of cosmetic products formulated with marine bioactive substances is expected. Both traditional treatments and innovative formulations with novel marine-derived components coexist in commercial skin and hair care products.

The research on bioactive compounds, particularly those that are found exclusively in marine media, is highly attractive due to the unique structures, which are not found in terrestrial sources, and their potent properties. In the next years, the research and development effort should be focused on the identification of the active metabolites, their detailed mechanisms of action, the design of clean extraction and purification technologies, and the development of efficient vehicles and products with enhanced activity, safety, and prolonged shelf-life. To succeed in this area with impressive potential, a close collaboration of different scientific and technical disciplines is encouraged.

45. Omega-3 Fatty Acids Produced from Microalgae

Munish Puri, Tamilselvi Thyagarajan, Adarsha Gupta, Colin J. Barrow

The applications of Omega-3 fatty acids for human health are rapidly expanding, which necessitates exploring alternative sources to fish. Many marine microorganisms across different kingdoms exhibit the ability to store a significant oil content, however are difficult to cultivate. Out of all marine microbes, thraustochytrids are considered a good source for the production of high value compounds such as polyunsaturated fatty acids (PUFAs). Optimization of culture conditions will be helpful in further enhancing cellular lipid content to suit fatty acid synthesis. This chapter describes some recent advances in the development of marine microbes for fatty acid production with a special emphasis upon thraustochytrids for biotechnological applications, focussing particularly on methods to enhanced docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) production.

45.1 Importance of Unsaturated Fatty Acids

The wealth of the ocean is infinite in terms of the discovery of nutraceuticals and biological compounds. One of the major components of interest among them is omega-3 fatty acids. Omega-3 fatty acids are naturally occurring polyunsaturated fatty acids (PUFA) that include mainly alpha-linolenic acid (ALA), eicosapentaenoic acid [45.1] docosahexaenoic acid (DHA). PUFAs play multiple roles in cell function and biology; they regulate various regulatory molecules such as prostaglandins and thromboxanes. Some of the recent updates on biological functions of omega-3 fatty acids are presented in Table 45.1.

The awareness of consumers with regard to the health benefits of the consumption of omega-3 fatty acids has made them an important functional food component on the market. Global finished products of PUFA sales for 2011 reached US$24.5 billion and is expected to reach US$34.5 billion by 2016 conferring to package facts. The target market for omega-3 fatty acids is diverse in terms of the various types of products, ranging from fortified foods, beverages, and dietary supplements to infant food and pet foods [45.14]. Global aquaculture production was 547 million tonnes in 2003 and it is increasing by an average of 9% ev-

Table 45.1 Biological benefits of Omega-3 fatty acids

Biological benefits of omega-3 fatty acids	Reference
Helps in bone formation and prevents chronic inflammatory diseases, rheumatoid arthritis, and inflammatory bowel disease	[45.2]
DHA plays a significant role in the development of the neural and visual system in infants by aiding in the development of the central nervous system	[45.3]
Prevents primary and secondary cardiovascular (CV) diseases	[45.4]
Dietary intake helps prevent Alzheimer's disease	[45.5]
Reduces bronchial allergic inflammation that causes asthma	[45.6]
Recommended in treatment of schizophrenia; clinical data suggests that patient DHA and ALA levels are lower than normal	[45.7]
Reduces osteoarthritis and helps prevent disease when taken in diet	[45.8]
Prevents gastrointestinal tract cancer and has been proved as a chemopreventive agent with respect to colorectal cancer	[45.9]
Supplement to patients with severe hypertriglyceridemia, reported decrease in triglyceride levels and cardiovascular disease risks	[45.10]
Supplement can decrease plasma homocystine, an independent risk factor for cardiovascular diseases	[45.11]
Supplement of EPA and DHA are reported to be beneficial in decreasing the risk of depression leading to suicide and delaying the onset of neurological degeneration of aging	[45.12]
PUFAs can help to reduce inflammation in overweight, middle-aged, and older adults, and thus promote broad health benefits	[45.13]

ery year. Although the global demand is growing, fish is a declining resource because of environmental issues due to the continuous exploitation of fish stock to meet the demands of market. A lack of environmental sustainability and the increasing global demand has driven us to search for alternative sources for the future [45.15].

The main focus of the current research is screening efficient microbial sources that may produce both EPA and DHA. Thus, chapter includes the origin of omega-3 fatty acids, biosynthesis, and fermentation optimization in marine microbes.

45.1.1 Unsaturated Fatty Acids – Focus on Marine Origin

ALA is also regarded as the parent PUFA that is converted into EPA and DHA. The rate of conversion from ALA in to EPA and DHA is low in humans, and there are no other means of PUFA synthesis in the human body; hence EPA and DHA are classified as essential nutrients. Vegetable oil is considered as a main source of ALA, whereas DHA and EPA are predominantly found in fish oil [45.9, 16, 17]. Among the various sources, oily fish such as sardines, salmon, tuna, and herring are considered to be the best dietary sources of omega-3 fatty acids. In many of the oily fish, these oils are derived from microorganisms through their food web (Fig. 45.1) [45.4]. Marine phytoplanktons are considered ocean factories of omega-3 fatty acids, as they are the primary producers in the marine food web [45.18]. A major source of PUFAs are microorganisms, as they are easy to grow and more eco-friendly in terms of extraction and refining when compared to animal fatty acids, which are associated with odor and the presence of cholesterol [45.19].

Microorganisms have an advantage over traditional energy crops because they have a higher growth rate, produce more biomass in a shorter time span, and do not compete for land space [45.20]. Biotechnology may contribute towards the industrial production of fatty acids to serve the nutritional demands of DHA and EPA by producing feed enriched with PUFAs, which in turn would increase the content of essential fatty acids in meat, milk, and eggs [45.21, 22].

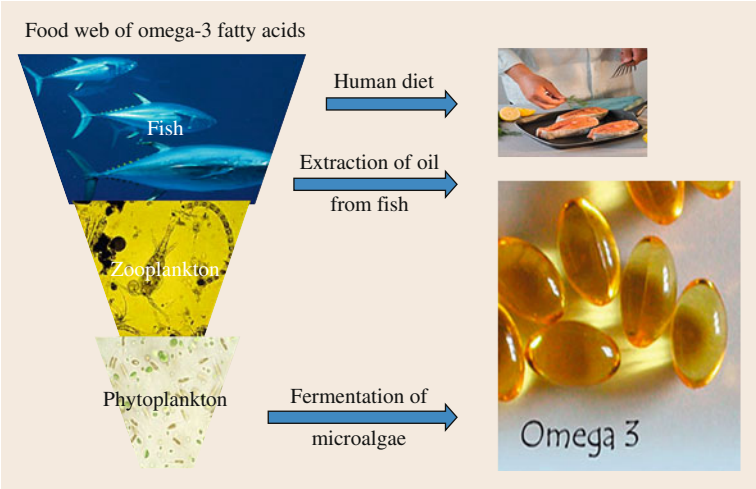

Fig. 45.1 Marine food web associated with the production of omega-3 fatty acids

45.2 Potential Alternative Sources for PUFA Production

Industrially, omega-3 fatty acids are extracted mainly from fish oil; various fish sources and their DHA and EPA contents are represented in Table 45.2. There are limitations in the use of fish oil due to the contamination of heavy metals by environmental pollutants [45.23]. In oily fish these oils were derived from microorganisms through their food web [45.18]. A few strains of bacteria and yeast were identified from the intestine of fish from the deep sea. Bacterial PUFAs are composed of phospholipids, which are 10–15% of the dry weight. Whereas in microalgae PUFAs in triacylglycerol constitutes to 80% of the dry weight [45.14]. Among phytoplankton, microalgae and marine diatoms are considered to play a significant role in the food web. In aquaculture, microalgae serve as feed for zooplankton and molluscs, which in turn serve as feed for fish and fish-eating sea animals. Especially the microalgae *Isochrysis* and *Nannochloropsis* are used as feed for rotifers, which, in turn, are supplied to fish to enrich their diet with EPA and DHA [45.24]. Food webs associated with omega-3 PUFAs are interrelated [45.25]. Humans mainly obtain DHA and EPA by consuming fish, whereas fish, in turn, obtain PUFAs from microalgae (Fig. 45.1). Microalgae-derived DHA and EPA can be used as a supplement for people who do not consume fish and seafood [45.26]. The food web association has led to the exploitation of marine microalgae to act as major reservoirs of PUFAs. PUFAs from microalgae are eco-friendly and more stable because of the presence of natural antioxidant carotenoids and vitamins that are bioencapsulated in the algal cell wall [45.27, 28]. Thus, microalgae can be considered as a potential source of production of PUFAs.

45.3 Marine Microalgae

Algae are spread in diversified ecosystems that include marine, the freshwater environment, the desert and hot springs, along with snow and ice. Their diversity in habitat is achieved by their ability to grow in natural environments under inorganic conditions by fixing CO_2 with the process of photosynthesis.

They are mainly classified into multicellular large seaweeds (macroalgae) and unicellular microalgae [45.30]. Based on their pigment composition they are further classified into nine divisions. Some of the largest groups include Chlorophyceae (green algae), Phaeophyceae (brown algae), Pyrrophyceae (dinoflagellates), Chrysophyceae (golden brown algae), Bacillariophyceae (diatoms), and Rhodophyceae (red algae) [45.31].

50 000 microalgae species have been reported, but not more than 30 000 species have been studied. The market for microalgae is 5000 tonnes per year, and

Table 45.2 Fish and seafood sources of DHA and EPA (after [45.29])

Fish and seafood sources of DHA and EPA	
Fish source (100 g portion)	**DHA + EPA (g)**
Carp, cooked, dry heat	0.45
Catfish, channel, farmed, cooked, dry heat	0.17
Cod, Atlantic, cooked, dry heat	0.15

the annual sale value is US\$6 $\times 10^9$ with a productivity of 7.5×10^6 tonnes per year [45.32]. Further, the market for marine microalgae-derived omega-3 has been growing recently, with US\$2 billion revenue in 2012, which is expected to increase to double digits by 2016 due to the potential target of the Asia-Pacific market [45.14].

Microalgae are effective in the reduction of carbon dioxide into biomolecules like carbohydrates, proteins, lipids and triglycerides. Microalgae have gained lot of industrial attention due to their wide product perspectives, which serve the needs of the human community. Various commercial applications of microalgae for the benefit of mankind are discussed in Table 45.3.

45.3.1 Cultivation of Marine Microalgae

Microalgae are divided into groups such as autotrophic, heterotrophic, mixotrophic, and photoheterotrophic algae based on the type of metabolism used to synthesize energy and the ability to utilize various forms of energy [45.56].

The autotrophic microalgae *Chlorella vulgaris* can convert solar energy to chemical energy through the process of photosynthesis. Photoheterotrophs require light for the utilization of organic carbon sources. In industry, photoautotrophs and photoheterotrophs are cultivated by open, closed, or semiclosed outdoor bioreactors [45.57].

The heterotrophic microalgae *Haemotococcus pluvialis, Chlamydomonas* sp. and *Phaeodactylum* sp. can utilize organic compounds to produce energy; they are commercially cultivated with the help of fermenters of various scaling up ranges based on the requirements. The mixotrophic microalgae *Arthrospira platensis* can produce the essential growth compounds either in the presence of light or organic compounds based on the available conditions [45.57]. Photo bioreactors and commercial fermenters share the common purpose of cultivation but the difference lies in the source of energy, oxygen supply, pH control, light illumination, and the process of sterilization [45.58].

45.3.2 Fermentation of Microalgae

Microalgae are exploited for the industrial production of various metabolites such as carbohydrates, lipids, enzymes, polymers, toxins, antioxidants, pigment biomass, and many more [45.59]. The cultivation of microalgae involves two basic processes, the autotrophic and heterotrophic modes of growth. Based on the requirement of microalgae and the demand of the process, autotrophic fermentation processes are further categorized as open system and closed system [45.31]. An open system is the simplest method of cultivation with the advantage of low production costs. The open

culture system requires a large surface area and shallow depth; various models of the open pond system are in use, which include natural or artificial ponds, raceways, tanks, circular ponds with impellers, rotating arms, or paddle wheels. In Western Australia, *Dunaliella* is used for the production of β-carotene using an artificial shallow pond system [45.56]. Growth in the open pond system can be enriched by supplying CO_2 and mixing when required. Limited control on cultivation conditions and contamination of other microorganisms means that the system is restricted for microalgae which are tolerant to extreme conditions. The open pond system mainly suits the cultivation of *Spirulina* and *Chlorella* and is applied in places such as Japan, Thailand, California, Hawaii, Taiwan, India, and China.

To overcome these disadvantages closed photo bioreactors are designed in various sizes and shapes to meet the requirements of microalgae growth and development. In this process, plexiglas, acrylic, glass tubes, and flexible plastic coils are used as solar collectors; where the microalgal suspension is circulated continuously through rows of connected transparent tubes or coils [45.60]. A horizontal tubular photo bioreactor in Florence, Italy, has led to high productivity for *Spirulina* [45.58].

Heterotrophic microalgae are very few and they require the addition of organic sources in the growth medium for energy generation, which leads to the production of various metabolites in the process. Growth is independent of light energy, which allows a simpler scale up process to overcome the disadvantage of large investments in infrastructure and it also supports the reproducible biomass yield in the heterotrophic mode of growth [45.56]. In Japan, *Chlorella* sp. produced by heterotrophic fermentation led to biomass of 500 ton, which amounts to 50% of the total Japanese production of this alga [45.60].

To make the process of fermentation cost effective, both the autotrophic and heterotrophic processes are mixed to achieve the maximum algal biomass and product yield. *Chlorella sorokiniana* is fermented in a two-stage heterotrophic and phototrophic culture strategy that allows heterotrophic seed culture in the autotrophic open algal culture system, resulting in higher growth rate, cell density, and productivity [45.61, 62]. The photoheterotrophic fermentation method of *Chlorella minutissima* led to an 11.9 times higher lipid content than the autotrophic condition reported earlier [45.63].

45.3.3 Isolation of Microalgae for the Production of PUFAs

Isolation of the desired microalgae for the production of PUFAs plays a major role in deciding various parameters of fermentation at lab scale that adds to the production cost during the industrial fermentation of PUFAs. In general, microalgae can be isolated from freshwater and marine water by using the traditional micropipette washing technique, the centrifuge washing technique, and the streak plating technique. Microalgae rich in PUFA content can be isolated with the help of high-throughput cell sorting coupled with flow cytometry. Photosynthetic pigments in microalgae

emit various kinds of fluorescence, this is applied as the principle behind the flow cytometry. Chlorophyll autofluorescence (CAF) of eukaryotic photosynthetic phytoplankton and green auto-fluorescence of dinoflagellates, along with red and orange autofluorescence to differentiate between algal strains are used in the process of identification and isolation of microalgae. Furthermore, the isolated microalgae are cultivated to screen the strains with respect to high biomass yield and lipid content [45.64].

Adoptability to diversified environmental conditions is well reflected with the composition of fatty acids in algae, very long-chain (VLC) (18C) fatty acids and PUFAs are noticed to be more in eukaryotic algae compared to cyanobacteria. PUFAs amount to 20% of lipids in algae and include arachidonic acid (ARA), eicosapentaenoic acid [45.1], and docosahexaenoic acid (DHA) hindered to exploit and increase the accumulated PUFAs with the help of biotechnology [45.65].

Thraustochytrids are microalgae like microorganisms that can accumulate 60% of their dry weight as lipids, of which more than 25% is normally DHA. A study of the ultrastructure with transmission electron microscopy [45.47] illustrated that cells are heterogeneous in size, approximately 6–21 μm in diameter with a granular cytoplasm, containing oil micelles [45.66]. The high lipid content lends thraustochytrids to the commercial production of omega-3 fatty acids. In general, they are isolated with the pine pollen technique [45.67, 68] and acriflavine direct detection (AfDD) techniques [45.69]. These two methods are reported as effective isolation techniques with respect to thraustochytrids.

45.4 Biosynthesis of Omega-3 Fatty Acids in Marine Algae

Microalgae are known to produce large amounts of C_20–C_22 PUFAs. PUFAs can be synthesized by aerobic and anaerobic pathways. The aerobic pathway involves the role of *desaturases* and *elongases* enzymes, whereas the anaerobic pathway uses polyketide synthase enzymes [45.70]. Biosynthesis of PUFAs starts with a double bond formation in the aliphatic chain of the fatty acid, and the elongation by two carbon units of the acyl chain, hence in this biosynthetic pathway the alternative action of the two enzymes *desaturase* and *elongases* contributes to the synthesis of PUFAs [45.71]. Various biochemical pathways for the production of DHA and EPA are represented in Fig. 45.2.

45.4.1 Synthesis of EPA

The red alga *Porphyridium cruentum* has been used extensively to study the biosynthetic pathway for the production of EPA with the help of exogenously supplied radiolabeled fatty acids, to reveal the omega-3 and omega-6 pathways for the conversion of EPA. In the omega-6 pathway with the action of desaturase, Υ-linolenate was formed from linoleic acid followed by elongation to dihomo Υ-linolenate, which was further de-saturated into arachidonate, followed with EPA formation. In the case of the omega-3 pathway, linoleate was de-saturated to α-linoleate, which was further converted to EPA from the intermediate fatty acids 18 : 4n-3 and 20 : 4n-3. Among the two pathways, the omega-6 pathway is considered to be the active route [45.65, 72].

45.4.2 Synthesis of DHA

Biosynthesis of DHA is assumed to involve $\Delta 6$ desaturation to form C18 : 4n-3 from α-linoleate, further elongated to C20 : 4n-3 which undergoes desaturation to form EPA, which is then converted to DPA followed by DHA formation. Conversion of DPA to DHA by $\Delta 4$ desaturase is identified in *Thraustochytrium* sp., this is noticed to be different from the mammalian pathway of DHA synthesis, the Sprecher pathway that involves two consecutive elongation steps [45.73].

In the case of *Aurantiochytrium* sp., (or *Schizochytrium* sp.) biosynthesis of DHA is reported by the alternative pathway known as polyketide synthase pathway (PKS). Biochemical experiments indicated that desaturase and elongase enzymes are not involved in the PKS pathway but showed the PKS protein complex on molecular-genetic analysis. Although the exact sequence of the PKS pathway remains to be determined, identification of the protein domain provides evidence for the mechanism of cis double bond insertion through the action of dehydratase/2-trans,3-cis isomerase (DH/2,3I) [45.74, 75].

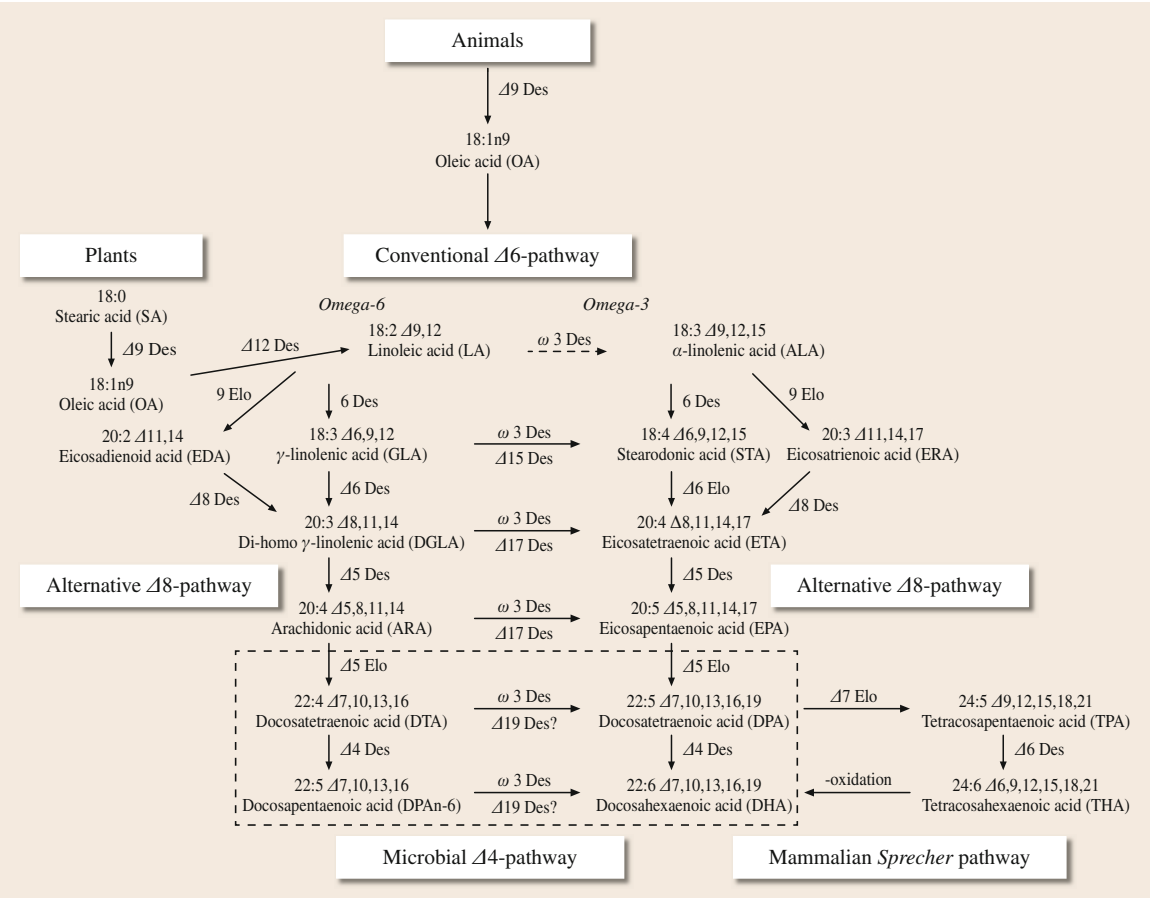

Fig. 45.2 Biochemical pathways for the synthesis of DHA and EPA (after [45.16])

45.5 Microalgae Fermentation for the Production of PUFAs

Microalgae are generally cultivated in natural lagoons or lakes to highly sophisticated bioreactors. Bioprocess engineering has contributed to process optimization of various parameters to ensure large-scale microalgae production [45.76]. Process optimization depends on the growth requirements of microalgae. Autotrophic, heterotrophic, or a mixture of both processes is applied based on the product yield aimed at low production cost. The heterotrophic-based microalgal production system favors a higher magnitude of PUFA production than that of outdoor autotrophic pond systems [45.60, 77].

Autotrophic growth of *Porphyridium cruentum* reported less total fatty acid accumulation when compared to heterotrophic growth with glucose and glycerol [45.83]. The microalgae *Pavlova lutheria*, grown under photoheterotrophic conditions of high and low light intensity produced significant results with the production of PUFAs, especially high light intensity favored high DHA yield and low light intensity reported high EPA yield [45.84]. Heterotrophically grown *Crypthecodinum* sp., *Chlorella* sp. are rich in DHA and ARA contents. Cells are broken by mechanical and enzyme hydrolysis methods to extract oil. The resulting algal biomass is further freeze dried and used as feed for rotifers and Artemia, which is further used in formulated brood stock diets of fish larvae [45.85]. A list of microalgae involved in PUFA production is given in Table 45.4. The mi-

croalgae *Crypthecodinium cohinii* or microalgae like the microorganism *Schizochytrium* sp. are used in the industry for the fermentative production of PUFAs. They are currently being explored for the production of DHA, especially for the enrichment of food products and feed additives in aquaculture [45.15, 86].

Here we describe one example of a marine microbe that is used commercially for the production of omega-3 fatty acids such as DHA and EPA.

45.6 Thraustochytrid Fermentation

Various fermentation conditions including the usage of different sources and other physical parameters have been employed for the production of PUFAs, particularly DHA and carotenoids. They are discussed below.

45.6.1 Effect of Carbon and Nitrogen Sources and Other Promoters on PUFAs Production and Carotenoids

Monosaccharide such as glucose is the most frequently used carbon source due to its easy availability to the microbes. Disaccharides, polysaccharides, and oils like corn and canola oil have also been reported to be used as carbon source [45.87, 88]. The role of the carbon source has been demonstrated as an important constituent in the medium that may result in high DHA yield [45.88]. Apart from this, various other alternative carbon sources such as pure glycerol, crude glycerol (from biodiesel waste), coconut water, distillery wastewater, liquid residues from the food industry, soybean cake, beer and potato processing waste, sweet sorghum juice, cellulosic biomass, and spent yeast from breweries have been used to make the fermentation process economical [45.82, 89–98]. Glucose basal medium supplemented with empty palm fruit bunches yields a good amount of lipids and DHA at 12.5 and 5.4 g L^{-1} [45.89]. Moreover, *Crypthecodinium cohnii* was reported to yield better DHA output when carob pulp syrup was used as the carbon source rather than glucose [45.99].

Similarly, the use of nitrogen sources has been studied, showing the effect on lipid accumulation. *Goldstein* proposed the use of inorganic nitrogen sources glutamate, aspartate, their amides, and alpha alanine to achieve a good biomass yield [45.100]. Thraustochytrids readily utilize organic nitrogen sources such as yeast extract, peptone, and corn steep liquor [45.101, 102]. Moreover, a higher carbon to nitrogen ratio (C:N) supports higher DHA production [45.81, 103]. However, the nitrogen depletion showed an increment in the lipid content [45.68]. In addition to this, various modulators such as Tween 80, acetyl co-enzyme A, and nicotinamide adenine dinucleotide phosphate (NADPH) have been used to alter the biomass and lipid content on the higher end [45.104, 105]. The oleate present in Tween 80 might have triggered the metabolism resulting into high biomass and lipid accumulation. Similarly, acetyl Co-A (as ethanol) and NADPH (as malic acid) elevated the DHA content when introduced at the late lipid accumulation phase.

Thraustochytrids have been well documented with respect to the production of carotenoids such as beta-carotene and xanthophylls like astaxanthin, zeaxanthin, canthaxanthin, echinenone, and phoenicoxanthin [45.101, 106–108]. Carbon and nitrogen sources are very important nutrient factors for carotenoid production. Low glucose concentration resulted in high beta-carotene production, whereas a high glucose concentration produced a high canthaxanthin content [45.106]. Further, it was reported that with the use

of mutation strategy, involving N-methyl-N′-nitro-N-nitroso guanidine (NTG), carotenoid production was increased manifold [45.109]. Other substrates such as distillery waste as the only nitrogen source in the culture medium have been used for the production of DHA and xanthophylls, yielding 3.4 g L^{-1} and 7.7 mg L^{-1}, respectively [45.89].

45.6.2 Effect of Physical Parameters and Other Fermentation Strategies on PUFA Production

Like the chemical constituent of the fermentation medium, physical conditions also contribute to enhance the production of PUFAs. Thraustochytrids can utilize the 20–30 °C temperature range for its growth and lipid accumulation, which is considered an optimal environment [45.110]. A temperature shift study (30–20 °C) was designed to improve the DHA content in the fatty acid profile (≈ 52% of TFA) [45.111]. Although the dip in the temperature may not yield as high biomass, 30 °C was found to be the optimum temperature for the fermentation study. It is pointed out that low temperature has an effect on the lipid metabolism of low temperature marine microbes [45.112]. Also, the natural environments from which the strains have been isolated, may show a different lipid profile [45.113].

The biomass yield achieved for thraustochytrids was highest at neutral pH [45.114], although no significant change was observed in the fatty acid profile. Similarly, salinity plays an important role in thraustochytrid fermentation. Salinity up to 50% is known to yield high biomass [45.103]. Artificial seawater (ASW) has been extensively used for providing salinity in the medium. However, there was a report of using only sodium chloride as the salt source [45.115]. This salinity factor may depend on the type of habitat where the thraustochytrid was isolated. Moreover, it may significantly affect the lipid content, biomass, and fatty acid profile [45.110].

Other factors such as oxygen level, volume of the liquid medium, and statistical design have shown their respective effect on thraustochytrid oil production. At 4–8% of the saturation level of oxygen supply during biomass growth and less than 1% during DHA production, there was improvement in the DHA yield [45.116]. A low dissolved oxygen (DO) level was found to assist in lower DHA production [45.117], thus a low volume medium was recommended in shake flask fermentation. A two-stage oxygen supply system was introduced based on the oxygen transfer coefficient yielding a high concentration of DHA and its productivity [45.118]. Statistical tools such as central composite design, fractional factorial, and response surface methodology were found to be useful while targeting the optimization of various factors to enhance DHA production [45.119, 120].

Further, DHA production has been achieved in large-scale fermenters as reported in [45.68, 101, 121–123]. Several fermentation processes have been designed to elevate biomass and lipid production. A higher biomass growth rate was observed in fed-batch cultivation of *Schizochytrium* sp. [45.115]. Another two-stage system was employed to increase biomass and lipid production [45.122].

A continuous fermentation process has been used, which resulted in high lipid accumulation when compared to batch cultivation [45.124]. *Aurantiochytrium* sp. KRS101 was used in another fed batch fermentation with DHA production up to 40% of total lipids [45.123]. Further, a modified fed-batch strategy using *Aurantiochytrium* sp. KRS101 has been reported to increase the palmitic acid (with respect to biodiesel production) and DHA yield (towards PUFA production) where distinctive yield coefficients were used [45.125].

A recurrent oxygen feeding method was employed to maintain a 50% DO level in the fermentation environment, which achieved a high biomass of 61.76 g L^{-1} and 65.2% of the total lipid content, which also improved the DHA proportion up to 70% of the total fatty acids in the fatty acid profile [45.126]. A recent study involved *Aurantiochytrium* sp. KRS101 in a stepwise fermentation strategy using spent yeast as the sole nutrient source, which supported good biomass growth and lipid productivity [45.98]. With respect to downstream processing of microbial lipids, the direct transesterification method was found to be more effective in achieving high fatty acid yields [45.127].

45.7 Conclusions

The importance of PUFAs, particularly DHA and EPA, is gaining considerable attention because of the increasing list of health benefits. Health-conscious consumers are willing to spend more to ensure its availability for the well-being of their families. Omega-3 fatty acids of marine origin (e.g., fish oil) are already available

on the market and are being consumed. Due to the many shortcomings of fish-derived oil, including undesirable taste and odor, its chemical processing methods, and the presence of contaminants such as mercury, research has been diverted towards the exploitation of other marine species for the development of suitable alternatives. Thus, marine microorganisms are the best alternative at present for the production of these high-value fatty acids. Marine omega-3 fatty acids are making their way onto the market and the estimation of the growth of nutraceutical industry is certainly expanding. Marine microalgae (e.g., thraustochytrids) have been recorded for high PUFA accumulation with a good amount of omega-3 fatty acids. Researchers are trying to increase the productivity by different means such as synthetic biology so that the process can be made economical based on the application of genetic tools.

46. Selenoneine in Marine Organisms

Michiaki Yamashita, Yumiko Yamashita

A novel selenium-containing compound, selenoneine, 2-selenyl-N_α,N_α,N_α-trimethyl-l-histidine, has been identified as the predominant form of organic selenium in the blood and tissues of tuna. This selenium compound has a selenium atom in the imidazole ring, and is a selenium analog of a thiol compound, ergothioneine. Selenoneine has radical scavenging activity and exerts an antioxidant effect by binding to hemoglobin and myoglobin, protecting them from iron auto-oxidation. In addition, selenoneine has detoxifying activity against methylmercury (MeHg). Selenoneine has been found to be a specific substrate for the organic cation/carnitine transporter OCTN1 (solute carrier family 22 member 4, SLC22A4), and mediated the excretion and demethylation of MeHg by exosomal small vesicle formation. The dietary intake of selenoneine through fish consumption is an important selenium source in the human diet. Since selenoneine and its related selenoproteins have strong antioxidant activities, disease protective functions, such as anticarcinogenesis and aging effects, may be expected.

46.1 Biochemistry of Selenium

Selenium is an essential micronutrient and a constituent of the selenocysteine residues of antioxidant selenoproteins, such as glutathione peroxidases, thioredoxin reductases and selenoprotein P [46.1–4]. The selenoproteome contains 25 genes encoding selenoproteins in the human genome, indicating that selenium is essential for protein synthesis [46.5]. The genes encoding the selenoproteins contain an in-frame TGA codon within their coding sequence, which directs the incorporation of selenium, in the form of selenocysteine, into these proteins. The selenocysteine-transfer RNA (Sec-tRNA) has its own special translation factor, which delivers it to the translating ribosome [46.4]. Thus, organic and inorganic selenium are used as a selenium source for selenoprotein synthesis. The molecular mechanisms of selenium incorporation into selenocysteine from other selenium compounds should be elucidated.

Selenium bioavailability may depend on the food source and chemical forms of selenium. The major compounds in plant foods are selenite, selenomethionine, and γ-glutamyl methylselenocysteine [46.6]. Although data on the chemical forms of organic selenium in foods of animal origin are limited, the major chemical forms of selenium are considered to be selenocysteine and selenomethionine,

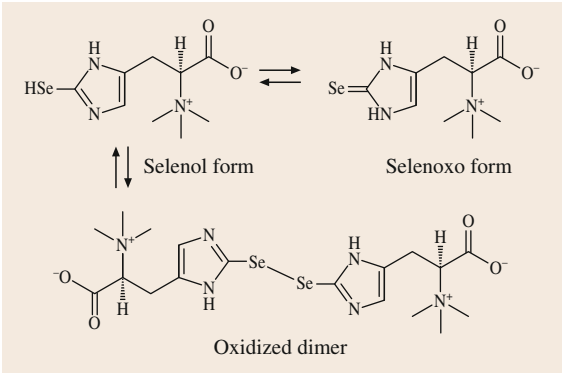

Fig. 46.1 Chemical structure of selenoneine. Selenoxo form bound to heme is present in vivo. A stable oxidized dimer is purified from fish tissues and is used for various bioassays

which is incorporated in muscle proteins. Dietary intake of selenium through fish consumption may be important for the enhancement of selenium redox functions. Fish are considered to be the major selenium source in Japan, contributing to approximately 35% of the total selenium consumed [46.1]. The selenium content and its chemical forms in the edible portions of fish and shellfish have been determined [46.7–9].

Recent studies showed that the muscles of tuna and other predatory fish contain high levels of the selenium-containing imidazole compound, 2-selenyl-N_α,N_α,N_α-trimethyl-l-histidine (selenoneine) (Fig. 46.1) [46.7]. This compound was identified as the major organic selenium source in the blood and muscle tissue of tuna. Selenoneine contains an imidazole ring with a unique selenoketone group and has radical scavenging activity [46.7]. Therefore, dietary intake of selenoneine through fish consumption is considered important for enhancing antioxidant effects in tissues and cells.

Selenium deficiency is associated with 50 human diseases, including prostate, lung, and colon cancers, as well as immunodeficiency, and heart diseases [46.4]. Diseases of domestic animals and birds, such as myopathy, exudative diathesis, and pancreatic degeneration, can be caused by selenium deficiency [46.1–4]. A selenium deficiency is often a result of eating food grown in soils deficient in selenium [46.1]. Also, some intestinal disorders are associated with a risk of developing selenium deficiency [46.10]. Therefore, the dietary intake of selenoneine through fish consumption might be important for free radical detoxification mechanisms in animal cells and tissues. Understanding the nutritional roles and biological significance of selenoneine may contribute to improving human diet and health.

46.2 Selenium and Selenoneine Determination

46.2.1 Selenium Analysis

Fluorometric Assay of Total Selenium

The total selenium concentration was measured using a fluorometric assay employing 2,3-diaminonaphthalene (DAN), according to the method described by *Hasunuma* et al. [46.11]. Each sample (0.1–0.2 g) was dissolved at 200–220 °C for 2–3 h in 1 ml of a 1 : 2 mixture of nitric acid and perchloric acid. The selenium(VI) binds with DAN and forms a fluorescent selenium-DAN heterocyclic compound. A linear relationship between fluorescence and selenium concentration was maintained within a 100 ng range of selenium.

Selenium Speciation Analysis

Thecomposition of selenium compounds in fish tissues was measured by high-performance liquid chromatography (HPLC) and inductively coupled plasma mass spectrometry (ICP-MS) [46.7, 9]. Chromatographic separation was performed using a 712 p HPLC pump (GL-Sciences, Tokyo, Japan) in conjunction with an Ultrahydrogel 120 (7.8 × 250 mm; Nihon Waters, Tokyo, Japan) analytic column equilibrated with 0.1 M ammonium formate buffer containing 0.1% (w/v) Igepal CA-630 (Sigma-Aldrich Japan, Tokyo, Japan). Each sample (0.1 g) was homogenized in 0.5 ml water, and 20 µl supernatant was analyzed after a two to fourfold dilution in the mobile phase. The injection volume was fixed at 20 µl and the mobile phase delivered isocratically at the rate of 1 ml/min. Selenium was detected through online HPLC-ICP-MS, performed using an ELAN DRC II mass spectrometer (Perkin Elmer, Waltham, MA, USA) in conjunction with a concentric quartz nebulizer (WE02-4371) and a quartz sample injector (2 mm id). During separation, glutathione peroxidase (GPx) and selenoneine were eluted at retention times of 5.4 and 10.1 min, respectively, and the selenium concentration was determined using the respec-

tive compounds as standards. To determine the tissue distribution of selenoneine and other organic selenium compounds, a speciation analysis method was used for organic selenium in animal tissues. This method was based on monitoring ^{82}Se using HPLC-ICP-MS with a gel permeation chromatography (GPC) column. Since selenoneine was associated with the gel matrix, it was eluted 10.1 min after the bed volume of the column (Fig. 46.2).

46.2.2 Selenium Contents in Seafood

The total selenium contents have been measured in the edible portions of various fish and shellfish in Japan [46.7, 9, 12]. The muscles of the alfonsino contain the highest level of selenium (16.1 nmol/g) among the fish muscles examined in this study. High levels of selenium (15.2–13.6 nmol/g) have also been found in the salted ovary products of mullet and Pacific herring. In other fish muscles, the selenium levels range between 1.5 and 9.8 nmol/g tissue.

Selenoneine concentrations in various tuna tissues have been determined [46.7]. Tuna red muscle contain selenoneine at 190 nmol/g and selenoproteins at 4.5 nmol/g. Almost all of the organic selenium 98% in the tuna muscle is present as selenoneine. Tuna and mackerel blood contain high levels of selenium as selenoneine (430–437 nmol/g). Other tissues, such as the spleen, hepatopancreas, heart, white muscle, and blood, also contain selenoneine at levels above 11.5 nmol/g. However, the data are limited to the cultured bluefin tuna in Japan. The selenoneine levels in the tissues may be dependent on fish size, stress, and nutritional conditions.

When the muscle contents of selenoneine were compared among various fish species, the selenoneine contents of bigeye tuna, Pacific bluefin tuna, albacore, yellowfin tuna, and alfonsino were 1.3–2.6 nmol/g tissue. In the muscles of these fish, the majority of organic selenium (9–42%) was present as selenoneine [46.9]. In other fish species, such as Pacific sardines, greeneye, skipjack, Pacific mackerel, horse mackerel, red sea bream, and Japanese barracuda, selenoneine levels were 0.1–1.4 nmol/g tissue, accounting for 3–34% of organic selenium [46.9]. In contrast, Japanese conger, Japanese anchovy, chum salmon, Pacific saury, white croaker, and marbled sole muscles contained levels of selenoneine below the detection level (0.05 nmol/g tissue) [46.9].

In comparison, tilapia blood, porcine kidney, chicken heart, gizzard and liver, and squid hepatopancreas contained low levels of selenoneine and selenoproteins [46.7]. Furthermore, porcine liver contained only selenoproteins and not selenoneine. Selenoneine

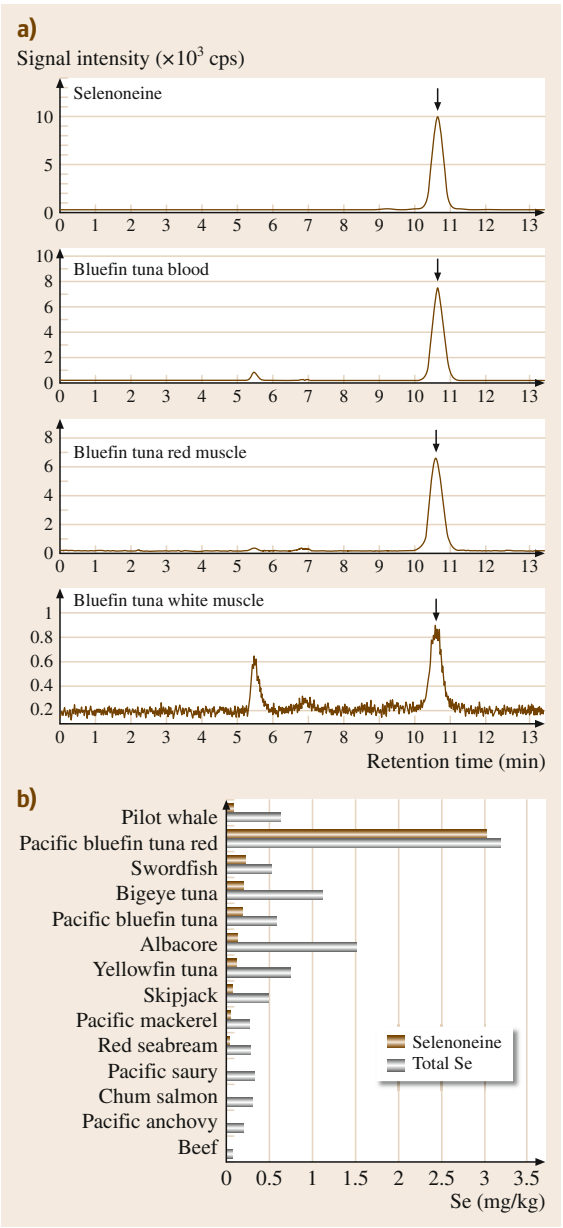

Fig. 46.2a,b Speciation analysis of organic selenium in the muscle of fishes by LC-ICP-MS. Water-soluble selenium compounds in fish muscle were speciated though LC-ICP-MS analysis. **(a)** Separation of selenoneine, **(b)** selenium concentration in muscles

was found to be distributed widely in various animal tissues and at especially high levels in tuna tissues [46.7]. These findings indicate that the chemical forms of organic selenium present in fish and terrestrial animals are very different. To determine selenoneine levels below the detection limit (0.05 nmol/g tissue), additional methods for extraction and concentration of selenoneine should be developed.

46.3 Biochemical Characterization of Selenoneine

46.3.1 Purification

Selenoneine can be purified from the blood and other tissues of tuna [46.7]. The red blood cells in tuna contain the highest levels of selenoneine, ranging from 188 to 638 nmol/g. Other tissues, such as red muscle, heart, gill, spleen, and hepatopancreas of ocean pelagic fish, including tuna, swordfish, yellowtail, and mackerel also contain high levels of selenoneine (> 10 nmol/g). The tissue concentration of selenoneine and selenium may depend on fish size and type of feed. Selenoneine is soluble in ultrapure water, methanol, and acetonitrile, and extractable in freshly prepared solvents. Because of its strong radical scavenging activity, selenoneine reacts with alcohols, oxidants, and metals. Selenoneine-oxidized dimer (yellow-green color) and selenoneine-heme complex (orange-red color) are extractable from the tissues. Selenoneine is monitored by detection by means of absorption at 260 and 430 nm wavelengths. A reverse-phase C18 column (Atlantis dC18, Waters) and GPC column (Ultrahydrogel 120, Waters) were used for purification. The selenoneine dimer was eluted in the flow-through fraction of the Atlantis dC18 column and eluted in the fractions after the bed volume in the GPC column. For large-scale preparation of selenoneine, a water soluble, extractable fraction after boiling, steam heating, or autoclaving of the tissues was used.

46.3.2 Radical Scavenging Activity

Strong antioxidant activity was assayed by radical scavenging activity with 1,1-diphenyl-2-picrylhydrazyl (DPPH). The activity of selenoneine was higher than ergothioneine and a water-soluble analog of vitamin E, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), Table 46.1. The redox potential of selenoneine was −0.69 V (vs. Ag/AgCl/sat. KCl reference electrode, −0.49 V vs. normal hydrogen reference electrode (NHE)). This value was similar to the redox potential of selenocysteine/selenocystine (−0.488 V NHE), but significantly different from that of cysteine/cysteine (−0.233 V vs. NHE) [46.13]. Therefore, selenoneine and selenocysteine are more reactive than thiol compounds.

46.3.3 OCTN1 as a Selenoneine Transporter

Selenoneine is a selenium analog of ergothioneine with one selenium atom in its imidazole ring. OCTN1, transports ergothioneine and carnitine, and is involved in the selenoneine uptake and detoxification of methylmercury (MeHg) [46.14]. OCTN1 is ubiquitously distributed in mammalian cells and tissues [46.15–20]. HEK293 cells transfected with an OCTN1 cDNA (complimentary DNA) construct showed specific uptake of selenoneine. Given its role in heme metabolism, the transporter gene has also been identified and expressed in zebrafish blood cells and other cell types.

Selenoneine is the ideal, specific physiological substrate for OCTN1. K_m values of selenoneine uptake in HEK293 cells and zebrafish red blood cells have been estimated to be 13.0 and 9.5 μM, respectively. Previously, human OCTN1 was characterized to bind specifically ergothioneine (K_m 21 μM in HEK293 cells). Selenoneine was incorporated into human cells, zebrafish red blood cells, and embryos within 30 min. OCTN1 regulates selenoneine absorption and selenium metabolism in animal tissues. Since selenoneine has a strong radical scavenging activity, the distribution and expression of OCTN1 may be responsible for maintenance of the selenium redox status. In addition to cation absorption, mammalian OCTN1 is thought to be involved in the secretion of cations in renal proximal tubules and the small intestine [46.15–20].

Table 46.1 DPPH radical scavenging activity

Product	RS_{50} (μM)
Trolox[a]	880
l-Ergothioneine	1700
Selenoneine	1.9

[a] The water-soluble vitamin E-like antioxidant

Furthermore, OCTN1 mediated the incorporation of selenoneine and the excretion of MeHg in human cells and zebrafish embryos, indicating a role in MeHg detoxification.

46.4 Nutritional and Functional Properties of Dietary Organic Selenium

46.4.1 Metabolism and in vivo Antioxidant Activity

Selenoneine exists as two tautomers, the selenol and selenoxo-form monomers, and as an oxidized dimer [46.7]. For practical reasons, the stable oxidized dimer is used for bioassays and animal trials. The dimer can be dissociated to a monomer under reduced conditions in the presence of glutathione (GSH). When selenoneine was added to HEK293 culture medium, cell growth was enhanced and reactive oxygen species (ROS) levels were reduced. Treatment of human umbilical vein endothelial cells (HUVECs) with selenoneine induced cell growth and anti-apoptotic activity in the presence of 2 mM hydrogen peroxide. Rabbit red blood cells treated with selenoneine showed protection of hemoglobin from autoxidation and metohemoglobin formation. Therefore, the selenoneine oxidized dimer may be reduced by GSH, thus existing as a reduced monomer intracellularly and acting as a radical scavenger (Fig. 46.3).

To characterize the in vivo antioxidant activity of selenoneine, post-mortem meat color change and metmyoglobin (Mb) formation in the red muscle of yellowtails were examined after intravenous injection of selenoneine [46.21]. The selenoneine concentrations in the red blood cells and red muscle were higher in the selenoneine-injected fish than in the control fish. A close correlation was detected between the selenoneine concentration in the red blood cells and red muscle. In addition, a negative correlation was observed between the selenoneine concentration in the red muscle and the ROS level in the plasma. After the cold storage of sliced meat at 4 °C overnight, Mb formation and ROS production in the selenoneine-injected fish were delayed, and the a^* value of the red muscle was conserved compared with the control fish. Therefore, selenoneine was determined to be responsible for the color change in the meat and the prevention of Mb formation in the red muscle of yellowtails.

Dietary selenoneine intake in animal trials also induced antioxidant effects in vivo. Selenoneine was incorporated in the blood and muscle tissues, and serum ROS levels were reduced. Selenoneine intake also induced GPx1 activity in red blood cells. Selenoneine can enhance selenium antioxidant functions and selenoprotein synthesis, and act as an antioxidant in vivo.

In the Japanese fish-eating population, selenoneine was highly concentrated in the red blood cells, in a manner dependent on the frequency of fish consumption [46.22]. The red blood cells contained 6.38 nmol/g total selenium, 2.65 nmol/g selenoneine, and 3.28 nmol/g selenoproteins, whereas the serum contained 2.18 nmol/g total selenium. The highest concentrations of selenoneine, total selenium, and MeHg in the red blood cells were 2.38, 2.40, and 0.47 μg Hg/g, respectively. Selenoneine is the major chemical form of selenium in the red blood cells of the Japanese fish-eating population and is an important biomarker of the selenium redox status.

In human disease, OCTN1 and blood ergothioneine have been identified as involved in the etiology of Crohn's disease. The OCTN1/1672T mutation was associated with an increased risk of colorectal cancer [46.23]. The blood ergothioneine concentration was also significantly reduced in Japanese patients with Crohn's disease. This result was confirmed by the reduced distribution of ergothioneine in the small intestine and renal reabsorption of ergothioneine in OCTN1 (–/–) mice [46.15]. Selenium deficiency is common in patients with severe gastrointestinal disorders, including Crohn's disease and ulcerative colitis, and is related primarily to malabsorption. Crohn's disease patients had reduced concentrations of selenium and glutathione peroxidase in their plasma and red blood cells. Therefore, metabolism and uptake of selenoneine by OCTN1 may be essential for the prevention of gastrointestinal disorders and cancers. However, the relationship between selenoneine depletion and intestinal diseases has not been proven. Selenoneine intake and metabolism through fish consumption might be important determinants of the selenium redox status.

46.4.2 Bioavailability of Selenium

In the human diet, selenium bioavailability is evaluated by the level of induced expression of GPxs

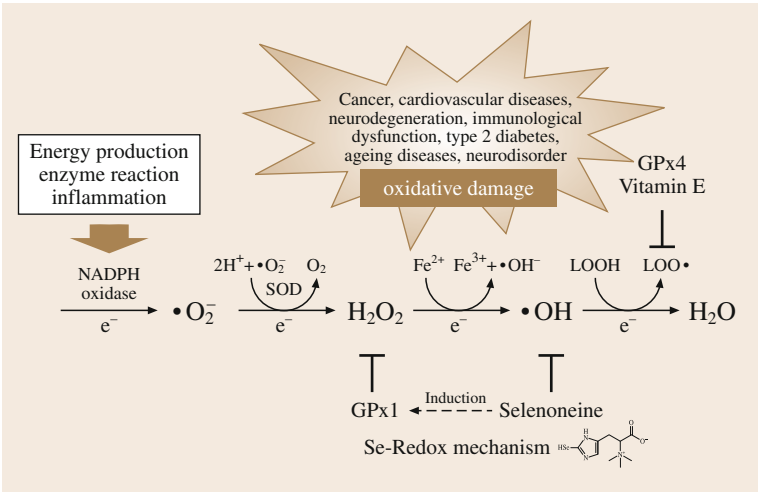

Fig. 46.3 Possible antioxidant mechanism of selenoneine. Selenoneine can react with hydroxyl radicals and block the radical production in the cells. Selenoneine induces expression of GPx1 and GPx4 at both transcriptional and translational levels

and other selenoproteins compared with the maximum expression level. The maximum selenoprotein expression is obtained by a daily dietary selenium intake of 0.1–0.2 mg/kg for animals and no more than 55 µg for humans [46.24]. The bioavailability of selenium depends on the food source due to the different chemical forms of selenium present. Plant foods contain selenite, selenomethionine, and γ-glutamyl methylselenocysteine, whereas terrestrial animal meat contains selenoproteins, including selenocysteine and selenomethionine [46.6, 25–31]. Ocean fish, such as tuna, mackerel, and swordfish were found to contain high levels of selenoneine [46.4, 7, 12]. Fish contain a highly bio available form of selenium. In Latvia, the number of fish meals consumed per month correlated with plasma selenium, selenoprotein P, and GPx levels [46.25]. The chemical form of selenium and the food source are considered key determinants of post-absorptive metabolism, and bioavailability evaluations should consider their metabolic retention and toxicity indices. Selenoneine is noncytotoxic and incorporated into cultured human and fish cells through the OCTN1 transporter. Selenoneine possesses a number of biological activities, including radical scavenging, cell growth promotion, and anti-apoptotic, as well as MeHg protection and demethylation functions. Since selenoneine induces the activities and gene expression of GPx1 in animal cultured cells, selenoneine can be used as the selenium source for selenoprotein synthesis. Therefore, the bioavailability of selenoneine should be compared with those of other selenium sources, such as sodium selenite, selenomethionine and selenomethionine-containing proteins, and selenoproteins.

46.4.3 Supernutritional Supplementation

Supplementation with inorganic and organic selenium compounds is considered to be anticarcinogenic at doses greater than those required to support the maximum expression of selenoproteins, which are generally regarded as wholly responsible for the nutritional effects of selenium [46.32–34]. In the rat model, the addition of sodium selenite to the diet at the 2–5 ppm level was effective in preventing chemical carcinogenesis using 7,12-dimethylbenzanthracene [46.35]. The effective doses of selenium for anticarcinogenic activity are close to the toxic dose (5 ppm) that causes a loss of body weight. *Combs* and *coworkers* [46.32–34] have suggested that antioxidant selenium compounds present in foods are metabolized to yield selenide or methylated selenides. Conversely, since selenoneine is nontoxic and shows powerful antioxidant activity, selenoneine supplementation can enhance antioxidant activity at concentrations of 10 pM to 1 mM, and induce the expression of GPx and other selenoproteins in cell culture and animal trials. DNA (deoxyribonucleic acid) damage induces GPx1 expression through the activation of the tumor suppressor protein p53 in cultured human cells [46.36]. Since selenoneine can activate GPx1 gene expression, it might also mediate activation of p53 and related DNA damage repair mechanisms. The antioxidant functions of selenoneine derived from seafood intake may mediate its anticarcinogenic activity; alternatively selenoneine may be biologically synthesized from other selenium sources in the cells and tissues. Therefore, the selenoneine de novo synthesis pathway in animal cells should be identified.

46.4.4 Burnt Meat

Selenoneine binds to the heme moieties of hemoglobin and myoglobin, protecting them from auto-oxidation by iron ions under hypoxic conditions. The selenoneine-heme complex is extracted in methanol from fish blood and muscles, and shows a bright red color, suggesting direct binding of selenium to the heme iron. Selenoneine levels in the tissues may be closely related to the low-oxygen adaptation mechanisms of marine animals, which prevent oxidation of heme proteins.

Burnt meat is a problem in aquaculture and fisheries of pelagic ocean fish, such as tuna, yellowtail, and mackerel in Japan [46.37]. The meat appears cooked, although it is raw, and the flesh lacks the typical bright red color of meat (Fig. 46.4). Burnt meat has a more watery, softer texture and is often seen in fish under stress conditions, for example those caught during the summer spawning period when the water temperature is high. The oxidative stress is caused by selenium deficiency and hypoxia. After being caught, extensive apoptosis and autophagy occur in the white muscle, and hemolysis occurs in fish that contain blood selenium levels of less than 1 μg/g tissue. The antioxidant effects of selenoneine may be essential in enabling fish to adapt and survive in low-oxygen marine environments. In rats, selenium deficiency was shown to induce hemolysis [46.38]. White muscle disease in selenium-deficient animals shows similar features [46.1]. Selenium levels

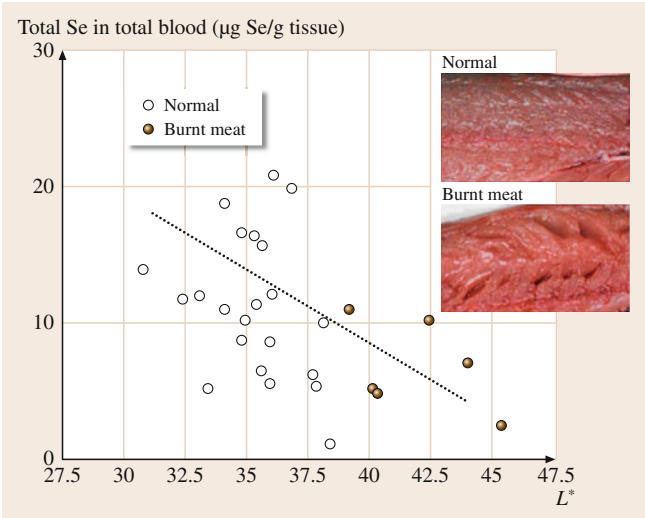

Fig. 46.4 Burnt meat of Pacific mackerel in spawning migration in summer. An index for burnt meat, L^* value, is negatively correlated to the selenium levels in the blood

were closely related to the DPPH radical scavenging activity against red blood cells in the blood of bluefin tuna [46.37]. Burnt meat in fish may be due to selenium deficiency. Therefore, selenium supplementation in cultured fish might reduce the burnt meat problem in aquaculture, and the nutritional selenium requirement of ocean fish species should be evaluated.

46.5 MeHg Detoxification

Dietary intake of selenium can reduce MeHg toxicity. In 1972, *Ganther* et al. [46.39] demonstrated that intake of canned tuna meat containing slightly elevated MeHg levels reduced the toxicity of Japanese quail and suggested a protective role of selenium. *Friedman* et al. [46.40] showed a protective effect of freeze-dried swordfish meat against MeHg toxicity in rats, and *Ohi* et al. [46.41] suggested that an unknown organic selenium compound in fish meat reduces MeHg neurotoxicity.

Recently, MeHg detoxification was shown to be mediated by selenoneine and its transporter OCTN1 in zebrafish embryos using morpholino antisense oligo (MO)-knockdown technology [46.14]. Upon exposure to 100–500 ppb MeHg-cysteine (MeHgCys) in culture medium, both selenium and mercury levels in normal control embryos decreased compared with OCTN1-deficient embryos. The addition of selenoneine to the culture medium (0.8–3.2 μM) reduced MeHg accumulation in the control embryos and resulted in the production of inorganic mercury. This result indicates that selenoneine mediates MeHg detoxification. In contrast, selenoneine had no effect on MeHg detoxification in OCTN1-deficient embryos. To further characterize MeHg detoxification mechanisms, MeHg was microinjected into the yolk, and MeHg accumulation in the embryos was examined (Fig. 46.5). In control embryos, the intracellular mercury level decreased to 0.7 ng/embryo following microinjection of MeHgCys (3 ng mercury), and inorganic mercury was produced (1.1 ng/embryo). This indicates that most of the MeHg introduced into the embryos was excreted. In contrast, the mercury level increased to 2.2 ng/embryo in OCTN1-deficient embryos, and a small quantity of inorganic mercury

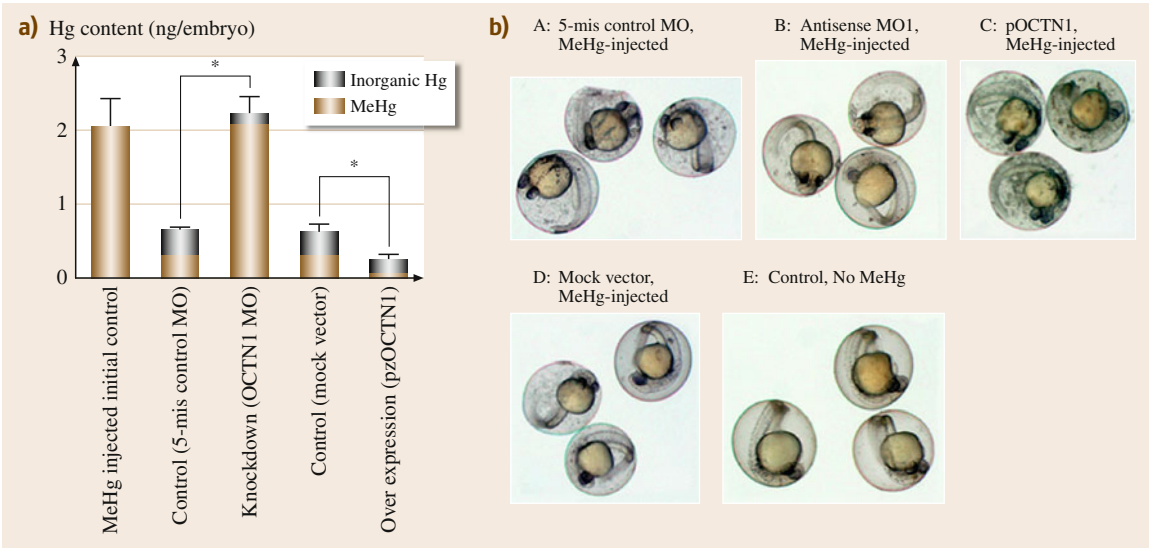

Fig. 46.5a,b Excretion of MeHg by the exosomal secretion pathway. **(a)** Mercury levels in embryos microinjected with MeHgCys (3 ng Hg/individual embryo) into the yolk sac. Embryos were cultured in Hank's medium at 28.5 °C for 12 h after MeHgCys microinjection at 12 hpf. MeHg and inorganic Hg contents of embryos were determined. **(b)** Production of gray granules by embryos after microinjection of MeHgCys

(0.1 ng/embryo) was produced. Bafilomycin A, an inhibitor of the vacuolar-type H^+-ATPase in lysosomes, inhibited the excretion of MeHg in the yolk and enhanced MeHg accumulation. Small vesicles, exosomes, were collected from the culture medium by ultracentrifugation. The exosomes contained high levels of mercury and lysosomal cathepsin L activity. Exosome production was induced by MeHg exposure, and inhibited by bafilomycin A1. These findings indicate that MeHg was excreted by the secretory lysosomal pathway through the function of OCTN1. The yolk exhibited strong excretion and MeHg demethylation mechanisms, mediated by the selenoneine-OCTN1 system. A similar MeHg detoxification function was identified in OCTN1-transfected HEK293 cells, which showed decreased selenium levels after MeHgCys treatment compared with the levels in mock vector-transfected cells, suggesting selenium transport by OCTN1. Mercury accumulation was decreased following selenoneine exposure in OCTN1-transfected cells, but not in mock

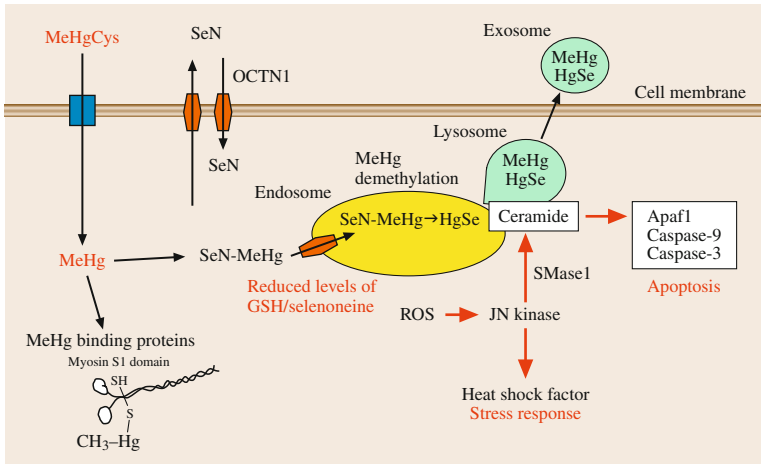

Fig. 46.6 Possible detoxification mechanism of MeHg. The OCTN1 and selenoneine (SeN) were essential for the MeHg detoxification. MeHg and selenoneine complex may be incorporated into the endosomes and lysosomes. The secretory lysosomal vesicle formation is stimulated by oxidative stress conditions. MeHg exposure induces ROS formation, c-Jun N-terminal kinases (JNK) activation, and ceramide formation. Demethylation reaction is accelerated in the lysosomes

vector-transfected cells, indicating that selenoneine and OCTN1 regulate MeHg detoxification in human cells.

From these recent findings, the mechanism of protection against MeHg toxicity is hypothesized to involve direct conjugation of selenoneine with MeHg (Fig. 46.6). The selenoneine–MeHg complex might be formed under reducing conditions in vivo and translocated into the lysosomal secretory vesicles by OCTN1. The MeHg complex may be decomposed to inorganic mercury, i. e., mercury selenide (HgSe). HgSe in the liver of marine mammals may be produced from the selenoneine–MeHg complex by this OCTN1-mediated secretory lysosomal mechanism. In the dolphin liver, the demethylation/accumulation of mercury is likely to involve the formation of HgSe and selenocompounds from selenium-containing residues of specific proteins [46.42–47]. In addition, the molar ratio of selenium and inorganic mercury was close to 1, suggesting that HgSe is the end product of MeHg detoxification [46.48, 49]. Therefore, the MeHg detoxification mechanism by which selenoneine–MeHg complexes are converted to HgSe by OCTN1 function may be commonly distributed in fish and mammals. Inorganic selenium and selenomethionine supplementation can reduce MeHg toxicity. Selenoneine may be biologically synthesized from other selenium sources in vivo and used in MeHg protection mechanisms.

Exosome vesicles are produced by ceramide stimulation under oxidative stress conditions [46.14]. Thus, MeHg exposure may induce an oxidative stress response and formation of exosome vesicles containing MeHg and inorganic mercury. Oxidative stress conditions activate c-Jun N-terminal kinases (JNK), which phosphorylate neutral sphingomyelinase 1 (SMase 1), a JNK substrate [46.50]. Ceramide generation by SMase 1 activation triggers the formation and release of exosomes, and the endosomal sorting complexes required for transport (ESCRT) machinery is thought to play important roles in cell–cell communication, antigen presentation, and pathogenesis [46.51, 52]. Thus, exosomal secretion mechanisms are also essential for MeHg detoxification. The detoxification of toxic chemicals and oxidants other than MeHg mediated by selenoneine appears to be a novel exosomal function in animal cells and tissues. Therefore, mercury and selenium in exosomes might be important biomarkers of detoxification of toxic chemicals. Selenium and mercury levels in serum exosomes should be measured in animal models and during medical checkups.

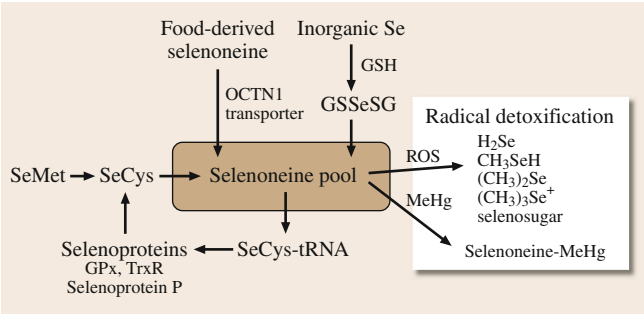

Fig. 46.7 Proposed model of selenium metabolism and radical detoxification. Selenoneine may be directly incorporated through OCTN1 transporter from fish consumption and biologically synthesized from other selenium sources. Selenoneine may be responsible for radical detoxification and used for selenoprotein synthesis

The findings presented here support the hypothesis that MeHg excretion is mediated by selenoneine and a specific OCTN1. Depletion of selenoneine and production of ROS after MeHg exposure may trigger ceramide generation and exosome formation. Although a MeHg demethylation enzyme, similar to bacterial organomercury lyases [46.53], could be present in the MeHg secretion pathway, MeHg can be converted to inorganic mercury directly and nonenzymatically in the presence of selenium. Further study is required to identify the demethylation reaction and mechanism of lysosomal vesicle formation.

46.6 Conclusion

To elucidate the nutritional and physiological significance of selenium as a micronutrient, which is linked to a variety of human and animal diseases, the organic selenium compounds responsible for the antioxidant and redox mechanisms must be identified and characterized. Selenoneine is related to a variety of biological activities as a strong radical scavenger in both fish and mammals (Fig. 46.7).

47. Biological Activities of Marine-Derived Oligosaccharides

Tatsuya Oda

Alginate is an acidic copolymer of α-L-guluronate (G) and its C5 epimer β-D-mannuronate (M), is arranged in homopolymer (polyguluronate or polymannuronate) or heteropolymer (a mixed sequence of these residues). Alginates extracted from brown algae are widely used in the food industry, biotechnology, and medical fields. In addition to the many interesting physicochemical properties of alginates, several studies have demonstrated that alginates have various bioactivities such as immunomodulation. Recent studies have demonstrated that alginate oligosaccharides prepared from alginate polymers show even many more improved bioactivities, not only in mammalian systems but also in plant systems. It is considered that the decreased viscosity and the loss of gel-forming properties of alginate oligosaccharides lead to an increase in biocompatibility.

47.1 Overview

Alginate is an acidic linear polysaccharide that is usually extracted from brown seaweeds such as *Macrocystis pyrifera* and *Ascophyllum nodosum*. This polysaccharide is composed of two forms of uronic acids α-L-guluronate (G) and β-D-mannuronate (M), which form three types of polymer blocks: namely homopolymers of guluronate (PG), homopolymers of mannuronate (PM), or heteropolymers (a mixed sequence of these residues); these block structures are expressed as G-blocks, M-blocks, and MG-blocks (MG: heteropolymers of mannuronate and guluronate), respectively [47.1]. The differences in the molecular weight, the M/G ratio, and the entire sequence seem to be responsible for the diversity of physicochemical properties and bioactivities of alginates [47.2–7]. Alginates have been utilized in a wide range of commercial applications including thickening agents and dispersion stabilizers. Since alginates have gentle gelling properties in the presence of divalent cations such as calcium, they are also used for live cell encapsulation in vitro [47.8] and in vivo [47.9], and for several tissue engineering applications [47.10, 11]. Alginate oligosaccharides prepared by the enzymatic degradation of alginate polymers with relatively low molecular weight are also known to have many biological activities, including suppression of fibroblast proliferation and collagen synthesis in human skin [47.12], stimulation of endothelial cell growth and migration [47.13], stimulation of human keratinocyte growth [47.14], suppression of T helper 2 cells (Th2) development, and immunoglobulin E (IgE) secretion through inducing interleukin (IL)-12 secretion [47.15].

In addition to these mammalian models, it has also been reported that enzymatically depolymer-

ized alginates promote the growth of bifidobacteria, while the original alginate polymer has no such effect [47.16]. Furthermore, alginate oligomers seem to have some biological effects on plants as well. Alginate oligomers prepared with bacterial alginate lyase increase shoot elongation of komatsuna (*Brassica rapa* var. *pervidis*) seeds [47.17] and promote the elongation of barley roots [47.18]. Our recent studies have demonstrated that alginate polymers induce the tumor necrosis factor (TNF)-α secretion from the mouse macrophage cell line RAW264.7, and the activity is significantly influenced by the molecular size and M/G ratio [47.19].

Interestingly, a mixture of enzymatically depolymerized alginate oligomers showed more than ten times higher activity in terms of TNF-α secretion from RAW264.7 cells as compared to original alginate polymers [47.19]. Since the alginate oligomers have fairly low viscosity in aqueous solution even at quite high concentration and has no gel-forming property in the presence of calcium, it is considered that alginate oligomers are more applicable for in vivo systems [47.19, 20]. In fact, it was found that intraperitoneal (i.p.) administration of enzymatically depolymerized alginate oligomers to mice resulted in a significant increase in the serum levels of various cytokines such as TNF-α and G-CSF (granulocyte colony-stimulating factor) [47.21]. This finding indicates that alginate oligosaccharides even in mixture are capable of inducing certain biological activities. In addition to the biological activities of alginate polymers and their oligomers described above, recent studies have demonstrated that alginate oligomers [47.22], as well as polymers [47.23], show potent antioxidant activities.

To gain insight into the structure–activity relationship of alginate oligomers, it is important to use highly purified samples with a defined structure. Such purified alginate oligomers can be prepared from homopolymers of guluronate (PG) and homopolymers of mannuronate (PM) blocks prepared from alginate polysaccharide. In this chapter, various biological activities of alginate oligosaccharides are described as in the following five points. First, the methods of preparation of alginate oligosaccharides are discussed. Second, antioxidant activities of alginate oligosaccharides are treated. Third, cytokine-inducing activities of highly purified alginate oligosaccharides from macrophage cell line RAW264.7 cells in terms of structure and structure-activity relationship analysis are discussed. Fourth, the in vivo activity of alginate oligosaccharide mixtures to induce cytokines in the mice model are considered. Fifth, the growth-promoting effect of alginate oligosaccharides mixture on marine unicellular microalga is discussed.

47.2 Preparation of Alginate Oligosaccharide Mixture

47.2.1 Enzymatic Method

Various alginate polysaccharides are commercially available. Sodium alginate (1000 cps grade) purchased from Nacalai Tesque Inc. (Kyoto, Japan) was mainly used in our study. The method for the preparation of enzymatically depolymerized alginate oligosaccharide mixtures, which were found to have various biological activities, is described. Enzymatic digestion of alginates was conducted by basically the same procedure as described previously [47.21]. Alginate lyase required for the preparation of alginate oligosaccharide was purified from the culture medium of *Pseudoalteromonas* sp. strain number 272, as described previously [47.24]. This purified enzyme, which can recognize both polyguluronate and polymannuronate, produced unsaturated guluronate and mannuronate oligomers with various degree of polymerization [47.24]. In brief, 5% of alginate samples in aqueous solution was incubated with alginate lyase (final 1 μg/ml) at 40 °C for 3 days. The enzymatic reaction was stopped by heating the solution in boiling water for 10 min. No significant changes in the compositions of digestion products were observed after further enzymatic treatment. Gel-filtration analysis suggested that the enzymatically digested product contained several oligomers with a degree of polymerization (DP) of 3–9 (i. e., with a molecular weight of 529 $\approx$ 1585) [47.19]. Gel-filtration chromatography suggested that a similar composition of the oligomer mixture can be prepared by this procedure even from different alginate polymers with different molecular sizes and M/G ratios [47.19]. Before use, all samples were filtered through an endotoxin-removing filter (Zetapor Dispo filter) purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). This filtration procedure reduced even the bioactivity of 1 μg/ml of lipopolysaccharide (LPS) to a negligible level.

47.2.2 Acid Hydrolysis

Another way to prepare alginate oligosaccharides is acid hydrolysis. Alginate polymer (1%) in 200 ml of acidic solution (0.3 M HCl, pH 4.0) was treated at 121 °C for 80 min. After cooling down to room temperature, the sample solution was neutralized with 1 M NaOH, and lyophilized in a vacuum freeze-dryer. By this procedure, saturated alginate oligosaccharide mixtures with free carboxyl groups were obtained [47.25].

47.2.3 Preparation of Purified Alginate Oligosaccharides

To prepare highly purified alginate oligosaccharides, it is necessary to obtain polyguluronate (PG) and polymannuronate (PM) first. PG and PM with 20–24 DP were prepared from sodium alginate by the method of *Haug* et al. [47.26]. The homogeneity of the prepared polyuronates was confirmed by circular dichroic spectral analysis with a Jasco spectropolarimeter J500A coupled with a data processor, based on the method of *Morris* et al. [47.27]. Guluronate and mannuronate oligosaccharides were prepared from PG or PM by enzymatic degradation or acid hydrolysis by basically the same methods as described before. Purification of each oligosaccharide with defined DP was conducted by gel-filtration chromatography with Bio Gel P-6 and subsequent re-chromatography with Bio Gel P-2, as described previously [47.28]. By this procedure, trimer to nonamer of G (G3–G9) and of M (M3–M9) oligosaccharides were obtained.

47.3 Antioxidant Activities of Alginate Oligosaccharides

From the viewpoint of the structure–activity relationship of alginate oligosaccharides as antioxidants, radical scavenging activities of PM and PG are described in this section [47.29]. The superoxide scavenging activities of PM and PG were examined by a luminol analog L-012-dependent chemiluminescence (CL) method [47.30]. As a source of superoxide, a hypoxanthine (HPX)-xanthine oxidase (XOD) system was employed. As shown in Fig. 47.1a, when XOD was added to the reaction mixture, a rapid CL response was observed, and the CL response was significantly reduced by the addition of superoxide dismutase (SOD), indicating that superoxide was generated in the system. By this system, the superoxide scavenging activities of PM and PG can be measured (Fig. 47.1b,c). Both PM and PG showed superoxide scavenging activity in a concentration-dependent manner. In the presence of 1000 μg/ml of PM or PG, the CL response was almost completely inhibited.

PG at 100 μg/ml showed a slightly stronger scavenging activity than PM, while neither oligosaccharide had significant activity at 10 μg/ml. Since PM and PG did not inhibit the production of uric acid from HPX with the catalytic reaction of XOD (data not shown), it was confirmed that the inhibition of the CL response was due to the direct superoxide scavenging activity of PM and PG, and not the results of the inhibition of XOD.

It is well known that hydroxyl radicals are an extremely reactive species that can react with various biological molecules, and their damaging action on various biological systems is the strongest among the reactive oxygen species (ROS) [47.31]. In the next experiment, the Fenton reaction was used as a hydroxyl radical generation system, in which Fe^{2+} and hydrogen peroxide are reacted to produce hydroxyl radicals. Although there are several methods for the detection of hydroxyl radicals, such as spectrophotometric or colorimetric methods, electron spin resonance (ESR) method has been used as the most reliable assay for monitoring free radicals because of its high sensitivity and rapidity. Thus, the scavenging activities of PM and PG on the hydroxyl radical were examined by the ESR method. When the spin-trapping agent 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) was added to a solution of the Fenton reaction system, the typical 1 : 2 : 2 : 1 ESR signal of the DMPO-hydroxyl (DMPO-OH) adduct (an adduct from DMPO and the hydroxyl radical) was observed. Figure 47.2b,c show the representative ESR spectra of DMPO-OH obtained by the addition of the solvent alone and various concentrations of PM and PG. In the presence of PM or PG, the decreases in the height of the second peak of the spectrum, which represents relative amount of DMPO-OH adduct, were observed. These results clearly indicate that PM and PG have the ability to scavenge hydroxyl radicals. PM and PG showed similar concentration-dependent profiles in terms of scavenging efficiency, but they required higher concentrations to attain an effect sim-

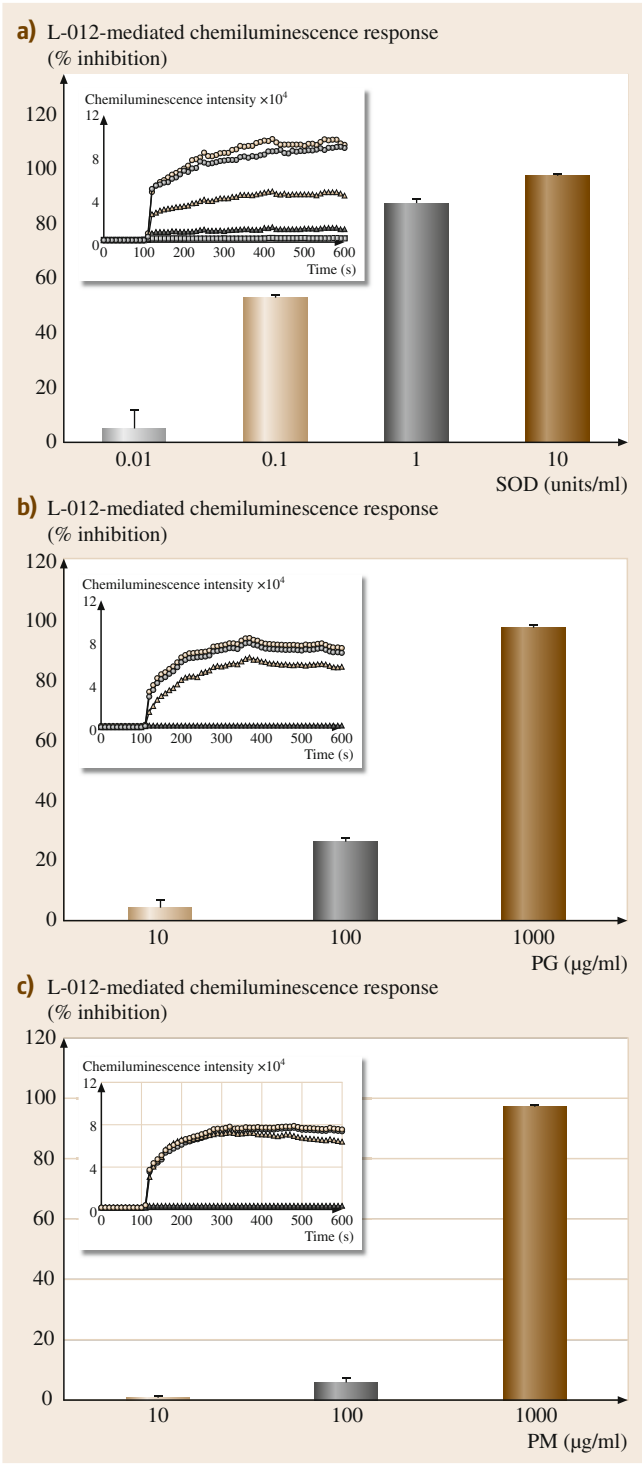

Fig. 47.1a–c Superoxide scavenging activity of PM and PG as measured by the L-012-dependent CL method. The effects of various concentrations of SOD **(a)**, PG **(b)**, and PM **(c)** on CL-responses in the HPX-XOD system were examined. *Insets* indicate the CL-response patterns during 10 min in the presence of 0 (●), 0.01 (○), 0.1 (▲), 1 (△), and 10 (■) units/ml of SOD **(a)**, or 0 (●), 10 (○), 100 (▲), and 1000 (△) μg/ml of PG **(b)**, or 0 (●), 10 (○), 100 (▲), and 1000 (△) μg/ml of PM **(c)**. *Columns* indicate percentage inhibition of the integrated CL-response intensity values during 10 min as compared to the control values. Each value represents the means ± standard deviation of triplicate measurements

ilar to mannitol as a known monosaccharide hydroxyl radical scavenger (Fig. 47.2a). Regarding the antioxidant activity of polysaccharides, it was proposed that polysaccharides can inhibit the formation of hydroxyl radicals, probably due to the hydrogen or electron abstraction mechanism [47.32]. It was also reported that the ease of abstraction of the anomeric hydrogen from the internal monosaccharide units made polysaccharides achieve the scavenging effect [47.33]. It is clear that further studies are required to clarify the molecular basis of the hydroxyl radical scavenging activities of PM and PG.

Regarding the hydroxyl radical scavenging mechanism of certain compounds, it has been pointed out that the scavenging activity was not due to direct scavenging but to inhibition of hydroxyl radical formation by chelating iron ions in the reaction system [47.34]. In fact, it was reported that molecules that can inhibit deoxyribose degradation are those that can chelate iron ions and inhibit the Fenton reaction [47.35]. Hence, the possible chelation of Fe^{2+} by PM and PG was estimated by the method of *Decker* and *Welch* [47.36]. As shown in Fig. 47.3, PM and PG had no significant chelating activity on Fe^{2+}, even at more than nearly 100 times the molar excess to Fe^{2+}, which was calculated by uronate bases, while 100 times mo-

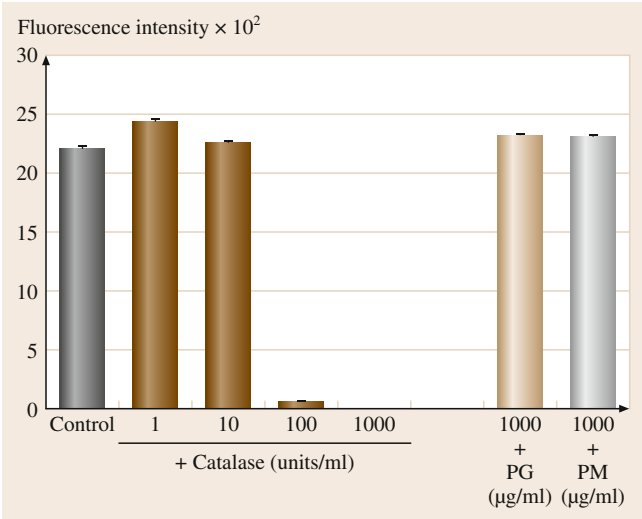

Fig. 47.4 Hydrogen peroxide scavenging activities of PM and PG measured by the PHPA-fluorescence method (PHPA: *p*-hydroxyphenyl acetic acid). *Columns* indicate fluorescence intensity obtained by the addition of indicated concentrations of catalase, PG, or PM to the PHPA-hydrogen peroxide system. Each value represents the means ± standard deviation of triplicate measurements

lar excess of Desferal, an Fe-specific chelater, completely inhibited color development in the reaction system. Similar to our results, it has been reported that alginate oligosaccharides showed no Fe^{2+} chelating activity, while chitosan oligosaccharides and fucoidan oligosaccharides exhibited a potent chelating activity on Fe^{2+} [47.22]. A comparative study on the radical scavenging activities of alginate oligosaccharides, chitosan oligosaccharides, and fucoidan oligosaccharides with similar molecular weight demonstrated that alginate oligosaccharides showed the highest hydroxyl radical scavenging activity among these marine oligosaccharides, whereas chitosan oligosaccharides had the highest superoxide radical scavenging activity [47.22]. Although the antioxidant mechanism of the oligosaccharides is not fully understood yet, these findings suggest that the chemical structure might be an important factor influencing the antioxidant activity.

Next, we examined the reactivity of PM and PG on hydrogen peroxide. Hydrogen peroxide is not a free radical, but it is cell-membrane permeable and can cause toxic effect on cells. In addition, it reacts with Fe^{2+} to form highly reactive hydroxyl radicals by the Fenton reaction, as mentioned above. As shown in Fig. 47.4, no significant scavenging activity of PM and PG toward hydrogen peroxide was observed up to 1000 μg/ml. Consistent with our results, it has been reported that the inhibitory effect of alginate oligosaccharides on hydrogen peroxide-mediated erythrocyte hemolysis is quite low as compared to that of chitosan oligosaccharides [47.22].

These results clearly indicate that PM and PG are capable of scavenging superoxide and hydroxyl radicals to a similar extent, but not hydrogen peroxide.

47.4 Cytokine-Inducing Activities of Alginate Oligosaccharides

As an immune stimulating activity of alginate oligosaccharides, their activities to induce cytokine secretion from macrophage cell line RAW264.7 cells are described in this section [47.20]. From the viewpoint of the structure–activity relationship, the results obtained by the studies conducted with purified alginate oligosaccharides are shown here. Figure 47.5 shows the structures of saturated or unsaturated mannuronate (M) and guluronate (G) oligosaccharides.

Pretreatment of RAW264.7 cells with polyguluronate (PG) and polymannuronate (PM) for 24 h did not result in any significant increase in the secretion of TNF-α into the medium. However, in the presence of enzymatically depolymerized unsaturated oligomers, the secreted levels of TNF-α markedly increased, depending on the oligomer structures. As shown in Fig. 47.6, similar structure-activity relationship profiles between guluronate oligomers and mannuronate oligomers were observed, although the maximum effect was found with G8 among guluronate oligomers and with M7 among mannuronate oligomers, respectively. On the other hand, the effects of saturated alginate oligomers, which were prepared by acid hydrolysis, on TNF-α secretion by RAW264.7 cells were fairly low or only trace levels as compared to those of unsaturated oligomers (Fig. 47.7). These results suggest that an unsaturated terminal structure with a double bond is important for the bioactivity of alginate oligomers regardless of the molecular size or structure (G or M).

Probably, RAW264.7 cells have a recognition mechanism that may be able to distinguish saturated and unsaturated terminal structures of alginate

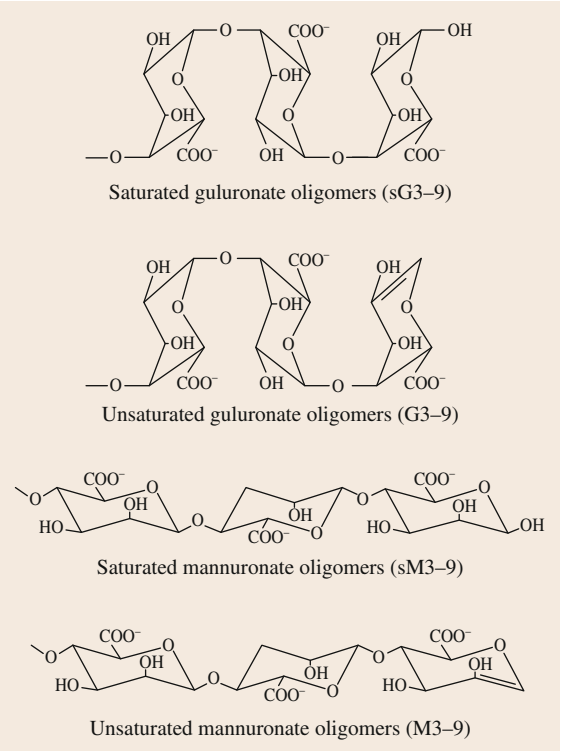

Fig. 47.5 Schematic representation of chemical structures of the saturated (sG3–9 and sM3–9) and unsaturated (G3–9 and M3–9) guluronate and mannuronate oligomers used in this study

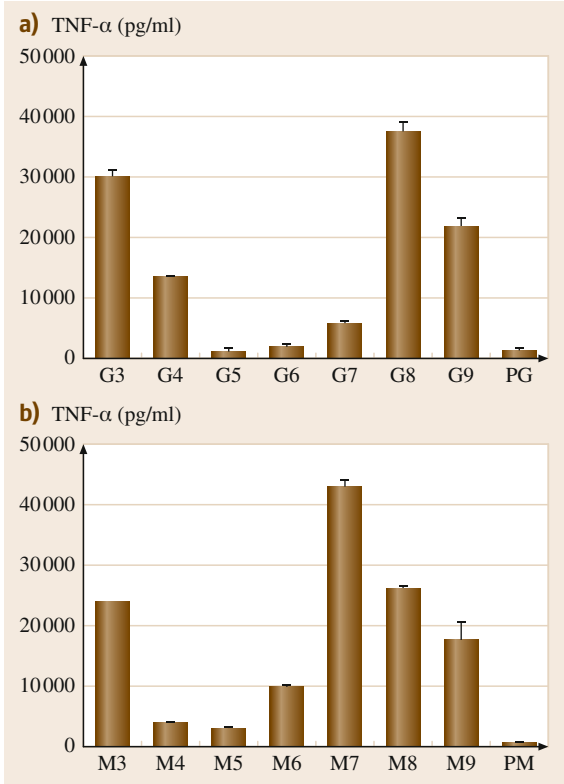

Fig. 47.6a,b Effects of unsaturated guluronate (G3–G9) **(a)** and mannuronate (M3–M9) **(b)** oligomers with various DPs on the production of TNF-α from RAW264.7 cells. Cells in 96-well plates (2×10^4 cells/well) were cultured in the growth medium in the presence of each purified alginate oligomer at a concentration of 1000 μg/ml at 37 °C. After 24 h, the supernatant was withdrawn from each well, and the amounts of TNF-α were measured by ELISA as described in the text. The effects of polymannuronate (PM) and polyguluronate (PG) were measured by the same way. Each value represents an average of triplicate measurements and each bar indicates the standard deviation

oligomers (Fig. 47.5). Since it has been reported that alginate polysaccharides stimulate human monocytes to produce IL-1 and IL-6 in addition to TNF-α [47.2], the effects of unsaturated alginate oligomers on the secretion of these cytokines from RAW264.7 cells were examined by the Bio-Plex assay system. The Bio-Plex assay is a suspension bead array technology that allows the simultaneous measurement of multiple cytokines in a single sample in a microplate well [47.21]. Similar to the results of enzyme-linked immunosorbent assay (ELISA), significantly high levels of TNF-α were detected in the cultured medium of RAW264.7 cells in the presence of some unsaturated oligomers, and the highest activities of G8 and M7 to induce TNF-α secretion were confirmed by this assay method (data not shown). As shown in Fig. 47.8, the secretion of IL-6 was also induced by unsaturated oligomers, whereas no significant effects of PG and PM were observed in this cytokine. The structure-activity relationship profiles of IL-6 were similar to those of TNF-α, although the induced levels of IL-6 were lower than those of TNF-α, and the activity of M7 was clearly higher than G8. Although the detected levels of IL-1α and IL-1β were lower than those of TNF-α, the patterns of the relationship between molecular structures of oligomers and the activities to induce secretion of IL-1α and IL-1β were similar to those of TNF-α (Fig. 47.9).

In a structure–activity relationship study of alginate oligomers, *Iwasaki* and *Matsubara* reported that an alginate oligosaccharide mixture had promoting ac-

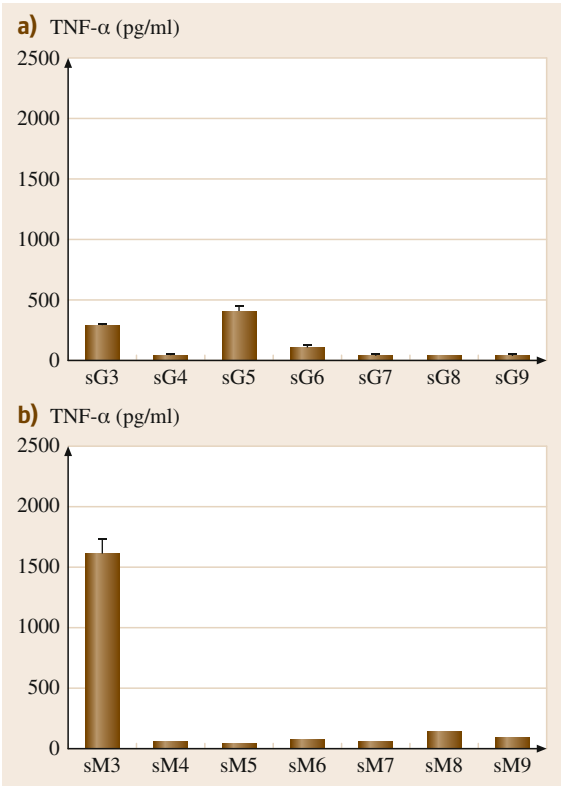

Fig. 47.7a,b Effects of saturated guluronate (sG3–sG9) **(a)** and mannuronate (sM3–sM9) **(b)** oligomers with various DPs on the production of TNF-α from RAW264.7 cells. The TNF-α inducing activities of saturated oligomers were measured as described in the legend to Fig. 47.6

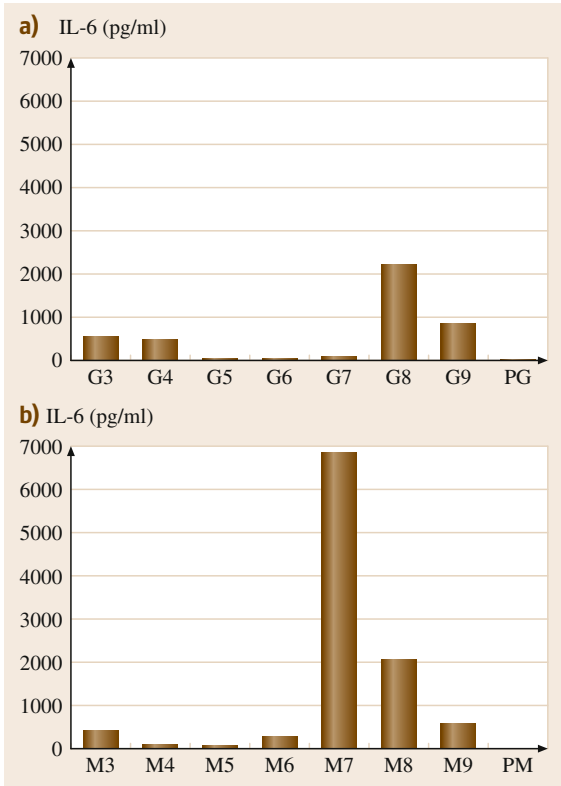

Fig. 47.8a,b Effects of unsaturated guluronate (G3–G9) **(a)** and mannuronate (M3–M9) **(b)** oligomers with various degree of polymerization DPs on the production of IL-6 from RAW264.7 cells. Cells in 96-well plates (2×10^4 cells/well) were treated with each oligomer as described in the legend of Fig. 47.2, and then the culture supernatants were subjected to Bio-Plex assay to determine IL-6 levels as described in the text. Each value represents an average of duplicate measurements. Differences between duplicate measurements for each value were within 5%

tivity toward the root growth of lettuce seedlings, and the tri, tetra, penta, and hexa-saccharides had especially strong activity [47.37]. In addition, it has been reported that penta-guluronate (G5) had the highest root growth-promoting activity on carrot and rice among the various alginate oligomers tested [47.28]. These findings together with the results described here suggest that there is the most effective structure or molecular size of alginate oligomer depending on each assay system in which the specific activities of oligomers are evaluated.

In the case of induction of cytokines from RAW264.7 cells, G8 and M7 showed the highest activity among each guluronate and mannuronate oligomer group, respectively. Previous structural studies have proposed that mannuronate and guluronate adopt different conformations, as shown in Fig. 47.5. Furthermore, X-ray diffraction analysis of the partial hydrolysis products of alginate has suggested that mannuronate blocks predominately form an extended ribbon structure, whereas guluronate blocks form a buckled chain [47.38]. Thus, such differences in the entire conformation between G8 and M7 may result in the fact that the most effective guluronate oligomer is one residue longer than the mannuronate oligomer. Since quite similar levels of TNF-α production were induced by G8 and M7, both oligomers may stimulate RAW264.7 cells with equal potency through a common recognition site on the cells.

Since the maximum activities of G8 and M7 were also observed in inductions of IL-1α, IL-1β, and IL-6

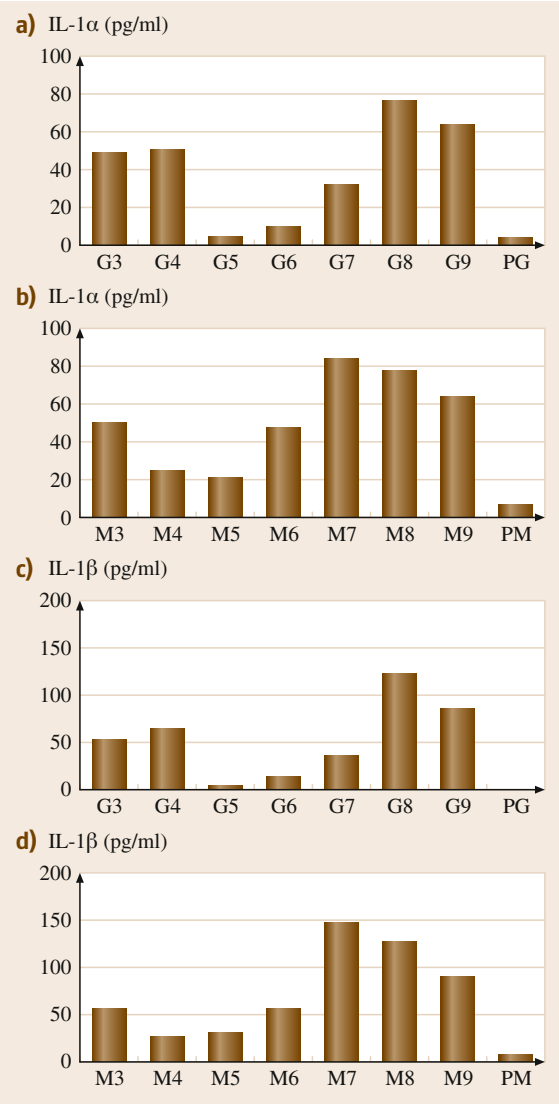

Fig. 47.9a–d Effects of unsaturated guluronate (G3–G9) **(a,c)** and mannuronate (M3–M9) **(b,d)** oligomers with various DPs on the production of IL-1α **(a,b)** and IL-1β **(c,d)** from RAW264.7 cells. Cells in 96-well plates (2×10^4 cells/well) were treated with each oligomer as described in the legend of Fig. 47.1, and then the culture supernatants were subjected to Bio-Plex assay to determine IL-1α and IL-1β levels as described in the text. Each value represents an average of duplicate measurements. Differences between duplicate measurements for each value were within 5% ◄

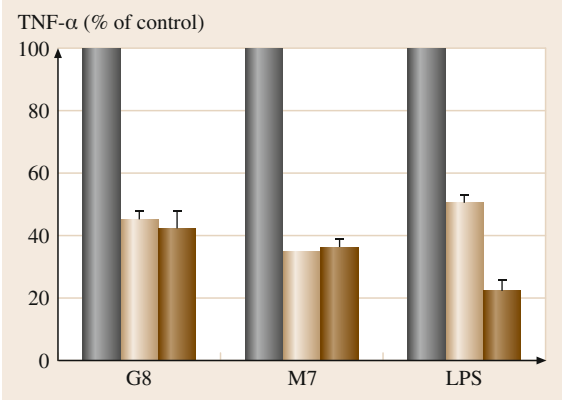

Fig. 47.10 Effects of anti-TLR2 and anti-TLR4 antibodies on the production of TNF-α by RAW264.7 cells stimulated with alginate oligomers (G8 and M7) and LPS. Cells in 96-well plates (2×10^4 cells/well) were pretreated with 10 μg/ml of anti-TLR2 (□) or anti-TLR4 (□) antibody for 1 h at 37°C. After washing with PBS, alginate oligomers (G8 or M7 at final concentration of 1000 μg/ml) or LPS (at final concentration of 1 ng/ml) were subsequently added, followed by incubation for further 24 h. Supernatants were analyzed for TNF-α levels as described in the legend of Fig. 47.2. Each value represents an average of triplicate measurements and each bar indicates the standard deviation. □: control without antibody

production, these cytokines may be induced simultaneously once stimulated by G8 and M7. Interestingly, G3 and M3, the smallest oligomers among the oligomers tested, also showed relatively high cytokine inducing activities, even higher than other larger oligomers. The reason for this is uncertain now, but the finding the cause may provide a clue to understanding the recognition site or mechanism on RAW264.7 cells by alginate oligomers.

Regarding the initial host defense against bacterial infection, it has been proposed that the recognition of microbial products such as LPS by the host defense system is mediated by members of the toll-like receptor (TLR) family [47.39]. TLRs are evolutionary conserved pattern recognition receptors that discriminate between self and non-self by recognition of pathogen-associated molecular patterns with no apparent structural similarity [47.39]. TLRs play important roles in signal transduction for the initiation of mammalian immunity responses, including cytokine production [47.40]. In addition to bacterial products, TLRs seem to be responsible for the polysaccharide-mediated stimulation processes. For instance, it has been shown that two

uronic acid-containing polysaccharides with different origins induce cell activation through TLR4 [47.41, 42]. Furthermore, it was recently reported that TLR2 and TLR4 are involved in the stimulation of cytokine production from human monocytes by mannuronate polymers isolated from mucoid produced by *Pseudomonas aeruginosa* [47.43]. To examine the possible involvement of TLR2 and TLR4 in G8 and M7-induced TNF-α secretion from RAW264.7 cells, the specific blocking antibodies were used. As shown in Fig. 47.10, both antibodies to TLR2 and TLR4 inhibited the activities of G8 and M7 to induce TNF-α secretion with similar efficiencies. On the other hand, LPS-induced TNF-α secretion was differently affected by these antibodies, and the influence of the antibody to TLR4 was greater than the antibody to TLR2 (Fig. 47.10). These results suggest that alginate oligomers with a molecular weight less than 2000 are also recognized by the innate immune system through TLRs, although the way of recognition might somehow be different from bacterial products.

This is the first report to indicate that alginate oligomers with defined chemical structures have cytokine-inducing activities in a structure-dependent manner. The highly purified sets of alginate oligomers obtained in this study are interesting agents, not only as potential therapeutic agents but also as a tool especially for analyzing pattern recognition mechanisms. Further study of the structure–activity relationship of alginate oligomers may provide insight into the TLR-mediated recognition mechanism as well as the signal transduction system leading to cytokine production.

47.5 Induction of Cytokines in Mice

It has been shown that enzymatically depolymerized alginate oligosaccharide mixture ((AOM) showed more than 10 times higher activity in terms of TNF-α secretion from RAW264.7 cells as compared to original alginate polymers [47.19]. In this section, the results of cytokine levels in mice serum after i.p. injection of AOM are described [47.21]. Since preliminary experiments indicated that G-CSF is a cytokine with the highest level among the cytokines detected in the mice serum after i.p. injection of AOM, time-course analysis focusing on G-CSF level in mice serum after i.p. administration of AOM was carried out. As shown in Fig. 47.11, the G-CSF level in the serum rapidly increased and reached the maximum level at 2 h after injection of 700 mg/kg body weight and the high level was sustained until 6 h, and then gradually decreased and returned to baseline level at 24 h. When the same dose (700 mg/kg) of original alginate polymer was injected, no significant G-CSF level was detected in the serum, at least during the time periods tested. These results suggest that the mixture of alginate oligomers is a superior cytokine inducer to the original polymer in vivo. In the in vivo system, the high viscosity as well as the gel-forming property of alginate polymers may prevent efficient transfer or even dispersion of the alginate polymer from the area injected to circulation system to reach the target organs or cells that may be involved in cytokine secretion. The improvement of these physicochemical drawbacks of alginate polymer by enzymatic degradation, as well as the increased cytokine-inducing activity at cellular level, may partly explain the reason for the potent cytokine-inducing activity of AOM in vivo.

A dose-response experiment was performed by i.p. injection of 0.07, 0,7, 7, 70, 700 mg/kg of the al-

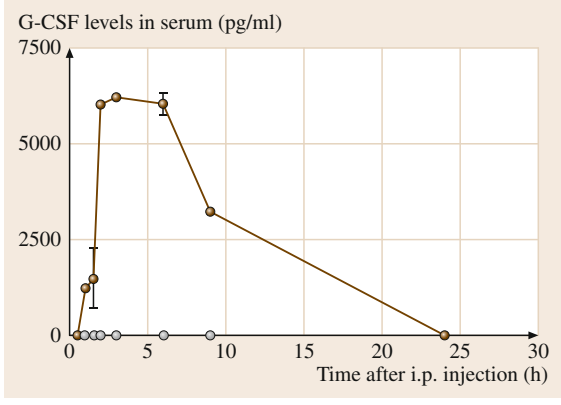

Fig. 47.11 G-CSF levels in the serum after i.p. injection of alginate oligomer mixture or alginate polymer. After single i.p. injection of alginate oligomer mixture (700 mg/kg bodyweight in 1 ml of PBS) or alginate polymer (700 mg/kg bodyweight in 1.0 ml of PBS), G-CSF levels in each serum collected at the indicated periods of time were measured by ELISA as described in the text. Each point represents an average of triplicate measurements and each bar indicates the standard deviation

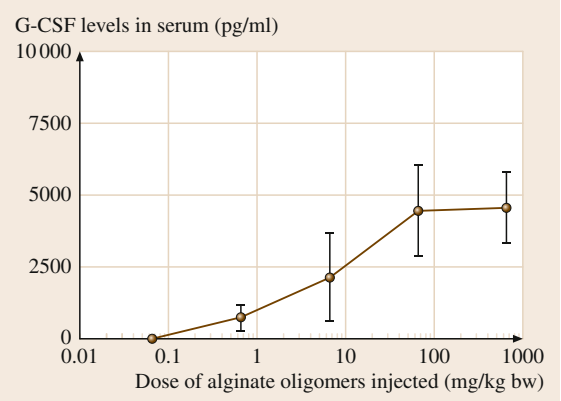

Fig. 47.12 G-CSF levels in the serum after i.p. injection of varying doses of alginate oligomer mixture. After single i.p. injection of varying doses of alginate oligomer mixture (0.07, 0.7, 7, 70, and 700 mg/kg bodyweight in 1 ml of PBS), G-CSF levels in each serum collected after 3 h were measured by ELISA as described in the text. Each point represents an average of triplicate measurements and each bar indicates the standard deviation

ginate oligomer mixture and examined G-CSF serum levels after 3 h. As shown in Fig. 47.12, G-CSF levels in the serum increased with the increased dose of the mixture and reached the plateau level at 70 mg/kg, which suggests that that i.p. injection of 70 mg/kg of the mixture is sufficient to induce the maximum serum level of G-CSF. Based on the result, it is calculated to be 4.2 g for 60 kg bodyweight, and this value is considered within applicable range for human beings.

As mentioned above, it has been generally considered that biological activities of alginate polymers are deeply influenced by the molecular size, M/G ratio, and entire molecular conformation. Therefore, it is necessary to select suitable alginate polymers or the appropriate origin of the polymer when it comes to the development of alginate polymers as certain therapeutic agents or food supplements that may require cytokine-inducing ability. However, because of the heterogeneous intramolecular arrangement of M-blocks and G-blocks, and the existence of the M/G random structure, the clarification of the structure–activity relationship of alginate polymers with a molecular weight more than 10 000 is almost impossible. Hence, enzymatic depolymerization may be a promising strategy to improve the bioactivities of alginate polymers regardless of their original activity. Although it is uncertain whether the cytokine-inducing activity is always responsible for the variety of bioactivities of alginates, the findings described here may suggest that alginate oligomers even in mixture are useful as bioactive agents in in vivo systems.

To investigate other cytokine levels in mouse serum after i.p. injection of alginate oligomer mixture, we employed the Bio-Plex bead assay that can detect 23 cytokines simultaneously. As shown is in Fig. 47.13, i.p. administration of alginate oligomers resulted in a significant increase in 20 cytokines in the serum with different levels and different kinetics depending on the cytokines. G-CSF, MCP-1 (monocyte chemoattractant protein), IL-6, KC (keratinocyte-derived chemokine), RANTES (regulated upon activation normal T cell expressed and secreted), and IL-12 (p40) levels were relatively high with an exceeded 5000 pg/ml serum level at the peak point. The serum level of TNF-α, interleukin (IL)-2, IL-3, IL-10, IL-12 (p70), IL-13, IL-17, GM-CSF (granulocyte-macrophage colony-stimulating factor), and interferon (INF)-γ clearly showed two peaks during the 24 h interval, whereas G-CSF, granulocyte macrophage (GM)-CSF, monocyte chemoattractant protein (MCP)-1, IL-1α, RANTES, KC, eotaxin, and IL-1α tended to show one peak. Although the exact reason for the biphasic kinetics of some cytokines is unclear now, resident cells in the intraperitoneal cavity may be responsible for the first peak of these cytokines, and then alginate oligomers transferred from the cavity to circulation may stimulate second target cells that, in turn, respond to the second peak of the cytokines. It was confirmed that among the cytokines induced by alginate oligomers mixture, the level of G-CSF was strikingly higher than others. To our knowledge, this is the first result indicating that alginate oligomers are capable of inducing G-CSF in vivo.

G-CSF is a hematopoietic factor that stimulates neutrophile production and release from bone marrow as well as activating mature neutrophilic function [47.44]. Since neutrophils are primary effectors in host defense against invading pathogens, the use of G-CSF has been tested in the treatment of bacterial infectious diseases [47.45], and even an antiviral effect of G-CSF on the hepatitis virus has also been reported [47.46]. Thus, the ability of the alginate oligomer mixture to induce G-CSF may be a useful bioactivity that should be taken into consideration in the application of alginate oligomers. This ability of alginate oligomers to induce G-CSF may partly explain the previous findings that i.p. administration of alginates with a high content of mannuronic acid enhanced the

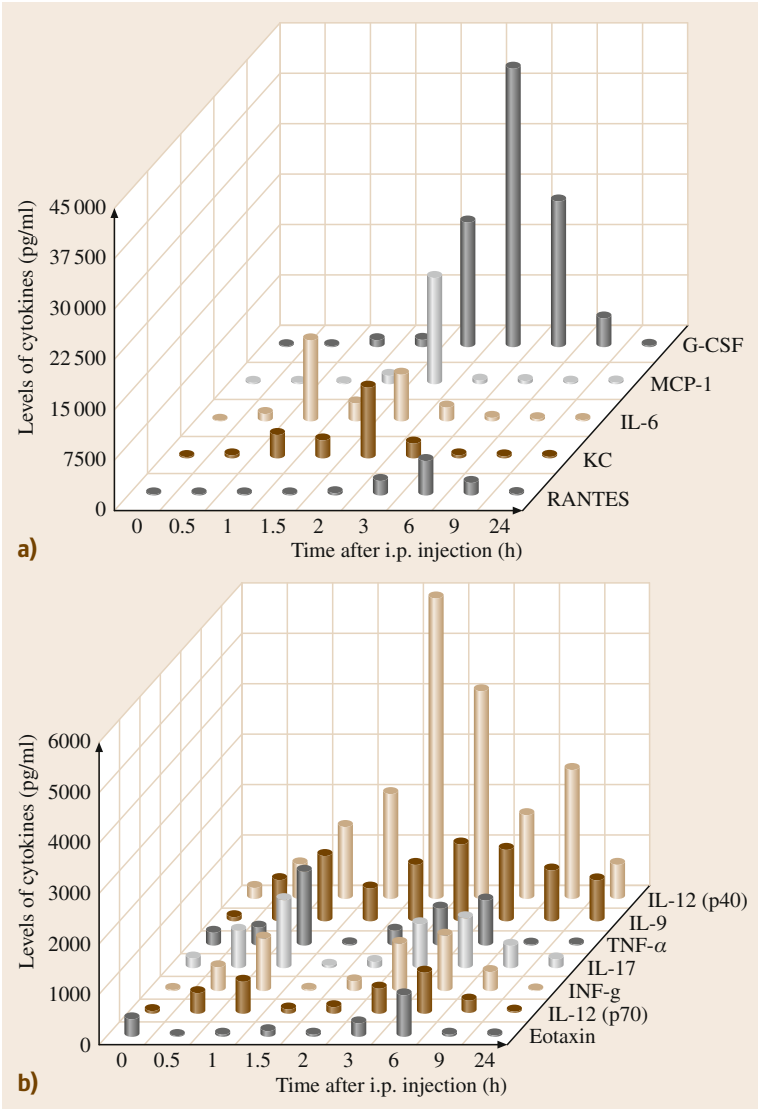

Fig. 47.13a–c Levels of various cytokines in the serum after i.p. injection of the alginate oligomer mixture. After a single i.p. injection of alginate oligomer mixture (700 mg/kg bodyweight in 1 ml of PBS), the levels of various cytokines in the serum collected after 3 h were measured by the Bio-Plex assay as described in the text. The results were summarized to relatively higher levels **(a)**, middle levels **(b)**, and lower levels **(c)** of cytokines. Each value represents an average of duplicate measurements. Differences between duplicate measurements for each value were within 5%. Abbreviations used in the figure: MIP – macrophage inflammatory protein

survival rate of lethally irradiated mice and stimulated murine hematopoiesis in vitro [47.47].

Regarding the biological effects of alginate oligomers in in vivo mammalian models, *Yoshida* et al. reported that i.p. injection of a mixture of alginate oligomers with an average degree of polymerization of 4.4 resulted in the suppression of both Th2 development and IgE production through IL-12 production [47.15]. Based on their results, *Yoshida* et al. proposed that alginate oligomers may be useful as a novel antiallergic agent.

In conclusion, the results clearly indicate that alginate oligomers in mixture are capable of inducing multiple cytokines, especially G-CSF, in vivo after i.p. administration. These findings may provide basic information about the potential activity of alginate oligomers as a potent cytokine inducer. Kinetics data of various cytokines obtained in this study may give a clue not only for the understanding of the underlying mechanism of the variety of biological activities of alginate oligomers reported so far but also for the study of future applications of alginate oligomers.

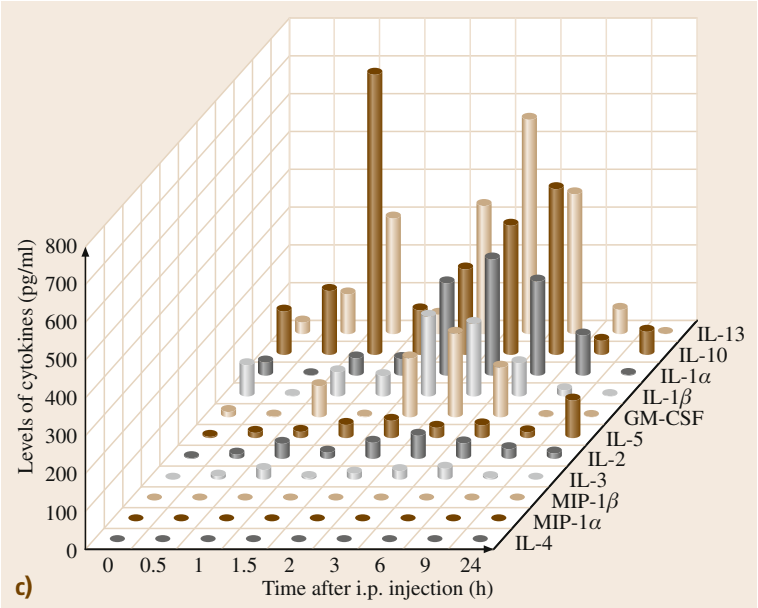

Fig. 47.13 (continued)

47.6 Growth-Promoting Effect of Alginate Oligosaccharides

In this section, the effects of AOM on the growth of unicellular marine microalga are described. In the aquaculture industry, microalgae are indispensable food sources for some species of bivalves, larvae of crustaceans, and fish species. They are also consumed by zooplankton used for feeding of larvae and juveniles of marine fish, as well as some crustaceans. *Nannochloropsis oculata* is a marine unicellular microalga classified in the class of Eustigmatophyceae and is frequently used in practical fish larval rearing in aquaculture industry.

Through the food chain initiated from microalgae, important nutrients such as vitamin E from microalgae are transferred to higher trophic levels via the intermediate zooplankton [47.48, 49]. It has been reported that *N. oculata* has a superior nutritional value with a relatively high level of vitamin E [47.50]. Thus, *N. oculata* is a highly important organism, not only as a direct food source for many aquatic animals but also as a feeding organism for zooplankton rotifers used as a second organism for fish larval rearing in aquaculture industry of marine fishes and crustaceans. Hence, the establishment of a stable and efficient culture procedure for useful microalgae is urgently required. It has been demonstrated that alginate oligosaccharides show growth-promoting activity in various higher plant systems. Since *N. oculata* is a unicellular marine phytoplankton with a eukaryotic plant cell type, it can easily be imagined that it has many functional and structural similarities to higher plant cells at cellular level and might be influenced by alginate oligomers. Under these circumstances, as a pilot study, the effects of AOM on the growth of *N. oculata* under normal conditions were examined. It was also investigated if AOM can improve Cu^{2+}-induced stress conditions [47.51].

N. oculata was supplied from the microalgae collection of the National Research Institute of the Aquaculture Fisheries Research Agency. *N. oculata* was cultured at 17 °C in 100 ml of modified Guillard's *f* medium in which $Na_2SiO_3 \cdot 9H_2O$, vitamin B_{12}, biotin and thiamine HCl were omitted from the originally reported constituents [47.52]. The culture was kept under illumination of fluorescent lamps at 30 $\mu mol/m^2$ s with a cycle of 12 h light and 12 h dark. All cultivations were done using sterilized instruments and were continuously stirred with a magnetic stirrer. Exponentially growing algal cells were used throughout the experi-

ments. The initial cell density of the algal cells was adjusted to about 10^5 cells/ml, and the culture started in the medium containing the indicated concentration of AOM under the conditions described above. To examine the effects of Cu^{2+} on the growth of *N. oculata*, the indicated final concentration of $CuSO_4 \cdot 5H_2O$ was added to the medium, which was cultured for a few days as described above. The algal cell densities were determined by haemocytometer counts, and the growth conditions were also monitored microscopically every day.

The effects of AOM with various concentrations on the cell growth of *N. oculata* are shown in Fig. 47.14. From the growth curve profiles, it is obvious that the algal growth was dramatically promoted by AOM in a concentration-dependent manner at the concentration range 1–20 mg/ml. Even with 1 mg/ml of AOM, a slight increase in the growth was observed. The maximum effect was attained at 20 mg/ml, after which the cell number reached a plateau level that was nearly five times higher than that of control without AOM. However, the growth-promoting effect of AOM was slightly decreased at 40 mg/ml to a level similar to that observed at 5 mg/ml. Thus, it seems likely that AOM has an optimum concentration to promote the growth of *N. oculata* at least under the conditions used. As judged from the patterns of growth of *N. oculata* in the presence of effective concentrations of AOM, the rate of cell division during the exponential growth phase also tended to be accelerated by AOM. Based on these data, it was suggested that AOM is capable of promoting the growth rate of *N. oculata* during the exponential phase and of increasing the maximum cell density at the stationary phase.

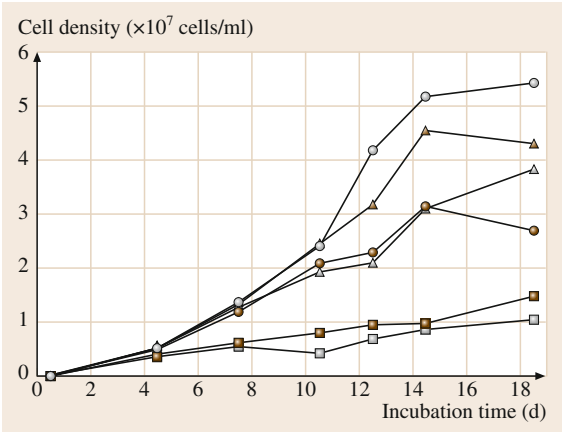

Fig. 47.14 Effects of AOM on the growth of *N. oculata*. *N. oculata* cells were inoculated into the medium (100 ml) containing 1 mg/ml (□), 5 mg/ml (▲), 10 mg/ml (△), 20 mg/ml (●), 40 mg/ml (○) of AOM or without AOM as a control (■), and cultured for the indicated periods of time under the conditions described in the text. The number of algal cells in each culture was counted daily as described in the text. Each value represents the average of duplicate measurements

The culture of microalga often suffers from various environmental stresses even under highly controlled conditions. Especially, trace amounts of contamination with heavy metals are known to cause suppression of the growth of microalgae [47.53]. Although Cu^{2+} is often used for extermination of parasites attached on cultured fish in aquaculture firms, this metal is also known to be toxic to microalga. Thus, Cu^{2+} was used as a representative heavy metal stressor for *N. oculata*. As shown in Fig. 47.15, the addition of 2.5 mg/ml of Cu^{2+} to the medium resulted in the complete inhibition of the growth of *N. oculata*. Even after 24 h incubation with Cu^{2+}, almost all cells were decolorized and became incapable of subsequent cell division. The potent toxic effect of Cu^{2+} on *N. oculata* disappeared almost completely with the addition of a semioptimal concentration of AOM (10 mg/ml), and the growth curve in the presence of AOM and Cu^{2+} together was similar to that of the control without AOM and Cu^{2+}. These results suggest that AOM is able to not only promote the growth of *N. oculata* under normal conditions but also to exert a beneficial effect on algal cells under stress-induced suppressive conditions. To our knowledge, this is the first demonstration that alginate oligosaccharide can promote the growth of marine microalga in addition to terrestrial higher plants. Since AOM was originally derived from seaweeds, it is a biologically nonhazardous and environmentally friendly material. Thus, AOM is one of the most promising candidates that can be introduced into actual aquaculture firms to establish a technique for stable mass culture of useful marine microalgae. Further studies are required to develop economically viable whole operations, including a low-cost AOM preparation procedure.

Although the underlying mechanisms of the beneficial effects of AOM on *N. oculata* is still unclear, it is possible to speculate that *N. oculata* is stimulated by AOM through the specific recognition and subsequent intracellular signal transduction, which may lead to the eventual growth promotion. Regarding this

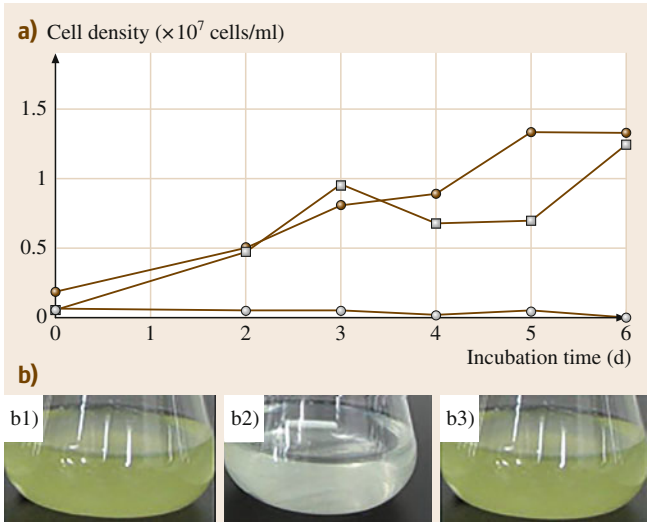

Fig. 47.15 Effects of AOM on the growth of *N. oculata* in the presence of Cu^{2+}. *N. oculata* cells were inoculated into the medium (100 ml) containing 2.5 mg/ml of Cu^{2+} and 10 mg/ml of AOM (●), 2.5 mg/ml of Cu^{2+} (○) or without these agents as a control (□), and cultured for the indicated periods of time under the conditions described in the text. The number of algal cells in each culture was counted daily as described in the text. During the incubation time, the algal cells were observed microscopically. Each value represents the average of quadruplicate measurements. **(b)** The pictures show the algal cells after 2 days incubation with 2.5 mg/ml of Cu^{2+} and 10 mg/ml of AOM (b1), 2.5 mg/ml of Cu^{2+} (b2) or without these agents as a control (b3)

point, there have been several reports on oligosaccharide molecules derived from the cell walls of plants or microbes that have various biological functions on plant cells [47.54]. Such biologically active oligosaccharides were first called oligosaccharins by *Albersheim* and *Darvill* [47.55]. Among such biologically active oligosaccharides, the capabilities of oligogalacturonides to regulate various physiological functions in plants have been well documented so far, and it has been suggested that oligosaccharin has a pleiotropic nature.

In conclusion, these results demonstrate that AOM not only promotes the growth of *N. oculata* but also overcomes Cu^{2+}-induced growth suppression of the alga. AOM is considered to be a useful and promising agent for the establishment of improved techniques for stable and efficient mass culture of *N. oculata*. Our recent study demonstrated that AOM prepared by enzymatic degradation shows a growth-promoting effect on the green alga *Chlamydomonas reinhardtii*, which is known as a model organism in fundamental molecular biology studies as well as a producer of biofuel. Interestingly, the fatty acid composition of *Chlamydomonas reinhardtii* was also influenced by the AOM; the content of C16 : 0, C18 : 2cis and C18 : 3*n-3* increased in AOM-treated cells. However, AOM prepared by acid hydrolysis had no effect on the growth of *Chlamydomonas reinhardtii* [47.56].

48. Vector and Agricultural Pest Control

Venkateswara Rao Janapala

Many of the small-scale farmers in developing countries continue to use high volumes of pesticides for crop protection due to their illiteracy, and lack of adequate information. Such practices have resulted in many environmental problems such as effect on nontarget species, pesticide residue accumulation, development of resistance to pests, ecological imbalance by elimination of natural predators as well as environment pollution. The current critical situation is that many of the previously used and economically affordable insecticides are no longer effective and are also banned in many countries. Therefore, there is an urgent need to develop newer, more effective, target specific and less persistent insecticides. In the search for developing newer insecticides, several researches had paid attention toward marine natural products. It is a well-known fact that the marine environment is an exceptional reservoir of bioactive natural products, which produce several novel structures with unique biological properties which may not be found in terrestrial natural products. In recent years, a number of studies have suggested that some of the bioactive compounds isolated from marine organisms exhibit pesticidal properties. Such bioactive metabolites from marine organisms may be an alternative source for vector and agricultural pest control agents. It is anticipated that these bioactive metabolites may potentially replace the existing and highly toxic synthetic insecticides and will play an important role in the future insecticide development program. This chapter provides an overview of recent trends in the exploration of marine secondary metabolites for pest management system.

48.1 Preamble

The ever-increasing global population presents an enormous challenge to existing agricultural infrastructure and practices. The global population will reach 9.1 billion by 2050, which is 34% higher than today. To meet the requirements the Global food production will need to jump by 70–100% to feed these people. Agricultural experts estimate that countrywide more than one-third crop yield is lost to insect pests, diseases, and weeds, both in the fields, and during storage and transport [48.1]. Much of the increase in agricultural productivity over the past half century has been due to the control of these pests with synthetic chemical pesticides [48.2]. Crop protection chemicals continue to be the major tools for protecting food and fiber crops from damaging pests.

Synthetic pesticides are well recognized as an economic approach to controlling pests; despite having several beneficial possessions to agriculture. These pesticides constitute some persistent problems in causing pollution to the environment [48.3]. Now there is growing concern worldwide over the indiscriminate use of such chemicals that results in environmental pollution and toxicity risk to nontarget organisms. Secondly, continuous usage of these pesticides results in developing resistance in pest organisms. To address environmental concerns, new agrochemicals developed from natural products may be perceived as more environmentally acceptable than that present scenario.

The investigation of several marine natural pesticides such as nereitoxin, bensultap, cartap, and thiocyclam derivatives have exhibited significant insecticidal properties against important insect pests [48.4]. According to *Peng* et al. [48.5], the macrolides, polypeptides, and alkaloids are the promising agents for insecticidal, herbicidal, and fungicidal, and they also noticed that manzamine F can be used as a new pesticide. In contrast, the plants, animals, and microorganisms in the marine environment, with their wide range of chemical and bioactive diversity, are still largely an unexplored resource for new agrochemical agents [48.6, 7].

The marine environment is an exceptional reservoir of bioactive natural products, which produced several novel structures with unique biological properties that may not be found in terrestrial natural products [48.7, 8]. These marine organisms have evolved chemical defence mechanisms to fight successfully against other invading organisms, which involve the production of secondary metabolites [48.9]. The current thrust of the investigations involves identifying newer drugs and other pharmaceuticals from marine origin, whereas comparatively little attention has been paid with respect to the discovery of pesticide molecules. The secondary metabolites isolated from marine organisms may be an alternative source for agrochemicals to replace the existing and highly toxic synthetic insecticides and will play an important role in the future insecticide development program. *Venkateswara Rao* et al. [48.10] suggested that the secondary metabolites isolated from the marine sponges may be an alternative source for vector control agents to replace the existing and highly toxic synthetic insecticides and will play an important role in future insecticide development program. Previously, *Bradford* et al. [48.11] described the marine potential natural products to serve as insect control agents via mechanisms of toxicity, interference with molting of metamorphosis and feeding deterrence. *Donia* and *Hamann*, [48.12], *Blunt* et al. [48.13], *Haefner* [48.14], and *Venkateshwara* et al. [48.7] demonstrated that the sponge consisting of sesquiterpenes and diterpenes – secondary metabolic compounds might be a source of new insecticides; it did not liberate compounds of commercially significant potency against important insect pests. Earlier studies have also suggested that some secondary metabolites isolated from marine organisms have been shown to exhibit larvicidal, insecticidal, and IGRs (insect growth regulators) activities [48.15–19].

This chapter aims to explore Indian marine biodiversity as a source of bioactive metabolites with potential application as agrochemicals. Such agrochemicals will act by new molecular modes of action and should be effective against vectors and pests that are resistant to current formulations.

48.2 Current Status of Research and Development in the Subject

Natural marine products have the potential to replace synthetic pesticides and other agents used to maximize crop yields and growth. The chapter in this area is likely to result in useful natural pesticides that would provide greater specificity and fewer harmful side effects than the conventional synthetic pesticides. Current biopes-

ticides from marine and other sources are expected to capture an estimated 10% of market [48.20].

An example of a marine biopesticide in use today is Padan, which was developed from a bait worm's toxin known to ancient Japanese fishermen. It was derived from nereistoxin, a naturally occurring insecticidal substance, isolated from marine segmented worms *(Lumbriconereis heteropoda)*. This insecticide was introduced globally as one of the major insecticides with a broad spectrum of activities. This natural pesticide has demonstrated activity against larvae of the rice stem borer, the rice plant skipper, and the citrus leaf miner, among other pests. It has strong stomach poison, contact, antifeed, and ovicide function. It is mainly used for preventing injurious insects such as Lepidoptera, Coleopteran, Hemiptrea, and Diptera.

48.2.1 Padan

Padan S,S'-(2-dimethylaminotrimethylene) bis(thiocabamate) hydrochloride; S,S'-[2-(dimethylamino)-1,3-propanediyl] dicarbamothioate hydrochloride.

Synonyms:
1,3-bis (carbamoylthio)-2-(*N*,*N*-dimethylamino) propane monohydrochloride, Cartap hydrochloride, and patapvegetox

In India, two formulations of this products were introduced by M/s. Coromandel Agrico Pvt Ltd., New Delhi (Padan 4G (4% Cartap hydrochloride in granule form and Padan-50SP (50% water soluble powder)). The formulation, Padan 4G is generally used in two major crops, i. e., rice and sugarcane. Padan 50SP has been found effective in the control of most of major pests on rice, potato, sweet potato, maize, cabbage, onion, ginger, grapes, tea, citrus, and other vegetables. The active ingredient is also effective against diamondback moth. These formulations are compatible with other insecticides and fungicides, for effective integrated pest management.

More recently, scientists in Montana discovered novel compounds in marine algae and marine sponges containing symbiotic microorganisms. A large number of compounds have been screened as newer pest control agent from marine flora. Sponges serve as sources of bioactive compounds and are capable of synthesizing many secondary metabolites and have been a prolific source of new molecules [48.21, 22]. Similarly, extracts derived from sponge (*Dysidea etheria*) and *Nudibranch* species also demonstrated powerful insecticidal activity against two species, grasshoppers and the tobacco hornworm [48.23]. The sponge, *D. etheria* and the *Nudibranch*, *Hypselodoris zebra* have yielded a number of sesquiterpenes, some of which exhibit feeding deterrent activity (antifeedant) in insects (Fig. 48.1). Furodysinin **(1)** was not toxic to advanced larval stage of tobacco hornworms at doses of 250 ppm in an artificial diet. Most of the insects were unable to shed their molts completely and two hornworms developed double head capsules [48.24]. The other two *Dysidea* metabolites tested, 5-acetoxy- and 5-hydroxynakafuran-8 **(2,3)**, exhibited a different activity profile against the grasshopper. The acetate **2** was toxic at the high dose and antifeedant at the lesser dose, while the alcohol **3** was antifeedant even at lower doses.

Recent past, some of the novel molecules isolated from sponges and soft corals with pesticide properties were identified. Among them, swinhoeiamide A **(4)** isolated from Guinean sponge *Theonella swinhoei* [48.16], exhibited insecticidal activity toward neonate larvae of the polyphagous pest insect, *Spodoptera littoralis* when incorporated in an artificial diet offered to the larvae in a chronic feeding bioassay (ED_{50} 2.11 ppm, LD_{50} 2.98 ppm).

Soft corals of the genus *Nephthea* (*Alcyonacea*, *Nephtheidae*) have yielded a variety of bioactivee sesquiterpenes and diterpenes. Among the seven isolated oxygenated sesquiterpenes, from the Indonesian soft coral, *Nephthea chabrolii*: hydroxycolorenone **(5)** exhibited insecticidal activity on a polyphagous pest *S. littoralis*, with an EC_{50} of 8.8 ppm and a LC_{50} of 453 ppm, when incorporated in artificial diet and offered to larvae in a chronic feeding bioassay [48.25]. Similarly, a new sesquiterpene, hydroxycolorenone **(6)** was isolated from the soft coral *N. chabrolii*, which showed strong insecticidal activity with an EC_{50} 35 μM and an LC_{50} 1.8 mM against neonate larvae of *S. littoralis* [48.25].

A tropical marine sponge, *Axinella carteri* afforded six unusual alkaloids, including the new brominated guanidine derivative, 3-bromo-hymenialdisine [48.19]. All alkaloids were screened for insecticidal activity against *S. littoralis*. The guanidine alkaloids hymenialdisine and debromohymenialdisine exhibited insecticidal activity at LD_{50} of 88 and 125 ppm, respectively, when incorporated into artificial diet and offered to the larvae in a chronic feeding bioassay. The marine-derived, alkaloid manzamine A **(7)** was reported to exhibit insecticidal activity toward neonate larvae of *S. littoralis* with an ED_{50} of 63 μM [48.26]. Pyriodacridine alkaloids are characterized by an 11H-pyrido (4,3,2-mn) acridine moiety. Kuanoniamin C **(8)** and kuaoniamine D **(9)** exhibited insecticidal activ-

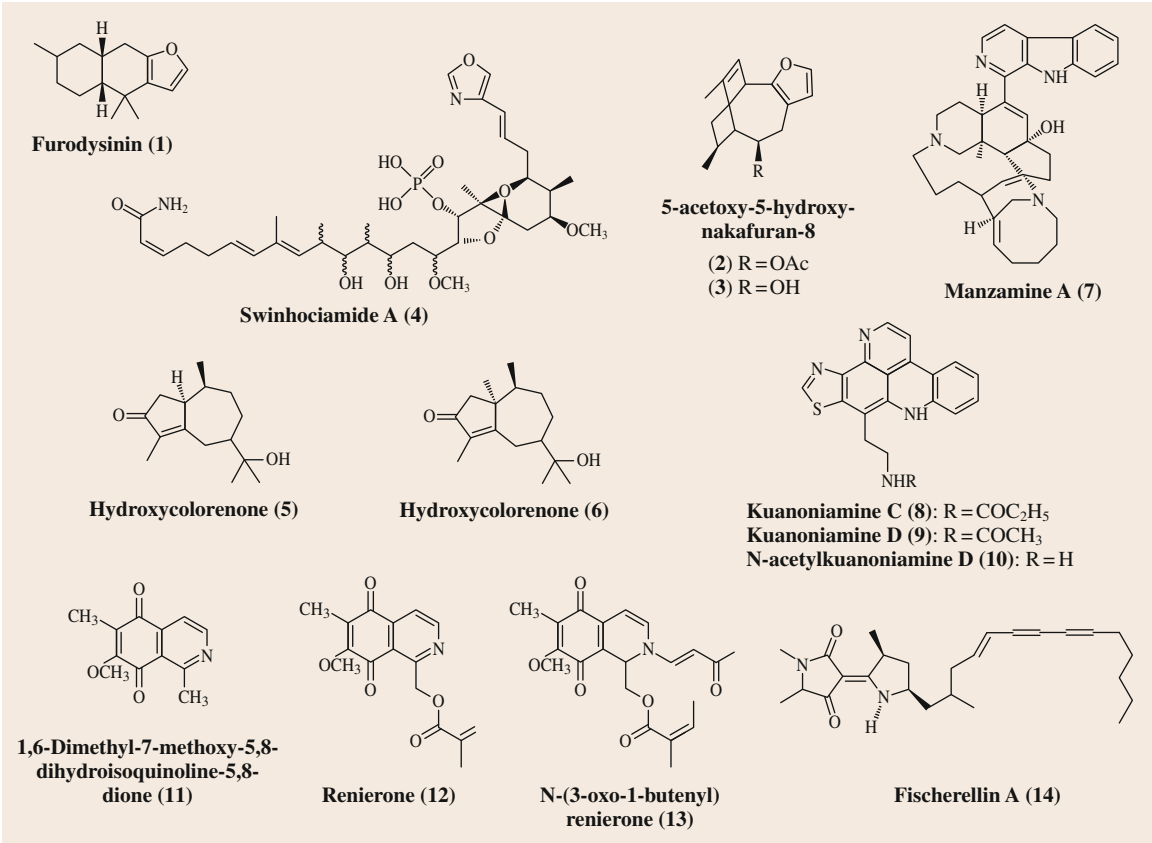

Fig. 48.1 Structures of the marine pesticidal molecules mentioned in the text

ity against *S. littoralis* with LC_{50} values of 0.42 and 0.16 mM, respectively, whereas *N*-acetylkuanoniamine D **(10)** was marginally active and inhibited the growth of the larvae with an ED_{50} of 0.44 mM [48.27]. The isoquinoline alkaloids isolated from the Philippine sponge of the genus *Xestospongia* also exhibited insecticidal activity [48.26]. 1,6-Dimethyl-7-methoxy-5,8-dihydroisoquinoline-5,8-dione **(11)** showed insecticidal activity with an EC_{50} of 35 ppm and an LC_{50} of 521 ppm against neonate larvae of *S. littoralis*. However, Renierone **(12)** and *N*-(3-oxo-1-butenyl) renierone **(13)** exhibited weak insecticidal activity, whereas 100% inhibition of the powdery mildew on barley (*Erysiphe graminis*) required a concentration of 2.4 mM. Fischerellin A **(14)** exhibited 80% inhibition of downy mildew (late blight, *Phytophthora infestanson* tomato) and rice blast (*Pyricularia oryzae*) at 2.4 mM. Less activity (30% growth inhibition at 2.4 mM) was observed against brown rot (blossom blight, *Monilinia fructigena*) and stem break (*Pseudocercosporella herpotrichoide*) grown on agar.

48.3 Research in India

The higher specificity, little or no toxicity to nontarget organisms and biodegradability combine to make natural compounds more suitable for insect control. It is well established that the plant kingdom is a rich source of chemicals with a potential, to be successful pest control agents, which could cause mortality or disrupt normal growth, development, and reproduction of insects [48.28–31]. Last few years, we have made an

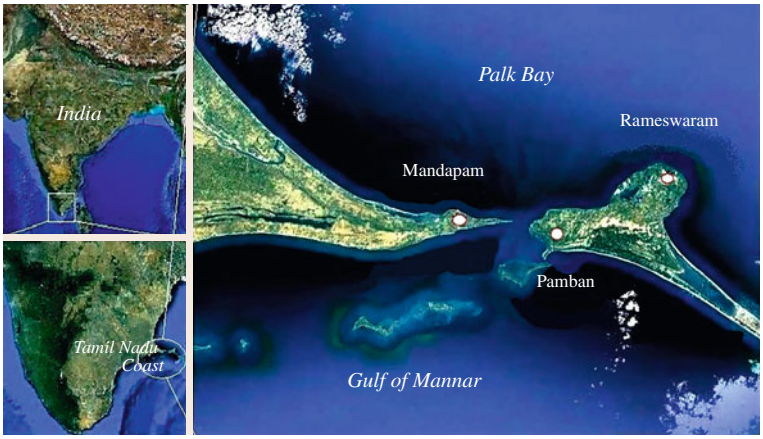

Fig. 48.2 Location map of the sampling sites (Mandapam, Pamban, and Rameswaram) in Gulf of Mannar, southeast coast of India

attempt at our institute, CSIR-Indian Institute of Chemical Technology, Hyderabad, to investigate the pesticidal activities of marine natural products of Gulf of Mannar (GoM), against some insect pest and vectors of public health importance. We found that there is a lot of scope to obtain new leads of pesticidal molecules especially new toxophoric groups from marine origin, which can be appropriately incorporated in molecules to obtain potent synthetic products with targeted features.

48.3.1 General Information on Gulf of Mannar

The GoM located in the Peninsular India and the Bay of Bengal, encompasses 21 coastal islands located between 8° 46′ – 9° 14′ N, latitude and 78° 9′ – 79° 14′ E longitude from Mandapam in the north to Tuticorin in the south (total distance 170 nautical miles) (Fig. 48.2). It is highly productive area endowed with 3600 species of flora and fauna, including 377 species that are endemic to the region [48.32, 33]. The Gulf, which has been declared as Gulf of Mannar Marine Biosphere Reserve GoMBR on February 18, 1989, is remarkable for its faunal and floral wealth, especially the world's most diverse ecosystems, the coral reefs and its associates.

48.3.2 Sample Collections and Identification

The marine flora and fauna were collected during low tide from the inter tidal zones at different localities (visually unpolluted and undisturbed areas) between 10–15 ft depth using skin diving, and deep water collections at different localities (30–40 ft) using self-contained under water breathing apparatus (SCUBA). The samples were collected from the following locations of Gulf of Mannar, Southeast coast of India.

Mandapam Coast

Situated between 09° 17.417′ N to 09° 17.479′ N, latitude and 079° 08.400 E to 079° 08.558′ E, longitude; on a narrow tongue of land projecting from the southern part of the east coast of India. To the north of the peninsular extension is Palk Bay and to the south is Gulf of Mannar. Sea grass beds have been abundantly disturbed along the coast.

Pambam Coast

Situated between 09° 17.523′ N to 09° 17.625′ N, latitude and 079° 13.164′ E to 079° 14.915′ E, longitude; at the western edge of Pamban Island. Most of Pamban Island is covered with white sand and hence is not suitable for cultivation. It is a fishing village with natural harbor.

Rameswaram Coast

The Rameswaram town is extending between 09°18.390′ N to 09° 18.853′ N, latitude and 079°19.662′ E to 079°20.076′ E, longitude; on the northeastern region of the Gulf of Mannar at the very tip of Indian peninsula. It is separated from mainland India by the Pamban channel and is connected to the mainland by the Pamban Bridge.

48.3.3 Marine Flora

Marine algae grow in the littoral and sub littoral regions of the sea on the rocks and other hard substrata. They are usually submerged. Winter season is the most favorable period for the rapid growth of marine algae, when

the atmospheric temperature is relatively low. The algal vegetation is well exposed along the collection sites when the tide is favorably low and collections were made by the hand-pick method, in littoral and sub littoral regions.

Large quantities of fresh macro algae (weighing approximately 50–100 kg for each species) belonging to different classes (Chlorophyceae, Rhodophyceae, and Pheophyceae) were collected from the intertidal zones and separated according to species based on external morphological characters. The collected algae were washed thoroughly with fresh water to get rid of the unwanted material. Then the algae were drip dried on nylon nets and were dried in the shade, with well aeration and intermediate mixings were carried out to avoid any fungal growth. The total dried material of each species was packed in separate bags, labeled, and transported to the laboratory for further work.

48.3.4 Marine Fauna

Various sponges and soft corals were collected during low tide from different localities by using skin and SCUBA divers. Specimens weighing approximately 10 kg of each species were collected and cut into small pieces. These pieces were placed in 5–15 L capacity corboyles containing methanol. Care is taken to properly dip or soak in the solvent so as to prevent putrefaction. Specimens of each species were separately preserved in 10% formalin for identification. The morphological description along with the date and site of collection of each specimen was recorded.

48.3.5 Identification of the Specimens

Marine Flora

The collected specimens were sent to the Central Marine Fisheries Research Institute (CMFRI), Mandapam, Tamil Nadu, India, Centre for Advanced Studies in Marine Biology, Parangipettai, Tamil Nadu, and also to Central Salt and Marine Chemicals Research Institute (CSMCRI), Bhavnagar, Gujarat, India, for identification.

Marine Fauna

All the intact sample specimens preserved separately, were sent with necessary details to the CMFRI, Trivandram, Kerala, India and National Institute of Oceanography (NIO), Goa, India, for their identification and repository purpose.

48.4 Preparation of Crude Extracts

48.4.1 Marine Flora

The respective washed and dried material of each species (macro algae belonging to different classes) was powdered thoroughly (0.5–5 kg) and extracted with dichloro methane and methanol (1 : 1 ratio) using Soxhlet apparatus. The pooled solvent extracts was filtered and the filtrate was concentrated under reduced pressure in rotavapor (Buchi rotavapor R 110) to obtain solvent-free crude extract. The extracts were stored in refrigerator until they were used for different bioassays against the insect pest and vectors of public health importance.

48.4.2 Marine Fauna

The methanol soaked cut pieces were separated and resoaked in dichloro methane and methanol in 1 : 1 ratio. The aqueous methanol extract was concentrated at reduced pressure and lyophilized for further extractions. The repeated dichloro methane and methanol (1 : 1 ratio) extracts were pooled and concentrated at 10 L capacity industrial rotavapor (Buchi rotavapor R 151) for obtaining solvent free crude extract. The lyophilized powder was once again extracted with the same solvents and the crudes were combined and used for studying their pesticidal activities against houseflies and mosquitoes.

48.5 Active Extracts of Marine Origin

The crude extracts prepared were subjected to their biological activities against public health important vectors like houseflies and mosquitoes. Though a good number of extracts exhibited pesticidal activities, but for the convenience of rapid screening the highest dose or concentration ranges were fixed for

200 µg/insect or 200 ppm as active extracts. The pesticidal properties (larvicidal and insecticidal activities) of active crude extracts are presented in Tables 48.1 and 48.2. As a first attempt, the active crude extract, *Dictyosphaeria favulosa* was subjected for fractionation to identify the active principle. The original crude extract of *D. favulosa*, a green alga was fractionated by using silica gel column chromatography. The details of the fractionation are as follows.

The 34 aliquots were pooled into 7 fractions (Table 48.3) based on thin layer chromatography (TLC). All the seven fractions were bioassayed and fraction 1 (DF1) has shown more activity. This fraction was crystallized from hexane to obtain heavy colorless cubes (700 mg, i. e., 0.14% on dry weight basis) and was analyzed for its characteristics. The structure of the compound was determined based on ^{1}H NMR spectrum, and mass and X-ray crystallography with the help of the chemists at Organic Chemistry Division, IICT, Hyderabad. The structure of the compound, ethylene bisisobutyl xanthate (1) [48.34] is shown below.

The compound was synthesized in good quantities to reconfirming its biological properties. It was tested against various aquatic stages of *Aedes aegypti* mosquito for larvicidal, and female adult housefly, *M. domestica* for insectidal properties. The synthesized compound exhibited larvicidal and insect growth regulatory activity in dose-dependent manner [48.35]. Around 35 analogs were synthesized and tested against vectors of human health importance and agricultural polyphagous lepidopteron pests. Among them six analogs have been identified as good antifeedant and insect growth regulators (IGRs). Three of the compounds from the six analogs are structurally known but the activity was identified for the first time (Table 48.5) and remaining three are totally new structures with pesticidal properties (Table 48.6).

Table 48.1 Larvicidal activity of marine crude extracts against fourth instar larvae of *Aedes aegypti*[a]

Crude extracts of marine organisms	Regression equation $Y = Y^{bar} + b(x - x^{bar})$	$LC_{50} \pm SE$ (µg mL^{-1})

[a] Fourth-instar larvae of *Aedes aegypti* were used as an experimental model to determine the larvicidal activity. The cyclic colony of *Aedes aegypti* (yellow fever mosquito vector) were reared in our insectary at $27 \pm 1\,^{\circ}C$ and $80 \pm 5\%$ RH with a photo period of 14 : 10 h light and dark cycles followed by the methods of [48.36] and [48.37], respectively, with little modifications. Fourth-instar larvae were treated with different concentrations of sponge extracts for 24 h and lethal concentration was investigated through probit analysis. Regression equation $Y = Y^{bar} + b(X - x^{bar})$ or $(Y^{bar} - bx^{bar}) + (bx)$. Y^{bar} = weighted average of working probit values, x^{bar} = average of $\log_{10}$ (concentration), b = slope of the line, $X = x$-scale concentration in log. Four replicates for each concentration and the control (without sponge extract), were tested for larval bio-efficacy and the data were used to calculate the probit regression equation. LC_{50} is defined as the concentration of extract that can cause 50% mortality in the exposed population.

[a] Housefly, *M. domestica* was used as an experimental model to determine the insecticidal activity. The cyclic colony of houseflies were reared in our insectary at 27 ± 1 °C and 80 ± 5% RH with a photo period of 14 : 10 h light and dark cycles followed by the methods of [48.36] and [48.37] respectively, with little modifications. Three to four days old of female houseflies, *M. domestica* were treated with different concentrations of sponge extracts for 24 h and lethal dose was investigated through probit analysis. Regression equation $Y = Y^{bar} + b(X - x^{bar})$ or $(Y^{bar} - bx^{bar}) + (bx)$. Y^{bar} = weighted average of working probit values, x^{bar} = average of $\log_{10}$ (dose), b = slope of the line; X = x-scale dose in log. Four replicates for each dose and the control (without sponge extract), were tested for insecticidal bio-efficacy and the data was used to calculate the probit regression equation. *LD_{50} is defined as the dose of extract that can cause 50% mortality in the exposed population.

48.6 Pesticidal Properties of Alkyl Xanthates

48.6.1 Larvicidal Activity of Alkyl Xanthates Against Mosquito

The toxicity of active alkyl xanthate analogs to *Aedes aegypti* larvae is listed in Table 48.4. The results indicated that about six compounds (out of 35) exhibited excellent activities against mosquito at less than 15 $\mu g\,mL^{-1}$ (ppm). In particular, compound **3** still maintains high larvicidal activity even at 3.77 $\mu g\,mL^{-1}$ (LC_{50} value). All the title compounds exhibited significant larvacidal activities against mosquito.

48.6.2 Developmental Inhibition Activity of Alkyl Xanthates Against Second Instar Larvae of *Aedes Aegypti*

The sublethal concentrations of all the analogs (LC_{10} to LC_{20} concentrations) have exhibited developmental inhibition on mosquito, *Aedes aegypti*. Abnormal pupal formation and pupal case attachment to emerged adults (leads to mortality) were quite common in most of the alkyl xanthates. Among them, compounds **4** and **5** have shown significant IGR properties. The activities of the compounds (**4** and **5**) were analyzed to compare with control experiments (with out treatment) and are presented in Table 48.7.

The majority of the abnormal pupae (> 60%) were appeared at high concentrations of both the compounds (Fig. 48.3a). The higher concentrations of compound **4** inhibited the adult emergence by attaching pupal casing to the abdominal region of emerging adults (Fig. 48.3b).

Similar effects were also observed in compound **5** in which majority of the adult wings and legs were attached to the puparium at the time of emergence (Fig. 48.3c). Although the significant number of adults emerged in the lower concentrations of compounds **4** and **5**, which appears to be normal but they were not in a position to take off even after few hours of emergence and led to mortality (Fig. 48.3d).

48.6.3 In Vivo Toxic Activity of Alkyl Xanthates Against Brine Shrimp, *Artemia Salina*

The in vivo toxicity of alkyl xanthates was evaluated against shrimp larvae. The assay was performed in triplicate vials at different doses (2.5–25 ppm) as

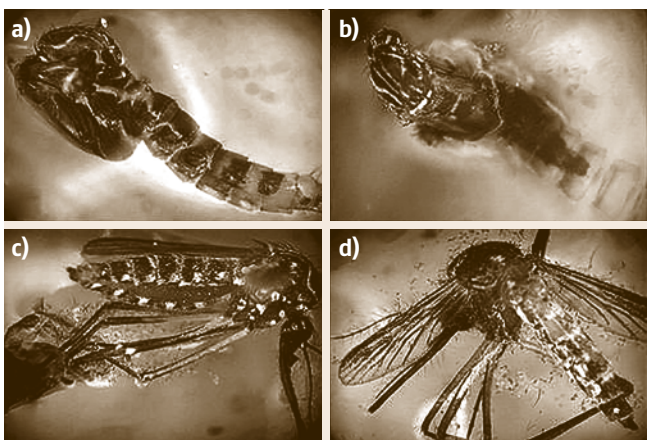

Fig. 48.3a–d Effect of alkyl xanthates on the formation of pupae and adult emergence after larval treatment. The digital photographs (at 50×) of deformed pupae and adults were computerized with a compound microscope (Polyvar, Reichert- Jung light microscope) attached to Ethovision – version 2.3 (Noldus Information Technology, The Netherlands) through a CCD camera (Sony CCD IRIS, Model No: SSC-M370CE). The treated larvae took unusually longer periods to enter into the pupal stage, compared with control larvae

described by [48.38] and modified by [48.39]. All the 35 analogs were tested against brine shrimp, *Artimia salina*, and the lethal concentrations (LC_{50}) of active alkyl xanthates are listed in Table 48.8. Experimental data revealed that a new structure, methylene bis(tetrahydrofurfurylxanthate) with an LC_{50} values of 5.63 ± 0.62 (ppm) was the most toxic among the active compounds.

Table 48.6 The new structures with pesticidal properties

Methylene bis(tetrahydrofurfurylxanthate) 	
Physical state	Colorless liquid
Molecular formula	$C_{13}H_{20}O_4S_4$

UV (MeOH)	λ_{max} 214 (ε 37190), 220 (35674), and 274 nm (27378)

48.7 Antifeedant and IGR Activities of Xanthates

48.7.1 Antifeedant Activity

Antifeedant activity of the alkyl xanthates was studied using leaf disk no-choice method [48.40]. Fresh castor leaf (*Ricinus communis* L.) disks of 4 cm in diameter were punched using cork borer and their surfaces were painted with different concentrations ranging from 5–100 $\mu g\,cm^{-2}$, individually. The leaf disks treated with acetone were used as negative control and a natural product isolated from Neem seed kernel, Azadirachtin (5, 10, 15, and 20 $\mu g\,cm^{-2}$) was used as positive control. In each petri dish (1.5 × 9 cm^2) wet filter paper was placed to avoid early drying of the leaf disks and single third-instar larva was introduced into each petri dish. Progressive consumption of leaf area by the treated and control larvae after 12 and 24 h was recorded using leaf area meter (CI-203 Area meter, CID, Inc., USA). Based on the data, the percent protection of individual compound was calculated and compared with positive control. Control and test larvae were transferred on fresh leaves and monitored till adult emergence to study the growth and behavioral aspects of the insect.

Newly-synthesized alkyl xanthates exhibited a significant antifeedant activity in a dose dependent manner (Fig. 48.4). Data pertaining to the experiment clearly revealed that maximum antifeedant activity was recorded

in methylene bis(*n*-butylxanthate) followed by *m*-fluorobenzyl isobutylxanthate, *p*-xylene bis(*n*-butylxanthate), methylene bis(tetrahydrofurfurylxanthate), and ethylene bis(isobutylxanthate). They are relatively three to seven times less active than positive control, Azadirachtin (Table 48.9).

48.7.2 Growth Inhibitory Activity

In continuation to anteefedant experiments, the larvae (leaf consumed along with compound-calculated) were individually monitored till adult emergence. Based on the formation of normal, abnormal pupae, normal adult emergence, and abnormal adult emergence were recorded and the growth regulatory activity of the compound in comparison with standard was calculated. Relative inhibition 50 values of alkyl xanthates on *S. litura* were statistically analyzed.

Table 48.8 Toxic activity of alkyl xanthates and its analogs against Brine shrimp, *Artemia salina*

7	Standered *Campothecin*	2.53 ± 0.43

IGR activity of alkyl xanthates against *S. litura:* Insect growth regulation properties of marine extracts are very interesting and unique in nature, since insect growth regulator works on juvenile hormone. The enzyme ecdysone plays a major role in shedding of old skin and the phenomenon is called ecdysis or molting. When the active marine compounds enter into the body of the larvae, the activity of ecdysone is suppressed and the larva fails to moult, remaining in the larval stage and ultimately dying [48.41]. Growth inhibitory activity of xanthates was compared with the activity of Azadirachtin and presented in Table 48.10. Further experiments were performed on *Helicoverpa armigera (Hubner)*, a lepidopteron pest was used as an experimental modal to reconfirm the IGR activities of alkyl xanthates (Table 48.11).

The topical application of alkyl xanthates analogues proved as IGR against two polyphagous lepidopteron pests and their mode of action is as similar to a natural product isolated from neem seed kernel, Azadiractin (standard compound). Among the alkyl xanthates, methylene bis(tetrahydrofurfurylxanthate) produced a maximum percentage of deformed larvae, pupae, and adults. The morphological deformities at larval, pupal, and adult stages are due to the toxic effects of alkyl xanthates on growth and development

Data represented as the mean of five replicates in three different sets of experiments.

$$\text{A.I} = \text{Anti-feedant index} = \frac{(\text{Control consumption}) - (\text{Treated consumption}) \times 100}{(\text{Control consumption}) + (\text{Treated consumption})}$$

Normal and control worms consumed 45–50% leaf in 12 h and 87–95% leaf consumption in 24 h

processes (Figs. 48.5–48.7). Since morphogenetic hormones regulate these processes, it can be suggested that these alkyl xanthates interfere with the hormones of the insect. These xanthates have simple structures unlike Azadiractin and possessing a similar kind of mode of action, which can be synthesized easily in the laboratory.

The present results clearly indicated that the marine originated molecules have a significant effect on agricultural pest and human health-related important vectors. Further extensive work is in progress to isolate many active substances as pesticide molecules for sustainable arthropod insect control agents.

48.8 Conclusions

The results of the above studies reveal that the marine natural products acted as toxicants and insect growth regulators. Such extracts or compounds having varied properties are more attractive along with their low cost, biodegradability, and safety to the environment as vector/pest control agents. As an alternate method, natural products especially, marine natural products can support chemical control methods or can play an important role in integrated pest control programs (IPCP). From the current investigations, it has become apparent that alkyl xanthates could be used as a new lead for developing novel insect growth regulators. However, further investigations must be conducted for practical development of this class of compounds as new IGRs, i. e., more lipophilicity must be provided to the molecule to increase the penetration rate through the insect cuticle. It is hoped that the knowledge gained by studying these natural compounds especially marine natural products will be helpful for the development of newer vector/pest control programs. Their use in interference with insect's biochemistry and physiology has promising potential for the development as safe and biodegradable chemicals.

49. Nanotechnology – from a Marine Discovery Perspective

Ramachandran S. Santhosh, Visamsetti Amarendra

Among the technologies reinvented from nature in the twentieth century, nanotechnology is an application of material science to improve the quality of human life. In this chapter, the authors mainly highlight how different nanoparticles (NP), nanocomposites, and nanodevices that exist in nature is supporting life on earth. Oceans harbor a large number of microorganisms; a few can synthesize NPs through green technology and are much superior in quality to the ones produced in the conventional way. The marine organisms themselves can detoxify nanomaterials, so a natural cycle is maintained to produce and detoxify nanomaterials in nature. The design and functioning of the organs of several marine organisms and their cellular organization can help to construct many nanodevices for medical treatment and daily life. Natural biological models are available in the ocean to design novel nanomachines, optical devices, sensors, filters, fuel cells, and acoustic machines. Seawater NPs can control the earth's climate. By incorporating biotechnological techniques into nanotechnology the wide scope for marine nanotechnology can be enhanced.

49.1 Marine Nanotechnology

Nanotechnology is emerging with potential applications utilizing components with unique properties at the nanoscale level. There is a vast development in nanotechnology research all over the world, using resources either of organic/inorganic, or/and biodegradable/renewable nature. It is a broad and interdisciplinary science that is involving applications in physics, chemistry, electronics, biology, space, military, and environmental sciences (Fig. 49.1). The study of matter at nanoscale requires sophisticated instrumentation. It has created a huge impact on the materials utilizing in the day-to-day activities. The application of nanoscale components lies in its unique structural alignment and its precise interactions within the molecule. The modification of the arrangements of atoms/molecules is the most targeted prospects in nanotechnology research. However, in addition to its robust usage in various applications, the production of nanoscale components requires extreme conditions like temperature, pressure, acid/base, etc.

The biological process for the synthesis/development of nanomaterials has given new dimensions to the formulation of a product at low/ambient temperatures and pressures, in a precise and controlled

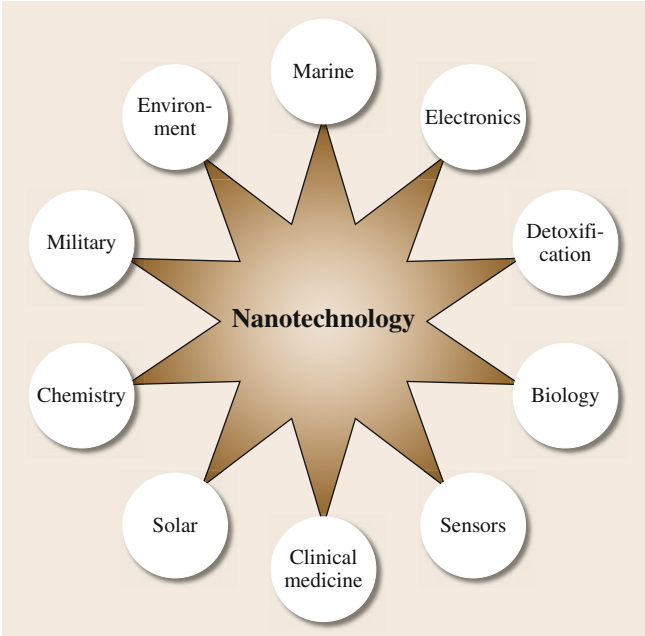

Fig. 49.1 Diverse applications of nanotechnology through marine biomaterials and biological sources

manner. The biological route of synthesis is a new trend in research for replacing all unfavorable conditions for the production of huge range of nanoscale components. Mostly microbial cell factories are vastly utilized for the manipulation and fabrication of submicrometer objects to nanometer-scaled products [49.1]. The synthesis of high surface area/volume ratio materials involves controlled and efficient processes and the reduced release of toxic by-products. Bacteria, algae, fungi, viruses at macromolecular level, and polypeptides, proteins, deoxyribonucleic acid (DNA) duplexes, ribonucleic acid (RNA) complexes, glycolipid components, and lipopeptides are natural biological elements utilized for the synthesis of nanomaterials for diverse applications. Biosynthesized materials can be used in the synthesis of metal NPs, as carriers in drug delivery applications, as therapeutics, in diagnosis, in imaging, as biosensors, electro-conductive transducers, in optics, nanorobotics/nanomachines, as water purifiers, water repellents, dust proof fabrics, and so on.

Marine resources can be used for the synthesis of nanostructured components. They mainly include marine organisms such as diatoms, sponges, echinoderms, mollusks, and its nonliving components, such as cellulose and carrageen of sea weeds, chitin of dead crustaceans, mollusk shells, silica shells of diatoms, siliceous spicules of sponges, etc. Biological materials such as diatom shells and sponge spicules from marine environments are extracted in the laboratory conditions, processed well, and replaced the molecular components with inorganic molecules to increase their mechanical/optical properties [49.2, 3].

In another case, the recombinant proteins of silicatein are synthesized, modifying its active site for synthesizing biomechanical structures [49.4]. Biomimetics is a new field of interest in nanotechnology by replicating the nature to create artificial nanostructures. The biological structures of organisms are studied and applied in the fabrication of material. Skin scales of sharks [49.5, 6], cellulose nanowhiskers of the marine tunicate, *Ascidiella aspersa* [49.7], and microlens array from the marine echinoderm, *Ophiocoma wendtii* [49.8] are various marine sources used for successful biomimicking for engineering purposes.

The present chapter describes various sources and applications of marine-derived products and possible marine-based designs used for fabrications in the field of nanotechnology.

49.2 The Ocean as Source for Nanomaterials and Nanodevices

The ocean comprises many organic and inorganic matter either in living (marine organisms) or nonliving forms (their exudates). The organisms and their biomolecules are involved in the synthesis or processing of many nanoparticulate matters. This chapter discusses the utilization of various marine sources for fabricating nanomaterials and nanodevices.

49.2.1 Metal Nanoparticles

The physical properties of NPs vary significantly from the bulk material; in that the particle possesses a large surface area, surface energy, spatial confinement, and decreased imperfections. Metal NPs are advantageous over bulk material because of their surface plasmon resonance (SPR), enhanced Rayleigh scattering, surface

enhanced Raman scattering (SERS), the quantum size effect in semiconductors and super magnetism in magnetic materials. These metal NPs are useful in various applications of optoelectronics, electronics, and in various chemical and biochemical sensors. Metal NPs are synthesized by top-down and bottom-up approaches. The former one breaks down the bulk material and the latter works by constructive synthesis of atomic or molecular structures.

Biological synthesis of NPs is the recent trend because of its controlled synthesis at normal temperatures and it is nonhazardous to the environment. Since physical and chemical methods result in the release of toxic and hazardous chemicals to the environment, the biological route of synthesis is focused for safe and ecofriendly usage of nonhazardous, economically sustainable raw materials. The major concern in the biological synthesis of metal NPs is their polydisperse nature and slow rate of synthesis. Modifications of pH, temperature, substrate concentration, and other physiological conditions enhance the controlled size and increase the rate of NPs synthesis.

Exploitation of microbes in the fields of bioremediation, biomineralization, bioleaching, and biocorrosion are emerging trends in the research for reducing metal toxicity in the environment. There are two modes of detoxification, either extracellularly through biomineralization, biosorption, complexation, precipitation, or by intracellular accumulation. The presence of various detoxification mechanisms in the microbes is responsible for the resistance towards toxic heavy metals. The application of various methodologies aims to detoxify the metal complexes and synthesize metal NPs, which has more commercial applications in different fields. Metabolic redox reactions are the major mechanisms underlying the synthesis/conversion to metal NPs. Energy-dependent ion efflux from the cell by membrane proteins such as ATPase, chemiosmotic cation/proton antitransporters, detoxifies either by reduction or precipitation of the soluble inorganic particles to insoluble nontoxic metal particles.

Treatment by ultrasonication and various detergents release the intracellularly synthesized metal NPs. Metal NPs are produced inside region of the cell, depositing onto inside cell wall [49.9, 10], precipitating in periplasmic space [49.11–13] and accumulating on the cell surface [49.14, 15]. Extracellular production of metal NPs are due to the presence of cell wall reductive components or soluble secreted enzymes. Modes of synthesis of metal NPs, their growth, and controlled structural development have been addressed by various research groups. Mechanism of modes of action and the components involved should be unraveled to increase the efficiency of biological synthesis.

Amino acid moieties in proteins help in the nucleation reaction for the formation of silver NPs. The face centred cubic (FCC) form of silver crystals are synthesized by the AG3 (AYSSGAPPMPPF) and AG4 (NPSSLFRYLPSD) peptides using the aqueous solution of silver ions [49.16]. Peptides rich with proline and hydroxyl group are found to be effective for the formation of metallic particles from the solution. The outer membrane bound *c*-type cytochrome (*Mtrc*) of the dissimilatory metal-reducing bacterium, *Shewanella oneidensis* MR-1, is involved in the reduction of uranium(VI) forming the extracellular polymeric substance uranium dioxide (UO_2) NPs and the enzyme was also previously reported in the reduction of Mn(IV) and Fe(III) [49.17, 18]. Other than enzymes that fall in the major part of the reduction; membrane bound quinines, the derivatives of naphthoquinones and anthraquinones and cytosolic pH-dependent oxidoreductases were also involved in the catalytic reduction of soluble metal complexes [49.19].

Viral mediated conversion of soluble organic complexes to pure inorganic metal ions were also defined [49.20]. Biological synthesis of NPs are aided by both aquatic and terrestrial forms. Since aquatic forms have quiet different habitats, the synthesis of NPs is focused on them. A few marine microbes are described here with their respective applications. Among them, gold, silver, and lead NPs are well studied.

Gold (Aurum) Nanoparticles (AuNPs)

Monodisperse AuNPs ranging in size between 7–20 nm were synthesized for the first time using aqueous extracts of marine sponge, *Acanthella elongate* by reducing the aqueous solution of $AuCl_4$ [49.21]. Cells of the marine bacteria *Marinobacter pelagius* were able to synthesize monodisperse AuNPs of 10 nm size using $HAuCl_4$ solution [49.22]. Synthesis of stable monodisperse AuNPs ranging between 8–12 nm from $HAuCl_4$ was done with the marine algae *Sargassum wightii* [49.23].

Silver (Argentum) Nanoparticles (AgNPs)

Because of its usage in various applications, such as selective coatings for solar panels, polarizing filters, reaction catalysts, bio-labeling, and as an antimicrobial agent, the biological synthesis of AgNPs is of increas-

ing interest to make the synthesis simple, reliable, eco-friendly, and economical. For the last few years the trend in AgNPs synthesis has marched towards using marine organisms, especially bacteria, fungi, and yeast because of their ability to reduce metal ions to metallic silver [49.24]. The major difference observed among the AgNPs with respect to their terrestrial source and their counter aquatic source, is size. AgNPs synthesized by the *Stapylococcus aureus* of terrestrial origin range from 160–180 nm [49.25]. *Penicillium* sp. isolated from soil was shown to synthesize AgNPs with a size of 75 nm [49.26]. Marine isolates have showed AgNPs in the range of 1–100 nm. Extracellular synthesis of AgNPs ranging from 5 to 25 nm at faster rate was done using the culture filtrate of the marine fungus *Penicillium fellutanum*, isolated from coastal mangrove sediment. Silver ions started converting to AgNPs within 10 min of coming in contact with the culture filtrate [49.27].

The rapidity of NPs synthesis was previously reported by *Bhainsa* and *D'Souza* [49.24] by synthesizing NPs using *Aspergillus fumigatus*. Maximum production was observed using culture supernatant of *P. fellutanum* under the optimized conditions of pH (6.0), temperature (5 °C), NaCl (0.3%) and concentration of $AgNO_3$ as 1 mM for 24 h incubation and the formation of NPs was confirmed by observation of the wavelength peak at 430 nm, which is a typical characteristic for AgNPs [49.27]. Thermophilic *Bacillus* sp. obtained from the marine environment of the Ramanathapuram district (India) synthesized AgNPs with sizes ranging between 10–100 nm [49.28]. *Streptomyces albidoflavus* isolated from marine sediment of the Bay of Bengal; it synthesized AgNPs with sizes ranging 10–40 nm, with an average mean size of 14.5 nm [49.29]. AgNPs show potent antimicrobial action compared to bulk silver. The synergistic action of the AgNPs in combination with standard antibiotics increased the drug sensitivity of the pathogen [49.30]. AgNPs were synthesized intracellularly in the marine bacterium, *Idiomarina* sp. PR58-8 with a size of 26 nm, and x-ray diffraction calculated the crystal size to be 25 nm [49.31].

Lead (Plumbum) Nanoparticles (PbNPs)

Synthesis of stable lead sulfide NPs from lead nitrate was carried out using the lead resistant marine yeast *Rhodosporidium diobovatum*. Stable PbNPs are used as quantum dots applied in solar concentrators and as bioconjugates with antibodies for targeted near-infrared molecular imaging because of their semiconductor properties [49.32].

49.2.2 Nanoparticles in MRI

Biocompatible chitosan and dextran sulfate hybrid biopolymer were used as coating agents for magnetic NPs to develop potential magnetic resonance imaging (MRI), T2 contrasting agent [49.33]. For controlled size distribution and to prevent aggregation, polyelectrolyte complexes are made to form a colloidal solution with metal oxides, resulting in the even dispersal of NPs throughout the polymer. Chitosan is one of the most abundant polymers present in the exoskeleton of crustacean shells, and in many marine mollusks, squid, etc. The polymer of chitosan and dextran sulfate are preferred because of the unique properties of chitosan with its biological properties, biodegradability, biocompatibility, and with its degree of acetylation responsible for charge density; and dextran sulfate for its negatively charged sulfur residues. The iron chloride salts of ferrofluids are directly co-precipitated inside the above mentioned complex polymeric matrixes. Cellular toxicity was checked using BALB/c 3T3 fibroblast cells that were loaded with different concentrations of ferrofluid and detected using propidium iodide staining. No toxicity was observed in the range of 5–80 μg/ml.

49.2.3 Biosurfactants

Surfactants are amphiphilic molecules containing both hydrophobic tails and hydrophilic heads. These molecules are in interface between two immiscible liquids, such as oil and water, and help in miscibility, solubilizing the polar compounds in nonpolar solvents [49.34]. Besides solubility, surfactants are also of interest because of their stability, lower toxicity, biodegradability, higher foaming capacity, and optimum activity at extreme temperature, pH, and salinity, which has led to significant growth in industrial and research fields. Biologically/chemically synthesized surfactants possess a hydrophilic shell comprised of acids, peptide cations, anions, mono, di, and polysaccharides, and a hydrophobic shell comprised of unsaturated or saturated hydrocarbon chains or fatty acids. Surfactants are synthesized either by chemical/physical methods/biological processes. Many microbial fauna are characterized for synthesizing stable and diverse biosurfactants. The use of these biosurfactants increases the stability, shelf-life, and solubility of NPs. Stability of NPs is important for their sustained usage for many applications. Green synthesis of biosurfactants have increased in recent years because of the eco-friendly nature and availability of a variety of low-cost raw materials, such

as plant-derived oils, starchy materials, and distillery waste [49.35]. Many biological systems have been discovered for screening reliable and stable biosurfactants. Marine sponge-derived microbes were screened for the presence of surfactants. *Brevibacterium casei*, an actinobacterium associated with *Dendrilla nigra*, collected from the southwest coast of India was reported to produce a glycolipid biosurfactant [49.36]. The synthesis and stability of AgNPs using biosurfactants was monitored and was proved to be stable for 2 months, which elicits the usage of biologically-derived surfactants to stabilize NPs [49.36].

49.2.4 Nanocomposites

Nanocomposites are polymeric matrixes that enhance and alter the stability, then physical and chemical properties of the different kinds of NPs embedded within them. Their reliability in extreme environments, high mechanical strength, and electrical properties are applicable in various fields such as biological implant materials, electronic packages, and automotive or aircraft components. Various reinforcing materials used are mineral particles; exfoliated clay stack sheets, carbon nanotubes, and electrospun fibers. Addition of nanocomposite material enhances the optical, dielectric properties, heat resistance, mechanical properties and resistance to wear and tear. Mostly synthesized nanocomposites are categorized into ceramic-matrix nanocomposites, metal-matrix nanocomposites, and polymer-matrix nanocomposites. Ceramic-matrix nanocomposites are mixture of ceramic and titanium oxide (TiO_2)/copper (Cu) in which metal particles are comprised as secondary components. The inclusion of metal components improves the optical, electrical, and magnetic properties, and the resistance to corrosion [49.37].

However, the only constraint is the requirement of higher temperatures to form polydispersed immiscible ceramic nanocomposites. The use of high tensile strength and electrical conductive carbon nanotubes in metal matrix nanocomposites improves the electrical, thermal, corrosive resistance, and hydrogen storage properties [49.38]. NPs filling the matrices of polymer composites enhance performance, such as mechanical, optical, and crystallization behavior. For example, polymers of poly(propylene fumarate) nanocomposites, carbon nanotubes, single and multiwalled grapheme oxide nanoribbons, graphene oxide nanoplatelets, and dodecylated nanocomposites are used in medical implants as a scaffolds for bone tissue engineering increased with mechanical properties [49.39]. But chemically or physically synthesized nanocomposites release by-products that are toxic to humans and require extreme conditions for synthesis.

Increased utilization of biological sources for various applications is focused towards the synthesis of nanocomposite materials. Many marine organisms are involved in the synthesis of structures made out of composites throughout their lifetime. For example, mollusk shells, nacre in gastropods, eventhough not marine wings of vultures, the enamel of mammal teeth, sponge spicules, diatom shells, and so on are various fabrications made by diverse organisms. These naturally occurring nanocomposites inspire the synthesis of nanocomposites through biological route. Shells of diatoms and mollusks and silicatein molecules of sponges are the major sources for synthesizing nanocomposites [49.40]. *Gutu* and his co-workers incorporated germanium into the shell of the marine diatom, *Nitzschia frustulum*, by a two-stage photobioreactor cultivation process where organic materials were removed by specific hydrogen peroxide treatment to incorporate germanium [49.41].

Germanium embedding into dielectric silica at nanoscale is of significant interest for development of optoelectronic devices and nonvolatile memory devices. Fabrication of nanostructured materials by bio-inspired or biologically mediated synthesis is carried out at low temperatures and at ambient pressures. In a study done by *Jeffryes* et al. [49.3], the cell division cycle of a diatom was focused for incorporation of germanium oxide into silica matrix. In the first stage, diatom cells were grown until the starvation period for silicon uptake. In the second stage, the cells were co-fed with soluble silicon and germanium to promote one cell division for uptake of germanium oxide into the cell. The nanocomposite material of the silicon-germanium incorporated into the diatom frustules increased the mechanical and optoelectronic properties [49.3].

Marine sponges are very peculiar in synthesizing skeletal elements such as calcareous lamina, siliceous spicules, and other organic filaments. The most noticed siliceous element is attracting researchers to understand the molecular mechanism for its controlled nanofabrication, which could be used for many industrial applications [49.2]. *Schröder* et al. [49.2] synthesized recombinant silicatein with the replacement of cysteine residues by serine to enhance the rate of reaction. The various applications of silicatein in nanotechnology are for the preparation of surface coating of metal oxides, metals, biomaterials glasses, the synthesis of nanocon-

tainers, nanodevices, and the encapsulation of bioactive molecules – which allows controlled release of these substances – biosilicification in lithography and for the production of microelectronics [49.2].

Titanium oxide from water stable alkoxide-titanium was synthesized biocatalytically by purified silicatein protein from composites of *Tethya aurantia* collected from Santa Barbara, California (USA). Purified silicatein filaments were mixed with aqueous solution of titanium(IV) bis(ammonium lactato)-dihydroxide and incubated at 20 °C for 24 h at 50 rpm. The controlled fabrication of titanium oxide and nanocrystalline anatase molecules upon photoluminescence showed a broad peak between 450 and 550 nm, with a maximum absorbance at 475 nm (ca.) (2.76–2.26 eV with 2.61 eV ca.). In comparison with photoluminescence of standard anatase powders (2.92 eV), titanium/protein composites showed a lower value by 0.31 eV. Avoiding higher temperatures and extreme pH the enzymatic method leaves space for accessing potentially useful parameter space of structures and properties [49.42]. In another study, surface immobilized silicatein was shown to synthesize titanium oxide and zirconium oxide particles from precursor molecules of titanium bis(ammonium lactato)-dihydroxide and anionic hexafluorozirconate (ZrF_6^{2-}). Recombinant silicateins having a histidine tag was used for the experiment described below. A reactive polymer, poly(acetoxime methacrylate) bound to amine group of cysteamine coated on gold particles, can provide the groups for binding of nitrilo-triacetic acid (NTA) which complexes with metal ions to hold histidine tag of recombinant silicatein. The hydrolytic activity of surface immobilized silicatein helped in the formation of titania and zirconia NPs which was confirmed by scanning electron micrographs of 50–60 nm sized TiO_2 and ZrO_2 particles. The enzymatic activity of silicatein was not found good in the synthesis of titania and zirconia, since there is a vast difference in the charge density and co-ordination number of metal complexes [49.43].

49.2.5 Nanomachines

Nature's molecular mechanisms are inspirations for developing nanoscale machines that are applicable in various fields, such as aerospace, medical, environment and climate sensing, and military applications. Controlled assembly, sensing, signaling, information processing, intelligence and swarm behavior should be the in-built behavior for an ideal machine to work at the nanoscale level. The development of essential properties, dynamic laws, design, and computation are key factors for an active machine. The exploration of molecular components from a biological source and applying its conventional activity in an artificial manner at qualitative and quantitative levels are a challenging issue.

In the medical field such devices help to perform operations in diagnosis and treatment in situ in the patient body, and to deliver drugs right way to the infected site. In the following sections, wide ranges of applications of nanomachines are discussed, including applications of nanomachines in the fields of medicine, optics, sensors, photonics, purification, electronics, sonar, and so on.

Medicine

Technological advances in computation methods are taking another step towards diagnosis and treatment of disease. Qualitative and quantitative diagnostic tools have been developed in the form of microarrays; one-touch strips that require only a minute quantity of sample. However, diagnosing the disease in vivo requires much intellectuality and more defined programming devices that specifically target the mutilated tissue. Nanomachines have been developed to sense change in molecular levels in vitro and act as miniaturized detectives. Preprogrammed devices are injected into the biological system and targeted a particular site either by an external magnetic field or by using cell/tissue specific ligands [49.44, 45]. Two broad fields in medicine: diagnosis and therapeutics, targeted by molecular and computational biologists, are briefly discussed below.

Diagnosis. Replacing silica chips, biological molecules themselves are used for targeting the diseased condition. Autonomous biomolecular computer can be used in medical diagnosis and treatment. The *Benenson* [49.46] research group developed molecular devices made out of DNA that can analyze the messenger RNA levels and produce a molecule in response to affect the gene expression. Models of small-cell lung cancer and prostate cancer are identified for the levels of messenger ribonucleic acid (mRNA) in vitro using computer programmed devices [49.46, 47]. A nanochip is a microelectronic chip designed to diagnose samples at nano-quantities. The integration of electronics and molecular biology has resulted in the development of nanochips that are useful in diagnostics, biomedical research, genomics, and genetic testing. Fluorescence imaging probes such as quantum dot bioconjugates, quantum dot-fluorescent protein, fluorescent resonance energy transfer (FRET) probes, molecular beacons,

and different NP-based MRI and computer tomography (CT) contrast agents are diverse components of nanomachines towards diagnosis [49.48].

Therapy. An ideal drug delivery should target the infected area of cell/tissue, be 100% reliable in the biological system, be biocompatible, site specific, have controlled supervision, be manipulative, and excrete out from the body without any side effects [49.49]. The transport of drugs from the external environment to inside tissue can be done by bacterial systems that possess engineered flagellum and type III injectisome [49.50]. Nanodiscs made of apolipoproteins conjugated with hydrophobic molecules are used as drug delivery vehicles for hydrophobic drugs. In vitro studies have been carried out using amphotericin B and trans-retinoic acid against fungal and protozoal diseases, and against cancer, respectively [49.51]. The usage of NPs for drug delivery applications has implicated necessary choices in the reduction of hazardous chemical usage. Biological materials that are modified and conjugated with different NPs are made biocompatible in delivering the drug at the targeted site. Chitosan-bound carriers, microcapsule devices from cnidarians, are a few biological sources studied for drug delivery vehicles.

Chitosan and Carrageenan NPs. Chitosan and carrageenan are naturally occurring polymers from the exoskeleton of crustaceans and extract of seaweed respectively. Both have been well appraised for their low toxicity, biocompatibility, and biodegradability. These polymers are currently used to deliver sodium diclofenac and diltiazem hydrochloride in the form of beads and tablets. The use of these polymers for sustained release of NPs in the infected site would be a promising one [49.52]. A model protein, ovalbumin, was used for loading into NPs of chitosan and carrageenan as drug delivery vehicles. The ionic complexation of both polymers by their opposite charges, such as positively charged amino groups of chitosan, interact with negatively charged sulfate groups on the carrageenan formed the nanosized range of 640 nm. Ovalbumin was loaded into carrageenan NPs at concentrations of 10, 20, and 30% (w/w) of protein with respect to the chitosan material. In vitro assays were done to determine the protein release into supernatants using the Micro BCA Protein assay. The controlled release of the protein for more than 3 weeks suggested the application of chitosan/carrageenan NPs as a nanocarriers in the field of tissue engineering and regenerative medicine, where an adequate release profile of a specific growth factor for a prolonged time in the infected area is ensured [49.52].

Microcapsules as Drug Delivery Vehicles. A transdermal route of drug administration is efficient for local and systemic drug delivery. Cnidarians, distinguished by the presence of cnidocytes, comprise both sessile (sea anemones, corals, sea pens) and swimming (jellyfish) forms of life and possess specialized cells called sting cells that are equipped with submicron-diameter injection system with a condensed matrix of short chains of polyglutamate and cations. Upon activation by cellular sensors, water flows through the microcapsules, disassociating the matrix and resulting in an increase in osmotic pressure to 150 mbar, releasing the folded tubule at an acceleration of $5 \times 10^6 g$ at less than 3 ms. The physical phenomenon of the injection system could serve as a vehicle for hydrophilic drug delivery systems [49.53]. The marine sea anemone *Aiptasia diaphana* was used to isolate the acontia (microfilaments) consisting of microcapsules. Microcapsules were prepared in 2% hydroxypropyl cellulose in absolute ethanol; lidocaine HCl was used as a drug to demonstrate its delivery using microcapsules, and methylene blue dye was used to activate the hydrophilic dye. Eight week-old female nude mice skin was used for the drug delivery assay. The amount of drug encapsulated in 1×10^6 microcapsules was applied to per square centimeter of skin above this number of microcapsules the delivery was inefficient. The experimental results confirmed the delivery of the drug through the transdermal route with less than 1 μm diameter and 50 μm length with controlled and rapid release [49.53].

Optical Devices

Traditional microscope are restricted with diffraction limit and there is an urgent need to develop nano-optics and photonic devices. Near-field scanning optical microscopy (NSOM), photo-assisted scanning tunneling microscopy, and surface plasmon optics are technologies based on nano-optics [49.54]. Research is focused on optical devices at the nanolevel to explore in nanolithography, high-density optical data storage, and high-efficiency electronic devices for engineering applications. Nano-optics are found in natural biological systems such as beetles, butterflies, birds, moths, and marine diatoms. Marine-based nano-optics that assists in development of microlenses is discussed below.

Microlenses. Frustules of the marine diatom, *Coscinodiscus wailesii* have been well studied for their

lensless light-focusing nature – for designing microoptic devices [49.55]. Microlenses are made of peculiar cell wall composite, hydrated silica valves, that are interconnected in specific patterns giving a regular array of holes (areolae). Within the distance of 104 μm, the 100 μm spot size of a red laser beam was narrowed to less than 10 μm after its transmission through the diatom frustules. Numerical simulations of the hypothesis proved to be the same in experimental results. The surface of the diatom valve comprising numerous holes scattered at regular intervals that lead to the superimposition of waves resulting in a focusing effect. Its high reproduction rate and reproducible nanoscale patterns which are at cost effective, could be beneficial in fabricating optical microarrays, semiconductor devices, and organic light-emitting devices [49.55].

Nanophotonics. Nanophotonics is another contribution of nanotechnology. The eyes of marine shrimp has 12 different photo receptors and can visualize in polarized light, whereas humans can not and have only three photoreceptors. This capability could be used in compact disc (CDs) and digital video disc (DVDs). Special light-sensitive cells in mantis shrimp eyes act as quarter-wave plates – which can rotate the plane of the oscillations (the polarization) of a light wave as it travels through them. This capability makes it possible for mantis shrimps to convert linearly polarized light to circularly polarized light and vice versa. Man-made quarter-wave plates perform this essential function in CD and DVD players and in circular polarizing filters for cameras. However, these artificial devices only tend to work well for one color of light, while the natural mechanism in the mantis shrimp's eyes work visible spectrum and ultra violet to infra-red light [49.56]. Photonic devices are fabricated using biological models such as shells of diatoms and spicules of sponges. Biocatalytically formed silica can form ultrafast holographic patterning. For this a nanostructure of silica sphere was made using a polycationic peptide obtained from *Cylindrotheca fusiformis* into a polymer hologram created by two-photon-induced photopolymerisation. The polycationic peptide was obtained from silaffin-1 protein of the organism.

These materials could be used for fabricating photonic devices, and in diagnosing antigens by incorporating the respective antibodies in the holograms [49.57]. In natural environments of the glass sponge, *Hyalonema sieboldi*, silicon dioxide present in the water is extracted by the spongin protein giving unique optical and mechanical properties. The synthesis and assembly of silicon dioxide NPs on the macromolecules of proteins (collagen) and polysaccharides (chitin) which acts as a matrix form a natural organic-inorganic hybrid nanocomposite material that combines both the elastic nature of polymer matrixes and the flexibility and durability of silica [49.58]. These nanocomposites comprising hydrated quartz in the axial layers were studied for their optical characteristics [49.59]. A fluorescence intensity at longer wavelengths of 770 nm was observed as second-harmonic pulses from an Nd:YAG (neodymium-doped yttrium aluminum garnet) laser, which excited the basal spicules with longer durations compared to common multimode quartz optical fibers. The transmission spectra of ultra-short pulses (USP) of spicules showed comparatively stronger nonlinear optical properties than the quartz optical fibers. Because of the high heterogeneous distribution of organic complexes, these nonlinear energy conversions in the spicules are classified into a new type of self-organizing photonic crystals, which could be used for optoelectronic instruments such as lasers, fiber amplifiers, and compressors of ultrashort pulses [49.59].

Biosensors

Biosensors are coming up with more accuracy to detect the underlying changes in concentration, displacement, gravitational, electrical, magnetims, pressure, temperature, velocity, and volume of cells. Nanosensor research has made an immense development of sensory devices to measure the release of toxic gases/fumes in the atmospheric environment, coal mines, and monitoring pollutants. An ideal sensor converts the physiological/physical/chemical changes into electrical signals that can be amplified and detected. Nanosensors are made of inorganic/organic molecules such as cadmium telluride (CdTe) nanocrystals for oxygen sensors [49.60]; perovskite barium titanate ($BaTiO_3$) [49.61] and polyacrylic acid/poly(vinyl) alcohol for humidity sensors [49.62]; metal oxide nanotubes for nitrogen dioxide and methanol sensors [49.63]; gold-coated carbon nanotubes (Au-CNT) for glucose sensors, hydrogen peroxide sensors, DNA and other biomolecular sensors, arsenic and parathion sensors, tramadol sensors, ethanol sensors, hydrogen sulfide sensors [49.64–69]; carbon nanotube-copper sulfide NP hybrid material for infrared sensors [49.70]; palladium wires deposited on graphite surfaces for hydrogen sensors [49.71]; and boron doped silicon nanowires for chemical and biological sensors [49.72]. Marine-derived biological components are used in the preparations of biosensors for controlled

synthesis at normal temperatures for eco-friendly functioning.

Detection of Pathogens. With an insight for rapid and early detection of pathogenic bacteria in an infected site, nanotechnology stepped into another approach through biosensors. The rapid and efficient identification of bacteria using gold NP-poly(*para*-phenylene ethynlyene) (PPE) constructs was developed to diagnose the bacteria in environmental samples and in food samples. The negatively charged polymer loses its fluorescent nature on binding with AuNP [49.73]. On addition of the bacterial sample, due to the negative charges on the cell wall, the positively charged NPs bind to them and release the fluorescent PPE into the solution, which results in fluorescence. So, the live bacteria increases the fluorescence by releasing PPE from AuNP-PPE. Different responses can be generated by different types of bacteria, resulting in specific identification [49.73, 74].

Nitrogen Sensors. Advances in nanotechnology using biological processes for various applications have recently been involved in sensing chemicals from released gaseous molecules. Marine diatoms made of amorphous silica shells with a complex and intricate skeleton (frustule) have been reported as possessing gas sensitive optical properties. The marine diatom *Thalassiosira rotula Meunier* has been identified for its photoluminescence emission to quench or enhance in the presence of nitrogen dioxide gases and organic vapors because of its polarization ability [49.75].

Nanofilters

Removal of total dissolved salts, inorganic and organic matter, and the treatment of water co-produced from oil and gas manufacturing companies increases the quality and reusability of water in this water scarce era [49.76–79]. Nanotechnology improved the water of purification systems. The development of nanofilters/membranes and co-filtration of samples with reverse osmosis has radically increased the quality of filtration compared to what was obtained with conventional technologies. The pore sizes of nanofilters are measured by the molecular weight cut-off ranging less than 1000 Da. Nanofiltration technology is capable of the removal of soluble salts, organic/inorganic chemicals, taste, odor, parasites and their cysts, pathogenic microbes, and viral particles. The protozoans *Giardia* and *Cryptosporidium* are the main parasites targeted in surface water and drinking water systems in USA, which are qualitatively treated by nanofiltration [49.80]. Pharmaceutical drug contaminants such as hydrochlorothiazide, ketoprofen, diclofenac, propyphenazone, and carbamazepine in surface water were successfully removed using nanofiltration and a reverse osmosis membrane, and the retentates were analyzed by liquid chromatography-mass spectrometry (LC-MS) for confirmation [49.81]. In vitro studies have been carried out on the removal of 60–90% of arsenic content in waste water treatment using nanofiltration [49.82]. Naturally occurring nanofilters have been discovered in marine environments that possess nanofabricated structures comprised of both filtration and sensing properties. Marine diatoms such as *Glyphodiscus stellatus*, *Cyclotella meneghiniana*, *Roperia tesselata*, and *Isthmia nervosa* are involved in the synthesis of amorphous silica glass valves on micro and nanoscale with particular shapes and sizes that are useful in various applications of biomedicine, electronics, sensing, semiconductor, nanolithography, and as drug delivery vehicles [49.83, 84]. A thermodynamically favored reaction was executed by replacing the silicon atoms in the silicon oxide structures of diatom shells by keeping at the atmosphere of magnesium gas at 900 °C for 4 h. A replicate of a diatom shell of magnesium oxide that resembles silicon oxide with no change in its 3-D shape was formed, thus transforming to magnesium oxide from a silicon dioxide, which has limited applications in nanotechnology. The modified diatom shells could be useful in the preparation of microcapsules for medications, water filters, catalytic substrates, sensors, optical diffraction gratings, and actuators. In another case, the frustules of the diatoms were proposed for water purification by filtration. Diatomaceous earth consists of fossils of dead diatoms remaining in the earth. The different grades of the composition of silica and its sizes determine the porosity and its permeability [49.83].

Nanoelectronics

The next generation of electronics is becoming completely transformed into nanometer-scale electronics that utilize the quantum mechanics phenomenon instead of field-effect transistor technology, which currently used in the conventional transistors ranging between 100–250 nm [49.85]. The fundamental approaches in designing nanoelectronics are nanofabrication, nanomaterial electronics, molecular electronics, nanoionics, and nanophotonics. Various devices under production applying the principles of nanoelectronics are computer devices, memory storage, optoelectronics, displays, quantum computers, radios, energy produc-

tion (solar cells), and medical diagnostics. *Xu* and *Lavan* [49.86] discovered biological cells that synthesize a high voltage of current in the electric eel *Electrophorus electricus*. The miniature structure of the cells impressed researchers and led them to produce a quantum of voltage to be utilized for electronic devices. Electric eels process a special kind of cells (electrocytes) known to produce a high voltage of current of about 600 V, which could be sufficient to kill a human-being. Electrocytes consist of numerous ion channels and ion pumps, which could trigger the release of action potential by forming ion concentration gradients throughout the membrane. The physiological process is used for designing artificial cells that could be used as medical implants for supplying energy and in other tiny devices [49.86]. The artificially synthesized cells performed 31% more efficiently than biological cells. A synthetic biological battery has been developed by *Xu* and his colleagues [49.87], which comprises two droplets separated by a lipid bilayer stabilized with membrane proteins. It acts as a biological battery that converts transmembrane ionic gradients by membrane-protein regulated ion transport into electricity. An energy conversion efficiency of 10% is observed while using synthetic cells other than lead-acid batteries [49.87].

Bio-Sonar

Animals of either terrestrial or aquatic habitats possess a typical property called echolocation. Determining the presence of an object, prey, or hurdle by measuring the time the echo takes to return, is called echolocation. Echolocation can be seen in mammals such as dolphins, whales, and in bats. Artificial SONAR (sound navigation and ranging), which comprises a sound transmitter and a receiver have been developed for submarines, aircraft radar systems, and in industrial, robotic, and medical applications. Whales and dolphins communicate with the surrounding environment and other mammals by producing sounds and listening to the echoes returning to them. This method is used either to communicate, avoid obstacles, hunt prey, and localize objects. The detection of fish by echolocating bottlenose dolphins and harbor porpoises have been studied. In noise-limited environments, the bottlenose dolphin's echolocation of fish was calculated to be 70–93 mts and in quiet environments it was calculated to be 107–173 mts [49.88]. The anatomy of the inner ear, called cochlea, is used as a model for artificial sonar devices that could be used in the medical field, audio frequency range, and ultrasonic transducers. The polyvinylidene fluoride (PVDF) ultrasonic transducer resembles a basilar membrane in which acoustic pressure is amplified by a piezoelectric effect into electrical signals [49.89]. PVDF is a ferroelectric polymer, applicable in the fields of electroacoustics, electro-mechanics, audio frequency, ultrasonics, underwater, optics, and pyroelectric transducers. It is largely used in the medical field as an ultrasonic transducer [49.90, 91].

Tolerating Pressure

Deep-sea animals survive under extreme conditions of osmotic pressures quite easily because of the presence of piezolytes, which regulate the osmotic pressure of the cell. Piezolytes are osmolytes present in soluble form in cytoplasms composed of oligomers of β-hydroxy butyrate (β-HB) units found in the deep-sea bacterium *Photobacterium profundum* strain SS9 [49.92]. This strain was isolated from an amphipod-enriched material collected in the Sulu Sea at a depth of 2551 m [49.93]. In vitro experiments were performed on *P. profundum*, maintaining the cultures at 0.1 MPa and 28 MPa pressure in glucose fermentation conditions. Cells were harvested, extracted with ethanol, and analyzed by natural abundance using ^{13}C nuclear magnetic resonance (NMR) for intracellular osmolytes. At lower pressure conditions, betaine and glutamates were observed in major concentrations, with minor amounts of alanine and glycine. At higher pressure conditions, along with the constant concentrations of betaine, glutamate, and alanine, larger amounts of β-HB units and oligomers of β-HB were observed. This suggests that accumulated β-HB monomers and oligomers are involved in maintaining osmotic balance at higher pressures. The effect of temperature and sodium chloride on the levels of solutes were also assayed. Accumulation of β-HB units was pronounced to be higher in lower temperatures and at increased concentrations of sodium chloride. From these results, piezolytes that function to tolerate extreme pressures could also tolerate osmotic pressures [49.92].

49.3 Ocean in Climate Control

49.3.1 Cooling Effects of Ocean and Cloud Formation

Due to their alkalinity sea salt aerosols are involved in the production of sulfate particles from sulfur dioxide (SO_2) oxidation by ozone and thus act as a sink SO_2. The major protion of SO_2 are released from the combustion of fossil fuels, industrial processes, and volcanoes, and in the reduced form of organic sulfur, such as dimethyl sulfide which is released into the atmosphere by phytoplankton [49.94]. Once the aerosol particles become cloud condensation nuclei (CNN), a major part of the sulfate production occurs on the cloud particle. Because of its hygroscopic nature and optical properties, the sulfate particles scatter the radiation from sunlight, acting as main climate cooling aerosols and are thus effective CNN [49.95]. The mixture of aerosols and sulfate particles possesses different optical properties and hygroscopic nature depending on the size of the particles, which diminishes the cooling effect of sulfate particles. Thus an increase of sea salt aerosols and their interactions with the sulfate particles result in climatic control and formation of a cloud in the marine troposphere and marine boundary layer [49.94–96].

49.3.2 Effect of Environmental Parameters

Temperature and evaporation results in the precipitation of NPs in water bodies. Such an incident happened in 2001 at Lake Michigan in North America. The lake, which is based in a limestone basin, precipitated out calcium carbonate at the end of the summer. Calcium carbonate remained in soluble form throughout the winter and on an increase in temperature during the summer decreased the solubility, which resulted in precipitation in the form of nanometer-scale particles of clouds that could be viewed as bright swirls from satellite images. The precipitation was probably due to the warming up of the ocean, resulting in dissolved carbon dioxide leaving the water body, thus increasing the pH (making it basic) which decreases the solubility of calcium carbonates [49.97]. The salt aerosols were used to treat severe impairment of mucillary transport in patients affected with cystic fibrosis [49.98].

49.4 Detoxification of Nanomaterials

49.4.1 Biotransformation

The increased usage of different kinds of NPs of various sizes, applicable in diverse fields, has increased the accumulation of toxic NPs in the environment. Besides their advantages, the accumulation in aquatic and biological habitats has had an adverse affect over life. Ultrafine NPs can easily pass through the pores of the lipid layers and accumulate in tissues [49.99]. Along with natural aerosols (asbestos), prolonged exposure of man-made fibers are also associated with an increased risk of pulmonary fibrosis and cancer [49.99]. Mussels are well known as biological markers for polluted environments. The aquatic mussel *Corbicula fluminea* was studied for uptake and biological accumulation of bovine serum albumin-coated AuNPs [49.100]. Marine mussels are proficient in taking up the metal NPs by filtering them out from the water body [49.100, 101]. Filtration of engineered cerium oxide (CeO_2) and zinc oxide (ZnO) NPs were studied in an artificial set-up of a water body containing suspension feeding mussels, *Mytilus galloprovincialis*, supplemented with dissolved CeO_2 and ZnO NPs. Mussels are likely to accumulate higher amounts of ZnO than CeO NPs, which was confirmed from the quantification of pseudofeces. The solubility differences between the ZnO and CeO_2 are responsible for the difference in accumulation. Soluble ZnO is readily taken up by mussels, where insoluble CeO_2 is filtered out through the water column and packed in the pseudofeces. Besides the differences in the accumulation in engineering NPs, the experiment proves the biotransformation of NPs released into the environment [49.101].

49.5 Biomimetics

Living organisms are well known for their diverse biological activities, and their significant changes through the course of evolution have adapted to the changing environments. The study of the biological route and the components involved in the activities are trends in research for mimicking its usage. The natural activities that have inspired research groups are nacre synthesis from pearl oysters (for materials science and coatings in biomedical science) [49.102], skin scales of sharks [49.5, 6] (Fig. 49.2a), cellulose nanowhiskers of the marine tunicate *Ascidiella aspersa* [49.7] (Fig. 49.2b), and microlens arrays from the marine echinoderm *Ophiocoma wendtii* [49.8] (Fig. 49.2c). The marine originated species involved in the biomimetic approach for various applications are briefly discussed below.

49.5.1 Nanocoatings and Fabrication

Shark skin scales of a superoleophobic nature are used as a model for preparing low-drag surface materials in swim suits. The superoleophobic nature provides self-cleaning and anti-fouling properties and avoids oil contaminants in the air and water interface to adhere with the surface. Riblets (shark scales) have a lower shear stress than smooth surfaces. The physical phenomenon behind the decrease in shear stress is the presence of small ribs between the previous ribs, which results in sloshing the water particles away from the surface [49.104]. It is hoped that the model can be applied to paintings on airplanes, ships, and wind mills to decrease air drag and to resist the flow of air currents [49.103]. This attempt will reduce the costs of paint and result in more economical fuel savings every year and a decrease in carbon emissions. These superoleophobic surfaces can be used for reducing residual oil loss in oil tanks and pipes [49.105]. The models of shark skin denticles, which reduce water drag during swimming, are used in artificial shark skin-like surface materials in swimsuit preparations. These artificial shark skin preparations reduce the hydrodynamic drag and were proved through a comparison with the self-propelled swimming speed of a flapping foil robotic device on Speedo shark-line swim suit fabric, a silicone riblet-made material, and shark skin membranes. There was a 12.3% increase in swimming speed with the shark skin membranes, compared to a 7.2% increase in speed with the riblet material, and no change in speed with the Speedo shark-line fabric [49.106].

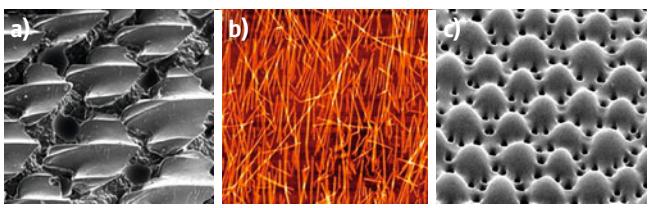

Fig. 49.2a–c Electromicrographs of marine-originated biological designs used for various biomimetic applications. **(a)** shark skin replica [49.103]; **(b)** cellulose nano whiskers [49.7]; **(c)** array of microlenses [49.8]

49.5.2 Nanowhiskers

Chitin Whiskers

Chitin, a naturally occurring biodegradable biopolymer found as the exoskeleton of shrimps, crustaceans (sea crabs, beetles), pens of squid, and cell walls of fungi and yeasts [49.107]. Since chitin is one of the most abundant biocompatible polymers, its usage in various applications is increasing. Suspensions of acid hydrolyzed chitin polymer are used as composite films in preparing complex materials involving various synthetic and nonsynthetic matrixes. Chitin whiskers are used as reinforcing fillers in natural polymeric matrixes such as chitosan to improve their water resistance and mechanical properties [49.108]. Along with their major application as reinforcing fillers, chitin whiskers are also applicable in preparing scaffolds, wound dressings, water purification, adsorbents in industry, transformation in bacteria by exogenous genes, protein immobilization, and preparation of hydrogels [49.107, 109].

Cellulose Whiskers

Besides its abundance as a natural polymer, its biodegradable, renewable, and nontoxic nature, a variety of applications in food, paper production, and pharmaceutics, and as biomaterial, cellulose material is a new area of research in nanotechnology. It is used in preparing cellulose nanofibrils or nanowhiskers for applications in drug delivery, nanocomposite films, protein immobilization, and metallic reaction templates [49.110]. Cellulose nanowhiskers are extracted from the native cellulose by removing lignin, extractives, inorganics, and hemicelluloses [49.111]. Acid hydrolyzed cellulose materials are the main source for the production of cellulose nanowhiskers. The marine tunicate *Ascidiella aspersa* was the first ani-

mal source used for extracting cellulose nanowhiskers. These nanowhiskers were used as nanoscale materials for engineering skeletal muscle tissues [49.7].

49.5.3 Microlens Array

Due to their acute sight capabilities, marine deep-sea organisms are used as a model in developing microlens arrays for highly tunable optical elements, which are used in various applications. The ophiuroid *O. wendtii*, which is called brittle star and belongs to echinoderms, forms a different class because of its strong responses to the light [49.8]. The physiological and phototactic behavior is noted as having a dark brown color during the day and being gray and black during night as an escape mechanism from predators. The dorsal arm plates (DAPs) composed of an array of calcite crystal structures that possess the typical double lens design involved in high photosensitivity. The optical properties of DAPs have the perfect features of being micron-scale, lightweight, mechanically strong, aberration-free, birefringence-free, and having individually addressed lenses that provide a unique focusing effect, signal enhancement, intensity adjustment, angular selectivity, and photochromic activity. A biomimetic model of optical microarray lenses was developed by *Aizenberg* and *Hendler* [49.8] based on numerical simulations of the existing natural model of ophiuroid photosensing calcite structures. A porous hexagonal microlens of a diameter of $1-8\,\mu m$ was created from photoresist materials using multi-beam interface lithography. The controlled size, shape, symmetry, connectivity, and polarization of the lens are adjusted by beam wave vectors, and pore sizes are controlled by laser intensity, exposure time, and concentration of the photosensitizer. The synthetically manufactured microarrays possess nearly perfect structures as naturally occurring lenses and gear up for potential use in optical devices [49.8]. In the same way, deep-sea dragon fishes (*Malacosteus niger, Aristostomias tittmanni*, and *Pachystomias microdon*) and a teleost (*Lestidiops affinis*) were characterized with specialized cells for increasing sensitivity for visualization [49.112, 113]. Most of them are bioluminescent and capable of converting luciferin by photophores present in specialized glandular cells [49.112, 113]. These species could also be studied well for exploiting the interactions of the eye lens with a wide range of radiations for designing new optical devices with a diverse range of applications of nano and bioimaging, optical lithography, optical memory storage, and nanosensing [49.114].

49.6 Conclusions

Nanotechnology plays an important role in the advances of modern technology. There is an important need for the synthesis of various biomaterials and bioparticles in the field of nanotechnology by the improvement of reliable and eco-friendly sources. This can only be accomplished in biological ways. The incorporation of biological sources and derivatives or the biology of the organism or organisms themselves for the synthesis are a better way to achieve a sustainable environment. The synthesis may be partially difficult if only biological sources are used and, moreover, changes in the pH, temperature, and to a lesser extent pressure may favor the synthesis.

The formation of naturally occurring biomaterials and the study of their biological mechanisms may improve the incorporation of diverse elements during their in vitro synthesis. Applications of nanotechnology in utilizing renewable sources in energy production will decrease the rate of extinction of nonrenewable sources. Marine sources are portrayed as being best for the various applications. The uptake of marine sources for the field of nanotechnology may increase the processes of various commercial applications. Thus, the knowledge of the biological mechanisms underlying the synthesis may be used in applications of medicine, optics, electronics, filtration, space, military, environmental monitoring, sensors, and detoxification.

50. Algal Photosynthesis, Biosorption, Biotechnology, and Biofuels

Ozcan Konur

The issues relating to the global warming, air pollution, and energy security have been one of the most important public policy issues nowadays and with the increasing global population, food security has also become a major public policy issue. The development of algal biofuels as a third-generation biofuel has been considered as a major solution for these global problems. Although there have been many reviews on the use of the marine algae in energy, medicine, and health care and there been a number of scientometric studies on the algal biofuels, there has not been any study on the citation classics in the algal photosynthesis, biosorption, biotechnology, and biofuels as in other research fields. As North's New Institutional Theory suggests, it is important to have up-to-date information about the current public policy issues to develop a set of viable solutions to satisfy the needs of all the key stakeholders. Therefore, a selected set of citation classics in the algal photosynthesis, biosorption, biotechnology, and biofuels are presented in this chapter to inform the key stakeholders about the use of marine algae for the solution of these problems in the long run complementing a number of recent scientometric studies on the biofuels and global energy research.

50.1 Overview

50.1.1 Issues

The global warming, air pollution, and energy security have been one of the most important public policy issues nowadays [50.1–3]. With the increasing global population, food security has also become a major public policy issue [50.4]. The development of biofuels generated from the biomass has been a long awaited solution to these global problems [50.5–7]. However, the development of the early biofuels produced from the agricultural plants such as sugar cane [50.7] and agricultural wastes such as corn stovers [50.8] have resulted in a series of substantial concerns about the food security [50.9]. Therefore, the development of algal biofuels as a third-generation biofuel has been considered as a major solution for the global problems of global warming, air pollution, energy security, and food security [50.5].

Although there have been many reviews on the use of the marine algae in energy, medicine, and health care [50.10–14], and there been a number of scientometric studies on the algal biofuels [50.15], there has not been any study on the citation classics in the algal photosynthesis, biosorption, biotechnology, and biofuels as in the other research fields [50.16–24].

As North's New Institutional Theory suggests, it is important to have up-to-date information about the current public policy issues to develop a set of viable solutions to satisfy the needs of all the key stakeholders [50.25–34].

Therefore, a selected set of citation classics in the algal photosynthesis, biosorption, biotechnology, and biofuels are presented in this chapter to inform the key stakeholders relating to the global problems of warming, air pollution, food security, and energy security about the use of marine algae for the solution of these problems in the long run complementing a number of recent scientometric studies on the biofuels and global energy research [50.15, 35–47].

50.1.2 Methodology

A search was carried out in the SCIE (science citation index expanded) and SSCI (social sciences citation index) databases (version 5.9) in February 2013 to locate the papers relating to the algal research using the keyword set of (*micro** *alga** or *macro** *alga** or algal or algae or microalga* or macroalga*) in the abstract pages of the papers. For this paper, it was sufficient to focus on the key algal search terms rather than for a collection of the search terms on the specific names such as diatoms, cyanobacteria, etc., for the algal plants.

It was found that there were 88 582 papers indexed by these indexes between 1956 and 2013. The key subject categories for the algal research were Marine Freshwater Biology (24 358 references, 29.7%), Plant Sciences (14 249 references, 17.4%), Environmental Sciences (9655 references, 11.8%), and Ecology (8951 references, 10.9%) comprising 79% of all the references on the algal research.

Next, the results were refined to Document Types = (Article or Review) and Web of Science Categories = (Biotechnology Applied Microbiology or Multidisciplinary Sciences or Energy Fuels or Engineering Chemical or Chemistry Medicinal or Agricultural Engineering or Agriculture Multidisciplinary or Materials Science Multidisciplinary) and 11 852 articles and reviews were located in both indices. The topical focus was necessary to locate the key papers on the applications of the algal technology in many areas from solar fuels to Medicine and Fuels. It was also necessary to focus on the key references by selecting articles and reviews.

The located papers were arranged in the order of the decreasing number of citations and a cut-off point of 100 citations was used to locate the citation classics in algal research. Then the abstract pages of the papers related to biotechnology, biofuels, photosynthesis, and metal biosorption were grouped under the headings of the topical areas. In order to check whether these collected abstracts correspond to the larger sample on these topical areas new searches were carried out for each topical area.

The summary information about the located citation classics are presented under the four headings of algal biofuels, algal photosynthesis, algal biotechnology, and algal biosorption in the order of the decreasing number of citations for each topical area.

50.2 Algal Photosynthesis

50.2.1 Introduction

The research on the algal photosynthesis has been one of the most dynamic research areas in recent years. Papers of 2011 were located as indexed in the SCIE and SSCI as of February 2013. The United States and Germany produced over 45% of these papers whilst University of California was the most prolific institution. The research output increased significantly in the last two decades with 155 papers in 2012. *Photosynthesis Research* was the most prolific journal publishing over 8% of the papers whilst nearly 41% of the papers were indexed under the subject category of *Plant Sciences*. The citation impact of the papers on the algal photosynthesis has been significant with 29.2 citations per paper and H-index of 97.

Ten citation classics in the field of algal photosynthesis with more than 100 citations were located and the key emerging issues from these papers were presented below in the decreasing order of the number of citations [50.48–57]. These papers give strong hints about the structural determinants of the algal photosynthesis,

informing the following sections. Photosystems I and II (PSI and PSII) which reaction centers that capture light energy in order to drive oxygenic photosynthesis play an important role in this field of research.

50.2.2 Research on the Algal Photosynthesis

Jordan et al. study three-dimensional structure of cyanobacterial photosystem I at 2.5 Å resolution in a paper with 1156 citations [50.48]. They find that the photosynthetic conversion from light energy to chemical energy in algae is driven by the involvement of two large protein–cofactor complexes, namely, photosystems I and II, located in the thylakoid photosynthetic membranes of algae. The structural information on the proteins and cofactors and their interactions provides valuable information on photosynthetic efficiency of photosystem I in the stages of light capturing and electron transfer. For example:

> *the crystal structure of photosystem I from the thermophilic cyanobacterium Synechococcus elongatus provides a picture at atomic detail of* 12 *protein subunits and* 127 *cofactors comprising* 96 *chlorophylls,* 2 *phylloquinones,* 3 Fe_4S_4 *clusters,* 22 *carotenoids,* 4 *lipids, a putative* Ca^{2+} *ion, and* 201 *water molecules.*

Loll et al. study complete cofactor arrangement in the 3.0 angstrom resolution structure of cyanobacterial photosystem II in a paper with 977 citations [50.49]. They note that as in plants, oxygenic photosynthesis in algae is initiated at photosystem II, a homodimeric multisubunit protein–cofactor complex embedded in the thylakoid membrane. Photosystem II captures sunlight and powers the unique photo-induced oxidation of water to atmospheric oxygen. They find that:

> *Crystallographic investigations of cyanobacterial photosystem II provide several medium-resolution structures (*3.8–3.2 Å*) that explain the general arrangement of the protein matrix and cofactors. Assignment of* 11 *beta-carotenes yields insights into electron and energy transfer and photoprotection mechanisms in the reaction center and antenna subunits. The high number of* 14 *integrally bound lipids reflects the structural and functional importance of these molecules for flexibility within and assembly of photosystem II.*

They propose a lipophilic pathway for the diffusion of secondary plastoquinone that transfers redox equivalents from photosystem II to the photosynthetic chain. The structure provides information about the Mn_4Ca cluster, where oxidation of water takes place. They conclude that these near-atomic details are necessary to understand the processes that convert light to chemical energy.

Escoubas et al. investigate whether light-intensity regulation of cab gene-transcription is signaled by the redox state of the plastoquinone pool in eukaryotic green alga *Dunaliella tertiolecta* in a paper with 395 citations [50.50]. They note that the eukaryotic green alga *D. tertiolecta* acclimates to decreased growth irradiance by increasing cellular levels of light-harvesting chlorophyll protein complex apoproteins associated with photosystem II (LHCIIs), whereas increased growth irradiance elicits the opposite response:

> *Light intensity-dependent changes in LHCII are controlled at the level of transcription, cab gene transcription in high-intensity light is partially enhanced by reducing plastoquinone with 3-(3,4-dichlorophenyl)-1,1-dimethyl urea (DCMU), whereas it is repressed in low-intensity light by partially inhibiting the oxidation of plastoquinol with 2,5-dibromo-3-methyl-6-isopropyl-p-benzoquinone (DBMIB):*

They find that uncouplers of photosynthetic electron transport and inhibition of water splitting has no effect on LHCII levels. These results strongly implicate:

> *the redox state of the plastoquinone pool in the chloroplast as a photon-sensing system that is coupled to the light-intensity regulation of nuclear-encoded cab gene transcription.*

They conclude that:

> *the accumulation of cellular chlorophyll at low-intensity light can be blocked with cytoplasmically directed phosphatase inhibitors, such as okadaic acid, microcystin L–R, and tautomycin.*

Cells grown in high-intensity light contain proteins that bind to the promoter region of a cab gene carrying sequences homologous to higher plant light-responsive elements. In their model for a light intensity signaling system, cab gene expression is reversibly repressed by a phosphorylated factor coupled to the redox sta-

tus of plastoquinone through a chloroplast protein kinase.

Hoganson and *Babcock* propose a metalloradical mechanism for the generation of oxygen from water in photosynthesis in a paper with 384 citations [50.51]. They note that in algae, photosystem II uses light energy to oxidize water to oxygen at a metalloradical site that comprises a tetranuclear manganese cluster and a tyrosyl radical. They propose a model that, the tyrosyl radical functions by abstracting hydrogen atoms from substrate water bound as terminal ligands to two of the four manganese ions. They find that molecular oxygen is produced in the final step in which hydrogen atom transfer and oxygen–oxygen bond formation occur together in a concerted reaction. They conclude that this mechanism establishes clear analogies between photosynthetic water oxidation and amino acid radical function in other enzymatic reactions.

Stroebel et al. study an atypical haem in the cytochrome b_6f complex in alga *Chlamydomonas reinhardtii* in a paper with 346 citations [50.52]. They note that photosystems I and II (PSI and II) are reaction centers that capture light energy in order to drive oxygenic photosynthesis. However, they can only do so by interacting with the multisubunit cytochrome b_6f complex. This complex receives electrons from PSII and passes them to PSI, pumping protons across the membrane and powering the Q-cycle. They find that:

> *unlike the mitochondrial and bacterial homologue cytochrome* bc_1, *cytochrome* b_6f *can switch to a cyclic mode of electron transfer around PSI using an unknown pathway and the X-ray structure at* 3.1 Angstrom *of cytochrome* b_6f *from the alga* C. reinhardtii *provides information about this process.*

The structure bears similarities to cytochrome bc_1 but also exhibits some unique features, such as binding chlorophyll, beta-carotene and an unexpected haem sharing a quinone site. They conclude that *this haem is atypical as it is covalently bound by one thioether linkage and has no axial amino acid ligand* and this haem is perhaps the missing link in oxygenic photosynthesis.

Collini et al. investigate coherently wired light harvesting in photosynthetic marine algae at ambient temperature in a paper with 295 citations [50.53]. They note that photosynthesis makes use of sunlight to convert carbon dioxide into useful biomass and is vital for life on Earth. Crucial components for the photosynthetic process are antenna proteins, which absorb light and transmit the resultant excitation energy between molecules to a reaction center. The efficiency of these electronic energy transfers has inspired much work on antenna proteins isolated from photosynthetic organisms to uncover the basic mechanisms at play. Intriguingly, recent work has documented that light-absorbing molecules in some photosynthetic proteins capture and transfer energy according to quantum-mechanical probability laws instead of classical laws at temperatures up to 180 K. This contrasts with the long-held view that long-range quantum coherence between molecules cannot be sustained in complex biological systems, even at low temperatures. They present:

> *two-dimensional photon echo spectroscopy measurements on two evolutionarily related light-harvesting proteins isolated from marine cryptophyte algae, which reveal exceptionally long-lasting excitation oscillations with distinct correlations and anti-correlations even at ambient temperature.*

They conclude that:

> *these observations provide compelling evidence for quantum-coherent sharing of electronic excitation across the* 5 nm*-wide proteins under biologically relevant conditions, suggesting that distant molecules within the photosynthetic proteins are wired together by quantum coherence for more efficient light-harvesting in cryptophyte marine algae.*

Niyogi et al. study the roles of specific xanthophylls in photoprotection in green alga *Chlamydomonas reinhardtii* in a paper with 245 papers [50.54]. They note that xanthophyll pigments hare critical structural and functional roles in the photosynthetic light-harvesting complexes of algae and vascular plants. Genetic dissection of xanthophyll metabolism in the green alga *C. reinhardtii* reveal functions for specific xanthophylls in the nonradiative dissipation of excess absorbed light energy, measured as nonphotochemical quenching of chlorophyll fluorescence. They find that:

> *mutants with a defect in either the alpha- or beta-branch of carotenoid biosynthesis exhibited less nonphotochemical quenching but were still able to tolerate high light.*

In contrast:

> *1a double mutant that was defective in the synthesis of lutein, loroxanthin (alpha-carotene*

branch), zeaxanthin, and antheraxanthin (beta-carotene branch) had almost no nonphotochemical quenching and was extremely sensitive to high light.

They conclude that:

in addition to the xanthophyll cycle pigments (zeaxanthin and antheraxanthin), alpha-carotene-derived xanthophylls such as lutein, which are structural components of the subunit of the light-harvesting complexes, contribute to the dissipation of excess absorbed light energy and the protection of plants from photo-oxidative damage.

Amunts et al. investigate the structure of a plant photosystem I supercomplex at 3.4 Å resolution in a paper with 160 citations [50.55]. They note that all higher organisms on Earth receive energy directly or indirectly from oxygenic photosynthesis performed by plants, green algae and cyanobacteria. Photosystem I (PSI) is a supercomplex of a reaction center and light-harvesting complexes. It generates the most negative redox potential in nature, and thus largely determines the global amount of enthalpy in living systems. They report the structure of plant PSI at 3.4 Å resolution, revealing 17 protein subunits. PsaN is identified in the luminal side of the supercomplex, and most of the amino acids in the reaction center are traced. The crystal structure of PSI provides a picture at near atomic detail of 11 out of 12 protein subunits of the reaction center. They find at this level:

168 *chlorophylls (*65 *assigned with orientations for* Q_x *and* Q_y *transition dipole moments),* 2 *phylloquinones,* 3 Fe_4S_4 *clusters and* 5 *carotenoids.*

They conclude that this structural information extends the understanding of the most efficient nano-photochemical machine in nature.

Bonardi et al. investigate whether photosystem II core phosphorylation and photosynthetic acclimation require two different protein kinases in green alga *Chlamydomonas* and the plant *Arabidopsis* in a paper with 138 citations [50.56]. They note that illumination changes elicit modifications of thylakoid proteins and reorganization of the photosynthetic machinery. This involves, in the short term, phosphorylation of photosystem II (PSII) and light-harvesting (LHCII) proteins. PSII phosphorylation is thought to be relevant for PSII turnover, whereas LHCII phosphorylation is associated with the relocation of LHCII and the redistribution of excitation energy (state transitions) between photosystems. In the long term, imbalances in energy distribution between photosystems are counteracted by adjusting photosystem stoichiometry. They find that in the green alga *Chlamydomonas* and the plant *Arabidopsis*, *state transitions require the orthologous protein kinases STT7 and STN7, respectively*. They show that:

in Arabidopsis a second protein kinase, STN8, is required for the quantitative phosphorylation of PSII core proteins.

However:

PSII activity under high-intensity light is affected only slightly in stn8 mutants, and D1 turnover is indistinguishable from the wild type, implying that reversible protein phosphorylation is not essential for PSII repair.

They conclude that:

acclimation to changes in light quality is defective in stn7 but not in stn8 mutants, indicating that short-term and long-term photosynthetic adaptations are coupled.

Therefore, the phosphorylation of LHCII, or of an unknown substrate of STN7, is also crucial for the control of photosynthetic gene expression.

Zak et al. study the initial steps of biogenesis of cyanobacterial photosystems occur in plasma membranes in cyanobacteria in a paper with 101 citations [50.57]. They note that during oxygenic photosynthesis in cyanobacteria and chloroplasts of plants and eukaryotic algae, conversion of light energy to biologically useful chemical energy occurs in the specialized thylakoid membranes. Light-induced charge separation at the reaction centers of photosystems I and II, two multisubunit pigment–protein complexes in the thylakoid membranes, energetically drive sequential photosynthetic electron transfer reactions in this membrane system. In general, in the prokaryotic cyanobacterial cells, the thylakoid membrane is distinctly different from the plasma membrane. They have recently developed a two-dimensional separation procedure to purify thylakoid and plasma membranes from the genetically widely studied cyanobacterium *Synechocystis* sp. PCC 6803. Immunoblotting analysis demonstrates that the purified plasma membrane contained a number of protein components closely associated with the reaction centers of both photosystems. Moreover:

these proteins are assembled in the plasma membrane as chlorophyll-containing multiprotein com-

plexes, as evidenced from nondenaturing green gel and low-temperature fluorescence spectroscopy data.

Furthermore, electron paramagnetic resonance spectroscopic analysis shows that:

in the partially assembled photosystem I core complex in the plasma membrane, the P700 reaction center is capable of undergoing light-induced charge separation.

Based on these data, they propose that:

the plasma membrane, and not the thylakoid membrane, is the site for a number of the early steps of biogenesis of the photosynthetic reaction center complexes in these cyanobacterial cells.

50.2.3 Conclusion

The research on the algal photosynthesis has been one of the most dynamic research areas in recent years with 2011 papers and with H-index of 97. Ten citation classics in the field of algal photosynthesis with more than 100 citations were located and the key emerging issues from these papers were presented above in the decreasing order of the number of citations [50.48–57]. These papers give strong hints about the structural determinants of the algal photosynthesis, informing the following sections. Photosystems I and II (PSI and PSII) which reaction centers that capture light energy in order to drive oxygenic photosynthesis played an important role in this field of research.

50.3 Algal Biofuels

50.3.1 Introduction

The research on the algal biodiesel has been one of the most dynamic research areas in recent years with 909 papers and H-index of 54. Fifteen citation classics in the field of algal biodiesel with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.10, 11, 58–70]. These papers give strong hints about the determinants of the efficient algal biofuel production and emphasize that marine algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks.

The research on the algal biohydrogen has been one of the most dynamic research areas in recent years with 144 papers and H-index of 25. Seven citation classics in the field of algal biohydrogen with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.12, 71–76]. These papers give strong hints about the determinants of the efficient algal biohydrogen production and emphasize that marine algae are efficient biohydrogen feedstocks.

The research on the algal bio-oil has been one of the most dynamic research areas in recent years with 89 papers and H-index of 21. Three citation classics in the field of algal bio-oil with more than 100 citations are located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.77–79]. These papers give strong hints about the determinants of the efficient algal bio-oil production and emphasize that marine algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks.

50.3.2 Algal Biodiesel

Introduction

The research on the algal biodiesel has been one of the most dynamic research areas in recent years. Nine hundred and nine papers were located as indexed in the SCIE and SSCI as of February 2013. The United States and China produced over 45% of these papers whilst Chinese Academy of Sciences was the most prolific institution. The research output increased significantly in the last decade with 346 papers in 2012. In comparison with the research field of algal photosynthesis, it is a new research field as over 90% of the papers were published after 2008. *Bioresource Technology* was the most prolific journal publishing over 19% of the papers whilst nearly 50% and 46% of the papers were indexed under the subject category of *Biotechnology & Applied Microbiology* and *Energy & Fuels*, respectively. The citation impact of the papers on the algal biodiesel has been significant with 14.1 citations per paper and H-index of 54.

Fifteen citation classics in the field of algal biodiesel with more than 100 citations have been located and the

key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.10, 11, 58–70]. These papers give strong hints about the determinants of the efficient algal biofuel production and emphasize that marine algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks.

Research on the Algal Biodiesel

Chisti reviews the literature on the algal biodiesel in a paper with 1039 citations. He notes that renewable, carbon neutral, and transport fuels are necessary for environmental and economic sustainability as an alternative to the fossil-based fuels [50.10]. He argues that biodiesel derived from the biomass is a potential renewable and carbon neutral alternative to the fossil-based fuels and in comparison with oil crops, waste cooking oil, and animal fat, microalgae are the only source of renewable biodiesel as transport fuels. He notes that like plants, microalgae use sunlight to produce oils through the photosynthetic conversion in a more efficient way. He finds that oil productivity of many microalgae greatly exceeds the oil productivity of the best producing oil crops and there are a number of methodological approaches for making microalgal biodiesel economically competitive with petroleum-based diesel.

Chisti further reviews the literature on the algal biodiesel in a paper with 338 citations. He notes that renewable biofuels are needed to displace fossil-based transport fuels, which contribute to global warming and are scarce [50.11]. He points out that biodiesel and bioethanol are the two potential renewable fuels that have attracted the most attention. However, biodiesel and bioethanol produced from agricultural crops using existing methods cannot sustainably replace fossil-based transport fuels, but there is a viable alternative. He argues that algal biodiesel is perhaps the only renewable biofuel that has the potential to completely displace fossil-based transport fuels without adversely affecting supply of food and other crop product as a third-generation biofuel. Most productive oil crops, such as oil palm, do not come close to microalgae in being able to sustainably provide the necessary amounts of biodiesel and bioethanol from sugarcane is no match for microalgal biodiesel as the first- and second-generation biofuels.

Demirbas reviews the literature on the biomass resource facilities and biomass conversion processing for biofuels and biochemicals [50.58]. He notes that biomass resources include wood and wood wastes, agricultural crops and their waste byproducts, municipal solid waste, animal wastes, waste from food processing, and aquatic plants as well as algae. He further notes that biomass is used to meet a variety of energy needs, including generating electricity, heating homes, fueling vehicles, and providing process heat for industrial facilities. He separates the conversion technologies for utilizing biomass into four basic categories: direct combustion processes, thermochemical processes, biochemical processes, and agrochemical processes. Furthermore, he subdivides thermochemical conversion processes into gasification, pyrolysis, supercritical fluid extraction, and direct liquefaction. On the other hand, pyrolysis is:

> *the thermochemical process that converts biomass into liquid, charcoal and noncondensable gases, acetic acid, acetone, and methanol by heating the biomass to about* 750 K *in the absence of air.*

He argues that to maximize the yield of liquid products resulting from biomass pyrolysis, a low temperature, high heating rate, short gas residence time process are necessary. On the other hand, for high char production, a selection of a low temperature and low heating rate process are necessary. However, to maximize the yield of fuel gas resulting from pyrolysis, a high temperature, low heating rate, and long gas residence time process are required.

Mata et al. recently reviews the literature on the biodiesel production from microalgae and other applications in a paper with 285 citations [50.59]. They note that sustainable production of renewable energy is a recent public policy issue since the first-generation biofuels, primarily produced from food crops, and mostly oil seeds are limited in their ability to achieve targets for biofuel production, climate change mitigation, and economic growth. They argued that these concerns about the first- and second-generation biofuels have increased the interest in developing third-generation biofuels produced from nonfood feedstocks such as microalgae, which potentially offer greatest opportunities in the longer term. They review the current status of microalgae use for biodiesel production, including their cultivation, harvesting, and processing. They present the microalgae species most used for biodiesel production and describe their main advantages in comparison with other available biodiesel feedstocks. They further focus on the various aspects associated with the design of microalgae production units, giving an overview of the current state of development of algae cultivation systems such as photobioreactors and open ponds.

They also discuss the other potential applications and products from microalgae such as for biological sequestration of CO_2 wastewater treatment, in human health, as food additive, and for aquaculture.

Miao and *Wu* study biodiesel production from heterotrophic microalgal oil in a paper with 295 citations [50.60]. They introduce an integrated method for the production of biodiesel from microalgal oil. They find that heterotrophic growth of *Chlorella protothecoides* result in the accumulation of high lipid content (55%) in cells and they extract large amount of microalgal oil from these heterotrophic cells by using *n*-hexane. They obtain algal biodiesel comparable to traditional diesel from heterotrophic microalgal oil by acidic transesterification. They point out that the best process combination is

> 100% *catalyst quantity based on oil weight with* 56 : 1 *molar ratio of methanol to oil at temperature of* 30 °C*, which reduced product specific gravity from an initial value of* 0.912 *to a final value of* 0.8637 *in about* 4 h *of reaction time.*

They conclude that the new integrated process, which combined bioengineering and transesterification, is a feasible and effective method for the production of high quality biodiesel from microalgal oil.

Schenk et al. discuss second-generation biofuels: high-efficiency microalgae for biodiesel production from the third-generation biofuel feedstocks in a paper with 258 citations [50.61]. They note that the use of fossil fuels is unsustainable due to depleting resources and the accumulation of greenhouse gases in the environment that have already exceeded the *dangerously high* threshold of 450 ppm CO_2–*e*. They further note that to achieve environmental and economic sustainability, fuel production processes are required that are not only renewable, but also capable of sequestering atmospheric CO_2 and currently, nearly all renewable energy sources such as hydroelectric, solar, wind, tidal, and geothermal energy sources target the electricity market, while fuels make up a much larger share of the global energy demand. The market demand for biofuels resulted in the third-generation microalgal systems having the advantage that they can produce a wide range of feedstocks for the production of biodiesel, bioethanol, biomethane, and biohydrogen. They argue that producing biodiesel from algae is one of the most efficient ways of generating biofuels and represents the only current renewable source of oil that could meet the global market demand for transport fuels. They conclude that the main advantages of third-generation microalgal systems are that:

> *they have a higher photon conversion efficiency as evidenced by increased biomass yields per hectare; they can be harvested batch-wise nearly all-year-round, providing a reliable and continuous supply of oil; they can utilize salt and waste water streams, thereby greatly reducing freshwater use; they can couple* CO_2*-neutral fuel production with* CO_2 *sequestration; and they finally produce nontoxic and highly biodegradable biofuels.*

However, the harvesting process and in the supply of CO_2 for high efficiency production limit the efficient algal biofuel production.

Brennan and *Owende* recently review the literature on the algal biofuels with a focus on the technologies for production, processing, and extractions of algal biofuels and co-products in a paper with 209 citations [50.62]. They note that sustainability is a key principle in natural resource management, and it involves operational efficiency, minimization of environmental, impact and socioeconomic considerations where all of them are interdependent. The continued reliance on fossil fuel energy resources is unsustainable, owing to both depleting world reserves and the green house gas emissions associated with their use. Therefore, there are large-scale research initiatives to develop alternative renewable and potentially carbon neutral solid, liquid, and gaseous biofuels as alternative energy resources. However, alternate energy resources based on the first-generation biofuels derived from land crops such as sugarcane, sugar beet, maize, and rapeseed place an enormous strain on world food markets, contribute to water shortages and precipitate the destruction of the world's forests. Second-generation biofuels derived from lignocellulosic agriculture and forest residues and from nonfood crop feedstocks address some of the above problems although there is still concern over competing land use or required land use changes. Therefore, they argue that third-generation biofuels specifically derived from microalgae are a technically viable alternative energy resource that is devoid of the major drawbacks associated with first- and second-generation biofuels. They note that microalgae are photosynthetic microorganisms with simple growing requirements such as light, sugars, CO_2, N, P, and K that can produce lipids, proteins, and carbohydrates in large amounts over short periods of time and these prod-

ucts can be processed into both biofuels and valuable co-products. They review:

> *the technologies underpinning microalgae-to-biofuels systems, focusing on the biomass production, harvesting, conversion technologies, and the extraction of useful co-products.*

They also review the

> *synergistic coupling of microalgae propagation with carbon sequestration and wastewater treatment potential for mitigation of environmental impacts associated with energy conversion and utilization.*

They conclude that although there are outstanding issues related to photosynthetic efficiencies and biomass output, algal biofuels can progressively substitute a significant proportion of the fossil fuels required to meet the growing global energy demand.

Xu et al. investigate high quality biodiesel production from a microalga *C. protothecoides* by heterotrophic growth in fermenters in a paper with 182 citations [50.63]. They produce high quality biodiesel from a microalga *C. protothecoides* through the technology of transesterification. They apply the technique of metabolic controlling through heterotrophic growth of *C. protothecoides*, and obtain the heterotrophic *C. protothecoides* with the crude lipid content of 55.2%. They use corn powder hydrolysate instead of glucose as organic carbon source in heterotrophic culture medium in fermenters to increase the biomass and reduce the cost of alga. They find that cell density significantly increases under the heterotrophic condition, and the highest cell concentration reach $15.5\,g\,L^{-1}$. They extract large amount of microalgal oil from the heterotrophic cells by using *n*-hexane, and then transmute into biodiesel by acidic transesterification. The algal biodiesel has a high heating value of $41\,MJ\,kg^{-1}$, a density of $0.864\,kg\,L^{-1}$, and a viscosity of 5.2×10^{-4} Pa s at 40 °C. They conclude that the transesterification method has great potential in the industrial production of liquid fuel from microalga.

Gouveia and *Oliveira* investigate biofuels production from microalgae – *Chlorella vulgaris*, *Spirulina maxima*, *Nannochloropsis* sp., *Neochloris oleabundans*, *Scenedesmus obliquus* and *D. tertiolecta* – in a paper with 149 citations [50.64]. They note that market demand for biofuels is substantial in order to reduce gaseous emissions such as fossil CO_2, nitrogen, and sulfur oxides and their greenhouse, climatic changes and global warming effects, to reduce energy dependence, contributing to security of supply, promoting environmental sustainability, and meeting the EU target of at least of 10% biofuels in the transport sector by 2020. Although the biodiesel is usually produced from the first-generation biofuel feedstocks such as rapeseed, soybean, sunflower, and palm, microalgae is a suitable alternative feedstock as the third-generation biofuel feedstocks because certain species contain high amounts of oil, which could be extracted, processed, and refined into transportation fuels, using currently available technology. Microalgae have also:

> *fast growth rate, permit the use of nonarable land and nonpotable water, use far less water and do not displace food crops cultures*

and their production is not seasonal and they can be harvested daily. They screen microalgae – *C. vulgaris, S. maxima, Nannochloropsis* sp., *N. oleabundans*, *S. obliquus*, and *D. tertiolecta* – in order to choose the best one(s), in terms of quantity and quality as oil source for biofuel production. They find that:

> N. oleabundans – *fresh water microalga – and* Nannochloropsis *sp. – marine microalga – are suitable as raw materials for biofuel production, due to their high oil content*

at 29.0, and 28.7%, respectively. Both microalgae, when grown under nitrogen shortage, show a great increase by 50% in oil quantity. They conclude that:

> S. obliquus *have the most adequate fatty acid profile, namely in terms of linolenic and other polyunsaturated fatty acids*

when used alone. However, they argue that the microalgae *N. oleabundans*, *Nannochloropsis* sp., and *D. tertiolecta* can also be used if associated with other microalgal oils and/or vegetable oils.

Griffiths and *Harrison* investigate lipid productivity as a key characteristic for choosing algal species for biodiesel production in a paper with 123 citations [50.65]. They note that microalgae are a promising alternative source of lipid for biodiesel production and one of the most important decisions is the choice of species to use as the high lipid productivity is a key desirable characteristic of a species for biodiesel production. They review information available in the literature

on microalgal growth rates, lipid content, and lipid productivities for 55 species of microalgae, including 17 Chlorophyta, 11 Bacillariophyta, and 5 Cyanobacteria as well as others. They find that the data available in the literature are far from complete and rigorous comparison across experiments carried out under different conditions is not possible. However, they argue that:

> *the collated information provides a framework for decision-making and a starting point for further investigation of species selection.*

They highlight the shortcomings in the current dataset and show the importance of lipid productivity as a selection parameter over lipid content and growth rate individually.

Carvalho et al. provides a review of enclosed system designs and performances for microalgal photobioreactors in a paper with 122 citations [50.66]. They note that one major issue in:

> *industrial microalgal culturing is to devise and develop technical apparata, cultivation procedures and algal strains susceptible of undergoing substantial increases in efficiency of use of solar energy and carbon dioxide.*

They argue that there is no such thing as *the best reactor system* – defined, in an absolute fashion, as the one able to achieve maximum productivity with minimum operation costs, irrespective of the biological, and chemical system at stake. In fact, they argue that, choice of the most suitable system is situation dependent, as both the species of alga available and the final purpose intended play a role. As the need of accurate control impairs use of open-system configurations, current investigation has focused mostly on closed systems. They review several types of closed photobioreactors described in the technical literature to support production of microalgae using transport phenomenon and process engineering methodological approaches with a focus on the reactor design, which includes tubular reactors, flat plate reactors and fermenter-type reactors as well as the processing parameters, which include gaseous transfer, medium mixing, and light requirements.

Li and *Liu* review the literature on the perspectives of microbial oils for biodiesel production in a paper with 119 citations [50.67]. They note that biodiesel has become more attractive fuel recently because of its environmental benefits, and the fact that it is made from renewable resources and biodiesel is prepared through transesterification of first-generation biofuel feedstocks such as vegetable oils or animal fats with short chain alcohols. However, the lack of oil feedstocks limits the large-scale development of biodiesel to some extent. Recently, much attention has been paid to the development of microbial oils and many microorganisms, such as algae, yeast, bacteria, and fungi, have the ability to accumulate oils under some special cultivation conditions. They argue that:

> *compared to other plant oils, microbial oils have many advantages, such as short life cycle, less labor required, less affection by venue, season and climate, and easier to scale up.*

They predict that with the rapid expansion of biodiesel, microbial oils become one of potential oil feedstocks for biodiesel production in the future, though there are many limitations associated with microorganisms producing oils.

Sialve and *Bernard* review the literature on the anaerobic digestion of microalgae as a necessary step to make microalgal biodiesel sustainable in a paper with 118 citations [50.68]. They note that the potential of microalgae as a source of biofuels and as a technological solution for CO_2 fixation has been studied immensely. They argue that in the perspective of setting up massive cultures, the management of large quantities of residual biomass and the high amounts of fertilizers must be considered and anaerobic digestion is a key process that can solve this immense issue as well as the economical and energetic balance of such a promising technology. Indeed, they find that the conversion of algal biomass after lipid extraction into methane is a process that can recover more energy than the energy from the cell lipids. They identify three limitations to digest microalgae. First, the biodegradability of microalgae can be low depending on both the biochemical composition and the nature of the cell wall. Second, the high cellular protein content results in ammonia release which can lead to potential toxicity. Finally, the presence of sodium for marine species can also affect the digester performance. They argue that:

> *physicochemical pretreatment, co-digestion, or control of gross composition are strategies that can significantly and efficiently increase the conversion yield of the algal organic matter into methane.*

They conclude that when the cell lipid content does not exceed 40%, anaerobic digestion of the whole biomass

is the optimal strategy on an energy balance basis, for the energetic recovery of cell biomass. Lastly, they discuss the ability of these CO_2 consuming microalgae to purify biogas and concentrate methane.

Dismukes et al. review the literature on the aquatic phototrophs as efficient alternatives to land-based crops for biofuels in a paper with 118 citations [50.69]. They propose the use of biofuels derived from aquatic microbial oxygenic photoautotrophs (AMOPs), more commonly known as cyanobacteria, algae, and diatoms to mitigate some of the potentially deleterious environmental and agricultural consequences associated with current land-based-biofuel feedstocks. They review their productivity in mass culturing and aspects of their physiology that are particularly attractive for integration into renewable biofuel applications. They argue that:

> *compared with terrestrial crops, AMOPs are inherently more efficient solar collectors, use less or no land, can be converted to liquid fuels using simpler technologies than cellulose, and offer secondary uses that fossil fuels do not provide.*

However, AMOPs pose a new set of technological challenges to be used as biofuel feedstocks.

Huang et al. discuss biodiesel production by microalgal biotechnology in a paper with 107 citations [50.70]. They note that although numerous reports are available on the production of biodiesel from the first generation biofuel feedstocks such as soybean, sunflower, and palm oils, the production of biodiesel from microalgae is a newly emerging field. They argue that microalgal biotechnology have high potential for biodiesel production because a significant increase in lipid content of microalgae is now possible through heterotrophic cultivation and genetic engineering approaches. They provide an:

> *overview of the technologies in the production of biodiesel from microalgae, including the various modes of cultivation for the production of oil-rich microalgal biomass, as well as the subsequent downstream processing for biodiesel production.*

Conclusion

The research on the algal biodiesel has been one of the most dynamic research areas in recent years with 909 papers and H-index of 54. Fifteen citation classics in the field of algal biodiesel with more than 100 citations were located and the key emerging issues from these papers were presented below in the decreasing order of the number of citations [50.10, 11, 58–70]. These papers give strong hints about the determinants of the efficient algal biofuel production and emphasize that marine algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks.

50.3.3 Algal Biohydrogen

Introduction

The research on the algal biohydrogen has been one of the most dynamic research areas in recent years. 144 papers were located as indexed in the SCIE and SSCI as of February 2013. The United States, India, and China produced over 48% of these papers whilst Chinese Academy of Sciences, Ruhr University, and University of California were the most prolific institutions. In comparison with the research field of algal photosynthesis, it is a new research field as over 80% of the papers were published after 2008 starting with only one paper in 1997 and ending up with 45 papers in 2011. *International Journal of Hydrogen Energy* was the most prolific journal publishing nearly 28% of the papers whilst nearly 54% and 42% of the papers were indexed under the subject category of *Energy & Fuels* and *Biotechnology & Applied Microbiology*, respectively. The citation impact of the papers on the algal biodiesel has been significant with 22.7 citations per paper and H-index of 25.

Seven citation classics in the field of algal biohydrogen with more than 100 citations were located and the key emerging issues from these papers were presented below in the decreasing order of the number of citations [50.12, 71–76]. These papers give strong hints about the determinants of the efficient algal biohydrogen production and emphasize that marine algae are efficient biohydrogen feedstocks.

Research on the Algal Biohydrogen

Das and *Veziroglu* provide one of the first surveys of the literature on the algal biohydrogen in a paper with 676 citations [50.71]. They note that hydrogen is a major alternative to fossil-based fuels due to its high conversion efficiency, recyclability, and nonpolluting nature. Furthermore, biological hydrogen production processes are more environment friendly and less energy intensive as compared to thermochemical and electrochemical processes. They are mostly controlled by either photosynthetic or fermentative organisms whilst nitrogenase and hydrogenase play very important role. They find

that genetic manipulation of cyanobacteria – hydrogenase negative gene – improves the hydrogen generation. They further find that the focus of the research is on the microorganisms and biochemical pathways involved in hydrogen-generation processes and they argue that immobilized system is suitable for the continuous hydrogen production. They conclude that as about 28% of energy can be recovered in the form of hydrogen using sucrose as substrate, fermentative hydrogen production processes have some edge over the other biological processes.

Kapdan and *Kargi* study biohydrogen production from waste materials in a paper with 357 citations [50.12]. They note that hydrogen is a valuable gas as a clean energy source and as feedstock for some industries resulting in an increased market demand for hydrogen production in recent years. They argue that although electrolysis of water, steam reforming of hydrocarbons and auto-thermal processes are the usual methods for hydrogen gas production, they are not cost-effective due to high energy requirements. On the other hand, they argue that biological production of hydrogen gas has significant advantages over chemical methods:

> *The major biological processes utilized for hydrogen gas production are biophotolysis of water by algae, dark and photofermentation of organic materials, usually carbohydrates by bacteria.*

However, *sequential dark and photofermentation process is a rather new approach for bio-hydrogen production* although it has raw material cost limitations. They argue that:

> *carbohydrate rich, nitrogen deficient solid wastes such as cellulose and starch containing agricultural and food industry wastes and some food industry wastewater such as cheese whey, olive mill, and baker's yeast industry wastewater can be used for hydrogen production by using suitable bioprocess technologies.*

Utilization of these wastes for hydrogen production provides inexpensive energy generation with simultaneous waste treatment. They conclude that the types of potential waste materials, bioprocessing strategies, microbial cultures to be used, and bioprocessing conditions are the important parameters in the production of hydrogen gas from algae and waste materials.

Ghirardi et al. review the literature on the microalgae as a green source of renewable hydrogen in a paper with 217 citations [50.72]. They summarize recent advances in the field of algal hydrogen production. They find that there are two fundamental approaches for the algal biohydrogen production. The former one involves the temporal separation of the usually incompatible reactions of O_2 and H_2 production in green algae, and the latter one involves the use of classical genetics to increase the O_2 tolerance of the reversible hydrogenase enzyme. They also discuss the economic and environmental impact of a renewable source of H_2.

Barbosa et al. investigate acetate as a carbon source for hydrogen production by photosynthetic bacteria in a paper with 171 citations [50.73]. They note that hydrogen is a clean energy alternative to fossil-based fuels and photosynthetic bacteria produce hydrogen from organic compounds by an anaerobic light-dependent electron transfer process. They look into the:

> *hydrogen production by three photosynthetic bacterial strains* – Rhodopseudomonas *sp.,* Rhodopseudomonas palustris *and a nonidentified strain–, from four different short-chain organic acids – lactate, malate, acetate, and butyrate.*

They also study the effect of light intensity on hydrogen production by supplying two different light intensities, using acetate as the electron donor and they compare hydrogen production rates and light efficiencies. They find that:

> Rhodopseudomonas *sp. produce the highest volume of* H_2 *where this strain reach a maximum* H_2 *production rate of* 25 ml H_2 L^{-1} h^{-1}, *under a light intensity of* 680 µmol photons m^{-2} s^{-1}, *and a maximum light efficiency of* 6.2% *under a light intensity of* 43 pmol photons m^{-2} s^{-1}.

Furthermore, they find that *a decrease in acetate concentration from* 22–11 mM *result in a decrease in the hydrogen evolved from* 214–27 ml H_2 *per vessel.*

Ghirardi et al. study the oxygen sensitivity of algal hydrogen production in an early paper with 108 citations [50.74]. They note that photoproduction of H_2 by green algae utilizes electrons originating from the photosynthetic oxidation of water and does not require metabolic intermediates. However, they find that algal hydrogenases are extremely sensitive to O_2, which limits their usefulness in future commercial H_2 production systems. They design:

> *an experimental technique for the selection of* O_2*-tolerant,* H_2*-producing variants of* C. reinhardtii *based on the ability of wild-type cells to survive*

a short (20 min) exposure to metronidazole in the presence of controlled concentrations of O_2.

They find that the number of survivors depends on the metronidazole concentration, light intensity, preinduction of the hydrogenase, and the presence or absence of O_2. Finally, they demonstrate that some of the selected survivors in fact exhibit H_2-production capacity that is less sensitive to O_2 than the original wild-type population.

Melis studies green alga hydrogen production with a focus on the progress, challenges and prospects in a paper with 107 citations [50.75]. He argues that:

the recently developed single-organism, two-stage photosynthesis and H_2*-production protocol with green algae is of fundamental importance because it reveals the occurrence of hitherto unknown metabolic, regulatory, and electron-transport pathways in the green alga* C. reinhardtii.

It is also of practical importance that the sustainable light-dependent production and accumulation of significant amounts of H_2 gas, generated from sunlight and water. He argues that this method may serve as a tool to probe and improve photobiological hydrogen production. He concludes that:

the long-term advantage of photobiological hydrogen production is that it does not entail the generation of any toxic or polluting byproducts and it may even offer the advantage of value-added products as a result of the mass cultivation of green algae.

These issues are critical for the long-term success of a renewable hydrogen production process.

Kosourov et al. investigate sustained hydrogen photoproduction by *C. reinhardtii* with a focus on the effects of culture parameters in a paper with 107 citations [50.76]. They note that the green alga, *C. reinhardtii*, is capable of sustained H_2 photoproduction when grown under sulfur-deprived conditions as a result of the partial deactivation of photosynthetic O_2-evolution activity in response to sulfur deprivation. At these reduced rates of water oxidation, oxidative respiration under continuous illumination can establish an anaerobic environment in the culture. They find that after 10–15 h of anaerobiosis, sulfur-deprived algal cells induce a reversible hydrogenase and start to evolve H_2 gas in the light. Using a computer-monitored photobioreactor system, they investigate the behavior of sulfur-deprived algae and find that:

(1) The cultures transition through five consecutive phases: an aerobic phase, an O_2*-consumption phase, an anaerobic phase, a* H_2*-production phase and a termination phase.*
(2) Synchronization of cell division during pregrowth with 14 : 10 h *light: dark cycles leads to earlier establishment of anaerobiosis in the cultures and to earlier onset of the* H_2*-production phase.*
(3) Re-addition of small quantities of sulfate (12.5–50 μM $MgSO_4$*, final concentration) to either synchronized or unsynchronized cell suspensions results in an initial increase in culture density, a higher initial specific rate of* H_2 *production, an increase in the length of the* H_2*-production phase, and an increase in the total amount of* H_2 *produced.*
(4) Increases in the culture optical density in the presence of 50 μM *sulfate result in a decrease in the initial specific rates of* H_2 *production and in an earlier start of the* H_2*-production phase with unsynchronized cells.*

They conclude that:

the effects of sulfur re-addition on H_2 *production, up to an optimal concentration, are due to an increase in the residual water-oxidation activity of the algal cells.*

They also conclude that, in principle:

cells synchronized by growth under light: dark cycles can be used in an outdoor H_2*-production system without loss of efficiency compared to cultures that up until now have been pregrown under continuous light conditions.*

Conclusion

The research on the algal biohydrogen has been one of the most dynamic research areas in recent years with 144 papers and H-index of 25. Seven citation classics in the field of algal biohydrogen with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.12, 71–76]. These papers give strong hints about the determinants of the efficient algal biohydrogen production and emphasize that marine algae are efficient biohydrogen feedstocks.

50.3.4 Algal Bio-oil

Introduction

The research on the algal bio-oil has been one of the most dynamic research areas in recent years. Eighty nine papers were located as indexed in the SCIE and SSCI as of February 2013. The United States and China produced over 49% of these papers whilst University of Michigan and Tsing Hua University were the most prolific institutions. In comparison with the research field of algal photosynthesis, it is a new research field like algal biohydrogen as over 86% of the papers were published after 2008. *Bioresource Technology* and *Energy Fuels* were the most prolific journals publishing over 29% and 11% of the papers, respectively, whilst nearly 68% and 37% of the papers were indexed under the subject category of *Energy & Fuels* and *Biotechnology & Applied Microbiology*, respectively. The citation impact of the papers on the algal biodiesel has been significant with 16.0 citations per paper and H-index of 21.

Three citation classics in the field of algal bio-oil with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.77–79]. These papers give strong hints about the determinants of the efficient algal bio-oil production and emphasize that algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks.

Research on the Algal Bio-oil

Rodolfi et al. investigate microalgae for bio-oil with a focus on the strain selection, induction of lipid synthesis, and outdoor mass cultivation in a low-cost photobioreactor in a paper with 256 citations [50.77]. They screen 30 microalgal strains in the laboratory for their biomass productivity and lipid content. They select four strains – two marine and two freshwater – since they are robust, highly productive, and with a relatively high lipid content and cultivate them under nitrogen deprivation in 0.6 L bubbled tubes. They find that only the two marine microalgae accumulate lipid under such conditions. One of them, the eustigmatophyte *Nannochloropsis* sp. F&M-M24, which attain 60% lipid content after nitrogen starvation, is grown in a 20 L Flat Alveolar Panel photobioreactor to study the influence of irradiance and nutrient – nitrogen or phosphorus – deprivation on fatty acid accumulation. They find that fatty acid content increases with high irradiances up to 32.5% of dry biomass and following both nitrogen and phosphorus deprivation up to about 50%. To evaluate its lipid production potential under natural sunlight, the strain is grown outdoors in 110 L Green Wall Panel photobioreactors under nutrient sufficient and deficient conditions. They find that:

> *lipid productivity increased from* 117 mg L^{-1} d^{-1} *in nutrient sufficient media with an average biomass productivity of* 0.36 g L^{-1} d^{-1} *and* 32% *lipid content to* 204 mg L^{-1} d^{-1} *with an average biomass productivity of* 0.30 g L^{-1} d^{-1} *and more than* 60% *final lipid content in nitrogen deprived media.*

They find further

> *in a two-phase cultivation process which is nutrient sufficient phase to produce the inoculum followed by a nitrogen deprived phase to boost lipid synthesis, the oil production potential can be projected to be more than* 90 kg ha^{-1} d^{-1}.

They provide the first report of an increase of both lipid content and areal lipid productivity attained through nutrient deprivation in an outdoor algal culture. They conclude that this

> *marine eustigmatophyte has the potential for an annual production of* 20 metric tons *of lipid per hectare in the Mediterranean climate and of more than* 30 tons lipid ha^{-1} *in sunny tropical areas.*

Miao and *Wu* study high-yield bio-oil production from fast pyrolysis by metabolic controlling of *C. protothecoides* in a paper with 105 citations [50.78]. They note that the use of renewable energy sources is increasingly necessary to mitigate global warming and recently much research has been focused on identifying suitable biomass species, which can provide high-energy outputs, to replace conventional fossil fuels. They report an approach for increasing the yield of bio-oil production from fast pyrolysis after manipulating the metabolic pathway in microalgae through heterotrophic growth. They find that the yield of bio-oil (57.9%) produced from heterotrophic *C. protothecoides* cells is 3.4 times higher than from autotrophic cells by fast pyrolysis and the bio-oil has a much lower oxygen content, with a higher heating value (41 MJ kg^{-1}), a lower density (0.92 kg L^{-1}), and lower viscosity (0.02 Pa s) compared to those of bio-oil from autotrophic cells and wood. They note that these properties of the bio-oil are comparable to fossil oil. They conclude that the research could contribute to the creation of a system to produce

bio-oil from microalgae, and microalgae also can have great commercial potential for bio-oil production.

Minowa et al. investigate bio-oil production from algal cells of *D. tertiolecta* by direct thermochemical liquefaction in a paper with 105 citations [50.79]. They convert *algal cells of D. tertiolecta with a moisture content of* 78.4 wt% *directly into bio-oil by thermochemical liquefaction at around* 300 °C *and* 10 MPa and they find that the oil yield is about 37% on an organic basis. They conclude that the bio-oil obtained at a reaction temperature of 340 °C and holding time of 60 min have a viscosity of 150–330 mPa s and a calorific value of 36 kJ g^{-1}, comparable to those of fuel oil.

Conclusion

The research on the algal bio-oil has been one of the most dynamic research areas in recent years with 89 papers and H-index of 21. Three citation classics in the field of algal bio-oil with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.77–79]. These papers give strong hints about the determinants of the efficient algal bio-oil production and emphasize that algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks.

50.3.5 Conclusion

The research on the algal biodiesel has been one of the most dynamic research areas in recent years with 909 papers and H-index of 54. Fifteen citation classics in the field of algal biodiesel with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.10, 11, 58–70]. These papers give strong hints about the determinants of the efficient algal biofuel production and emphasize that algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks.

The research on the algal biohydrogen has been one of the most dynamic research areas in recent years with 144 papers and H-index of 25. Seven citation classics in the field of algal biohydrogen with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.12, 71–76]. These papers give strong hints about the determinants of the efficient algal biohydrogen production and emphasize that algae are efficient biohydrogen feedstocks.

The research on the algal bio-oil has been one of the most dynamic research areas in recent years with 89 papers and H-index of 21. Three citation classics in the field of algal bio-oil with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.77–79]. These papers give strong hints about the determinants of the efficient algal bio-oil production and emphasize that marine algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks.

50.4 Algal Biotechnology

50.4.1 Introduction

The research on the algal biotechnology has been one of the most dynamic research areas in recent years. 455 papers were located as indexed in the SCIE and SSCI as of February 2013. The United States and Germany produced over 31% of these papers whilst Wageningen University, Ben Gurion University, and University of California were the most prolific institutions. In comparison with the research fields of algal biodiesel, algal biohydrogen, and algal bio-oil, it is a more established research field as only 53% of the papers were published after 2008 with papers starting back in 1984. *Journal of Applied Phycology* and *Journal of Bioscience and Bioengineering* were the most prolific journals publishing over 8% and 4% of the papers, respectively, whilst nearly 48% and 17% of the papers were indexed under the subject category of *Biotechnology and Applied Microbiology*, and *Marine and Freshwater Biology*, respectively. The citation impact of the papers on the algal biodiesel has been significant with 24.1 citations per paper and H-index of 55.

Eighteen citation classics in the field of algal biotechnology with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.13, 80–96]. These papers give strong hints about the determinants of the efficient algal biotechnology applications and emphasize that marine algae are more efficient biofuel feedstocks in com-

parison with the first- and second-generation biofuel feedstocks necessitating the efficient design of the algal photobioreactors.

50.4.2 Research on the Algal Biotechnology

Spolaore et al. reviews the literature on the commercial applications of microalgae in a paper with 382 citations [50.13]. They note that although the first consumer use of microalgae by humans dates back 2000 years to the Chinese, who used *Nostoe* to survive during famine, microalgal biotechnology only really began to develop in the middle of the last century and nowadays, there are numerous commercial applications of microalgae for consumers. For example, microalgae can be used to enhance the nutritional value of food and animal feed owing to their chemical composition; they play a crucial role in aquaculture; and they can be incorporated into cosmetics. Moreover, they are cultivated as a source of highly valuable molecules. For example, polyunsaturated fatty acid oils are added to infant formulas and nutritional supplements and pigments are important as natural dyes. Stable isotope biochemicals help in structural determination and metabolic studies. They conclude that microalgal products would in that way become even more diversified and economically competitive with a focused research on the improvement of production systems and the genetic modification of strains.

Borowitzka study the commercial production of microalgae with a focus on the ponds, tanks, tubes, and fermenters in a paper with 241 citations [50.80]. He notes that the commercial culture of microalgae is now over 50 years old with the main microalgal species grown being *Chlorella* and *Spirulina* for health food, *Dunaliella salina* for p-carotene, *Haematococcus pluvialis* for astaxanthin and several species for aquaculture. The culture systems used in the 1990s to grow these algae are generally fairly unsophisticated. For example, *D. salina* is cultured in large (up to approx. 250 ha) shallow open-air ponds with no artificial mixing. Similarly, *Chlorella* and *Spirulina* also are grown outdoors in either paddle-wheel mixed ponds or circular ponds with a rotating mixing arm of up to about 1 ha in area per pond. The production of microalgae for aquaculture is generally on a much smaller scale, and in many cases is carried out indoors in 20–40 L carboys or in large plastic bags of up to approximately 1000 L in volume. Furthermore, a helical tubular photobioreactor system has been developed which allows these algae to be grown reliably outdoors at high cell densities in semi-continuous culture and other closed photobioreactors such as flat panels are also developed. He argues that the main problem facing the commercialization of new microalgae and microalgal products is the need for closed culture systems and the fact that these are very capital intensive as the high cost of microalgal culture systems relates to the need for light and the relatively slow growth rate of the algae. He concludes that although this problem has been avoided in some instances by growing the algae heterotrophically, not all algae or algal products can be produced this way.

Lorenz and *Cysewski* discuss the commercial potential for *Haematococcus microalgae* as a natural source of astaxanthin in a paper with 237 citations [50.81]. They note that as a result of high production costs, commercial products from microalgae have high prices. Astaxanthin produced by *Haematococcus* is a product that has become a commercial reality through novel and advanced technology. They further note that cultivation methods have been developed to produce *Haematococcus* containing 1.5–3.0% astaxanthin by dry weight, with potential applications as a pigment source in aquaculture, poultry feeds and in the worldwide nutraceutical market.

Pulz and *Gross* review the literature on the commercial products from biotechnology of microalgae in a paper with 222 citations [50.82]. They note that the biotechnology of microalgae has gained considerable importance in recent decades as the applications range from simple biomass production for food and feed to valuable products for ecological applications. However, for most of these applications, the market is still developing and the biotechnological use of microalgae will extend into new areas. They argue that considering the enormous biodiversity of microalgae and recent developments in genetic engineering, microalgae represent one of the most promising sources for new products and applications. They conclude that with the development of sophisticated culture and screening techniques, microalgal biotechnology can already meet the high demands of both the food and pharmaceutical industries.

Grima et al. reviews the literature on the recovery of microalgal biomass and metabolites with a focus on the process options and economics in a paper with 213 citations [50.83]. They note that:

> *commercial production of intracellular microalgal metabolites requires large-scale monoseptic production of the appropriate microalgal biomass, recovery of the biomass from a relatively dilute broth,*

extraction of the metabolite from the biomass, and purification of the crude extract.

They examine the options available for recovery of the biomass and the intracellular metabolites from the biomass and they discuss the economics of monoseptic production of microalgae in photobioreactors and the downstream recovery of metabolites using eicosapentaenoic acid (EPA) recovery as a representative case study.

Pulz reviews the literature on the algal photobioreactors with a focus on the production systems for phototrophic microorganisms in a paper with 182 citations [50.84]. He notes that microalgae have a large biotechnological potential for producing valuable substances for the feed, food, cosmetics, and pharmacy industries as well as for biotechnological processes whilst the design of the technical and technological basis for algal photobioreactors is the most important issue for economic success in the field of phototrophic biotechnology. He argues that for future applications, open pond systems for large-scale production seem to have a lower innovative potential than closed systems. He concludes that for high-value products in particular, closed systems of algal photobioreactors are more promising fields for technical developments despite very different approaches in design.

Schwarz et al. investigate the production of the pharmaceuticals from cultured algae in a paper with 177 citations [50.85]. They undertake an algae screening program, including cultured macroalgae, cultured cyanobacteria, and cultured eukaryotic microalgae and develop methods for the isolation, purification, preservation, and cultivation of axenic cyanobacteria and eukaryotic cultures. They find that screening of these groups of algae for biologically active components has lead to the isolation of pachydictyol and caulerpenyne from cultured macroalgae, while they have isolated a series of hapalindoles and an antifungal depsipeptide from cyanobacteria

Borowitzka discusses microalgae as sources of pharmaceuticals and other biologically active compounds in a paper with 137 citations [50.86]. He notes that in the 1980s the screening of microalgae, especially the cyanobacteria (blue–green algae), for antibiotics and pharmacologically active compounds has received substantial interest. A large number of antibiotic compounds, many with novel structures, have been isolated and characterized. Similarly many cyanobacteria have been shown to produce antiviral and antineoplastic compounds and a range of pharmacological activities have also been observed with extracts of microalgae, although the active principles are as yet unknown in most cases. He predicts that several of the bioactive compounds may find application in human or veterinary medicine or in agriculture whilst others should find application as research tools or as structural models for the development of new drugs. He concludes that:

the microalgae are particularly attractive as natural sources of bioactive molecules since these algae have the potential to produce these compounds in culture which enables the production of structurally complex molecules which are difficult or impossible to produce by chemical synthesis.

Smit reviews the literature on the medicinal and pharmaceutical uses of seaweed natural products in a paper with 136 citations [50.87]. He notes that in the last four decades the discovery of metabolites with biological activities from macroalgae has increased significantly although very few products with real potential have been identified or developed. Based on MEDLINE and Aquatic Biology, Aquaculture & Fisheries Resources databases, he searches the literature for natural products from marine macroalgae in the Rhodophyta, Phaeophyta, and Chlorophyta with biological and pharmacological activity. He finds that substances that currently receive most attention from pharmaceutical companies for use in drug development, or from researchers in the field of medicine-related research include sulphated polysaccharides as antiviral substances, halogenated furanones from *Delisea pulchra* as antifouling compounds, and kahalalide F from a species of Bryopsis as a possible treatment of lung cancer, tumors, and AIDS (acquired immune deficiency syndrome). Furthermore, other substances such as macroalgal lectins, fucoidans, kainoids, and aplysiatoxins are routinely used in biomedical research and a multitude of other substances have known biological activities. He then discusses the potential pharmaceutical, medicinal, and research applications of these compounds.

Kobayashi et al. study astaxanthin production by a green-alga, *H. pluvialis* accompanied with morphological changes in acetate media in a paper with 121 citations [50.88]. They develop two acetate containing media for astaxanthin production by a green unicellular alga, *H. pluvialis*. They find that the basal medium, a vegetative growth medium facilitate the algal cell growth, whereas the modified medium induces morphological changes with the formation of

large cysts and bleached cells which seemed to consequently enhance the carotenoid biosynthesis. They further find that in the two-stage culture, the injection of ferrous ion with acetate into the basal medium on the fourth day, is greatly stimulative for both the algal cell growth and the astaxanthin formation at a high light intensity. In addition, carotenoid precursors, mevalonate and pyruvate are effective on the carotenoid formation in the modified medium. They conclude that pyruvate is an especially good carbon source both for the algal cell growth and the carotenoid synthesis.

Belay et al. assess the current knowledge on potential health benefits of algae with a focus on *Spirulina* in an early paper on the algal biotechnology with 113 citations [50.89]. They note that spirulina is a microscopic filamentous alga that is rich in proteins, vitamins, essential amino acids, minerals and essential fatty acids like γ-linolenic acid (GLA). It is produced commercially and sold as a food supplement in health food stores around the world. Up to very recently, the interest in *Spirulina* is mainly in its nutritive value. Currently, however, they argue, numerous the possible therapeutic effects of *Spirulina* are also considered as:

> *many preclinical studies and a few clinical studies suggest several therapeutic effects ranging from reduction of cholesterol and cancer to enhancing the immune system, increasing intestinal lactobacilli, reducing nephrotoxicity by heavy metals and drugs and radiation protection.*

They present a critical review of the literature on therapeutic effects of *Spirulina*.

Ugwu et al. review the literature on the photobioreactors for mass cultivation of algae in a paper with 109 citations [50.90]. They note that algae have attracted much interest for production of foods, bioactive compounds and also for their usefulness in procuring the clean environment. They argue that in order to grow and tap the potentials of algae, efficient photobioreactors are required as only a few of them can be practically used for mass production of algae. They point out that one of the major factors that limit their practical application of photobioreactors in algal mass cultures is mass transfer. Thus, they argue that a detailed understanding of mass transfer rates in photobioreactors is necessary for efficient operation of mass algal cultures. They discuss various photobioreactors with a substantial potential for mass production of algae.

Hayashi et al. investigate calcium spirulan, an inhibitor of enveloped virus replication, from a blue–green alga *Spirulina platensis* in an early paper with 109 citations [50.91]. They find that

> *bioactivity-directed fractionation of a hot* H_2O *extract from a blue–green alga* S. platensis *lead to the isolation of a novel sulfated polysaccharide named calcium spirulan (Ca-SP) as an antiviral principle.*

This polysaccharide is composed of rhamnose, ribose, mannose, fructose, galactose, xylose, glucose, glucuronic acid, galacturonic acid, sulfate, and calcium. Ca-SP inhibits the replication of several enveloped viruses, including Herpes simplex virus type 1, human cytomegalovirus, measles virus, mumps virus, influenza A virus, and HIV-1 (human immunodeficiency virus). They show that Ca-SP selectively inhibits the penetration of virus into host cells and they conclude that retention of molecular conformation by chelation of calcium ion with sulfate groups is indispensable to its antiviral effect.

Rosenberg et al. study engineered algae to redirect metabolic engineering to fuel a biotechnology revolution in a recent paper with 104 citations [50.92]. They note that microalgae have the potential to revolutionize biotechnology in a number of areas including nutrition, aquaculture, pharmaceuticals, and biofuels. They argue that although algae have been commercially cultivated for over 50 years, metabolic engineering now seems necessary in order to achieve their full processing capabilities as recently, the development of a number of transgenic algal strains boasting recombinant protein expression, engineered photosynthesis, and enhanced metabolism encourage the prospects of designer microalgae. Given the vast contributions that these solar-powered, carbon dioxide-sequestering organisms can provide to current global markets and the environment, an intensified focus on microalgal biotechnology is necessary. They conclude that recent advances in cultivation techniques coupled with genetic manipulation of crucial metabolic networks will further promote microalgae as an attractive platform for the production of numerous high-value compounds.

Grima et al. look into algal photobioreactors with a focus on the light regime, mass transfer, and scale-up in an early paper with 104 citations [50.93]. They discuss design and scale-up of tubular photobioreactors for outdoor culture of microalgae as culture productivity is invariably controlled by availability of light, particularly as the scale of operation increases. Thus, they emphasize light regime analysis with details of a methodology for computation of the internal culture illumination levels in outdoor systems. They also dis-

cuss supply of carbon dioxide as another important feature of algal culture. Finally, they outline potential scale-up approaches including novel concepts based on fundamentals of the unavoidable light–dark cycling of the culture.

Chen looks into the high cell density culture of microalgae in heterotrophic growth in an early paper with 102 citations [50.94]. He notes that microalgae are a great source of many highly valuable products such as polyunsaturated fatty acids, astaxanthin, and bioactive compounds. He argues that large-scale production of these products, however, has been hindered by an inability to obtain high cell densities and productivities in conventional photoautotrophic systems as high cell density processes suitable for heterotrophic cultures of microalgae may provide an alternative means for the large-scale production of algal products of high value. He reviews recent studies on the formation of algal products in various cultivation systems, with emphasis on the use of heterotrophic techniques and discusses the potential employment of heterotrophic high cell density strategies for commercial production.

Olaizola discusses the commercial development of microalgal biotechnology from the test tube to the marketplace in a paper with 100 citations [50.95]. He notes that only recently that we have come to realize the potential of microalgal biotechnology as microalgal biotechnology has the potential to produce a vast array of products including foodstuffs, industrial chemicals, compounds with therapeutic applications, and bioremediation solutions from a virtually untapped source. He argues from a commercial perspective that, the goal of microalgal biotechnology is to make money by developing marketable products and for such a business to succeed:

> *identifying a desirable metabolite and a microalga that produces and accumulates the desired metabolite and establishing a large-scale production process for the desired metabolite, and market the desired metabolite*

are necessary. He finds that microalgae that produce dozens of desirable metabolites have been identified and he argues that aided by high throughput screening technology even more leads will become available. He discusses achievements and drawbacks from the market point of view with examples from industry with a focus on Mera Pharmaceuticals.

Lee looks into microalgal mass culture systems and methods with a focus on their limitation and potential in a paper with 100 citations [50.96]. He notes that cultivation of microalgae using natural and designed open ponds is technologically simple, but not necessarily cheap due to the high downstream processing cost. Furthermore, products of microalgae cultured in open ponds can only be marketed as value-added health food supplements, specialty feed, and reagents for research. The need to achieve higher productivity and to maintain monoculture of algae necessitates the development of enclosed tubular and flat plate algal photobioreactors. He finds that despite higher biomass concentration and better control of culture parameters, data show that the illuminated areal, volumetric productivity, and cost of production in these enclosed photobioreactors are not better than those achievable in open-pond cultures. The technical difficulty in sterilizing these algal photobioreactors hinders their application for the production of high value pharmaceutical products and the alternative of cultivating microalgae in heterotrophic mode in sterilizable fermentors has some commercial success. He finds that the:

> *maximum specific growth rates of heterotrophic algal cultures are in general slower than those measured in photosynthetic cultures.*

The biomass productivity of heterotrophic algal cultures is not at a level that is comparable to the industrial production of yeast and other heterotrophic microorganisms. He concludes that:

> *mixotrophic cultivation of microalgae takes advantage of their ability to utilize organic energy and carbon substrates and perform photosynthesis concurrently.*

Moreover, the production of some algal metabolites is light regulated. He concludes that design of sterilizable bioreactors for mixotrophic cultivation of microalgae needs to consider the organic substrate as the main source of energy and light as the supplemental source of energy as well as a change in mindset.

50.4.3 Conclusion

The research on the algal biotechnology has been one of the most dynamic research areas in recent years with 455 papers and H-index of 55. Eighteen citation classics in the field of algal biotechnology with more than 100 citations were located and the key emerging issues from these papers were presented

above in the decreasing order of the number of citations [50.13, 80, 82–96]. These papers give strong hints about the determinants of the efficient algal biotechnology applications and emphasize that marine algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks necessitating the efficient design of the algal photobioreactors.

50.5 Algal Biosorption

50.5.1 Introduction

The research on the algal biosorption has been one of the most dynamic research areas in recent years. Eleven thousand one hundred and forty eight papers were located as indexed in the SCIE and SSCI as of February 2013. *Volesky* was the most prolific author with 39 papers and India, Turkey, and China produced over 35% of these papers whilst McGill University and CSIR (Council of Scientific Industrial Research) of India were the most prolific institutions. In comparison with the research fields of algal biofuels, it is a more established research field as only 37% of the papers were published after 2008 with papers starting back in 1990. *Journal of Hazardous Materials* and *Bioresource Technology* were the most prolific journals publishing over 10% and 8% of the papers, respectively, whilst nearly 36% and 28% of the papers were indexed under the subject category of *Environmental Sciences* and *Biotechnology and Applied Microbiology*, respectively. The citation impact of the papers on the algal biodiesel has been significant with 26.1 citations per paper and H-index of 78.

Twenty two citation classics in the field of algal biosorption with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.14, 97–117]. These papers give strong hints about the determinants of the efficient algal biosorption applications and emphasize that algae are efficient organisms in comparison with other organisms necessitating the efficient design of the algal biosorption processes.

50.5.2 Research on the Algal Biosorption of Heavy Metals

Volesky and *Holan* review the literature on the biosorption of heavy metals from metal-bearing industrial effluents in an early paper with 877 citations [50.14]. They note that biomass materials have potential of metal biosorption as they serve as a basis for newly developed metal biosorption processes for the detoxification of metal-bearing industrial effluents. For example:

> *lead and cadmium have been effectively removed from very dilute solutions by the dried biomass of some ubiquitous species of brown marine algae such as* Ascophyllum *and* Sargassum*, which accumulate more than* 30% *of biomass dry weight in the metal.*

Additionally, Mycelia of the industrial steroid transforming fungi *Rhizopus* and *Absidia* are excellent biosorbents for lead, cadmium, copper, zinc, and uranium and also bind other heavy metals up to 25% of the biomass dry weight.

> *Biosorption isotherm curves, derived from equilibrium batch sorption experiments, are used in the evaluation of metal uptake by different biosorbents and new methodologies are developed for the mathematical modeling of biosorption systems and their effective optimization.*

They argue that elucidation of mechanisms active in metal biosorption is essential for successful exploitation of the phenomenon and for regeneration of biosorbent materials in multiple reuse cycles. They conclude that the complex nature of biosorbent materials makes this task particularly challenging with a focus on the composition of marine algae polysaccharide structures, which are instrumental in metal uptake and binding.

Kratochvil and *Volesky* review the advances in the biosorption of heavy metals in an early paper with 406 citations [50.97]. They find that the biosorption of heavy metals by certain types of biomass is a highly cost-effective new alternative for the decontamination of metal-containing effluents and argue that packed-bed sorption columns are perhaps the most efficient for this purpose. They conclude that regenerating the biosorbents increases the process economy by allowing their reuse in multiple sorption cycles whilst the process results in metal-free effluents and small vol-

umes of solutions containing concentrated metals to be recovered.

Juhasz and *Naidu* review the literature on the bioremediation of high molecular weight polycyclic aromatic hydrocarbons with a focus on the microbial degradation of benzo[*a*]pyrene (BaP) in a paper with 293 citations [50.98]. They note that in recent years, research on the microbial degradation of polycyclic aromatic hydrocarbons (PAHs) has resulted in the isolation of numerous genera of bacteria, fungi, and algae capable of degrading low molecular weight PAHs which are compounds containing three or less fused benzene rings. They find that high molecular weight PAHs which are compounds containing four or more fused benzene rings are generally recalcitrant to microbial attack, although some fungi and algae are capable of transforming these compounds. They point out that:

> *only a few genera of bacteria have been isolated with the ability to utilize four-ring PAHs as sole carbon and energy sources while cometabolism of five-ring compounds*

has been reported. They focus on the high molecular weight PAH (BaP) as

> *there has been concern about the presence of BaP in the environment because of its carcinogenicity, teratogenicity and toxicity. BaP accumulate in marine organisms and plants which could indirectly cause human exposure through food consumption.*

They finally provide the outline of the occurrence of BaP in the environment and the ability of bacteria, fungi and algae to degrade the compound, including pathways for BaP degradation by these organisms.

Holan et al. study the biosorption of cadmium by biomass of marine-algae in an early paper with 286 citations [50.99]. They note that biomass of nonliving, dried brown marine algae *Sargassum natans*, *Fucus vesiculosus*, and *Ascophyllum nodosum* exhibit high equilibrium uptake of cadmium from aqueous solutions. They evaluate quantitatively the metal uptake by these materials using sorption isotherms. They find that biomass of *A. nodosum* accumulate the highest amount of cadmium exceeding 100 mg Cd^{2+} g^{-1} at the residual concentration of 100 mg CdL^{-1} and pH 3.5, outperforming a commercial ion exchange resin DUOLITE GT-73. They obtain a new biosorbent material based on A. nodosum biomass by reinforcing the algal biomass by formaldehyde cross-linking. They find that the prepared sorbent possess good mechanical properties, chemical stability of the cell wall polysaccharides and low swelling volume and desorption of deposited cadmium with 0.1–0.5 M HCl result in no changes of the biosorbent metal uptake capacity through five subsequent adsorption/desorption cycles. They also find that there is no damage to the biosorbent which retain its macroscopic appearance and performance in repeated metal uptake/elution cycles.

Aksu studies the equilibrium and kinetic modeling of cadmium(II) biosorption by *C. vulgaris* in a batch system with a focus on the effect of temperature as a function of the temperature, initial pH and initial metal ion concentration in a paper with 246 citations [50.100]. She finds that:

> *the algal biomass exhibits the highest cadmium(II) uptake capacity at* 20 °C*, at the initial pH value of* 4.0 *and at the initial cadmium(II) ion concentration of* 200 mg L^{-1}.

Additionally, biosorption capacity decreased from 85.3–51.2 mg g^{-1} with an increase in temperature from 20–50 °C at this initial cadmium(II) concentration. She applies the Freundlich and Langmuir isotherm models to represent the equilibrium data of cadmium(II) biosorption depending on temperature and finds that:

> *equilibrium data fit very well to both the models in the studied concentration range of cadmium(II) ions at all the temperatures studied.*

She also applies the:

> *pseudo first- and pseudo second-order kinetic models to experimental data assuming that the external mass transfer limitations in the system can be neglected and biosorption is sorption controlled*

She concludes that:

> *cadmium(II) uptake process follows the second-order rate expression and adsorption rate constants decrease with increasing temperature.*

She finally evaluates the second-order kinetic constants and the activation energy of biosorption.

Ahluwalia and *Goyal* review the microbial and plant derived biomass for removal of heavy metals from wastewater in a recent paper with 282 citations [50.101]. They note that discharge of heavy metals

from metal processing industries have adverse effects on the environment as the conventional treatment technologies for removal of heavy metals from aqueous solution are not economical and generate huge quantity of toxic chemical sludge. On the contrary, they find that:

> *biosorption of heavy metals by metabolically inactive nonliving biomass of microbial or plant origin is an innovative and alternative technology for removal of these pollutants from aqueous solution*

and point out that:

> *due to unique chemical composition biomass sequesters metal ions by forming metal complexes from solution and obviates the necessity to maintain special growth-supporting conditions.*

They find that:

> *algal biomass of* Aspergillus niger, Penicillium chrysogenum, Rhizopus nigricans, A. nodosum, Sargassum natans, Chlorella fusca, Oscillatoria anguistissima, Bacillus firmus, *and* Streptomyces *sp. have the highest metal adsorption capacities ranging from* 5–641 mg g^{-1} *mainly for* Pb, Zn, Cd, Cr, Cu, *and* Ni.

They conclude that algal biomass generated as a by-product of fermentative processes offers great potential for adopting an economical metal-recovery system.

Holan and *Volesky* study the biosorption of lead and nickel by biomass of marine-algae in an early paper with 228 citations [50.102]. They find as a result of the screening tests of different marine algae biomass types *a high passive biosorptive uptake of lead up to* 270 mg Pb g^{-1} *of biomass in some brown marine algae* and *members of the order Fucales perform particularly well in this descending sequence:* Fucus > Ascophyllum > Sargassum. They argue that *although decreasing the swelling of wetted biomass particles, their reinforcement by cross linking may significantly affect the biosorption performance*. They also observe lead uptakes up to 370 mg Pbg^{-1} in cross-linked *F. vesiculosus* and *A. nodosum*. At low equilibrium residual concentrations of lead in solution, however, ion exchange resin Amberlite IR-120 has a higher lead uptake than the biosorbent materials.

Wilde and *Benemann* review the literature on the bioremoval of heavy metals by the use of microalgae in an early paper with 212 citations [50.103]. They note that bioremoval, the use of biological systems for the removal of metal ions from polluted water, has the potential to achieve greater performance at lower cost than conventional wastewater treatment technologies for metal removal. They find that:

> *although microalgae are not unique in their bioremoval capabilities, they offer advantages over other biological materials in some conceptual bioremoval process schemes*

as:

> *selected microalgae strains, purposefully cultivated and processed for specific bioremoval applications, have the potential to provide significant improvements in dealing with the global problems of metal pollution.*

In addition to strain selection:

> *significant advances in the technology are possible by improving biomass containment or immobilization techniques and by developing bioremoval process steps utilizing metabolically active microalgae cultures.*

They conclude that the latter approach is especially attractive in applications where extremely low levels of residual metal ions are required. They outline the current literature, highlighting the potential benefits and problems associated with the development of novel algal-based bioremoval processes for the abatement of heavy metal pollution.

Aksu looks into the equilibrium, kinetic, and thermodynamic parameters of the batch biosorption of nickel(II) ions onto *C. vulgaris* in a paper with 197 citations [50.104]. She notes that the kinetics of the metal uptake process and the description of the thermal properties of biosorption remain essentially unknown and she therefore studies the biosorption equilibrium, kinetics and thermodynamics of nickel(II) ions to *C. vulgaris* in a batch system as a function of temperature and initial metal ion concentration. She finds that:

> *algal biomass exhibits the highest nickel(II) uptake capacity at* 45 °C *at an initial nickel(II) ion concentration of* 250 mg L^{-1} *and an initial pH of* 4.5

and *biosorption capacity increased from* 48.1–60.2 mg g^{-1} *with an increase in temperature from* 15–45 °C *at this initial nickel(II) concentration*. She then applies Freundlich, Langmuir, and Redlich–Peterson isotherm models to experimental equilibrium data of nickel(II) biosorption depending on temperature and she finds that equilibrium data fit very well to all the equilibrium models in the

studied concentration range of nickel(II) ions at all the temperatures studied. She then applies the saturation type kinetic model to experimental data at different temperatures changing from 15–45 °C to describe the batch biosorption kinetics assuming that the external mass transfer limitations in the system can be neglected and biosorption is chemical sorption controlled. She also determines the activation energy of biosorption (EA) as 25.92 kJ mole^{-1} using the Arrhenius equation and evaluates the thermodynamic constants of biosorption (ΔG, ΔH, and $\Delta S°$) using the thermodynamic equilibrium coefficients obtained at different temperatures.

Donmez et al. carry out a comparative study on heavy metal biosorption characteristics of some algae in a paper with 199 citations [50.105]. They test the biosorption of copper(II), nickel(II), and chromium(VI) from aqueous solutions on dried (*C. vulgaris*, *S. obliquus* and *Synechocystis* sp.) algae under laboratory conditions as a function of pH, initial metal ion, and biomass concentrations and they determine optimum adsorption pH values of copper(II), nickel(II), and chromium(VI) as 5.0, 4.5, and 2.0, respectively, for all three algae. They find that at the optimal conditions, metal ion uptake increases with initial metal ion concentration up to 250 mg L^{-1}. They additionally find that alga concentration influences the metal uptake for all the species and they conclude that both the Freundlich and Langmuir adsorption models are suitable for describing the short-term biosorption of copper(IT), nickel(II), and chromium(VI) by all the algal species.

Leusch et al. investigate the biosorption of heavy-metals (Cd, Cu, Ni, Pb, Zn) by chemically reinforce biomass of marine-algae in a paper with 170 citations [50.106]. They crosslink particles of two different sizes (0.105–0.295 mm and 0.84–1.00 mm diameter) of two marine algae, *Sargassum fluitans* and *A. nodosum*, with formaldehyde (FA), glutaraldehyde (GA) or embed in polyethylene imine (PEI), followed by glutaraldehyde cross linking. They are used for equilibrium sorption uptake studies with cadmium, copper, nickel, lead and zinc. They find that the metal uptake by larger particles (0.84–1.00 mm) is higher than that by smaller particles (0.105–0.295 mm).

> *The order of adsorption for* S. fluitans *biomass particles is* Pb > Cd > Cu > Ni > Zn, *for* A. nodosum *copper and cadmium change places and uptakes of metals range from* $q(max) = 378$ mg Pb g^{-1} *for* S. fluitans *(FA, big particles), to* $q(max) = 89$ mg Zn g^{-1} *for S. fluitans (FA, small particles) as the best sorption performance for each metal.*

They conclude that generally, *S. fluitans* is a better sorbent material for a given metal, size, and modification, although there are several exceptions in which metal sorption by *A. nodosum* is higher. They also conclude that the metal uptake for different chemical modifications show the order GA > FA > PEI and the Langmuir sorption model fit the experimental data best.

Chong and *Volesky* investigate 2-metal biosorption equilibria by Langmuir-type models in a paper with 158 citations [50.107]. They examine a biosorbent prepared from *A. nodosum* seaweed biomass, FCAN2, for its sorption capacity and perform equilibrium batch sorption studies using two-metal systems containing either (Cu + Zn), (Cu + Cd), or (Zn + Cd). They further evaluate three Langmuir-type models in order to model the isotherm surfaces mathematically and they use the apparent one-parameter Langmuir constant (b) to quantify FCAN2 *affinity* for one metal in the presence of another one. They find that the uptake of Zn decrease drastically when Cu or Cd were present and the uptake of Cd is much more sensitive to the presence of Cu than to that of Zn. They conclude that the presence of Cd and Zn alter the *affinity* of FCAN2 for Cu the least at high Cu equilibrium concentrations and the mathematical model of the two-metal sorption system enable quantitative estimation of one-metal (bio)sorption inhibition due to the influence of a second metal.

Donmez and *Aksu* look into the removal of chromium(VI) from saline wastewater by *Dunaliella* species in a paper with 150 citations [50.108]. They note that some industrial wastewater contain higher quantities of salts besides chromium(VI) ions so they investigate effect of these salts on the biosorption of chromium(VI) and test the biosorption of chromium(VI) from saline solutions on two strains of living Dunaliella algae under laboratory conditions as a function of pH, initial metal ion and salt (NaCl) concentrations in a batch system. They find that the biosorption capacity of both Dunaliella strains strongly depends on solution pH and maximum. They then determine chromium(VI) sorption capacities of both sorbents at pH 2.0 in the absence and in the presence of increasing concentrations of salt and they perform chromium(VI)-salt biosorption studies at this pH value. They find that:

> *equilibrium uptakes of chromium(VI) increases with increasing chromium(VI) concentration up to*

> *250–300 mg L^{-1} and decreases sharply by the presence of increasing concentrations of salt for both the sorbents*

whilst *Dunaliella* 1 and *Dunaliella* 2 biosorb 58.3 and 45.5 mg g^{-1} of chromium(VI), respectively, in 72 It at 100 mg L^{-1} initial chromium(VI) concentration without salt medium. On the other hand, when salt concentration arises to 20% (w/v), these values drop to 20.7 and 12.2 mg g^{-1} of chromium(VI) at the same conditions. They point out that:

> *both the Freundlich and Langmuir adsorption models are suitable for modeling the biosorption of chromium(VI) individually and in salt containing medium by both algal species as they apply the pseudo second-order kinetic model successfully to single chromium(VI) and chromium(VI)–salt mixtures biosorption data.*

Matheickal and *Yu* study biosorption of lead(II) and copper(II) from aqueous solutions by pretreated biomass of Australian marine algae in a paper with 149 citations [50.109]. They note that chemically modified biomass of marine algae can effectively remove heavy metals from waste water. They develop and study Australian marine algae (*Durvillaea potatorum* and *Ecklonia radiata*)-based biosorbents (DP95Ca and ER95Ca) for their heavy metal removal properties from aqueous solutions. They find that a two stage modification process substantially improves the leaching characteristics of the biomass as batch equilibrium experiments show that the maximum adsorption capacities of DP95Ca for lead and copper are 1.6 and 1.3 mmol g^{-1}, respectively, and the corresponding values for ER95Ca are 1.3 and 1.1 mmol g^{-1}. They point out that these capacities are comparable with those of commercial ion exchange resins and are much higher than those of natural zeolites and powdered activated carbon. They then find that the:

> *heavy metal uptake process is rapid with* 90% *of the adsorption completed in about* 10 min *in batch conditions as heavy metal adsorption is observed at pH values as low as* 2.0 *and maximum adsorption is obtained approximately at a pH of* 4.5.

They conclude that both biosorbents are effective in removing lead and copper in the presence of chelating agents and other light metal ions in waste water.

Aksu and *Tezer* study biosorption of reactive dyes on the green alga *C. vulgaris* in a paper with 142 citations [50.110]. They examine biosorption of three vinyl sulphone type reactive dyes (Remazol Black B (RB), Remazol Red RR (RR) and Remazol Golden Yellow RNL (RGY)) onto dried *C. vulgaris*, a green alga in a batch system. They find that the:

> *algal biomass exhibit the highest dye uptake capacity at the initial pH value of* 2.0 *for all dyes whilst the effect of temperature on equilibrium sorption capacity indicates that maximum capacity is obtained at* 35 °C *for RB biosorption and at* 25 °C *for RR and RGY biosorptions.*

They further find that:

> *biosorption capacity of alga increases with increasing initial dye concentration up to* 800 mg L^{-1} *for RB and RR dyes, and up to* 200 mg L^{-1} *for RGY dye.*

Among the three dyes, RB is adsorbed most effectively by the biosorbent to a maximum of approximately 419.5 mg g^{-1}. They use the Freundlich, Langmuir, Redlich–Peterson, and Koble–Corrigan adsorption models for the mathematical modeling of the biosorption equilibrium and they evaluate isotherm constants at different temperatures. They find that equilibrium data of RB biosorption fit very well to all models except that the Langmuir model, while this model is most suitable for modeling the biosorption of RR and RGY dyes in the studied concentration and temperature ranges. They also apply the pseudo first- and second-order and saturation-type kinetic models to the experimental data assuming that the external mass transfer limitations in the system can be neglected. They conclude that the dye uptake process follows the pseudo second-order and saturation type rate expressions for each dye *C. vulgaris* system.

Mehta and *Gaur* discuss the use of algae for removing heavy metal ions from wastewater in a paper with 140 citations [50.111]. They note that many algae have immense capability to absorb metals and there is considerable potential for using them to treat wastewater. Metal sorption involves binding on the cell surface and to intracellular ligands where the adsorbed metal is several times greater than intracellular metal and carboxyl group is most important for metal binding. They find that concentration of metal and biomass in solution, pH, temperature, cations, anions, and metabolic stage of the organism affect metal sorption. Algae can effectively remove metals from multi-metal solutions

and dead cells absorb more metal than live cells. Various pretreatments enhance metal sorption capacity of algae and $CaCl_2$ pretreatment is the most suitable and economic method for activation of algal biomass. Algal periphyton has great potential for removing metals from wastewater whilst an immobilized or granulated biomass-filled column can be used for several sorption/desorption cycles with unaltered or slightly decreased metal removal. They argue that Langmuir and Freundlich models, commonly used for fitting sorption data, cannot precisely model metal sorption since they ignore the effect of pH, biomass concentration, etc. They conclude that for commercial application of algal technology for metal removal from wastewater:

> *emphasis should be given to selection of strains with high metal sorption capacity; adequate understanding of sorption mechanisms; development of low-cost methods for cell immobilization; development of better models for predicting metal sorption; genetic manipulation of algae for increased number of surface groups or over expression of metal binding proteins; and finally economic feasibility.*

Hashim and *Chu* look into the biosorption of cadmium by brown, green, and red seaweeds in a paper with 137 citations and examine seven species of these seaweeds for their abilities to sequester cadmium ions from aqueous solution [50.112]. They observe considerable variability in their biosorption performance although all the seaweed types investigated are capable of binding appreciable amounts of cadmium and they find that maximum cadmium uptake capacities at pH 5 range from the highest value of $0.74\,\mathrm{mmol\,g^{-1}}$ for the brown seaweed *Sargassum baccularia* to the lowest value of $0.16\,\mathrm{mmol\,g^{-1}}$ for the red seaweed *Gracilaria salicornia*, representing a 363% difference. In general, they find that brown seaweeds exhibit the best overall cadmium ion removal. They conduct additional experiments to evaluate the biosorption characteristics of the brown seaweed *S. baccularia* and they find that the equilibrium uptakes of cadmium are similar within the pH 3–5 range but decrease significantly when the solution pH is reduced to pH 2. Additionally, the presence of background cations such as sodium, potassium, and magnesium, and anions such as chloride, nitrate, sulphate, and acetate up to a concentration of $3.24\,\mathrm{mmol\,L^{-1}}$ have no significant effect on the equilibrium uptake of cadmium. However, the biosorbent uptake of cadmium inhibits substantially in the presence of calcium ions at $3.24\,\mathrm{mmol\,L^{-1}}$ and kinetic studies show that cadmium uptake is fast with 90% or more of the uptake occurring within 30–40 min of contact time.

Liu et al. investigate reduction kinetics of Fe(III), Co(III), U(VI) Cr(VI), and Tc(VII) in cultures of dissimilatory metal-reducing bacteria in a paper with 125 citations and examine the reduction kinetics of Fe(III)citrate, Fe(III)NTA, Co(III)EDTA$^-$, U(VI)O_2^{2+}, Cr(VI)O_4^{2-}, and Tc(VII)O_4^- in cultures of dissimilatory metal reducing bacteria (DMRB) (*Shewanella alga* strain BrY, *Shewanella putrefaciens* strain CN32, *Shewanella oneidensis* strain MR-1, and *Geobacter metallireducens* strain GS-15) [50.113]. They find that reduction rates are metal specific with the following rate trend for the Fe(III)citrate: Fe(III)NTA > Co(III)EDTA$^-$ much greater than $UO_2^{2+} > CrO_4^{2-} > TcO_4^-$, except for CrO_4^{2-} when H_2 is used as electron donor. The metal reduction rates are also electron donor dependent with faster rates observed for H_2 than lactate$^-$ for all *Shewanella* species despite higher initial lactate (10 mM) than H-2 (0.48 mM). They also find that the bioreduction of CrO_4^{2-} is anomalously slower compared to the other metals with H_2 as an electron donor relative to lactate and reduction ceased before all the CrO_4^{2-} have been reduced. They perform transmission electron microscopic (TEM) and energy-dispersive spectroscopic (EDS) analyses on selected solids at experiment termination and find precipitates of reduced U and Tc in association with the outer cell membrane and in the periplasm of the bacteria. As the kinetic rates of metal reduction are correlated with the precipitation of reduced metal phases and they discuss their causal relationship. They model the experimental rate data by a Monod kinetic model with respect to the electron acceptor for all metals except CrO_4^{2-}, for which the Monod model is modified to account for incomplete reduction. However, they notice that the Monod models become statistically over-parametrized, resulting in large uncertainties of their parameters. A first-order approximation to the Monod model also effectively models the experimental results, but the rate coefficients exhibit far less uncertainty. They conclude that the more precise rate coefficients of the first-order model provide a better means than the Monod parameters, to quantitatively compare the reduction rates between metals, electron donors, and DMRB species.

Cruz et al. carry out kinetic modeling and equilibrium studies during cadmium biosorption by dead *Sargassum* sp. biomass in a paper with 117 citations and conduct an experiment on the removal of *cadmium*(II) ions from aqueous solutions by dead *Sargas-*

sum sp. in batch conditions where they focus on the effect of different experimental parameters such as initial pH, shaking rate, sorption time, temperature, and initial concentrations of cadmium ions on cadmium uptake [50.114]. They find that:

> *cadmium uptake can be modeled by the Langmuir adsorption model whilst being the monolayer capacity negatively affected with an increase in temperature.*

Analogously, the adsorption equilibrium constant decreases with increasing temperature. The kinetics of the adsorption process follows a second-order adsorption, with characteristic constants increasing with increasing temperature where the activation energy of biosorption is 10 kcal mol^{-1}. The biomass used is suitable for removal of cadmium from dilute solutions as its maximum uptake capacity is 120 mg g^{-1}. They conclude that *Sargassum* sp. has great potential for removing cadmium ions especially when concentration of this metal is low in samples such as wastewater streams.

Sakaguchi et al. study the accumulation of heavy-metal elements in biological systems with a focus on the accumulation of cadmium by green microalgae (*Chlorella regularis*) in an early paper with 108 citations [50.115]. They find that the amount of cadmium absorbed by *Chlorella* cells is rapid during the first 30 min following addition of cadmium and then continues to be absorbed more slowly and the uptake of cadmium by *Chlorella* is not markedly affected by temperature or metabolic inhibitors whilst most of the cadmium absorbed by *Chlorella* cells is easily released by EDTA. The amount of cadmium absorbed differ markedly with the pH value of the solution and is inhibited by the presence of other divalent cations whilst heat-killed *Chlorella* cells take up cadmium to a greater degree than living ones. They conclude that:

> *the uptake of cadmium into* Chlorella *cells is not directly mediated by metabolic processes, rather it is completely dependent upon physicochemical adsorption on the cell surface*

whilst

> *the ability to accumulate cadmium is species specific and is in decreasing order of* C. reinhardtii > C. regularis > Scenedesmus bijuga > S. obliquus > Chlamydomonas angulosa > Scenedesmus chlorelloides.

Volesky and *Prasetyo* investigate the cadmium removal in a biosorption column in a paper with 103 citations as they examine new biosorbent material derived from a ubiquitous brown marine alga *A. nodosum* in packed-bed flow-through sorption columns [50.116]. They find that algae effectively remove 10 mg L^{-1} of cadmium down to 1.5 ppb levels in the effluent representing 99.985% removal. The experimental methodology used is based on the early Bohart and Adams sorption model, resulting in quantitative determination of the characteristic process parameters which can be used for performance comparison and process design.

> *An average metal loading of the biosorbent (N_0) determined is* 30 mg Cd g^{-1}*, corresponding closely to that observed for the batch equilibrium metal concentration of* 10 mg Cd L^{-1}*. The critical bed depth (D_{min}) for the potable water effluent quality standard (*0.005 mg Cd L^{-1}*) varies with the column feed flow rate (*2.4 *to* 9.6 L $h^{-1}cm^{-2}$*) from* 20–50 cm.

They finally determine the sorption column mass transfer and dispersion coefficients, required for solving the sorption model equations.

Ying et al. investigate the uptake of cadmium and zinc by the alga *C. vulgaris* with a focus on the individual ion species in a paper with 102 citations [50.117]. They note that the ability of algae and bacteria to accumulate heavy metals from the surrounding environment has a number of important implications. They report on the development of a quantitative model that addresses the basic mechanisms inherent in many uptake processes. The model postulates two mechanisms where an initial rapid metal ion uptake due to attachment onto the cell wall followed by a relatively slow uptake due to membrane transport of the metal into the cell. They test this mathematical model using the alga *C. vulgaris* in the presence of cadmium and zinc in solution under various experimental conditions.

50.5.3 Conclusion

The research on the algal biosorption has been one of the most dynamic research areas in recent years with 1148 papers and H-index of 78. Twenty two citation classics in the field of algal biosorption with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.14, 97–117]. These papers give strong hints about the determinants of the efficient algal biosorption applications and emphasize that marine algae are efficient organisms in comparison with other organisms necessitating the efficient design of the algal biosorption processes.

50.6 Conclusion

The issues relating to the global warming, air pollution, and energy security have been one of the most important public policy issues nowadays [50.1–3]. With the increasing global population, food security has also become a major public policy issue [50.4]. The development of algal biofuels as a third-generation biofuel has been considered as a major solution for the global problems of global warming, air pollution, energy security, and food [50.5].

Although there have been many reviews on the use of the algae in energy, medicine, and health care [50.10–14], and there been a number of scientometric studies on the algal biofuels [50.15], there has not been any study on the citation classics on the algal photosynthesis, biosorption, biotechnology, and biofuels as in other research fields [50.16–24]. As *North*'s New Institutional Theory suggests, it is important to have up-to-date information about the current public policy issues to develop a set of viable solutions to satisfy the needs of all the key stakeholders [50.25–34].

Therefore, a selected set of citation classics in the algal photosynthesis, biosorption, biotechnology, and biofuels are presented in this paper to inform the key stakeholders relating to the global problems of global warming, air pollution, food security, and energy security about the use of marine algae for the solution of these problems in the long run complementing a number of recent scientometric studies on the biofuels and global energy research [50.15, 35–47].

The research on the algal photosynthesis has been one of the most dynamic research areas in recent years with 2011 papers and with H-index of 92. Ten citation classics in the field of algal photosynthesis with more than 100 citations were located and the key emerging issues from these papers were presented above in the decreasing order of the number of citations [50.48–57]. These papers give strong hints about the structural determinants of the algal photosynthesis, informing the following sections. Photosystems I and II (PSI and II) which reaction centers that capture light energy in order to drive oxygenic photosynthesis played an important role in this field of research.

The research on the algal biodiesel has been one of the most dynamic research areas in recent years with 909 papers and H-index of 54. Fifteen citation classics in the field of algal biodiesel with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.10, 11, 58–70]. These papers give strong hints about the determinants of the efficient algal biofuel production and emphasize that marine algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks.

The research on the algal biohydrogen has been one of the most dynamic research areas in recent years with 144 papers and H-index of 25. Seven citation classics in the field of algal biohydrogen with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.12, 71–76]. These papers give strong hints about the determinants of the efficient algal biohydrogen production and emphasize that marine algae are efficient biohydrogen feedstocks.

The research on the algal bio-oil has been one of the most dynamic research areas in recent years with 89 papers and H-index of 21. Three citation classics in the field of algal bio-oil with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.77–79]. These papers give strong hints about the determinants of the efficient algal bio-oil production and emphasize that marine algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks.

The research on the algal biotechnology has been one of the most dynamic research areas in recent years with 455 papers and H-index of 55. Eighteen citation classics in the field of algal biotechnology with more than 100 citations were located and the key emerging issues from these papers were presented above in the decreasing order of the number of citations [50.13, 80–96]. These papers give strong hints about the determinants of the efficient algal biotechnology applications and emphasize that algae are more efficient biofuel feedstocks in comparison with the first- and second-generation biofuel feedstocks necessitating the efficient design of the algal photobioreactors.

The research on the algal biosorption has been one of the most dynamic research areas in recent years with 1148 papers and H-index of 78. Twenty two citation classics in the field of algal biosorption with more than 100 citations were located and the key emerging issues from these papers are presented below in the decreasing order of the number of citations [50.14, 97–117]. These papers give strong hints about the determinants of the efficient algal biosorption applications and emphasize that algae are efficient organisms in comparison with

other organisms necessitating the efficient design of the algal biosorption processes.

The citation classics presented under the four main headings in this paper confirm the predictions that the marine algae has a significant potential to serve as a major solution for the global problems of warming, air pollution, energy security, and food security. These papers also provide evidence that marine algae has significant benefits for the biosorption of heavy metals, for the photosynthetic processes, and development of commercial products for a range of industries including healthcare, medicine, and pharmacy besides as a feedstock for biofuels.

Further research is recommended for the detailed studies in each topical area presented in this paper including scientometric studies and citation classic studies to inform the key stakeholders about the potential of the marine algae for the solution of the global problems of warming, air pollution, energy security, and food security.

51. Biofuel Innovation by Microbial Diversity

Thiago Bruce, Astria D. Ferrão-Gonzales, Yutaka Nakashimada, Yuta Matsumura, Fabiano Thompson, Tomoo Sawabe

Biofuels represent a viable alternative to the use of fossil fuels. They contribute to the reduction of greenhouse gas emission and do not compete with agricultural land. However, biofuels are not yet capable of replacing the current energy matrix based on fossil fuels because they cannot compete with standard fuels such as diesel and gasoline. Therefore, innovation is necessary to promote technical, economical, and environmental viability of biofuels. For this purpose, the marine realm is a promising source of bioresources to promote innovation in biofuel production. The marine biomass can be converted into biofuels such as biodiesel, bioethanol, and biogases (i. e., methane and hydrogen) through microbial activity. Microbial diversity plays a fundamental role in marine ecosystems by recycling of organic matter, which is a reflection of the vast genetic diversity associated to the marine microbial species available for biotechnological exploitation. The present study provides an overview of the importance of microbial fuels and presents innovative findings which can be applied to the production of biofuels in the near future.

51.1 Bioprospecting of Marine Microbial Diversity

Microorganisms are involved in biogeochemical cycles such as carbon, nitrogen, sulfur, and other key elements playing crucial role in the homeostasis of marine environments by recycling of nutrients [51.1, 2]. A major challenge currently is the sustainable use of marine bioresources. The ability to convert a wide range of organic molecules in the environment indicates that marine microbial communities represent an important source of enzymes that can be used in the conversion of biomass for biofuel production.

Biofuels are produced by converting of biomass of organisms or by using products of their metabolism. Microbes annually hydrolyze 10^{11} t of plant biomass, principally plant cell wall material, which contains the energetic equivalent of 640 billion barrels of crude oil [51.3]. Advancement in molecular techniques has enabled access to the genetic diversity of marine microorganisms that are able to convert biomass.

High-throughput sequencing is a powerful tool for evaluating the metabolic potential of marine microbial communities. Genomics and metagenomics approaches have shown to be very promising with regard to exploration of marine microbial diversity. This has allowed

a thorough analysis of their genetic content, expanding our understanding about metabolic potential of marine microorganisms. These advances have directed the search for microbes, clusters, and genes of biotechnological interest.

The development of relevant projects in recent years (i. e., Global Ocean Sampling and International Census of Marine Microbes) [51.4, 5] have been developed by the scientific community towards a better understanding and use of marine microbial diversity. The number of microorganisms in the oceanic subsurface is estimated to be up to 3.5×10^{30}, spread over thousands of species per milliliter [51.6, 7]. However, it is estimated that only 1% of microorganisms is detected on plates with culture medium due the selective conditions of the culture media. Isolation and characterization of 10^6 or 10^9 bacterial species are beyond the capabilities of current microbiologists. The difference between the known diversity (the 10^3 described bacterial species) and the estimated total diversity (10^6–10^9 bacterial taxa) is the unknown fraction.

The diversity and abundance of free-living marine microorganisms have been described using culture-independent methods by means of 16S ribosomal ribonucleic acid (rRNA) and metagenomes from a variety of marine environments worldwide [51.4, 5, 8–13]. These efforts represent further knowledge about a vast genetic diversity associated to the marine realm. Marine microbial communities present greater taxonomic diversity highlighting tropical marine regions [51.14–16]. This represents a potential source of new genes for biotechnological applications. However, the still limited number of studies pursued to date on bacterioplankton diversity has been unable to cover the whole marine microbial functional diversity [51.17–21]. Marine samples demonstrate a greater potential to mining enzymes involved with biomass conversion for biofuel production.

The aim of this chapter is to provide an overview about the main aspects of microbial fuels that make them an interesting alternative for fossil fuels. To find this goal, we present marine bioresources that can be explored by biotechnology for biofuel production and examples of strategies that are being developed to consolidate microbial fuels (bioethanol, biodiesel, and biogas such as hydrogen and methane) by using marine bioresources. These examples address the functional diversity of entire communities to specific taxonomic groups (i. e., Vibrios). The following sections will clarify the role played by marine microbial diversity towards to biofuel innovation.

51.1.1 Marine Biomass for Biofuel Production Through Marine Microbial Activity

Fuels are produced in large quantities and low unit value. Gasoline is the current standard fossil fuel consumed around the world and currently its price is about $1\,\text{US\$}\,\text{L}^{-1}$. Thus, raw material prices are crucial to the final cost due the high consumption required for its production. Hence, the ideal raw material for biofuel production be inexpensive, easy to obtain, and should not compete with land for food production [51.22]. Marine biomass meets these requirements and shows advantageous features relative to terrestrial biomass (i. e., sugarcane, corn, and soybeans).

Seaweed and phytoplankton, for example, produce more oxygen than used in breathing, being responsible for 90% of the world production of O_2, unlike forests which consume the same rates of O_2 produced during the breathing process. This means marine organisms are extremely efficient in the conversion of CO_2 into organic matter and consequently the production of biomass. Thus, marine biomass represents an abundant resource that can be obtained only with the input of solar energy, water, and CO_2 during the photosynthesis process, making it a lower cost production with high capability of producing energy by biomass conversion.

The marine biomass available in the oceans can be converted into different types of biofuels by microbial activities with the cooperative use of microbial enzymes. Biomass conversion into bioethanol can be accomplished by hydrolysis of the different sugars that comprise the marine organisms. Bioethanol produced by macroalgae biomass represents the third generation of ethanol. Seaweeds are rich in sugars such as alginate, mannitol, cellulose, laminarin, carrageenan, and starch, and has a low lignin content in its composition, which is an important advantage over terrestrial biomass [51.23]. First and second generations of ethanol are well established and are based on terrestrial biomass. The first generation of ethanol is based on fermentable sugars arising from sugarcane juice, while the second generation uses glucose from cellulose degradation, which constitutes the major part of the biomass present in the bagasse. Yet among liquid fuels, biodiesel production using microalgae shows great potential because they are able to duplicate their biomass several times per day and produce at least 15 times more oil per hectare than food crops. Some species can achieve an oil content

Table 51.1 Lipid (oil and/or fatty acids) content of marine microalgae commonly applied to biodiesel production

Marine microorganisms	Lipid content (% dry weight)
Schizochytrium sp.	50–77
Nitzschia sp.	45–47

Beyond liquid biofuels, marine biomass allows biogas production as methane and hydrogen to produce energy through anaerobic fermentation. Methane may have been one of the early building blocks of life, and there are numerous areas of the ocean floor where methane produced by methanogenic microorganisms percolates up from the deep subsurface. Hydrogen production from microbial metabolism may be obtained from a photosynthetic process or by fermenting marine biomass [51.24, 25].

Microbial fuels represent a valuable alternative to promote diversification of the world energy production pattern. The main objective to introduce microbial biofuel is to innovate in service offerings, using technologies to reduce the carbon footprint, taking steps to preserve the environment. Currently, we are already aware about demand for biofuels aiming at reducing dependency on volatile petroleum products. For example, all cars in Brazil run on pure or mixed alcohol because the government has ruled that gasoline must include a 20–26% mixture of ethanol. The use of bioethanol of the second and third generations in the mixture might be stimulated by environmental and economical policies followed by the innovation of production processes. The same has applied for diesel since 2010, when Brazilian diesel started to require a 5% biodiesel blend. This has enabled a steady expansion of the Brazilian biodiesel market, with 43 plants operating today and production capacity currently at 3.6 billion L (950 million gallons) per year.

The increasing of use of blended fuel is a tendency around the world. Europe supports low biofuel blends (10% of ethanol in gasoline and 7% of biodiesel for diesel) as a first step. Higher biofuel blends seem attractive if they meet criteria agreed upon for greenhouse gas performance, quality, sustainability, and availability. Microbial biofuels have the potential to be applied as a mixture in fossil fuels, with the aim to replace them completely in the future. Reasons to support this idea are given in the following.

51.1.2 Critical Issues to Support Microbial Biofuels

Microorganisms have the widest genetic repertoire on Earth, and the biofuel sector has shown particular interest in microbial enzymes. This interest occurs primarily due to environmental, economic, and social issues [51.26], as discussed below.

The first aspect concerns the worn model of the energy matrix based on fossil fuels, which has been proved to be damaging to the environment. Currently, the fuel sector meets an annual demand of 13 TW, mainly by consumption of fossil fuels. Efforts to develop new alternatives for energy production based on the concept of sustainability encourage research on biofuels. The use of fossil fuels over the last 200 years has had serious consequences on the quality of environmental health. Among the main ones is the increased greenhouse effect, which has directly contributed to the acidification of the oceans, promoting significant changes in marine life, as well as an increase in global temperature. Therefore, many efforts are being made in an attempt to develop fuels that are environmentally friendly (or *greener*). The application of biocatalysts decreases environmental hazards related to industrial processes, as by-products, and generally are less harmful than those produced by physicochemical processes.

From an economic standpoint, microbial enzymes represent an important alternative for reducing the costs of procedures for processing biomass used as feedstock for biofuel production. Currently, biomass must be processed to remove the high lignin content. However,

the physical and chemical processes used represents much of the cost involved in biofuel production [51.23]. Microbial enzymes can be obtained by purification from natural sources such as environmental isolates and genetically improved microorganisms. The use of microbial enzymes is among the most viable alternatives in terms of technical, economic, and environmental optimization of biofuel production. Therefore, the study of the functional diversity of marine microbial communities allows us to discover and characterize a still underexploited enzymatic repertoire in the context of biotechnology.

From a social view, biotechnological innovation through the exploitation of marine resources for microbial biofuel production plays an important role in the development of industrial processes that require less use of agricultural land for biofuel production. It can reduce pressure on food prices. Also, production and commercialization of marine biomass can promote an economic and social insertion of people who have no farmland into the production chain of biofuels. Thus, exploitation of marine microbiological resources is promising for the development of alternatives to current patterns of fuel production. Much research is being conducted to enable sustainable ways to obtain microbial biofuels. Innovations of biofuel production are indispensable to become technically and economically viable.

51.2 Marine Microbial Diversity Applied to Biofuel Innovation

The increase of the global consumption pattern has increased the urgency to reduce greenhouse gas emission and the risk of increasing food prices. The demand for fuel can be met through biofuel innovation by exploration of marine microbial resources. This section provides some examples of how biodiversity has been exploited in the quest for sustainable energy in the near future.

Here we present different forms of the exploration of microbial diversity for the production of microbial fuel as an alternative to fossil fuels. The first topic gives an overview of the main advantages and challenges related to the use of cyanobacteria and microalgae for biodiesel production. In the following section, we show that the marine environment represents a vast untapped repertoire of microbial enzymes applied to bioethanol production. The third topic shows that in contrast to this entirely new fraction of functional diversity from microbial communities, studies of well-known marine bacteria such as Vibrios open doors to genetic manipulation to optimize the production of bioethanol and hydrogen using marine biomass. The same marine biomass also serves as a substrate for methane production by a fermentation process using methanogenic microbes associated to the marine sediments addressed in the last topic of this section. Thus, these four topics are connected, because they clearly show the potential of marine microbial diversity to promote innovations in biofuel production as an alternative to the use of terrestrial bioresources for bioenergy.

51.2.1 Biodiesel Production from Microbial Marine Resources

Biodiesel has been widely investigated as an alternative source to using fossil fuels. Such fuels are potentially carbon neutral because they do not result in a net increase in atmospheric greenhouse gases, resulting in negative carbon dioxide emission and net carbon dioxide removal from the atmosphere, and thus constitute a form of greenhouse gas remediation.

Biodiesel is a lipid-derived biofuel obtained by a transesterification reaction of triglycerides of vegetable oil or animal fats, or by esterification of free fatty acids with low chain alcohols, used to generate mechanical energy. The enzymes involved with this step are called lipases. Microbial lipases now occupy a special place among biocatalysts due to their ability to catalyze a variety of reactions in aqueous and non-aqueous media [51.27].

Biodiesel consists either of fatty acids-methyl-esters (FAME) from methanolysis reactions or fatty acids-ethyl-esters (FAEE) when using ethanolysis reactions catalyzed by strong alkali or acids. Considering the existing restrictions on greenhouse gas emissions, biodiesel provides significant advantages compared with petroleum-based fuel; the major problem in using and producing biodiesel is associated with feedstock resources, which nowadays is mainly edible seed crops, such as soybean, rapeseed, sunflower, etc., leading to a great controversy about food security, which is a great threat especially to the poor countries. Until 2007 about

14 million ha of farmland were used for the production of biofuels, which represent approximately 1% of the entire cultivated land in the world.

Characteristics such as performing oxygenic photosynthesis using water as an electron donor and growing to high densities, and having high per-acre productivity compared to typical terrestrial oil-seed crops are present in marine organisms and represents a requirement for sustainable biofuel production. Mass cultivation for commercial production can be performed efficiently, and, consequently, does not demand arable land. Indeed it utilizes a wide variety of water sources (fresh, brackish, seawater, and wastewater), and produces both biofuels and valuable co-products.

Prospecting of marine microbes for biodiesel production has been performed, and microalgae and cyanobacteria are the main focus for the development of technological strategies for biodiesel to become a competitive biofuel as an alternative to fossil fuels. Here, we discuss the main issues concerning the barriers and advantages related to the production and commercialization of microbial biodiesel.

Challenges in Biodiesel Production from Microbial Marine Resources

Although it may become a promising strategy, biodiesel production from microalgae and *Cyanobacteria* is not yet a viable process. There are still technical, economic, and environmental challenges that need to be addressed [51.28–30]. For example, the open pond cultivation system presents two difficulties in terms of water conditions: thermic and carbon dioxide regulation. Enclosed photobioreactors are still too expensive, as they need a material with high transparency to capture sunlight, or a special illumination system made of optical fiber cables.

The algae biofuel industry is pursuing pilot and demonstration-scale algae cultivation projects. Bioenergy industries are still developing numerous initiatives, but commercial algae biomass production is restricted to high-value nutritional products. Nevertheless, different algae cultivation systems, such as closed photobioreactors, raceway ponds, and closed ponds, in addition to different methods to produce biofuels, such as oil extraction and algal biorefinery, are being investigated worldwide [51.31]. Although biofuels from microalgae are considered technically viable, current barriers to the commercial implementation of microalgal-derived biofuels are expected to be overcome by technology developments. The limitations have a direct influence on oil production by microorganisms.

Microalgal oil contains a high degree of polyunsaturated fatty acids (with four or more double bonds) when compared to vegetable oils, which makes it susceptible to oxidation in storage and, therefore, reduces its acceptability for use in biodiesel [51.32]. The oil content (triacylglycerols – TAGs) is one of the positive aspects of using microalgae for biodiesel production, as TAGs are the main storage compound present in any algal species, especially in stress conditions such as nitrogen starvation. However in stress conditions the biomass of the microalgae is dramatically decreased and this is another point of research to make the industrial process viable. Nutrient limitation is one of the most efficient triggers to enhance lipid accumulation in a single microalgal cell when energy source (light) and carbon source (CO_2) are available [51.33]. Many aspects of lipid production are considered for the optimum cultivation of marine microalgae because lipid accumulation is a feature of an unbalanced metabolism. However, to achieve this performance it is pivotal to optimize strains and culture media to obtain biomass for the production of lipids in microalgae on a large scale [51.34]. The growth temperature, pH, micronutrient availability; salinity, and nutrient limitation (especially nitrogen and phosphorus supply) need to be under control to improve microalgae biomass and lipid production for industrial application.

Since algae production systems are a complex composite of several subsets of systems (i. e., production, harvesting, extraction, drying systems), reducing the number of steps in the production of algae biofuels is essential for providing easier, better, and lower cost systems [51.35]. Currently, the cost of biodiesel production by microalgae is still not competitive compared to that of diesel. The costs of biofuel production from algal biomass amounts to approximately $50\,€^{-1}$, that is, to high to be attractive for the commercial production of algal biofuels [51.32].

Moreover, it is necessary to pay attention to an obvious problem concerning environmental aspects related to biodiesel use. While promoting a significant reduction in CO_2 emissions, NO_x emission by biodiesel engines is a subject of considerable research. Biodiesel can be considered as an oxygenated fuel. A high oxygen content results in the improvement of its burning efficiency and reduction in the particulate matter, CO, and other gaseous pollutants. However, it also leads to higher production of NO_x (approximately 10%) com-

pared to fossil diesel, particularly in a high-temperature burning environment. Indeed, there are few studies on possible environmental impacts, since the toxicity of biodiesel has not yet been properly assessed. More ecotoxicity studies will be needed to develop the secure production and storage of biofuel. Strategies of containment and environmental decontamination in possible spill events need to be developed to allow the process of production and commercialization of biodiesel on an industrial scale. Nevertheless, efforts are being made because it is understood that there are positive aspects that make biodiesel a promising energy source.

Positive Aspects About Marine Microbial Biodiesel

There are several aspects of cyanobacterial and microalgal biodiesel production that have combined to capture the interest of researchers around the world. Cyanobacteria can convert up to 10% of the sun's energy into biomass by photosynthesis. It is highly efficient if compared to the 1% recorded by conventional energy crops (corn or sugarcane) or the 5% achieved by algae. Indeed, microalgae (phytoplanktons) and cyanobacteria (blue–green algae) are a reasonable choice [51.36] as an alternative energy source, because most are great lipid producers (7–23% of cell composition, 20–50% dry weight) (Table 51.1) and both display simple growth requirements using light, carbon dioxide, and other inorganic nutrients efficiently [51.37]. When microalgal cells grow actively, polar membrane lipids (phospholipids and glycolipids) generally predominate, but as the cell enters the stationary phase many species accumulate TAGs. The majority of microalgal TAGs include saturated or monosaturated C14–C18 fatty acids, but long-chain polyunsaturated fatty acids (PUFAs) are often present. Even so, compared to others sources used for biodiesel production, microalgae oil production is about 10–20-fold higher [51.32].

Another advantage of microalgae cultivation is the environmental benefits, as it does not require the application of herbicides or pesticides and can be used in wastewater bioremediation, because microalgae is capable of removing NH_4^+, NO_3^-, and HPO_3^- from a variety of wastewater sources (e.g., agricultural runoff, concentrated animal feed operations, and industrial and municipal wastewaters [51.28]. Moreover, by removing nitrogen and carbon from water, microalgae can help reduce eutrophication in the aquatic environment, leading to a successful sustainable process [51.38].

Many species of freshwater and marine microalgae have been isolated and characterized by their lipid content [51.32, 34, 38–42]. In general freshwater microalgae works better for this purpose, but marine microalgae such as the *Dunaliella*, *Nitzschia*, and *Schizochytrium* species present a higher lipid content, which can reach more than 35–50% of their dry weight (Table 51.1).

Recently, some efforts were made with respect to cost minimization, as done by the integration of the biodiesel production system with methane production via anaerobic digestion of microalgae, which can further be converted to generate electricity. The consumption of the energy required in microalgal cultivation, dewatering, extraction, and transesterification process could be surrogated by this approach and theoretically could reduce about 33% of the cost of biodiesel production [51.43]. Moreover, the main components of a typical algae feedstock are proteins, carbohydrates, lipids, and other valuable components, e.g., pigment, antioxidants, fatty acids, and vitamins; so as it occurs as another vegetable feedstock, microalgae oil is a by-product that can be sustained by other valuable higher priced products, such as carotenoids, lutein, and PUFAs [51.44]. This is the concept of an algal biorefinery, which can be a possible way to make microalgae biodiesel production a promising industrial process.

51.2.2 Marine Metagenomes as a Source of Novel Hydrolases for Bioethanol Production

The term metagenomics refers to a culture-independent approach based on the study of deoxyribonucleic acid (DNA) molecules in a mixture of microbial populations [51.45]. The application of metagenomics approaches to the study of microbial communities from environmental samples has allowed a fast increment in the number of new sequences in databases. This has been achieved by the impressive development of sequencing techniques and analysis tools to investigate the position of these sequences in the sequence space [51.46]. An unprecedented volume of data has been generated by high-throughput sequencing, and most of these sequences represent novel genes or uncharacterized sequences. This diversity represents a huge catalog of genes available to be chosen according to specific goals for a number of biotechnological applications, for instance, for biofuel production.

The search for high-performance enzymes such as hydrolases comes is meeting the interests of the bioenergy industries, with emphasis on the production of bioethanol from the second and third generation. The discovery of new glycoside hydrolases with improved biocatalytic properties for efficient conversion of cellulosic materials is a critical challenge for the development of economically viable routes to production of fuels and chemicals. Glycoside hydrolases (category EC 3.2.1) are a widespread group of enzymes that hydrolyze glycosidic bonds between two or more carbohydrates, or between a carbohydrate and a non-carbohydrate moiety from biomass.

Recalcitrance of organic matter can be overcome by the application of microbial enzymes, influencing the reduction of costs and the environmental impact generated by pretreatment of lignocellulosic material used for the production of second generation bioethanol. The search for marine microbial enzymes opens new avenues for the optimization of marine biomass conversion to produce third-generation bioethanol. The diversification of sources of organic molecules used as raw material for biofuel production also represents an important strategy for the development of a sustainable productive process. The exploration of microbial diversity by cultivation-independent methods has led to the discovery of an impressive number of new sequences and related genes of industrial interest for biofuel production.

Molecular Approaches Reveal the Functional Diversity of Marine Microbial Communities for Bioprospecting

The two main approaches to study microbial diversity include dependently and independently cultivated methods. Molecular studies using sequences of small-subunit rRNA genes have shown that the diversity of microbial communities is composed of two components: i) a set of abundant and actively growing taxa and, ii) a seed bank of many rare taxa [51.47–49]. Common organisms may not play a critical role in the dynamics of a given community despite their numbers, and organisms that only muster 0.1% prevalence can be of pivotal importance. This suggests the presence of a rare repertoire of enzymes related to specific metabolic pathways, which can be used for biotechnological applications. A deeper knowledge about marine microbial diversity allows us to access microbial genetic diversity for bioprospecting [51.50].

Metagenomics allows correlating members of microbial communities to functional gene sequences by whole metagenome sequencing. Quantitative analysis of gene content reveals habitat signatures that reflect the particular characteristics of an environmental sample. This allows us to compare the complexity of communities and distinguish them as depending on the metabolic repertoire represented by metagenome sequences [51.51–53].

In nature, organic matter is decomposed by complexes and efficient microbial processes by hydrolytic enzymes which act synergistically to decompose biomass. In recent years, there has been a tendency to search for hydrolases in typical plant biomass degrading environments [51.54–59]. The main targets are animal rumen microbiota, termite guts, and microbiota associated with decomposed biomass of forests. However, a low identification rate of specific hydrolases (0.01−0.5%) [51.57, 59–63] was recovered in those environments. On the other hands microbial communities of marine environments represent an underdeveloped alternative source to the discovery of new enzymes as glycoside hydrolases. Bioprospecting of glycosyl hydrolases has been performed for application to bioenergy production [51.64–66].

Bioprospecting Glycosyl Hydrolases in the Southwestern Atlantic Ocean

Functional screening based on whole metagenome sequencing is a strategy used to find new sequences of glycosyl hydrolases in the Abrolhos Bank, opposite to other metagenomics studies based on phenotypic screening from previous samples [51.54, 62, 63]. The strategy used in Abrolhos revealed a higher number of new sequences related to carbohydrate degradation. The advantages of screening based on sequences are that target genes can be isolated regardless of the gene expression.

Recently, metagenomic strategies have been applied for a better understanding of the genetic diversity associated with bacterioplankton along the Southwestern Atlantic Ocean, with particular interest in the Abrolhos Bank. It is the most important coral reef area of the South Atlantic Ocean [51.67]. The Abrolhos Bank represents an interesting resource for bioprospecting of carbohydrate-active enzymes encoded by genes which participate in many important steps of carbohydrate metabolism (i. e., glycoside hydrolases). The region presents high turnover rates of organic matter. With the metagenomic approach it was possible to identify a high contribution of genes involved in carbohydrate metabolism [51.21]. The search for those genes in the Abrolhos Bank metagenomes re-

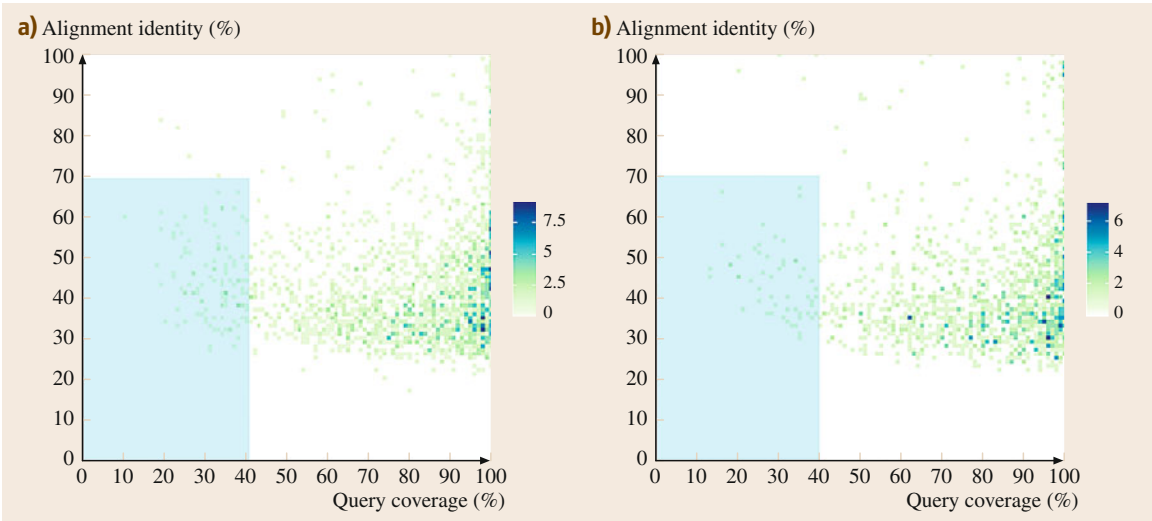

Fig. 51.1a,b Potential novel carbohydrate active enzymes from marine metagenomes. Sequences were submitted to BlastX against protein database (Swiss-Prot) and homology was evaluated by means of alignment identity and query cover. Sequences presenting identity and covering more than 40% and 70%, respectively, were assigned as homologs of known sequences from the database and those out of that cut-off were considered as potential novel proteins involved with carbohydrate metabolism. The *colored zone* highlights sequences assigned as potential novel carbohydrate active enzymes found in Southwestern Atlantic Ocean samples. **(a)** Coastal reefs surrounding water metagenome sequences from the Abrolhos Bank region and **(b)** metagenome sequences from the reef structure called Buraca (only found in the Abrolhos Bank region, Brazil) where an enrichment of sequences assigned as glycosyl hydrolases compared to coastal reef samples was found. The number gradients is the number of sequences for each dot

vealed a high diversity of glycoside hydrolases protein families and the presence of novel amino acid sequences.

Sequencing of five coastal reef regions in the Abrolhos Bank region (about 700 000 sequences) allowed the identification of thousands (about 2000 sequences) of glycoside hydrolase sequences. More than 50% of the total number of known proteins of the glycoside hydrolase family were identified (71 families). Those that do not have any close relatives form deeply branched lineages and even represent novel families. Among the sequences in the Abrolhos Bank, about 30% were identified as putative new glycoside hydrolases (Fig. 51.1). These sequences presented identity and covered less than 40 and 70%, respectively, compared to protein sequences deposited in curated databases (Swiss-Prot) [51.68]. Identification of glycoside hydrolase families was based in homology of conserved domains of amino acid sequences. Searches based on conserved domains have been shown to be more efficient than a simple search for similarity of nucleotide sequences for identification of new proteins [51.69]. That strategy is based on using domain signatures as probes to find isofunctional homolog proteins, increasing the chance of finding novel ones.

In addition to the coastal coral reefs of the Abrolhos Bank, a new reef structure that was recently described in this region has been addressed [51.70]. Within the large mesophotic reef, unusual sinkhole-like depressions (called *buracas*) are outstanding features with potentially important ecological roles in the middle and outer shelf [51.71]. These cup-shaped structures trap and accumulate organic matter, acting as productivity hotspots in the central portion of the Abrolhos Bank shelf. Buracas showed an increment in abundance of glycoside hydrolases gene sequences (2.0% of metagenome sequences) reaching a contribution five times higher than in a coral reef structure but with similar diversity of glycosyl hydrolase genes. This is clearly an interesting number if compared with other metagenomes that have been explored, where the contribution reaches up to 1.5% of (i. e., termite guts) glycosyl hydrolase gene sequences [51.72].

A recent search in the GOLD database (197 environmental studies) [51.73] for glycosyl hydrolase

putative homologs retrieved 7338 genes for different ecosystems (including terrestrial and microbiome ones, including only two for marine metagenomes). If this is compared with data obtained in the Abrolhos Bank, it is clear that there is an enormous potential of marine metagenomes to find hydrolase genes waiting to be discovered and applied to bioethanol production. So far, only 5% of metagenomes (a total of 2055 samples) available in GOLD are from marine environments. This reinforces the idea that marine metagenomes represent a still underexploited reservoir of new genes for hydrolytic enzymes.

The steps that will lead to the application of these gene sequences to bioprocesses need to be harnessed through several complex procedures that include gene synthesis and cloning, heterologous expression, and fermentation efficiency evaluation, which shows that there is a long way to their practical application.

51.2.3 Recent Advances in Biofuel Production by Marine Vibrios

In contrast with the last topic, which addressed microbial communities, here we explore a well-known cultivated marine microbial taxonomic group to access our biotechnological potential. Vibrios are huge groups that show facultatively anaerobic, widespread marine bacteria, but one of their major habitats is the gut of marine fish/shellfish. There are many kinds of seaweed-eating animals in which the unique gut bacteria may be harbored *Vibrio halioticoli*, and related species are isolated from *Haliotis* abalone (Gastropoda) as novel alginate degrading vibrios [51.74–76]. Intensive screening of marine microbes showing biofuel production from seaweed contributes to advances in innovative research for marine biofuel production because they are rich in seaweed carbohydrates and anaerobic environments which are likely to be suitable conditions of fermentation [51.77]. During the last 5 years, studies on evaluating the potentials of marine vibrios for biofuel production, namely, *V. halioticoli* have been undertaken, and a novel vibrio species has been raised as a candidate.

Degradation and utilization of marine resources are the key metabolic pathways to launching the idea of bioethanol and biohydrogen production using fast growing kelps as raw material. Kelp is not only cultured and/or harvested for food purposes but also for industrial purposes as polysaccharide production, especially in Asian countries, including Japan and Chile. Such traditional cultivation could easily be refined to be adapted to energy-aimed cultivation systems, the recently so-called *energy line* [51.78].

In the meantime, constructions of metabolically engineered *Escherichia coli* and *Sphingomonas* sp., implemented with homoethanologenic pathways, have been successful by Japanese groups [51.79, 80]. However, *Escherichia coli* and *Sphingomonas* did not originally inhabit marine environments and are incapable of showing the best fermentation performance in saline environments using kelp as feedstock. We must seek better microbes for excellent performance in biofuel production from seaweed feedstock under marine conditions.

Bioethanol Production

Generally, biomass consists of complex carbohydrates, seaweed as well. Carbohydrate compositions vary in the algae groups: brown, red, and green. The major carbohydrates in brown, red, and green algae are alginate-mannitol, carrageenan-agar, and starch-cellulose, respectively. Kelp is a common name for gigantic brown algae. Kelp has been used as a marine substrate in the fermentation process to obtain biofuel. It is an abundant algae in Hakodate, which is one of the biggest kelp mariculture points in Japan. Typical carbohydrate contents consist of mannitol (30 w/w % dry material), alginate (30%), and cellulose (< 10%). Mannitol, alginate, and glucose were selected as substrates for the optimization of ethanol production by vibrios. *Vibrio* sp. AM2, as well as *V. halioticoli* [51.76] were tested for ethanol production in a marine broth culture supplemented with mannitol, alginate, and glucose. Ethanol production was the highest in broth supplemented with mannitol, and lowest in alginate-supplemented broth (Fig. 51.2). Especially, when mannitol was used as the substrate, ethanol production reached one third of the total fermentative products. This production was ca. one and half times higher than that of glucose-supplemented broth in both marine vibrios.

We further optimized ethanol production in two kinds of marine vibrios: *Vibrio* sp. AM2 and *V. halioticoli*. Both strains required best mix conditions of glutathione (1.2 w/v %) and mannitol (5 w/v %) for maximum ethanol production (Fig. 51.3). The detailed mechanism of glutathione in ethanol production has not been clarified yet, but it might function as a biological reducing agent inside the vibrio cells. Further transcriptomic analysis is necessary. In addition to these two factors, pH control and hydrogen addition were also important physicochemical factors to improve ethanol production in vibrios (unpublished data). Under the best

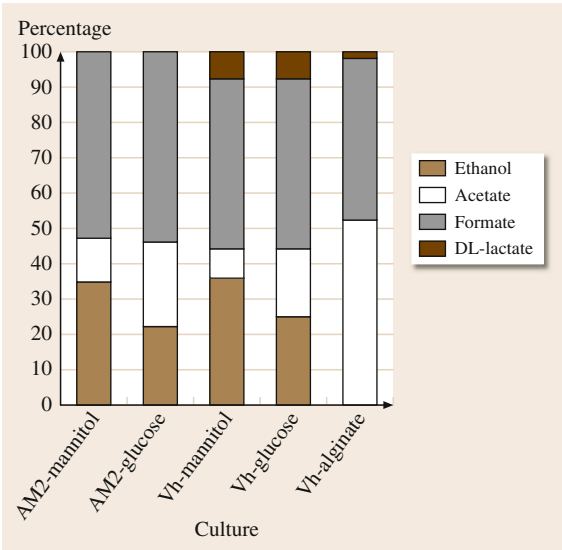

Fig. 51.2 Effect of carbohydrates on fermentation by marine vibrios. Ethanol (*light brown*), acetate (*white*), formate (*gray*), DL-lactate (*dark brown*). Glc: glucose, CMan-ol: mannitol, CAlg: alginate

culture condition, currently, 14.9 g L^{-1} ethanol production from mannitol under pH controlled batch culture (100 mL) has been achieved.

This shows an interesting potential of vibrios for biofuel production by consumption of marine algae biomass. Including this important finding, biogas production is another useful characteristic of vibrios that can help to establish this microbial group as a model for marine microbes for biomass conversion for biofuel production.

Biohydrogen Production

Hydrogen is one of the most reliable future clean energies in the world, nevertheless its infrastructure has not been devised yet. Biologically generated hydrogen by photosynthesis and dark fermentation is called as *biohydrogen* ($BioH_2$) [51.81]. The big advantages of dark fermentation are the applicability to practical use (especially on reactor-based production) and concerns about availability of a wide variety of feedstock, and faster production speed rather than H_2 production by photosynthesis [51.81, 82].

The recently isolated *Vibrio* sp. AM2 shows a unique gas production metabolism, which only small vibrio groups have [51.83–86]. As the gas was produced under culture supplemented by Glc and Man-ol, and the gas composition was determined as hydrogen and CO_2; the gases were estimated to be produced via a formate-hydrogen lyase pathway through formate. Intensive optimization of $BioH_2$ production in this strain from seaweed carbohydrates revealed that the strain possesses unexpectedly effective $BioH_2$ production machinery (unpublished data). Furthermore, based on the optimization experiments, a 3 L scale culture was achieved not only with mannitol-supplemented marine broth but also kelp powder-supplemented marine

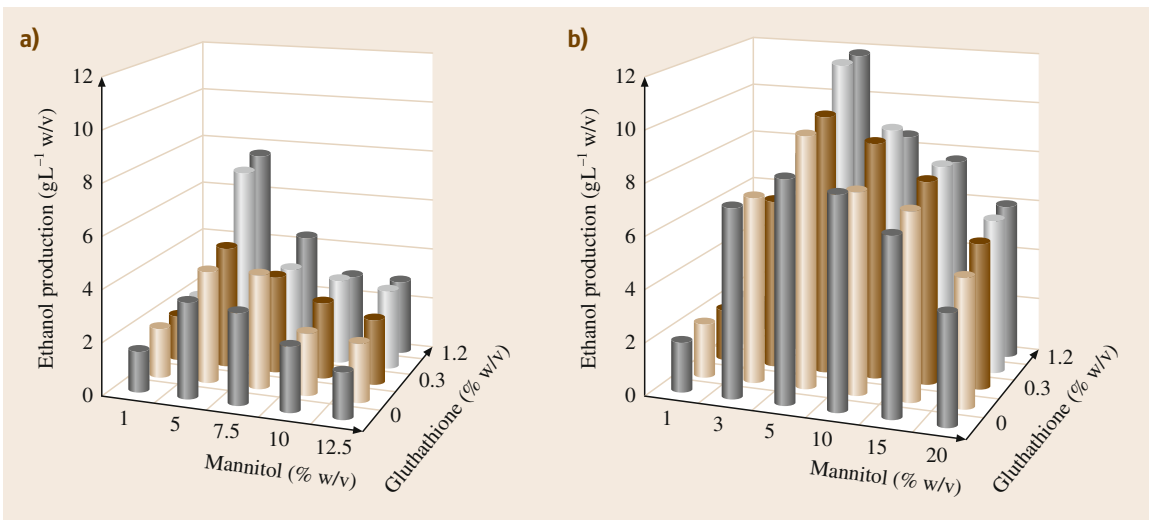

Fig. 51.3a,b Effect of mannitol and glutathione on ethanol production of marine vibrios. **(a)** *Vibrio halioticoli*, **(b)** *Vibrio* sp. AM2

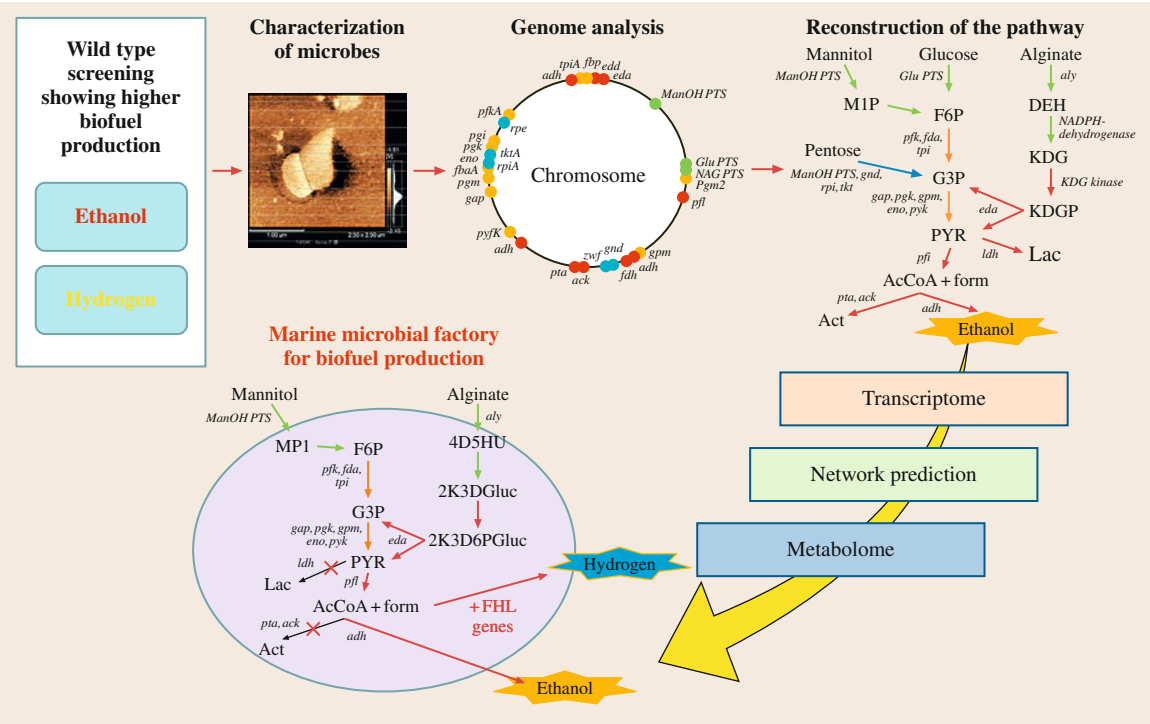

Fig. 51.4 Conceptual framework for the development of a marine microbial cell factory for biofuel innovation

broth with almost the same efficiency as a small-scale (100 mL) batch culture. Interspecific variation in $BioH_2$ production among AM2 related strains was also observed.

To power typical house life using 1 kW fuel cells, a total of 24 mol h^{-1} hydrogen is required. Reduction of the $BioH_2$ production system and the cost are major obstacles to achieving hydrogen economy and use in society. A variety of research concerning the understanding of the microbial hydrogen production machinery and metabolic engineering has been undertaken [51.82, 87].

Toward the Creation of a Marine Microbial Cell Factory

A conceptual framework for the development of a marine microbial cell factory based on marine vibrio cells has been established to obtain more efficient microorganisms for the fermentation of sugars of marine origins (seaweed) and bioenergy production. The workflow shown in Fig. 51.4 demonstrates how to obtain microorganisms with high capacity for fermentation. At the moment, we have two unique marine vibrios to push forward to construct a marine microbial cell factory in marine biofuel innovation. Using the vibrios and with genome analysis, transcriptomic analysis, and metabolic engineering, we shall elucidate these metabolic networks for seaweed carbohydrates. These results emphasize our technological advances.

Recently, whole genome sequences and draft genome sequences were obtained in *Vibrio* sp. AM2 and *Vibrio halioticoli* JCM 21271^T (IAM 14569^T), respectively (unpublished data). In addition to these two strains, draft genome sequences are available in five *Vibrio* species and ten are in progress. Based on the genome information, we recently succeeded in the reconstruction of three major central metabolic pathways for seaweed carbohydrates (Embden–Meyerhof pathway (EMP) Entner–Doudoroff pathway (EDP) and Pentose phosphate pathway (PPP)), and mining of the genes responsible for alginate degradation and utilization, diverse alcohol dehydrogenases, and hydrogen production machinery (unpublished data).

Nevertheless, ethanol production by *V. halioticoli* from alginate has not yet been achieved. However, the draft genome analysis also revealed many interesting aspects of the species for engineering the cell factory: the rather small genome size among Vibrionaceae, a

variety of alginate utilization gene clusters, and possible uptake hydrogenase (unpublished data). Based on the reconstructed metabolic network, we conducted mini-transcriptomic analysis using 44 genes focusing on seaweed carbohydrate metabolism, which revealed an unexpectedly higher expression on the genes responsible for mannitol uptake machinery. Using the *green fluorescent protein* (GFP) gene delivery vector for vibrios [51.74], engineered *Vibrio halioticoli* cells, which aim to biofuel production, were a little more successful; heterogeneous gene expression of *Zymomonas mobilis* genes in vibrio cells were recently successful.

The creation of a variety of engineered strains based on *V. halioticoli* or other species may open a new horizon in marine biofuel production. The development of techniques to convert seaweed to biofuels are quite challenging. Not only elucidation of the metabolic networks of seaweeds and metabolic engineering as shown in Fig. 51.4, but also breeding of energy-aimed seaweed or algae will be required in future.

51.2.4 Efficient Methane Production from Marine Biomass Resources

A variety of microorganisms are able to convert marine algae biomass beyond vibrios. Different biofuels can be produced using similar substrates from the marine realm by the action of different metabolic processes. Methane fermentation (anaerobic digestion) has been widely used to treat various organic matters such as food wastes, livestock wastes, or municipal wastes, and produce fuel gas simultaneously [51.88]. Methane fermentation is a multistep process, in which particular microorganisms participate in different steps such as hydrolysis, acidogenesis, (hydrogen forming) acetogenesis, and methanogenesis for methane formation from organic matter. In each step, many kinds of microorganisms with same metabolic function can be present simultaneously.

In particular, the recent development of high-rate methane fermentation processes has dramatically encouraged the broad use of the anaerobic treatment of high-strength wastewater [51.89]. This reinforces the needed to obtain microorganisms well adapted to marine conditions and execute methane production using marine biomass resources.

Since marine algae fall roughly into three categories; brown, red, and green algae as mentioned before. Their carbohydrate composition is complex, e.g. containing particular polysaccharides such as alginate and mannitol in brown algae or agar in red algae that are rarely contained in terrestrial biomass. Methane fermentation would be effective for bioconversion of macro algae because it can contain key player microorganisms which consume almost all of major carbohydrates in marine algae. However, it is still important to understand microbial diversity and characterize microorganisms that participate in each step for optimization of methane fermentation.

Alginate and Mannitol Anaerobic Degraders

Acclimation and characterization of microbial consortia that degrade alginate and mannitol are important because these are the main carbohydrates in brown algae, which are the most abundant macroalgae. A poor understanding of the microbial metabolism of such particular carbohydrates have hampered the efficient conversion of marine algae to biogas. A microbial consortium able to degrade alginate and mannitol has been developed and characterized.

Among the 70 microbial sources collected from sea environments in Japan and anaerobically cultured in a medium with alginate as the carbon source, 18 samples produced a detectable amount of end products such as ethanol and volatile fatty acids (VFA), mainly acetate. The microbial community obtained by continuous subcultivation (over 1 year) from sea sand collected from the seashore in Hiroshima Bay, Japan (named microbiota no. 11) showed a higher potential for alginate consumption.

Microbiota no. 11 continuously consumed alginate in the medium containing $5\,g\,L^{-1}$ of sodium alginate over 5 days (Fig. 51.5). From alginate, the major end product was acetate (22 mM) produced after 5 days. Additionally, 5mM ethanol was also produced. Since $4.2\,g\,L^{-1}$ of alginate was consumed during the culture, the carbon-based yield was 32 w/v % to acetate and 6% to ethanol. Phylogenetic assignment by means of rRNA 16S gene sequences identified sequences relative to *Clostridium saccharolyticum* (98% of 16s rRNA similarity), *Citrobacter freundii* (98%), and *Dysgonomonas capnocytophagoides* (95%).

Since stable microbial consortia consuming alginate and mannitol were established, a degradation of the brown algae *Sargassum fusiforme* was performed to evaluate VFA and alcohol production by a consortium composed of those taxonomic groups. Microbial growth and ethanol production were detected in the medium containing algae diluted preparations. This suggested that the dominant groups of the microbiota obtained could degrade actual macroalgae to produce VFAs and alcohols. Especially, with respect to the

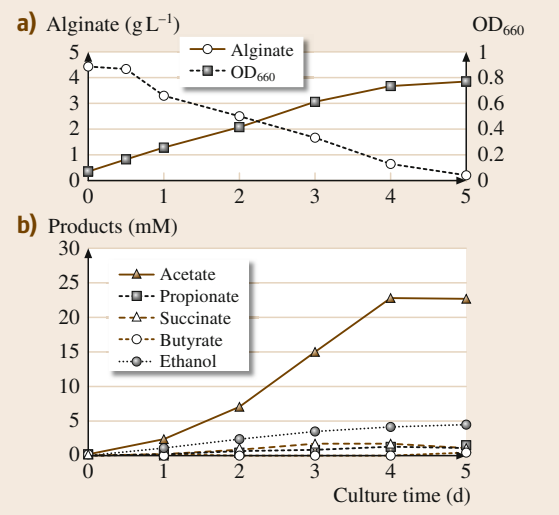

Fig. 51.5a,b Cell growth and alginate consumption **(a)**, and volatile fatty acids and ethanol production from consumed alginate **(b)** by microbiota no. 11 consisting of three kinds of microorganisms acclimated by continuous subcultivation for over 1 year from sea sand collected from the seashore in Hiroshima Bay

five times diluted medium, marine consortia yielded ethanol, lactate, succinate, and acetate as the main end products (Fig. 51.6a). The theoretical methane yield fermentation reached 0.08 L g^{-1}-VS (volatile solid).

This implies that microorganisms from marine samples can be efficiently used for the hydrolysis and acidogenesis steps in methane fermentation of brown algae.

Methane Production from Acetate Under Halophilic Conditions

To promote efficient marine biomass consumption by methane fermentation under halophilic conditions, it is desirable to use marine microbiota in the process. This limitation is significant for marine biomass resources such as macroalgae, microalgae, or other unused marine products because they are saline by nature. Thus, we investigated methane production by microbiota associated with marine sediments collected from Hiroshima Bay as a marine microbial source.

Marine sediment filled a UASB reactor kept at 37 °C for microbiota acclimation in the presence of substrates used to stimulate methane production as sodium acetate and sodium chloride (Fig. 51.6). A medium containing 5 g L^{-1} sodium acetate and 30 g L^{-1} NaCl was

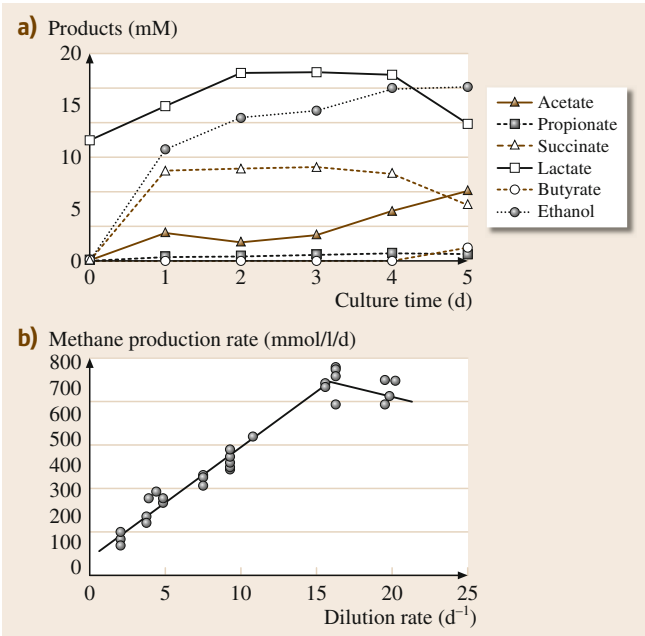

Fig. 51.6a,b Acidogenesis of brown algae and methanogenesis from acetate, a main product of acidogenesis of alginate, by marine microorganisms for methane production. **(a)** Acidogenesis of *Sargassum fusiforme* pretreated with a hydrothermal treatment by the microbiota no. 11; **(b)** continuous methane production from acetate under 3% NaCl with acetoclastic methanogens acclimated from marine mud sediments in the UASB (UASB) reactor

continuously fed from the bottom of the reactor and was withdrawn from the top of the reactor. The dilution rate of the medium was increased stepwise and methane production and acetate consumption were measured. From 2.0–4.9 d^{-1} acetate the removal efficiency was kept above 96%. A higher rate of methane production of 750 mmol L^{-1} d^{-1} (31 mmol L^{-1} h^{-1}) was achieved at 16.2 d^{-1} dilution rate (Fig. 51.6b), where the acetate removal efficiency was 77% and the ratio of the methane production rate and the acetate production rate was 1.

The effect of NaCl concentration on the specific methane production rate was investigated. Acclimated sludge could produce methane with a similar specific rate (0.15 h^{-1}) at 1.5 and 3.0% NaCl. This is much higher than the rates of the well-established acetoclastic methanogen *Methanosaeta soehngenii* (0.008 h^{-1}) [51.90]. Thereafter, although the specific methane production rate decreased, a significant amount of methane was produced even at 6.0% NaCl.

This investigation demonstrated that acetoclastic methanogens with tolerance to salt concentration contained in seawater could easily be acclimated. Moreover, acetate utilization under 3.0% NaCl was 3.2%. This is a significant rate because the specific acetate consumption of the known acetoclastic methanogen, *Methanosarcina barkeri* was only 0.7 mmol CH_4 g^{-1} MLVSS h^{-1} (MLVSS) [51.91].

These results suggest that the exploitation of acetoclastic methanogens in marine environments makes it possible to apply high-rate methane fermentation to marine biomass resources with high salinity. These findings imply that methane fermentation under high salinity may be a promising alternative energy source from marine macroalgae biomass.

51.3 Conclusions

It has been demonstrated that the use of fossil fuel has generated a high environmental impact during the last century. Its intensive use has promoted an increase of the greenhouse effect, in turn promoting significant changes in marine life. Biofuels represent a promising alternative to change the actual model of the energy production of the planet. Biofuels are alternative energy source that will lead to sustainable ways of production. This has stimulated research focused on innovation in biofuel production, because microbial diversity represents the largest genetic repertoire on Earth. Occupying about 70% of the planet, marine waters harbor a yet unexplored biodiversity, especially when it comes to the invisible-to-the eye but accounted for rich variety of metabolites that is still uncharacterized.

In this chapter we have addressed some challenging aspects of biodiesel production to highlight the main barriers that need to be overcome and positive features that make biodiesel one of the most important alternatives to fossil fuels. Indeed, positive initiatives in the exploration of marine microbial diversity can contribute to innovation with respect to different biofuels. The second and third bioethanol generations can benefit from microbial bioprospecting by mining new hydrolase genes from marine metagenomes.

Furthermore, vibrios have been presented as an interesting model to implement the microbial factory concept for ethanol and hydrogen production. Moreover, the potential application of marine microbial methane producers to obtain biogas by anaerobic fermentative processes has been discussed. These efforts show that there are good perspectives for innovation in biofuel production using marine bioresources in the near future. We can expect more utilization of enzymes and microbes prospected from marine microbial diversity, promoting an improvement in the bioprocesses applied to the bioenergy field.

52. Maraine Biomaterials as Antifouling Agent

Parappurath Narayanan Sudha, Thandapani Gomathi, Jayachandran Venkatsan, Se-Kwon Kim

Water is one of the most essential elements to good health – it is necessary for the digestion and absorption of food, helps maintain proper muscle tone, supplies oxygen and nutrients to the cells, rids the body of wastes, and serves as a natural air conditioning system. Polluted water is unsuitable for drinking, recreation, agriculture, and industry. The presence of highly toxic heavy metals and synthetic chemicals in ground water, surface water, drinking water, and aqueous effluent has impact on human and aquatic life. The methods used for the removal of heavy metals include filtration, precipitation, adsorption, ion exchange, reverse osmosis and electrolysis. These processes may be efficient but expensive. Biosorption is a feasible option because it is both efficient and cheap, compared with other conventional methods and having the advantage of low operating cost, minimization of volume of chemicals and biological sludge to be disposed off and high efficiency in detoxifying very dilute effluents. Chitin, chitosan, and alginate are polysaccharides from marine sources which are potential sorbents either in the native state or in the modified forms. Marine biofouling is the undesirable accretion of biological organisms on artificial surfaces immersed such as ship hulls, jetty pilings, navigational instruments, aquaculture net cages, and seawater intake pipes in sea-water. Membrane fouling is one of the most important challenges faced in membrane operations. Fouling results in flux decline, which increases the energy demand for filtration. Hence demands for antifouling membranes are high. This chapter describes the modification of chitin and chitosan marine products for effective antifouling membrane fabrication and the mechanism involved in the antifouling process.

52.1 Pollution

52.1.1 Pollution of Water and Need for Treatment

Water is one of nature's most important gifts to mankind. Essential to life, a person's survival depends on drinking water. Water is one of the most essential elements to good health – it is necessary for the digestion and absorbtion of food, helps maintain proper muscle tone, supplies oxygen and nutrients to the cells, rids the body of wastes, and serves as a natural air conditioning system. Polluted water is unsuitable for drinking, recreation, agriculture, and industry. It diminishes the

aesthetic quality of lakes and rivers. More seriously, contaminated water destroys aquatic life and reduces its reproductive ability. Eventually, it is a hazard to human health. Nobody can escape the effects of water pollution.

The effects of water pollution strongly impact the balance of nature, which ultimately impacts all humans. Water is polluted in many ways like effluent of leather and chemical industries and dye industries [52.1]. The presence of highly toxic heavy metals and synthetic chemicals in ground water, surface water, drinking water, and aqueous effluent has impact on human and aquatic life [52.2]. The methods used for the removal of heavy metals include filtration, precipitation, adsorption, ion exchange, reverse osmosis, and electrolysis. These processes may be efficient but expensive [52.3]. As a result, biological methods such as biosorption may provide an attractive alternate to physiochemical methods [52.4, 5].

Biosorption is a feasible option because it is both efficient and cheap, compared with other conventional methods and having the advantage of low operating cost, minimization of volume of chemicals and biological sludge to be disposed off and high efficiency in detoxifying very dilute effluents [52.6]. However, the necessity of investigating more biomaterials is still important in order to obtain the best material for industrial application [52.7].

52.2 Use of Marine Biomaterials for Water Treatment

Biosorption is a process that utilizes biological materials as adsorbents, and several researchers have studied this method as an alternative technique to conventional methods for the heavy metal removal from wastewater.

Marine environment is a source of untold diversity of materials with specific biological and chemical features, some of which are not known in terrestrial organisms. For instance, macroalgae synthesize a great diversity of polysaccharides-bearing sulfate groups that find no equivalent in land plants [52.8]. Having normally a support function in those organisms, together with other properties, these biopolymers can be considered to be further used for environmental protection.

52.2.1 Chitin/Chitosan

Chitin is one of the most abundant marine biopolymer. Chitosan is the derivative of chitin. Chitin and chitosan are polysaccharides which at carbon-2 of their cellulose-like backbone have acetamido and amino groups, respectively. The seafood industry waste product chitosan has good physical and biological properties. Chitosan molecules contain a large number of reactive hydroxyl ($-OH$) and amine ($-NH_2$) groups. *Chui* et al. [52.9] confirms that the amino sugars of chitin and chitosan are the major effective binding sites for metal ions, forming stable complexes by coordination. The nitrogen electrons present in the amino and *N*-acetylamino groups establish dative bonds with transition metal ions and some of the deprotonated hydroxyl groups' functions as the donar [52.10] and involved in coordination. Chitin is the one of the most abundant marine biopolymer. Chitosan is the derivative of chitin.

52.2.2 Alginate

Alginate is an unbranched anionic polysaccharide composed of β-D-mannuronic acid (M) and α-l-guluronic acid (G) linked by 1−4 glycosidic bonds [52.11]. Alginate is the main component of the cell wall of brown algae, thus having not only a structural function but also an important participation in ionic exchange mechanisms. Up to 45% of dry weight of algae contains alginate, occurring together with other polysaccharides (cellulose and fucoidan) and proteins, with the amount, as well as molecular structure, being dependent on the algal species, environmental conditions, and life cycle.

The binding mechanisms of heavy metals by biosorption could be explained by the physical and chemical interactions between the cell wall ligands and adsorbates by ion-exchange, complexation, coordination, and microprecipitation. The diffusion of metal from bulk solution to active sites of biosorbents occurs predominantly by passive transport mechanism [52.12] and various functional groups such as carboxyl, hydroxyl, amino, and phosphate existing on the cell wall of the biosorbents can bind the heavy metals [52.13].

From *Krajewska* [52.14], it is observed that by considering the increase of public health and environmental awareness together with the increase of stricter environmental regulations on disposal, biopolymer from renewable resources had been focused as an alternative to synthetic polymer. In spite of potential applications

of chitin and chitosan, it is necessary to establish efficient and appropriate modifications to fully explore the high potential of these biomacromolecules. Chemical modifications of chitin are generally difficult owing to the lack of solubility, and the reactions under heterogeneous conditions are accompanied by various problems such as the poor extent of reaction, difficulty in selective substitutions, structural ambiguity of the products and partial degradation due to severe reaction conditions. Therefore, with regard to developing advanced functions, much attention has been paid to chitosan both in terms of physical and chemical modifications [52.1, 15].

52.2.3 Chitosan in Wastewater Treatment

The binding mechanism of metal ions to chitosan is not yet fully understood. Various processes such as adsorption, ion exchange, and chelation are discussed as the mechanism responsible for complex formation between chitosan and metal ions. The type of interaction depends on the metal ion, its chemistry, and the pH of the solution [52.16, 17]. Metal anions can be bound to chitosan by electrostatic attraction. It is likely that the chitosan-metal cation complex formation occurs primarily through the amine groups functioning as ligands [52.18]. It is well known that chitosan may complex with certain metal ions [52.19]. Possible applications of the metal-binding property are wastewater treatment for heavy metals and radioisotope removal with valuable metal recovery and potable water purification for reduction of unwanted metals [52.20]. Chitosan is a good scavenger for metal ions owing to the amine and hydroxyl functional groups in its structure [52.21–23].

Chitosan has a strong metal binding ability. It was found that their adsorption of uranium is much greater than of the other heavy metal ions [52.24]. Chitosan, a polymer of biological origin, has been reported to be an effective adsorbent for Crs(VI) removal from waste water [52.25]. *Lasko* and *Hurst* [52.26] studied silver sorption on chitosan under different experimental conditions, changing the pH in the presence of several ligands [52.27]. Molybdate anions are selectively bound to chitosan in the presence of excess nitrate (or) chloride ions, with selectivity to chitosan in the presence of Ni^{2+}, Zn^{2+}, Cd^{2+} ions, with selectivity coefficients in the range of 10–10 000 [52.28]. Nair and Madhavan used chitosan for the removal of mercury from solutions and the adsorption kinetics of mercuric ions by chitosan was reported. The result indicates that the efficiency of adsorption of Hg^{2+} by chitosan depends upon the period of treatment, and the particle size [52.29].

52.3 Modification of Marine Biomaterials

Modification of chitosan is to introduce special properties into these abundant biopolymer and enlarge its fields of potential applications [52.30]. Physical and chemical modifications have been performed for improving metal sorption selectivity by template formation (or) the imprinting method [52.31–33].

One of the most interesting advantages of chitosan is its versatility. The material can readily be modified physically, preparing different conditioned polymeric forms such as powder, nanoparticles [52.34], gel beads [52.35], membranes [52.36], sponge [52.37], honeycomb [52.38], fibers [52.39], and hollow fibers [52.40] for various fields of applications such as wastewater treatment, biomedical, and textiles.

52.3.1 Beads

Chitosan has a very low specific area ranging between 2 and 30 $m^2 g^{-1}$ [52.41]. Glutaraldehyde-crosslinked chitosan gel beads have a higher specific surface area around 180–250 $m^2 g^{-1}$ [52.42]. Gel bead conditioning significantly modifies the porous characteristics of the polymer, which may explain the differences in the sorption properties of the material [52.43].

The crosslinked chitosan beads have very high adsorption capacities to remove the anionic dyes whose maximum monolayer adsorption capacity ranges from 1911–2498 g kg^{-1} at 300 °C. The adsorption capacities of the crosslinked chitosan beads are much higher than those of chitin for anionic dyes. It shows that the major adsorption site of chitosan is an amine group – NH_2, which is easily protonated to form – NH_3^+ in acidic solutions. The strong electrostatic attraction between the $-NH_3^+$ of chitosan and anionic dye can be used to explain the high adsorption capacity [52.44]. Chitosan bead is a good adsorbent for the removal of Congo red from its aqueous solution and 1 g of chitosan

in the form of hydro gel beads can remove 93 mg of the dye at pH 6 [52.45].

Alginate–chitosan hybrid gel beads were prepared and shown to very rapidly adsorb heavy metal ions [52.46]. Modified chitosan gel beads with phenol derivatives were found to be effective in adsorption of cationic dye, such as crystal violet and Bismark brown [52.47].

52.3.2 Flakes

Maruca [52.48] used chitosan flakes of 0.4–4 mm for the removal of Cr(III) from wastewater. The sorption of arsenate on to chitosan flakes has been studied. The maximum adsorption capacity occurs at an initial pH 3.5 [52.49]. Chitosan was chemically modified by introducing xanthate group onto its backbone using CS_2 under alkaline conditions. The chemically modified chitosan flakes were used as an adsorbent for the removal of Cd ions from electroplating waste effluent under laboratory conditions. The maximum uptake of Cd was found to be 357.14 mg g^{-1} at an optimum pH of 8 whereas for plain chitosan flakes it was 85.47 mg g^{-1} [52.50]. The Cr(VI) removal ratio was optimized by surface response methodology. Accordingly a maximum of 92.9% Cr(VI) removal was attained at pH 3 with 13 g L^{-1} chitosan flakes from a solution initially concentrated as 30 mg L^{-1} [52.51].

52.3.3 Fibers

Chitosan in the fiber form is not used much for wastewater treatment. Chitosan fibers were tested with aqueous solutions of copper sulfate and zinc sulfate for different periods of time to prepare samples containing different levels of metal ion contents. On chelation of metal ions the chitosan fibers gained substantial increase in both dry and wet strength. The metal ions were readily removed from the chitosan fibers by treatment with an aqueous EDTA solution [52.52]. The recovery of direct dye by adsorption on cross linked fiber was developed and appeared technically feasible. The concentration of amino group fixed in the adsorbent phase was 3.30 mol kg^{-1} dry fibers. A typical direct dye, brilliant yellow was used. The breakthrough curves for adsorption of the dye were measured for different flow rates, bed heights, influent concentration of the dye and temperature [52.53]. Chitosan fibers have been studied for the recovery of dyes and amino acids [52.54]. But less attention has been paid to the use of this conditioning of the polymer for the recovery of metal ions.

52.3.4 Hollow Fibers

Hollow fibers have recently received attention with the objective of performing the simultaneous sorption and desorption of the target metal. Hollow chitosan fibers were prepared and the system was used for the recovery of chromate anions. The hollow fibers were immersed in the chromate solution while an extractant was flowed through the lumen of the fiber. Chromate anions adsorbed on the fiber were re-extracted by the solvent extractant. The hollow fiber acts simultaneously as a physical barrier that can make the extraction process more selective [52.39, 55].

52.3.5 Membrane

Membranes and membrane processes were first introduced as an analytical tool in chemical and biomedical laboratories; they developed very rapidly into industrial products and methods with significant technical and commercial impact. Today, membranes are used on a large scale to produce potable water from sea and brackish water, to clean industrial effluents and recover valuable constituents, purity, and to separate gases and vapor in petrochemical process [52.56, 57].

Muizzarelli reported a decrease in the metal ion sorption efficiency of chitosan membranes compared to chitosan flakes and attributed this effect to a decrease in contact surface, despite the thickness of the membrane [52.58]. *Krajewska* prepared chitosan gel membranes and extensively characterized their diffusion properties [52.59]. The permeability of metal ions through these membranes was measured, Cu < Ni < Zn < Mn < Pb < Co < Cd < Ag [52.60]. Crosslinked chitosan membranes with epichlorohydrin has been proposed to improve pore size, distribution, mechanical resistance, chemical stability, and adsorption properties [52.61–63]. The maximum Cr adsorption capacity occurred in epichlorohydrin-crosslinked chitosan at pH 6 [52.64]. The removal of divalent metal ions including Cu(II), Co(II), Ni(II), and Zn(II) from aqueous solutions by chitosan-enhanced membrane filtration was studied. At neutral condition, the removal of Cu(II) was more efficient compared to other metals [52.65].

Chitosan membranes as sorbents for the trace elements determination in surface water have been tried by *Mladenova* et al. [52.66] and the authors have successfully used their membranes as an efficient sorbents for the pre concentration and they have recommended their membranes for solid phase extraction of Cd(II), Eu(II), Ni(II), and Pd(II) from surface water.

52.4 Antifouling Marine Biomaterials for Water Treatment

52.4.1 Fouling

Fouling is a problem encountered with most filtration processes as it reduces productivity and impairs the capabilities of the membrane due to the decline in flux because of concentration polarization or fouling of the membrane [52.67]. If the fouling effect is not controlled, membrane processes can become nonviable. Permeate flux usually decreases during fouling because of retained molecules that accumulate on, or within the membrane pores.

Biofouling is a major challenge for the biomedical industry as well. Healthcare-associated infections are attributed to biofilms on surfaces such as countertops, doors, beds, surgical tools, or medical devices such as catheters. The Centers for Disease Control and Prevention have reported that these healthcare-associated infections account for an estimated 1.7 million infections and 99 000 deaths annually in the United States [52.68]. Furthermore, these infections accounted for nearly $45 billion of patient costs in 2007 [52.69]. The formation of an atherosclerotic plaque within the arterial wall can be broadly described as a biofouling process [52.70].

Marine Organisms in Fouling

Marine biofouling is the undesirable accretion of biological organisms on artificial surfaces immersed such as ship hulls, jetty pilings, navigational instruments, aquaculture net cages, and seawater intake pipes in sea-water. There are over 4000 species worldwide, and marine biofouling communities will begin to grow on substrates immediately upon submersion. The groups of organisms that contribute to marine biofouling such as bacteria, algae, plant and animal colonies include seaweeds, bivalves, crustaceans, and barnacles. Biofouling on ships reduces their speed and manoeuvrability, resulting in increased fuel and maintenance costs. On static structures, such as buoys, piers, and jetties, biofouling can accelerate corrosion as well as increase the risk of mechanical failure. Fouling is a serious problem causing the blockage of seawater intake pipes. Fouling organisms and organisms hitch-hiking in the ballast tanks of ships are the major vectors for invasive organisms causing environmental impacts in many countries.

Based on the size of fouling material the marine biofouling can be divided into two groups. They are microfouling and macrofouling. The micron/submicron-size organisms such as bacteria's, algae, and microbes and quickly colonize any substrate placed in seawater forms microfouling. The macrofouling includes many larger animals and plants that may attach as individuals or in large colonies, such as barnacles, mussels, polychaetes, and various species of bryozoans and hydroids. Surface chemistry is a significant factor in the formation, stability, and release of adhesion of fouling organisms to surfaces. The work by *Baier* in the late 1960s demonstrated a correlation between relative adhesion of fouling organisms and the energy of the surface [52.71].

Membrane fouling is one of the most important challenges faced in membrane operations [52.72, 73]. Fouling results in flux decline, which increases the energy demand for filtration [52.74]. To counteract this problem, membranes are cleaned, often with aggressive chemicals, to remove the foulants adsorbed on membrane surfaces. When cleaning becomes ineffective, the membranes must be replaced [52.75]. Fouling by proteins, other biomolecules, and organic matter is generally attributed to the hydrophobic nature of membrane materials, which leads to a high interfacial energy with water-rich media that is reduced upon biomolecules adsorption [52.76].

The fouling is usually described by the formation of a *cake* on membrane surface [52.77]. The protein adhesion is affected by interactions between molecules and membrane surface, solution chemistry, pH, ionic strength, and membrane morphology [52.76]. An adjustment of these parameters could be the key to solve the antifouling phenomena. In food and biotechnological industries, ultra and microfiltration processes besides proteins often deal with polysaccharides. In fouling investigations, polysaccharide solution can be of great interest, namely starch that is an important dietary energy source and frequently present in complex mixtures of biomacromolecules.

Biofouling is a very dynamic process, which spans numerous length and time scales. Fouling of a new surface in the marine environment is typically described as a four-phase process: formation of a conditioning layer of organic molecules, primary colonization by microorganisms such as bacteria and diatoms, unicellular colonization by algal spores, and attachment of multicellular macrofoulers [52.78].

Marine Biomaterials as Antifouling Agents in Water Treatment

In general, membrane fouling occurs more seriously on hydrophobic membranes than hydrophilic ones because of hydrophobic interactions between solutes, microbial cells, and the membrane surfaces [52.79]. As a result, much attention has been made to reduce membrane fouling by modifying hydrophobic membranes to relative hydrophilic [52.80, 81].

Polysulfone (PSF) membranes have been widely used in the fields of ultrafiltration, gas separation, pervaporation, and hemodialysis, playing a decisive role in plasma separators, membrane oxygenators, and artificial organs [52.82]. However, due to the hydrophobic nature of PSF material, conventional PSF membranes easily suffer serious membrane fouling and may cause life-threatening complications [52.83].

On the basis of the empirical criteria recently proposed by *Ostuni* et al. [52.84], nonfouling polymers should be hydrophilic, electrically neutral and possess hydrogen-bond acceptors. Accordingly, several polymer classes have been explored [52.85], including polyacrylates [52.86], polyzwitterions [52.87], poly(ethylene glycol) (PEG) derivates [52.88] and chitosan derivatives. In a facile and effective method, chitosan coating and glutaraldehyde crosslink combined with pretreatment by ozone was developed for endowing nonwoven membrane with an antifouling and antibacterial surface [52.89].

Hydrogels – crosslinked polymer networks that swell in the presence of water – have also been investigated for antifouling applications. *Rasmussen* et al. demonstrated that hydrogel surfaces of alginate, chitosan, and polyvinyl alcohol substituted with stilbazolium groups (PVA-SbQ) inhibited settlement of *Balanus amphitrite*. This group also showed that the PVA-SbQ surface inhibited adhesion of the marine bacterium *Pseudomonas* sp. [52.90].

Biocompatible and naturally occurring chitosan was used as an additive for the preparation of a polysulfone ultrafiltration membrane. Two different compositions of polysulfone in *N*-methylpyrrolidone (NMP) and chitosan in 1% acetic acid were blended to prepare PSf–CS ultrafiltration membranes by the diffusion induced phase separation (DIPS) method. The PSf–CS membrane showed an enhanced hydrophilicity compared to a PSf ultrafiltration membrane. An improved antifouling property was observed for PSf–CS blend membranes as compared to pristine PSf ultrafiltration membranes. Both the permeation and antifouling properties of PSf–CS membranes increased with an increase in chitosan composition [52.91].

Using the very promising technology in water purification industry, *Lin* et al. [52.92] coupled chitosan/UF process for dissolved organic matter and arsenic removal. In this investigation, they concluded that even chitosan has weak affinity for arsenic but adsorbs effectively the dissolved organic matter. Also chitosan retards membrane fouling effectively. Under the experimental condition arsenic rejection is only about 10% but the humic compounds about 22%.

Strategies that are used to reduce fouling on membranes can be divided into three groups, i. e.:

i) Changing operating conditions
ii) Modification of the membrane
iii) Modification of the feed [52.93].

Suitability of chitosan as an antifouling agent by the biocatalyst (yeast cells) for the fouling of membrane was studied by *Le Roux* et al. [52.94].

It is assumed that the reduced fouling in the presence of chitosan flakes is largely due to the physical restriction (entrapment) of the yeast cells by the chitosan preventing the yeast cells from forming a cake on the membrane surface. However, at pH 7.5 (buffer solution) 5% of the amino groups of chitosan are positively charged (assume $pKa = 6.2$) [52.95] which implies that chitosan at pH 7.5 is polycationic. In a recent study, it was shown that the yeast cells of *Rhodosporidium toruloides* have the ability to adhere both to polycationic and polyanionic surfaces due to distinct cationic and anionic regions on the cellwall [52.96]. This means that irrespective of the essential charge of the chitosan (due to possible Donnan effects) there will be attractive forces between chitosan and yeast cells. This implies that apart from the physical restrictions, electrostatic attractions will contribute to the retainment of the cells by the chitosan.

Protein fouling in membrane processes is a complicated mechanism due to many factors affecting fouling formation. It is known that the electrostatic force and the hydrophobic interaction between certain domains in protein molecules and the hydrophobic membrane surfaces as well as between protein molecules are the main factors affecting membrane fouling [52.97]. The chitosan/alginate multilayers with either alginate or chitosan showed that the outermost layer displayed very low interaction with albumin showing the use of Chi/Alg multilayers as antifouling coatings to avoid interaction with proteins and to decrease cell uptake [52.98].

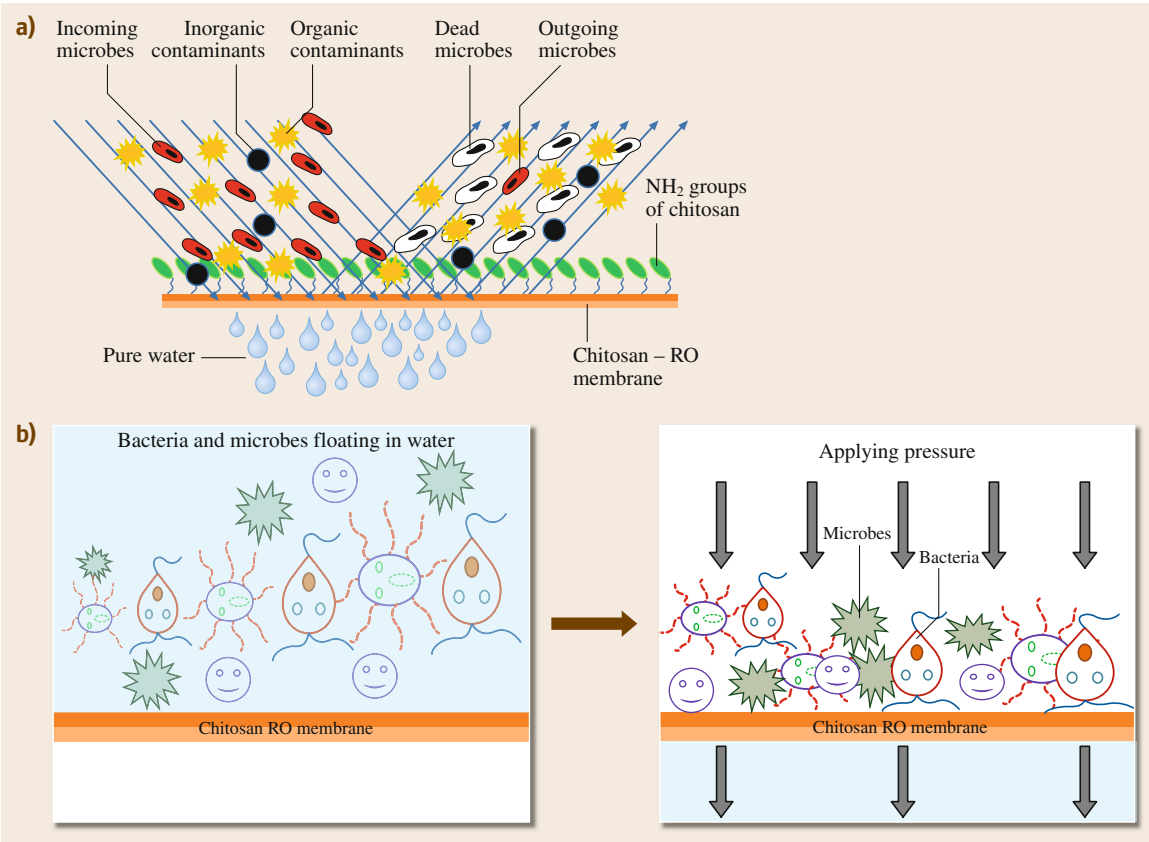

Fig. 52.1a,b Rejection of the microbes along with contaminants through RO membranes and removal of the same from membrane due to the pressure of feed. **(a)** Rejection of microbes through RO membrane. **(b)** Removal of microbes by applying pressure.

Possible mechanisms for the antifouling properties of chitosan-containing membranes are presented below:

1. Rejection of the microbes along with contaminants through RO membranes and removal of the same from membrane due to the pressure of feed (Fig. 52.1a,b).
2. Removal of the microbes due to the zwitterions complex formation with chitosan-based membranes (Fig. 52.2).
3. Synergistic effect of chitosan and nanosilver in killing the microbes (Fig. 52.3a,b).
4. Electrostatic repulsion of charged microbial cells by chitosan/alginate-based membranes (Fig. 52.4).

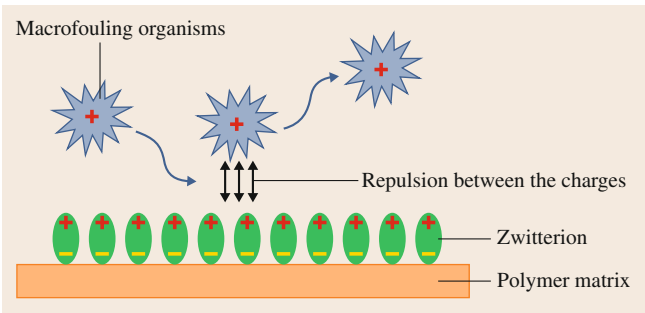

Fig. 52.2 Removal of the microbes due to the zwitterions complex formation with chitosan-based membranes

Huisman et al. [52.99] reported that membrane–protein interactions influenced the fouling behavior in the initial stage of filtration and in the later stage of filtration, protein–protein interactions dictated the overall performance. The interactions also depend on other parameters such as membrane materials, solution type, and operating conditions. Solution pH is an impor-

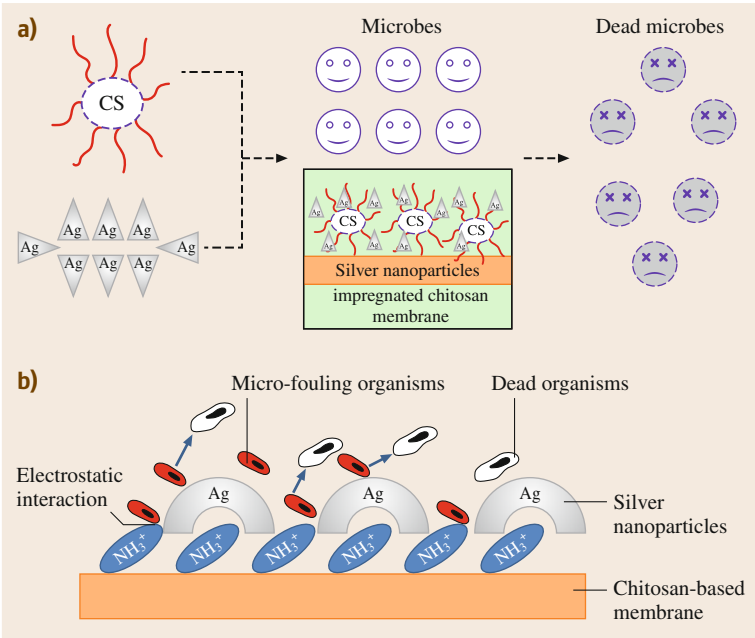

Fig. 52.3a,b (a) Synergistic effect of chitosan and nanosilver in killing the microbes. (b) Electrostatic interaction between the membrane and microbes

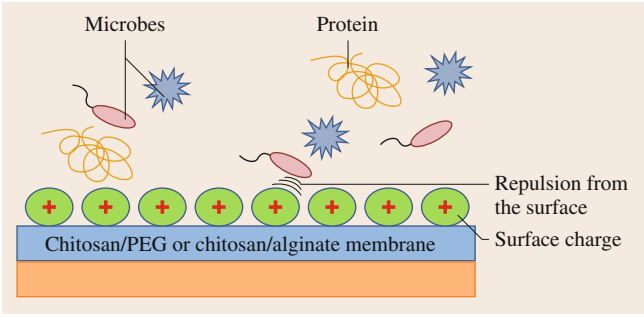

Fig. 52.4 Electrostatic repulsion of charged microbial cells by chitosan/alginate-based membranes

tant factor which can strongly affect membrane fouling and filtration performance. It was reported that change in pH could cause fouling in protein filtration. *Zhao* et al. [52.100] found that bovine serum albumin adsorption on chitosan/PES (polyethersulfone) composite microfiltration (MF) membrane was highest at the IEP (isoelectric point) and at low pH (3.0–4.7), the MF composite membranes had higher adsorption capacities of BSA than that at higher pH range (6.0–8.0). *Mo* et al. [52.101] emphasized the effect of pH on BSA fouling in reverse osmosis (RO) process.

To date, effective prevention strategies have primarily relied upon antimicrobial agents that usually show toxicity against nontarget organisms. While a variety of nontoxic surface modification technologies have been employed, their efficacy has been very limited in in-situ environments. A number of extracellular polysaccharide (EPS) formulations purified from marine bacteria were evaluated as potential antifouling agents. EPS from *Alteromonas, Pseudomonas*, and *Vibrio* spp. were dip-coated onto cleaned glass slides, placed into a flow cell apparatus with real-time imaging, and then exposed to natural flowing seawater under laboratory conditions over a 5 d timeframe. All six of the purified EPS formulations inhibited biofouling (primarily, bacteria) over the test period, with HYD 657, HE 800, HYD 1644, and HYD 1545 showing the most significant reductions in fouling. Surface area fouling was reduced by 90% relative to a cleaned glass control substrate [52.102]. EPS, proteins, and DNA are highly hydrated hydrophilic molecules, but some EPS have hydrophobic properties. There are also clear advantages to using natural polymers and especially bacterial exopolysaccharides for antifouling purposes. Exopolysaccharides do not contain toxic heavy metals or other molecules that adversely affect the local ecology. In addition, such polymers can easily be produced using relatively simple bacterial cultivation protocols and commercially available fermentation equipment.

Nanosilver is regarded as a new generation of antibacterial agents and has great potential to be utilized in antibacterial surface coatings for medical devices,

food package, and industrial pipes. However, disadvantages such as easy aggregation, uncontrollable release of silver ions, and potential cytotoxicity greatly hinder its uses. Recently, polymers possessing unique functions have been employed to fabricate nanocomposite coatings with nanosilver for better biocompatibility and enhanced antibacterial activity [52.103]. Regarding antimicrobial activity, chitosan film forming solutions showed antimicrobial behavior against *Escherichia coli* and *Lactobacillus plantarum* [52.104].

52.5 Conclusion

It is clear that protein, polysaccharide adsorption, and subsequent biofouling are strongly influenced by surface chemistry. Correlations have been observed between protein adsorption and biofouling in both the marine and biomedical environments. Resistance to protein adsorption could be used as an inexpensive way to screen new materials for antifouling properties. A single chemistry has not yet emerged as a universal antifouling strategy. However, a variety of surface chemistries have shown promise as fouling-release coatings. A combination of chemical and physical antifouling strategies is therefore necessary to produce an optimal coating.

53. Marine Biomaterials

Jayachandran Venkatesan, Se-Kwon Kim

In recent years, significant development has been achieved in marine biomaterials for various biological and biomedical applications. In the present chapter, we discuss isolation techniques and the application of marine-derived polymers and ceramics in detail. The main marine polysaccharides are alginate, chitin, chitosan, and fucoidan. The marine-derived polymers show substantial biological properties such as those of anti-inflammation, antimicrobial, anticancer, and osteoporosis. In addition, marine-derived ceramics play an important role in bone related treatment. Isolation procedures and the application of hydroxyapatite (HA) and biosilica are also discussed. HA that has been isolated or developed from different sources such as fish bone, fish scales, and coral is discussed along with its biomedical applications. Properly implemented marine-derived biomaterials will be promising materials for mankind.

53.1 Examples of Marine Biomaterials

Approximately 72% of the earth is covered by water that is divided by oceans, lakes, rivers, etc. The oceans contain 97% of the earth's water. They do not only consist of salty water but are an abundant resource for food, medicine, and various raw materials. Marine species are economically important to humans in various ways, including food fish. In recent years, marine-derived biomolecules (proteins, natural compounds, etc.) have been given much importance in medicine and engineering. Marine environments are the household to many exotic biological materials that may inspire biomimetic materials.

Biomaterial science is concerned with the interaction of substances with biological metabolism. Biomaterials can be derived from synthetic sources and natural sources. Synthetic materials are usually metallic, polymeric, and ceramic, or in the form of composite materials. These materials are often used for biomedical applications, including surgery, tissue engineering, and drug delivery. If the substance comes from a natural source (marine), it can be called marine biomaterial. The important sources of marine biomaterials are fish, invertebrates, mammals, reptiles, fungi, and corals. Fish skin is a rich source of collagen and bone for hydroxyapatite. Algae are a rich source for several polysaccharides. Marine-derived biomaterials have been checked to solve the bone related defects; they include materials from polymers, ceramics, and biomimetic materials. The main polymers derived include alginate, chitin, chitosan, fucoidan, etc. (Fig. 53.1).

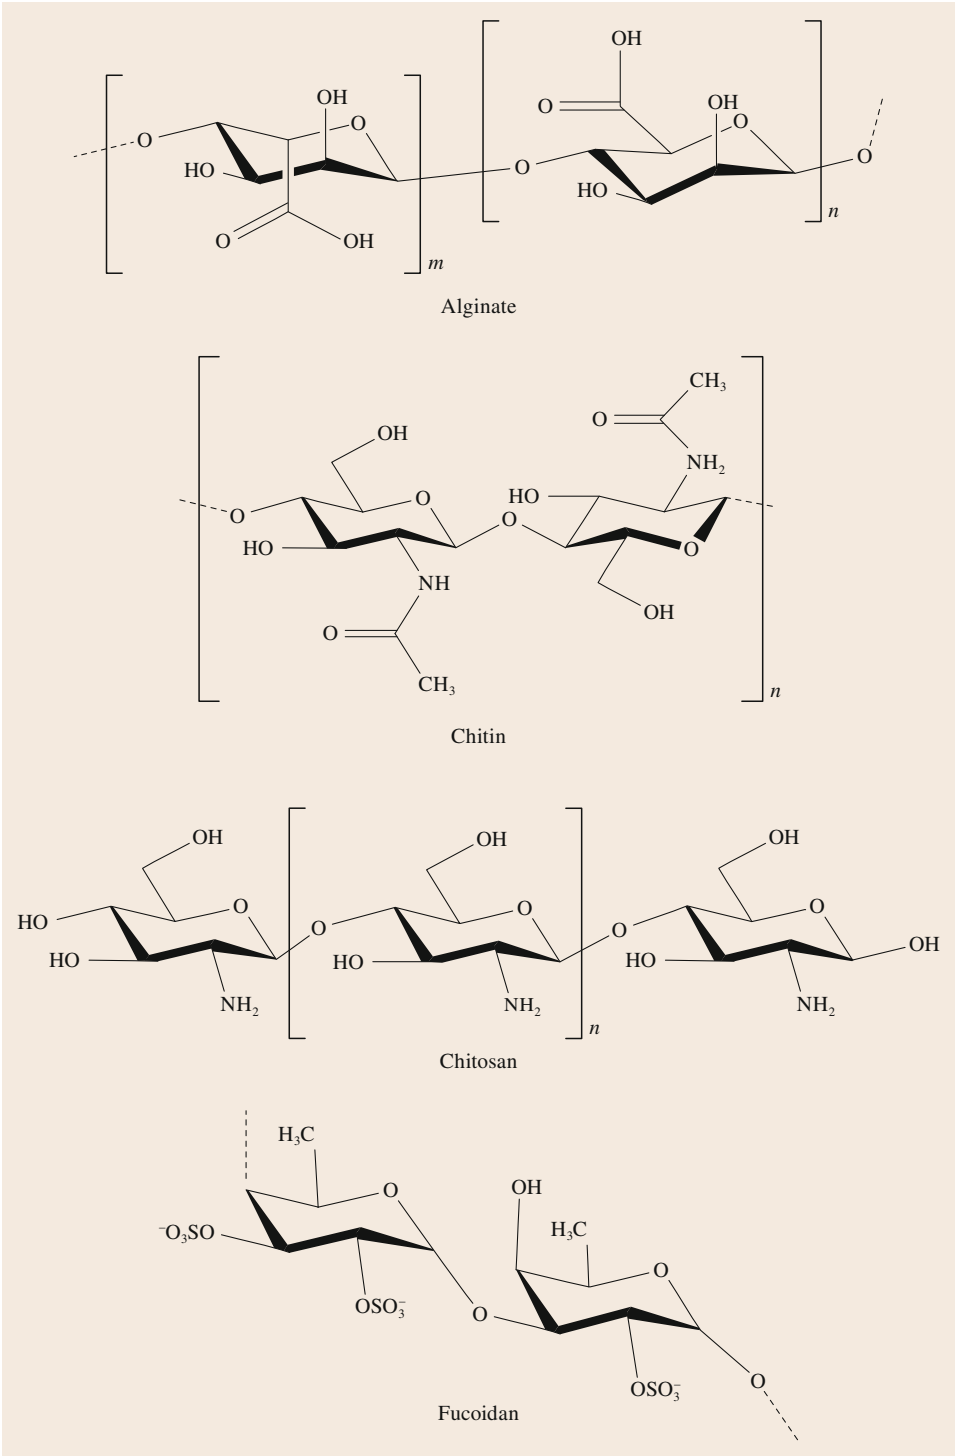

Fig. 53.1
Structure of important biomedical marine polysaccharides

53.2 Marine Polysaccharides

53.2.1 Alginate

Alginate is a biopolymer and found in seaweed and typically extracted from brown algae (*Phaeophyceae*) including *Laminaria hyperborea*, *Laminaria digitata*, *Laminaria japonica*, *Ascophyllum nodosum*, and *Macrocystis prrifere* by treatment with aqueous alkali solutions, typically with NaOH. The extract is filtered with calcium chloride and added to the filtrate in order to precipitate alginate. This alginate salt can be transformed into alginic acid by treatment with diluted HCl. Further purification produces water-soluble sodium alginate [53.1–3] (Fig. 53.2).

Bacterial alginate can be produced from *Azotobacter* and *Pseudomonas* [53.4]. The pathway of alginate biosynthesis is generally divided into four steps:

- Synthesis of precursor substrate
- Polymerization and cytoplasmic membrane transfer
- Periplasmic transfer and modification
- Export through the outer membrane.

Alginate is composed of guluronic acid (G) and mannuronic acid (M), which is considered to be biocompatible, nontoxic, nonimmunogenic, and biodegradable. Alginate extracted from different sources differs in mannuronate and gluluronate content, as well as in the length block. The alginate is known to form a hydrogel by hydrogen bonding at low pH. The alginate and alginate chemical modification can bring about new biomaterials, which are useful in cell immobilization, tissue engineering, and drug delivery. Alginate hydrogels have been proven to improve the neocartilage and neo-bone formation [53.5–8]. Alginate hydrogels are particulary used for several biomedical applications such as tissue engineering, drug delivery, and wound healing, due to their structural similarity with extracellular tissues [53.1]. Hydrogels are three-dimensionally cross-linked networks composed of hydrophilic polymers with high water contents. Chemical or physical cross-linking of hydrophilic polymers are typical approaches to form hydrogels and their physicochemical properties are highly dependent on the cross-linking type and amount of cross-linking agents [53.9]. The most widely used method to make the alginate gel is with calcium chloride, calcium carbonate, calcium sulfate, and sodium hexametaphosphate (ion cross-linking agents). Covalent cross-linking of alginate with poly (ethylene glycol)-diamines of various molecular weights was first investigated in order to prepare gels with a wide range of medicinal properties. Thermal gelation and cell cross-linking are some other processing methods to make the alginate hydrogels [53.1].

Biomedical Applications

Drug Delivery. The conventional application of alginate in pharmaceutics is to serve as thickening, gel forming, and stabilizing agents. Multiple drugs have been incorporated with alginate hydrogels with different materials such as poly (caprolactone) [53.10], carbon nanotubes [53.11], and chitosan [53.12]. Alginate is an excellent biomaterial for the delivery of drugs. Alginate microspheres are used to encapsulate or load the desired amount of protein for protecting the protein functions, transporting it to the targeted sites, and controlling the kinetics of the protein release. Alginate microspheres were prepared small scale with a water in oil emulsion technique and loaded with fluorescently labeled immunoglobulin G (IgG) [53.13]. Alginate microspheres have been coated with Bombyx mori silk fibroin using layer-by-layer deposition techniques, which provided mechanically stable shells as well as a diffusion barrier to the encapsulated proteins [53.14]. Calcium-cross-linked alginate microspheres and microspheres modified with CpG oligonucleotides are mixed with soluble *matrix* alginate in phosphate buffer saline (PBS) containing soluble IL-2. Diffusion of calcium ions in the microspheres into the surrounding solution induces cross-linking of the soluble alginate and gel formation. The inset figure outlines the process of calcium reservoir alginate microsphere synthesis via water-in-oil emulsion of alginate in isooctane in the presence of surfactants (Fig. 53.3) [53.15].

Wound Dressing. Alginate dressing materials are typically produced by ionic cross-linking of an alginate solution with calcium ions to form a gel, which is subsequently free-dried to obtain a porous sheet. Alginate dressing can retain a physiologically moist environment by absorption and desorption of the water from the gels. Several bioactive alginate wound dressing materials have been studied to date [53.16–19].

Tissue Engineering. Bone is a complex tissue with a hierarchical structure consisting of hydroxyapatite (HA) and collagen as a major portion. Bone defects can occur in several ways such as through trauma, neoplasm, congenital defects, motor accidents, osteoporo-

Raw material of alginate, a brown seaweed growing abundantly in the Ocean

Crushed seaweed, after it has been dried and pulverised for the production of alginate

By reaction with divarent metal cations from seawater (such as calcium), the alginic acid in seaweed forms a water insoluble alginategel. This alginate is partially cross-linked and retains its shape. After beeing rinsed in water, the seaweed swells in acidic water

To isolate alginic acid from thin sodium alginate solution, an acid is added. In an acidic system, insoluble alginic acid is precipitated and isolated. This is the so-called "acid precipitation method"

Precipitated alginic acid is dehydrated and the fibrous wet body (gel) is produced. The fibrous wet body is dried and pulverized to make alginic acid powder

Fig. 53.2 Isolation procedure of alginate from seaweed

sis, arthritis, etc. Various techniques have been used to solve bone defects, for example, autografting, allografting, and xenografting. However, all these techniques have advantages and disadvantages, for example, insufficient donor sites and transmittable disease [53.20]. Thus, considerable attention has been given by researchers and orthopedists to synthetic and natural materials that can solve the bone defect problem. Experiments are currently taking place at the laboratory and clinical levels. Synthetic materials are often made of hydroxyapatite or other naturally occurring biocompatible materials.

Alginate is the best-known material to form a scaffold-forming property, which can be useful to treat loss or failure of organs. Alginate gels have advantages for bone and cartilage regeneration due to their ability to be introduced into the body in a minimally invasive manner, their ability to fill irregularly shaped defects, the ease of chemical modification with adhesion ligands (e.g., arginylglycylaspartic acid (RGD)), and controlled release of tissue induction factors (e.g., BMP (bone morphogenetic protein), TGF-β (transforming growth factor beta)) [53.21–23] (Fig. 53.4).

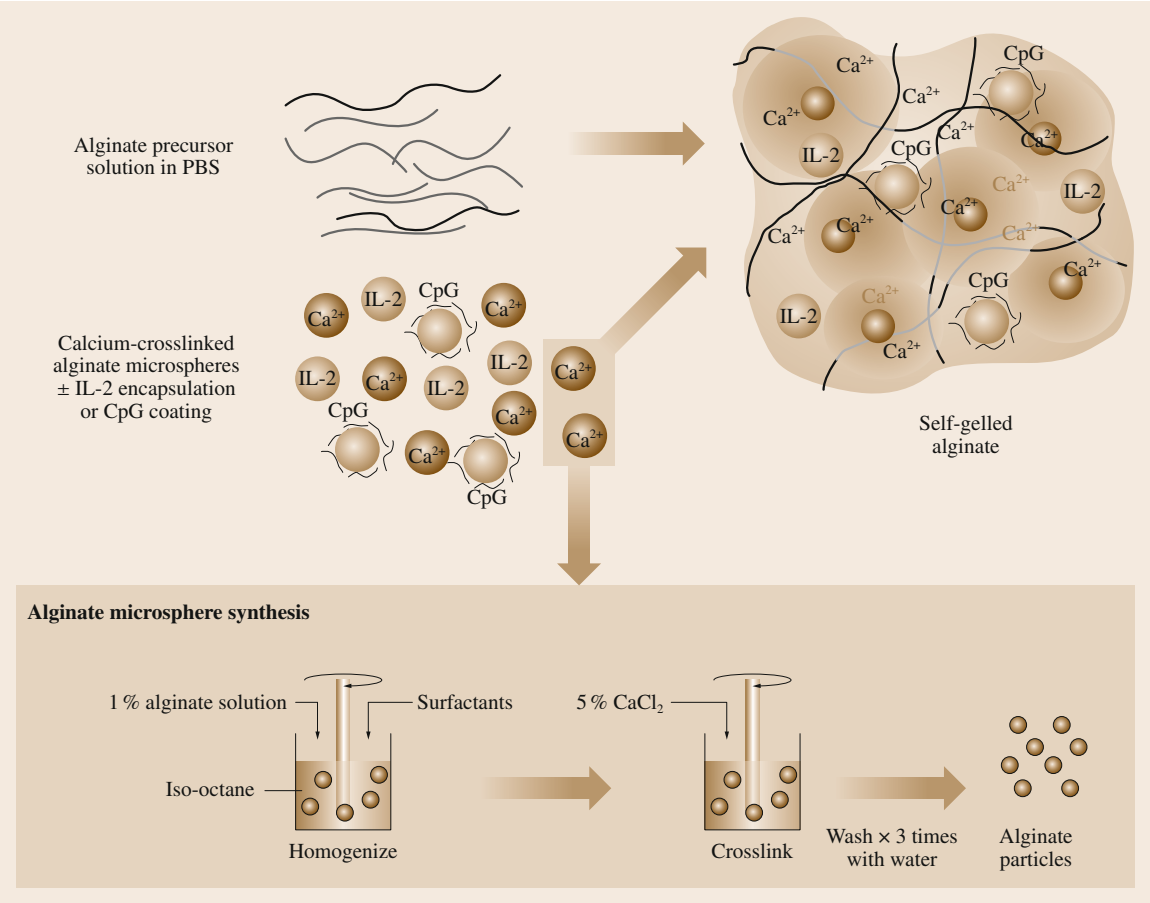

Fig. 53.3 Schematic of self-gelling alginate formulations based on calcium reservoir alginate microspheres (after [53.15])

The transplantation of stem cells using alginate hydrogels has been widely explored in bone tissue engineering [53.24]. The most widely examined application of alginate gels to promote blood vessel formation has exploited their ability to provide sustained and localized release of heparin binding growth factors such as VEGF [53.25, 26]. Due to a lack of mechanical strength of the alginate scaffold to mimic the natural function of bone, it is combined with inorganic materials to enhance strength as well as bone tissue formation. Alginate with hydroxyapatite is the better combination of the porous scaffold. This has been prepared with the phase separation method, which enhances the cell adhesion of osteosarcoma cells [53.27, 28]. Human mesenchymal stem cells (MSCs) encapsulated in the alginate gel bead have been cultured in a serum-free medium with the addition of a transforming growth factor, dexamethasone, and ascorbate, and have been found to form cartilage in large osteochondral defects [53.29–31]. Alginate scaffolds are being actively investigated for their ability to mediate the regeneration of other tissues and organs, including skeletal muscles, nerves, pancreas, and liver. Current strategies for skeletal muscle regeneration include cell transplantation, growth factor delivery, or a combination of both approaches, and alginate was found to be a good candidate in these strategies [53.32–37].

53.2.2 Chitin and Chitosan

Chitin are naturally occurring mucopolysaccharides, usually found in fungi, diatoms, nematodes, arthropids, shrimps, crabs, lobsters, krill, and squid [53.38–47].

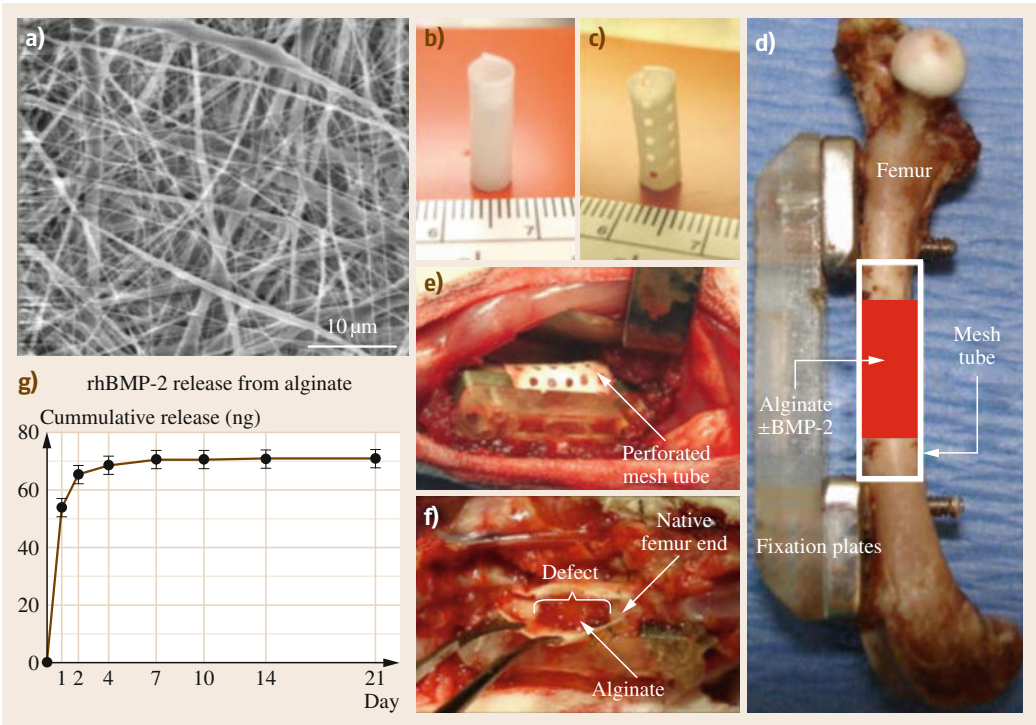

Fig. 53.4 **(a)** Nanofiber mesh tubes and alginate hydrogel for surgery. SEM (scanning electron microscope) image of an electrospun nanofiber mesh illustrating the smooth and bead-free nano-scaled fibers. **(b)** Hollow tubular implant without perforations made from nanofiber meshes. **(c)** Tubular implant with perforations. **(d)** Implants in a segmental bone defect. Modular fixation plates are used to stabilize the femur. A nanofiber mesh tube is placed around the 8 mm defect. In some groups, alginate hydrogel, with or without rhBMP-2, is injected inside the hollow tube. **(e)** Defect after placement of a perforated mesh tube. The alginate inside the tube can be seen through the perforations. **(f)** A specimen was taken after 1 week and the mesh tube was cut open. The alginate was still present inside the defect, with hematoma present at the bone ends, after [53.21]. **(g)** Alginate release kinetics over 21 d in vitro. Sustained release of the rhBMP-2 was observed during the first week

The chemical formula of chitin is 2-acetamido-2-deoxy-β-D-glucose through β (1–4) linkages (Fig. 53.1). This linkage can be easily degraded by the chitinase enzyme [53.48, 49]. Chitosan is a linear polysaccharide composed of randomly distributed β-(1–4)-linked glucosamine and *N*-acetyl-D-glucosamine. Chitosan can be obtained from chitin by a chemical method or an enzymatic production method. Chitosan can be isolated directly from the cell wall of certain fungi, but commercially available chitins are usually prepared from chitin. Chitin and chitosan are white, hard, inelastic nitrogenous polysaccharides and the major source of surface pollution in coastal areas. Chitosan is produced commercially by deacetylation of chitin, which is the structural element in the exoskeleton of the crustaceans crab and shrimp, and the cell walls of fungi. The degree of deacetylation can be determined by nuclear magnetic resonance (NMR) spectroscopy; it ranges from 60 to 100%, and the molecular weight is between 3800 and 20 000 Da.

Several methods have been introduced to isolate chitin and chitosan from shellfish waste, the most traditional and well-developed method is a chemical, enzymatic, fermentative method for industrial production, which is simple and convenient for large production [53.51–53].

Production of Chitosan by Chemical Methods

In the chemical hydrolysis method, four main steps are involved in the production from marine crustacean shells, as depicted in Fig. 53.5 [53.54–56]. They are:

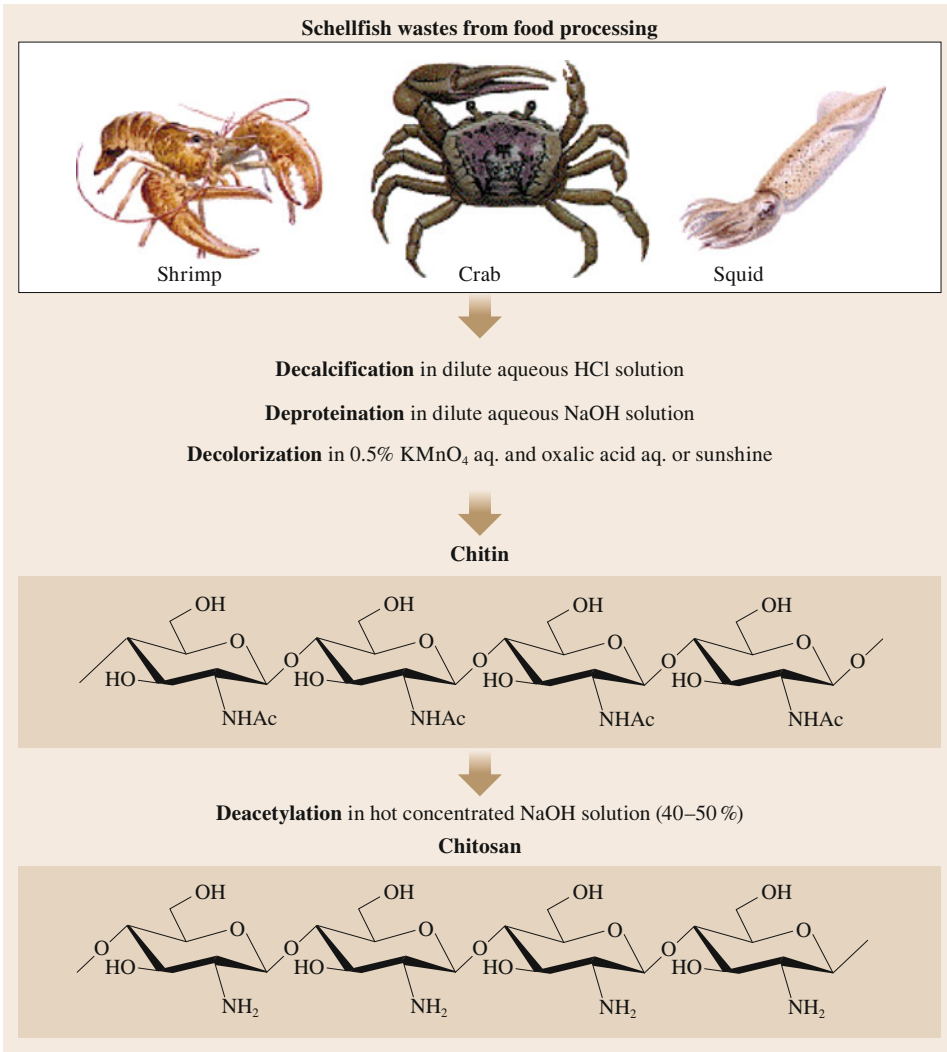

Fig. 53.5 Chemical method for the production of chitosan

- Decalcification in dilute aqueous HCl solution
- Deproteinization in dilute aqueous NaOH solution
- Discoloration in 0.5% aqueous $KMnO_4$ and aqueous oxalic acid or sunshine
- Deacetylation in hot concentrated NaOH solution (40–50%).

In general, proteins are first removed from ground shells by treatment with mild sodium hydroxide or potassium hydroxide solution at elevated temperature. Alkali concentration is usually between 1 to 10% with temperatures ranging from 30 to 100 °C, independent of the starting materials. These are the most common, and reaction times usually varies from 30 min to 12 h. Higher temperature reduces the molecular weight of the resultant chitosans. The removal of calcium carbonate, calcium phosphate, and other mineral salts found in shell waste is accomplished by extraction with dilute acids. To produce 1 kg of 70% deacetylated chitosan from shrimp shells, 6.3 kg of HCl and 1.8 kg of NaOH are required.

Enzymatic Methods

Enzymatic methods are an alternative to the chemical method for chitin and chitosan production. In addition, the protein often remains high and reaction times are significantly increased compared to chemical methods. Enzymatic methods are limited in industrial production

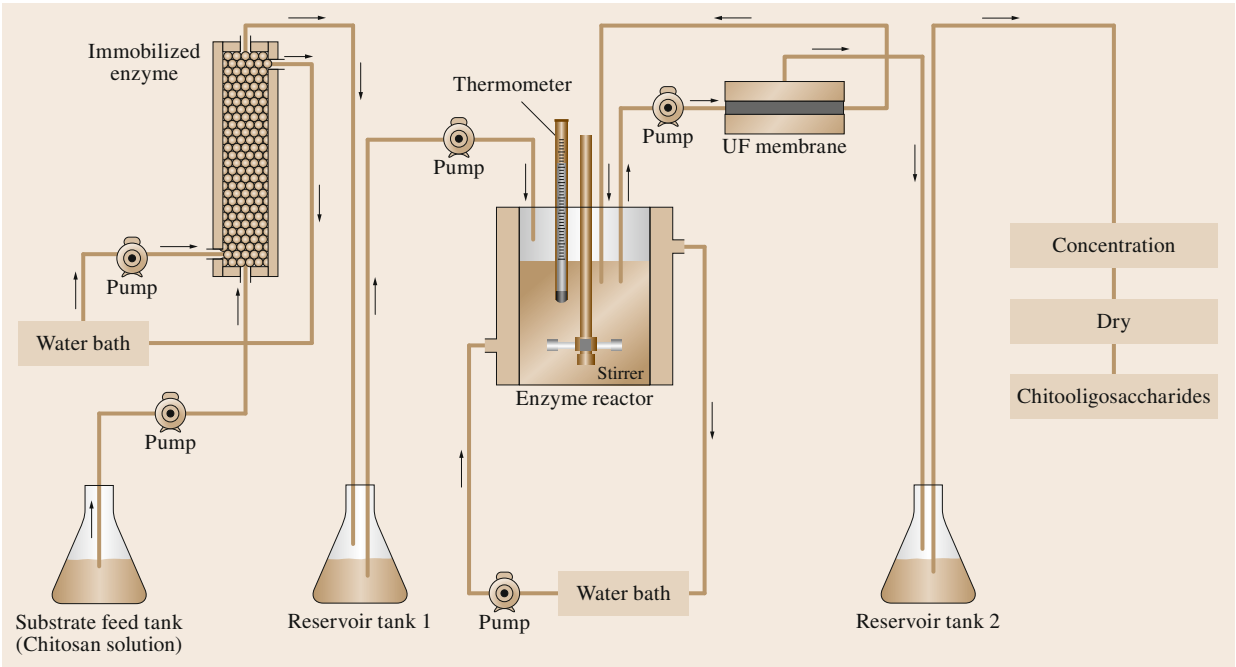

Fig. 53.6 Schematic diagram of the dual reactor system used for continuous production of chitooligosaccharide (after [53.50])

of chitosan, due to higher cost of enzymes [53.53]. Several commercially available enzymes such as alcalase, chymotrypsin, and papain are also used for the production of chitosan [53.57].

Fermentation Methods

Fermentation with bacteria producing proteolytic and chitinolytic enzymes has been researched as an alternative method [53.58]. Organic acid and protease produces a soil isolate of *Pseudomonas aeruginosa* F722 with crab shells. With an optimal fermentation temperature of 30 °C and a 10% glucose supplementation, the degree of demineralization was 92% and the degree of deproteinization was 63% after 7 days incubation [53.59].

Production of Chitooligosaccharides

Lower molecular and water soluble chitosan obtained by continuous hydrolysis of chitosan by chitinolytic enzymes, such as chitinase, chitosanase, papain, and lysozyme are widely used for the production of chitooligosaccharide (COS). Several research groups developed a method for the production of COS with a higher yield and a higher degree of polymerization [53.50, 60–63]. For the continuous production of COS by an enzymatic method, ultrafiltration reactors have been employed. The advantages of continuous production of COS is higher efficiency and greater enzyme productivity; it was found that high the viscosity of chitosan restricted continuous operation due to membrane fouling [53.50].

The continuous production of COS from chitosan has been attained with a dual reactor system with an ultrafiltration membrane reactor and a column reactor packed with an immobilized enzyme. The production of the COS was performed in two steps (Fig. 53.6):

1. Preparation of the partially hydrolyzed chitosan from viscose chitosan in the column reactor packed with an enzyme
2. Production of the oligosaccharides from partially hydrolyzed chitosan in the ultrafiltration membrane reactor.

Three kinds of partially hydrolyzed chitosan were obtained from three different outflow rates (3, 5, and 9 ml/min) in the column reactor and were supplied to a substrate feed tank of the following ultrafiltration (UF) reactor in order to identify the influence of the feed on membrane fouling. The partially hydrolyzed chitosan obtained with a 5 ml/min overflow rate was the most suitable substrate for alleviation of membrane

Table 53.1 Properties of chitosan and their applications

	Properties	Applications
Cationic	Linear polyelectrolyte with high charge density	Water purification
	Chelates toxic metal ions	Excellent flocculent
Chemical	High molecular weight	High viscosity, film forming
	Reactive amino and hydroxyl groups	Chemical modification for specific end uses
Biological	Biocompatible and biodegradable	Non-toxic, packaging films, coating
	Bioactivity	Antimicrobial, antitumor, anticancer, immuno potentiator
Pharmaceutical	Biocompatible, biodegradable	Wound, healing, drug delivery, tissue engineering, contact lens
General cosmetics	Moisture retention, excellent feed, protective film-coating, excellent tactile properties	Skin care products, hair lotions, natural ingredient
Food and agriculture	Binds anions (bile acids or free fatty acids)	Hypocholesterolemic agents, anticarcinogenic agents, dietary fibre, antiulcer
	Fungistatic	Increased crop production
Biotechnological	Extrapment and adsorption	Immobilization matrix, chitosan beads/gels

fouling and efficient hydrolysis under the operating conditions of the dual reactor system [53.50].

Some of other methods are also used for the production of chitin, chitosan and COS such as, gamma irradiation [53.64]. The method of preparation as follows, heads and shells from prawns found on the Algerian coast were collected, dried at 60 °C, and cut into small pieces that were then irradiated at a dose of 75 Gy/min to a dose of 25 kGy. Irradiation reduced the time needed for deproteinization from 3 to 1 h using 1 N sodium hydroxide and a reaction temperature of 85 °C.

Applications

Because it is a natural resource and is thus biologically reproducible, biodegradable and environmentally nonpolluting, biocompatible, nontoxic, and biologically functional, chitosan is a versatile material for various biological and biomedical applications [53.55] (Table 53.1).

Antimicrobial Activity

The antimicrobial activity of any substance is always directed toward its applicability. The film forming ability of any polymers with antimicrobial property can be used for food packaging. Antimicrobial packaging is one of the most promising active packaging systems that have been found to be highly effective in killing or inhibiting spoilage of pathogenic microorganisms that contaminate food [53.65]. Chitosan is best known for its antimicrobial property from the literature [53.66–69].

Variations in chitosan's bactericidal efficacy arise from various factors. According to the roles played, these can be classified into four categories as follows:

1. Microbial factors, related to species and cell age
2. Intrinsic factors of chitosan including positive charge density, molecular weight, concentration, hydrophilic/hydrophobic characteristic, and chelating capacity
3. Physical state, namely water solubility and solidity of chitosan
4. Environmental factors, involving the ionic strength in the medium, pH, temperature, and reaction time.

Chitosan is an ideal biopolymer for developing such antimicrobial films due to its nontoxicity. The inherent antibacterial/antifungal properties and the film-forming ability of chitosan make it ideal for use as a biodegradable, antimicrobial packaging material. The antimicrobial properties of chitosan can be enhanced

by irradiation, ultraviolet radiation treatment, partial hydrolyzation, chemical modifications, synergistic enhancement with preservatives, synergistic enhancement with antimicrobial agents, or in combination with other hurdle technologies.

Anti-Inflammatory Activity

Anti-inflammatory refers to the property of a substance or treatment that reduces inflammation. Chitin is rarely checked for anti-inflammatory property due to its lack of solubility.

Yang et al. reported that COS have shown considerable anti-inflammatory activity with different molecular weights [53.70]. The effects of COS on nitric oxide (NO) production and the cytokine expression TNF-α (TNF: tumor necrosis factor), and interleukin-6 (IL-6) have been checked as lipopolysaccharide (LPS) stimuli from RAW264.7. Stimulation with increasing concentrations of COS, the LPS-stimulated TNF-α, and IL-6 secretion recovered significantly within the incubation media of RAW264.7 cells [53.71].

Anticancer Activity

Chitosan shows several biological activities, as discussed above. Moreover, chitosan significantly inhibits the tumor growth [53.72]. The intra tumoral administration of chitosan compounds alone has been shown to promote antitumoral effects in a metastatic breast cancer model [53.73]. Chitosan was also found to activate macrophages into cytotoxic macrophages and suppressed Meth-A tumor growth in Balb/c mice [53.74]. COS is also shown to inhibit the growth of Meth-A solid tumors transplanted in mice [53.75].

Biomedical Application of Chitin, Chitosan, and COS

The wide array of tissue engineering applications exacerbates the need for biodegradable materials with broad potential. Chitosan is an excellent biodegradable and biocompatibility biomaterial. Natural polymer composite materials are promising scaffolds for bone tissue engineering [53.76]. Next generation biomaterials should combine bioactive and bioresorbable materials, which mimic the natural function of bone and activate in vivo mechanisms of tissue regeneration. Composite materials based on combinations of biodegradable polymers and bioactive ceramics are highly suitable for bone regeneration [53.77]. The important biomedical applications of chitin and chitosan are tissue engineering and drug delivery [53.54, 78–83].

Tissue Engineering

Tissue engineering has been a fascinating area of research in recent years to develop the artificial organs [53.84]. Several materials have been widely used to develop artificial organs; these are synthetic and natural derived materials. Chitosan is a promising biomaterial used for various biomedical applications. Chitosan can be modified to any form such as film, fibers, beads, and scaffolds (Fig. 53.7).

Dimensional structures of scaffolds are used to simulate the extracellular matrices naturally found in the body. The design consists of a large surface area so that cells can be seeded and are able to penetrate the pores. The pores are interconnected so that wastes and nutrients can be exchanged between the scaffold and the surrounding environment, thereby promoting cellular development. The properties of the scaffold are influenced by the method used in the creation of the scaffold. There are several methods used to create highly porous scaffolds, such as supercritical fluid technology [53.85] and the freeze drying method [53.86]. While chitosan has many desirable properties, its mechanical strength is poor, and to enhance the mechanical strength, it is often blended with other polymers and ceramics. Ceramics such as hydroxyapatite are biomaterials that are widely used with chitosan to make the scaffolds [53.76, 87–90].

Drug Delivery

Considerable research efforts have been directed towards developing safe and efficient chitosan-based particulate drug delivery systems [53.91–97]. Chitosan has been used as excipient in oral formulations and vehicles for parenteral drug delivery devices. Chitosan has further been used to manufacture sustained release systems deliverable by other routes (nasal, ophthalmic, transdermal, and implantable devices) [53.98]. Chitosan forms colloidal particles and entraps bioactive molecules through chemical cross-linking, ionic cross-linking, and ionic complex formation for the association of bioactive molecules to polymers and to control drug release [53.99, 100].

53.2.3 Fucoidan

Fucoidan is sulfated polysaccharides, mainly in found brown algae such as mozuku, komby, limu moui, bladderwrack, wakame, hijiki, and sea cucumber. Other common fucoidans are sourced from edible species such as *Fucus vesiculosis*, *Cladosiphon okamuranus*,

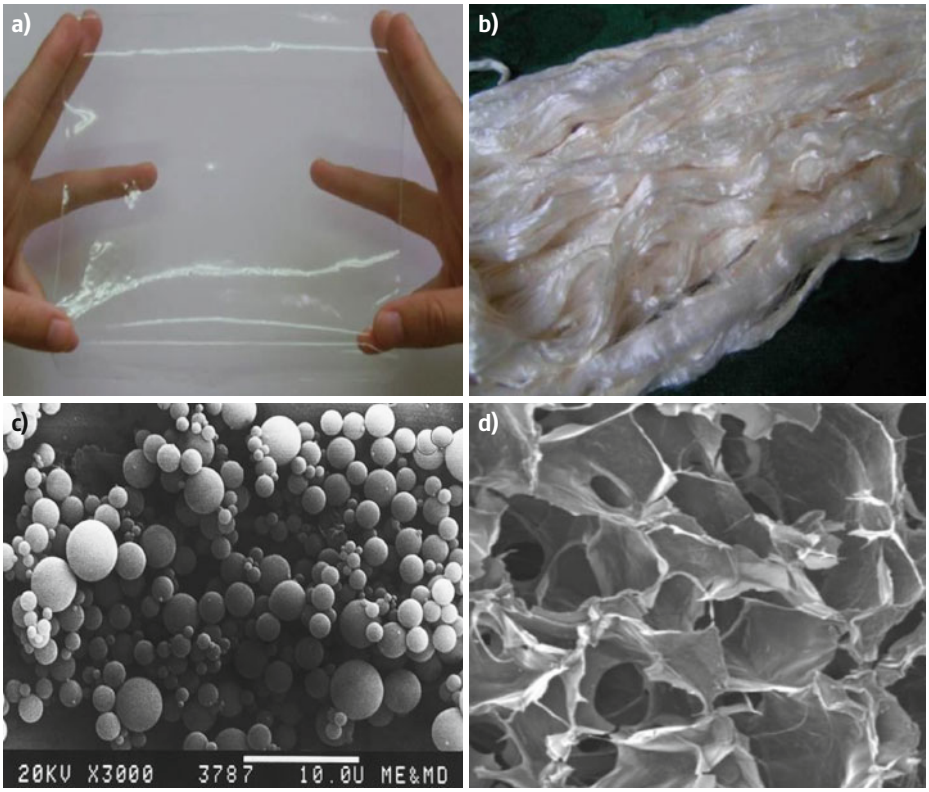

Fig. 53.7a–d Chitosan in different forms. **(a)** Film, **(b)** fiber, **(c)** beads, and **(d)** scaffolds

Laminaria japonica, and *Undaria pinnatifida*. The main skeleton of fucoidans consists of α-1,3-linked sulphated l-fucose; a repeating sequence of alternating $\alpha(1 \rightarrow 3)$ and $\alpha(1 \rightarrow 4)$ glycosidic bonds is also possible. Published research articles on fucoidans increased threefold between 2000 and 2010. Fucoidan plays a significant role in the control of acute and chronic inflammation via enzyme inhibition and inhibition of the complement cascade [53.101]. Fucoidans contain a high proportion of fucose in the sugar backbone of the polymer. They are sulfated, may be acetylated, and may also contain uronic acids. The yield of a crude first fraction of fucoidan is generally 2–10% by weight. Fucoidans derived from seaweed are all highly branched. A second source of linear rather than branched fucoidans is echinoderms, in particular sea cucumbers [53.102–104].

The chemical composition and structure of fucoidans are very diverse and vary significantly depending on the algae source, place of cultivation and habitat, harvesting time, etc. The biological activity and medicinal impact of fucoidans depends strongly on their structural properties. The extraction and purification procedures of fucoidan are shown in the Fig. 53.8. Fucoidan was isolated from the raw material by dilute acid extraction, ballast alginates were removed by $CaCl_2$ precipitation, and crude extract was purified by chromatography on DEAE-cellulose [53.105] (DEAE: diethylaminoethyl).

Biological Applications of Fucoidan

Anticancer Activity. Cancer is known to be one of the worst diseases that threaten human's lives. Unfortunately, drugs used for cancer therapy are toxic and affect not only cancer cells but also normal cells and tissues. It has been reported that fucoidans effectively inhibit proliferation and colony formation of cancer cells in vitro [53.107, 108] and also inhibitory activity in tumors growing in vivo [53.106]. Studies suggest that sulfate content, molecular weight, monosaccharide composition, and the structure of the main polymer chain of fucoidan have a great influence on their biological activities. A higher amount of sulfated content in fucoidan shows a higher antitumor activity with low degree substitution [53.109–113].

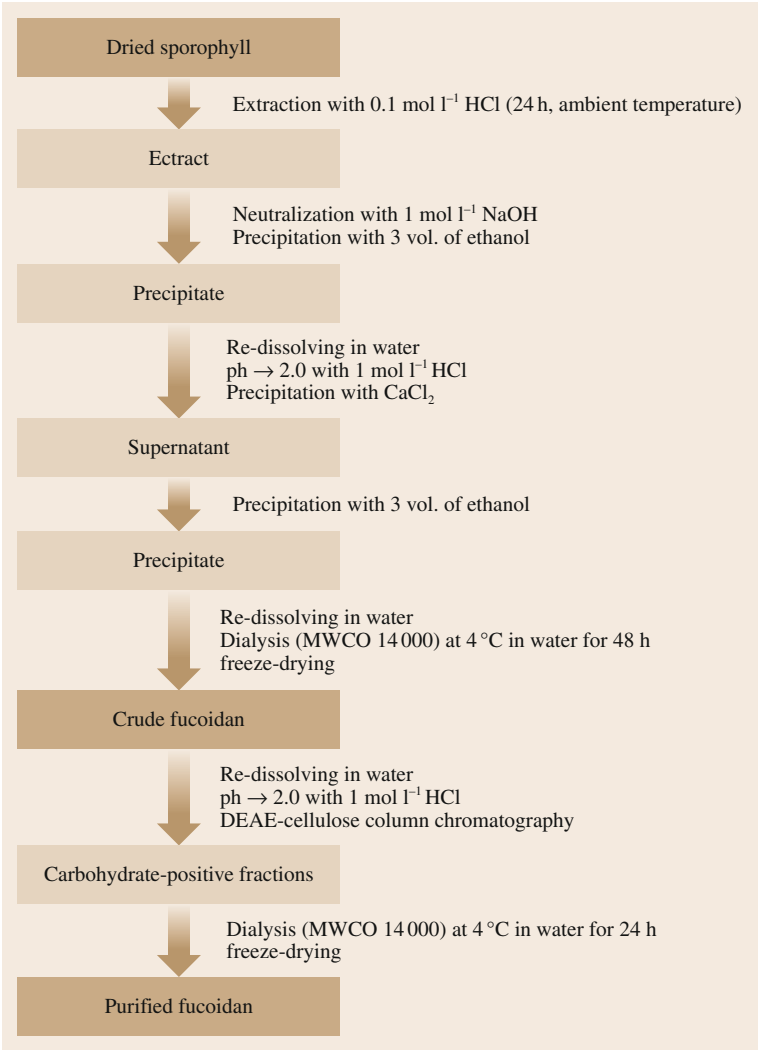

Fig. 53.8 Isolation and purification of the Miyeokgui fucoidan (after [53.106])

Anti-inflammatory Activity. *Park* et al. checked the inhibitory effects of fucoidan on production of lipopolysaccharide (LPS)-induced pro-inflammatory mediators in BV2 microglia. Results indicated that fucoidan treatment significantly inhibited excessive production of nitric oxide (NO) and prostaglandin E_2 (PGE2) in LPS-stimulated BV_2 microglia [53.114, 115].

Osteoporosis. Fucoidan has several biological activities and recent studies indicate that fucoidan can be useful in treating osteoarthritis. *Park* et al. used an animal model of collagen-induced arthritis and showed that orally administered *Undaria pinnatifida* fucoidan successfully inhibited pain [53.116]. Osteoarthritis symptoms were significantly inhibited by oral administration of fucoidan-rich seaweed extract; the symptoms were reduced by 52% [53.117].

Biomedical Applications of Fucoidan. *Changotade* et al. [53.118] reported that low molecular weight fucoidan explored to bone extracellular matrix to support human osteoblastic behaviors in 3-D culture. Fucoidan promotes cell proliferation, collagen type I expression, alkaline phosphatase activity, and mineralization [53.118, 119].

53.3 Marine Ceramics

Ceramics of marine origin such as corals, nacres, fish bone, and sponges provide significant amounts of ceramic materials for biomedical applications.

53.3.1 Hydroxyapatite

Hydroxyapatite (HA), is a naturally occurring mineral form of calcium apatite with the formula $Ca_{10}(PO_4)_6(OH)_2$. Several sources have been identified and used for isolation of HA, such as fish bone [53.120–123]. Considerable interest has been given to fish bone for the production of HA, which has several advantages such reduction of environmental pollution and results in value-added products. Several synthetic methods have been reported in the literature such as hydrothermal [53.124], liquid membrane [53.125], precipitation [53.126], radio frequency thermal plasma [53.127], ultrasonic precipitation [53.128], reverse microemulsion [53.129], sol-gel [53.130] and polymer-assisted methods [53.131], for example.

Hydroxyapatite from Fish Bone and Scales

The simplest method for the production of HA from fish is thermal treatment. HA is the main component of fish and the other is collagenous and noncollagenous protein. The amount HAp at different temperatures 600 °C, 900 °C, and 1200 °C were 62.12, 59.33, and 57.64% (Table 53.2 and Fig. 53.9). HA was isolated from *Thunnus obesus* bone using alkaline hydrolysis and thermal calcination methods. The results indicate

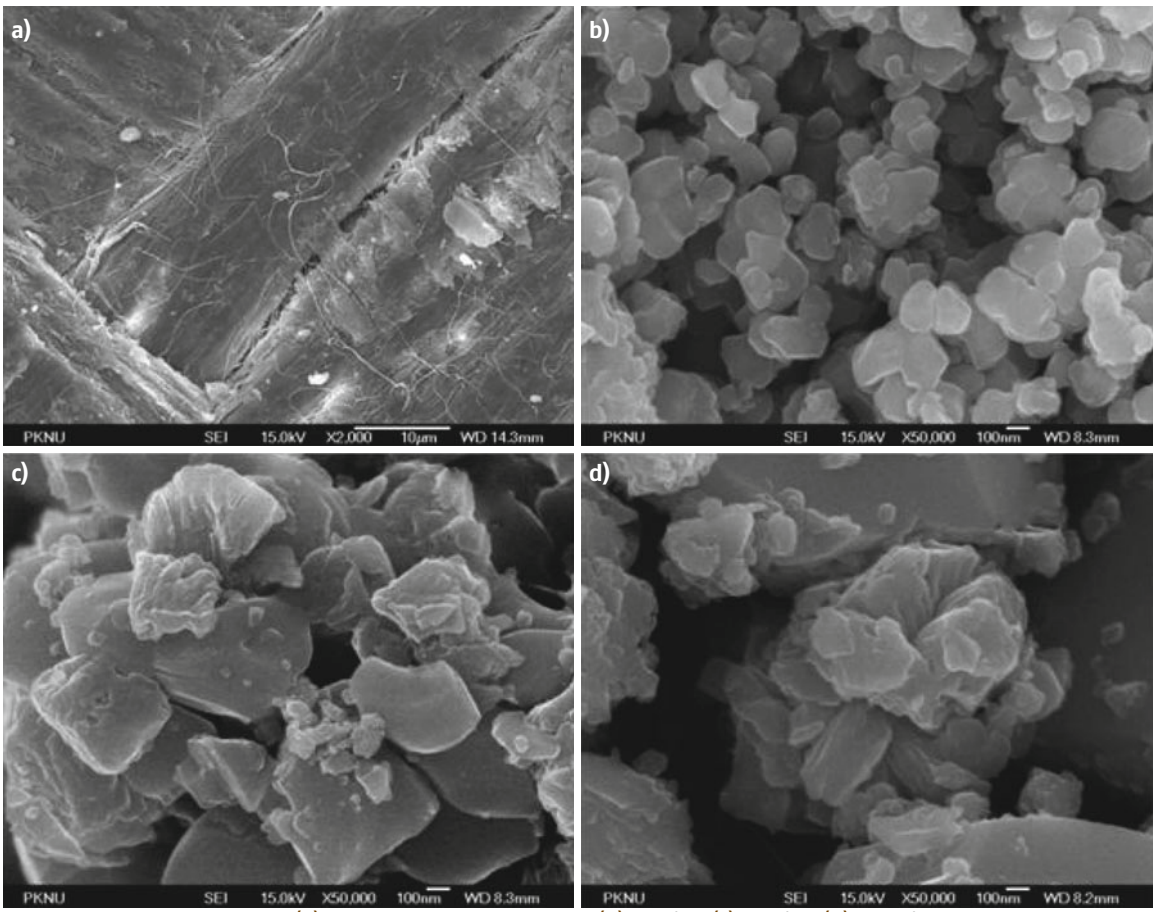

Fig. 53.9a–d SEM results of **(a)** raw fish bone and treated at **(b)** 600 °C, **(c)** 900 °C, **(d)** 1200 °C (after [53.120])

Table 53.2 Residues and color of calcined *Thunnus Obesus* bone (after [53.120])

Sample No.	Calcination temperature (°C)	Calcination period in (h)	Initial weight (g)	Weight after calcination (g)	Residue (%)	Description
1	1200	5	2.0000	1.1527	57.6350	White
2	1100	5	2.0020	1.1529	57.5874	White
3	1000	5	2.0024	1.1771	58.7845	White
4	900	5	2.0011	1.1872	59.3274	White
5	800	5	2.0030	1.1936	59.5906	White
6	700	5	2.0032	1.2129	60.5481	Off-white
7	600	5	2.0017	1.2434	62.1172	Off-white

9	400	5	2.0031	1.3402	66.9063	Tan
10	300	5	2.0061	1.5162	75.5795	Black
11	200	5	2.0000	1.7360	86.8000	Black
12	Raw fish bone	–	–	–	–	Yellow

that there are significant differences between the ceramics and *Thunnus obesus* bone, the thermal calcination method produces good crystallinity with dimensions 0.3–1.0 μm, whereas the alkaline hydrolysis method produces nanostructured HAp crystals with 17–71 nm length and 5–10 nm width [53.120–123].

HA ceramics isolated from natural sources like cuttlefish bone [53.132], bovine bone [53.133–138], and fish bone [53.120, 139–142] have the advantage of providing inexpensive raw materials from bone and teeth. *Ooi* et al. developed HAp from a bovine source with the thermal calcination method at a temperature range 600–1000 °C, which exhibited HA in a pure form [53.135]. The most important parameters that can affect the properties of HA are the temperature and the duration of the heat treatment [53.134]. While synthetic materials have been widely used in the biomedical field with great success, natural structural materials are now providing an abundant source for novel biomedical applications. Carbonate groups present in carbonated HA are eliminated by heating, which affects the biological properties of the apatite extracted by thermal calcination method [53.143]. *Ozawa* and *Suzuki* reported that HA was isolated from Japanese sea bream by the thermal calcination method up to 1300 °C. Weight loss was observed at the three temperature ranges 30–250 °C, 250–380 °C, and 380–520 °C. The first one corresponds to water content and other two are removal of organic substances [53.144]. Some researchers use fish scale for the production of HA [53.145]. Some researchers have used cuttlefish for the production of HA [53.146–148].

Hydroxyapatite from Corals

Coral is widely used for the production of HA [53.149, 150]. The main component of coral is calcium carbonate, normally in the form calcite. Some chemical reaction is required for conversion of coral to HA. Usually phosphate-containing substances are used.

$$10CaCO_3 + 6(NH_4)_2HPO_4 + 2H_2O \Rightarrow Ca_{10}(PO_4)_6(OH)_2 + 6NH_4CO_3 + 4H_2CO_3 \,.$$

Several commercially available HA based products are available based on the above reaction; they are ProOsten and Interpore200. These materials are widely used in several biomedical applications [53.151]. The above reaction condition can be varied according to the coral substance [53.152, 153].

Biomedical Applications

The natural trabecular structure of coralline HA is similar to that of bone by the hydrothermal conversion of the calcium carbonate skeleton of coral to HA. The benefits of carbonated hydroxyapatite (CHA) for bone grafts are predominantly its safety, biocompatibility, and osteoconductivity; it is used as a bone graft substitute and bone void filler [53.154–158].

53.3.2 Biosilica

Biogenic silica, commonly known as biosilica, consist of glassy amorphous silica and are formed in many aquatic organisms (and in terrestrials as well), such

as sponges, diatoms, radiolarians, and choanoflagellates [53.159]. In addition to being inspiring and a valuable source of marine collagen, as mentioned above, some sponge species are also an important source of biosilica.

There are two classes of sponge that have a silica skeleton: demospongiae and hexactinellida. The third class, calcarea, has a calcium carbonate skeleton. The process of biosilica formation in sponges is enzyme-mediated. The axial filament consists predominantly of the silicatein, which mediates the silicification process around it through the formation of the said concentric layers [53.160].

53.4 Current Understanding and Future Needs

Recent screening techniques have revealed the vast chemical diversity of oceans, which is much higher than what can be achieved by synthesis and standard chemical approaches; this opens new and exciting research scenarios. In fact, the real value of marine-derived materials and compounds can only be roughly checked; it is still to be discovered. Thus, the sustainable exploitation of ocean diversity for industrial and medical purposes is of enormous interest and promises a huge impact not only on research, but particularly on the progress of society, which is reflected on the emergence of marine biotechnology, also known as blue biotechnology, as a fast-growing sector [53.161].

53.5 Conclusions

Oceans not only consist of water, but it has been proven that they are an abundant source of various materials. There is a need to develop several bioactive biomaterials from the marine source. Isolation procedures need to be developed in order to obtain medical grade materials for human purposes. In recent years, several biotechnological processes have improved to help us obtain medical grade biomaterials from the marine source. Chemical derivatization is one promising approach to modify marine-derived polymers for use in tissue engineering, tissue delivery, or biosensors.

54. Marine Materials: Gene Delivery

Bijay Singh, Sushila Maharjan, Yun-Jaie Choi, Toshihiro Akaike, Chong-Su Cho

The hurdle in the gene therapy is a lack of suitable gene carrier although animal virus vectors have been mostly used in vivo and in clinical applications due to their high transfection efficiency. However, there are several problems such as potential infectivity, inflammation, immunogenicity, and complicated production. Therefore, nonviral vectors have been tried as alternatives. Among nonviral vectors, natural cationic polymers have been used as the gene carriers because they are biocompatible, less immunogenic, no-limitation of gene size to deliver, and easily produced with low cost. This review chapter covers the recent development of chitosan, alginate, and pullulan among marine polymeric materials as gene carriers.

54.1 Nonviral Vectors for Gene Delivery

Gene therapy, for curing inherited and acquired diseases by substituting missing genes, replacing defective genes or silencing gene expression, is one of a novel form of molecular medicine because it has a strong impact on human health in the next generation [54.1]. However, one of the big hurdles in the gene therapy is lack of a suitable gene carrier although recombinant animal viral vectors have been mostly used because they have high efficiency of gene transfer in vivo and in clinical applications. However, the use of animal viral vectors for the clinical trials often leads to several problems such as potential infectivity, inflammation, immunogenicity, and complicated production [54.2]. Therefore, nonviral vectors using liposomes and polymers have been promising alternatives because they have several advantages such as low immune response, biocompatibility, flexibility of delivered gene size, and easy production [54.3].

Among nonviral vectors, cationic polymers such as polyethylenimine (PEI) [54.4], poly(amino ester) [54.5], reducible poly(amido amine) (PAMAM) [54.6], PAMAM dendrimer [54.7], and chitosan [54.8] have been recently attracted as gene delivery carriers than cationic lipids because rapid clearance of deoxyribonucleic acid (DNA) from the bloodstream, acute of inflammation, tissue infiltration, and injury of liver and spleen by the lipids have been found [54.9]. Therefore, the objective of this chapter is to discuss the possibility of chitosan, alginate, and pullulan among marine polymeric materials as gene delivery carriers. These polysaccharides as natural polymers will be expected as promising nonviral vectors due to biocompatibility, low immunogenicity, and low toxicity. Moreover, these polymers can be easily manipulated for the proposed applications with desirable physicochemical and physiological properties.

54.2 Chitosan

Among marine polymeric materials, chitosan and chitosan derivatives have been mostly tried as gene delivery carriers because they have biodegradable, biocompatible, low toxic, and less immunogenic properties with positive charges as shown in Fig. 54.1. There are several parameters such as pH, molecular weight (MW), and degree of deacetylation of chitosan, N/P ratio, serum and cell type which affect transfection efficiency of chitosan/DNA complexes or gene silencing of chitosan/siRNA complexes [54.8]. Also, there are several steps for gene transfection of DNA or gene silencing of siRNA, including DNA or siRNA complexation and cellular uptake of the polyplexes at extracellular environment, release of DNA or siRNA from endosomes in cytoplasm, release of DNA or siRNA from the chitosan carrier, and DNA transfer into the nucleus at intracellular environment [54.10]. Particularly, one of the important issues of low transfection efficiency of DNA or gene silencing of siRNA by chitosan is slow release of DNA of chitosan/DNA complexes from endosomes into the cytoplasm [54.11]. Therefore, in this section, only pH-sensitive chemical modification of chitosan as the gene delivery carriers will be explained. The pH-sensitive moieties such as PEI, spermine, and amino acids will be included.

54.2.1 PEI

PEI has been used as a golden standard among nonviral vectors in vitro and in vivo because of high transfection efficiency and due to its excellent buffering ability [54.4] although high MW PEI has high cytotoxicity and nondegradability. On the other hand, low MW PEI has low cytotoxicity but it has low transfection efficiency. Therefore, much attention has been given to couple low MW PEI to the chitosan through degradable linkages for enhancing transfection efficiency of chitosan.

PEI-graft-chitosan (PEI-g-C) was first prepared by *Wong* et al. through cationic polymerization of aziridine by low MW chitosan [54.12]. Gel electrophoresis showed that the migration of DNA was completely retarded at the N/P ratio of 2.5. The PEI-g-C showed higher transfection efficiency in HepG2, HeLa, and hepatocyte cells as well as in bile duct of rat liver than PEI 25 K with a lower cytotoxicity.

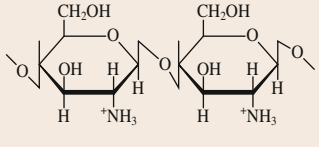

Fig. 54.1 Schematic diagram of chitosan

Chitosan-graft-PEI (C-g-PEI) was differently obtained by *Jiang* et al. [54.13] through an imine reaction between periodate-oxidized chitosan and low MW PEI (1800 Da) as shown in Fig. 54.2. The C-g-PEI showed good DNA binding capacity and protection of DNA from enzyme. Also, the C-g-PEI showed higher transfection efficiency in HeLa, 293T, and HepG2 cells than PEI 25 K with a lower cytotoxicity owing to the synergistic effect of proton sponge ability by PEI and low cytotoxicity by chitosan.

N-maleated chitosan-graft-PEI (NMC-g-PEI) was prepared by reaction of low MW PEI (800 Da) with *N*-maleated chitosan obtained by reaction of maleic anhydride with chitosan [54.14]. The NMC-g-PEI showed a good binding ability with DNA. Also, transfection efficiency of NMC-g-PEI in 293T and HeLa cells was comparable to PEI 25 K with a low cytotoxicity. However, the transfection efficiency depended on MW of NMC-g-PEI. They also prepared *N*-succinyl chitosan-graft-PEI (NSC-g-PEI) by reaction of low MW PEI (800) with *N*-succinyl chitosan obtained by introducing succinyl groups into the chitosan [54.15]. The NSC-g-PEI had good binding ability with DNA. Also, the transfection efficiency of NSC-g-PEI in 293T, HeLa, and CHO cells was higher than that of PEI 25K with a lower cytotoxicity. While the transfection efficiency of NSC-g-PEI increased with an increase in grafting degree of PEI, it was not affected in the presence of serum.

Low MW PEI (600 Da) was introduced into chitosan through a low MW PEG having biterminal epoxide rings as a spacer to increase water solubility and transfection efficiency of chitosan [54.16]. The PEI-PEG-chitosan showed higher transfection efficiency in 293T cells than chitosan with a higher cell viability although they did not compare with PEI 25 K.

Similarly, *Gao* et al. used 1,1′-carbonyl-diimidazole as another spacer to prepare chitosan-linked-PEI (CLP) for improving the transfection efficiency of chitosan [54.17]. The CLP showed higher and long term transfection efficiency in HepG2, A549, and HeLa cells with a lower cytotoxicity. Also, the tumor growth rate was significantly decreased by delivering CCL22 gene with CLP into mice due to the buffering capacity of introduced PEI.

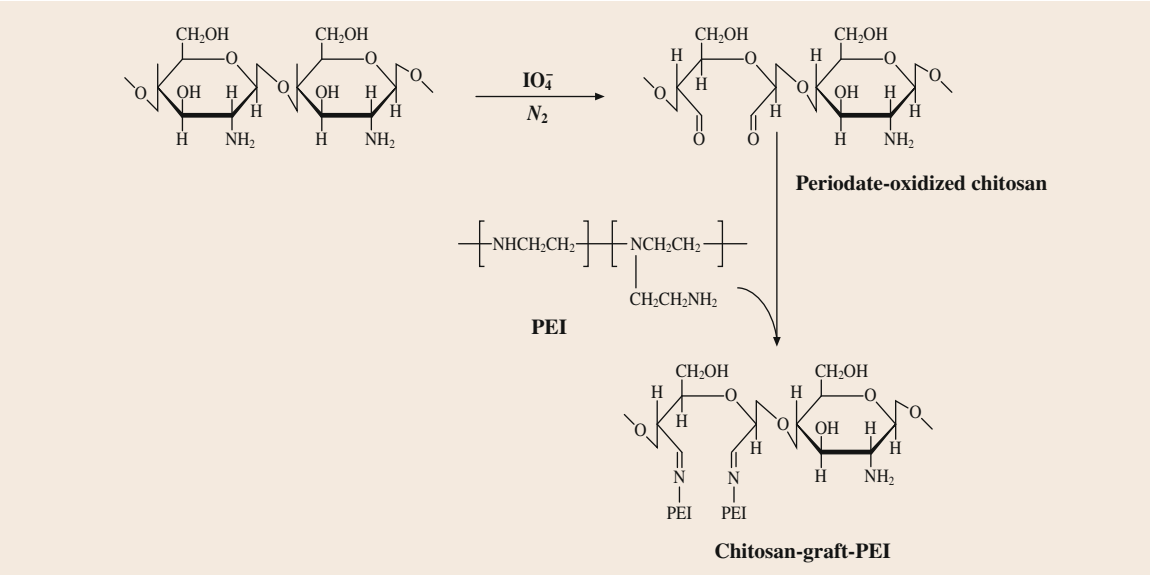

Fig. 54.2 Proposed reaction scheme for synthesis of chitosan-graft-PEI

PEG-graft-chitosan-graft-PEI (PCP) was prepared through polymerization of aziridine by PEG-g-chitosan to improve water solubility and transfection efficiency of chitosan [54.18]. The PCP showed higher tranfection efficiency in vitro than PEI 25 K with a lower cytotoxicity, and the transfection was markedly facilitated by serum owing to the PEG in the PCP.

PEI-conjugated stearic acid-graft chitosan (PEI-g-SAC) had good buffering capability and DNA binding capacity [54.19]. The transfection efficiency of PEI-g-SAC in HeLa and MCF-7 cells was comparable with Lipofectamine 2000 with a lower cytotoxicity and it was increased in the presence of serum. Furthermore, the PEI-g-SAC/pigment epithelium-derived factor DNA complexes effectively suppressed tumor growth without systematic toxicity after intravenous injection in mice.

Gene silencing experiment was also performed by using C-g-PEI to deliver Akt1 siRNA in A549 cells [54.20]. The C-g-PEI silenced more Akt1 protein, increased apoptosis, and decreased lung cancer proliferation malignancy than PEI 25 K.

Chitosan-graft-PEI-β-cyclodextrin (CPCD) was prepared through reductive amination between peroxidized chitosan and β-CD-PEI obtained by reaction of low MW PEI (600 Da) and tosylated β-CD to deliver siRNA in HEK293 and L929 cells [54.21]. The CPCD showed higher gene silencing in both cells than PEI 25 K with a lower cytotoxicity. The β-CD moieties in the pendent provided supramolecular architecture through self-assembly of adamantly modified PEG with the β-CD moieties and resulted in improved stability of the polyplexes under physiological conditions.

PEI-graft-chitosan was prepared by reaction of low MW linear PEI (2.5 K) with epichlorohydrin-modified chitosan containing three types of amines (1, 2, and 3°) for good buffering, proper binding and release of siRNA [54.22]. The PEI-g-chitosan showed higher green fluorescent protein (GFP) gene silencing than the Fugene system and 60% knockdown of JNKII, comparable to Lipofectamine, in HEK 293 cells.

54.2.2 Spermine

Spermine, which contains two primary and two secondary amine groups, is safe and naturally present in the body tissues [54.23]. It has a high buffering effect due to the secondary amine groups.

Chitosan-graft-spermine (CGS) was prepared through a reductive amination between periodate-oxidized chitosan and spermine to improve transfection efficiency of chitosan as shown in Fig. 54.3 [54.24]. The CGS showed good DNA binding ability and high protection of DNA from nuclease. The CGS also showed higher transfection efficiency in A549, WI-38, and HepG2 cells than chitosan itself and higher GFP expression in mouse lung compared with chitosan

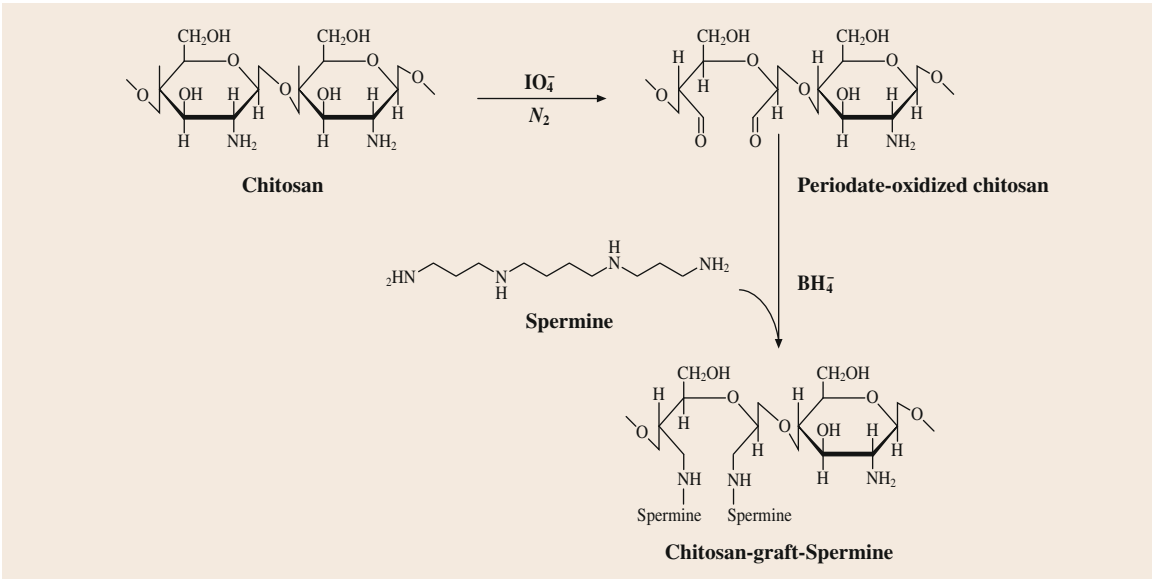

Fig. 54.3 Proposed reaction scheme for synthesis of chitosan-graft-spermine

after aerosol delivery due to high buffering ability of spermine.

Alex et al. [54.25] coupled spermine with galactosylated chitosan (GC) to improve transfection efficiency of chitosan and to target liver cells because asialoglycoprotein receptors on the hepatocytes can be recognized by galactose ligand [54.26]. The GC-g-spermine (GCS) showed higher transfection efficiency in HepG2 cells and the transfection efficiency was dramatically decreased by pretreatment of asialofetuin suggesting the receptor-mediated internalization of polyplexes. Similarly, GCS, prepared by different method, specifically delivered gene into HepG2 in vitro and liver cells in vivo due to the galactose ligand in the carrier [54.27]. Recently, they also prepared galactosylated PEG-chitosan-graft-spermine (GPCS) to deliver programmed cell death 4 (PCD4) as a therapeutic gene for suppression of tumor growth [54.28]. The GPCS had lower cytotoxicity in HepG2, HeLa, and A549 cells than PEI 25 K and showed good hepatocyte-targeting ability. Also, the GPCS showed higher GFP expression in the liver of mice after intravenous injection (IV) than PEG-chitosan-graft-spermine without remarkable inflammation. Furthermore, the GPCS/PCD4 complexes significantly suppressed tumor growth, proliferation and angiogenesis in liver tumor-bearing H-ras 12 V mice after intravenous injection, indicating the GPCS as a potential hepatocyte-targeting gene carrier.

54.2.3 Amino Acids

The introduction of amino acid moieties to the chitosan has been shown to increase the solubility and transfection efficiency of the chitosan. Among them, histidine, arginine, lysine, cysteine, or phenylalanine have been reported [54.29]. In this section, only pH-sensitive amino acid moieties will be covered.

Histidine

Histidine is mostly used as a modifying amino acid to improve transfection efficiency of chitosan due to its ability of endosomal escape as the imidazole ring present in the side chain of histidine has a pK_a of approximately 6.0 [54.30].

Urocanic acid (UA) containing imidazole group was first introduced into chitosan to increase transfection efficiency of chitosan [54.31]. The UA-coupled chitosan (UAC) showed about 1000-fold higher transfection efficiency in 293T cells than chitosan itself. Also, PCD4 gene was delivered to the K-ras null lung cancer model mouse via inhalation by UAC [54.32]. The UAC suppressed tumor angiogenesis and facilitated apoptosis in comparison with UAC. Furthermore, phosphatase and tensin homolog deleted on chromosome 10 (PTEN), a tumor suppressor gene, were delivered into a K-ras lung cancer model mouse via aerosol route using the UAC [54.33]. The UAC suppressed lung tumors through Akt-related signal pathway and cell cycle ar-

rest mechanism. The UAC was also used to deliver p53 into BALB/c nude mouse via intratumoral injection where the UAC similarly suppressed tumor growth in mouse [54.34].

Another type of imidazole acetic acid (IAA) was introduced to chitosan to improve transfection efficiency of chitosan by the buffering capacity of imidazole ring [54.35]. The IAA-coupled chitosan (IAAC) showed about 100-fold higher transfection efficiency than chitosan. Also, the IAAC was used to deliver β-galactosidase gene in 293T and HepG2 cells [54.36]. Although the transfection efficiency was increased by introduction of IAA into chitosan, the transfection efficiency was dependent on the substitution degree of IAA into chitosan. Furthermore, the IAAC was used to deliver glyceraldehyde 3-phosphate dehydrogenase (GAPDH) siRNA to the mouse through intravenous route after PEGylation of IAAC [54.37]. The carrier significantly knocked down GAPDH enzyme in lung and liver of the mouse at 1 mg kg^{-1} siRNA dose after intravenous administration.

4-Imidazole carboxaldehyde was introduced to the carboxymethyl chitosan obtained by reaction of monochloroacetic acid with chitosan to improve water solubility and transfection efficiency of chitosan [54.38]. The *N*-imidazolyl-*O*-carboxymethyl chitosan was soluble in a wide pH range (4−10) and showed higher transfection efficiency in HEK293T cells than chitosan without remarkable cytotoxicity. However, the transfection efficiency was dependent on the degree of imidazole substitution.

Arginine

Arginine-rich peptides as the cell-penetrating peptides (CPPs) have attracted much attention in gene delivery owing to promotion of cell internalization by the cationic property of the arginine [54.39]. Therefore, arginine-graft-chitosan (AGC) was prepared in order to deliver DNA into HEK293 and COS-7 cells [54.40]. The AGC showed higher transfection efficiency in both cells with pH-dependency than chitosan itself but the transfection efficiency was still lower compared to Lipofectamine 2000.

Noh et al. [54.41] prepared PEG-graft-chitosan-graft-polyarginine (PCPA) to deliver siRNA such as a murine survivin-specific siRNA in vitro and in vivo. The PCPA showed higher gene silencing than chitosan due to enhanced cellular delivery of siRNA by polyarginine, reduced hemolysis of erythrocytes and increased stability of the polyplexes in the biological conditions by PEGylation. Also, intratumoral administration of PCPA/red fluorescent protein (RFP) siRNA complexes silenced the expression of RFP in RFP-expressing tumor tissues in vivo.

Zhang et al. [54.42] studied endocytic pathways of AGC after conjugation of Alexa Flour 488 in A10 cells in the presence of several inhibitors of endocytosis pathways. Interestingly, they reported that the increase of cellular uptake and transfection efficiency by the AGC was probably due to preferentially caveolin-mediated endocytosis pathway in comparison with the chitosan because the caveolin-mediated endocytosis can avoid the endosomal/lysosomal degradation of the gene.

54.3 Alginate

Alginate has been produced from the primary structural component of brown seaweed. The alginate as the monovalent form of alginic acid is a linear polysaccharide consisting of β(1–4)-linked D-mannuronic acid and (1–4)-linked L-guluronic acid as shown in Fig. 54.4. Nonetheless, the ratio of mannuronic acid and guluronic acid in the alginate is dependent on the source of brown seaweed. The alginate has been widely applied for the delivery of cells and drugs because cells and drugs are easily loaded in the alginate due to rapid gelation property in the presence of divalent cations. In this section, we only explain alginate nanoparticles to deliver genes due to page limitation although alginate microspheres and alginate microcapsules have been used to deliver genes.

54.3.1 Alginate/Chitosan Nanoparticles

Alginate/chitosan nanoparticles were prepared by controlling the ratio of alginate to chitosan MW of both polymers and pH to apply for the gene delivery system [54.43]. The smallest nanoparticles around 323 nm were formed using low MW polymers with pH between 5 and 5.6 and having an alginate/chitosan weight ratio of 1 : 1.5. But, they did not perform gene transfection. On the other hand, alginate/chitosan nanoparticles were used to deliver smad3 antisense oligonu-

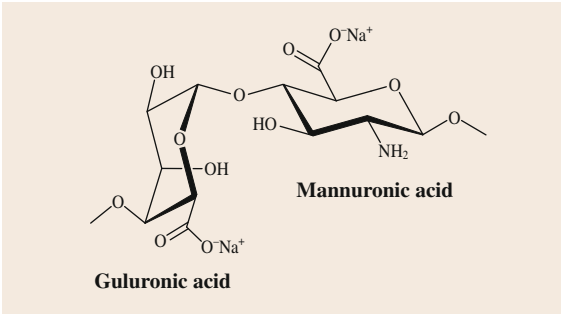

Fig. 54.4 Schematic diagram of alginate

cleotides for wound healing of excisional wounded mouse because the smad3 plays an important role in the elaboration of matrix pivotal to cutaneous wound healing [54.44]. The results indicated that wound closure and histological healing process were faster than other groups such as nanoparticles without gene, gene, and gauze dressing. Furthermore, *Azizi* et al. delivered epidermal growth factor receptor (EGFR) antisense by alginate/chitosan nanoparticles for checking release of the antisense and stability of nanoparticles in aqueous medium and after freeze drying [54.45]. The results showed that the antisense was released from antisense-loaded nanoparticles for 50 h and sizes of the nanoparticles were not much changed after freeze drying, but they did not perform the gene knock-down property.

54.3.2 Alginate/PEI Nanoparticles

Due to high MW PEI has high cytotoxicity in cells, alginate was used to shield partially positive charges of PEI [54.46]. Although the transfection efficiency of the PEI in COS-1 cells was improved by about 2 to 16 fold by hybrid with alginate, the optimum weight ratio of alginate to PEI is very critical in transfection efficiency. Also, alginate/PEI nanoparticles delivered siRNA into mammalian cells and resulted in 80% suppression of GFP expression. They also compared effect of MW of used PEIs on gene silencing of siRNA in COS-1 cells [54.47]. The results showed that 20 times lower concentration of GFP siRNA by the PEI 25 K was needed for gene silencing than PEI 750 K.

Recently, low MW PEI (2000 Da) was grafted onto alginate in order to achieve low cytotoxicity and high transfection efficiency of the polymer [54.48]. The alginate-g-PEI retained the buffering capacity of native PEI and mediated higher vascular endothelial growth factor (VEGF) expression in BEL7402, MSC, and RVMSC cells with a lower cytotoxicity than PEI25K.

54.3.3 Alginate/Calcium Carbonate Nanoparticles

Calcium carbonate ($CaCO_3$) has been used to deliver DNA because of its good biocompatibility and biodegradability. However, nanoparticles of $CaCO_3$/DNA complexes are uncontrollable, resulting in large sizes which affects cellular internalization and transfection efficiency of gene. Therefore, alginate was used to control the growth of gene-loaded $CaCO_3$ nanoparticles [54.49]. The results indicated that alginate retarded the growth of $CaCO_3$-based DNA co-precipitates and enhanced stability of $CaCO_3$/DNA nanoparticles. Also, gene transfection efficiency of alginate-modified nanoparticles was significantly enhanced as compared with the nanoparticles without alginate modification. They also loaded doxorubicin (DOX) as an antitumor drug into alginate/$CaCO_3$/p53 DNA nanoparticles for synergistic effect of antitumor activity by antitumor gene and drug [54.50]. The alginate/$CaCO_3$/DNA/DOX nanoparticles exhibited higher cancer cell inhibition rate of about 80% than $CaCO_3$/DNA/DOX, alginate/$CaCO_3$/DOX and alginate/$CaCO_3$/DNA nanoparticles.

54.3.4 Pullulan

Pullulan is a nonionic linear polysaccharide produced by the *Aureobasidium pullulans* isolated from marine environments [54.51]. It consists of maltotriose type units, i. e., α-(1–6)-linked (1–4)-α-D-triglucosides as shown in Fig. 54.5 [54.52]. The pullulan has been widely applied for the food, pharmaceutical and paper production and as a enzyme immobilization support due to nontoxic, biocompatible, nonimmunogenic, and biodegradable properties. In this section, pullulan derivatives will be explained as gene carriers.

54.3.5 PEI

PEI 25 K was grafted into pullulan-succinimidyl carbonate for liver cell gene delivery [54.53] because the pullulan has inherent liver affinity. The transfection efficiency of pullulan-graft-PEI in HepG2 cells was similar to PEI 25 K, with hemocompatibility and low cytotoxicity, and increased even in the presence of serum.

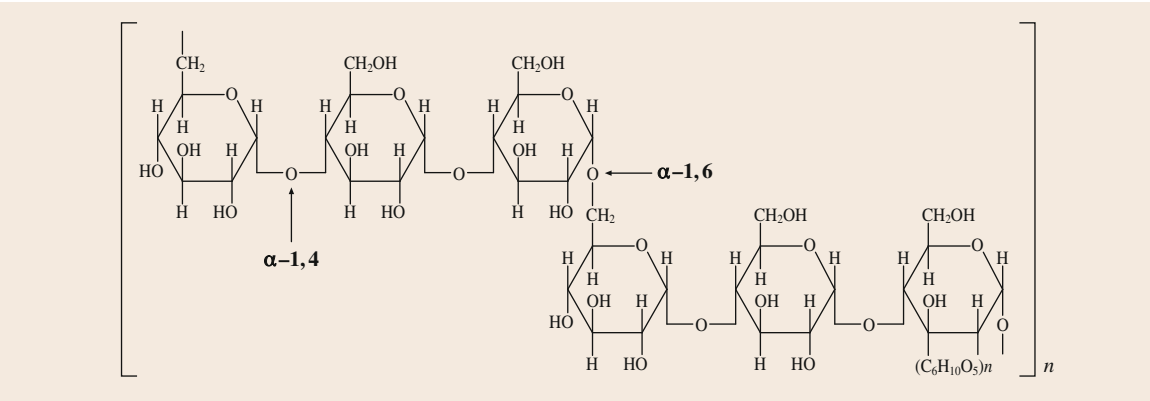

Fig. 54.5 Schematic diagram of pullulan

54.3.6 Spermine

Spermine was firstly introduced into the hydroxyl groups of pullulan using a *N*,*N*′-carbonylidiimidazole activation agent for liver targeting of gene [54.54]. The gene expression in the liver by pullulan-graft-spermine (PU-g-SP) was dependent on the degree of introduced spermine in the pullulan. Also, the tumor-bearing mice survived for a longer time and the number of tumor cells grown in the liver were lower than free DNA after intravenously injection of NK4 DNA by PU-g-SP. The efficient gene expression by the PU-g-SP was confirmed by the clathrin- and raft/caveolae-dependent endocytosis pathways [54.55]. The transfection efficiency of the PU-g-SP depended on the degree of introduced spermine [54.56] and MW of pullulan [54.57] in the PU-g-SP. They also found the highest transfection in rat sensory neuron cells by negatively charged PU-g-SP/DNA complexes obtained at the N/P ratio of 1 due to the glycoprotein-specific interactions and claveolae-dependent endocytosis cellular uptake [54.58]. However, they did not explain why negative charge zeta potential was obtained by polyplexes of N/P ratio of 1. Furthermore, the reverse transfection method was used to deliver mouse Notch intracellular domain (NICD) gene into bone marrow stomal cells (BMSCs) for induction of dopamine-producing neuronal cells by the PU-g-SP [54.59]. The introduced exogenous genes were expressed in the cytoplasm of BMSCs and the differentiation of induced neuronal cells into dopamine-producing cells was promoted by treatment with trophic factors.

Additionally, gene was delivered into rat mesenchymal stromal cells (MSCs) seeded into the biodegradable gelatin scaffold by the PU-g-SP [54.60]. The transfection efficiency was dependent on the method of complex during scaffold preparation. When hepatocyte growth factor (HGF) gene as the therapeutic gene for the treatment of liver antifibrosis was delivered in a rat model of liver fibrosis through intravenous injection by the PU-g-SP, the fibrosis area in the rat was significantly decreased compared with that of original MSCs [54.61].

Recently, human growth hormone 1 (hGH1) gene was delivered to rat brain endothelial (RBE) cells and human brain microvascular endothelial (HBME) cells by the PU-g-SP for allowing hGH1 protein to enter the brain [54.62]. It was found that transfection of HBME cells by the PU-g-SP led to secretion of hGH1 protein into the growth medium but they did not perform in vivo.

54.3.7 Diethylaminoethyl (DAE)

2-chloro-*N*,*N*-diethylethylamine hydrochloride was reacted with pullulan to deliver secreted form of alkaline phosphatase (SEAP) DNA in smooth muscle cells [54.63]. The pullulan-graft-DAE showed 150-fold higher SEAP activity than SEAP gene. Also, the pullulan-graft-DAE was crosslinked by phosphorus oxychloride to make 3-D matrices for loading DNA. The 3D matrices protected SEAP gene from enzyme and showed significant gene transfer without cell toxicity. Also, the tubular pullulan-graft-DAE hydrogel was used to deliver DNA in vascular smooth muscle cells [54.64] where the transfection efficiency was dependent on the degree of DAE in the pullulan-graft-DAE. Furthermore, the pullulan-graft-DAE hydrogel was used to coat stent for delivery of siRNA targeted to matrix metalloproteinase 2 (MMP2) in vascular

cells [54.65]. The siRNA-loaded pullulan-graft-DAE hydrogel in rabbit balloon-injured carotid arteries provided release of siRNA from the stent into the arterial wall and a decrease of pro-MMP2 activity.

54.3.8 Glycidyl Trimethyl Ammonium (GTA)

GTA was introduced into pullulan to deliver gene to hepatocytes in vitro and liver in vivo [54.66]. The pullulan-graft-GTA showed higher transfection efficiency in HepG2 cells and higher liver binding affinity in mice than PEI 2 K with a lower cytotoxicity and blood compatibility owing to specific interaction of pullulan with liver cells.

54.3.9 Chelate Residues with Zinc Ion Coordination

Triethylenetetraamine (TTE), diethylenetriamine pentaacetic acid (DTP) and spermine as the chelate residues with Zn^{2+} coordination were conjugated with pullulan to deliver gene into liver cells [54.67]. The level of gene expression in the pullulan-graft-DTP with Zn^{2+} coordination was significantly higher than that in the pullulan-graft-DTP after injection to mice through intraveneous route. Although the gene expression was dependent on the degree of chelate residues introduced, the function of Zn^{2+} coordination was not clear.

54.3.10 Summary

In this chapter, chitosan, alginate, and pullulan among polymeric materials have been explained as nonvirus vectors for gene delivery carriers. Chitosan and chitosan derivatives have been widely used in vitro and in vivo studies than alginate and pullulan due to the positive charge property of chitosan itself. Further research is needed to find the relationship between structure of marine materials and their gene delivery function. A number of scientific researches are still required to support the evidence of potential use of marine materials before preclinical trials.

55. Marine Organisms in Nanoparticle Synthesis

Pallavi Mohite, Mugdha Apte, Ameeta R. Kumar, Smita Zinjarde

The interdisciplinary science of nanotechnology requires input from physical, chemical, biological, and material scientists. The drawbacks associated with the conventional physical or chemical methods of synthesizing nanoparticles are often circumvented when biological systems are employed. The role of terrestrial organisms in nanoparticle synthetic procedures have been discussed on earlier occasions, and a summary on biological forms associated with marine ecosystems mediating such metal-reductive processes is given here. Organisms in the marine environments need to rapidly adjust to the dynamic conditions that they encounter. In order to resist metal fluxes, marine organisms synthesize novel biomolecules that can reduce metal ions and form nanostructures. In this chapter, the role of various marine organisms (bacteria, fungi, algae, plants, and sponges) in synthesizing metal nanoparticles, their structural characterization, applications in different fields, and the mechanisms involved in the synthetic procedures have been discussed. In the concluding section, the need to investigate the hitherto unexplored wide plethora of organisms in forming nanoparticles of different metals, means of increasing productivity, extending applications, and deciphering mechanisms is highlighted.

55.1 Basic Concepts in Nanotechnology

55.1.1 Brief History of Nanotechnology

Nanotechnology is an interdisciplinary science encompassing the fields of physics, chemistry, biology, materials science and medicine. The word *nanotechnology* is derived from the Greek word *nanos* meaning *dwarf*. Unlike the parent bulk material, nanoparticles display different physical, chemical, mechanical, and optical features [55.1]. These unusual properties are due to the quantum confinement of electrons within particles

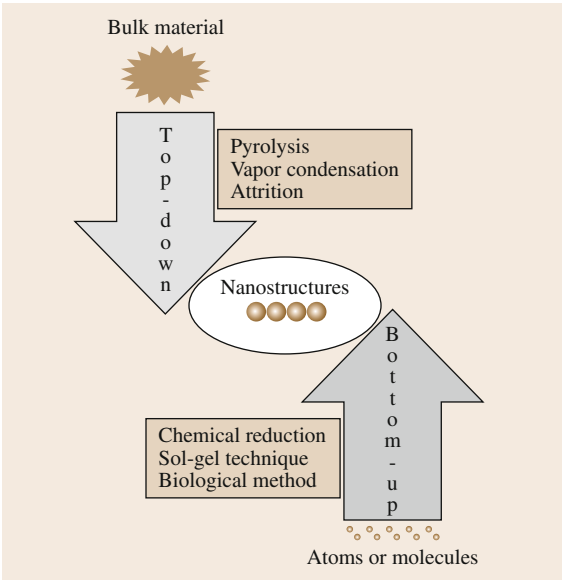

Fig. 55.1 General scheme for the synthesis of nanoparticles with representative methods

of dimensions smaller than the bulk electron delocalization length [55.2]. The concept of nanotechnology dates back to the ninth century. Nanoparticles of gold and silver were used by artisans to add glittering effects to pots and were also included in glass panes in cathedrals. The first scientific description of nanoparticles was given by Michael Faraday in an article entitled *Experimental relations of gold (and other metals) to light* [55.3]. In 1959, almost a century later, Richard Feynman explained the concept of nanotechnology in the lecture *There's plenty of room at the bottom* at the American Institute of Technology. The pioneering research article by *Drexler* entitled *An approach to the development of general capabilities for molecular manipulation* implicated the role of molecular engineering in the advancement of technology to different areas [55.4]. Thereafter, the concept of nanotechnology was revolutionized with advances in techniques such as the transmission electron microscope (TEM), the scanning electron microscope (SEM), the atomic force microscope (AFM), Fourier transform infra red spectroscopy (FTIR), and dynamic light scattering (DLS), to mention a few. At present, this field is at a juncture where it could provide solutions to a variety of challenges.

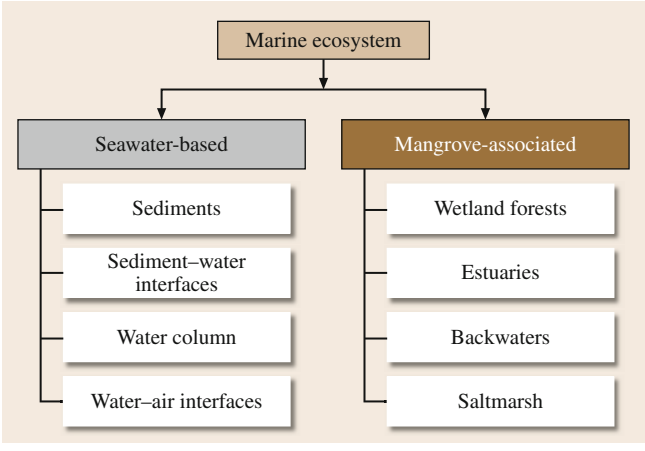

Fig. 55.2 Summary of marine ecosystems

55.1.2 Synthesis of Nanoparticles by Different Approaches

Nanoparticles can be synthesized by two approaches. The *top-down* method involves the gradual de-sizing of bulk material to nanostructures. Examples of such methods include pyrolysis, vapor condensation, and attrition. *Bottom-up* processes build nanostructures beginning at the atomic or molecular levels. The sol-gel technique and chemical reduction (with sodium borohydride or sodium citrate) are two representative examples involving this approach. Chemical and physical methods are often cost intensive, cumbersome, and may involve the use of toxic chemicals. These approaches have been summarized with representative examples in Fig. 55.1.

On account of these shortcomings, there was a need to develop some inexpensive, eco-friendly alternative methods. With pioneering studies on the use of biological systems in mediating nanoparticle synthesis, several of the aforementioned limitations were overcome. Nanoparticle synthesis by biological systems is a *bottom-up* approach based on oxidation-reduction potentials of different biomolecules. Various terrestrial and aquatic organisms such as plants, algae, filamentous fungi, yeasts, bacteria, and viruses are capable of synthesizing nanoparticles. Compared to the extensive reports on the synthesis of nanostructures by terrestrial or freshwater organisms, their counterparts in the marine environment have received less attention and are discussed in the following sections.

55.2 Marine Ecosystems

Oceans and seas account for about 71% of the total water on Earth. Ecosystems associated with these water bodies help in maintaining the balance of marine as well as terrestrial environments and contribute largely towards biological productivity. These systems can be broadly divided into two categories (i) seawater-based systems (sediments, sediment–water interfaces, water column, and water–air interfaces), and (ii) mangrove (wetland forests found along the coasts, in estuaries, backwaters, and marshes) associated ecosystems, as summarized in Fig. 55.2.

These are regarded as hotspots of biodiversity and varied biological forms with nutritional versatility are encountered here. Physical parameters such as light, temperature, pressure, and availability of organic substrates influence the biodiversity under these conditions.

55.3 Nanostructures Inherently Produced by Marine Organisms

Several marine biological forms inherently produce nanomaterials as a part of their physiology. The synthesis of such nanostructures involves the biomineralization and assimilation of inorganic compounds in definite sizes, morphologies, and patterns. Siliceous material in diatoms and magnetosomes in magnetotactic bacteria are classical examples of naturally occurring nanostructures in unicellular forms. In diatoms, specific proteins referred to as silaffins and long-chain polyamines mediate the conversion of silicic acid into silica particles [55.5]. In magnetotactic bacteria, biomineralization of iron occurs in specialized membrane-enveloped structures termed magnetosomes. Iron in the form of magnetite (Fe_3O_4) or greigite (Fe_3S_4) is accumulated in them. These structures are usually arranged in chains and enable the cells to align themselves along geomagnetic lines and move to microoxic zones favoring their growth [55.6, 7]. In both these cases, a degree of control over size, shape and assembly is observed. Higher forms such as seashells and fish bones also display natural nanostructures [55.8]. The pearly internal layer (nacre) of mollusc shells consists of aragonite (a form of calcium carbonate). These particles are layered in a brick-like arrangement and confer strength to the shells.

55.4 Metal Interactions in Marine Biological Forms

Conditions in the sea are dynamic, and organisms encountered here have developed the ability to adapt rapidly to these changes. Factors such as influxes of industrial effluents, transport, and oil-spills contribute

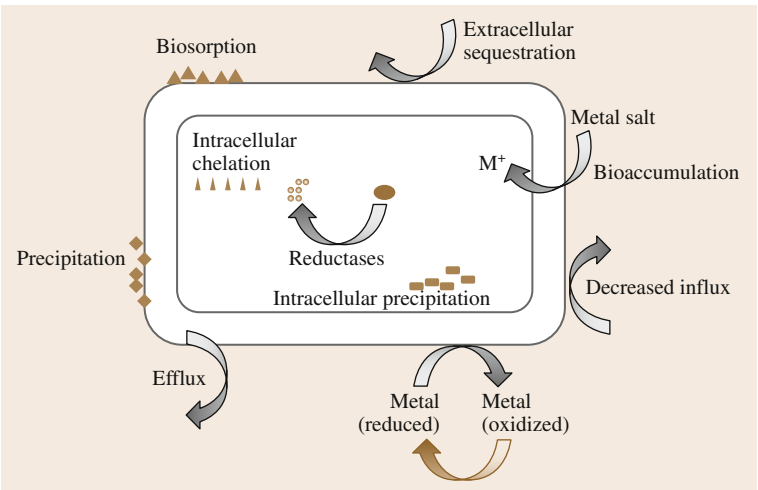

Fig. 55.3 Summary of biometal interactions

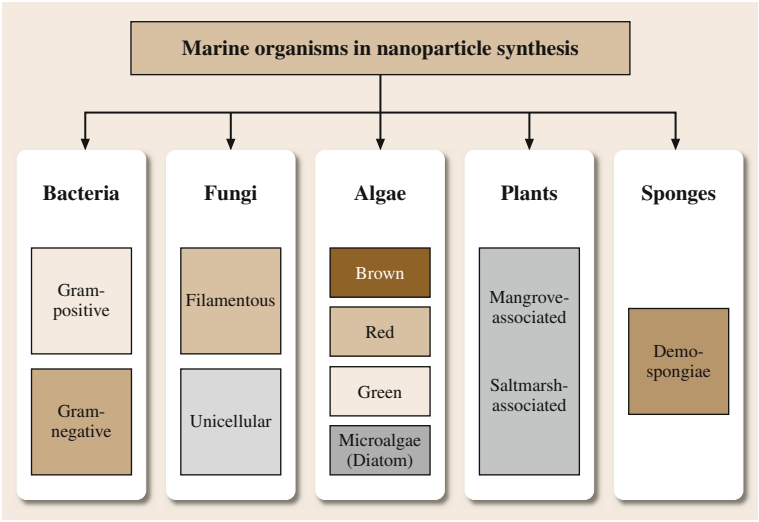

Fig. 55.4 Marine biosystems synthesizing metal nanomaterials

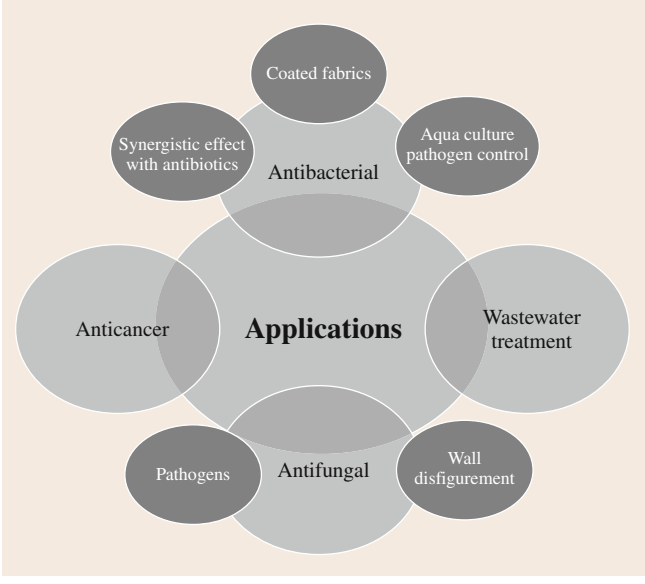

Fig. 55.5 Applications of nanoparticles derived from marine biosystems

towards shock loads of organic and inorganic constituents in the marine environment [55.9]. Organisms associated with such systems often synthesize a variety of biomolecules to combat the effect of different pollutants, including metal species. Most living forms adapt to the presence of metals via processes such as biosorption, bioprecipitation, extracellular sequestration, and/or chelation [55.10], as depicted in Fig. 55.3. An outcome of these processes may be the synthesis of metal nanoparticles either in a cell-associated form or in the extracellular manner [55.11].

Included here is an overview on the role of the different marine biosystems including bacteria, fungi, algae, plants, and sponges in synthesizing metal nanomaterials (Fig. 55.4).

The methodology adopted, characteristics, and mechanistic aspects of different types of nanostructures mediated by these marine systems are discussed. Most of the applications reported for these nanomaterials are in the field of medicine, particularly as antibacterial, antifungal, and anticancer agents as shown in Fig. 55.5. These applications are also described briefly in the appropriate sections.

55.5 Bacteria in Nanoparticle Synthesis

A variety of bacteria are associated with the marine environments. Most of them adapt to the physical and chemical conditions that they encounter, and diverse species have evolved. In general, bacteria have been extensively exploited for the synthesis of nanoparticles. One of the reasons for their preference is the ease with which they can be cultivated and manipulated in the laboratory. Since bacteria are exposed to different met-

als, they have developed mechanisms to resist them. They build up efflux systems, change the redox states of metal ions, mediate extracellular complexation or precipitation, and exclude metals via specific transport systems [55.12–14].

Marine species of *Escherichia*, *Pseudomonas*, *Serratia*, *Marinobacter*, *Shewanella*, *Halomonas*, *Brevibacterium*, *Bacillus*, and *Streptomyces* isolated from different sources are reported to mediate nanoparticle synthesis under laboratory conditions when challenged with metal salts. Most of these bacteria belong to the Gram-negative group. The low peptidoglycan content in the cell wall and the presence of a lipopolysaccharide layer with phosphate and carboxyl groups are said to be responsible for interaction with metal ions [55.15, 16].

Moreover, most of the reports are related to the synthesis of silver nanoparticles and the bacteria have mainly been isolated from mangroves or sponges. The following sections summarize the nanoparticle synthetic capabilities of these bacteria.

55.5.1 Gram-Negative Bacteria

Escherichia coli, a model system used for a variety of practical purposes, has been isolated from different environments. A strain of *E. coli* AUCAS 112 was obtained from a coastal mangrove sediment sample (Vellar estuary, India). This mediated the synthesis of silver nanoparticles in a short duration of time (6 h). When these nanoparticles were stabilized with polyvinyl alcohol, they displayed effective antimicrobial activity against a variety of clinical fungal and bacterial species as evaluated by a log reduction test. FTIR analysis suggested the role of proteins as capping and stabilizing agent [55.17].

Silver nanoparticles have also been synthesized by the cell-free extracts (CFE) of *Pseudomonas aeruginosa* M6 isolated from a mangrove forest in Pitchavaram, Tamil Nadu, India. The CFE was prepared by sonicating culture pellets and the cell debris was removed by centrifugation. Nanoparticle synthesis by two thermal methods was evaluated at pH 9 (i) by boiling, referred to as conventional thermal treatment (CTT), and (ii) via microwave treatment (MWT). The silver nanoparticles synthesized by the former method were smaller 10–12 nm and those by the latter technique were larger and were composed of silver oxide. The bioaccumulation of silver ions led to the synthesis of silver nanoparticles in the periplasmic space of the bacterium. The enzyme nitrate reductase was speculated to mediate the reductive process. Nanoparticles synthesized by both CTT and MWT displayed efficient antibacterial and anticandidal activities [55.18]. Another marine species of *Pseudomonas* (ram bt-1) has been effective in intracellular synthesis of silver nanoparticles. The nanoparticles ranged in size between 20–100 nm and they were stable even after 4 months. The particles were predominantly spherical although some nanotriangles were also observed [55.19].

A variety of culture collection strains and some marine bacteria were screened for their silver nanoparticle synthetic abilities. The marine bacteria screened were *Pseudomonas fluorescens*, *Vibrio natriegens*, and *Bacillus flexus*. While the marine cultures mediated rapid synthesis of silver nanoparticles (6–15 h), the terrestrial strains required longer incubation periods (24–48 h). Among the marine species, *P. fluorescens* mediated the extracellular synthesis of spherical silver nanoparticles (1–10 nm) in the shortest time duration (6 h). These nanoparticles could be coated on polycaprolactam (a biomaterial used extensively in medicine and the food industry) to form biocompatible composites. Moreover, the antibiofilm activities of the composites and the uncoated silver nanoparticles against *E. coli, Staphylococcus aureus* and *Candida albicans* were also evaluated. The nanoparticles caused extensive bacterial cell damage when assessed by the LIVE/DEAD kit [55.20].

Serratia marcescens associated with insect gut is known to mediate nanoparticle synthesis [55.21]. Marine isolates of *S. marcescens* have also effectively formed nanostructures of bismuth, antimony sulfide, and cadmium. A strain of *S. marcescens* was isolated from the Caspian Sea, Northern Iran and used for the biosynthesis of bismuth nanoparticles. The cell-associated nanoparticles were extracted by crushing with liquid nitrogen and purified by extraction with *n*-octanol : water (1 : 2). The biologically synthesized bis-

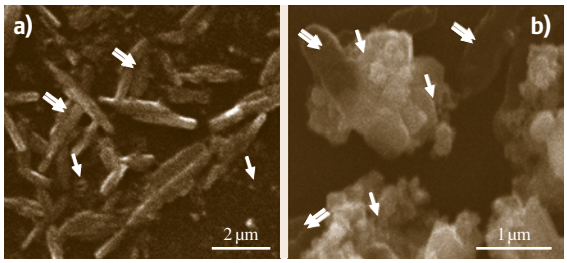

Fig. 55.6a,b Cell-associated synthesis of Cd nanostructures and aggregates by **(a)** *Serratia marcescens*, **(b)** *Bacillus pumilus*. The *white arrow* points to the nanostructures or aggregates and *double arrows* point to cells

muth nanoparticles formed amorphous aggregates. The strong magnetite properties displayed by bismuth at the nanoscale level caused the aggregation [55.22]. This bacterium also formed intracellular antimony sulfide (Sb_2S_5) nanoparticles (confirmed on the basis of energy dispersive spectra (EDS) profiles) that could be extracted by the above-mentioned protocol [55.23]. These nanoparticles were 10–35 nm in size and displayed a characteristic spectral peak at 258 nm. The role of a tropical marine strain of *Serratia marcescens* in synthesizing nanostructures of semiconducting materials was also reported recently. Cadmium oxide (CdO) and cadmium sulfide (CdS) nanostructures were effectively synthesized by this strain in a cell-associated as well as an extracellular manner (Fig. 55.6a). The CdO and CdS nanostructures were 40–45 nm and 15–20 nm, in size, respectively, and displayed fluorescence properties. These bio-inspired nanosized cadmium structures could be applied in biomedical imaging and in different devices [55.11]. The same strain also formed cadmium telluride quantum dots with strong photoluminescence properties. These non-toxic nanostructures were effectively used for imaging yeast and animal cells [55.24].

Different marine strains of bacteria (*Marinobacter pelagius* RS8, *M. pelagius* RS11, *Halomonas ventosae* RS15, *Pseudoalteromonas mariniglutinosa* LD4, *P. mariniglutinosa* LD14, *Alteromonas* sp., *A. macleodii*, *Marinobacter vinifermus*, *H. ventosae* K4, *M. salsuginis* K20, *Photobacterium ganghwense*) were isolated from Lakswadeep, Kakinada and West Bengal, India. Among these only *M. pelagius* RS11 mediated the synthesis of gold nanoparticles. This result suggests that not all marine bacteria have the ability to reduce metal salts to their nanostructures. The particles were 2–10 nm and a time-dependent change in particle size was observed. FTIR analysis indicated the possible involvement of proteins in the synthetic process [55.25].

The Gram-negative bacterium *Shewanella algae* is known to reduce metals such as iron, uranium, and plutonium under anaerobic conditions by using them as terminal electron acceptors. The resting cells of *S. algae* ATCC 51181 collected from the Great Bay estuary, USA, reduced platinum chloride to platinum nanoparticles within 60 min at pH 7.0 and 25 °C in the presence of lactate. A color change from yellow to black was observed. TEM images of thin sections of cells showed that the nanoparticles were 5 nm in size and were located in the periplasmic space. X-ray adsorption near edge spectroscopy (XANES) confirmed the presence of platinum in the elemental form. In this marine bacterium, the deposition of platinum was seen to occur in two steps: (i) $PtCl_6^{2-}$ ions were initially taken up from the aqueous solution into the periplasmic space, and (ii) the $PtCl_6^{2-}$ ions were reduced to platinum with lactate as the electron donor [55.26].

The halophilic archaeon, *Halomonas salina* has been exploited for the extracellular synthesis of gold nanoparticles. With 100 ppm gold salt concentration, optimum synthesis was observed at 30 °C, pH 9.0 in 24 h. These nanoparticles were found to be salt-stable (5 M NaCl). Under acidic conditions (pH 2.0, 3.0, and 4.0) the broad peaks and humps observed were indicative of the possible aggregation of the nanoparticles. Under alkaline conditions (pH 9.0 and 10.0), sharp peaks at 528 and 558 nm, respectively, typical of gold nanoparticles were obtained. The gold nanoparticles were anisotropic (spherical or triangular) between 30–100 nm at low pH. However, under alkaline conditions the formation of spherical nanoparticles was favored. It was hypothesized that some alkali stable components reduced and capped the nanostructures at specific facets, and the role of reductases was also suggested [55.27].

55.5.2 Gram-Positive Bacteria

A few Gram-positive marine bacteria are also reported to mediate the synthesis of nanoparticles under laboratory conditions. The role of cell wall-associated carboxyl groups and teichoic acids in metal deposition is well established in *Bacillus* sp. [55.28]. A strain of *Bacillus subtilis* MSBN17 associated with a marine sponge (*Collyspongia diffusa)* from the south-east coast of India was isolated. The production of a polysaccharide bioflocculant by this bacterium was optimized using response surface methodology. The ethanol precipitated bioflocculant mediated the synthesis of spherical silver nanoparticles (60 nm) at pH 7.0 after 12 h. The role of sugar derivatives in the formation and stabilization of nanoparticles was indicated by FTIR analysis. The synergistic antibacterial effect of silver nanoparticles with different antibiotics was demonstrated and these could also be applied in wastewater treatment procedures [55.29]. Another species, *Bacillus pumilus*, has been isolated from titanium coupons immersed in seawater near Kalpakkam, India [55.30]. This isolate mediated the synthesis of cell-associated and extracellular CdO and CdS nanostructures. The cell-associated nanostructures are depicted in Fig. 55.6b. These photoluminescent nanostructures displayed an absorption

maximum at 328 nm and could be used for a variety of applications [55.11]. The same marine culture of *Bacillus pumilus* also formed CdTe quantum dots that were photoluminescent. These were used for fluorescence staining of yeast and animal cells [55.24].

There are a few reports on marine actinomycetes involved in nanoparticle synthesis. An example of this is a glycolipid biosurfactant producing strain of *Brevibacterium casei* (MSA19). This has been isolated from the marine sponge *Dendrilla nigra* found along the south-west coast of India. Solid state fermentation on agro-industrial and industrial waste resulted in the increased production of this surfactant. Since there have been reports on biosurfactant mediated synthesis and stabilization of nanoparticles [55.31] further studies on the *Bacillus casei* surfactant were undertaken. This biosurfactant formed water-in-oil-microemulsions and reduced silver salts to nanoparticles. These nanoparticles were stable at room temperature for 2 months. The biosurfactant acted as a stabilizing agent and prevented aggregation of the nanostructures [55.32].

A few species of *Streptomyces* of marine origin are also implicated in the formation of nanostructures. Extracellular and intracellular synthesis of silver nanoparticles by *Streptomyces albidoflavus* has been reported. The nanoparticles were spherical and monodispersive in nature with a size ranging between 10–40 nm. The nanoparticles were capped with proteins and displayed antimicrobial activity [55.33]. Another species of *Streptomyces* (*S. hygroscopicus*) was isolated from the Pacific Ocean, near the Philippines. The extracellular synthesis of silver nanoparticles by using this strain was carried out at pH 6.5 for 24 h at 30 °C. The silver nanoparticles synthesized were spherical and 20–30 nm in size. On extended incubation, anisotropic structures were formed. The antimicrobial activity of silver nanoparticles was checked against Gram-positive and Gram-negative bacteria, and yeasts [55.34]. Zinc and copper oxide nanoparticles were synthesized by another *Streptomyces* sp. isolated from the Pichavaram mangrove, India. The supernatant and pellet mediated the formation of metal oxide nanoparticles that were 100–150 nm in size. These bio-inspired nanoparticles were coated on cotton fabric. The antibacterial activity of these coated fabrics was checked against pathogenic bacterial and fungal cultures. Copper oxide nanoparti-

Table 55.1 Summary of nanoparticles synthesized by different types of marine bacteria

Bacteria	Type of nanoparticle	Size (nm)	Location	References
Escherichia coli	Ag	5–20	Extracellular	[55.17]
Pseudomonas aeruginosa M6	Ag	12–42	Extracellular	[55.18]
Pseudomonas sp. *ram bt-1*	Ag	20–100	Intracellular	[55.19]

Phormidium tenue NTDM05	CdS	5	–	[55.38]

cle coating was more effective and these fabrics could be used in medical settings to prevent or minimize infections [55.35].

55.5.3 Blue–Green Bacteria

A few species of blue–green bacteria are also reported to synthesize nanostructures. Washed cells of *Oscillatoria willei* (NTDM01) obtained from Kurusadai Island, India, were incubated with silver nitrate at 2 °C for 28 days and kept in the dark. Silver nanoparticles were synthesized in an extracellular manner. They were spherical nanoparticles and 100–200 nm in diameter. FTIR analysis indicated the role of proteins in the synthesis of the nanoparticles. The reduction of the silver ions was thought to be mediated by nitrate reductase and phytochelatin. The silver nitrate killed the cells and the biomolecules released outside mediated the synthesis of silver nanoparticles [55.36].

Biomass of another cyanobacterium *Phormidium cyanobacterium* was used for synthesizing copper oxide nanoparticles. After 36 h of incubation with $CuSO_4$ and centrifugation, the UV-visible spectra of the supernatants showed a blue shift, indicating the synthesis of nanoparticles. TEM images after 42 h of incubation showed that particles that were quasi-spherical with a size of about 10–40 nm. Some irregular aggregates were also seen. It was suggested that the uniform distribution of the nanoparticles was due to the presence of a protein moiety which formed a matrix-like structure in which they were embedded. Furthermore, three additional proteins were found to be induced when the cells were exposed to the gold salt. These possibly acted as reducing and capping agents [55.37]. Another species of *Phormidium*, (*P. tenue* NTDM05) was used to synthesize cadmium sulfide nanostructures. TEM analysis revealed the size of the CdS nanoparticles to be about 5 nm. The pigment-stabilized (C-phycoerthrin) nanoparticles could be applied in biolabeling studies [55.38]. A summary of nanoparticle synthesis by different types of marine bacteria is presented in Table 55.1.

55.6 Fungi in the Synthesis of Nanomaterials

Fungal species isolated from different marine environments represent approximately about 0.6% of the total fungi studied [55.39]. They are found as free-living forms or maybe associated with other marine organisms such as sponges [55.40]. It is known that some fungi play an important role in the bioremediation of toxic metals and possess the necessary enzymatic setup for their detoxification [55.41]. Filamentous fungi and yeasts isolated from marine habitats can mediate the synthesis of a variety of nanoparticles. A general observation is that most of the marine fungi mediating nanoparticle synthesis are ascomycetous in nature. Fungi offer certain advantages over bacteria when bulk production of nanoparticles is desired. They often secrete large quantities of enzymes, proteins and biomolecules in an extracellular manner and can grow rapidly on relatively simple media.

55.6.1 Filamentous Fungi

Compared to their terrestrial counterparts, there are relatively few reports on the synthesis of nanoparticles by fungi of marine origin. Most of the filamentous fungi reported to synthesize nanoparticles have been isolated from mangrove ecosystems. The growth of such saprophytic fungi is favored by the plant debris present in this habitat [55.42]. The conditions in these ecological niches fluctuate with respect to the presence of salt and other organic compounds depending on the tidal conditions [55.43]. In order to adjust to these changes, fungi associated with this ecosystem often produce novel biological compounds that may be involved in the synthesis of nanoparticles.

Aspergillus species are found in almost all climatic conditions worldwide. This fungus is often associated with environments that are rich in starchy material. Since mangrove ecosystems offer such conditions (due to the accumulation of debris from leaves, inflorescence, and stems), *Aspergillus* sp. have been isolated from these habitats [55.44]. A strain of *A. niger* (AUCAS 237) isolated from a mangrove sediment (Vellar estuary, India) synthesized silver nanoparticles. The nanoparticles were 5–35 nm in diameter and spherical in shape. They displayed effective antimicrobial activity towards clinical pathogens (especially Gram-negative bacteria and some fungi). The activity was enhanced when the nanoparticles were stabilized with polyvinyl alcohol. FTIR analysis revealed the possibility of proteins as possible capping and stabilizing agents [55.17]. Silver nanoparticles were also synthe-

sized by using another strain of *A. niger* isolated from the Gulf of Cambay, India. The nanoparticles were spherical, 5–26 nm in size, and displayed laser optical speckles, which could have several applications in the future [55.45]. Microorganisms are known to be symbiotically associated with different marine forms such as sponges. A strain of *A. terreus* (MP1) was isolated from a marine sponge. The mycelial extract of this fungus synthesized silver nanoparticles. SEM and TEM analysis showed the presence of spherical nanoparticles 15–20 nm in size. These particles effectively inhibited the growth of pathogenic bacterial strains of *Staphylococcus aureus*, *Klebsiella pneumoniae*, and *Salmonella typhi* [55.40].

Another fungus, *Penicilium fellutanum* associated with the rhizosphere of an Indian endemic mangrove plant (*Rhizophora annamala*) was isolated and evaluated for the synthesis of silver nanoparticles. The nanoparticles were synthesized optimally at 5 °C, with 1 mM silver nitrate concentration, 0.3% sodium chloride, and at pH 6.0 after 24 h. The extracellularly synthesized nanoparticles were spherical and had a size of 5–25 nm. A protein of about 70 kDa from the cell-free supernatant was proposed to be responsible for converting the metal ions to their zero valence state [55.46].

Apart from the above-mentioned *Aspergillus* and *Penicilium* species, *Hypocrea lixii* (MV1) associated with mangrove sediment soil also mediated the synthesis of silver nanoparticles. The cell-free supernatants of this fungus on incubation with silver nitrate at 28 °C produced nanoparticles that displayed antimicrobial activity against *S. aureus* (ATCC 29213) and *E. coli* (ATCC 25922) [55.47].

55.6.2 Yeast

Yeasts are unicellular fungi that predominantly reproduce by budding. Marine yeasts are important producers of enzymes such as amylases, lipases, proteases, and phytases [55.48]. On account of their inherent capabilities to synthesize a diverse range of products, they have been used as a source of riboflavin, siderophores, single-cell oil SCO, and as probiotics. A few species of marine yeasts are also reported to mediate the synthesis of nanoparticles. Twelve mangrove-associated yeast species, namely, *Candida tropicalis, C. albicans, Cryptococcus dimennae, Debaryomyces hansenii, Geotrichum* sp., *Pichia capsulata, P. fermentans, P. salicaria, Saccharomyces cerevisiae, Rhodotorula minuta, Trichosporon* sp., and *Yarrowia lipolytica* were screened for the synthesis of silver nanoparticles. After a preliminary screening procedure, it was concluded that *P. capsulata* had better synthetic abilities. This was followed by *S. cerevisiae*, *R. minuta*, *P. salicaria* and *D. hansenii*. Other species did not show significant nanoparticle synthetic activity. A rapid method for the synthesis of silver nanoparticles from *P. capsulata* was demonstrated. The optimum conditions were pH 6.0, 0.3% NaCl concentration, and a temperature of 5 °C. The nanoparticles were mostly spherical with a size of 5–25 nm. An NADH-dependent (NADH: nicotiamide adenine dinucleotide) protein similar to nitrate reductase was partially purified and was suggested to mediate the reduction process [55.49].

Y. lipolytica is biotechnologically important in the bioremediation of hydrophobic substrate contaminated environments, in the treatment or up-gradation of wastes, biotransformation of organic compounds, production of novel enzymes, and in the cloning and expression of heterologous proteins. This yeast has been isolated from polluted areas containing toxic and hazardous metals. Metal tolerance in this yeast is attributed to the presence of superoxide dismutase (a copper tolerating protein), reductases, CRF1, metallothioneins, efflux mechanisms, and melanin [55.50]. A tropical marine isolate of *Y. lipolytica* (NCIM 3589), obtained from oil-polluted seawater near Mumbai, India, mediated the synthesis of gold nanoparticles. The synthesis took place at 30 °C within 72 h. The cell wall-associated synthesis of nanoparticles was confirmed by TEM analysis. The yeast, as well as the mycelial forms of this dimorphic fungus, synthesized the gold nanostructures. The size of the nanoparticles was found to be pH-dependent. At pH 2.0, gold nucleation was observed within 15 min. Over a period of time, these developed into large triangular and hexagonal plates. The size of the nanostructures at pH 7.0 and at 9.0 was 15 nm [55.51]. In a further study, this system was used in the custom designing of gold nanoparticles with specific sizes. With increasing cell numbers and the same concentration of gold salt, the particle size was found to decrease. On the other hand, with increasing concentration of the gold salt and the same cell numbers, there was an increase in the size of the particles. The cell-associated gold nanoparticles could be released into the medium by incubation at 20 °C [55.52]. Melanin, a dark-colored pigment from this yeast was found to be one of the factors responsible for nanoparticle synthesis. Cell-extracted and induced melanin (obtained by incubating resting cells with L-3,4-dihydroxyphenylalanine (L-DOPA) mediated the

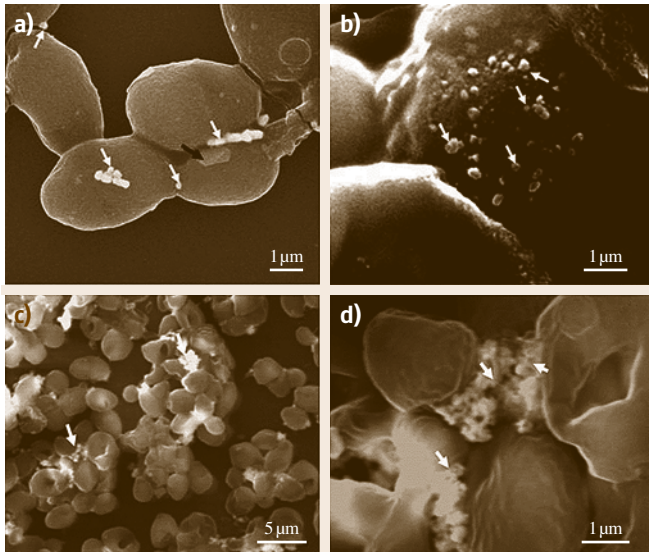

Fig. 55.7a–d Nanostructures associated with marine yeasts. **(a)** Gold nanoparticles and microplates synthesized by *Yarrowia lipolytica* NCIM 3590; **(b)** CdO nanoparticles mediated by *Y. lipolytica* NCIM 3589. *White arrows* point to nanostructures and the *black arrow* to a microplate

synthesis of gold nanostructures [55.53]. Another cold-adapted marine strain of *Y. lipolytica* (NCIM 3590) also synthesized gold nanostructures (Fig. 55.7a,b).

The synthetic ability in this case was also associated with the dark-colored pigment, melanin. These nanoparticles displayed antibiofilm activity against pathogenic bacteria [55.54]. Since the inherent content of melanin in this organism was low, the yeast was induced to overproduce melanin by incubation with a precursor, L-DOPA. This melanin also mediated the rapid formation of silver and gold nanoparticles. The former displayed effective antifungal properties against a wall-disfigurement causing fungus [55.55]. In addition, the tropical marine strain (*Y. lipolytica* NCIM 3589) described above was able to synthesize CdO and CdS nanostructures in a cell-associated and extracellular manner. The SEM images of cell-associated nanostructures in this yeast are depicted in Fig. 55.7c,d. Certain functional groups on the cell surface were thought to play a role in the reductive and stabilization processes [55.11].

A variety of the *Candida* species are also associated with the marine environment [55.8]. Three species of *Candida* were isolated from a coastal soil sample (Nicobar Islands, India) and screened for silver nanoparticle synthesis. Of the three isolates, the *Candida* sp. designated as VITDKGB was selected further. The nanoparticles were 87 nm and displayed antibacterial activity against the multidrug resistant pathogens *Staphylococcus aureus* and *Klebsiella pneumoniae* [55.56].

Rhodosporidium diobovatum, a marine yeast resistant to lead synthesized lead sulfide (PbS) nanostructures. These were characterized and found to be 2–5 nm in diameter. A sulfur-rich peptide was suggested to be the capping agent. In the presence of lead, this yeast produced increasing contents of non-protein thiols during the stationary phase. These were possibly involved in forming the nanoparticles [55.57]. A brief overview of nanoparticles synthesized by filamentous fungi and yeasts is depicted in Table 55.2.

55.7 Algae in the Synthesis of Nanoparticles

Algae inhabit natural as well as metal-contaminated freshwater and marine environments. Various species of algae are also known to interact with heavy metal ions. Some of these species are involved in the detoxification and bioremediation of metal wastes from water [55.81, 82].

The first alga reported to synthesize gold nanoparticles was the brown alga *Sargassum wightii* [55.63]. Following this, there have been several other reports on the application of algal systems for the synthesis of metal nanoparticles. Eleven species of brown algae, four species of red algae, ten species of green algae, and three microalgae have been implicated in the synthesis of nanoparticles. The largest number of reports is on brown algae. This group has adapted to a wide variety of marine ecological niches, including tidal splash zones, rock pools, intertidal zones, and relatively deep near-shore waters. A summary of the nanoparticle biosynthetic capabilities of different algal species is listed in Table 55.3.

55.8 Marine Plants in Nanoparticle Synthesis

Various terrestrial and aquatic plants have been used for the detoxification of heavy metals via phytoremediation procedures. Polyphenols, metallothioneins, and glutathiones are a few examples of phytochemicals that interact with metals. While metallothioneins and glutathiones are metal binding entities, the antioxidant property of phenolic compounds is attributed to the presence of hydroxyl groups that alternate between the hydroxyl and quinone forms [55.83]. Mangrove plants often sequester metal ions and prevent their entry into aquatic ecosystems. In a representative mangrove species, namely, *Rhizophora*, the presence of metal ions does not affect plant growth significantly [55.84]. One of the strategies employed by such mangrove plants to overcome the toxic effect of metal ions is the synthesis of respective nanostructures. All reports on the synthesis of nanoparticles by marine plants are related to silver. The water soluble heterocyclic components such as polyols present in these plant systems are said to be responsible for the reduction and stabilization of silver ions [55.83].

Aqueous leaf extracts of *Rhizophora apiculata* (located in Pichavaram, India) mediated the synthesis of silver nanoparticles. For comparison purposes, silver nanoparticles synthesized by using 1% glucose as the reductant were evaluated. TEM observations showed that the nanoparticles were spherical and varied in size from 19–42 nm. Biologically synthesized silver nanoparticles showed higher antibacterial activity than the glucose-mediated ones [55.85]. Leaf bud extract of another *Rhizophora* species namely, *R. mucronata*, also formed silver nanoparticles when incubated with aqueous silver nitrate solution at 15 psi pressure and 121 °C for 5 min. High-resolution transmission electron microscope (HRTEM) observations revealed the diameter of these to be between 4–26 nm. These nanoparticles exhibited antimicrobial activity against the bacterial pathogens *Proteus* spp., *Proteus fluorescens*, and *Flavobacterium* spp., isolated from infected marine ornamental fish, *Dascyllus trimaculatus* [55.86].

Three plants from Parangipettai, south-east coast of India, were evaluated for the synthesis of silver nanoparticles. The leaf and callus extracts of the saltmarsh plant *Sesuvium portulacastrum* mediated the synthesis of spherical silver nanoparticles (5–20 nm) within 24 h. In comparison to the leaf extracts, the callus extracts were more effective in mediating the synthesis of monodisperse silver nanoparticles. Typically, callus cultures contain a mass of young cells with different ploidy states. Such cells were thought to be metabolically more active in producing the phytochemicals responsible for the reduction of silver ions. When stabilized with polyvinyl alcohol, these nanoparticles displayed prominent antibacterial activity [55.87]. The callus and leaf extracts of *Citrullus colocynthis* displayed moderate antibacterial activity. Spherical silver nanoparticles, 31 nm in diameter, were observed when callus extracts and silver salt were incubated at 35 °C for 24 h. The anticancer potential of the silver nanoparticles on the human epidermoid larynx carcinoma (Hep-2) cell line was evaluated. The toxicity was assessed by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), caspase-3, lactate dehydrogenase leakage, and deoxyribonucleic acid (DNA) fragmentation assays [55.88]. Silver nanoparticles were also synthesized by another coastal plant *Prosopis chilensis* isolated from the same location. The nanoparticles were synthesized by leaf extracts after 24 h incubation with silver salts. TEM analysis showed that the nanoparticles were mostly spherical and ranged between 5–25 nm. The silver nanoparticles were applied in controlling vibriosis in the shrimp *Penaeus monodon* [55.89].

Avicennia marina plant was collected from Karangadu mangroves, Tamil Nadu, India. Among the different mangrove plants, this species is important because it displays antibacterial, antiplasmodial, and antiviral activities [55.93]. It is also rich in secondary metabolites such as polyphenols, flavonoids, alkaloids, and tannins [55.94]. On account of these characteristics, extracts of different plant parts (leaves, barks, and roots) were evaluated for the synthesis of silver nanoparticles. Of the three plant parts, the leaf extracts were most effective in nanostructure formation after 8 h of incubation. AFM analysis showed the particle size

Table 55.4 Marine plants mediating nanoparticle synthesis

Plants	Size (nm)	Reference
Rhizophora apiculata	19–42	[55.85]
Rhizophora mucronata	4–26	[55.86]
Sesuvium portulacastrum (L.)	5–20	[55.87]
Citrullus colocynthis (L.)	≈31	[55.88]
Prosopis chilensis (L.)	5–25	[55.89]
Avicennia marina	71–110	[55.90]
Mayaca fluviatilis	–	[55.91]
Suaeda monoica	≈31	[55.92]

to be between 71–110 nm. The silver nanoparticles synthesized using leaf aqueous extracts were effective against Gram-negative bacteria [55.90]. *Mayaca fluviatilis* another marine plant was effective in synthesizing silver nanoparticles at low temperatures (4 °C). The polydisperse particles were reported to be stable even after 6 weeks of incubation [55.91].

The leaves of *Suaeda monoica* were collected from the Kollidam coast, Tamil Nadu, India. The leaf extract was incubated with silver nitrate at 35 °C for 5 h to synthesize the silver nanoparticles. AFM analysis showed that the nanoparticles were spherical and 31 nm in size. The in vitro cytotoxicity effects of these nanoparticles were studied using human epidermoid larynx carcinoma cell lines (Hep-2) [55.92]. The role of marine plants in mediating nanoparticle synthesis is summarized in Table 55.4.

55.9 Nanoparticle Synthesis by Sponges

As described earlier, certain bacteria and fungi associated with sponges mediate nanoparticle formation. For example, *Bacillus subtilis* MSBN17 (associated with the sponge *Collyspongia diffusa*), *B. casei* MSA19 (isolated from *Dendrilla nigra*), and *Aspergillus terreus* (MP1) were able to form silver nanostructures [55.29, 32]. It is suggested that structurally unique natural products accumulated by invertebrates such as sponges and molluscs may bring about the conversion of metals to their respective nanostructures. There are two such reports on the use of sponges for the synthesis of nanoparticles.

The extract of the marine sponge *Acanthella elongata* (collected from the Gulf of Mannar, Tamil Nadu, India) synthesized stable gold nanoparticles within 4 h at 45 °C. TEM analysis showed that polydisperse spherical nanoparticles with variable sizes from 7–20 nm were present [55.95]. Another marine sponge (*Haliclona implexiformis*) was collected from the same region. The sponge extract was used for the synthesis of silver nanoparticles. Nanoparticles were formed after 12 h and their size was found to be 12 nm. The antimicrobial activity of silver nanoparticles was studied against *Pasteurella multocida*, *E. coli*, *Klebsiella pneumoniae*, *B. subtilis*, *Enterococcus fecalis*, and *Pseudomonas* sp. In vivo toxicity testing in chick embryos revealed their non-toxic nature [55.96].

55.10 Mechanistic Aspects

Reduction reactions involving the conversion of metal ions to their respective nanostructures are thought to be mediated by different biomolecules. The synthesis of silver nanoparticles is attributed to the presence of peptides, amino acids, reducing sugars, and enzymes such as reductases and proteases.

55.10.1 Proteins in Nanoparticle Synthesis

The role of some proteins in the biosynthesis of nanoparticles has been proposed by several investigators. For example, in bacteria such as *E. coli* AUCAS 112 and *Marinobacter pelagius* RS11, as well as in the fungus *Aspergillus niger* AUCAS 237, the role of proteins as capping and stabilizing agents has been suggested indirectly on the basis of FTIR profiles [55.17, 25]. In *Phormidium cyanobacterium* three proteins were actually induced in response to the presence of gold salt. Two of them demonstrated hydrolytic activity and the third probably acted as a capping

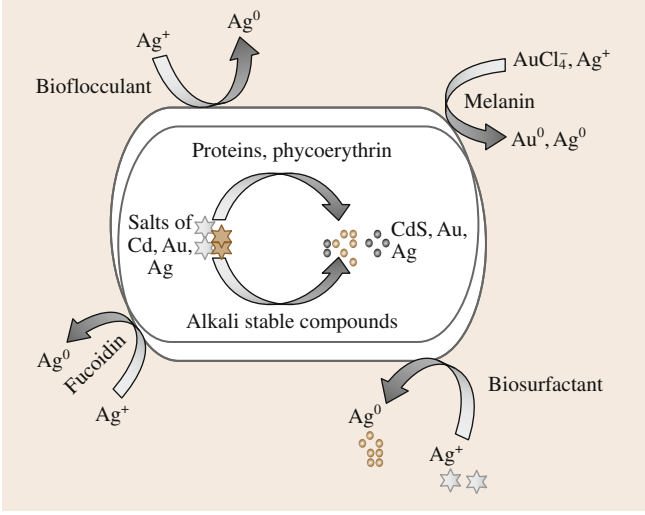

Fig. 55.8 Mechanisms involved in nanoparticle synthesis by marine systems

agent [55.37]. In the fungus *Penicillium fellutanum*, a protein of about 70 kDa was reported to be involved in nanoparticle synthesis [55.46]. In addition, certain non-protein thiols are proposed to form lead nanoparticles in the yeast *Rhodosporidium diobovatum* [55.57].

The importance of nitrate reductase in nanoparticle synthesis has been implied in the bacterium *Pseudomona aeruginosa* M6 and the yeast *Pichia capsulata* [55.18, 49]. In the cyanobacterium *Oscillatoria willei* NTDM01 this enzyme along with phytochelatin were thought to be involved [55.36]. In the Archaeon *Haloterrigena salina*, this enzyme in conjunction with alkali stable components mediated nanoparticle synthesis [55.27].

55.10.2 Role of Biosurfactants, Bioflocculants, and Polysaccharides

Biosurfactants, bioflocculants, and polysaccharides are also proposed to have a possible mechanism in nanostructure formation. For example, in *Bacillus subtilis* MSBN17 and *B. casei* MSA19, a bioflocculant and biosurfactant respectively, reduced silver salts to nanoparticles [55.29, 32]. Fucoidans (sulfated polysaccharides) from the two marine algae *Cladosiphon okamuranus* and *Kjellmaniella crassifolia* reduced gold salts and stabilized the nanoparticles [55.66].

55.10.3 Pigments as Mediators

The role of pigments in nanoparticle formation has been suggested in two marine systems. Melanin, a complex polymer of phenolic compounds has been described in the yeast *Yarrowia lipolytica*. The cell-associated and precursor-induced pigment plays a role in the formation of gold and silver nanostructures [55.53–55]. Another pigment, C-phycoerythrin (C-PE) extracted from the marine cyanobacterium *Phormidium tenue* NTDM05 was involved in the synthesis of CdS nanoparticles [55.38]. Some of the proposed mechanisms involved in nanoparticle synthesis in marine biological forms are summarized in the following section and in Fig. 55.8.

55.11 Current Understanding and Future Needs

A variety of prokaryotic and eukaryotic marine organisms have been investigated with respect to their nanoparticle synthetic abilities. Most of these reports deal with eukaryotic forms such as fungi, algae, and plants. The vast biodiversity encountered in the prokaryotic world has been relatively less explored. Furthermore, most of the studies are related to the synthesis of silver nanoparticles, followed by those of gold. One reason for this could be the relative ease with which the noble metal ions of gold and silver are reduced. Nanoparticles of platinum, bismuth, cadmium (CdO, CdS, CdTe), antimony sulfide, copper oxide, zinc oxide, and titanium oxide have been described on fewer occasions. It is observed that a majority of the reports deal with application of novel biological systems in mediating the synthesis of nanoparticles, their characterization, and applications in the biomedical field, particularly as antimicrobial agents. However, there is a need to understand the mechanisms involved in the synthetic process. Another limitation of the studies is that the experiments have been conducted at laboratory scale and there are hardly any efforts for the scale-up of these processes. In the future, these shortcomings need to be addressed in an effective manner to harness the actual nanoparticle synthetic potential of the marine resources to their full extent.

56. Marine Biomaterials in Therapeutics and Diagnostics

Ashutosh Srivastava, Arti Srivastava, Ananya Srivastava, Pranjal Chandra

Marine organisms are constituted of compounds with several properties and characteristics. In the last decade lot of biomaterials like various types of polymers and bioactive ingredients have been identified, isolated, and characterized. These biomaterials have a vast range of applications in the medical sector including controlled drug delivery, tissue engineering, and diagnostic device etc. In this chapter, biomaterials have been defined and classified in general, followed by an account of mainly various polymers like collagen, chitin, chitosan, chondroitin sulfate, hyaluronic acid, alginate, biosilica, calcium carbonate and phosphate. Their structure, source, and application in the medical field have been discussed. A brief account of bioactive compounds as therapeutic agents has also been given. Marine biomaterials are also emerging as promising materials for the development of biosensors for medical diagnostics. This chapter also discusses biosensors and the role of biomaterials from marine origin in the development of biosensors for medical diagnostics. The chapter concludes with the scopes of the biomaterials in near future.

56.1 Biomaterials

Biomaterials are materials with unique properties which make them suitable for intimate contact with living tissues. Biomaterials are produced through process that mostly employ or mimic biological phenomena.

As per the definition for biomaterials [56.1]:

A biomaterials can be defined as any material used to make devices to replace a part or a function of the body in a safe, reliable, economic and physiologically acceptable manner

Biomaterials are not necessarily of biological origin they may be of nonbiological origin as well. Most important criteria for the biological material are that they will be in intimate contact with living tissues. They must be biocompatible and either bioresorbable or biodurable.

The biomaterials should have four properties. There should be biocompatibility, sterlizability, functionability, and manufacturability [56.2]. Biomaterials are used for various purposes (Table 56.1).

56.2 Classification of Biomaterials

Various authors classified biomaterials in different ways. Broadly biomaterials can be classified in four groups:

a) Polymers
b) Metals
c) Composite materials and
d) Ceramics.

56.2.1 Polymers

There are a large number of polymers which have been used in the human body as implants or part of the implant system. These polymers include acrylics, polyamides, polyesters, polyethylene, polyurethane, polysiloxanes, and many others reprocess biological materials.

These polymers can be used in tissue engineering, implantation of medical devices, and artificial organs due to its inert nature, prostheses, dentistry, bone repair, drug delivery, and targeting into sites of inflammation or tumors, plastic tubing for intravenous infusion, and catheter etc. Advantages with the polymers are that they are resilient and easy to fabricate but disadvantages are many like they are not strong enough, they deforms with time and may degrade. Most common biodegradable polymers are the polylactic and glucolic acid polymers and copolymers, trimethylene carbonate copolymers, and polydioxanone.

56.2.2 Metals

Metals are used as biomaterial due to their excellent electrical and thermal conductivity and mechanical properties. Some metals are used as passive substitute for hard tissue replacement such as total hip, knee joints, for fracture healing aids as bone plates and screws, spinal fixation devices, dental implants, vascular stents, and catheter guide wires.

Following metallic systems are most frequently used in the body:

a) Stainless steel – (e.g., in fracture plates, screws, and hip nails)
b) Titanium and titanium-base alloys (e.g., in knee joint replacement, dental implants, etc.)
c) Cobalt-base alloys (e.g., in dentistry, in making artificial joints, for making the stems of prostheses for heavily loaded joints such as knee and hips).

Titanium and its alloys are getting great attention in both medical and dental fields because of excellent biocompatibility, light weight, excellent balance of mechanical properties, and corrosion resistance.

Table 56.1 Use of biomaterials in biomedical science

Use of Biomaterials	
1.	Replacement of diseased and damaged part (e.g., artificial hip joint)
2.	Assist in healing (e.g., sutyres, bone plates, and screws)
3.	Aid to treatment (e.g., catheters, drains)
4.	Aid to diagnosis (e.g., probes and catheters)
5.	Improve function (e.g., cardic pacemaker)
6.	Plastic surgery etc.

56.2.3 Composite Materials

Composite can be generally defined as those materials having two or more distinct material phase [56.2]. For example, combination of silane-coated inorganic filter particles with dimethacrylate resin which is used in dentistry. The filter particles used are either barium silicate glass, quartz, or zirconium silicate and are usually combined with 5–10% weight of 0.04 μm particles of colloids silica. A hydroxyapatite–polyethylene is also an example of composite which is used in orthopedic implants.

Many biomineralized tissues of many invertebrate origins are composite materials, containing a biologically produced organic matrix and nano or microscale amorphous or crystalline minerals. Composite materials have lot of advantages in comparison with homogenous materials. Those include the ability to have control over material properties. This is the potential for stiff, strong, light-weight materials, as well as for highly resilient and compliant materials.

Composite biomaterials can be used in various ways. Few of them are as follows:

(a) Dental filing
(b) Reinforced methyl methacrylate bone cement and ultrahigh molecular weight polyethylene
(c) Orthopedic implants with porous surfaces.

The properties of composite materials depend very much upon the structure.

56.2.4 Ceramics

Ceramics are used for the repair and restoration of diseased or damaged parts of the musculoskeletal systems. Four types of bioceramics are mostly used in human system:

Type 1 – Bioinert like aluminum oxide (Al_2O_3) and zirconium oxide (ZrO_2).
Type 2 – Micro-porus bioceramics like hydroxyapatite-coated metals, alumina.
Type 3 – Bioactive materials like hydroxyapatite, bioactive glasses, and glass–ceramics.
Type 4 – Resorbable like tri-calcium phosphate (TCP).

Application of the bioceramics includes: Replacement for hips, knees, teeth, tendons and ligaments, and repair for periodontal disease, maxillofacial reconstruction, augumentation and stabilization, spinal fusion, and bone fillers after tumor surgery.

56.3 Marine Biodiversity

Ocean is rich in biodiversity. The world's ocean covers more than 70% of our planet's surface with over five lakh species belonging to 32 animal phyla. Microbes constitute 90% of oceanic biomass. Marine organisms produce novel compounds to survive in extreme variation in pressure, salinity, and temperature, prevailing in the marine environment. With 3.5 billion years of existence on earth and experience in biosynthesis, the marine organisms especially microbes are the nature's best source of chemicals. Because of the immense biological diversity in the ocean, it is well established that a large number of natural products and novel chemical entities exist in the oceans, with biological activities that may be useful in finding drugs with greater efficacy and specificity for the treatment of many human diseases [56.3]. Some marine organisms are proved to be the potent sources of biomaterials for therapeutic and medical diagnostic purpose. These are mostly invertebrates that include sponges, soft corals, seafans, seahares, nudibranchs, bryozoans, tunicates, etc. It is believed that microorganisms associated with the invertebrates are responsible for the production of bioactive compounds. In addition to the marine invertebrates, microbes (bacteria, fungi, and actinomycetes), microalgae, seaweeds, and mangroves also provide compounds of therapeutic value [56.4]. The vast marine biodiversity offers great scope for new therapeutic biomaterials.

56.4 Biomaterials from Marine Origin

Marine organisms are constituted by materials with a vast range of properties and characteristics that explains their potential applications within the biomedical field. Some of the biomaterials from marine origin have been disused below.

56.4.1 Collagen

Collagen is the most widely found protein in mammals. Collagen is found in connective tissues. It is derived from the soluble precursor procollagen. Collagen is a left-handed-α helix and has three amino acid residue per turn (Gly-X-Pro or Gly-X-Hyp; X = any amino acid). Collagen is also a coiled coil, three separate polypeptide are super twisted in right-handed manner. Typically they contain about 35% Gly, 11% Ala, and 21% Pro-4-Hyp.

There are many types of collagen, differing in their structure, function, location, and other characteristics. The predominant form used in biomedical applications, however is type I collagen. Type I collagen is a *rope forming* collagen and can be found in skin and bones. Collagen may also be processed into a variety of formats, including porous sponges, gels and sheets, and can be cross-linked with chemicals to make stronger or to change its degradation rate.

The primary sources of industrial collagens are calf skin and bone. However, these carry a high risk of bovine spongiform encephalopathy or transmissible spongiform encephalopathy. Collagen has been used in

various types of surgery, cosmetics drug delivery, and also in bio-prosthetic implants and tissue engineering of multiple organs as well. Cells grown in collagen often come close to behaving as they do within the body, which is why collagen is so promising when one is trying to duplicate natural tissue function and healing.

Nagai et al. reported the isolation and characterization of collagen from rhizostomous jellyfish (*Rhopilema asamushi*) [56.5]. In a research report by *Song* et al., jellyfish collagen exhibited higher cell viability than other naturally derived biomaterials [56.6]. Jellyfish collagen scaffolds also had a highly porous and interconnected pore structure, which is useful for a high-density cell seeding, an efficient nutrient and an oxygen supply to the cells cultured in the three-dimensional matrices. *Song* et al. prepared the porous scaffolds composed of jellyfish collagen by freeze-drying and cross-linking with 1-ethyl-(3,3-dimethylaminopropyl) carbodiimide hydrochloride/*N*-hydroxysuccinimide to be used in tissue engineering applications.

Collagen sponge is also one of the biomedical materials frequently used in clinical medicine, especially in dermatology and plastic reconstructive surgery [56.7]. Collagen sponges have been reported for the treatment of burn [56.8–10], trauma [56.11], chronic skin ulcer [56.12, 13], excised skin tumor [56.14–16], etc. Collagen sponge is also used as scaffold for tissue engineering because of its high ability of cell adherence and biological affinity. It has been used to regenerate various tissues such as skin [56.17, 18], cartilage [56.19, 20], bone [56.21, 22], cornea [56.23, 24], teeth [56.25, 26], etc., by being employed as a scaffold. *Matsumoto* et al. reported the usefulness of the collagen and elastin sponge (CES) derived from salmon as an artificial dermis and scaffold for tissue engineering. Report suggested that the CES has the same potential of forming the granulation tissue as the traditional artificial dermis and could be used as a scaffold for tissue engineering [56.7].

Sirbu et al. reported that collagenic gels containing marine algae extracts and chlorhexidine salt could be used in dental medicine as pharmaceutical formulae with optimum efficiency, having well-profiled organoleptic properties [56.27]. They tested the extract from marine algae *Ulvae lactuca, Cystoseira barbata*, and *Ceramium rubrum* from the Black sea. The marine algae extract and chlorhexidine salt were incorporated in type I nondenatured fibrillar collagen matrixes for the experiment.

Depending on the processing, collagen can cause alteration of cell behavior (e.g., change in growth or movement), have inappropriate mechanical properties, or undergo contraction. Because cells interact so easily with collagen, cells can actually pull and reorganize collagen fibers, causing scaffolds to lose their shape if they are not properly stabilized by cross-linking or mixing with another suitable material. Collagen can be easily combined with other biological or synthetic materials, to improve its mechanical properties.

56.4.2 Chitin and Chitosan

Chitin was first isolated from mushrooms by Braconnot in the year 1811. It remained unused biomass resource for a long time but in the last decade, lot of demand has been reported for the chitin and chitosan in different markets, like cosmetics, medicine, biotechnology, food, and textiles.

Chitin (polymer of β-(1→4)-linked 2-acetamido-2-deoxy-D-glucopyranose) are found in shells of marine crustaceans such as crabs and shrimps. These shells are available as waste from the seafood processing industry and used for commercial production of chitin. The shells contain approximately 15–40% chitin (Table 56.2).

Chitin is generally classified into two forms, β-chitin and α-chitin, depending on the crystalline structure. The most abundant and easily accessible form is α-chitin with maximum intermolecular hydrogen bonding [56.29]. Dissolution or swelling converts β-chitin to α-chitin, but not α-chitin to β-chitin. Chitosan is deacylated form of chitin.

Chitin and chitosan are attracting a great deal of attention because of their biological and physiochemical characteristics. They are nontoxic, biocompatible, and biodegradable. Chitosan may be easily combined with other materials like polyvinyl alcohol, polyethylene glycol, or collagen, in order to increase its strength and cell attachment potential.

Table 56.2 Contents of chitin from different marine resources [56.28]

Source	Chitin (%)
Crab cuticle	15–30
Shrimp cuticle	30–40
Krill cuticle	20–30
Squid pen	20–40
Clam/oyster shell	3–6

Chitin and chitosan have been reported for various bioactivities including promotion of wound healing [56.30, 31], hemostatic activity, immune enhancement, hypolipidemic activity [56.32], mucoadhession, eliciting biological responses, and antimicrobial activity [56.33, 34]. Chitosan is also used as supporting polymer for gene delivery, cell culture, and tissue engineering [56.28]. Nonwoven chitin fabrics and chitin threads are used as artificial skin and sutures with the advantages of wound healing, biocompatibility, and biodegradation. Glucosamine, the monomeric unit of chitosan, has proved clinically effective against osteoarthritis. Chitosan has already been investigated for use in the engineering of cartilage, nerve and liver tissues.

56.4.3 Chondroitin Sulfate (CS)

Chondroitin sulfate is the most valued glycosaminoglycan because of its abundance in mammalian tissues, physiological functions and high activity. CS contains repeating units of glucuronic acid and *N*-acetylgalactosamine linked by β-(1→3) glycosidic bonds and sulfated in different carbon positions. Classification and types of CS depend on sulfate group placing: carbon 4 (CS-A; present in dog fish and ray), 6 (CS-C; present in ray), both 4 and 6 (CS-E; present in squid, salmon, crocodile), position 6 of *N*-acetylgalactosamine and 2 of glucuronic acid (CS-D-present in shark and dog fish), and 4 of *N*-acetylgalactosamine/2 of glucuronic acid (CS-B) [56.35].

Chondroitin sulfate has been isolated from whale, shark, skate, squid, salmon, king crab, and sea cucumber. It is also present in marine invertebrates like Cnidaria, Polychaeta, and Mollusca [56.36]. Shark cartilage has been the most commonly used as a commercial source of nonmammalian CS. But price of raw material and ecological aspects are really concern today. Due to its high biocompatibility, CS demand in the industry is increasing day by day. It is used in engineering of biological tissues associated with the process of bone repair, cartilage, and cutaneous wound. Marine CS is also reported for its potential as biomedical gel forming polymer, anticoagulant activity, and as a supplement in arthritis-related diseases [56.36]. Moreover, it can also be combined with other polymers to formulate scaffolds with slow and controlled biodegradability. Recent studies also indicate that CS-E is a potent antiviral whereas CS-proteoglycan is a potential target for the development of vaccines against malaria. Sulfation pattern of CS can be used as potential biomarker to early detection of diverse types of cancer [56.35]. Fucosylated CS (CS-F) obtained from sea cucumber inhibit adenocarcinoma growth in lungs using mouse model [56.37].

56.4.4 Hyaluronic Acid (HA)

Hyauronic acid (HA) or hyaluronan is a naturally occurring nonsulfated glycosaminoglycan consisting of alternate disaccharide units of α-1,4-D-glucuronic acid and β-1,3-*N*-acetyl-D-glucosamine, linked by β (1→3) bonds. It is present in intracellular matrix of most connective tissues such as cartilage, vitreous of the human eye, umbilical cord, and rooster comb. HA is also present in cartilaginous fishes and in vitreous humor of different fish species [56.38]. However, the most important alternative in recent years has been development of microbial HA production by *Streptococcus* bacteria it also avoid the risk of animal derived pathogens [56.39, 40].

The activity of HA is dependent on its size [56.41, 42]. HA holds a large number of water molecules in its molecular domain. This *swelling* property and its chemical structure gives it a wide ranging of physiochemical and biological function such as lubricity, viscoelasticity, biocompatibility, angiogenic, and immunostimulatory. High concentration of high molecular mass HA in synovial fluid provides lubrication and serves as shock absorber. In osteoarthritis or rheumatoid arthritis, high molecular mass HA is degraded by reactive oxygen species, which reduces its viscosity and impairs its lubricant and shock absorbing properties leading to deteriorated joint movement and pain [56.36, 43]. In the skin, HA acts as scavenger of free radicals generated by the UV rays from sunlight, which otherwise would cause oxidative stress on cells [56.44]. This polymer has great economic value with numerous applications in biotechnology, regenerative medicine, major burns, and intraocular surgery [56.35]. HA is used as diagnostic marker for cancer, rheumatoid arthritis, and live pathologies [56.45], and also in drug delivery system [56.46].

56.4.5 Alginate

Alginate is a polysaccharide derived from brown seaweed. It is an unbranched anionic copolymer composed of two monomers, (1→4) linked β-D-mannuronic acid and α-L-guluronic acid. Commercial extraction of the alginate is from species of *Laminaria, Macrocystis*,

Ascophyllum, Eclonia, Lessonia, Durvillea, and *Sargassum* [56.47]. It is nontoxic and noninflammatory in nature due to which it has been approved in some countries for wound dressing and for use in food products.

Alginate is biodegradable and has controlled porosity. Alginate has been explored for being used in liver, nerve, heart, and cartilage tissue engineering. Drawbacks of the alginate include mechanical weakness and poor cell adhesion which can be overcome by mixing with other materials. The ability of alginate to cross-link with calcium ions may be used to produce scaffolds.

56.4.6 Biosilica

Biosilica or biogenic silica is formed in sponges, diatoms, radiolarians, and choanoflagellates [56.48]. There are two classes of sponges that have silica skeleton: Desmospongiae and Hexaactinellida. The silica skeleton is made up of siliceous spicules which are rod-like glassy spikes consisting of an axial filament surrounded by several hundreads concentric layers of hydrated silica. The process of biosilica formation catalyzed by the enzyme silicatein present in axial filament [56.36]. The silicateins were first identified in the axial filament of demosponge *Tethya aurantium*. Three isoforms have been identified, silicatein-α, silicatein-β, and silicatein-γ [56.49]. Sponge spicules have mechanical, optical, and electric properties. These natural biocomposites have been characterized as highly flexible and tough.

Another important source of biosilica is diatoms. Diatoms are a major group of microalgae. They are unicellular organisms, although some form chains or simple colonies. The living part of the diatoms is within a box, which is made up of silicon dioxide [56.50]. These exoskeleton-named frustules are made of silica nanoparticles assembled in a highly organized structure with porous network at different scales.

The biocompatibility of the biosilica is excellent and has no toxicity. Due to these properties, biosilica is being considered for biomedical approaches, namely, for bone replacement and regeneration strategies. It has been observed that human osteogenic sarcoma cells (SaOS-2) show increased mineralization when cultivated on biosilica surfaces in the presence of β-glcerophosphate. Moreover, concurrent coating of the substrate with biosilica and type1 collagen not only increased the cellular Ca phosphate deposition but also stimulated cell proliferation [56.36]. Biosilica has been identified for promoting morphogenesis on both osteoblast and osteoclasts. This polymer elicits cytokines that affect bone mineralization (hydroxyapatite formation) [56.49].

56.4.7 Calcium Carbonates and Phosphates

Calcium carbonate ($CaCO_3$; aragonic or calcite forms) can be found in many marine organisms like corals (*Coralline officinallis, Lithothamnion glaciale, and Phymatholithon calcareum*), sponges (calcareous sponge spicules from triactines of *Pericharax heteroraphis*) mollusc shells (nacre from *Haliotis* (abalone), *Mytilus galloprovincialis* and *Ostrea edulis* and *Pinctada maxima*) and fish bones (*Prionace glauca* (Blue shark)) [56.36]. Although there are many sources of calcium carbonate. Coral skeletal carbonate is a promising substitute material for orthopedics and dentistry. Coral-derived calcium carbonate has been in use as bone filler. Calcium carbonate can also be used as precursor material for bioceramics coatings. $CaCO_3$ can be the precursor material for obtaining different calcium phosphates.

Calcium phosphorous compounds such as hydroxyapatite (HAp) – $Ca_{10}(PO_4)_6(OH)_2$, have a special importance in the biomedical field due to its similarities with the mineral constituents of bones. Besides using $CaCO_3$ as precursors, hydroxyapatite can be found and obtained directly from marine resources like fish bones. Calcium phosphate has been used in drug delivery system as bioceramics, tissue engineering scaffolding, bone graft substitute, and facial fillers [56.36].

56.5 Status of Marine Natural Product as Therapeutic Agents

Marine flora and fauna continue to provide a prolific source of novel lead compounds for the pharmaceutical industry. The effort to extract bioactive compounds from the ocean started in the late 1960s. The systematic investigation began in the mid-1970s [56.4]. Approximately 200 patents were issued between 1969 and 1995 [56.51]. One hundred and thirty five patents were issued between 1996 and July 2003 [56.52]. Some of the recently patents compounds are given in Table 56.3.

Table 56.3 Some of the recently patented compounds (compiled from Ocean Drug Alert, Lucknow, India and [56.52])

Organism	Compound	Activity	Assignee	Year
1. Marine bacteria and fungi				
Marine bacteria *Myxobacterales* AJ 13395	Polyene SMP-2 and its isomers	Antifungal against *C. albicans, Aspergillus fumigates, A. niger* and *Mucor hiemalis*	Ajinomoto Co. Inc.	2000
Marine fungus *Aspergillus* CNC358	Avrainvillamide	Anticancer	University of California	2000
Ascomycete isolated from marine algae *Porphyra yezoensis*	M-3-A	Fungicide	Marine Biotechnology Institute of Japan	2001
Marine actinomycete strain ES20-008	Bafilomycin derivative	Anti-invasive and antitumour	Instituto Biomar SA	2001
Actinomycete from marine sponge	Indolocarbazole alkaloids	Anticancer	Instituto Biomar SA	2001
Marine *Pseudomonas* sp.	Acidic sulfated polysaccharide	Apoptosis in U-937 human leukaemia cells	Okuya Koichi	2002
Marine actinomycetes	Certain fermentation products	Antineoplastic agents	Regents of the University California, US	2005
Marine actinomycetes	Indole, carbozole, alkaloids	Anticancer	Institute of Biomarine SA, Spain	2005
2. Marine algae				
Bryothamnion seaforthii and *B. triquetrum*	Lectins	Analgesic	Braz. Pedido PI	2001
Brown seaweed *Cladosighon okamuranus*	Fucoidans	Antiulcer	University of South Coralina	2001
Green algae, *Chlorella* sp.	Glutamic Acid	Antagonist growth inhibitor	Yakult Honsha Co. Ltd.	2001
Laminaria sp.	Crude extract	Antioxidant, osmo protectors	Mekideche N	2001
Brown seaweed, *Padina pavonnica*	Crude extract	Calciotropic activity	Texinfine SA	2001
Brown seaweeds, *Laminaria japonica, Undaria pinnatifida, Kjellmaniella crassifolia*	Sulfated fucose containing polysaccharide	Anticancer and anticarcinostatic	Takaro Shuzo Co. Ltd. Japan	2001
Brown algae *Sargassum micracanthum*	Macrocyclic ether	Antioxidant and antiviral	Toyama-Ken and Lead Chemical Co. Ltd.	2002
Ascophyllum nodusum	Crude extract	Antiobesity	Riken Vitamin Co. Ltd., Japan	2002
Cynobacteria *Symploca hydnoides*	Peptid	Antitumor activity	Instituto Biomar SA	2003
Red algae, *Pophyra* sp.	Crude extract	Stress protein inducing	Larena 13, Avenue De-Segur F-75007, France	2003
Seaweed	Mixed extracts of brown, red and green algae	Antidiabetic	Endomatrix Inc USA	2004

Several bioactive ingredients have been isolated and characterized from the marine resources in the last decade. These active ingredients are against various types of diseases. Recently *de Jesus Raposo* et al. [56.53] reviewed the bioactivity and applications of sulfated polysaccharides from marine algae.

Aquired Immuno Deficiency Snydrom (AIDS) is a major concern around the world these days. It is a major viral disease caused by Human immunodefi-

3. Sponges				
Raspailia sp.	Asmarine A and B – novel diterpene alkaloids	Cytotoxic	Instituto Biomar SA	1999
Sponogosorites sp.	Toposentin D	Antineurogenic inflammatory property	Harbour Branch Oceanographic Inst. Inc.	1999
Sponge	Manzamine A	Inhibit growth of *Plasmodium falciparum* in mice	National Institute of Singapur et al.	1999
Sponge from South China Sea	Rhabdasterol acetate	Blood pressure reducing and arrhythmia-resisting utility	Guangzhou Inst. of Chem.	1999
Crambe crambe	Crambescidin 816, 844, and 800	Inhibit herpes simplex virus	Pharma Mar SA	1999
Sponge	Manzamine A–F	Antineurogenic inflammatory property	Harbor Branch Oceanographic Inst. Inc., Midwestern Univ.	2000
Marine sponge *Batzella* sp.	Aminoiminoquinone and Aminoquininie alkaloid compounds	Capsase inhibitor	Harbor Branch Oceanographic Inst. Inc.	2000
Haliclona tulearensis	Halitulin	Cytotoxic	Pharma Mar SA	2000
Stylotella aurantium	Sesquiterpenes	Antitumor	Pharma Mar SA	2001
Plakortis lita	3,6-dihydro-1,2-dioxins	Antitumor	Sagami Chem. Res. Center	2001
Marine sponge *Discodermia*	Discalamides A and B	Antitumor	Harbor Branch Oceanographic Inst. Inc.,	2001
Xestospongia exigua	Motuporamine C	Inhibition of angiogenesis	University of British Columbia	2002
Blue marine sponge *Cribrochalina*sp.	Cribrostatins 3-5	Anticancer, antibacterial, and antifungal	The Arizona Board of Regents	2002
Stelletta hiwasaensis	Orostanal	Anticancer	Kyushu TLO Co. Ltd.	2002
Sponge	Polymeric-1,3-alkylpyridinium	Toxins	Aberdeen University, UK	2004
Aplysina cavernicola, A. fulwa, Oeanapia sp.	A spiro hetrocyclic unit connected through a linker of certain length to another spiro cycle, an imidezole ring or an amide group	Against connitive and neuro-degenerative disorders	Neuropharma SA	2005
4. Cnidaria				
Soft coral *Sinularia dissecta*	Rameswaralide and its derivative	For the treatment of arthritis, psoriasis, and inflammatory bowel disease.	The regents of University of California	2000
Erythropodium caribaerum	Eleutherobin, desmethyleleutherobin, and isoeleutherobin	Antimitotic	University of British Col	2001
Jelly fish *Carybdea alata*	CaTX-A and CaTX-B	Hemolytic proteins	Suntory Ltd.	2001

ciency virus (HIV). Due to the emergence of resistance in virus, present anti-AIDS treatment is not successful. Therefore, the search for potential drug candidate with higher inhibitory activity against various HIV strains is the need of hour. Recently *Vo* and *Kim* [56.54] gave an overview for potential anti-HIV agents from marine resources.

Oxidative stress and inflammation are common pathophysiological features of artherosclerotic cardiovascular disease. Astaxanthin, a xanthophylls

5. Echinoderms				
Sea cucumber *Cucumaria echinata*	Proteins	Cytotoxic against leukaemia	National Institute of Advanced Industrial Sci. and Tech. et al.	2001
Sea urchin *Echinocardium cordatum*	Alkanesulfonic acids and derivatives	Antitumor activity and antibacterial activity against *Rhodospirillum salexigens* SCRS-113, a marine adhesive bacteria	Nagoya Industrial Sci. Res. Inst.	2002
Sea cucumber	Carotenoid lipid	Anti-inflammatory auto immune	Neptune technologies and bioress; Sampalis Tina,	2002
Holothuria scabra	Dye	Fluorescent dye	Council of Scientific and Industrial Research (CSIR-India)	2003
6. Molluscs				
Clam *Spisula polynyma*	Spisulosines 285	Antitumor activity	The Board of Trustees of the University of Illinois	1999
Bivalve mollusc shellfish *Mytilus galloprovincialis*	Myticin peptide	Antimicrobial activity	Center national De La Recherche Scientifique et al.	2001
Nudibanch *Jorunna funebris*	Jorumycin	Antitumor	Instituto Biomar	2001
7. Tunicates				
Cystodytes violatinctus	*n*-alkaloid-Shermilamine D	Antitumor	Instituto Biomar	1999
Ascidian *Lissoclinum* sp.	Tridecanolids	Antitumor	Sagami Chem. Res. Center	2000
Ascidian	Coproverdine – A carbazole alkaloid	Cytotoxicity against P-388, A-549, HT-29, MEL-28 and DU-145 cell lines	Pharma Mar.	2002

carotenoid present in various marine organisms like microalgae, seafood etc., is an antioxidant with anti-inflammatory properties. It may have a potential therapeutic role in cardiovascular disease [56.55]. *Fassett* and *Coombes* summarized various animal studies investigating the cardiovascular effects of astaxanthin [56.55]. Some studies also reported the role of astaxanthin in the prevention of diabetic nephropathy [56.56].

Anti-inflammatory ingredients obtained from marine algae can be used in regenerative therapy for tissues affected by the periodonthal disease [56.27]. *Sirbu* et al. presented the possibility of application of collagen gels with active compound from marine algae (*Ulva letuca, Cystoseira barbata*, and *Ceramium rubrum*) [56.27]. Report indicate that collagenic gels containing marine algae extracts and chlorhexidine salt could be used as pharmaceutical formulae with optimum efficiency, having well-profiled organoleptic properties. Some of the noble active pharmaceutical ingredients are listed in Table 56.4.

56.6 Marine Resources for Medical Diagnostic Devices

Since the past two decades, in vitro and in vivo implantable medical devices such as biosensor has been developed for the point of case medical diagnostics. The major advantage of the biomaterial directly obtained from marine source or biomaterial of marine origin is the biocompatibility and stability. This section will deal briefly with the biosensors types, and certain important examples of biosensor fabrication utilizing biomaterials of marine origin.

56.6.1 Biosensors: An Introduction

Biosensors are analytical devices that are based on the coupling of an immobilized biologically active com-

Table 56.4 Some of the bioactive compounds isolated from marine resources

Species/source	Active ingredient	Property	References
Algae			
Sargassum graminifolium (Turn.)	Polysaccharide (SGP)	Inhibit calcium oxalate crystallization and antioxidant. Could be a candidate for treating *urinary stones*	[56.57]
Caulerpa sp.	Caulerpin	Analgesic and anti-inflammatory activity	[56.4]
Laminaria	Laminine	Reduce hypertension	[56.4]
Eisenia bicyclis	Phloroglucinol – Eckol and dieckol	Inhibit glycation and α-amlyase, so many have an effect on complications of diabetes	[56.58]
Arthrospira	Extract	To lower hyperlipidaemia, hyperglycaemia and hypertension	[56.59–61]
Sponge			
Luffariella variabilis	Manoalide	Antibiotic	[56.62]
Batzella sp.	Batzelladine A&B	Potent inhibition to the binding of HIV glycoprotein on CD4 receptors of T cells	[56.63]
Corals			
Sarcophyton glaucum	Sarcophytol A, hydroperoxyl cembranoids	Anticancer	[56.64–66]
Lobophytum crassum	Ceramides	Antibacterial	[56.67]
Mollusc			
Dicathais orbita	Tyrindoleninone and 6-bromoisatin	Potential for development of treatment against female reproductive cancers	[56.68]
Dolabella auricularia	Dolastatin-10 and 15	Antitumor activity against breast and liver cancer	[56.69, 70]
Elysia rufescens	Kahalalide F	Antitumor activity against breast, hepatoma, melanoma, and pancreatic carcinoma	[56.71, 72]
Marine Tunicate			
Ecteinascidia turbinata	Trabectedin	For the platimum sensitive ovarian cancer and tumor soft tissue sarcoma	[56.73]
Eudistoma sp.	Eudistomins	Antiviral activity	[56.74]
Marine Fish			
Syngnathus acus	Protein syngnathusin	Antitumor	[56.75]
Shark	Protein	Antitumor	[56.76]
Manta birostris	Protein	Antitumor	[56.77]
Arca subcrenata Lischke	Protein	Antitumor	[56.78]

pound called a receptor with a signal transducer and an electronic amplifier. Physiochemical change produced by specific interactions between a target and the biorecognition element is measured by a transducer. The transducer then converts the biochemical response into quantifiable electronic signal that is processed into an analog or digital format. The concentration of the analyte is directly proportional to the amount of signal generated, allowing for both quantitative and qualitative measurements. A general schematic of a biosensor is shown in Fig. 56.1. Biosensors have improved the performance of the analytical detection over the conventional analytical methods due to certain advantages, such as specific, rapid, and simple to operate, can be easily fabricated with minimal sample pretreatment involved. The apparently alien marriage of two contrasting disciplines combines the specificity and sensitivity of biological systems with the computing power of microprocessor. The potential applications of biosensors have continued to lie in the clinical diagnosis, bioprocess, food analysis, environmental monitoring, and etc. [56.79–81].

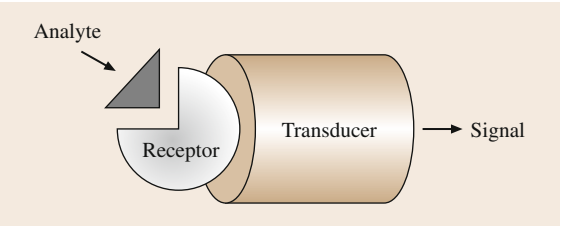

Fig. 56.1 Schematics diagram of the principle of biosensors

56.6.2 Components of Biosensors

Biosensors are highly selective technique due to the high substrate specificity of the enzyme and the interference free indication of the reaction product. Biosensors have offered the possibility of real-time analysis which is important for the rapid measurement of biological analysis. Various components have been received considerable interest in the fabrication of biosensors which included receptors, matrix for immobilization, methods of immobilization, and transducers as shown in the schematic diagram (Fig. 56.2).

Receptors

The biological elements that have been used in the creation of biosensors vary widely in type and include aptamers proteins, enzymes, nucleic acids, lipids, and living cells. The first step involved in a biosensor fabrication is the selection of biomolecule that forms a specific complex between an immobilized biologically active compound and a desired analyte.

The biological structure required for the biocatalytic receptor is usually derived from subcellular components and include enzymes, proteins, cells, and tissue [56.82]. These devices are based on immobilizing a biocatalyst into a transducer, transient, or steady-state responses are monitored by integrated detector that is finally displayed on a panel after processing and choice of the biological material and the adjusted transducer depends on the properties of each sample of interest and the type of physical magnitude to be measured. The type of a biocomponent determines the degree of selectivity or specificity of the biosensor. Thus, biosensors are classified, according to the type of involved active biological component in the mechanism, into biocatalytic and bioaffinity receptors (Fig. 56.3) [56.82–84].

56.6.3 Biosensor Fabrication Utilizing Biomaterials

For the immobilization of receptors or preparation of composites, several biomaterials such as collagen, chitosan, chitin, and alginate have been utilized in recent times for the fabrication of biocompatible, stable, and sensitive biosensors. For instance, a three-dimensional porous and biostable collagen scaffold has been developed to improve the biocompatibility of implantable glucose sensors by minimizing tissue reactions while stimulating angiogenesis around the sensors [56.85].

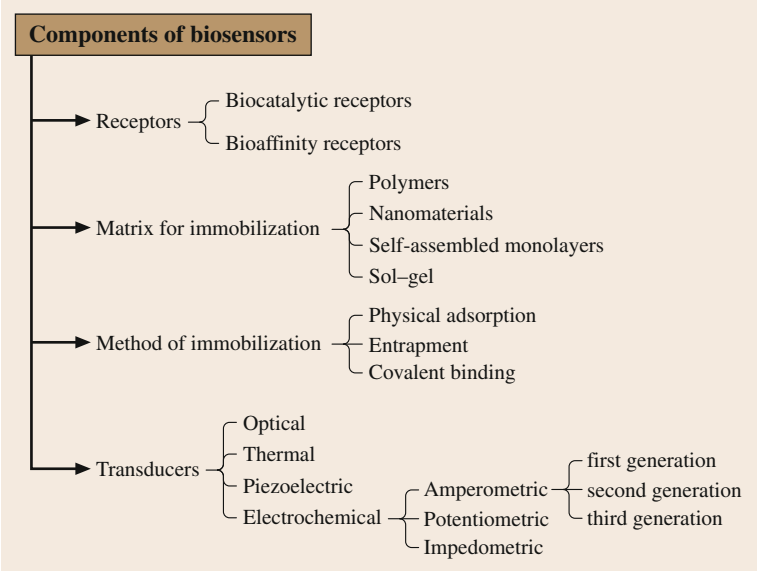

Fig. 56.2 A general component of biosensors

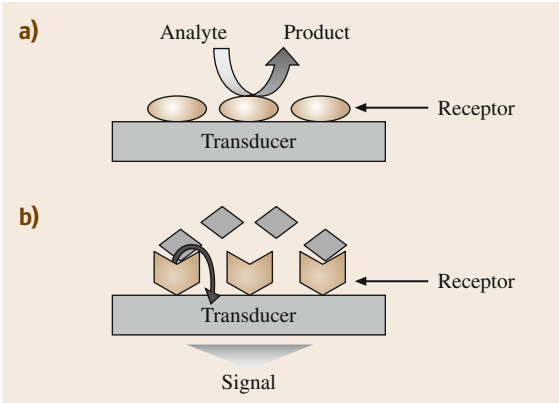

Fig. 56.3a,b Schematics illustration of the types of receptors: **(a)** biocatalytic and **(b)** bioaffinity receptors

The biostability of the collagen scaffold was enhanced through the cross-linking of nordihydroguaiaretic acid (NDGA) which was stable without any physical twist in the tissue of rats for 4 weeks. The response (i. e. sensitivity) of the developed sensors with porous scaffolds was not significantly changed when compared with sensors without, while the response time (T(95%)) was slightly delayed after a glucose concentration increase from 5 to 15 mM. These results indicate that the developed NDGA-cross-linked collagen scaffold biosensor was stable.

In another example, a multiwell plate-based biosensor containing B-cell hybridoma, Ped-2E9, encapsulated in type I collagen matrix, was developed for quick detection of living cells of *Listeria*, the toxin listeriolysin O, and the enterotoxin from *Bacillus* species [56.86]. This sensor measures the alkaline phosphatase release from infected Ped-2E9 cells colorimetrically. Pathogenic *L. monocytogenes* cells and toxin preparations from *L. monocytogenes* or *B. cereus* showed cytotoxicity ranging from 24 to 98% at 3–6 h postinfection. In contrast, nonpathogenic *L. innocua* (F4247) and *B. subtilis* induced minimal cytotoxicity, ranging only 0.4–7.6%. Laser scanning cytometry and cryo-nano scanning electron microscopy confirmed the live or dead status of the infected Ped-2E9 cells in gel matrix. The results shown by the author presents the first example of a cell-based sensing system using collagen-encapsulated mammalian cells for rapid point of the care detection system.

In recent times, chitosan has also been used extensively for the development of biocompatible biosensors. In some reports, chitosan is found to decrease the electron transfer process of the biosensors. Hence, a chitosan–nanomaterials composite are developed. In one example, direct electrochemistry of a glucose oxidase (GOD) – graphene–chitosan nanocomposite was studied [56.87]. The immobilized enzyme retains its bioactivity, exhibits a surface confined, reversible two-proton and two electron transfer reaction, and has good stability, activity. A much higher enzyme loading is obtained as compared to the bare surface without the nanobiocomposite. This nanobiocomposite film was used for sensitive detection of glucose from 0.08 to 12 mM glucose with a detection limit of 0.02 mM and much higher sensitivity as compared with other nanostructured supports. The excellent performance of the biosensor is attributed to a large surface-to-volume ratio and high conductivity of graphene and good biocompatibility of chitosan, which enhances the enzyme absorption and promotes direct electron transfer between redox enzymes and the surface of electrodes. Chitosan has also been widely used as electrochemical biosensor component for electrochemical nucleic acid biosensors, immunosensors, enzyme biosensors, and chitosan-modified voltammetric electrodes for trace analysis in real samples [56.88].

Chitin, the next most abundant biopolymer and imminent into its natural synthesis, enzymatic degradation, and chemical interactions with other biopolymers is vital in bioengineering and medical-device development such as implantable devices and detectors. Biosensors based on the ionic liquid (IL) and corn peroxidase immobilized on chemically cross-linked chitin have also been developed for the determination of adrenaline. The IL 1-butyl-3-methylimidazolium hexafluorophosphate ($BMIPF_6$) were constructed in a homogenate as a source of peroxidase, which was immobilized in chitin chemically cross-linked with carbodiimide and glyoxal. In the presence of hydrogen peroxide, the peroxidase catalyzes the oxidation of adrenaline to the corresponding *o*-quinone, which is electrochemically reduced at a potential of −0.23 V *vs.* Ag/AgCl. The developed biosensor demonstrated long-term stability and reproducibility and it was also applied for the determination of adrenaline in pharmaceutical samples indicating the applicability of chitin as a good substrate for enzyme immobilization and biosensor fabrication. This strategy can easily be adopted for the immobilization of other biomolecules. Very recently, chitin films were formed by spin coating trimethylsilyl chitin onto gold or silica substrates, followed by regeneration to a chitin film for the development of biosensors [56.89]. Infrared and X-ray photoelectron spec-

troscopy, X-ray diffraction, ellipsometry, and atomic force microscopy were used to confirm the formation of smooth, homogeneous, and amorphous chitin thin films. Quartz crystal microbalance with dissipation monitoring (QCM-D) solvent exchange experiments showed these films swelled with 49% water by mass. The utility of these chitin films as biosensors was evident from QCM-D and surface plasmon resonance studies revealed the adsorption of a bovine serum albumin monolayer. This system in future can be extended for in vitro bioimaging and cell proliferation platform generation.

Another biomaterial alginate has also been well utilized in the biosensor fabrication. One of the important applications of alginate in the sensor development is toward cholesterol determination in the human body which is important in diagnosis of diseases like coronary heart disease, arteriosclerosis, diabetes, and obstructive jaundice. In this direction, fluorimetric cholesterol biosensor based on self-assembled mesoporous alginate-silica (algilica) microspheres has been reported. For the fabrication of the biosensor, Pt(II)-octaethylporphine (PtOEP; oxygen sensitive metalloporphyrin) dye was loaded in the algilica microspheres using the solvent-mediated precipitation process. Cholesterol oxidase (ChOx) was then covalently immobilized to PtOEP/algilica microspheres using the carbodiimide coupling reaction. The analytical response of the biosensor to standard cholesterol displayed a linear dynamic range from 1.25 to 10 mM of cholesterol with regression coefficient of 0.996 (1.25–3.75 mM), 0.976 (1.25–6 mM), and 0.959 (1.25–10 mM) with the response time of 10 min. Thus, the developed cholesterol biosensor based on the alginate shows great potential in the diagnosis of hypercholesterolemia. This kind of marix can also be extended toward the development other enzyme-based biosensors. In another example, two biosensor configurations based on the entrapment of algal cells of *Chlorella vulgaris* into either a regular alginate gel or pyrrole-alginate matrix have been reported [56.90].

These developed biosensors were compared in terms of their amperometric current measurements to *p*-nitrophenyl phosphate when used as substrate for the detection of an algal alkaline phosphatase activity. The high stability of the pyrrole–alginate gel when compared to that of the alginate coating is herein demonstrated.

56.6.4 Scope for Biomaterials

According to a market research report reported by Markets & Markets (www.marketsandmarkets.com), the total global biomaterials market is expected to be worth USD 88.4 billion by 2017. The biomaterials are broadly used in orthopedic, cardiovascular, plastic surgery, wound healing, neurological, dental, ophthalmology, and tissue engineering. Of these, cardiovascular biomaterial market dominated the biomaterial market in 2012, followed closely by orthopedic. Stents, pacemakers, and implantable cardiac defibrillators are the largest segments marking the growth of the cardiovascular biomaterial market. The plastic surgery and wound healing applications are expected to spur the demand for biomaterials in the coming years (www.marketsandmarkets.com). Metals and polymers dominate the biomaterials market.

Ocean is a huge source of materials, even though the available knowledge of marine materials and mechanism is still in its beginning stage. The diversity of the biomaterials from marine resources and its potential can be increased further by chemical and physical modifications. These modifications in marine polysaccharides or other compounds are continuing challenge to polymer and biomedical scientists but output from these kinds of researches will widen up perspective and potential applications in the future. It is envisaged that marine-derived biomaterials have role of major relevance in biomedical field, due to its use on tissue repair and regeneration. Lot of research is going on in this field.

56.6.5 Conclusion

Biomaterials are the focus of major research efforts around the world as they have huge potential for all. Progress in this field requires a multisidisciplinary approach. An increasing number of compounds are currently being identified and isolated from marine organisms ranging from bioactive ingredients to medical devices. However, strong efforts are still needed to obtain medical-grade biomaterials from marine resources. Till now most of the biomaterial-based biosensors are developed are synthetic biomaterials. It is interesting to obtain the marine biomaterials such as sponge collagen, chitin, etc., to obtain more biocompatible biosensors. It is also be interesting to compare the sensitivity of the sensor systems based on the various types of biomaterials.

57. Enzymatically Synthesized Biosilica

Xiaohong Wang, Heinz C. Schröder, Werner E.G. Müller

Structural biomaterials are hierarchically organized and biofabricated. Biosilica represents the main mineral component of the sponge skeletal elements, the spicules. We summarize recent data on the different levels of molecular, biological, and structural hierarchies controlling the synthesis of the picturesquely and intricately architectured spicules/skeletons.

Biosilica is a promising material/substance for the amelioration and/or treatment of human bone diseases and dysfunctions. It has been demonstrated that biosilica causes in vitro, a differential effect on the expression of the genes OPG (osteoprotegerin) and RANKL (ligand of the receptor activator of NF-κB), as well as induces the expression of the key mediator BMP-2 (bone morphogenetic protein 2); they are promising candidates for treatment of osteoporosis.

57.1 The Sponges: The Earliest Ancestor of the Metazoa

Sponges (phylum Porifera) are aquatic, sessile, and multicellular organisms with a Bauplan that appears simple at a first glance and lacks similarities to any other living organism. Therefore, during early studies, it was difficult to determine morphological characters that would conclusively allow us to group sponges into either one of two kingdoms of multicellular life: Metazoa or Plantae. After comprehensive isolation, cloning, and phylogenetic analyses of many poriferan genes by our group, it became obvious that the phylum Porifera comprises of three classes – Hexactinellida, Demospongiae, and Calcarea – and forms the basis of the metazoan kingdom [57.1]. A few years later, it could be clarified that Hexactinellida (glass sponges), Demospongiae (silicate/sponging sponges), and Calcarea (calcareous sponges) are monophyletic and closely related to the common ancestor of all metazoans, the Urmetazoa [57.2].

Sponges appeared during the Neoproterozoic, the geologic period from 1000 to 542 Ma; [57.3]. Two major reasons contributed to the evolutionary success of the poriferan taxon: (a) symbiosis with microorganisms and (b) presence of hard skeletons [57.3]. The maintenance of symbiotic relationships with unicellular organisms allowed sponges to survive adverse environmental conditions because the autotrophic microbial symbionts represented rich organic carbon sources for them. On the other hand, the development of skeletal elements facilitated an increase in size, a common metazoan phyletic trend also known as Cope's rule [57.4]. Since changes in the body size affect almost every aspect of life, two strategies have been developed in animals to circumvent any constraints [57.5], first by acquisition of a hydrostatic skeleton, as it is known from the *worm*-like phyla of the Ediacaran and pre-Ediacaran Eon [57.6], or second

by acquisition of rigid solid skeletal elements [57.7, 8], as they were realized in Neoproterozoic siliceous sponges [57.3].

Skeletal elements (spicules) of siliceous sponges, Hexactinellida and Demospongiae, are composed of amorphous opal ($SiO_2 \cdot nH_2O$). They already existed in pre-Ediacaran sponges and represent a general and basic morphological character until today [57.9]. It is easily conceivable that why the animals integrated silicon instead of calcium as the fundamental element for their inorganic skeleton, since the Neoproterozoic oceans were rich in silicic acid and continuously replenished by products of the silicate weathering-carbonate precipitation cycle [57.10]. Sponges are provided with a sophisticated aquiferous canal system and hence, their body can be stabilized to some extent by internal hydrostatic pressure, even though a vasculomuscular system does not exist. The presence of a siliceous skeleton, however, allowed them to obtain sizes larger than 20 mm, even up to 2.5 m [57.11].

57.2 Silicatein-Based Siliceous Spicule Formation

The biogenic basis of spicule formation and the turnover of silica in spicules have already been depicted by *Duncan* [57.12]. He formulated *The spicule which has lived, has to decay, and may live again in another form*. However, it took up until 1999 until *Cha* et al. discovered that the main constituent of the proteinaceous filament within the axial canal of spicules is an enzyme [57.13], subsequently termed silicatein, which might be involved in biosilica formation. Soon after having identified this anabolic enzyme, also the corresponding catabolic enzyme (silicase) was discovered [57.14]. The identification of a biosilica degrading enzyme supported the view that the siliceous components in spicules are under metabolic turnover [57.15]. Studies on the metabolism of spicules on the cellular level became possible after the introduction of a poriferan cell culture system, primmorphs [57.16, 17]. Already the first contribution on that topic resolved that the spicule formation starts intracellularly in *J* sclerocytes, by the formation of an initial organic axial filament, around which the inorganic silica mantel is deposited. This result had later been corroborated by the application of more advanced immunochemical and electron microscopy techniques [57.18].

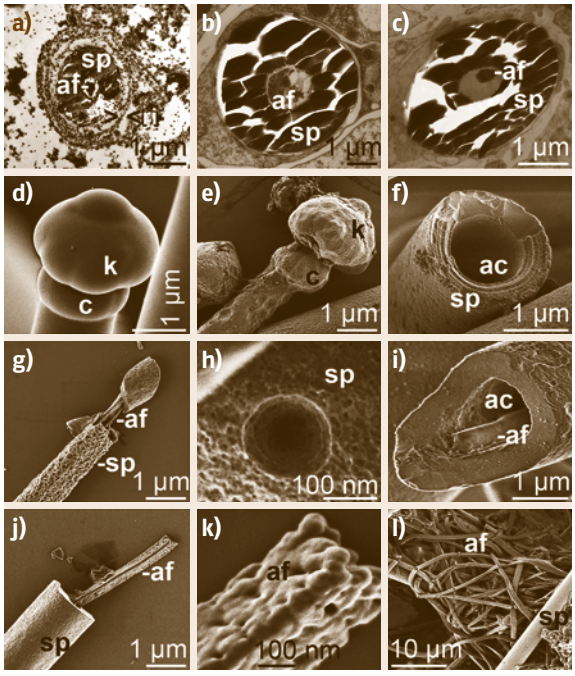

Fig. 57.1 Localization of the silicatein, packed within the axial filament, in the spicules from *S. domuncula*. **(a)** After raising of antibodies to silicatein it became possible to demonstrate, by electron immunogold labeling technique that concentric rings (ri) surround the growing spicules (sp) and react also with the axial filament (af). This approach also showed that the silicatein molecules are attached to the string- and net-like structures. **(b)** Immature spicule harboring a space-filling axial filament (af) within the axial canal. **(c)** In a more mature spicule (sp) the axial filament (af) had been shrunk. **(d)** A tylostyle head, the knob (k), that is based on a collar (c) at one end of the monaxonal pin. High-resolution scanning electron microscopy (HR-SEM): **(e)** after exposure of the tylostyle to HF vapor, the silica is progressively dissolved,exposing granular structures. **(f)** A broken *S. domuncula* spicule (sp), a tylostyle, displaying the axial canal (ac). **(j)** Progressive dissolution of the siliceous shell of the spicules (sp) releasing the axial filament (af). **(h)** At a higher magnification the plait cable-like organization of the axial filament (af) becomes obvious. **(i)** Bundles of axial filaments (af) released after HF treatment

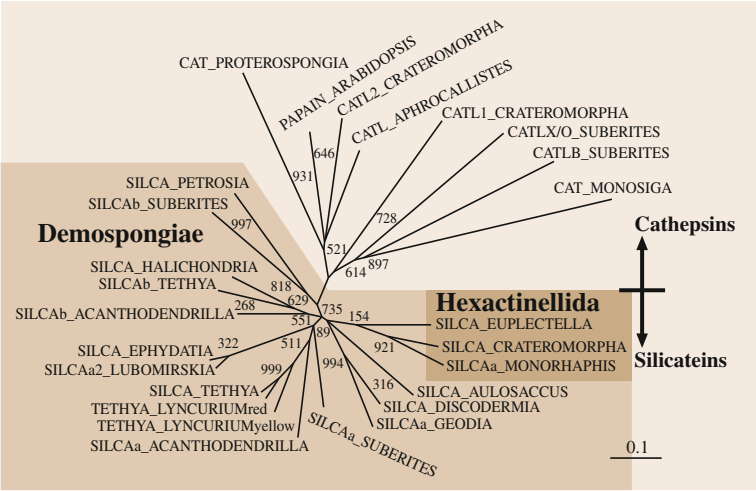

Fig. 57.2 Phylogenetic analysis of silicatein within the cathepsin family. The deduced proteins were aligned and the phylogenetic tree was constructed. The hitherto-known four hexactinellid sequences were included; silicatein from *Euplectella aspergillum* (SILCA_EUPLECTELLA; FR748156), *Crateromorpha meyeri* (SILCA_CRATEROMORPHA; AM920776), *Monorhaphis chuni* (SILCAa_MONORHAPHIS; FN394978) and the silicatein-like protein *Aulosaccus* sp. (SILCA_AULOSACCUS; ACU86976.1). The bulk of silicatein sequences have been identified in demosponges. Firstly, the silicateins-α sequences from *Suberites domuncula* (SILCAa_SUBERITES; CAC03737.1), *Tethya aurantium* (SILCAa_TETHYA; AAC23951.1), *Tethya lycurium* red variation (TETHYA_LYCURIUMred; FR748154) and *T. lycurium* yellow variation (TETHYA_LYCURIUMyellow; FR748155), *Discodermia japonica* (SILCA_DISCODERMiA; FR748157), *Geodia cydonium* (SILCAa_GEODIA; CAM57981.1) and *Acanthodendrilla* sp. Vietnam (SILCAa_ACANTHODENDRILLA; ACH92669.1), as well as from *Lubomirskia baicalensis* (SILCAa2_LUBOMIRSKIA; AJ968945) and *Ephydatia fluviatilis* (SILCA_EPHYDATIA; BAE54434.1). Secondly, the silicatein-β sequences from *S. domuncula* (SILCAb_SUBERITES; CAH04635.1), *T. aurantium* (SILCAb_TETHYA; AF098670_1) and *Acanthodendrilla* sp. Vietnam (SILCAb_ACANTHODENDRILLA; FJ013043.1). Thirdly, the silicateins that had been identified in marine sponges from which only one isoform had been obtained; silicatein from *Petrosia ficiformis* (SILCA_PETROSIA; AAO23671.1) and *Halichondria okadai* (SILCA_HALICHONDRIA; BAB86343.1). As reflected in the rooted tree, these silicateins derived from the cathepsins among which in this tree the following sequences have been included; cathepsin-like protein 2 *C. meyeri* (CATL2_CRATEROMORPHA; CAP17585.1), cathepsin-like protein 1 *C. meyeri* (CATL1_CRATEROMORPHA; CAP17584.1), mRNA for cathepsin L (catl gene) *Aphrocallistes vastus* (CATL_APHROCALLISTES; AJ968951); cathepsin B *S. domuncula* (CATLB_SUBERITES; CAH04630.1), cathepsin X/O *S. domuncula* (CATLX/O_SUBERITES; CAH04633.1). The resulting tree was rooted with the sequence from the papain-like cysteine peptidase XBCP3 *Arabidopsis thaliana* (PAPAIN_ARABIDOPSIS; AF388175_1). In addition, the cathepsins from choanoflagellates had been included to show that they derived, according to this tree, from the sponge cathepsins; the cysteine protease from *Proterospongia* sp. (PRL00000040) and the cathepsin from *Monosiga ovata* MNL00000103

57.2.1 Silicatein

Thorough dissolution of the inorganic silica from spicules (Fig. 57.1d; *Suberites domuncula* (demosponge) spicules) with hydrofluoric acid (HF) vapor revealed in addition to the presence of the axial filament a spicule-enfolding proteinaceous coat (Fig. 57.1e). The siliceous shell of the spicules can be dissolved by exposure to HF. During this process the polymerized silicic acid undergoes dissolution into monomeric silicic acid under the release of the organic component(s) of the spicules. Focusing on the tylostyles from the demosponge *S. domuncula*, both the knobs of the spicules (Fig. 57.1d,e) and the axial rod (Fig. 57.1f) undergo dissolution under release of the organic axial filament, located within the axial canal and additional proteins that are obviously initially localized within the silica coat of the spicule (Fig. 57.1d–f). While in the imma-

ture spicules the axial filament fills the complete axial canal, it shrinks at later stages (Fig. 57.1a–c). A pile of isolated axial filaments is shown in Fig. 57.1i.

After the discovery of the cathepsin L (cysteine protease)-related silicatein [57.13, 19] in spicules of the demosponge *Tethya aurantium*, several related genes were elucidated in both marine and freshwater demosponges [57.18]. The corresponding deduced polypeptides comprise of about 325 amino acids (aa) with a molecular weight of ca. 35 kDa. During maturation, this primary translation product (proenzyme) is processed by cleaving off a signal peptide (aa_1 to aa_{17}; *S. domuncula* (demosponge)silicatein-α) and the adjacent propeptide (aa_{18} to aa_{112}), resulting in the mature enzyme that has a size of 24–25 kDa. Similar to cathepsins, the catalytic center of silicatein contains His and Asn. However, the Cys of the cathepsins' catalytic triad is exchanged by Ser in silicatein. In addition to about 10 putative protein kinase phosphorylation sites, silicateins display a cluster of serine residues that is found close to the central aa residue of the catalytic triad, but is otherwise missing in cathepsins.

Subsequent phylogenetic analyses revealed that silicateins form a separate branch from cathepsins [57.18]; Fig. 57.2. The difficult accessibility of hexactinellids, which live primarily in depths of more than 300 m, generally results in a very poor sampling. Accordingly, only recently the first hexactinellid silicatein (*Crateromorpha meyeri*) could be identified and characterized [57.20]. This molecule shares high similarity to the demosponge sequences (expect value of 8×10^{-58}) and contains the same catalytic triad amino acids. However, striking in the *C. meyeri* sequence is a second Ser-rich cluster, which is located between the second and the third aa of the catalytic triad. Strong binding of the protein to the spicule silica surface has been attributed to this cluster [57.21]. The post-translational modifications of silicatein have been found to be essential for the enzyme activity with respect to (a) association with other structural and functional molecules within the tissue and (b) self-association/self-assembly. For those studies, silicatein had been isolated from spicules in the absence of HF, but in the presence of a glycerol-based buffer. Following this rationale, it could be demonstrated that silicatein exists not only in the axial canal but also in the extraspicular and extracellular space [57.22, 23]. The enzymatic reaction mechanism of silicatein had been proposed by *Cha* et al. [57.13]; the detailed properties of the reaction kinetics have been specified experimentally [57.24].

57.3 Spiculogenesis

With the primmorph cell culture system, the first solid evidence was provided that the synthesis of the spicules starts intracellularly [57.22]. The process of spicule formation can be divided into an initial intracellular phase and a subsequent extracellular shaping phase. Silicic acid, the substrate for silicatein, is actively taken up by cells (sclerocytes) via the $Na^+/HCO_3^-[Si(OH)_4]$ cotransporter. In parallel, silicatein is synthesized, processed, and stored with silicic acid in special organelles of the sclerocytes, the silicasomes. Within these organelles, the axial filaments are formed, around which silica is deposited enzymatically.

After formation of a first biosilica layer, immature spicules are released into the extracellular space, where they grow in length (axial/longitudinal direction) and in diameter (radial direction), by appositional layering of silica lamellae [57.23]. During growth in the axial direction, biosilica is formed through the enzymatic function of the axial filament silicateins. The growth of the spicule is driven by the elongating biosilica core cylinder, which is synthesized by the 23 kDa processed form of silicatein. The radial thickening of the spicules, their appositional growth (radial direction), occurs by deposition of silica on the surface of the growing spicule, and is mediated by the extraspicular 34.7 kDa immature silicatein. There is no evidence at all that, in demosponges, either in the axial filament or on the surface of the spicules, there is collagen that is causatively involved in biosilica formation.

57.3.1 Radial Growth

The radial, appositional thickening of the spicules and then the axial elongation process [57.23] were first understood (Fig. 57.3). In the extracellular space, the silicatein molecules are organized into larger entities, by concentric rings/cylinders around the spicule surface. These structures become stabilized by the protein galectin and Ca^{2+}; within these cylinders, the silicatein-mediated biosilica formation occurs. In hexactinellid spicules, these appositionally layered silica lamellae remain separated, and can reach 1000 in number [57.11].

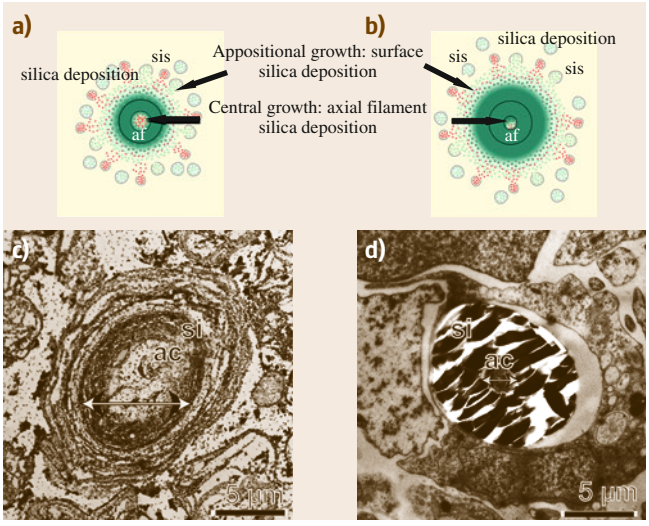

Fig. 57.3a–d The growth of the spicules occurs in two directions. This scheme shows the process of radial thickening of the spicule. **(a,b)** In the radial direction the spicules increase in thickness by appositional layering of the growing spicule (scheme). Both within the axial canal (ac), where the axial filament (formed of silicatein) is located (central growth), and on the surface of the spicules (appositional growth), the silica shell (si) increases in dimension through enzymatic synthesis of biosilica via silicatein. In the extra-spicular space, both silicatein and silica is released from silicasomes (sis); those silicasomes are set free from the surrounding cells. **(c,d)** Shrinkage of biosilica during biosilicification. **(c)** Growing siliceous spicules comprise a telescoped cylindrical arrangement. Approximately seven cylinders, formed from galectin, surround the axial canal (ac). Silicification, reflected by the densely packed grana, proceeds progressively from the central cylinders towards the surface of the spicule. Transmission electron microscopy (TEM): immunogold labeling with antisilicatein antibodies. **(d)** Section through a mature spicule, showing the axial canal in the center. The shrinking both of the spicule during formation/maturation, and of the axial canal is obvious

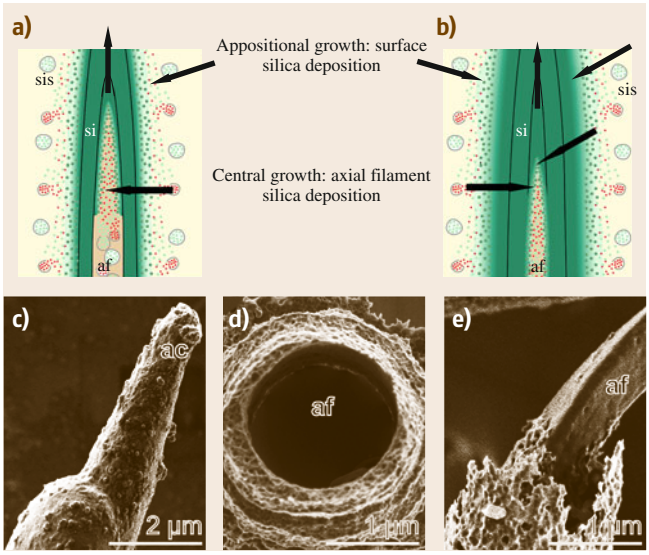

Fig. 57.4a–d Longitudinal growth of the spicules. **(a,b)** After the release of the immature spicule into the extracellular space via evagination of a cell protrusion the growing spicule is pushed away from the cell (sclerocyte) that initially has formed the immature spicule (scheme). This process is driven by an elongation of the cell protrusion and in turn an elongation of the axial filament (af) within the axial canal. Again it is highlighted that silica deposition occurs within the axial canal and onto the surface of the spicules. Around the spicules silicasomes (sis) exist that release silicatein and ortho-silicate to allow biosilica formation to occur. **(c)** A protruding axial canal (ac) is shown that harbors an axial filament. **(d)** Silica shell around the axial canal/axial filament (af). **(e)** A liberated axial filament (af) projecting from a spicule

In contrast, in demosponges, the individual lamellae fuse/bio-sinter together, and form a *solid* siliceous shell that surrounds the centrally located axial filament.

57.3.2 Longitudinal Growth

We provided, for the first time, experimental evidence for the involvement of cellular processes in the control of the axial growth of spicules (Fig. 57.4). Using the primmorph system, we demonstrated that these cell processes originate from evaginations of the spicule-forming cells (sclerocytes) into the growing and elongating axial canal. The experiments showed that, around a cell extension that protrudes from a sclerocyte into the axial canal of a given spicule, silicatein molecules are released into the extracellular space of the axial canal (the space between the cell membrane and the inner surface of the siliceous mantel) to catalyze biosilica deposition from the inner surface. This causes the axial canal to narrow from > 1 to $< 0.5\,\mu$m. Intracellularly, both the enzyme and its substrate (silica precursor) are stored in vesicles that have been termed as silicasomes [57.25]. These vesicles are released into the axial canal to allow the enzymatic polycondensation reaction.

Therefore, spicule formation requires two mechanistically independent biosilica condensation/deposition processes: first, biosilica formation, which gives rise to the inner core of the growing spicule, mediated by silicatein present in the axial filament; and second, lamellar, appositional growth (thickening), which proceeds on the elongating siliceous core via the formation of organic cylinders, enabling the layer-by-layer deposition of individual silica lamellae, which bio-sinter together in demosponges or remain separated, to a large extent, in hexactinellids.

57.4 Bio-Silica: The Enzymatically Formed Scaffold of Siliceous Sponge Spicules

Initially two different mechanisms had been proposed for silicatein reaction that might describe the condensation reaction of ortho-silicic acid or silicon alkoxide (TEOS) substrates [57.13, 26]. These models explain the hydrolytic activity of silicatein toward its synthetic substrate, TEOS, or the initial formation of disilicic acid from ortho-silicic acid as the natural substrate, but none of them is able to describe the biocatalytic formation of the polymeric silica from its monomeric precursors(s).

Recently, we proposed a new model which includes the two necessary assumptions for silicatein reaction: implication of the crucial Ser moiety and using ortho-silicic acid as substrate [57.27]. Using this model, it is possible to explain both the initial condensation reaction, the formation of disilicic acid, and the subsequent oligomerization process. As in the previous models, the initial catalytic step involves a nucleophilic attack (S_N2 type) of the (electronegative) oxygen atom from the hydroxy group of the active site Ser to the (electropositive) silicon atom of a silicic acid molecule. It is proposed that this reaction is facilitated by hydrogen bridge formation between the Ser hydroxy and the His imidazole within the catalytic center, a reaction that increases the nucleophilicity of the Ser hydroxy group. Then, a proton transfer from the His imidazole nitrogen (Ser · His hydrogen bond) to one of the silicon OH ligands of the pentavalent intermediate (in the transition stage) occurs, resulting in the release of a water molecule. In the next step, the silicic acid molecule which remains covalently bound through an ester-like linkage to the enzyme Ser moiety undergoes a nucleophilic attack on the silicon atom of a second ortho-silicic acid molecule, pulling it to the substrate pocket of the enzyme. Subsequently, the nucleophilicity of the attacking oxygen atom of the first (enzyme-bound) silicic acid molecule is assumed to be increased via formation of a hydrogen bond with the imidazole nitrogen of His, in analogy to the reaction proposed [57.28]. The loss of a water molecule generates a disilicic acid molecule, which remains bound to the enzyme. Now, a rotation of the ester bond allows the interaction of a second OH ligand of the enzyme-bound silicic acid unit with the imidazole nitrogen of the His in the catalytic center, giving rise to a further growth of the disilicic acid by a third orthosilicic acid molecule under a release of a further water molecule. Adopting previous data [57.29], our model proposes a final cyclization step. The products released from the enzyme by hydrolytic cleavage (cyclic trisilicic acid and higher oligomers) are much more reactive than the silicic acid monomers and promote further condensation reaction.

Enzyme kinetic studies were performed with recombinant silicatein-α and the model substrate bis(*p*-aminophenoxy)-dimethylsilane (BAPD) which contains two silicic ester-like and two silane bonds [57.24].

In this assay, the temperature optimum was in the range of 20–25 °C, revealing a value for the temperature coefficient (Q_{10}) that decreased by 2.5-fold above 25 °C (25 °C/35 °C) and increased by 2.9-fold below 25 °C (15 °C/25 °C). The Michaelis constant (K_m) was determined to be 22.7 μM. In comparison, the K' value for human recombinant cathepsin L, the closely related enzyme to silicatein, was 1.1 μM by using the substrate benzyloxycarbonyl-Phe-Arg-4-methylcoumarin-7-amide [57.30]. The turnover value (molecules of substrate converted per enzyme molecule per second) for silicatein in the silica esterase assay was 5.2, close to the value found for the human cathepsin L [57.31]. Very recently, the activity of the recombinant silicatein-α was determined in in vitro, assays and compared with the silica-forming activity during spicule formation in vivo [57.32]. The silica-forming activity in vivo, was assessed by calculating the amount of biosilica formed from the growth rate of the spicules of the demosponge *Ephydatia fluviatilis*. The growth rate of those spicules with an average size of 200–350 μm and a thickness of 15 μm was determined to be 1–10 μm h^{-1} in length [57.33]. This implies that the total weight of one spicule is approximately 88.3×10^{-9} g, which is equivalent to about 4.4×10^{13} molecules of biosilica being formed during 1 h in one spicule. Adopting a protein content of about 5% (mainly silicatein-α) in a siliceous spicule [57.21], it follows that 2.2×10^{-10} g of protein catalyze the synthesis of 4.4×10^{-9} g of biosilica per hour. Since the molecular mass of mature silicatein is 25 kDa, it follows that 8.8×10^{-15} mol of silicatein (5.3×10^{9} molecules) synthesize 4.4×10^{-9} g (equivalent to 7.33×10^{-11} mol (4.4×10^{13} molecules)) of biosilica per hour. In turn, and referring to native silicatein, the turnover number of silicate per silicatein on a molar basis is 8×10^{3} molecules of converted substrate per silicatein molecule per hour in spicules. With respect to recombinant silicatein-α, a value of 18.7×10^{3} molecules per molecule of silicatein-α per hour (substrate BAPD) had been determined for the esterase activity [57.24] and 5.4×10^{3} molecules per molecule of silicatein-α per hour using ortho-silicic acid as a substrate [57.32]. This value can even increase by the addition of silintaphin-1 in a 4 : 1 molar stoichiometric ratio (silicatein-α : silintaphin-1) by > 5-fold. Based on these calculations, it is most likely that the silica polymerization activity during spicule formation is mediated enzymatically by silicatein only [57.34].

57.5 Self-Healing Property of Silicatein Embedded in Spicules

The central canal of the spicules contains the proteinaceous axial filament (Fig. 57.5b) that is laterally assembled by about 10 nanofibrils [57.35]. By completion of the formation of the mature spicules, the axial filament remains embedded in this central structure. After treatment of the spicules with HF, the proteinaceous filaments can be recovered [57.35] and stained with Coomassie brilliant blue. With progressing time, the silica is dissolved, leaving behind only the organic axial filament. It is surprising that the proteinaceous axial filament remains preserved in the spicules, even in spicules of an age of about 2 Ma, as demonstrated for the Baikalian sponge *Lubomirskia baicalensis* [57.36]. The silicatein in these axial filaments remains functionally active as silica-binding protein [57.13], or as enzyme [57.32] after dissolution of the biosilica shell. This functional activity of the axial filament can be demonstrated by incubating them with prehydrolyzed TEOS (orthosilicate). If the incubation is performed in the presence of 6 μg/mL of axial filament protein in a 50 mM Tris/HCl buffer (pH 7.4; 150 mM NaCl), containing 200 μM orthosilicate bulky depositions of biosilica onto the axial filament structures can be visualized. Those structures cover almost completely the axial filaments after an incubation period of 180 min. Axial filaments do not exist not only as rods, like those isolated from the tylostyles from *S. domuncula* but also appear as radial tufts, as in asters from *G. cydonium* [57.37].

After indenting and partial cracking the spicule, the silicatein molecules become exposed to the environment (Fig. 57.5b) and the silica mantel crumbles. In case if orthosilicate is present in the aqueous environment at sufficiently high concentrations, the silicatein can associate with those monomers and can form biosilica. The concentrations of silica in the present-day oceans, with about 5–20 μM [57.38], might be sufficient to realize an extensive biosilica deposition as the K_m value for silicatein was determined to be 22.7 μM [57.24]. In turn, even spicules directly exposed to the aqueous environment have the capacity to self-heal (partially) broken spicules. If existing as skeletal elements in the body, the high concentrations of silica in the spicule-synthesizing cells, the sclerocytes,

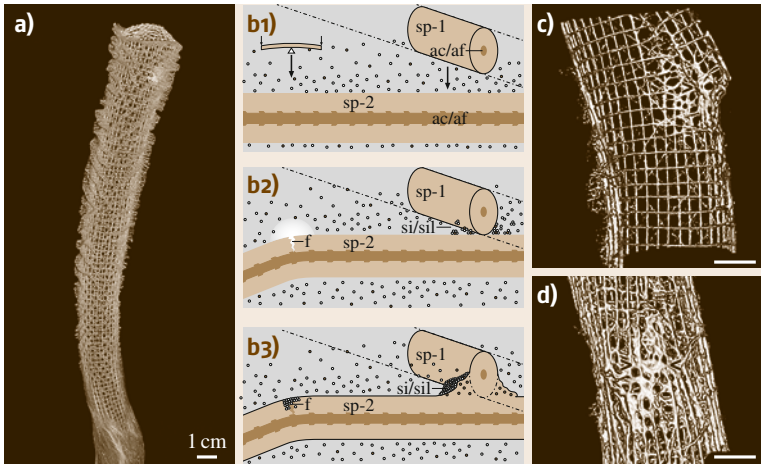

Fig. 57.5a–d Silicatein-mediated self-healing process in sponge spicules. **(a)** *Euplectella aspergillum* skeleton, formed of spicules that are fused to a biosilica continuum. The spicules are regularly organized in a modular segments. **(b)** Schematic outline of the silicatein-driven self-healing process in sponge spicules. **(b1–b3)** In sponge tissue (primmorphs) that has been treated with Mn-sulfate, biosilica is un-physiologically deposited outside of two crossing spicules, spicule sp-1 and sp-2. The fusion of the two spicules occurs by biosilica deposition; biosilica is enzymatically formed from silicatein (sil) and its substrate ortho-silicate (si). This fusion process is catalyzed by silicatein that is released by cells into the extracellular space; there it becomes associated with the surface of the spicules. In the second self-healing process, silicatein oozes out from the axial canal (ac), which harbors the axial filament (af). This axial filament is composed of silicatein. During this process of self-healing, silicatein is oozing out into the fissure (f) that happened in the silica mantel of the spicule. In the presence of ortho-silicate this rupture is resealed again. **(c,d)** Very rarely the biosilica formed spicular skeleton had been broken and reunified (><)

are sufficient to provide silicatein with the appropriate level of silica for the enzymatic synthesis of biosilica.

Repair, self-healing, processes taken place within spicules can be frequently recognized within hexactinellid spicules in their lamellar regions, for example, within the giant basal spicules of *M. chuni* or in the skeleton of *Euplectella aspergillum* (Fig. 57.5a–c). Fractures that have been introduced into the spicules, followed by a stay in a dry environment for a short time, remain nonsealed. However, fractures within the lamellae that occur in spicules during the growth phase fuse almost completely together (Fig. 57.5c,d).

57.6 Bio-Silica: The Osteogenic Bioinorganic Polymer

The formation of the skeletal system from the earliest metazoans, the sponges (phylum Porifera) [57.36] to the crown taxa, the mammalians [57.39], and the insects [57.40], is dominated by a tuned communication between cells controlling anabolic processes and cells executing catabolic reactions. Basically, two kinds of inorganic scaffold materials had been applied in the metazoan kingdom to form skeletons: calcium (calcium-based skeletal systems) and – only found in siliceous sponges – silica (silica-based skeletons).

A breakthrough in the understanding of the siliceous spicule formation of the demosponges and the hexactinellid sponges came from the discovery that the axial filaments of the spicules, the skeletal elements of these sponges (demosponges [57.13]; hexactinellids [57.20]) contain an enzymatically active protein which synthesizes polymeric silicate, the biosilica. This enzyme, silicatein, has been found to catalyze/polycondensate biosilica during the axial and radial growth of the spicules. In contrast to plant phytoliths and diatom frustules, where biosilica is deposited from a supersaturated solution onto organic templates, the siliceous spicules of sponges are formed in a hypo-saturated intraorganism environment following an enzymatic mechanism by lowering the activation energy of the polycondensation reaction. In in vitro, systems,

orthosilicic acid or tetraethyl orthosilicate (TEOS) has been used as substrate/biosilica precursor for the enzymatic reaction. During the latter process, ethanol is released [57.13]. The silicatein-mediated formation of silica proceeds at silica substrate concentrations of around 200 μM, far below the concentrations which are required for the chemical condensation of 1 mM or higher at neutral pH [57.34, 41, 42].

Silica is an essential nutrient both for the natural ecosystem in general [57.43] and for humans and other vertebrates in particular [57.44, 45]. Importantly, silicon deprivation results in severe skeletal malformations [57.46]. The experimental studies showed that in avian connective tissue, the highest silicon concentrations are found, in contrast to heart or muscle tissue, where the silicon concentrations are much lower. Moreover, a spatial correlation could be established between the areas of bone formation within animal tissue and the accumulation of silicon. Based on these data, it has been concluded that a burst of silicon accumulation occurs around the osteoid and osteoid–bone interfaces, implying that this inorganic component is essential for bone formation. Consequently, we studied the effect of biosilica on the activity of osteoblasts and osteoblasts in vitro. SaOS-2 cells were grown in the activation cocktail on a support, coated either with hydroxyapatite (HA) or with biosilica. The cell layers that were grown on HA did not form HA crystals on their surfaces, while the cells that had been cultivated for 5 days on biosilica well formed HA crystals that are often fusing to clusters [57.47]. This observation which had been supported by alizarin red S staining assays underscores that biosilica displays an inductive effect on SaOS-2 [57.47, 48].

The tuned interaction of osteoblasts and osteoclasts during bone formation is well established. Furthermore, the decisive role of the osteoclastogenic ligand RANKL (ligand of the receptor activator of NF-κB) had also been discussed. This ligand is processed by metalloproteases to a soluble form and interacts with RANK (receptor activator of NF-κB) and finally induces osteoclastogenesis [57.49]. This molecular cross-talk that coordinates osteoclastogenesis is controlled by the third component, OPG (osteoprotegerin); this osteotropic effector acts as a soluble bone protector [57.50]. In turn, the molecular triad, OPG/RANK/RANKL (NF-κB ligand) [57.51], is not only crucially controlling osteoclast differentiation, but is also involved in cell differentiation pathways of the immune and vascular systems [57.49]. Vice versa, recent results provided experimental evidence demonstrating that osteoclasts contribute with their cytokines to the fine-tuning of the osteoclast/osteoblast balanced functions [57.52].

Previous experimental evidence showed that silicate/silicon is an essential trace element in vertebrate nutrition [57.46, 53, 54]. In continuation, we showed that biosilica induces HA crystallite formation in SaOS-2 cells [57.55]. More recently, we demonstrated that in SaOS-2 cells, after exposure to biosilica, a differential gene expression is seen that strongly up-regulates the steady-state level of OPG transcripts and leaves the level of RANKL transcripts almost unchanged. Based on the observed increase of the OPG/RANKL ratio, it was intriguing to suggest that silica/silicate has a favorable biomedical potential for the treatment and/or prophylaxis of osteoporotic disorders [57.48]; Fig. 57.6. Since silica was found to elicit in vitro, an increased (^{3}H)dThd incorporation into DNA and a likewise increased HA formation, an osteogenic potential of silica had been deduced [57.47]. Finally we discovered that SaOS-2 cells, after exposure to biosilica, release a soluble factor, the *osteoblasts-derived inhibitory factor*, which causes an inhibition of RAW 264.7 cell growth [57.56].

57.7 Future Design of Novel Bioinspired, Silica-Based Materials

The longest-lived animals, existing at present on Earth, are the species of the hexactinellid *M. chuni*, which reach an age of 11 000 years [57.57]. During this period, the biosilica-based giant basal spicule persisted as the main skeletal element in the bodies of this sponge. This observation reflects one of the properties of sponge biosilica to be durable and simultaneously flexible and resistant against breakage. Even more, since the major organic component of the biosilica nano-hybrid particles is silicatein, it can be assumed that the biosilica material comprises a self-repair property as well [57.58]. The biosilica-based sponge spicules, as intelligent structures, do not always function in the same way; they have the adaptive ability to adjust their degree of polycondensation to reach the preferred physical and chemical properties. Through the genetic and biological means provided by the silicatein-based system, the polycondensation/gelation process can be controlled and in turn the level of polymerization, coarsening, and phase trans-

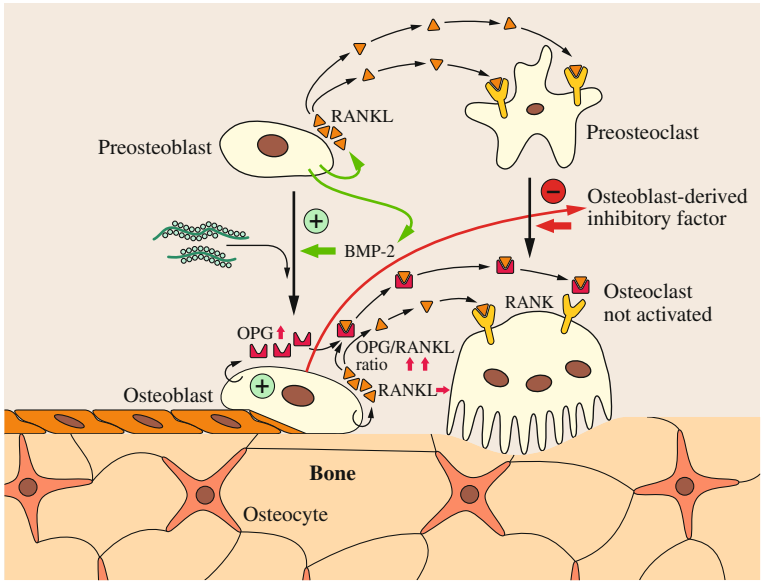

Fig. 57.6 Proposed effects of biosilica on osteoblasts, osteoclasts, and their progenitor cells; schematic representation. Biosilica causes an increased expression of OPG in osteoblasts. In addition, the differentiation of osteoblasts is induced and accelerated by BMP-2 (bone morphogenetic protein 2). It is assumed that in turn the osteoblasts acquire the potential to differentiate to osteocytes and to lining cells. Furthermore, OPG counteracts various effects of RANKL, a cytokine that induces preosteoclast maturation and osteoclast activation. Finally, it could be identified that the osteoblasts release a factor, the osteoblasts-derived inhibitory factor that strongly inhibits the proliferation of osteoclasts; the nature of this factor is not yet known

formation can be adjusted. Since it is common in biological systems that reactions are reversible, a feedback control might also exist in the silicatein-based biosilica reaction, allowing a proof-reading process of the quality of the product (here the polymeric silica) formed. This property, a characteristic feature of all living systems, provides them with high flexibility and robustness. It should be mentioned that also the silicatein reaction is reversible [57.24]; the action of this usually acting enzyme, the silicase [57.14]. Dynamic feedback control mechanisms are crucial elements adjusting the dynamic homeostasis of the internal environment of living systems [57.59] and are very difficult to realize and to adapt for artificial bionic processes.

The work on biosilica in sponges already provides us with strategies to fabricate nano-hybrid particle-based glass materials which are moldable and might be used as potential biomaterials accelerating bone-repair processes [57.60]. In the near future, it is expected that intelligent materials based on biosilica can be produced in cell culture systems, by controlling the gene expression of the key molecules, silicatein and silintaphins. A first success has already been achieved by the demonstration that the process of aging and syneresis in the sponge cell system, the primmorphs, can be modulated by inhibition of the function of the aquaporin membrane pores [57.61, 62]. Through this approach, a fusion of individual biosilica spicules can be induced that had not been seen in nature before.

58. Biomineralization in Marine Organisms

Ille C. Gebeshuber

This chapter describes biominerals and the marine organisms that produce them. The proteins involved in biomineralization, as well as functions of the biomineralized structures, are treated. Current and future applications of bioinspired material synthesis in engineering and medicine highlight the enormous potential of biomineralization in marine organisms and the status, challenges, and prospects regarding successful marine biotechnology.

58.1 Overview

Marine biotechnology has huge potential across a broad spectrum of applications, ranging from biomedicine to the environment. However, marine biotechnology has not yet matured into an economically significant field [58.1]:

> *Fundamental knowledge is lacking in areas that are pivotal to the commercialization of biomedical products and to the commercial application of biotechnology to solve marine environmental problems, such as pollution, ecosystem disease, and harmful algal blooms.*

One of the recommendations of the 2002 report of the Ocean Studies Board and the Board on Life Sciences is that better tools should be developed for the use of marine biotechnology to help solve environmental problems such as biofouling, pollution, ecosystem degradation, and hazards to human health.

This chapter gives a functional approach to biomineralization in marine organisms. It presents the materials that are biomineralized (which include simple precipitated minerals, biologically produced perfect crystals, and composites of minerals and an organic matrix with interesting new properties) and the proteins that are important in biomineralization, gives an overview of some of the thousands of marine organisms that produce such materials, including information on the respective biomineralized struc-

tures and their functions, and finally presents current and possible future applications of bioinspired material synthesis in engineering (including mining) and medicine.

One of the amazing properties of biomineralization in organisms is that material, structure, and function are strongly correlated. Biominerals are highly controlled in structure, composition, shape, and organization, and can yield new, more benign approaches in engineering. The complex shapes of biominerals cannot be explained with simple mechanistic models of crystal growth [58.2].

Biotechnologists, material scientists, biologists, geologists, engineers, and medical doctors have long been fascinated by mineral structures in organisms. Now, with highly developed measurement devices at our disposal, we can investigate and understand biological materials, structures, and processes, and increasingly produce related bioinspired analogs [58.3].

Minerals are usually stiff, brittle, and cheap energy wise. Organic materials are soft and pliable. The synergistic combination of both yields biominerals with amazing functionalities, with a lightweight organic frame (which saves metabolic energy), filled with *cheap* inorganic material (e.g., calcium carbonate), yielding inorganic-organic hybrids (biocomposites) with well-defined mechanical properties [58.4].

Biominerals have functional structures and shapes, e.g., curved teeth and light baskets. The organic matrix acts as a meditator of mineralization and as crystal modifier. Characteristics of materials produced by controlled biomineralization are uniform particle sizes, well-defined structures and compositions, high levels of spatial organization, complex morphologies, controlled aggregation and texture, preferential crystallographic orientation, and higher-order assembly into hierarchical structures.

In contrast to most other biological transformations, biomineralization leaves far-reaching effects on the biosphere and lithosphere, including traces such as bones, shells, and fossils, but also mountain ranges and cliffs [58.5]. Biomineralization has implications on the global scale, via the Earth sciences. It is important in the global cycling of elements, in sedimentology, in fossilization (paleontology and taxonomy), in marine chemistry, and in geochemistry [58.4].

In the course of biomineralization, mineral products (biominerals) are created in organisms. Biomineralization has been around since the first Prokaryota appeared in the Archaean, the geological aeon from about 4 to 2.5 billion years ago. Biomineralization is of high interest to biologists and also to engineers, material scientists, and tissue engineers.

Biomineralization is characterized by interesting chemical reactions involving proteins, the creation of perfect crystals, the control of crystal growth and inhibition depending on the crystallographic axis, as well as the production of composite materials with properties that are of high value to engineering. Many biological fluids are supersaturated with respect to certain inorganic minerals, but crystals do not form spontaneously. An example of such crystal growth inhibition is saliva; it is supersaturated with respect to hydroxyapatite formation, yet teeth do not grow continuously. The overgrowth is prevented by phosphoprotein macromolecules that bind to enamel crystals.

Solubility controls biomineralization. Organisms produce hard parts by exceeding the solubility of the mineral component. Increased CO_2 in the oceans increases carbonate mineral solubility, making biomineralization of calcium carbonate structures more difficult. Many of these calcium carbonate biomineralizing organisms are important parts of the marine food chain.

The number of marine biomineralizers is vast. There are 128 000 species of molluscs, 700 species of calcareous green, red, and brown algae, more than 300 species of deep-sea benthic foraminifera, and 200 000 diatom species [58.6].

Biomineralization describes the formation of organized mineral structures through highly regulated cellular and molecular processes. Examples of biomineralized materials are enamel (97% mineral) and dentin (70% mineral), as well as bone (70% mineral). Crystal formation takes place in two steps: crystal nucleation (requires a high degree of saturation) and crystal growth (requires lower degree of saturation).

58.1.1 Marine Biomining

Current methods of mining are, in many cases, not environmentally sustainable. It might be interesting to focus on bio-assisted ways of obtaining resources such as Fe, Al, and Ti from marine environments (Table 58.1) [58.7]. All kinds of microbes contribute actively to geological phenomena, and central to many such geomicrobial processes are transformations of metals and minerals. Bioremediation is the use of biological systems for the clean-up of organic and inorganic pollution, with bacteria and fungi being the most important organisms for reclamation, immobilization, or detoxification of metallic and radionuclide pollutants [58.8].

Table 58.1 Concentration of transition metals and zinc in seawater (after [58.11], original references after [58.12–14])

Element	Seawater (M) × 10^8
Fe	0.005–2
Zn	8.0
Cu	1.0
Mo	10.0
Co	0.7
Cr	0.4
V	4.0
Mn	0.7
Ni	0.5

Biomining is the use of microorganisms and plants (phytomining) to aid in the extraction and recovery of metals from ores [58.9]. The microorganisms that grow in this aerobic, lithotrophic, and acidic environment are usually chemolithoautotrophic, using reduced forms of sulfur and iron, and acidophilic [58.10, p. 307].

Microorganisms themselves might be very beneficial in this kind of approach or processes inspired by biological processes that go on in biomineralizing organisms [58.15, 16]. The usage of controlled microbial cultures in order to concentrate certain minerals and ores was discussed already in 1972 [58.17]. It might be worth reconsidering such ideas, with the increased knowledge of biomineralization and environmental impact, as well as the novel methodologies that we now have at our disposal.

Bacteria that are active in marine microbial corrosion are promising with respect to marine mining. *Acidithiobacillus ferrooxidans*, for example, lives in pyrite deposits, metabolizes iron and sulfur, and produces sulfuric acid. *Acidithiobacillus thiooxidans* consumes sulfur and produces sulfuric acid. Both of these bacteria are already used as catalysts in bioleaching, whereby metals are extracted from their ores through oxidation. *Sulfobacillus* sp. are ferrous-iron and mineral-sulfide-oxidizing bacteria. *Sulfurivirga caldicuralii* is a microaerobic, thermophilic, thiosulfate-oxidizing chemolithoautotroph that is related to pyrite, arsenical pyrite, and chalcopyrite. The archaea *Sulfolobus shibitae, Metallosphaera* sp. and *Acidianus infernus* are related to chalcopyrite [58.18].

> *In low-temperature, aqueous habitats with oxygen, bacteria can affect the dissolution or precipitation of minerals through their reduction or oxidation of compounds containing Mn, Fe, S, C, U, Cu, Mo, Hg, and Cr* [58.10, p. 306].

Certain organisms are involved in the deposition of marine minerals, e.g., bacteria in deep-sea polymetallic nodules and coccoliths in seamount crusts [58.19]. Biosynthesis and bioleaching, i. e., extraction of specific metals from their ores through the use of bacteria and further organisms, are of increasing importance.

Limestone and other fixed carbonates represent 1.8×10^{22} g carbon in the Earth's lithosphere [58.20]. 40% of the Earth's limestone deposits that were previously thought to be of abiotic origin are, in fact, the consequence of heterotrophic bacterial metabolism [58.21], which thus emphasizes the role of microbial mineralization (carbonation) in the process of locking atmospheric and organic carbon as carbonate rocks back to the Earth's lithosphere, a long-term carbon storage compartment. While the precipitation of carbonate leads to CO_2 release in the ocean, this reaction must be considered in terms of final balance, as the buried sedimentary layers of carbonate, which no longer interact with the ocean water, constitute a long-term carbon sink [58.22]. The oceans absorb about half of the carbon dioxide that is generated when burning fossil fuels. As a consequence of this increased amount of carbon dioxide, the oceans are becoming increasingly acidic, which is resulting in less calcium carbonate biomineralization and a potential collapse of the marine ecosystem.

58.2 Materials – Biominerals

Many organisms build inorganic structures in various shapes and forms. The synthesis, as well as the size, morphology, composition, and location of these biogenic materials is genetically programmed and controlled. Detailed investigations and descriptions of biomineralization have only become possible with the modern methods that are now at the disposal of biologists. Many of the crystals and composite materials made up of proteins and amorphous inorganic parts are still unknown in current inorganic chemistry. Nowadays we know more than 70 minerals that are produced by organ-

Table 58.2 Non-exhaustive list of biominerals produced by marine organisms (after [58.4, 23–27])

Biomineral	Chemical formula	Marine biomineralizers of the respective biomineral
Carbonates		
Calcite	$CaCO_3$	Foraminiferans (e.g., *Rosalina leei* and *Spiroloculina hyaline*), coccolithophorids, brachiopod and mollusc shells, crustaceans, mammals, birds, corals, Archaeocyatha, bryozoans, echinoderms (brittle star, sea urchin, star fish, sand dollars, sea cucumbers…), Serpulidae (tube-building annelid worms in the class Polychaeta), barnacles, cyanobacteria, sponges, algae
Mg-calcite	$Mg_xCa_{1-x}CO_3$	Foraminiferans, calcareous and hypercalcified sponges, calcareous sponge spicules, octocorals, crustaceans, echinoderms, corals, bryozoans
Magnesite	$MgCO_3$	Tropical coralline alga *Hydrolithon onkodes*, cyanobacteria
Aragonite	$CaCO_3$	Hypercalcified demosponges, scleractinians, brachiopods, molluscs, teleosteans, bryozoans, Serpulidae (tube-building annelid worms in the class Polychaeta), algae, bacteria
Vaterite	$CaCO_3$	Ascidians
Monohydrocalcite	$CaCO_3 \cdot H_2O$	
Protodolomite	$CaMg(CO_3)_2$	Sea urchin teeth (protodolomite: a crystalline calcium-magnesium carbonate with a disordered lattice in which the metallic ions occur in the same crystallographic layers instead of in alternate layers as in the dolomite mineral)
Hydrocerussite	$Pb_3(CO_3)_2(OH)_2$	
Amorphous calcium carbonate (at least five forms)	$CaCO_3 \cdot H_2O$ or $CaCO_3$	Vascular plants, crustaceans
Dolomite	$CaMg(CO_3)_2$	Tropical coralline alga *Hydrolithon onkodes*, sea urchin teeth, embryos of the Nudibranch gastropod *Aplysia punctata*
Strontianite	$SrCO_3$	Marine snail shells, microbes, cyanobacteria
Siderite	$FeCO_3$	Bacteria
Phosphates		
Octacalcium phosphate	$Ca_8H_2(PO_4)_6$	Vertebrates (bone/teeth precursor)
Hydroxyapatite	$Ca_5[OH\|(PO_4)_3]$	Vertebrate bones, vertebrate teeth (enamel), brachiopods, conodonts (teeth), fish (scales), in the radular apparatus of the mollusc *Falcidens* sp.
Brushite	$CaHPO_4 \cdot 2H_2O$	Tropic bivalve species *Codakia orbicularis* and *Tivela mactroides*
Francolite	$Ca_{10}(PO_4)_6F_2$	Linguliformea (brachiopods)
Carbonated hydroxyapatite	$Ca_5(PO_4,CO_3)_3(OH)$	Bones
Carbonated apatite (dahlite, dahllite)	$Ca_5(PO_4,CO_3)_3F$	Bones, dental enamel, dentin
Whitlockite	$Ca_{18}H_2(Mg,Fe^{2+})_2(PO_4)_{14}$	Dental plaque
Struvite	$Mg(NH_4)(PO_4) \cdot 6H_2O$	Bacteria, embryos of the Mediterranean mussel *Mytilus galloprovincialis*
Vivianite	$Fe_2^{3+}(PO_4)_2 \cdot 8H_2O$	Bacteria
Amorphous calcium phosphate (at least six forms)	Variable	Vertebrates, bivalves, crustaceans, chitons (teeth), gastropods (gizzard plates)
Amorphous calcium pyrophosphate	$Ca_2P_2O_7 \cdot 2H_2O$	Granules in the hymenostomatidian ciliate *Tetrahymena pyriformis*

Table 58.2 (continued)

Biomineral	Chemical formula	Marine biomineralizers of the respective biomineral
Oxides and hydroxides		
Magnetite	Fe_3O_4	Eubacteria, Archaebacteria, teleosteans, polyplacophorans (chitons)
Amorphous ilmenite	$Fe^{+2}TiO_3$	Foraminifera, snail radulae
Maghemite	γ-Fe_2O_3	Magnetotactic bacteria
Amorphous iron oxide	Fe_2O_3	In the radular apparatus of the mollusc *Falcidens* sp.
Amorphous manganese oxide	Mn_3O_4	Bacteria
Manganese(III) oxohydroxide	MnOOH	Bacterial spores of the marine *Bacillus*, strain SG-1
Goethite	α-FeOOH	Gastropods, limpet teeth, marine sponges
Akaganeite	β-FeOOH	Bacteria
Lepidocrocite	γ-FeOOH	Polyplacophorans (chitons), marine sponges
Ferrihydrite	$(Fe^{3+})_2O_3 \cdot 0.5H_2O$	Lamprey *Geotria australis*, chitons, snails
Todorokite	$(Na,Ca,K,Ba,Sr)_{1-x}(Mn,Mg,Al)_6O_{12} \cdot 3{-}4H_2O$	Hydrothermal vent microbes
Birnessite	$(Na_{0.3}Ca_{0.1}K_{0.1})(Mn^{4+},Mn^{3+})_2O_4 \cdot 1.5H_2O$	Microbes
Sulfates		
Gypsum	$CaSO_4 \cdot 2H_2O$	Cnidarians, statoliths of certain medusae, Desmidae (algae), cyanobacteria
Bassanite	$CaSO_4 \cdot 0.5H_2O$	Statoliths of certain medusae
Barite	$BaSO_4$	Cyanobacteria, Spirogyra (alga), Loxididae (protozoa), *Chara fragilis* (higher alga), Xenophyophorea (large deep-sea protists), diatoms, foraminifera, Loxodes (gravity receptor)
Celestite	$SrSO_4$	Radiolarians, Acantharia, algae, foraminifera *Rosalina leei* and *Spiroloculina hyaline*, snail shell
Jarosite	$KFe_3^{3+}(SO_4)_2(OH)_6$	*Purpureocillium lilacinum* (an acidophilic fungus), *Acidithiobacillus ferroxidans*
Sulfides		
Pyrite	FeS_2	Magnetotactic bacteria
Amorphous pyrrhotite	$Fe_{(1-x)}S$ ($x = 0$ to 0.2)	
Hydrotroilite	$FeS \cdot nH_2O$	Sulphate-reducing bacteria, *Desulfovibrio* spp.
Sphalerite	(Zn,Fe)S	Magnetotactic bacteria
Galena	PbS	Sulfate reducing bacteria
Greigite	Fe_3S_4	Magnetotactic bacteria
Mackinawite	$(Fe,Ni)_{1+x}S$ ($x = 0$ to 0.11)	
Wurtzite	(Zn,Fe)S	
Cadmium sulfide	CdS nanoparticles	Marine cyanobacterium *Phormidium tenue*
Acanthite	Ag_2S	Polychaete worm *Pomatoceros triqueter*
Arsenates		
Orpiment	As_2S_3	Bacteria
Native elements		
Sulfur	S nanoparticles	
Gold	Au nanoparticles	Tropical marine yeast *Yarrowia lipolytica*, marine sponge *Acanthella elongate*, marine alga *Sargassum wightii*
Silver	Ag nanoparticles	Marine fungus *Penicillium fellutanum*, *Fusarium oxysporum* (a fungus that is reported to infect marine mammals)

Table 58.2 Continued

Biomineral	Chemical formula	Marine biomineralizers of the respective biomineral
Native Elements		
Selenium	Se nanoparticles	Bacteria *Sulfurospirillum barnesii* and *Pseudomonas marina*
Uranium	U nanoparticles	*Shewanella oneidensis* (bacterium); reduction of Uranium by *Desulfovibrio vulgaris*, a bacterium that builds marine aerobic biofilms
Silicates		
Silica (opal)	$SiO_2 \cdot nH_2O$	Radiolarians, diatoms, demosponges, hexactinellid sponges, most sponge spicules, Opal teeth in copepods and limpets, mollusc penial structures, heliozoan spines and scales
Sepiolite	$Mg_4Si_6O_{15}(OH)_2 \cdot 6H_2O$	Microorganisms (?)
Halides		
Fluorite	CaF_2	Vertebrate and invertebrate skeletons, fish skin, mollusc shell, gizzard plates of gastropods, statoliths of marine mysid crustaceans
Hieratite	K_2SiF_6	Gravity receptors
Amorphous fluorite	CaF_2	*Archidoris* (sea slug) spicules
Atacamite	$Cu_2(OH)_3Cl$	Jaws of the marine bloodworm *Glycera dibranchiata*
Organic minerals		
Weddellite	$CaC_2O_4 \cdot 2H_2O$	*Thalassia testudinum* (turtle grass), sea grass, vascular plants, Bornetella (marine alga) skeleton, gizzard plates of the deep water gastropod *Scaphander cylindrellus*, renal sac of the ascidian tunicate (marine filter feeder) *Mogula manhattensis*, molluscs
Whewellite	$CaC_2O_4 \cdot H_2O$	
Manganese oxalate	$MnC_2O_4 \cdot 2H_2O$	
Calcium tartrate	$CaC_4H_4O_6$	Chiton
Calcium malate	$C_4H_4CaO_5$	
Earlandite	$Ca_3(C_6H_5O_7) \cdot 4(H_2)O)$	
Guanine	$C_5H_5N_5O$ (one of the four main nucleobases found in the nucleic acids DNA and RNA)	Fish scales (fish silver), *Tetragnatha* spiders (silver color)
Uric acid	$C_5H_4N_4O_3$	
Paraffin hydrocarbon	C_nH_{2n+2}	
Wax	organic compounds that characteristically consist of long alkyl chains	
Magnesium oxalate (glushinskite)	$Mg(C_2O_4) \cdot 2(H_2O)$	
Copper oxalate (moolooite)	$Cu(C_2O_4) \cdot 0.4H_2O$	
Anhydrous ferric oxalate		
Sodium urate	$C_5H_3N_4O_3Na$	

isms in various ways (Table 58.2). Biomineralization takes place at normal temperatures and pressures, both much lower than those required to form the same mineralized structures by conventional chemical synthesis.

Biomineralized products comprise metals and alloys, ceramics, polymers, and composites. Examples are Ba, Ca, Cu, Fe, K, Mn, Mg, Na, Ni, Pb, Sr, and Zn; as hydroxides, oxides, and sulfates or sulfides, carbonates, and phosphates [58.23, p. 25]. Some bacteria

(e.g., from the species *Geobacter* and *Citrobacter*) accumulate and passivate toxic metal ions, such as UO_2^{2+}, Pb^{2+}, and Cd^{2+}. Bacteria have learnt to cope with most elements of the periodic table, e.g., with encoded resistance systems for toxic metal ions. For many chemical elements, bacteria have found uses either in ultralow concentrations in functional biomolecules (e.g., vanadium), or in vast amounts (e.g., calcium for the formation of shells) [58.28]. Gold, silver, uranium, palladium and CdS nanocrystals are produced by various organisms [58.29], Chaps. 25 and 55. The size of nanocrystals strongly determines fundamental properties such as their color or the external field required to switch a magnetized particle in hard disk drives. The perfect control of the size of the biomineralized nanocrystals is one major reason why bioassisted nanocrystal production is widely viewed as highly promising regarding base materials for new man-made optical and electrical materials. Zinc (Zn) is present in the jaws of the marine worm *Nereis* sp. [58.30], and copper (in the form of the biomineral atacamite, $Cu_2(OH)_3Cl$) is present in the jaws of the marine bloodworm *Glycera dibranchiate* [58.31]. The metals reinforce protein fibres in worm jaws.

The three different types of biominerals are either produced by simple precipitation, as perfect crystals,or as composites.

58.2.1 Biominerals Produced by Simple Precipitation and Oxidation Reactions

Calcium carbonate, iron(III)-oxide hydrate (FeOOH), manganese(IV)-oxide (MnO_2), and pyrite, as well as marcasite (both FeS_2) are generated in organisms by precipitation and oxidation reactions, i. e., relatively simple reactions in which solved substances are translated into insoluble ones via the metabolism of organisms. Example: $CaCO_2$ in stromatolites that were built by autotrophic cyanobacteria as far back in time as 3.5 billion years ago.

Calcium Carbonate $CaCO_3$

$[Ca^{2+} + 2HCO_3^-]$ (carbonate) $\rightarrow$ $CaCO_3$ (stromatolite) + CO_2 (insertion to the biomass) + H_2O.

The advantage for the cyanobacteria might be mechanical fixation of the biofilm in water.

Iron(III)-Oxide-Hydroxide FeOOH Goethite

Gallionella ferruginea is a chemoautotrophic iron-oxidizing chemolithotrophic bacterium that has been found in a variety of different aquatic habitats. It uses the energy it obtains from oxidization, remains of its activities are drains clogged with iron depositions, iron(III)-oxide (Fe_2O_3) and iron(III) oxide-hydroxide ($HFeO_2$). This bacterium or some of its biochemicals related to the oxidization of iron might be of high interest for an alternative way of mining iron in the sea.

Manganese Dioxide MnO_2

Manganese(IV)-oxide (MnO_2) is precipitated via microorganisms such as *Leptothrix discophora* [58.32]. The sheaths of the organisms of the Sphaerotilus-Leptothrix group often are coated with $Fe(OH)_3$ or MnO_2 [58.33].

The Mn and Fe oxidizing/depositing bacteria in freshwater habitats belong to the genera *Sphaerotilus*, *Gallionella*, and *Leptothrix* [58.34, 35].

> *In marine environments, the direct evidence for Fe-oxidizing bacteria is not well documented. The one notable exception was the finding of abundant Gallionella-like stalk material and microscopic identification of putative G. ferruginea cells from a shallow water volcanic system near Santorini Island in the Mediterranean Sea.* [58.36]

Pyrite and Marcasite FeS_2

Sulfate reducing bacteria gain energy from the reduction of sulfates. When iron(II) ions are present, FeS_2 can be produced,

$$2SO_4^{2-} + 3.5C + 2H^+ + Fe^{2+} \rightarrow FeS_2 + 3.5CO_2 + H_2O$$

(the C comes from organic substances).

58.2.2 Biological Production of Perfectly Crystallized Minerals

Ice H_2O

Ice is a mineral with a relatively low melting point. Organisms actively protect themselves against this unwanted mineral in their bodies via two strategies: either they prevent freezing of their bodily fluids via freeze protection proteins (Sect. 58.3) or they enrich ice nucleation proteins in their blood, which promote and control freezing so that their cells do not suffer. Some bacteria such as *Pseudomonas syringae* produce proteins that promote freezing; they are used for the production of artificial snow. Various organisms such as arctic fish, plants, fungi, microorganisms, and bacteria build an-

tifreeze and ice structuring proteins. With the help of these proteins, the organisms can survive in temperatures below the freezing point of water.

Antifreeze proteins bind to ice crystals and prevent their growth and recrystallization, thereby preventing the cells of the organisms from being destroyed by ice crystals. Due to their ice binding properties, antifreeze proteins in living nature work at very low concentrations (300–500 times less than conventional man-made antifreeze agents). Frost-tolerant species survive the freezing of their body fluids [58.37].

Calcium Carbonate $CaCO_3$ (Calcite, Aragonite, and Vaterite)

Calcite is the most stable polymorph of calcium carbonate. It is transparent, with a refractive index of 1.6584 and 1.4864 (depending on the crystallographic axis). These properties make it a good material for the production of optical lenses. The brittle star *Ophioma wentii* has calcite eyes of optically corrected microlenses all over its body (Fig. 58.1).

Already 350 millions of years ago some trilobite species used calcite lenses; up to 15 000 lenses making up one single eye! Calcium carbonate is also present in the ear: zebra fish use Starmaker proteins to biomineralize aragonite otoliths for hearing and their vestibular sense [58.39].

Magnetite Fe_3O_4

Magnetite is a ferromagnetic black iron oxide that can, e.g., be found in a chain of magnetosomes, i. e., single magnetic domain crystals in magnetotactic bacteria (Fig. 58.2), e.g., *Magnetospirillum magnetotacticum*. The anaerobic bacterium uses the magnets to orient itself along the magnetic field lines of the Earth, and thereby determine up and down (it cannot do this via gravity, because as a small bacterium it lives a life at a low Reynold's number, like a piece of dust in honey – which is no way to rely on gravity). Magnetosomes were also found in migratory birds, trout, and salmon. Magnetite particles with molecular precision have even been identified in the human brain (Fig. 58.3). Biogenic magnetite in the human brain may account for the high-field saturation effects observed in magnetic resonance imaging and, perhaps, for a variety of biological effects of low-frequency magnetic fields.

The formation of bacterial magnetite crystals is as follows: first, the bacterium takes Fe(III) ions from the environment. Then it reduces Fe(III) to Fe(II) ions during the transport across the cell membrane. Sub-

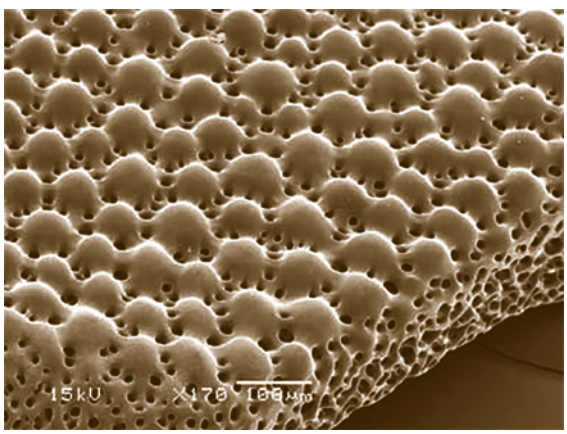

Fig. 58.1 The calcite microlenses of the brittle star. Each of the lenses is only some tens of micrometers in diameter. Scale bar 100 µm

Fig. 58.4 Pearls

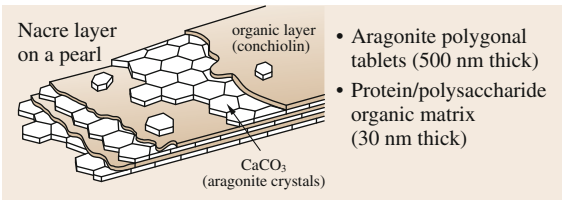

Fig. 58.5 Nacre layer on a pearl. The conchiolin protein/polysaccharide matrix is about 30 nm thick, the aragonite polygonal tablets are about 500 nm thick. The beautiful luster of the pearl comes from optical interference effects of light on the thin tablets. Permission pending

sequently, Fe(II) ions are transported to and across the vesicle membrane (the magnetosome membrane), amorphous hydrated Fe(III) oxide is precipitated within the vesicle, and the amorphous phase is transformed to magnetite by surface reactions involving mixed-valence intermediates [58.40, 41].

58.2.3 Composite Biomaterials

Composite materials combine two or more materials yielding new materials with interesting properties. Many biomaterials are composites. In most cases, the functionality of the biological composites is based on nanoscale structures. Examples for such nanocomposites (also known as hybrid biomaterials) are nacre (the beautifully iridescent layer in, e.g., abalone shells or pearls, Figs. 58.4 and 58.5), bones and enamel, as well as egg or mollusc shells. In many cases, the mechanical properties of such nanocomposites are outstanding: abalone nacre, for example, has a fracture toughness that is 3000 times higher than that of calcite crystals [58.43].

Calcium Carbonate $CaCO_3$ Nanocomposites

Calcium carbonate is an important ingredient in the nanocomposite that makes up the shells of foraminifers [58.44], eggs of birds and mollusc shells. Calcium carbonate is the material that is biomineralized most: remnants of calcium carbonate biomineralizing organisms yielded whole mountain ranges. The calcium carbonate shell serves as mechanical protection for the soft bodies of the organisms, be they foraminifers, other single-celled organisms, mussels, molluscs, or other animals.

Nacre is an iridescent form of aragonite (which is a calcium carbonate with orthorhombic symmetry as opposed to the trigonal symmetry in calcite) that is made by certain marine animals. Its protein content is about 5%.

Sea urchins biomineralize calcium carbonate in their shells, teeth, and spines. Sea urchin spines can reach a length of 10 cm, with their toughness by far outnumbering the toughness of pure calcium carbonate. Sea urchin teeth are single crystal calcites [58.45].

In corals, sensitive little animals (polyps) biomineralize with the help of algae, with whom they live in symbiosis, an exoskeleton of calcium carbon-

ate. The algae consume the CO_2 and aid in $CaCO_3$ precipitation.

Nanostructured Silicon Dioxide SiO_2 in Diatoms and Glass Sponges

Diatoms are unicellular algae that live in fresh or saltwater and on moist surfaces, and that at normal temperature and pressure biomineralize an exoskeleton of rigid, tough, and hard silica [58.46]. These exoskeletons are nanostructured and of exquisite beauty (Fig. 58.6). Sometimes, single diatom cells are connected via hinges and mechanical interconnecting devices. Such linkages have a size on the order of several hundreds of nanometers. No signs of wear in diatoms have ever been reported, not even when they fossilized and were alive tens of millions of years earlier (as is the case for the fossil diatom depicted in Fig. 58.6). Diatoms can serve as inspiring natural microsystems when it comes to tribological or mechanical aspects of microengineered devices, especially 3D microelectromechanical systems (MEMS) [58.47, 48].

Proteins that are involved in the biomineralization of silica are called silicatein, silaffin and silicase. Silicateins are high molecular weight proteins that strengthen the silica structure; silaffins are low molecular weight proteins that yield silica precipitation within minutes.

Diatomaceous earth is a natural resource that is mined in various places on the Earth. It contains the remnant shells of diatoms. Because of the porous nanostructured shell of the diatom, diatomaceous earth has huge surface area and is, therefore, used for filtering drinks such as beer and apple juice, or for the production of explosives such as dynamite.

A second type of marine organisms that biomineralize silica are the about 500 species of glass sponges (Hexactinellida) [58.50]. Glass sponges are exclusively marine organisms; they comprise about 7% of all sponges currently known. Their skeleton is made from amorphous hydrated silica needles (spicules) of exquisite shapes (Fig. 58.7). One single species can have up to 20 different types of needles. *Monorhaphis chuni* produces a silica needle of up to 3 m in length and 8 mm in diameter, which it uses to stabilize itself at the bottom of the Indian and Pacific oceans.

Glass sponges are an important ecological factor in the Antarctic; spicules of dead animals can build woolly layers up to 2 m high. The single spicules have concentric layers of silica, arranged around a hollow central canal. The spicules are a composite material of silica and proteins and are in many cases highly elastic.

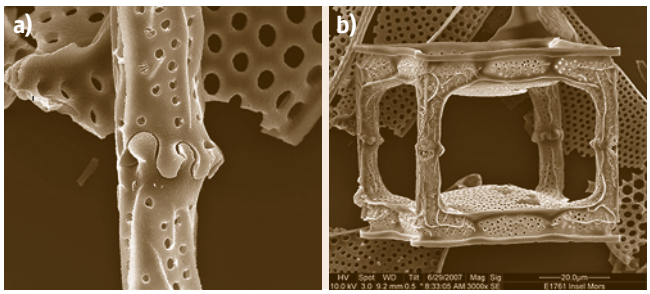

Fig. 58.6a,b Diatoms are silica biomineralizing phytosynthetic single-celled organisms. The fossil diatom *Solium exsculptum* from the island of Mors in Denmark depicted in the image lived 45 millions of years ago. It beautifully shows an expedient nanostructured shell, reinforcement ribs, connections, and primary mechanical structures. Panel **(a)** is a zoom into the most left junction in panel **(b)**. The sample is from the Hustedt Collection in Bremerhaven, Germany, # E1761 (Courtesy of F. Hinz, AWI Bremerhaven). Image reproduced with kind permission

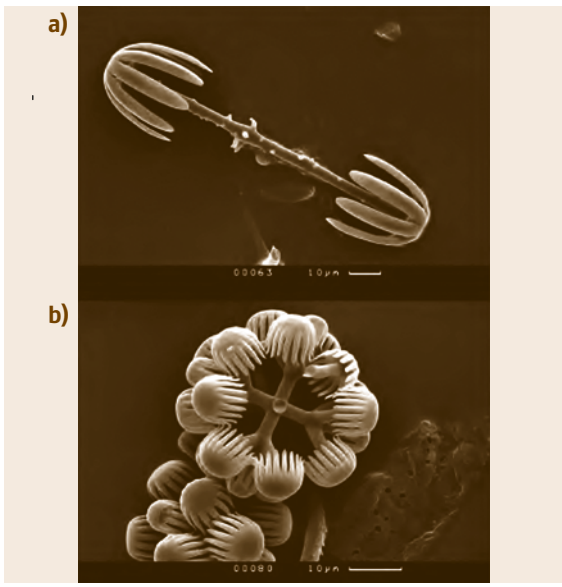

Fig. 58.7a,b Hexactinellida (glass sponge) spicules. Glass sponges consist of a network of such spicules covered by a thin layer of living cells. In this way they are heavily defended both inside and out. Single glass sponges have up to 20 different types of spicules in various shapes, some of them needle like **(a)**, some ball-like **(b)**, some in star shapes. Scale bars 10 μm

Hydroxyapatite $Ca_5[OH|(PO_4)_3]$

Animal bones consist of about 65% inorganic components, mainly hydroxyapatite (a calcium phosphate with the chemical formula $Ca_5[OH|(PO_4)_3]$), providing compressive strength, and about 35% inorganic components, mainly collagen, providing high tensile strength. Further ingredients in bones are proteins and fats. The high strength of bone is due to the fact that hydroxyapatite crystals are ordered mainly along the lines of tension and compressive stress, which results in a strut-like arrangement. See Fig. 58.8 for a drawing of the seven layers of hierarchy in bone.

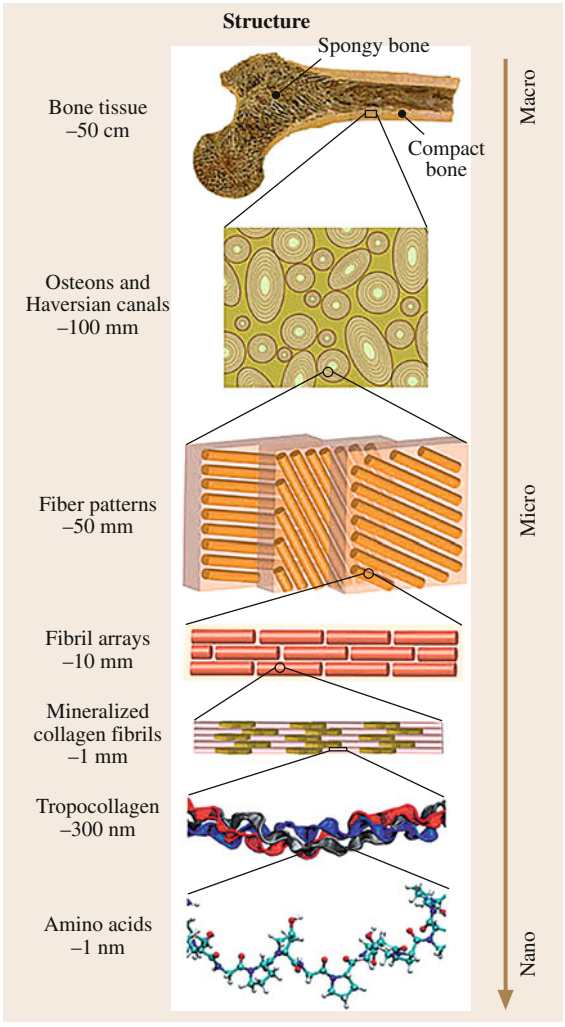

Fig. 58.8 The hierarchical levels of bone, a biomineralized structure with added functionality on each level of hierarchy, resulting in a tough and strong, yet lightweight material [58.49], with permission

Fluorapatite $Ca_5(PO_4)_3F$

Enamel has 95% inorganic components, mainly hydroxyapatite. In fluorapatite the OH group is replaced with F – this makes enamel more resistant against acids and provides a better protection against caries.

58.2.4 Example of Uptake and Conversion of a Very Rare Element: Selenium

In 1983, *Foda* et al. [58.51] described uptake and conversion of the very rare element selenium by the marine bacterium *Pseudomonas marina* in seawater containing either selenite or selenate. *Pseudomonas marina* bioconverts selenite into water-soluble non-Se(IV) metabolite(s) and subsequently releases them back into the medium. It is also capable of reducing Se(IV) to elemental Se; this pathway becomes increasingly evident at higher concentrations of selenite.

In 2011, selenium-reducing microorganisms that produce elemental selenium nanoparticles were reported [58.52]. This study identified high-affinity proteins associated with such bionanominerals and with non-biogenic elemental selenium. Proteins with an anticipated functional role in selenium reduction, such as a metalloid reductase, were found to be associated

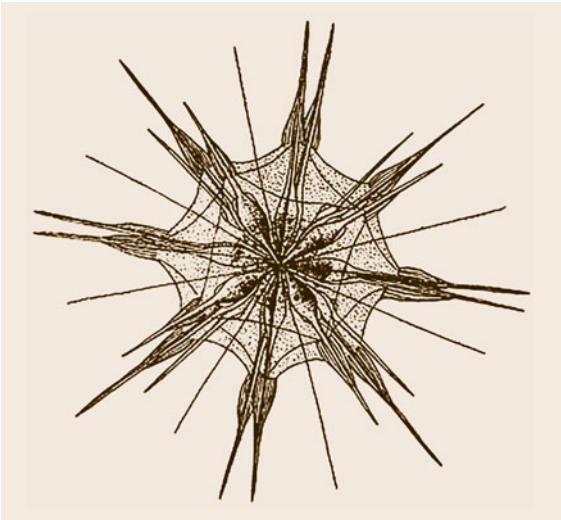

Fig. 58.9 An Acantharea exoskeleton. These planktonic, free living, exclusively marine protozoa range in size from 0.05–5 mm in diameter

with nanoparticles formed by one selenium respirer, *Sulfurospirillum barnesii*.

58.2.5 Example of Strontium Mineralization in Various Marine Organisms

Strontium is an alkaline earth metal that occurs naturally in the minerals celestine ($SrSO_4$) and strontianite ($SrSO_3$). These two minerals also occur as biominerals in radiolarians, acantharia, algae, the foraminiferae *Rosalina leei* and *Spiroloculina hyaline* [58.53], and in snail shells.

Acantharea are one of the four types of large amoebae that occur in the marine water column. Acantharea have a very regular exoskeleton and are of high importance for strontium circles in the sea. Their sizes range between 0.05–5 mm (Fig. 58.9).

58.2.6 Example of Biomineralization of the Unstable Calcium Carbonate Polymorph Vaterite

Vaterite is a polymorph of calcium carbonate and is less stable than calcite or aragonite. Vaterite occurs naturally in some organisms, such as in the spicules of sea quirts [58.54], in turtle eggshells [58.55], and in gastropod (e.g., snail, abalone, limpet) shells (e.g., [58.56]). In those circumstances, impurities such as metal ions or organic matter may stabilize the vaterite and prevent its transformation into calcite or aragonite.

58.3 Materials – Proteins Controlling Biomineralization

We are just beginning to understand the role of proteins in biomineralization [58.57]. Proteins have several important active roles in biomineralization: they inhibit spontaneous mineral formation from solution (e.g., the protein statherin in the mouth inhibits spontaneous precipitation of calcium phosphate), they inhibit the growth of existing crystals, and they are responsible for directing crystal nucleation, phase, morphology, and growth dynamics. The crystal shape is, for example, affected by proteins with specific structures and sequences that adsorb to different faces of the crystal, leading to regulation of shape (crystal faces have different charges and arrangements of atoms so proteins can selectively adsorb). Furthermore, proteins can self-assemble into ordered arrays that guide the formation of organized mineralized structures.

Proteins ultimately contribute to the extraordinary mechanical, optical, etc., properties of the biomineralized material and structures. Chitin and collagen seem to be universal and alternative templates in biomineralization.

Table 58.3 gives a non-exhaustive list of the proteins involved in biomineralization and the respective biomineralized material.

The three main organic structuring and scaffolding polymers are chitin, cellulose, and collagen. All three have common principles in their organization: they form nanofibrils with 1.5–2 nm diameter, they have the ability to self-assemble, they produce fibrillar and fiber-like structures with hierarchical organization from the nanolevel up to macrolevels, they have the ability to act as scaffolds and as templates for biomineralization, and they form rigid skeletal structures [58.23].

Certain proteins provide active organic matrices that control the formation of specific mineral structures; others act as catalysts that facilitate the crystallization of certain metal ions [58.58].

58.4 Organisms and Structures That They Biomineralize

Marine vertebrates, invertebrates, and plants biomineralize more than 70 different substances (Tables 58.2 and 58.4); some specific crystals produced by living nature cannot be produced by conventional chemical synthesis (e.g., the defect-free magnetosomes in magnetotactic bacteria or some crystal classes that obviously need proteins for their build-up – they do not exist in geological crystal formations). The number of marine biomineralizers, and with them the range of different structures, materials, processes, and functions, is tremendous: 128 000 species of molluscs have been described, 700 species of calcareous green, red, and brown algae, more than 300 species of deep-sea benthic foraminifera, and 200 000 diatoms species [58.23, p. 26].

Many biomineralized structures are built from nanostructured, hierarchical materials, and sometimes even functional gradient materials. Bone, for example,

Table 58.3 Biominerals and the respective proteins involved in biomineralization (non-exhaustive list)

Biomineral	Proteins
Apatite	Collagen (controls apatite) (in Porifera, coelenterates, molluscs, echinoderms)
Bone	Biglycan (a small leucine-rich repeat proteoglycan (SLRP) found in a variety of extracellular matrix tissues, including bone, cartilage, and tendons; essential for the structure and function of mineralized tissue) Osteonectin (a bone-specific protein linking mineral to collagen) Osteopontin (an extracellular structural protein and, therefore, an organic component of bone) Sialoprotein (BSP) (a component of mineralized tissues such as bone, dentin, cementum, and calcified cartilage) Osteocalcin, phosphophoryn, bone sialoprotein, proteoglycans, glycoproteins, glycosaminoglycans
CdS nanoparticles	C-phycoerythrin (from the marine cyanobacterium *Phormidium tenue*)
Calcium carbonate	Calcified cartilage sialoprotein (BSP) (a component of mineralized tissues such as bone, dentin, cementum, and calcified cartilage) Orchestin (a calcium-binding phosphoprotein in the calcified cuticle of a crustacean) Snail shells conchiolin (conchin) Calmodulin-like protein (from pearl oyster *Pinctada fucata*) Eggshell matrix proteins Otoconin (in octoconia, small crystals of calcium carbonate, also called statoconia, as gravity and acceleration sensors) Statherin (growth *inhibiting* protein, inhibits spontaneous precipitation of calcium phosphate in the mouth) Pancreatic stone protein (PSP) *inhibits* calcium carbonate precipitation in pancreatic fluid Starmaker proteins (in zebrafish, aragonite biomineralization)
Calcium phosphate	Serum protein fetuin-A (inhibition of calcium phosphate precipitation, *inhibiting* smooth muscle cell calcification)
Dentin	Dentin sialoprotein (BSP) (a component of mineralized tissues such as bone, dentin, cementum, and calcified cartilage)
Enamel	Amelogenin (a series of closely related proteins involved in amelogenesis, the development of Tuftelin) Enamelin and amelogenin (tooth enamel proteins) Tuftelin (enamel) Transcription factor FoxO1 (essential for enamel biomineralization) Phosphoprotein (inhibits hydroxyapatite formation)
Goethite	Chitin (in limpet teeth, as template for goethite growth)
Gold	Cytochrome C Lysosome
Ice	Antifreeze proteins (control of ice crystal growth) Ice interaction polypeptides
Magnetite	MamA (required for the activation of magnetosome vesicles) MamJ (directs the assembly and localization of magnetosomes) Mms6 (regulates magnetite crystal morphology)
Nacre	Nacre proteins (perlucin, n16N,...)
Silica	Polyamines, silicatein and silaffine (in diatoms) Frustulin, pleuralin (in diatoms)
Uranium	Cytochrome c3 (reduction of uranium, from *Desulfovibrio vulgaris*)
Vaterite	Eggshell pelovaterin (turtle eggshells, vaterite crystals)

Table 58.4 Examples for biomineralizing organisms in all six biological kingdoms

Kingdom	Examples
Plants	*Thalassia testudinum* (turtle grass), sea grass, vascular plants
Animals	Avian egg shell ($CaCO_3$) Archaeocyatha ($CaCO_3$) Brachiopod and mollusc shells ($CaCO_3$) Sea-mats (Bryozoans) ($CaCO_3$) Calcareous sponge spicules ($CaCO_3$) Calcareous tunicate (marine filter feeders) spicules ($CaCO_3$) Conodonts (apatite (phosphate carbonate)) Enamel (vertebrate teeth) (apatite (phosphate carbonate)) Echinoderms ($CaCO_3$) Corals ($CaCO_3$) Glass sponges such as the Venus flower basket *Euplectella aspergillum* (amorphous hydrated silica) Lanternshark (mineralized spines) Crystal structures in the inner ear in zebrafish Japanese pearl oyster *Pinctada fucata* Cephalopods such as the Giant Pacific octopus (beak) Sea urchins (needles, larval skeleton) Fanworms (Serpulidae) ($CaCO_3$) Vertebrate bone (apatite (phosphate carbonate)) Whale teeth Narwhal whale *Monodon monoceros* tooth (up to 9 feet long) Shells, snail shell (strontium, calcium) Rhopaliophoran medusae (Cnidaria) statoliths (calcium sulfate hemihydrate) Demosponges (silica) Brittle star crystal eyes (Calcite) Most sponge spicules (silica) Hypercalcified sponge (calcium carbonate basal skeleton in addition to their spicules) *Petrobiona massiliana* (Calcarea, Calcaronea), *Ceratoporella nicholsoni*, *Goreauiella auriculata* (Astroscleridae), *Astrosclera willeyana*, *Hispidopetra miniana*, *Stromatospongia norae* (Ceratoporellidae: Porifera), *Calcifibrospongia actinostromarioides*
Protista	Coccolithophores ($CaCO_3$) Diatoms, radiolarians and silicoflagellates (hydrated silica) Foraminifera ($CaCO_3$, $SrSO_4$)
Fungi	Fungi in corals (pearl-like skeletons)
Bacteria	Chemosynthetic marine organisms Magnetotactic bacteria (e.g., *Magnetospirillum gryphiswaldense*, *Magnetospirillum magneticum*) Cynobacteria in stromatolithes Marine bacteria ($CaCO_3$, Selenium nanoparticles)
Archaea	*Sulfolobus shibitae*, *Metallosphaera* sp., *Acidianus infernus* (iron, sulfur, uranium)

has seven layers of hierarchy, spanning from the components of collagen fibrils to the whole bone. Level 1 consists of the components themselves, including proline and hydroxyproline. On level 2, one step up in size, in hierarchy, and with added functionality, comes the mineralized collagen. On level 3 there are arrays of fibers, which on level 4 build patterns, e.g., spirals. On level 5 the osteons, cylindrical motifs in bone structure, appear. Level 6 brings in as added functionality, integrated into the whole bone structure, spongy *vs.* compact bone, and level 7 is the whole bone (Fig. 58.9).

Nature's nanostructures are built by benign chemistry and via self-assembly and templating. Human chemical synthesis is slowly reaching the efficiency and

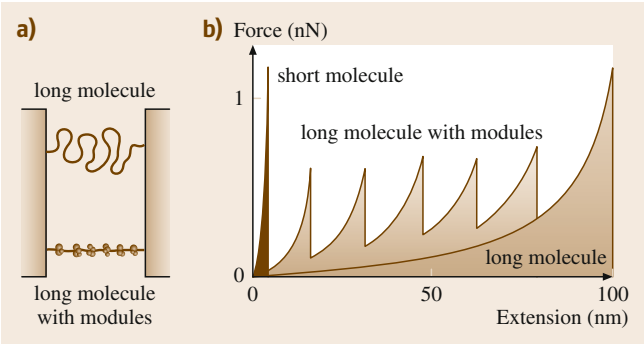

Fig. 58.10a,b Concept for a self-repairing adhesive [58.43]. **(a)** Two ways to attach two particles: with a long molecule or with a long molecule with nodules. **(b)** When stretched, a short molecule can only be extended a little and would then break. A long molecule would be stretched much more and finally break. However, a long molecule with nodules, with sacrificial bonds that break before the backbone of the molecule breaks, increases the toughness of the adhesive. Such a strategy is applied in the abalone shell and also in diatom adhesives (after [58.43], with permission) ►

purity of natural biomineralized crystals, and in terms of controlling morphology and hierarchy, there is still a lot for us to learn [58.59].

From nanometer small crystals that serve as nucleation centers up to meter-long silica spicules in certain marine glass sponges – biomineralized structures span many orders of magnitude in length.

58.4.1 Example: Molluscan Shells

The main material in molluscan shells is calcium carbonate: it amounts to about 95–99% of the weight. The remaining 1–5% are made up of proteins. The complex biocomposite (Fig. 58.10) of molluscan shells is far more fracture resistant than a calcite crystal: in the case of the abalone shell, this factor amounts to 3000 [58.43]. The proteins controlling the biomineralization (for an overview, see Sect. 58.3) allow for calcium carbonate (and/or strontianite, celestite, and fluorite, see Sect. 58.2) synthesis at ambient conditions, and control the crystal nucleation, phase, morphology, and growth dynamics. The abalone shell is an example of a biomineralized material with high fracture toughness. The blue-rayed limpet *Ansates pellucida* has a shell that shows stripes of green-blue dynamic structural coloration (photonic structures). It exerts different control over the calcium carbonate crystal phases in different parts of its shell, utilizing different proteins and making different structures. Several phases of $CaCO_3$ can exist locally next to each other, each containing its characteristic proteins [58.60].

58.4.2 Example: Coccolithophores

Coccolithophores (Fig. 58.11) are small unicellular photosynthesizing protists that produce exoskeletons of elaborate calcite plates with a size of about

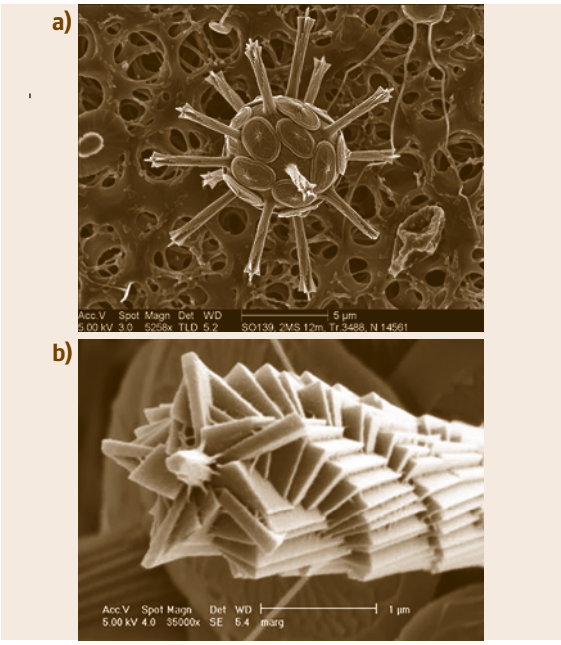

Fig. 58.11a,b The coccolithophorid *Rhabdosphaera clavigera*. **(a)** Whole organism. **(b)** Detail of the tip of a single spine showing spiral structure formed from consistently aligned crystal units with rhombic faces (after [58.61], permission pending)

1–10 μm. These microscopic organisms control the nucleation as well as the growth of the plates. Coccolithophores form a significant proportion of total marine primary production and carbon fixation; the biomineralized structures of dead coccolithophores are the largest single component of deep-sea sediments and they also make up the white cliffs of Dover [58.61, 62].

58.5 Functions

Most structures in biological systems are multifunctional. Their integrated approach allows for highly compact, cheap solutions to various chemical, dynamic, structural, mechanical, or physical demands *in one go*. Structures in organisms can be great teachers for engineers and inspire novel, sometimes even revolutionary, new approaches. However, because of their intrinsic multifunctionality, not always can one single aspect of an organism be successfully isolated in pure form for man-made applications, sometimes not even concept-wise. One fascinating example of the multifunctionality of living nature is biomineralized structures and their respective functions. Especially more complex arrangements, such as the silica micro- and nanostructures in diatoms, are envisaged to provide substantial inspiration in micro- and nanotechnology, especially tribology (regarding friction, adhesion, lubrication, and wear of small rigid interacting parts in relative motion) [58.63]. Further examples of tribological optimization in biomineralized structures are chitons, where iron is stored close to their magnetite-coated teeth, and the teeth can easily be renewed as they wear [58.64], and the jaws of certain marine worms that contain copper and zinc-reinforced proteins [58.30, 31].

The generalized principle *use structure rather than material* can be identified in various organisms. Especially for micro- and nanoscale organisms with rigid interacting parts in relative motion (e.g., some diatoms) straightforward biomimetic principle transfer to novel MEMS can be envisaged [58.47, 48].

Examples of functions of biomineralized structures are given in Table 58.5 and contain, for example, the calcite cell wall scales in coccolithophorids that are used as exoskeleton, the calcite shells of foraminifera and molluscs, the aragonite cell walls of scleractinian corals, aragonite mollusc shells, and vaterite gastropod (e.g., snail, abalone, limpet) shells. Calcite was used for optical imaging in the now extinct trilobites (it constituted their eye lens), and provides mechanical strength to the cuticle of crustaceans, e.g., crabs. In eggshells it provides mechanical protection. Mg-calcite provides mechanical strength to the spicules of octocorals, and strength as well as protection to the shell and spines of echinoderms (marine invertebrates with tube feet and five-part radially symmetrical bodies, such as sea stars and sea urchins). Chitin is the material of the poison dart in certain marine gastropods. Aragonite provides buoyancy devices in cephalopod (e.g., octopus) shells, as well as gravity receptors in fish heads. Vaterite spicules provide protection for ascidians (sessile coral-looking animals, e.g., sea squirts), and amorphous calcium carbonate in the crab cuticle provides these crustaceans with mechanical strength, whereas in the leaves of marine plants it serves as calcium storage. Iron-silica biominerals provide cyanobacteria with an effective UV screen [58.65].

58.6 Applications

58.6.1 Current Applications of Bioinspired Material Synthesis in Engineering and Medicine

Micro- and nanoengineers profit from the fact that in biological systems very often structure rather than material is used to achieve certain functionalities. In many cases, the structures are solely responsible for the respective functions, allowing for simple biomimetic transfer of principles from the inspiring structure to the respective application in engineering. This is of relevance in current MEMS design (where only a handful of base materials can be used, and the MEMS designer therefore has to work with structure rather than material), and will be even more relevant in the future when we finally mass-produce various 3D MEMS.

The abundance and distribution of chemical elements in seawater is a function of their solubility, reactivity, and involvement in biotic and abiotic processes, as well as oceanic circulation; it shows similarity to the composition of the human body (Fig. 58.12). Animals have a similar composition; in plants the first four most abundant elements are the same as in people or animals (O, C, H, and N), but the fifth most abundant element is P. The elemental composition of the cell phone (which shall serve here as a representation of a technical device) is completely different (Fig. 58.12). Potential future marine biotechnology might provide materials and structures for new technologies that are less focused on plastics and metals. For each such marine biotechnology attempt, careful considerations regarding the potential benefit of

Table 58.5 Non-exhaustive list of already identified functions in biomineralized structures of marine organisms, sorted by chemical, dynamic, mechanical, physical, and structural functions

Chemical functions	Dynamic functions	Structural functions
Calcium storage High performance nanocomposites Molecular glue in composite structures Storage (biominerals are ion reservoir for cellular functions) Mineralized holdfast (byssus of the jingle shell *Anomia*) Underwater adhesives Waste disposal (inside, like some nanocrystals or pearls, perhaps also outside)	Lubrication (bearing-like structures) Mobility Motion Movable rigid parts (ensuring a certain maximum and minimum distance) Pumps	Sclerites (a component section of an exoskeleton, especially each of the plates forming the skeleton of an arthropod) Spicules Structure building (corals) Surface texturing for optimized mechanical properties

Mechanical Functions	Physical Functions
Click-stop mechanism Crack redirection Distance holder Fixation (e.g., click stop in diatoms) Fracture resistance Hinges Injection Interlocking devices Mechanical connection Mechanical fixation Mechanical protection Mechanical strength Protection Reinforcement Scaffolds Skeleton (endoskeleton, exoskeleton) Springs Stability Strength and Integrity Teeth for cutting, rasping and grinding (e.g., iron in the teeth of chitons) Toughness (abalone) Weapons (defensive: e.g., sea urchin needles, aggressive: e.g., pistol shrimp dactyl club, conch snail harpoons) Wear protection (addition of zinc or copper for reinforcement)	Buoyancy Co-orientation mechanisms in biominerals (control of crystal orientation) Dynamic colors (diatoms, polychaete worms) Electrically conductive bacterial nanowires (nanowiring in microbial communities) Energy dissipation Gravity sensing (otoconia, statoliths) Lenses (optical) Magnets (for navigation, location) Optical components (antireflective layers, lenses, transparent containers for photosynthesizing organisms) Ossicles Photonic components (e.g., light guiding in deep-sea organisms) Photoprotective coatings Reflectivity (fish silver) Gravity sensing Magnetic sensing Optical sensing Balance sensing UV protection Whiteness

biomimetic and biomineralization approaches need to be made, taking energy and other factors into account. One of the advantages of technology as opposed to functional entities in organisms is the freedom of choice in materials. Organisms are stuck with a certain material as soon as they start using it. Examples are $SrSO_4$ in the exoskeleton of Acantharea (Sect. 58.2.5), or SiO_2 in diatoms (Sect. 58.2.3) – with the abundance of Sr and Si in ocean water being about 8 and 2 ppm, respectively [58.66].

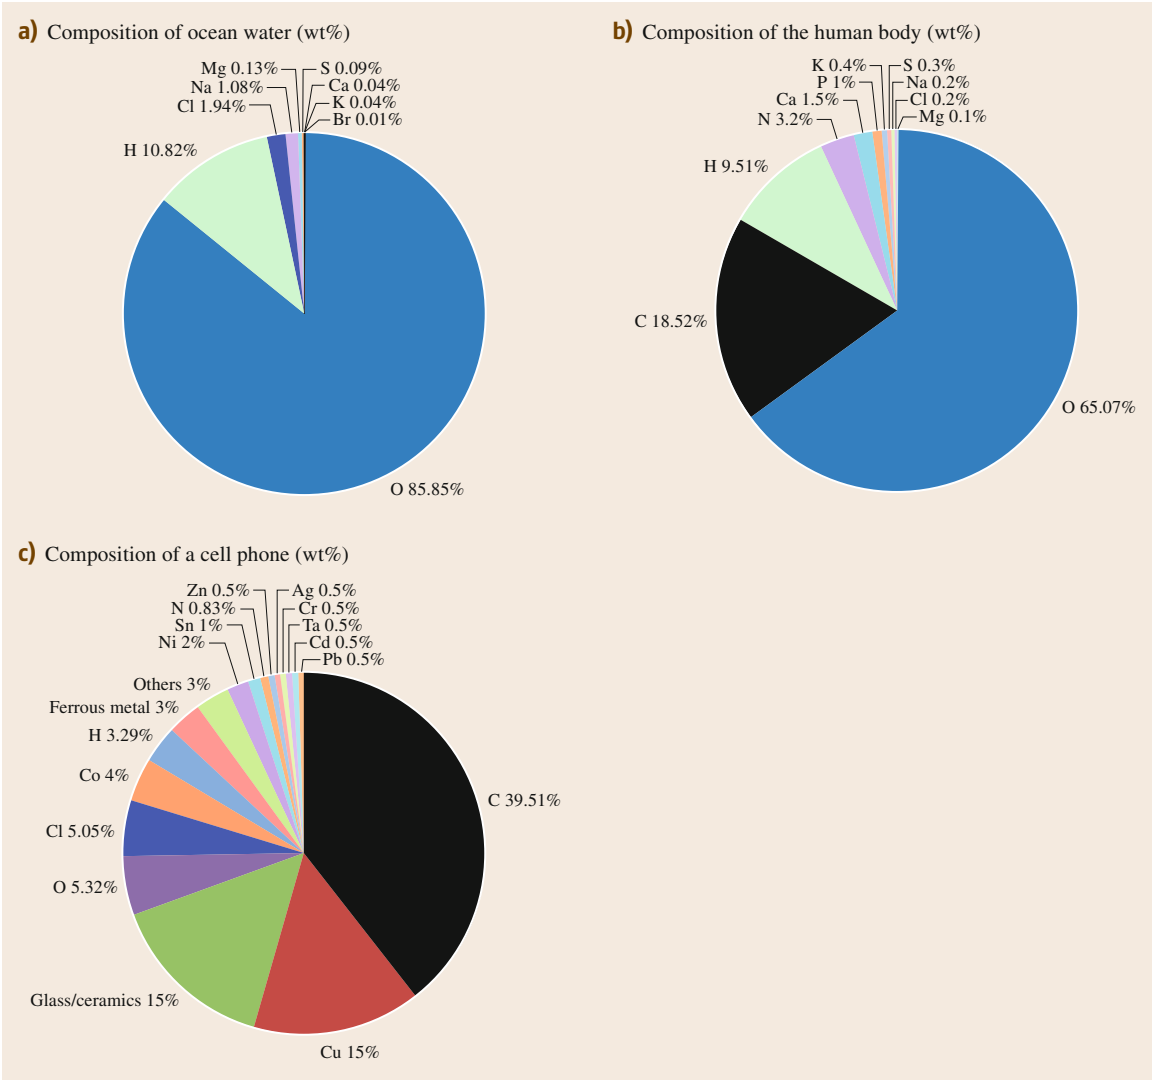

Fig. 58.12a–c The elemental compositions of ocean water, the human body, and a cell phone. The elemental composition of ocean water **(a)** is similar to the elemental composition of the human body **(b)** and very different from the composition of current engineering devices such as a cell phone **(c)**. Novel disruptive engineering approaches that learn from living nature (e.g., by using the principle *use structure rather than material*) might in the future yield marine biotechnology inspired machines and devices that need less metal and plastics, but rather achieve the needed functionality mainly from their structure (e.g., a navigation device inspired by homing sea turtles, with no dependence on satellites or metal parts)

Bioinspired material synthesis is also of increasing importance in tissue engineering, especially regarding applications for scaffolding (Chap. 53). Important factors are similar in a scaffold and in a biomineral, and relate to the chemical composition, the pore structure and architecture, the degradation rate and mechanical properties. The strength of the scaffold must be high enough to resist fragmentation before the cells synthesize their own extracellular matrix. The modulus of elasticity (i. e., the stiffness) must be high enough to resist compressive forces that would collapse the pores, must transmit stress (and strain) in the physiological range to surrounding tissues, and must prevent concentrated loading and *stress shielding*.

Also the synthesis of scaffold materials using principles and processes underlying biomineralization is of high interest. Biomineralized materials can be used as biomaterial scaffolds, either as they occur naturally or after treatment for modification. Further applications are bioinert and biodegradable materials, in medical devices, for tissue engineering, and for the coating of implants.

We have already started to initiate chemical reactions by printing reagents directly into a 3D reactionware matrix (i. e., printing of molecules and tissues with a commercially available 3D printing platform), and time will tell how far we can get with printing whole organs or machines, from basic ingredients, simple base materials, in our homes [58.67, 68].

Current biotechnology allows the usage of proteins that are important in biomineralization across species. *Natalio* and coworkers used silicatein-α (from sponges) to guide the self-assembly of calcite *spicules* similar to the spicules of calcareous sponges. As opposed to the rather brittle natural spicules, the synthetic spicules show greatly enhanced bending strength, and furthermore waveguiding properties even when they are bent [58.69].

58.6.2 Possible Future Applications of Bioinspired Material Synthesis in Engineering and Medicine – Outlook

The future of marine biotechnology is dependent upon the development of an enhanced understanding of the physical, chemical, and biological properties of marine organisms and ecosystems. Materials, structures and processes related to marine environments can provide valuable contributions to engineering, resource management, medicine, and various other fields. A prerequisite for this is the understanding of the connection between functionalities of biomineralized materials and structures from the nanoscale to the macroscale, including the effect of hierarchy and structuring. Especially interesting are models where macroscale properties can be understood from distinct functionalities at various length scales and subsequent implementation in technological processes. Efficient successful synthesis of biomineralized materials and structures, where form follows function, will pave the way towards tailored multiscale marine biotechnology, which starts at the molecular level and incorporates the hierarchical functionalities of biological materials through the length scales up to the macroscale, perfectly integrating nanotechnology and biology.

Higher-order organization by mesoscale self-assembly and transformation of hybrid nanostructures as proposed by *Cölfen* and *Mann* [58.70] is a key challenge in the design of integrated materials with advanced functions. Macromolecules and surfactants could be used to significantly increase the scope for controlled materials synthesis.

Biomimetic silica biosynthesis opens a new route to semiconductor nanofabrication [58.71, 72]. In 2008, *Jeffryes* and coworkers succeeded in metabolically inserting nanostructured Ge into a patterned silica matrix of the diatom *Pinnularia* sp. at levels ranging from 0.24 to 0.97 wt % Ge [58.72]. Embedding nanoscale germanium (Ge) into dielectric silica is of high importance for optoelectronic applications. The same group succeeded in incorporating amorphous titania into the frustule, which maintained its native structure even when local TiO_2 concentrations within the nanopores approached 60 wt %. Similar to germanium-silica nanocomposites, titanium dioxide nanocomposites are of high interest for optoelectronic, photocatalytic, and solar cell applications.

Genetic approaches to engineering hierarchical scale materials, engineered virus and protein cage architectures for biomimetic material synthesis, and bone-like materials by mineralization of hydrogels are further promising areas of research and development.

Biomineralization processes will play increasingly important roles in biology, biotechnology, medicine, chemistry, interfacial science, materials science, and nanotechnology [58.73]. With cellular and genetic controls of mineral formation, we could shape the minerals exactly as we need them. In vitro models of mineralization would allow us to understand in great detail the interactions and molecular contacts between macromolecular and mineral components. Macromolecular scaffolds for materials synthesis and organization would open up new directions in tissue engineering. A detailed understanding of the complex matrix–mineral relationships from the molecular level to the skeletal tissue, its properties and structure–function relations will open completely new approaches in engineering and medicine. For jewelery applications, we might even think about growing facetted crystals by spatially controlling growth inhibition and promoting proteins (control of crystal orientation and shape by interface engineering). Just imagine crystals grown in gels, with exactly the shape and size needed!

Ehrlich proposed bamboo corals as living bone implants [58.23, pp. 195–199]. The high content of calcium carbonate scaffolds of the commonly used coral resembles bone in terms of structure and mechanical properties. The coral exoskeleton is biocompatible, osteoconductive, and biodegradable, and allows for attachment, growth, spreading, and differentiation of bone cells. Coralline hydroxyapatite can be manufactured by hydrothermal conversion of the calcium carbonate coral skeleton.

Nature can furthermore serve as a teacher concerning the nanofabrication of crystalline materials, optical structures, nanoscale attenuators (for micro- and nanoelectromechanical systems (MEMS/NEMS)), and dynamic and hierarchical structures [58.74].

Microbe–mineral interactions that lead to sedimentary structures such as microbially induced sedimentary structures (MISS) and stromatolites, banded iron formations, cherts, sandstones, and carbonate rocks might one day be reproduced in the laboratory or in the field, and allow a more benign, environmentally friendly way of mining.

Although synthetic bone replacement materials are now widely used in orthopaedics, much research and development is still needed before we will be able to replicate both the structure as well as the exquisite mechanical properties of natural bone. Synthetic biomimetic materials fabricated according to biological principles and processes of self-assembly and self-organization are promising new approaches for a new generation of biologically and structurally related bone analogs for tissue engineering [58.75]. Current strategies for bone repair have accepted limitations. Marine organisms with naturally occurring porous structures as templates for bone growth might be an inspiration for novel ex vivo bone tissue engineering approaches [58.76].

Marine invertebrate cell cultures are currently not well established. They could serve as tools for biomineralization studies [58.77] and ultimately yield a new generation of advanced, high-performance composites required for new construction materials, new microelectronic, optoelectronic and catalytic devices, chemical and biological sensors, energy transducers and harvesters, smart medical implants, and faster and higher capacity biochips. Marine biotechnology regarding applications of bioinspired material synthesis in engineering and medicine has enormous potential.

59. Functional Feeds in Aquaculture

Jorge Olmos Soto, José de Jesús Paniagua-Michel, Lus Lopez, Leonel Ochoa

The development of functional feed (FF) represents a great opportunity in the aquaculture industry. FF must promote the growth and health of cultivated organisms, improve their immune systems, and induce physiological benefits beyond traditional feeds. FF must be economically attractive and environmentally friendly. In this sense, the inclusion of animal products in FF formulations must be partially or totally eliminated, increasing the inclusion of alternative economical vegetable products. However, the kind and amount of vegetable protein, carbohydrates (CHO), and lipids added to formulations are of great concern for growth, health, environmental, and economical issues. Therefore, deficiencies in proteases, carbohydrolases, and lipases in shrimp/fish are a major impediment to the digestion and assimilation of vegetable sources, limiting its high-level inclusion in formulations. In this sense, the utilization of probiotic bacteria has emerged as a solution with huge applications in the aquaculture industry. Today, *Bacillus* species are the most investigated bacteria for animal probiotic development due to:

a) The versatility of their growth nutrients
b) High level of enzyme production
c) Secretion of antimicrobial compounds.

In addition, *Bacillus subtilis* (Bs) is generally recognized as safe (GRAS) by the Food and Drug Administration (FDA), meaning that it is harmless to animal and humans. In this work, we present the potential benefits of the utilization of FF in the aquaculture industry.

59.1 Overview

59.1.1 Importance of Aquaculture Development

Aquaculture is the fastest growing sector of the world food economy, increasing by more than 10% per year and currently accounts for more than 50% of all shrimp/fish consumed. The United Nations Food and Agriculture Organization (FAO) defines aquaculture as the farming of aquatic organisms including fish, mollusks, crustaceans, and aquatic plants. Farming implies some sort of intervention in the rearing process to enhance production, such as regular stocking, feeding, protection from predators, etc. Farming also implies that individual or corporate ownership of the stock being cultivated [59.1].

The global population's demand for aquatic food products is growing in importance; however fisheries' capture production has leveled off and most of the main fishing areas have reached their maximum potential [59.2, 3]. Because of this, fishmeal and oil prices have increased considerably in recent years (Fig. 59.1). In addition, concern has also arisen about the negative impact of fishmeal production on the ecology of global fisheries and on the environment [59.4, 5]. Aquaculture, which is probably the fastest growing food-producing sector, represents the greatest potential to meet demands for aquatic food supply. However, instead of helping to ease the crisis in wild fisheries, unsustainable aquaculture development may exacerbate the problems and create new ones, damaging our important and already-stressed coastal areas [59.6]. In order to accomplish these goals, the sector will face significant challenges to increase aquaculture profitability and, environmental and ecological sustainability.

59.1.2 Development of Functional Feed

Today, feeding represents 40–60% of the total production costs in shrimp/fish farming, making the aquaculture industry a great challenge for future generations; therefore, new feed formulations must be directed to be well-balanced and less expensive [59.7]. Use of animal protein sources, such as fish meal (FM) in shrimp/fish feeds, is expected to be considerably reduced or totally eliminated as a consequence of increasing economical, environmental and sanitary regulations [59.8–11]. Partial or complete FM substitution by vegetable protein and complex carbohydrates sources has been a major concern to the field for more than 10 years, without promising results [59.12, 13]. In this sense, functional feeds development as *foods with dietary ingredients that provide growth, health, environmental and economical benefits beyond traditional feeds* represents a great opportunity to guarantee the future of Aquaculture [59.14]. FF must be primarily supplemented with high levels of vegetable protein, complex carbohydrates and specifically selected innocuous probiotic bacteria (Fig. 59.2). A well formulated FF could transform aquaculture in a sustainable and competitive industry for new generations [59.15]. The present work evaluated a FF supplemented with high levels of soy bean meal (SBM), high levels of complex carbohydrates and a *Bacillus subtilis* probiotic strain on; *Litopennaeus vannamei, Oreochromis niloticus* and *Atractoscion nobilis*. Excellent results were obtained opening great opportunities to new functional feeds development for shrimp and fish.

59.2 Food Formulation Ingredients

Feeds considered *traditional* are mainly made from meal and fish oil ingredients and with vegetable flours as a carbohydrate source. These vegetable flours must be kept in the formulation of FF and, in fact, must be increased; besides carbohydrates, FF must contain protein and oil from vegetable origin, preferentially from soy [59.15]. Soy contains a large enough quantity of proteins and lipids to substitute both animal ingredients in shrimp and fresh-water fish diets. Additionally, *Litopenaeus vannamei* and *Oreochromis niloticus* require or tolerate protein and carbohydrate (starch) concentrations of around 30% [59.16, 17]. However, carnivorous marine fishes require or tolerate carbohydrate concentrations no greater than 10%, but they need 50% protein concentration for adequate development [59.18]. It is logical to speculate that such extreme demands are due to the fact that this kind of fish does not contain adequate types and/or amounts of carbohydrolases to digest starches; therefore their energy requirement must be obtained from protein, increasing the cost for its cultivation.

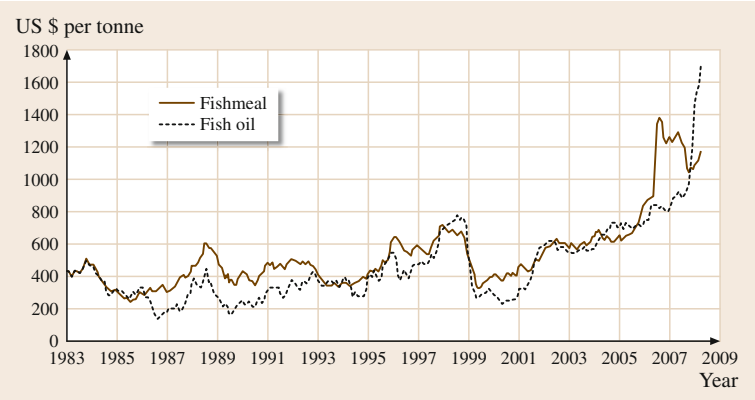

Fig. 59.1 International market price for fish oil and fish meal

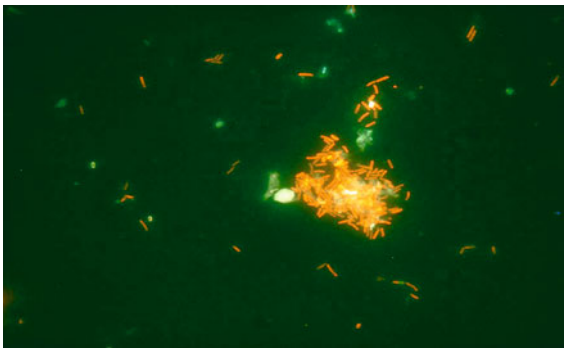

Fig. 59.2 Functional feed particle formulated with SBM, CHO's, vegetable oil and *Bacillus subtilis* multifunctional probiotic strain

On the other hand, it is important to point out that there are 20 most represented amino acids in the majority of proteins present in nature, coming from animal or vegetable origin. In this sense, the conformation structure is the greatest difference between proteins [59.19]. Furthermore, if added probiotics bacteria are capable of transforming the proteins into amino acids, there will be no problems for shrimp and/or fish to assimilate and incorporate them into their biosynthetic pathways.

Similar situations occur with carbohydrates regarding digestion. Although this is more marked in marine fishes, also fresh-water fishes and shrimp present enzymatic deficiencies in their digestion, but in smaller magnitude [59.20–22]. This is logical if we consider that aquatic animals did not evolve with starch, the main component used in formulations, therefore, they did not have the need to produce carbohydrolases to digest it, producing severe digestive, health and contamination problems. Hence, in the last 10 years, many ingredients of animal and vegetable origin have been used to substitute meal and fish oil, without the expected success [59.23]. Subsequently, with the increasing knowledge of the digestive physiology, we have tried to adapt the diets to the enzymatic capability of animals, which has not been practical or economically viable for commercial aquaculture. In this sense, our innovation has been focused on understanding the enzymatic deficiencies in animals and the benefits of vegetable ingredients, to general knowledge we will generate FF that contains enzymatic profiles adequate for digestion and assimilation of proteins, carbohydrates, and lipids, independently from the source that they come from.

59.2.1 Fish Meal and Oil

Several decades ago small pelagic fish, were the greatest economical and nutritional source of protein and oil that existed. However, the growing aquaculture and livestock activities in general have provoked an excessive demand, and consequently the over-exploitation of fish stock used for this purpose, causing an ecological imbalance and an increase in prices, making it unaffordable to producers. Worse than the elevated prices is the fact that the capture of fish has been decreasing since 1996, and human need for consumption of aquatic products has been increasing [59.3]. Reduced inclusion of fish meal and oil in the formulations is a tendency for almost a decade. Furthermore, it has been predicted that by 2020, the amount of fish meal and oil in diets used in aquatic cultures will be minimal or null [59.3]. It is evident that in times of abundance, excessive quantities of fish meal and oil were used, without having a clear idea of the real nutrient necessities for these animals. Now that we have enough knowledge, we know that if the amount of protein and oil is reduced be-

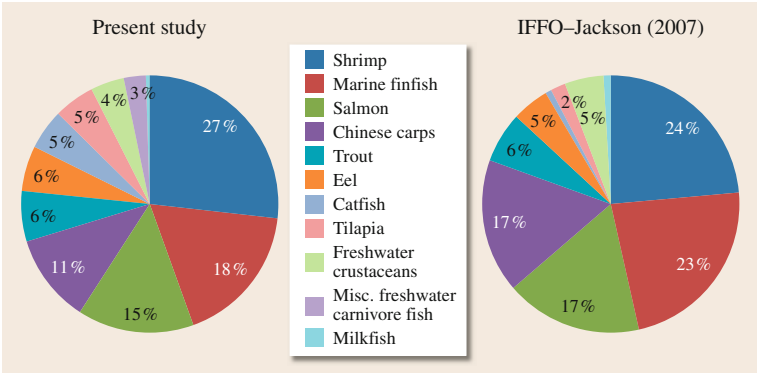

Fig. 59.3 Estimated global use of fish oil within compound aquafeeds

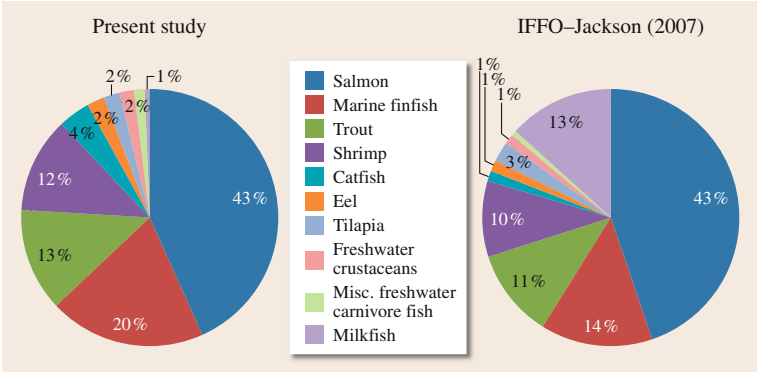

Fig. 59.4 Estimated global use of fish oil within compound aquafeeds

low the nutritional requirements, the animals will not grow and gain weight properly. From a ton of processed fish, approximately 25% of meal is obtained, containing an average of 60% digestible protein. In shrimp and marine fish feeds the fish meal is added in concentrations of about 20–50%, respectively (Fig. 59.3). Nowadays, we know that most carnivores require between 20–30% protein and similar amounts of carbohydrates. Regarding this, the aquaculture industry has had to search for viable alternative digestible and economical ingredients to satisfy the nutritional requirements of cultivated animals. Soy is the most probable candidate due to its high concentration of protein, carbohydrates, and lipids [59.24].

In addition, the limited capacity of fish and shrimp to digest starch has induced fish meal to be used by animals as a source of protein and energy, making feeding less efficient and more expensive [59.20–22, 25–29].

Regarding fish oil, the problem is even greater than with fish meal, because the amount generated by a ton of processed fish is less than 10%, and the requirements in shrimp and fish diets are between 10 and 40%, respectively (Fig. 59.4) [59.3, 18]. In fact, all the produced oil is used in aquaculture feeds, increasing the price of this ingredient even higher than fish meal (Fig. 59.1). The possible candidates to replace fish oil are vegetable oils with profiles of saturated and unsaturated fatty acids, similar to those present on fish. In this sense, the oil of some microalgae species fulfills all the requirements necessary to replace fish oil. Analyzing fatty acids, especially the unsaturated ones contained in fish oil, most come from marine phytoplankton, since the animals does not produce them de novo (Table 59.1). Presently, the technology to produce fatty acids from microalgae is well established, due to the interest in the use of these lipids to generate biodiesel. This technology can facilitate lipid production in the required volumes for aquaculture, assure its availability, and reduce its cost [59.30].

59.2.2 Soybean Meal and Oil

SBM is the most studied ingredient for the substitution of fish meal in aquatic animal feeds, because it contains high levels of proteins and carbohydrates and may represent half or less of the FM price. However, un-

satisfactory results have been obtained because SBM contains compounds that are toxic and antinutritional to monogastric animals, and no more than 20% can be included in shrimp/fish formulations without causing health problems [59.31, 32].

Furthermore, flour from oleaginous seeds offer annually more than 200 million metric tons (MT), soy being the most abundant and in expansion. Soybean meal has a natural resistance to oxidation and in storage it stays fungus and bacteria free, that can be pathogenic to shrimp and fish development [59.33, 34]. The protein fraction of soybean meal is between 45–48% for common meals, while the *premium* grade exceeds 50%.

Concerning its carbohydrate composition, soybean meal contains approximately 32% from which 12% are soluble sugars, distributed as follows; 4–5% sucrose, 1–2% raffinose, 3.5–4.5% stachyose, as well as small amounts of melibiose and verbascose. 20% the remaining fraction which is difficult to digest are known as anti-nutritional compounds, due to the toxic effects they causes in monogastric animals (Table 59.2) [59.34].

Soybean oil is another possible candidate to replace fish oil, since it also contains enough quantities of essential polyunsaturated fatty acids (omega 3 and 6), to satisfy aquaculture and consumer needs. The growing demand of soybean oil in homes around the world is due to its low cost and the amounts of omega 3 (linolenic 7.5%), omega 6 (linoleic 54%), and omega 9 (oleic 22%). It is important to comment that oleic acid is a monounsaturated fatty acid, which can be transformed to polyunsaturated acid by the enzymatic machinery of animals. Furthermore, soybean oil also contains saturated fatty acids such as palmitic acid (11–12%) and stearic acid (3–5%).

59.2.3 Complex and Most Used Carbohydrates

Today starch present in corn and wheat flour is the most utilized source of energy; for economical and availability reasons. Additionally, it has been shown that starch may replace protein as an energy source without de-

Table 59.2 Non-starch polysaccharide (NSP) content from cereals and soybean meal

Dry matter %	Carbohydrates	Corn	Wheat	Barley	Soybean meal
NSP		9.9	11.9	18.7	21.9

creasing growth [59.20, 35]. However, starch is one of the less digestible ingredients in fish and crustaceans, and high-level inclusions represent an important obstacle to shrimp/fish aquaculture; the carbohydrate digestion capabilities of animals are limited to no more than 10% in carnivorous fishes and 30% in tilapia and shrimps [59.20, 21, 36]. Nevertheless, higher carbohydrate levels are included in feeds because they are the most economical and for this reason the most used ingredient in the aquaculture industry. The identification of glucosidases producing probiotic bacteria and their addition to low-cost diets as a digestive promoting supplement should lead to better assimilation, lower production cost, faster animals growth, and less pollution and diseases [59.22].

59.2.4 Probiotic Bacteria

Recently, beneficial microorganisms (probiotics) were utilized to improve nutrient assimilation and to enhance the growth performance and health of monogastric animals [59.22, 37, 38]. Additionally, pollution of shrimp effluent ponds was also treated with microorganisms [59.39]. In this sense, we have defined a probiotic as a living microbial supplement that:

a) Positively affects hosts by modifying the host-associated microbial community and immune system.
b) Secretes a variety of enzymes to improve feed degradation, enhancing its assimilation.
c) Improves the quality of environmental parameters [59.14].

Bacillus probiotic strains have been used to improve growth performance, digestive enzyme activity, and immune response, with good results being obtained in all the parameters measured [59.22, 40–42]. The genus *Bacillus* constitutes a diverse group of rod-shaped, Gram-positive bacteria, characterized by their ability to produce a robust spore. Most *Bacillus* species are not harmful to mammals, including humans, and are commercially important as producers of a high and diverse amount of secondary metabolites, antibiotics, heterologous proteins, fine chemicals, and enzymes [59.43–47]. *Bacillus* enzymes are very efficient in breaking down a large variety of proteins, carbohydrates, and lipids into smaller units. *Bacillus* species grow efficiently with very low-cost carbon and nitrogen sources [59.43]. They also degrade organic accumulated debris in ponds of shrimp cultures [59.14, 48–50]. Taking into account the advantageous characteristics of *Bacillus* strains, these bacteria are good candidates for consideration as probiotics in diets of crustaceans and fish [59.14, 15]. Additionally, *B. subtilis* is generally recognized as safe (GRAS) by the FDA, meaning that this bacterium is not harmful to animals or humans (Fig. 59.5).

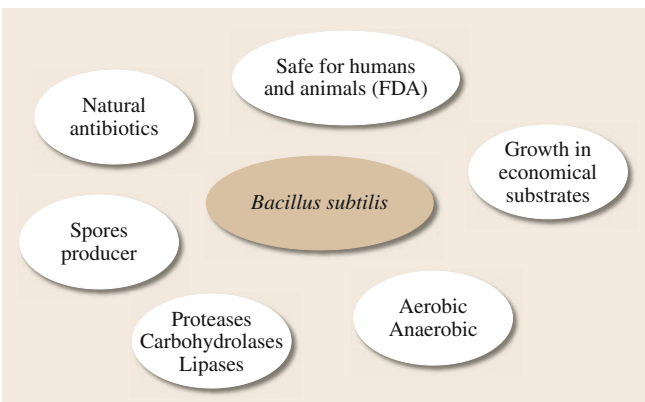

Fig. 59.5 *Bacillus subtilis* multifunctional probiotic capacities

59.3 Conventional Feeds Versus Functional Feeds

Currently, the cultivation of shrimp and fish is very important, socially and economically speaking, being *Litopenaeus vannamei* and *Oreochromis niloticus* the most produced around the world. However, apart from the questions about which culture is the most important or which generates the greatest economical dividends, the diets utilized for the aquaculture of any animal are developed with mainly three ingredients:

1) Fish meal, because it contains high concentrations of easily digestible protein, which promotes optimal growth and weight gain in cultivated animals.
2) Carbohydrates that come from vegetable flour, specially those present in corn and wheat starches, which give the necessary energy for vital functioning.
3) Lipids that are obtained as a by-product from the processing of fish meal and are the structural base for the production of hormones and other important bioactive macromolecules.

However the use of fish meal and oil in the production of feeds is limited due to costs, principally since these ingredients come from fish that are at risk due to unmeasured exploitation [59.3, 51]. In this sense, the production of feeds that does not depend on the utilization of fish products has been widely investigated during the last 10 years, and there has been experimentation with a wide range of animal and vegetable ingredients [59.52]. Unfortunately, up to now even the high cost of fish products and by-products, feeds are for aquaculture still being formulated with them. This means that alternative formulations that can compete with the benefits of survival, weight gain, and growth that fish meal and oil ingredients generate has not yet been found. Alternative feeds produced and sold in a commercial manner as a consequence of the high prices, are mixtures reduced in fish meal and oil content and increased in the amount of vegetable protein and oils. This has brought as a consequence low food conversion factors (FCF), poor growth, intoxication and health status detriment. Also, the use of vegetable products has generated an increase in environmental contamination due to the low digestibility and, consequently, pathogen proliferation and massive death of the cultured animals.

For these reasons, our research group has been trying for more than 10 years to understand the most important strengths and weaknesses of cultivated animals [59.14, 19]. Additionally, alternative vegetable ingredients economically viable to substitute fish meal and oil have been investigated [59.15, 22]. Also, the animal-environment-pathogen relationship had been studied to generate innovations that can fully satisfy aquaculture necessities [59.53, 54]. After all this time, and after having experimented with crustacean and fish cultivations, we believe that we have found healthy formulas that are sustainable with the environment and that are economically viable, that we have named *functional feed*.

According to our concept, FF must be formulated with little or no fish meal and oil, instead vegetable ingredients increase is recommended; this will decrease its price and ammonium pond contamination considerably. Furthermore, it will relax the fish population and environmental stress. However, vegetable ingredients are not recommended by most nutritionists, due to their low digestibility, contents of highly toxic compounds, and mortality increase. We believe that FF must contain high levels of vegetable flour and oils; rich in proteins, carbohydrates, and lipids. Micronutrients must be supplemented for the optimal development of the animals. In this sense and in our particular point of view, the most important components of FF are probiotic bacteria, since they produce enzymes with several capacities to amplify the digestive spectrum and help the animals to assimilate the ingredients, even if they come from vegetable origin. Likewise, the enzymes must have the capacity to degrade the toxic compounds contained in vegetable flour [59.55]. The enzymatic diversity and activity of proteases, carbohydrolases, and lipases must be maintained, even in adverse physicochemical or environmental conditions such as temperature, pH, oxygenation, etc.; so the enzymes will not be inhibited in the digestive system of animals or in cultivation ponds once they are excreted. This also will help with the effluent bio-remediation. Probiotics must be harmless to animals and humans, but must have the capacity to selectively inhibit pathogen growth.

59.4 Aquaculture Regulations

Recently, the massive development of aquaculture has promoted the establishment of sanitary and environmental regulations in most countries where this activity is practiced. This is particularly due to the spread of diseases and environmental contamination generated by poor cultivation management (Fig. 59.6). It is important to emphasize that the majority of these regulations have been generated in little or in great measurement due to the feed; starting with the ingredients and concentrations utilized in them, up to the amount of feed administered during cultivation. Furthermore, the time period of water exchange in ponds is also a consequence of the feed and the enzymatic limitation of animals must digest and assimilate them. Therefore, poorly formulated feeds can be the main reason of environmental deterioration due to the contamination generated, resulting in the spread of diseases and death of cultivated animals (Fig. 59.7).

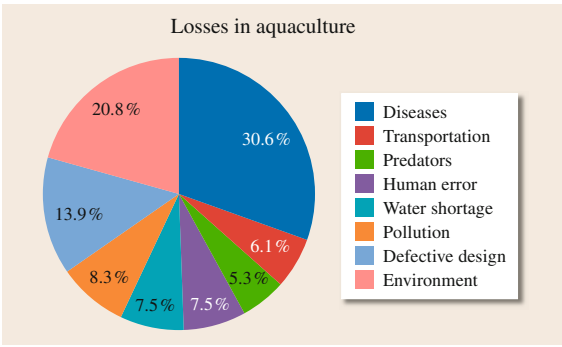

Fig. 59.6 Schematic representation of loss percentages in aquaculture

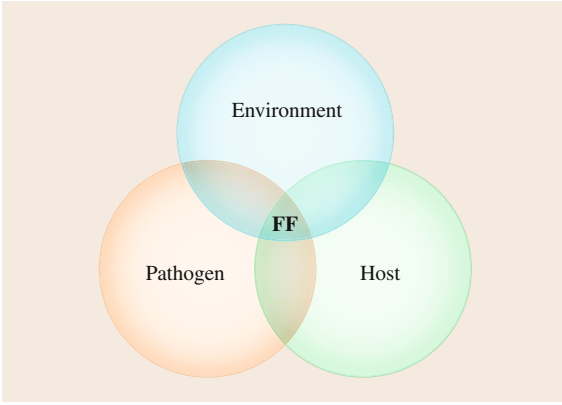

Fig. 59.7 Illustration of the balance involved in the state of health and disease of a cultivated organism with or without FF

59.4.1 Sanitary Regulations

The formulation of feeds with animal origin ingredients can be a factor in the spread of viral as well as bacterial diseases, that can be contained in animal-based ingredients. The feed utilized in aquaculture is sometimes distributed around the world and can generate global pandemics and epizooties, like the ones produced by *Vibrio* genera and the white spot syndrome virus [59.56, 57]. Therefore, animal products and by-products used for the formulation of feed must be certified by the sanitary authorities of each country to verify that it does not contain pathogen microorganisms above the concentrations permitted by the official norms. This will assure its innocuousness but raises the production costs of these ingredients, and thus, the cost of the formulated feed. Furthermore, cysts and spores are forms of life that are resistant to extreme conditions presented by some pathogenic bacteria [59.58]. This characteristic allows them to survive the conditions used in the preparation of products and by-products of animal origin, only to germinate once the product is in contact with water and the cultivated animal. In this sense, the prevention of diseases has also generated an unmeasured use of antibiotics, which has induced the development of pathogenic bacteria stock resistant to a great variety of these compounds. It is important to keep in mind that human beings can be susceptible to the antibiotics used in aquaculture, as well as to pathogens present in cultivated animals, especially when that person has an immune compromised system. *Vibrio parahemoliticus* is an opportunistic pathogen that can cause death to individuals with problems such as liver cirrhosis, if they consume contaminated oysters. The transmission of the disease known as Mad Cow Disease and other diseases that come from poultry stock are examples of the importance of the innocuousness and sanitary regulations that have to be implemented in products from animal origin [59.59]. In this sense, the use of vegetable ingredients in FF can eliminate the pathogen transference contained in animal products, as well as the unmeasured use of antibiotics.

59.4.2 Environmental Regulations

Environmental regulations with respect to aquaculture, even when they are stipulated in the official norms and are very clear regarding the compounds and quantities that can be thrown into rivers or seas; in most of the countries where massive production of fishes and crustaceans is being practiced, are not being complied. Therefore, high concentrations of organic contaminant compounds are indiscriminately thrown into rivers and seas each year, generating constant contamination and deterioration of the environment and ecosystem that surrounds farms. Unfortunately, most countries where aquaculture is being practiced, even with the existence of official norms, do not count with mechanisms to carry out those norms. In addition, the formulation and usage of FF of easy digestion and assimilation by cultivated animals will generate low concentrations of organic waste, and can be a direct mechanism to reduce contamination of ponds and waste that is thrown into rivers and seas [59.14, 60]. In this sense, the probiotics used in FF must also have the capacity to degrade the contaminants generated in farms.

59.5 Functional Feeds in Aquaculture

Autochthonous bacteria of crustaceans and fishes can be recommended as probiotics, only if they have the capacity of secreting a wide variety of enzymes that will allow them to take adequate advantage of different sources of protein, carbohydrates, and lipids. Also, they must be capable of producing antimicrobial compounds to inhibit the growth of different pathogens, without having any effect on beneficial bacterial flora. They must also be able of surviving sudden nutritional and environmental changes, such as temperature, pH, oxygenation, etc. Furthermore, autochthonous strains are, in general, bacteria that adhere to the cells of the animal's intestine and, therefore, are circumscribed to scarcely variable nutritional and environmental conditions. For this reason, most of them do not have the capacities mentioned before. On the other hand, free life strains like *Bacillus subtilis* have all these capacities, hence it can be considered as a potential probiotic. Also, this bacterium is classified by the FDA as GRAS, which means that is not a pathogen to animals or humans [59.22].

59.5.1 Advantages and Disadvantages of Adhesion

The advantage of adhesion is that probiotics should only be used a few times until they have colonized the digestive tract, which would reduce the cost and would increase the profitability of producers. Otherwise, the capacity of adhesion means that the strains are adapted to live within the host, which assures a high percentage of interaction, as long as the conditions of the environment are satisfactory. Unfortunately, most pathogens have a highly developed capacity of adhesion as an invasive mechanism. In this sense, it is almost a general rule that when cultivation is in its initial stage, the bacterial flora present is composed by certain groups. However, once cultivation advances and conditions deteriorate, more capable bacterial groups surge, taking advantage of the reigning nutritional and environmental conditions. Most proliferating bacteria are opportunistic pathogens with a high capacity of adhesion. Therefore, if we isolate bacterial strains from aquatic cultivated organisms with the purpose of utilizing them as probiotics, it is recommended to isolate them from the first stages of the cultivation or from finalized healthy and high-productivity cultures.

In the late stages of cultivation, the possibility of the isolation of opportunistic pathogenic bacteria rises [59.54, 60]. Lately, it has been very complicated to keep healthy cultures with economically income, mainly due to food expenses and the great amount of energy used for water exchange in the required percentages. This is one of the reason for the huge proliferation of pathogens and the consequent mortality in cultures. Generally, when an opportunistic pathogenic bacterium has adequate conditions it takes advantage of it to proliferate.

If we take probiotics from humans as an example, most of them are *Lactobacillus* species with adhesion capacity to epithelial intestinal cells, which means that a daily dose must be taken to maintain their active growth and probiotic capacity. In this sense, we know for a fact that up to this date there is no commercial strain that is taken once and maintains its activity during the rest of the host life. For example, daily or almost daily consumption of *Lactobacillus*-based products is needed to keep its positive effects; this is due

to the feeding conditions and stress factors that restrict the proliferation of probiotic strains on cultivated animals. Yet, it is more complicated to maintain probiotic strains that are permanently in contact with a water flow in the digestive tract, as is the case for fish and crustaceans. If we add the fact that most of enzymes and antimicrobial compounds are produced in a short window of the stationary phase from most bacteria, the protection due to the production of these compounds will also be restricted to when the probiotic remains inside the animal. Additionally, due to its evolutionary environment the autochthonous bacteria of crustaceans and fish have never been in contact with carbohydrates of terrestrial origin such as starch, which is the main ingredient in used formulations. Therefore, the physiological and economical conditions to utilize an autochthonous probiotic strain added to the epithelium cells, do not appear, in theory, to have advantages with respect to those free living bacteria. Otherwise, if we have a probiotic that adheres well to epithelium cells, we need to take into consideration that the elimination of these bacteria from the digestive tract of the animals is more complicated. In this sense, if the probiotic is not recognized as safe and is not approved by the FDA, it can generate problems when the time comes to commercialize the animal for human consumption. This also happens with unauthorized antibiotics and hormones.

Even though the diverse marine and aquatic systems represent 85% of all forms of life on earth, it is important to point out that if we are going to use FF especially formulated with nutrients of land origin, we should select probiotic strains with the capacity to digest them without any problem. Therefore, if we develop free living bacteria probiotics strains accustomed to surviving in extreme conditions, with an abundance as well as limitations of nutrients, salts, temperature, and variable pH, they will have a greater adaptive response to sudden changes in the culture. Moreover, if these strains count with the capacity of enzyme secretion to degrade any kind of nutrient, as well as to produce compounds to solely kill pathogenic microorganisms and do not present toxic effects in animals and humans, these strains can be considered as a potential probiotics. The only inconvenience is that good fortune and capacity is needed to isolate and characterize them adequately. Additionally, continuous probiotic supplementation must be carried out to obtain an effective and therapeutic dose, and consequently, maintain its probiotic properties. In this sense, FF are the adequate vehicle to introduce probiotics into the animal, considering stability and price.

59.6 Results Obtained in Crustaceans and Fish Using Functional Feeds

59.6.1 Functional and Commercial Feed Proximal Composition Used in *Litopenaeus vannamei* and *Oreochromis niloticus*

Table 59.3 shows the proximal composition of the ingredients in diets utilized for white shrimp and tilapia cultivation. The formulated FF (basal diet + probiotic), was the same for *L. vannamei* as for tilapia because the nutritional requirements are similar for both animals. In this sense, analyzing the commercial diet for tilapia we could see its similarity regarding the formulated basal diet. The origin of the ingredients contained in the commercial diet for tilapia are not known to us, although the basal diet ingredients were reported previously [59.14]. It is important to point out that the protein in the basal diet comes from 100% soybean meal. In both diets, the carbohydrate concentration is around 50%, which could originate health problems in shrimp, since this amount surpasses the nutritional requirements of this ingredient [59.61]. This is not the case for tilapia because it is an omnivore with the capacity to tolerate high concentrations of carbohydrates.

The commercial diet for shrimp has 10% more protein than the basal diet formulated by our research group. The origins of the ingredients of the commercial diet for shrimp are unknown to us, although

Table 59.3 Functional and commercial feed proximal composition used in *Litopenaeus vannamei* and *Oreochromis niloticus*

Items %	Basal + P FF	Commercial feed to *L. vannamei*	Commercial feed to *O. niloticus*
Crude protein	27.41	36.39	32
Total lipid	6.46	3.98	5
Carbohydrates	49.50	38.42	50
Moisture	11.34	9.88	5
Ash	5.29	11.33	8
Probiotic (P)	1 kg t^{-1}	–	–

it is a fact that the protein used is of animal origin. The commercial diet for shrimp contains 10% less carbohydrates than the basal diet, which is the closest to what is required and/or tolerated for this crustacean [59.61].

59.6.2 Basal and Functional Feed Proximal Composition Used in *Atractoscion nobilis*

Table 59.4 shows the basal diet containing the required ingredients and concentrations for *Atractoscion nobilis*, a strictly carnivorous fish. From the diets CHO10 to CHO22, the corresponding carbohydrate percentage was increased and the lipid concentrations reduced, as indicated in the table. The probiotic was added to all the CHO diets in concentrations of $1\,kg\,t^{-1}$. It has been widely reported that *A. nobilis* presents a health problem when the carbohydrates contained in the diet surpass 10%. Additionally, the development for marine fishes is limited when the lipid concentrations in the diet is reduced. Moreover, it is most important to maintain the high levels of fish protein in this species, which is why this ingredient was maintained at 50% in all the formulated diets.

59.6.3 Functional Feed Effects on Survival and Growth Performance of *L. vannamei*, *O. niloticus* and *A. nobilis*

Once the animals were fed in controlled conditions, biometry studies were carried out to determine the dietary effects on growth, survival, etc. In experiments with *Litopenaeus vannamei* (Fig. 59.8), Table 59.5 shows that the parameters analyzed improved considerably in animals fed with the basal diet containing the probiotic (FF), with respect to the commercial diet and the basal diet without the probiotic. The food conversion ratio (FCR) was the parameter showing the best result, which confirms that *L. vannamei* has difficulties digesting vegetable sources of proteins and high levels of CHO. These results also confirm that the probiotic is the most important ingredient in the formulation of FF, since the inclusions of the bacteria allows the use of alternative, economical, healthy and available nutrients [59.14, 22].

Table 59.4 Basal and functional feed proximal composition used in *Atractoscion nobilis*

Items %	Basal feed	CHO 10 FF	CHO 14 FF	CHO 18 FF	CHO 22 FF
Crude protein	56.5	56.1	56.0	54.2	55.9
Total lipid	19.3	18.3	15.0	15.0	14.3
Carbohydrates (CHO)	10.3	10.5	13.9	18.8	21.4
Ash	9.8	10.5	10.2	10.8	8.9
Energy Cal g^{-1}	5076	5102	5037	5071	5066
Probiotic (P)	–	$1\,kg\,t^{-1}$	$1\,kg\,t^{-1}$	$1\,kg\,t^{-1}$	$1\,kg\,t^{-1}$

Fig. 59.8 *Litopenaeus vannamei* Pacific Ocean white shrimp

Fig. 59.9 Effect of FF on *Oreochromis niloticus* development. From *left* to *right*: animals fed with basal diet + probiotic (FF), commercial diet + probiotic, commercial diet, and basal diet

Table 59.5 FF effects on survival and growth performance in *Litopenaeus vanammei*

Items	Basal feed	Basal + P FF	Commercial feed
Initial weight (g)	5.98 ± 0.22^a	5.96 ± 0.20^a	6.06 ± 0.18^a
Final weight (g)	9.48 ± 0.13^c	10.71 ± 0.11^a	10.38 ± 0.16^b
Daily weight gain ($g\,d^{-1}$)	0.125 ± 0.003^c	0.169 ± 0.003^a	0.154 ± 0.001^b
Food conversion ratio (FCR)	2.49 ± 0.15^c	1.54 ± 0.07^a	2.06 ± 0.22^b
Survival (%)	96.67 ± 3.87^a	100^a	96.67 ± 3.87^a
Probiotic (P)		$1\,kg\,t^{-1}$	

Means in the same row with different superscripts are significantly different ($P < 0.05$)

Table 59.6 shows that the values obtained for *O. niloticus* using the basal plus the probiotic bacteria (FF), where almost twofold greater than the results obtained using the basal and the commercial diet, with the exception of the survival rates, which were similar in the three assays. These results mean that the basal diet formulated for this experiment and the commercial diet are very similar with respect to the energy content. Moreover, it also means that even though *O. niloticus* is an omnivore it shows certain problems digesting vegetable protein and high concentrations of carbohydrates. When the probiotic was added to the vegetable diet (basal diet), all parameters improved almost 100% (Fig. 59.9). The biomass and its size doubled in the same period of time and with the same amount of food, which opens great possibilities and hopes for the development of healthy, sustainable, and profitable feeds in the immediate future.

Table 59.6 FF effects on survival and growth performance in *Oreochromis niloticus*

Items	Basal feed	Basal + P FF	Commercial feed
Initial weight (g)	3.46^a	3.90^c	3.63^a
Final weight (g)	5.40^a	9.40^c	6.74^b
Absolute growth (g)	1.94^a	5.50^c	3.11^b
Biomass gained (g)	55^a	165^c	81^b
Specific growth rate (SGR)	3.16^a	8.12^c	5.40^b
Efficiency feed consumption	0.21^a	0.49^c	0.30^b
Food conversion ratio (FCR)	4.71^a	2.04^c	3.37^b
Protein efficiency ratio (PER)	4.95^a	10.78^c	6.92^b
Survival (%)	100^a	100^a	90^b
Probiotic (P)		$1\,kg\,t^{-1}$	

Means in the same row with different superscripts are significantly different ($P < 0.05$)

With respect to the results obtained in *Atractoscion nobilis*, the CHO22 diet tripled its weight and duplicated its size in comparison with the basal diet (Fig. 59.10). According to studies on this marine

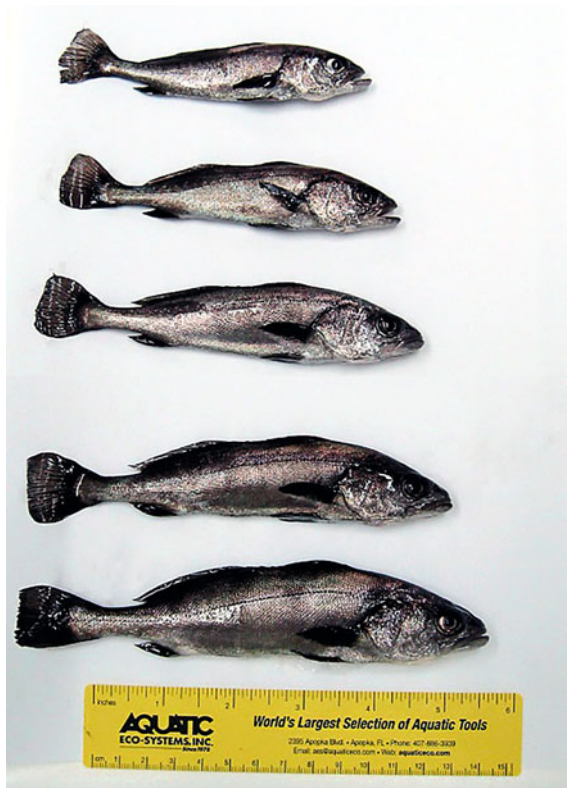

Fig. 59.10 Effect of FF on *Atractoscion nobilis* development. From *top* to *bottom*: animals fed with basal diet, CHO10, CHO14, CHO18, and CHO22 FF

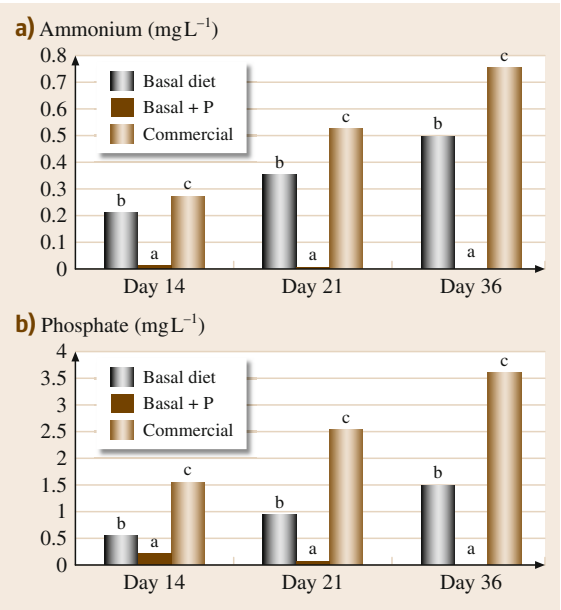

Fig. 59.11a,b FF environmental parameter reduction. **(a)** Ammonium evaluation and **(b)** phosphate evaluation

and strictly carnivorous species, it tolerates a maximum of 10% carbohydrates in its diet without having health problems. However, the results in Table 59.7 show that it is possible to increase the carbohydrate levels up to 22% without producing toxic effects in the animal. These results also demonstrate that if these animals have sources of energy that are easier to assimilate than protein, they will prefer them because the energy wasted to metabolize them is less significant [59.19]. In this sense, the CHO22 FF diet was very successful in all the parameters evaluated, due to this diet, the animal used protein to grow and carbohydrates as a source of energy. Because the weight was tripled using FF, regarding the basal diet, it is probable that the extra energy from digested-assimilated carbohydrates was canalized to generate protein, as happened in assays carried out with *L. vannamei* [59.14]. The interconnection of the biosynthetic pathways gives the possibility to redirect the carbon flow and send it to where it is required most, as long as the system is in balance between the nutrient entry and the output waste discarded from the animal cells. All this shows, as demonstrated in this experiment and in the one with tilapia and shrimp, that it is possible to use complex sources of proteins, carbohydrates, and lipids, when probiotic bacteria are included to carry out processes to control the liberation of nutrients independently of their origin.

According to the results obtained in this study (Tables 59.5–59.7), the FF effects were more impressive in fish for the basic and simple reason that fish eat the pellet complete and shrimp chew their food. This small but great difference induces fish to obtain a complete dose of FF and its consequent benefits. This is not the same for shrimp, which because of the way they feed, only take advantage of half or less of the FF.

Table 59.7 Effect of FF on survival and growth performance of *Atractoscion nobilis*

Items	Basal feed	CHO 10 FF	CHO 14 FF	CHO 18 FF	CHO 22 FF
Initial weight (g)	9.63 ± 0.07	9.52 ± 0.04	9.50 ± 0.20	9.37 ± 0.20	9.51 ± 0.11

Stress tolerance to high ammonium concentrations	0.0^b	83.33 ± 0.11^b	0.0^b
Stress tolerance to low oxygen concentrations	66.67 ± 2.22^b	91.67 ± 3.20^a	41.67 ± 4.18^c

Means in the same row with different superscripts are significantly different ($P < 0.05$)

59.6.4 Functional Feed Effects on *L. vannamei* and *A. nobilis* – Health Status

The capacity of the probiotic used to inhibit the growth of the pathogens due to the production of antimicrobial compounds was demonstrated previously [59.15]. Additionally, the improvement in the health status of the animals was evidenced with the increase of blood cells and energy sources like glucose and lactate; these results were obtained exclusively in treatments where FF had been used (Table 59.8). This means that animals assimilate nutrients in greater amounts, due to the increase in the digestibility processes that was made possible by the probiotic enzymes. Because of the increase in weight and size, it was evident that if the animals have a greater nutrient concentration in the bloodstream, a greater generation of biomass and energy will be obtained in animals that consume FF. Conventional nutrition classifies the increase in glucose, lactose, etc. as stress indicators in animals. However, if we consider that the animals are in perfect shape, are bigger, weigh more, and are more vigorous, it is logical to translate these increases in blood parameters as a direct measurement of health status improvement, rather than a state of stress in animals consuming FF. A greater number of blood parameters evaluated in *O. niloticus* and *A. nobilis* will be shown in studies published in specialized journals in the near future.

59.6.5 Functional Feed Effects on Environmental Parameters in *L. vannamei*

The environment where cultivated animals develop is as important as their nutrition and/or state of health, since the three parameters are in close relationship with each other (Fig. 59.7). Because the conditions of the environment are directly related with the quality of food, our conception of a FF take into account the decrease in water contamination; due to the characteristics of the food with vegetable ingredients, and/or the intrinsic capacity of bioremediation by the probiotic added to the FF. In this sense, all the contaminants evaluated in the culture shrimp ponds that used FF showed a considerable decrease in water concentration, in comparison to the assays where no FF were used (Fig. 59.11). Regarding the results obtained with the basal diet without the probiotic, this is due in part by the nature of the food, which is less pollutant than the commercial diet [59.14, 22].

59.6.6 Functional Feed Effects on Stress Tolerance in *L. vannamei*

Ammonia stress experiments carried out by *Olmos* et al. [59.14] showed that shrimp fed with FF tolerated well high levels of ammonia throughout the 24 h of the experiment (Table 59.9). Taking into account that basal and commercial diet do not presented any survival rate and that glucose and lactate were higher and statistically different in animals treated with FF (Table 59.8), we can hypothesize that:

a) Shrimp survived due a higher energy level availability on the circulatory system, giving them a greater response capacity,
b) by a direct ammonia conversion-transformation reaction accomplished by the probiotic bacteria [59.14].

On the other hand, even when oxygen depletion stress-experiments do not presented such drastic mortality results as the one presented by the ammonia experiments, 35 and 60% shrimp mortality was occurred with the use of basal and commercial diets, with respect to 10% mortality showed by the FF treated animals (Table 59.9). These results clearly indicate that:

a) Shrimp fed with FF have the capacity to tolerate well oxygen depletion.
b) The basal diet without the probiotic bacteria, in comparison with the commercial diet, presented less oxygen consumption by itself or by less ammonia contamination [59.14].

The results obtained in the stress experiments indicate that FF utilization in shrimp/fish aquaculture would help them to tolerate extreme variation of environmental parameters in a better way than commercial diets do.

59.7 Conclusions

The benefits of FF are the following:

1. FF promotes the digestion of ingredients and assimilation of nutrients, improving growth, weight gain, and FCR.
2. FF increases the health *status* of animals, eliminating pathogens and stimulating the immune system.
3. FF improves the quality of water in culture ponds, making them environmentally sustainable.
4. FF eliminates ecological stress in seas by using economical and abundant vegetable ingredients.
5. FF are cheaper than traditional feeds, which improves the competitiveness and profitability of the producers.
6. There is no alternative than the development of FF to assure the future of aquaculture.
7. The *movie star* is the probiotic, and therefore we need to isolate a multifunctional strain.
8. *Bacillus subtilis* is an ideal probiotic bacteria.

60. Mussel-Derived Bioadhesives

Bong-Hyuk Choi, Bum J. Kim, Chang S. Kim, Seonghye Lim, Byeongseon Yang, Jeong H. Seo, Hogyun Cheong, Hyung J. Cha

Marine mussels use MAPs (MAPs) for their adhesion. MAPs have fascinating properties, including strong adhesion to various material substrates, water displacement, biocompatibility, and controlled biodegradability. In this work, among six types of MAPs, including fp-1–fp-6, biosynthetic constructs of MAPs are considered; hybrid type recombinant MAPs are designed to improve productivity and purification. Hybrid recombinant fp-151, which comprises six decapeptide repeats of fp-1 at both N and C-termini of fp-5, was successfully overexpressed in a bacterial system, showing approximately ≈ 1 g/L production yield in a pilot scale fed-batch bioreactor culture. For industrial applications, it was attempted to use MAPs in tissue engineering fields as coating extracellular matrix (ECM) through surface modification and constructing nanofibrous scaffolds. As a result, the MAP-based coating strategy could be generally applied for facile and efficient surface modification of negatively charged bioactive molecules for tissue engineering. The use of MAP-based nanofibers could provide bioactive peptides efficiently onto the scaffold surface, enhancing the cell attachment and proliferation on the nanofibers fabricated using RGD peptide-conjugated MAPs compared with bare polycaprolactone (PCL) polymer nanofibers as well having a four times higher mechanical strength. Also, easy fabrication through blending with diverse types of synthetic polymers and significant bone regeneration was observed. In addition, there was a trial for utilization of MAPs in pharmaceutics, cosmetics, and food industries with encapsulating active molecules such as chemical drugs, proteins, cells, and flavor ingredients through a complex coacervation technique based on MAPs.

Finally, MAPs have been suggested as immobilization material for biosensors due to their unique adhesive property on various materials, including biomolecules, glass, polymers, and metals. MAP was genetically fused with C-termini of the BC domain of protein A and can be successfully used as a functional material for the development of various immunosensors and immunoassays. The MAP-based whole cell biosensor can be successfully used for industrial applications, including environmental monitoring of chemicals and heavy metals, and food screening. Collectively, MAPs might be a useful and applicable biomaterial in diverse industrial fields due to their superior adhesion properties (even in water), biocompatibility, and controlled biodegradable properties.

60.1 Marine Mussel Adhesion

Marine-fouling invertebrates such as mussels, barnacles, and sandcastle worms endure continuous mechanical stresses due to the tide, buoyancy, and drag through a strong attachment to the marine substratum with their specialized physical and chemical underwater adhesives [60.1–3]. These marine adhesions have given us many unveiled lessons to learn; especially because the materials for attachment used by these marine organisms have revealed their potential, the investigation of the underwater adhesives from these marine organisms has proceeded with much effort to develop real-world underwater adhesives. The adhesion of mussels is one of the best model systems. Marine mussels use mussel adhesive proteins (MAPs) for their adhesion, and MAPs have fascinating properties including strong adhesion to various material substrates, water displacement, biocompatibility, and controlled biodegradability [60.5]. Importantly, MAPs contain a high level of 3,4-dihydroxy-L-phenylalanine (DOPA), which is transformed by the hydroxylation of tyrosine residue via post-translational modification. DOPA is regarded as a key factor for strong adhesion [60.6]. DOPA has the ability to form hydrogen bonds and complexes with metal ions and oxides by chelation or covalent bond formation, which can explain the rapid, strong adhesion to various surfaces [60.7, 8]. In the meantime, DOPA-quinone, an oxidized form of DOPA, can form cross-links with other DOPA-quinone molecules via aryl coupling and a thiol group of cysteine residue, providing cohesive interactions [60.9–13]. As a result, DOPA plays dual roles in surface adhesion with the substrate and in cohesive cross-linking [60.13].

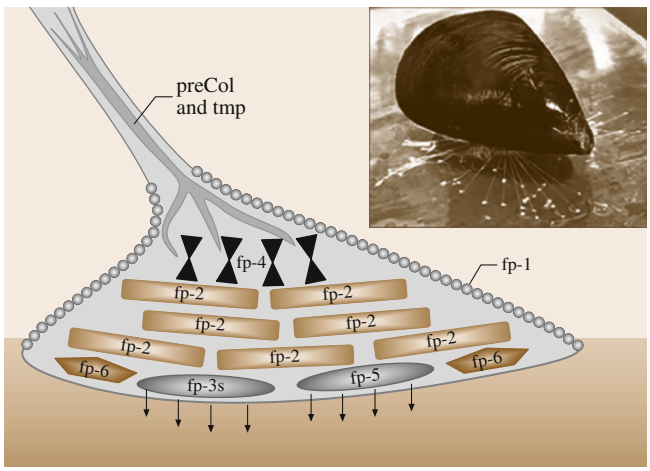

Fig. 60.1 Mussel adhesive proteins of *Mytilus* at the byssal plaque. The mussel (*Mytilus galloprovincialis*, *inset*) attached to a mica sheet is shown. One of its plaques (*red circle*) is enlarged as a schematic illustration of the approximate distribution of proteins (after [60.4], courtesy of the American Society for Biochemistry and Molecular Biology)

60.1.1 Mussel Adhesive Proteins (MAPs)

To adhere to the substratum, the mussel fabricates and utilizes byssus, which is a bundle of threads. The individual thread is called a byssal thread, and there is an adhesive plaque called a byssal plaque at the end of individual byssal thread, where underwater adhesion occurs between the byssal thread and the substratum [60.4]. Byssus is a proteinous structure, primarily composed of proteins (slightly greater than 90%); therefore, the adhesive proteins have been focused as the main research material. To date, six types of MAPs, including foot proteins type 1 (fp-1) to type 6 (fp-6), have been discovered, and each protein is distributed at a specific location and plays a different role (Fig. 60.1) [60.4, 14–16].

Composed of 50–80 repeats of a tandem decapeptide, fp-1 (≈108 kDa), the first identified and the most studied MAP is a coating protein that covers the entire exposed surface of the byssus. This protein is highly posttranslationally modified so that around 60–70% of amino acids are hydroxylated [60.17]. fp-3 (5–7 kDa) and fp-5 (≈9 kDa), which are abundant in the adhesion interface, are very small proteins containing a high DOPA concentration (10–30 mol %). It is proposed that they have a primer-like function in adhering to substrata, mediating strong surface interaction with a high DOPA content [60.12, 18]. fp-6 (≈11 kDa) is cysteine rich with an abundant thiol group, modulating interprotein thiol-mediated redox of DOPA [60.11]. fp-3, fp-5, and fp-6 form a thin primer layer on the substrate surface. Above this layer, the bulk of the byssus plaque is formed with fp-2 and fp-4. fp-2 (≈45 kDa); fp-4 (≈94 kDa) has a low DOPA content, and these proteins are relatively resistant to proteolysis. fp-2 is an adhesive protein that has repetitive motifs similar to the epidermal growth factor, and play a stabilization role [60.19]. fp-4 has high levels of histidine, lysine, and arginine, which seem to serve as coupling agent and thread collagen anchor, connecting with the byssus thread made up of fp-1 and collagen [60.20].

60.1.2 Production of Recombinant MAPs

Natural extraction, initially used for the isolation of MAPs, is an expensive and inefficient method. For 1 gram of fp-1, around 10 000 mussels are required [60.21]. To obtain large amounts of MAPs for bulk-scale adhesives and practical applications, recombinant DNA technology has been proposed as a solution. However, the recombinant MAP production was faced with difficulties with low production and purification yields [60.22, 23]. Herein, synthetic constructs of MAPs are considered; hybrid recombinant MAPs have been designed to improve the productivity and purification yields. The hybrid recombinant fp-151, which comprises six decapeptide repeats of fp-1 at both N and C-termini of fp-5, was constructed and successfully overexpressed in *Escherichia coli* [60.24]. The production yield showed approximately 100 mg/L in 5 L laboratory-scale cultures and ≈1 g/L in a pilot-scale fed-batch bioreactor culture. This approach has improved the productivity greatly and has expanded the practical applications of MAPs. In addition, low production yields of individual MAPs, such as fp-3 and fp-5, were recently overcome by sequence optimization based on *E. coli* codon preference and the application of diverse vector systems [60.25].

60.2 Application of MAPs to Tissue Engineering

One of the most promising areas for recombinant mussel adhesive protein is the field of tissue engineering. The central issue of tissue engineering has concentrated on designing structurally and biologically similar materials to the extracellular matrix (ECM) through surface modification [60.26]. Because ECM is mainly composed of several proteins and glycosaminoglycans (GAGs), tremendous efforts have been made to modify the surface of material using ECM components. Surface modifications for materials with ECM components are usually accomplished by two approaches.

One strategy is to incorporate ECM components into materials through physical modifications [60.27, 28]. The physical immobilization method is advantageous in terms of simplicity, but desorption of coating materials can easily occur. The other strategy is to provide biomaterials with ECM components by chemical modifications [60.29, 30]. Although this approach is a very powerful method to immobilize bioactive components, modification procedures are generally complicated; in addition, potentially cytotoxic chemical cross-linkers are commonly used for immobilization. General characteristics of MAPs show that they can be a powerful alternative to overcome the problems of previous immobilization methods. Herein, applications of MAPs in tissue engineering will be discussed as coating materials to immobilize various ECM components.

60.2.1 Protein Components

Various protein components derived from ECM and growth factors have been directly utilized to modify the material surface via covalent conjugation or physical adsorption [60.31–33]. Even though they showed good biological activity in in vitro systems, several complications, such as uneconomical production, random folding on the surface, undefined characteristics, and immunogenicity, hamper their biomedical application [60.34, 35]. The usage of bioactive peptides derived from proteins can overcome these complications, so it can be effectively applied to modify the surface of materials in tissue engineering [60.36, 37]. The protein-derived bioactive peptides immobilized or incorporated onto well-defined surfaces act as receptor binding motifs, and, therefore, the artificial surfaces efficiently promote various cellular behaviors, including adhesion, proliferation, survival, and differentiation [60.35, 38–40].

Recombinant MAP, fp-151, is a hybrid protein, so that various types of bioactive peptides can be introduced into it through genetic fusion strategy. Several ECM-derived bioactive peptides have been conjugated with fp-151 to make self-adhesive artificial ECM mimics [60.41]. Self-adhesive artificial ECM mimics can be effectively used to immobilize ECM-derived short peptides on surfaces (Fig. 60.2); the strong adhesion

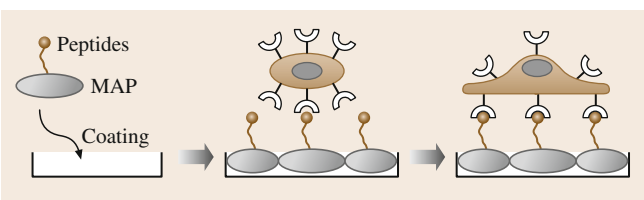

Fig. 60.2 A scheme for the usage of fp-151-peptides as self-adhesive ECM mimics (after [60.41], courtesy of Elsevier)

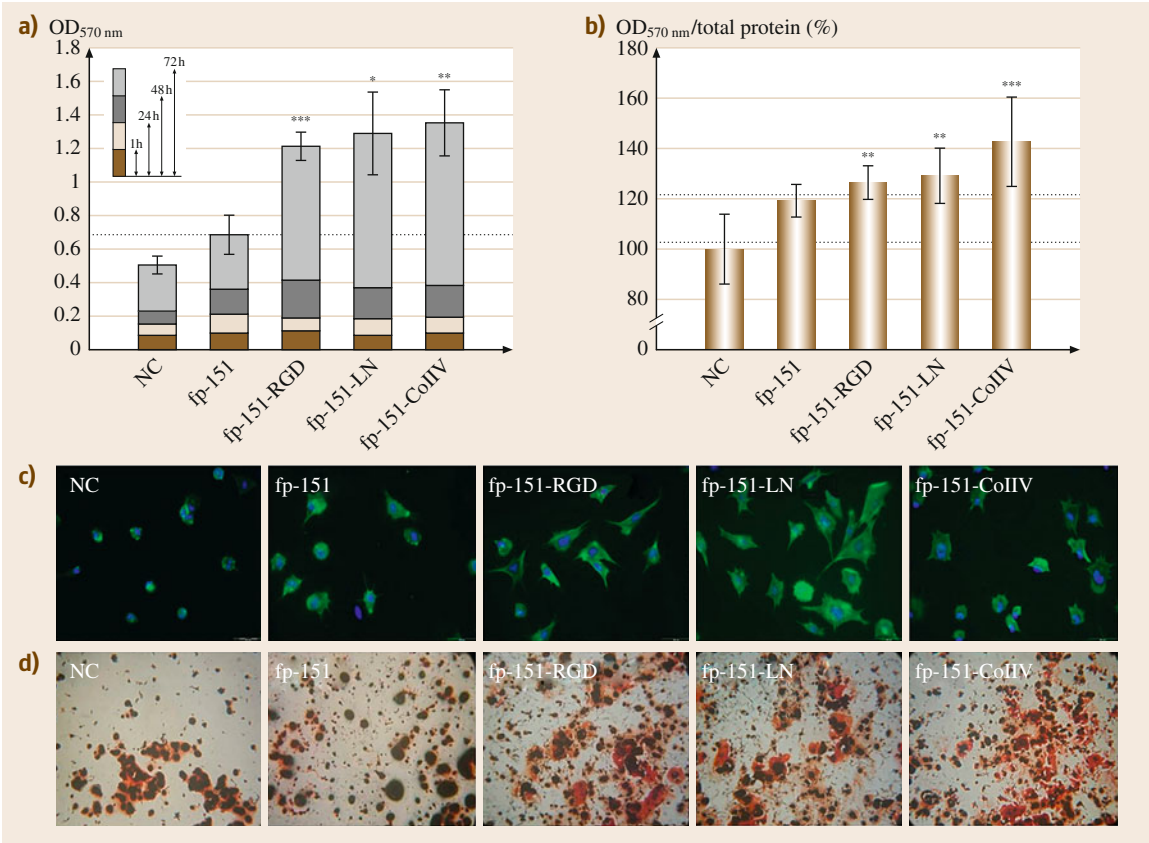

Fig. 60.3 (a) Proliferation, (b) alkaline phosphatase activity, (c) spreading, (d) alizarin red S staining results of MC3T3-E1 pre-osteoblast cells on self-adhesive artificial ECM mimics-coated tissue culture plate (after [60.41], courtesy of Elsevier)

ability of MAPs facilitates efficient surface modification of ECM-derived active peptides on scaffold materials without protein and/or surface modifications, and signaling-mediated ECM-derived active peptides efficiently promote diverse cellular events, including adhesion, spreading, proliferation, differentiation, and survival.

In three mouse cell lines of pre-osteoblasts, chondrocytes, and pre-adipocytes, immobilized ECM-derived active peptides via MAP coating significantly enhanced the essential cell behavior patterns of adhesion, proliferation, and spreading through interactions between ECM-derived active peptides and cellular receptors. Moreover, ECM-derived active peptides conjugated with MAP substantially improved survival and differentiation of pre-osteoblast cells (Fig. 60.3). Based on these data, fusion strategy using MAP successfully immobilized ECM-derived active peptides on the surface of material, and self-adhesive artificial ECM mimics can be usefully employed in cell and tissue engineering.

60.2.2 Glycosaminoglycan (GAGs) Components

Glycosaminoglycans (GAGs), mainly composed of heterogeneous carbohydrate, have also contributed to many cell signaling events [60.43, 44]. Because of their sulfated or carboxylated disaccharides, GAGs are strongly hydrophilic and negatively charged ECM components [60.18]. In contrast, MAPs are highly positive charged proteins (≈10 pI) because their composition includes DOPA (modified from tyrosine), positively charged lysine, and flexible glycine residues [60.24]. Therefore, immobilization of GAG components was performed by general characteristics

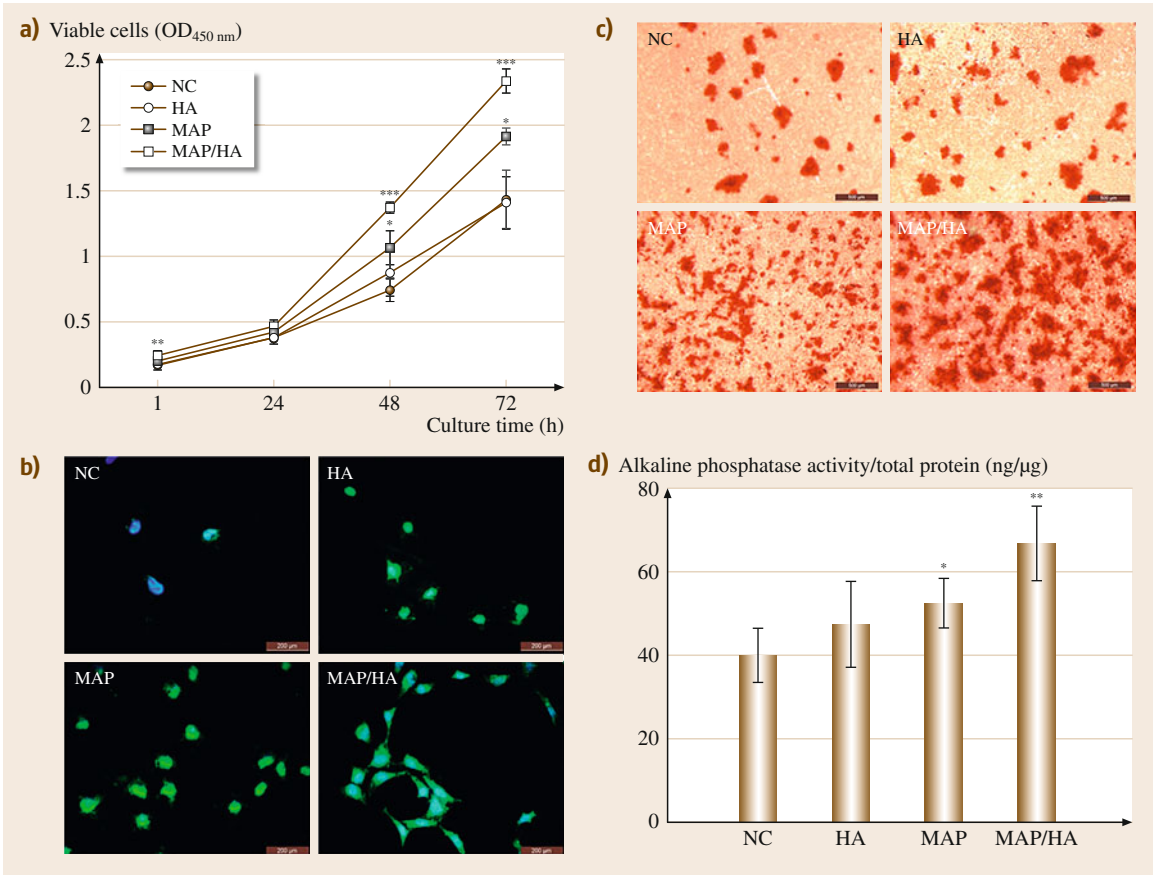

Fig. 60.4 **(a)** Proliferation, **(b)** spreading, **(c)** alizarin red S staining, **(d)** alkaline phosphatase activity of MC3T3-E1 pre-osteoblast cells on HA-immobilized titanium surface using MAP-based coating strategy (after [60.42], courtesy of Mary Ann Liebert, Inc.)

of MAP, such as adhesive property and highly positively charged protein [60.42]. This strategy using MAP is a new and facile method for the preparation of an artificial ECM via the immobilization of GAG molecules without any chemical modifications in a wet environment.

Titanium has been widely used in diverse medical applications due to its biocompatible property, although it has several limitations such as the insufficient osteointegrative property [60.45]. In order to overcome these problems, surface treatment and functionalization using bioactive molecules, such as hyaluronic acid (HA), have mainly been utilized to improve the biological activity of titanium-based materials [60.46, 47]. HA immobilized by the MAP-based coating strategy brought an increase in diverse pre-osteoblast behaviors, such as proliferation, spreading, and differentiation (Fig. 60.4).

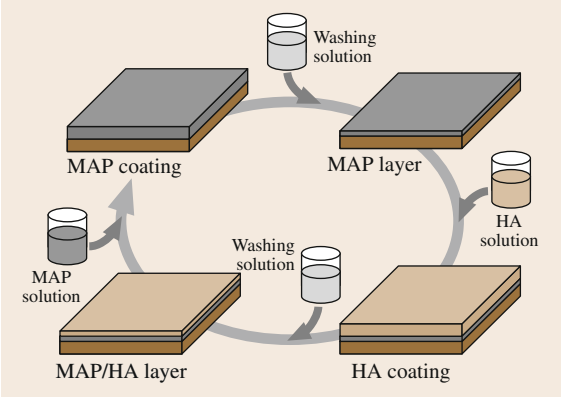

Fig. 60.5 A scheme for HA surface immobilization using the MAP-based coating strategy (after [60.42], courtesy of Mary Ann Liebert, Inc.)

Various negatively charged GAG molecules, including HA, heparin sulfate (HS), chondroitin sulfate (CS), and dermatan sulfate (DS), were successfully immobilized on a titanium surface using the MAP-based coating strategy. Moreover, because the MAP-based coating strategy uses two counter-ionic molecules, it can be applied to fabricate a multilayer film on to a titanium surface using MAP and counter-ion partners (Fig. 60.5). The MAP-based coating with counter-ion partners offers a facile and efficient surface modification of negatively charged bioactive molecules for tissue engineering applications.

60.3 Application of MAP to Tissue Engineering Scaffolds

Tissue engineering is an interdisciplinary field that utilizes principles of biology and various types of engineering technologies for the purpose of tissue regeneration [60.48]. Since the needs of patients for the treatment of their tissue loss or organ failure are becoming bigger and bigger, tissue engineering has been recognized as an important field to many scientists and surgeons. The main strategy of tissue engineering utilizes the combinatorial treatment of cells, scaffolds, and bioactive factors. Among these three factors, the scaffold is considered as the most important one; thus, the development of scaffolds that have bioactive factors and can support cells should be followed for successful tissue engineering applications.

Nowadays, the roles of tissue engineering scaffolds often require a three-dimensional architecture that can modulate specific cell functions, which goes beyond just being a supporting structure for seeded cells. In this manner, an ideal tissue engineering scaffold needs to provide a similar structure to the natural ECM, structurally, mechanically, and chemically. MAPs could be considered as potential biomaterial candidates for tissue engineering scaffold components due to their biocompatibility, biodegradability, and superior cell adhesive and bioactive properties. In this section, several examples where MAPs have been utilized as blending materials of nanofibrous scaffolds and three-dimensional solid freeform scaffold coating materials for tissue engineering application will be discussed.

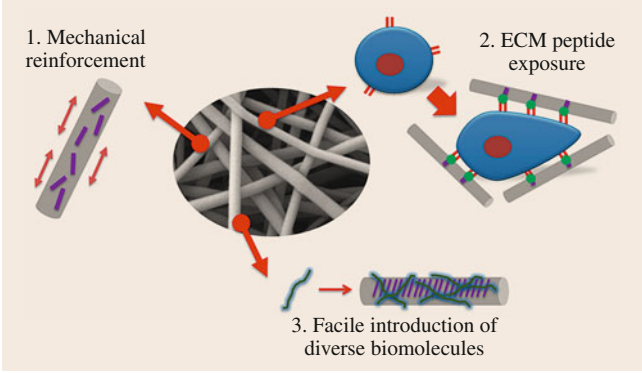

Fig. 60.6 Schematic representation of MAP-based reinforced multifunctional nanofibrous scaffolds (after [60.49], courtesy of Wiley-VCH)

60.3.1 MAP-Based Reinforced Multifunctionalized Nanofibrous Scaffolds

Nanofiber technology has been greatly recognized due to its ability to fabricate multiple nanosized fibers that are structurally similar to collagen fibrils of natural ECMs [60.50]. The large surface area of nanofibers is a major advantage, since these are the sites at which cell-substrate interactions occur. Therefore, rendering the nanofiber surface to be bio-functional is critical for its successful application in tissue engineering [60.51].

Recently, mechanically-reinforced multifunctional composite nanofibrous scaffolds were developed using MAPs, which showed outstanding adhesive and coating performance (Fig. 60.6) [60.49]. Via simple blending MAP solutions with various biodegradable synthetic polymers and an electrospinning process, the composite nanofibers based on MAPs were easily fabricated. With the help of the peculiar adhesive and coating ability of MAP-based nanofibers, various forms of biomolecules that can be useful in the medical industry, such as proteins, nucleic acids, and a variety of biomaterials, can be easily combined on the surface of composite nanofibers without physical and chemical pretreatment. Generally, in order to introduce bioactive molecules, such as ECM proteins, ECM carbohydrates, ECM-derived peptides, and growth factors, onto the nanofiber surfaces, typical conjugation chemistry and physical adsorption procedures are used after the completion of surface activation steps, including plasma and wet chemical treatments or surface graft polymerization [60.52]. However, these strategies are limited in availability due to the multiple, complicated procedures that are required to complete them. Therefore, this novel, multiple biofunctional

coating nanofiber platform based on MAPs may be a promising surface functionalization tool for successful tissue engineering applications.

Moreover, using MAPs fused with bioactive peptides, these MAP-based nanofibers could provide bioactive peptides efficiently onto the surface. It was identified that through MC3T3-E1 cell culture experiments, cell attachment and proliferation was mostly enhanced on the nanofibers fabricated using RGD peptide-conjugated MAPs, compared with bare PCL polymer nanofibers. In addition, it was also confirmed that the MAP-based nanofibers had four times higher mechanical strength than polymer nanofibers. Because easy fabrication is possible through blending with diverse types of synthetic polymers, MAP-based nanofibers can be successfully applied for various purposes.

60.3.2 Bone Regeneration Using MAP-Coated Three-Dimensional Scaffolds

Artificial tissue engineering scaffolds have been fabricated using biodegradable synthetic polymers through diverse methods, such as solvent casting/particulate leaching, gas foaming, emulsion freeze-drying, phase separation, and fiber bonding using synthetic polymers [60.53]. However, controlling interconnectivity and scaffold geometry is quite difficult when these methods are used. Furthermore, practical tissue engineering applications are limited due to the toxic organic solvents that can remain during the fabrication process.

Alternatively, the solid freeform fabrication (SFF) method, which is able to construct a fully interconnected and well-defined porous structure, was recognized [60.55]. In addition, highly permissive transportation of oxygen and nutrients throughout the scaffolds is considered as another advantage. A multihead deposition system (MHDS) has been developed as one form of SFF technology, which has high mechanical strength and biocompatibility because of its organic solvent-free environment during the fabrication process [60.56]. Indeed, several studies reported that cell growth and tissue regeneration were significantly promoted by controllable architectures of SFF-based tissue engineering scaffolds fabricated using MHDS [60.57, 58]. However, the lack of cell-recognition motifs and hydrophobic surface properties of synthetic polymer-based scaffolds still remain limitations of this method. In addition, the introduction of natural polymers or biomolecules (e.g., ECM proteins, carbohydrates, ECM-derived peptides, and growth factors) that can enhance cellular function is also limited in several scaffold fabrication methods due to thermal or solvent-employed procedures.

The development of bio-functionalized SFF-based scaffolds by simple coating of MAPs for the purpose of bone regeneration was reported recently [60.54]. In that work, MAPs were efficiently coated on the surface of SFF-based poly(D,L-lactide-co-glycolide)/polycaprolactone (PLGA/PCL) scaffolds via simple dipping of the MAP solution. RGD-fused MAPs were also applied with same method to obtain RGD peptide-exposed SFF-based scaffolds. Those MAP coating performances were assessed as a powerful coating tool for modifying synthetic polymer-based surfaces into biofunctional scaffolds and for other diverse biomedical fields.

The biofunctionality of MAP-coated SFF-based scaffolds was evaluated by in vitro human adipose-derived stem cell (hADSC) culture experiments. Through investigating diverse cell behaviors such as cell attachment, growth, and bone cell differentiation, it was identified that all of the aspects were signif-

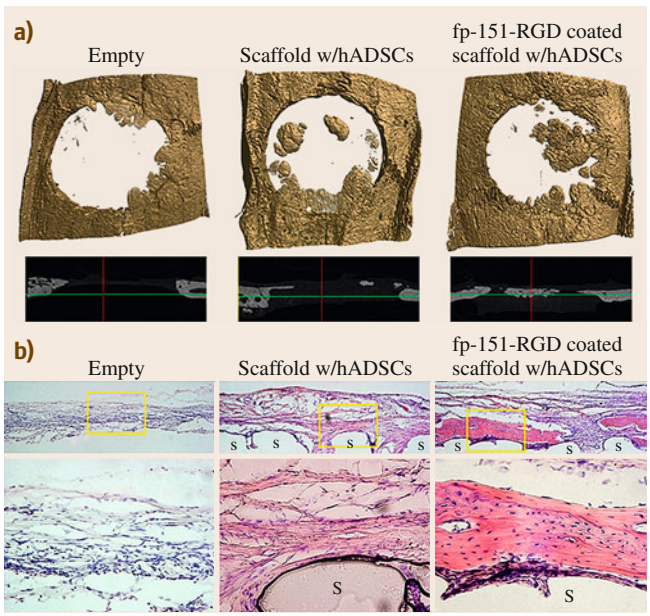

Fig. 60.7a,b Bone regeneration effect of MAP-coated SFF-based scaffolds implantation using a rat calvaria defect model **(a)** micro CT scan 3-D (*upper panel*) and X-ray 3-D axis images (*lower panel*) of rat calvaria. **(b)** Histological analysis of in vivo bone regeneration in the defect area of the (*left*) empty group and implanted groups of (*middle*) uncoated scaffold with hADSCs and (*right*) fp-151-RGD-coated scaffold with hADSCs (after [60.54], courtesy of Elsevier)

icantly enhanced on the surface of RGD-conjugated MAP-coated scaffolds compared to polymer and sole MAP-coated surfaces. Moreover, in order to validate the actual bone regeneration effect in vivo, a rat calvaria defect animal model study was performed. In this experiment, significant bone regeneration was observed in the sample where an hADSC-seeded MAP-RGD-coated scaffold was implanted after 8 weeks (Fig. 60.7).

60.4 Application of MAP Using Complex Coacervation

60.4.1 General Features of Complex Coacervation

Complex coacervation is a liquid–liquid phase separation process where two oppositely charged polyelectrolytes are met. After processing, a condensed coacervate phase and a diluted phase are separated, and they are immiscible (Fig. 60.8). The phenomenon was defined by *Bungenberg de Jong* [60.59] and theoretically investigated by *Voorn* and *Overbeek* [60.60]. Complex coacervation depends on ambient pH and salt concentration, mixing ratio, molecular weight, and ionic strength of componential polyelectrolytes [60.61, 62]. Generally, the coacervation phase has low interfacial tension in water [60.59]. Thus, the coacervation phase easily surrounds various particles in water. Moreover, coacervates can be gelated and cross-linked by pH or temperature change such as casein and gelatin. Because of those behaviors, a complex coacervation technique is utilized in the pharmaceutics, cosmetics, and food industries with encapsulating active molecules such as chemical drugs, proteins, cells, and flavor ingredients [60.62–65].

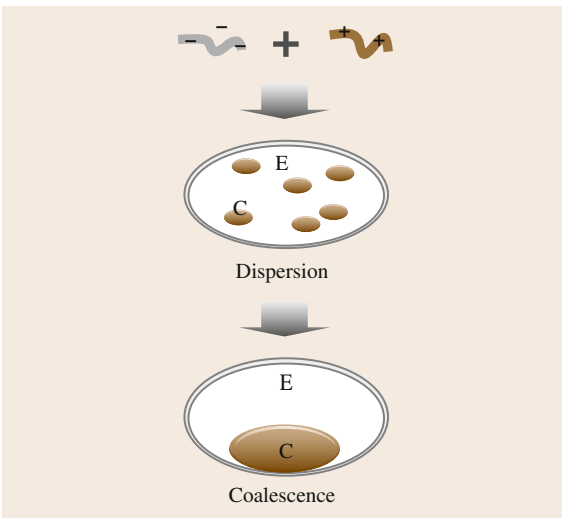

Fig. 60.8 Conceptual figure of complex coacervation

60.4.2 Complex Coacervation in Nature

Complex coacervation is naturally found in the case of the California sandcastle worm, *Phargmatopoma californica*. Such a marine polychaete builds a protective tube made of minerals, such as sand and shells, and then these minerals stick together through a coacervation mechanism with secreted cement proteins from the core body to seawater [60.77, 78]. Similarly, an aquatic insect, the caddisfly larvae, is another candidate for exploiting the coacervation process using its sticky underwater silk, which contains a high density and balanced ratio of positive to negative charges [60.79]. Condensation of MAPs to levels as high as 30 w/v % in vacuoles remain poorly understood. Complex coacervation was suggested to explain this condensation [60.80], but it has not been experimentally confirmed with the natural type of MAPs due to their limited availability.

60.4.3 Applications Using Complex Coacervated MAPs

Complex Coacervation of MAPs

Recently, complex coacervations using recombinant hybrid MAPs, fp-151, and fp-131 were investigated (Fig. 60.9). Complex coacervation was confirmed by observing morphology where positively charged fp-151 and fp-131 were mixed with the negatively

Fig. 60.9 Complex coacervated fp-151 in distilled water

Table 60.1 Microencapsulation using a complex coacervation system

Complex coacervation systems	Encapsulated products	Fields of application	References
Gelatin-acacia gum	Olive oil, squalane, oleic acid, indomethacin, sulfamethoxazole, liposomes, acetyl salicylic acid, vitamin A	Biotechnology, cosmetic, pharmaceutics	[60.66–72]
Gelatin-pectin	Sulfamerazine	Pharmacy	[60.73]
Gelatin-gellan gum	Paraffin oil, sunflower oil, aluminum powder, dowex ion-exchange resin	Biotechnology, food industry	[60.74]
Collagen-chondroitin sulfate	Albumin	Pharmaceutics	[60.75]
Whey proteins-maltodextrins, starch, corn syrup solids	Milk fat	Food industry	[60.76]

charged partner, HA. The optimal condition for complex coacervation was determined by turbidity measurement among various combined conditions of pH, salt concentration, molecular weight of HA, and mixing ratio between MAPs and HA. It was found that the optimal mixing ratio of MAP : HA was irrelevant to salt concentration and HA molecular weight [60.81].

Microencapsulation Using Complex Coacervation of MAPs

Complex coacervation has been utilized in the food industry, pharmaceutics, cosmetics, and biotechnology by microencapsulation (Table 60.1). Microencapsulation is the most common method for hydrophobic molecules and PLGA/PCL systems [60.82]. The microencapsulation process is generally composed of four steps:

1) Formation of a three-immiscible chemical phase (liquid manufacturing vehicle phase, core material phase, and coating material phase)
2) Deposition of the coating
3) Solidification of the coating (thermally, cross-linking, desolvation)
4) Collection by filtration, or centrifugation, washing and drying by spray drying or fluidized bed drying [60.83, 84].

Oil, the representative hydrophobic material, was microencapsulated using coacervation with fp-151/HA and fp-131/HA, which confirmed the formation of oil-encapsulated coacervates by fluorescence monitoring [60.81]. Oil microencapsulation allows a proposal that complex coacervation systems based on combinations of adhesion properties of MAPs and bioactive property of HA can be used as superior adhesive biomaterials, including self-adhesive drug carriers.

Adhesive Ability Enhancement of Complex Coacervated MAPs

The bulk-scale adhesive properties of a recombinant hybrid mussel protein, fp-151, were measured and exhibited significant adhesion strength where the weight and cross-linking process were added ($\approx$1 MPa) [60.85]. These large-scale measurements indicate that recombinant fp-151 MAP holds potential for the many biomedical applications in which water-resistant adhesives are needed. However, the sole recombinant MAP needs to be changed in order to obtain more suitable formula and enhanced adhesive strength.

Coacervated fp-151 and fp-131 were highly condensed like naturally stockpiled foot proteins in mussel foot cells ($\approx$800–1000 g/L), and their density was more increased than the maximal solubility of sole fp-151 and fp-131. The bulk adhesive strengths of sole hybrid MAPs and sole fp-5 were $\approx$2 MPa and $\approx$1 MPa in a dry condition, respectively. The coacervation process enhanced the adhesive strength approximately twofold (to $\approx$3–4 MPa for hybrid MAPs and $\approx$2 MPa for fp-5) on aluminum adherends [60.24, 81]. It was assumed that this improvement in the bulk adhesive strength came from the significant density increment and better wettability from low interfacial energy (0.1–3 mJ/m^2) in MAP-based complex coacervates [60.81, 86]. Therefore, in practical applications, coacervated adhesives can be utilized for a wet environment, such as human tissues that are full of body fluid, because the coacervate phase is immiscible, the coacervate adhesive has a strong adhesive ability, and the coacervate is well-spread over on diverse substrates underwater. In the meantime, the coacervation process with MAPs has extremely enhanced the MC-3T3 cell proliferation on a titanium surface [60.86]. Therefore, coacervated MAPs are also expected to be utilized for cell adhesion materials.

60.5 MAP-Based Biosensors for Industrial Applications

MAPs have been suggested as immobilization material for biosensors [60.87, 88] as they are able to adhere to various materials, including biomolecules, glass, polymers, and metals [60.89]. However, as quantities of mussel-extracted proteins are extremely small, and attempts to overproduce recombinant MAP have failed [60.90–92], the application of MAPs to immobilize biomolecules (or whole cells) on surfaces has been limited. Recently, hybrid versions of recombinant MAPs were designed and successfully overexpressed in *E. coli* [60.24, 41, 93].

Antibody-binding proteins, such as proteins A and G, have been used to enhance the sensitivity and specificity of immunosensors [60.94]. For efficient immobilization of antibody-binding proteins onto solid supports, proteins fused with severalbiomolecules [60.95–99], such as cysteine residue(s), gold-binding peptides, hexahistidine $(His)_6$ peptide, oligonucleotides, and glutathione-S-transferase, have been developed. However, they have limitations for the preparation of immunosensors: (1) they can only be immobilized onto a corresponding reactive group-derived surface, and (2) modifying the surface is time consuming and sometimes difficult for nonexperts.

To overcome the limitations, recombinant MAP fp-5 was genetically fused with C-termini of the BC domain of protein A, which consists of five domains (A–E) (Fig. 60.10) [60.93]. The recombinant BC-MAP (fp-5) fusion protein was overexpressed in *E. coli* and purified with high purity. The BC-MAP fusion proteins were successfully immobilized onto diverse surfaces, including glass, polymer, and metal, and the fusion protein-immobilized surfaces, showed antibody binding, followed by selective detection of antigen on the surfaces. The BC-MAP fusion protein presented an excellent antibody-binding ability compared to that of the BC protein. This was due to a more oriented exposure of the BC domain of the fusion protein but not the adhesive ability of the MAP. The MAP of the fusion protein contributed to direct and efficient attachment of the fusion protein onto diverse surfaces without any surface treatment, and the BC domain enabled oriented immobilization of antibodies on the surfaces. The BC-MAP fusion protein can be successfully used as a functional material for the development of various immunosensors and immunoassays.

Whole cell-based biosensors have been widely utilized in high-throughput drug discovery, environmental

This research was originally published in [60.100], courtesy of Elsevier Advanced Technology

monitoring of chemicals and heavy metals, and clinical diagnosis [60.101–105]. Efficient surface immobilization of cells is critical because it affects both sensitivity and stability of whole cell-based biosensors [60.104, 106–110]. Physical and chemical immobilization methods have been widely used for cell immobilization, but they still have several limitations, including limited mass transfer, loss of immobilized cells, and nega-

tive cell viability [60.106, 107, 111, 112]. Recombinant MAPs can improve the limitations of the method due to their efficient adhesion ability and biocompatibility; they have been used as a cell adhesion material for mammalian and insect cells [60.24, 41, 113, 114]. Recently, an organophosphorus hydrolase (OPH)-expressing *E. coli*-based whole cell biosensor was developed by using MAP as a cell-immobilizing material for the detection of organophosphorus compounds (OPs) (Fig. 60.11) [60.100]. The MAP-based immobilization method showed enhanced cell-immobilizing efficiency and stability compared to the simple physical adsorption-based immobilization method. This result is attributed to strong adhesion ability of MAPs. The whole cell biosensor, where *E. coli* expressing OPH in periplasmic space was immobilized onto MAP-coated 96-well microplates, showed a low detection concentration of 5 μM paraoxon with high reproducibility, a good long-term stability for ≈1 month with 80% retained activity, and a proper reusability of up to 20 times. MAP-based whole cell biosensors can be successfully used for industrial applications, including environmental monitoring of chemicals and heavy metals, and food screening.

61. Marine Silicon Biotechnology

Katsuhiko Shimizu

The discovery of the catalytic capability in silicatein, a constituent of the protein axial filament occluded in biosilica of the marine demosponge *Tethya aurantia*, for hydrolysis and polycondensation of silicon alkoxides to yield silica, as well as its role as a template for silicon biomineralization brought about emergence of a new field, *silicon biotechnology*, as a part of marine biotechnology. This new discipline focuses on understanding the mechanisms controlling biomineralization of silicon elements and its application to the development of new routes to the synthesis of silicon-based materials under environmentally benign conditions. However, as demonstrated by recent studies, the capability of silicatein is not limited to the synthesis of silicon-based materials but is also applicable to the production of various metal oxide materials and organic polymers. Thus, silicon biotechnology represents technology involved in or inspired by silicatein and actually covers the synthesis of silicon-based materials as well as materials consisting of other elements. In this chapter, the molecular biological properties of silicatein and its possible mechanisms on silica polycondensation are summarized, and then a variety of examples of silicatein for the synthesis of silica as well as other materials in environmentally benign routes are described.

61.1 Overview

61.1.1 Silicon in Biological Systems

The element silicon, the second most abundant element in the Earth's crust, exists as silicon dioxide or silicates in minerals. Some silicon is dissolved as silicic acid from minerals by weathering and is carried to aqueous environments such as rivers, lakes, and ocean. The concentration of silicic acid in the world's oceans averages about 70 μM, which is much lower than saturated concentration of silicic acid (at pH <10 and room temperature, ≈ 1 mM) [61.1]. Our life is full of silicon-based materials. Clay and stone are used without processing in bulk. Industrial products ranging from traditionally manufactured glasses and ceramics to highly technological semiconductors and elastic polymers are also silicon-based.

Silicon exists in the biosphere as a mineralized structure containing silicon or silicon biomineral in the form of amorphous hydrated silica. Living organisms that produce silicon biominerals include higher plants,

diatoms, radiolarians, sponges, and mollusks. After organisms die, silicon biominerals (mainly diatoms and radiolarians) are dissolved at the surface or become sediments at the sea floor, where biogenic silica are recycled to the lithosphere.

Silicon biominerals made by these organisms are exquisitely controlled in a species-specific manner from the nanoscale to the macroscopic scale. The morphological appearance of silicon biominerals have been well documented for a long time because of their importance for the classification of the species. However, information on the mechanisms underling silicon biomineralization remains limited. Most of our knowledge on silicon biomineralization has been obtained from studies on diatoms and sponges.

Diatoms are eukaryotic unicellular photosynthetic algae. These organisms contribute to one-third of global production. At the same time, they produce 240×10^{12} mol Si each year [61.1]. Silicon is deposited with species-specific intricate ornaments in the organic matrix of diatom cell walls. Diatoms are experimentally advantageous for elucidation of silicon biomineralization in many aspects, as follows: a number of diatom species can be cultured in the laboratory; whole genome sequences of two species *Thalassiosira pseudonana* [61.2] and *Phaeodactylum tricornutum* [61.3] have been accomplished; methods for genetic manipulation have been established [61.4–10]; and cell cycles can be synchronized by depletion of silicic acid in the culture media [61.11, 12]. Organic molecules have been identified from silica structures of diatoms. These molecules are silaffin [61.13, 14], long-chain polyamines [61.15], and singulin [61.16], which involved in silica production as acceleration of silica deposition.

Sponges or Porifera are aquatic sessile animals living at various depths from the intertidal zone to several thousand meters in marine or freshwater environments. Sponges lack distinct tissues and organs and are thought to be the most primitive among multicellular animals. Two classes of sponges, demosponges and hexactinellid sponges, produce silicon biominerals as needle-like spicules that are usually millimeters, and exceptionally meters in length. Spicules in some species, the hexactinellid sponge *Euplectella aspergillum*, for example, are fused by cementing to construct a skeleton.

61.1.2 Marine Biotechnology with Silicon

The manufacture of commercial silicon-based products often requires high energy-consuming conditions and processes that have harsh impacts on the environment. By contrast, biological silicon-containing materials are produced through physiological activities under mild conditions with remarkable exquisite structural complexities and high fidelities. These conspicuous properties of biological silicon-containing materials indicate the involvement of genetic control in the underlying mechanisms. Recent advances in molecular biological approaches have accumulated information on the genes, proteins, and molecular mechanisms controlling silicon biomineralization. Harnessing the knowledge of biology to the technology offers the prospect of developing environmentally benign routes to synthesize new silicon-based materials. We call this biotechnological discipline *silicon biotechnology* [61.17]. Most of the recent knowledge on silicon biomineralization was obtained from marine organisms, especially from diatoms and sponges, making silicon biotechnology an important field in marine biotechnology.

Since the identification of silicatein from the demosponge *Thetya aurantia* [61.18], several organic substances associated with silicon biominerals of diatoms and sponges have been identified and characterized. Among these molecules, silicatein is one of most frequently utilized for application in vitro. In this chapter, marine biotechnology of silicon biominerals is described by focusing on the structure and the function of silicateins.

61.2 Silicateins: Structure and Molecular Mechanisms

61.2.1 Structure of Silicateins

Silicateins were first identified as protein constituents of the axial filaments of silica spicules in *T. aurantia* (Fig. 61.1) [61.18]. Three subtypes, α, β, and γ were isolated, and then complementary DNAs (cDNAs) of α and β were cloned. Sequence analyses revealed that silicateins are highly similar to cathepsin L, animal lysosomal proteases, belonging to the papain-like cysteine protease superfamily (Fig. 61.2). The sequence identity between *T. aurantia* silicatein α and human cathepsin L is 52%, and correspondence of

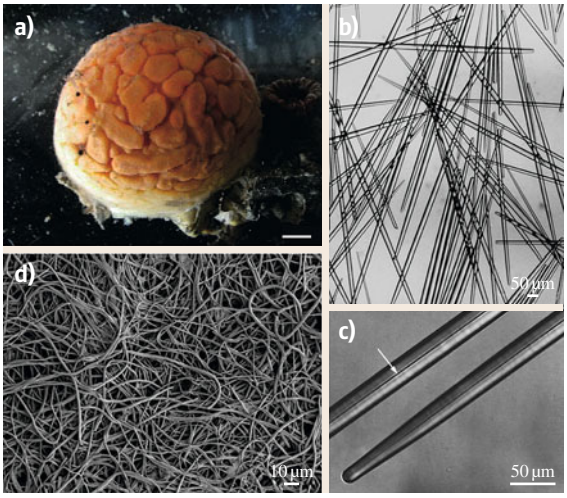

Fig. 61.1 **(a)** The marine demosponge *T. aurantia*. The *bar* indicates 1 cm. **(b)** An optical micrograph of strongyloxea from *T. aurantia*. **(c)** Enlarged optical micrograph of strongyloxea. The *arrow* indicates the axial filaments. **(d)** Scanning electron micrograph of axial filaments (**(b–d)** after [61.19], courtesy of Wiley-Liss)

residues with biochemically identical or similar side chains is 75%. The same degree of similarity was found between silicatein α and cathepsin L from the marine demosponge *Suberites domuncula* (50% identity; 78% similarity) [61.20]. Identities include the six cysteine residues that form intramolecular disulfide bridges in the proteases, making it likely that the three-dimensional structure of silicatein α is similar to that of cathepsin L (Fig. 61.3).

The catalytic cysteine (sulfhydryl) residue at the active site of the proteases is replaced in silicatein α with a serine(hydroxyl). The silicateins from *T. aurantia* did not display proteolytic activity as seen with a mutant form of cathepsin L, in which the catalytic cysteine replaced by serine is also inactive as a protease. However, the silicateins extracted from the demosponge *S. domuncula* under mild conditions with Tris-glycerol solution and the silicatein filaments of the freshwater sponge *Lubomirskia baikalensis* displayed proteolytic activity [61.21, 22], indicating that proteolytic activity was not completely lost, at least in these species.

Although the calculated isoelectric points (pIs) of silicatein α and cathepsin L are identical, there are fewer charged amino acids in silicatein α and somewhat more hydroxy amino acids than in the protease (20.3% in mature silicatein versus 17.2% in mature cathepsin L). This observation is consistent with our finding that silicateins are released from the filament by treatment with sodium dodecylsulfate (SDS) or urea, indicating that the subunits associate by means of nonionic, noncovalent interactions. The assembly of macroscopic filaments exhibiting a highly ordered nanostructure from protein subunits that are small and presumably globular appears to be a distinctive feature of silicateins, which has not been reported previously for cathepsin L or related proteases.

X-ray diffraction studies of oriented spicules from *T. aurantia* demonstrated some degree of order between the silicatein proteins comprising the central protein filament, in common with other demosponge spicules [61.24]. Although the three-dimensional structure of silicatein α was similar to that of cathepsin L, which was a highly soluble monomer with mixed α-helix and β-sheet, Fourier transform infrared spectroscopy of the protein filament of spicules of *T. aurantia* showed that the β-sheet structure was predominant. The analysis with the soluble silicatein α/cathepsin L

chimeric proteins demonstrated immediate conformational transition from mixed α-helix/β-sheet structure to β-sheet structure at neutral pH [61.25], which explains that the β-sheet structure was dominant in the silicatein filaments of spicules of *T. aurantia*.

A comparison of the hydrophobicity of silicateins α and β versus human cathepsin L and K reveals five regions that differ appreciably between the soluble cathepsins and the insoluble silicateins, identifying hydrophobic regions that may be important in the formation and stabilization of the silicatein filament [61.26]. Superimposition of those unique hydrophobic patches on a three-dimensional model of silicatein α, constructed with energy minimization using the structure of cathepsin L as a template, shows that these regions are present on the solvent-accessible surface of the silicatein α monomer. The interaction of these hydrophobic patches on the surfaces is suggested to produce the driving force for self-assembly of the silicatein subunits to the oligomers, which then assemble into a fractal network that subsequently condenses and organizes into a filamentous structure.

Clusters of the hydroxy amino acids – serine, tyrosine, and threonine – constitute one of the most distinctive features of silicatein α. Serine-rich sequences including Ser-Ser-Cys-Thr-Tyr and Ser-Ser-Arg-Cys-Ser-Ser-Ser-Ser sequences, and the Ser-Tyr sequence at the site of the serine-replaced active site of the protease are notable examples of the localized high concentrations of hydroxyls in this protein. These clusters of hydroxyls were conserved among silicateins from various species, although the extent varied.

Since silicateins were identified from *T. aurantia*, the corresponding proteins and genes have been isolated from the axial filaments of various demosponges. To date, 27 complete cDNAs of the silicateins have been cloned from 10 demosponge species, and cDNAs from 19 species in the demosponges have been described (Table 61.1). Whole genome shotgun sequencing of the marine demosponge *Amphimedon queenslandica* revealed that the species carries six silicatein-like genes [61.27] (GenBank Accession No. NW_003546256, NW_003546249, NW_003546859). Molecular phylogenetical analysis suggested that the ancestral silicateins were separate from cathepsin L [61.28], and, in addition, demonstrated that the silicateins of marine sponges and silicateins of freshwater sponges form two clearly distinguished clusters on the tree [61.29].

Recently, silicateins were identified in the hexactinellid sponges *Euplectella aspergillum*, *Monorhaphis chuni*, and *Crateromorpha meyeri* as proteins recognized with anti-silicatein antibodies [61.30, 31] followed by isolation of partial silicatein cDNA from these species [61.32, 33]. *Veremeichik* et al. [61.34] attempted to isolate silicatein genes from the three glass sponges (*Pheronema raphanus*, *Aulosaccus schulzei*, and *Bathydorus levis*) by polymerase chain reaction (PCR) with the degenerated primers targeting conserved regions within silicatein/cathepsin proteins. Although three clones from *A. schulzei* were found to represent transcripts that can be related to silicateins, the deduced protein sequences contained a catalytic cysteine instead of the conventional serine. It is not clear whether the corresponding protein is involved in the production of spicules. These results demonstrate that silicateins are commonly expressed in the silica producing sponges for biomineralization of silica through common mechanisms.

61.2.2 Roles of Silicateins in Silicon Biomineralization

Silicateins bear more than single role in spicule formation. It has been proposed that these axial filaments play an essential role in the determination of the gross

morphology of the spicules, meaning that silicateins, constituents of the axial filaments, were in charge of this role. *Mohri* et al. [61.51] isolated six isoforms of silicateins from the freshwater sponge *Ephydatia fluviatilis*, which has two types of morphologically and functionally different spicules, called megascleres and gemmoscleres, and demonstrated the spicule-type-specific messenger RNA (mRNA) expression of these isoforms and differential expression during spicule development. The marine demosponge *Geodia cydonium* possesses two types of spicules, megascleres and microscleres. Polyacrylamide gel electrophoresis (SDS-PAGE) analysis with the isolated axial filaments demonstrated that the axial filaments of the microscleres contained only one form of silicatein, termed silicatein-α/β, with a size of 25 kDa in contrast to the composition of the silicateins in the megascleres (isoforms: -α, -β, and -γ) [61.52]. These two cases suggested that the different composition of the axial filaments with respect to silicateins, contributes to the morphology of the different types of spicules.

The second role of silicateins was demonstrated with the filaments as well as the silicateins dissociated from the filaments [61.53]. The silicateins accelerated the in vitro polymerization of silica from tetraethoxysilane (TEOS) at neutral pH. The formation of a dendritic silica precipitate was confirmed under electron microscopy. Normally, under these conditions, polymerization of silica from TEOS requires either an acid or a base catalyst. The activity of the silicateins was abolished by thermal denaturation, which indicates a dependence on the native three-dimensional conformation of the subunit proteins. Denaturation with the detergent SDS also abolished the activity. Recombinant silicatein α, when expressed in *Escherichia coli* from a recombinant DNA template and subsequently purified and reconstituted, proved to be sufficient to accelerate the polymerization of silica from TEOS at neutral pH. In this case also, thermal denaturation abolished the reactivity with the silicon alkoxide. The intact silicatein filaments were also active, promoting the condensation of silicon alkoxides

Table 61.2 Environmentally benign synthesis of materials with silicateins

to form the corresponding polymerized silica at neutral pH. The macroscopic filaments serve as scaffolds to organize the deposition of the resulting silica and silsesquioxanes. The activity of the silicatein filaments is abolished by thermal denaturation, indicating a dependence on the native conformation of the constituent proteins.

Proteolytic activity is the additional role of silicateins. As mentioned above, silicateins from *T. aurantia* did not display proteolytic activity as seen with a mutant form of cathepsin L in which the catalytic cysteine is replaced by serine is also inactive as a protease. However, silicateins of the marine sponge *S. domuncula* and the freshwater sponge *Lubomirskia baikalensis* displayed proteolytic activity, which was specific to cathepsin L [61.21, 22]. In addition, protease activity was displayed with silicatein(-related 27 kDa protein) extracted from the giant spicules of the deep sea hexactinellid sponge *M. chuni* [61.54]. Although the substrate of silicateins as proteases has not yet been identified, there is a possibility that silicateins digest the pro-peptide for maturation of the proteases, as seen in cathepsin L and other proteases of this class.

61.2.3 Catalytic Mechanism of Silicateins in Silica Polycondensation

Comparison of the silicatein α and cathepsin L sequences suggested that the overall three-dimensional structures of the two proteins are quite similar. The activity of silicatein to accelerate silica production was abolished by thermal denaturation of the enzyme, demonstrating that the activity was dependent upon the tertiary conformation of silicatein as the activity of the proteases.

Of the three residues of the *catalytic triad* of the active site in cathepsin L, two, His and Asn, were conserved in silicatein α, but the third active-site residue in cathepsin L, Cys, was replaced in silicatein by Ser. The three amino acids of silicatein α are identical to the catalytic triad of the other major class of proteases, the serine proteases, which include trypsin and chymotrypsin as typical members. Site-directed mutagenesis results confirmed the requirement for Ser26 and His165 residues of *T. aurantia* silicatein α for catalysis of the siloxane polymerization [61.55].

The cleavage of peptide bonds by the proteases proceeds through a hydrolysis reaction accelerated by

general acid–base catalysis. Similarly, the condensation of silicon alkoxides promoted by silicateins may occur through hydrolysis reaction and accelerated by general acid–base catalysis. Therefore, the mechanism of action of silicatein α may be related to that of the well-characterized serine proteases carrying the Ser/His active-site. The enzymatic mechanism of the serine proteases involves nucleophilic attack of the alcohol functionality on the peptide amide bond at the carbonyl carbon. In the proposed enzyme mechanism for silicatein, hydrogen bonding between the hydroxyl group of the active site serine and the imidazole nitrogen of the conserved histidine is postulated to increase the nucleophilicity of the serine oxygen, facilitating nucleophilic attack on the substrate silicon center (Fig. 61.4). Nucleophilic attack is followed by elimination of ethanol and the formation of a protein-O-Si intermediate that is potentially stabilized by nitrogen donation from the imidazole to form a pentacoordinate silicon center. The addition of water completes the hydrolysis of the alkoxide bond to form a silanol, or Si-OH, with subsequent condensation occurring to build up the silica framework [61.53].

Fairhead et al. [61.56] made a series of cathepsin L mutants that increasingly match the sequence features unique to silicatein α. These cathepsin L/silicatein α chimera molecules were water-soluble and showed the ability to condense silica from silicic acid solution, although any of the mutant proteins did not precipitate silica from TEOS. The most active mutant carried mutations matching catalytic serine and residues flanking catalytic serine. The authors suggested that the mutation at the residues flanking catalytic serine enlarged the volume of the active site just enough to accommodate the silicic acid substrate. The three-dimensional structure of the chimera was determined at 1.5 Å resolution by X-ray crystallography to confirm its structural similarity to cathepsin L. Furthermore, the crystal structure indicated that the distance between serine hydroxyl and imidazole nitrogen of the histidine of the active site was 3.6 Å, which is beyond the H-bonding distance, which presumably decreases the nucleophilicity of the serine. Instead, the authors proposed an alternative mechanism that the catalytic histidine deprotonated one molecule of silicic acid, which then further condensed with other silicon centers. It is important to note, however, that neither cathepsin L nor cathepsin L/silicatein α chimeras hydrolyzed TEOS, suggesting that there was a fundamental difference at some level between the structures of these mutants and the native and recombinant forms of silicatein α.

61.3 Silicatein-Mediated Synthesis of Inorganic Materials

61.3.1 SiO_2

Since the catalytic capability of silicateins for hydrolysis and polycondensation of silicon alkoxides to produce silica was demonstrated, the capability has been applied in various ranges from silica to organosilicons, metal oxides, and biopolymers. Some of the applications are introduced in this section.

Living cells and proteins have been encapsulated in silica gels, maintaining their biological activities. However, the cells were not stable for a long time due to remaining alcohols and other additives in silica gels made by sol-gel methods. The introduction of silicatein improved this problem. The bacteria *Escherichia coli* transformed with the silicatein gene and produced enzymatically active recombinant silicatein proteins [61.43]. Electron microscopic analysis revealed that the bacteria that expressed silicatein were covered with silica around them when growing in the presence of silicic acid.

Biological silica produced through the activity of silicateins can be useful for medical applications, especially the area of orthopedics, because silicon is thought be essential for mineralization of vertebrate bones [61.57, 58].

Human osteosarcoma SaOS-2 cells grow and produce calcium phosphate biomineral on culture plates precoated with type I collagen. When the cells were cultured on the plates precoated with type I collagen and silicatein, and subsequently modified by coating with biosilica produced with TEOS as a precursor, SaOS-2 demonstrated a marked enhancement of its capability to produce calcium phosphate, although the growth of SaOS-2 cells was not affected by these treatments [61.49].

Recombinant silicateins with Glu-tag, which is known to have high affinity to hydroxyapatite, were immobilized on the surfaces of microcrystalline hydroxyapatite, synthetic hydroxyapatite nanofibrils, and dental hydroxyapatite. These silicateins on the hydrox-

yapatite materials catalyzed synthesis of biosilica coatings from sodium metasilicate [61.50]. This technology indicates that Glu-tagged silicatein reveals considerable biomedical potential with regenerative and prophylactic implementations. The silica surface induced proliferation of SaOS-2 cells that expressed the genes involved in osteogenesis and produced a hydroxyapatite structure (Fig. 61.5) [61.59, 60].

Wiens et al. [61.61] prepared the silicatein/bio-silica-based implant materials aiming at the application in the area of the regenerative medicine. Microspheres

containing both silicatein and silica were prepared by encapsulating silicatein together with sodium metasilicate in poly(D,L-lactide)/poly(vinyl pyrrolidone)-based microspheres. Then, the microspheres were embedded in a poly(vinyl pyrrolidone)/starch-based matrix. A blend of two components formed a biocompatible, moldable, and biodegradable functional implant material that hardened at a controlled and clinically suitable rate within approximately 30 min to 6 h to implants that were tightly integrated in artificial defects of rabbit femurs. No toxic reactions were observed in vitro or in vivo.

Silica layers with electrically-insulating properties are especially useful as gate dielectrics for field-effect transistors and sensing devices, which are currently attracting increasing interest in the field of organic electronics. *Polini* et al. [61.41] reported a novel approach for realizing layers of silica exploiting the enzymatic activity of immobilized recombinant silicatein and demonstrated the properties of biomineralized films as electrical insulators potentially usable in bio and microelectronic applications. The recombinant silicatein was patterned on silicon substrates by microcontact printing-mediated physisorption and then incubated in a silica precursor TEOS solution. Biosilica layers were formed with an estimated thickness of 200–220 nm after 120–132 h of incubation. By applying voltages in the range 0–10 V to a two-terminal configuration, biosilica layers exhibit currents down to the nA range, which corresponds to leakage current densities around 10^{-5} A cm^{-2} through the dielectrics. Patterning recombinant silicatein to realize silica dielectrics can be particularly useful for producing electrical insulating elements in microelectronics under mild conditions and bioactive materials for biomedical applications.

Polini et al. [61.62] also showed the use of recombinant silicatein α to direct the formation of optical waveguides through soft microlithography. The recombinant protein was first patterned by microfluidics on a hydroxylated Si/SiO_2 substrate, exploiting an elastomeric mold, and then incubated in a TEOS solution for 120 h after peeling off. The patterned recombinant silicatein layer mostly exhibited linear, parallel-oriented protruding features, which indicated assembled filaments aligning along the flow direction. The artificial biosilica fibers mimicked the natural sponge spicules, exhibiting refractive index values suitable for the confinement of light within waveguides, with optical losses in the range of 5–10 cm^{-1}, which is suitable for application in lab-on-chips systems. Biosilification can be extended to the controlled fabrication of optical components by physiological processing conditions.

The formation of uniform silica films with controlled thickness, roughness, and hydrophilicity was achieved by silicatein immobilized on gold-coated surfaces [61.40]. Recombinant silicateins were immobilized by glutalaldehyde with the gold surface amine-functionalized with cystamine or cysteamine. Silica coating of the silicatein-immobilized gold surface was achieved by treatment with prehydrolized tetramethoxysilane. The thickness (20–100 nm), roughness (1.2–5.2 nm), and water contact angle 48–16° of the gold films covered with silica could be controlled by varying the amount of silicatein absorbed (10–30 ng/cm^2) and time of treatment with silica precursors (30–120 min).

The capability of silicateins to produce silica was used for preparation of the nanoparticles composed of the maghemite core with the silica shell [61.48]. Maghemite nanoparticles were coated with poly(pentafluorophenyl acrylate) polymer functionalized with both dopamine and nitrilotriacetic acid (NTA) through the binding capability of dopamine to maghemite. His-tagged silicatein was immobilized on the surface of the polymer-coated maghemite particles in the presence of Ni^{2+}. Incubation of the particles with TEOS facilitated synthesis of the maghemite nanoparticles covered with silica.

61.3.2 Organo–Silicon

Silicateins can be useful for synthesis of various and industrially important organo-silicon molecules under environmentally benign conditions. *Cha* et al. [61.53] demonstrated that intact silicatein filaments promote the condensation of organically modified silicon alkoxides to form the polymerized silsesquioxanes $(RSiO_{3/2})_n$ (silicones in which R represents an organic side chain such as methyl and phenyl) at neutral pH in addition to silica condensation from silicon alkoxides. If silicateins can catalyze hydrolysis and polymerization of a wide variety of organically modified silicon alkoxides (mono-, di-, tri-alkoxides), we will be able to synthesize numerous organo-silicon materials that have not been obtained due to harsh reaction conditions.

Recombinant silicatein α was shown to catalyze condensation of alkoxy silanes at neutral pH and ambient temperature to yield silicones like the straight-chained polydimethylsiloxane [61.39]. Silicatein α dissolved in buffer solution at neutral pH was covered with dimethoxydimethylsilane dissolved in diethyl ether. In

control assays, heat-denaturated silicatein or bovine serum albumin, or no protein was added. After incubation periods of up to 5 h at 20 °C under intense shaking, an extensive increase in the formation rate of oligomers and in the chain length of the silicones in the presence of silicatein was observed, but not heat-denaturated silicatein or bovine serum albumin, or no protein. This biocatalytic reaction may have an impact for the sustainable synthesis of silicones.

Organo-metallic pincer complexes (NCN-Pt, PCP-Pd) bearing siloxanes were immobilized on the surface of the silicatein filaments under mild conditions (Fig. 61.6) [61.38]. A suspension of the silicatein filaments in water was mixed with a solution of the siloxy functionalized organo-metallic pincers NCN-Pt or PCP-Pd complexes in toluene and TEOS. The

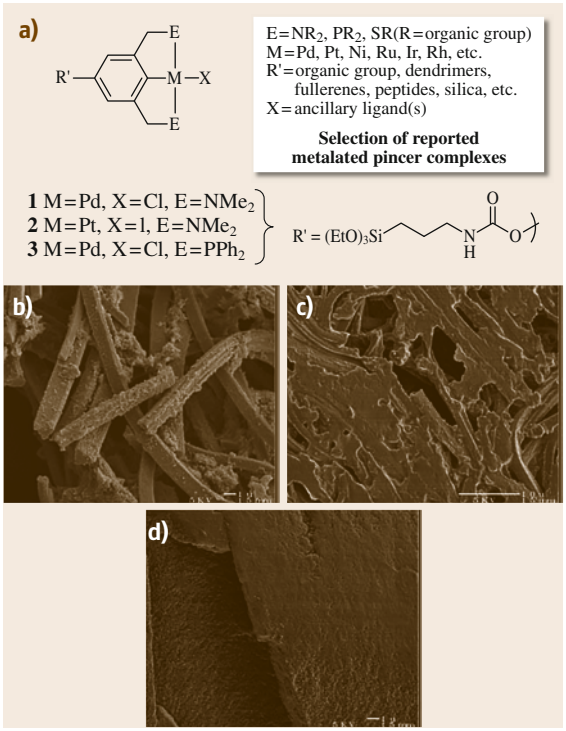

Fig. 61.6 **(a)** Pincer metal complexes. *Bottom*, Scanning electron microscopy images of products. **(b)** The NCN-Pd pincer alkoxysilane 1 in the presence of protein filament with no TEOS added. **(c)** The PCP-Pd pincer alkoxysilane (3) and TEOS in the presence of the silicatein filaments. **(d)** The NCN-Pt pincer alkoxysilane (2) and TEOS in the presence of silicatein filaments (after [61.38], courtesy of the Royal Society of Chemistry)

filament immobilized NCN-Pt pincer changed colors with reversible binding of SO_2, which indicates that this material can be used as a gas sensor. The PCP-Pd pincer immobilized on the silicatein filament was shown in the reaction profile as precatalyst, similar to those of the immobilized catalysts obtained by chemical means. This observation confirmed that silicatein-mediated immobilization of organometallic pincer complexes was practically useful.

61.3.3 Metal Oxides

The catalytic activity of silicatein filaments and isolated silicateins for hydrolysis and polycondensation of silicon alkoxides inspired us to utilize the catalysts for synthesis of metalloid oxides and metal oxides in addition to silica and organosilicons. Titanium dioxide (TiO_2 or titania) is used in a wide range of applications, including in pigments, solar cells, and photo-catalysts. Most titanium alkoxides are very reactive and spontaneously react with water at room temperature to form an amorphous TiO_2 precipitate, which indicates that these compounds are not suitable as precursors for use with silicatein. To circumvent this problem, titanium bis(ammonium lactato) dihydroxide (Ti(BALDH)) was identified as a water-stable, alkoxide-like target substrate that could potentially be converted to TiO_2 by silicatein-mediated hydrolysis and polycondensation [61.35]. Indeed, silicatein catalyzed the hydrolysis and subsequent polycondensation of this substrate. Incubation of TiBALDH with silicatein filaments at neutral pH and 20 °C for 24 h resulted in a layer of TiO_2 covering the surface of the protein filaments. Unexpectedly, TiO_2 produced with silicatein was nanocrystalline anatase. Crystalline polymorphs of TiO_2, such as rutile and anatase, are usually only accessible through high temperature routes (>500 °C) or very low pH conditions (<pH 3) at lower temperatures.

This technology was used for modification of the surfaces of inorganic materials [61.64]. A titania coating was obtained on the WS_2 nanotubes, which was functionalized with the polymer carrying NTA side chains by complexation through Ni^{2+}, followed by attaching the silicatein-containing His-tag to the NTA ligands on the surface of the nanotubes by complexation of Ni^{2+} ions through the His-tag. The formation of the titania coating was mediated by the immobilized silicatein onto the surface of WS_2 nanotubes with TiBALDH as a substrate.

Titania and zirconia layers were obtained on the gold surface functionalized with recombinant silicateins through Ni-NTA from Ti(BALDH) and hexafluorozirconate as substrates, respectively [61.44, 45].

The gold surface was also coated with titania as follows (Fig. 61.7) [61.63]. Recombinant silicatein, genetically engineered to carry a polycysteine sequence, which possessed an affinity to gold, was patterned by microcontact printing methods on gold surfaces. The silicatein-patterned gold surface was subjected to precursor solution TiBALDH, resulting in the formation of photocatalytically active titania on the gold surface. The gold surface with the silicatein-mediated TiO_2 micropattern enhanced the decrease of the color in a methylene blue solution by UV irradiation through the photocatalytic activity of TiO_2.

When TiBALDH was incubated in phosphate buffer saline with a surface-displayed recombinant silicatein α at the exterior of a bacterial cell, a layered titanium phosphate was synthesized [61.42]. The synthesis of titanium phosphate instead of TiO_2 indicated that during the enzymatic hydrolysis and subsequent polycondensation of TiBALDH, sodium and phosphate groups from the isotonic reaction buffer were incorporated into the titanium-based product.

Perovskite and perovskite-like materials have considerable technological value, which makes innovative low cost and/or low energy fabrication routes to kinetically controlled nanostructures extremely desirable. Nanocrystalline $BaTiOF_4$, a multimetallic perovskite-like material, was synthesized and templated along the silicatein filaments by low temperature silicatein-mediated hydrolysis/condensation of $BaTiF_6$ in the presence of H_3BO_3 (Fig. 61.8) [61.37]. The $BaTiOF_4$ grew as floret microstructures composed of nanostructured petals along the silicatein filaments. In addition, $BaTiOF_4$ with silicatein filaments was transformed to $BaTiO_3$ with a 1 : 1 ratio of Ba and Ti by pyrolysis. The result is significant because nanocrystalline perovskite-like materials was obtained from single-source molecular precursors with silicatein.

In addition to SiO_2, TiO_2, and $BaTiO_3$, nanostructured cassiterite SnO_2 was synthesized from Na_2SnF_6

through the catalytic activity of silicatein α immobilized on glass slides through a histidine-tag chelating anchor at room temperature and neutral pH in a buffered system [61.47]. The glass slides after the catalytic deposition of SnO_2 remained colorless and transparent in the UV range. The result demonstrated that technologically interesting transparent conductive oxides were obtained by this simple method, which can be applied to the development of new composite materials.

The silicatein filaments were capable of hydrolysis and polycondensation of a gallium oxide precursor, hydrated gallium nitrate (GNO), to yield GaOOH or spinel gallium oxide (γ-Ga_2O_3) with confined structure at room temperature [61.36]. With an aqueous solution of highly concentrated GNO at 16 °C, GaOOH was formed in the presence of native silicatein filaments but not heat-denatured filaments, as observed in the case of the formation of silica from TEOS. At lower precursor and silicatein concentrations with the same precursor/silicatein molar ratio as in the case above, a dispersed coating of nanocrystallites adhering to the surface of the filaments were observed, while no reaction product was seen with heat-denatured filaments. Analysis of high-resolution transmission electron microscopy demonstrated that the nanocrystallines were spinel polymorphs of gallium oxide, γ-Ga_2O_3, which formed typically at more than 400 °C. In addition, the particles were single crystals with (311) planes preferentially oriented relative to the surface of silicatein filaments, suggesting that the orientation of the crystal growth was directed with the surface of silicateins, especially the array of hydroxyls at the serine clusters.

Recently, silintaphin-1, a minor constituent of the axial filament, was identified as a protein with high affinity to silicateins [61.66], and it was demonstrated that the protein can modify the capability of silicateins to deposit metal oxides [61.65]. A template was prepared by grafting silicatein α onto a TiO_2 nanowire followed by co-assembly of silintaphin-1 through its specific interaction domains (Fig. 61.9). The organic-inorganic hybrid nanowires were incubated with TEOS or K_2ZrF_6, resulting in nanofibers with a TiO_2 core with SiO_2 shells or a TiO_2 core with ZrO_2 shells, respectively. In the presence of silintaphin-1, silicatein α facilitated the formation of a dense layer of SiO_2 or ZrO_2 on the protein-covered TiO_2 backbone template. The experiment indicated that the coassembly of silicatein α and silintaphin-1 contributed to the efficient synthesis of metal oxides in the proper conditions.

61.3.4 Biocompatible and Biodegradable Polymers

Biocompatible and biodegradable polymers have been used for medical applications and rapidly commercial-

ized for industrial uses such as packaging. Polylactide (PLA) is one of the most popular polymers and is also known to be derived from renewable resources and recyclable.The catalytic capability of silicateins was expanded to synthesis of PLA from the cyclic precursor L-lactide through ring-opening polymerization [61.67]. Native silicatein filaments mixed with L-lactide in an organic solvent were seen to accumulate PLA at the filament surface under scanning electron microscopic observation. Over longer timescales, coagulated structures were seen in which product formation was sufficient to join individual filaments. The heat-denatured filaments showed little change in surface morphology after incubation with L-lactide for 16 h.

PLA was also synthesized through recombinant silicatein displayed on the surface of bacteria cells (Fig. 61.10). The bacteria *Escherichia coli* carrying the gene encoding silicatein α inserted into the first extracellular loop of the *E. coli* outer membrane protein A (OmpA) expressed the recombinant silicatein at the external surface of cells. Solubilized L-lactide was introduced to a suspension of silicatein-displaying cells in isotonic phosphate-buffered saline solution. After

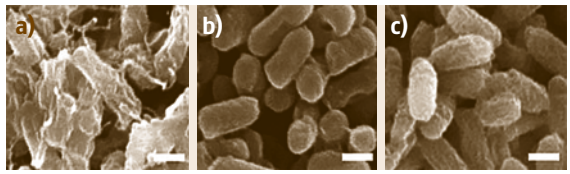

Fig. 61.10a–c Cell-based synthesis of poly(L-lactide). **(a)** *E. coli* cells displaying silicatein α. Polymeric products were observed as thread-like structures between cells. **(b)** Control cells preincubated with the protease inhibitor PMSF. **(c)** Control cells expressing recombinant OmpA only. The product was significantly reduced in **(b)** and **(c)**. Scale bar = 0.5 mm (after [61.67], courtesy of Wiley-VCH)

overnight incubation, polymeric products were apparent at the cell surface and were characterized by an increase in cell surface roughness and as *threads* between cells. These products were significantly reduced when cell suspensions were preincubated with the protease inhibitor phenylmethylsulfonyl fluoride (PMSF) and in cell preparations that expressed recombinant OmpA only.

61.4 Genetically Engineered Silicateins

Recombinant DNA technology is a powerful tool to produce numerous variants of molecules thatcan be useful for the determination of structure and elucidation of the molecular mechanisms and that have capabilities exceeding those of the wild type proteins. Silicateins have been shown to have unique capabilities to produce silica and other metal oxide compounds and, at the same time, to self-assemble into insoluble filaments. The latter property often makes recombinant silicateins insoluble and causes limitation in analysis of molecular mechanisms for silica polycondensation and application for material synthesis. The production of the water-soluble cathepsin L/silicatein α chimera molecules was allowed to analyze the three-dimensional structure [61.56] and conformational transition at neutral pH [61.25] as described above.

Capabilities of silicateins were further developed by an in vitro gene evolution system coupled with in vitro compartmentalization for the expression of proteins and trapping of the expressed proteins on the

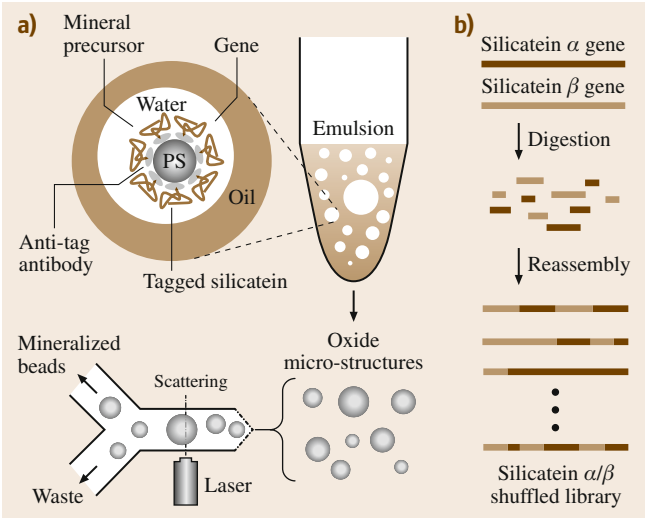

Fig. 61.11a,b Overview of the biomimetic mineralization platform for in vitro evolution by gene shuffling and selection. **(a)** In vitro compartmentalization and separation of mineral-producing beads. **(b)** Construction of a chimeric library of variant silicateins by gene shuffling. After [61.68], courtesy of the National Academy of Sciences ◄

surface of polystyrene microbeads (Fig. 61.11) [61.68]. The gene library of silicatein variants originating from silicatein α and β was constructed by gene shuffling and the introduction of random point mutations. Each silicatein variant was linked to the beads (less than one DNA molecule per bead), which equipped the antibody against the tag sequence. Variant proteins corresponding to the attached DNA were synthesized by mixing the bacteria extracts for protein expression from DNA and absorbed to the bead through the tag on the proteins and the antibody against the tag in water-in-oil emulsions. The capability of the protein variants for biomimetic mineralization was tested by mixing the beads with precursor solutions (TEOS or TiBALDH). Mineralized beads were separated from non-mineralized ones by a light scattering-equipped flow cytometer. The DNA sequence of the protein variants that produced minerals can be obtained by PCR amplification of the DNA attached to the beads followed by sequencing. When TEOS was mixed, one of the silicatein variants catalyzed the formation of crystalline silicates that the wild type silicateins never produced. The other variants demonstrated efficient production of crystalline TiO_2 from TiBALDH.

61.5 Prospectives

Since silicatein was surprisingly discovered as a catalyst for silica polycondensation as well as a template for silicon biomineralization, information on the protein has accumulated and a variety of applications has been exemplified. Also amazing is the broad range of substrates from precursors of metal oxides to organic polymers beyond silica. The capability of silicatein's hydrolysis of precursor molecules to synthesize various species of metal oxides and organic polymers in environmentally benign conditions must make it possible to manufacture energy-reduced and hazardous chemical-free products in a wide range of fields. In addition, the development of genetic engineering has made it easy for us to produce the recombinant form of silicatein and its variants, including chimeras, mutants, and tagged proteins. Therefore, silicon biotechnology with silicatein is a promising field as the development of novel routes to synthesis of various materials. Meanwhile, the discovery of silicatein tells us to learn more about marine organisms to shed light on hidden properties and then to be inspired to bring about novelties in marine biotechnology.

62. Microalgal Biotechnology: Biofuels and Bioproducts

José de Jesús Paniagua-Michel, Jorge Olmos-Soto, Eduardo Morales-Guerrero

In the twenty-first century, energy is considered as the most important issue for human sustainability. The world's dependence on unsustainable fossil fuels (almost 90%), and the increasing population demand new sources of energy for sustainable human activities. Algae, and particularly microalgae have nowadays become of enormous importance as a new potential source of feedstock for renewable bioenergy production. As photosynthetic microorganisms, microalgae may potentially be produced as carbon neutral and can be produced on non-arable land and cultured in marine and wastewater effluents. Furthermore, microalgae can be used to produce a range of products such as protein-rich animal feed in aquaculture, high-value products, viz, polyunsaturated fatty acids, bioactive and functional pigments and natural dyes, health foods, cosmetics, and pharmaceuticals. In this chapter, an update of the advances in microalgal biotechnology is presented as a new biomass for the potential development of biofuels, and as a realistic source of highly valuable molecules of industrial interest. The potential to harness endogenous carbon storage compounds, triacylglyceride (TAGs) and starch, as products of photosynthesis, including the photoproduction of hydrogen, can contribute to diversify the sources and yields of feedstocks for biofuel production. Even if the production of microalgae for biofuels is highly promissory and clearly has potential for contributing to environmental, social, and economic sustainability, presently this alternative is unsustainable. Definitely, the combination of biofuel production by microalgal biotechnology with co-products may contribute to the sustainability of biofuels, a condition with null or less impact on natural resources and biodiversity. The integration of all the components of the uses of microalgae, i. e., high-value compounds, aquaculture, and bioremediation coupled to the production of biofuels will play an important role in the near future to make the production of biofuels from microalgae sustainable. The integration of genomics, metabolic engineering, nanotechnology, and other areas to the aforementioned issues shall lead to a wide range of benefits for the tasks demanded by the forthcoming bioenergy industries.

62.1 Sustainable Biofuels from Marine Microalgae: Closer to Reality than Fiction

Even when terrestrial plants are employed for biofuel production, the strategies are recognized as functional at the small scale and highly controversial when scaled up by the conflict with food production, extended surface agricultural land, and uses of potable water, which make this and other hybrid technologies unsustainable to supplant a significant fraction of petroleum for the global demand for liquid fuels [62.1, 2]. Aquatic and marine biomass has been proposed as a very promising source for biofuel production; however, in order to realize this, a complete analysis of the full life cycle impact of algal biofuel production in the context of issues such as water resource management, energy balance, and the type of algae is very necessary [62.3]. According to [62.3], biofuel production will be sustainable only if it guarantees eco-friendly processes and respective interactions with other fields. In this eco-context, the reduction of the greenhouse gas (GHG) emission, can be achieved without effecting air, water, soil, or biodiversity, etc. These issues can be accomplished by using microalgae; however, other aspects such as social acceptability and economical viability still need to be overcome. Even though all these potentials can be met theoretically, in practice many scientific and technological aspects must still be applied in order to fully consider this biotechnology as sustainable. Nevertheless, in our concept and criteria, microalgae are one of the most promising renewable feedstocks for biofuel production and biorefineries.

Microalgae can be grown almost anywhere, even in sewage, manure, salt water, ice, and in aerial conditions [62.4, 5] and do not require fertile land or food crops. Their processing requires less energy than the algae provides [62.6]. These indicators reflect the potential that renewable technologies have to supplement or replace liquid fossil fuels by biofuels and microalgae, which are still in their early developmental stages. According to specialized expertise, the expectative to expand will depend on whether underdeveloped petroleum fields are not sustainable, as reported by the International Energy Agency [62.7]. According to The National Research Council of the US National Academies, large-scale production of biofuels from algae is unsustainable using existing technologies.

The expectations and promises of the sustainable production of biofuels from microalgae are very high. However, present challenges of biofuels need to be overcome, mainly in issues related to the uses of industrial wastewater and flue gases, as well as CO_2 sequestration, under carbon neutral conditions. It is expected that several major impacts will be able to influence the sustainability of biofuels, such as its contribution to the change in land use, their feedstock, and aspects of technology and scale [62.3].

The production of different biofuels has its own profits, uncertainties, and risks for sustainability, with many more still to come. It is only in a concerted action among governments, researchers, and companies that the benefits of biofuels from microalgae will become feasible for society. The production of sustainable liquid biofuels from microalgae will need to combine fuel production with co-products and bioprocesses, a strategy which could definitely contribute to the achievement of environmental and economic viability, as well as the adoption of this potential fuel source. In this chapter, we will address the issue of microalgal biotechnology and biofuel production, considering the aspects and conditions needed to achieve sustainability, viz, combining the production of compounds and processes of industrial interest with the production of biofuels. In all situations this alternative is closer to reality than to fiction when compared to other biotechnologies and sources of biomass.

62.2 Why Microalgae is Promissory for Biofuel Production

The autotrophic algae drive photosynthesis to harness sunlight and fix the inorganic carbon from CO_2. There are many algal species that are heterotrophic and able to take up small organic molecules and perform bioconversion into the building blocks of their own. Certain algae can perform mixotrophy by using either inorganic carbon from the atmosphere or organic carbon from the environment. Any of these processes confers to algae the ability to produce carbohydrates, lipids, and proteins that can be processed to produce biofuels. Microalgae are recognized as fast-growing photosynthetic organisms and have been reported to reach transforma-

tion of 5–6% of incoming light energy into biomass. Such figures, as well as its productivity place microalgae as the most promissory candidates for providing unlimited amounts of cheap biomass as food, fodder, or energy. It is recognized that microalgae have the potential to displace other feedstocks for biodiesel owing to their high vegetable oil content and biomass production rates. The potential of microalgae as a feedstock for biofuels production has led to bioprospection and bioscreening programs, hoping to find the ideal microalga. Figure 62.1 shows that in *Chlamydomonas* JSC4, nitrogen depletion can trigger the lipid content (from 15.3 to 41.1%), whereas the protein decreased from 45.4 to 17.9% (after [62.7]). The following main advantages can be mentioned: uniqueness to thrive in seawater at growth rates five to ten times higher than that of higher plants and than any other source; efficient sunlight photo conversion for active growth and photosynthesis; and the massive accumulation of lipids and carbohydrate production, which do not compete with arable land and potable water. The property of microalgae in performing photosynthesis is considered the only process that uses sunlight as the energy source and carbon dioxide as the carbon source for the production of biomass.

In general terms, it is recognized that sustainable production of microalgal biofuels still faces challenges to overcome. Its economic feasibility could be achieved if combined with bioprocesses and production of chemical compounds coupled to the use of low cost products and nutrients. According to [62.8], microalgae can be suitable feedstock for biofuels because certain species are among the most efficient biological producers of oil on the planet and a versatile biomass source. This is why some authors pointed out that microalgae may soon be one of the Earth's most important renewable fuel crops [62.9]. Moreover, they are grown in variable climates and on non-arable land, including marginal areas unsuitable for agricultural purposes (e.g., desert and seashore lands), in non-potable water or even as for waste treatment purposes, use far less water than traditional crops, and do not displace food crop cultures; their production is not seasonal and can be harvested daily [62.8, 10]. Moreover, CO_2 fixation by algae is also an important advantage for removing gases from power plants or other polluting activity and thus can be used to reduce greenhouse gases with a higher production of microalgal biomass and, consequently, a higher potential for biodiesel production [62.11]. A flow diagram of the carbon cycle pathway, biofixation, and the remarkable steps of algal biomass technologies for the production of biofuels is shown in Fig. 62.2.

Several authors have emphasized that the key for large scale production of biofuels is to grow suitable biomass species in an integrated biomass production conversion system (IBPCS). In principle, a profit in the cost of operation of the overall system should be pursued. A conceptual model for integrated biomass production is shown in Fig. 62.2 which can be adopted for microalgal biodiesel production [62.13]. The design and implementation of such systems requires the integration and optimization of several components such as biomass culture, growth management, transport to conversion plants, drying, product separation, recycling, waste management, transport of saleable products and marketing. This model may has several options, for instance the conversion plants may be located in or near the biomass growth areas to minimize the cost of trans-

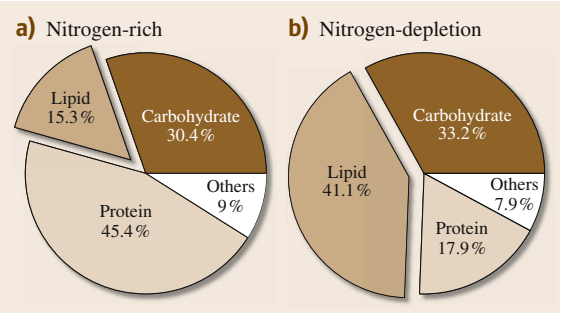

Fig. 62.1a,b Changes in biochemical composition of Chlamydomonas sp. JSC4 cultivated on nitrogen- rich **(a)** nitrogen-rich (70 to 80 % nitrogen consumed) and **(b)** in nitrate-depleted conditions (after [62.7]).

porting biomass to the plants, of which all the non-fuel effluents are recycled to the growth areas (Fig. 62.2). Based on the versatility of that kind of models, the feasibility to simultaneously integrate microalgae to synfuel production is not so far from reality in the near future.

62.3 Biodiesel Production by Microalgal Lipid Transesterification

In recent years considerable attention has been focused on methods to convert biomass to competitive liquid biofuels from various biomass materials, which may offer a promising alternative to petroleum based transportation fuels. In an epoch when fossil hydrocarbon are likely to become scarce and costly, two liquid transportation fuel at global scale from land plants are emerging. Among these emerging feedstocks, jatropha seems that can be converted to biodiesel with commercial processes, while processes capable of converting algae, are still at pre-commercial stages, but not far from outperform existing terrestrial plant sources into a comprehensive concept of sustainability. Most of bio-oils produced presently are derived from the following main sources: crop seed, animal feed, algal biomass, among others, through a transesterification process. Table 62.1 shows the yield of plant oils compared to microalgae, according to [62.10]. One of the undeniable advantage of microalgae species is it high content of oils in the cytosols and chloroplasts. Oil is extracted from microalgal biomass, which during the process of esterification is converted into biodiesel, a chemical reaction between triacylglycerols (TAGs) and alcohol in the presence of a catalyst. Finally, monoesters are produced, which are termed as biodiesel [62.3]. As a multiple step reaction, transesterification, is composed of three reversible steps in series, where triglycerides are converted to diglycerides, then diglycerides are converted to monoglycerides, and monoglycerides are then converted to esters (biodiesel) and glycerol (a by-product) [62.15].

Table 62.1 Yield of main plant oils compared to microalgae

Crop	Oil yield (L/ha)
Corn	172
Soybean	446
Canola	1190
Sunflower	952
Jatropha	1892
Palm	5950
Microalgae	100 000

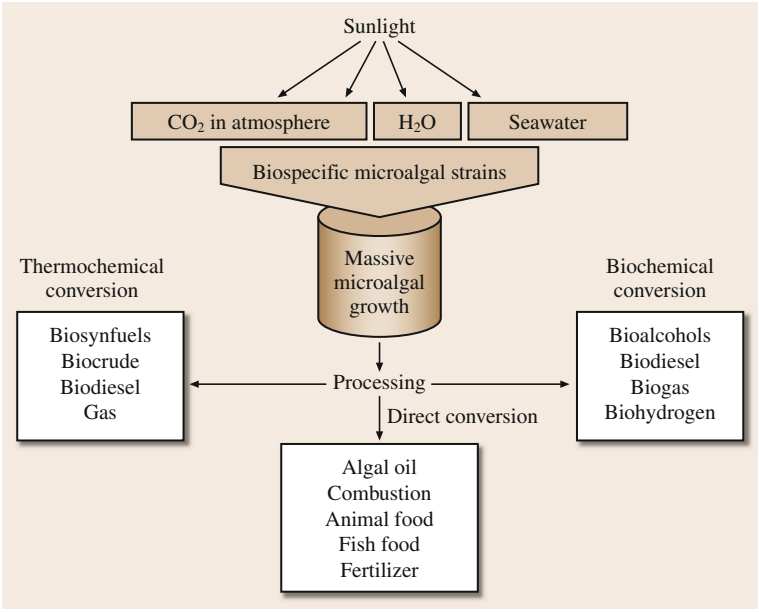

Fig. 62.3 Flow diagram of main steps of bioconversion and processing of algal biomass for the production of biofuel (after [62.14])

The fact that microalgal or bio-oils are characterized by high viscosity, high molecular weight, a higher flash point (above 200 °C), and low volumetric heating values compared to diesel fuels [62.3] imposes challenges that need to be overcome. The associated problems with substituting triglycerides for diesel fuels are: high viscosities, low volatilities, and the polyunsaturated character [62.16]. It is generally accepted that the refinement of these molecules, is an essential step for turning bio-oils into quality fuel (biodiesel) [62.17]. Moreover, biochemical and engineering processes are applied in vegetable oil derivatives in order to approximate the properties and performance of hydrocarbon-based diesel fuels. As shown in Fig. 62.3, biomass conversion processes fall into three major categories: chemical, biological, and thermochemical, but the most efficient processes may be those that combine two or more processes and use the entire plant [62.14]. Present calculations on biofuels from algae reported that one hectare algae farm on wasteland can produce over 10–100 times of oil as compared to any other known source of oil-crops. While a crop cycle may take from three months to three years for production, algae can produce oil and can be harvested all year-round using sea water and non-potable water. These facts firmly reinforced and corroborates that *algae for biofuels* shall provide an ending point solution to food vs. fuel battle. An exemplification to that approach is conceptualized in Fig. 62.3, exhibiting the main steps of algal biomass technologies coupled to biofuel production [62.14].

62.4 Bioethanol from Microalgae: A Simpler Procedure

Algae have a high photon conversion efficiency and can synthesize and accumulate large quantities of carbohydrate biomass for bioethanol production, from inexpensive raw materials. This is an effective and promissory alternative to the low yield of lignocellulosic biomass materials as a feedstock and the high cost of the hydrolysis process based on current technologies [62.19]. Even when bioethanol can be produced from several different types biomass feedstock, the algal alternative has gained acceptation, as will be described in the following. The structural composition of microalgal cells (lacking hemicelluloses and lignins) confers advantages for the production of ethanol, by eliminating the chemical and enzymatic pre-treatment steps to transform these polymers in sugars [62.19]. Microalgae (*Chlorella, Dunaliella, Chlamydomonas, Scenedesmus*) are recognized as having a high content (> 50% of the dry weight) of starch, cellulose, and glycogen, which are the basic components for ethanol production [62.20]. The starch biosynthesized by microalgae can be extracted from the cells with enzymes and then separated by extraction with water or an organic solvent and used for fermentation to yield bioethanol. Besides starch, several algae, especially green algae, can accumulate cellulose as the cell wall carbohydrate, which can also be used for ethanol production. The algal photosynthesis is mainly based on the Calvin cycle, in which ribulose-1,5-bisphosphate (RuBP) combines with CO_2 to produce 3-phosphoglyceric acid (3-PGA), which is utilized for the synthesis of glucose and other metabolites to make carbohydrates (CH). The CH molecules are vital source of storage of energy and provide the precursors to make the organic molecules and macromolecules of nearly all living cells. The process of ethanol from microalgae is more based on the carbohydrate conten of the biomass. The possibilities to utilize algal biomass for the production of biofuels, can follow different life cycle (LCA) as exemplified in Fig. 62.4 [62.6]. The assessment of the LCA options is based on indicators to compare alternative energy routes in terms of environmental impact and indirect natural resource costs towards different services and commodities. Among these, the life-cycle water and nutrients usage of microalgae-based biofuels production, which revealed that water footprint and nutrients usages during microalgae biodiesel production is an important aspect. From that, was calculated that 3726 kg water is required to generate 1 kg microalgae biodiesel if freshwater is used without recycling [62.6]. When seawater and wastewater were used for algal culture, a reduction up to 90 % was reported in nitrogen usage, which eliminates the need of other ions such as potassium, magnesium, and sulfur. The geographic position of each country play a critical role when the life-cycle assessment is performed on the overall water footprint of microalgae-based biodiesel, which production gradually decreases from north to south as solar radiation and temperature increase. Nevertheless, the potential of microalgae as an energy source is confirmed, but emphasizes the need of decreasing the energy and fertilizer consumption. This aspect is actually considered in similar initiatives, and present models had reduced

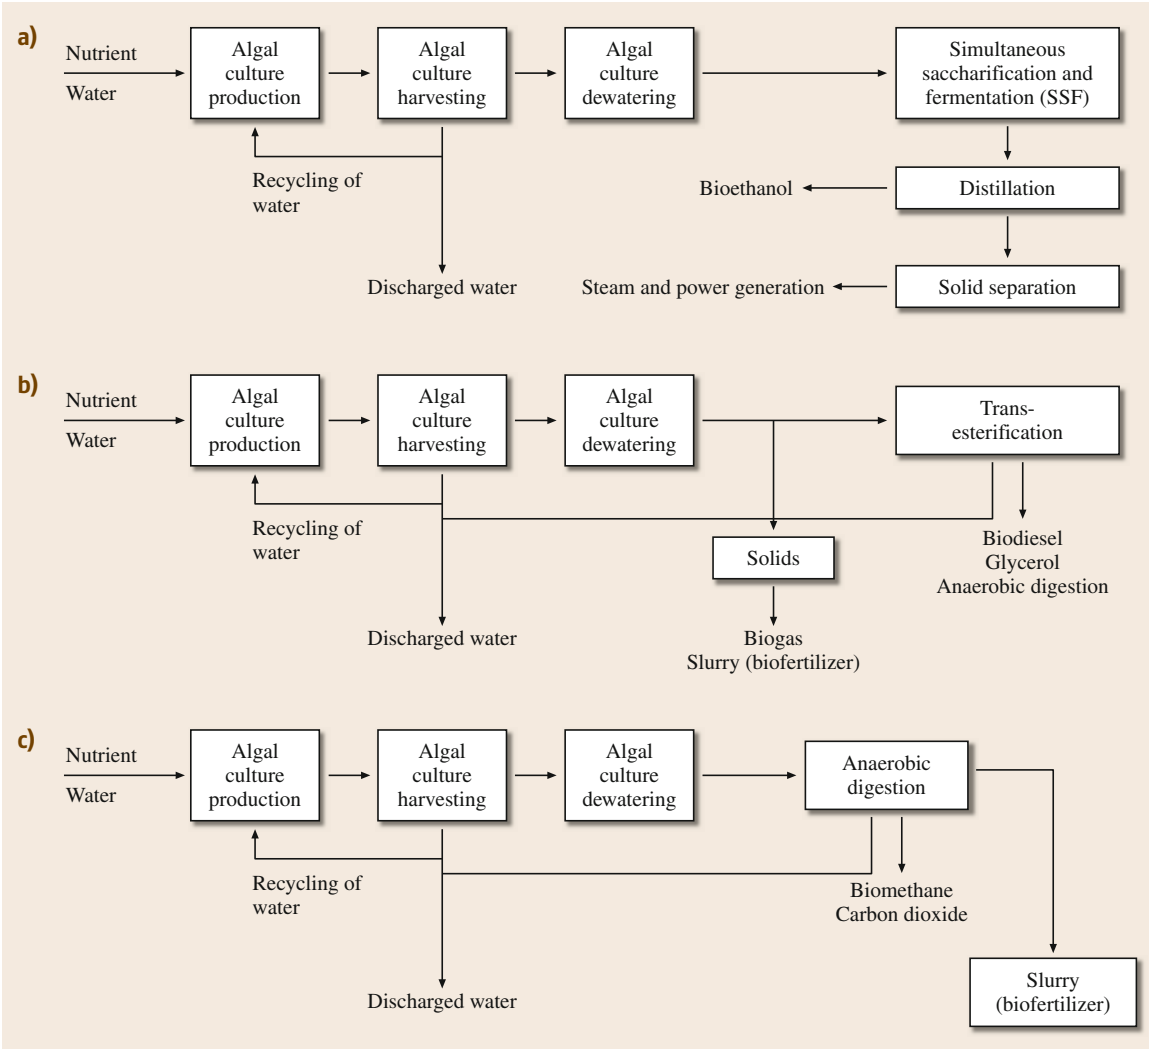

Fig. 62.4a–c Schemes of the life cycle stages of the production of biodiesel, bioethanol, and biomethane from algal biomass **(a)** exemplifies the production of biodiesel from microalgal glycerol; **(b)** shows the culturing process of microalgae to produce bioethanol; and **(c)** main steps to generate biomethane from cultured microalgae. In all three cases the produced water is recycled and bio-fertilizers are obtained (modified after [62.3, 18])

dependence on energy and fertilizers by using algae innate attributes such as CO_2 sequestration and nutrients recovering from wastewater bioremediation initiatives. Hence, algal biomass can be utilized for the production of a range of different biofuels; their life cycles are presented in Fig. 62.4.

62.5 Microalgal Biohydrogen Production Through Sunlight and Seawater

The production of biohydrogen from microalgae is not new; this process has been known for more than 65 years and was first observed in the green alga *Scenedesmus obliquus* [62.3, 15]. More recently, this

mechanism was corroborated in many other prokaryotic photosynthetic species, including cyanobacteria [62.6]. The microalgal photoproduction of hydrogen from water is a promising mechanism and has been explored as a potentially emission-free fuel stream for the future. It is expected that the desired sustainability in biofuels from microalgae can be accomplished by the photoproduction of biohydrogen because of its natural feasibility of atmospheric CO_2-sequestration [62.15]. The green microalga *Chlamydomonas reinhartii* is a successful model that has been studied for algal hydrogen production [62.21].

One of the most attractive characteristics of the bio-H_2 process is that it uses sunlight to convert water to hydrogen and oxygen, which are released in a two-phase process occurring in all oxygenic photosynthetic organisms, such as marine microalgae. A second reaction by special iron-containing chloroplast-hydrogenase enzymes also occurs in a specific group of microalgae. Cyanobacteria also exhibit a natural production of H_2 from water in a different and alternative photo-biochemical process, involving a water-splitting reaction under light and aerobic conditions. In this process, hydrogen and electrons from the water-splitting reaction of photosynthesis are used for the synthesis of adenosine triphosphate (ATP) and nicotine adenine disphosphonucleotide (NADPH), reduced). In the absence of O_2, both ATP production and the formation of NADH/NADPH are inhibited, and the stored energy in carbohydrates (starch, glycerol) is re-oriented [62.22] to the chloroplast hydrogenase to facilitate ATP production via photophosphorylation. Thus, under fermentative conditions hydrogenase plays the role of a releasing valve of protons/electrons, a condition in which protons from the medium and e- from reduced ferredoxin are balanced to produce hydrogen gas that is excreted from the cell [62.23]. *C. reinhardtii* is one of the microalgae most studied for solar-driven bio-H_2 production from water and can also use other fermentative processes. The fact that hydrogen production does not accumulate in the culture but instead is quickly released into the gas phase, makes photoproduction of hydrogen one of the most preferred biofuels.

62.6 Genomics and Metabolic Engineering of Microalgae for Biofuels Production

The gene reservoir of microalgae is only beginning to be explored. In general, microalgal genomes are structurally complex, the reported size ranges from 12.6 Mbp for Chlorophyte *Ostreococcus tauri* while 10.000 Mbp for *Karenia brevis*. The present development in genetic manipulation in microalgae has been expanded in algal biofuels which is limited a very small number of alga models. The significant advances achieved until now include the efficient expression of transgenes, the mechanisms of gene regulation, and the action of inducible nuclear promoters as well as inducible chloroplast gene expression. The nuclear genomes of a number of algae have been transformed, with a variety of reporter genes, as well as drug-resistance genes; however, extensive analysis of transgene expression has only been performed in *C. reinhardtii* [62.1]. *C. reinhardtii* has been extensively studied, and presently, abundant genomic biological and physiological data are available from this alga [62.24], which is probably not the best species for biofuel production, but as a model of study has potential for application in other suitable algal species. Microorganisms are especially attractive for biofuel production because the content in lipids is higher, 8–24 times more lipids, than in any plant [62.25]. Presently, more than 25 complete genomes have been sequenced in lipid producing cyanobacteria. In eukaryotic microalgae having significant amounts of lipids, the nuclear genome of only 10 species has been sequenced, viz, *Chlamydomonas reinhardtii*, *Volvox carteri*, *Ostreococcus marinus*, *Phaeodactylum tricornutum* and *Thalasiosira pseudonana* [62.24].

The growing interest in biofuels has led to the overexpression of acetyl-CoA carboxylase (ACCase) in the diatom *Cyclotella cryptica* to improve lipid content by increasing the first enzyme in the lipid biogenesis pathway. The result of these studies evidenced discrete results as the alga did not yield increased lipid production. The first successful transformation of microalgal strains with potential for biodiesel production was achieved in 1994, *C. triptica* and *Navicula saprophila* [62.26, 27]. Currently there are only a few species of microalgae that fulfill even some of these crucial requirements. Apart from *C. reinhardtii* and *P. tricornutum*, only *Chlorella kessleri*, *Porphyridium*, and fairly recently *Nannochloropsis* and *Dunaliella salina* have been successfully transformed [62.28]. Acetyl CoA carboxylase and other enzymes of the lipid

biosynthesis pathway have been used as targets for improving oil production. Lipid metabolism and the biosynthesis of fatty acids, glycerolipids, sterols, hydrocarbons, and ether lipids in eukaryotic algae were recently reviewed in the context of optimization for biodiesel production. Enhancement of the algal potential for the genetic modification of their lipid pathways can be followed either by up-regulation of fatty acid biosynthesis or by down-regulation of β-oxidation. By knocking out or modifying the enzymes responsible for the synthesis of polyunsaturated lipids in the cell, it should be possible to enhance the proportion of monounsaturated lipids. In this aspect, the specificity of algal species will drive its own biosynthetic pathway of lipids, which is why it is highly recommended to utilize species that have a suitable lipid profile for biodiesel production. At present, the mechanisms involved in the fatty acid biosynthetic pathway in microalgae have not been extensively studied [62.29]. Genes encoding the key enzymes involved in fatty acid biosynthesis have been identified in *Ostreococcus tauri*, *T. pseudonana*, *C. reindhardtii*, and in *P. tricornutum*. Recently [62.26] studied lipid metabolism and glycerol biosynthesis in the diatom Phaedactylum tricornutum (genome sequence available at: http://genome.jgipsf.org/Phatr2/Phatr2.home.html). Overexpression of Glycerol-3-phosphate dehydrogenase (GPDH) involved in lipid metabolism and glycerol biosynthesis led to the successful conversion of dihydroxyacetone phosphate to glycerol-3-phosphate and indicates that the GPDH transgene was incorporated into the transgenic diatom cells. The transcriptional expression of the introduced transgene consequently increased the GPDH transcript abundance in the transgenic diatom cells. The obtained results reported glycerol content, 6.8 fold in GPDH-overexpressing cells of *P. tricornutum*, compared with the wild type (Fig. 62.5). Moreover, genomics, transcriptomics, proteomics, and metabolomics are elucidating aspects of metabolic pathway regulation and integration linked to targets to optimize biofuel production. The recent progress in metabolic engineering toward biofuel production has incorporated random insertional mutagenesis and targeted gene disruption in microalgae. However, further research is required to better understand the partitioning of fixed carbon toward the increased production of starch for subsequent fermentation into H_2 or ethanol, or the redirection of photosynthate from starch into lipids for conversion to diesel fuels. New developments in metabolic engineering toward enhanced carbon storage in unicellular microalgae capable of synthesizing a range of biofuels are actually under development, as in the case of lipids and carbohydrates (the main energy storage molecules in algae). These approaches are basic for the understanding of primary metabolism to manipulate electron flux toward these products or H_2 for bioenergy applications. But at the level of organelles, the situation becomes more complex, such

in the case of isoforms of phosphoenolpyruvate carboxylase (PEP-C). This enzyme that carboxylates PEP, have been identified in *C. reinhardtii*, both of which are responsive to inorganic carbon and nitrogen levels. Additionally, six pyruvate kinase and five malate dehydrogenase homologs are present in the *C. reinhardtii* genome exhibiting different level of expression. These results emphasizes the complexity of algal metabolism and the need to characterize the systems on an enzymatic level.

62.7 Microalgal Culture Systems: A Contribution to the Sustainability of Biofuels

62.7.1 Culture Conditions and Better Yields of Biomass for Biofuels

It is recognized that the optimization of the microalgal production system is an important factor for the achievement of sustainability of microalgal-based biofuels. Successful histories of high-value products from microalgaehave been reported with the use of conventional open-pond algal production systems, although closed algal bioreactors have already achieved economic viability in the case when the production of high-value products such as astaxanthin and nutraceuticals are aimed for human consumption. Moreover, many interrelated factors affecting strains can each be limiting in the final yield of biomass, and hence in the outcome of biofuels.

Another critical and important factor, is media formulation, which is important to ensure a sufficient and stable supply of nutrients to attain maximal growth acceleration and cell density, and ultimately to produce biofuels at higher efficiencies [62.30]. There are many different recipes and formulations, depending on the species and particularities of the objective being sought. In the process of biomass optimization, the culture mode plays a preponderant role in the yield and biofuel production. It has been recognized that batch feeding of heterotrophic algal cultures and CO_2 enrichment of photoautotrophic algal cultures can significantly increase the biomass. On the other hand, the proper selection and optimization of mineral nutrients increases culture productivity. Two important nutrients that are constitutive of the microalgal metabolism are nitrogen and phosphorous, mostly at early stages in the mineral optimization of the media formulations. Other equally important components of the growth media are minerals, which are vital elements for support of the structural and metabolic biochemistry of the cell and in modulating the molecular configuration of photosynthetic complexes and enzymatic reactions. Unless otherwise stated, vitamins are generally omitted in massive cultures because of the susceptibility of the large-scale level, which in general are more fragile and hard to control, apart from economic reasons.

The use of organic substances is a common task for the improvement of the growth and strain preferences. Organic nutrition can sometimes be supplied with the use of domestic waste water, after secondary treatment. The dilemma is how to conciliate sanitation with water shortage due to the increasing scarcity of freshwater resources in many countries. In such situation, the use of wastewater bioremediated is an attractive presently explored for biofuel production. Maintenance of an acceptable pH range throughout culturing is of utmost importance as it impacts all aspects of media biochemistry and culture progression. Both ionic absorption from the media and the metabolic biochemistry of the cell exert significant pressure upon the pH. In high-performance cultures their effect is powerful enough to overcome the neutralizing capacity of exogenous buffering agents. Currently, microinjection of strong acids and alkalis, metabolic balancing in heterotrophic cultures, and regulated CO_2 dissolution in both photoautotrophic and heterotrophic cultures are the most practical and economical strategies for pH control.

62.7.2 Open Ponds and Raceways: Low-Cost Production Systems

Most of the microalgae produced presently are cultured in open ponds. Open ponds and raceways are built in whatever shape best suits the location. According to the needs and objectives, these are usually not mechanically mixed but driven by gravity flow or provided with paddle wheels. Traditional open ponds are highly diverse in shape, size, and technology, but the most commonly used design is the raceway pond. In these, the whole area is sectioned into a rectangular grid, with each divided rectangle containing a chan-

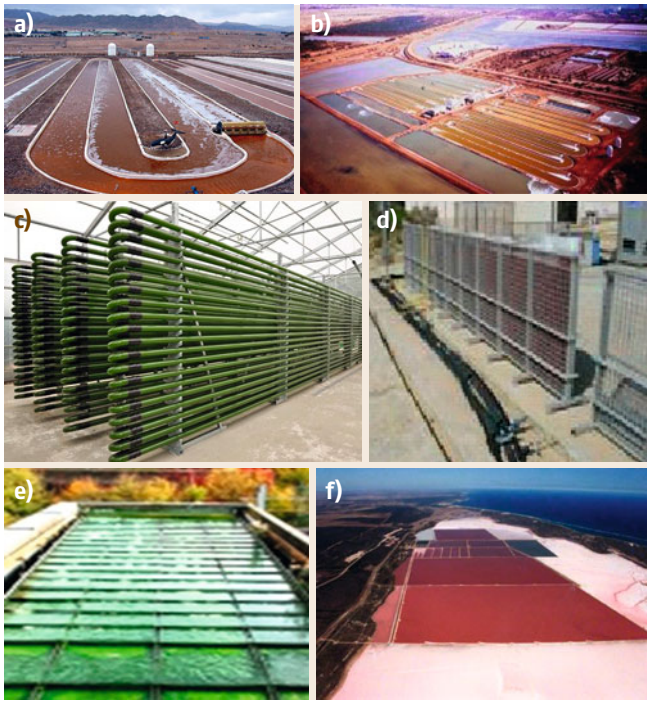

Fig. 62.6a–f Different culture systems for the industrial production of microalgae. **(a)** raceway facilities (NBT, Eliat Israel); **(b)** closed bioreactors; **(c)** alveolar panels (Beer Sheva, Israel); **(d)** cascade systems (University of Liege, Belgica); **(e,f)** open ponds (*Dunaliella salina* plant at Hutt Lagoon Western Australia, Cognis)

nel in the shape of an oval. The water flow is driven continuously by a paddle wheel all around the circuit. The reported functional and operational water depth of 15–20 cm are preferred for obtaining biomass concentrations of 1 g dry weight per liter productivities of 60–100 mg/L/day (i. e., 10–25 g/m_2/day) [62.31]. However, differences and year round productivities cannot be maintained. Raceway ponds are more expensive to construct due to the extra technologies required (paddle wheel) and the need to keep pond integrity and cell properties, a condition imposed by the flow rates. Probably, open ponds are the simplest facilities to construct, since no transparent material is required in their construction and they are relatively easy to maintain considering the large open access, which facilitates the cleaning of overgrowth and biofouling of unwanted microorganisms that builds up on surfaces. The conditions of an open culture system to the atmosphere are one of the main disadvantages that faces this system, because it is a constant exposition to unwanted species and the loss of water by evaporation, and the consequent increase of salinity. These kinds of ponds are suitable for the growth of extremophile microalgal species that tolerate and outcompete other species in conditions imposed by its particular requirements (e.g., high/low pH or salinity, or alkalinity). Examples of these conditions can be found in strains of *Arthrospira platensis/maxima* and *Dunaliella salina/bardawil*. Figure 62.6 shows the different culture systems of the massive production of microalgae worldwide.

62.7.3 Closed Bioreactors: Improving Feedstocks for Biofuels

There are different and unlimited designs of closed photobioreactors for the production of high yields of biomass. The most common shapes and designs are tubular reactors, plate reactors, or bubble column reactors. These different bioreactors have several advantages, such as saving water, energy and chemicals, and many other advantages that are increasingly making them the reactor of choice for biofuel production. Probably the most important advantages are the high control and quality of products that can be obtained [62.32].

It is to be mentioned that the most important among these aspects is that they support up to fivefold higher productivity with respect to reactor volume and consequently have a smaller *footprint* on a yield basis. The latter advantage is reinforced by the fact that they can collect as much solar energy as possible per square meter. The higher yields per square meter obtained in photobioreactors contributes to compensating for, or in some cases amortizing, the cost of photobioreactors [62.33]. Nevertheless, there are structures and operations of bioreactors that need to be optimized in order to design a performing reactor according to the needs of the algal cells at the lowest cost, ensuring the economic viability of the process [62.32]. According to the current energy cost and productivity, bioreactor costs should not exceed US$ 15 per m^2 [62.32]. Sunlight energy is another important parameter to control when dealing with photobioreactors, since most microalgae exhibit growth/light kinetics at which light saturation occurs. Sunlight may exert photoinhibition or even photobleaching in microalgae, and as a consequence, low figures in productivity and final biomass yields.

Another important factor in bioreactors is mixing, which prevents sedimentation of the cells and allows efficient homogenization of CO_2 and O_2. Recently, the use of more economical material for bioreactor construction, viz, polyethylene bags on annular reactors

or plate reactors, has contributed to refine the challenges of productivity by footprint bioreactors. The algal productivity registered based on the theoretical maximum average accounts for a yield of 100 $g/m^2/d$. According to the present expectative for the development of second-generation microalgal biofuelsystems, higher microalgal yields and photobioreactor optimization can lead to optimal and economically viable systems [62.33]. It is emphasized that the yield of terrestrial crops for the production of biodiesel cannot compete with that of algae, as exemplified from the case of soybean: 450 L of oil/ha/year, while microalgae, depending on their oil composition, can produce up to 100 000 L/ha/year [62.33, 34].

62.8 Products of Industrial Interest from Microalgae

Microalgae are an important source of food and chemicals for different industries (Table 62.2).

The demand for shellfish feed is increasing for human consumption, because of the environmental concerns over open-ocean fishing and because of the high demand for aquaculture markets. Microalgal biomass is rich in proteins, fatty acids, oils, and carbohydrates. These biomass and respective primary and secondary metabolites are of paramount importance for biotechnology and are among the most promising sources for new products and applications. With the development of sophisticated culture and screening techniques, microalgal biotechnologycan already meet the high demands of both the food and pharmaceutical industries [62.31].

In the last 20 years, most of the relevant developments in microalgal biotechnology were performed in four microalgae, viz, the green algae (Chlorophycea) *Chlorella vulgaris*, *Haematococcus pluvialis*, and *Dunaliella salina*, and the cyanobacteria *Arthrospira (Spirulina) maxima* or *platensis*, which have been commercialized worldwide and applied as ingredients and supplements for humans and animal feed additives. The characteristics and attributes of each of these microalgal species, emphasizing their functional pigments and respective industrial applications, are described in the following.

Spirulina (Arthrospira) under the tribal name of tecuitlatl [62.35] was part of the diet of the Mexican Aztec population. This Cyanophyte has attracted special attention due to its importance as a nutritious supplement and its demonstrated (in vitro and in vivo) functional properties. The high protein content of this microalga, up to 70% dry weight, and its amino acid composition is of great interest, not only because *S. platensis* possesses all of the essential amino acids, but also because these amino acids have a great bioavailability [62.36, 37]. The phycobiliproteins (allophycocyanin and c-phycocyanin) are one of the major compounds in *Arthrospira* [62.37]. Important medical and pharmacological attributes such as hepatoprotective, anti-inflammatory, and antioxidant properties have been described and are thought to be basically related to the presence of phycobilins. Besides, phycobiliproteins might have an important role in different photodynamic therapies of various cancer tumors and leukemia treatment [62.38]. Another equally important microalga, the green unicellular *D. salina*, is an extremophilic microalga well-known for being the most abundant natural source of β-carotene (up to 14% of its dry weight) [62.39]. This microalgae is undoubtedly one of most studied [62.40, 41] because β-carotene has important applications in the food, pharmaceutical, and cosmetics industries. Studies on carotenogenic *D. salina* samples carried-out by *Olmos-Soto* et al. [62.42], successfully differentiated carotenogenic from non-carotenogenic species based on introns within 18S rDNA.

Haematococcus pluvialis is especially important due to its ability to accumulate, under stress conditions, large quantities of astaxanthin, up to 2–3% on a dry weight basis [62.43]. The carotenogenic process in *Haematococcus* induces different changes in the cell physiology and morphology of this alga, resulting in large red palmelloid cells. Astaxanthin is present in lipid globules outside the chloroplast, although the signal for induction to the massive accumulation of astaxanthin has been reported as originating in cytosol [62.44]. The pigment arsenal in *Haematococcus* possesses powerful biological activities, including antioxidant capacity [62.45], ulcer prevention, immunomodulation, and cancer prevention [62.46]. Experimental studies carried out on *Chlorella* demonstrated its antitumor effect, hepatoprotective and antioxidant properties [62.46, 47], antibacterial effects [62.48], or even the immunostimulant activity of enzymatic protein hydrolysates from this microalgae. *Chlorella* contains many dietary antioxidants,

Table 62.2 Main microalgal species and respective products and applications of biotechnology (modified after [62.12])

Species/group	Product	Application areas
Arthrospira platensis	Phycocyanin, biomass	Health food, cosmetics
Chlorella vulgaris	Biomass	Health food, food supplement, feeds
Dunaliella salina	Carotenoids, β-carotene	Health food, food supplement, feeds
Haematococcus pluvialis	Carotenoids, astaxanthin	Health food, pharmaceuticals, feeds
Odontella aurita	Fatty acids	Pharamaceuticals, cosmetics,
Porphyridium cruentum	Polysaccharides	Pharmaceuticals, cosmetics,
Isochrysis galbana	Fatty acids	Animal nutrition
Phaedactylum tricornutum	Lipids, fatty acids	Nutrition, fuel production
Lyngbya majuscule	Immune modulators	Phamaceuticals, nutrition

which may be responsible for some of its functional activities.

62.8.1 Health Foods and High-Value Added Substances from Microalgae

During the past decades, microalgal biomass was predominately utilized in the health food market, with more than 75% of the annual microalgal biomass. Currently, most products launched to serve the health food market are supplied as tablets or in powder or liquid formulations. However, algal extracts in various product forms are creating a new market sector for each algal species (Table 62.2). The market of functional foods is believed to be the most dynamic sector in the food industry and could constitute up to 20% of the entire food market within the next few years. Food supplemented with microalgal biomass might have other positive influences, e.g., prebiotic effects or mineral fortification.

There is an increasing demand for products from microalgae, which after special biotechnological processes acquire a higher value in the market considering the uniqueness of microalgae as specialty products. Among these products, polyunsaturated fatty acids occupy a preponderant position, because according to [62.49], only plants and algae are able to synthesize omega-3 fatty acids (ω-3) (Fig. 62.7). Polyunsaturated fatty acids (PUFAs) are essential components for the growth of higher eukaryotes and provide significant health benefits, reducing cardiac diseases and having other beneficial effects for depression, rheumatoid arthritis, and asthma [62.29]. Currently, the main source of these fatty acids for human consumption is marine fish. Actually, the relevant advantages from microalgae over fish oils, such as the lack of unpleasant odor, the reduced risk of chemical contamination, and a better purification potential, place microalgae as an excellent and preferred source of PUFAs. Microalgal PUFAs are established on the market both for food and feed, e.g., health-promoting purified PUFAs are added to infant milk formulas in Europe, and hens are fed with special microalgae to produce *OMEGA* eggs. The production of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) products from microalgal biotechnology for human and other applications has already been released by biotechnological companies.

Some microalgae have also developed protective mechanisms to prevent the accumulation of free radicals and reactive oxygen species, and thus counteract cell-damaging activities. These attributes confers the properties of antioxidants to some microalgae. For functional food/nutraceuticals, the radical-scavenging capacity of microalgal products is of growing interest, especially in the beverage market segment and in pharmaceutical applications for the therapy of oxidation-associated diseases like inflammation. Microalgae, including cyanobacteria, are overcharged with a multitude of photosynthetic and accessory pigments, which improve the efficiency of light energy utilization (phycobiliproteins) and protect them against solar radiation (carotenoids). The structure and function of these pigments have acquired anthropogenic importance due to their bioactivity, especially as health promoting compounds in human health and as therapies for functional disorders, neurodegenerative diseases, and cancer.

62.8.2 Microalgae in Aquaculture: A Successful Living History

Aquaculture is a fast growing industrial food sector. Aquaculture plays an important and critical function in the food system, because supply nearly 3 billion people with at least 15 % of their animal protein intake. In many developing countries, aquaculture has

accomplished its role and has been sufficiently profitable which has enhanced and harnessed strong growth in different world regions. Microalgae as live foodis undeniably one of the most important components in aquacultural enterprises. In fact, no activity is conceived in aquacultural production systems if lacking in live microalgae. The main applications of microalgae for aquaculture are directly related with nutrition, being used fresh or as food additive of health and coloring feeds or for inducing other biological functions. Worldwide, two trends dominate the field of microalgal applications in aquaculture: (1) the production of microalgal species, as live feeds to meet the feeding requirements of invertebrate larvae, and (2) the selection and production of specific strains of microalgae into shellfish feed to increase yields at industrial scale. As the basis of the natural food chain, microalgae play a key role in aquaculture, especially mariculture, being the food source for larvae of many species of mollusks, crustaceans, and fish. In addition, microalgae serve as a food source for live zooplankton production (Artemia, rotifers, copepods), which in turn are reused as feed for rearing fish and mollusk larvae [62.50]. More than 40 species of microalgae are used in aquaculture worldwide, depending on the special requirements of local seafood production.

Concerning the microalgal species used in aquaculture, a remarkable feature is the fact that presently, almost 40 years after the initial efforts, hatcheries are still using essentially the same strains for their production. The attributes of microalgae for filter feeder invertebrates reflect their importance in production nurseries and hatcheries of aquaculture species of commercial importance. Microalgae are required for larva nutrition, directly or indirectly at least in a short period of their life cycle of most of cultured shellfish species. Microalgal strains to be used in aquaculture have to meet various criteria of efficiency and functionality. In first term, it has to be easily cultured and nontoxic and needs to be of the correct size and shape to be ingested. Moreover, microalgae for aquaculture must have high nutritional qualities and a digestible cell wall to make nutrients available [62.51]. Moreover, they should undergo fast growth rates, and be scalable to mass culture, and a high nutritional value, including absence of toxins. Among these properties, protein and highly unsaturated fatty acid (e.g., eicosapentaenoic acid (EPA), arachidonic acid (AA) and docosahexaenoic acid (DHA)) content are major factor determining the nutritional value of microalgae. Recently, the role of ratios of DHA, EPA and AA has be elucidated as more important than their absolute levels as well as microalgal vitamin content. The following microalgae genera are usually supplied in aquaculture facilities: *Chaetoceros, Thalassiosira, Tetraselmis, Isochrysis*, *Nannochloropsis*, *Pavlova*, and *Skeletonema*. However, the use and time period of uses of each can vary depending on the cultured shellfish species. For practical reasons, we have chosen the representative group of shellfish species, in which these microalgal strains are an unavoidable source of feed. Bivalve mollusks are probably the most dependent and representative group of aquaculture species, as in the case of oysters, clams, and abalones. The intensive rearing of these bivalves relies on live algae and they represent the largest biomass in the hatchery and demand the highest weight-specific rations. It is well known that the suitable algal species: *C. calcitrans*, *T. pseudonana* (3H), *I. galbana*, and *T. suecica* (for larvae $>120\,\mu m$ in length) are preferred for the larvae of bivalves, either as single monoculture (unialgal diets) or in combinations with different other microalgal strains (flagellates and diatoms).

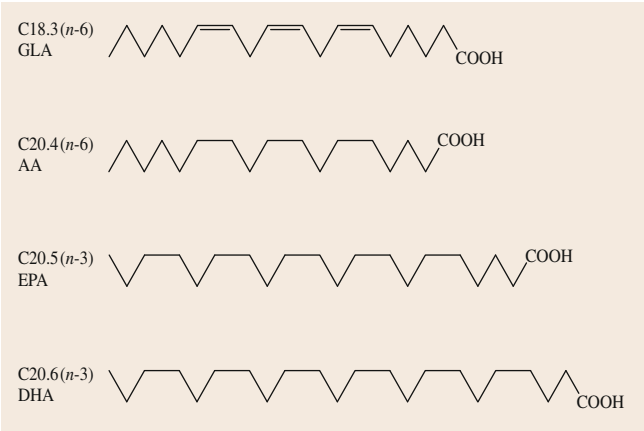

Fig. 62.7 PUFAs of high pharmaceutical and nutritional value that can be obtained from plants and microalgae (after [62.29, 50])

A different scheme of intensive feeding in hatcheries is exhibited by penaeid shrimp. The penaeid shrimp species, which is cultured worldwide, usually refers to the white shrimp *Penaeus vannamei*, the blue shrimp *P. stilirrostris*, or *P. monodon*. These crustaceans are fed with algae added during the non-feeding nauplius stage in order to have algae available upon molting into the protozoa stage. The most often used algal species are *Tetraselmis chui*, *Chaetoceros gracilis*, and *Skeletonema costatum*. As feeding preferences change from primarily herbivorous to carnivorous during the

mysis stages, the quantity of algae is reduced. Nevertheless, a background level of algae is maintained as this may stabilize water quality. In spite of all efforts to replace live algae by inert feeds, aquaculturists are still dependent on the production and use of microalgae and microinvertebrates (Zooplankton, *Artemia* and *Brachionus* sp.) as live food for commercially important fish, molluscs and crustaceans, during at least part of their life cycle. However, it is expected that technological advances in the integration among complementary approaches such as synbiotics, probiotics, bioengineered and functional feeds as well as microalgae of bioremediation activities shall lead to a more sustainable production and efficient use of microalgae. But in any situation for the purposes of industrial enterprises of microalgae, the main factor to consider is to reduce production costs while maintaining reliability in microalgae feed [62.51].

62.9 Future Needs: Making Sustainable the Unsustainable Lightness of Biofuels

The promising and clear potential of algal biofuels for contributing to environmental, social, and economic sustainability need to be transformed into a sustainable reality. Which biofuel will win: biodiesel, bioethanol, or biohydrogen? There is no doubt that an important volume of research, bioengineering, and technology is needed in order to answer these questions and to confer the sustainability tag. Microalgae are presently the most promissory renewable resource to achieve sustainable production of biofuels, considering the following aspects and uniquenesss:

a) Low impacts on the environment and in the world's food supply
b) High photon bioconversion efficiency and biomass production from photosynthesis
c) Supply energy, food and nutraceuticals for the human population
d) Can be used in bioremediation processes and simultaneously coupling CO_2-neutral fuel production with CO_2 sequestration
e) Can be cultured and harvested all-year-round
f) Can be grown on non-arable land, and in seawater and wastewater streams (avoiding the use of freshwater and recycling nutrients).

However, an assessment of the life cycle, energy and carbon balance, biofuels yield per unit area, and high efficiency production, are important issues and current limitations needed to overcome in order to make sustainable the biofuels production from microalgae.

An important strategy is the combination of fuel production with co-products, which could contribute to sustainable biofuels and reinforced by eco-friendly initiatives with minimum impact on the present reserves of air, water, and biodiversity. Moreover, it must be socially acceptable and economically viable. There is no doubt that integration of all the components of uses of microalgae: high-value compounds, aquaculture, bioremediation coupled to the production of biofuels, will play an important role in the near future to make sustainable the unsustainable lightness of biofuels from microalgae. Even with these potentialities and strategies, we believe that biofuel production from microalgae will achieve cost competitiveness in the next couple of decades, only if the aforementioned issues are considered, as well as aspects of engineering to the particular tasks demanded by bioenergy industries that are now under development. However, present innovations of new ways to make the process economically feasible shall provide many improvements and technologies contributing to the sustainability of the biofuels production from microalgae.

63. Marine Actinobacterial Metabolites and Their Pharmaceutical Potential

Panchanathan Manivasagan, Jayachandran Venkatesan, Kannan Sivakumar, Se-Kwon Kim

Marine actinobacteria are one of the most efficient groups of secondary metabolite producers and are very important from a pharmaceutical industry point of view. Among its various genera, *Streptomyces*, *Saccharopolyspora*, *Amycolatopsis*, *Micromonospora*, and *Actinoplanes* are the major producers of commercially important biomolecules. Several species have been isolated and screened from soil in the past decades. Consequently, the chance of isolating a novel actinobacteria strain from a terrestrial habitat, which would produce new biologically active metabolites, has been reduced. The most relevant reason for discovering novel secondary metabolites is to circumvent the problem of resistant pathogens, which are no longer susceptible to the currently used drugs. Existence of actinobacteria has been reported in the hitherto untapped marine ecosystem. Marine actinobacteria are efficient producers of new secondary metabolites that show a range of biological activities including antibacterial, antifungal, anticancer, antitumor, cytotoxic activities, etc. Bioactive compounds from marine actinobacteria possess distinct chemical structures that may form the basis for the synthesis of new drugs that could be used to combat resistant pathogens.

63.1 Marine Actinobacteria

Marine actinobacteria are the most economically and biotechnologically valuable prokaryotes able to produce wide range of bioactive secondary metabolites, such as antibiotics, anticancer, antitumor, and immunosuppressive agents and enzymes. These metabolites are known to posses antibacterial, antifungal, neuritogenic, anticancer, antialgal, antimalarial and anti-inflammatory activities [63.1].

Marine actinobacteria have the capacity to synthesize many different biologically active secondary metabolites such as cosmetics, vitamins, nutritional materials, herbicides, antibiotics, pesticides, anti-parasitic ones, and enzymes like cellulose and xylanase used in waste treatment [63.2]. They are free living, saprophytic bacteria, and a major source for the production of antibiotics [63.3].

As the frequency of novel bioactive compounds discovered from terrestrial actinobacteria decreases with time, much attention has been focused on the screening of actinobacteria from diverse environments for their ability to produce new secondary metabolites. Actinobacteria isolated from the marine environment are metabolically active and have adapted to life in the sea. Streptomyces are especially prolific and can produce a great many antibiotics (around 80% of the total antibiotic production and active secondary metabolites) [63.4].

Of the total sea surface, only 7–8% is coastal area and the rest is deep sea, of which again 60% is covered by water more than 2000 m deep. The deep sea is a unique and extreme environment characterized by high pressure, low temperature, a lack

of light and variable salinity and oxygen concentrations. Although the geographical area of the deep sea is vast, our knowledge, understanding, and studies of deep-sea microorganisms are meagre. However, it is a good source of novel organisms for microbiologists and biotechnologists [63.5]. Moreover, it has been shown to be a good source of novel microorganisms for the discovery of new antibiotics [63.6]. Actinobacteria isolated from deep-sea sediments in earlier studies, however, were poorly characterized [63.7]. More recently, culture-independent studies have shown that indigenous marine actinomycetes certainly exist in the oceans [63.8]. These include members of the genera *Dietzia*, *Rhodococcus* [63.9–12], *Streptomyces* [63.13], the newly described genera *Salinispora* [63.14–16], and *Marinispora* [63.15, 17], both of which require seawater for growth and have marine chemotype signatures, and *Aeromicrobium marinum* [63.18], which also has an obligate requirement for salt. Another recently characterized genus, *Salinibacterium*, can tolerate up to 10% NaCl but does not have a salt requirement for growth [63.19]. The recently reported *Verrucosispora* strain AB-18-032 [63.20] might also qualify as an indigenous marine actinobacterium. Some of these species were found to produce unique compounds, such as salinosporamides, that are now in clinical trials as potent anticancer agents [63.21].

About 23 000 antibiotics have been discovered from microorganisms. It has been estimated that approximately 10 000 of them were isolated from actinomycetes. Actinomycetes, mainly the genus *Streptomyces*, have the ability to produce a wide variety of secondary metabolites as bioactive compounds, including antibiotics. The group has an enormous biosynthetic potential, which remains unchallenged among other microbial groups. The immense diversity, along with its underutilization is the fundamental reason for attracting researchers towards it for discovering novel metabolites. The genus *Streptomyces* is represented in nature by the largest number of species among all the genera of actinomycetes and figures over 500 species. The name *Streptomyces* was introduced in 1943 for the aerial mycelia producing actinomycetes. Actinomycetes comprise about 9% of the bacteria colonizing marine aggregates and can be isolated from various marine sources. Many of these secondary metabolites are potent antibiotics, which has made streptomycetes the primary antibiotic-producing organisms exploited by the pharmaceutical industry. In this book chapter, research and application of marine actinobacterial metabolites in the pharmaceutical industries are outlined in detail.

63.2 Research on Marine Actinobacteria

Marine microbiology is developing strongly in several countries, with a distinct focus on bioactive compounds. Analysis of the geographical origins of compounds, extracts, bioactivities, and actinobacteria up to 2003 indicated that $\approx 67\%$ of marine natural products were sourced from Australia, the Caribbean, Indian Ocean, Japan, the Mediterranean, and Western Pacific Ocean sites [63.22]. Interestingly the latest data [63.22] reveal a dramatic rise in reports pertaining to the China Sea, reflecting growing international attention on marine natural products.

The old impression that the diversity of actinobacteria in the oceans was small and restricted has been completely dispelled by 16S phylogenetic diversity inventories and estimates, and cultivation approaches. Thus, deep-sea sediments have been found to contain > 1300 different actinobacterial operational taxonomic units, a great proportion of which are predicted to represent novel species and genera [63.23]. Complementing this strategy are intelligent approaches to sample handling and growth conditions, which have led to the recovery in culture of many new taxa. Among newly described marine genera are: *Salinispora* (Micromonosporineae) [63.24], *Demequina* (Micrococcineae) [63.25], and others awaiting formal taxonomic description: *Marinispora* [63.17], *Solwaraspora* [63.26], and *Lamerjespora* [63.27]. New species of known actinobacterial genera are being described on a regular basis [63.28–32]; the only serious limitation in this endeavor is the availability of qualified taxonomists.

Several issues merit reiterating and updating from the perspective of effective biodiscovery. First, the question of whether to sample shallow or deep marine sites, associated with the assumption that the former can be dominated by strains originating from terrestrial runoff. Although intuition points to the deep seas (the more unusual, least explored environment) it is cautionary to note that novel genera are being recovered from surface seawater (*Serinicoccus* [63.33]) and tidal mud flats (*Demequina* [63.25]). Based on an obligate requirement for salt several indigenous genera have been identified (*Salinibacterium* [63.19], *Serinicoccus* [63.33], and

Salinispora [63.24]), whereas deep-sea polar strains of *Dietzia* and *Rhodococcus* have obligate salt requirements and psychrotolerance [63.34], and several actinomycetes taxa isolated from Palau seem to be obligate marine taxa [63.35]. To date no obligate piezophilic marine actinobacteria have been reported, but organisms isolated at atmospheric pressure can exhibit significant piezotolerance [63.12, 36].

Second, it was thought that actinobacteria were largely associated with marine sediments or occurred as invertebrate symbionts, and that the planktonic lifestyle was rare. Recent studies, however, are challenging this assumption and pointing to the need for a more comprehensive understanding of ocean dynamics and biology. *Morris* et al. [63.37] recorded significant increases in populations of planktonic actinobacteria in response to deep ocean convective mixing and, thereby, nutrient availability, thus drawing attention to the importance of temporal sampling [63.37]. In an important paper *Bouvier* and *Del Giorgio* [63.38] reported the potential effect of viruses on marine bacterioplankton composition and abundance. When these communities were incubated in virus-free ambient seawater an *unexpected and dramatic increase in the relative abundance of bacterial groups that are generally undetectable in the in situ assemblages* occurred; in open ocean regions the proportions of actinobacteria rose from zero to 35% of the bacterioplankton [63.38].

Finally, there is the question of marine actinobacterial biogeography [63.39]. In general a large body of research supports the hypothesis of biogeographical distribution of free living microorganisms and that such spatial variation reflects the proposition that *the environment selects* [63.40]. *Martiny* et al. [63.41] provide an excellent analysis of the contributions of environmental and historical effects and a framework for experimental testing of microbial biogeography; they argue that such studies should involve systematic sampling and recording of data from various distances, habitats, and environmental factors [63.41]. Such crucial data for free-living marine actinobacteria are lacking, but a study of bacterial symbionts in the sponge *Cymbastela concentrica* in tropical and temperate locations of Australia [63.42] showed that symbiotic communities had similar compositions at temperate locations, but different communities (which included actinobacteria) occurred in the temperate and tropical sponge populations, which might reflect endemic distribution or environmental selection, or both. The biogeography debate is not simply of academic interest because a greater understanding of distribution patterns is of clear importance for biodiscovery. For example, although the three currently known species of *Salinispora* co-occur at six widely separated and distinct locations [63.43], only strains of *Salinispora tropica* isolated from the Caribbean produce the potent anticancer compound salinosporamide A [63.15]. In conclusion, progress in isolating actinobacteria from the seas and oceans, especially from sediments, has been notable in the past few years.

63.3 Novel Metabolites from Marine Actinobacteria

Although more than 30 000 diseases have been clinically described, less than one third of these can be treated symptomatically and fewer can be cured [63.44]. New therapeutic agents are urgently needed to fulfill the medical needs that are currently unmet [63.45]. Natural products once played a major role in drug discovery [63.46]. Although the exploitation of marine actinobacteria as a source for discovery of novel secondary metabolites is at an early stage, numerous novel metabolites have been isolated in the past few years [63.47].

63.3.1 Antimicrobial Activity

Development of multiple drug resistant microbes revealed the need to search for new and novel antimicrobials [63.48]. Among the antibiotic producing microbes, the class Actinobacteria represents a broad range of valuable and prominent sources of pharmaceutically active metabolites in which, the members of the genus *Streptomyces* alone contributes more than half of the naturally occurring metabolites discovered up to date. Besides, 60% of antibiotics developed for agricultural purpose were isolated from the same genus [63.49]. However, the discovery of new metabolites from these common and ubiquitous actinobacteria has declined [63.50]. Hence, in the present era, search for rare actinobacteria has gained much importance in order to enhance the rate of discovery of new and potent antimicrobial agents [63.51].

Bisanthraquinone **(1)** (Fig. 63.1) is a new antibiotic isolated from *Streptomyces* sp. Biological activities were measured against clinically-derived isolates of vancomycin-resistant *Enterococcus faecium*

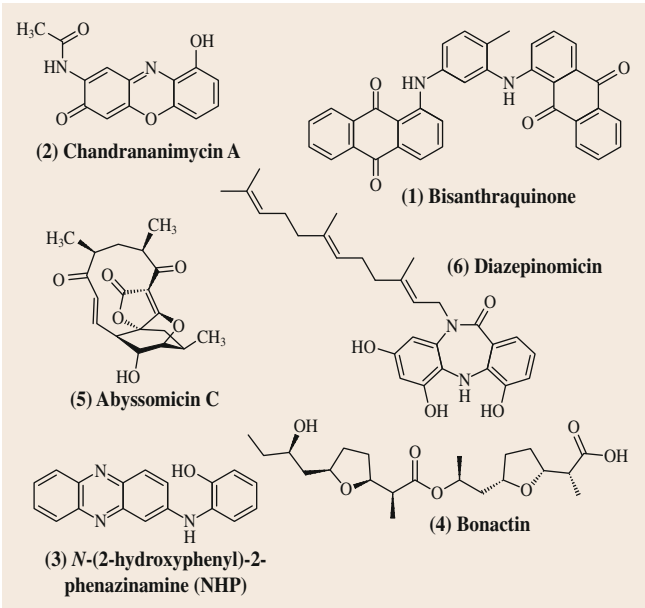

Fig. 63.1 Chemical structures of bisanthraquinone, chandrananimycin A, *N*-(2-hydroxyphenyl)-2-phenazinamine (NHP), bonactin, abyssomicin C and diazepinomicin

(VRE),and methicillin-susceptible, methicillin-resistant, and tetracycline-resistant *Staphylococcus aureus* (MSSA, MRSA, and TRSA, respectively). The most potent antibiotic displayed MIC_{50} (minimum inhibitory concentration) values of 0.11, 0.23, and 0.90 μM against a panel ($n = 25$ each) of clinical MSSA, MRSA, and VRE, respectively, and was determined to be bactericidal by time-kill analysis [63.52].

Chandrananimycin A **(2)** (Fig. 63.1) is a novel antibiotic isolated from *Actinomadura* sp. Chandrananimycin A possesses potent antifungal activity against *Mucor miehei*. It also exhibits antialgal activity against the microalgae *Chlorella vulgaris* and *C. sorokiniana*, and antibacterial activity against *Staphylococcus aureus* and *Bacillus subtilis*, along with anticancer activity [63.53]. *N*-(2-hydroxyphenyl)-2-phenazinamine (NHP) **(3)** (Fig. 63.1) is a new antibiotic isolated from *Nocardia dassonvillei*. The new compound has shown significant antifungal activity against *Candida albicans*, with a MIC of 64 $\mu g\,mL^{-1}$ and high cancer cell cytotoxicity against HepG2, A549, HCT-116, and COC1 cells [63.54].

A new compound, assigned the trivial name bonactin **(4)** (Fig. 63.1), has been isolated from the liquid culture of a *Streptomyces* sp. BD21-2, obtained from a shallow-water sediment sample collected at Kailua Beach, Oahu, Hawaii. Bonactin displayed antimicrobial activity against both Gram-positive and Gram-negative bacteria as well as antifungal activity [63.55]. Abyssomicin C **(5)** (Fig. 63.1) is a novel polycyclic polyketide antibiotic produced by a marine *Verrucosispora* strain [63.28]. It is a potent inhibitor of *para*-aminobenzoic acid biosynthesis and, therefore, inhibits the folic acid biosynthesis at an earlier stage than the well-known synthetic sulfa drugs [63.56]. Abyssomicin C possesses potent activity against Gram-positive bacteria, including clinical isolates of multiple-resistant and vancomycin-resistant *Staphylococcus aureus*. Abyssomicin C or its analog [63.57] has the potential to be developed as antibacterial agent against drug-resistant pathogens.

Diazepinomicin **(6)** (Fig. 63.1) is an unique farnesylated dibenzodiazepinone produced by a *Micromonospora* strain [63.58]. It possesses antibacterial, anti-inflammatory and antitumor activity. It has a broad spectrum of in vitro cytotoxicity and has demonstrated in vivo activity against glioma, breast, and prostate cancer in mouse models. Frigocyclinone **(7)** (Fig. 63.2) is a new angucyclinone antibiotic isolated from *Streptomyces griseus* strain NTK 97, consisting of a tetrangomycin moiety attached through a *C*-glycosidic linkage with the aminodeoxysugar ossamine. Frigocyclinone has shown antibacterial activities against Gram-positive bacteria. Chlorinated dihydroquinones **(8)** (Fig. 63.2) are novel antibiotics produced by a new marine *Streptomyces* sp. [63.59]. The compounds formally possess new carbon skeletons, but are related to several previously reported metabolites of the napyradiomycin class. Structures of the new molecules possess significant antibacterial and cancer cell cytotoxicities.

Himalomycins A **(9)** and B **(10)** (Fig. 63.2) are anthracycline antibiotics. They were obtained from *Streptomyces* sp. 6921, isolated from the marine sediments of Mauritius and exhibited strong antibacterial activity [63.60]. Glyciapyrroles A **(11)**, B **(12)**, and C **(13)** (Fig. 63.3) are a new pyrrolosesquiterpenes antibiotic isolated from *Streptomyces* sp. NPS008187. They exhibited antibacterial activity [63.61]. Tirandamycin C **(14)** (Fig. 63.3) is a novel dienoyl tetramic acid isolated from *Streptomyces* sp. 307-9. Tirandamycin C showed inhibitory activity against vancomycin-resistant *Enterococcus faecalis* [63.62]. Essramycin **(15)** (Fig. 63.3) is a novel triazolopyrimidine antibiotic isolated from *Streptomyces* sp. The compound is antibacterially active with MIC of 2–8 $\mu g\,mL^{-1}$ against Gram-positive

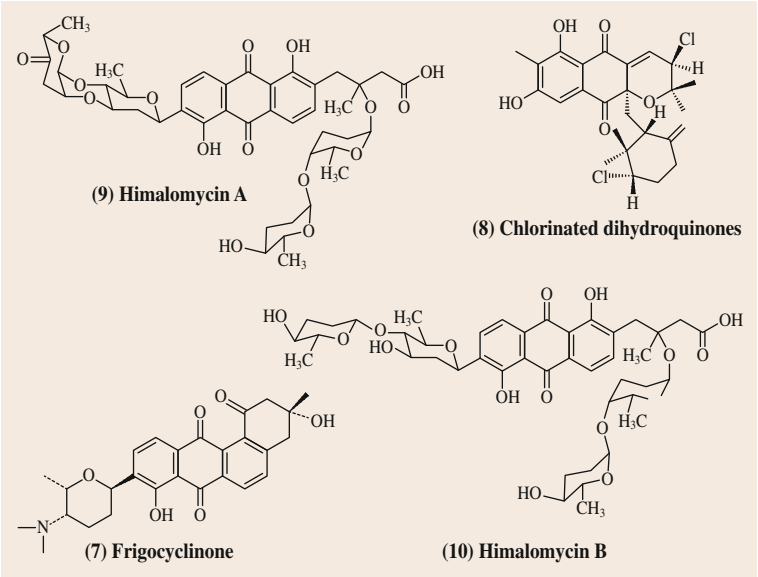

Fig. 63.2 Chemical structures of frigocyclinone, chlorinated dihydroquinones, himalomycin A and B

and Gram-negative bacteria [63.63]. Lynamicins **(16)** (Fig. 63.3) are chlorinated bisindole pyrroles, isolated from *Marinispora* sp. The antimicrobial spectrum of these compounds was evaluated against a panel of 11 pathogens, which demonstrated that these substances possess broad-spectrum activity against both Gram-positive and Gram-negative organisms. Significantly, compounds were active against drug-resistant pathogens such as methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant *Enterococcus faecium* [63.64].

Caboxamycin **(17)** (Fig. 63.3) is a new benzoxazole antibiotic and was detected by HPLC-diode array screening in extracts of *Streptomyces* sp. NTK 937, another strain that was isolated from the sediments collected from the Canary Basin. The compound caboxamycin was named after the first letters of the collection site from where the organism was isolated and from letters drawn from its chemical structure. Caboxamycin showed inhibitory activity against both Gram-positive bacteria and against the tumor cell lines gastric adenocarcinoma (AGS), hepatocellular carcinoma (HepG2), and breast carcinoma cells (MCF7). The antibiotic also showed an inhibitory activity against the enzyme phosphodiesterase [63.65]. Marinopyrroles **(18)** (Fig. 63.3) are densely halogenated and axially chiral metabolites that contain an uncommon bispyrrole structure isolated from *Streptomyces* sp. The marinopyrroles possess potent antibiotic activities against methicillin-resistant *Staphylococcus aureus* [63.66].

63.3.2 Anticancer Activity

Thousands of antibiotics have been successfully applied to prevent and treat diseases caused by microbes in clinical settings over the past half-century. It is, therefore, no wonder that more and more tumor cells and bacteria have developed antimicrobial resistance or even multidrug-resistance. In the past, solutions to the problem depended primarily on the development of novel antineoplastic and antimicrobial agents from common resources.

A great number of structurally interesting and biologically active secondary metabolites produced by microorganisms have been reported, many of them being exploited by the pharmaceutical industry as potent antibiotics [63.49, 67]. However, the number of these new antibiotics is noted to have decreased dramatically in recent years due to the exhaustion of common resources [63.67]. In this regard, focus on rare resources, such as marine actinomycetes, has attracted special attention. This is due to their capability to produce biologically active secondary metabolites, with many of them as potent antibiotics and/or lead compounds that would otherwise not be discovered in terrestrial microorganisms [63.68–71]. This has facilitated the development of new and novel drugs with greater therapeutic efficiency and/or fewer side effects [63.48, 72–74], and hence led to an urgent need to explore the secondary metabolites produced by these microorganisms.

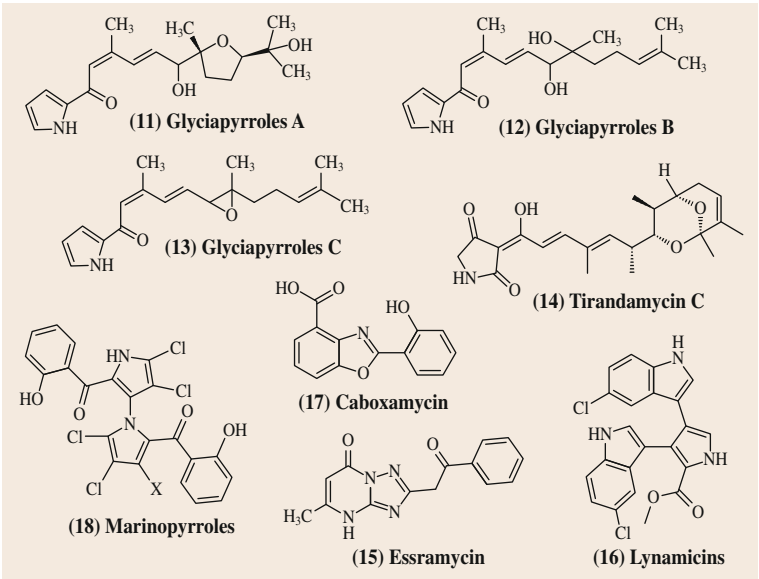

Fig. 63.3 Chemical structures of glyciapyrroles A, B, C, tirandamycin C, essramycin, lynamicins, caboxamycin, and marinopyrroles

Prudhomme et al. (2008) tested salinosporamide A for its utility as an anticancer and antimalarial drug. It was shown to have inhibitory activity against parasite development in vitro (*Plasmodium falciparum*) and in vivo (*P. yoelii*). The exact mode by which salinosporamide A inhibits *Plasmodium* erythrocytic development is unknown; however, it is likely due to the inhibition of the proteasome complex. It is interesting to note that chloroquine resistant strains are still sensitive to salinosporamide A.

Targeting the proteasome system has a huge therapeutic implication as it can restrain growth and survival of most cell types [63.75]. These attributes, along with the fact that it is already in phase I clinical trials as an antitumor agent, make it an excellent candidate for alternative therapies, such as antibacterial, anti-parasitic, antifungal, or antiviral treatments. Caprolactones **(19)** (Fig. 63.4) are new antibiotics isolated from *Streptomyces* sp., which show moderate phytotoxicity and promising activity against cancer cells with concomitant low general cytotoxicity [63.76].

Pure active compounds extracted from the marine actinobacterium, *Salinispora tropica* have shown inhibitory effects in many malignant cell types [63.75]. In particular, salinosporamide A **(20)** (Fig. 63.4) is a novel rare bicyclic beta-lactone gamma-lactam isolated from the obligate marine actinobacterium, *Salinispora tropica* [63.21, 77]. Salinosporamide A is an orally active proteasome inhibitor that induces apoptosis in multiple myeloma cells with mechanisms distinct from the commercial proteasome inhibitor anticancer drug Bortezomib [63.78]. It is being developed by Nereus Pharmaceuticals, Inc. (as NPI-0052) and was scheduled to enter clinical studies for the treatment of cancer in humans in 2006. NPI-0052 is currently being evaluated in multiple phase I trials for solid tumors, lymphoma, and multiple myeloma (http://www.nereuspharm.com/NPI-0052.shtml). NPI-0052 represents the first clinical candidate for the treatment of cancer produced by saline fermentation of an obligate marine actinobacterium [63.79].

63.3.3 Antitumor Activity

Marinomycins **(21)** (Fig. 63.4) are new antitumor antibiotics isolated from *Marinispora* sp. Marinomycins show significant antimicrobial activities against drug resistant bacterial pathogens and demonstrate impressive and selective cancer cell cytotoxicities against six of the eight melanoma cell lines in the National Cancer Institute's 60 cell line panel. The discovery of these new compounds from a new, chemically rich genus further documents that marine actinobacteria are a significant resource for drug discovery [63.17].

Manumycins constitute a class of compounds with antibiotic, cytotoxic, and other biological activities. It has been reported that manumycin A **(22)** (Fig. 63.4) and its analogs inhibit Ras farnesyl transferase and the growth of *Ki*-ras-activated murine fibrosarcoma in mice [63.80]. The side chains in

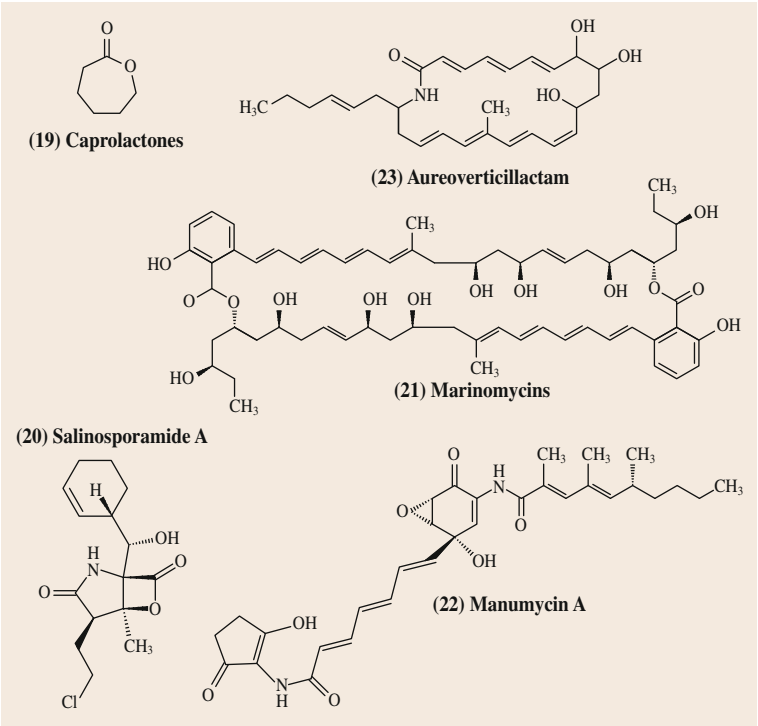

Fig. 63.4 Chemical structures of caprolactones, salinosporamide A, marinomycins, manumycin A, and aureoverticillactam

manumycins appear to be a typical polyketide-derived moiety, differing with respect to their combinations of starter and elongation units. The central cyclohexene ring may be derived from the polyketide as in the case of manumycins or from some modified amino acid-like 3-amino-5-hydroxybenzoic acid. Manumycin A and chinikomycins A and B (the quinone form of chinikomycin A) were isolated from *Streptomyces* sp. M045 derived from the sediments of Jiaozhou Bay in China [63.81].

Aureoverticillactam **(23)** (Fig. 63.4) is a 22-membered macrocyclic lactam produced by *Streptomyces aureoverticillatus* NPS001583 isolated from marine sediments. Aureoverticillactam was found to possess moderate growth inhibitory activity against human colorectal adenocarcinoma HT-29, Jurkat leukemia and mouse melanoma B16F10 cell lines [63.82]. Chinikomycins **(24)** (Fig. 63.5) are two novel antitumor antibiotics isolated from *Streptomyces* sp. They exhibited antitumor activity against different human cancer cell lines, but were inactive in antiviral, antimicrobial, and phytotoxicity test [63.81].

A higher number of type I polyketide-derived compounds with antitumor activity have been isolated from marine actinobacteria. One such compound is arenicolides **(25)** (Fig. 63.5), 26-membered polyunsaturated macrolactones, produced by the obligate marine actinobacteria *Salinispora arenicola* strain CNR-005, isolated from the marine sediments, at a depth of 20 m from the coastal around the island of Guam. In particular, arenicolide A was found to exhibit moderate cytotoxicity toward the human colon adenocarcinoma cell line HCT-116 with an IC_{50} of $30\,\mu g\,mL^{-1}$ [63.83]. Chalcomycin **(26)** (Fig. 63.5), a 16-membered macrolide, is produced by *Streptomyces* sp. M491 isolated from the Qingdao coast (China). Chalcomycin has been found to inhibit protein synthesis in HeLa human cervix carcinoma cell line [63.84, 85]. Glyciapyrroles A **(27)** (Fig. 63.5) is a new pyrrolosesquiterpenes antibiotic isolated from *Streptomyces* sp. (NPS008187). Glyciapyrrole A possesses potent antitumor activity against the pair tumor cell lines at concentration up to 1 mM [63.61].

Aureolic acid **(28)** (Fig. 63.6) (chromomycin B, A_2, and A_3) are a new antitumor antibiotics isolated from *Streptomyces* sp. WBF16. These compounds showed strong cytotoxicity against SGC 7901 (human gastric cancer cell line), HepG2, A549 (human alveolar epithelial cells), HCT116 (human colorectal carcinoma

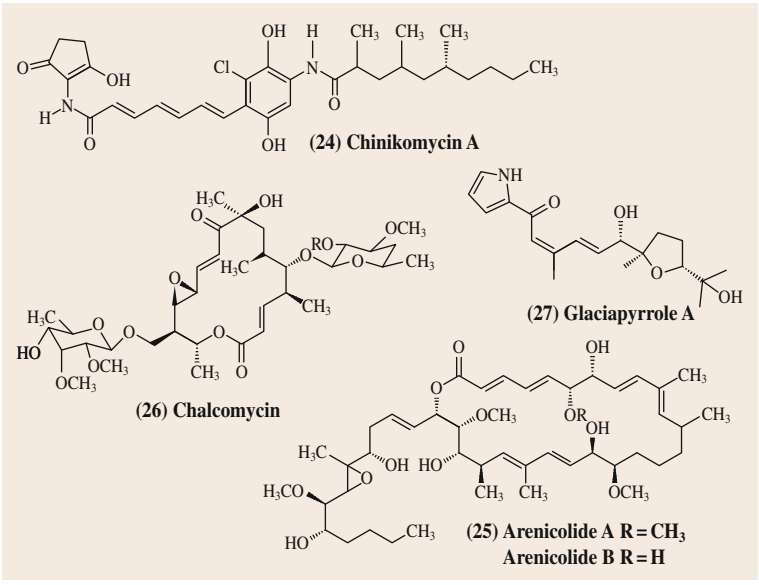

Fig. 63.5 Chemical structures of chinikomycin A, arenicolide A, B, chalcomycin, and glaciapyrrole A

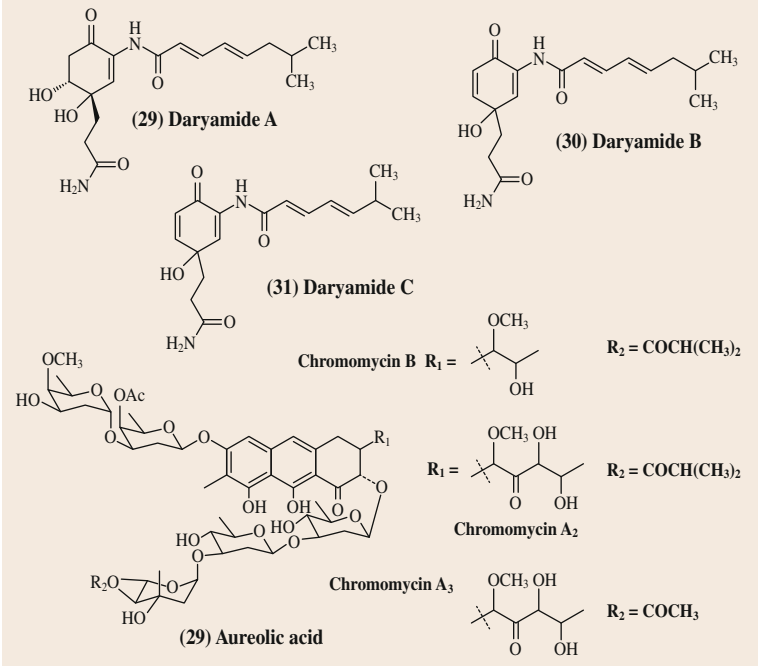

Fig. 63.6 Chemical structure of aureolic acid, daryamide A, B, and C

cell line), and COC1 (human ovarian adenocarcinoma cisplatin-sensitive cell) and HUVEC (human umbilical vein endothelial cells) [63.86]. Daryamides are new antitumor-antibiotics isolated from marine-derived *Streptomyces* strain CNQ-085. Daryamides A **(29)** (Fig. 63.6), B **(30)** and C **(31)** (Fig. 63.6) were subjected to cytotoxicity evaluation against the human colon carcinoma cell line HCT-116. Daryamide A exhibited significantly more potent cancer cell cytotoxicity, with an IC_{50} of 3.15 $\mu g\,mL^{-1}$, than daryamides B, and C and very weak antifungal activity against *Candida albicans* [63.87].

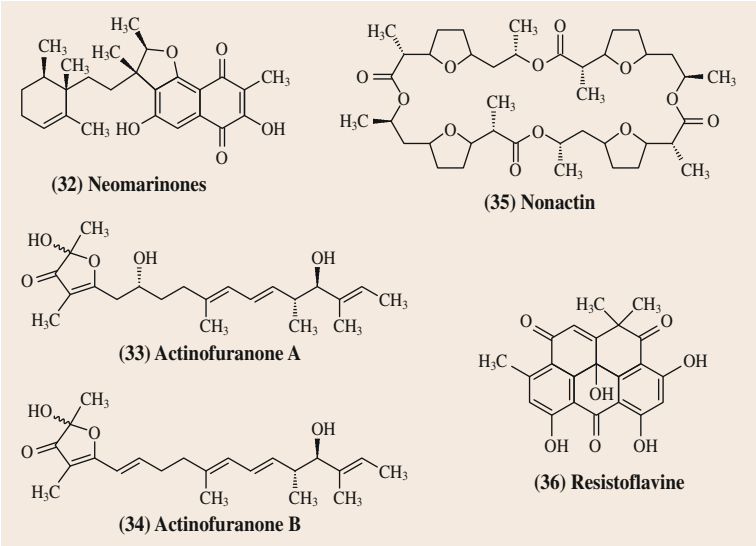

Fig. 63.7 Chemical structure of neomarinones, actinofuranone A, B, nonactin, and resistoflavine

63.3.4 Cytotoxic Activity

Neomarinones **(32)** (Fig. 63.7) are sesquiterpenoid naphthoquinones with a mixed polyketide-terpenoid origin [63.88]. Neomarinone, isomarinone, hydroxydebromomarinone, and methoxydebromomarinone were produced by the actinobacterial isolate CNH-099 obtained from sediments at 1 m depth in the Batiquitos Lagoon, North of San Diego, California. These compounds showed moderate in vitro cytotoxicity, (IC_{50} of 8 $\mu g\,mL^{-1}$) against human colon carcinoma HCT-116 cells. In addition, neomarinone generated a mean IC_{50} value of 10 μM in the NCI's 60 (human tumor cell line) cancer cell line panel [63.89, 90].

Two new polyketides, actinofuranones A **(33)** and B **(34)** (Fig. 63.7), were isolated from the culture extract of a marine-derived *Streptomyces* strain, designated as CNQ766. It showed weak in vitro cytotoxicity against mouse splenocyte T-cells and macrophages with IC_{50} values of 20 $\mu g\,mL^{-1}$ and were inactive against human colon carcinoma HCT-116 cells [63.91]. Nonactin **(35)** (Fig. 63.7), a cyclic polyether also known as macrotetrolide, has been isolated from cultures of *Streptomyces* sp. KORDI-3238, isolated from deep-sea sediments collected at Ayu Trough in the Western Pacific Ocean [63.92]. Biosynthesis of the gene cluster of nonactin has previously been isolated and characterized from *Streptomyces griseus* DSM40695 [63.93], revealing that it is synthesized by a non-iteratively acting type II PKS that involves five ketosynthases and lacks the acyl carrier protein. Nonactin exhibited significant cytotoxicity against the multidrug-resistant human erythroleukemia cell line K-562 [63.94]. Resistoflavine **(36)** (Fig. 63.7) is a cytotoxic compound, isolated from *Streptomyces chibaensis* AUBN$_1$/7. It showed cytotoxic activity against human gastric adenocarcinoma HMO2 and hepatic carcinoma HePG2 cell lines [63.95].

Lucentamycins **(37)** (Fig. 63.8), 3-methyl-4-ethylideneproline-containing peptides, are produced by *Nocardiopsis lucentensis* strain CNR-712, isolated from the sediments of a shallow saline pond from the island of Little San Salvador, in the Bahamas. Lucentamycins A and B showed significant in vitro cytotoxicity against the human colon carcinoma HCT-116 cell line with IC_{50} values of 0.20 and 11 μM, respectively. However, lucentamycins C and D were not cytotoxic in the same assay, suggesting that the presence of an aromatic ring is essential for the biological activity of this class of compounds [63.96].

Two new cytotoxic antibiotics, piericidins C7 and C8 **(38)** (Fig. 63.8), were isolated from a marine *Streptomyces* sp. [63.97]. The biological activity of piericidins was examined using rat glial cells transformed with the adenovirus E1A gene (RG-E1A-7), neuro-2a mouse neuroblastoma cells, C6 rat glioma cells, and 3Y1 rat normal fibroblast. The adenovirus E1A gene product inactivated the retinoblastoma tumor suppressor protein that plays an important role in cell-cycle and apoptosis control in mammalian cells and is inactivated during the development of

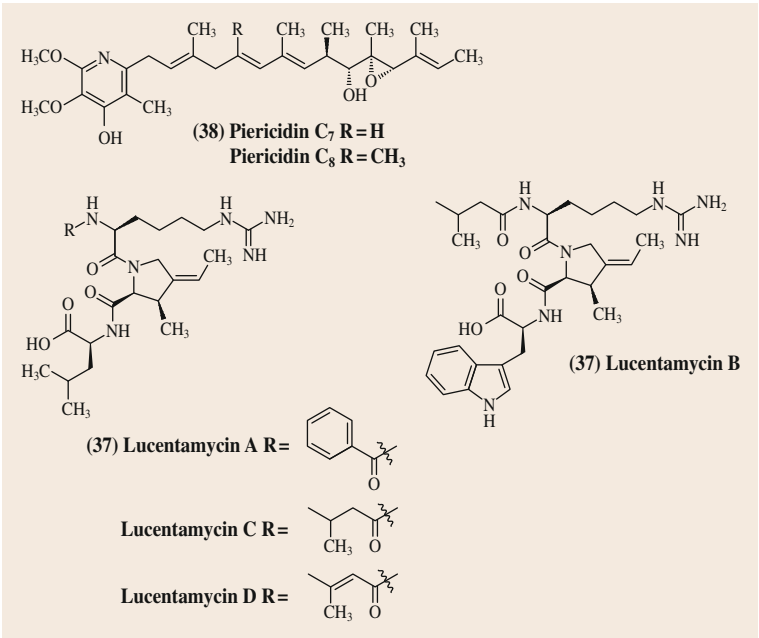

Fig. 63.8 Chemical structures of lucentamycin A, B, C, D, piericidin

a wide variety of cancers [63.98]. Piericidins C7 and C8 showed selective cytotoxicity against RG-E1A-7 cells (IC_{50} of 1.5 nM and 0.45 nM, respectively), and inhibited the growth of neuro-2a cells (IC_{50} of 0.83 nM and 0.21 nM, respectively) without cytotoxic cell death. On the other hand, C6 rat glioma cells and 3Y1 rat normal fibroblast were not affected by piericidins [63.99].

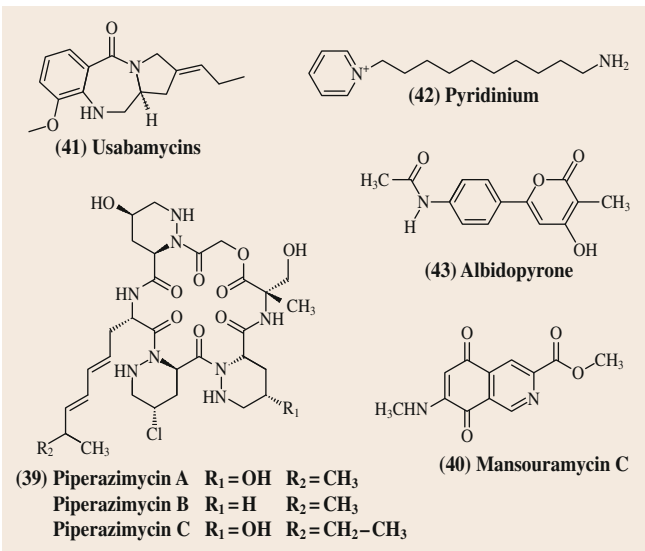

Fig. 63.9 Chemical structures of piperazimycin A, B, C, mansouramycin C, usabamycins, prydinium, and albidopyrone

Piperazimycins **(39)** (Fig. 63.9) are cyclic hexadepsipeptides isolated from the fermentation broth of a *Streptomyces* sp. strain CNQ-593, isolated from marine sediments at a depth of approximately 20 m near the island of Guam. Cytotoxic activities of piperazimycins were initially evaluated in vitro against the human colon carcinoma HCT-116 cell line. All compounds exhibited significant cytotoxicity with an average GI_{50} of 76 ng mL for each. Piperazimycin A also showed potent biological activity when evaluated against the NCI's cancer cell line panel, with mean GI_{50} (growth inhibition), total growth inhibition (TGI) and lethal concentration (LC_{50}) values for all the cell lines of 100 nM, 300 nM, and 2 μM, respectively. Overall, piperazimycin A exhibited a nearly threefold more potent activity against solid tumors (average LC_{50} of 13.9 μM) than against the leukemia cell lines tested (average LC_{50} of 31.4 μM). It was most active against the melanoma (average LC_{50} of 0.3 μM), central nervous system (average LC_{50} of 0.4 μM) and prostate cell lines (average LC_{50} of 0.6 μM) cancers [63.100]. Mansouramycin C **(40)** (Fig. 63.9) is an isoquinolinequinones antibiotic isolated from *Streptomyces* sp. Cytotoxicity profiling of mansouramycins in a panel of up to 36 tumor cell lines indicated significant cytotoxicity of several derivatives, with pronounced se-

lectivity for non-small cell lung cancer, breast cancer, melanoma, and prostate cancer cells [63.101].

Usabamycins **(41)** (Fig. 63.9) are new anthramycin-type analogs isolated from *Streptomyces* sp. NPS853. Usabamycins show weak inhibition of HeLa cell growth and selective inhibition of serotonin (5-hydroxytrypamine) 5-HT_{2B} uptake [63.102]. Pyridinium **(42)** (Fig. 63.9) is a salt antibiotic isolated from *Amycolatopsis alba*. The compound showed potent cytotoxic activity against cancer cell lines of cervix (HeLa), breast (MCF-7), and brain (U87MG) in vitro and also exhibited antibacterial activity against Gram-positive and Gram-negative bacteria [63.103]. This new α-pyrone containing secondary metabolite was detected by high-performance liquid chromatography with diode-array detection (HPLC-DAD) analysis in a culture filtrate extract of *Streptomyces* sp. NTK 227, a strain isolated from Atlantic Ocean sediments and found to be a member of the *Streptomyces albidoflavus* 16S ribosomal ribonucleic acid (rRNA) gene clade. Albidopyrone **(43)** (Fig. 63.9) showed moderate inhibitory activity against protein-tyrosine phosphatase B [63.104].

Four new polyketides, salinipyrones A **(44)** (Fig. 63.10) and B **(45)** (Fig. 63.10), and pacificanones A **(46)** and B **(47)** (Fig. 63.10) have been isolated from cultures of the obligate marine actinobacteria *Salinispora pacifica* CNS-237, found in the sediments collected from the Palau island, Western Pacific Ocean. The biological activity of these compounds is currently being examined in diverse bioassays. In the initial screening, salinipyrones and pacificanones displayed no significant activity in a cancer cytotoxicity assay using HCT-116 human colon cancer cells. In an isolated mouse splenocyte model of allergic inflammation, salinipyrone A displayed moderate inhibition of interleukin-5 production by 50% at 10 $\mu g\,mL^{-1}$ without measurable human cell cytotoxicity [63.105].

Three new cyclohexadepsipeptides, arenamides A **(48)** (Fig. 63.10), were isolated from the fermentation broth of a marine actinobacterial strain identified as *Salinipora arenicola* CNT-088, which was obtained from the marine sediments at a depth of 20 m off the Great Astrolab Reef, in the Kandavu Island chain, Fiji. Arenamides A and B exhibited weak in vitro cytotoxicity against human colon carcinoma HCT-116 with IC_{50} values of 13.2 and 19.2 $\mu g\,mL^{-1}$, respectively [63.106]. In addition, arenamides have been associated with chemoprevention of carcinogenesis by suppression of NF-κB activation. NF-κB regulates the expression of a number of genes, the products of which are involved in tumorigenesis [63.107, 108]. The effect of arenamides on NF-κB activity was studied with stably transfected 293/NF-κB-Luc human embryonic kidney cells, induced by treatment with a tumor necrosis factor (TNF). Arenamides A and B blocked TNF-induced activation in a dose and time-dependent manner with IC_{50} values of 3.7 and 1.7 μM, respectively [63.106].

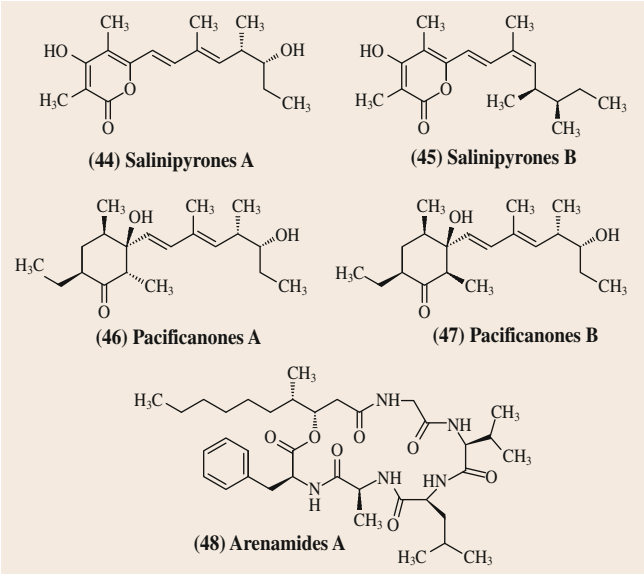

Fig. 63.10 Chemical structure of Salinipyrones A, B, Pacificanones A, B and Arenamides A

63.4 Conclusion

The marine environment has a vast biological diversity and has been recognized as a potential source of a large number of novel chemical entities. Bioactive substances derived from marine actinobacteria are just beginning to be realized. In order to improve the future exploitation of bioactive substances from marine actinobacteria and to make the process technically and economically feasible, there are numerous parameters to follow, and these include the application of appropriate isolation media (with optimal salinity, pressure, temperature, and nutrient concentration) for the various sources from the depths of the ocean and primary screening of the

fermentation broth extracts using classical methods to define the metabolites combined with techniques such as high pressure liquid chromatography with diode array detection ((HPLC–DAD)) for metabolite profiling, structural information through mass spectrometry and nuclear magnetic resonance (NMR) and two-dimensional (2-D)NMR spectra arrays.

Recent culture-independent studies [63.14] have shown that the marine environment still contains a high diversity of rare actinomycetes. Culture-independent studies of the presence and distribution of marine actinomycetes in the samples and the information obtained from these studies have also been used to design selective isolation schemes enabling successful isolation of a wide variety of marine actinomycetes including novel taxa from the same environmental samples [63.24]. Therefore, the adaptation of more efficient techniques [63.109] for the screening of new chemical compounds in the marine ecosystem and an understanding of the biology, ecology, taxonomy, and chemical biology of actinomycetes combined with polyphasic taxonomy and advanced molecular techniques [63.109] will provide detailed information on the taxonomy, ecology and chemical characteristics of uncultivable or rare actinomycetes. The development of methods for the culture of currently unculturable or rare marine actinomycetes would represent a unique and promising source for the discovery of novel secondary metabolites. It is clear from the analysis of the low or rare diversity marine actinomycete taxon (the genus *Salinispora*) that patterns of secondary-metabolite production are highly complex and that molecular studies can improve the drug discovery process.

64. Marine Microbial Biosurfactins

Jen-Leih Wu, Jenn-Kan Lu

The marine biosphere offers a wealth of flora and fauna and represents a vast natural resource of imperative functional commercial-grade products. Marine bacterial natural products are predicted to become an important resource for drug discovery and enzyme mining. Among the various bioactive compounds, biosurfactants (BS) are attracting major interest and attention due to their structural and functional diversity. New techniques for the isolation of these marine bacteria are opening the possibility for the isolation of novel and potential products and processes from them. This will also help to improve our understanding of marine bacterial physiology, genetics, biochemistry, and ecology in order to provide model systems for research and production systems for commerce, and to contribute to understanding and conservation of the seas. The recent discovery of new secondary metabolites from novel bacteria and new approaches for accessing gene products from marine bacteria are contributing to the increasing development of the field. Here, we discuss the role and applications of marine microbial biosurfactants, focusing on applications for cosmeceutical and nutraceutical industry perspectives. Nutraceuticals are food products that provide health as well as medical benefits, including the prevention and treatment of disease. Few nutraceuticals are being used as pharmaceuticals and a number of others are being used and purchased by the general public as self-medication. This article outlines biosurfactants as a novel nutraceutical with their therapeutic and cosmeceutical applications.

64.1 Overview

64.1.1 Introduction to Marine Microbial Biosurfactants

The marine environment offers a wealth of flora and fauna, which represents a vast natural resource of imperative functional commercial-grade products. Marine bacteria comprise a comparatively untapped reservoir of commercially valuable antimicrobial substances. Marine bacteria provide a luxuriant resource for screening new drugs, and several of these agents are in the process of entering clinical trials. The development of marine compounds as therapeutic agents is still in its infancy due to the lack of an analogous ethno-medical history as compared with terrestrial habitats. Over the

last few decades, significant efforts have been made, by both pharmaceutical companies and academic institutions, to isolate and identify new marine-derived, natural products. Specific programs directed towards the collection and characterization of marine natural products and evaluation of their biological activity has been established.

A surfactant is an amphiphilic agent with both lipophilic and hydrophilic structural moieties in its molecule. Surfactants are widely used in industrial, agricultural, food, cosmetic and pharmaceutical applications. Most of these compounds are chemically synthesized and potentially cause environmentally and toxically problems [64.1]. However, it is only in the past few decades that surface active molecules of microbial origin, referred to as biosurfactants, have gained considerable interest [64.2, 3].

Among the various marine bioactive compounds, BS are attracting major interest and attention due to their structural and functional diversity. The features that make biosurfactants commercially promising alternatives to chemically synthesized surfactants are their lower toxicity, higher biodegradability, and hence, greater environmental compatibility and better foaming properties (which are useful in mineral processing). Also unlike most synthetic surfactants, many biosurfactants function effectively in extreme conditions of pH, temperature, and salinity [64.13–19]. Some biosurfactants produced by certain species of bacteria and yeasts also exhibit effective antimicrobial, antifungal [64.20–23], antiviral, moisturizing, and antioxidant properties. Some biosurfactants have demonstrated they are potentially useful surface-active agents for emulsion [64.24–26] in various industrial processes. Moreover, they can be used for emulsification, foaming, water binding capacity, phase dispersion, de-emulsification component, and the effect of their wetting properties on viscosity and on product consistency. Thus they can be efficiently utilized by the cosmetics industry [64.27, 28]. In pharmaceutics, biosurfactants can be used for gene delivery and recovery of intracellular products. They can also serve as antimicrobial substances and emulsifying agents. The discovery of potent BS/BE (BE: bioemulsifer) producing marine microorganisms would enhance the use of environmental biodegradable surface active molecules and hopefully reduce total dependence or the number of new applications oriented towards the chemical synthetic surfactant industry (Table 64.1). The surfactant industry exceeds US$ 9 million per year. Although most are of petrochemical origin, biosurfactants are gaining importance and need to compete with chemical surfactants with respect to cost, functionality, and production capacity to meet the demand. This review provides a general overview with respect to biosynthesis, fermentative production, purification, analytical methods, and applications of surfactin (SF), an important lipopeptide type biosurfactant produced by various strains of *Bacillus subtilis*.

64.2 Methodology of Production of Marine Biosurfactants

Surfactants are amphiphilic molecules that preferentially partition at the interface between two fluid phases. In addition to lowering interfacial tension, the interfacial tension can have an impact on the interfacial rheological behavior and mass transfer. Due to these properties, surfactants are gaining importance in various industrial applications such as foam creation and stabilization in food processing, detergents for household cleaning, phase dispersion for cosmetics and textiles, or solubilization of agrochemicals. Numerous attempts have been made to reduce the cost of the production of biosurfactants. Various strategies have

been implemented to achieve improved biosurfactant production such as strain improvement, medium optimization, bioreactor design, or using agro-industrial wastes for fermentation to reduce the raw material cost.

64.2.1 Biosynthesis of Surfactins

High-Yield Mutant Biosurfactant

Surfactin was discovered by *Arima* et al. [64.29] from the culture broth of *Bacillus subtilis*. It was named thus due to its exceptional surfactant activity. Natural SFs are a mixture of isoforms A, B, C, and D with various physiological properties obtained from *B. subtilis*. They contain at least 8 depsipeptides with the number of carbon atoms between 13 and 16 as part of the ring system. Surfactin was initially identified as a potent inhibitor of fibrin clot and later found to lyse erythrocytes, protoplasts, and spheroplasts. Surfactin is a very powerful bio-surfactant; it lowers the surface tension of water from 72–27 $mN\,m^{-1}$ [64.30].

A large number of bioactive oligopeptides are produced by bacteria and fungi through a unique nonribosomal mechanism. Large modular enzymes, referred to as nonribosomal peptide synthetases, catalyze the biosynthesis of these low molecular mass peptides. All these multimodular enzymatic assemblies carry out acyl chain initiation, elongation, and chain termination, catalyzed by the protein molecules. Studies on the biosynthesis of SF began with the work of *Kluge* et al. [64.31], who proposed a nonribosomal mechanism catalyzed by multi-enzymatic thiotemplates constituting the SF synthetase. The SF synthetase complex consists of four enzymatic subunits. Three of these are enzymes SrfA (E1A, 402 kDa), SrfB (E1B, 401 kDa), SrfC (E2, 144 kDa), and the fourth is SrfD (E3, 40 kDa), which plays an important role in the SF initiation reaction [64.30, 32].

Production Strain

The bioindustrial production process is highly dependent on hyperproducing strains. Organisms that produce the final product in high concentrations are preferred, and the genetics of the producing organism is important. Apart from natural biosurfactant-producing strains, a few mutants [64.33] and recombinant strains have been reported in literature (Table 64.2). The recombinant strains of *B. subtilis* ATCC 21332 produced a lipohexapeptide, which showed less toxicity towards erythrocytes and enhanced lysis of *B. licheniformis* cells, making it useful for therapeutic applications [64.34, 35]. Thus, recombination strains not only improved the production but also gave better product characteristics.

64.2.2 Fermentative Production of Surfactin

Commercialization of any biotechnological product depends on its bioprocess economics. Although a large number of biosurfactant producers have been reported in the literature, the product enhancement has been restricted to a few organisms such as Bacillius, Pseudomonas, and Candida. Both submerged fermentation (SMF) and solid-state fermentation (SSF) have been tried for SF production [64.38].

Surfactin Production by Submerged Fermentation (SMF)

Several approaches have been tried to improve the SF yield at both flask level and fermenter level by changing environmental parameters and optimizing medium components or trace elements (Table 64.3) [64.29, 40, 41].

Surfactin Production by Solid-State Fermentation (SSF)

A cost-effective approach to produce biosurfactants is to use inexpensive raw materials, which accounts for 10–30% of the production cost. *Thompson* et al. [64.44] used high-solid (HS) and low-solid (LS) potato effluents for SF production. The growth rate of *B. subtilis* 21332 was higher in all HS and LS-based media, although the SF production was better in LS ($0.39\,g\,L^{-1}$) media compared to HS media ($0.097\,g\,L^{-1}$). The recombinant *B. subtilis* MI113 and the original strain of *B. subtilis* RB14 were also checked for their SF-producing capacity in both SSF and SMF methods [64.34, 35], a maximum of $1.8–2.0\,g\,kg^{-1}$ of SF wet mass was achieved by *B. subtilis* MI113 at 37 °C and 48 h. Among the factors affecting the results obtained in SSF processes, the moisture content of the fermenting medium plays an important role. Depending on the process, the moisture content must be maintained in a given optimum interval in order to obtain the desired results. In order to obtain higher productivity of SF, we employed a *B. subtilis* mutant strain and a semi-solid state cultivation method and used soybean as substrate. To avoid antifoaming agent interference with SF purity from the culture broth in the subsequent purification process and to improve the homogenous distribution of nutrients surrounding the substrates and initial moisture content, the semi-solid state cultivation

Table 64.2 Mutant and recombinant strains of *B. subtilis* with enhanced biosurfactant yield and improved product characteristics (after [64.36])

Mutant/recombinant strain	Characteristic feature	Yield or improved production property	References
B. subtilis ATCC 55033	Random mutagenesis with *N*-methyl-*N′*-nitro-*N*-nitrosoguanidine	Approximately 4–6 times (2–4 g L^{-1} crude SF)	[64.33, 37]
B. subtilis Th1	Random mutagenesis with ethidium bromide & UV	Approximately 3–4 times (5–7 g L^{-1} crude SF)	*Wu* and *Lu* (unpublished data)
Recombinant *B. subtilis* MI113	Incorporation of a plasmid containing *Ipa-14* gene	8 Times more SF production	[64.34]
B. subtilis SD901	Random mutagenesis with *N*-methyl-*N′*-nitro-*N*-nitrosoguanidine	4–25 Times more SF production (8–50 g L^{-1})	[64.38]
Recombinant *B. subtilis* ATCC 21332	Contains recombinantly modified peptide synthetase	Production of lipohexapeptide with reduced toxicity	[64.39]

process was carried out in a fermentative tray containing a 30% enriched MS medium. A high yield of SF biomass was achieved by SSSF. These yields were about 7.6 g kg^{-1} higher than the yield by SSF and SMF methods. In addition, after fermentation and removal of the crude biosurfactant biomass by a rinse process, the fermented soybean substrate can be re-utilized as modified raw material for soya for food or feed products.

64.2.3 Recovery of Biosurfactants

The recovery and concentration of biosurfactants account for a major portion of the total production cost. The separation strategies for biosurfactants vary according to the fermentation process and the physicochemical properties of the surfactant in question. The selection of a method for purification and recovery of surfactants depends on the nature of their charge, solubility characteristics, whether the product is intracellular or extracellular, and on the economics of recovery and downstream processing (Table 64.4) [64.45].

64.2.4 Identification of Biosurfactants

Chemical and structural analysis of lipopeptides is carried out using a broad range of techniques varying from simple colorimetric assays to sophisticated mass spectrometry (MS) and sequencing techniques. After extraction, the purification procedures of lipopeptides include chromatography methods (thin layer chro-

Table 64.4 Biosurfactant recovery methods and their advantages (adapted from [64.46])

Downstream recovery procedure	Biosurfactant property responsible for separation	Advantages	References
Acid precipitation	Biosurfactants become insoluble at low pH values	Low cost, efficient in crude biosurfactant recovery	[64.47]
Organic solvent extraction	Biosurfactants are soluble in organic solvents due to the presence of hydrophobic end	Efficient in crude biosurfactant recovery and partial purification, reusable nature	[64.48–50], *Wu* and *Lu* (unpublished data)
Ammonium sulfate precipitation	Salting-out of the polymeric or protein rich biosurfactant	Effective in isolation of certain type of polymeric biosurfactants	[64.51]
Centrifugation	Insoluble biosurfactants get precipitated because of centrifugal force	Reusable, effective in crude biosurfactant recovery	[64.52]
Foam fractionation	Biosurfactants, due to surface activity, form and partition into foam	Useful in continuous recovery procedures, high purity of product	[64.53]
Membrane ultrafiltration	Biosurfactants form micelles above their critical micelle concentration (CMC), which are trapped by polymeric membranes	Fast, one-step recovery, high level of purity	[64.54]
Adsorption on polystyrene resins	Biosurfactants are adsorbed on polymer resins and subsequently desorbed with organic solvents	Fast, one-step recovery, high level of purity, reusability	[64.48]
Adsorption on wood-activated carbon	Biosurfactants are adsorbed on activated carbon and can be desorbed using organic solvent	Highly pure biosurfactants, cheaper, reusability, recovery from continuous culture	[64.47]
Ion-exchange chromatography	Charged biosurfactants are attached to ion-exchange resins and can be eluted with proper buffer	High purity, reusability, fast recovery	[64.48]

matography (TLC) ion exchange chromatography and reversed phase high performance (RP-HPLC)). Each step of the purification will be monitored by bioassays. The bioassays could be bioautographic methods or dual culture plate [64.45, 55]. Generally, identification of the relative percentage of the lipid and protein portions is carried out using simple colorimetric assays, such as the ultraviolet absorbance spectrum and Bradford assay for protein determination, and spectroscopic methods (FTIR: Fourier transform infrared spectroscopy). The determination of the molecular mass of the compounds of interest may be facilitated by mass spectrometry using assisted laser desorption ionization time of flight mass spectrometry (MALDI-TOF MS). This should be followed by analysis of the fatty acid portion and determination of the peptide sequence using automated Edman degradation sequencing. This combined approach would provide the necessary information required for complete structural identification [64.55].

64.3 Applications of Marine Bioactive Biosurfactants

64.3.1 Biosurfactants in the Cosmeceutical Industry

Cosmetic products using surfactants include: insect repellents, antacids, bath products, acne pads, antidandruff products, contact lens solution, hair colors and care products, deodorants, nail care products, body massage accessories, lipsticks, lip makers, eye shadows, mascaras, soap, tooth pastes and polishes, denture cleansers, adhesives, antiperspirants, lubricated condoms, baby products, foot care products, mousses, antiseptics, shampoos, conditioners, shaving and depilatory products, moisturizers, and health and beauty products [64.1]. All of these applications could be replaced by using biosurfactants. Moreover, biosurfactants as emulsifiers, foaming agents, solubilizers, wetting agents, cleansers, antimicrobial agents, mediators of enzyme action in various dosage forms like creams, lotions, liquids, pastes, powders, sticks, gels, films, sprays could be used and may be replaced by biosurfactants [64.56, 57].

Cosmetics with a petroleum base may contain cancer-causing impurities. Biosurfactants are not derived from petroleum and will not have those impurities. Biosurfactants have mild toxicity and are easily biodegradable compared to synthetic surfactants. They are low or have anti-irritancy effects and are compatible with skin. Cosmetic ingredients can be contaminated with the cancer-causing impurity 1,4-dioxane, which penetrates the skin. It is considered to be a carcinogen. Those impurities of petroleum-based ingredients are found in trace amounts in products such as facial moisturizers, anti-aging products, body lotion, eye creams, hair products (relaxers, dyes, bleaches, removers), baby soap, sunless tanning products, and body firming lotion.

Marine Biosurfactants as Natural Antibiotics and Preservatives

To keep products like cleansers, hand soaps, moisturizers and toothpaste free from bacteria, parabens are used as a preservative in cosmetics. A recent study found that parabens can mimic natural hormones, including estrogen. Disruption of sex hormones may increase the risk of certain cancers. Parabens have been found in breast cancer tissue, although it is not known if the parabens caused the cancer [64.58]. Hydroquinone is banned in parts of Europe, but not in the US, as a cancer risk [64.59]. It is still used in hair dye and skin fresheners in under 2% concentrations. Formaldehyde and acrylamide are both carcinogens and irritants and are also used in cosmetics. Allergies to cosmetic products can be due to chemicals such as man-made synthetics. This can lead to a skin rash where the product is applied. If an allergy to a cosmetic product is suspected, it is important to determine which ingredients may be causing the problem.

The diverse structures of biosurfactants confer them to display versatile performance [64.60, 61]. By its structure, a biosurfactant is supposed to exert its toxicity on the permeability of the cell membrane as a detergent-like effect. A useful property of many biosurfactants is their antimicrobial activity [64.62]. Several biosurfactants have shown antimicrobial action against bacteria, fungi, algae, and viruses. A rhamnolipid mixture obtained from *Pseudomonas aeruginosa* AT10 showed inhibitory activity against the bacteria *Escherichia coli*, *Micrococcus luteus, Alcaligenes faecalis* (32 mg ml^{-1}), *Serratia arcescens*, *Mycobacterium phlei* (16 mg ml^{-1}), and *Staphylococcus epidermidis* (8 mg ml^{-1}) and excellent antifungal properties against *Aspergillus niger* (16 mg ml^{-1}), C*haetonium globosum, Enicillium crysogenum*, and *Aureobasidium pullulans* (32 mg ml^{-1}) [64.63]. Our study also indicated that marine SF is an effective substance against Gram-negative bacteria, Gram-positive bacteria (such as *Propionibacterium acnes* and *S. epidermidis*), and fungi [64.64]. *Das* et al. [64.65] reported a biosurfactant produced by marine *Bacillus circulans* that had a potent antimicrobial activity against Gram-positive and Gram-negative pathogenic and semi-pathogenic microbial strains, including multi-drug resistant (MDR). The main trump of surfactins is that they are natural compounds.

Biosurfactants in Acne Treatment

Staphylococci are the most abundant skin-colonizing bacteria and the most important causes of nosocomial infections and community-associated skin infections. Acne is the most common skin disorder of adolescence and early adulthood with a prevalence of approximately 85%. Several marine biosurfactants have a strong inhibitory effect on *P. acnes* and *S. epidermidis*. The minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) values were the same (36 μM) for both bacterial species against *P. acnes* and *S. epidermidis*, respectively [64.64, 66]. In response to *P. acnes* and inflammation, the biosurfactants have the ability not only to kill *P. acnes* but also to significantly

reduce its inflammatory potential. Therefore, marine biosurfactants would be an interesting topic for further study and possibly for an alternative treatment for acne. The data presented here illustrate that marine biosurfactants have great potential as a broad-spectrum anti-infective and anti-inflammatory therapeutic for alternative treatment of dermatological conditions such as acne vulgaris and atopic dermatitis, and potential in the preservation of cosmetic preparations. The advantages of using biosurfactants as cosmetic preservatives is not only their strong spectrum and rapid cidality against wide spectrum pathogens, but also that they do not engender resistance and are not cross-resistant with other mechanisms of action. Biosurfactants have the potential to provide significant clinical benefits.

Biosurfactants as Natural Emulsifiers

Marine microorganisms such as *Acinetobacter*, *Arthrobacter*, *Pseudomonas*, *Halomonas*, *Myroides*, *Corynebacteria*, *Bacillus*, and *Alteromonas* sp. have been studied for the production of BS/BE. We are currently testing the influence of pH, temperature, and SF from *B. subutilis* spp. on emulsifier stability from diesel oil in water and common cosmetic oils in water. Results have shown that SF has emulsion activity for diesel and common cosmetic synthetic oils when dissolved (4–40 μg/ml) in saline solution and its emulsion activity remains half at 60 °C [64.64, 66].

Biosurfactants as Foaming Agents and Skin Cleansing Cosmetics

There is a growing market for formulating proteins into a wide variety of products, including laundry detergents, bath soap, conditioning shampoo, and cream hand cleanser. Foams are formed by a bubbling technique. The excellent foaming properties of SF were shown by its high ability to form density and stabilize the foam at concentrations as low as 0.05 mg mL^{-1}, in comparison with major detergents such as, sodium dodecyl sulfate (SDS), sodium laureth sulfate (SLS), disodium lauryl sulfosuccinate (DSLSS), and bovine serum albumin (BSA) where it provides good detergency combined with an excellent wetting ability [64.67]. Furthermore, SF containing a lipidic chain length of 14 carbon atoms provides lipopeptides with the best foaming properties in terms of foam density and liquid stability in foams. We are currently testing marine and aquatic biosurfactants used to partially replace detergents; they not only retained excellent foaming properties but also exhibited enhanced emulsifying properties (Table 64.3) [64.66]. These results indicate that marine biosurfactants may be used in laundry and cosmetic products to fulfill market demands.

Biosurfactants as detergents can be used advantageously to stabilize membrane proteins in the absence of a phospholipid bilayer in a manner that preserves the native conformation and permits subsequent crystallization. Cleansing cosmetics containing biosurfactants exhibit excellent washability with extremely low skin irritation. Moreover, skin moisturizing and cleansing cosmetics have been prepared in oily gel with high stability [64.68, 69].

Biosurfactant-Mediated Transdermal Drug Delivery

Transdermal drug delivery (TDD) is gaining prominence over other forms of drug delivery due to its potential advantages, such as minimal trauma induction, noninvasiveness, reduction of the enzymatic degradation associated with oral delivery, increased patient compliance, and potential for continuous, controlled delivery [64.70]. Consequently, in recent years, numerous transdermal products have been introduced into the market. The current US market for transdermal patches is over US$3 billion, and annual sales worldwide are estimated to be US$31.5 billion by 2015. The world-wide transdermal drug delivery market is quite large, but only a small number of agents have Food and Drug Administration (FDA) approval. The primary reason for such a limited development of this market is the difficulty in permeating the stratum corneum (SC) layer of human skin, which is the outermost layer of skin.

Drug delivery via the skin is not a simple task; the SC, is a formidable barrier both to water transport out of the body and to inward chemical permeation [64.71]. The SC is composed of keratin-filled, nonviable cells (corneocytes) embedded in a crystalline intercellular lipid domain. These intercellular lipids compose the continuous domain of the SC and provide its primary barrier properties. Two main pathways for transdermal penetration are normally considered (although additional alternative pathways are proposed either via the SC through the intercellular lipid lamellae or through cutaneous appendages, i. e., hair follicles and sweat glands [64.72, 73]. It is generally assumed that, under normal circumstances, the predominant route is through the intercellular spaces in the SC.

Numerous methods have been suggested to overcome the skin barrier for transdermal drug delivery. Chemical penetration enhancement methods have received the most attention, where addition of various

chemical agents, such as fatty acids, fatty esters, alcohols, terpenes, pyrrolidones, sulfoxides, and surfactants, has been tested to increase skin permeability. However, few have succeeded in delivering the relevant agents at the appropriate flux levels without causing notable skin irritation or damage [64.74, 75].

Enhancement of Penetration of Drugs and Moisturizers Through the Skin

Membrane destabilization is a key mechanism of action of SF. A conformational change in the peptide chain facilitates hydrophobic interaction, which leads to penetration of the membrane by SF [64.76–78]. Adequate penetration may occur at low concentrations ($\approx 20\,\mu\text{mol}\,\text{L}^{-1}$) and SF may be completely miscible with the phospholipids forming mixed micelles [64.79]. We have demonstrated that the lipophilic SF is capable of entrapping hydrophobic and hydrophilic drugs and increasing skin penetration of drugs (i. e., dexamethasone) and cosmetic moisturizers such as hyaluronic acid (HA) and γ-polyglutamic acid (γ-PGA) [64.64].

Enhancement of the Penetration of Gold Nanoparticles Through Skin SC and Rejuvenation of Skin

Egyptians believed that the healing powers of gold could cure all manner of physical, mental, and spiritual ailments. Romans used gold preparations for the treatment of skin lesions and sores. In ancient Chinese medicine, gold was the secret to youthful skin. The application of gold compounds to medicine, called chrysotherapy, reduces inflammation, which is beneficial in the treatment of a variety of diseases. However, this therapy often causes adverse gold-related skin reactions. Many luxury spas use 24-carat gold leaf treatments to hydrate, firm, and moisturize the skin, claiming reduced fine lines and wrinkles and resulting in smooth and radiant skin. Gold leaf also had been used for ischemic skin ulcer treatment [64.87]. The dermal application of drugs is promising due to the ease of application. In this context, nanoscale carrier systems have already been evaluated in several studies with respect to skin interaction and the impact on drug penetration. However, the data obtained do not show a clear image of the effect of nanocarriers. Especially the penetration of such particles is an open and controversially discussed topic [64.88, 89]. We are currently testing that nanogold particles using SFs as transdermal carrier can enhance penetration of Au-NP through skin SC of BALB/c (an albino, laboratory-bred strain of the House Mouse) mouse skin (Fig. 64.1). After permeation, Au-NP transformed fibroblast with multiplications of mRAN in keratinocyte growth factor (KGF) and epidermal growth factor (EGF). The application of nanogold effected the indication of balance for superoxide dismutase (SOD), metallothionein, and EGF indirectly. SOD can eliminate hydroxyl-free radicals, while metallothionein resisted skin cell damage from ultra-violet rays to achieve an anti-aging effect.

Antiwrinkle, Anti-Aging, and Rejuvenation Effects of Biosurfactants

Peptides have become very important ingredients in cosmetic products, especially in anti-aging preparations. According to their mode of action, they have been divided into three main groups: signal peptides, neurotransmitter-affecting peptides, and carrier peptides. These small sequence amino acid chains are being incorporated in cosmetic formulas to improve the signs of aging skin (Table 64.5). Chronologically aged skin demonstrates lower procollagen type I messenger ribonucleic acid (RNA) and protein, resulting in decreased production of new collagen. In addition, aging skin, and particularly aging skin that is exposed to ultraviolet (UV) light, overexpresses the proteolytic activity of the matrix metalloproteinase-1, also known as interstitial collagenase. Additionally, aging fibroblasts have a lower rate of proliferation than fetal fibroblasts [64.90]. Much of the research demonstrating the role of amino acids and peptides in reversing the cutaneous signs of aging has been a secondary benefit of research on wound healing. These peptides are small sequence amino acid chains that may stimulate angiogenesis, production of granulation tissue, and new collagen synthesis.

However, proteins and peptides are hydrophilic and are often charged molecules at physiological pH. They range in molecular weight from small peptides as small as 300 Da to proteins of size greater than 1000 kDa. These properties result in poor skin permeation and despite generally having high potency, most are therapeutically ineffective if administered transdermally because of this poor permeation. To overcome the skin barrier and facilitate the permeation of biodrugs through the skin, a number of skin penetration enhancement techniques have been investigated. Formulation and chemical enhancement techniques have potential for the local delivery of small peptides for dermatological and cosmetic applications [64.74]. The effectiveness of coupling tetrapeptide linked with a short hydrocarbon chain can enhance transepidermal delivery of protein inhibitors [64.75]. It has been demonstrated that

Table 64.5 Cosmeceutical peptides for anti-aging and antiwrinkle effects (after [64.80])

Name	Indication of topical use	Suggested Functions in cosmetic products	Efficacy	Reference
Acetyl hexapeptide-3 (Argireline)	Skin conditioning (anti-aging)	Anti-aging, relaxes facial wrinkles, reducing the degree of existing wrinkles	Significantly more reduction in the depth of wrinkles for Argireline group	[64.81]
Leuphasyl (palmitoyl pentapeptide)	Anti-aging	Antiwrinkle and collagen production stimulation		[64.82]
Palmitoyl pentapeptide-4 (Pal-KTTKS) (Matrixyl)		Healing skin wounds & tighten skins, reduces wrinkle	Antiwrinkle and lifting effects	[64.83]
Octapeptide SNAP-8		Prevention & reducing the depth of wrinkles		[64.84]
Lipopeptide (SF)		Boosts cells' natural productivity levels & functions	Significant increased sirtuin-1 and collagen I, inhibit MMP-9 mRNA	*Wu* and *Lu* (unpublished data)
GHK-Cu^{2+}	Anti-aging	Increases skin density, repairs skin cells, wound healing and revascularization of tissues	Significant improvements in all evaluations were found for both products	[64.85]
PAL-GHK (palmitoyl oligopeptide)	Anti-aging	Anti-aging and antiwrinkle effects, cutaneous restructuring and repair, stimulation of collagen repair & photoaged skin		[64.82]
Pal-GQPR (palmitoyl tetrapeptide-3)	Anti-aging	Anti-aging, wrinkle smoothing, cutaneous barrier repair, increases firmness of the skin area around the eye	Significant increase in skin thickness and firmness with active cream. AcTP1 was more effective than the placebo	[64.86]

oligopeptides linked together and attached to a fatty acid to enhance the oil solubility of peptides and thus better skin penetration.

Cutaneous absorption of interferon (INF)-a linked to various palmitoyl molecules was about 5–6 times greater than that of the parent peptides [64.91]. The lipopeptides are amphiphatic and consist of a hydrophobic chain containing between 8–24 carbon atoms and of a peptide chain that is hydrophilic or has been rendered hydrophilic. One of the applications for lipopeptides has been in antiwrinkle, anti-aging, and rejuvenation cosmetics [64.92]. Lipopeptides (such as palmitoyl pentapeptide) are at least as effective against wrinkles as retinol, but do not cause skin irritation, which is a common side-effect of retinoids. Furthermore, it has found that when added to the culture of fibroblasts (the key skin cells), palmitoyl pentapeptide stimulated the synthesis of the key constituents of the skin matrix: collagen, elastin, and glucosamnoglycans. How exactly palmitoyl pentapeptide did that remains unclear [64.80].

We have currently demonstrated the applicable in cosmetology and dermatology of using SF as an agent for stimulating skin dermis cell metabolism and more particularly, as an agent for stimulating collagen neosynthesis at low concentration in formulation. Our data indicated that SF not only up-regulated expression of the anti-aging gene (such as sirtuin I) effectively (Fig. 64.1), but also stimulated the proliferation of fibroblasts and increased the cell survival rate and repair ability after oxidative stress and UV damage. Figures 64.3 and 64.4 show that the amount of collagen and the elastin gene expression were increased and MMP-9 expression was inhibited in BALB/3T3 clone A31 *Mus musculus* embryo

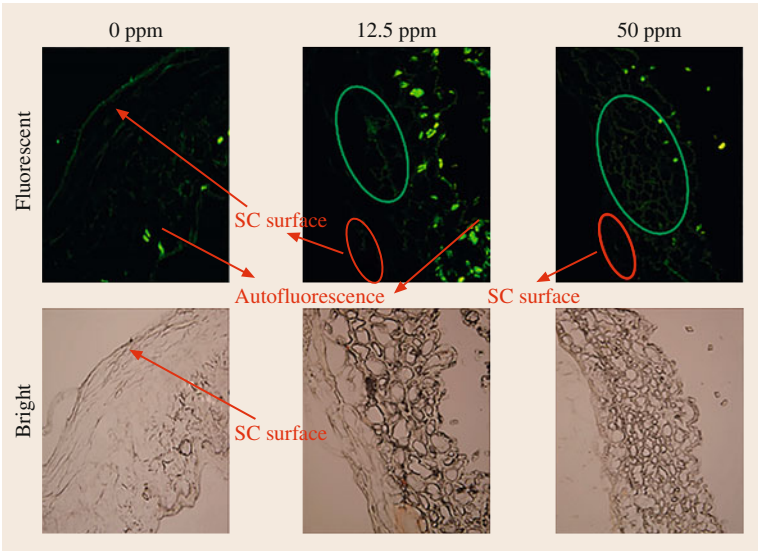

Fig. 64.1 The enhancement effect of SFs on the penetration of gold nanoparticles (2 nm) through mouse skin. The levels of Au-NP were measured with fluorescence microscopy. The *green color* represents the presence of Au-NP, which was increased in SF treatment (50 ppm) on the BALB/c dermal layer. The *green bright spot* was the fair follicle autofluorescence in BALB/c

fibroblasts by SF treatment. By encouraging the inducing extracellular matrix by efficacious stimulating the dermis cells and synthesis of new collagen fibres, purified SF can be used both as a preventive measure against aging of the skin and used as repair and restructuring products in creams for the body, and in body milks, lotions, and gels for the skin [64.66].

64.3.2 Applications of Marine Biosurfactants in the Nutraceutical Industry

Marine organisms represent a valuable source of nutraceuticals and functional compounds. The biodiversity of the marine environment and the associated chemical diversity constitute a practically unlimited resource of novel active substances for the development of bioactive products. Recently, a great deal of interest has been expressed in marine-derived bioactive peptides because of their numerous beneficial health effects. Moreover, several studies have reported that marine bioactive peptides exhibit immunomodulatory activity, anti-inflammatory, antioxidative, and antimicrobial properties in functional foods or nutraceuticals and pharmaceuticals due to their therapeutic potential in the treatment or prevention of disease. In this chapter, we provide an overview of bioactive peptides derived from marine organisms, as well as information about their biological properties and mechanisms of action with potential applications in different areas.

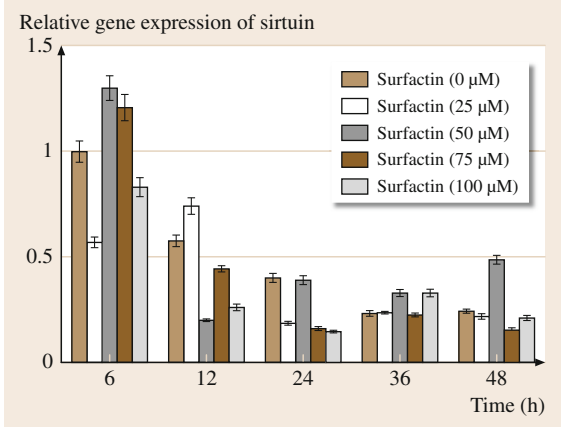

Fig. 64.2 Effect of SF on sirtuin I mRNA level in a BALB/3T3 clone A31 *Mus musculus* embryo fibroblast on treatment with different SF concentrations. The levels on sirtuin I mRNA were measured in real-time PCR. The *Mus musculus* embryo fibroblast cells were treated with varying concentrations of SF (0, 25, 50, 75, 100 μM) for 6, 12, 24, 36, 48 hours

Biosurfactants as Immunomodulators

Biosurfactants are not only useful as antibacterial, antifungal, and antiviral agents, but also have potential for use as major immunomodulatory molecules. Toll-like receptors (TLR) are critical mediators of the immune response to pathogens and human polymorphisms in this gene family regulate inflammatory pathways and are associated with susceptibility to infection [64.93].

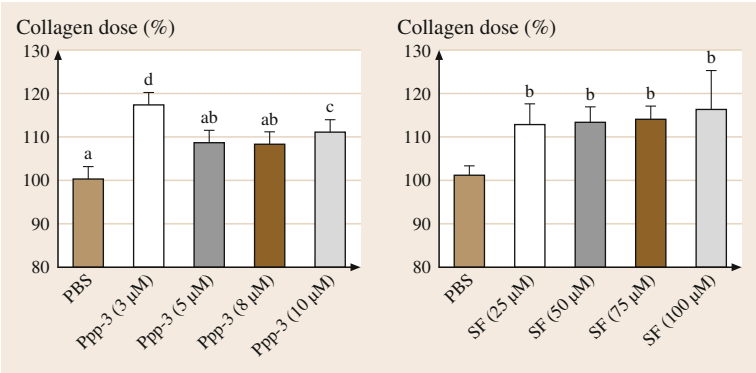

Fig. 64.3 Effect of palmitoyl pentapeptide-3 (ppp-3) and SF (SF) on collagen dose. The levels of the collagen dose were measured in the Sircol collagen assay. The *Mus musculus* embryo fibroblast cells were treated with varying concentrations of SF (0, 25, 50, 75, 100 μM) and ppp-3 (0, 3, 5, 8, 10 μM) for 24 hours

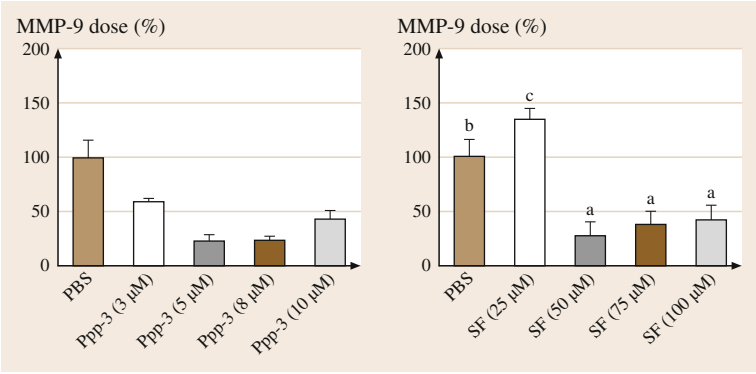

Fig. 64.4 Effect of ppp-3 and SF on matrix metalloproteinase-9 inhibitory ability. The levels of the matrix metalloproteinase-9 dose were measured in enzyme-linked immunosorbent assay (ELISA). *Mus musculus* embryo fibroblast cells were treated with varying concentrations of SF (0, 25, 50, 75, 100 μM) and ppp-3 (0, 3, 5, 8, 10 μM) for 24 hours

Lipopeptides are present in a wide variety of microbes and stimulate immune responses through TLR1/2 or TLR2/6 heterodimers [64.94]. We examined the immunomodulatory activity of marine microbial biosurfactin treatment on innate acquired immune influence and observed the expression of innate immune response in BALB/c mice. In in vivo studies we studied the stimulation of immune response in BALB/c mice after feeding them with SF for 1 week. Figure 64.5a–c shows the ratio between $CD4^+$ T cells, $CD8^+$ T cells and B cells were greatly changed in BALB/c mice. Especially, the percentage of $CD4^+$ T cells increased by over 20%. In in vivo studies, SF was shown to reduce the size of tumor in mice and prolong the survival time as well. This implies that SF has potential for the application as food additives.

Biosurfactants as Anti-Inflammatory Agents

Park et al. [64.95] demonstrated the antineuroinflammatory properties of SF in lipoteichoic acid (LTA)-stimulated BV-2 microglial cells. SF can significantly inhibit excessive production of the pro-inflammatory mediators TNF-α, IL-1β, IL-6, monocyte chemoattractant protein-1 (MCP-1), prostaglandin E2 (PGE2), nitric oxide (NO), and reactive oxygen species (ROS), and suppressed the expression of matrix metalloproteinase-9 (MMP-9), inducible NO synthase (iNOS), and cyclooxygenase-2 (COX-2). It also showed that SF can significantly suppress lipopolysaccharide-induced expression of CD40, CD54, CD80, and MHC-II, but not of CD86 and MHC-I. *Park* and *Kim* [64.96] indicated that SF-treated macrophages also exhibited impaired phagocytosis and reduced IL-12 expression. In addition, SF inhibited the phosphorylation and degradation of IκB-alpha, and suppressed the activation of IKK (inhibitor of nuclear factor κ-B kinase subunit beta), Akt (nuclear phosphatidylinositol 3,4,5-triphosphate phosphotidyinositol 3-kinase), JNK (c-Jun N-terminal kinase), and p38 kinase. Microbial lipopeptides constitute potent nontoxic, nonpyrogenic immunological adjuvants when mixed with conventional antigens [64.97]. Low molecular mass antigens such as Iturin AL and Herbicolin A can enhance the humoral immune response [64.22]. In addition, biosurfactants represent

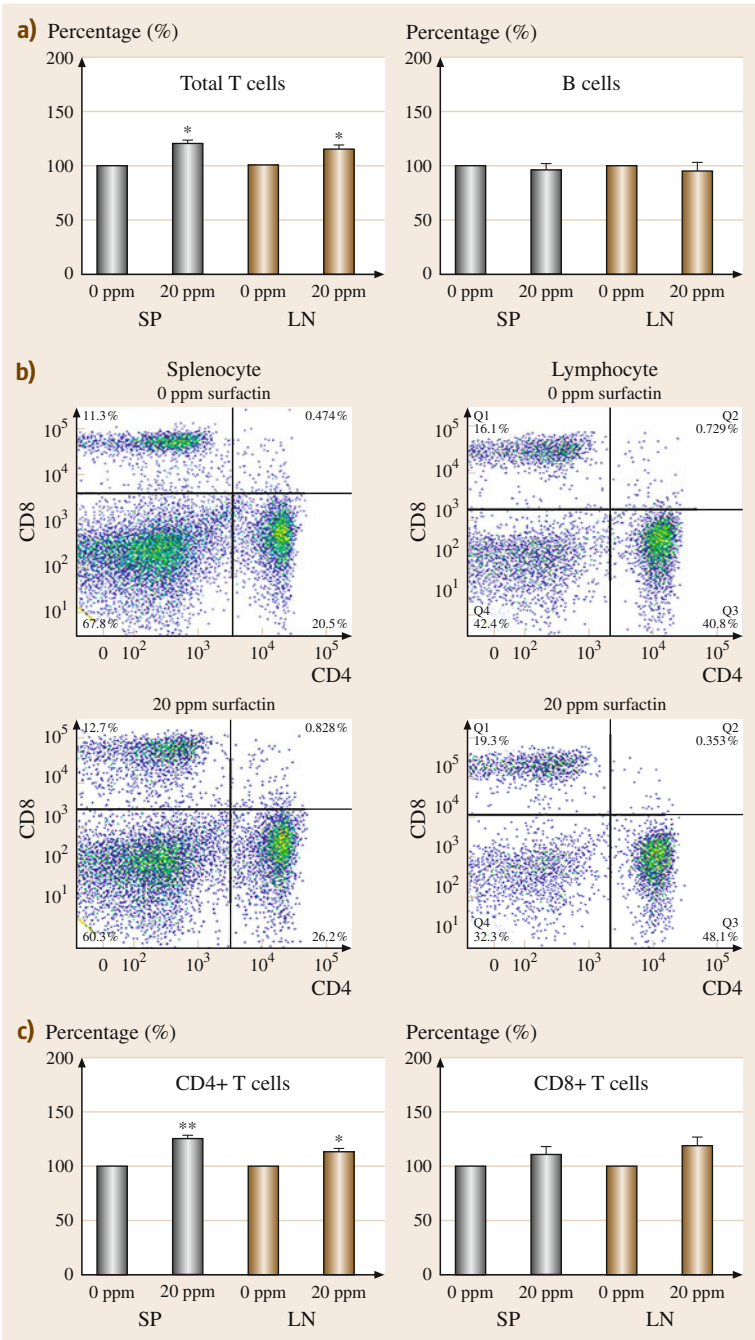

Fig. 64.5 **(a)** Effect of SF on the expression of total T cells and B cells in splenocytes (SPs) and lymphocytes (LN) (*left*). Mouse SP and LN were isolated from mice that were orally administered 20 ppm SF and PBS control for 1 week, stained with FITC-conjugated anti-CD3 monoclonal antibodies, and analyzed using flow cytometry. PBS is the only group with 100% standard (*right*). SP and LN were also stained with PE-conjugated anti-CD45R monoclonal antibodies. $*P < 0.05$ versus PBS only group. **(b)** The percentage of $CD4^+$T cells were up-regulated by SF. 20 ppm/mouse of SF was used for oral administration for 1 week with mice. $CD3^+$T cells were stained with FITC-conjugated anti-CD4 and PE-conjugated anti-CD8 monoclonal antibodies, and analyzed using flow cytometry. The results are from one of the three experiments performed. **(c)** Effect of SF on BALB/c mice $CD4^+$ T and $CD8^+$T cell percentage. The percentage of CD4 and CD8 marker-positive cells in SP and LN. PBS is the group with 100% standard. $*P < 0.05$, $**P < 0.01$ versus PBS group

a promising immunomodulatory adjuvant that could enhance the therapeutic potency of vaccines in cancer therapy [64.98].

Biosurfactants as Antiviral Agents

It has been found that lipopeptides (i. e., SF) or salts or esters have a surprisingly high inactivation potential for lipid-enveloped viruses such as herpes or retroviruses, and in addition they offer the advantage of an exceedingly low in vivo toxicity, so that the step of removing the inactivating agent from pharmaceutical products or cell cultures can be omitted [64.99–101]. We have demonstrated that SF can inactivate both enveloped viruses such as the betanodavirus, and nonenveloped virus such as the iridovirus [64.66].

Biosurfactants as Antitumor Agents

Over the past years, a few studies have examined the actual effect of lipopeptides on tumor cells. *Kameda* et al. [64.102] proved that lipopeptides can inhibit the proliferation of Ehrlich ascites carcinoma cells. *Sudo* et al. [64.103] reported the ability of lipopeptides to inhibit growth and induce differentiation in HL60 human promyelocytic leukaemia cells . In addition, *Wakamatsu* et al. [64.104] discovered that lipopeptides induce neuronal differentiation in rat adrenal pheochromocytoma PC12 cells and provided the groundwork for the use of microbial extracellular lipopeptides as a novel reagent for the treatment of cancer cells. An antitumor lipopeptide purified from *Bacillus natto* TK-1 was able to inhibit the proliferation of MCF-7 human breast cancer cells in a dose and time-dependent manner [64.105]. The antitumor activity of the *Bacillus natto* SF in MCF-7 cells was associated with cell apoptosis determined by typical morphological changes and sub-G(1) peak in cell growth-phase distribution. The cell cycle was arrested at the G(2)/M phase. In addition, the caspase activity assay revealed that lipopeptide-induced apoptosis in MCF-7 cells was associated with caspase 3.

64.3.3 Development of Fermented Soy Nutraceuticals Containing Marine Biosurfactants

Nutraceuticals are food products that provide health as well as medical benefits, including the prevention and treatment of diseases. There are many nutraceutical (such as soy protein) that are beneficial in the prevention or symptom reduction of coronary heart disease (CHD). In 1999, the FDA gave permission to manufacture soy foods. At least 25 mg administration of soy protein per day reduces the risk of developing CHD [64.106].

A few studies have shown that biosurfactins have therapeutic and preventive properties against different types of cancers and pathogen-induced inflammatory causes by virus infection. Since we have developed a semi-solid-state culture technique that uses soybeans as the substrate to produce SF, these fermented soybeans might be used to make various soy food products (such as soy powder, soy beverages, etc.) (Fig. 64.6). Furthermore, after the SSSF process, the fermented soybeans contain 10 times more small peptides and 39% less phytic acid. This novel fermented soy nutraceutical, can be used within the context of chemoprevention and in therapeutics, as a main stay treatment and as adjuvant nutrition for disease prevention and the enhancement of well-being.

64.4 Conclusions

Chemically synthesized surface-active compounds are widely used in the pharmaceutical, cosmetic, petroleum, and food industries. However, with the advantages of biodegradability and production of renewable-resource substrates, biosurfactants may eventually replace their chemically synthesized counterparts. So far, the use of biosurfactants has been limited to a few specialized applications because biosurfactants have been economically uncompetitive. There is a need to gain a greater understanding of the physiology, genetics, and biochemistry of biosurfactant-producing strains and to improve process technology to reduce production costs.

Biosurfactants (SF and other lipopeptides) produced by marine microorganisms are nontoxic and inexpensive to produce and have excellent surface properties and biological activities suitable for cosmeceutical applications. Biosurfactants have good skin compatibility with low irritation and can potentially be applied as a topical dermatological product. The application of the SF approach to cutaneous delivery is relatively new and is of merit on a scientific basis. The diversity of lipopeptide activities outlines their importance as a multifunctional cosmetic ingredient.

Several studies have reported that marine bioactive peptides exhibit immunomodulatory activity, anti-in-

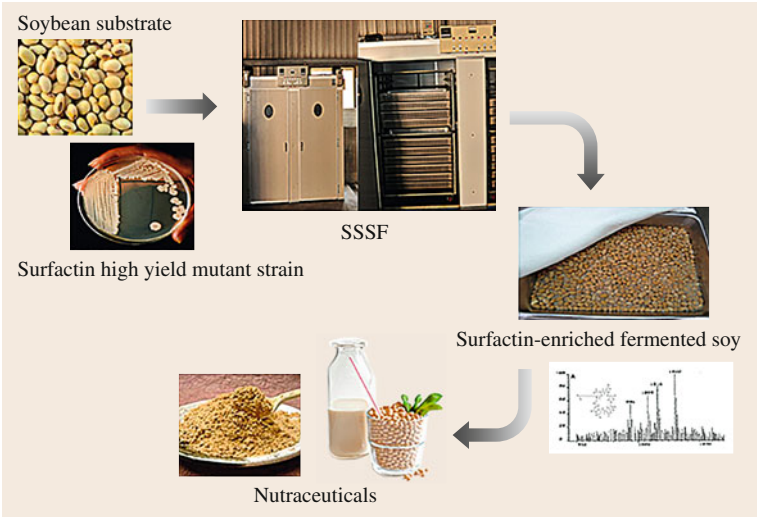

Fig. 64.6 Process of producing fermented soy nutraceutical enriched biosurfactants by SSSF culture

flammatory, antioxidative, antitumor, and antimicrobial properties, which might suggest this marine biosurfactant have therapeutic potential in the treatment or prevention of disease.

Nutraceuticals is growing healthcare industry in Asian countries. The growth of nutraceuticals is also increasing because people want treat a disease by improving their health with the help of healthcare goods. Consumers are turning massively to food supplements to improve well-being where pharmaceuticals fail. Soy and soy products have been a staple in the standard diet in China, Japan, Indonesia, and other Asian countries for centuries. In this chapter, we have proposed a possible application of biosurfactants in functional food or nutraceuticals through soy-fermented products. Soy food containing biosurfactants can be made from fermented, cooked whole soybeans. Because the fermentation process breaks down the beans' complex proteins, this soy food containing SF is more readily absorbed.

65. Nutraceuticals and Bioactive Compounds from Seafood Processing Waste

V. Venugopal Menon, Smita S. Lele

Seafood items are rich in several valuable nutrients and other useful components. The rising global demand for the community is witnessing an increasing quantity of processed seafood entering world markets. Commercial processing of seafood items for diverse products results in significant amounts of wastes consisting of shells, heads, intestines, scales, bones, fins, etc. Moreover, fishing operations aimed at popular species also lead to the capture of substantial amounts of fish that are commercially nonviable and, therefore, regarded as by-catch. Currently, most of these materials are discarded as landfill or converted on a limited scale into products such as animal feed and leather, which leads to serious environmental hazards. With rapid developments in biotechnology there is vast scope to make use of the wastes as sources of valuable nutraceuticals and other ingredients, which encompass proteins including collagen and gelatin, protein hydrolyzates, bioactive peptides, lipids rich in polyunsaturated fatty acids, squalene, carotenoids, polysaccharides such as chitin, chitosan, glycosaminoglycans and their derivatives, mineral-based nutraceuticals, among others. These products, depending upon their characteristics, have potential for various applications such as natural food additives, bioactive compounds, nutraceuticals, medicinal drugs, biodegradable packaging, and as encapsulation materials for diverse nutraceuticals. This chapter highlights the potential benefits of secondary processing of seafood discards, for the isolation of various valuable compounds, such as unsaturated oils, carotenoids, minerals, fine biochemicals, enzymes, proteins, nucleic acids and pharmaceuticals, antimicrobials, antioxidants, enzyme inhibitors, and other bioactive compounds.

The food and nutritional value of fishery products have been well recognized in the last few decades. The diverse species of fish and shellfish from varied marine environments provide opportunities for the development of food products with different flavor, high nutritional value, and hence good consumer acceptance, which has resulted in a rising global demand for the commodity. In the year 2012, capture fisheries and aquaculture supplied the world with about 158 million tons (Mt) of fishery products, of which about 136 Mt was utilized as human food [65.1]. During the last 50 years, the world per capita food fish supply has almost doubled from an average of 9.9 kg (live weight equivalent) in the 1960s to 19.2 kg in 2012. In the same year, aquaculture set an all-time production high of 66 Mt. In 2008, about 39% of global seafood production at a value of US$ 102 billion entered diverse global markets, making fishery products the most internationally traded food commodity [65.2, 3]. This has resulted in huge amounts of processing discards in processing centers all over the world, causing serious environmental hazards.

65.1 Seafood as a Source of Nutraceuticals

Seafood items with their biodiversity are recognized as a functional food due to the presence of several nutraceuticals and biologically active compounds. The term *functional food*, which was coined in Japan in the 1980s, describes foods that contain nutraceutical ingredients that provide nutrition and offer protection against diseases [65.4]. The term *nutraceutical* is defined as any substance that may be considered a food or part of a food and provides medical or health benefits including the prevention and treatment of diseases. These ingredients are not identified as essential nutrients, but are considered as bioactive substances with one or more health benefits. Public health authorities consider prevention and treatment with nutraceuticals as a powerful instrument to maintain health and to act against nutritionally induced acute and chronic diseases, thereby promoting optimal health, longevity, and quality of life [65.5–7]. Over the past two decades, more than 3000 new compounds have been isolated from various marine organisms, including fishery items, seaweed species, corals, sponges, and microorganisms [65.8]. Nutraceuticals from fishery sources include calcium, unsaturated oils, carotenoids, fine biochemicals, enzymes, proteins, nucleic acids and pharmaceuticals, antimicrobials, antioxidants, enzyme inhibitors, and other specific bioactive compounds [65.9–11]. The US National Oceanic and Atmospheric Administration (NOAA), with support from the Food and Drug Administration in a study titled, *Seafood choices: balancing benefits and risks* concluded that *seafood is a nutrient-rich food that makes a positive contribution to a healthful diet* and, therefore, advises regular consumption of seafood by Americans [65.12].

65.2 Bio-Waste from Processing of Seafood

Several items of seafood such as shrimp, prawns, salmon, tuna, ground fish, flatfish, sea bass, and sea bream are commodities of international trade, involving about 200 countries, and equivalent to US$ 129.8 billion in 2011. Besides marine fish, freshwater and maricultured species such as shrimp, prawns, salmon, mollusks, tilapia, catfish, sea bass, and sea bream also constitute the trade [65.1]. Commercial processing of fish and shellfish for trade generates significant portions of the raw material as waste, which consists of heads, filleting frames, scales, viscera, gills, dark flesh, bone, and skin [65.14]. The various preprocessing operations involve beheading, skinning, gutting, descaling, filleting, etc. Processing discards are as high as 40% of whole shrimp and krill, 50% of crab, and 24% of squid and of crab and consists of heads, exoskeleton, cephalothorax, and carapace. It has been estimated that annually 500 000, 100 000, 490 000, and 60 000 t of wastes are generated from shrimp, squid, crabs, and krill, respectively [65.15]. About 250 000 and 45 000 t of processing discards are generated annually from the processing of Atlantic cod and tuna, respectively. Norwegian fisheries annually produce more than 615 000 t of waste; most of it being converted into fish silage and fish meal, while about 180 000 t of bycatch is dumped into the sea [65.16, 17]. Pre-processing of freshwater fish such as trout, carp, pike-perch, pike, and bream into various products such as gutted, headed, and free or skin on fillets results in 40–60% of the fish as waste. Frames after filleting are a good source of minced meat [65.18]. Scale constitutes $\approx 2\%$ of the weight of large fish. Freshwater fish such as perch, bream, pike-perch, and carp are rich in thick scales. Approximately 49 000 t of scales have been reported to be produced annually [65.1]. Table 65.1 indicates the proportions of waste generated during seafood processing operations. In addition to the tremendous amounts of processing wastes, about 20 Mt of fish consisting of

Table 65.1 Waste (percentage of whole fish) generated during seafood processing operations (after [65.13])

Processing operation	Waste
White fish filleting	Skin, 4–5 Head: 21–25 Bones: 24–34
Oily fish filleting	40–45
Canning	25 (head/entrails)
Scaling of white fish	2–4
Beheading of white fish	27–32 (heads and debris)
Filleting of oily fish	40 (entrails, tails, heads, and frames)
Trimming and cutting white fish	24–34 (bones and cut-off)
Precooking of fish for canning	15 (inedible parts)

various unconventional and underutilized species are landed during commercial fishing operations [65.19]. Processes for better utilization of these underutilized fish have been discussed [65.20].

65.3 Seafood Waste and Discards as Sources of Nutraceuticals

Conventionally, fishery wastes are mostly converted into low market value products, such as fish meal, ensilage, fertilizer, animal feed, and biofuel. Fish skin from larger fishes such as shark, salmon, lingcod, hagfish, tilapia, Nile perch, carp, and sea bass is used as a source of leather for making clothing, shoes, hand bags, etc. In many countries such wastes are discarded as landfill [65.17]. In 2012, about 21 Mt fish was used for fishmeal production [65.1]. In the last two decades, there has been a global awareness of the environmental, economic, and social impacts of fish processing, calling for efficient utilization of the discards [65.10, 13, 23–26]. Because seafood is nutritionally rich, as mentioned above, there is scope for the marine industry to bioprocess seafood discards and also by-catch to extract compounds that are of practical use [65.8]. Many such compounds can possess interesting bioactivities such as antihypertensive, antioxidant, antimicrobial, anticoagulant, antidiabetic, anticancer, immunostimulatory, calcium-binding, and other properties [65.8, 27, 28]. Table 65.2 shows components that can be isolated from seafood waste. For the convenience of the present discussion, these compounds can be classified into four groups (Fig. 65.1) according to their chemical origin, namely:

i) Nitrogenous compounds including proteins and peptides.
ii) Lipid and lipid-derived compounds.
iii) Polysaccharide-based compounds such as chitin, chitosan, glycosaminoglycans, and their derivatives.
iv) Mineral-based compounds.

These aspects are discussed below.

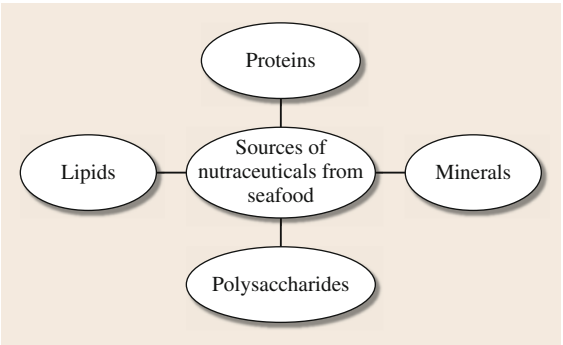

Fig. 65.1 Major sources of nutraceuticals from seafood processing waste

65.4 Nitrogen-Derived Compounds

The interest in protein goes beyond its importance to basic nutrition to specific roles in enhancing the quality of life. A portion of 150 g of fish can provide about 50–60% of an adult's daily protein requirements. In the year 2010, fish accounted for almost 16.7% of the world population's intake of animal protein and 6.5% of all protein consumed [65.1].

65.4.1 Proteins and Protein Hydrolyzates

Fish proteins are rich in all the essential amino acids, particularly methionine and lysine. While there are no significant differences in the amino acid composition of freshwater and marine fish, certain marine fish such as mackerel, tuna, etc., may be exceptionally rich in the amino acid histidine. The nutritive value of marine fish proteins is equal to or better than that of casein and red meat proteins. The protein efficiency ratio (PER) of fish proteins is slightly above that of casein, the major milk protein, and ranges from 3.1 to 3.7. The net protein utilization (NPU) of fish flesh is between 80 and 100, the values for red meat and egg, respectively. Evidently, the protein quality of most fish may exceed that of meat or are equal to that of an ideal protein such as lactalbumin [65.29]. In view of their high nutritive value, recovery of proteins from fish processing wastes for use as food ingredients has received attention. Fish proteins have been isolated by methods such as enzymatic hydrolysis, pH shifting, membrane filtration, and ohmic heating [65.30]. Different methods

Table 65.2 Components from seafood waste and uses (summarized from [65.13, 21, 22])

High-value components and nutraceuticals	Feed, color, flavor, and packaging materials	Nonfood uses
Chitin Chitosan Carotenoid pigments Glucosamine Glycosaminoglycans Chondroitin sulfate Collagen and gelatin Alkaline phosphatase Proteolytic enzymes (pepsin, trypsin, chymotrypsin, collagenases and calpains) Omega-3 fatty acids Deoxyribonucleic acid (DNA) processed as drug in Norway and used in treatment of the human immunodeficiency virus (HIV) Squalene (hydrocarbon found in fish oils useful to treat diabetes and tuberculosis)	Animal feed Crustacean meal Fish/pet food Mollusc shells (used in animal feeds as a calcium source) Encapsulation materials Edible packaging materials Coloring agents (for fish feed) Food flavoring from shrimp heads	Fertilizer Lime Filter media Leather (skin from shark, salmon, ling, cod and hagfish skins) Pearl essence from pelagic fish (iridescent chemical called guanine which gives fresh fish)

Table 65.3 Methods for isolation of proteins and their merits

Methods	Advantages	Disadvantages
Chemical hydrolysis (acid or alkali)	High recovery, inexpensive process	Potential decrease of protein functionality Bitterness Heterogeneous hydrolyzates
Enzymatic hydrolysis	High recovery yields High selectivity Low-salt final product Low contamination of wastes	Bitterness High-cost enzymes (except autolysis) Long-time process Potential decrease of protein functionality
pH shifting	High recovery	Potential decrease of protein functionality
Ultrafiltration	Simultaneous recovery and concentration of soluble proteins	Time-consuming process Expensive membranes
Supercritical fluid extraction with CO_2	Low environmental impact Easy penetration on food systems Mild processing conditions (room temperature and low pressures) Low level of solvent residues in products Inert and nontoxic technique Cost-effective technique	Equipment complexity Necessity of using high pressures Normal use of modifiers, such as ethanol
Ohmic treatment	Rapid process Relatively uniform heating	High-cost installation Possible electrolytic effect

for protein isolation and their merits are pointed out in Table 65.3.

Fish protein hydrolyzates (FPH) have been prepared from several types of fish meat, including processing wastes using various proteolytic enzymes as described in Fig. 65.2. FPHs have obvious nutritional advantages over products like fish protein concentrate or even human grade fish meal. They are useful ingredients to provide functional effects such as whipping, gelling, and texturing properties of foods [65.8, 31, 32]. Techniques for enhancing the storage stability of FPH have been pointed out [65.33]. Proximate compositions of FPHs are moisture, 1–8%, protein, 81–93% fat, 0–5.0%, and ash, 3–8%. Proteins from skin of the blue shark have been isolated using commercial proteinase at an optimal temperature of 51 °C and pH 7.1, with a recovery of 91%. The isolate, which contained all the essential amino acids was rich in low molecular weight (< 6.5 kDa) peptides having high nutritional content and antioxidant activity [65.34]. Proteins were

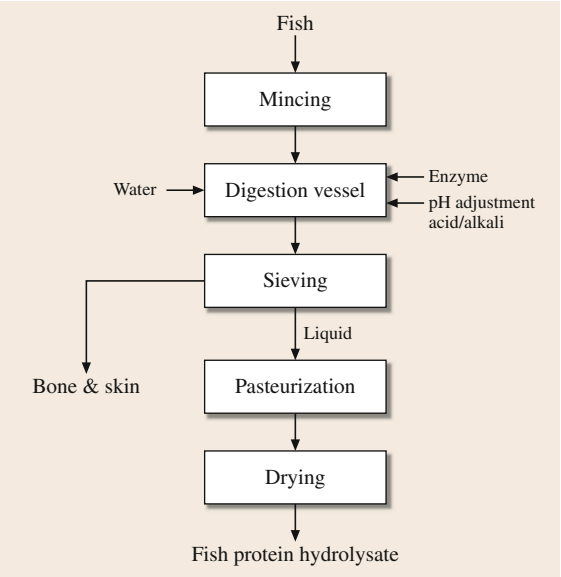

Fig. 65.2 Production of fish protein hydrolysate

recovered from the by-products of silver carp filleting waste using a combination of neutral proteases, giving 82% recovery [65.35].

A novel method is the use of glycation reaction under controlled conditions to effectively isolate functional proteins with gelling and emulsifying capacities [65.36]. Soluble powders prepared from the by-products of the processing of fish and shellfish such as Alaska pollock, herring, salmon, and arrowroot flounder had protein contents ranging between 65–79%. They are good sources of essential amino acids, meeting the requirements of FAO/WHO (FAO: food and agriculture organisation, WHO: world health organization) 1990 recommendations [65.37]. Up to 70% of the protein content of shrimp waste was recovered by boiling water extraction under controlled alkaline conditions [65.38]. Isolates from shrimp head with 12.5% protein, 6.5% chitin, and relatively low ash, can find use as aqua-feed [65.39] weight management, athletic recovery, and maintaining strength and muscle tone for good health in later life. The possible bitter taste of protein hydrolyzates may prevent their use in many products as food additives [65.31]. FPHs are good sources of peptides because they have various bioactive properties, which will be discussed later. In addition, opportunities also exist for isolation of other bioactive substances, including hydroxyapatite, taurine, and creatine [65.23].

Skin and bone waste are rich sources of collagen. Head waste in cod fisheries, yielding ≈ 20% of the whole fish, forms an excellent source of the protein [65.16]. Collagen consists of three identical or different peptide chains, each chain possessing a helical structure, together forming a triple-stranded helix consisting of repeating triplets $(\text{glycine-X-Y})_n$, where X and Y are often proline and hydroxyproline. This basic structural unit of collagen fiber, called tropocollagen, has a molecular weight of ≈ 30 kDa, a length of 280 nm, and a diameter of 1.4–1.5 nm. The process of extraction of collagen from fish bones, which form a major source of the filleting operation, involves initial acetone extraction for about 12 h at room temperature to remove lipids, drying of the treated material, decalcification using a tenfold 0.6 M hydrochloric acid for 1 day to yield collagen [65.40]. Acid-soluble collagen (ASC) and pepsin-solubilized collagen (PSC) were isolated from fish bones and scales. The molecular weights of the collagen subunits were between 110 and 130 kDa. The melting temperatures of ASC and PSC were > 34 °C. Collagen from cod and Pacific whiting surimi processing water showed better functional properties than that from skin and was similar to acid soluble collagen in whiteness, solubility, emulsifying activity, and cooking stability [65.16, 41]. The fish skin collagen was comparable to typical type-I collagens of land-based animals and has potential therapeutic effects in terms of anti-inflammatory activity and inhibition of angiogenesis. However, fish collagen has lower melting temperatures in the range of 25–45 °C compared with mammalian collagens, which melt between 60 and 70 °C.

Collagen from squid waste has also been isolated and characterized [65.42]. Collagen and another connective tissue protein, and elastin have many applications in cosmetics. They provide smoothness to the skin and prevent skin irritation. The proteins are antistatic, film forming, and humectant moisturizers. Collagen combined with the moisturizing properties of chitosan (see Sect. 65.5 on polysaccharide-derived nutraceuticals) is claimed to help restore the elasticity of the skin [65.43, 44].

Collagen is the source of gelatin. The process of isolation of gelatin from collagen involves successive extraction of fish waste at room temperature with dilute alkali and mineral acid [65.45]. Gelatin is a heterogeneous mixture of single or multistranded polypeptides containing 50–1000 amino acid residues. It is translucent, colorless, brittle, and flavorless. Because it is hydrophilic it interacts with water and undergoes changes of its physicomechanical properties depending on the moisture content. It forms transparent elastic

thermoreversible gels when heated and then cooled below ≈ 35 °C. The melt-in-the-mouth property is one of the important characteristics responsible for its wide applications in the food and pharmaceutical industries [65.46]. Fish gelatin has a lower melting point of ≈ 10 °C, compared with a melting point of 30 °C of mammalian gelatin, and hence has the potential to replace conventional porcine or bovine gelatin. It can be also used for encapsulation of heat-sensitive compounds. Fish gelatins have a comparable bloom strength (the gel strength equivalent used in the industry), viscosity, and solubility in comparison with mammalian gelatin. Their viscosities range between 15 and 75 mP [65.47–50]; gelatin hydrolyzates are sources of antioxidant and antimicrobial peptides, as will be discussed below. The food uses of gelatin are given in Table 65.4.

65.4.2 Bioactive Peptides

In addition to functioning as sources of essential amino acids, bioactive peptides play significant roles in maintaining health and in preventing diseases of the cardiovascular, nervous, or immune systems. While these peptides are inactive within the sequence of the parent protein, they become active upon release from the parent proteins. They usually contain 3–20 amino acid residues, and their activities are based on their amino acid composition and sequence. Hydrolysis of fish meat by trypsin or other pancreatic enzymes or bacterial and fungal enzymes, either alone or in combination, can give a variety of peptides depending upon the treatment conditions. The prepared hydrolyzates are then subjected to ultrafiltration and/or nanofiltration to fractionate peptides [65.8, 32, 51, 52].

The interesting bioactivities of peptides involve varied functions such as antihypertensive agents, antioxidant, immunomodulatory, antithrombotic, anticancer, and antimicrobial agents. High blood pressure is one of the major risk factors for cardiovascular diseases. The angiotensin-I-converting enzyme (ACE, EC 3.4.15.1) plays a crucial role in the regulation of blood pressure as it promotes the conversion of angiotensin-I to the potent vasoconstrictor angiotensin II. Many peptides, including those from marine sources, can inhibit ACE activity, thereby controlling hypertension [65.32, 53]. The first marine ACE inhibitory peptide was isolated from sardines. Later, ACE-inhibitory peptides were isolated from other fishery items including salmon, sardines, oysters, wakame, yellowfin sole, and dried bonito [65.8, 51, 54, 55].

Some peptides function as excellent antioxidants that can control a wide array of physiological disorders such as cancer, diabetes mellitus, and neurodegenerative and inflammatory diseases. The mechanisms involve binding of metal ions, scavenging of oxygen, converting hydroperoxides to nonradical species, deactivating singlet oxygen and, thereby, suppressing the generation of free radicals. Their antioxidant potency is suggested mostly due to the presence of hydrophobic amino acids and/or their ability to chelate metal ions [65.28, 52]. Antioxidant peptides have been isolated from seafood, including jumbo squid, oysters,

Table 65.4 Food uses of gelatin

Application	Product type
Gelling agent	Jelly confectionery
Whipping agent	Aerated confectionery
Stabilizer	Icings
Emulsifier	Fruit chews, etc.
Adhesive (sticking agent)	Various products
Coating and encapsulation agent	Various nutraceuticals

Table 65.5 Bioactive peptides from various fishery products (after [65.8, 28, 51])

Bioactivity	Fishery source
Antihypertensive action through inhibition of angiotensin-I converting enzyme activity	Sardine, salmon, big-eye tuna, Pacific hake, sea bream, oyster wakame, fish bone collagen, dried bonito digest, shrimp, hard clam, sea cucumber
Antioxidant activity	Alaska pollock, capelin, cod, eel, hake, mackerel, round scad, saithe, sole, sea cucumber, mussel, squid, gelatins from tuna, hoki, squid
Calcium-binding oligophosphopeptide	Bone from the fish hoki
Gastrin and calcitonin gene-related peptides (CGRP)	Atlantic/Greenland cod, sardine, winter flounder, industrial seafood waste
HIV-I protease inhibiting activity	Oyster
Stimulation of nonspecific immune defense system	Chub mackerel, other fish
Antimicrobial activity	Lobster, shrimp and green sea urchin, blue crab, lobster
Anti-coagulant activity	Blue mussel

Table 65.6 Enzymes from seafood wastes

Enzymes	Function	Source	Remark/benefit
Gastric proteases (e.g., pepsins, gastricsins, chymosins)	Cold *renneting* milk, Digestion aid for fish feed	Fish viscera from fishery sources[1]	Catalytic activity at lower temperatures, minimizing unwanted chemical reactions and bacterial growth
Serine and cysteine proteases (e.g., trypsins, chymotrypsins, collagenases, elastases, cathepsin B)	Inactivation of polyphenol oxidase preventing unwanted color changes in foods, low-temperature protein digestion, meat tenderization, fermentation	Pyloric ceca, pancreatic tissues, intestines, hepatopancreas (stomachless bone fish[2])	Catalytic activity at lower temperatures minimizing unwanted chemical reactions and bacterial growth
Lipases	Numerous uses in the fats and oils industry (e.g., production of omega-3-enriched triglycerides)	Various fish items[3]	Higher specificity for omega-3 fatty acids
Polyphenol oxidases (e.g., tyrosinase, polyphenolase, phenolase, catechol oxidase, cresolase, catecholase)	Processing and fermentation of tea, coffee, raisins, and prunes	Crustaceans	Higher activities at lower temperatures, as compared with terrestrial counterparts
Chitinolytic enzymes	Replace HCl for conversion of chitin into oligomeric units	Digestive tracts of fish, shellfish, and shellfish waste, squid liver, octopus saliva	Less harsh than HCl and results in more consistent products
Transglutaminase	Creates protein cross-links to improve rheological properties of gels, i. e., surimi, gelatin	Various fishery items[4]	Strengthens gels with protein cross-linkages

[1] Atlantic cod, carp, harp seals, American smelt, sardine, capelin, salmon, mackerel, orange roughy, tuna; [2] sardine, capelin, cod, cunner, salmon, anchovy. Atlantic white croaker, carp, hybrid tilapia, herring, spiny dogfish, rainbow trout, crustaceans, mollusks, short-finned squid; [3] Atlantic cod, seal, salmon, sardine, Indian mackerel, red sea bream, and others; [4] Red sea bream, rainbow trout, mackerel, walleye, pollock liver, scallop muscles, shrimp, squid

prawns, blue mussels, hoki, tuna, cod, capelin, scads, mackerels, herrings, yellow fin tuna, Alaska pollock, sea cucumbers, and other species. A heptapeptide having a molecular weight of 962 kDa purified from fermented marine blue mussel could scavenge superoxide, hydroxyl, carbon-centered, and 1,1-diphenyl-2-picrylhydrazyl (DPPH) radicals. Its ability to inhibit lipid peroxidation was higher than α-tocopherol [65.52].

Peptides with antimicrobial activities have been isolated from marine invertebrates, including spider crabs, oysters, American lobsters, shrimp, and green sea urchins [65.28, 30, 51, 54, 56]. Peptides exhibiting high affinity for calcium isolated from pepsin hydrolyzates of Alaska pollack and hoki are able to reduce the risk of osteoporosis. Calcitonin is a hormone (32 amino acid peptide containing a single disulfide bond) known to participate in calcium and phosphorus metabolism. The major source of calcitonin is the thyroid gland, but it is also synthesized in a wide variety of other tissues, including the lung and intestinal tract. The hormone prevents the loss of calcium and phosphorus in urine by reabsorption in the kidney tubules. Calcitonin from salmon can decrease osteoporosis and, hence, is a bone density conservation agent. Salmon calcitonin is about 30 times more potent than that secreted by the human thyroid gland. Nowadays, fish calcitonin is also being made synthetically [65.57]. In addition, the wound healing potential of administering marine collagen peptides (MCP) from chum salmon skin has been demonstrated [65.58]. Some peptides can function as protectants against freezing injury, thereby providing cryostabilization of myofibrils in meat products. Gelatin peptides have been reported to cure osteoporosis. Table 65.5 summarizes various bioactivities of peptides from diverse fishery products.

Marine Enzymes

Seafood processing waste is a rich source of digestive proteolytic enzymes such as gastric, serine, cysteine or thiol proteases, lipases, polyphenol oxidases (PPOs), chitinolytic enzymes, muscle proteases, transglutaminase, and collagenases. Pepsins and gas-

tricins have been isolated from fish gastric mucosa, trypsins and chymotrypsins from pyloric ceca, and trypsin like enzymes from hepatopancreas of marine fish, including cod, mackerel, and salmon, among others. Alkaline phosphatase, hyaluronidase, β-*N*-acetylglucosaminidase, and chitinase have been recovered from shrimp shell waste in good yield. Arctic scallop and clam wastes are good sources of lysozyme, a potential preservative for refrigerated foods [65.8, 59, 60]. A large-scale process for the recovery of enzymes from wastewater of the shrimp processing industry involves flocculation of the water by ferric chloride, concentration by cross-flow ultrafiltration, and then freeze-drying [65.61]. The characteristic properties of marine fish proteinases are a higher catalytic efficiency at low temperatures, lower sensitivity to substrate concentrations, and greater stability at a broader pH range, which are highly useful for their varied applications [65.62].

Collagenase prepared from crab hepatopancreas has been used for skinning of squid (*Loligo* spp.). Protease from mackerel intestines was used for recovery of fish bone from hoki [65.30]. Other applications of endogenous proteases are roe processing, fish sauce, silage, hydrolyzates, and caviar production [65.62, 63]. Because some marine fish and shellfish are inhabitants of extreme low temperatures, their enzymes have significant activities at low temperatures. Further, they may also possess other interesting properties such as salt tolerance and stability to high pressure. Cold-adapted enzymes display a high specific activity associated with relatively high thermosensitivity and lower free energies of activation. Marine enzyme biotechnology can offer novel biocatalysts with properties like high salt tolerance, hyperthermostability, barophilicity, cold adaptivity, and ease in large-scale cultivation. Genes encoding chitinases, proteases, and carbohydrases from microbial and animal sources have been cloned and characterized. Their commercial applications include food processing, biomass conversion, molecular biology, environmental biosensors, bioremediation, and several other processes. Proteases and peroxidases have found industrial applications [65.22, 63–65]. Table 65.6 depicts various enzymes from seafood wastes.

65.5 Lipid-Based Nutraceuticals

65.5.1 Omega-3 Fatty acids

Marine fish generally contain high (> 7%) amounts of lipids, composed of neutral lipids comprised of triacyl glycerols, phospholipids, sterols, wax esters, and some unusual lipids, such as glyceryl esters, glycolipids, sulfolipids, and hydrocarbons. Commercial fish oils are characterized by fatty acids with 12–26 carbon atoms with 0–6 double bonds. The fatty acids are made up of saturated (15–25%), monounsaturated (35–60%) and polyunsatured (25–40%). Marine lipids are rich in long-chain polyunsaturated fatty acids (PUFA) (with more than 14 carbon atoms), particularly, omega-3 (also referred to as ω-3 and or *n*-3) fatty acids (3 indicating the position of the first double bonds at the third carbon from the methyl end of the fatty acid structure). Other dietary fatty acids include *n*-6 PUFA, namely, linoleic, $C_{18:2w6}$, γ-linolenic, $C_{18:3w6}$, and arachidonic, $C_{20:4w6}$ acids. The popular ω-3 fatty acids are eicosapentaenoic acid containing five double bonds ($C_{20:5w3}$, cis-5,8,11,14,17-eicosapentaenoic acid, designated as EPA), and the 22-carbon docosahexaenoic acid, containing six double bonds ($C_{22:6w3}$, cis-4,7,10,13,16,19-docosahexaenoic acid, DHA). In contrast with other fats and oils, marine fish oils contain large amounts of EPA and DHA, in the range of 14–19 and 5–8%, respectively. Fish oils such as those from tuna, salmon, etc., may contain more DHA than EPA. Commercial cod liver oil is a complex mixture of more than 50 different fatty acids, forming triacyl glycerols, of which there is usually 8–9% each of EPA and DHA. Marine oils also contain significant amounts of fat-soluble vitamins A and vitamin D. Halibut, shark and cod liver oils are rich sources of vitamin A and D. A 3.5-oz portion of salmon can provide 90% of daily human need of vitamin D. The content of vitamin E (α-tocopherol) is a powerful antioxidant related to its availability from feed. Vitamin E can help protect skin cells and tissues because of its antioxidant activity. The fat soluble vitamin A and carotenes are relatively stable at normal cooking temperatures. Oil from Antarctic krill (*Euphausia suberba*) is rich in omega-3 fatty acids, phospholipids, and also natural pigments and vitamins [65.66, 67].

The beneficial health effects of marine fish oils, because of the rich presence of omega-3 PUFA, have been well documented. A significant body of evidence

indicates that intake of the long-chain *n*-3 polyunsaturated fatty acids (omega-3 fatty acids) found in fish is cardio-protective [65.68]. Besides, they can reduce hypertension, lower autoimmune and inflammatory diseases, depression, attention-deficit hyperactivity disorder (ADHD) in children and muscle degeneration in the elderly, arthritis and some types of dermatitis. These fatty acids are also involved in the structure of cell membranes, the development of the nervous system and influence the synthesis of cell mediators (prostaglandins and leukotrienes), which play important roles in coagulation, inflammation and proliferation of certain cells. DHA and arachidonic acid (*n*-6) are also important in visual function. Deficiency of these compounds causes disorders such as restrictive growth, abnormal skin and hair, damage of reproductive system, among others [65.69, 70]. Many psychiatric disorders, particularly schizophrenia and major depressive disorder (MDD), have shown positive results when supplementation has been used as an adjunct to standard pharmacotherapy [65.71, 72]. Cod liver oil has been shown to help slow the destruction of joint cartilage in patients with osteoarthritis [65.73]. The health benefits of PUFA have encouraged regulatory agencies to recommend regular public consumption of fatty fish such as herring, sardine, and mackerel. The WHO recommends consumption of 1–2 servings of fish, containing 200–500 mg of EPA and DHA, per week. The American Heart Association recommends that persons diagnosed with cardiovascular diseases consume 1 g each of the fatty acids per day [65.72, 74]. Table 65.7 summarizes potential health benefits of PUFAs.

Whole or processing wastes (particularly liver) of fish, including anchovies, capelin, Atlantic cod, Atlantic herring, Atlantic mackerel, Atlantic menhaden, cod, saithe, haddock, salmonids, and sardines are rich sources of marine lipids rich in PUFA, particularly EPA and DHA. However, lipid composition in these fish varies with season and also depends upon the tissues being analyzed. The oil contents can be as high as 21% in herring, 22% in tuna, and 18% in sardines in winter. Fish livers are the ideal source of these lipids. Enzymatic methods using proteases are useful to release the bound oil from fish tissues. Depending on the proteolytic enzyme used, oil yield from red salmon heads varied between 4.9–10.6% [65.37]. Figure 65.3 depicts a typical alkaline refining process for fish oil extraction. PUFA contents in different marine fishes and methods for their extraction and fractionation, in terms of fatty acid constituents in the form of methyl esters have also been provided. Methods of isolation consist of molecular and fractional distillation, solvent, and supercritical extraction [65.75, 76]. Because omega-3 fatty acids in oil are highly unsaturated, they are sensitive to oxidation with the formation of hydroperoxides, which depends on exposure to heat, light, and moisture, and the presence of metal ions. Therefore, during their isolation PUFAs must be protected against oxidation by incorporating small amounts of antioxidants such as tertiary butylhydroquinone (TBHQ), butylated hydroxytoluene (BHT), and octyl gallate, and the oil must be stored in ampoules with minimum headspace [65.77]. Supercritical fluid extraction (SFE) is a popular technology due to its nontoxic and nonflammable nature. The carbon dioxide atmosphere employed during extraction also protects PUFAs from oxygen-induced oxidation. In the process, PUFAs are usually extracted at an elevated pressure of 10–30 MPa and at 40–80 °C [65.76].

Table 65.7 Potential health benefits of omega-3 fatty acids

Prevention of atherosclerosis
Protection against arrhythmia
Reduction of blood pressure
Beneficial for diabetic patients
Good against manic-depressive illness
Reduction of symptoms in asthma patients
Protection against chronic obstructive pulmonary diseases
Alleviation of symptoms of cystic fibrosis
Prevention of relapse in patients with Crohn's disease
Prevention of various cancers
Good for bone health
Improvement of brain functions in children

Marine oils have been isolated commercially from several gadoid finfish species [65.3, 77–81]. Tuna fish has a total lipid content of about 22% with up to 20 and 4% of DHA and EPA, respectively Monounsaturated and *n*-6 fatty acids are also present at 23.3 and 3.8%, respectively. The huge discards from the global tuna canning industry, estimated at 450 000 t annually, could be a rich source of oil [65.78]. Total lipid contents in the head, meat, and waste of three commercial varieties of Indian marine fishes, namely, pink perch, Indian mackerel, and Indian oil sardine are in the range of 4.3–13.6, 2.53–10.97, and 2.7–15.1% (wet weight basis), respectively. Neutral lipids were higher in the head (83.2–89.2%). The saturated fatty acid, palmitic acid, was present in all the fishes, irrespective of the body components. EPA and DHA, however, were found in higher concentrations [65.82]. Shark liver is 22–30% of the body weight, with an oil content as high as 90%. Liver oils of some sharks found under a depth

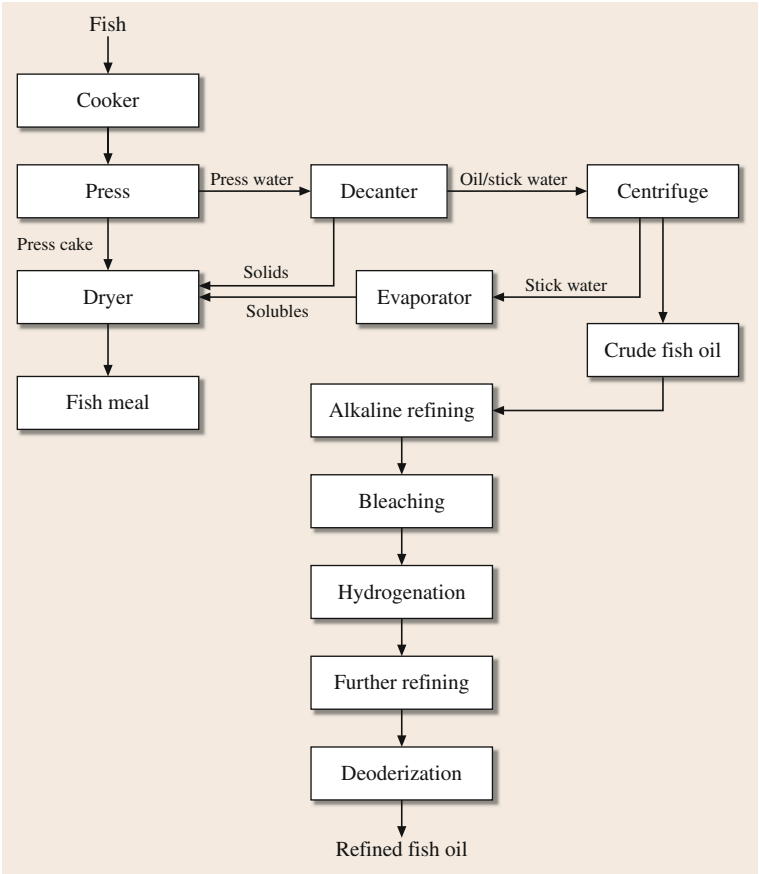

Fig. 65.3 Process for recovery of fish oil

of 300–3000 m in the Pacific, North Atlantic, and Indian Ocean contain ≈ 85–90% unsaponifiable matter, mainly the hydrocarbon, squalene. Shovelnose dogfish liver oil contains 60% hydrocarbons, consisting mainly of squalene and pristane, and 25% diacyl glyceryl ether. Squalene, $C_{30}H_{50}$ is 2,6,10,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaene) and squalamine, an amino sterol antibiotic, are found in shark liver. The recovery of oil from shark liver consists of natural decomposition, acid ensilage in presence of formic acid, alkali digestion, and steam rendering. The oil recovered is degummed, bleached, and deodorized. The process for isolation of squalene from shark oil consists of heating chopped liver in 2% caustic soda solution for 30–40 min to separate the oil. After removing water by anhydrous sodium sulfate, the oil was subjected to vacuum distillation at 240 °C [65.79]. Herring oil has been extracted from dried fish, giving 41% oil rich in PUFA [65.3]. Enrichment of marine oil to increase the contents of PUFA has been attempted by making use of lipolysis [65.83, 84]. Several industries specialize in fish oil production and purification [65.84–86]. Table 65.8 shows the contents of omega-3 fatty acids in as a percentage of total fatty acids in various commercial fish oils.

65.5.2 Carotenoids

Carotenoids are a family of fat-binding compounds responsible for the red and yellow color of crustaceans and also many plants, algae, and cyanobacteria. The carotenoids found in nature can be classified into two groups, namely, hydrocarbons, such as β-carotene and xanthophylls, and the oxygenated derivatives such as astacene, astaxanthin, canthaxanthin, cryptoxanthin, neoxanthin, violaxanthin, and zeaxanthin, lutein, etc. The color of carotenoids is due to chromophores containing conjugated double bonds. The naturally abundant β-carotene ($C_{40}H_{56}$) is a polyunsaturated hydrocarbon made up of two retinal molecules.

Table 65.8 Contents of omega-3 fatty acids in commercial fish oils (values give the percentage of fatty acids in total fatty acids; after [65.87], courtesy of Wiley-VCH)

Species	18 : 3	18 : 4	20 : 5	22 : 5	22 : 6	EPA + DHA
Anchovy	1	2	22	2	9	31
Atlantic menhaden	1	3	14	2	12	26
Sardine/ pilchard	1	3	16	2	9	25

Salmon, farmed	1	3	9	2	11	18
Sprat	2		6	1	9	15
Tilapia, farmed	2			3	5	5
Catfish, farmed	1		1	1	3	4

Approximately 60 carotenoids possess varying levels of provitamin A activity, β-carotene possessing maximal provitamin A activity. Carotenoids possess remarkable antioxidant properties, which is their primary beneficial role in the diet of humans and animals. Astaxanthin is about ten times stronger in antioxidant activity than other carotenoids (including β-carotene, canthaxanthin, and lutein). Animals, including humans, do not synthesize carotenoids de novo and rely upon diet for these compounds. Oral supplementation of carotenoids appears to increase the photo-protective properties of the epidermis and dermis against environmental stress (e.g., UV radiation, pollution, smoke) by quenching free radicals generated by oxidative stress. Studies have also shown the ability of carotenoids to reduce DNA damage and protect against depletion of Langerhans cells, a key component of immune function. Because of their potent antioxidant properties, carotenoids have been suggested to have a protective role against cancer, aging, ulcers, heart attack, and coronary artery disease [65.88].

Crustacean wastes are abundant sources of β-carotene and astaxanthin (3,3′-dihydroxy-β, β-carotene-4 and 40-dione), the oxidized form of β-carotene. Astaxanthin is responsible for the pink-to-red pigmentation of crustaceans and wild salmonids [65.89–91]. The process of extraction of carotenoids from shell waste consists of initial treatment with proteases to detach the pigments from the bound proteins, followed by extraction in organic solvents. Upon treatment with trypsin at the optimum temperature 45–55 °C for 2 h the carotenoid-rich head wastes of commercially important Indian marine shrimp species yielded significant quantities of astaxanthin, and also minor amounts of β-carotene, canthaxanthin, lutein, zeaxanthin, and crustacyanin [65.74]. Astaxanthin in the form of carotenoprotein can be extracted with a yield of 49% by treating shrimp waste with proteolytic enzymes such as trypsin in the presence of ethylenediamine tetraacetic acid (EDTA) at a pH of 7.7 and 4 °C [65.56].

65.6 Polysaccharide-Derived Nutraceuticals

Chitin is a cationic polysaccharide formed by units of *N*-acetyl-D-glucosamine, joined by (1–4) β-bonds, viz., β-(1-4)-*N*-acetyl-D-glucosamine, which is β-(1-4)-*N*-acetyl-2-amino-2-deoxy-D-glucose.

65.6.1 Chitin and Chitosan

Marine crustaceans, which include shrimp, crabs, squid, cuttlefish, krill, and oysters, are rich in chitin. Chitin forms the outer protective coatings of crustacean shells in a covalently bound network with proteins and dihydroxy phenylalanine, together with some metals and carotenoids. Chitin occurs in three polymorphic forms, α, β, and γ, which differ in the three-dimensional arrangements of the molecular chains. Its most common form is α-chitin, where two units of *N*-acetyl-D-glucosamine are in an anti-parallel arrangement. Chitin is a very light, white or yellowish, powdery/flaky prod-

uct. It is insoluble in water, almost all common organic solvents, and in acidic and basic aqueous solutions. Chitin may be solubilized in carbon disulfide after treatment with caustic soda and then re-precipitated as a filament or film in the manner of viscose rayon. Chitin swells in cold alkali when deacetylation takes place [65.8, 15, 44, 92–96].

Shellfish waste consisting of crustacean exoskeletons is currently the main source of biomass for chitin production. The isolation process for chitin consists of three-step treatments of shell wastes, and includes demineralization, deproteinization, and bleaching, followed by extraction of chitin using acetone [65.97]. Demineralization is usually carried out by an extraction of 1−3 h with diluted hydrochloric acid, but harsher conditions such as 90% formic acid, 22% HCl, 6 N HCl, or 37% HCl have also been applied. Deproteinization is performed by treating the raw material with either sodium hydroxide or potassium hydroxide at concentrations between 1−10%(w/v) and at temperatures of 65–100 °C for a duration ranging from 0.5–6 h. Since the harsh conditions of alkaline digestion may cause depolymerization and deacetylation of chitin, enzymatic deproteinization by digestion with proteolytic enzymes such as papain, pepsin, trypsin, or pronase has been used. The following step of solvent extraction (e.g., acetone, chloroform, ethanol) helps remove pigments like melanins and carotenoids [65.15, 93–95].

Chitosan is a collective name representing chitin deacetylated to different degrees. Structurally, chitosan is poly-(1-4)-linked-2-amino-2-deoxy-D-glucose. Commercially chitosan is produced by deacetylation of crustacean chitin using 30−60% (w/v) sodium or potassium hydroxide at 80−140 °C. The preparation is purified by dissolving it in dilute acetic acid, reprecipitation with alkali, followed by washing and drying to obtain flakes of chitosan. The resulting molecular weight distribution of deacetylated units along the polysaccharide chain depends on the alkali concentration applied, and the temperature and time of the process. The degree of deacetylation of the polysaccharide can be increased by using high temperatures in the process, but such harsh conditions also cause depolymerization and lead to a reduction in the size of the molecules. To obtain more defined chitosans and to avoid polysaccharide degradation by oxygen it is also recommended to carry out the deacetylation process under nitrogen or to employ thiophenol or sodium borohydride addition as scavengers of oxygen. Alternately, chitin deacetylases derived from different organism sources can be used [65.94]. Shell waste can also be used for fermentation to produce chitinase [65.98]. Figure 65.4 shows a typical process for chitin extraction and its subsequent processing to yield chitosan.

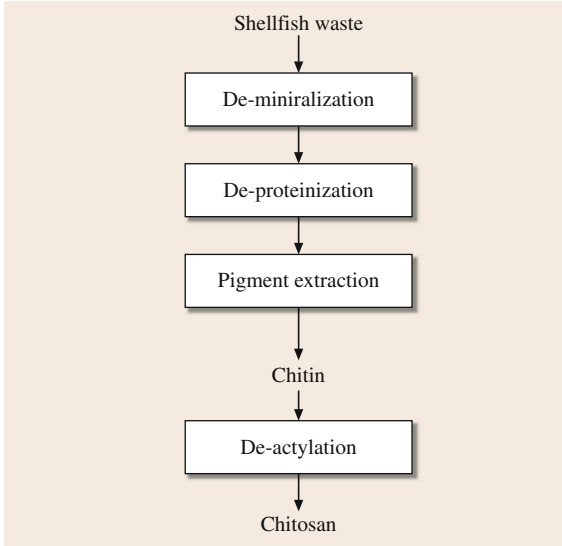

Fig. 65.4 Recovery of chitin and chitosan from shellfish waste

The molecular weight of natural chitosan is generally higher than 10^6 Da. Chitosan is a polycationic, long-chain biopolymer because of the presence of one free amino group and two free hydroxyl groups for each glucose ring. Because of this chemical nature, it has a natural affinity for negatively charged compounds, including biological membranes. Chitosan is insoluble in pure water, but unlike chitin it is soluble in weakly acidic aqueous media. A minimum deacetylation of 70% is required for chitosan to be acceptable for various purposes. The pK_a value for the positively charged ammonium group is ≈ 6.2. When the pH is raised to ≈ 6.5, chitosan precipitates in a gel form. The multidimensional utilization of chitin derivatives, including chitosan, is due to a number of characteristics, including their polyelectrolyte and cationic nature, the presence of reactive groups, the high adsorption capacities, and bacteriostatic and fungistatic influences, which make them very versatile biomolecules [65.99]. Because of its cationic nature, chitosan is incompatible in solution with most anionic water-soluble gums such as alginates, pectate, sulfated carrageenan, as well as carboxymethyl cellulose. On the other hand, acidic solution of chitosan is compatible with nonionic water soluble gums such as starch, dextrins, glucose, polyhydric alcohols, oils, fats, and nonionic emulsifiers.

Chitosan can form films, which are tough, flexible, and transparent. Chitosan is biodegradable by the specific enzyme, chitosanase. By enzymatic treatment, soluble chitosan can also be obtained in oligosaccharide form. Chitosan derivatives in the form of acetate, ascorbate, lactate, malate, and others are water-soluble and have varying functional properties. The role of chitosan as a fiber, however, is challenged by popular fiber products such as oats, soy, and bran. Chitosan film can be extruded from its acidic solution into a 70 °C coagulating bath containing caustic soda and sulfonic acid esters of high molecular weight alcohols. Chitosan in microcrystalline form has several advantages when compared to standard chitosan [65.8, 95, 100, 101].

Polysaccharide-based biomaterials, particularly chitosan, are emerging for applications in several biomedical fields, such as tissue regeneration, particularly for cartilage, drug delivery devices, and gel entrapment systems for the immobilization of cells. Their salient beneficial properties are controllable biological activities, biodegradability and the ability to form hydrogels [65.101]. Recent years have witnessed a marked growth in chitosan and its derivatives, the applications encompassing food and nutrition, biotechnology, material science, drugs and pharmaceuticals, cosmetics, water treatment, cosmetics, agrochemicals, biotechnology, environmental protection, and gene therapy. The medical applications of chitosan cover such diverse fields as hemodialysis membranes, artificial skin, hemostatic agents, hemoperfusion columns, and drug delivery systems. Oral administration of chitosan suppresses the serum cholesterol level and hypertension. The bacteriostatic and fungistatic properties of chitosan mean that it can be used as an ingredient in tropical skin ointments as a wound healing agent [65.43]. The property of chitosan to form gel at slightly acid pH provides antacid and anti-ulcer activities. The antimicrobial activity and film-forming property of chitosan make it a potential source of food preservatives or a coating material of natural origin. Chitosan is also a popular drug carrier. It enhances dissolution properties of poorly soluble drugs and also helps transdermal delivery of drugs [65.43, 95, 102–105]. When intravenously injected, chitin/chitosan oligosaccharides enhance antitumor activity by activating macrophages [65.106]. Chitosan-based scaffolds are useful for tissue regeneration [65.107]. The use of chitin as a source of dietary fiber in chicken feed enhances the growth of bifidobacteria in the guts, which reduce other microorganisms and produce the β-galactosidase necessary for the digestion of feed supplemented by whey or other dairy by-products. The effect has also been noticed in the case of chitosan feed meant for pigs and fish [65.43].

65.6.2 Glucosamine

Glucosamine is natural amino sugar found in large concentrations in certain foods such as milk, eggs, liver, yeast, molasses, and yeast. Glucosamine is obtained by extensive hydrolysis of chitosan with mineral acid, such as hydrochloric acid. If it is produced from chitin, it must be deacetylated. Glucosamine can easily be absorbed into the human intestine [65.93].

65.6.3 Glycosaminoglycans (GAGs)

Glycosaminoglycans are multifunctional polysaccharides composed of repeating disaccharide units. Based on the disaccharide composition, linkage type, and the presence of sulfate groups, GAGs include chondroitin sulfate, dermatan sulfate, heparin sulfate, keratin sulfate, and heparin, and are present in the connective tissues of living systems together with collagen, elastin, fibronectin, and laminin, forming a complex extracellular

Table 65.9 Useful features of chitosan in food applications

Properties	Applications
Renewable resource	Abundantly available from marine sources and hence renewable
Bioactivity	Antimicrobial activity and its use in food packaging as antimicrobial additive, stimulation of immune system, anti-cholesterolemic activity, use as fiber in foods, obesity control
Biodegradability	Substrate for single cell production, biodegradable packaging material, controlled release of drugs, nutrients, etc.
Reactivity of deacetylated amino groups	Moisture control, thickening action
Chelating capacity	Removal of metals, water treatment, antioxidant activity
Complex formation with other macromolecules	Complexes with proteins (useful to remove hypoallergenic β-lactoglobulin from whey, clarification of wines). Chitosan-alginate removes protein from seafood industry waste water
Biocompatibility	Nontoxic and biological tolerance
Film-forming properties	Useful as edible packaging, encapsulation materials, and delivery of nutraceuticals

Table 65.10 Applications of chitin, chitosan, and some of their derivatives in healthcare (after [65.43, 101, 102, 105, 108])

Compound	Applications
Chitin	Wound dressing In vivo absorbable sutures Drug delivery Dialysis membrane
O-Carboxymethyl chitin and *O*-hydroxypropyl chitin	Cosmetic ingredient
N-Actylchitohexasacharide	Antitumor agent
Chitosan and its various derivatives	Artificial skin Blood anticoagulant and hemostatic materials Chitin and chitosan hydrogels for delivery of nutraceuticals Protein absorbents Drug delivery systems Haemodialysis membranes Immunostimulation, molecular recognition, and entrapment of growth factor, etc. Nanofiber scaffold for nerve tissue regeneration Hypocholesterolemic agents Wound-healing materials Nutrition (dietary fiber, weight reduction, hypocholesterolemic agent, etc.) Water treatment (removal of metals, radioisotopes, pesticides, etc.) Cosmetics (shampoo, skin products)
N-Hexanoylchitosan and *N*-octanoylchitosan	Antithrombogenic material for artificial blood vessels Contact lenses Blood dialysis membranes Artificial organs
N-Carboxybutylchitosan	Wound dressing
5′-Methylpyrrolidinone chitosan	Dentistry
Sulfates of chitin and chitosan	Anticoagulant and lipolytic agents

matrix providing a cushion between bones and joints. Most sulfated GAGs are covalently linked to proteins to form proteoglycans. Chondroitin is composed of a chain of *N*-acetylgalactosamine and glucuronic acid residues linked through alternating β (1–3) and β (1–4) bonds. Chondroitin sulfate (CS) has anti-inflammatory properties, as well as anticancer properties. While chondroitin provides cartilage with strength and resilience, glucosamine inhibits inflammation and stimulates cartilage cell growth [65.109]. Table 65.9 summarizes food applications of chitosan and Table 65.10 shows applications of chitin, chitosan, and some of their derivatives in healthcare.

GAGs in terrestrial vertebrates have been well studied. Cartilage of marine animals such as shark, skate, mussels, and squid can be good sources of these polysaccharides. Shark cartilage, which is rich in chondroitin sulfate, has been found to have several therapeutic effects against diseases such as arthritis and tumors. Shark cartilage along with glucosamine is a highly effective treatment for arthritis and osteoporosis. A process for the preparation of chondroitin sulfate from skate cartilage has been reported [65.84]. Another compound, hyaluronic acid (HA), is a natu-

Table 65.11 Some applications of glycosaminoglycans in medicine (after [65.44, 101, 105])

Glycosaminoglycans	Applications
Chondroitin sulfate and other glycosaminoglycans	Helps rebuild cartilage and joints. Supports body's ability to joint health integrity
Hyaluronic acid	Eye surgery, osteoporosis, tumor marker etc.
Dermatan sulphate	Stimulates cell growth. Role in wound healing, cardiovascular disease, etc.
Heparin	Anticoagulant
Keratan sulfate	Eye treatment (corneal transparency)
Chitin	Chitin and chitosan have wide applications
Chondroitin	Helps rebuild cartilage and joints. Supports body's ability keep joints healthy

rally occurring polysaccharide consisting of glucuronic acid and *N*-acetyl-Dglucosamine units. HA functions as an effective moisturizer due to its strong water holding capacity. With age, the levels of HA in the body decrease, reducing the moisture binding capacity of the skin, resulting in dry skin and wrinkles. Oral consumption of HA can help increase moisture on the surface and within the skin. A combination of gelatin, hyaluronic acid, and chondroitin can have potential in wound healing [65.53]. Table 65.11 shows some medical applications of glycosaminoglycans. The global market for marine-derived drugs was US$ 4.8 billion in 2011 and is expected to reach US$ 8.6 billion in 2016 [65.110].

65.7 Mineral-Based Nutraceuticals

Bone comprises a significant part of seafood processing wastes. Filleting of fish generates a large amount of fish frames. For instance, backbone wastes from the processing of Atlantic cod account for approximately 15% of the wet weight of the fish. Fish bone contains about 40% crude protein and 6% collagen, on a dry weight basis. Inorganic minerals constitute approximately 60% of bones, the major ash components being calcium and phosphorus [65.11, 23, 111]. The mineral constituents can be classified as into three groups, composed mainly of either hydroxyapatite (HAP), tricalcium phosphate, (TCP), or a mixture of HAP and TCP. Sea bream, horse mackerel, carp, and shark have hydroxyapatite type phosphate (as in the case of cattle, swine, and fowl), while Japanese anchovy has TCP type phosphate [65.112].

Fish bone is a potential source of calcium. To isolate the mineral in a bioavailable form, the bone is initially softened by either hot water or hot acetic acid. Superheated steam can reduce the loss of soluble components from fish tissue, which enables better recovery of bone within a shorter period. The treated bones are subjected to saponification, degreasing, and degumming. The preparation is a source of dietary calcium, in addition to some phosphorus [65.113]. Peak bone stone is the bony structure situated near the vertebral column of the dorsal fin base obtained from large fishes like ghol (*Protonibea diacanthus*), koth (*Otolithes biauratusa*), and dara (*Filamanus heptadactyla*). There is potential to use the product as raw material for calcium powder [65.8]. The skeleton discarded from the industrial processing of hoki was digested by a heterogeneous enzyme extracted from the intestine of bluefin tuna, which yielded a fish bone oligophosphopeptide containing 23.6% phosphorus. The peptide (molecular weight of 3.5 kDa) could be a nutraceutical with a potential calcium-binding activity [65.114]. Fish and shellfish are also rich sources of selenium [65.66, 67].

65.8 Novel Marine Organisms and Compounds

Marine invertebrates have been recognized as rich sources of more than 400 bioactive compounds, including hypotensive agents, cardio active substances, muscle relaxants, antibiotics, and antiviral and antitumor agents [65.115]. Sea cucumbers or holothurians are spiky-skinned animals of the phylum Echinodermata (class Holothuroidea). They are commonly found in shallow water areas of the sea to deep ocean floors. Related species are the sea lily, sea urchin, star fish, and sand dollars. The cell wall of the sea cucumber contains large amounts of sulfated glycans. The cell wall polysaccharide is comparable in backbone structure to mammalian chondroitin sulfate, but some of the glucuronic acid residues display sulfated fucose branches. The specific spatial array of the sulfated fucose branches in the fucosylated chondroitin sulfate not only confers high anticoagulant activity to the polysaccharide but also antithrombin activity [65.116].

These glycans also exhibit a wide range of other biological activities, which include recombinant HIV reverse transcriptase activity, anti-inflammatory, antiangiogenic, and antiadhesive properties [65.117]. Green fluorescent protein (GFP) is a novel photoactivatable fluorescent protein (PAFP) compound that was first isolated from jellyfish in 1962. The green color of the protein turns red when exposed to an intense pulse of visible blue light. GFP is an invaluable tool that is useful for in vivo bioprocess monitoring such as protein interactions and drug interaction [65.118].

The ink of squid and cuttlefish has been found to possess some therapeutic activity. Mollusks are another important species that have a wide range of uses in pharmacology. Guanine, (2-amino-6-oxypurin) found as a constituent in scale membranes is responsible for the gleaming effect of fish. Guanine combines with collagen and calcium phosphate, yielding a silvery white thinning substance. The lustrous material can be extracted as crystals from fish scales like those of sardine, herring, ribbonfish, carp, etc. The yield of the recovered material, often called pearl essence because of its luster, is $\approx 0.3\%$ of the body weight in the case of ribbon fish.

65.9 Commercial Aspects

In recent years marine compounds, including those derived from seafood, have been entering commercial markets. Some marine nutraceuticals currently marketed in the US include fish and algal oils that are rich in omega-3 fatty acids, chitin and chitosan, fish and shark liver oil, and marine enzymes and chondroitin from shark cartilage, sea cucumbers, and mussels. Commercially important nitrogen-based seafood nutraceuticals include peptides, fish bone phosphopeptide with calcium binding activity, salmon calcitonin, and squalamine. Salmon calcitonin (CAS No. 47931-85-1) is approved for postmenopausal women who cannot tolerate estrogen.

In Japan foods fortified with nutraceuticals are approved as food for specified health uses (FOSHU). Several FOSHU products with a fish (e.g., sardine) peptide as the functional ingredient have been approved for the control of mild hypertension [65.119]. Enzymes such as trypsin and chymotrypsin, purified from cod viscera, are available commercially. The global market for industrial enzymes was valued at US$ 3.9 billion in 2011 and is supposed to grow to reach $ 6 billion in 2016 [65.110]. Sea cucumber, processed after boiling and sun-drying, marketed as *beche-de-mer* (meaning processed sea slug or sea cucumber) is a highly priced product on the international market. It is said to cure low blood pressure, kidney disorders, and impotence and to prevent ageing [65.120]. The global market for marine-derived drugs was US$ 4.8 billion in 2011 and is expected to reach US$ 8.6 billion in 2016 [65.110].

Omega-3 fatty acids remain one of the most successful and promising functional ingredients in the food and beverage industry. The global market for the product is about 49 000 t annually, worth around US$ 700 million. Marine-based oils used in the food industry include oils from cod, sardine, tuna, and salmon, and also algal oil, many of these oils finding use in margarine and butter. Capsules containing PUFA-rich oils of fish such as cod and salmon, rich in DHA and EPA, as well as vitamins A and D, are being prescribed to reduce blood pressure and to and improve joint mobility. Foods fortified with omega-3 fatty acids are marketed particularly in the US, Europe, Japan, and Southeast Asia. Incorporation of DHA into baby foods is being practiced to enhance memory development. Other fortified products include bakery items, bread spreads, salad dressing, and others [65.85]. The market for these products was propelled when the US Food and Drug Administration (FDA) in 2004 approved a qualified health claim for omega-3 fatty acids (EPA and DHA). About 75% of fortified products on the European market include milk, cake, pasta, cheese, yogurt and chocolate milk, and infant formulae, which contain omega-3 from marine fish and the rest from algae and flax seed oils [65.7]. The demand for omega-3-enriched consumer packaged goods (CPGs) is expected to exceed a value of US$ 13 billion in 2015 [65.49]. Marine oils are also being used to fortify livestock and aquaculture feed to produce omega-3-rich farmed fish, eggs, and milk. The current interests in Japan encompass the potential anticancer properties of deep.sea shark liver oil and tuna body oil as a less expensive source of DHA [65.119].

The worldwide carotenoid demand is growing at an estimated average annual rate of 2.9%. Currently, β-carotene from the alga *Dunaliella salina* is a commercialized high-value product, its major producers being Australia, US, and Israel. β-Carotene is sold mainly as an extract or suspension in vegetable oil or as β-carotene-rich algal powder. Astaxanthin is widely used to pigment salmon and trout, although in recent times, canthaxanthin has become popular in fish pigmentation and also in poultry to give a red color to egg yolks.

Japan is the major producer of chitin and chitosan from the shells of crabs and shrimp (FAO, 2012). The market for chitosan in the US is about US$ 20 million [65.13]. Chitosan is essentially used to assist

weight loss. Chitosan-fortified fruit juices and chocolates are marketed in the US. In Europe chitosan is sold as dietary capsules to assist weight loss. Some of the products include *Fat Absorb*, a US product containing 250 mg of chitosan per capsule, the *Seaborne* range of products such as *Essential Sea* and *EssentialSeaPlus*, which contain chitosan together with lecithin, vitamins C and E, garlic, and β-carotene, and the fat trimmer, *Minfat*. In Japan, chitosan is added to noodles, potato crisps, and biscuits. There is potential for supplementing beverages with glucosamine in hydrochloride or sulfate forms prepared from chitosan. It is expected that current clinical trials in Japan and many other countries will result in identifying new functional ingredients beyond the fish oils, chitosan and peptides, that can throw more light on the health protection ability of seafood and other marine products [65.119]. As was pointed out recently [65.121], the refinement of existing technologies with inputs from advances in biotechnology can further help with the isolation of seafood components that are safe and can retain their potential bioactivities for diverse applications.

Acknowledgements

A.2 Marine Fungal Diversity and Bioprospecting

by Kalaiselvam Murugaiyan

It is my pleasure to thank my doctoral research scholars: Dr.A. Elavarasi, Dr. K.A. Thillaimaharani, Dr. A.R. Logesh, and Dr. K. Sharmila for allowing me to refer their data. Gratefully acknowledge to Prof. K. Kathiresan, Director and Dean for his useful comments and motivation. My heartfelt gratitude and sincere indebtedness to the authorities of Annamalai University for providing the necessary facilities and the University Grants Commission for financial support.

A.8 Marine Sponges – Molecular Biology and Biotechnology

by Stephen A. Jackson, Jonathan Kennedy, Lekha Menon Margassery, Burkhardt Flemer, Niall O'Leary, John P. Morrissey, Fergal O'Gara, Alan D. W. Dobson

This project was supported by the Beaufort Marine Research Award under the Sea Change Strategy and the Strategy for Science Technology and Innovation (2006–2013), with the support of the Marine Institute, funded under the Marine Research Sub-Programme of the National Development Plan 2007–2013.

B.11 Microbial Bioprospecting in Marine Environments

by Mariana Lozada, Hebe M. Dionisi

H.M. Dionisi and M. Lozada are researchers from the Argentinean National Research Council (CONICET). The work at the Environmental Microbiology Lab, CENPAT-CONICET, is supported by grants from CONICET, the National Agency for Science and Technology Promotion of Argentina (ANPCYT), The Secretary of Science, Technology and Innovation from the Chubut Province, Argentina, and the Community Sequencing Program, Joint Genome Institute.

B.12 Novel Bioreactors for Culturing Marine Organisms

by Debashis Roy

This chapter is respectfully dedicated to my teacher Prof. Pinaki Bhattacharya, whose teaching, guidance and paternal affection I shall treasure forever.

Assistance provided by my postgraduate student Arka Roychowdhury in preparation of the manuscript is also thankfully acknowledged.

B.13 Transgenic Technology in Marine Organisms

by Thomas T. Chen, Chun-Mean Lin, Maria J. Chen, Jay H. Lo, Pinwen P. Chiou, Hong-Yi Gong, Jen-Leih Wu, Mark H.-C. Chen, Charles Yarish

Some results presented in this paper were supported by a grant from USDA (CONTR # 58-1930-0-009) to TTC.

B.15 Biofouling Control by Quorum Quenching

by Vipin C. Kalia, Prasun Kumar, Shunmughiah K. T. Pandian, Prince Sharma

The authors wish to thank the Director of the CSIR Institute of Genomics and Integrative Biology (IGIB), CSIR-INDEPTH for providing the necessary funds and facilities. PK is thankful to CSIR for granting a Senior Research Fellowship.

VCK, PK, SKP, and PS have contributed towards collection of material and preparation of article. VCK has contributed towards the conceptualization and writing the article.

B.16 Detection of Invasive Species

by Nathan J. Bott

Thanks are due to the Australian Department of Environment, Water, Heritage and Arts, the Australian Department of Agriculture, Fisheries and Forestry, Biosecurity SA, and the Adelaide and Mount Lofty Ranges Natural Resources Management Board for funding.

D.22 Cell Wall Polysaccharides of Marine Algae

by Andriy Synytsya, Jana Čopíková, Woo J. Kim, Yong Il Park

This work was supported by the Czech Science Foundation (project No. 503/11/2479), by the Ministry of Education, Youth and Sport of the Czech Republic (project No CEZ: MSM6046137305), and by the Gyeonggido Regional Research Center (GRRC) program at The Catholic University of Korea.

D.23 Iodine in Seaweeds: Two Centuries of Research

by Frithjof C. Küpper

The author would like to thank Bernard Kloareg, Hans Vilter, Philippe Potin, Erwan Ar Gall, and Jean-Michel Legendre for their mentoring and support during his undergraduate and graduate research in Roscoff and for inciting his interest in the field (1995–2001). The studies of volatile emissions of iodocarbons and molecular iodine would not have been possible without the collaboration of Lucy J. Carpenter, Gordon B. McFiggans, Carl Palmer, Peter Liss, and Gill Malin. George W. Luther III and Tim Waite are thanked for their collaboration on investigating iodine efflux upon oxidative stress. FCK is most grateful to Martin C. Feiters and Wolfram Meyer-Klaucke for their visionary collaboration to conduct X-ray absorption spectroscopy to study iodine metabolism in situ, and to Peter M.H. Kroneck and Alison Butler for their collaboration, mentoring, and long-standing support with this research. FCK would like to thank Studienstiftung des deutschen Volkes (German Academic Merit Foundation), the European Commission, the UK Natural Environment Research Council and the TOTAL Foundation for funding.

E.27 Marine Actinomycetes in Biodiscovery

by D. İpek Kurtböke, Tanja Grkovic, Ronald J. Quinn

Authors thank Rachel Hancock at the Analytical Electron Microscopy Facility, Institute for Future Environments, Queensland University of Technology for the electron micrographs of the USC-633.

F.32 Marine-Derived Fungal Metabolites

by Sherif S. Ebada, Peter Proksch

Peter Proksch thanks the Federal Ministry of Education and Research (BMBF), Berlin, Germany for the continued support of his research efforts.

F.33 Marine Dinoflagellates-Associated Human Poisoning

by Samanta S. Khora

The author is grateful to the authorities of VIT University, Vellore for the facilities and support. He also thanks his research scholars for their assistance with preparation of the References.

F.36 Fatty Acids of Marine Sponges

by Pravat Manjari Mishra, Ayinampudi Sree, Prasanna K. Panda

The authors are grateful to the Director of the CSIR-Institute of Minerals and Materials Technology, Bhubaneswar, India, for the encouragement and for providing the laboratory facilities for this research.

G.42 Marine Functional Foods

by Ana C. Freitas, Dina Rodrigues, Ana P. Carvalho, Leonel Pereira, Teresa Panteleitchouk, Ana M. Gomes, Armando C. Duarte

This work was supported by the Portuguese Science Foundation (Fundação para a Ciência e Tecnologia), through the individual research grants references SFRH/BPD/73781/2010 and SFRH/BD/77647/2011 under QREN–POPH funds, co-financed by the European Social Fund and Portuguese National Funds from MCTES and project PEst-C/MAR/LA0017/2013 supported by European Funds through COMPETE and by National Funds through the FCT.

G.44 Cosmetics from Marine Sources

by Elena M. Balboa, Enma Conde, M. Luisa Soto, Lorena Pérez-Armada, Herminia Domínguez

The authors are grateful to the Spanish Ministry of Education and Science for the financial support of this work (Research Project reference CTM2009-12664, which had partial financial support from the FEDER funds of the European Union). E.M. Balboa is grateful to the Spanish Ministry of Education and Science for her FPI grant BES-2010-041807.

G.45 Omega-3 Fatty Acids Produced from Microalgae

by Munish Puri, Tamilselvi Thyagarajan, Adarsha Gupta, Colin J. Barrow

The authors are thankful to the Special Research Centre (SRC) for Chemistry and Biotechnology, Deakin University, Australia, for providing the necessary support to pursue research work on *nutraceuticals*.

G.48 Vector and Agricultural Pest Control

by Venkateswara Rao Janapala

The author thank the Director, IICT for providing the facilities and constant encouragement throughout the study and also thankful to Department of Ocean Development (DOD) and Department of Biotechnology (DBT) for financial support to carry out the research.

H.49 Nanotechnology – from a Marine Discovery Perspective

by Ramachandran S. Santhosh, Visamsetti Amarendra

The authors thank SASTRA University for the continuous support.

H.51 Biofuel Innovation by Microbial Diversity

by Thiago Bruce, Astria D. Ferrão-Gonzales, Yutaka Nakashimada, Yuta Matsumura, Fabiano Thompson, Tomoo Sawabe

TB acknowledges CAPES and CNPQ for funding this research. TS and FLT are grateful to the a funding from the Brazil-Japan Strategic Cooperative Research project hosted by JST-CNPq. TS also thanks Professors Hayashi and Kurokawa, and Drs. Ogura and Maruyamathe in the KAKEN and MEXT genome supporting projects.

H.52 Marine Biomaterials as Antifouling Agent

by Parappurath Narayanan Sudha, Thandapani Gomathi, Jayachandran Venkatsan, Se-Kwon Kim

The authors wish to thank the authorities of DKM College and Thiruvalluvar University, Vellore, Tamil Nadu, India for their encouragement. Thanks are also due to the editor Dr. Se-Kwon Kim, Marine Bio Process Research Center, Pukyong National University, South Korea for the opportunity and support.

I.54 Marine Materials: Gene Delivery

by Bijay Singh, Sushila Maharjan, Yun-Jaie Choi, Toshihiro Akaike, Chong-Su Cho

This work was supported by the National Research Foundation of Korea Grant funded by the Korean Government (MEST) (NRF-2011-0009592).

I.55 Marine Organisms in Nanoparticle Synthesis

by Pallavi Mohite, Mugdha Apte, Ameeta R. Kumar, Smita Zinjarde

PM wishes to thank the Council of Scientific and Industrial Research, India, for the Junior Research Fellowship. All authors are grateful to the University Grants Commission, India, for financial support under UPE phase II.

I.56 Marine Biomaterials in Therapeutics and Diagnostic

by Ashutosh Srivastava, Arti Srivastava, Ananya Srivastava, Pranjal Chandra

PC would like to thank the in-house research facility provided by Amity Institute of Biotechnology, Amity University, Uttar Pradesh, India.

I.57 Enzymatically Synthesized Biosilica

by Xiaohong Wang, Heinz C. Schröder, Werner E.G. Müller

W.E.G.M. is a holder of an ERC Advanced Investigator Grant (No. 268476 *BIOSILICA*). This work was supported by grants from the German Bundesministerium für Bildung und Forschung (project *Center of Excellence BIOTECmarin*), the Deutsche Forschungsgemeinschaft (SCHR 277/10-2), the European Commission (Seventh Framework Programme, Marie-Curie Initial Training Network *BIOMINTEC*, Grant No. 215507; as well as the Industry-Academia Partnerships and Pathways *CoreShell*; Grant No. 286059), and the International Human Frontier Science Program.

I.58 Biomineralization in Marine Organisms

by Ille C. Gebeshuber

This research was supported by Universiti Kebangsaan Malaysia, Arus Perdana Project UKM-AP-NBT-16-2010 and MOHE Malaysia, Project FRGS/1/2013/TK02/UKM/01/1.

The author thanks Anha Jan (Amity University, India) and Dr. Mark Macqueen (Aramis Technologies, Malaysia) for their kind help in the preparation of Fig. 58.12.

J.59 Functional Feeds in Aquaculture

by Jorge Olmos Soto, José de Jesús Paniagua-Michel, Lus Lopez, Leonel Ochoa

The authors wish to thank Rosalia Contreras Flores for technical assistance and Lidia Martinez Esquer for English language improvement.

J.63 Marine Actinobacterial Metabolites and their Pharmaceutical Potential

by Panchanathan Manivasagan, Jayachandran Venkatesan, Kannan Sivakumar, Se-Kwon Kim

The authors acknowledge with thanks the Marine Biotechnology Project of the Marine Bioprocess Research Center, funded by the Ministry of Land, Transport and Maritime Affairs, Republic of Korea.

About the Authors

Toshihiro Akaike

Tokyo Institute of Technology
Graduate School of Bioscience and Biotechnology
Yokohama, Japan
akaike@fais.or.jp

Chapter I.54

Toshihiro Akaike is a Professor Emeritus of Tokyo Institute of Technology and the Director and Principal Investigator of Biomaterials Center for Regenerative Medical Engineering at the Foundation for Advancement of International Science, Japan. He received his PhD in Synthetic Chemistry from University of Tokyo in 1974. He gradually became an Associate Professor at Tokyo University of Agriculture and Technology (1980), and a Professor of Bioscience and Biotechnology (1990) at the Tokyo Institute of Technology. His current research interests include biomedical polymers, bioceramics for biomaterials in stem cell technology and regenerative medicine.

Visamsetti Amarendra

SASTRA University
School of Chemical and Biotechnology
Thanjavur, India
amarendravissamsetty@yahoo.co.in

Chapter H.49

Amarendra received his Master degree from SASTRA University, India, in 2010 and is working in the field of marine biotechnology for his PhD. He is an author of a book chapter entitled *Sponges*.

Mugdha Apte

University of Pune
Institute of Bioinformatics and Biotechnology
Pune, India
mapte@unipune.ac.in

Chapter I.55

Mugdha Apte is pursuing the PhD in microbiology at the University of Pune. Earlier, she worked as a Lecturer in the Department of Biotechnology, V.E.S. College of Arts Science and Commerce, Chembur, Mumbai. Her research interests lie in the exploitation of different marine microorganisms for a variety of environmental applications.

Elena M. Balboa

University of Vigo
Department of Chemical Engineering
Ourense, Spain
elenamba@uvigo.es

Chapter G.44

Elena Balboa received her BS degree on Food Science and Technology (2008) and MS degree (2010) on Agro-Food Science and Technology, both from the University of Vigo. Now she is a PhD student in the Department of Chemical Engineering at the University of Vigo and is working on the valorization of invasive brown algae at the Galizian costs, Spain.

Colin J. Barrow

Deakin University
Centre for Chemistry and Biotechnology, LES
Victoria, 3217, Australia
cbarrow@deakin.edu.au

Chapter G.45

Colin Barrow graduated with a BSc (Hons) and PhD from the University of Canterbury in New Zealand in 1984 and 1988, respectively. His research is focused on omega-3 food biotechnology and the application of nanomaterials for industrial purposes. He has 180 peer-reviewed publications, several patents, and has presented at numerous conferences and workshops.

Begoña Ben-Gigirey

Ministry of Health
EU Reference Laboratory for Marine Biotoxins
Vigo, Spain
bbeng@msssi.es

Chapter F.37

Begoña Ben-Gigirey graduated both as a Pharmacist and Food Technologist from the University of Santiago de Compostela (Spain), where she then received the PhD degree. Her research has focussed on the analysis of seafood products, performing microbiological, sensorial and chemical analysis for the determination of biotic and non-biotic contaminants. She is now working in the Marine Biotoxins field with a special focus on the analysis of ASP and PSP toxins, on the organization of Interlaboratory Studies and in the coordination of the EU Reference Laboratories for marine biotoxins.

Francesca Beolchini

Polytechnic University of the Marche
Department of Life and Environmental Sciences
Ancona, Italy
f.beolchini@univpm.it

Chapter D.24

Francesca Beolchini (MS in Chemical Engineering 1995, PhD 1998) is an Assistant Professor of Development of Chemical Processes. Her main research activities are in the field of chemical engineering for the environment, dealing with the development of innovative bio/hydrometallurgical processes for the remediation of contaminated sediments and wastewater and for the exploitation of metal bearing wastes as well as low-grade ores.

A. Mir Bilal

YeungNam University
Department of Biotechnology
Gyeongsan, Korea
biobilal14@ynu.ac.kr

Chapter B.10

I received my BSc in Bioscience and MSc in Biochemistry from Jamia Millia Islamia, New Delhi, India in 2010 and 2012, respectively. In 2013 I joined the Molecular Biology lab, YeungNam University, Korea, as research scholar. Since then I have been involved in animal stem cell biology and culture, molecular mechanisms of skeletal muscle myogenesis and skeletal muscle development. Since October 2013 I am a BK21+ (Brain Korea 21 plus) project fellow.

Nathan J. Bott

RMIT University
School of Applied Sciences
Bundoora, Australia
nathan.bott@rmit.edu.au

Chapter B.16

Nathan Bott is an academic in the School of Applied Sciences, RMIT University. His research incorporates aspects of fundamental (taxonomy and systematics) and applied (molecular approaches, monitoring strategies) marine science. His research utilizes cutting-edge molecular technologies; in particular for the development into informative marine surveillance and monitoring tools, as well as to answer important ecological and evolutionary questions.

Vincent Boursicot

Ifremer, Atlantic Center
Marine Resources and Biotechnology
Nantes, France
vboursicot@gmail.com

Chapter F.39

Vincent Boursicot was a fellow at Ifremer (funded by Ifremer and Région Pays de la Loire) and received his PhD in molecular biology and microbiology from the University of Nantes in 2012. His research was focused on the molecular biosynthesis mechanism of a marine-derived exopolysaccharide.

Thiago Bruce

Faculdade de Tecnologia e Ciências (FTC)
Department of Bioenergy
Salvador, Brazil
thbruce@gmail.com

Chapter H.51

Thiago Bruce received PhD in Genetics from the Federal University of Rio de Janeiro in 2011 and became Titular Professor at the FTC in 2012. Now he teaches in the Bioenergy Master Program and performs research focused on bio prospecting of microbial molecular diversity. He received a Young Scientist Award for his Dissertation.

Dumitru Bulgariu

University Alexandru Ioan Cuza of Iasi
Department of Geology
Iasi, Romania
dbulgariu@yahoo.com

Chapter D.25

Dumitru Bulgariu is an Associate Professor at the Department of Geology, Faculty of Geography and Geology, *Alexandru Ioan Cuza* University of Iasi and a researcher at Collective of Geography from Iasi Filial of Romanian Academy. His research interests include: analytical geochemistry, pedo-geochemistry, thermodynamic of geochemical processes. He is laureate of the Romanian Academy.

Laura Bulgariu

Technical University
Gheorghe Asachi of Iasi
Environmental Engineering and Management
Iasi, Romania
lbulg@tuiasi.ro

Chapter D.25

Laura Bulgariu is Lecturer Professor at the Technical University Gheorghe Asachi of Iasi, Romania. She received the PhD degree in Chemistry in 2006, and in 2013 her Habilitation degree in Environmental Engineering. Her research interests are in environment-friendly methods for removal of toxic heavy metals from aqueous media. She is Laureate of Romanian Academy.

Ana G. Cabado

ANFACO-CECOPESCA
Food Quality and Safety
Vigo-Po, Spain
agcabado@anfaco.es

Chapter F.37

Dr. Ana G Cabado is a senior scientist and the Scientific Coordinator at ANFACO-CECOPESCA, the Spanish National Association of Seafood Producers and Technological Centre for Seafood and Aquaculture Products Preservation. She is the Head of the Food Quality and Safety Department where she gained experience in food microbiology, biotic and abiotic contaminants, including marine biotoxins, with a focus on detection methods and toxicology.

Ricardo Calado

University of Aveiro
Campus Universitário de Santiago
Department of Biology
Aveiro, Portugal
rjcalado@ua.pt

Chapter F.35

Ricardo Calado is a Principal Researcher in the Department of Biology & CESAM at the University of Aveiro, Portugal. He received his PhD in 2005 from the University of Lisbon, Portugal in Animal Biology. His research interests include the integrated use of applied marine ecology and aquaculture to enhance the sustainability of bioprospecting for marine natural products.

Ana P. Carvalho

Universidade Católica Portuguesa
Escola Superior de Biotecnologia
Porto, Portugal
ana.p.santos.carvalho@gmail.com

Chapter G.42

Holds a PhD in Biotechnology since 2005. She has worked atthe Centro de Biotecnologia e Química Fina from Universidade Católica Portuguesa, and is currently Researcher at REQUIMTE – *Laboratório Associado* for green chemistry. Her actual research areas are microalgal biotechnology for the production of bioactive metabolites, green extraction and characterization of functional ingredients for food applications and valorization of marine by-products and residues.

Hyung J. Cha

Pohang University of Science and Technology
Department of Chemical Engineering
Pohang, Korea
hjcha@postech.ac.kr

Chapter J.60

Hyung Joon Cha is Chair Professor in the Department of Chemical Engineering, Pohang University of Science and Technology (POSTECH), Pohang, Korea. He obtained his PhD in Biochemical Engineering from Seoul National University, Seoul, Korea in 1995. From 1996 to 1998, he was postdoctoral associate in University of Maryland Biotechnology Institute, and 1998/1999 Assistant Research Professor in the Department of Chemical Engineering, University of Maryland, College Park, USA. He joined POSTECH in August 1999. His area of interests includes marine biomaterials, tissue and biomedical engineering, and biochip-based diagnosis. Currently, he is a Research Director of Marine Biomaterials Research Center funded by the Ministry of Oceans and Fisheries, Koreathrough recognition of his prominent works on mussel-inspired bioadhesive materials.

Pranjal Chandra

Amity University Uttar Pradesh
Amity Institute of Biotechnology
Noida, India
pranjalmicro13@gmail.com

Chapter I.56

Dr. Pranjal Chandra earned his PhD degree from Pusan National University, South Korea. Currently he is Assistant Professor at Amity University, Uttar Pradesh, India. He has published more than 30 research articles. Dr. Pranjal research focus is to combine biotechnology, nanotechnology, electroanalytical chemistry approaches to address the problems of biomedical significance and diagnostics.

María José Chapela

ANFACO-CECOPESCA
Research & Development
Vigo-Po, Spain
mjchapela@anfaco.es

Chapter F.37

María-José Chapela was graduated in Marine Sciences from the University of Vigo and she received the PhD degree from the University of Santiago de Compostela in 2003. In 2006 she began at ANFACO-CECOPESCA as a postdoctoral researcher. Her research activities since then are focused on different aspects of food science, mainly food quality and safety, including marine biotoxins and food pathogens detection.

Jyh-Yih Chen

Academia Sinica
Institute of Cellular and Organismic Biology, Marine Research Station
Ilan, Taiwan
zoocjy@gate.sinica.edu.tw

Chapter F.31

Jyh-Yih Chen received the PhD degree from Institute of Zoology of the National Taiwan University in 1997 and is currently an Associate Research Fellow at Marine Research Station, Institute of Cellular and Organismic Biology, Academia Sinica. His main research interests are in antimicrobial peptides, antimicrobial agents, immunobiology, and marine biotechnology.

Maria J. Chen

University of Connecticut
Department of Molecular and Cell Biology
Storrs, CT, USA
maria.chen@uconn.edu

Chapter B.13

Maria Chen received her BSc degree from the National Chung Hsing University, Taiwan in 1967. She has been serving as a research assistant to Dr. T.T. Chen for over 20 years. Her research interest focusses on establishing fish cell lines and investigating the anti-cancer activities of fish and human E-peptide of pro-IGF-I.

Mark H.-C. Chen

National Taiwan University College of Medicine
Department of Orthopedics
Taipei, Taiwan
blackfishgenome@me.com

Chapter B.13

Previously, my research interests primarily focused on GH-IGF-I-Progranulin axis on the teleost body growth in the lab of Dr. Jen-Leih Wu at Academia Sinica. I developed a zebrafish model for xenobiotics screening at Huangkuang University. My current research is focused on bone tissue engineering and stem cell to generate a bio-ceramic 3D scaffold for large bone defect and bone regeneration.

Thomas T. Chen

University of Connecticut
Department of Molecular and Cell Biology
Storrs, CT, USA
thomas.chen@uconn.edu

Chapter B.13

Thomas T. Chen received a PhD degree (1973) in Genetics from University of Alberta, Canada. He has served all professorial ranks at McMaster University, University of Maryland and University of Connecticut. His research interests encompass the molecular action of GH and IGF-I/II in fish, development and application of transgenic fish technology, and anticancer cancer activities of the E-peptide of proIGF-I.

Hogyun Cheong

Pohang University of Science and Technology
Department of Chemical Engineering
Pohang, Korea
hcheong2@postech.ac.kr

Chapter J.60

Hogyun Cheong is PhD Candidate in the Department of Chemical Engineering at Pohang University of Science and Technology (POSTECH), Pohang, Korea. He obtained his Bachelor's degree in Chemical and Biomolecular Engineering at University of Illinois at Urbana-Champaign, IL in 2011. Then he joined the PhD program at POSTECH, where his research interest is on developing tissue engineering scaffolds from functional marine biomaterials.

Pinwen P. Chiou

Academia Sinica
Institute of Cellular and Organismic Biology, Marine Research Station
Yilan, Taiwan
ppchiou@gate.sinica.edu.tw

Chapter B.13

Dr. Chiou is Assistant Research Fellow at the Academia Sinica, Taiwan. His current research focuses on the mechanism and application of pathogen recognition receptors (PRRs) against viral infection in grouper (*Epinephelus* spp.), a group of economically important aquaculture species.

Chong-Su Cho

Seoul National University
Research Institute for Agriculture and Life Sciences
Seoul, Korea
chocs@snu.ac.kr

Chapter I.54

Chong-Su Cho received PhD degree in Polymer Engineering from Tokyo Institute of Technology in 1979. He is currently a Research Professor at Seoul National University, where his research activities include tissue engineering, gene therapy, and drug delivery system. He is a member of The Korean Academy of Science and Technology and Fellow of World Biomaterials Society.

MyoungLae Cho

Korea Institute of Ocean Science and Technology (KIOST)
East Sea Research Institute
Uljin, Gyeongbuk, Korea
mlcho@kiost.ac.kr

Chapter F.40

MyoungLae Cho received his PhD in Applied Marine Biotechnology and Engineering from the National University of Gangneung-Wonju, Korea, in 2011 and is currently Postdoctoral Fellow at the Korea Institute of Ocean and Science Technology (KIOST). His research interests are the structural characteristics and biological activities of secondary metabolites from marine resources including seaweeds and marine invertebrates.

Bong-Hyuk Choi

Pohang University of Science and Technology
Department of Chemical Engineering
Pohang, Korea
bbongs@postech.ac.kr

Chapter J.60

Bong-Hyuk Choi is Postdoctoral Researcher in the Department of Chemical Engineering, Pohang University of Science and Technology (POSTECH), Pohang, Korea. He obtained his PhD in Chemical Engineering from POSTECH in 2013. His areas of interest include biomaterial for tissue engineering, medical application of mussel-inspired biomaterials, cell biology, surface modification, and biosensor-based diagnostics.

Inho Choi

YeungNam University
Department of Biotechnology
Gyeongsan, Korea
inhochoi@ynu.ac.kr

Chapter B.10

Dr. Choi is currently a Professor in the School of Biotechnology at the YeungNam University in South Korea. He has broad research interests and utilizes interdisciplinary approaches to explore the benefits and advantages of in vitro cell culture system of animal muscle stem cells, and investigates the molecular mechanism of muscle growth, differentiation, and recovery in humans as well as animals. Currently, he is a member of the Expert Committee in the National Science and Technology Council in Korea.

Yun-Jaie Choi

Seoul National University
Department of Agricultural Biotechnology
Seoul, Korea
cyjcow@snu.ac.kr

Chapter I.54

YunJaie Choi received degrees in Stock Breeding from Seoul National University (BS and MS) and completed his PhD degree in Nutritional Physiology at the North Dakota State University in 1987. He has served as a Professor in the Department of Agricultural Biotechnology in Seoul National University since 1988. His research expertise has been mainly in high valued and eco-friendly livestock products using genetic engineering and biotechnology.

Sylvia Colliec-Jouault

Ifremer, Atlantic Center
Marine Resources and Biotechnology
Nantes, France
Sylvia.Colliec.Jouault@ifremer.fr

Chapter F.39

Sylvia Colliec-Jouault received the PhD degree in Chemistry and Biomedical Engineering from the University of Paris Nord, France, in 1990. She was Postdoctoral Associate at the MIT from 1990 to 1993 and is currently a Research Scientist in Ifremer. Her research interests cover the isolation of marine polysaccharides and the design of osidic derivatives as new therapeutics. She was involved in several projects with academic and industrial partners. Now she is coordinator of a ANR funded project IONIBIOGEL.

Enma Conde

GLECEX Global and Ecofriendly Natural Extracts, S.L.
Edificio CEI
San Cibrao das Viñas, Spain
econde@glecex.com

Chapter G.44

Enma Conde graduated in Agricultural Engineering and in Food Science and Technology from the University of Vigo in 2003 and 2005, respectively. She received the European PhD degree from the University of Vigo in 2011. Her research focuses on the manufacture, fractionation, purification, characterization, and evaluation of antioxidant properties and new applications of novel food additives derived from vegetal biomass. She is currently R&D Director and cofounder of the technology-based company GLECEX, S.L.

Jana Čopíková

Institute of Chemical Technology in Prague
Department of Carbohydrates and Cereals
Prague, Czech Republic
copikovj@vscht.cz

Chapter D.22

Jana Čopíková is a Professor at the Department of Carbohydrates and Cereals, ICT Prague. Her research field is food technology including isolation and structural analyses of food polysaccharides using modern separation methods (HPLC, GC and SEC). She is a member of the section of Oligosaccharides and Polysaccharides, ICUMSA and the representative of Czech Republic in the Steering Committee EGSF (ESF).

Vernon E. Coyne

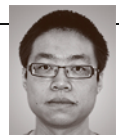
University of Cape Town
Molecular and Cell Biology Department
Rondebosch, South Africa
vernon.coyne@uct.ac.za

Chapter C.18

Vernon Coyne obtained his PhD in Microbiology from the University of Cape Town (UCT), South Africa in 1985. He is currently Head of the Molecular and Cell Biology Department at UCT. His current research interests include the role of the innate immune system in the stress and disease response of abalone, particularly in context to climate change.

Jing Dai

Auburn University
Mechanical Department
Auburn, AL, USA
JZD0011@auburn.edu



Chapter C.20

Jing Dai received his PhD degree in Materials Engineering from Auburn University, USA, in 2013. His research interests are in the development of point-of-care diagnostic devices, high-throughput drug-screening systems, antimicrobial therapy domains, and single cell analysis platforms.

Christine Delbarre-Ladrat

Ifremer, Atlantic Center
Marine Resources and Biotechnology
Nantes, France
Christine.Delbarre.Ladrat@ifremer.fr

Chapter F.39

Christine Delbarre-Ladrat received an engineer degree in1989 from INSA Toulouse and a PhD degree in from the University of Technology of Compiègne in 1993 in the fields of Enzymatic Engineering, Bioconversion and Microbiology. Since then, she has been a researcher at Ifremer. She joined the polysaccharide team in 2002 to develop studies on carbohydrate-related enzymes including enzymes to modify microbial polysaccharides and proteins involved in their biosynthesis.

Hebe M. Dionisi

Patagonian National Research Center
(CENPAT-CONICET)
Environmental Microbiology Laboratory
Puerto Madryn, Chubut, Argentina
hdionisi@cenpat.edu.ar

Chapter B.11

Hebe Dionisi received her Doctorate degree in Biology in 1998 from the National University of Rosario, Argentina. She is currently a researcher of the National Research Council of Argentina (CONICET), in the Environmental Microbiology Laboratory of the Patagonian National Research Center (CENPAT-CONICET). Her research focuses on exploring the biotechnological potential of microbial communities from cold coastal habitats using metagenomic approaches.

Alan D. W. Dobson

University College Cork
Marine Biotechnology Centre,
Environmental Research Institute
Cork, Ireland
a.dobson@ucc.ie

Chapter A.8

Alan Dobson is Professor of Environmental Microbiology at the School of Microbiology at University College Cork in Ireland. He is also currently Director of the Environmental Research Institute at the University. He received a PhD in Biochemistry in 1985 and was awarded a DSc in Microbiology & Molecular Biology in 2005. He is an elected member of the Royal Irish Academy. His multidisciplinary research team employ both genomic and metagenomic approaches to exploit the microbiota associated with marine sponges and sediments with the goal of identifying novel bioactive compounds with potential biopharmaceutical applications.

Herminia Domínguez

University of Vigo
Department of Chemical Engineering
Ourense, Spain
herminia@uvigo.es

Chapter G.44

Herminia Domínguez received the MS and PhD degrees from University of Santiago de Compostela. Her research interest is the development of novel green processes for the extraction, concentration and purification of plant compounds. She has been working on the valorization of forest, agroindustrial and marine wastes into products for food, cosmetic and pharmaceutical applications.

Armando C. Duarte

University of Aveiro
Department of Chemistry
Aveiro, Portugal
aduarte@ua.pt

Chapter G.42

Armando C. Duarte graduated in Chemical Engineering (1977) from the University of Oporto and obtained a PhD in Public Health Engineering (1981) from the University of Newcastle-upon-Tyne. He is a Professor of Environmental and Analytical Chemistry at the University of Aveiro and he has collaborated in more than 350 peer-reviewed research papers leading to an h-factor of 30.

Sherif S. Ebada

Ain-Shams University
Faculty of Pharmacy, Department of
Pharmacognosy and Phytochemistry
Cairo, Egypt
sherif_elsayed@pharma.asu.edu.eg

Chapter F.32

Sherif S. Ebada received his PhD from the Heinrich-Heine University of Düsseldorf in 2010 and is currently an Assistant Professor of Pharmacognosy and Phytochemistry in the Faculty of Pharmacy, Ain-Shams University, Egypt, where he had received his MSc in Pharmacognosy in 2006. His current research interests are directed towards isolation and identification of bioactive marine natural products from marine invertebrates and their fungal endosymbionts.

Don A. S. Elvitigala

Jeju National University
Department of Marine Life Science
Jeju, Korea
anushka@jejunu.ac.kr

Chapter G.41

Don Anushka Sandarwan Elvitigala (MSc), is a graduate research scholar (2011 – present) at Marine Molecular Genetics Lab, Department of Marine Life Science, Jeju National University, Rep. of Korea. Elvitigala is currently reading for a PhD in Marine Life Science at the same University and is involved in identification and characterization of immune relevant genes from several economically important fish and shellfish species.

Astria D. Ferrão-Gonzales

Universidade do Estado da Bahia-UNEB
Departamento de Ciências da Vida
Salvador, Brazil
agonzales@uneb.br

Chapter H.51

Astria D. Ferrão-Gonzales is a Biochemistry Professor at the UNEB and FTC. She graduated in Pharmacy (1996), did Masters (1998) and PhD (2001) degrees in Biological Chemistry at the Universidade Federal do Rio de Janeiro. She is affiliated with the Environmental Biotechnology Laboratory (FTC) and teaches in the Bioenergy Master Program. Her research focuses on agricultural waste reuse, applied to enzyme production.

Burkhardt Flemer

University College Cork
Alimentary Pharmabiotic Centre
Cork, Ireland
bflemer@gmail.com

Chapter A.8

Burkhardt Flemer graduated from Beuth-Hochschule, Berlin, Germany with a Major in Biotechnology. His PhD thesis was about the microbial ecology of marine sponges and the discovery of novel, sponge-derived bioactive substances. He is currently a postdoctoral researcher at the Alimentary Pharmabiotic Centre, University College Cork. He is conducting research on the human gut microbiota with a focus on colorectal cancer associated dysbiosis.

Ana C. Freitas

University of Aveiro
Department of Chemistry
Aveiro, Portugal
afreitas@ua.pt

Chapter G.42

Ana C. Freitasreceived her PhD in Biotechnology from the Catholic University of Portugal in 1999. Since then, she is Assistant Professor at the Instituto Piaget, Portugal. Since 2011, she is an integrated member at CESAM (Centre for Environmental and Marine Studies), University of Aveiro, Portugal. Currently, her research is focused on the development of novel foods incorporating bioactive compounds derived from marine natural sources.

Alejandro Garrido-Maestu

ANFACO-CECOPESCA
Microbiology and Bioassays Laboratory
Vigo-Po, Spain
a.garrido@anfaco.es

Chapter F.37

Alejandro Garrido-Maestu obtained a MSc in Biotechnology in the University of Vigo in 2010, and a PhD with honours in 2013. His research interests are focused in development and application of molecular methods for detection of food and waterborne pathogens. At present is part of the Microbiology and Bioassays Laboratory of ANFACO-CECOPESCA.

Ille C. Gebeshuber

Universiti Kebangsaan Malaysia
Institute of Microengineering and Nanoelectronics
Bangi, Malaysia
Vienna University of Technology
Institute of Applied Physics
Vienna, Austria
gebeshuber@iap.tuwien.ac.at

Chapter I.58

Ille C. Gebeshuber is University Professor of Physics at the National University of Malaysia and the Vienna University of Technology, Austria. Expeditions to deep virgin rainforests as well as to the coastal regions of Malaysian Borneo and peninsular Malaysia inspire her and her team to develop benign and sustainable ways of resource management, anthropogenic production and use of things.

Thandapani Gomathi

D.K.M. College for Women
Department of Chemistry
Vellore, India
chemist.goms@gmail.com

Chapter H.52

T. Gomathi is presently working as a Assistant Professor at Department of Chemistry, at DKM Autonomous College for Women and affiliated to Thiruvalluvar University, Vellore, Tamilnadu, India. She received her MSc and MPhil degrees in Chemistry from Thiruvalluvar University in 2006 and 2008, respectively. She is pursuing her doctoral studies at the Department of Chemistry at DKM. Her research interests are in computational chemistry, drug design and drug delivery, and expanding to the development of nano drug delivery.

Ana M. Gomes

Universidade Católica Portuguesa
CBQF – Centro de Biotecnologia e Química Fina
Porto, Portugal
amgomes@porto.ucp.pt

Chapter G.42

Ana Gomes holds a PhD in Biotechnology since 1999. Currently, she is Assistant Professor/Researcher at the Catholic University of Portugal, where she coordinates the Degree in Nutrition Sciences. Her research activities related with diet (functional foods) and gut health for over two decades, especially in fields of probiotics and prebotics including sources, delivery vehicles, microencapsulation, in vitro GIT systems.

Hong-Yi Gong

National Taiwan Ocean University
Department of Aquaculture
Keelung City, Taiwan
hygong@mail.ntou.edu.tw

Chapter B.13

I serve as an Assistant Professor at the National Taiwan Ocean University and focus on molecular mechanisms of growth and immune regulation in teleost by molecular genetics and functional genomics approaches. Transgenic fish are established by tissue-specific promoters/enhancers to study functional genes involved in fish growth and immunity and are developed as bioreactors for production of recombinant proteins or biomaterials.

Virginia González

ANFACO-CECOPESCA
Food Quality and Safety
Vigo-Po, Spain
virginia@anfaco.es

Chapter F.37

Virginia González owns a PhD degree in Chemistry from the University of Oviedo. She has a master's degree in Science and Technology for the conservation of fishery products and a master's degree in Science and Food Technology. Since 2006 she is working ANFACO-CECOPESCA in Food Safety Division carrying out research activities and development of new methods of analysis of abiotic contaminants, residues of antibiotics and veterinary drugs and lipophilic marine biotoxins by LC-MS-MS.

Tanja Grkovic

Griffith University
Eskitis Institute for Drug Discovery
Nathan, Australia
t.grkovic@griffith.edu.au

Chapter E.27

Tanja Grkovic obtained her BSc, MSc and PhD degrees from the University of Auckland. She carried out postdoctoral research at the Molecular Targets Laboratory at the National Cancer Institute in Maryland, USA and at the Eskitis Institute for Drug Discovery in Brisbane. She is currently a Research Fellow at the Eskitis Institute.

Adarsha Gupta

Deakin University
Centre for Chemistry and Biotechnology, LES
Victoria, 3217, Australia
agupt@deakin.edu.au

Chapter G.45

Adarsha Gupta did his MTech in Industrial Biotechnology at the National Institute of Technology, Karnataka (India) before joining the PhD program at the Centre for Chemistry and Biotechnology, Deakin University, Geelong, Victoria (Australia) in 2010. His thesis is focused mainly on screening and cultivation of thraustochytrids from local Australian habitat for omega-3 fatty acids and other metabolites (carotenoids) production. Research interests include fermentation, optimization and analytical techniques.

Soumya Haldar

CSIR-Central Salt & Marine Chemicals Research Institute
Discipline of Marine Biotechnology & Ecology
Bhavnagar, India
shaldar@csmcri.org

Chapter C.21

Dr. Haldar did his PhD at the University of Madras in Marine Biology and Oceanography and then moved to Osaka Prefecture University, Japan, where he pursued research on bacterial fish disease and rapid, molecular diagnostic methods for bacterial pathogens. At present, Dr. Haldar is working as Senior Scientist at CSIR-CSMCRI, Bhavagar, India. His research interests include coral-bacterial interactions, marine microbiology etc.

Morgan Hamon

Auburn University
Department of Mechanical Engineering
Auburn, AL, USA

Chapter C.20

Morgan Hamon obtained his MS in Biomaterials in 2001 and his PhD degree in Biomedical Engineering in 2004, both from Paris XIII University. His research interests include microfluidics and its applications in biotechnology, bioengineering and biomedical engineering.

S.W.A. Himaya

Pukyong National University
Marine Bio-Process Research Center
Busan, Korea
himayaswa@yahoo.com

Chapter G.43

S.W.A. Himaya received her BSc (2008) with honors from the University of Peradeniya Sri Lanka and completed both her MSc (2010) and PhD (2013) in the field of Marine Biochemistry in Pukyong National University, South Korea. At the Pukyong National University she is affiliated with the Marine Bio-Process Research Centre. Her research focuses on identification and functional characterization of peptides from marine microalgae and invertebrates.

Jong W. Hong

Auburn University
Department of Mechanical Engineering
Auburn, AL, USA
hongjon@auburn.edu

Chapter C.20

J.W. Hong is a Professor of Bionano Engineering at Hanyang University, Korea. He has been appointed as a Visiting Professor of Pharmacy at Seoul National University and an Associate Professor of Materials Engineering in the Department of Mechanical Engineering at Auburn University, USA. Hong's research interests cover BioMEMS/NEMS; automated high-throughput systems for synthetic biology; early stage diagnostics; and marine biotechnology. He received his PhD in Chemical Engineering from the University of and also worked at the Institute of Physical and Chemical Research (RIKEN), Japan, Institute of Industrial Science (IIS) of the University of Tokyo, and the T.J. Watson Laboratories of Applied Physics at Caltech, Pasadena, USA.

Stephen A. Jackson

University College Cork
Department of Microbiology
Cork, Ireland
sjackson@ucc.ie

Chapter A.8

Stephen Jackson received his BSc in Microbiology and his PhD in Marine Microbial Ecology, Metagenomics and Biotechnology, from the University College Cork, Ireland, and the Environmental Research Institute, UCC, where he is now a Postdoctoral Researcher in the field of marine natural product biodiscovery.

Sachin Jambovane

Pacific Northwest National Laboratory
Environmental Molecular Sciences Laboratory
Richland, WA, USA

Chapter C.20

Sachin Jambovane holds the MTech degree in Mechanical Design Engineering from the Indian Institute of Technology (IIT) and the MS and PhD degree in Materials Engineering from Auburn University, AL. Currently, he is researcher at the Pacific Northwest National Laboratory (PNNL), where his research involves development of microdevices for the US Department of Energy's (DOE) mission in critical areas including biofuel discovery and proteomics.

Venkateswara Rao Janapala

CSIR-Indian Institute of Chemical Technology
Biology Division
Hyderabad, India
jv@iict.res.in

Chapter G.48

He is an expert in the area of aquatic toxicology and isolation of newer bioactive molecules from marine origin. He has supervised 19 PhD theses to a successful conclusion and all of his doctoral students occupied respective positions in various scientific organizations around the world.

You-Jin Jeon

Jeju National University
Department of Marine Life Science
Jeju, Korea
youjinj@jejunu.ac.kr

Chapter G.41

Dr. You-Jin Jeon is a Professor in the Marine Bioresource Technology Lab, School of Marine Biomedical Science, Jeju National University, Republic of Korea. He is the Technical Director of Aqua Green Technology Co. Ltd, and counselor of leading industries in Korea. Dr. Jeon received his BSc (1991), MSc (1994) and PhD (1998) degrees in Marine Biotechnology from Pukyong National University, Korea, followed by a postdoc fellow at the Memorial University of Newfoundland, Canada. Further, he worked as researcher in the Department of Animal, Food and Nutrition, University of Alberta, Canada. He has authored more than 300 international publications including total 30 patents in Korea.

Murugaiyan Kalaiselvam

Annamalai University
Centre of Advanced Study in Marine Biology, Faculty of Marine Sciences
Parangipettai, Tamil Nadu, India
kalaifms@gmail.com

Chapter A.2

Murugaiyan Kalaiselvam is an Associate Professor in Centre of Advanced Study in Marine Biology, Faculty of Marine Sciences, Annamalai University, Tamil Nadu, India. He received his graduation in 1985 from Bharathidasan University and the Master in Zoology and M.Phil., and PhD degrees in Marine Biology from Annamalai University in 1988, 1990 and 1996, respectively. His research focuses on fungal diversity and bio-prospecting from the marine ecosystems.

Vipin C. Kalia

CSIR–Institute of Genomics and Integrative Biology
Microbial Biotechnology and Genomics
Delhi, India
vckalia@igib.res.in

Chapter B.15

Vipin Chandra Kalia, MSc and PhD in Genetics from IARI, New Delhi. He is presently the Chief Scientist, at CSIR- IGIB and Professor of AcSIR. He is a Fellow of the Association of Microbiologists of India and Fellow of National Academy of Sciences (FNASc). His current interests are bioenergy, biopolymers, and quorum sensing.

Valliappan Karuppiah

Shanghai Jiao Tong University
School of Life Sciences and Biotechnology
Shanghai, China
vkactinobacteria@gmail.com

Chapter C.17

Karuppiah received his master degree in Biotechnology from the Sourasthra College, India. He earned his PhD in Marine Biotechnology from the Centre of Advanced Study in Marine Biology, Annamalai University, India, where he studied the ecology, diversity and bioactive compounds from the coral reef sediment actinobacteria. Currently, he is a postdoctoral fellow in the Marine Biotechnology Laboratory of Professor Zhiyong Li at the Shanghai Jiao Tong University to investigating the diversity and natural products of sponge-associated actinobacteria.

Jonathan Kennedy

University College Cork
Marine Biotechnology Centre,
Environmental Research Institute
Cork, Ireland
jonathan.kennedy@ucc.ie

Chapter A.8

Jonathan Kennedy is a Senior Research Fellow at University College Cork. His research is focused on novel approaches to access microbial secondary metabolism pathways from the marine environment. He has published over 40 papers and has extensive experience with the study of secondary metabolism pathways from terrestrial and marine bacteria and fungi gained in academia and in the biotechnology industry.

Mohammad Kazem Khalesi

Sari University of Agricultural Sciences and Natural Resources (SANRU)
Department of Fishery Sciences
Sari, Iran
m.khalesi@sanru.ac.ir

Chapter A.7

Mohammad Kazem Khalesi is an Assistant Professor of Marine Biotechnology at the University of Agricultural Sciences and Natural Resources, Sari, I.R. of Iran. He received his PhD in Marine Biotechnology from Wageningen University, the Netherlands in 2008. At the Department of Fishery Sciences, he is engaged in courses and research focusing mainly on ecological and biotechnological aspects of aquatic organisms.)

Samanta S. Khora

Vellore Institute of Technology
University
School of Biosciences and Technology
Vellore, India
sskhora@vit.ac.in

Chapter F.33

Samanta S. Khora received his PhD degree from Berhampur University, India in 1986 and DAg degree from Tohoku University, Japan in 1990. He was Associate Professor in JITM, Odisha, India. He joined the VIT University as Professor at in 2007 and since 2009 he has been Senior Professor at the School of Biosciences and Technology, VIT University, Vellore, India. His research interests are seafood toxicology, marine biodiversity, bio-prospecting, and biotechnology.

Bum J. Kim

Pohang University of Science and Technology
Department of Chemical Engineering
Pohang, Korea
yougio@postech.ac.kr

Chapter J.60

Bum Jin Kim is a Postdoctoral Researcher in the Department of Chemical Engineering, Pohang University of Science and Technology (POSTECH), Pohang, Korea. He obtained his PhD in Biomaterials/Biochemical Engineering from POSTECH in 2014. His research interests include adhesive-based biomaterials and its application for biomedical engineering.

Chang S. Kim

Pohang University of Science and Technology
Department of Chemical Engineering
Pohang, Korea
redcskim@postech.ac.kr

Chapter J.60

Chang Sup Kim is Postdoctoral Researcher in the Department of Chemical Engineering, Pohang University of Science and Technology (POSTECH), Pohang, Korea. He obtained his PhD in Chemical Engineering from POSTECH in 2013. His areas of interest include biosensor-based diagnostics, surface modification, biomolecular conjugation, cellular engineering, biomaterial for biosensor and tissue engineering, and enzyme characterization.

Se-Kwon Kim

Pukyong National University
Department of Marine-Bio. Convergence Science Specialized Graduate School
Science & Technology Convergence Marine Bioprocess Research Center
Busan, Korea
sknkim@pknu.ac.kr

Chapters .1, F.34, G.43, H.52, I.53, J.63

Se-Kwon Kim is presently working as a Distinguished Professor at the Department of Marine-Bio Convergence Science, Specialized Graduate School of Science and Technology Convergence and as a Director of the Marine Bioprocess Research Center (MBPRC) at Pukyong National University, Busan, South Korea. He received his MSc and PhD degrees from Pukyong National University and conducted his postdoctoral studies at the Laboratory of Biochemical Engineering, University of Illinois, Urbana-Champaign, IL, USA. Later, he became a visiting scientist at the Memorial University of Newfoundland, Canada. His major research interests are investigation and development of bioactive substances from seafood processing wastes and other marine sources. His immense experience of marine bio-processing and mass-production technologies for marine bio-industry is the key asset of holding majorly funded marine bio projects in Korea. Furthermore, he expanded his research fields up to the development of bioactive materials from marine organisms for their applications in oriental medicine, cosmeceuticals and nutraceuticals.

Woo J. Kim

The Catholic University of Korea
Research Center for Biopharmaceutical Lead Molecule (GRRC)
Bucheon, Korea
wj0504@catholic.ac.kr

Chapter D.22

Woo Jung Kim received the PhD degree from the Catholic University of Korea in Biotechnology. He is currently an Associate Researcher of the Research Center for Biopharmaceutical lead Molecule (GRRC) at the Catholic University of Korea. His research interests include structure and bioactivities of polysaccharides and oligosaccharides and related enzymology.

Ozcan Konur

Yildirim Beyazit University, Faculty of Engineering and Natural Sciences
Department of Materials Engineering
Ankara, Turkey
okonur@hotmail.com

Chapter H.50

Ozcan Konur is a member of the academic staff of the Yildirim Beyazit University, Faculty of Engineering and Natural Sciences, Department of Materials Engineering, Ankara, Turkey. His research interests include the algal biofuels and biotechnology, solar energy, nanocomposites, nanoengineering, microbial fuel cells, biohydrogen and materials science.

Ameeta R. Kumar

University of Pune
Institute of Bioinformatics and Biotechnology
Pune, India
ameeta@unipune.ac.in

Chapter I.55

Ameeta Ravi Kumar received the PhD in Biochemistry from the University of Pune in 1991. She worked as a Research Associate at National Chemical Laboratory, Pune untill 1999. Later she was as a Lecturer, Associate Professor at the University of Pune and is currently the Director of the Institute of Bioinformatics and Biotechnology. Her research interests lie in protein chemistry, development of anti-diabetic agents, biofuels and bioremediation.

Prasun Kumar

CSIR–Institute of Genomics and Integrative Biology
Microbial Biotechnology and Genomics
Delhi, India
prasun.kumar@igib.in

Chapter B.15

Prasun Kumar, received the MSc in Biotechnology from KIIT University, Bhubaneswar, India. He is currently working as a Senior Reserch Fellow, at CSIR-IGIB, Delhi, India. His current interests are biopolymers, biofuels, and quorum sensing with a main research topic of production of polyhydroxyalkanoates from biowastes. He is a life member of Association of Microbiologists of India (AMI) and member of American Society for Microbiology (ASM).

Frithjof C. Küpper

University of Aberdeen
School of Biological Sciences
Newburgh, UK
fkuepper@abdn.ac.uk

Chapter D.23

Frithjof C. Küpper obtained his PhD in a joint enrolment at the Universität Konstanz and Université de Paris-Sud XI Orsay. After 2 years as a postdoc at the University of California, Santa Barbara, he was appointed initially to a lectureship and as Head of the Culture Collection of Algae and Protozoa at the Scottish Association for Marine Science in Oban. In 2003, he was appointed to the Chair in Marine Biodiversity, a professorship at the University of Aberdeen. Research activities include the biochemistry and biodiversity of marine algae and microbes, in particular in the context of defense, stress and biogeochemical cycles.

D. İpek Kurtböke

University of the Sunshine Coast
Faculty of Science, Health, Education and Engineering
Maroochydore DC, Australia
ikurtbok@usc.edu.au

Chapter E.27

Dr. Ipek Kurtböke has been working in the field of Biodiscovery since 1982, firstly at the research laboratories of Eczacibasi Ilac AS (Istanbul, Turkey), 1983-1986 University of Milan, Italy where she received an Italian CNR fellowship. Subsequent PhD research took place at the University of Liverpool and post-doctoral research at the University of Western Australia and later at the Western Australian Department of Agriculture and Murdoch University. In 1995 she was appointed a Senior Research Scientist for the then newly-founded AMRAD Discovery Technologies Pty. Ltd. (ADT). Since 2001 she has been with the University of the Sunshine Coast in Queensland, Australia as a Senior Lecturer continuing research linked with eminent overseas companies as well as regional industry partners.

Miguel Leal

University of Aveiro
Campus Universitário de Santiago
Department of Biology
Aveiro, Portugal
miguelcleal@gmail.com

Chapter F.35

Miguel Leal is a PhD candidate at the University of Aveiro, Portugal. He received his BS (2007) and MS (2009) degrees in Biology and Marine Ecology, respectively, from the University of Lisbon, Portugal. His research interests include marine invertebrates' ecology and biotechnology, marine trophic interactions and application of ecological concepts to marine natural products' research.

Smita S. Lele

Institute of Chemical Technology
(Formerly UDCT/UICT)
Food Engineering and Technology
Mumbai, India
ss.lele@ictmumbai.edu.in

Chapter J.65

Dr. Smita Lele is a technologist with industrial, academic and research experience over 3 decades. She is currently Controller of Examination and Professor of Biochemical Engineering at the ICT Mumbai. She was the first woman engineer to join Hindustan Lever Research Centre in 1977. She is a Fellow of Biotech Research Society of India and also Maharashtra Academy of Sciences and was President AFST, Mumbai Chapter. She has received the Hari Om Ashram Prerit Shri. S.S. Bhatnagar Research Award, on Prevention of Water Pollution, (2005). And Dr. Bains – AFST life time achievement award for Woman Food Scientist (2010). Professor Lele's research interest includes food products/process development, biological effluent treatment and nutrition product development.

Zhiyong Li

Shanghai Jiao Tong University
School of life Sciences and
Biotechnology
Shanghai, China
zyli@sjtu.edu.cn

Chapter C.17

Zhiyong Li is currently a Professor of Microbiology and Bioengineering at the Shanghai Jiao University and the State Key Laboratory of Microbial Metabolism, P.R. China. He received his PhD degree from the South China University of Technology (SCUT) in 1998, and conducted his postdoctoral research at the East China University of Science and Technology (ECUST). He joined Shanghai Jiao Tong University (SJTU) and set up the Marine Biotechnology Laboratory.His research interests focus on the microorganisms associated with sponges and corals, including the microbial diversity, natural products, molecular ecology and omics.

Yue Liang

Tokyo University of Agriculture and
Technology
Division of Biotechnology and Life
Science, Institute of Engineering
Tokyo, Japan
y_liang@cc.tuat.ac.jp

Chapter A.5

Yue Liang is a postdoctoral research fellow at the Division of Biotechnology and Life Science, Institute of Engineering,Tokyo University of Agriculture and Technology (TUAT), Tokyo, Japan. She received the PhDfrom Graduate School Bio-Applications and Systems Engineering (BASE), TUAT in March 2014. Her research interests cover microalgal biofuels, systems biology, lipids metabolism on marine diatoms, and MS-based lipidomics.

Seonghye Lim

Hanwha Chemical Co.
Biologics Business
Daejeon, Korea
seonghye.lim@hanwah.com

Chapter J.60

Seonghye Lim is Senior Research Scientist in the R&D center at Hanwha Chemical Co. , Biologics Business. She obtained her PhD in Chemical Engineering from Pohang University of Science and Technology (POSTECH), Korea in 2013. Her areas of interest include recombinant protein engineering and formulations for bio-pharmaceuticals.

Chun-Mean Lin

University of Connecticut
Department of Molecular and Cell Biology
Storrs, CT, USA
chun-mean.lin@uconn.edu

Chapter B.13

I have been in the research fields of plants and fish molecular biology for over twenty years. During the course of research, I was able to produce both transgenic fish and seaweed with great success. Currently, I am continuing to work on the biological functions of small E-peptide derived from pro-IGF I protein for Rainbow Trout.

Jay H. Lo

University of Connecticut
Department of Molecular and Cell Biology
Storrs, CT, USA
hung-chieh.lo@uconn.edu

Chapter B.13

Dr. Lo received his PhD in Cell Biology from University of Connecticut. Dr. Lo's past research was focused on studying regulatory mechanism of hormonal/growth factors in teleost fish. He further broadened interests into biomedical aspects of endocrine research at Northwestern University where he studied the correlation between nuclear receptors and uterine fibroid. Dr. Lo's current research concentrates on receptor purification of an anti-tumor peptide.

Lus Lopez

Universidad Autónoma de Baja California (UABC)
Facultad de Ciencias Marinas, Laboratorio de Nutrición Acuícola
Ensenada, B.C., Mexico
llopez@uabc.edu.mx

Chapter J.59

Lus Lopez is Professor at the University of Baja California, Mexico, where she founded and directs the Fish Nutrition Group at the Marine Science School (MSS). She obtained her PhD at the University of Southampton, UK in 2000. She has taught fish nutrition and physiology courses in both graduate and postgraduate programs at the MSS. Her research focuses on the effect of dietary and endogenous factors on the efficiency of nutrients used by marine carnivorous fish and other marine species.

Mariana Lozada

Patagonian National Research Center (CENPAT-CONICET)
Environmental Microbiology Laboratory
Puerto Madryn, Chubut, Argentina
lozada@cenpat.edu.ar

Chapter B.11

Mariana Lozada has a Dr. in Biological Sciences from the University of Buenos Aires (UBA), Argentina. She is currently a researcher at the Argentinean National Research Council, working at the Centro Nacional Patagónico, Puerto Madryn, Argentina. Her research interests are in diversity, ecology and metagenomics of the microbial communities in the marine environment.

Jenn-Kan Lu

National Taiwan Ocean University
Department of Aquaculture
Keelung City, Taiwan
F0008@mail.ntou.edu.tw

Chapter J.64

Jenn-Kan, Lu received the MS degree from the University of Washington, School of Fishery in 1986 and his PhD degree from University of Maryland in 1996. He is currently an Associate Professor of Aquaculture Biotechnology in the Department of Aquaculture of National Taiwan Ocean University, Keelung, Taiwan. Research activities include aquaculture biotechnology, marine bioactive compounds and probiotics.

Gian M. Luna

National Research Council of Italy
Institute of Marine Sciences
(ISMAR – CNR)
Venice, Italy
gianmarco.luna@ve.ismar.cnr.it

Chapter E.26

Gian Marco Luna received his PhD in Marine Biology and Ecology in 2005 at the Polytechnic University of Marche, Italy. His current research focuses on the diversity of marine microbes in coastal and deep-sea ecosystems, how biodiversity changes across spatial and temporal scales, and the ecology and evolution of bacterial pathogens in coastal areas.

Sushila Maharjan

Seoul National University
Agricultural Biotechnology
Seoul, Korea
ruma_sushila@snu.ac.kr

Chapter I.54

Sushila Maharjan is a Postdoctoral Fellow at the Laboratory of Biomedical Polymer and Tissue Engineering, Seoul National University, Korea. She received the MS degree in Organic Chemstry from *Tribhuvan* University, Nepal and the PhD degree in Biochemistry from Sunmoon University, Korea.Her research interests lie in the utilizing and developing organic chemistry as a tool to understand biological and biomedical disciplines.

Panchanathan Manivasagan

Pukyong National University
Department of Marine-Bio Convergence Science
Busan, Korea
manimaribtech@gmail.com

Chapter J.63

Panchanathan Manivasagan is a Postdoctoral Fellow in the Department of Chemistry and Marine Bioprocess Research Centre (MBPRC) at Pukyong National University, Busan, South Korea. He received his MSc, MPhil, and PhD degrees from the Faculty of Marine Sciences, Centre of Advanced Study in Marine Biology, Annamalai University in India, with a research focus in marine biotechnology.

Pravat Manjari Mishra

CSIR-Institute of Minerals & Materials Technology
Department of Bioresources Engineering
Bhubaneswar, India
pravatmanjari@immt.res.in

Chapter F.36

Dr. Pravat Manjari Mishra is working as a Scientist in the Department of Bioresources Engineering of CSIR-Institute of Minerals and Materials Technology, Bhubaneswar-751 013, India, where she received her PhD degree. Her present research activities include biomaterials, nanobiotechnology and marine natural products.

Lekha Menon Margassery

University College Cork
Marine Biotechnology Centre,
Environmental Research Institute
Cork, Ireland
lekha513@gmail.com

Chapter A.8

Lekha Menon Margassery obtained her MS from PSG College of Arts and Science, affiliated to Bharathiar University, India, in 2003. She worked as a Guest Lecturer in the Department of Biotechnology, Bharathiar University, India. In 2013, she received her PhD in Microbiology from the University College Cork, Ireland. Her research interests include drug discovery from marine organisms.

Aníbal Martínez

ANFACO-CECOPESCA
Food Quality and Safety
Vigo-Po, Spain
anibal@anfaco.es

Chapter F.37

Aníbal Martínez graduated as Molecular Biologist in 2003 from the Universidad de Santiago de Compostela. He is currently working in the Spanish National Association of Seafood Producers-Technological Centre (ANFACO-CECOPESCA) in Food Safety Division. His research activities included the evaluation of several POPs in fish and shellfish products, and nowadays he works in the field of lipophilic marine biotoxins and the effect of processing in bivalve molluscs.

Yuta Matsumura

Kao Corp.
Haga, Japan
matsumura.yuuta@kao.co.jp

Chapter H.51

Yuta Matsumura is a researcher in Kao Corp. He received his BSc and the MSc degree in Fisheries Sciences from Hokkaido University in 2011, and 2013, respectively. At Hokkaido University, he belongs to the Laboratory of Microbiology advancing research in biohydrogen production of marine bacteria.

Tadashi Matsunaga

Tokyo University of Agriculture and Technology
Tokyo, Japan
tmatsuna@cc.tuat.ac.jp

Chapter A.5

Yuta Matsumura is a researcher in Kao Corp. He received his BSc and the MSc degree in Fisheries Sciences from Hokkaido University in 2011, and 2013, respectively. At Hokkaido University, he belongs to the Laboratory of Microbiology advancing research in biohydrogen production of marine bacteria.

André Luiz Meleiro Porto

University of São Paulo
Institute of Chemistry of São Carlos,
Department of Physical Chemistry
São Carlos, Brazil
almporto@iqsc.usp.br

Chapter E.28

André Luiz Meleiro Porto graduated in Chemistry from the Institute of Chemistry (UNESP, Araraquara, SP, Brazil, 1994). He did his MSc in Natural Products Chemistry at the Institute of Chemistry (UNICAMP, Campinas, SP, Brazil, 1997) and his PhD in Chemistry (Biocatalysis) at the Institute of Chemistry (UNICAMP, 2002). Since 2006 he has been Professor at the Institute of Chemistry of São Carlos, University of São Paulo (IQSC-USP). He has experience in biocatalysis, biotransformation, and biodegradation of organic compounds using enzymes and microorganisms isolated from Brazilian territory.

V. Venugopal Menon

Bhabha Atomic Research Center
Food Technology Division
Mumbai, India
vvenugopalmenon@gmail.com

Chapter J.65

V. Venugopal Menon received his MSc (Chemistry) from the University of Kerala and the PhD (Biochemistry) from the University of Bombay, India. He has extensive research experience in seafood processing. He was a Postdoctoral Research Fellow at the National Institutes of Health, Bethesda, MD, USA and a Visiting Scientist at the Memorial University of Newfoundland, St. John's, Canada. He has more than 120 publications including several book chapters and reviews and has authored three books. He is a Fellow of the National Academy of Agricultural Sciences, New Delhi, India.

Hideaki Miyashita

Kyoto University
Graduate School of Global Environmental Studies, Graduate School of Human and Environmental Studies
Kyoto, Japan
miyashita.hideaki.6v@kyoto-u.ac.jp

Chapter A.3

Hideaki Miyashita received his Dr. (Sci) degree from the University of Tokyo in 1997. Before moving to Kyoto University, he worked for the Marine Biotechnology Institute Co. from 1989 to 2000 and Tokyo University of Agriculture and Technology from 2000 to 2002. His research focuses on the diversity of microalgal photosynthesis, and the technological applications of microalgae against the global environmental problems.

Kalpana H. Mody

CSIR-Central Salt & Marine Chemicals Research Institute
Discipline of Marine Biotechnology & Ecology
Bhavnagar, India
khmody@csmcri.org

Chapter C.21

After obtaining MSc and PhD degrees in Microbiology, Dr (Mrs) Kalpana Mody joined the CSIR-Central Salt & Marine Chemicals Research Institute, Bhavnagar, India in 1978. Currently she is Chief Scientist and Group Leader of the Marine Environmental group of the institute. Her research interests include environmental monitoring, environmental microbiology, seaweed based value added products, microbial products.

Pallavi Mohite

University of Pune
Institute of Bioinformatics and Biotechnology
Pune, India
pmohite@unipune.ac.in

Chapter I.55

Pallavi Mohite is a research student working for the PhD degree in Microbiology at the University of Pune. Her interest lies in the use of halotolerant yeast strains for the development of biosensors and in nanoparticle synthesis.

Eduardo Morales-Guerrero

Centro de Investigacion Cientifica y de Educacion Superior de Ensenada (CICESE)
Department of Marine Biotechnology
Tijuana-Ensenada, Mexico
edmorale@cicese.mx

Chapters F.29, J.62

Eduardo Morales-Guerrero received the MSc degree from the Centro de Investigación Científica y de Educación Superior de Ensenada, Mexico in 2000. He gives advanced training courses on spectroscopy and chromatography for biotechnology. One of his current activities is the analysis and characterization of biomolecules by chromatography (ionic and HPLC) as well as providing support for marine biotechnology activities at The Centro de Investigacion Cientifica y de Educacion Superior de Ensenada, Mexico.

John P. Morrissey

University College Cork
Department of Microbiology
Cork, Ireland
j.morrissey@ucc.ie

Chapter A.8

John Morrissey graduated in 1990 from University College Cork with a BSc in Microbiology and received his PhD from the European Molecular Biology Laboratory, Heidelberg, Germany. Following postdoctoral research at the University of California, Berkeley and the John Innes Research Centre, Norwich, he returned to Ireland (2003) to establish a research programme in the areas of microbial ecology and yeast biotechnology.

Kai Muffler

University of Kaiserslautern
Institute of Bioprocess Engineering
Kaiserslautern, Germany
muffler@rhrk.uni-kl.de

Chapter B.14

Kai Muffler studied chemistry at the universities of Bremen and Hannover (Diploma 2001) and received his Dr.-Ing. from the University of Kaiserslautern, Institute of Bioprocess Engineering/Department of Mechanical and Process Engineering, in 2007 where he is currently working as a group. His main research objectives comprise biotransformation of (marine) natural products, plant cell culture technology, application of productive biofilms, and reactor development for cultivation of (phototrophic) biofilms.

Joydeep Mukherjee

Jadavpur University
School of Environmental Studies
Kolkata, India
joydeep_envstu@school.jdvu.ac.in

Chapter B.14

Joydeep Mukherjee (M Tech PhD in Biotechnology) received post-doctoral training at the University of Hannover, Germany and the Australian Institute of Marine Science. Dr. Mukherjee is an Associate Professor at the School of Environmental Studies, Jadavpur University, India. His research interests include exploration of estuarine microbial diversity for biotechnological applications e.g. bioplastics production, marine, intertidal biofilms and marine sponge pathogenesis.

Werner E.G. Müller

University Medical Center of the Johannes Gutenberg University Mainz
Institute for Physiological Chemistry
Mainz, Germany
wmueller@uni-mainz.de

Chapter I.57

Werner E. G. Müller is a University Professor at the University Medical Center of the Johannes Gutenberg University Mainz, Germany. At present, he is the President of the International Marine Biotechnology Association (IMBA), a holder of the Advanced Investigator Grant from the European Research Council (ERC) and the Coordinator of the Integrated Project *Blue-Genics* funded by the European Commission. He has received almost 20 national and international scientific awards. His scientific achievements are presented in over 1000 publications and 20 patents. His recent research interests are evolution, cell and molecular biology, biochemistry, as well as genomics of siliceous sponges. Recently, he made substantial progress in the field of applied biomaterials, in particular in tissue engineering.

Masaki Muto

Tokyo University of Agriculture and Technology
Division of Biotechnology and Life Science
Koganei, Japan
m_muto@cc.tuat.ac.jp

Chapter A.5

Masaki Muto received the PhDfrom the Graduate School of Bio-Applications and Systems Engineering (BASE), Tokyo University of Agriculture and Technology (TUAT), Tokyo, Japan, in 2013. He is working as a postdoctoralResearchFellow at the Division of Biotechnology and Life Science, Institute of Engineering, TUAT. His research interests include microbiology, molecular and environmental biology, and metabolic engineering of marine microalgae.

Yutaka Nakashimada

Hiroshima University
Department of Molecular Biotechnology
Hiroshima, Japan
nyutaka@hiroshima-u.ac.jp

Chapter H.51

Yutaka Nakashimada received his Doctorate degree in Chemical Engineering from Nagoya University in 1995. Since 2008 he has been Associate Professor at Department of Molecular Biotechnology, Hiroshima University. His current research interests are in effective control of anaerobic digestion of solid biomass and syngas fermentation for biogas conversion to more useful materials using a thermophilic acetogen.

Leonel Ochoa

Centro de Innovación Biotecnológica AC (CENBIOTEC)
Ensenada, B.C., Mexico
Leonel.ochoa@gmail.com

Chapter J.59

Over 10 years, Leonel Ochoa has led the innovation and development research in the Centro de Innovación Biotecnológica AC. He received the BS (1993) and MS (2001) degrees in Aquaculture; and his PhD in Marine Biotechnology in 2006 from the Centro de Investigación Científica y de Educación Superior de Ensenada (CICESE). Professor Ochoa´s research interest includes functional nutrition and nutrigenomic in humans and living organisms.

Tatsuya Oda

Nagasaki University
Division of Biochemistry, Faculty of Fisheries
Nagasaki, Japan
t-oda@nagasaki-u.ac.jp

Chapter G.47

Tatsuya Oda received the PhD degree from Kyushu University. He joined the Department of Microbiology, Kumamoto University Medical School in 1988 as a research assistant. Since 2001, he has been Professor at the Division of Biochemistry, Faculty of Fisheries, Nagasaki University, Japan. His research interests are mainly toxic mechanisms of red tide phytoplankton and bioactivities of polysaccharides from seaweeds.

Jorge Olmos Soto

Centro de Investigación Científica y de Educación Superior de Ensenada (CICESE),
Molecular Microbiology Laboratory,
Departement of Marine Biotechnology
Ensenada, B.C., Mexico
jolmos@cicese.mx

Chapters F.29, J.59, J.62

Jorge Olmos Soto obtained the master and doctoral degree, both at National Autonomous University of Mexico (UNAM) in 1994 and 1996, respectively. He is currently a Professor in Marine Biotechnology and head of group in CICESE. He received the National Award in Biotechnology by SMBB 2002 and the National Award of Innovation by ADIAT 2006. His research interests include the production of sustainable, realistic and profitable innovations using beneficial microorganisms. He has published patents, articles and book chapters.

Fergal O'Gara

University College Cork
Marine Biotechnology Centre
Cork, Ireland
f.ogara@ucc.ie

Chapter A.8

Professor Fergal O'Gara is Director of the Biomerit Research Centre at University College Cork. He received his PhD in 1974 in Molecular Microbiology and was awarded a DSc in 1991 for his published research work. He is an elected member of the Royal Irish Academy and served as Vice President. He runs a multidisciplinary research team in the Biomerit Research Centre in the molecular biology and genomics of microbial pathogenesis and infection control exploiting novel metagenomic derived bioactive compounds from marine environments. He has published over 280 peer reviewed papers in international journals.

Niall O'Leary

University College Cork
Department of Microbiology
Cork, Ireland
n.oleary@ucc.ie

Chapter A.8

Niall O'Leary received his BSc and PhD in environmental microbiology both at University College Cork (UCC), Ireland. He is now a lecturer in the School of Microbiology at UCC and a Principal Investigator at the university's Environmental Research Institute. His research interests are in industrial wastewater remediation, biopolymer synthesis and microbial degradation of toxic aromatic hydrocarbons.

Prasanna K. Panda

CSIR-Institute of Minerals & Materials Technology
Department of Bioresources Engineering
Bhubaneswar, India
pkpanda@immt.res.in

Chapter F.36

Dr. Panda is the Chief Scientist and Head of the Department of Bioresources Engineering of CSIR-Institute of Minerals and Materials Technology, Bhubaneswar-751 013, India. His current area of research is the development of microalgal strains for optimization of biomass accumulation and large-scale production of biofuel-relevant molecules, such as triacylglycerols. His other research areas of interest include algal genomics, biocomputing, and microbial biosurfactants.

Shunmughiah T. K. Pandian

Alagappa University
Department of Biotechnology
Karaikudi, India
sk_pandian@rediffmail.com

Chapter B.15

Shunmugiah Thevar Karutha Pandian is Professor and Head of the Department of Biotechnology, Alagappa University, Karaikudi, India. He obtained his BSc degree (1984) from Madurai Kamaraj University; MSc (1986) and PhD (1996) from the University of Madras, India. He had his Postdoctoral trainings at Centre for Cellular and Molecular Biology (CCMB), Hyderabad (1995-1997) and National Tsing Hua University, Taiwan (1997-1998). He has been serving Alagappa University in various positions, notable ones include Director of the Science Campus and Dean of the Faculty of Science. His research group is actively involved in studying the biofilm formation and gene regulation of various human bacterial and fungal pathogens.

Ratih Pangestuti

Indonesian Institute of Sciences
Research Center for Oceanography
Jakarta Utara, Indonesia
pangesturth@yahoo.com

Chapter F.34

Ratih Pangestuti received her BSc from Diponegoro University (Indonesia), MSc from Glasgow University, UK and PhD from Pukyong National University, South Korea. From 2012-2013, she was postdoctoral Research Associate at Marine Bioprocess Research Center, South Korea. She's now working as scientist at the Indonesian Institute of Sciences. Her research interests include marine pharmacology, marine nutraceuticals and functional foods, and marine biotechnology.

José de Jesús Paniagua-Michel

Centro de Investigacion Cientifica y de
Educacion Superior de Ensenada (CICESE)
Department of Marine Biotechnology
Tijuana-Ensenada, Mexico

Chapters F.29, J.59, J.62

J. Paniagua-Michel received the Dr. Sc degree from the University of Liege, Belgium in 1992. He is Professor in Marine Biotechnology at The Centro de Investigacion Cientifica y de Educacion Superior de Ensenada, Mexico. His research interests include marine natural products, microalgal biotechnology and bioremediation of marine effluents. He recently authored the book Biotecnologia Marina (Marine Biotechnology) and is a pioneer of Marine Biotechnology in Mexico and Latin America.

Teresa Panteleitchouk

Instituto Piaget
Lordosa, Viseu, Portugal
teresa.p@viseu.ipiaget.pt

Chapter G.42

Teresa Santos Luís Panteleitchouk received her PhD in Biology from Moscow State University in 1993. Since 2003, she is Associate Professorat the Instituto Piaget, Portugal. Currently, her area of research interest is the evolutionary / microevolutionary models of differentiation of polymorphic species.

Yong Il Park

The Catholic University of Korea
Department of Biotechnology and The
Research Centre for Biopharmaceutical
Lead Molecule (GRRC)
Bucheon, Korea
yongil382@catholic.ac.kr

Chapter D.22

Yong Il Park received the PhD degree from the University of Florida at Gainesville, Florida, in 1996. He joined the Johns Hopkins University as a Postdoctoral Fellow and Research Associate in 1997. He is currently a Professor in the Department of Biotechnology of the Catholic University of Korea. His research interests include structure and bioactivities of natural compounds such as polysaccharides, oligosaccharides, and plant flavonoids. He has been a member and is currently President of the Korean Society for Glycoscience.

Chiara Pennesi

Polytechnic University of the Marche
Department of Life and Environmental
Sciences
Ancona, Italy
c.pennesi@univpm.it

Chapter D.24

Chiara Pennesi received the Laurea degree in Biological Sciences and the Research Doctorate in Marine Biology both from the Polytechnic University of the Marche (Italy). She is currently a Researcher at the Polytechnic University of the Marche and involved in international scientific collaborations. Her research activity concentrates on the study of heavy metals biosorption with marine macrophytes used as eco-compatible solution for the reuse of the wastewater. In addition, she studies the systematic and taxonomic classification of microphytobenthos and phytoplankton.

Leonel Pereira

University of Coimbra
IMAR, Department of Life Sciences
Coimbra, Portugal
leonel.pereira@uc.pt

Chapters A.6, G.42

Leonel Pereira received the BSc degree in Biology and the PhD degree in Biology (Cellular Biology speciality) from the University of Coimbra in 1991 and 2005, respectively. He is currently an Assistant Professor at the University of Coimbra and an integrated researcher at IMAR (Institute of Marine Research). His research interests include marine biodiversity, biotechnology and ecology.He is the author and editor of the Portuguese Seaweeds Website, and coordinator of the Biodiversity Database MACOI (www.uc.pt/seaweeds).

Lorena Pérez-Armada

University of Vigo
Department of Chemical Engineering
Ourense, Spain
lorenaperezarmada@gmail.com

Chapter G.44

Lorena Pérez-Armada received her degree in Agricultural Engineering from the University of Vigo, Ourense, Spain, in 2013. Her research is centered on the use and recovery of residues from marine origin, in particular the invasive brown seaweed *Sargassum muticum* and mussel shells.

Peter Proksch

Heinrich-Heine University
Institute of Pharmaceutical Biology and Biotechology
Düsseldorf, Germany
proksch@uni-duesseldorf.de

Chapter F.32

Peter Proksch received his PhD in Biology from the University of Cologne followed by a postdoc at the University of California, Irvine. He was an Associate Professor at the University of Würzburg and serves currently as a Full Professor at the University of Düsseldorf. His research interests focus on the discovery of bioactive natural products with emphasis on compounds from marine invertebrates and from fungi.

Munish Puri

Deakin University
Centre for Chemistry and Biotechnology
Geelong, Australia
Munish.puri@deakin.edu.au

Chapter G.45

Associate Professor Munish Puri is an established leader in the field of protein biotechnology and is working as Group Head of bioprocessing at the Centre for Chemsitry and Biotechnology, Deakin University, Australia. He has contributed towards the development of protein biotechnology processes with respect to the use of industrial proteins/enzymes. Currently, he is employing enzyme-based technology for producing biofuels and extraction of bioactives (lipids,carotenoids) from marine microbes with potential application in food, pharmaceutical and bioenergy sector.

Ronald J. Quinn

Griffith University
Eskitis Institute for Drug Discovery
Nathan, Australia
r.quinn@griffith.edu.au

Chapter E.27

Professor Quinn is the Foundation Director of the Eskitis Institute at Griffith University. He is anHonorary Professor (2012), College of Pharmacy, South-Central University for Nationalities, Wuhan, China. He is the author of over 200 publications and patents. His research concentrates on the use of natural products as tools to understand interactions in biological systems. Most recently he has developed a novel approach to fragment-based drug discovery based on natural products and the use of bioaffinity mass spectrometry. He was honored in the Australia Day Awards 2010 as a recipient of a Member of the Order of Australia (AM) for service to scientific research, in the field of chemistry as a leader in the development of therapeutic compounds from marine organisms and plant materials.

Venugopal Rajanbabu

Tamil Nadu Agricultural University
Centre for Plant Molecular Biology and Bioinformatics
Coimbatore, India
vrajanbabu@hotmail.com

Chapter F.31

Dr. Rajanbabu received his Master degree from Tamil Nadu Agricultural University, India, and his PhD in Biotechnology from the National Chung Hsing University and Academia Sinica, Taiwan. He has worked as visiting researcher at the University of Medicine and Dentistry New Jersey, Postdoctoral fellow at the University of South Florida, Tampa and Academia Sinica. His present research focuses on plant molecular biology and biotechnology.

Julieta Rangel de Oliveira

Federal University of Pernambuco
Departamento de Química Fundamental
Recife, Brazil
julietaquimica@yahoo.com.br

Chapter E.28

Julieta Rangel is a Postdoc at the Federal University of Pernambuco in the Department of Chemistry. She has interests in reduction and biotransformation of alkynones and nitriles by Brazilian microorganisms from Caatinga Biome, Northeastern Brazil. She received her PhD in Organic Chemistry (Biocatalysis) in 2012 from the Institute of Chemistry of São Carlos, University of São Paulo (IQSC-USP).

Mirna H. Reagli Seleghim

Federal University of São Carlos
Ecology and Evolutive Biology (DEBE)
São Carlos, Brazil
seleghim@uol.com.br

Chapter E.28

Mirna Helena Regali Seleghim is a graduated biologist and received her Master and PhD degree in Ecology and Natural Resources from the Federal University of São Carlos, Brazil, in 1991. She is Currently Assistant Professor/Researcher at the Federal University of São Carlos and researcher at the University of São Paulo. She has experience in aquatic microbial ecology and biotechnology.

Fabio Rindi

Università Politecnica delle Marche
(DISVA–UNIVPM)
Dipartimento di Scienze della Vita e dell'Ambiente
Ancona, Italy
f.rindi@univpm.it

Chapter D.24

Fabio Rindi is an Assistant Professor in Botany at the Università Politecnica delle Marche, Ancona, Italy. He received his MSc (1992) and PhD (1999) degrees from the University of Pisa and obtained his current position after postdoc experiences at the National University of Ireland, Galway, and the University of Alabama, Tuscaloosa. His research interests include systematics, phylogeny, biogeography and ecology of selected groups of marine and terrestrial algae.

Joana Rocha

University of Aveiro
Campus Universitário de Santiago
Department of Biology
Aveiro, Portugal
joanacmrocha@gmail.com

Chapter F.35

Joana Rocha is a PhD candidate at the University of Porto and Aveiro, Portugal. She received her BS (2003) in Microbiology and MS (2007) in Quality Control from Portuguese Catholic University and University of Porto, Portugal, respectively. Her research interests include microbial and marine invertebrates' ecological and biotechnological status in marine natural products' research.

Dina Rodrigues

University of Aveiro
Department of Chemistry
Aveiro, Portugal
dinarodrigues@ua.pt

Chapter G.42

Dina Rodrigues has a BS in Chemical and Environment Sciences from ISEIT/Instituto Piaget (2007) and a Master degree in Biomolecular Methods from Aveiro University in 2009. From 2007 to 2010, she worked in the research project PROBIOCAPS - Microencapsulation technology adapted for probiotic bacteria with a research Grant. She is currentlya PhD student being involved in the research on new functional foods with ingredients from marine and mushrooms sources, with support of Portuguese Science Foundation.

Gregory L. Rorrer

Oregon State University
School of Chemical, Biological, and Environmental Engineering
Corvallis, OR, USA
gregory.rorrer@oregonstate.edu

Chapter B.9

Gregory Rorrer holds a PhD degree in Chemical Engineering from Michigan State University and is currently Professor of Chemical Engineering at Oregon State University. Dr. Rorrer has expertise in algal biotechnology and photobioreactor analysis, and his current research focuses on harnessing the unique biosynthetic capacity of diatoms for production of nanoscale semiconductor materials, energy-dense molecules for biofuels, and chitin biopolymers.

Debashis Roy

Jadavpur University
Department of Chemical Engineering
Kolkata, India
deebie_roy@yahoo.com

Chapter B.12

Debashis Roy obtained his B.Chem.Engg., M.Chem.Engg. and PhD degrees from Jadavpur University, Kolkata, where he is presently Associate Professor in the Department of Chemical Engineering. His research interests span both bioreactions and bioseparations. Currently, he is interested in the design and development of novel bioreactors for attached-growth cultures, particularly small-scale, extended surface area shaken vessels with novel configurations for enhanced productivity. Dr. Roy has been a Visiting Scientist at the Chemical Engineering Department, McMaster University, Canada.

Constantin Rusu

University Alexandru Ioan Cuza of Iasi
Department of Geography
Iasi, Romania
c.v.rusu@yahoo.com

Chapter D.25

Constantin Rusu is the President of Senate "*Alexandru Ioan Cuza* University of Iasi, Head of Collective of Geography from Iasi Filial of Romanian Academy of Science and Professor at the Department of Geography, at *Alexandru Ioan Cuza* University of Iasi. His research interests include soil science, geomorphology, hazards, and natural risks. He is laureate of Romanian Academy Scines.

H. Mir Sajjad

Yamagata University
Chemistry and Chemical Engineering
Yonezawa, Japan
sajjad.h.mir@gmail.com

Chapter B.10

I received my BS and MS degrees from Aligarh Muslim University, India in 2009 and 2011, respectively, in Industrial Chemistry. In 2012 I was research scientist at the Bio-Physiosensor Technology, Pusan National University, South Korea. I fabricated sensors for cancer cell detection. Since 2013 I am a Japanese Government scholarship fellow (MEXT), perusing my PhD in Organic Material Engineering, at Yamagata University Japan. I am working on novel organic / inorganic hybrid materials and investigating their electronic applications.

Kalpa W. Samarakoon

Industrial Technology Institute (CISIR)
Herbal Technology Division
Colombo, Sri Lanka
kalpa.samarakoon@gmail.com

Chapter G.41

Dr. Kalpa W. Samarakoon is a Research Scientist at Herbal Technology Division, Industrial Technology Institute (CISIR), Colombo 07, Sri Lanka. He has obtained his BSc (2004) from the University of Colombo, Sri Lanka, and his MSc (2010) from the same University in Applied Organic Chemistry. He obtained his PhD (2014) in Marine Biotechnology from the Department of Marine Life Science, Jeju National University, Rep. of Korea. His research majorly focuses on isolation and characterization of novel functional ingredients including secondary metabolites and bioactive peptides from marine organisms using organic and enzymatic extractions.

Barindra Sana

p53 Laboratory
Agency for Science, Technology and Research
Singapore
bsana@p53Lab.a-star.edu.sg

Chapters B.14, F.38

Barindra Sana received the PhD degree from Jadavpur University, India. He worked as a Postdoctoral Fellow at Nanyang Technological University, Singapore and also held Fellow Scientist position at Central Salt & Marine Chemical Institute (CSIR), India. Presently, he is working as a researcher at p53 Laboratory, A*STAR, Singapore. His recent research includes enzyme/protein engineering for biomass conversion and nanobiotechnology applications.

Ramachandran S. Santhosh

SASTRA University
School of Chemical and Biotechnology
Thanjavur, India
rs_santhosh@yahoo.co.in

Chapter H.49

Dr. Santhosh is Senior Assistant Professor at SASTRA University, Thanjavur, India. He received the Master from G. B. Pant University of Agriculture and Technology, Pantnagar, and PhD in Biotechnology from Madurai Kamaraj University, Madurai, India. His research focuses on antimicrobial compounds from natural resources and its mode of action. He is affiliated to The Centre for Nanotechnology and Advanced Biomaterials, SASTRA University.

Tomoo Sawabe

Hokkaido University
Faculty of Fisheries Sciences
Hakodate, Japan
sawabe@fish.hokudai.ac.jp

Chapter H.51

Tomoo Sawabe is a Professor at the Hokkaido University, Japan. He received BSc in Fisheries in 1989 from Hokkaido University, and the Masters and PhD degrees in Fisheries from Hokkaido University in 1991 and 1997, respectively. At Hokkaido University, he is affiliated with the Laboratory of Microbiology. His current research focuses are marine biofuel production and metabolic engineering of marine microbes.

Heinz C. Schröder

University Medical Center of the Johannes Gutenberg University Mainz
Institute for Physiological Chemistry
Mainz, Germany
hschroed@uni-mainz.de

Chapter I.57

Heinz C. Schröder studied Chemistry and Medicine, and completed his PhD and MD with distinction. In 1985 he became a Professor at the University Medical Center of the Johannes Gutenberg University Mainz, Germany. He has been involved, together with Prof. Dr. W. E. G. Müller, as coordinator or partner, in 20 European projects. His research interests include the study of the mechanisms of biomineral formation, in particular biosilicification and its application in nanomedicine and nanobiotechnology, as well as bioprospecting, marine biotechnology and molecular and cell biology of sponges. He has about 25 patent applications (8 patents granted) and is author or co-author of more than 350 scientific articles.

Jeong H. Seo

Yeungnam University
School of Chemical Engineering
Gyeongsan, Korea
jhseo78@yu.ac.kr

Chapter J.60

Jeong Hyun Seo is Assistant Professor in the School of Chemical Engineering, Yeungnam University, Gyeongsan, Korea. He obtained his PhD in Chemical Engineering from Pohang University of Science and Technology (POSTECH), Pohang, Korea in 2008. From 2009 to 2011, he was Postdoctoral Researcher in University of California, Davis, and Research Assistant Professor in the Department of Chemical Engineering, POSTECH (2012–2014). He joined the Yeungnam University in March 2014. His area of interests includes carbohydrate research, biomedical engineering, and biosensor development.

Prince Sharma

Panjab University
Department of Microbiology
Chandigarh, India
princess@pu.ac.in

Chapter B.15

Prince Sharma, MSc (Hons. School) Microbiology, PhD Microbiology, Professor in Panjab University; Area of Specialization is Molecular and Industrial Microbiology. Research interests are metagenomics of thermostable, novel industrially relevant enzymes and their diversity; reverse vaccinology; alternate therapy with novel molecules that inhibit quorum sensing; Biosensors for the detection of pathogens.

Yoon-Bo Shim

Pusan National University
Bio-Physio Sensor Technology, Chemistry Department
Busan, Korea
ybshim@pusan.ac.kr

Chapter B.10

I have received all degrees from Pusan National University, South Korea in Electro-chemistry. Since 1981 I am Professor in department of chemistry, Pusan National University, South Korea. Since 2002, I am Director of the centre for Bio-Physio Sensor Technology. My research activities include bio-sensors, dye solar cells, development of bio-battery, and separation chemistry with lab-on-chip. Since recently, we are working on fabrication of sensors for diagnosis of cancer cells.

Katsuhiko Shimizu

Tottori University
Organization for Regional Industrial Academic Cooperation
Tottori, Japan
kshimizu@cjrd.tottori-u.ac.jp

Chapter J.61

Katsuhiko Shimizu received his PhD in Biology from Tokyo Metropolitan University in 1992 and is currently an Associate Professor at Tottori University. His research interest focuses on understanding the molecular mechanism controlling silicon biomineralization in sponges for the development of novel routes to synthesize silicon-based inorganic-organic composite materials with outstanding properties in environmentally benign manner.

Bijay Singh

Seoul National University
Department of Animal Cell Biotechnology
Seoul, Korea
singhbijay@hotmail.com

Chapter I.54

Bijay Singh received the Master degree (2003) in Organic Chemistry from Tribhuvan University (Nepal) and PhD (2011) in Biochemistry from Sun Moon University, Korea. Since 2011, he is a postdoctoral research associate at Seoul National University in Korea. His current interest lies on the emerging research area at the intersection of nanotechnology, molecular biology and biomedical sciences.

Kannan Sivakumar

Annamalai University
Centre of Advanced Study in Marine Biology, Faculty of Marine Sciences
Parangipettai, India
oceanactino@gmail.com

Chapter J.63

Kannan Sivakumar is an Assistant Professor in the Faculty of Marine Sciences and CAS in Marine Biology, Annamalai University in India. He received his MS in Botany from AVC College in India, and his PhD degree from the Faculty of Marine Sciences, CAS in Marine Biology, Annamalai University in India. His research field is marine actinobacteriology.

M. Luisa Soto

IES Lauro Olmo
O Barco, Spain
marisa-sotoalvarez@edu.xunta.es

Chapter G.44

Maria Luisa Soto received her graduate and MS degree from University of Santiago de Compostela and she has completed her Chemical Engineering PhD at the University of Vigo. She is Professor of Vocational Education and Training in Personal Image. Her research activities include refining of natural extracts, formulation of novel cosmeceuticals and their sensory evaluation.

Ayinampudi Sree

CSIR-Institute of Minerals & Materials Technology
Department of Bioresources Engineering
Tenali, India
asree18@yahoo.in

Chapter F.36

Dr. Ayinampudi Sree received his MSc in Organic Chemistry in 1972 and PhD in 1978. He has worked extensively on steroid drug intermediates, chemistry of marine natural products, exploration of bioactivity of marine sedentary organisms of the east coast of India, and biotechnological potential of microbial associates of marine sponges.

Ananya Srivastava

Deen Dayal Upadhaya Gorakhpur University
Department of Chemistry
Gorakhpur, India
ananya.gkp@gmail.com

Chapter I.56

Ananya Srivastavais presently a final-year doctoral researcher at the Department of Chemistry IIT Delhi, India. She works on the synthesis of novel organic molecules of biomedical importance and has keen interest in exploring biomaterials as a substrate material for various biomedical applications. She was awarded the Gold Medal for her graduate studies in chemistry.

Arti Srivastava

Amity University Uttar Pradesh
Amity Institute of Biotechnology
Noida, India
asrivastava@amity.edu

Chapter I.56

Arti Srivastava is working as Research Fellow at Amity University UP, India. She published seven research articles in international peer reviewed journals. Previously she worked at All India Institute of Medical Science, New Delhi India as junior research fellow. Her current research interest is marine pharmacology and aquatic toxicology.

Ashutosh Srivastava

Amity University Uttar Pradesh
1. Amity Institute of Marine Science and Technology
Noida, India
asrivastava4@amity.edu

Chapter I.56

Ashutosh Srivastava is Assistant Professor and Coordinator at Amity Institute of Marine Science and Technology, Amity University Uttar Pradesh, India. He received his PhD from University of Delhi. He was awarded the Norwegian Yggdrasil young guest and doctoral researchers' Annual scholarship 2009–2010 and Norwegian Government Research Fellowship 2004–2005. His current research interest is marine pharmacology and aquaculture nutrition.

Jeeva Subbiah

Konkuk University
Department of Infectious Disease
Seoul, Korea
jeevabio@gmail.com

Chapter A.4

Jeeva Subbiah received his PhD in Virology from Pukyong National University and is currently Postdoctoral Researcher at Konkuk University. His research interests are reverse genetic manipulation of viruses and vector vaccines.

Parappurath Narayanan Sudha

D.K.M. College for Women
Department of Chemistry
Vellore, India
parsu8@yahoo.com

Chapter H.52

Dr. Sudha, is presently working as a Principal, at DKM College for Women (Autonomus), Affiliated to Thiruvalluvar University, Vellore, Tamilnadu, India. She has obtained her Doctoral degree in Chemistry – Biology Interdisciplinary science from Madras University. She is a Fellow of International Congress of Chemistry and Environment and National Environmentalists Association. Her research interests are polymer chemistry, environmental chemistry, bioremediation and phytochemistry. She has authored 11 books and 8 book chapters. Her immense experience in research is the key asset for the devalopment of research among the young women researchers in the rural area. She has published 90 research articles mainly on the wastewater treatment and biomedical applications of chitin and chitosan.

Andriy Synytsya

Institute of Chemical Technology in Prague
Department of Carbohydrates and Cereals
Prague, Czech Republic
sinicaa@vscht.cz

Chapter D.22

Andriy Synytsya is an Associate Professor in the Department of Carbohydrates and Cereals, Institute of Chemical Technology in Prague. His research focuses on structural characterisation of natural polysaccharides of biological importance using spectroscopic and other analytical methods. He also works on chemical modifications of polysaccharides with the aim to obtain derivatives suitable for medicinal applications.

Haruko Takeyama

Waseda University
Department of Life Science and Medical Bio-Science
Tokyo, Japan
haruko-takeyama@waseda.jp

Chapter C.19

Professor Haruko Takeyama received her doctoral degree in Engineering from Tokyo University of Agriculture and Technology (TUAT) in 1992. Since 2007 she is appointed as a Professor at Waseda University, Tokyo. Her current research interests are conservation and utilization of main bio/gene resources, metagenomic research for screening novel bio-function and enzymes genes, and single-cell analysis.

Tsuyoshi Tanaka

Tokyo University of Agriculture and Technology
Division of Biotechnology and Life Science, Institute of Engineering
Tokyo, Japan
tsuyo@cc.tuat.ac.jp

Chapter A.5

Tsuyoshi Tanaka is an Associate Professor at Tokyo University of Agriculture and Technology, Japan, from where he received the PhD degree in 2000. He was a Research Associate at the Heriot-Watt University, Edinburgh, UJK, from 2000 to 2002. His research interests include marine microalgal biofuels, metabolic engineering of marine diatoms for biodiesels, cell-chip device development, and electrochemical biosensor.

Fabiano Thompson

Federal University of Rio de Janeiro
Department of Marine Biology
Ilha do Fundão, CCS, Brazil
fabiano.thompson@biologia.ufrj.br

Chapter H.51

Fabiano Thompson became Director of Research at the Institute of Biology, Federal University of Rio de Janeiro (UFRJ), in 2012, Professor of Genetics in 2006 in the Institute of Biology, UFRJ; and Professor of Marine Biology in 2011 at the same university. Thompson's Lab currently performs research on marine microbiology in the Blue Amazon, the realm in southwestern Atlantic.

Tamilselvi Thyagarajan

Deakin University
Centre for Chemistry and Biotechnology, LES
Victoria, 3217, Australia
tthyagar@deakin.edu.au

Chapter G.45

I got my masters graduation in Biotechnology and further strengthened my skills in fermentation by joining as research project trainee in R&D of Biocon, an Indian biopharmaceutical company. Currently, I am pursuing PhD degree from Deakin University. My research is on isolation and screening of marine microbe thraustochytrids from Victoria for the production of various nutraceuticals such as omega-3 fatty acids, squalene, carotenoids and biofuel.

Cecilia Totti

Università Politecnica delle Marche
(DISVA–UNIVPM)
Dipartimento di Scienze della Vita e dell'Ambiente
Ancona, Italy
c.totti@univpm.it

Chapter D.24

Cecilia Maria Totti (PhD) is Senior Researcher at the Polytechnical University of Marche, Ancona, where she teaches Botany and Biodiversity of marine plants. She is the leader of the Marine Botany Laboratory. Her research activity is focused on ecology and taxonomy of marine microalgae, both planktonic and benthic: phytoplankton long time series, harmful algal blooms, microphytobenthic communities (epipelic, epilithic, epiphytic, epizoic).

Antonio Trincone

Instituto di Chimica Biomolecolare
Consiglio Nazionale delle Ricerche
Pozzuoli, Naples, Italy
antonio.trincone@icb.cnr.it

Chapter F.30

Antonio Trincone is a Senior Researcher working since 1983 in Naples at the Istituto di Chimica Biomolecolare affiliated to the Consiglio Nazionale delle Ricerche, Italy. He edited the book *Marine enzymes for biocatalysis: Sources, biocatalytic characteristics and bioprocesses of marine enzymes* and is Specialty Chief Editor in Marine Science.

Roland Ulber

University of Kaiserslautern
Institute of Bioprocess Engineering
Kaiserslautern, Germany
ulber@mv.uni-kl.de

Chapter B.14

Roland Ulber studied chemistry at the University of Hannover, Germany, where he graduated in 1994. He then joined the University of Münster, Germany, and received his PhD in 1996 from the Institute of Technical Chemistry at the University of Hannover. At the same university he received his Habilitation in 2002 and has been Professor for Bioengineering at the Technical University of Kaiserslautern since 2004. Roland Ulber´s main research interest is the use of renewable resources as feedstock for chemical and biotechnological processes.

Jayachandran Venkatesan

Pukyong National University
Department of Marine-Bio Convergence Science
Busan, Korea
venkatjchem@pknu.ac.kr

Chapters .1, H.52, I.53, J.63

Jayachandran Venkatesan is presently working as a Research Professor in the Department of Marine-Bio Convergence Science and Marine Bioprocess Research Center (MBPRC) at Pukyong National University, Busan, South Korea. He received his MSci in Chemistry from Thiruvalluvar University in 2005 and his PhD from Pukyong National University in 2011 where he also conducted his postdoctoral studies. His major research interests are marine-derived biomaterials for tissue engineering and drug delivery. He is currently doing a research on marine biomaterials with stem cell interaction for bone tissue engineering application. To date, he has published 40 research papers and holds 2 patents.

Juan M. Vieites

ANFACO-CECOPESCA
General Management
Vigo-Po, Spain
direccion@anfaco.es

Chapter F.37

Juan M Vieites Baptista de Sousa is a Doctor in Chemical Sciences. He has more than 30 years of experience in seafood and aquaculture products preservation with a focus on food quality and safety as well as technological development and environmental aspects. Since 1991 he has worked as the General Manager of ANFACO-CECOPESCA, the Spanish National Association of Seafood Producers and Technological Centre for Seafood and Aquaculture Products Preservation.

Xiaohong Wang

University Medical Center of the Johannes Gutenberg University Mainz
Institute for Physiological Chemistry
Mainz, Germany
wang013@uni-mainz.de

Chapter I.57

Xiaohong Wang obtained her PhD at Beijing University (China). She became a Professor at the National Research Center for Geoanalysis, Chinese Academy of Geological Sciences in 2005. She received the Excellent Young Scientist Award of the Ministry of Land and Resources, China in 2003. At present, she is working at the University Medical Center of the Johannes Gutenberg University Mainz (Germany), where, she is coordinating the Joint German–Chinese Center on *Bioinspired Materials*. Her major interest is to synthesize the bioinspired biosilica-based materials to be used in biomedical applications.

Jen-Leih Wu

Academia Sinica
Institute of Cellular and Organismic Biology
Taipei, Taiwan
jk.lu@msa.hinet.net

Chapters B.13, F.31, J.64

Jen-Leih Wu received the MS degree from National Taiwan University and obtained his PhD degree in Biochemistry & Molecular Biology from the University of Arkansas for Medical Sciences, USA (1975). Hewas appointed an Associate Research Fellow in the Institute of Zoology (now ICOB) of the Academia Sinica in 1976 and promoted to the Distinguished Research Fellow in 2007. He ist devoted to the study of fish molecular biology and gene function, organogenesis, virus-host interaction, zebrafish cancer model and aquaculture biotechnology. He served as the Vice Director and Director of the Institute of Zoology at Academia Sinica from 1984 to 1996, He activately participates the international organizations such as ICSU, IUBS, and CODATA etc. He initiated the Taiwan Marine Biotechnology Society in 2012 and served as the first President.

Michiaki Yamashita

National Research Institute of Fisheries Science
Food Safety Assessment Research Group
Yokohama, Japan
mic@affrc.go.jp

Chapter G.46

Michiaki Yamashita is currently the Head of Food Safety Assessment Research Group at National Research Institute of Fisheries Science and Visiting Professor at the Tokyo University of Marine Science and Technology and at the University of Tokyo. His fields of expertise include biochemistry, and genetic engineering of marine organisms. He characterized the molecular mechanisms on environmental adaptation using fish models.

Yumiko Yamashita

National Research Institute of Fisheries Science
Food Safety Assessment Research Group
Yokohama, Japan
ymk0125@affrc.go.jp

Chapter G.46

Yumiko Yamashita is currently a Senior Researcher at the National Research Institute of Fisheries Science, Japan. She received her MS in Chemistry in 1986 from Saitama University and her PhD in 2012 from the University of Tokyo, Japan.Her research focuses on seafood safety related with trace elements. Her achievements included techniques for isolating selenium-containing compounds in seafood and the discovery of a novel compound, selenoneine.

Byeongseon Yang

Pohang University of Science and Technology
Department of Chemical Engineering
Pohang, Korea
yangbs0520@postech.ac.kr

Chapter J.60

Byeongseon Yang is a PhD candidate in the Department of Chemical Engineering at Pohang University of Science and Technology (POSTECH), Pohang, Korea, in the PhD program at POSTECH since 2011. His research interest is on developing mussel-inspired underwater bioadhesive materials.

Charles Yarish

University of Connecticut
Department of Ecology & Evolutionary Biology
Storrs, CT, USA
charles.yarish@uconn.edu

Chapter B.13

Professor Charles Yarish received his PhD from Rutgers University (1976) and then joined the faculty at the University of Connecticut (1976) where he is in the Departments of Ecology and Evolutionary Biology and Marine Sciences. He has developed an internationally known laboratory for seaweed research and aquaculture. He is the recipient of the 1992 Marinalg Award's First Prize; the 2007 UCONN-Stamford Faculty Recognition Award, which recognizes sustained outstanding achievements in teaching. In 2012, Prof. Yarish received the Provost Award from The University of Connecticut for Public Engagement and Outreach. In 2013, Prof. Yarish and his coauthors received the Fernald Award for the best paper of the year published in Rhodora and in 2014 received the speaker of the year award Connecticut Society of Cosmetic Chemists.

Tomoko Yoshino

Tokyo University of Agriculture and Technology
Division of Biotechnology and Life Science, Institute of Engineering
Tokyo, Japan
y-tomoko@cc.tuat.ac.jp

Chapter A.5

Tomoko Yoshino is an Associate Professor at Tokyo University of Agriculture and Technology, Japan, from where she received her PhD in 2005. She is a Research Associate at Waseda University, Tokyo, Japan in 2005. Her research interests are metabolic regulation of marine cyanobacteria for biofuels, single cell analysis, and protein display on bacterial magnetic particles.

SangGuan You

Gangneung-Wonju National University
Department of Marine Food Science and Technology
Gangneung-si, Korea
umyousg@gwnu.ac.kr

Chapter F.40

SangGuan You is an Associate Professor in the department of Marine Food Science and Technology at Gangneung-Wonju National University, Korea. He received his PhD from the University of Manitoba. His research focuses on the structural analysis and the bioactivities of functional polysaccharides from marine resources as well as their modifications for improving functionality and targetability on cell surface receptors.

Smita Zinjarde

University of Pune
Institute of Bioinformatics and Biotechnology
Pune, India
smita@unipune.ac.in

Chapter I.55

Smita Zinjarde received her PhD in Microbiology from the University of Pune in 1997. Thereafter, she worked as a Lecturer, Associate Professor at the University of Pune and is currently a Professor in the Institute of Bioinformatics and Biotechnology. Her research interests lie in the exploitation of marine microorganisms for a variety of therapeutic, bioremedial and other biotechnological applications.

Part B Tools and Methods in Marine Biotechnology

9 **Bioprocess Engineering of Phototrophic Marine Organisms**
Gregory L. Rorrer 257
9.1 Introduction to Marine Process Engineering 257

9.1.1 Phototrophic Marine Organisms: A Diverse Source of Valuable Natural Products 258
9.1.2 Marine Bioprocess Engineering and the *Cell Factory* 259
9.2 Growth Characteristics of Phototrophic Suspension Cultures 261
9.2.1 Nutrient Requirements and Photosynthetic Biomass Stoichiometry 261
9.2.2 Specific Growth Rate 264
9.3 Basic Elements of Photobioreactor Design and Operation 267
9.3.1 Common Requirements 267
9.3.2 Biomass Production in Well-Mixed Batch or Continuous Operation 267
9.3.3 Enclosed Photobioreactor Configurations 270
9.4 Limiting Factors in Photobioreactor Design and Operation 277
9.4.1 Five Steps for Photobioreactor Design 277
9.4.2 Light-Limited Growth 277
9.4.3 Carbon Dioxide-Limited Growth 281
9.4.4 Process Scale-Up and Other Limiting Factors 286
9.4.5 Process Monitoring and Control 287
9.4.6 Illustration of a Photobioreactor Design Problem 287
9.4.7 Design Needs Statement 287
9.5 Future Directions for Process Scale Enclosed Photobioreactors 290
9.6 Notation 291

28 **Biotransformation of Nitriles by Marine Fungi**
Julieta Rangel de Oliveira, Mirna H. Reagli Seleghim, André L. Meleiro Porto 677
28.1 Overview 678
28.1.1 Biocatalysis and Biotransformation 678
28.1.2 Marine Microorganisms 678
28.1.3 Nitriles 679
28.1.4 Nitrilases, Nitrile Hydratases, and Amidases 682
28.1.5 Application of Nitrilases, Nitrile Hydratase, and Amidases to Biocatalysis 684
28.1.6 Biodegradation of Nitriles 689
28.2 Experimental Methods 691
28.2.1 Isolation, Identification, and Preparation of Stock Cultures of Marine Fungi 691
28.2.2 Cultivation of Marine Fungi on a Solid Medium in the Presence of Phenylacetonitrile **1** 691

28.2.3 Biotransformation of Phenylacetonitrile **1** by Marine Fungi in a Liquid Medium 691
28.2.4 Isolation of 2-Hydroxyphenylacetic Acid **1a** from Culture Media Produced by *A. sydowii* CBMAI 934..... 691
28.2.5 Biotransformation and Isolation of Phenylacetonitrile Derivatives **2–4** by *A. sydowii* CBMAI 934 692
28.2.6 Biotransformation of Cyclohexenylacetonitrile **5** by *A. sydowii* CBMAI 934..... 693
28.2.7 Biotransformation of Aromatic Nitriles 693
28.2.8 Growth of Marine Fungus *A. sydowii* CBMAI 934 in the Presence of 2-Cyanopyridine **14** in Solid and Liquid Media..... 694
28.2.9 Biotransformation of Benzonitrile **6** and 2-Cyanopyridine **14**..... 695
28.3 Results and Discussion..... 696
28.3.1 Screening of Marine Fungi with Phenylacetonitrile **1** in Solid and Liquid Media 696
28.3.2 Biotransformation of Phenylacetonitrile Derivatives **2–4** by the Marine Fungus *A. sydowii* CBMAI 934..... 699
28.3.3 Biotransformation of Cyclohexenylacetonitrile **5** by the Marine Fungus *A. sydowii* CBMAI 934..... 702
28.3.4 Biotransformation of Aromatic and Hetero(aromatic) Nitriles by the Marine Fungus *A. sydowii* CBMAI 934 705
28.4 Conclusion 705

Part F Marine Derived Metabolites

29 **Drugs and Leads from the Ocean Through Biotechnology**
José de Jesús Paniagua-Michel, Jorge Olmos-Soto, Eduardo Morales-Guerrero 711
29.1 Overview and Current Status 712
29.1.1 The Marine Environment, a Unique and Prolific Source of Bioactive Natural Products..... 712
29.2 Approved Marine Drugs as Pharmaceuticals 713
29.2.1 ω-Conotoxin MVIIA: An Analgesic for Neuropathic Pain 713
29.2.2 Ecteinascidins: A Therapy for Soft Tissue Sarcoma 714
29.2.3 Cytarabine to Treat Meningeal Leukemia; Vidarabine, An Ophthalmic, Non-Corticosteroid Antiviral 714
29.2.4 Marine Natural Products in Advanced Clinical Trials 716
29.3 Marine Natural Products – Overcoming Hurdles 718
29.4 *Quo Vadis*? Marine Natural Products and Clinical Trials 718
29.4.1 *(C)-Discodermolide*..... 719
29.5 Marine Natural Products: New and Recurrent Challenges 720

29.5.1 Facing Supply Obstacles: Advances and Strategies 720
29.5.2 Marine Natural Products: Paradigms, Genomics, and Biosynthesis Exemplified 721
29.5.3 Marine Natural Products at the Crossroad Between Functional Foods and Pharma 723
References 724

30 **Biocatalysts from *Aplysia*: Sweet Spot in Enzymatic Carbohydrate Synthesis**
Antonio Trincone 731
30.1 Biocatalysis, Glycosylation and Marine Enzymes 731
30.2 Biocatalytic Methodologies to Access Glycosides and Oligosaccharides 732
30.2.1 Enzymes 732
30.2.2 *Natural* and Engineered Methods for Synthesis 734
30.3 The Marine Ecosystem as a Source for New Glycoside Hydrolases ... 734
30.4 Glycoside Hydrolases Present in the Genus *Aplysia* 735
30.5 Other Enzymatic Activities of Interest Present in *Aplysia* sp. 741
30.6 Conclusion 742
References 742

31 **Antimicrobial Peptides from Marine Organisms**
Venugopal Rajanbabu, Jyh-Yih Chen, Jen-Leih Wu 747
31.1 Marine Antimicrobial Peptides 747
31.2 Isolation of Antimicrobial Peptides 748
31.3 Characterization and Functions of AMP 748
31.3.1 Alpha Helical AMPs 748
31.3.2 Beta Sheet/Cysteine-Rich AMPs 749
31.3.3 AMPs with Coil Structure and Modified Amino Acids 752
31.3.4 Ring Structured AMPs 753
31.4 Future Directions in Marine AMP Applications 753
References 755

32 **Marine-Derived Fungal Metabolites**
Sherif S. Ebada, Peter Proksch 759
32.1 Overview 759
32.2 Drug Screening from Marine Organisms 760
32.2.1 US FDA-Approved Marine-Inspired Pharmaceuticals 760
32.2.2 Marine Pharmaceuticals in Phase III Clinical Trials 761
32.2.3 Marine Pharmaceuticals in Phase II Clinical Trials 762
32.2.4 Marine Pharmaceuticals in Phase I Clinical Trials 763
32.2.5 Marine Pharmaceuticals in the Preclinical Phase 764
32.3 Marine Organic Compounds 765
32.3.1 Alkaloids 765
32.3.2 Diketopiperazines 769
32.3.3 Polyketides 770
32.3.4 Terpenes 777
32.3.5 Marine Peptides and Proteins 781

32.4 Conclusions 782

33 **Marine Dinoflagellate-Associated Human Poisoning**
Samanta S. Khora 789
33.1 Preface 789
33.2 Historical Perspective 791
33.3 Marine Dinoflagellates 792
33.3.1 Swimming Behavior 792
33.3.2 Heterotrophy 792
33.3.3 Symbiosis 792
33.3.4 Bioluminescence 792
33.3.5 Toxicity 793
33.4 Algal Blooms and Red Tide Dinoflagellates 793
33.5 Toxigenic Dinoflagellate-Associated Human Poisoning 794
33.5.1 Fish Poisoning in Humans 795
33.5.2 Human Shellfish Poisoning 798
33.6 Biotechnological Significance of Toxic Marine Dinoflagellates 805
33.7 Control and Prevention 806
33.8 Discussion and Conclusion 807
References 808

34 **Carotenoids, Bioactive Metabolites Derived from Seaweeds**
Ratih Pangestuti, Se-Kwon Kim 815
34.1 Seaweeds 815
34.2 Biological Activities of Carotenoids and Health Benefit Effects 816
34.2.1 Antioxidant Activity 816
34.2.2 Anticancer Activity 817
34.2.3 Anti-Obesity Activity 817
34.2.4 Anti-Inflammatory Activity 818
34.2.5 Anti-Angiogenic Activity 819
34.2.6 Other Biological Activities 819
34.3 Concluding Remarks 819
References 819

35 **Marine Bioactive Compounds from Cnidarians**
Joana Rocha, Miguel Leal, Ricardo Calado 823
35.1 Cnidarians 823
35.1.1 Overview of Natural Product Discovery from Cnidarians 825
35.2 The Most Promising Marine Natural Products from Cnidaria 828
35.2.1 Class Anthozoa 828
35.2.2 Class Hydrozoa 837
35.2.3 Class Scyphozoa 838
35.2.4 Other Classes 838
35.3 Concluding Remarks and Future Challenges 838

36 **Fatty Acids of Marine Sponges**
Pravat Manjari Mishra, Ayinampudi Sree, Prasanna K. Panda 851
36.1 Fatty Acids – Pharmaceutical and Biomedical Importance 851
36.1.1 Fatty Acids – An Introduction 851
36.1.2 Importance of Fatty Acids 852
36.1.3 Biological Functions of PUFAs and Their Biomedical Applications 853
36.2 Sponge Fatty Acids 854
36.2.1 Saturated Fatty Acids 854
36.2.2 Unsaturated Fatty Acids 856
36.2.3 Fatty Acids with Unusual Structures 860
36.3 Bioactive Lipids/FAs from Marine Sponges 862
36.4 Summary 863
References 863

37 **Marine Biotoxins**
Aníbal Martínez, Alejandro Garrido-Maestu, Begoña Ben-Gigirey, María José Chapela, Virginia González, Juan M. Vieites, Ana G. Cabado ... 869
37.1 Marine Toxins 870
37.2 Lipophilic Toxins 871
37.2.1 Okadaic Acid-Group (OA) Toxins and Pectenotoxin-Group Toxin (PTXs) 871
37.2.2 Yessotoxin-Group Toxins (YTXs) 871
37.2.3 Azaspiracid-Group Toxins (AZAs) 871
37.3 Hydrophilic Toxins 872
37.3.1 Saxitoxin-Group Toxins (STXs) 872
37.3.2 Domoic Acid 872
37.4 Other Toxins 873
37.4.1 Ciguatoxins-Group Toxins 873
37.4.2 Brevetoxins (BTXs) 873
37.4.3 Tetrodotoxin (TTXs) 874
37.4.4 Palytoxin (PITXs) and Analogs 874
37.4.5 Cyclic Imines (CIs) 874
37.4.6 Maitotoxins (MTXs) and Gambierol 875
37.5 Biotechnological Techniques Used to Study Toxic Microalgae and Marine Biotoxins 875
37.5.1 Immunological Methods 875
37.5.2 Enzymatic, Colorimetric, and Other Tests 878
37.5.3 Receptor Binding Assay (RBA) 878
37.6 Biotechnology Application for Phytoplankton Detection, Monitoring, and Toxins Production 879
37.6.1 Genomics 880
37.6.2 Transcriptomics 882
37.6.3 Proteomics 882
37.6.4 Metabolomics 883
37.7 Potential Pharmacological Uses of Phycotoxins 884
37.7.1 Lipophilic Toxins (LTs) 884

37.7.2 Hydrophilic Toxins 886
37.7.3 Other Toxins 887

Detailed Cont.

Part G Application of Marine Biotechnology

41 **Marine-Derived Pharmaceuticals and Future Prospects**
Kalpa W. Samarakoon, Don A. S. Elvitigala, You-Jin Jeon 957
41.1 Marine Bioresources 957
41.2 Marine Secondary Metabolites 958
41.2.1 Halogenated Terpenes 958
41.2.2 Steroids and Sterols 959
41.2.3 Polyphenols 960
41.3 Marine Proteins 961
41.4 Marine Lipids 963
41.5 Molecular Biology Approaches 963
41.6 Future Trends in Marine Pharmaceuticals 964
References 965

42 **Marine Functional Foods**
Ana C. Freitas, Dina Rodrigues, Ana P. Carvalho, Leonel Pereira, Teresa Panteleitchouk, Ana M. Gomes, Armando C. Duarte 969
42.1 General Overview 969
42.2 Marine Sources as Healthy Foods or Reservoirs of Functional Ingredients 971
42.2.1 Seaweeds 972
42.2.2 Microalgae 973
42.2.3 Fish and Fish By-Products 973
42.2.4 Crustaceans 974
42.2.5 Marine Fungi and Bacteria 974
42.3 Food Marine-Derived Ingredients with Biological Properties 974
42.3.1 Polysaccharides 974
42.3.2 Proteins, Peptides, and Amino Acids 976
42.3.3 Fatty Acids 978
42.3.4 Pigments 978
42.3.5 Phenolic Compounds 979
42.3.6 Minerals 979
42.4 Functional Foods Incorporating Marine-Derived Ingredients 979
42.4.1 Foods Incorporating Marine Organisms: Seaweeds 980

42.4.2 Foods Incorporating Marine-Derived Ingredients: Polysaccharides 981
42.4.3 Foods Incorporating Marine-Derived Ingredients: Fish Oils and Fatty Acids 984
42.5 Current Understanding and Future Trends 987
References 988

43 **Marine Nutraceuticals**
S.W.A. Himaya and Se-Kwon Kim 995
43.1 Marine Bioactives as Potential Nutraceuticals 995
43.2 Functional Carbohydrates 996
43.2.1 Chitosan and Chitosan Oligosaccharides (COS) 996
43.2.2 Nutraceutical Potentials and Applications of COS and COS Derivatives 998
43.2.3 Glucosamine 999
43.2.4 Sulfated Polysaccharides 1000
43.3 Polyunsaturated Fatty Acids 1002
43.4 Carotenoids 1003
43.5 Soluble Calcium 1005
43.6 Fish Collagen and Gelatin 1006
43.7 Marine Probiotics 1007
43.8 Nutraceutical Market Trends and Quality Control 1008
43.9 R&D for Facing the Challenges and Supply for the Demand 1008
References 1009

44 **Cosmetics from Marine Sources**
Elena M. Balboa, Enma Conde, M. Luisa Soto, Lorena Pérez-Armada, Herminia Domínguez 1015
44.1 Scenario of Marine Sources in the Cosmetic Industry 1015
44.2 Cosmetics: Definition and Regulations 1016
44.3 Cosmeceuticals 1017
44.4 Target Organs and Cosmetics Delivery Systems 1018
44.5 Components of Cosmetics 1019
44.5.1 Active Compounds in Cosmetics 1019
44.5.2 Excipients 1019
44.5.3 Additives 1019
44.6 Major Functions of Some Marine Components in Cosmetics and Cosmeceuticals 1020
44.6.1 Physicochemical and Technological Properties 1020
44.6.2 Biological Activities 1023
44.7 Treatments Based on Marine Resources 1029
44.7.1 Firming 1030
44.7.2 Cellulite 1030
44.7.3 Hair Growth Disorders 1032
44.8 Products Based on Marine Resources 1032
44.9 Conclusions 1033
References 1033

45 **Omega-3 Fatty Acids Produced from Microalgae**
Munish Puri, Tamilselvi Thyagarajan, Adarsha Gupta, Colin J. Barrow 1043
45.1 Importance of Unsaturated Fatty Acids 1043
45.1.1 Unsaturated Fatty Acids – Focus on Marine Origin 1044
45.2 Potential Alternative Sources for PUFA Production 1045
45.3 Marine Microalgae 1045
45.3.1 Cultivation of Marine Microalgae 1046
45.3.2 Fermentation of Microalgae 1046
45.3.3 Isolation of Microalgae for the Production of PUFAs 1047
45.4 Biosynthesis of Omega-3 Fatty Acids in Marine Algae 1048
45.4.1 Synthesis of EPA 1048
45.4.2 Synthesis of DHA 1048
45.5 Microalgae Fermentation for the Production of PUFAs 1049
45.6 Thraustochytrid Fermentation 1051
45.6.1 Effect of Carbon and Nitrogen Sources and Other Promoters on PUFAs Production and Carotenoids 1051
45.6.2 Effect of Physical Parameters and Other Fermentation Strategies on PUFA Production 1052
45.7 Conclusions 1052
References 1053

46 **Selenoneine in Marine Organisms**
Michiaki Yamashita, Yumiko Yamashita 1059
46.1 Biochemistry of Selenium 1059
46.2 Selenium and Selenoneine Determination 1060
46.2.1 Selenium Analysis 1060
46.2.2 Selenium Contents in Seafood 1061
46.3 Biochemical Characterization of Selenoneine 1062
46.3.1 Purification 1062
46.3.2 Radical Scavenging Activity 1062
46.3.3 OCTN1 as a Selenoneine Transporter 1062
46.4 Nutritional and Functional Properties of Dietary Organic Selenium 1063
46.4.1 Metabolism and in vivo Antioxidant Activity 1063
46.4.2 Bioavailability of Selenium 1063
46.4.3 Supernutritional Supplementation 1064
46.4.4 Burnt Meat 1065
46.5 MeHg Detoxification 1065
46.6 Conclusion 1067
References 1068

47 **Biological Activities of Marine-Derived Oligosaccharides**
Tatsuya Oda 1071
47.1 Overview 1071
47.2 Preparation of Alginate Oligosaccharide Mixture 1072
47.2.1 Enzymatic Method 1072
47.2.2 Acid Hydrolysis 1073
47.2.3 Preparation of Purified Alginate Oligosaccharides 1073

47.3 Antioxidant Activities of Alginate Oligosaccharides 1073
47.4 Cytokine-Inducing Activities of Alginate Oligosaccharides 1076
47.5 Induction of Cytokines in Mice 1080
47.6 Growth-Promoting Effect of Alginate Oligosaccharides 1083

48 **Vector and Agricultural Pest Control**
Venkateswara Rao Janapala 1089
48.1 Preamble 1090
48.2 Current Status of Research and Development in the Subject 1090
48.2.1 Padan 1091
48.3 Research in India 1092
48.3.1 General Information on Gulf of Mannar 1093
48.3.2 Sample Collections and Identification 1093
48.3.3 Marine Flora 1093
48.3.4 Marine Fauna 1094
48.3.5 Identification of the Specimens 1094
48.4 Preparation of Crude Extracts 1094
48.4.1 Marine Flora 1094
48.4.2 Marine Fauna 1094
48.5 Active Extracts of Marine Origin 1094
48.6 Pesticidal Properties of Alkyl Xanthates 1099
48.6.1 Larvicidal Activity of Alkyl Xanthates Against Mosquito ... 1099
48.6.2 Developmental Inhibition Activity of Alkyl Xanthates Against Second Instar Larvae of *Aedes Aegypti* 1099
48.6.3 In Vivo Toxic Activity of Alkyl Xanthates Against Brine Shrimp, *Artemia Salina* 1099
48.7 Antifeedant and IGR Activities of Xanthates 1101
48.7.1 Antifeedant Activity 1101
48.7.2 Growth Inhibitory Activity 1104
48.8 Conclusions 1108
References 1108

Part H Bioenergy and Biofuels

49 **Nanotechnology – from a Marine Discovery Perspective**
Ramachandran S. Santhosh, Visamsetti Amarendra 1113
49.1 Marine Nanotechnology 1113
49.2 The Ocean as Source for Nanomaterials and Nanodevices 1114
49.2.1 Metal Nanoparticles 1114
49.2.2 Nanoparticles in MRI 1116
49.2.3 Biosurfactants 1116
49.2.4 Nanocomposites 1117
49.2.5 Nanomachines 1118
49.3 Ocean in Climate Control 1123
49.3.1 Cooling Effects of Ocean and Cloud Formation 1123
49.3.2 Effect of Environmental Parameters 1123

49.4 Detoxification of Nanomaterials 1123
49.4.1 Biotransformation 1123
49.5 Biomimetics 1124
49.5.1 Nanocoatings and Fabrication 1124
49.5.2 Nanowhiskers 1124
49.5.3 Microlens Array 1125
49.6 Conclusions 1125

59 **Functional Feeds in Aquaculture**
Jorge Olmos Soto, José de Jesús Paniagua-Michel, Lus Lopez, Leonel Ochoa 1303
59.1 Overview 1304
59.1.1 Importance of Aquaculture Development 1304
59.1.2 Development of Functional Feed 1304
59.2 Food Formulation Ingredients 1304
59.2.1 Fish Meal and Oil 1305
59.2.2 Soybean Meal and Oil 1306
59.2.3 Complex and Most Used Carbohydrates 1307
59.2.4 Probiotic Bacteria 1308
59.3 Conventional Feeds Versus Functional Feeds 1309
59.4 Aquaculture Regulations 1310
59.4.1 Sanitary Regulations 1310
59.4.2 Environmental Regulations 1311
59.5 Functional Feeds in Aquaculture 1311
59.5.1 Advantages and Disadvantages of Adhesion 1311
59.6 Results Obtained in Crustaceans and Fish Using Functional Feeds 1312
59.6.1 Functional and Commercial Feed Proximal Composition Used in *Litopenaeus vannamei* and *Oreochromis niloticus* 1312
59.6.2 Basal and Functional Feed Proximal Composition Used in *Atractoscion nobilis* 1313

59.6.3 Functional Feed Effects on Survival and Growth Performance of *L. vannamei*, *O. niloticus* and *A. nobilis* . 1313
59.6.4 Functional Feed Effects on *L. vannamei* and *A. nobilis* – Health Status 1316
59.6.5 Functional Feed Effects on Environmental Parameters in *L. vannamei* 1316
59.6.6 Functional Feed Effects on Stress Tolerance in *L. vannamei* 1317
59.7 Conclusions 1317

Erratum to: Springer Handbook of Marine Biotechnology

Se-Kwon Kim

Erratum to:

S.-K. Kim (Ed.), Springer Handbook of Marine Biotechnology, DOI 10.1007/978-3-642-53971-8,

Dear Reader,

thank you for your interest in this Springer Handbook. In spite of careful checking by the editorial und production team, a mistake has unfortunately slipped in, which we only noticed after printing.

The name of the contributor Christine Delbarre-Ladrat was misspelled. We corrected this error in the electronic version. We apologize to the reader and Christine Delbarre-Ladrat.[1]

[1] The online version of the original book can be found under DOI 10.1007/978-3-642-53971-8.
